TISUN

Space-saving design, simple installation, modern design and high efficiency make the TiSUN products to the ideal solution for sustainable energy saving. A tight distribution and service network ensures that TiSUN professionals are always close at hand. TiSUN will advise you which solar solution is best for your private house, company or project. Our specialists will endeavour to design and produce an energy optimisation solution which is right for you.
For more than 25 years TiSUN has been working to convince the world that using the inexhaustible source of solar energy is cost-effective. In addition to our quality and innovation, our customer service has made us one of the top European suppliers in the area of solar heating.

MENERGA

We supply air conditioning systems individually designed for your require-ments. Our philosophy, “Creating a good indoor climate – through Minimal ENERGy Application“, is something we have succeeded in every single day, since the company was founded over 35 years ago. We are proud to be part of the international successful Systemair group since 2013. Our systems are first-class, intelligent works of engineering and handcraft. They remain reliable in operation for many, many years, significantly reducing operating costs. How is this possible? In the basic design stages we already integrate all the components for air conditioning, such as the ventilation, heating and refrigeration systems, and equip everything with an intelligent control and regulation system. Every system is fully tested before delivery within the framework of a test run. The compact units are always delivered “ready for connection“. At the building site, they are connected up and made operational in just a few work stages. With over 40,000 systems installed worldwide, we cover almost every area of application. We do not only sell the units, but also offer you our many years of experience. When looking for the best solution, we jointly analyse the specific conditions at the location together with you. For the optimal solution we ask a lot of questions. Might it also be possible to use an alternative source of energy in order to reduce the operating costs even further? In this manner, we and our partners have jointly implemented countless projects which have received many awards for being energy efficient. We are proud of this. But what we really like about this is the know- how from jointly developed solutions, which allows operators and investors to save hard earned money- day after day, month after month, and year after year. The investment costs are amortised within a short period. We will be happy to produce reference lists for the building types in which you are interested in. And in the event that you surprise us with a totally new project: We are convinced to find the right solution for you. With our eyes sharpened by countless special projects, e.g. the “ALMA” telescope facility in the Atacama Desert or the “Princess Elisabeth Station” at the South Pole, we will be happy to accept the challenge.

VELA SOLARIS

The company Vela Solaris develops and distributes the simulation software Polysun. Polysun software offers valuable support with the design, analysis and calculation of installations in the field of renewable energies.
We offer the right solution for every need. Our offer contains:
Polysun Simulation Software - the sales and design tool
Polysun Online - the online version for a first approach to simulations
Individual company solutions
Most important facts and figures
1992: The first version of Polysun is released by the SPF Institut für Solartechnik
2007: Vela Solaris is founded as a spin-off company of SPF Institut für Solartechnik
Head office of Vela Solaris in Winterthur (Switzerland)
Vela Solaris employs about 10 people
Key attributes: Innovation - Because of the origins of our company, we work closely with universities and the industry. We are constantly developing Polysun software. That way, you are always up-to-date, and can advise your customers in a professional and reliable way.
Mission: We feel responsible for making our contribution to a cleaner future. Polysun software supports the transition of the global energy supply to renewable energies.
Corporate culture – Also in our daily work, we rely on sustainable energy, covering our energy demand exclusively with certified solar electricity. Brochures and business cards are printed without water, chemicals or VOC.

ISES International Solar Energy Society

Conference Proceedings

EuroSun 2016

Palma de Mallorca (Spain), 11 – 14 October 2016

Foreword to the EuroSun 2016 International Conference on Solar Energy for Buildings and Industry

Andreu Moià[1], Wolfgang Streicher[2], José González[3] and Víctor Martínez[3]

[1] Chair of the Organizing Committee

[2] Chair of the International Committee

[3] Chairs of the Scientific Committee

It is a pleasure for us to introduce the Proceedings of the ISES EuroSun 2016 conference. Since its first edition in 1996, the ISES European solar energy conferences gather the research community on solar energy in Europe and nowadays it has become an international must-attend event in this field. For the first time, Spain hosted the ISES EuroSun conference in its 11th edition, an event jointly organized by the University of the Balearic Islands (UIB), the Spanish Association on Solar Energy (AEDES) and the International Solar Energy Society (ISES). EuroSun 2016 has been a unique platform to discuss the latest developments with leading solar energy specialists as well as policy makers and industry representatives. Topic sessions, keynote speakers, plenary sessions and open discussion forums, as well as social events, have offered an exceptional opportunity to network, to meet old friends and to make new contacts.

Thermal demands on buildings and industrial processes account for one of the largest amounts of energy consumption worldwide. As the energy supply chain shifts to a more sustainable model, a number of issues arise, such as “What would be the future energy mix for those sectors?”, “Would in-situ energy production take a significant share of that mix?” or “How will the variability of the renewable sources be managed?”

In any case, solar energy, in any of its forms, is called to play a key role in the future supply of such demands. In a fast-evolving market, options that just ten years ago were regarded as non-feasible, such as the use of PV for thermal applications, the construction of net zero energy buildings, the operation of solar district heating networks or the generalized use of solar energy for industrial processes, are now regarded as promising options under different phases of development.

This context creates new opportunities (for example, the Concentrated Solar Power industry may now find new markets in process heat or the PV market goes thermal via heat pumps), but it also creates new challenges like the requirement to develop safe-and-cost effective storage solutions at different temperature ranges and to establish standards, testing procedures, and application guidelines that cover the novel as well as more consolidated technologies. This ever-changing panorama provides a continuous source of challenges for the scientists and engineers as well as to the academic

community involved in solar energy.

Several conclusions of the ISES EuroSun 2016 conference can be highlighted:

• A 100% Renewable Energy Society is possible and affordable by means of combination of energy efficiency measures and an intelligent mix of all renewable energy technologies

• Transition towards an energy system scenario using 100% renewable energy can be achieved within 20 to 30 years from a technical point of view, although important transformations have to be initiated now, especially regarding market and policy aspects.

EuroSun 2016 has accomplished all the initial expectations. 310 participants from 53 nations around the world attended the event. Attendees from Africa, Asia, Australia and North and South America joined their European colleagues making the EuroSun 2016 truly international.

357 extended abstracts were submitted to the 2016 EuroSun conference, resulting in 140 oral presentations, 150 poster presentations and 187 submitted and accepted full papers, which are now published in these proceedings. The proceedings of the ISES EuroSun 2016 conference, which collect those manuscripts carefully reviewed by the Scientific Committee, are published by ISES with a Digital Object Identifier for each paper.

Last but not least, we would like to say a special thank you to all members of the scientific and organizing committees for their valuable support, strong effort and commitment, which has made it possible to achieve this successful conference.

Energy strategies to nZEB sports hall

Alessia Accili, Joana Ortiz[1] and Jaume Salom[1]

[1] Catalonia Institute for Energy research (IREC), Barcelona (Spain)

Abstract

The Energy Performance of Buildings Directive recasts that by 2020 all new buildings constructed within the EU after 2020 and public buildings after 2018 should reach nearly zero energy (nZEB) levels. The present work aims to test, through the dynamic simulation tool TRNSYS, different energy strategies to design nearly zero energy sports halls in Mediterranean climates. The study is complemented with short period measurements of thermal comfort parameters and air quality indicators in a selected sports hall. The nZEB concept is achieved implementing passive strategies in combination with renewable energy systems. The impact of the identified energy solutions on the indoor thermal comfort and environmental indoor quality is also evaluated.

Key words: nZEB; sports hall; energy efficiency; TRNSYS simulation; IEQ; thermal comfort

1. Introduction

As reported in the article 2 of the European Union Directive 2010/31, a "nearly zero energy building" (nZEB), due to its very high efficiency, is characterized by very low energy requirements, satisfied by significant extent trough renewable sources available on-site or nearby. More than half of the member states (MS) are managing sport facilities as a precise nZEB subcategory (D'Agostino 2015). The Catalan region of Spain alone accounts for 2417 public buildings identified as sport facilities, responsible for 14% of the total primary energy consumption of the public building stock (Radulov 2014). Specifically, a standard sports pavilion uses 238 kWh/m^2 of primary energy every year. More than half of the current energy consumption of Catalan sports halls are relate to lightning (56%), a relevant energy use is due to domestic hot water (DHW) (28%), while heating and ventilation demand accounts for 4% (other electric consumptions accounts for 12% of the total) (ICAEN 2012). Those figures suggest that the energy performance improvement of sport facilities has a key role in the fulfilment of the article 9 of the Energy Performance of Buildings Directive. It states that MS shall ensure that all new public buildings must be nZEBs by December 31, 2018. The energy demand profile of a sports hall is closely related to the performed sport activity, the timetable of the sports centre, the public attendance during the matches and the climate conditions (Arutso and Santangeli, 2008). Sport halls in the continental European zone require the double amount of energy than the Mediterranean ones (Trianti-Stourna et al. 1998). In the German sports halls of Dresden-Weixdorf, through the installation of renewable energy technologies, storage systems and high efficiency devices, passive house standards have been achieved and the energy use optimized (Felsmann et al. 2015). Similarly, the study conducted by Flourentzou et al. (2015) assesses natural ventilation as strategy for energy consumption and costs reduction in a Swiss gym designed as a typical passive building. However, few researches investigated the energy use and generation patterns in relation to the comfort level perceived by the users of sports facilities. Summer overheating in passive sports structure is a studied phenomenon. It is possible to find in literature evaluations of effective and low energy demanding methods for thermal discomfort mitigation, as direct evaporative cooling, shading strategies, night ventilation, and openings optimization (Kisilewicz and Dudzińska 2015) (Tsoka 2015). The approach proposed in this paper supports the design of a nearly zero energy sports hall in Mediterranean climate through the implementation of different energy strategies and the evaluation of the

doi:10.18086/eurosun.2016.01.17 Available at http://proceedings.ises.org

thermal comfort condition in the different scenarios, aiming to guarantee a comfortable environment to the building users.

2. Methodology

Firstly, the indoor air quality and thermal behaviour of an existing sports facility are evaluated trough a field measurements campaign. The collected data are used to perform a comfort analysis according to the adaptive comfort methodology and the procedures described in the ASHRAE 55 (ASHRAE 55, 2004) and UNE-EN 15251 (AENOR 2008) standards. Consequently, a typical Spanish sports hall is identified as base case study and nZEB strategies are introduced. When the base case sport hall 3D geometry is defined in Google Sketch Up, energy efficiency measures are tested using the dynamic simulation tool TRNSYS, in order to estimate their impact on thermal comfort, air quality and energy needs. The implementation of renewable energy systems, specifically the potential contribution of the installation of a photovoltaic system, is estimated trough the Google Sketch Up plug-in Skelion.

2.1 Measurements campaign

The data regarding occupation patterns and environmental indoor quality are collected through field measurements in an existing facility. The main goal is to evaluate the indoor environment quality (IEQ) and the thermal condition of the sports hall. The field measurement campaign is realized in the "Poliesportiu Pla Del Bon Aire" located in Terrassa (Barcelona) and currently not equipped with a ventilation system neither a heating system. The measurements are performed along two days during the second weekend of March 2016. The thermal parameters as indoor air temperature at different heights, radiant temperature, air velocity, relative humidity and air quality indicators, as CO_2 concentration, are measured under different usage conditions. The instrumentation is installed compromising between quality of measurements, equipment safety and reduction of the interaction with building users. All data are recorded with 3 minutes intervals. The appropriate clothing insulation and metabolic activity profiles are estimated (tab.1). At the same time of the measurements campaign, the subjective perception of the users has been investigated through a questionnaire survey. Following the procedures described in ASHRAE 55 standard, the adaptive thermal comfort model is applied to evaluate the indoor comfort conditions, for spectators and for players. The exterior CO_2 concentration is considered equal to 450 ppm.

Tab. 1: **Metabolic activity (expressed in met; 1 met = 58.2 W/m^2 body surface) and clothing parameters (expressed in clo; 1 clo = 0.155 m^2 °C/W) (ASHRAE 55, 2004)**

	Activity	Metabolic activity [met]	Garments	Clothing insulation [clo]
Players	Basketball	6.3	Walking shorts, short sleeve shirt	0.36
Audience	Seated, heavy limb movement	2.2	Trousers, long-sleeve shirt plus long-sleeve sweater	1.01

2.2 Energy strategies to nearly zero energy sports halls

As mentioned, sports halls are characterized by very specific consumption profile. With the goal of fulfil the energy requirements of this particular kind of installation satisfying the users comfort needs and achieving a significant reduction of the primary energy use, appropriate nZEB strategies have been identified. The selection has been made in the light of the climatic conditions and of the type of use that characterize the investigated sports facility. Consequently, a suitable set of passive approaches, energy efficiency measures and renewable energy systems have been applied to the analysed base case building (table 2).

Tab. 2: Proposed nZEB strategies

	Measures	Implementation	Objective
Passive strategies and control	Thermal behaviour	• Selection of building materials to ensure low thermal transmittance of the envelope • Optimization of the ratio opaque components/ windows of the façade according to the building orientation • Installation of shading device in the South-east façade	✓ ensure good thermal insulation ✓ take advantage of the solar gains ✓ avoid risk of overheating
	Natural light	• Design of the South-east façade to maximize the contribution of natural light • Installation of diffuses light sources • Installation of skylight devices	✓ ensure visual comfort ✓ avoid glare
	Natural ventilation	• Definition of control system • Nigh ventilation • Design independently from the natural light system	✓ ensure thermal comfort of the users ✓ ensure good air quality
Renewable energy system	PV installation	• Design of the façades and the roof to allow the installation of PV panels • Study of the optimal roof slope and orientation to maximize the energy production	✓ reduce energy costs ✓ reduce CO_2 emissions
Active system	Artificial light	• Installation of LED lamps • Regulation with control system	✓ reduction of energy costs

2.3 Building simulation

The base case sports hall is defined following the technical indications provided by the Catalan sports council (Consell Català de l'Esport 2005, *CCE*) concerning a triple sports hall. A triple sports hall is a sports installation equipped with a playing field that can be divided in three transversal spaces, increasing its versatility. It results that 133 on 564 Catalan sports halls fall in this category; therefore, it is a representative building typology. The studied sports installation is located in Barcelona. The building geometry is modelled in Google Sketchup (fig.1) and then is introduced in the simulation by a 3D model, using the plugin Trnsys3D. The sports halls energy consumption is closely related to the number of users of the installation. For this reason, with the contribution of the data collected during the measurements campaign, realistic profiles of the sports hall occupancy have been defined. Two main occupancy patterns are identified, corresponding to weekdays and weekend. The information regarding the occupancy schedule is reported in table 4. The air tightness of the building is assumed equal to n_{50} = 2.6/h. According to UNE-EN 15242 (AENOR 2007), the considered value corresponds to a level of airtightness medium. Only the behaviour of the playing arena of the sports hall is simulated. Thermal performance and energy consumption of other environments, as lockers rooms, that typically form part of this type of buildings, are not taken into account in this research. Moreover, it is specified that, being based on a real sports hall project, this work has to comply with some limitations and does not involve the study of default parameters, as the building orientation.

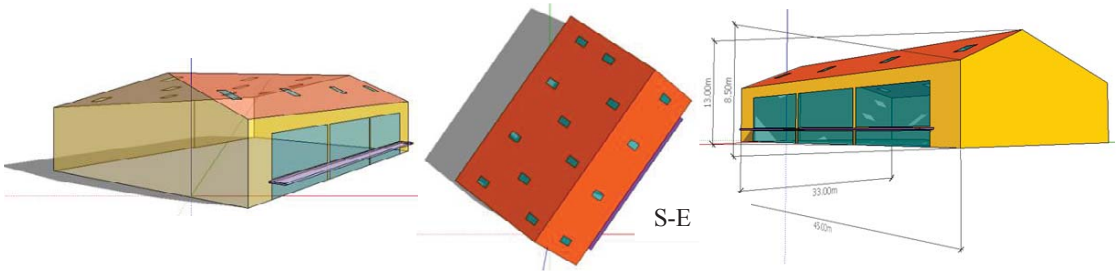

Fig. 1: Sports Hall 3D model

2.3.1 Thermal behaviour

The thermal characteristics of the selected opaque components of the envelope are reported in table 6, while the thermal performance of the windows in table 5. The façades and the windows are in contact to the exterior environment. There is only an interior wall located in the North West direction and assumed in contact to the lockers room. The boundary temperature for this partition wall is considered of 23 °C or 18 °C, respectively during the summer and winter occupied periods. While, the unoccupied periods are characterized by a boundary parameter evaluated as average of the previous values and the exterior registered temperature. The thermal behaviour of the building is affected by the installation of a fix horizontal overhang that aims to prevent excessive temperature increase during the warm season.

Floor	1.366

2.3.2 Natural ventilation

Natural ventilation has been investigated in detail. It is chosen as the main strategy to ensure optimal indoor air quality and thermal comfort, avoiding the energy consumption due to mechanical system. The thermal comfort is evaluated applying the adaptive comfort model. The comfort conditions are set according to the limits defined in the standard UNE-EN 15251 and observing the requirements reported in the document redacted by the Catalan sports council. The indoor optimal operative temperature (Top_{opt}) is calculated following the procedure proposed by the standard. The CO_2 concentration is the parameter used to evaluate the indoor air quality (table 7). Cross-natural ventilation is modelled through TRNFLOW (Weber et al., 2003), the extension for the integration of the airflow and pollutant transport model COMIS into the building thermal model of TRNSYS. Two identical openings are introduced in opposite façades of the building, taking into account the prevalent wind direction of the site. The characteristic of the openings are reported in table 8. The wind pressure coefficients, the discharge coefficients and the wind velocity profile are introduced according to the parameters reported in literature and in the TRNFLOW manual. The flow coefficient is calculated taking into account the desired infiltration in the building. $CO_{2\ is}$ the only examined pollutant inside the zone. The outside concentration is set to 450 ppm and assumed constant for all the external nodes and directions. The occupants of the sports halls are considered as CO_2 sources in proportion to their metabolic activity. Therefore, the contaminant exhalations from the audience accounts for 21.5 l/s per person while players are responsible for 62.5 l/h per person (Demianiuk et al. 2010). The air velocity in the building is assumed equal to 0.25 m/s when the natural ventilation is not operating and of 0.5 m/s when the openings are open. The selected values are in the range of acceptability considering that the recommended upper limit for indoor air movement is usually 0.8 m/s (Allard 2002). The control of the simulated natural ventilation system depends on the occupancy, the interior operative temperature and the CO_2 concentration. Natural ventilation is activated only when the building is occupied. Natural ventilation activation implies that the openings are opened if the operative temperature exceeds the upper limit of the selected thermal category or if the indoor CO_2 concentration is outside the air quality range. Specifically, the interval of indoor tolerable concentration is restricted respect to the recommendations of the standard.

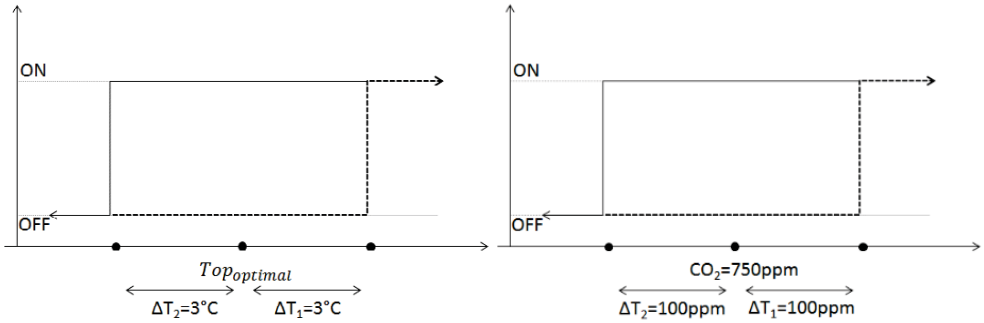

Fig. 2: Natural ventilation control. Simple line: openings behaviour if the actual state of the natural ventilation system is ON. Dashed line: openings behaviour if the actual state of the natural ventilation system is OFF

This configuration is introduced to give stability to the system, to avoid frequent on / off cycles and to allow the removal of the excess CO_2 while there is continuous emission from the occupants. The operation of the

control system is schematized in figure 2. Additionally, the opening factor is adjusted to reduce the risk of overcooling and air draft. At this scope, the openings are more or less opened depending on the difference between the interior and exterior temperature during the cold season and on the wind velocity during the warm one, as table 9 shows. Moreover, during the weekend, when the CO_2 production is significant, the system is forced to work with an opening factor equal to 1, unless the wind velocity is greater than 6 m/s. Again, this condition is suggested to maintain the stability of the system, namely to avoid that a substantial flow of air can rapidly reduce the pollutant concentration causing the closure of the openings. Indeed, it is desirable that the natural ventilation system works constantly during the period of high occupancy. To verify the effect on overheating risk reduction, night ventilation is also tested. In summer, natural ventilation is activated after that the users leave the sports hall if the exterior air temperature is lower than the interior one. In general terms, set this conditions, natural ventilation stays on until the morning hours.

Tab. 7: Comfort parameters

	Lower limit	Upper limit	Source
Operative temperature (°C)	$Top_{opt} - 3$	$Top_{opt} + 3$	UNE-EN 15251

0.8	7.5 -3.75	5 - 4
1	< 3.75	< 4
1	if Occ=max and wind velocity < 6m/s	

2.3.3 Internal gains

The internal gains of a building are formed by the release of sensible and latent heat from indoor heat sources. This study considers the contribution of the building occupants and of the lights appliances. The sensible heat produced by the occupants depends on their metabolic activity and on the indoor air temperature, as reported in Michaelsen and Eiden (2009). The total sensible heat produced by the users of the sports hall is considered 30% convective and 70% radiative (ASHRAE 1993). The artificial lights system is mounted at 13 meters high. It is composed of 30 led lamps consuming 276 W each, with luminous efficiency of 80% (Ortiz et al., 2015). The installed systems is designed to ensure 300 lux of indoor illuminance, following the recommendation of ICAEN (2012) for basket arenas. Therefore, the contribution of the lights equipment to the internal heat load is calculated in function on the natural light availability. Artificial lights are assumed to be on when the sports hall is occupied and the natural light provided by the 14 skylights placed on the roof and by the windows on the façade is lower than the required illuminance level (according to Consell Català project). The data, regarding the hourly average daylight availability are provided by an external collaborator for a typical day of each month and introduced as input in TRNSYS.

2.3.4 PV system

PV Building Integration (BIPV) is a practice that refers to the use of PV modules as architectural elements, being a collaborative part of the design of the building envelope and having an architectural function in symbiosis with functional properties and economic regenerative energy conversion (Achenza and Desogus, 2013). Part of this research has dealt with the test of different PV system configurations designed to contribute to the energy needs of the investigated sports facility. The analysis is performed through the Google Sketchup plug Skelion and the relative findings are shown in the results section 3.3.

3. Results and discussion

3.1 Measurements campaign

After the data acquisition phase, the measured indoor conditions of the reference sports building have been analyzed in combination with the weather variable, the results of the survey and the assumed parameters. According to the survey answers (54), 84% of the audience was experiencing a thermal discomfort, mainly due to overheating: 33% affirmed that the environment was slightly warm, 28% that it was warm and 17% that it was very warm (only 3 people considered it slightly cold). Regarding the humidity variable, the majority of the audience (65%) considered the environment neutral, while the air movement was perceived mainly as inadequate (slightly low for 33% and very low for 37%). However, results of the comfort analysis show that the adaptive comfort requirements reported in the ASHRAE 55 standard are complied, as well as the design criteria established by the standard UNE-EN 15251 (fig.3) in relation to the acceptable indoor relative humidity. Conversely, looking at the level reached by the interior CO_2 concentration, it results that the comfort condition recommended by the UNE-EN 15251 standard are not always met (fig.4).

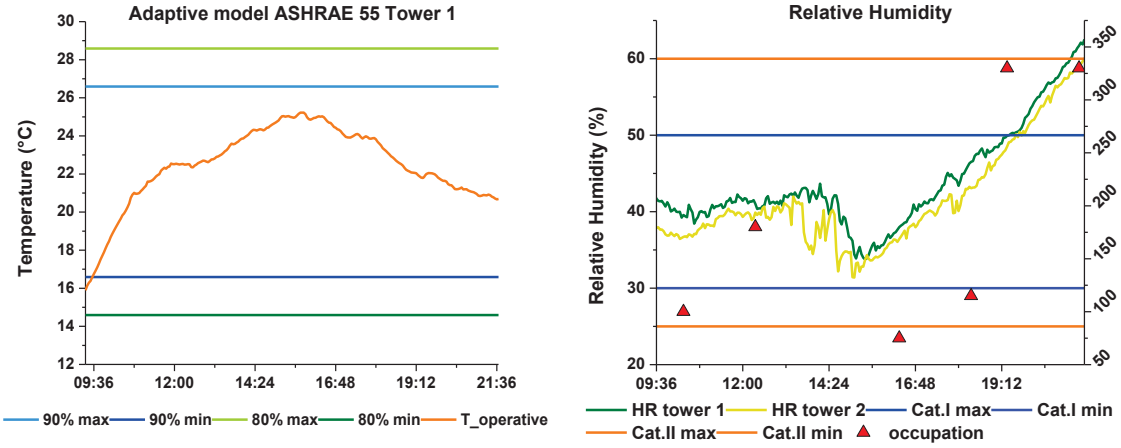

Fig. 3: Left: Adaptive thermal comfort evaluation; Right: relative humidity measurements and comfort categories

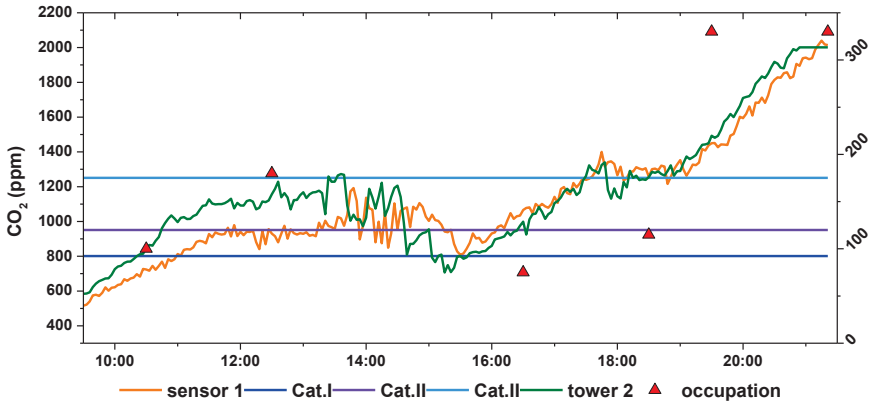

Fig. 4: CO_2 concentration measurements and comfort categories

Therefore, taking also into account that the mentioned standards are not specifically elaborated for sports facilities and for the consequent high level of metabolic activity of the users, the sharp increase of the indoor relative humidity and the excessive CO_2 concentration during the hours of maximum occupation appear as the main cause of perceived discomfort.

3.2 Building simulation

The objective of the building simulation is to verify to which extend the selected nZEB strategies are able to reduce the primary energy consumption of the studied sports hall without causing discomfort to the users. The TRNSYS results are organized in table 10 and reported in function of the natural ventilation state, being the only variable parameter. Observing figure 5, that shows the TRNSYS simulation outputs for a selected winter week, it results that the designed control system works correctly. The thermal discomfort and the air quality are assessed only during the occupied hours. It is assumed that the overheating phenomenon occurs if $Top_{int} > Top_{opt} + 3$, as the technical indications provided by the Catalan sports council do not set a maximum indoor temperature requirement. The building is overcooled if the condition $Tair_{int} < 14°C$ is verified. The maximum registered ACH is 9.97h^{-1}. The average ACH with natural ventilation on is 1.57h^{-1}, while the infiltration on average equals to 0.05h^{-1}. The presented results are achieved without the introduction night natural ventilation. As shown in table 10, the discomfort due to overheating is very low thank you to the contribution of the infiltration and the high thermal insulation of the building. The effect of additional night ventilation further reduces the overheating phenomenon to 0.1% of the occupied time. Therefore, the implementation of night ventilation technique results to have a limited impact on the thermal comfort improvements of this study case building situated in a moderate climate. However, night cooling can be considerably beneficial in extreme climate conditions and if heat wave phenomenon occurs in moderate climate. Closely analysing the discomfort events, it results that for 2 days overcooling occurs during 2.75 hours, the maximum consecutive period of overcooling thermal discomfort. The maximum consecutive period of discomfort due to excessive CO_2 concentration is 3 hours and it occurs only one day along the annual simulation. Overall, considering thermal and air quality parameters, annually the sports hall users experience 16 days of discomfort with the distribution shown in figure 6. The results deviates from the limit values for maximum 329 ppm, 4.61°C in case of overcooling and 0.48°C in case of overheating.

Tab. 10: Building simulation results

	% of the occupied time	
	winter	summer
natural ventilation ON	54.76	50.09
Overcooling	1.69	-
Overheating	-	0.36
CO_2 > 1200 ppm	1.20	0.71

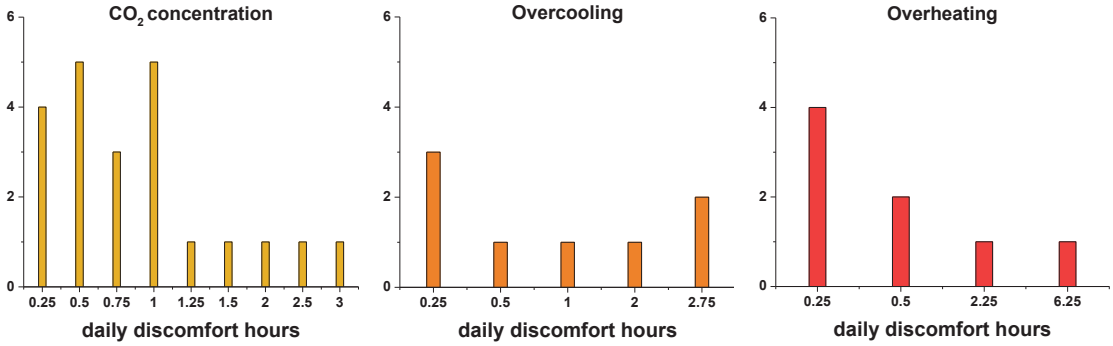

Fig. 6: x-axis= discomfort hours; y-axis=number of day

3.3 PV system

Table 11 summarizes the results of the PV designs analysis. The economic data are extrapolated from Hulb el al. (2014). The comparison of the different PV system configuration suggests that, considering the available surface for PV modules integration and the weather condition of the site, the most advantageous solution is the one tested in case 10. In a range of acceptability of 5%, case 2 and case 6 have similar performance. The mentioned cases are characterized by the installation of the panels with a slope of 38° and an orientation toward the south direction (182°). The integration of the PV panels in the façade and on the shading device of the building results less convenient.

Tab. 11: PV system configurations

		Azimuth	Slope	Panels	kWp	Specific generation (kWh/kWp)	Total generation (kWh)	Specific cost (€/kWh)
1		135	20	367	42	1255	52985	1.11

Within the 16 tested PV system configurations, case 2 has been selected and simulated in TRNSYS through type 94. The obtained results allow evaluating, for every time step along the yearly simulation, the energy balance between electricity demand and electricity production. According to the TRNSYS calculation, the total annual generation of case 2 is 35'426 kWh. This value differs from the output obtained through Skelion. In this regard, it must be taken into account that weather data and the PV module technical features used by the two software are also different. The PV system is able to cover 10% of the electricity building energy demand, including artificial lighting and ventilation.

3.3.2 Energy balance

From the analysis of the building energy needs, it results that the thermal load necessary to comply with the minimum temperature requirements equals to 213 kWh/y (0.14 kWh/m^{2}y) while the light consumption accounts for 13'968 kWh/y. The electricity demand due to the automation of the natural ventilation systems is estimated at 509 kWh/y. Elaborating the data made available by ICAEN (2012), the obtained results are compared to the heating, lighting and ventilation performance of a standard triple sports hall and of an efficient one, concerning which energy efficacy measured are applied. Additionally, the respective not renewable primary energy requirements are compared in figure 7. It is assumed that the thermal demand of the simulated sports hall is covered by the installation of a condensing boiler (η=1.09) combined with an emission and distribution system consisting of radiant panels (η=0.9). The considered not renewable primary energy conversion factor are 1.954 kWhPE/kWhFE and 1.190 kWhPE/kWhFE, used respectively for electricity and natural gas consumption (RITE 2014). It is evident that the selected energy strategies substantially contribute to the objective of energy consumption reduction set for the simulated building. Overall, it consumes 87.5% less energy than a standard sports hall and 70% less than an efficient one.

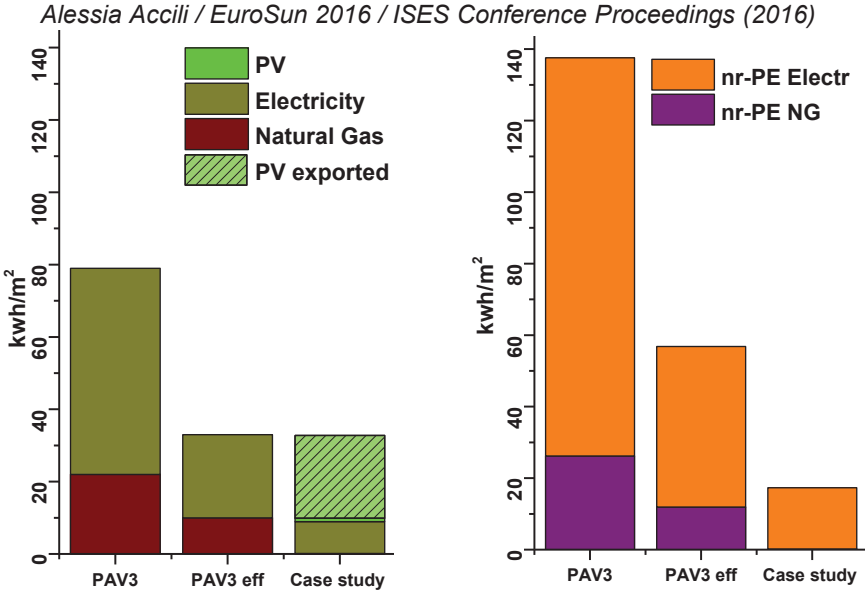

Fig. 7: Left: final energy; right: not renewable primary energy

4. Conclusion

Under a holistic approach, different energy measures to design nearly zero energy Sports halls have been tested. A novel aspect of the study is the focus on the peculiarity of the Mediterranean climate context. The first step of the research involves a field measurement campaign in an existing facility. The obtained data suggest that in a standard sports hall comfort issues are closely linked to indoor air quality. Excess of CO_2 concentration causes discomfort perception, even though the registered thermal parameters fall within the acceptability range. Secondly, TRNSYS simulation confirms that the combination of reduction of thermal transmittance of the envelope, optimization of the window surface, correct façades orientations, introduction of shading devices, installation of energy efficiency systems, and use of natural and night ventilation, is advantageous for the reduction of heating, cooling and artificial lightning demand. The described strategies minimize the period of overcooling and overheating, and provide good air quality conditions for most of the occupied time along one-year simulation. The design of the natural ventilation system and of the relative control play a relevant role. It is estimated that a natural ventilated sports hall, not equipped with a heating system, will be overcooled for 1.69% of the winter occupied time, while CO_2 concentration will exceed normative limits only during 0.95% of the year. It is verified as well that PV system integration positively affects the sports hall performance toward nZEB standards. Future development of the study can involve the evaluation of the sports hall DHW needs and investigate the potential contribution of a thermal solar system. Furthermore, it is important to report that the accuracy of this investigation is compromised by the absence of comfort and thermal standards specifically elaborated for the sports building category.

Abstract

Industries are responsible of emitting 40% of total energy-related CO_2 emissions and about one third of total final energy consumption. Introducing energy management systems allow companies to manage and control their energy use, enabling them to lower energy costs, and enhance productivity and competitiveness. Demand side management using thermal energy storage and off-grid solar photovoltaic technologies could enhance the performance of energy systems and reduce on-peak demand for industries. In the present paper, the feasibility of reducing the annual electricity bill mainly by peak shifting will be studied by applying cold TES and off-grid solar PV along with a proper time-of-use tariff structure. Simulations results have shown that adopting a proper time-of-use tariff structure in combination with cold TES coupled with off-grid solar PV can considerably increase annual energy savings mainly by shifting electricity demand to nighttime off-peak period. Additionally, it was estimated that for the analyzed case study (450 kW of electrical demand 9 hours/day for cooling processes) 5000 € to 75000 € of annual energy bills can be saved by applying TES and solar PV with different capacities. Moreover, it was found that the combination of TES and solar PV technologies based on time-of-use tariff structure can improve the economic savings by 3% to 9% in comparison to using the two mentioned technologies separately.

Keywords: *cold storage, thermal energy storage, solar PV, demand side management, optimization.*

1. Introduction

Industry accounts for about one third of total final energy consumption and almost 40% of total energy-related CO_2 emissions which are expected to rise by 46% by 2040 (Makridou et al., 2016). The European Union´s (EU) Energy Roadmap 2050 explores solutions towards decarbonisation by 2050 by over 80% while at the same time guaranteeing security of energy supply and competitiveness (European Commission, 2011). On this basis, the European commission (European Commission, 2011) is placing increasing priority on energy savings in all decarbonisation scenarios and furthermore, supporting the significant increase of renewable energy sources. Electricity storage in a large scale is not feasible; therefore electricity has to be consumed in real time covering the demand. On the other hand, since generation plants with different supply sources such as thermal, solar photovoltaic (PV), hydro, wind and other renewables of variable efficiency are used to meet demand, the cost of electricity varies hour to hour, day to day, and month to month (Faruqui et

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/eurosun.2016.03.07 Available at http://proceedings.ises.org

al., 2010). Additionally, variability in both demand profiles and renewable energy sources makes the energy management of the grid more difficult and increases the cost of electric power generation (Batalla-Bejerano and Trujillo-Baute, 2016).

Peak electricity demand is a global policy concern which causes transmission constraints and congestion, and increases the cost of electricity for all end-users. Further on, a huge investment is needed to upgrade electricity distribution and transmission infrastructure, and build generation plants to provide power during peak demand periods (Strengers, 2012). Furthermore, commonly service suppliers charge a higher price for peak-time services than for off-peak services in order to compensate for the costly electricity generation at peak hours (Kim et al., 2016). So that, cutting off some of this peak demand would benefit the whole energy system since, on one hand, it would eliminate the need to install expensive extra generation capacity such as combustion turbines for peak hours which are less than a hundred hours a year (Faruqui et al., 2007) and on the other hand, consumers can eliminate penalties due to exceeding power demands in their electricity bill. In addition, due to infrequent use of peak plants, making them more efficient is not fair. So that, normally it is cheaper to feed peak electricity generators by oil which results in more CO_2 emissions (Faruqui et al., 2010). Accordingly, even a small percentage of peak demand reduction can promise substantial savings in generation, transmission, and distribution costs (Faruqui and Sergici, 2010). Using flexible resources in the power system such as renewable generation, storage, and demand management could be a solution to increase the security and satiability of the whole energy system, to save energy and to reduce the hazardous emissions (European Commission, 2011).

Demand side management (DSM) is a proactive way to make customers energy-efficient in the long-term (Barbato and Capone, 2014). The most prominent DSM methods include reducing peak loads, shifting load from on-peak to off-peak , increasing the flexibility of the load and reducing energy consumption in general (Müller et al., 2015) where load shifting has been found as the most effective load management technique (Esther and Kumar, 2016). DSM can reduce both the electricity peak power (kW) and the electricity consumption (kWh) (Warren, 2014; Zhou and Yang, 2015). Further on, some countries have adopted or are investigating time-of-use distribution network tariffs such as Spain (Real Decreto 1164/2001, 2016), which aim at shifting consumption to off-peak hours to avoid grid constraints (European Commission, 2015). Time-of-use tariffs can encourage customers to take advantage of price variations in different periods of time to regulate their electricity use. In such schemes, a group of prices are determined in advance and they apply to different periods of time, where the electricity prices are discriminated by patterns and rates (Li et al., 2016). Thus, based on the information provided by suppliers, high energy consumers can decide how to distribute their loads according to variable electricity tariffs using different technologies (Buryk et al., 2015; Yalcintas et al., 2015). They will be able to shift their electricity consumption away from times of high prices (peak hours) to times of low prices (off-peak hours) and by that reduce their energy bill.

Energy storage technologies can have a valuable role to play in any energy system, including those with high and low proportions of renewable generation (e.g. solar PV) with variable nature due to weather conditions (Kousksou et al., 2014). Thermal energy storage (TES) has been the center of attention of many researchers during the past decades (Zalba et al., 2003). In particular, the application of cold storage systems has been broadly developed in the power generation sector, the building sector, and the industrial sector because of their high potential to temporally shift the increasing cooling demand, reducing the stress on the energy system (International Energy Agency, 2011) and on the other hand, reduce the greenhouse gas emissions (Cabeza et al., 2015; Yau and Rismanchi, 2012). Refrigeration systems producing artificial cold with electrical or heat driven chillers, infrequently operate at full capacity. They usually operate during day to meet the cooling demand and are designed to satisfy the maximum cooling demand, which occurs only a few days each year. A wide range of economic, technical and energetic advantages are attainable by integration of a cold storage in such a system to supply cold such as: energy cost reduction, investment cost reduction by selecting a smaller chiller, possibility of using off-peak cheap electricity tariffs, increasing the flexibility of the system, reduction of peak electricity loads on the grid (if compression chiller is used), improving energetic efficiency (COP) of chiller, etc. (Mehling and Cabeza, 2008; Oró et al., 2014). However, further research and advancement are required for electric load management (Arteconi et al., 2012) to address the potential energy savings and peak load shaving regarding the new time-of-use tariff structure and elevated

electricity prices, high surplus demand charges, and variable solar PV share and its uncertainties in the energy system. On this ground, numerous studies have focused on DSM applying optimization techniques (Ikeda and Ooka, 2016; Muralitharan et al., 2016). The present study is an attempt to address the potential for implementation of incentive time-of-use tariffs (according to the Spanish electricity tariff structure) by an industrial consumer to reduce the electricity bill. However, it should be noted that, this method could be implemented in other countries with incentive time-of-use tariff structure. Particularly of interest are, on one hand, to reduce contracted power demands and to shift electrical chiller peak loads from high price times (peak hours) to low price times (off-peak hours), by taking advantage of cold TES (sensible systems, ice or phase change materials) and off-grid solar PV; and on the other hand, to find out the optimum combinations of power demand contracts with TES and solar PV technologies to reduce final electricity bill and comparing that with a conventional energy system.

2. Methodology

To have a better understanding of the methodology an overview is presented in this section. In section 2.1 the case study is described; section 2.2. is dedicated to the solar PV simulation; in section 2.3. the cold TES model is explained; section 2.4. focuses on the time-of-use tariff structure; and eventually section 2.5 defines the optimization procedure. Figure 1 shows a schematic of the implemneted approach.

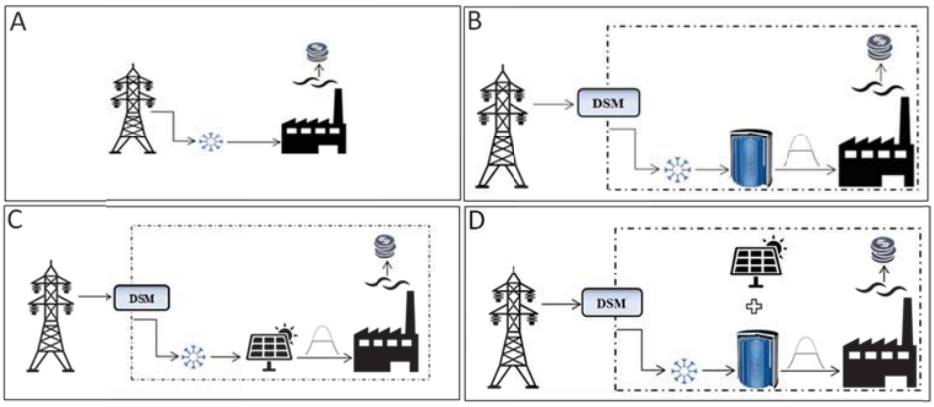

Figure 1. Schematic view of the methodology.

2.1. Case study

To give an estimate of the annual energy bill for an industrial consumer it has been assumed that for running the industrial processes of this industrial unit, a conventional energy system with no demand management facilities and with a conventional tariff structure has been used. So that, the industrial consumer directly uses the electricity network to provide electricity for its processes whenever it is required without considering the on-peak demand and off-peak demand periods (Figure 1.A). The industrial processes take place from 8:00 to 17:00 all days except Saturdays and Sundays requiring 450 kW of electrical demand for cooling processes. On this basis, the monthly electricity bill was calculated according to the Spanish electricity tariff structure (6.1A plan) which is divided into six different tariff periods (according to month and hourly basis) and is explained in detail in section 2.4.1.The annual electricity bill can be calculated using eq.1. Moreover, it is assumed that for all tariff periods the industrial consumer contracts 450 kW power demand with 100% of load factor during operational hours.

$$Elec_{tot} = (E_p + E_e) + [(E_d + E_e) \times \text{VAT}] \qquad \text{(eq. 1)}$$

$$E_p = \sum_{i=1}^{i=6}(P_i \times CP_{pi})$$

$$E_e = \sum_{i=1}^{i=6}(P_i \times CEp_i \times h)$$

Where $Elec_{tot}$ is annual electricity bill, E_p is power demand cost, E_e is energy consumption, VAT stands for

value added taxes; P stands for different tariff periods; CP and CE are cost of power [kW] and energy [kWh] for different periods according to Table 2, respectively. Investigation will be made into the possibility of shifting peak loads from daytime to nighttime by integrating a tariff-based DSM system with three different energy system designs. 1. tariff-based design coupled with a cold TES system (Figure 1.B), 2.tariff –based design coupled with an off-grid solar PV (Figure 1.C), and 3.tariff-based design coupled with both cold TES and off-grid solar PV systems (Figure 1.D). In case 1 (Figure 1.B), the cold TES tank has to be charged at nighttime during the cheapest tariff period and later on, it has to be discharged during day especially at expensive hours of electricity rates. In case 2 (Figure 1.C), the feasibility of applying only off-grid solar PV to reduce the energy bill will be assessed. Eventually, in case 3 (Figure 1.D) the possible energy benefits due to coupling both cold TES and solar PV and their mutual impacts on each other will be investigated.

2.2. Simulation of PV module

In order to analyze the solar PV electrictiy generation in the desired climate, TRNSYS 17 (transient system simulation tool) (Klein, 2010) was used. This software has an extensive library of components in which appropriate models (called types) could be selected for simulating thermal and electrical energy systems. In the present study, Type 15.3 (weather file reader), Type 16a (radiation processor), Type 94a (crystalline solar PV module), Type 25c (printer), and Type 65d (online printer) were selected and appropriately interconnected to carry out the solar PV simulation.

The potential solar-generated electricity can be calculated using Type 94a which models the electrical performance of a photovoltaic array and could be used in simulations involving electrical storage batteries, direct load coupling, and utility grid connections. It applies equations for an empirical equivalent circuit model to predict the current-voltage characteristics of a single module. This circuit consists of a DC current source, diode, and either one or two resistors. The strength of the current source is dependent on solar radiation and the IV characteristics of the diode are temperature-dependent (TRNSYS 17, 2016). Sunrise SR-M762315-B solar PV (Figure 2) (Sunrise, 2016) technical data as shown in Table 1 was introduced to Type 94a and four different nominal installation power of 25, 50, 80, and 100 kWp were considered. Further on, all the solar PV modules were considered to have 40º of array slope and 0º of azimuth.

Figure 2. Sunrise SR-M672315 module (Sunrise, 2016).

Maximum series fuse [A]	15
Wind bearing [Pa]	2400
Pressure bearing [Pa]	5400
Standard Test Conditions (STC):1000W/m^2 AM=1.5 25 ºC	

Simulations were performed using time steps of 15 minutes for fifteen consecutive years (1991-2005) using historical solar radiation data of Denver international airport, Colorado, US (Köppen-Geiger classification: BSk) which was derived from NREL data base (National Renewable Energy Laboratory, 2007). This climate was selected because of two reasons, first, because we did not have historical weather data of the desired climate and second, the climate classification of the desired city which is in Lleida provice, Spain presents the same climate classification as Colorado.

2.3. Cold TES model

Cold TES system was included into the design to shift both the electric demand (kW) and the energy consumption (kWh) from higher cost (on-peak) and middle cost (partial-peak) periods to the lower cost (off peak) period. This design was based on an operating schedule with two modes: mode (1) charging the cold TES during the nocturnal period (the cheapest period); and mode (2) discharging the cold TES tank during the diurnal period (avoiding or reducing compressor operation), with assumed peak capacities ranging from 2 to 250 kW. The cold TES was sized to hold different storage capacities (25 to 3000 kWh) in order to evaluate the effect of the storage capacity in the economic benefits. Commonly, standby heat gains occur in storage tanks due to the heat conduction, convection and infiltration. These losses are very dependent on the indoor and outdoor boundary conditions, insulation level of storage tanks etc. On this basis, in order to take into account these heat losses, some heat loss values corresponded to cold storage tanks were derived from experimental results available in literature (Stovall, 1993; Therese K. Stovall, 1991; Therese K.Stovall, 1991a, 1991b). Afterwards, standby heat losses values of 0, 0.50, 1, 1.5 kW were considered to be implemented into a model with 50 kWp solar PV to see the impact of heat losses on the final energy cost.

2.4. Time-of-use tariff structure

2.4.1. Electricity tariffs

The electricity tariffs used in this case study are based on the Spanish current prices. Spain has several major electricity companies, of which Endesa S.A. (“Endesa S.A.,” 2016) is the holding company for the active players in the electricity market. These players include generation, transmission, and customer relations. Transmission includes the network which delivers electricity from generators to customers. They are responsible for constructing and servicing this grid. This service is charged via a network charge priced in €/kW. These charges are regulated by government legislation and therefore transparent. Generators are large conventional power stations which generate power and either sells it to the electricity market or through contract with customer relations. The electricity spot market involves bids and purchases by generators and customer relations, and prices are cleared every period. Customer relations are the principle agent by which households and businesses interact with the electricity grid. They pass on transmission charges at cost, and an energy price charged per kWh usage. The energy price is negotiated but there are standard prices publicly available. Many large customers have their own transformer and make Endesa transmission manage it. Alternatively, Endesa transmission pays for the transformer and manages it, and this is negotiated.

2.4.2. The electricity bill

The electricity bill consists of an energy charge, peak demand charge, and taxes. Taxes are significant and include an electricity tax of 5.1% and a value-added tax (VAT) of 21%. The charges depend on your demand category as followings: 2.0 A: demand less than 10 kW; 2.1 A: 10 < demand < 15 kW; 3.0 A: demand > 15 kW; 3.1 A: demand < 450 kW; and 6.1 A: demand > 450 kW. Depending on which demand category the

consumer fits in, it determines how many charge categories are applied to the contract. The residential sector has P1 and P2 charge categories, where the 6.1A demand categories vary from P1 to P6. In each charge category a peak and energy charge is applied. For category 6.1, the one contracted by the case study of the present paper and by most of the industrial applications, the applied incentive time-of-use tariffs are shown in Figure 3.

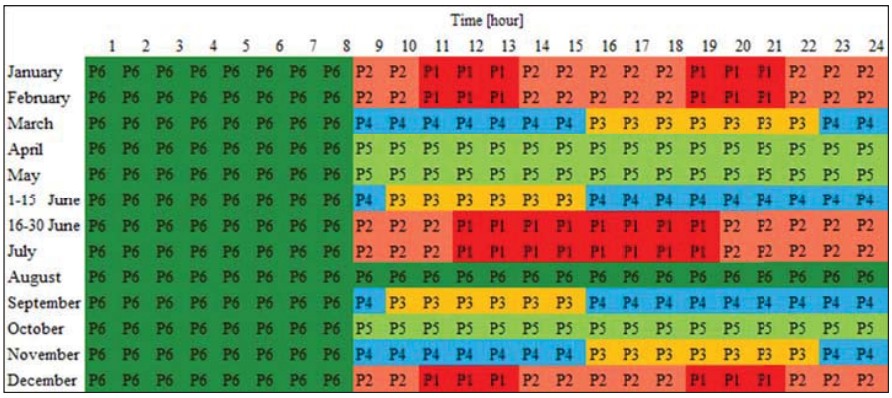

Figure 3. Hourly distribution of electricity rates.

Figure 4 shows the hourly and monthly periods during which each tariff structure is applied. PX refers to the tariff price profile consisting of a peak, off peak and middle peak price. P6 refers to all prices at off peak rates. The tariff consists of both an energy price and a demand price per period (see Table 2).

Table 2.Incentive time-of-use electricity prices ("Endesa S.A.," 2016).

	P1	P2	P3	P4	P5	P6		
Power	39.139	19.586	14.334	14.334	14.334	6.540	€/kW/ year	Regulated price
Energy	0.120	0.096	0.092	0.074	0.0708	0.065	€/kWh	Standard free price

2.4.3. Charges due to power excess

In case that an industrial consumer requires more demand that it is contracted in each determined time interval (for some minutes or even hours), a penalization due to power excess is charged to the bill. This penalization is calculated according to the power contracted in each tariff period and, if applied, depending on each tariff period, the actual demanded power rates are metered using electricity metering equipment. The billing of the excesses of power for the 6.1 tariffs is calculated according to the formula established in Royal Decree 1164/2001 (Real Decreto 1164/2001, 2016) (see (eq.2) and (eq.3)), and it is measured every 15 minutes.

$$F_{ep} = \sum_{i=1}^{i=6} K_i \text{ x } 1.4064 \text{ x } A_{ei} \qquad \text{(eq. 2)}$$

Where F_{ep} stands for charges in Euros and A_{ei} is a factor that weights excess of demand depending on the period (Real Decreto 1164/2001, 2016), K_i is the coefficient that takes the values depending on the tariff period i as shown in Table 2, A_{ei} is calculated according to the following formula:

If Pdj <= Pci

$A_{ei} = 0$

Else if

Pdj > Pci

$$A_{ei} = \sqrt{\sum_{j=1}^{j=6} (Pdj - Pci)^2} \qquad \text{(eq. 3)}$$

Where Pdj is demanded power in each quarter of hour which is excessed (higher than Pci), Pci is contracted power in each period and in the considered period.

Table 2. Ki coefficients according to the tariff periods.

Period	1	2	3	4	5	6
K_i	1	0.5	0.37	0.37	0.37	0.17

These powers are expressed in kW and the excesses of power are billed monthly. For tariffs 6.1 at every breach is charged a penalty i.e. every 15 minute breach. Thus, it means that if the user overpasses the contracted power during one hour, the penalty is charged four times.

2.5. Optimization

A large and growing body of literature has been published on optimization techniques for DSM based on TES and solar PV to reduce energy-related costs of residential buildings and industrial processes (Barbato and Capone, 2014; Lee et al., 2009; Muralitharan et al., 2016). Some of these optimization methods are namely, mixed integer linear programming (MILP) and dynamic programming for a global optimal solution. Further on, metaheuristic methods such as particle swarm optimization and evolutionary algorithms have been implemented by many researchers (Müller et al., 2015). It could be understood that for given electricity consumption requirements, an optimization problem can be derived based on the power contracting plan, i.e. how much power is contracted for each one of the 6 period tariffs. The optimization problem results deterministic when no PV production is considered. Otherwise, PV uncertainty will lead to stochastic optimization. On both cases, Constraint Integer Programming (CIP) has been used as a novel paradigm that integrates constraint programming (CP), mixed integer programming (MIP), and satisfiability (SAT) modeling and solving techniques in order to model and solve our problem (Achterberg, 2009, 2008; Achterberg et al., 2008). Without PV production, the system may be described as sets, parameters and functions as follows:

$P = \{P_1 .. P_6\}$, is the set of tariff periods; $CE_i, i \in \{1..6\}$ is the cost of energy consumption during period P_i according to Table 1 in €/kWh; $K_i, i \in \{1..6\}$ is the coefficient as defined in Table 2; *SL* is the cold TES storage limit capacity in kWh; *H, D* and *M* are the set of hours, days and months respectively; *T=H*D*M* is the set of hour periods in a year; $Period: T \rightarrow P$, is a function that maps an hour period to its corresponding tariff as corresponding to Figure 4; $C_i, i \in H$, is the required energy during an hour. However, in our particular case:

$$C_i = \begin{cases} 450kW \cdot h, & i \in 8..17 \\ 0, & Otherwise \end{cases}$$

It should be noted that for a constant energy demand, $C_i = 4 \cdot P_{dj}$, being P_{dj} the demanded power in each quarter of hour as stated in eq.3.

$$f(x) = \begin{cases} x, & x > 0 \\ 0, & x \leq 0 \end{cases}$$

$PC_i \in \mathbb{R}, i \in 1..6$, is the contracted power for tariff P_i; $S_t \in \mathbb{R}, t \in T$, is the supplied energy from the grid in time *t.* When suitable, one can also denote S_t as $S_{h,d,m}$. Therefore, the cost of contracting power (*CP*) can be expressed as:

$$CP = \sum_{i=1..6} CP_i \cdot PC_i \qquad \text{(eq. 4)}$$

and the cost of the consumed energy is:

$$CE = \sum_{t \in T} S_t \cdot CE_{Period(t)} + K_{Period(t)} \cdot 1.4064 \cdot f\left(S_t - PC_{Period(t)}\right) \quad \text{(eq. 5)}$$

Finally, the following assumptions have been made: 1. PCM storage period ranges from hour 00:00 to 07:00. This is an obvious optimal assumption because those are the cheapest periods and no demand exists. 2. The stored energy can only be consumed during the same day. The objective is to find an optimum assignment of $PC_i \in \mathbb{R}, i \in 1..6$, that minimizes CP+CE, which could be written as:

$$\min_{PC_i}(CP + CE) \quad \text{(eq. 6)}$$

subject to the following constraint:

$$SL > \sum_{h=0}^{7} S_{h,d,m} > \sum_{h=8}^{17} C_h - S_{h,d,m}, \forall (d,m) \in D * M \quad \text{(eq. 7)}$$

For example, for each day, the stored energy must not surpass the storage limit and must supply the eventual lack of obtained energy from the grid. In order to reduce the number of variables, symmetries may be considered. As energy requirements are invariant from day to day (C_i), the number of variables can be drastically reduced. More specifically, S_i can be indexed in *H*M* instead of *T*. We encoded and solved eq.6 and eq. 7 with SCIP version 3.2.0 ("SCIP Optimization Suite," 2015) in a 1.9 GHz processor. The problem results in 581 variables and 484 constraints, being solved in less than 2 seconds. When solar PV production is considered, it can be taken into account as a multivariate random variable $PV_y = \left(pv_{1,y}..pv_{|T|,y}\right)$, being $pv_{i,y}$ the PV production at hour $i \in T$ in year *y*. Then, for a given year *y*, eq.7 becomes:

$$SL > \sum_{h=0}^{7} S_{h,d,m} > \sum_{h=8}^{17} C_h - S_{h,d,m} - pv_{h,d,m,y}, \forall (d,m) \in D * M \quad \text{(eq. 8)}$$

When PV production is available over a set *Y* of years, we compute the expected optimization as:

$$E\left[\min_{PC_i}(CP + CE)\right] = \frac{1}{|Y|} \sum \min_{PC_i} (CP + CE)$$

subject to constraint as in eq.8. Under this scenario, symmetry reduction as previously stated is no longer feasible and each year optimization problem results in 16469 variables and 16846 constraints, with a resolution time from 5 to 25 minutes depending on SL value.

3. Results

3.1. DSM economic benefits

3.1.1. Influence of time-of-use DSM with cold TES capacity

Optimization results due to the use of only cold TES with different capacities are shown in Figure 4. Note that the y-axis is logarithmic base 10 scale; otherwise the correlation between energy savings and storage capacity will be misinterpreted as a linear trend. It can be seen that energy savings sharply increase by adding storage of about 200 kWh and this trend continues gradually up to approximately 500 kWh. After this point, the increase of storage capacity has a very little impact on energy bill savings, despite being upward.

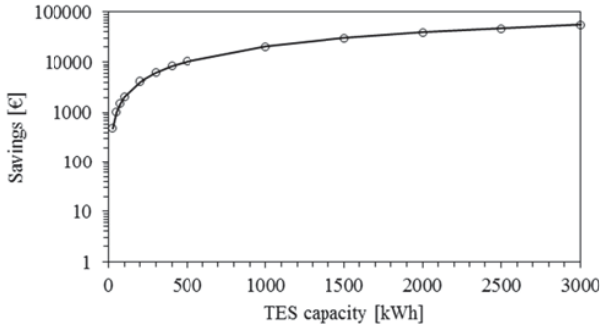

Figure 4. Energy savings by using DSM and cold TES.

3.1.2. Influence of time-of-use DSM with solar PV

The energy impact of tariff-based DSM coupled with off-grid solar PV system has been compared with a conventional energy system and the results are shown in Figure 5. It could be seen that energy savings vary from approximately 2% to 10% (4300 to 17000 euros) depending on the nominal installation capacity. However, it should be taken into account that the saving trend line is sharper from 25 to 80 kW of solar PV capacity and by increasing the solar PV to 100 kW this trend increases slightly. It should be considered that in previous results the impact of heat losses was not considered, on this basis calculations have been carried out taking into account three different levels of heat losses (0.50, 1, 1.50 kW/h) of the storage tank. It was found that 0.2 to 1% of the final energy bill could be increase due to heat losses of storage tank.

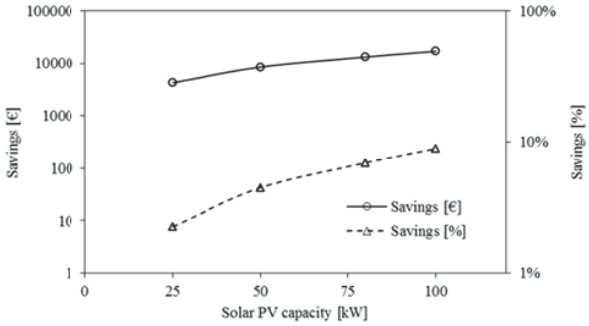

Figure 5. Energy savings by using only solar PV.

3.1.3. Influence of time-of-use DSM with cold TES coupled with solar PV

An important issue that should be discussed herein is how the combination of solar PV and short-time cold TES technologies coupled to a proper time-of-use DSM can shift peak demands and eventually improve the energy system and save final energy bill. To determine benefits due to interconnection of these two systems, savings due to integration of only cold TES and only solar PV should be summed and then subtracted from savings due to coupling cold TES with solar PV. For example in case of integrating PV 50 kW and TES with storage capacity of 1000 kWh, the benefits will lead to savings of about 8500 euros due to PV (see Figure 5) and 20600 euros due to storage (see Figure 4), however, the coupling of these two technologies achieved savings of 30400 euros.

Figures 6 and 7 show energy improvements ratios and energy savings (logarithmic base 10 scale), respectively, due to interconnection of solar PV and cold TES. It could be seen that the energy improvement is not linear and it is highly depends on the storage size and the solar PV power. For example, by looking at the trend line of solar PV with 25 kW power in Figure 6 it can be seen that the peak energy improvement occurred when storage with less than 200 kWh was coupled to the system and the increase of storage capacity decreased the performance of the whole system. Actually, when the solar PV share of the system is smaller, lower storage capacity is needed to provide the smoothness in the system. On the other hand, when higher shares of solar PV considered, higher short-term TES storage was required which is consistent with

findings of Bussar et al. (Bussar et al., 2016). This could be also seen in Figure 8, in case of 25 kW PV savings sharply increase by coupling TES in the range of 50-200 kWh; after this point by the increase of TES capacity further savings could be achieved, however, it would not be as beneficial as the efficient range of 25-200 kWh. In other words, the higher the dependency of energy system on the solar PV, the higher the storage is needed to ensure the security of electricity supply of the system without intermittency. Further on, it can be derived from Figure 7 that adding energy storage has the potential to further improve the performance of the whole system by reducing demand charges during periods when the solar PV system is not producing enough power due to weather conditions. Also, it can be derived that higher demand shifting is feasible by integration of cold TES, whereas, off-grid solar PV can reduce the energy consumption when solar radiation is available.

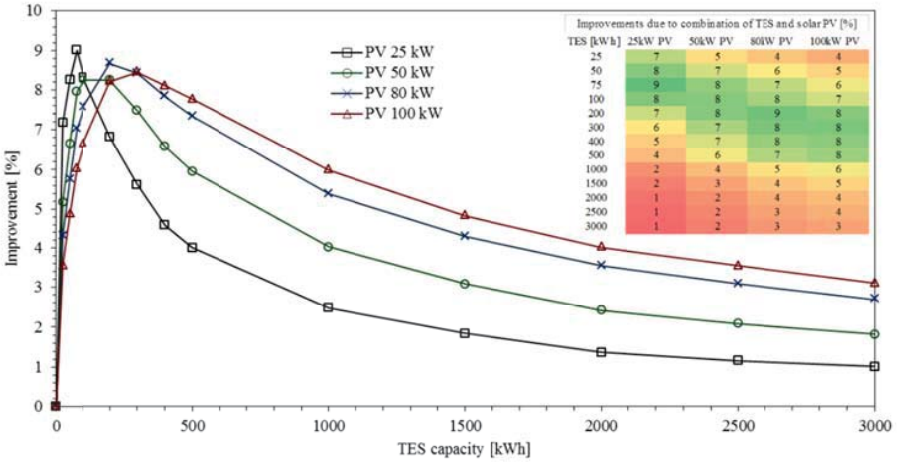

Figure 6. Improvements due to combination of solar PV & TES.

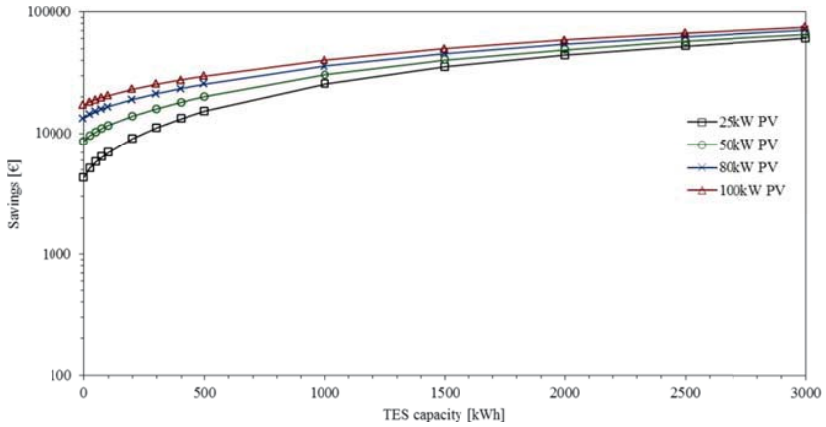

Figure 7. Energy savings due to combination of solar PV & TES.

4. Conclusions

The present paper is a simulation-based optimization study which investigates the implementation of time-of-use DSM combined with short-term TES and off-grid solar PV technologies to shift on-peak demand of an industrial electricity consumer under a certain climate zone. Through numerical optimization and simulation it has been found that both the cold TES and the off-grid solar PV coupled to an appropriate tariff structure can yield savings in final energy bills. Analyzing the results, it could be derived that savings attributed to the integration of TES are generally higher than those achieved by only off-grid solar PV. This is basically because of variability of solar radiation intensity and climate condition since when the expected solar power is not achieved; excess power is demanded from the consumer by cost of considerable charges. In addition, solar PV without storage can reduce the energy term and not significantly the power term of the

energy bill. However, it should be highlighted that when an interconnected TES and solar PV energy system was analyzed, it was found that further energy improvements are attainable due to combination of these two systems. By this, it could be explained that the implementation of TES not only can shift the on-peak load but also can improve the performance of the off-grid solar PV system.

Abstract

Application of energy saving technologies and renewable energy sources is one of the main directions in residential building. The central part of Russia has moderate continental climate with the average temperature of -10.6 °C in January and in July - + 19.7°C, the heating season lasts for about 200 days. Therefore the solution of energy saving problem is important. The paper presents the research results on determining optimum conditions of renewable energy sources choice, on definition of architectural solutions for construction of a power efficient house, the monitoring results of power supply system operation of the house and its operation costs.

Keywords: *architecture, energy saving, renewable energy*

1. Introduction

Energy saving is the most important goal in residential building. Now, when the prices for electricity, public services constantly grow, it is necessary to look for new approaches for the problem solution of the energy operation costs reduction.

The central part of Russia, in particular, Ryazan region, has moderate continental climate. The average temperature in January is -10.6 °C, in July - + 19.7°C, the heating season lasts for approximately 200 days. This data determines to a large extent the design and technological approaches to the energy saving problem solution in residential building.

The paper presents the research results for the choice of renewable energy sources for energy and heat supply of a residential house: photovoltaics, wind power, solar collectors and heat pumps; approaches to the energy-efficient house design, the monitoring results of the house energy system and maintenance costs.

2. Approaches to house design

A multifamily residential house located in Russia, Ryazan region, Rybnoe town (latitude 54 north, longitude 39 east) was chosen as the object for the project engineering design (Fig. 1) [1].

The basic house features:

- number of floors – 2,
- number of sections – 2,
- architectural volume – 3902 m^3,
- total house area – 713.5 m^2,
- common corridors and common areas – 52.2 m^2,

doi:10.18086/eurosun.2016.01.15 Available at http://proceedings.ises.org

- total apartments area – 622.6 m^2,
- living space – 322.4 m^2,
- number of apartments – 13, including:
  - one-room – 1,
  - two-room – 9,
  - three-room – 3.

Fig. 1: Multifamily residential house with hybrid power supply

As a whole, the measures implemented at the house design can be divided in the following groups (Table 1): Group 1 – heat loss reduction; Group 2 – reasonable consumption of energy resources; Group 3 – independent power generation for reduction of operating costs on living space maintenance by the house tenants; Group 4 – introduction of automated CONTROL SYSTEMS of the house, in particular, control of consumed energy resources.

Tab. 1: The complex of power-efficient solutions used in the house

Group 1	Group 2	Group 3
- heating-up of the building: basement, basement area, walls, attic floor, roof; - installation of glass units with low-emissivity glass; - equipping of entrances with lobbies; - application of door closers for front doors; - installation of supply-extract ventilation system with heat recuperation.	- installation of motion sensors in common areas; - LED equipment for courtyard lighting; - application of energy-saving lamps in apartments; - one button electric power switching off; - meridian orientation of the house; - horizontal distribution of the house heat supply system; - apartments decoration using light colours.	- installation of bivalent heating system using low-potential heat of lower layer of the Earth (heat pump); - installation of PV modules generating emergency power, and for courtyard area lighting; - installation of water heating vacuum solar collectors.
Group 4		
- installation of **consumed resources meters** in each apartment; - installation of meters registering the consumption of the house energy resources; - installation of independent meters registering power resources generated and consumed by the equipment using renewable energy sources.		

The applied design and technological concepts allow to cut expenses for the house operation, to make direct observations, measurements of quantitative and qualitative changes of maintenance by the tenants of the multiafamily residential house having a high class of power efficiency.

Due to space-planning solution of the house the biggest area of windows is located in the south. The outside walls of the house are made of ceramsite concrete with external heat insulation. To minimize the heat loss through walls,

base, attic floor and roof the modern heat insulating materials have been used. The windows consist of three chamber glass units with low-emissivity glass. The staircases are equipped with lobbies with automatically closing doors and reliable pressurization system. The heating of the house is made as a bivalent plant: geothermal heat pumps and a block boiler room with condensation boilers, having a heat meter in each apartment.

3. The analysis of renewable energy sources operation for energy and heat supply of the house

In order to choose a renewable energy source for power and neat supply it is necessary to take into account the following factors:

- geographic location of the house and climate pattern of the place;
- the building characteristics (area, architectural volume, building location);
- power consumption of the building (energy consumption and heat flow rate) during a year.

The use of combined power sources (wind-solar power stations, solar collectors, heat pumps) for heat and energy supply is optimal. The present paper studies the application of power from a PV power station and wind generator for electrical power generation. A heat pump was used for heat supply and solar collectors – for hot water supply.

3.1. The use of wind-solar power

When analyzing the wind-solar power station operation the scheme for monitoring the power generation was used (Fig. 2) [3]. The monitoring data was used for working out recommendations for the house engineering and building. Figure 3 shows simulation and the average value of solar and wind power generated during the investigated period. The calculation was carried out by standard methods on the basis of total month irradiation data and the most apparent wind speeds [3].

For calculation the simple models of the components were used.

- Power generated by a PV generator is directly proportional to irradiation (when using PV modules with good fill factor, 36 cells in series).
- Current of the wind generator is proportional to the cube of wind speed of up to 14m/sec (stronger wind was not taken into account due to its small probability).
- The storage battery charge efficiency was considered to be constant, the depth of discharge (DOD) was equal to70 % (in order to exclude overdischarge losses), the battery operating range was 20 … 28 V. The battery overcharge losses were not taken into account.

We observed coincidence of the calculated and monitoring data. The deviation does not exceed 20%. The largest deviation is observed in winter. It is connected with more cloudy weather during last years. This period is considered to be more critical and is characterized by shortage of power, especially as far as photovoltaics is concerned: it does not exceed 20 kWh/kW that is 5 times less than that of wind energy – up to 100 kWh/kW. In summer solar energy dominates (up to 140 kWh/kW) while wind energy is not more than 25 kWh/kW. Such different potential of wind and solar energy results in irregular power supply of consumers.

Below the most optimal proportions of nominal capacity of the wind and PV generators ($P_{nomwind}/P_{nomPV}$) are analyzed. The optimization was conducted by minimum irregularity of average monthly power production according to the formula:

$$\frac{\sum_{n} |\,(P_{average} - P_n)\,|}{P_{average}} = min \qquad (1)$$

where $P_{average}$ - simple average of power production for the investigated period (one year or one season), P_n- monthly power production (n=1 … 12).

Figure 4 shows the obtained curve shapes for different proportions of nominal capacities of wind and PV generators.

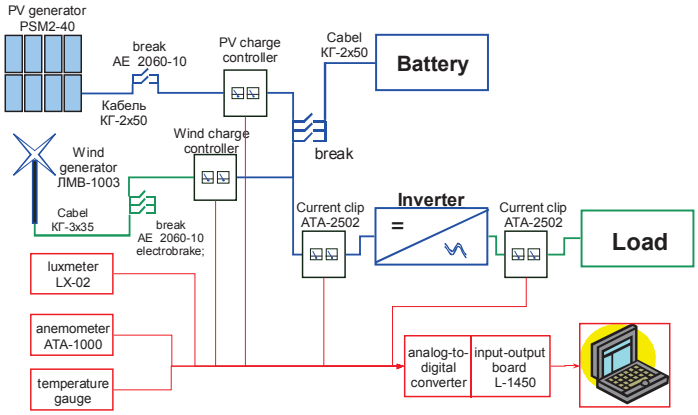

Fig. 2: Monitoring scheme

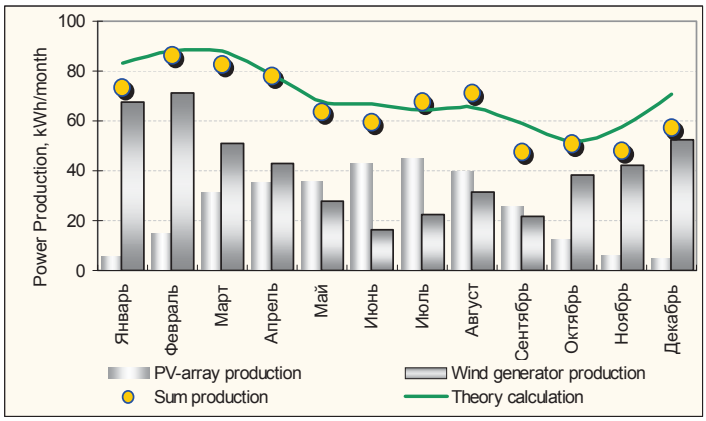

Fig. 3: Monitoring data

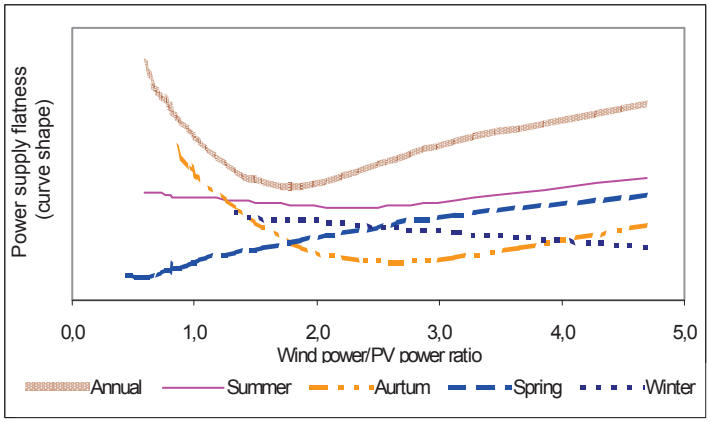

Fig. 4: The curve shapes for different proportions of nominal capacities of wind and PV generators. X-axis is the wind and PV generator ratio; y-axis is the change of the output power in dimensionless units (the figure shows only the curve form).

The flat trend of curves in winter and summer indicates the absence of influence of PV generator power increase on the character of power supply in winter and increase of the wind generator power in summer.

In spring, and especially in autumn, the variation of the power ratio is usually extreme. The optimal ratio for spring is 0.6, for autumn – 2.5-3. The optimal proportion for the whole year is 1.9.

The choice of proportions depends on the character of load consumption, its criticality to power supply irregularity in different seasons or in a year, and also on the proportion of the prices per watt of wind and solar energy. In the station under consideration the proportion of 2.35 is realized.

When designing the house only a PV power station was used as it was difficult to locate a wind generator in the apartment complex. A PV power station had to provide power supply of the house communal facilities (stairs, corridors), a courtyard territory and a heat pump. The calculated peak power of the PV station was 7.5 kW. For the calculation the procedure developed in [2] was used.

Monthly electrical energy generation E_{pv} for a PV generator is determined by the following equation:

$$E_{pv} = G_m(\beta) \cdot S \cdot \eta_{pv} \cdot (1 - \eta_{cable}) \cdot \eta_{mp} \quad (2),$$

where S is the PV generator area, η_{pv} - conversion average efficiency of a PV module, η_{cable} - cable losses (value 0.03), η_{mp} – losses identified by absence of mpp tracking (value 0.8).

The coefficient η_{mp} allows for losses appearing when mpp tracking system is absent. The application of MPP tracking device in the system results in necessity to calculate hourly amounts of solar irradiation and also to have the data of monthly average temperature.

For a battery the stored energy was calculated by:

$$E_{bat} = E_{pv} \cdot \eta_{bat} \quad (3),$$

where ηbat - conversion mean efficiency of battery. The battery capacitance was calculated by

$$C_{bat} = \frac{E_{bat}}{DOD} \cdot (N + 1) \quad (7),$$

where N – quantity of sunless days, DOD – depth of discharge.

Input data for the calculation is the monthly amount of global solar irradiation for the given region, geographic latitude, modules slope (season optimisation is provided). The programme allows to calculate the required quantity of PV modules to provide load power supply during specific period of time and to calculate storage battery minimum capacity taking into account sunless days. The calculation data was taken from [3].

PV power plant structure:

Peak power – 7.5 kW

PV modules – RZMP-235-T, 32 pcs.

Inverter – TripleLinx 8k, 1 pc.

Storage battery – 200A2/12Bx32

3.2. Heat pump choice

In order to use heat pumps the information about the source of low potential heat, power consumed by the pump, necessary volume of the released heat was analyzed. The heat pump scheme and its structure was chosen taking into account this data.

Corsa-30 (Russia) geothermal heat pump with the rated heat power of 24 kW was used for the house heat supply. This heat pump can operate at high temperature modes (to warm a heat carrier up to +80°C) maintaining a high operation factor of renewable natural heat. To provide pump operation the electric energy of 6.4 kW is necessary. The power is supplied from a PV station. Copeland scroll compressor was used in a heat pump. The compressor has a high transformation ratio of 3.14: the ratio of obtained heat power to consumed energy.

3.3. Solar collector choice

For solar collector use optimal operation time when the collectors work effectively, providing the house with hot water, was chosen.

On the basis of design works the system of vacuum solar collectors, EE-SHS/250 (12 collectors) and EE-SHS/100 (6 collectors), was chosen and installed. The system used Cordivari boilers. The system provides 210 liters of hot water (55°C) during 6 months per year (May-September). The designer and installer of the hot water supply system is EnergEco (Moscow, Russia).

Fig. 5: Solar collectors for seasonal (summer) water heating

4. Architectural and other solutions

Ventilation in the apartments is made as supply-extract system of recuperation, returning the heat of removing air at venting.

The system of natural and controlled forced ventilation provides energy saving and prevents mould growth on the house enclosing structures.

Flat solar collectors for seasonal (summer) water heating in a hot water supply system and a PV power plant accumulating electric power from PV modules were installed (Fig. 5).

Illumination of the courtyard area and common areas is carried out from the combined power supply system with the application of a PV station. Motion sensors providing electric light switching off have been installed at each entrance. For street lighting LED lamps are used.

Energy-efficient electrical equipment is installed in apartments and common areas. In each apartment the light is switched off with one button.

The whole building and each apartment is equipped with an automated power consumption measurement system.

5. Economic aspects of the project

During the development of the project the comparison of different options of its realization has been made (Table 2).

Tab. 2: Comparative characteristics of variants of power and material saving in a 13-apartment house in Ryazan region

Variant	Total cost, mln. Rub	Cost of 1 m^2	Saving
Traditional	17.7	27 500	-
With effective heat insulation of enclosure structures and use of effective insulating glass units	25.7	40 000	50%
With application of heat pumps and PV modules	34.1	53 000	90%

Table 3 shows the technical-and-economic indexes of the project.

Tab. 3: Technical-and-economic indexes

Indexes	Energy efficient house	Standard house
Apartment area, m^2	644	644
Estimated costs, kRub.	30 036	19 964
Cost of 1 m^2, Rub.	46 640	31 000
Building heat losses, kW	19	27
Savings due to architectural solutions, kWh/m^2	20	-
Power from renewables, kWh/m^2	46.1	-

The value of the building energy efficiency according to the calculations is 98 kWh/m^2 per year whereas the target energy efficiency is 66.4 kWh/m^2.

The monitoring of the house economic efficiency within 3 years has shown that total operational costs decrease twice.

6. Research results

1. It is established that for uninterruptible power supply of the house in this territory, taking into account meteorological data and use of the previously developed calculation program, the optimum ratio of capacities of the PV and wind generator is 2:1. The 7.5 kW PV generator was developed and installed.

2. It is defined that for the chosen region the optimum time for solar collector use is May - September. For providing the house with hot water a solar collector with the capacity of 2100 liters per days is used.

3. A 24 kW heat pump providing year-round heat supply was installed on the ground.

4. The following design solutions have been developed:

- the requirements for thermal insulating materials were established and the materials were chosen;
- energy efficient ventilation system was chosen;
- lighting system was chosen;
- automated accounting and control systems of energy carrier for each flat and the house was chosen;
- power and heat supply system monitoring during 3 years demonstrating stability of all systems operation was carried out;
- the house operating costs monitoring was done. It was established that the costs were two times lower.

6. Conclusion

The paper shows the possibility of efficient application of renewable energy sources for power and heat supply of a residential house in the central part of Russia. The multipurpose use of renewable energy and energy efficient architectural and design solutions allowed to decrease considerably (two times) the house operation costs.

MONITORING AND PROCESS OPTIMIZATION- THE WILLIBALD-GLUCK-GYMNASIUM IN NEUMARKT (i.d.OPF)

Christian Kley, Franziska Bockelmann and M. Norbert Fisch

Technische Universität Braunschweig – Institut für Gebäude- und Solartechnik (IGS),
Mühlenpfordtstraße 23, 38106 Braunschweig, Tel:0531-391 3557, Fax: 0531-391 8125,

Abstract

The newly constructed building of the Willibald-Gluck-Gymnasium in Neumarkt i.d. OPf. is a great example for integral planning of school buildings and enables the study of future-oriented technical and energy concepts.

Within the scope of this Federal Ministry for Economic Affairs and Energy-funded research project and the participation in the accompanying research "Energieeffiziente Schulen" (EnEff:Schule), the building's performance is being monitored and optimized to obtain and document verified insights about the system's performance. Innovative operation strategies for educational buildings are developed and evaluated with respect to high energy efficiency and increasing consumption of self-produced electricity. Accordingly geothermics as a low temperature heat source combined with heat pumps are used for heating the school building and gym.

The integral building concept unifies architectural ideas of alignment and shape of the building, a high quality and air-tight building shell with small heat transfer coefficients, and energy efficient building technology for heat and electric supply. Furthermore the available space is used optimally as an area collector is installed below the sports ground.

Keywords: School, energy concept, heat pump, low temperature heat source, monitoring, optimization

doi:10.18086/eurosun.2016.01.06 Available at http://proceedings.ises.org

1. Introduction

In the town of Neumarkt i.d. OPf. the Landkreis Neumarkt erected the new building of the Willibald-Gluck-Gymnasium (WGG) for approximately 1400 students including a gym. The four-story-building with inner atria and a net floor area (NFA) of about 11500 m² started operation in the winter term of 2015/2016. The sports hall with three fields and a NFA of 2900 m² was built at the same time (Fig. 1).

Fig. 1: Site plan of the school and gym

Prospective to the EU directive regarding the overall energy efficiency of buildings, the complex was to be realised as an "EnergyPLUS-School". It thereby implements the standard of "nearly zero energy buildings" as a demonstration project. The integral and innovative energy concept is based on energy optimised, sustainable, functional, comfortable, and architecturally valuable design. The necessary technology has been implemented and evaluated. The project demonstrates these conceptual aspects visibly and takes a role model function for public educational buildings.

The realised, innovative technologies are taken into operation using the new method of the "Performance Test Bench (PTB)" and monitored throughout their operation. The built-in measurement and monitoring infrastructure allows the sophisticated analysis of operation variables, building performance and air quality in the rooms.

A learning platform for teachers and students benefits the transparency and acceptance of this future-oriented project. To this purpose, the "Active Functional Specification (AFS)" is implemented in the PTB, a web-based platform for specifying building services' functions, validating their implementation, and detecting errors. It was developed by the IGS and Synavision. Energy performance and comfort in school buildings are to be visualised for the students and teachers. The treatment and analysis of the processes will take place during an energy laboratory lesson in the school's schedule.

2. Architecture

Light, transparency, open communication, and clear alignments are just some of the self-stated quality factors for interior architecture and the architecture of the new school. The main goal is creating an optimal learning and teaching climate for both students and teachers. Coloured windows, weather protection for wings of the windows, create cheerful atmosphere. Noise reducers are integrated as formative elements (Fig. 3).

Students and teachers experience open and bright rooms in the entire building, e.g. through apertures in the rooms' walls. Light and visibility are enhancing an open and communicative school. Two great atria are sending daylight into the building's core. Lucid corridors connect all areas. Dark hallways are nowhere to be found. The halls are more like open streets with open spaces for free communication and calm alcoves for resting (Fig. 2 and Fig. 3).

3. Energy concept

As a lighthouse project for the new building type EnergyPLUS-School, the WGG utilises photovoltaics, heat pump and the new vanadium redox battery (VR-battery). With these components the building works as a decentralised energy producer. The concept's main medium is electricity, causing an economic and energetic interest to use the photovoltaic power in the building.

Geothermal energy is used as both source and sink. It works as a thermal storage with its more than 99 foundation piles (piles) and its area collector (ground-heat exchanger "Agrothermiefeld") below the sports ground. The geothermal heat pumps cover the heat demand of the floor heating system, the concrete core activation, and the ventilation system.

All class rooms are ventilated manually to ensure the room air quality (CO_2-concentration lower than 1500 ppm) that is essential for educational buildings (Fig. 4). The ventilation system has an integrated heat recovery to reduce heat losses and an adiabatic air humidification for cooling in summer. The supply air reaching corridors, halls, and resting areas is taken in through the class rooms. The exhaust ventilation is accomplished by a central suction system stored in the roof area in each of the two atria. A night time ventilation assists the school's cooling. For rapid heating of the class rooms during the heating period, the rooms are preheated before the beginning of the classes in the morning. The ventilation system can deliver variable amounts of supply air based on demand signalled by the CO_2-concentration ($\leq$ 1.500 ppm). The maximum flow rate is limited to 4.4 1/h.

The cooling of the class rooms and the IT/electrical installation rooms is realised passively (recirculation) in connection with the foundation piles and the area collector. The heat generation is adapted to the heat sources and provides heat with low temperature. This improves the integration and usage of renewable energy and serves as a foundation for energy efficient operation of the building and especially the heat pumps. The renewably generated electricity from the photovoltaics is primarily used in the building. Surplus power is fed into the electricity grid. The energy concept estimates that approximately 70 % of the heat demand will be covered by the heat pumps. Peak load (30 %) will be covered by a gas condensing boiler.

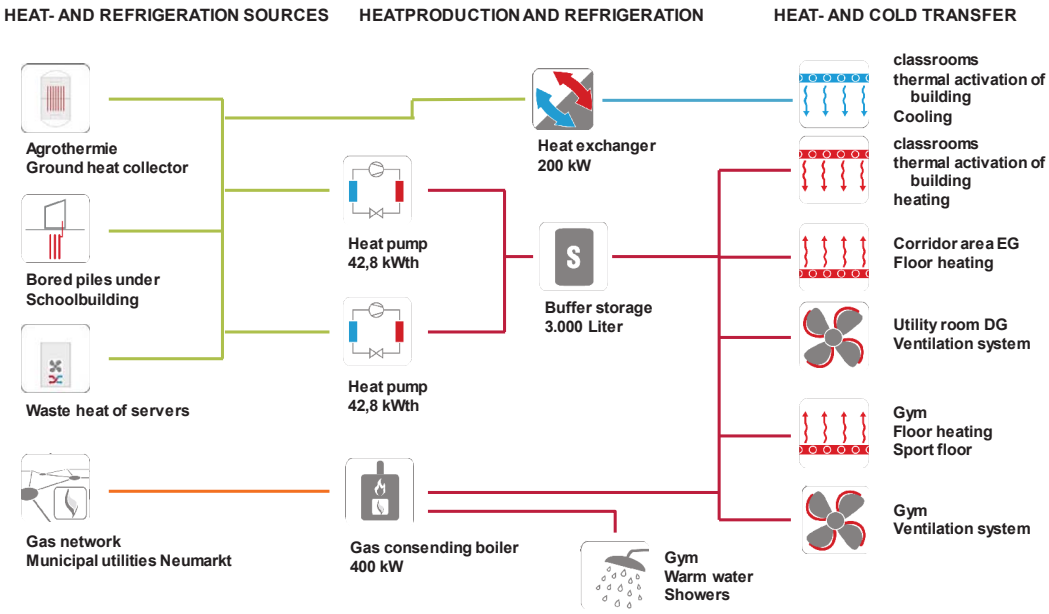

Fig. 4: Energy concept- heating and cooling

With a power capacity of approximately 290 kW_p the rooftop mounted PV-installation on the school building and the gym (Fig. 5) produces the greater part of the electrical power demand in the year's theoretical balance. For reaching the state of the EnergyPLUS building and later a negative primary energy consumption, the power capacity would need to be increased to approximately 500 kW_p. An enlargement of

the system up to 600 kW_p has already been taken into consideration during the planning of the building and the structure is suitable. The enlargement of the installation will be implemented at a later time by the building owner.

The concept includes a usable fraction of the electric energy of 65 % by including a VR-battery. The other 35 % will be fed to the electrical grid. The combination of the PV-system and the VR-battery facilitates a solar coverage of 40 % according to the design (Fig. 6).

Fig. 5: Aerial photos of the PV-installation on the school building (left) and the gym (right)

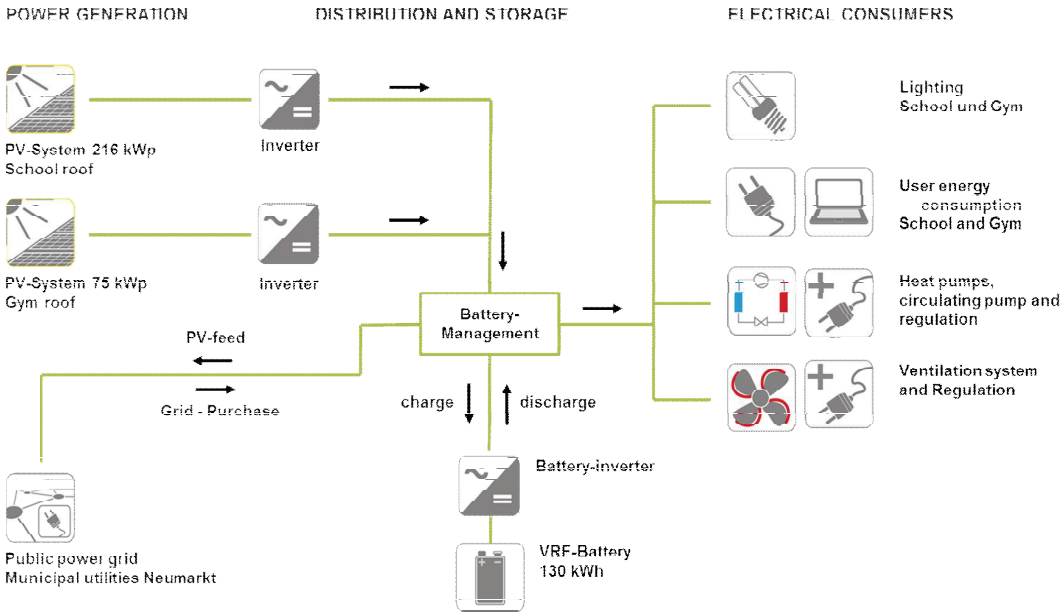

Fig. 6: Energy concept- electricity

3.1 Ground-heat exchanger "Agrothermiefeld"

Below the sports grounds next to the school an "Agrothermiefeld" has been realised. The field, an area collector, has been installed using an innovative technique in the field of geothermics. The piping system is brought two meters into the ground by specially designed plough. An active area of up to 4400 m² has been installed in total (Tab. 1). The installation process has been completed in August, 2015, without any major complications (Fig. 7).

Tab. 1: Information „Agrothermiefeld"

Number of pipes	47 pipes à 93,5 m
Dimensions of pipes	D_a 40 x 3,7
Installation depth	ca. 2,26 m (ploughing)
Collector area	ca. 4.400 m²

Fig. 7: Ploughing with pipe installation and completed sports field including the pipes

3.2 VR-battery

The installation and start-up of the vanadium redox battery manufactured by Gildemeister took place between September and October, 2015. In December the battery took up full operation. In January and February, 2016, minor changes in the internal control system were implemented. Since March 2016 the battery is being charged, discharged, and controlled as designed. Already in August, 2016, an optimisation of the internal controlling parameters has been executed. The overview information about the battery is listed in Tab. 2. Photos of delivery and installation are shown in Fig. 8.

Tab. 2: Overview vanadium redox battery

Manufacturer	Gildemeister
Type	CellCube FB 30-130
Electrical storage capacity	130 kWh
Utilisable capacity	100 %
Max. charge power	30 kW_p
Max. discharge power	30 kW_p
Weight of the filled system	14.000 kg

Fig. 8: Delivery and installed VR-battery

3.3 Energy balance

The energy consumption has been certificated based on the current "Energieeinsparverordnung" (EnEV 2009 / DIN V 18599-1:2007-02). Furthermore, the user electricity consumption is to be supplied sustainably. The heating power consumption takes less than one third of the annual energy demand. Two thirds belong to electricity consumption for ventilation, lighting, and other purposes (Fig. 9).

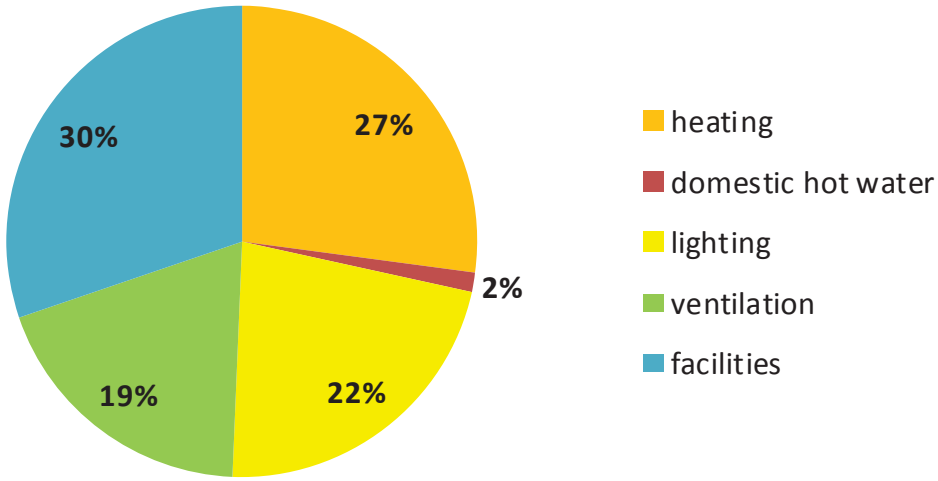

Fig. 9: Overall energy distribution

The quality of the implemented edificial standard and building technology undercuts the legally defined specifications of the EnEV 2009 (EnEV 2014) to the primary energy consumption by approximately 50 %. The characteristics for the EnEV-calculation are summed up in Tab. 3. In addition to the values contained in the balance of the EnEV, the equipment's power consumption is being included. The school complex is supposed produce a net surplus in primary and overall energy. The demand values are calculated based on DIN V 18599 (Fig. 10).

Tab. 3 Characteristics of the WGG-building

	School	Gym
Year of construction	2015	2015
Net floor area (NFA based on DIN V 18599)	12.732 m²	2.855 m²
Heated edifice volume V_e	63.056 m³	17.264 m³
Annual heating energy demand	25 kWh/(m^2_{NFA}a)	
Annual cooling energy demand	10 kWh/(m^2_{NFA}a)	
Overall electricity demand incl. equipments	40 kWh/(m^2_{NFA}a)	

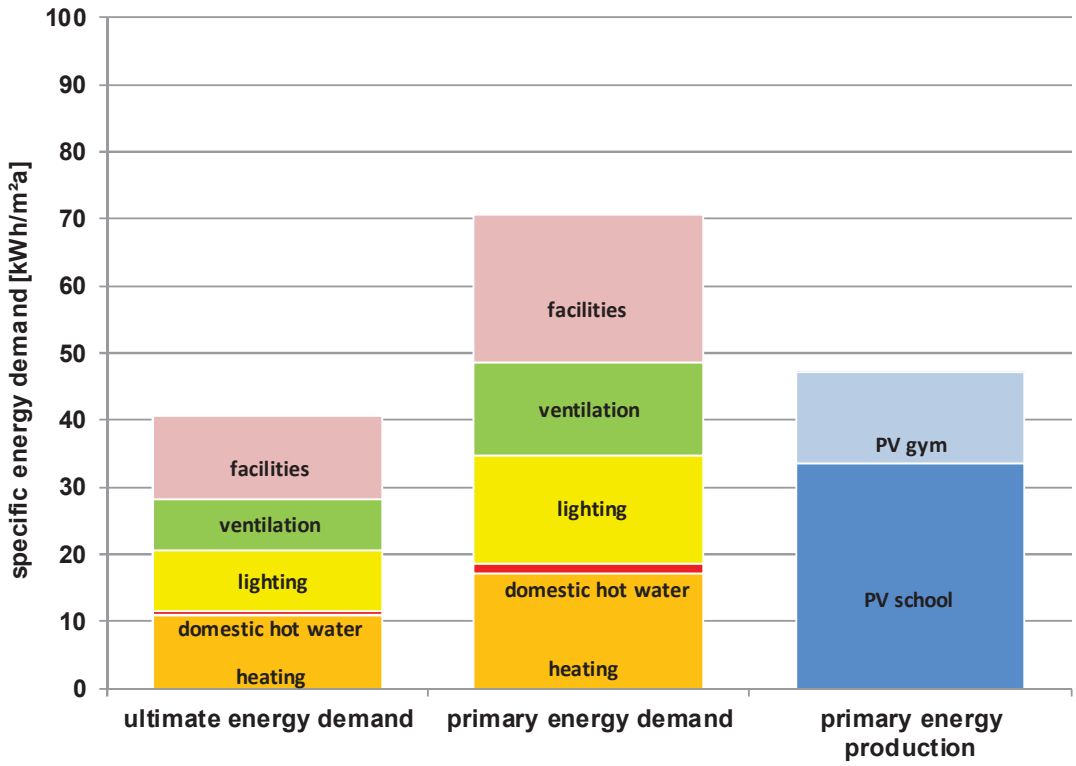

Fig. 10: Energy balance demand vs. production (DIN V 18599)

4. Monitoring

A concept containing a set of indicators for the system and building performance has been developed. It enables the analysis and assessment of the energy efficiency and different modes of operation. Based on the definition of aims, a measuring and monitoring concept has been realised. Respective specification for process measuring and control technology / building automation have been formulated.

Due to delay in construction and the installation of the process measuring and control technology, the recording of data started in May / June 2015.

4.1 Comfort monitoring

Fig. 11 shows the results of the comfort monitoring in the rooms 115, 216, and 230 in July 2016. The results show that the room air quality is mostly held within an acceptable or good state. Room 230 temporarily reaches temperatures >26 °C. The room is an IT room in the inside of the building causing greater thermal loads. By tendency, the room temperatures lie within the warmer comfort zone. The night time ventilation (01:00 to 06:00) achieves a temperature drop of 1 or 2 Kelvin. The average room temperature of the three rooms lies between 24 and 25 °C.

Fig. 11: Room temperatures in July 2016 between 07:00 and 18:00

The maximum CO_2-concentration of 1500 ppm is satisfied on most occasions in all of the three rooms (Fig. 12). Temporarily the limit is succeeded. On average, the concentration during the classes (07:00 – 18:00) moves between 515 and 730 ppm. This corresponds with good comfort.

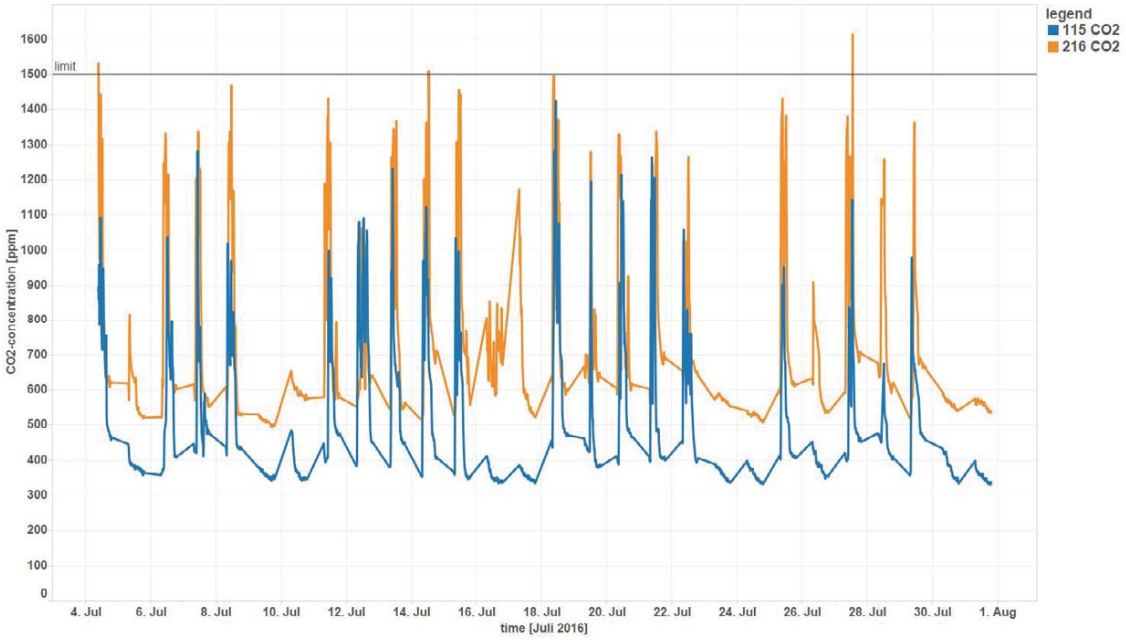

Fig. 12: CO_2-concentration in the rooms R115 und R216 July 2016 between 07:00 and 18:00

4.2 PV-production

Fig. 13 shows the electricity production of the PV-plant, the overall electricity consumption, and the resulting amount of coverage in the week of 11.-17.07.2016. Depending on the PV-power, the electricity demand of school and sports hall can temporarily be covered entirely by the plant (coverage = 100 %). The weekly average is approximately 40 %.

The photovoltaic electricity production in the time between 01.01. and 31.07.2016 amounts to 116,3 MWh (400 kWh/kW_p). Of this amount, 60,6 MWh are being consumed in the school and sports hall, corresponding to an ad-hoc-consumption of about 52 %.

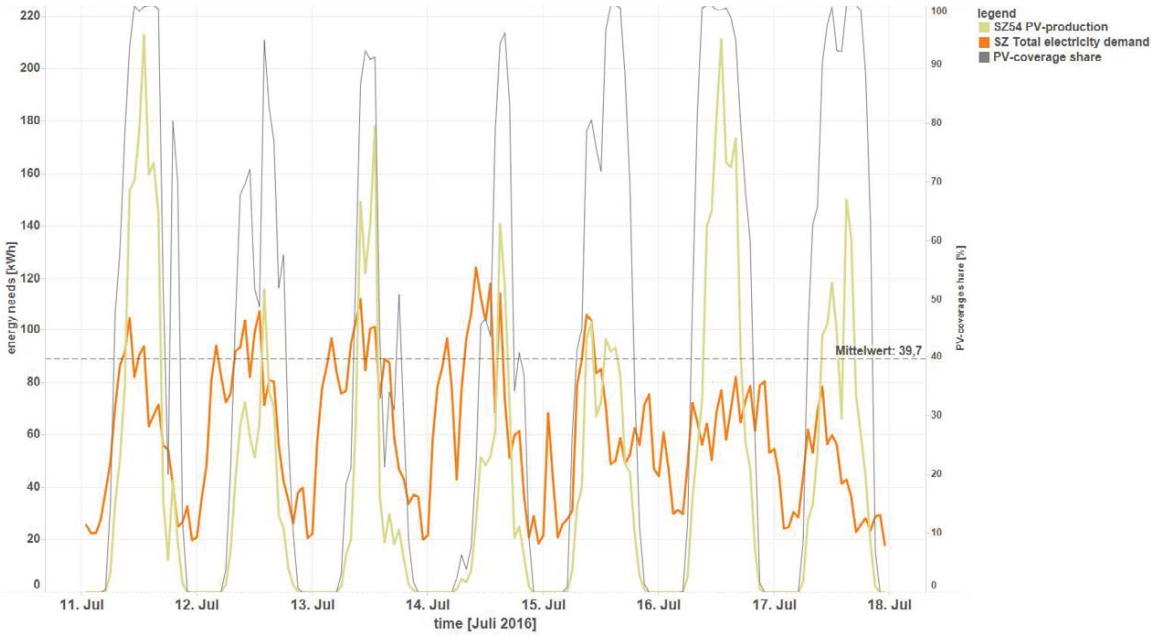

Fig. 13: PV-production, electricity consumption and amount of coverage (11.-17.07.2016)

4.3 VR-battery

After initial difficulties with the control system, the VR-battery is in orderly operation since 18.08.2016. During the day, the battery is being charged (up to battery level 100 %). During the night time, the battery is discharged down to a level of 5 %. Fig. 14 shows the battery level in the time 19.-26.08.2016.

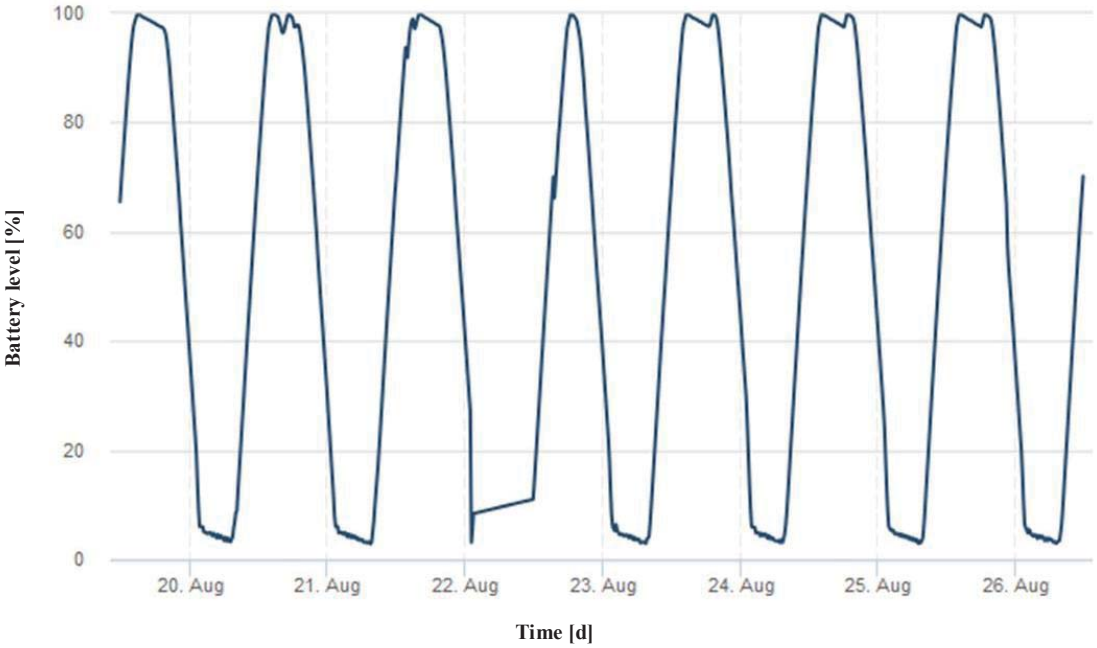

Fig. 14: Battery level in the time 19.-26.08.2016

5. Conclusion

The pilot project gives a great example of future building standards. It reveals the frame for the development and evaluation of necessary methods and tools for educational building and public edifices.

The scheduled completion of the technical system at the beginning of the school year in August 2015 was tenable. The school's operation started in the winter term 2015/16, though with limited and unplanned operation of heating and ventilation. The heat pumps were activated in February 2016. From August 2015 to February 2016 the school and sports hall were solely heated by the condensation boiler which was intended as a peak-load unit. The concrete core activation was started up in January 2016. Before that, the heat was transferred solely by ventilation air and floor heating.

The notable optimisation potential of the building system became visible in the course of the first months of operation. The results and insights uncovered in this research project help avoiding these problems and optimising operation in future construction projects. The new buildings serve as role models and are, due to their typical use and characteristics, suitable to be multiplied.

Only in practical application, singular technologies can be observed in their effective behaviour and integrated into the construction process. The operator's and user's ability to work and maintain the systems in a suitable manner can also only be assessed after the installation and start-up of the actual machinery. The necessity of early planning, documentation, and intensive surveillance for the successful implementation of an energy concept containing low-ex-heat sources has been proven within this project. The final realisation of the project is only possible in interdisciplinary cooperation of all parties involved.

6. Expression of thanks

The research project „EnOB: Monitoring und Betriebsoptimierung des Willibald-Gluck-Gymnasiums in Neumarkt (i.d.OPf.)“ is funded by the Federal Ministry for Econimic Affairs and Energy under the reference number 03ET1308B.

Study of Passive Solar House SOLAR-SB

Pavel A. Kazantsev [1], Valeriy V. Knyazhev[2] and Vladimir V. Loschenkov[2]

[1] Engineering school of Far Eastern Federal University, Vladivostok (Russia)

[2] Institute of Marine Technology Problems FEB RAS, Vladivostok (Russia)

Abstract

One of the first specially designed passive solar house on Russian Far East monitoring in winter 2015-16 has confirmed a high efficiency of a traditional architectural model of solar heating in the natural climatic conditions of the south part of region. Continuous examination of the passive system for the all cold season in the house without additional heating sources was held in the region for the first time. The revealed causes of system's high inertia in the morning hours, as well as a positive effect of additional solar warming of the house in the evening time, will allow developing measures in perfecting the passive solar systems of residential buildings in the region.

Keywords: *solar heating, solar house, solar architecture, ecological architecture, passive solar system.*

1. Introduction

Passive solar heated houses design in the Russian Far East was a design in drawings to the present. For this reason it was impossible to confirm the effectiveness of passive solar systems here, which also stopped their development in the mass construction. For example, in 2005, a designer company Argus-Art developed an experimental project design of a single-family eco-house Solar-5 (authored by Pavel Kazantsev, an architect) [5]. The active solar system of the eco-house was designed by Laboratory 07 of FEB RAS IMTP (Fig.1).

Fig. 1: Eco house Solar-5. Project views

doi:10.18086/eurosun.2016.01.10 Available at http://proceedings.ises.org

According to the lab calculations, the passive solar system accounted for up to 57% of the house heating during the cold season. (Fig.2). This result was mainly achieved via a non-standard architectural solution patented as invention of an energy-efficient architectural form RU2342507 and awarded at international and Russian exhibitions.

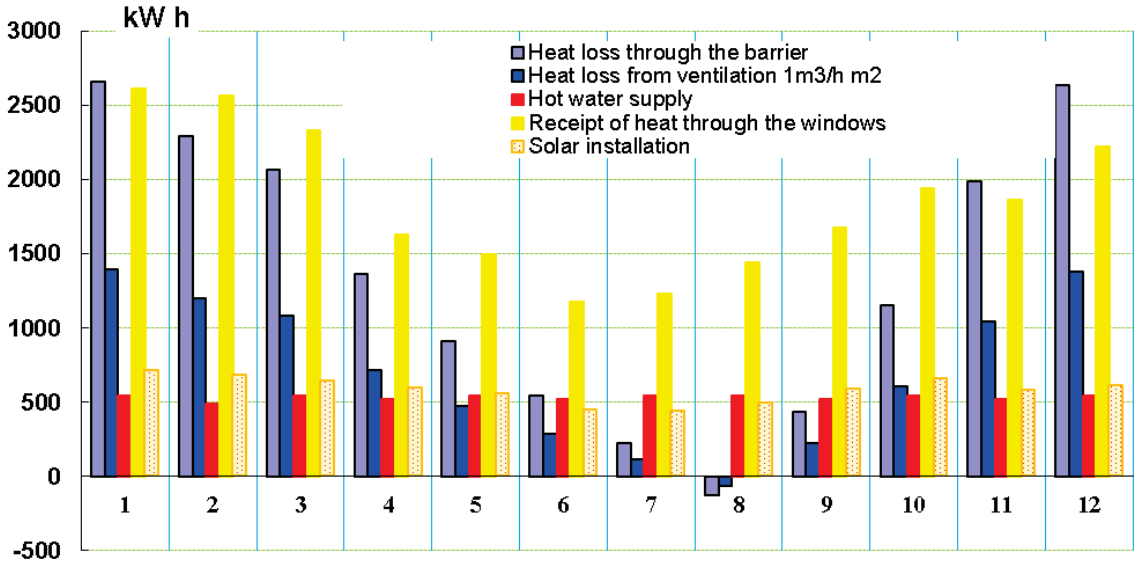

Fig. 2: Estimation of the heat balance of eco house Solar-5 throughout the year. According to the calculation, the contribution of passive and active solar heating system should reach 81%

In 2011, the FESPI/FEFU Technopark implemented a one-floor sample of the eco-house – a training-experimental eco-module Solar-5m (Fig.3); however, there was no opportunity to confirm the high expected properties of the passive solar heating in practical terms [3].

Fig. 3: Training-experimental eco-module Solar-5m

Therefore, in order to define the properties of the passive solar system in the conditions of south part of Far East, research was conducted in the winter of 2015-16 at the constructed single-family house with passive solar heating. The research was conducted jointly with the Training studio of resource-saving architecture within the Department of Architecture and Urban Planning in FEFU and Laboratory 07 of the FEB RAS IMTP – Energetics of the Underwater Robotic Complexes. Absence of the heating sources other than direct solar radiation during the observation period was the primary criteria for choosing the object. It is for this reason that measurements have been allowed in an uninhabited house with an incomplete interior finish, but practically closed external warm contour.

2. Specific features of the eco-house architectural solution

A single-family house with passive solar heating has become an object of this research. The house shell is made of pressed straw panels. The project design was developed in 2012-2013; the house has been under construction since June, 2014 in Primorsky Krai, Nadezhdinsky district, Novyi settlement. The design project was authored by architects Pavel Kazantsev (FEFU, Vladivostok) and Anna Lyashko (M-ARC, Vladivostok). The structural design and straw panel technology were developed by Domantas Surkys, Audris Krucius, Marius Tarvidas (Ecococon company, Vilnius, Lithuania). Customer: Vladimir Kazantsev (Fig.4, 5).

Fig. 4: General view of the house from the south-east in the winter of 2015-2016

Fig. 5: The design of the house at the end of construction

An architectural model traditional for temperate latitudes of the Northern Hemisphere was taken as a basis for structuring the passive solar system of the pilot straw eco-house Solar-Sb. A double-height atrium with a south-facing stained-glass window and dormer windows in the roof is a building core of the house. The atrium was to have included

massive inner walls providing for the thermal inertia of the house, but in the process of construction they were replaced with a frame (Fig.6). Living room spaces open into the atrium. In depth the house is divided in 2/3 proportion of living space in the south and 1/3 of the buffer space from the north, with the account for the depth of solar ray penetration in winter. A sleeping area on the second floor also takes into account the effect of "heat sack" and reduces the heating expenses for the first floor area at night. The width of the house is increased providing for its exposure to the sun. The northern windward façade is blind; the roof pitch is lowered to the wearing floor of the second floor. Balconies in the shorter side of the house form intermediate half-open spaces providing for additional protection in bad weather conditions. They are supposed to reduce the façade overheating in summer (in combination with a vertical green screen) and cover the eastern façade from slanting rains.

Fig. 6: The interiors of the house during the observation period in the winter 2015-2016.

The works are not completed

The attic on the third level is a part of living space; however, it will be separated from the warm core of the house with heat-insulated dividers to ensure its seasonal use. In the first half of the summer, the windows in the opposite walls of the attic contribute to additional airing of the atrium through the divider opening by air draft under the roof ridge. A connected structure of the roof is the only innovation in the shape of the straw house: its angles are optimized for installing the solar collector of water heating system (the Sun in the late January) and the photoelectric system (the equinox solar altitude in Vladivostok latitude).

The major technical and economic features of the project are as follows: construction area 117 m^2., living space 133.7 m^2., total area 187.8 m^2. The type of passive solar system: Direct gain (Haggard, Bainbridge, et al., 2009). The windows are triple-pane selective Low-e Ro = 0.7-0.76 m^2 KW^{-1} (according to the design project), the area of southward stained-glass windows – 25.0 m^2, thermal area at the moment of observation – 24.0 m^2 light-grey concrete floor with 0.15 m insulation, without matte black coating. External walls are made of 3.0x0.8x0.4m straw panels with 120 kgm^{-3} density and 15% humidity level of the straw; the heat conductance in the panel center is U = 0.23 W $m^{-2}K^{-1}$.

3. Research provisions

Two types of measurements have been made. The first one involved operator's recording of internal air temperature with alcohol thermometers in three points: first, second floor and attic, and external air temperatures – near the northern façade at 9 a.m., 1 p.m., and 7 p.m. in order to reveal the general dynamics of internal (by levels of the indoor living space) and external air temperatures between December 14, 2015 and February 19, 2016 (the coldest period in southern Primorsky Krai, 68 days), (Fig.7).

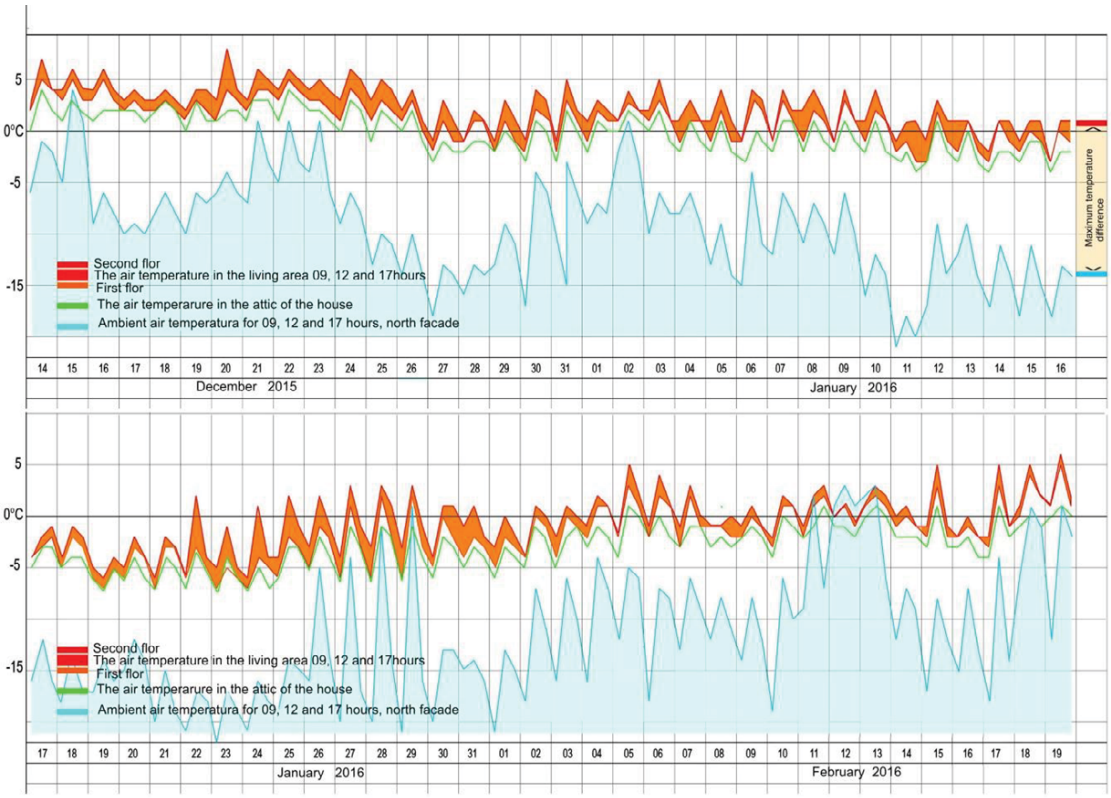

Fig. 7: Operator record results from December 14, 2015 to February 19, 2016

The second type of measurements involved a non-stop recording of external meteorological parameters at automated meteorological stations HOBO Weather Station between February 8 and March 14, 2016 (the complete observation period until March 31, 2016) including the speed and direction of winds, humidity, temperatures, and rate of solar radiation on horizontal surface tilted southward by 450, on southward vertical surface of the vertical stained-glass windows of the house as well as a non-stop recording of the 24-hour dynamics of temperature, air humidity indoors and the rate of solar radiation entering the house through the southward stained-glass window (Fig.8.).

The software developed by HOBOware Pro Onset Computer Corporation was used to assess the observation results at automated meteorological station HOBO Weather Station. Comparison of the data obtained from both types of measurements of the indoor air temperature at the level of 1st and 2nd floors between February 8 and February 19 has shown a high degree of similarity between the results of operator's recordings and observation results at the automated station.

4. Observation of passive solar system properties

Winter temperatures in Primorsky Krai. are much low than those in the same latitudes of the European part of Russia. However, substantial solar resources of the territory can compensate for its low temperatures. Thanks to its south latitude and monsoon climate, Primorsky Krai. has a high potential for developing the generation of thermal solar energy. Radiation balance in the north of the region is 1885 MJm^{-2}, in the south – 2010.2 MJm^{-2}, the length of the sunshine is 1900-2500 hours per year [1]. The majority of sunny days are observed in the cold season (Fig.9).

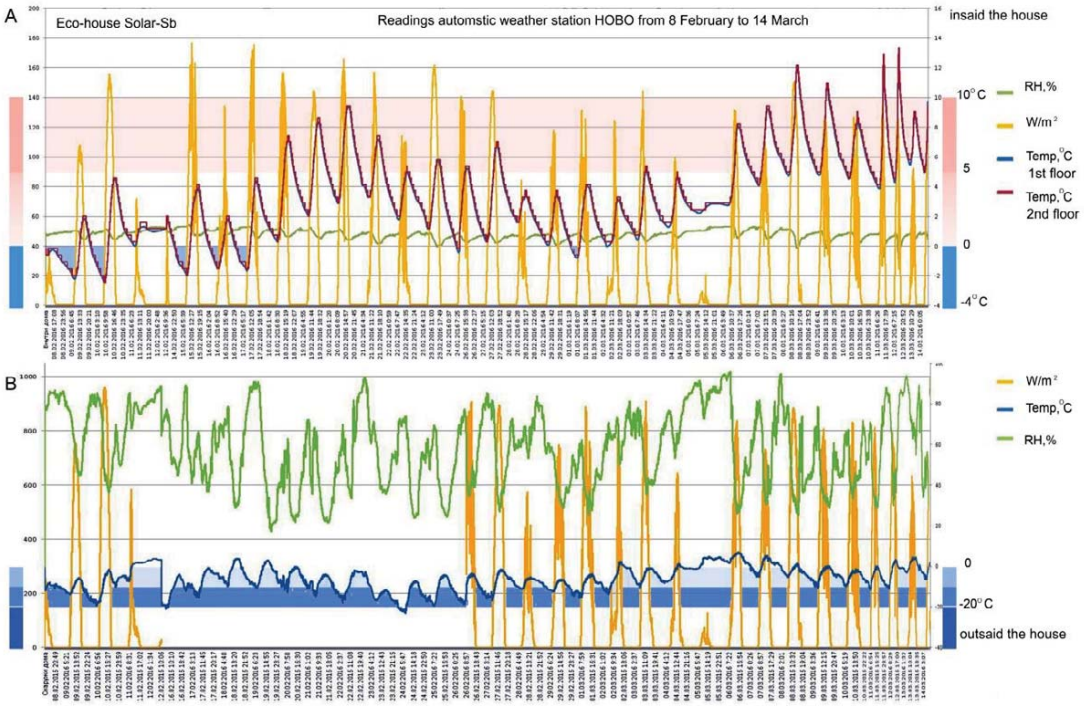

Fig. 8: General view of the readings of the automatic weather station from 8 February to 14 March

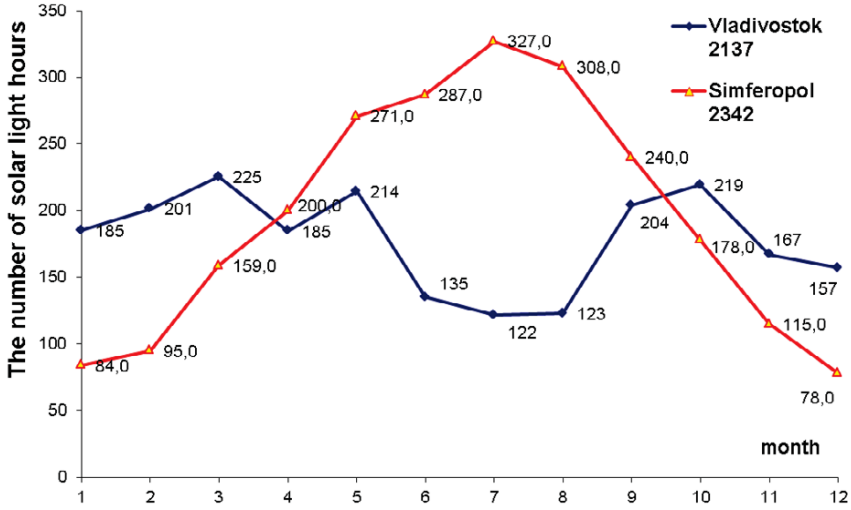

Fig. 9: Duration of solar glowing. Vladivostok and Simferopol

In general, during the observation period between December 14 and March 14, the air temperature in the living spaces of the house (1 and 2 floor) was around 0ºC. The temperature was slowly going down from positive numbers in December (+9ºC on December 20) until the mid-January, reaching the minimum numbers on January 9 after a two-day snowstorm (-7ºC at 13.00 and -4ºC at 17.00). The indoor air temperature started growing with the growing sunshine exposure comprising +7ºC at 1 p.m. on February 19 (Fig.10,11). Out of 92 observation days, the daytime air temperatures below 0ºC were recorded inside the living section of the house only during 6 days – January 17-21 and January 23. The temperature about -5ºC inside the house at night was registered only for 4 days. At the same time, the daylight air temperature -10ºC and below in the basin of the horticultural cooperative Serebryanka (Novyi settlement) was observed for 26 days, below -15ºC at night – for 34 days.

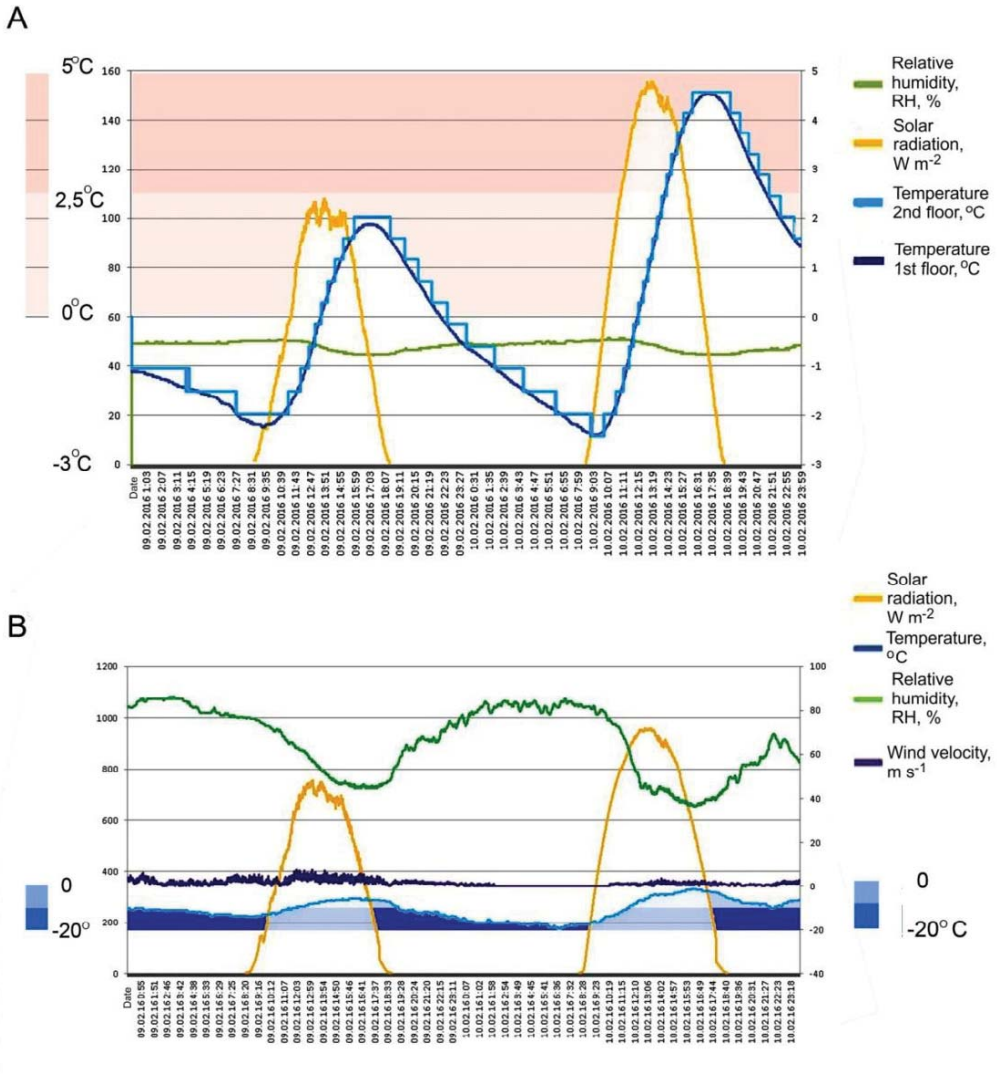

Fig. 10: General view of the readings of an automatic weather station on 9-10 February.

A - in the house, B - outside the house.

Maximal numbers of integral flow of solar radiation through the vertical southward stained-glass window of the atrium were 150 – 179 Wm^{-2} around noon – much lower than the numbers observed on the vertical outside surface of the house – 775 – 1039 Wm^{-2}. All figures and tables should be cited in the text, numbered in order of appearance and followed by a centered title. All table columns should have a brief explanatory heading.

Maximal difference between external and internal air temperatures in the coldest days with minimal cloud cover have reached 12 – 20ºC (for example, 11.01, 23.01., 9-10.02., 16.02). During the days with clear sky, the lowest temperatures inside the house were registered about 9 a.m., the temperature minimum held until 11 a.m. despite the incoming solar heat through the southwards stained-glass windows approximately from 9 a.m. Starting from 11 a.m., the air temperature in the house grew substantially reaching the maximal numbers by 5-6 p.m. when incoming solar heat through the southward window was already dramatically low. The observed maximum of internal temperatures lay behind the maximum by 3 hours approximately. (Fig.10,11; Tab.1,2)(days with clear sky and minimal outdoor temperature in February).

Good inertia properties of the house were also shown by the obvious consistency of indoor air temperatures regardless of dramatic changes in the outdoor air temperatures; for example, from -6ºC down to -21ºC in three days in January (9-11.01, Fig.7). High circadian dynamics of external temperatures can probably be attributed to the effect of the night air drainage and accumulation of cold air in the basin of the horticultural cooperative Serebryanka (Novyi settlement).

5. Observation results

Disadvantages of the traditional scheme: Observation results have shown the need in adding a convectional solar system to work mostly in the morning to the passive system of solar heating of the house. They also seem to confirm a positive effect of additional solar heating of the house in the evening in February through the westward stained-glass windows (the total area of stained-glass windows is 12.5 m²; the amount of incoming solar radiation was not estimated).

Evaluation of the passive system contribution: As a result of unfinished interior works, the volume of space heated by the passive solar system was a third bigger than designed in the winter of 2015-2016. Thus, there were no dividers between the living and the buffer zones, there was no warm floor between the second level and the attic, and the attic was not insulated completely; the wind porches had not been built yet for the front and back doors. Also the interior straw panels were not covered with clay plaster. This partially explains a high inertia of the system in the morning hours of solar exposure as well as a substantial circadian dynamics of temperatures inside the house during the

observation period (in some days 6-7°C decrease from the day maximum to the minimum at 9 a.m.).
Nevertheless, to confirm the effectiveness of passive solar heating in the southern Far East, the data obtained can be taken into account. First of all the data of the passive system should be expected to improve after the warm contour of the attic is completed. Also, a passive solar system with direct gain was not designed as the main heating system, but the data obtained showed its high potential for contributing to the overall house heating system. It also took into account the fact that continuous monitoring of the passive solar system during the all cold period was carried out in the region for the first time.

6. Additional heating the house from renewable energy sources.

Taking into account the obtained data, we can propose that the traditional architectural solution can provide relatively comfortable conditions on a sunny winter day, replenishing up to 50% of the required heating. Since the number of sunny days per winter is about 80% it is possible to consider the autonomous system of generating heat from renewable energy sources for single-family houses in region.
In accordance with the project design, the passive solar system works together with the active solar system of heating and hot-water supply based on vacuum trickle collectors SUNRAIN TZ58-1800-25R1 (was not installed yet during the observation period). Photoelectric panels were supposed to support the autonomous functioning of the solar system of heating and water supply. But the system improvement may be proposed.
In the conditions of cold monsoon climate of Russian Far East, this design of a house needs a combined system of heating and cooling with a solar-geothermal heat pump (GSHP) [6, 7]. A hybrid system and seasonal accumulation of heat surpluses from the solar system and cold from the winter night air will provide for 90% of the annual heating and cooling. The remaining 10% will be used as electricity for devices, automatic equipment, a reverse-running heat pump and will be provided by the photoelectric panel. The exploitation results obtained for the hot-water supply and heating solar panels created by the Laboratory 07 of FEB RAS IMTP (Fig.12), [8], confirm the efficiency of using solar power in south part of Far East in a single-family house construction, which is of great importance in terms of preserving natural resources and establishing a prospective sustainable model of natural resource exploitation in the region.

Fig. 12: Experimental solar installation of hot water and heating.

7. Conclusion.

The research conducted in the constructed passive solar house in the winter of 2015-16 with no additional heating sources is relevant since it has confirmed a high efficiency of passive solar architectural solutions, even within a traditional architectural model of the solar house. High efficiency of a passive solar system and simultaneous use of a seasonal active solar system make it possible to consider dwelling houses autonomous from the heating utility networks in the region.

Abstract

One way to improve the efficiency of renewable energy system is by integrating two or more devices or so called the hybrid system. In this study, the change of the Ground Source Heat Pump (GSHP) seasonal performance factor will be observed when it is integrated with Photovoltaic-Thermal (PVT) to meet the multiple loads of house and office. Basically, the strategy to get this efficiency improvement is by combining the water outlet of GSHP which firstly heated by desuperheater and the output of PVT in one (preheat) tank. In the solar preheat tank, the heat from PVT will be added through heat exchanger as the supplementary to the hot water which is previously from city water passing desuperheater of GSHP. The final output of GSHP with the heat addition from PVT and the efficiency of stand-alone GSHP will be compared. GSHP-PVT hybrid system has the lowest energy consumption followed by GSHP stand-alone and reference case (simple sum of house and office) with 31.8kWh/m2-yr, 78.7kWh/m2-yr and 107

Keywords: *Ground Source Heat Pump (GSHP), Photovoltaic-Themal (PVT), Multi-Load, Energy*

1. INTRODUCTION

The requirement for alternative low-cost and efficient energy sources has triggered people to the development of Ground Source Heat Pump (GSHP) system for residential and commercial heating and cooling applications. Earth temperature always sTab. throughout the year and this is also the reason why GSHP is very attractive. The heat pump on GSHP system operates using the same cycle as a vapor compression refrigeration cycle. Both systems absorb heat at a low temperature level and reject it to a higher temperature level. The difference between these two systems is that a refrigeration application is only concerned with the lower temperature effect produced at the evaporator, while a heat pump may be concerned with both cooling effect produced at the evaporator as well as the heating effect produced at the condenser in GSHP system. A reversing valve system is used to switch between heating and cooling modes by changing the refrigerant flow direction. GSHP system can be seen in Fig.1

A photovoltaic-thermal or PVT module is a combination of photovoltaic cells with a solar thermal collector, forming one device that converts solar radiation into electricity and heat simultaneously. The excess heat that is generated in the PV cells is removed and converted into useful thermal energy. The PVT system can produced efficiency up to 75% and as the efficiency of PVT increases, the cell temperature is decreased. PVT can be distinguished into two types based on the manufacturing process: PVT collectors and PVT panels. PVT collectors are very similar in appearance to a regular solar thermal collector, consisting of a PV-covered absorber in an insulated collector box with a glass cover. PVT panes on the other hands are similar in appearance to regular PV panels. Due to lack of extra insulation and a glass cover, PVT panes have a lower thermal efficiency but higher electrical yield. Fig.2 shows the PVT panels. In this study, two cases will be compared which are GSHP system and GSHP coupled by PVT system in order to perform the annual performance analysis.

2. MICRO-GENERATION SYSTEM MODELING FOR EACH CASE STUDIES

In this study, three systems will be introduced for applications in residential and commercial buildings. Case one is simple sum of residential and commercial buildings (house and office) heating/cooling demand. Both thermal loads of residential and commercial buildings are provided by boiler and chiller system also fan coil unit as presented in Fig.3. The fan coil unit is located inside the building and a duct system is used to distribute the cooling/heating air inside the building. Domestic hot water (DHW) tank in installed inside the house and connected with the boiler via pipelines. This case will be the reference case for this simulation study.

Case two is a load sharing system with Ground Source Heat Pump (GSHP) to meet the combined load of houses and offices. Case two is load sharing hybrid system of GSHP integrated with PVT module. Load sharing in this case means houses and offices will use one system to provide heating and cooling demand instead of using separate system for each house and office. In case one, as presented in Fig.4, uses GSHP system to provide the heating/cooling demand instead of boiler/chiller system (conventional system). The desuperheater of GSHP is used to preheat the city water for DHW usage. A hot water storage tank is equipped to provide space heating and DHW heating. A gas burner is located at the bottom of the tank to provide supplementary heat in cases where GSHP alone cannot provide sufficient heat in very cold days or to heat the DHW water in summer. Water from the hot water tank is supplied to the two buildings through pipelines for DHW demand loads. In this case, the city water has enough pressure to flow the water in the system without using a pump. A cold water storage tank is used in the cooling season to provide chilled water for the cooling coils. Three way valves are used to switch between GSHP heating and cooling loops in winter and summer cooling seasons.

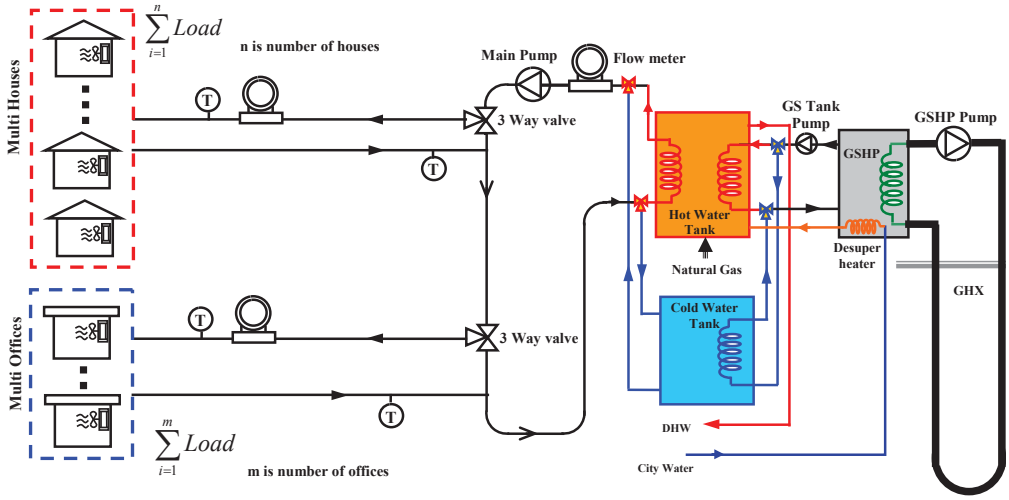

Fig.4. Load Sharing (Houses & Offices) Using GSHP System

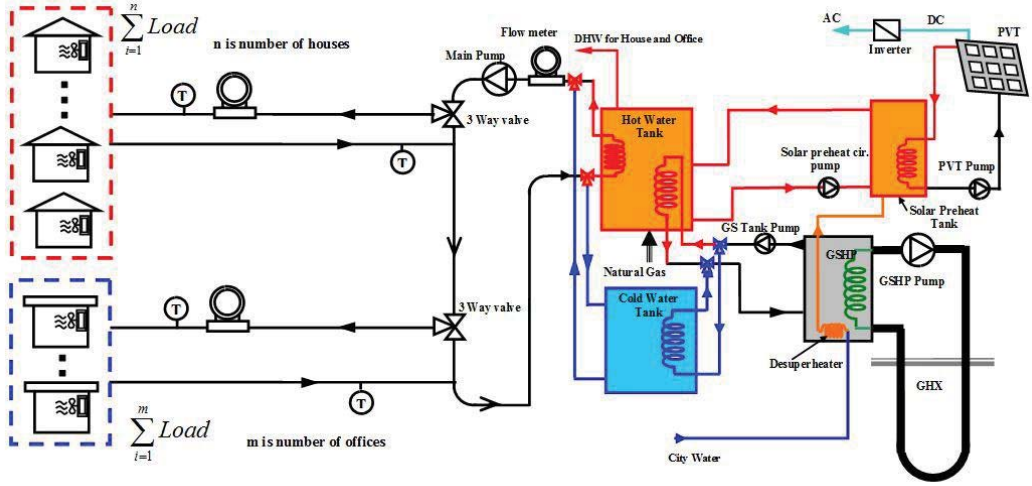

Fig.5. Load Sharing (Houses & Offices) Using Hybrid Micro-Generation System (GSHP-PV/T)

Tab. 1. Summary of Modelling Cases

Cases	Heating/Cooling Systems			Remarks
	Cooling	Heating	DHW	
Case 1	Chiller + Fan-Coil	Boiler + Fan-Coil	Boiler + DHW Storage Tanks	Simple Sum Loads (House + Office)
Case 2	GSHP - Fan-Coil	GSHP - Fan-Coil	GSHP (DSH) + Storage Tanks	Load Sharing
Case 3	GSHP - Fan-Coil	PV/T- GSHP- Fan-Coil	PV/T-GSHP (DSH) + Storage Tanks	Load Sharing

Case three is a hybrid micro-generation system integrating a photovoltaic thermal system to a GSHP system. PVT panels can generate both electric and thermal energy. The generated energy can be used to reduce the electrical power import from the grid to houses and offices and also used for space and water heating. There are many possible ways to integrate the PVT's thermal system to the GSHP system. In this study, system configuration with solar preheat-tank as shown in Fig.5 was chosen for the present study. The collected solar thermal energy is stored in a preheat-tank for two purposes: preheat the DHW and transfer the heat to the hot water storage tank in condition where the preheat-tank bottom temperature is few degree Celsius higher than the top of hot water storage tank. The remaining part of the system is same as that in case one.

Tab. 1 presents a summary of different modeling case studies and the corresponding technologies used for space heating, space cooling and DHW heating

3. SIMULATION AND ANALYSIS METHODOLOGIES

In the present study, all hybrid system models analysis from previous chapter are done by TRaNsient SYStems (TRNSYS-17) which a popular software platform for advanced dynamic building energy simulation. TRNSYS library includes a large database of component models related to buildings, thermal and electrical energy system, input and output data management and other dependent functions. All components models in this study were selected from TRNSYS libraries and enhanced with latest manufactures' system performance data. Additional models were developed for some components that are not present in the TRNSYS libraries such as PV module, GSHP desuperheater and etc.

Based on that approach, detailed simulation models were developed and applied for all three cases. In order to evaluate the load sharing system performance, multi-building block consists of five identical houses (with floor area 200m2 each) and two identical houses (with floor area of 500m2 each) were introduced. The building specifications meet the building envelope requirements for climate zone 4 recommended by ASHRAE Standard 90.1-2007.

For systems serving multiple buildings, it will typically have a lower thermal peak than the sum of thermal peaks of each homogeneous house and office. This is mainly due to the fact that individual buildings reach their respective thermal peaks at different times during the day. A load diversification factor is commonly used to take this phenomenon into consideration in load estimation and equipment sizing for systems that serve a number of mixed buildings. This factor is commonly in the range of 0.90 and tends to be lower when the central system serves a mix of office and residential buildings with peak demand occurring at different times.

The simulation models were run with Incheon, South Korea weather data over a year to simulate and analyze the energy systems' performance. The energy consumption results from the TRNSYS simulations were then used for energy and cost analyses to evaluate and compare the performance of various systems (cases)

4. ENERGY ANALYSIS RESULTS AND DISCUSSION

In this section, simulation results of the case one, case two and case three systems that serving multiple buildings (five houses and two offices) will be presented and discussed. While the houses are identical to the house studied in the previous section with a floor area of 200 m2 per house, the office is enlarged and each has a floor area of 500m2. The total combined floor area with five houses and two offices is 2000 m2.

Both thermal and non-HVAC electric loads of the simulated houses and offices were analysed through appropriate time series methodology prior to the system simulation models development. The houses and offices were assumed to be separated from each other with no thermal interaction between them. Both type of buildings are square shaped and are assumed with a single interior zone in the simulations. The domestic

hot water volume assumption was according to ASHRAE-124 recommendations for residential and small office buildings. Non-HVAC electric loads were developed based on "average" consumption of a detached house and a small office in Canada which is 43.9 kWh/m2-yr. Those are presented in Tab. 2:

Tab. 2. Annual Thermal Load and Non-Electric Load Intensities

Load Intensity (kWh/m^2-yr)	Building Blocks Five Houses + Two Offices ($5x200\ m^2 + 2x500\ m^2 = 2000\ m^2$) Incheon	
DHW	8.6	6.6%
Space Heating	47.2	36.1%
Space Cooling	31.2	23.8%
Non-HVAC Electricity	43.9	33.5%
Total	*130.9*	*100%*

Initial simulation study found out that if a GSHP system integrates with PVT panels only, the PVTs thermal and electrical energy generations are restricted by the volume and temperature of the solar pre-heat tank directly and building thermal demand indirectly. Therefore, it may be more efficient to design a GSHP-PV/T system with combination of both PVT and PV panels rather than installing PVTs only. In this way, the electricity generation will not be restricted or reduced by the thermal demand compare to systems with all PVT panels. In addition, it is anticipated that the initial capital cost could be reduced as PV panels are usually cost less than PVTs. For this reason, 5 GSHP-PVT systems (Case 3) with various combinations of PVT and PV panels were simulated, as shown in Tab. 3:

Tab. 1. GSHP-PVT Systems for Simulation Study

Number of PV Panels	Number of PVT panels	
	0	60
0	GSHP	GSHP-PVT60-PV0
120	GSHP-PVT0-PV120	GSHP-PVT60-PV120

Total (Net) Energy Use	*107.6*	*78.7*	*69.8*	*59.7*	*50.8*	*40.7*	*31.8*
Energy Savings	-	*28.9*	*37.8*	*47.9*	*56.8*	*66.9*	*75.8*
Energy Savings (%)	-	*26.9%*	*35.1%*	*44.5%*	*52.8%*	*62.1%*	*70.4%*

The result shows that the reference case (Case 1) has the highest total energy consumption at 107.6 kWh/m2-yr followed by GSHP system at 78.7 kWh/m2-yr and GSHP-PVT systems are showing better energy consumption compared to others ranged from 31.8 kWh/m2-yr until 69.8 kWh/m2-yr. The main reason why GSHP-PVT has better energy consumption is because this system only use small amount of natural gas for auxiliary burner inside the hot water burner and also GSHP-PVT system produced electricity so that reduced the net amount of energy consumption. Those results are shown in Tab. 4 and Fig. 6

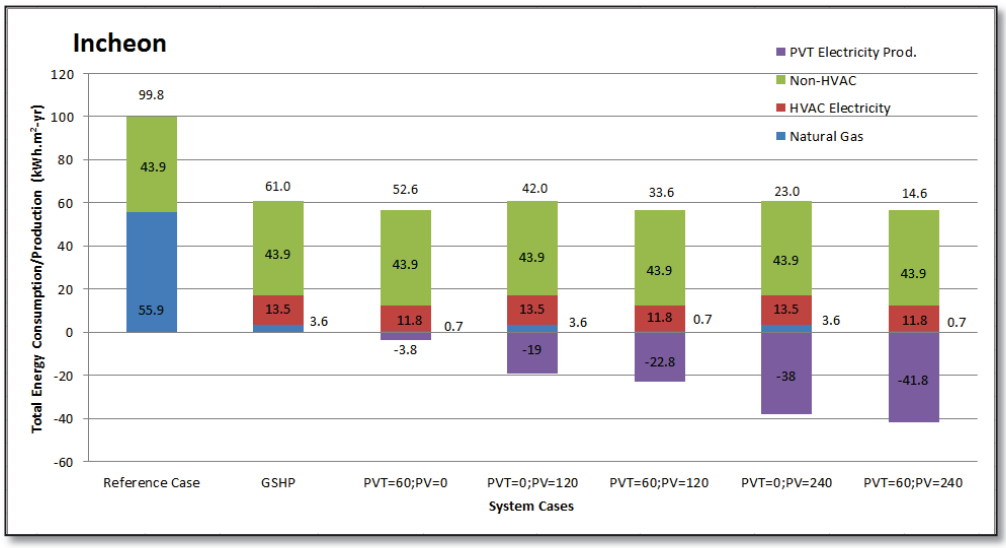

Fig. 6. Energy Analysis Results for Each Study Case

Based on those Tab. and graph, the system performance is evaluated and presented in COP values for the three studied cases. The COP is the ratio of the total energy delivered to the buildings (which includes space heating, space cooling, and DHW energy as well as electricity production if any) to the total consumed energy (natural gas and electricity) in the respective period as shown in Tab. 6

Tab. 3. System Performance (COP) For Multi-Building Cases In Incheon

Incheon	COP		
	Heating Period	Cooling Period	Overall/Annual
Reference System	0.92	1.47	1.08
GSHP	2.87	2.09	2.50
GSHP-PVT60-PV0	3.09	2.56	2.85
GSHP-PVT0-PV120	3.42	2.64	3.05
GSHP-PVT60-PV120	3.70	3.24	3.49
GSHP-PVT0-PV240	3.97	3.19	3.59
GSHP-PVT60-PV240	4.30	3.92	4.13

The result in Tab. 5 shows that Case 3 which is GSHP-PVT system has the highest COP ranged from 2.56 to 4.30 followed by GSHP system (Case 2) and simple sum of residential and commercial buildings (case 1).

This result indicates that hybrid system has a better performance compared to conventional system and GSHP-PVT is the best combination. One of the reasons is the additional contribution from solar energy to produce electricity so that electricity that consumed from the grid can be reduced as shown in Tab. 6

Tab. 4 Annual Electricity Generation and Supply of Various GSHP-PVT system

Incheon	PV/T Electricity Generation		System Electricity Supply	
	Used by System	Exported to Grid	Supplied by PV/T	Supplied by Grid
Reference System	-	-	-	100%
GSHP	-	-	-	100%
GSHP-PVT60-PV0	100.0%	0.0%	5.2%	94.8%
GSHP-PVT0-PV120	83.4%	16.6%	21.1%	78.9%
GSHP-PVT60-PV120	80.5%	19.5%	25.2%	74.8%
GSHP-PVT0-PV240	62.3%	37.7%	31.5%	68.5%
GSHP-PVT60-PV240	60.0%	40.0%	34.4%	65.6%

The results in Tab. 6 indicate that the PV/T panels, depending on its capacity, meets 5.2% to 34.4% of the total electrical loads in Incheon. The remaining 65.6% to 94.8% required electricity is imported from the grid. Increase of the PV/T capacity certainly reduces the hybrid MG system's dependency on the electric grid, on the other hand this will result high initial capital costs

5. CONCLUSION AND FURTHER WORK

In this study, three different renewable and hybrid micro-generation cases were analyzed for application in combination of residential and commercial buildings. Five houses and Two Offices were selected in this study to perform the annual energy performance for each technology. Based on the result in previous chapter, we can conclude that:

• The total energy consumption of all the studied GSHP-PV/T systems (Case 3) is lower than that of the GSHP system (Case 2), and also the reference case (case 1) due to the use of geothermal and solar renewable energies. The overall system performance (COP) increases with the increase of the PV/T panels.

•The simulation results show that it is more efficient to design a GSHP-PVT system with combination of both PVT and PV panels. The PVT panels (operated with thermal-load control strategy) are primary used for covering part of the building heating loads and the PV panels (operated when there is solar radiation available) are mainly used for generating electricity for building usage. In this way, the electricity generation will not be restricted or reduced by the thermal demand compared to systems with all PVT panels. Any excessive electricity could be sold to the grid for additional income or stored in batteries for later use.

• Due to the PV/T electricity production is intermittent and not synchronized with the building demand, the GSHP-PV/T systems not only require electricity from the grid, but also have excessive electricity to be exported to the grid. The amount of electricity imported and exported to the grid is dependent on the number of the PV/T panels integrated to the systems.

• The GSHP-PV/T systems are able to meet 5.2%-34.4% of the building total electric load in Incheon. The remaining electric load is met by the grid. Increase the number of PV/T panels certainly reduces the system

dependency on the electric grid.

• For the simulated GSHP-PV/T systems, between 60% and 100% of the PV/T generated electricity is used by the buildings themselves and the remaining 0% to 40% excessive electricity is exported to the grid. The percentage of exported electricity increases with the increase of the PV/T panel numbers.

For Further work, an artificial intelligence (AI) control strategy to be embedded in a gateway wireless platform for optimal control of the hybrid system will be developed. The strategy will be simulated and investigated for variety of system sizes and applications. The hybrid systems will be optimized and the optimal component and system configurations will be simulated and assessed for maximum utilization. Variety of simulations will be conducted using system integration optimization technique to approach real life situations where a group of multi-type buildings will be served by the hybrid energy system in load sharing applications. Further, and more in depth, economic analyses will be performed to investigate the viability of the hybrid energy systems in selected scenarios and their impact on the overall installation and operation costs.

Abstract, Dates and Facts

A rundown 1958 post-war housing estate in the west of Munich was first an object of study, then a planning model and finally a showcase project for holistic wood renovation. For an ideal lifecycle balance and overall economy, the following is vital: maintain the carrier substance, rebuild, recompress, passive-building envelope pre-fabricated in wood, timeless design and regenerative energy supply.

Keywords: Solar architecture, renew stock, recompress, set of objectives, lifecycle balance, grey energy, wooden construction, pre-fabrication, passive house, solar thermal and photovoltaic energy.

The prototypical GWG project received important awards and it attracts visitor groups from Europe and many other countries. But may be the most important research result is: The tenants feel notably very happy in their new wooden houses ..

1. How is our 'big house' doing?

'Holistic' solutions for building restoration – is that just a new name for an age-old problem? We don't think so. I would like to try to briefly explain why, an idea and a concrete project example. The question here is what does sustainable mean? The answer is to get started with the holistics .. let me start with a very personal story. My children, Leoni, 19, and Lucia, 16, grew up in the south of Munich. Their ecological footprint on the world is still small – and it should stay that way. But if we listen to serious forward thinkers – which we definitely should – by the time they reach our age, their world should be a completely different one than today...

Should we be afraid of that? Well, we probably don't need to be and fear is never a good starting point when trying to find sustainable solutions. The term 'respect' fits better here – faced with the boundless complexity of global events as a result of a burn out of our knocking off economy. The more we think we know, the less we manage to maintain a natural balance. Prof. Radermacher, for example, calls it the boomerang effect. No wonder that there are children who say: we cannot leave the shaping of our future up to the adults anymore. What more can you say to that?

How to handle this 'seven-headed Hydra'? I have found a suitable approach for myself: it is the daily effort to constantly contribute to a solution instead of the problem. Only by living out that idea can a temporary state of calm be reached. Planning and construction offer a rewarding area of work in this respect. The key functions of energy, material and capital circulation are each approximately half directly or indirectly linked to our building construction and present the highest potential by far for sustainable collaboration with their owners and users. Success solely depends on us, the social skills towards high priorities, strength of character and communication.

2. Challenge and objective

Buildings are and will remain our most costly and longest lasting commodity. We are faced with the simple fact that with the turn of the millennium, we entered an era in which we need to reflect on those unique key energies and materials, which have always made living even possible: our sun, its light. High-tech on the roof, smart-tech in the house and/ or religious beliefs of divine salvation is not enough. But what does 'solar construction and restoration' mean? Integral planning concepts are aimed at a rational, sustainable overall context of:
- Induced energy and land consumption in urban building or landscape preserving credibility,
- energy consumption due to production and transport and the minimisation of synthetic materials in construction,

- of operational energy consumption when using the building and installations, linked to optimised quality of use,
- energy input and problem waste on ‘re-use/ down-cycling/ disposal’ after restoration or demolition,
- and the easing or reshaping of our social, cultural and economic network of relationships.

Energy, anything material and also our culture are not reproducible. Solar architecture is about the complex equilibrium of energy and material balance of our earth. Above all, it is pleasing and works simply, is flexible and long-lasting – three barely perceived, but ultimately decisive multiplier properties for the ecologically rational lifecycle balance. This suggests a decisive turnaround against our political and economic behaviour, our smart and responsible contribution towards an open solution process – as an essential contribution towards peace and the well-being of generations.

The building owners may ask: Who should pay for that? The counter question is: what is the future worth to us? Stay calm, thinking helps. Independent expertise and creative reflection are by far the most cost efficient resources for real sustainable construction. A macroeconomic observation – compiled under ecological cost transparency – leads to extensive different decisions than in today’s building industry. Relevant research results have expressly proven this several times. The simple, comprehensive dynamic CO2 taxation would be a highly effective motor.

Long-term ecology will become long-term economy by the time the overdue internalisation of external costs at the latest. ‘Holistic and sustainable’ will become the only form of building construction we will be able to afford in the future. Good architecture has so much more to offer than low energy demand values, but only when architects and engineers take on this system-changing planning attitude in design realisation and render a backward-looking, knotted sustainability certification redundant, will a substantial economy, new ‘archi-culture’ and genuine quality of life synergistically arise – wouldn’t that be a legacy worth striving for?

3. The example: From object of study to prototype

A large part of the overall housing stock in Germany is functionally outdated, has high operational costs, is inadequate in terms of energy consumption and does not comply with society’s living standards of today, let alone of the future. That means, that our central construction tasks lie in the renewal of our existing building stock. This necessity poses many dangers, however, when thought through it poses unique opportunities: it calls for a fundamental approach and new interpretation of old housing. Structural sins of the past can be alleviated or even eliminated and the demand for a more sensitive recompression and redesign presents the possibility of sustainable urban corrections linked with high overall economic efficiency and an attractive future orientation.

As an example we present a Munich GWG housing estate in Sendling: Mass commodity in the 1950s, masonry bolts with unit floor plans and individual room heating, after two generations it is still in its original condition for the most part. The heating requirement is approximately at factor 5 above the new construction value according to EnEV2009/13. It was only the excellent location, that kept the building from permanent vacancy. In 2006/7 we had focused on a study design about sustainable development goals by the chair of wooden constructions at the TU Munich – with remarkable results. A research project ‘TES Energy Facade’ subsequently followed, then the contract for the planning and implementation by the public housing association to our ArGe Kaufmann.Lichtblau.Architects – in short: it got serious!

Fig. 2: Renewal post-war housing estate Munich, paths of the sun 21 March / Sept.

So the modern engineer's wooden construction was to become the renovation method of building stock?! Until now, a lot was theory as in architecture. The design, it is said, shows the talent; the art begins with the implementation and realisation. The building owner and our planning team – after detailed preliminary discussions – agreed on a set of objectives. This corresponds entirely with the requirements and, among other things, the widest possible preservation of existing primary structures to the prevention of grey energy and waste from demolition and reconstruction. An upgrade-free economic life expectancy of at least 40 years for complete renovation – 46 flats and new regional administration in the lowest energy standard – essentially covers three areas, our set of objectives:

A / The use: Quantity, quality and environment
- Compress rentable living areas of the 1b site by above 100 % - use building ground, ensure revenue,
- Create market-conform mix of flats with light, attractive layout – offer new living quality,
- Interlock disabled, elderly and child friendly functional residential use – include demography,
- Make the new living environment spacious, social, close to nature and robust – design urbanity,
- Studies of the yearly suncycles show daylight quality in each residential area in the quarter.

B / The energy concept: Standard, maintenance, economy
- Lower the energy demand, heating, air and light to under 50 % of a new construction – achieve maintenance security,
- As much as possible, provide regenerative residual energy from heating and electricity – achieve zero emissions,
- 'triple win' – ease the burden of the owner/ tenant/ environment – produce overall profitability,
- Offer simple, safe, long-lasting technology for ease and cosiness – promote health and comfort.

C / The structure: Ecology, process and design
- Perfectly ecological assembly system of high quality and precision – optimise life cycle balance,
- Constructive integration of sound insulation and fire protection, as well as statics, hvac and solar active components – understand flexibility,
- Digital on-site measurement and a maximum pre-fabrication, low weight and short construction period – track process efficiency,
- Low maintenance surfaces and many selectable design variations – enable time-less, attractive architecture.

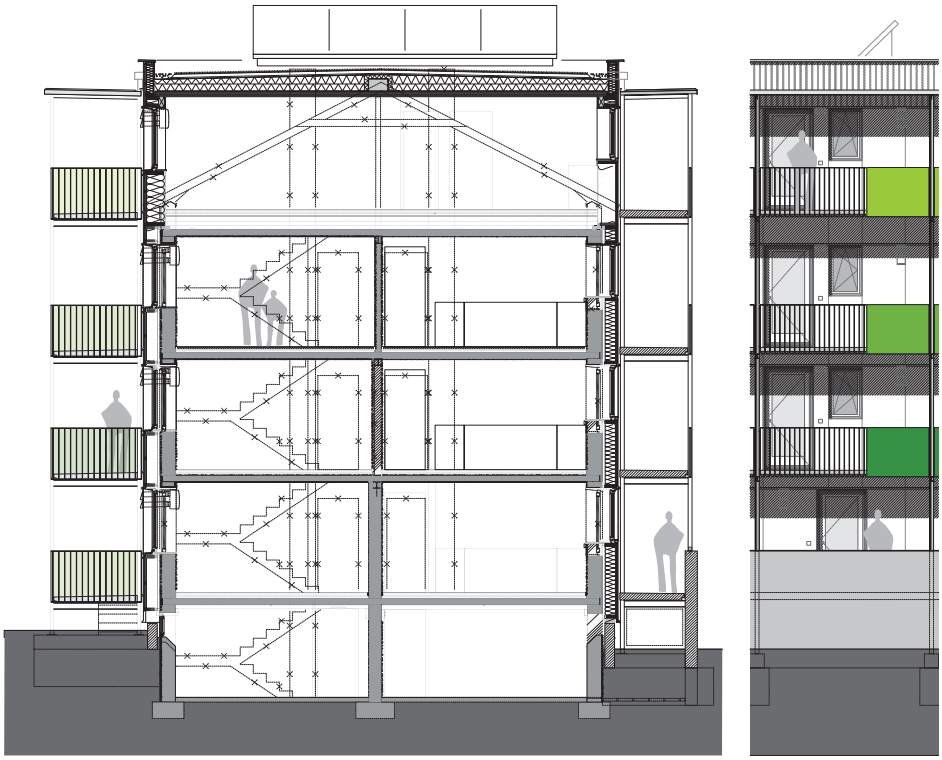

Fig. 3: Renewal post-war housing estate Munich, layout construction in wood, phase 1

The provocative demand of the building owners to the planners: all aforementioned objectives should be reached cost-neutrally within public housing subsidies. The unavoidable extra costs for prototypes with 'sustainable attributes' must be financed in full by appropriate subsidies for energy renovations and 1 € / m2 rent exclusive of service charges as a user contribution for minimal energy costs. That should occur through the holistic added value as described, and furthermore a new 'league of efficiency' will be reached. Despite obstacles and risks we accepted the challenge.

The planning team led by Kaufmann.Lichtblau.Architekten developed a higher-density 'Rejuvenation' model, 100 % additional living area where realised. Construction Phase 1: By incorporating a new building for the district office of GWG, the load-bearing structure of the original buildings could be retained but the access was changed, and the flats were transformed into individual modern residential units, barrier-free and with attractive outdoor areas. The new building envelope, including that for an added storey, consists of pre-fabricated wooden elements meeting passive-building standards, with maintenance-free wall cladding and green roofs.

Exemplary solutions were developed for life-cycle and energy balances, building science and structural aspects, fire safety, sound insulation and an efficient construction process. Construction Phase 2: The existing structures prooved to be quite unflexible, the necessary quantity and quality of flats, including an underground garage, could not be found in a reasonable way. So the client decided to break the old structure down and design and optimised new building in wood construction as in phase 1. The minimal energy demand is primarily covered by regenerative sources.

The first building phase was completed in 2012, phase 2 in 2014. An extensive monitoring for result validation was carried out and prooved: holistic value enhancement, energy efficiency which is fit for the future and a wooden construction offering active climate protection, combined with optimal usage quality, promise the highest total economic viability for generations. With a widely successful completion of the comprehensive mutual set of objectives, K.L.A. has consciously entered new territory for GWG and in doing so has also reached unforeseeable limits to the affordable input of working time. We owe that to our cause, our building owners and their (happy) tenants.

Provisional conclusion: The obtained result is an example of the simple fact that the renewal of existing buildings with the title 'real sustainability' – on today's conditions – is achievable, of course not by means of standard planning, standard processes with standard partners and at standard costs. We also had to deal with obstacles and risks, as well as priority struggles and completely new solutions. Follow-up work shows plenty of valuable experience and learning success, which we will hopefully be able to consistently develop. We cannot go back. The reward for all our efforts lies in durable high use and structural quality with unbeatable overall profitability, but with reference to the life cycle – just like in sustainable forestry.

4. The second chance: Future perspectives ..

At this point a discussion about the new planning and construction techniques 'wooden pre-fabrication' would be appropriate. What systematic wooden construction is really capable of achieving for climate change was first shown at the 'Building with wood – ways into the future' exhibition at the architecture museum in Munich, then in Vienna, actually in Berlin. It aroused an interest which never existed before in modern wooden construction, our GWG project was chosen as the restoration example. We urgently demand a policy be issued to duly support planners and building owners on the development of this enormous CO2 reduction, active climate protection potential.

The focus is on attaining industrial cost-saving production and in doing efficiently increase building stocks' slowing restoration rate, using the most natural, healthy and environmentally friendly materials and processes as possible. Only through competently optimised planning under equal observation of effective land use, ecological structural engineering, zero-emission building operation as well as first class use and design quality is macroeconomic, affordable and real sustainability achieved. 'Solar construction and restoration' as we know it does not harm anybody, it presents the basis for personal freedom and in doing so embodies true modernism.

Therefore it should be up to us construction masters to change the attitude from the bottom up, to learn something new, to present results and to tell happy customers: it really works! Wooden construction marks the most sensible way of using raw material, whose abundance and innocence will finally pass. Every well-

made, energy autonomous and nice looking wooden architecture can become a clear sign of change. Let's protect our riches of timber against foreign desires and wrong usage. With wood as a construction material, warmth returns as a life metaphor, haptic trust creates a new confidence that there are solutions for our problem of the century: sustainability. They grow in the forest and demand nothing more than our sensitivity, fantasy and unity. That is why it is important to endlessly discover new things, rediscover and develop further.

I would like to finish the illustrated boardsheet with this: let me quote what occurred to me when I woke up in the night and luckily found a pencil and paper. I will take the liberty of including our partners and building owners: 'We have not dedicated our lives to architecture to later on have to say: we failed on the most important dimension of construction: a universal sustainability. It may appear quite emotional to some people – nevertheless and now more than ever: we will not stop being nonconformist and controversial until we hand over to our children and grandchildren'. That is what we can do - and what you can do with us. Thank you all the best !

Cold-Climate Supermarket attached Greenhouse: A Case Study

Anders MacGregor[1] and Caroline Hachem-Vermette[1]

[1]University of Calgary, Calgary (Canada)

Abstract

Supermarkets are responsible for large amounts of energy consumption, for building operations (HVAC and refrigeration) as well as for transportation of produce and other goods. This study is based on an on-going research to reduce the energy consumption of this type of buildings by attaching a greenhouse to an energy efficient supermarket for locally grown organic produce. Using a parametric approach, a design model for a supermarket attached greenhouse for improved energy performance is proposed. The analyzed parameters pertain to passive design (building envelope, shape, day-lighting, PCMs, aerogels) and active design (photovoltaic, semi-transparent photovoltaics, supermarket waste heat harnessing), to develop a model for year-round production in Calgary, Canada (51ºN). The results indicate that energy consumption can be reduced by up to 85% as compared to the base case.

Keywords: *Supermarket, Energy efficiency, Parametric study, optimization, building envelope, phase change material, photovoltaics*

1. Introduction

The population of Canada and the world is increasing with higher concentrations of people living in dense urban areas (Ackerman, et al. 2014). With the global risk of climate change, it is pertinent to centralize commodities, mainly food, to restrict GHG emissions and energy consumption associated with rural agriculture (Sanyé-Mengual, et al. 2015). Supermarkets are already a centralization of commercial products, however, energy required to transport these products to the consumer site of purchase, and the associated GHG emissions, can be significant. Coupling energy efficient greenhouse to supermarkets for locally grown organic produce has the potential to achieve two goals: utilization of waste heat from the supermarket in the greenhouse, and reducing the negative impact of food transportation. The supermarket can generate significant amount of heat (MacGregor and Hachem, 2016) that can be used to supply some of the heating requirement of the greenhouse.

Designing a greenhouse to operate year-round is presented with some obvious challenges when the target location is Calgary, Canada (51ºN). The most apparent challenge is harsh winters that embrace the city for nearly half of the year with temperatures often dropping to sub-zero levels. The second is the high-latitude location of this city resulting in low angled sun in the winter and limited day length, increasing thus dependencies on artificial lighting and heating. The summer season can also be relatively warm with higher incident solar radiation and temperatures reaching 30-35ºC (EnergyPlus, Weather Data Sources) for several weeks leading to potential overheating especially when designing an all-glass greenhouse.

This paper investigates the feasibility of implementing an on-site greenhouse, attached to a supermarket, for the year round growth of organic produce in Calgary, Alberta, Canada (51ºN). This in-depth study aims at examining the potential of coupling these two structures (greenhouse and supermarket) in view of exploring methods of energy sharing between these buildings, and consequently the mitigation of the negative environmental impact, of both types of buildings.

2. Methods

doi:10.18086/eurosun.2016.01.01 Available at http://proceedings.ises.org

The study employs a model of supermarket that has been previously optimized (MacGregor and Hachem, 2016). and an attached glass greenhouse, built according to standards (see below). This paper presents, in addition to an outline of the optimized supermarket design, the optimization process of the greenhouse, and the potential of energy sharing between the two buildings.

A number of parameters are explored to increase the energy efficiency of the greenhouse including the insulation values in the opaque wall assemblies (Fokaides, et al. 2014), the window assemblies (Carmody and Haglund, 2012) and advanced building materials such as aerogels (Buratti, 2012) and phase change materials (PCM) to passively regulate heat (Tabares-Valasco et al., 2012). The parametric study also focuses on designing building envelope components which maximize the buildings ability to generate on-site electricity through the use of building integrated photovoltaics (BIPV) and semi-transparent photovoltaics (STPV) while still maintaining energy efficiency.

2.1 Supermarket Design

The design of the supermarket is optimized for increased energy performance and to achieve a near net zero energy status (MacGregor and Hachem, 2016). This is reached by using high efficiency LED lighting and a thermally optimized building envelope as well as the use of on-site generation of electricity. The characteristics of this energy efficient supermarket design are summarized in Table 1. The supermarket model accounts for essential electrical and thermal loads associated with this building type, such as refrigeration units, cooking appliances, lighting, occupancy and miscellaneous electrical equipment. This supermarket design consumes 25% less energy (234 kWh/m^2) than a base model (319 kWh/m^2) designed to be representative to those found in the location of study.

The rooftop of the supermarket is designed to maximize the solar capture at Calgary's latitude. A saw-tooth roof configuration is adopted (Fig.1) with 50 ° tilt angle, towards the south. This tilt angle is optimal for year-round solar collection in Calgary (Hachem. *et al* 2011). The south facing surfaces of the saw-tooth structures are covered with BIPV panels of 18% electrical efficiency. Taking into account the BIPV electricity generation, the net energy consumption is about 94 kWh/m^2, representing 70% less than the base model, described above (Macgregor and Hachem, 2016).

Role of the supermarket

The supermarket can benefit the attached greenhouse in two ways. The rooftop space of the supermarket can be utilized for photovoltaic generation to subsidize some of the energy costs of the building complex (i.e. supermarket + greenhouse). The other method of utilization of the supermarket is the use of refrigerator waste heat to reduce the heating load for the entire building complex. These refrigerator compressors are constantly running to maintain safe temperatures for food preservation, releasing thus large amounts of heat. This heat is partially vented to the exterior and partially transferred into the supermarket interior space increasing thus the cooling load of the building. Theoretically, a thermal storage tank and heat pump can be used to capture the heat and utilize it in the adjacent thermal zone- namely the greenhouse. This paper presents an estimation of the amount of waste heat is needed to fully subsidize the complex total heating load.

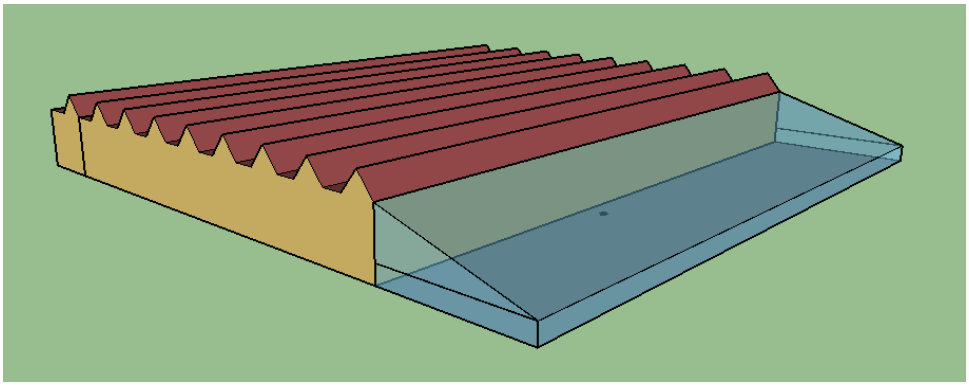

Figure 1: SketchUp model of attached greenhouse on supermarket. Saw-tooth structures on supermarket are sloped at 50° for photovoltaic generation.

Table 1: Supermarket Design Considerations (MacGregor and Hachem, 2016)

Design Parameters and Conditions	Value
Insulation	Wall: 3.3 m^2K/W; Roof: 5 m^2K/W
Windows	No Windows
Lighting	High efficiency LED; 8w/m^2
Phase Change Material	In ceiling and in walls
Building Integrated Photovoltaics	18% efficiency, on south facing side of saw-tooth roofing design
Dimensions	45 m x 35 m x 4.3 m
Annual Electrical Load	474 MWh (includes refrigerators, lighting, electrical HVAC and miscellaneous equipment)
Annual Electricity Generative Capabilities	258 MWh

2.2 Base case design

The base model is used as a reference case for the simulations presented hereafter. This base model is defined as the base level greenhouse attached to the optimized supermarket. Loads analyzed below are those associated with the entire complex.

EnergyPlus (Version 8.4.0, 2016) is employed to carry out the simulations within this parametric study. This energy simulation tool allows control over individual processes and designs within the reference building as well as an extensive array of output options. Assumptions and initial inputs adopted for simulations are shown in Table 2. The heating, cooling and lighting loads are studied to analyze the effect of various parameters on the energy performance of the complex.

Table 2: EnergyPlus initial assumptions or inputs for base model

Assumption/Input	Value
Run Period	1 Year, simulated at 10 m intervals
Weather File and Location	Calgary, Alberta, Canada
Heat Balance Algorithm	Conduction Finite Difference
Base Window Assembly	Single Pane
Ventilation Rate	0.5 ACH, only day-time. Only available above 0°C (1)
Infiltration Rate	0.03 ACH
HVAC System	COP 1. (EnergyPlus' Ideal Loads System)
Thermostat Range	20 – 26°C (2)
Humidity Range	50-90% (2)
Lighting Requirements	25 W/m^2 (3)
Daylighting Set-Point	7000 lux, on dimmer control (3)

[1](Vadiee, 2013), [2](von Zabeltitz, C. 2010), [3](Jahns, T.R, 2009)

2.3 Parametric investigation

This section presents the studied parameters, in view of optimizing the overall energy performance of the complex of buildings.

Greenhouse Design. The designs used in this study are based on the standard, all-glass greenhouses. Three different shapes of greenhouses are investigated to identify the impact on heating, cooling and lighting loads. All three of the cases are attached to the south facade of the supermarket with the roof sloping downwards until it intersects with the south façade of the greenhouse. This façade is the aspect of the design which is modified to determine the impact on the various loads, while other parameters remain constant (as for the base case design, see above). The south façade is 1.7 m, 2.7 m and 3.7 m high for the cases 1, 2, and 3, respectively (Figure 2). 1.7 m is chosen for the shortest south façade height such that a person can attend easily to the plants

against the wall. The north façade, as it is attached to the supermarket at this side, is of an opaque wall assembly.

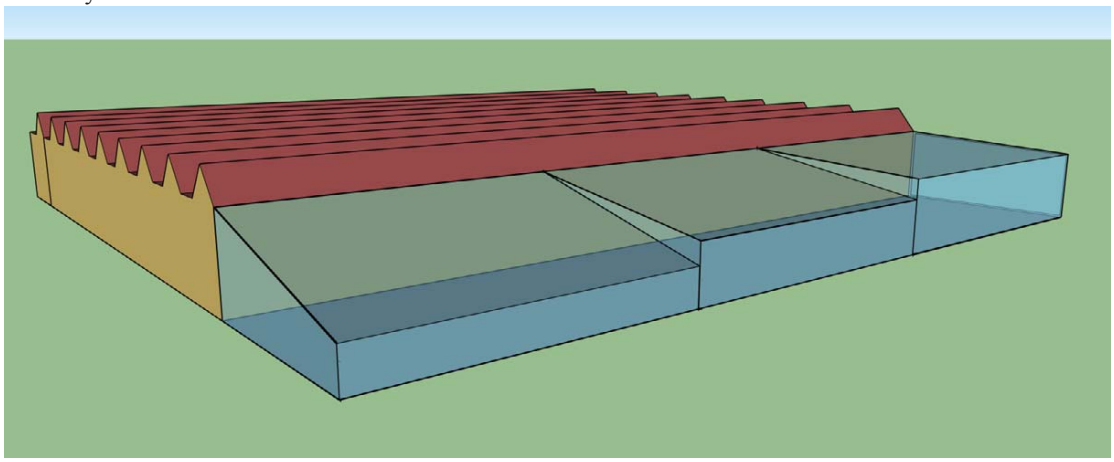

Figure 2: SketchUp design of the three different designs. In the image they have been presented beside each other to better showcase the differences. In the simulations, the designs span the entire length of the supermarket.

Boundary Insulation. The insulation level of the barrier between the two thermal zones (i.e. greenhouse and the supermarket) is systematically changed to determine the insulation level that reduces the HVAC loads of the entire complex. The optimal thermal resistance value for the supermarket's walls are found to be 3.3m^{2}K/W (MacGregor and Hachem, 2016) and the values chosen for the boundary wall's insulation are iterated between 25 – 400 % of this value.

Window Assemblies. The envelope construction of the greenhouse consists of transparent fenestration in nearly 100% of the surfaces. Determining the optimal window assembly to reduce the greenhouse loads is essential to the goal of designing a high energy performing supermarket with attached growing area. Clear, single paned windows are used as the base model to simulate commonly used fenestration surfaces in greenhouses. The different assemblies are as shown in Table 3. The building's heating, cooling and lighting loads are used to determine which assembly is optimal for this design.

Table 3: Window assemblies and corresponding characteristics used in simulations. (Carmody and Haglund, 2012)

Assembly	Frame	U-Value (W/m^{2}K)	SHGC	VT
Single, Clear	Aluminum	5.778	0.82	0.88
Double, Clear	Aluminum	4.71	0.65	0.63
Double, low-e, High SHGC, Argon Filled	Aluminum	3.63	0.38	0.61
Triple, low-e, High SHGC, Argon Filled	Improved non-metal	1.14	0.41	0.5
Triple, low-e, Low SHGC, Argon Filled	Improved non-metal	1.08	0.18	0.37
Double, low-e, Low-SHGC, Argon Filled	Aluminum	3.57	0.26	0.49
Quadruple, low-e, High, SHGC, Krypton Filled	Improved Nonmetal	0.77	0.41	0.36

Infiltration. Airtightness has an important impact on the thermal loads of a building. For the greenhouse the effect of this parameter is studied over a range of 0.03 - 10 air change per hour (ACH) under normal atmospheric pressure. The results are compared to the base model's performance with an infiltration rate of 0.03 ACH. This minimal infiltration rate is selected to control the CO_2 levels for healthy agricultural production. A ventilation rate of 0.5 ACH is adopted during day-light hours which replenishes the carbon dioxide for photosynthesis (Vadiee and Martin, 2013). The effect of increasing the infiltration rate is investigated.

Aerogels. Aerogels are transparent or semi-transparent building materials which offer much higher thermal resistance than the traditional window assemblies. Two different aerogel products are used in the simulations and the characteristics of both are shown in Table 4. Aerogels are employed in two different scenarios: 1) to replace all the glazed areas, 2) to replace all glazed areas except for the roof. The roof in the latter scenario is assumed to take the configuration of the optimal window assembly, determined above.

Table 4: Aerogel characteristics used in simulations (Buratti, 2012)

AeroGel	U-Value (W/m^{2}K)	SHGC	Visible Transmittance
Monolithic	0.65	0.74	0.8
Granular	0.44	0.31	0.8

Shades and Moveable Insulation. Due to the nature and design of greenhouses, the interior can overheat due to high solar radiation. Two types of moveable fenestration covers are introduced in this study. The first being an inflatable thermal barrier that expands and covers the greenhouse. This thermal barrier is an inflating polyethylene cover which sheathes the greenhouse portion of the building at sunset and then is deflated at sunrise. When inflated, the cover has a thermal resistance value of 1.79 m^{2}K W-1 (Arinze, et al, 1988). A rollout shading device on the roof of the greenhouse is explored in this study to reduce overheating. The shades are assumed to have no effective thermal resistance but block out a portion of the incoming radiation. Three different transmittance values are investigated; 75%, 50% and 25%. These solar screens are activated when the solar radiation is high during the summer months.

Semi-Transparent Photovoltaics. Semi-transparent photovoltaics is investigated as means to subsidize the electrical loads while providing some shade to the interior due to the inherent design of these panels. The semi-transparent photovoltaics simulated in this study are termed STPVXX, where XX is the percentage of the photovoltaics per area of surface. The remaining surface area is comprised of double paned glass window assemblies. The characteristics of each of the cases and their corresponding thermal and transmittance qualities are shown in Table 5. STPVs are assumed to replace all transparent surfaces. This is to determine the maximum on-site electricity generation that can be produced.

Table 5: Semi-transparent photovoltaics characteristics used in simulations (Kapsis, 2015)

Assembly	U-Value (W/m^{2}K)	SHGC	Visible Transmittance
STPV90	1.634	0.146	0.061
STPV80	1.634	0.219	0.122
STPV70	1.634	0.292	0.183
STPV60	1.634	0.364	0.244
STPV50	1.634	0.437	0.305

Phase Change Material. Phase change materials can regulate internal climate due to their ability to store thermal energy within the material as they undergo phase transition. When the material then reverts back to its prior state, this thermal energy is released back into the room. This cycle can help reduce cooling loads as the PCM is melting and also reduces heating loads as the PCM freezes. This type of material is shown to be effective in controlling the heat gain within the attached supermarket associated with the refrigeration and lighting (MacGregor and Hachem, 2016). An example of this material exists in the EnergyPlus and has been added to the boundary wall between the supermarket and greenhouse in this study.

3. Analysis of Results

This section presents the results of the optimization of the energy performance of the complex coupling the greenhouse and the supermarket. The supermarket performance is analyzed, both as isolated structure and as a part of the complex. In addition, this section analyses the impact of the building envelope design parameters, and outlines the aspects of the supermarket which can be utilized in developing a more unified and efficient complex.

3.1 Base Case Building Loads

The two components constituting the complex investigated in this study are the supermarket and the greenhouse. Figure 3 compares the building loads of the isolated supermarket, and then as attached to the greenhouse in addition to the entire base case complex's energy consumption, on per unit are basis. The base case-complex combines the optimized supermarket and the standard greenhouse. Coupling the greenhouse to

the supermarket, the building loads of the supermarket decreases due to thermal transfer with the inefficient greenhouse as well as the slightly reduced size of the supermarket. The southernmost 10 m of the supermarket is replaced by the greenhouse for this study in order to maintain the same size of complex. In the parametric analysis below, the entire complex will be the object of optimization.

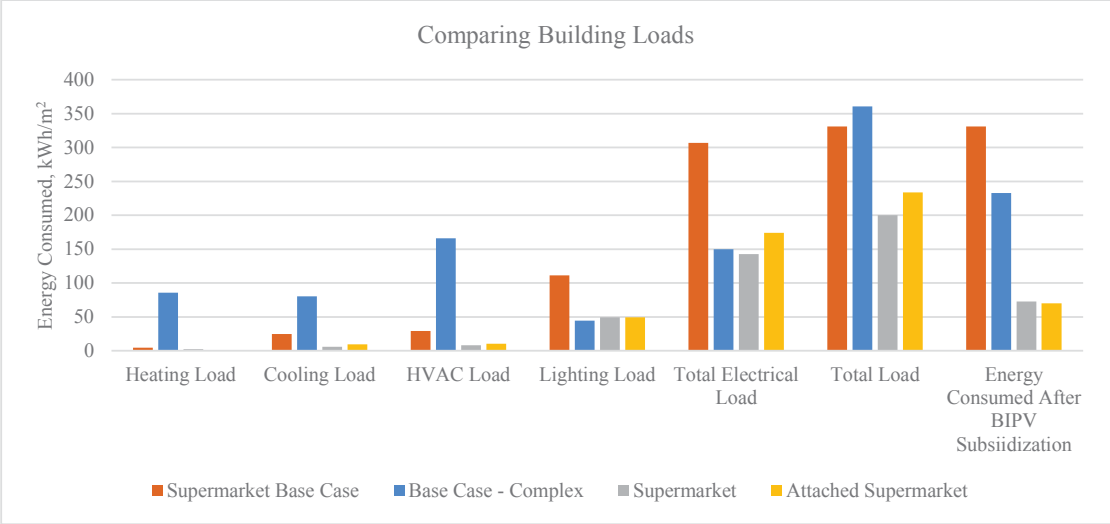

Figure 3: Comparison of the building loads of the supermarket by itself, attached to the greenhouse and then as the entire complex. The base case-complex loads are the target of optimization in this study.

3.2 Effect of greenhouse design parameters

Greenhouse shape. The three different geometrical designs of the greenhouse, perform very similarly. Each design has approximately the same total energy consumption, with case 3 (largest south façade and lowest sloping roof) having marginally more energy consumed annually. The increase in height with the front façade, and the resulting decrease in slope angle for the roof, the heating load increases as cooling load decreases. The lighting load is not affected. The front façade height of 1.7 m is adopted for all following models.

Boundary Insulation. The thermal resistance in the boundary wall between the supermarket and greenhouse does not have significant effect on energy consumption. Since the impact is less than 1%, the optimal insulation of the supermarket is maintained as it is the larger energy consumer of the two zones.

Window Assemblies. Triple paned, low-e, low shgc and argon filled assembly reduces the energy consumed in the design significantly as compared to other assemblies. For instance, this assembly reduces the heating and cooling energy consumption by 80% as compared to the base case. Limiting the solar heat gain in the greenhouse the cooling load is substantially reduced, as displayed in Fig. 4.

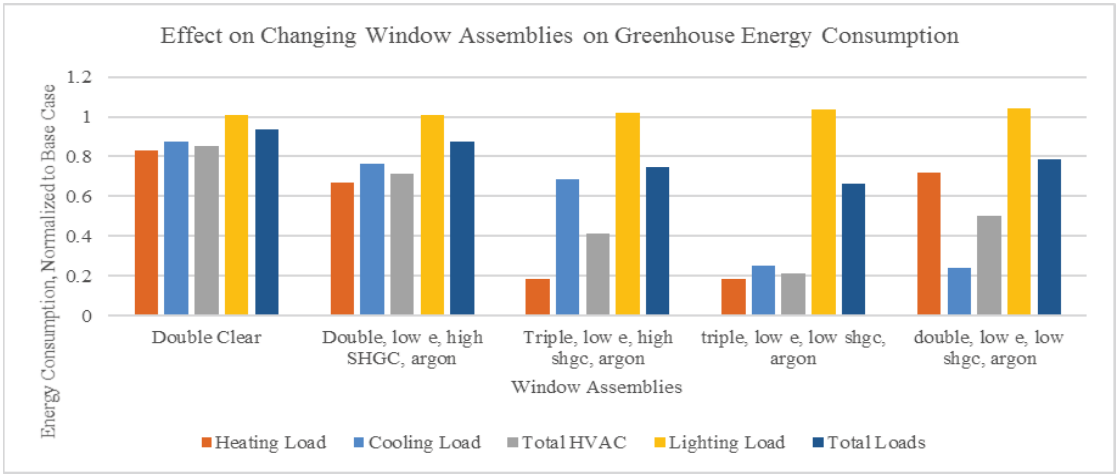

Figure 4: Best case window assemblies are triple, low-e, low shgc and argon filled. Reduces combined heating and cooling load by 80%

Infiltration. These simulations are completed using the optimal window assembly found above as these assemblies allow significant improvements to the interior environment. The results of analyzing the impact of increased infiltration rate indicate that the lowest rate is the most favorable for reducing heating and cooling loads.

Aerogels. Aerogels show promise in reducing HVAC energy loads while allowing light to penetrate the envelope. The insulating qualities of these materials leads to an increase in cooling loads, when used in place of all window (see Figure 5). Replacing all fenestrations but the roof (which maintains the optimal window assembly; triple, low-e, low shgc, argon filled) with aerogel leads to a total reduction in heating and cooling loads of 70%. However, even though these reductions are significant, the scenarios which contain the triple, low-e, low-shgc and argon filled assemblies in all fenestrations perform marginally better (2% difference in total load reduction).

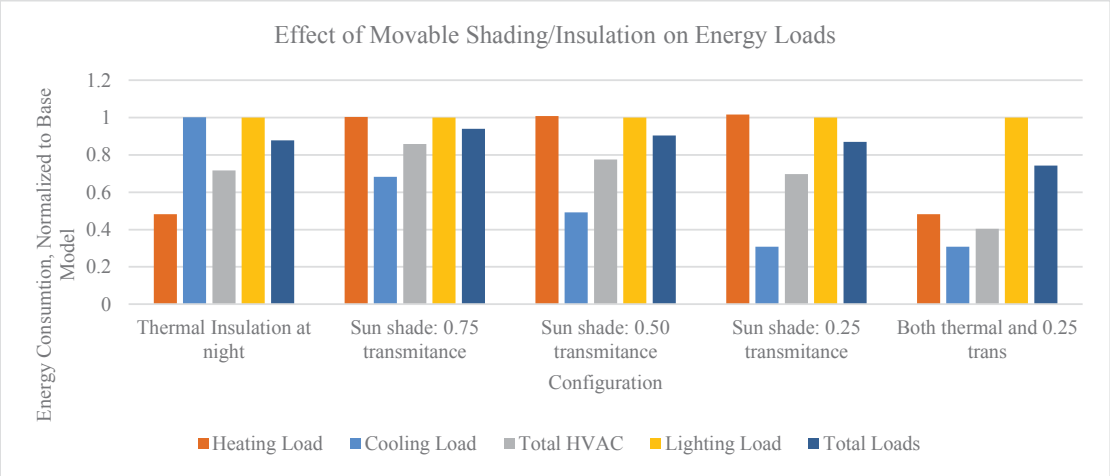

Figure 5: Granular aerogel in all fenestration but the greenhouse roof shows reduction in total energy consumption of 25%

Shades and Movable Insulation. The polyethylene inflatable cover which activates at sunset, reduces the heating load by 52% as compared to the base case, while it does not impact the other loads. The rolling shade with 75% transmittance qualities shows a reduction in the cooling load by 32%. Rolling shade with 25% solar transmittance shows even greater results with a reduction in cooling loads by 70% as compared to the base model. The best case of all these scenarios is the addition of the night time insulation to the 25% transmittance shade with a simulated reduction in heating and cooling loads by 60% (See Fig 6) and an overall reduction in energy consumed by 26%.

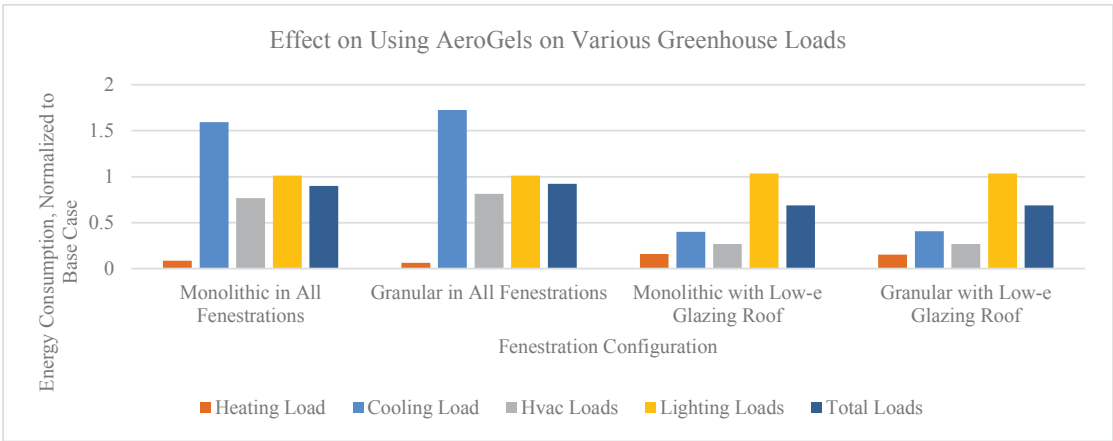

Figure 6: Using night-time thermal covers and 25% transmittance roll-out shade shows reduction in combined heating and cooling loads by 60%.

Semi-Transparent Photovoltaics. The STPV are useful in two aspects. The first is the reduction of the heating and cooling loads by the thermal and optical properties of these assemblies. The STPV assemblies are in part

opaque which blocks solar radiation from entering the greenhouse, thus reducing cooling loads. This cooling load increases linearly with the decrease in opaque areas of the different assembly configurations. The thermal properties of the assembly (Low –e, argon fill gap) reduce the heating loads by 70% as compared to the base case across the different configurations (Fig. 7).

The electrical loads are high in the supermarket-greenhouse complex and using semi-transparent photovoltaics help in the reduction of energy consumed from non-renewable sources. There is an obvious increase in the lighting load as the STPV assemblies block incoming radiation, however, this assists in minimizing the cooling loads. The potential electricity generation can reduce the total energy consumption by approximately 20%, in the case of STPV 90. This potential decreases to 10% in the case of STPV 50.

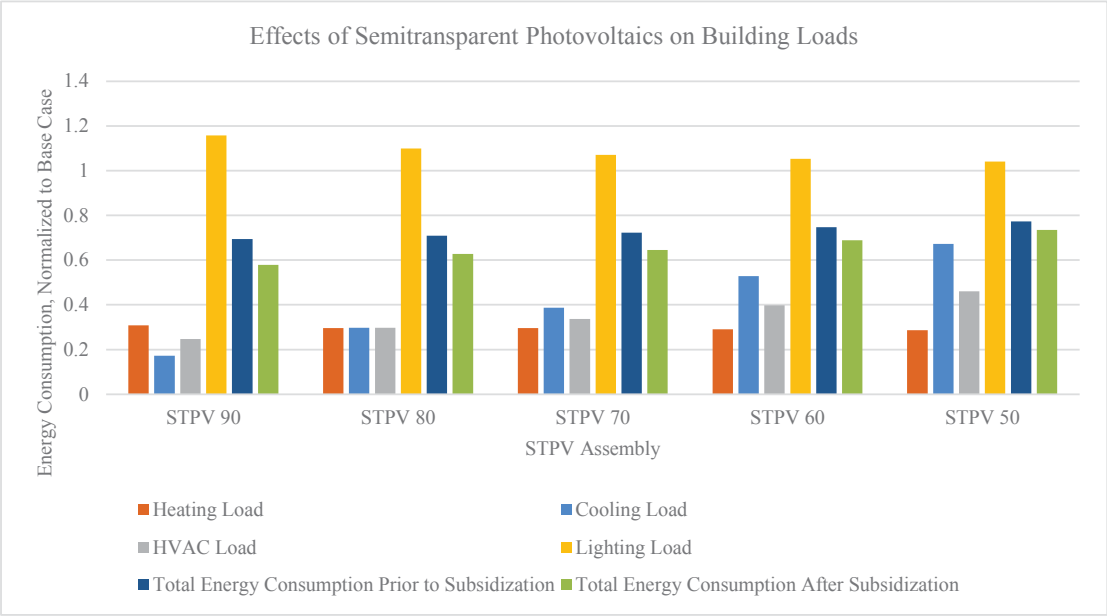

Figure 7: STPV can reduce the total energy consumption by 42% by blocking incoming solar radiation and generating electricity.

Phase Change Materials. Using PCMs in the greenhouse boundary wall shows that some of the heating and cooling loads can be controlled. The simulations are carried out for the base case as well as the optimal window assembly case. In both cases, the combined heating and cooling load reduction is about 10% and 5% for the base case and the low-e glazing case, respectively.

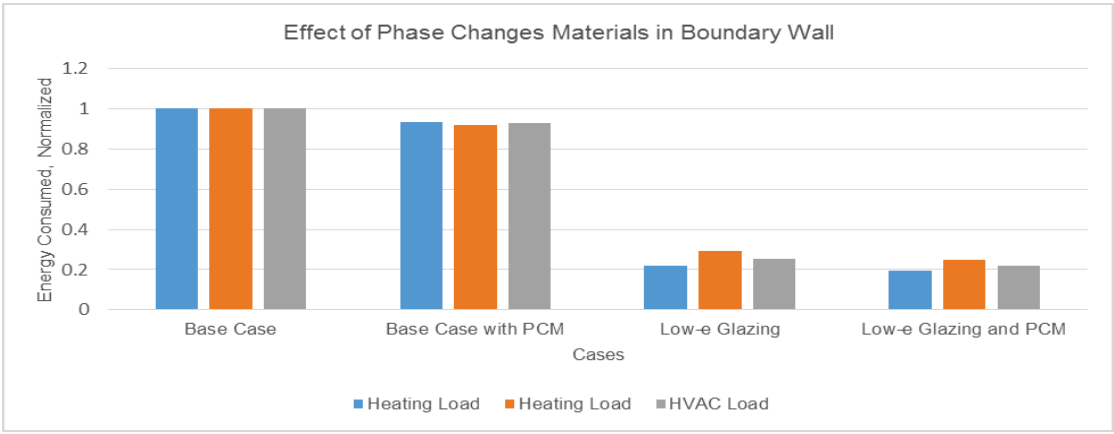

Figure 8: Phase change materials can reduce some of the heating and cooling loads by adding them to the boundary wall construction.

3.2 Utilization of Supermarket

BIPV electricity generation. A BIPV is assumed to cover the south surfaces of the saw-tooth roof structures

This BIPV system generate about 258 MWh annually. This amounts to 35% of the total energy requirements of the base model (base model consumes 360 kWh/m^2 annually) and 53% of the total energy consumption of the optimized model (241 kWh/m^2, annually). If combined with the energy generated from the semi-transparent photovoltaic assemblies, 80% of the energy requirements of the entire complex can be met with on-site generative means.

Heat recovery potential. The supermarket has two sets of refrigerator units with their corresponding compressor racks; the self-contained refrigerators with built in compressors as well as the medium (4°C) and low (-15°C) temperature refrigerators and their back-room standalone compressor rack. The supermarket back-room refrigerator compressor racks generate about 521 MWh of heat. Much of this heat is ejected into the outdoor environment as to have a minimal impact on the building's HVAC system. The heating requirements of the base model is 153 MWh annually, and the case with optimal window assemblies is 34 MWh, annually. Both of these loads are a fraction of the available heat of the compressor racks (30% and 6%, respectively). Especially in the case of the high efficiency windows, it can be assumed that the entirety of the heating load can be accounted for by a mechanism which captures the necessary amount of waste heat from this ejected source. On the other hand, the self-contained refrigerator/compressor units are responsible for a large portion of the internal heat gain, in the supermarket. Implementing a mechanism to capture all or part of this available heat has the potential to significantly reduce the cooling load. For instance, assuming that all heat gain generated by the self-contained refrigerator/compressor is captured, the cooling loads of the whole complex can be reduced by approximately 40%. When 50% of the available heat is captured, reduction of about 25% can be achieved.

3.3 Proposed Models

Table 6 shows the most influential parameters, selected based on the above analyses, to represent an optimized model. Heating and cooling loads are reduced by up to 95% as compared to the base model. The lighting loads are slightly higher than the original base model due to the shading devices and to the properties of the window assemblies. The overall electrical energy consumption, without accounting for the BIPV electricity generation, is reduced by 39% (241 kWh/m^2). With the utilization of the supermarket BIPV system, an overall energy consumption reduction to 62% of the original values is realized. Including STPV assemblies in only the roof portion of the greenhouse, a reduction of 82% in energy consumption is achieved. Finally, when the supermarket is fully utilized with the use of the refrigerator compressor racks to supply the heating requirements, 86% of the base model's energy consumption are reduced to a final value of 54 kWh/m^2.

Table 6: Parameters Chosen for Optimized Model

Parameter	Value
Greenhouse Design	Case 1; 1.7 m south façade
Boundary Insulation	3.3 m^{2}K/W
Window Assembly	Triple, low-e, low shgc, argon filled. On roof only
Aerogels	Granular. All fenestrations but roof
Infiltration	0.03 ACH
Movable shades and insulation	25% transmittance shade and night-time thermal insulation
STPV	STPV90 in roof only (In specified case in Figure 9)
PCM	Located in boundary wall

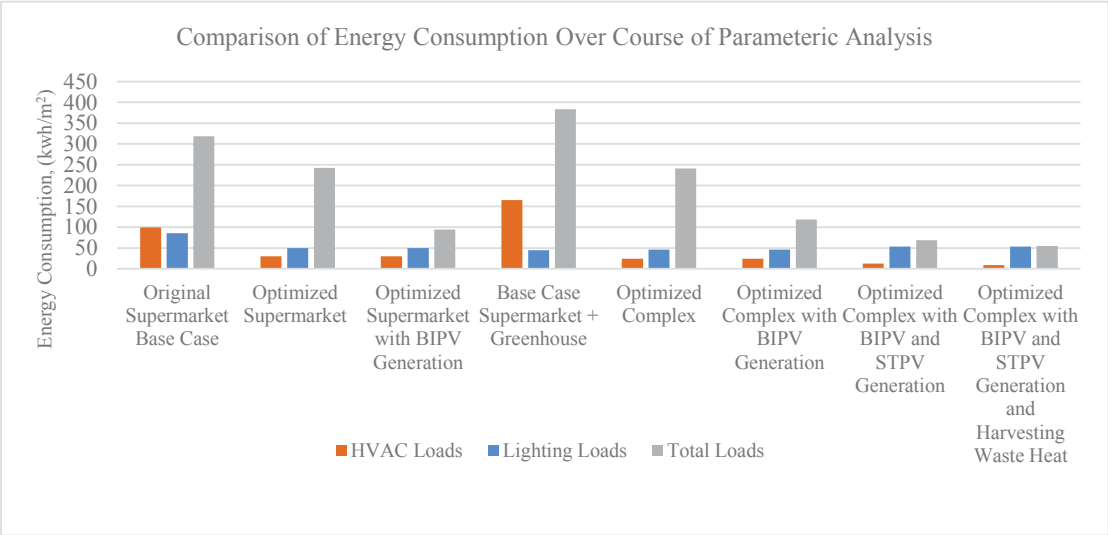

Figure 9: Total energy can be reduced by 86% as compared to the base model with a yearly electrical consumption of 54 kWh/m2. Final model performs 50% more efficiently than optimized supermarket design.

Discussion and Concluding Remarks

This study examines the potential of coupling greenhouse and supermarket in view of reducing energy consumption of the two buildings and exploring methods of energy sharing between them. An 86% reduction in energy requirements is reached through an optimized building envelope and increased potential of on-site electricity generation and heat recovery. However, despite this reduction, the building's energy intensity is 54 kWh/m^2, largely due to the use of inefficient refrigeration/compressor systems. This reduction is the topic of future research as followed:

- *Mechanical Optimization of Refrigeration.* The supermarket still relies on a number of refrigeration units to keep food at safe temperatures. However, these refrigerators often do not utilize the exterior temperatures for the source of the cooling, rather a reliance on compressor racks. Utilizing exterior temperatures in Calgary's cold winters may prove worthwhile in electrical load reduction.
- *Investigating Minimally Glazed Greenhouse Design.* The design adopted in this report adheres to greenhouse standards. A transparent greenhouse, as compared to an opaque building design, requires much less artificial lighting and allows for a higher degree of solar heating. However, an opaque building construction for the greenhouse could perform better in an environment whose temperatures fluctuate so rapidly over the course of the year as is shown in another study where limiting transparent fenestration to only 30% of the south façade and implementing, rooftop photovoltaics, day-lighting devices and increased insulation values produced a net-positive energy scenario of a stand-alone growing facility (Hachem and MacGregor, 2016). Investigation of this opaque design applied to the supermarket-greenhouse complex is an important next step.

This study is a step towards a more sustainable future by increasing the resiliency of communities. Providing the means for communities to centralize their source of food in a low energy consuming manner will further reduce the dependencies of these communities on fossil fuels and associated GHG emissions.

Energy savings through solar reflectance and thermal insulation on roofs of residential and non-residential buildings in Mexico.

Jorge Lucero-Álvarez[1], Ignacio R. Martín-Domínguez[2]

[2] Centro de Investigación en Materiales Avanzados, S.C. - Unidad Durango, Durango, Dgo. (México)

Abstract

Thermal building simulations were carried out for the climate conditions of 20 cities in Mexico. We analyze the effects on thermal loads of variations in both solar reflectance and thermal insulation of a roof's exterior surface. The results are quantitative estimates of the reductions in annual (cooling + heating) loads reachable through adequate solar reflectance and thermal insulation of buildings in each city. Additionally, the adequate range of solar reflectance values is defined for each climate zone.

Keywords: *Solar Reflectance, Thermal Insulation, Cool Roofs, Energy Savings, Buildings*.

1. Introduction

According to the 2014 National Energy Balance, 17.97% of the total energy consumption in Mexico (including liquefied petroleum gas, firewood, electricity, natural gas, and thermal solar energy) occurs in buildings—residential, commercial, and public. Of the total energy consumption, 14.71% goes to residential buildings and 3.26% goes towards commercial and public buildings combined. It is estimated that, of the total energy used in residential buildings, 18.7% is used for heating and air conditioning (Fernández, 2011), but this percentage varies with the local climate conditions. In extremely hot climates, up to 50% of the electricity consumed can be dedicated to air conditioning.

The number of households with air conditioning in Mexico has increased since 1996, with an average annual growth rate of 7.5%, while the total number of households in the country has increased 2.7% over the same period (Oropeza and Østergaard, 2014). Rosas-Flores *et al.* (2011) published data on the increase in the fraction of Mexican households with air conditioning, which reached 24% in 2006. Due to the distribution of building types around the country, the greatest consumption of electricity comes from residential buildings, followed by schools and then restaurants/hotels (CMM, 2010).

This indicates that an important and growing part of the total energy consumption in Mexico is dedicated to air conditioning. The energy consumption needed for cooling a building depends to a large extent on the materials used in the building envelope, since some physical properties of these materials affect the heat flux that occurs between the building interior and the environment.

In Mexico, and generally in any location with tropical and arid regions, the roof is the part of a building's envelope that presents the greatest heat fluxes. One of the most effective measures for reducing energy consumption is to select an adequate value of solar reflectance (SR) for the roof. In warm climates, a combination of high SR values and high infrared emissivity (IE) is most energy-efficient. High SR reduces the amount of heat absorbed (rather than reflected) by the roof, which contributes to the heat flow to the building interior. A high IE, meanwhile, allows for more building heat to be emitted from the building and into the atmosphere.

doi:10.18086/eurosun.2016.01.18 Available at http://proceedings.ises.org

The annual savings associated with high SR in buildings have been estimated to reach 51 USD per 1000 ft^2 (about 0.55 USD per m^2) in residential buildings (Akbari *et al.*, 1999), and up to 1.14 USD per m^2 in commercial buildings (Levinson and Akbari, 2010); other studies have calculated the reductions in CO_2 emission (Akbari *et al.*, 2009), and the mitigating effects on urban heat islands in the USA (Rosenfeld *et al.*, 1995; Taha, 2008; Santamouris, 2014). Many other effects of cool roofs have been studied and reported for various other regions of the world; these effects include energy savings, improvements in thermal comfort, reduction of greenhouse gas emissions, and compliance with national and international standards (Boixo *et al.*, 2012; Bozonet *et al.*, 2011; Zinzi and Agnoli, 2012; Dias, *et al.*, 2014; Hamdana *et al.*, 2012, Hernández-Pérez *et al.* 2014). Some countries have even implemented cool roof regulations that specify minimum values of SR and IE—or indexes that include both properties—for the exposed surfaces of building roofs (Akbari and Levinson, 2008; Akbari and Matthews, 2012).

However, there are also downsides to cool roofs. In cities with temperate climate, where there are both heating and cooling needs, high values of SR and IE create a benefit during the summer but an added energy cost during the winter (Syneffa *et al.*, 2007). If applied to sloping roofs, furthermore, high-albedo coatings can be uncomfortably bright for people on the ground or in nearby buildings. Similarly, radiation reflected from a roof can impact neighboring high-rise buildings and affect their own energy balance.

Thermal insulation greatly increases the resistance of building envelopes to conductive heat transfer. However, the benefits of insulation in roofs depend greatly on the SR of the roof surface. Certain combinations of low thermal insulation but high SR can yield overall cooling costs similar to those of high thermal insulation and low SR (Simpson and McPherson, 1997).

Gentle *et al.* (2011) studied the combined effect of three factors—SR, IE, and conductive heat transfer resistivity (R)—on the heat gains and losses through the roof, using simulation in EnergyPlus. These authors used a simple building model with no windows, high R in walls and roof, and the arid climate conditions of Sydney, Australia. One of their main conclusions was that the highest benefits of reflective roofs (high SR) appear when R is small. In fact, high SR and low R result in lower energy use overall than high R alone, due to the contribution of low R to desirable nocturnal heat dissipation. A cost-benefit analysis of thermal insulation in walls and roofs of 6 Mexican cities with different energy needs showed that thermal insulation is not effective in reflective roofs for the tropical city of Acapulco (Lucero-Álvarez-García *et al.*, 2016).

Mexico has implemented some standards related to the thermal energy efficiency of buildings, including NOM-008-ENER-2001 and NOM-020-ENER-2011, which limit heat gains through the envelope of non-residential and residential buildings, respectively. The recommended measures for reducing heat transfer during the summer include insulation of walls and roof, as well as the shading of windows. Studies have measured the energy savings from both these passive methods, and those studies were used to develop the standards mentioned above (Halverson *et al.*, 1994; Álvarez-García *et al.*, 2014), but both these cases considered only the energy costs from cooling. A new non-mandatory standard for evaluating the solar reflective performance of roof coatings (PROY-NMX-U-125-SCFI-2015) is currently also under development (Mendez-Florián *et al.*, 2016).

For the purpose of building thermal analysis, Mexico has been divided into four climate zones based on the Degree-Day method (NMX-C460-ONNCCE-2009). Climate zones 1 and 2 have high cooling needs, with refrigeration degree-days (RDD) above 5,000 and above 3,000, respectively. Climate zone 3 has high energy requirements for both refrigeration (2,500 to 3,500 RDD) and heating (<3,000 heating degree days, HDD), which climate zone 4 has higher heating (>2,000 HDD) than refrigeration needs (Table 1).

Tab. 1: Criteria for defining climate zones in Mexico

Climate Zone	Refrigeration Degree-Day (RDD10)	Heating Degree Day (HDD18)	Type of Region
1	> 5,000		Low elevation, tropical and arid-warm
2	3,500 - 5,000		Sub-tropical and arid-dry
3*	2,500 - 3,500	< 3,000	Mexican Plateau, semi-arid and temperate
4*	< 2,500	> 2,000	Semi-arid and temperate, cold winters

*Climate Zones 3 and 4 are subdivided into three categories (A, B and C), according to the average annual precipitation.

A detailed dynamic simulation study evaluated the impact of cool roofs on 7 Mexican cities (Alvarez *et al.*, 2014). The analysis consisted of varying the roof SR of non-residential and residential buildings meeting Standard NOM-008-ENER-2001 and NOM-020-ENER-2011, to determine the effect of SR on the cooling loads of these buildings. The greatest savings were observed for hot and dry climates, with no significant savings in temperate climates. Due to its extensive urban area, in Mexico City there were significant savings for non-residential buildings.

Another previous work evaluated the effect of roof SR, IE, and R on the annual energy load of buildings, including cooling as well as heating (Lucero-Álvarez *et al.*, 2014). This work included a parametric analysis in which the optical properties were changed between 0.1 and 0.9, at 0.1 intervals, for low income single-family houses with two levels of insulation and one case of no insulation. The authors used climate data from 20 Mexican cities, and found that the greatest energy savings occur in cities from climate zones 1 and 2. Both zones require high levels of SR, and insulation (R) has a significant effect only if the SR values are inadequate.

In this work, we analyze the combined effect of SR and R on two building models. Both models (one residential and one non-residential building) are comparable to those used to develop the Mexican regulations. This study considers both cooling and heating, in order to determine the specific values of solar reflectance most appropriate for various cities and when it is most useful to use thermal insulation.

2. Methodology

TRNSYS simulations were used to estimate energy needs, considering both SR and R. 20 cities in Mexico were selected to represent the 4 climate zones defined by Mexican regulations for energy efficiency in buildings. These 20 cities are listed in Table 2 and are ordered according to their climate zones as they appear on the Mexican Standard NMX-C460-ONNCCE-2009.

Tab. 2: Representative cities in the thermal zones

Zone 1	Zone 2	Zone 3A	Zones 3B and 3C	Zone 4
1. Acapulco	5. Cuernavaca	9. Mexico City	13. Chihuahua (3B)	17. Tlaxcala (4A)
2. Campeche	6. Guadalajara	10. Morelia	14. Coahuila (3B)	18. Toluca (4A)
3. Culiacán	7. Hermosillo	11. Puebla	15. San Luis Potosí (3B)	19. Pachuca (4B)

Figure 1 presents a map of the climate zones in Mexico and the cities studied in this work.

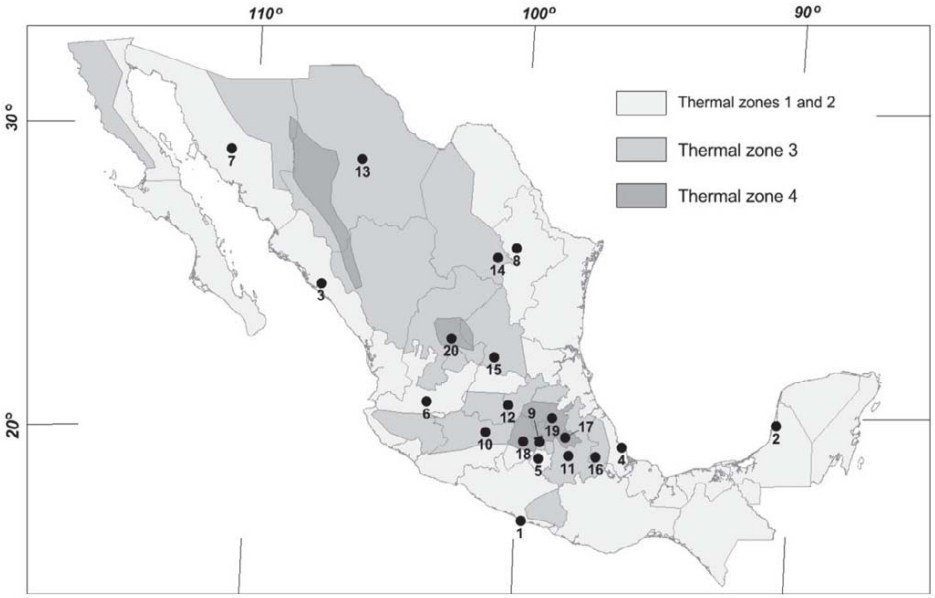

Fig. 1: Location of cities considered in this analysis. The borders of the thermal zones are illustrative and based on the standard NMX-C-460-ONNCCE-2009. Numbers correspond to the list of cities in Table 2

The roof coatings most commonly used in Mexico include asphalt-based waterproofing (SR of about 0.1) and acrylic paint that vary from red (SR ~ 0.3) to white (SR ~0.8). The values of SR in our simulation were varied between 0.1 and 0.9, in increments of 0.1. In addition to the base cases (zero insulation), we considered two common thicknesses of building insulation, 1 and 2 inches of extruded polystyrene, which we approximated as 25 and 50 mm. The prices of different coatings vary over a small range, compared to the typical cost of thermal insulation.

The main parameter evaluated in this study was the annual thermal load, which corresponds to the sum of the thermal loads of cooling and heating. We considered a set point temperature of 25ºC for cooling calculations, in agreement with previous studies, and a set point temperature of 20ºC for heating.

2.1. Climate data

In order to perform thermal simulations of buildings, it is necessary to have climate data representative of the city where the building is located. These data include ambient temperature, relative humidity, wind speed, and solar radiation, all available at relatively short time intervals (1 hour). In this work, that climate data was generated in TRNSYS from mean monthly measurements of the same variables. The mean monthly values of solar radiation were obtained from the Solar Radiation Data Service (SoDA, 2012), while the mean values for temperature, relative humidity, and wind speed were obtained from the Mexican National Meteorological System (SMN, 2010).

2.2. Building characteristics

The relevant parameters for residential and non-residential buildings were obtained from a report prepared for WinBuild Inc (Álvarez-García *et al.* 2014). These buildings models correspond to those used to develop the Mexican Standards NOM-008-ENER-2001 and NOM-020-ENER-2011 (Halverson *et al.* 1994; Álvarez-García *et al.* 2014), which makes it possible to compare these results with those from previous works. Both kinds of buildings are built with brick walls and single-pane windows, and have roofs made of a 10 cm concrete slab with plaster finish on the inside and waterproofing on the outside.

Residential building

The residential building is a typical Mexican 2-story house, with a total construction area of 100 m², a roof area of 54 m², and a north-facing façade. The geometry of the house was an important determinant of the shading of walls and windows. The walls were simulated with an SR of 0.1. The building is inhabited by 4 people, who are present in the building from 0:00 to 8:00 hours and 15:00 to 24:00 hours every

weekday, and 24 hours on Saturday and Sunday. The heat gains from the inhabitants were calculated in TRNSYS according to the parameters established in Standard 7730, and added to heat gains from electrical appliances and lighting. The infiltration for the building is 2 air change per hour (ACH), not considering the ventilation.

The windows were modeled as single-pane glass with the thermo-physical properties given by the TRNSYS library (thermal transmittance or U-value of 5.68 W/m²•K and solar transmittance of 85.5%). The windows cover a surface of 5.20 m² in the walls that face north, 5.60 m² that face south, 0.8 m² that face east, and 2.0 m² that face west.

Non-residential building

The non-residential building model has three stories, each with 625 m² of surface area and a square floor plan (25 m on the side). The walls each contain 40% window space, and have an albedo (SR) of 0.25. This work's simulation considered internal heat gains from electrical equipment, lighting, and people that were present Monday through Friday, between 8:00 AM and 10:00 PM. The ventilation requirements during work hours correspond to ASHRAE Standard 62, which states an air exchange value of 0.043 m³/min•m² (Halverson *et al.* 1994). The properties of the building materials and their distribution throughout the building envelope (of both building models) are shown in Table 3.

Tab. 3: Construction materials and their thermal-physical properties

Building section	Material	Thickness l [m]	Thermal conductivity λ [kJ/h·m·K]	Specific heat Cp [kJ/kg·K]	Density ρ [kg/m³]
Ground floor	Tile	0.01	4.0896	0.795	2600
	Concrete	0.1	6.264	0.84	2300
Upper floors	Tile	0.01	4.0896	0.795	2600
	Concrete	0.1	6.264	0.84	2300
	Plaster	0.015	1.3392	1	800
Wall	Plaster	0.015	1.3392	1	800
	Brick	0.14	2.916	0.8	1600
	Mortar	0.015	2.592	0.837	1890
Roof	Plaster	0.015	1.3392	1	800
	Concrete	0.1	6.264	0.84	2300
	Waterproofing	0.02	0.612	0.8	1127

3. Results

3.1. Comparison with previous studies

Figure 2 compares the cooling loads from this study with those obtained by Álvarez-García *et al.* (2014). The annual loads agree for some cities, such as residential buildings in Monterrey and Hermosillo. Other city results disagree, such as non-residential buildings in Guadalajara. The greatest reduction in cooling load attributable to SR (the difference between the highest and lowest cooling loads for a given building and location) varied the most between these two studies for residential buildings in Hermosillo.

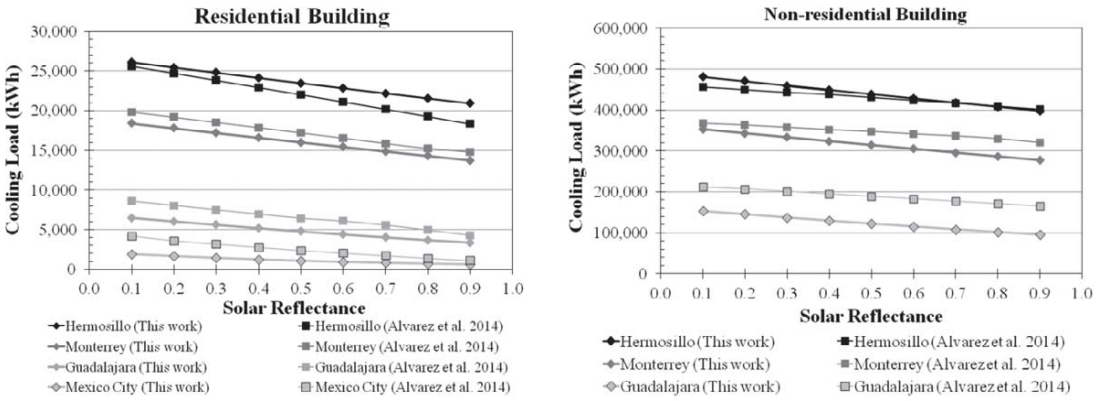

Fig. 2: Comparisons between this work and Alvarez-Garcia *et al.* (2014)

3.2. Effect of SR on a roof with no thermal insulation.

Figures 3 to 7 show the effect that different values of SR can have on the annual cooling load of the two types of modeled buildings. Climate zones 1 and 2 correspond to the hottest climates (and to Figures 3 and 4, respectively), where cooling needs dominate over heating needs. These zones show an inverse linear relationship between thermal load and SR; moreover, the annual loads were consistently higher per m^2 for the non-residential building. This thermal load varies between 230 and 370 kWh/m^2 in the non-residential building, and between 150 and 230 kWh/m^2 in the residential building. Despite this difference in magnitudes between the two buildings, the effect of SR (given by the slope of the lines) was very similar. These are the climate zones with the greatest energy savings achievable through changes in SR.

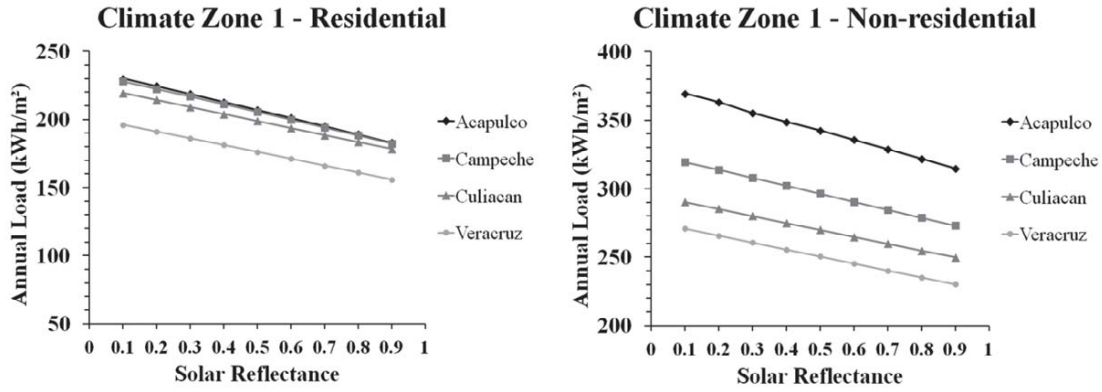

Fig. 3: Annual thermal load as a function of solar reflectance for cities in climate zone 1

The annual load can vary significantly among cities in Thermal Zone 2. Hermosillo and Monterrey, for example, show annual loads comparable to those of cities in Thermal Zone 1. Figure 4 compares the annual loads for these two cities against those of Cuernavaca and Guadalajara, which are also located in Thermal Zone 2 but have very different local climate.

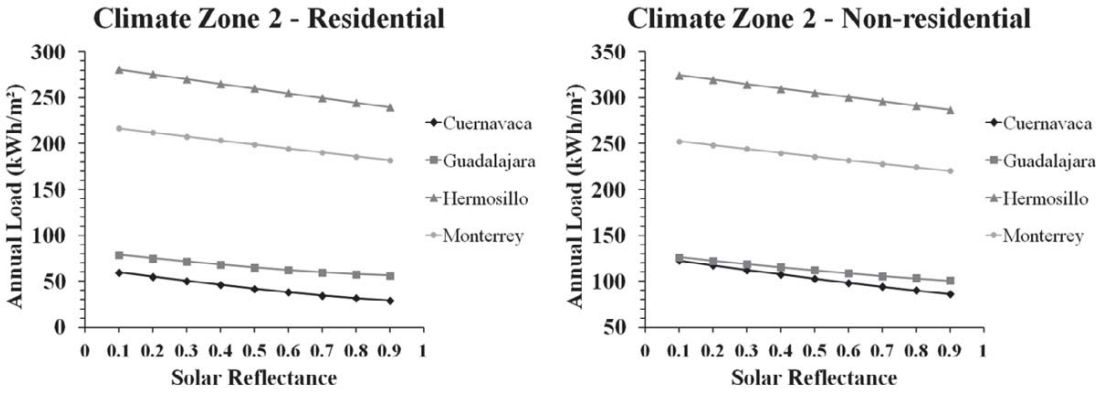

Fig. 4: Annual thermal load as a function of solar reflectance for cities in climate zone 2

Figures 5 and 6 show the results for climate zone 3. This zone has lower cooling needs than climate zones 1 and 2, but higher need of heating. Some of the cities in climate zone 3 present a linear relationship between annual energy load and SR, as had been observed in climate zones 1 and 2. The optimal reflectance for these cities is 0.9, similar to that of climate zones 1 and 2. However, in zone 3 there potential for energy savings is lower than in the hotter zones. The graphs for cities like Mexico and Puebla contain local maxima, marking optimal SR values different than 0.9, and also have smaller differences between the minimum and maximum values of the annual load (Figure 5).

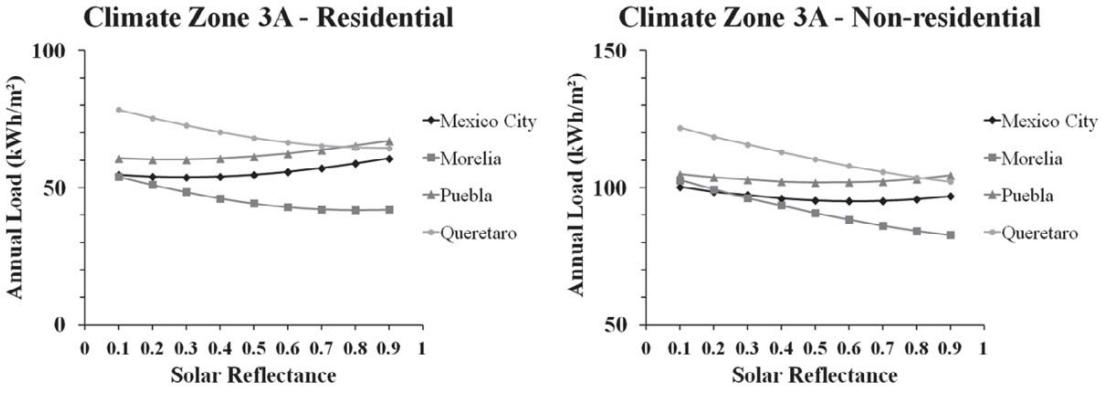

Fig. 5: Annual thermal load as a function of solar reflectance for cities in climate zone 3A

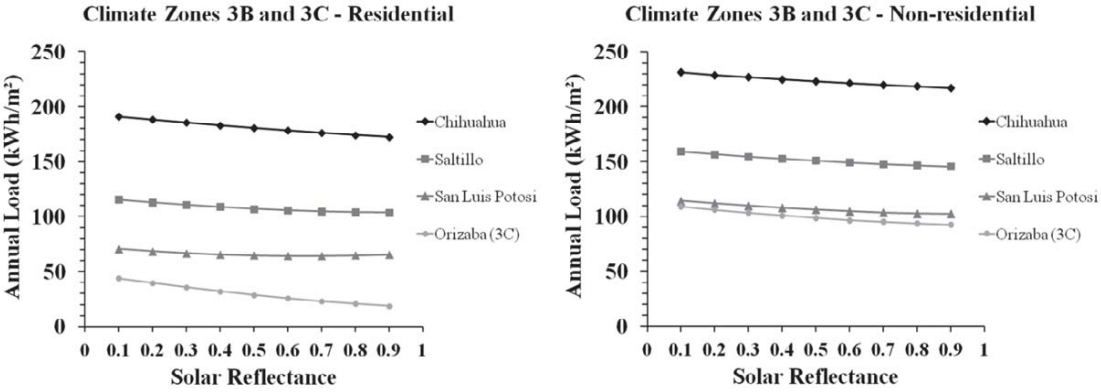

Fig. 6: Annual thermal load as a function of solar reflectance for cities in climate zones 3B and 3C

Climate zone 4 has drastically higher heating needs and lower cooling needs compared to the other zones. This results in relatively horizontal curves; SR has little effect on the annual load. In Toluca, heating needs actually dominate cooling needs and the normal relationship between SR and thermal load is inverted. Thus, the optimal value of SR for this city is very low (Figure 7).

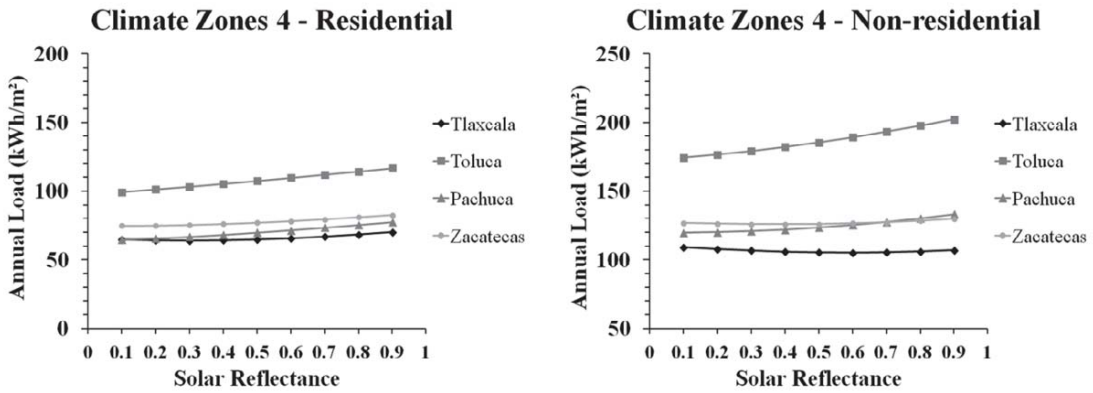

Fig. 7: Annual thermal load as a function of solar reflectance for cities in climate zone 4

3.3. Combined effect of thermal insulation and solar reflectance

The effect of insulation depends to a great extent on the use of an adequate value of SR in the roof. Figure 8 shows the annual energy load for three levels of insulation in the residential building, using climate data for Acapulco and Chihuahua. In Acapulco, insulation can have a very important effect only for low values of SR. If, on the other hand, roofs have a proper value of SR such as 0.9, then the added savings from insulation are negligible. In some cities with a significant cost of heating, such as Chihuahua, insulation has a significant effect even for optimal values of SR (Figure 8).

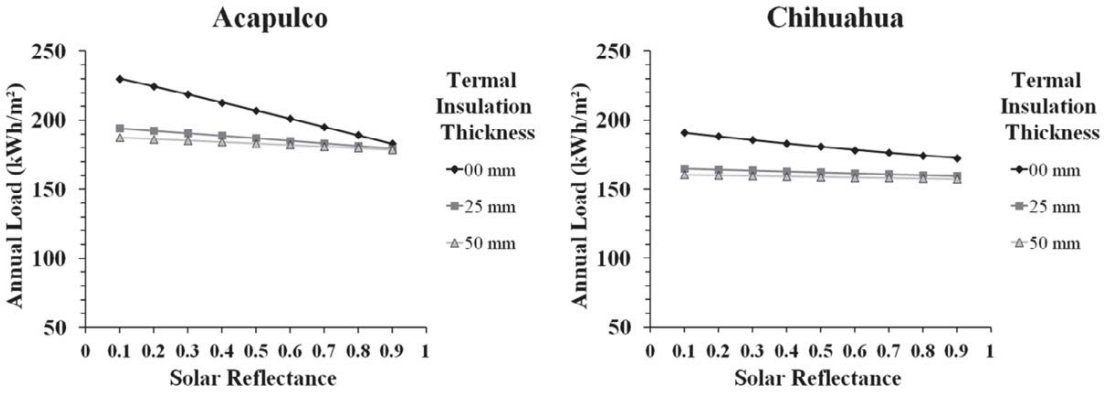

Fig. 8: Annual thermal load as a function of both solar reflectance and thermal insulation of roofs in Acapulco and Chihuahua

Although some improved coatings have SR values as high as 0.9, it is important to consider that this value tends to diminish over time. That is why we consider 0.8 to be the highest realistic value of SR. The value of SR has a strong effect on the benefits of insulation on the cost of energy needed to maintain the inside of buildings within comfortable ranges. Figure 9 shows the annual energy savings from 25 mm of insulation for 3 values of SR that correspond to coatings commonly used in Mexico (0.1 for black asphalt, 0.3 for red acrylic, and 0.8 for white acrylic). This figure shows how the savings from insulation vary greatly between different values of SR, especially in cities from climate zones 1 and 2. In a few cities such as Mexico City, Puebla, and Tlaxcala, the savings from insulation are almost the same for all three values of SR.

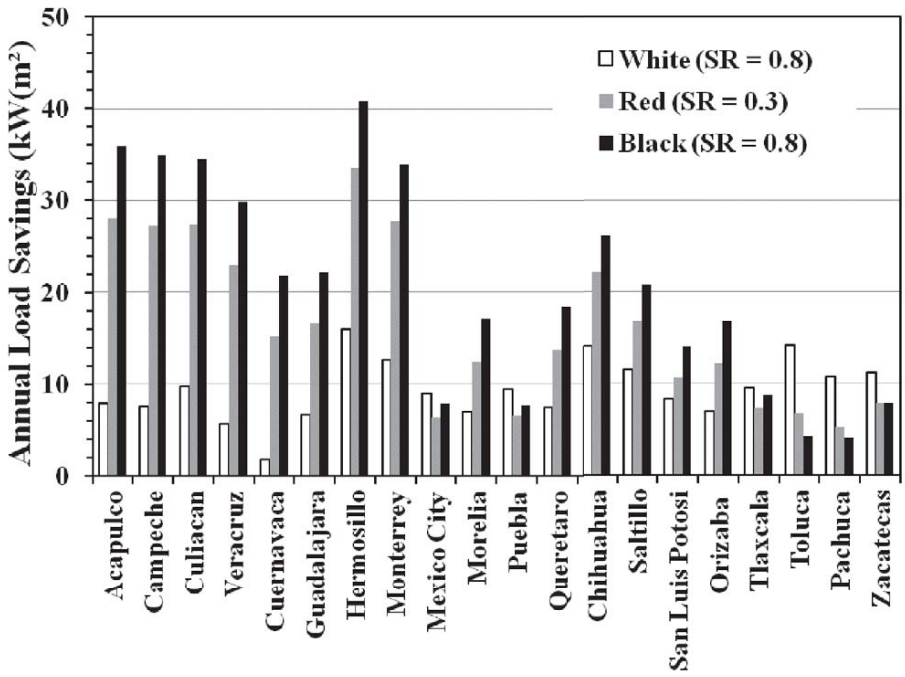

Fig. 9: The annual load savings from 25 mm of thermal insulation for three common values of solar reflectance of roof coatings used in Mexico

Insulation is a very costly investment, compared to the difference in cost between coatings with very different SR values. Figures 10 and 11 show the difference in energy costs between buildings with the best and worst coatings (black bars). The additional savings from insulation are shown in gray bars; these additional savings are calculated considering an optimal choice of coating.

In both building models it is apparent that for climate zones 1 and 2 the selection of a high SR value is a key factor in reducing the annual thermal load. Only in some cities from climate zone 2 (semi-arid climate, such as Monterrey and Hermosillo) can insulation be an important measure for increasing energy savings; this occurs at an SR value of 0.8.

Climate zone 3 (where optimal SR values vary between 0.3 and 0.9) and climate zone 4 (0.1 to 0.5) present a lower effect of SR on thermal load than climate zones 1 and 2. This is due to the penalty associated with using extreme SR values during the wrong period, such as a high SR when trying to heat the building or a low SR when trying to cool it. For some cities from climate zones 3 and 4, which have relatively high heating needs, the use of insulation is more important than the choice of SR—especially for non-residential buildings.

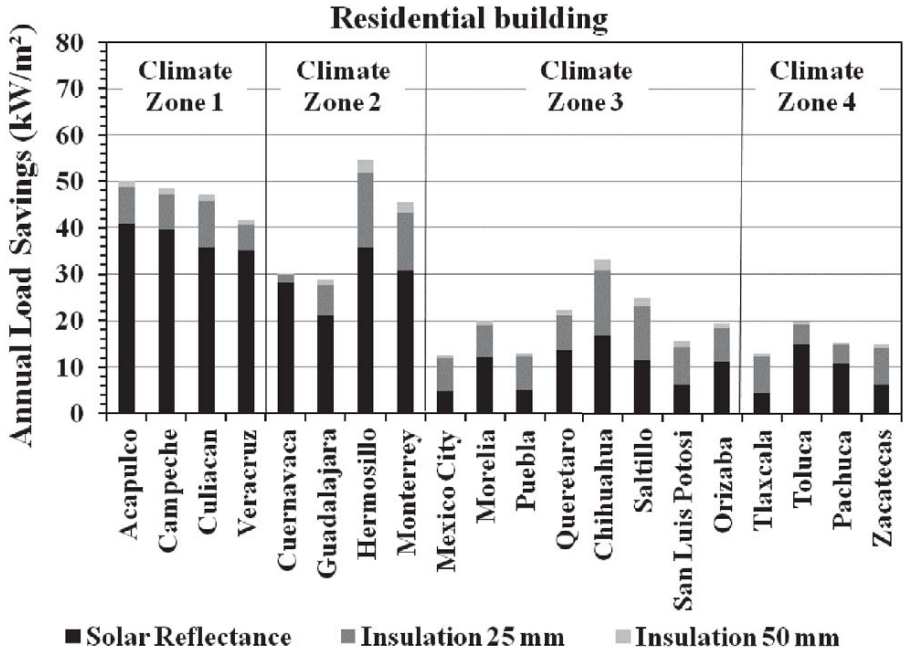

Fig. 10: Annual load savings achievable through solar reflectance optimization, followed by 25mm and 50mm of thermal insulation, in residential buildings

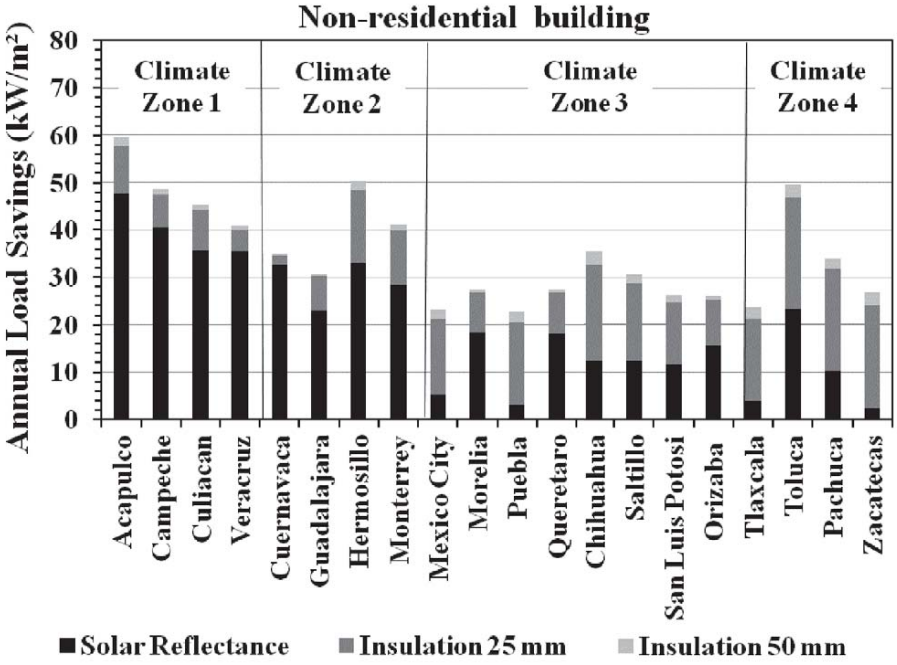

Fig. 11: Annual load savings achievable through solar reflectance optimization, followed by 25mm and 50mm of thermal insulation, in non-residential buildings

4. Conclusions

In warm climates with minimal heating needs, it is best to reduce energy consumption through adequately

high values of solar reflectance. In Mexico, cool roof regulations that maximize the values of SR are justified in climate zones 1 and 2. The use of insulation can be suggested in cities with semi-arid climate that have heating needs during the winter, or required to replace the effect of a high SR in cases where buildings choose to have lower reflectances. This may be the case for buildings with heavily sloped rooftops, which can reflect a significant amount of radiation to neighboring buildings, but also for short buildings next to taller ones or for homeowners that simply want non-reflective roofs for aesthetic purposes.

The use of insulation is appropriate for climate zones 3 and 4, where heating is an important component of the thermal load. The effect of SR is very modest in some of these cities, which is why a deeper analysis is needed on whether it is useful to regulate a range of acceptable SR values. Insulation may be suggested—or even required for non-residential buildings—since it does create an important extra reduction in the energy load than can be obtained from proper choice of SR.

Energetic analysis of the implementation of renewable energies in a Canary Island Hotel

Ana I. Palmero-Marrero[1], João Costa[1], Isabel Martín[2] and Armando C. Oliveira[1]

[1] Faculty of Engineering of University of Porto, Porto (Portugal)

[2] Department of Industrial Engineering, Universidad de La Laguna (ULL), La Laguna (Spain)

Abstract

The European Directive on Energy Performance of Buildings has established a target of Nearly Zero-Energy Buildings (nZEB) for a sustainable future. For this target, hotels take a special interest, as shown in the neZEH project (Nearly Zero Energy Hotels project) (neZEH, 2016), (Tsoutsos et al., 2013). In this work, a hotel located in Tenerife (Canary Island, Spain) is analyzed. With the objective of reaching the nZEB label, an exhaustive energetic analysis of the hotel was performed and the implementation of different renewable energy systems was proposed. The utilization of solar thermal collectors, photovoltaic collectors and heat pumps are analyzed in this work. Also, the passive solar characteristics, namely related to internal shading, were considered.

Keywords: *hotel, renewable energies, island, energy performance, TRNSYS*

1. Introduction

Buildings consume 40% of the total energy and emit 36% of greenhouse gases in Europe, therefore representing a high potential for energy savings. Specific measures to reduce energy consumption in the building sector have been introduced by the European Union with the European Directive on Energy Performance of Buildings in 2002 (EU Directive, 2002) and its recast in 2010 (EU Directive, 2010). These directives have established a target of Nearly Zero-Energy Buildings (nZEBs) for a sustainable future. The implementation of nZEB as the building target from 2018 onwards represents one of the biggest challenges to increase energy savings and minimize greenhouse gas emissions (Delia, 2015). An nZEB is a building that "has a very high energy performance with a low amount of energy required covered to a very significant extent by energy from renewable sources, including energy from renewable sources produced on-site or nearby" (EU Directive, 2010). However, the concept of nZEB is still not well developed in most EU countries. Large scale renovations of existing buildings towards Zero Energy are in the forefront of the European Union and national policies. For this goal, longstanding hotels located in places with high solar exposition take a special interest for the implementation of renewable technologies.

To know the energy performance of a hotel, and if it should be a nZEB, it is necessary to analyze the amount of energy consumed by the hotel from conventional sources and renewable sources (if any renewable systems are installed). In this work, for a given hotel and after this analysis, the possibility of using alternative renewable sources to replace conventional ones is proposed.

2. Building description

In this work, a hotel located in Tenerife (Canary Island, Spain) was analyzed. The location and a hotel view are shown in figure 1. The hotel is located 99 m above the sea level and 1.4 km from the coast. The hotel main façades are 29ºNW oriented. It is surrounded by gardens, with very high solar exposition (no significant shading from the surroundings). The latitude and longitude of the place are 28.4ºN and 16.2ºW, with sub-tropical climate. Using the METEONORM software, the meteorological data of the local were obtained. At the hotel location, the annual horizontal incident solar radiation is 1640 kWh/m^2 and the annual average temperature is 21ºC.

doi:10.18086/eurosun.2016.01.02 Available at http://proceedings.ises.org

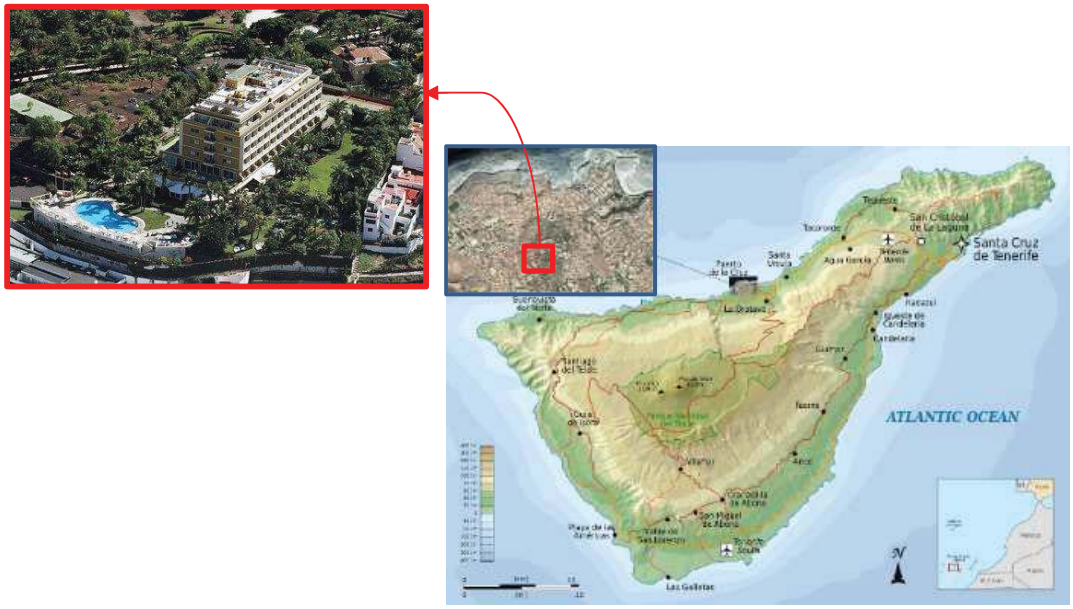

Fig. 1: Hotel location in Tenerife Island and hotel view.

The hotel was opened in 1959 and renovated by July 2015. This is a medium size hotel with high standards regarding the environment. The hotel management has been certified several times and received different awards from 1995 until today, always with the motivation to have a sustainable hotel. The hotel category is 4 stars, with 83 rooms distributed in 4 floors, ground floor and cave, with 5940 m^2 of net floor area. The east and west façades are characterized by extensive glazed areas and balconies with high solar exposition. The characteristics of each floor, such as floor areas, façade areas and percentage of glazed area per façade area, are shown in Table 1. The façade areas are detailed for each orientation (N: North, S: South, E: East and W: West).

Tab. 1: Characteristics of the different floors of the hotel.

Floors	Floor area (m^2)	Façade area (m^2)				Glazed area / Façade area (%)			
		N	S	E	W	N	S	E	W
Cave	1482	106	28	247	247	85	0	13	39
Ground floor	1278	75	75	171	165	63	56	50	52
Floor 1	840	53	53	144	144	16	0	38	50
Floor 2	840	53	53	144	144	16	0	38	50
Floor 3	840	53	53	144	144	16	0	38	50
Floor 4	660	45	45	132	132	36	48	0	71

The external walls of the hotel are massive and constituted by plaster, two concrete layers and insulation between the concrete layers, with a total thickness between 37 cm and 47 cm, depending on the floor, and U-value of 0.70 W/m^2K approximately. The other U-values are: 0.49 W/m^2K for the ground and 0.35 W/m^2K for the roof. All windows have double glazing with a U-value equal to 3.21 W/m^2K and a g-value equal to 0.72.

The hotel has unglazed solar thermal collectors to heat the water of the external swimming pool, and flat plate collectors (FPC) to heat the water consumed in the hotel, as can be seen in figure 2. The thermal collectors installed on the roof have a useful area of 117 m^2 and an annual heating useful energy of 107 MWh/year. The average occupancy of the hotel is 138 guests per day during the year.

Fig. 2: Top view of the hotel with the solar thermal collectors on the roof (GoogleEarth).

For the air-conditioning, a new Water-Sourced Liquid Chiller/Heat Pump (Carrier 61W) was installed in 2014, with 99 kW of heating capacity ($COP_{heating}$ = 3.1) and 67 kW of cooling capacity ($COP_{cooling}$ = 2.1), in the most unfavorable case (condition in heating mode: condenser water entering/leaving temp.=55ºC/65ºC).
For both water and air heating applications, the strategy at the hotel is to use the solar thermal collectors (FPC), the heat pump and only after the diesel boiler (as backup). When solar radiation is not enough to heat the swimming pool, the diesel boiler is also used. In the kitchen only propane is used.

3. Modelling system

The hotel and its components were modelled with the TRNSYS 17 simulation program. The climatic data were obtained through METEONORM, provided by TRNSYS and distributed under license from Meteotest.

For the building simulation in TRNSYS, the floors were divided in different sub-zones with similar characteristics of utilization. In total, 14 sub-zones were considered for the numerical simulation. For example, as can be seen in Figure 3, the ground floor (GF) was divided in 3 sub-zones: lounge (zone GF.1), rooms (zone GF.2) and reception (zone GF.3). The cave was divided in 3 sub-zones and each floor was divided in 2 sub-zones, corresponding to the east and west façades.

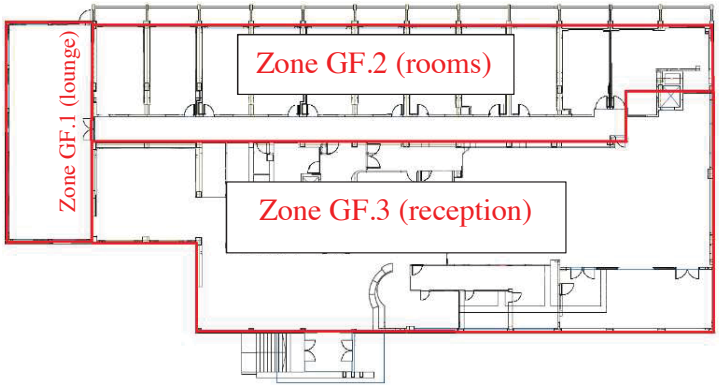

Fig. 3: Ground floor and sub-zones.

The building cooling and heating load, for an indoor air temperature thermostatic control of 25ºC and 20ºC, were calculated for the cooling and heating seasons, under climatic conditions of Tenerife. These temperatures were considered to maintain operative temperatures in the range proposed in ISO 7730 (between 20ºC and 26ºC for 1.2 met), within thermal comfort requirements. The study was extended throughout a whole year. Also, indoor temperatures were calculated through numerical simulations.

A multi-zone building model (TRNSYS type 56) was used. Besides the definition of geometry and materials, other input data considered were: infiltration rate of 1.2 air changes per hour, room internal gains corresponding to two persons per day in each room, artificial lighting of 5 W/m^2, TV, computers in the reception, different equipment in the kitchen, etc. The metabolic rate (heat production depending on action level) was assumed as

1.2 met (1 met = 58.2 W/m^2). This corresponds to seated and light activity at home, office, hotels, etc. (ISO 7730:2005).

Also, the installation of the photovoltaic collectors (PV) and thermal solar collectors (FPC) were analyzed through numerical simulation. Table 2 shows the FPC and PV modules characteristics used in the numerical simulation.

Tab. 2: Characteristics and technical data of the FPC and PV collectors.

FPC		**Constante Solar-Cu-1208-P**
Collector efficiency parameters related to aperture area:	η_0	0.79
	a_1	3.64 W/m^{2}K

4. Results

4.1. Analysis of hotel energy demand

For estimating the hotel energy demand, space heating and cooling requirements were determined for all sub-zones, according to the operating conditions presented in Section 3. Monthly incident solar radiation (total) on horizontal and vertical façades is shown in Fig. 4. The annual horizontal incident solar radiation is 1640 kWh/m^2.

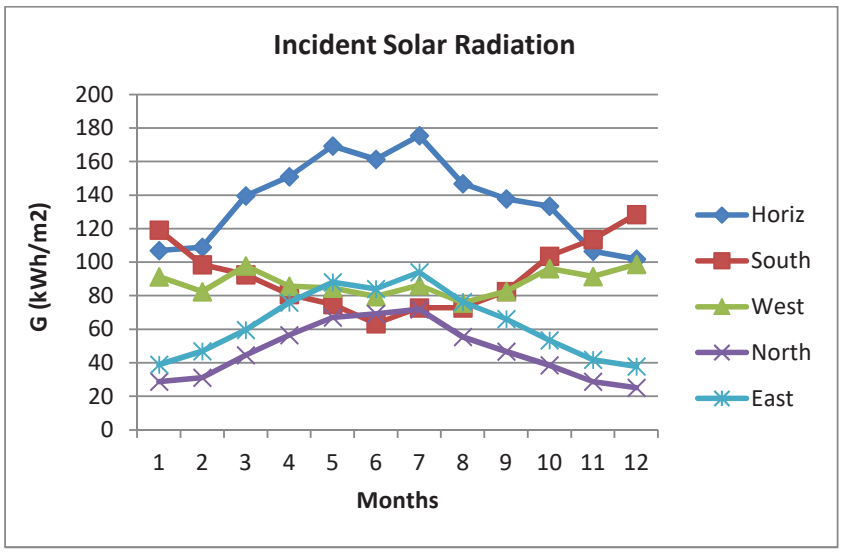

Fig. 4: Monthly incident solar radiation for horizontal and vertical façades.

Figure 5 and Figure 6 show the hourly simulated indoor air temperature without cooling or heating system, and the outdoor ambient temperature for 2 sub-zones (Ground Floor-reception and East sub-zone in Floor 3), during the 21st of July (when the incident solar radiation and the ambient temperature are very high) and 21st of December (when the incident solar radiation and the ambient temperature are lower). In these figures, no use of internal or external shading, such as blackout curtains or blinds, was considered.

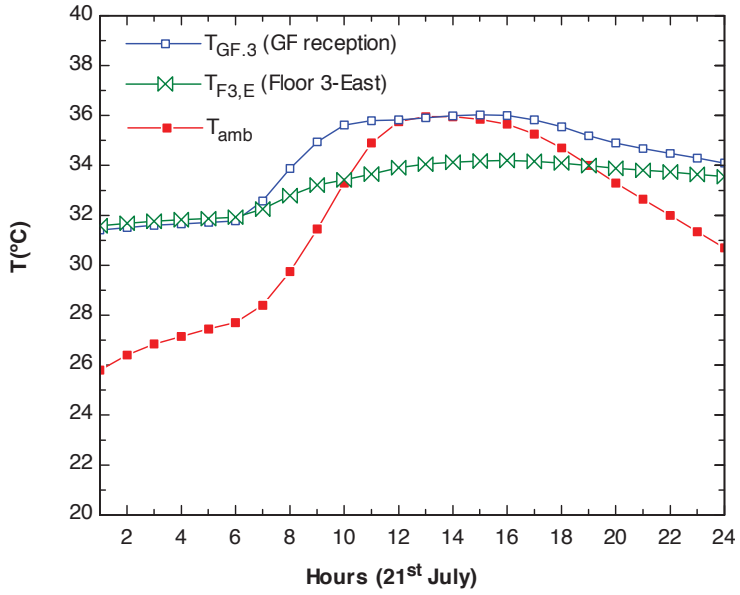

Fig. 5: Hourly indoor air temperature without cooling, and outdoor ambient temperature during 21st July.

Note that the indoor air temperature is higher than 25ºC during the July day, when the cooling system (Chiller/Heat Pump) is not used. Also, during the cooling season higher indoor air temperatures could be achieved in the different floors if solar passive strategies were not used; then, comfort conditions could almost never be reached in the hotel during this period.

A solar passive strategy adopted by the hotel employees is to close the interior blackout curtains during the day in the cooling season, after cleaning the rooms. This possibility was also studied in this work. When the interior curtains are closed during the day, the internal average temperature in the rooms decreases between 0.2 to 0.9ºC, depending on the floor.

When comparing the indoor air temperatures of the East and West sub-zones in each floor, it was possible to verify that the West sub-zones have a higher temperature than the East sub-zones (about 0.2ºC difference). It can be justified by the higher glazed area/façade area in the West façade, as seen in Table 1.

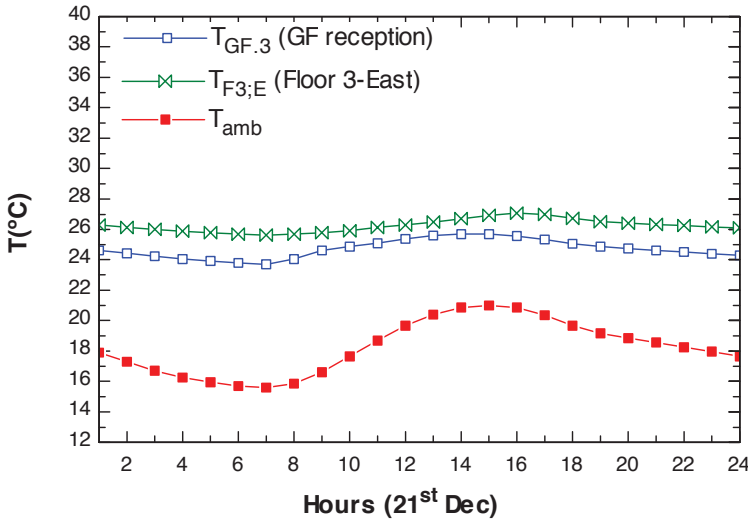

Fig. 6: Hourly indoor air temperature without cooling or heating, and outdoor ambient temperature during 21st December.

As can be seen in Figure 6, in a cold day in winter the outdoor temperature range is between 16 and 21ºC. If the indoor air temperature thermostatic control for the heating season is set for 20ºC, the heating system will be

connected only a few hours during the year in the hotel. The usual guests of this hotel are foreign elderly persons in the winter time. For that, usually the air-conditioning with a thermostatic control of 24ºC is used in the rooms.

Table 3 shows the monthly and annual energy demand for heating and cooling with different thermostatic control set points. In the last row, the annual energy demand is divided by the net floor area of the hotel (5940 m^2).

Tab. 3: Monthly and annual energy demand for heating and cooling.

Month	Heating (MWh) ($T_{control}$=20ºC)	Heating (MWh) ($T_{control}$=24ºC)	Cooling (MWh) ($T_{control}$=25ºC)
January	0.08	10.33	2.31
February	0.08	6.03	3.97
March	0.01	2.88	10.81
April	0.00	0.87	14.67
May	0.00	0.27	26.41
June	0.00	0.00	38.67
July	0.00	0.00	63.79
August	0.00	0.00	62.13
September	0.00	0.00	52.90
October	0.00	0.00	45.48
November	0.00	0.37	19.69
December	0.00	2.19	9.58
Annual (MWh)	**0.18**	**22.95**	**350.42**
Annual (kWh/m^2)	**0.03 kWh/m^2**	**3.86 kWh/m^2**	**58.99 kWh/m^2**

Note that the energy demand for cooling is considerably higher than the energy demand for heating. These values are similar at hotels with similar climates as shown in the literature (Polanco and Yousif, 2015).
Using the Chiller/Heat Pump installed in the hotel ($COP_{heating}$ = 3.1 and $COP_{cooling}$ = 2.1), the annual electricity consumption in the hotel for air-conditioning is 7.4 MWh/year for heating and 167 MWh/year for cooling. Considering the energy consumed in 2015, see Figure 7, the air-conditioning represents about 30% of the electricity consumption of the hotel.

4.2. Actual hotel energy consumption

- Domestic Hot Water (DHW)

Considering the occupancy 138 guests per day during the year, and a water heating consumption of 60 l/guest, the annual energy consumed for hot water (HW) is about 160 MWh/year. Knowing that the useful energy from the solar thermal collectors (FPC) for water heating is 151 MWh/year, the utilization of the heat pump is also necessary for HW.
On the other hand, the useful energy from the other solar collectors used for swimming-pool heating, may not be enough for the whole year. For that, the utilization of the boiler should be considered.

- Energy consumption (electricity, propane and diesel)

The energy consumed in the hotel from non-renewable energy sources is shown in Figure 7. These values were obtained from the invoices delivered by the hotel staff.

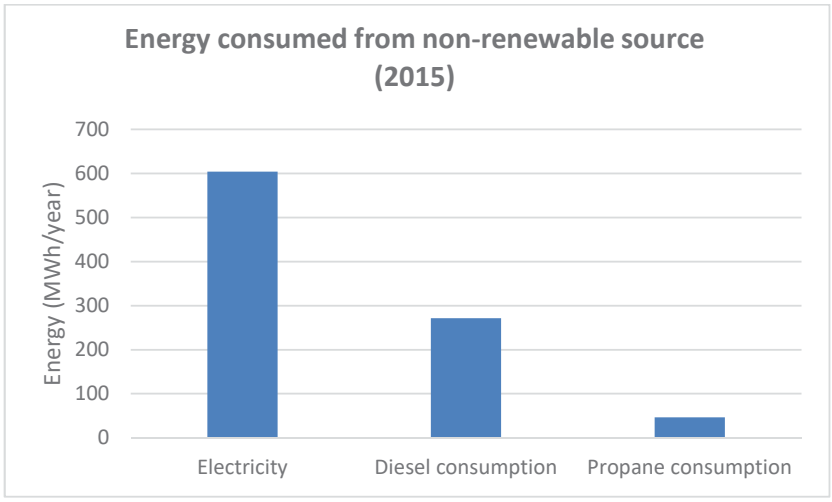

Fig. 7: Main hotel consumptions from non-renewable sources during the year 2015.

Figure 7 shows the energy consumed in the hotel without considering the contribution from the FPC installed on the roof. In this distribution, electricity represents 66%, diesel 29% and propane 5% of the total consumption. Note that diesel is used in the boiler and propane is only used for the kitchen equipment. When the contribution of FPC is considered (151 MWh/year) these percentages change, as can be seen in Figure 8. The annual energy consumption from non-renewable sources was 1073 MWh/year for the year 2015.

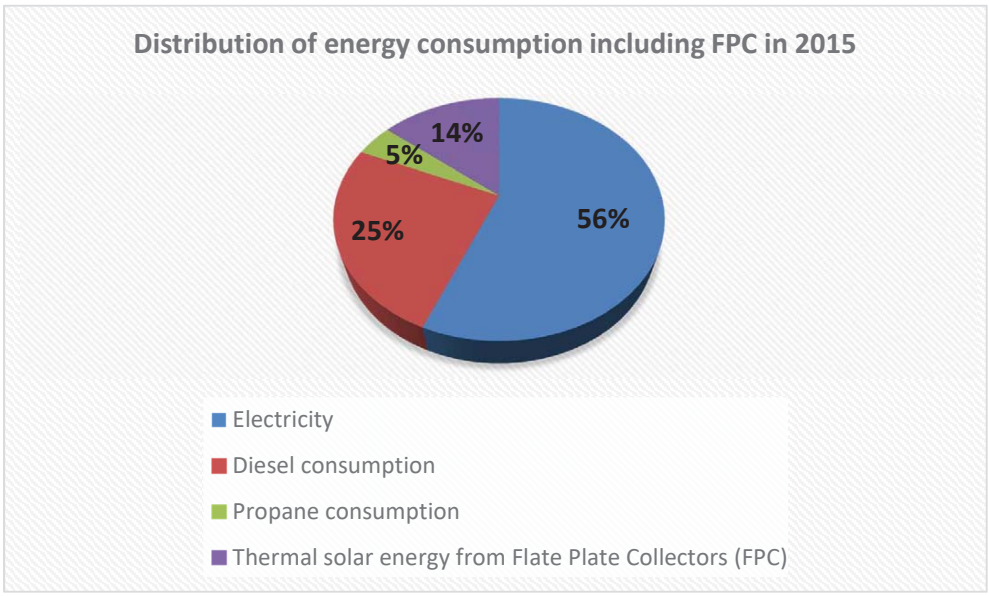

Fig. 8: Main hotel consumption from non-renewable and renewable sources during the year 2015.

After analyzing the annual energy consumption of the hotel, different options using renewable energy should be considered. The next section analysis the different options proposed in this work to achieve the nZEB for the hotel.

4.3. Energy consumption using renewable sources

Figure 8 demonstrates that electricity represents the most important energy consumption in the hotel. For that, the utilization of photovoltaic collectors (PV) is proposed. After analyzing the available space in the hotel to place photovoltaic collectors, two places were chosen: the car park and a nearby parking area. The number of panels to install will be 355 modules with a total aperture area of 689 m^2, and the electricity production was obtained

At the same time, it is possible to increase the number of solar thermal collectors on the roof of the hotel. Thus, using the same type of collectors, the useful area will increase 30 m^2 (from 117 m^2 to 147 m^2) and the annual heating useful energy will increase from 151 MWh/year to 189 MWh/year.

Table 4 shows the hotel energy consumption in 2015 and the expected energy consumption with the referred PV and FPC collectors' implementation in the hotel.

Tab. 4: Annual energy consumption using PV and FPC collectors.

		Energy consumed in 2015 (MWh)	Energy consumed improved with Renewable Sources (MWh)
Non-renewable sources	Electricity from grid	604	426
	Diesel consumption	271	233
	Propane consumption	47	47
Renewable sources	Thermal energy from FPC	151	189
	Electricity from PV	0	178
Total energy consumption		1073	1073

Figure 9 shows the annual distribution of the energy consumption considering the data of 2015, using FPC and PV. As can be seen, it is possible to achieve a total of 34% of the consumed energy with renewable energies (18% from FPC and 16% from PV).

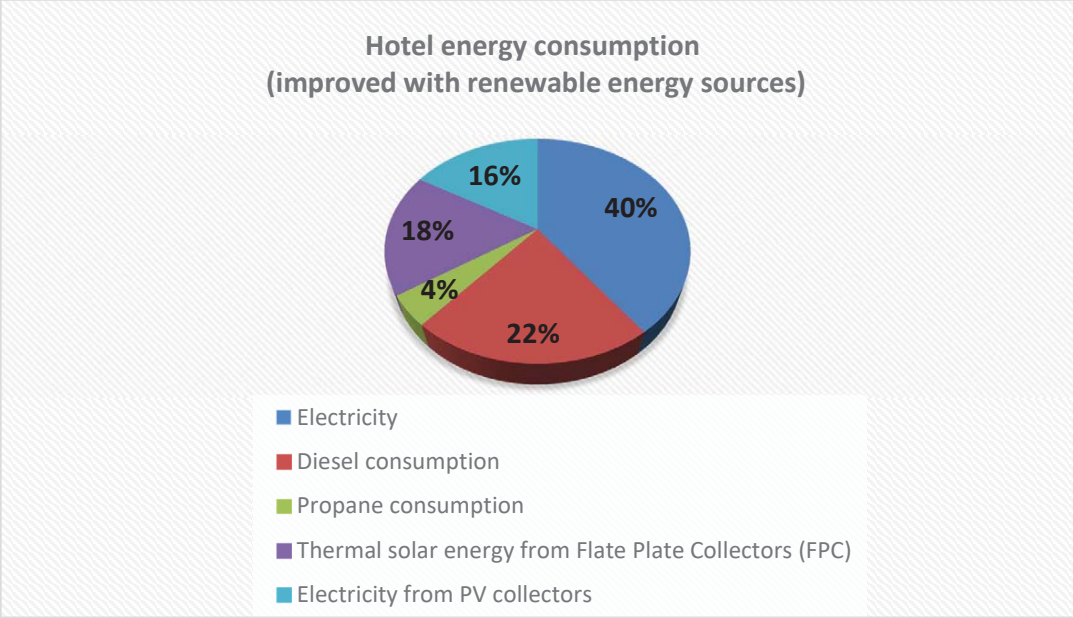

Fig. 9: Annual energy consumption distribution using renewable systems.

Using the definition of nZEB explained in the Introduction (Section 1), with the results obtained through the utilization of solar collectors, the target of nZEB for this hotel is still not achieved.

On the other hand, the diesel consumption used in the hotel is very high due to the utilization of the boiler during a long period. This boiler is used especially for water heating in HW and swimming-pool. We can propose to replace the actual diesel boiler by a biomass boiler. Biomass is considered a renewable source and it could be a good solution to reduce fossil fuel consumption. In Canary Island, the utilization of biomass boilers in hotels is starting and it has shown a promising future (Arlangton comp., 2016).

If a biomass boiler is used in this hotel for water heating, the diesel consumption will be null. In this case, it is possible to achieve 56% of the energy consumption with renewable energies (18% from FPC, 16% from PV and 22% from biomass).

5. Conclusions

In this work, the energetic analysis of a hotel located in Tenerife was performed and the implementation of different renewable energy systems was proposed.

During the cooling season it was demonstrated that higher indoor air temperatures could be achieved in the different floors, if the chiller or solar passive strategies were not used. The annual energy demand for cooling, to maintain the indoor air temperature below 25ºC, is about 350 MWh/year (58.99 kWh/m^2). When shading devices are considered, the indoor air temperature decreases between 0.2 to 0.9ºC, depending on the floor. Using the Chiller/Heat Pump installed in the hotel, the annual electricity consumption for air-conditioning is 7.4 MWh/year for heating and 167 MWh/year for cooling. Then, air-conditioning represents about 30% of the hotel electricity consumption.

After analyzing the annual energy consumption, different options using renewable energy (FPC and PV) were considered. It was demonstrated that it is possible to achieve 34% of the consumed energy with renewable energies (18% from FPC and 16% from PV). On the other hand, the diesel consumption is high because of the use of the boiler for water heating. If the actual diesel boiler is replaced by a biomass boiler, it is possible to achieve 56% of the consumed energy with renewable energies (18% from FPC, 16% from PV and 22% from biomass).

With the results obtained through the utilization of solar collectors and biomass, the target of nZEB is still not achieved for this hotel. Anyway, with the proposed improvements, the energy consumption using renewable sources would increase 4 times, from 14% to 56%.

Acknowledgments

The authors gratefully acknowledge the assistance provided by Mr. Enrique Talg, Director of Tigaiga Hotel, to access all information about the hotel (plans, energy consumption, etc.).

Abstract

In the context of dense cities, which typically suffer from the Urban Heat Island (UHI) phenomenon, environmental quality is strongly affected by urban design choices and can significantly vary depending on the local boundary conditions and local climate phenomena. In this scenario, the present work analyzes the complex relation between the urban built environment and its local microclimate at neighborhood-urban scale, by means of both experimental field monitoring and numerical analysis. To this aim, an historic urban district in the city center of Perugia (central Italy) was continuously monitored during summer 2015 and the UHI intensity was assessed. Therefore, the validated numerical analysis of the area was carried out through ENVI-met simulation engine in order to quantify the thermal benefits achievable by applying specific tailored mitigations strategies, i.e. green façade, cool roof, and cool pavement, in both summer and winter conditions. The monitoring campaign confirmed that buildings' density and greenery percentage are able to considerably affect outdoor microclimate even in historical districts where the design choices are relatively limited compared to the new urban developments. The numerical analysis highlighted the major role of green façade in generating the most important air temperature drops in a summer day. Moreover, the effectiveness of the proposed mitigation technique is demonstrated also in winter conditions.

Keywords: *Outdoor microclimate, Urban Heat Island, Experimental monitoring, Numerical analysis, Local boundary conditions*

1. Introduction

Nowadays, more than half of the world's population lives in urban districts and it was assessed that in 2050 the 66% of the world's population will be an urban population (United Nations, 2015). This represents a great growth compared to the 30% registered in 1950. For this reason, the necessity to design healthy, efficient, and sustainable built environments is becoming a crucial issue for both designer and urban planners.

As underlined in various studies (Chen and Ng, 2012; Nikolopoulou and Lykoudis, 2006), human outdoor comfort depends on both physiological factors and the thermal conditions of the environment, which have a considerable role in influencing people's usage of urban spaces. Therefore, human thermal comfort has been detected to be one of the most important factors determining the quality of outdoor environments (Lai et al., 2014). One of the main threaten to the quality of urban microclimate is represented by the Urban Heat Island (UHI) phenomenon, which consists in higher air temperatures inside urban areas compared to those of the surrounding rural environment (Mirzaei and Haghighat, 2010). A huge research effort about this local climate phenomenon is carried out with the aim of understating and defining it from both a qualitative and a quantitative point of view. In this view, different approaches have been developed by means of both experimental analyses through in-field measurements and numerical analysis (Mirzaei and Haghighat, 2010). For instance, Papanastasou and Kittas (2012) detected a maximum temperature difference of 3.4 K and 3.1 K

doi:10.18086/eurosun.2016.01.16 Available at http://proceedings.ises.org

in winter and summer, respectively, between the city center and a suburban area of Volos (i.e. a medium-size coastal city in Greece) by comparing data collected from two fixed meteorological stations. Similarly, Mhosin and Gough (2012) assessed the great UHI variability in Toronto, by detecting an increase of about 0.02 K per decade between 1970-2000. On the other hand, mobile surveys were implemented in Padua (Busato et al., 2014) to experimentally characterize the UHI phenomenon. Such approach was able to reveal an UHI up to 6 K inside the city.

UHI is able to influence the weather conditions of a built environment at several scales (Oke, 1976), and the consequences at the urban canopy layer can significantly affect the well-being and health of citizens. Moreover, the global climate change and the increase in frequency and intensity of extreme heat events (Luber and McGeehin, 2008) may contribute in threatening human society even at a local scale, in terms for instance of outdoor visual and thermal comfort for pedestrians (Rosso et al., 2015), human health (McMichael et al., 2006), building energy consumption (Santamouris, 2014b), and also from an economy point of view (Stern and Treasury, 2007). Therefore, the investigation of the complex relationship existing between local variations of urban/suburban microclimate and the built environment could help to (i) reduce the negative effects of the UHI, (ii) find suitable mitigation strategies for each specific urban contest, and (iii) support a sustainable and energy efficient urban planning. In this scenario, Santamouris et al. (2015) showed how a deep knowledge of the microclimate conditions of a city could help to develop specific policy issue and the most appropriate resilience plan to fight the UHI. By using numerical analysis i.e., Teleghani et al. (2014) studied the relationship between the environment configuration and its microclimate by implementing in ENVI-met the model of five simple ideal urban forms. The aim was to provide basic suggestions for urban planners to be easily adapted to realistic situations.

On the contrary, Coronel and Álvarez (2001) found that the ancient neighborhood of Santa Cruz (Seville, Spain) during summer presents better thermal behavior compared to the new areas of the city due to peculiar characteristics of the urban environment, such as diffuse presence of trees and water fountains, high thermal mass of the external walls, mostly white-colored, and aspect ratio and orientation of the narrow streets. In fact, the alteration of local microclimate parameters in built environment is mainly due to a modification of the energy balance inside urban areas which depends on the above mentioned factors, and the presence of anthropogenic heat sources (Giridharan et al., 2007). Over the years different mitigation strategies were demonstrated to be able to improve such energy balance, i.e. the implementation of greenery (Bowler et al., 2010) and high-albedo materials inside built areas (Santamouris, 2014a). Such UHI mitigation techniques have been studied and tested through both experimental and numerical analysis to evaluate their effectiveness (Bruse and Fleer, 1998; Ridder et al., 2004). In the specific context of dense historical cities, Pisello et al. (2015b) tested a combination of these two strategies, since other invasive mitigation techniques cannot be applied due to architectural constraints. Furthermore, in order to overcome such constraints, innovative cool colored coatings were developed to ensure the same esthetic properties of the traditional coatings, but a more selective absorption band in the infrared part of the spectrum. Synnefa et al. (2007) found a maximum temperature difference of 10.2 K between a cool and standard colored coating, and almost the same values were obtained by Pisello et al. (2013) for a clay tile coatings suitable for applications in historic constructions.

2. Motivation

During summer 2015, a monitoring campaign of the outdoor environmental parameters was conducted in four different districts inside the historical city of Perugia, in central Italy. Data collected underlined the presence of higher air temperatures inside the area of the historical city center, which is characterized by dense urban design and lack of green areas. Building upon these finding and previous studies, the purpose of the present work is to investigate the effectiveness of studied suitable strategies to reduce the summer overheating in this context. Therefore, through numerical analysis, green facades, cool roofs, and cool pavements were implemented inside a realistic validated model of the area of interest to assess the benefits achievable in terms of local microclimate parameters and pedestrians' comfort.

Although the main aim is to mitigate summer overheating, microclimate variations were studied also in

winter conditions so as to evaluate possible consequences or benefits of the proposed mitigation techniques on outdoor thermal parameters during the cold season.

3. Materials and Methods

In order to pursue the outlined targets, a numerical model of the monitored area within the historical center of Perugia during summer 2015 (Fig. 1a) was developed. To ensure the reliability of simulation results, a (i) preliminary phase of validation was conducted. Once reached an acceptable correspondence between measured and simulated data, (ii) alternative scenarios to the real one (with well-acknowledged mitigation strategies), were simulated during a summer and a winter day. More in detail, the daily weather profiles were selected from the typical July (July, 15th) and typical January (January, 15th) provided by IGDG TMY (Typical Meteorological Year) for the city of Perugia, built on 1951-1970 period of record (U.S. Department of Energy, 2014). Therefore, (iii) the microclimate output obtained from the simulation were analyzed in terms of the outdoor thermal comfort index PET (Physiological Equivalent Temperature) (Chirag and Ramachandraiah, 2010) to assess how these mitigation strategies could affect pedestrian perception of the surrounding environment (Fig. 1).

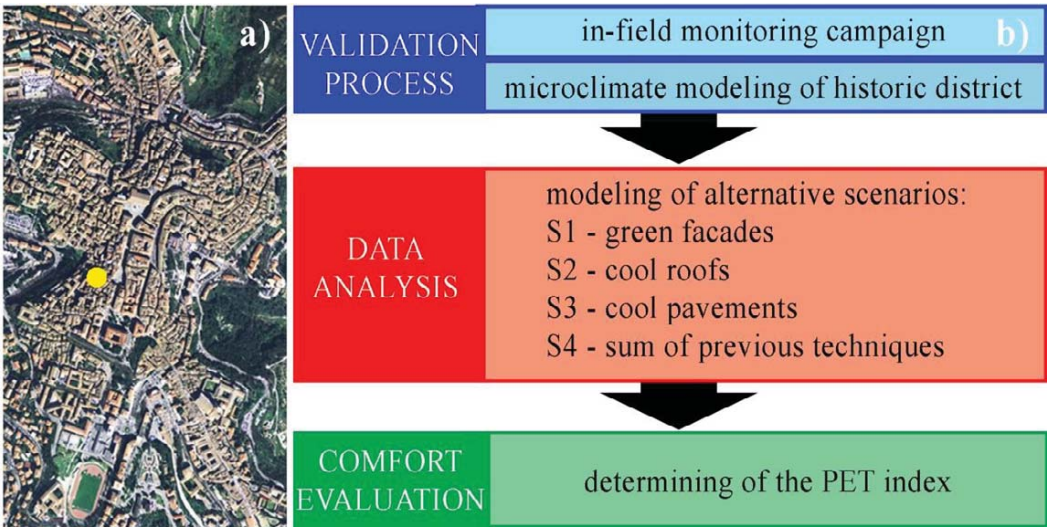

Fig. 1: (a) Position of the modeled area within the historic center of Perugia and (b) scheme of the adopted methodology

3.1. Modeling and validation process

The studied area is an East-West oriented street, 40 m long with a width varying from 3 to 12 m along its length (Fig. 2). Moreover, between the eastern and western side there is a height difference of 5 m. As the area is located in the historical center of the city, buildings surrounding the street are characterized by thick stone walls and the outdoor pavements are covered by bricks and plates made of *pietra serena* (except for the final western side which was recently asphalted) (Fig. 2c).

A three-dimensional microclimate modeling system, i.e. within ENVI-met V4 environment, designed to simulate the surface-plant-air interactions with a resolution from 0.5 to 10 m in space and from 1 to 5 sec in time, was used for the numerical analysis (Huttner and Bruse, 2009). The choice of the software was related to the high accuracy in space provided, which is optimal to study urban microclimate at a low scale, i.e. within the Urban Canopy Layer, where this work is focused. A realistic model of the area was developed and calibrated by using experimental data collected during the summer 2015 monitoring campaign. The calibration was performed following the suggestions of the ASHRAE GUIDELINE 14-2002 (ASHRAE, 2005), through both a statistical and graphical approach. The geometrical base of the model is a 3D grid of dimensions 30x60x35 having 1m side cube as unit. The materials used to characterize walls, roofs, and pavements were selected from the software database and their thermo-physical properties are summarized in Tables 1 and 2.

In order to have the necessary data for the calibration, during the monitoring campaign a portable weather

station placed at 15 m height (Pisello et al., 2014) and two Tinytag temperature and relative humidity probes and data-loggers (Pisello et al., 2015a) located at 2 m above the ground (Fig. 2d) were installed. As weather input the following data were used:

- Initial wind speed: value collected from the weather station at 6 a.m., start time of the simulation;
- Wind direction: value prevailing during the three days of the monitoring campaign;
- 24h air temperature and relative humidity forcing: data collected by the probe located on the South-oriented side (Fig. 2d, point B).

The simulation has been running for 24h and the data comparison for the calibration corresponded to those collected from the North-oriented probe (Fig. 2d, point A) and those extracted from its representative point within the model.

Fig. 2: View of the street from the (a) western and (b) eastern sides, (c) view of the street crossing the studied one on the East, and (d) localization in the plant of the monitoring probes

Tab. 1: Characteristics of the walls and roofs composing the reference scenario

Element	Albedo [-]	Emittance [-]	Specific heat [J/kg·K]	Thermal conductivity [W/m·K]	Density [kg/m^3]
Walls	0.30	0.90	840	0.86	930
Roofs	0.50	0.90	800	0.84	1900

Tab. 2: Characteristics of the different pavement profiles composing the reference scenario

Pavement profile	Albedo [-]	Emittance [-]	Volumetric Heat Capacity (upper layer) [J/m^3·K]	Heat Conductivity (upper layer) [W/m·K]
Brick Road	0.30	0.90	$2.00 \cdot 10^6$	1.00
Basalt Brick Road	0.80	0.90	$2.39 \cdot 10^6$	1.73
Asphalt Road	0.20	0.90	$2.25 \cdot 10^6$	0.90

3.2. Modeling of alternative scenarios

Alternative scenarios to the reference one, named S0, were developed by modeling the application at urban level of the following strategies for Urban Heat Island mitigation:

- Increase of urban greenery: introduction of vertical green systems on the buildings' facades, i.e. scenario S1;

- Replacement of traditional materials with high-reflectance ones: highly reflective roofs, i.e. scenario S2, and pavements, i.e. scenario S3, developed by using cool solutions for the coating material;
- Combination of the three mitigation strategies, i.e. scenario S4.

All the strategies, as summarized in Table 3, were selected to be realistically implemented in the case study area, which presents architectural constrains since it is located inside the historical center of the city. In particular, cool materials characterized by the same spectral response of traditional ones in the only visible region were considered in order to preserve buildings' heritage value, while providing higher reflectance values in the other ranges of the solar spectrum (Pisello et al., 2013). Moreover, pavement's thermal properties were optimized based on the real necessity to substitute the current asphalt area. The last technique, i.e. green façade, can be well integrated with the existing context as it is already installed in a building facing the crossing street (Figure 2c).

Tab. 3: Characteristics of the components modified in each mitigation scenario

Scenario	Element	Mitigation technique	Properties
S1	Walls' Façade	Greenery	Leaf Area Density: 2 m^2/m^3 Foliage albedo: 0.60
S2	Roofs	Cool material	Albedo: 0.75
S3	Pavement	Cool material	Albedo: 0.85
S4	Combination of all the above mentioned techniques		

The five scenarios were simulated during a representative summer and winter day in the climate context of Perugia, Italy, by using as weather input the TMY weather files for the months of July and January, respectively.

3.3. Outdoor thermal comfort analysis of mitigation scenarios

In order to evaluate the benefits achieved through the implementation of the mitigation strategies, the weather data obtained as output in the numerical simulation were analyzed in terms of thermal comfort improvements inducted in the surrounding outdoor area. A comparison between data obtained in the reference and alternative scenarios was performed by analyzing (i) the spatial distribution of the environmental parameters through describing maps and (ii) their variation in time during the day. Maps were generated when air temperature reaches its maximum value (i.e. 3:00 p.m.) and just after the sunset (i.e. 9:00 p.m.). Time series were extracted at 1.5 m, i.e. pedestrian level, from the ground in two different points selected because of their different characteristics (Fig. 3).

Furthermore, the Physiological Equivalent Temperature (PET) was chosen as the parameter representative of the outdoor comfort of pedestrians. The index was evaluated through RayMan data post-process software (Matzarakis et al., 2007).

	Location	SVF	Time range when reached by direct solar radiation
Point 1 [x=12, y=28, z=5]	3 and 4 m distant from the east-west and the north-south oriented green walls, respectively	0.15	12:00-2:00 p.m.
Point 2 [x=5, y=8, z=1]	above the area originally presenting pavement made by asphalt	0.51	3:00-8:00 p.m.

location of green facades

asphalted area

Fig. 3: Location in the model of the two points selected to extract simulation data (at 1.5 m height)

4. Results and Discussion

4.1. Model calibration

The graphical and statistical approach followed for the model calibration was carried out as suggested by the ASHRAE GUIDELINE 14 (ASHRAE, 2005). The results depicted in Fig.4 show that the difference in terms of air temperature, between the measured and simulated values, is always lower than 3 K and mostly lower than 1 K. The maximum gap is reached during the hottest hours of the day, when the software tends to overestimate this parameter. Moreover, the difference in terms of air relative humidity is always lower than 10 %.

In addition to the graphical analysis presented in Fig. 4, two statistical indexes, i.e. *Mean Bias Error* (MBE) and *Root Mean Square Error* (RMSE) (ASHRAE, 2005), were evaluated, as reported in Table 4. According to the obtained results, the model can be considered representative of the real area with good approximation. Therefore, it can be used to simulate which could be the improvements in the outdoor microclimate of the zone due to the application of the selected mitigation strategies.

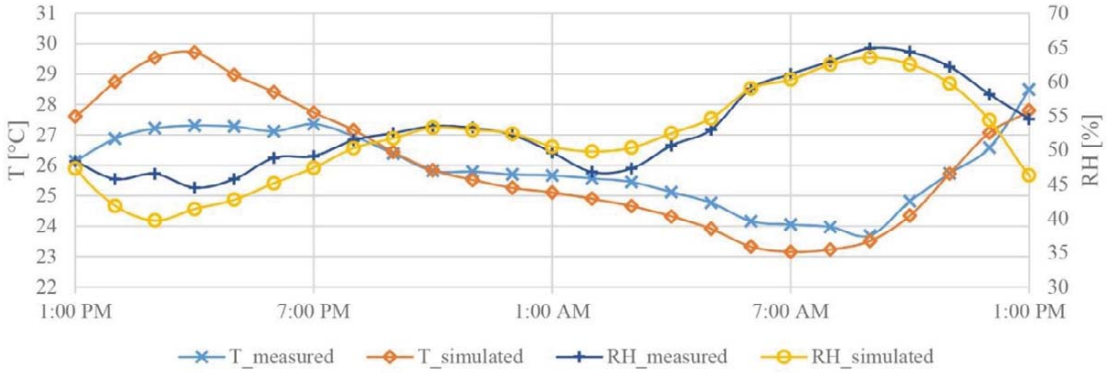

Fig. 4: Comparison of measured and simulated air temperature and relative humidity values trend for model validation

Tab. 4: Calibration parameters results

Parameter	MBE	RMSE
Air Temperature	0.82 K	1.05 K
Relative Humidity	2.21 %	2.96 %

4.2. Summer analysis

The analysis of the alternative simulated scenarios shows that, as expected, scenario S4, combining all the mitigation solutions, is the most advantageous one in summer (July, 15th) in terms of air temperature reduction, especially at pedestrian level (Fig. 5). In fact, by examining the air temperature values in the two analyzed positions, a decreasing trend is detected in the daytime. The best improvement is achieved at point 2, the one located in the previously asphalted area, where an air temperature decrease is registered during all the daytime, varying from -0.5 K (at 8:00 a.m.) to -0.85 K (at 3:00 p.m.).

By analyzing each strategy contribution, the implementation of greenery (S1) seems to be the most effective solution. Moreover, this strategy is the only one leading to benefits in both the points selected. However, in the point closest to the green façade (point 1) the maximum cooling, equal to -0.36 K, is obtained at around 3:00 p.m., i.e. in the peak temperature hours. Whereas, in point 2 the cooling benefit is not perceived during the daytime and the maximum cooling (about 0.4 K) is reached during the coolest hours, i.e. at around midnight, given the different exposition to direct solar radiation of the two points and the reduced heat emission from the walls due to the presence of greenery.

Opposite results, but similar behavior, are detected in S2, where high reflectance tiles are applied on the building roof. In both the points the air temperature increases during the daytime if compared to the reference scenario, especially in point 2. However, these worst values registered in presence of solar radiation (the

maximum increment of air temperature, equal to +0.21 K, is found at 7:00 p.m.) are balanced by improvements obtained during the night, leading to a difference up to -0.26 K at 6:00 a.m. This effect is due to the lower surface temperatures of the built surfaces and, therefore, to their lower contribution in the thermal balance during the nighttime.

Unlike previous results, a different behavior can be noticed in scenario S3, where the pavement reflectance is increased. In particular, in point 2 a drop in temperature is registered during the whole day leading to a mean daily reduction equal to -0.29 K, compared to the reference scenario, i.e. S0. On the other hand, at point 1 the temperature values are slightly increased from 12:00 to 7:00 p.m., with negligible differences up to +0.04 K (at 2:00 p.m.). In fact, point 2 is located above the ground surface covered by asphalt in the reference configuration and, therefore, the thermal properties improvement of the proposed materials are mostly perceived. On the contrary, point 1 seems to suffer from the presence of solar radiation, both direct and diffuse, since it is reached by higher mutual reflections of short wave radiation from the surrounding structures.

The relative humidity trend is strictly connected to the air temperature. However, relevant differences can be noticed just in scenarios S1 and S4 where greenery acts like a vapor source due to plants transpiration. The ratio between the ΔT and ΔRH is detected to be around -0.32 in the scenarios without greenery, but gets lower (-0.19 at point 1, the closer to the green facades, and -0.25 at point 2) after the introduction of vegetation.

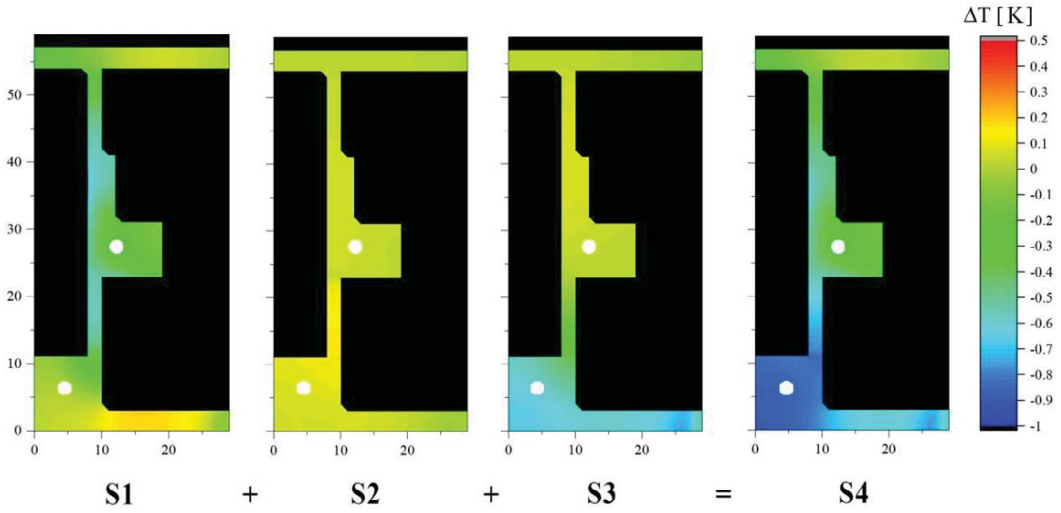

Fig. 5: Air temperature difference between reference (S0) and different mitigation scenarios in the summer day at 3:00 p.m.

Furthermore, the mean radiant temperature (MRT) values were analyzed (Fig. 6). The trend of the MRT shows one peak at point 1, while two peaks at point 2, since direct solar radiation occurs at different times in the two selected locations. At point 1, the peak coincides with the maximum values of reflected solar radiation (at around 1:00 p.m.). At point 2, a first relative peak is detected due to the maximum value of reflected radiation and an additional one is achieved at 3:00 p.m., when the point is reached for the first time by direct solar radiation. Additionally, unlike the previous results in terms of air temperature, the scenario S4 shows worst MRT values with respect to S0, and the solution which mostly influences this effect is the cool paving, i.e. scenario S3. In fact, the pavement reflectance, where high-albedo materials are applied, is able to significantly affect this parameter. Therefore, in the new comprehensive solution S4, a higher mean radiant temperature is observed during the daytime with respect to S0. Although this behavior is registered in both points, a wider range of values is detected in point 2, where MRT achieves its worst value (i.e. +7.62 K at 1:00 p.m.). However, it maintains lower values during the night (mean nighttime increase of +0.1 K) if compared to point 1 (mean nighttime increase of +1.5 K), where the SVF is lower. This is also the reason why in S4 an enhancement of the MRT, i.e. up to -0.11 K, is registered after sunset only in point 2.

An opposite behavior, but with relatively minor impact on the final results, is detected for S2, where

modification of buildings' roof reflectance properties are implemented by increasing the albedo of a 50% (i.e. from 0.5 to 0.75). In this scenario, the wider temperature variation is registered in point 1, from a minimum of -0.9 K at 8:00 a.m. up to a maximum of +0.8 K at 8:00 p.m., while in point 2 the range is between -0.55 K and +0.42 K.

Finally, benefits are registered also in terms of MRT by comparing the scenario characterized by the presence of greenery, i.e. S1, and S0. In detail, at point 1, which is closer to the green façade, lower values of MRT are detected, compared to S0, for almost all the daytime reaching a maximum of -2.84 K at 2:00 p.m. Therefore, an average daily reduction of MRT equal to -0.28 K is detected. Similar but lower effect is registered at point 2, where the achieved mean daily drop of MRT is equal to -0.21 K.

In order to assess the effect of the proposed strategies on the outdoor thermal comfort conditions, the PET index was calculated for the different scenarios (Fig. 7). The PET is strictly related to the trend of the mean radiant temperature, and it was obtained by imposing a clo (static clothing insulation) equal to 0.5. Results show how the midday MRT increase due to the implementation of the high reflective paving causes the increase of the PET in scenario S3 and S4 when the two points are reached by the direct solar radiation and when the peak of reflected solar radiation occurs. Whereas, the pedestrian comfort is improved in particular in point 1 due to the positive effect of the green facades.

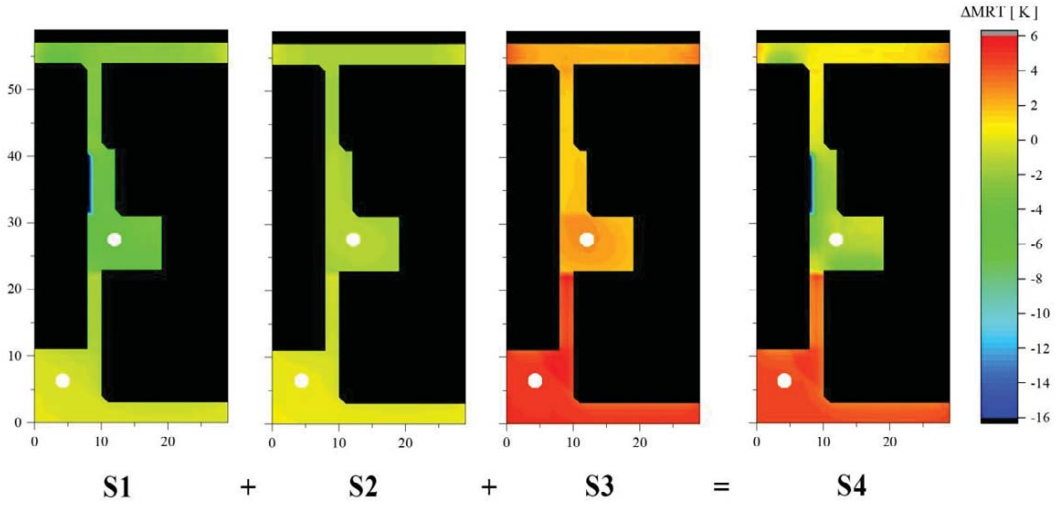

Fig. 6: Mean radiant temperature difference between reference (S0) and different mitigation scenarios in the summer day at 3:00 p.m.

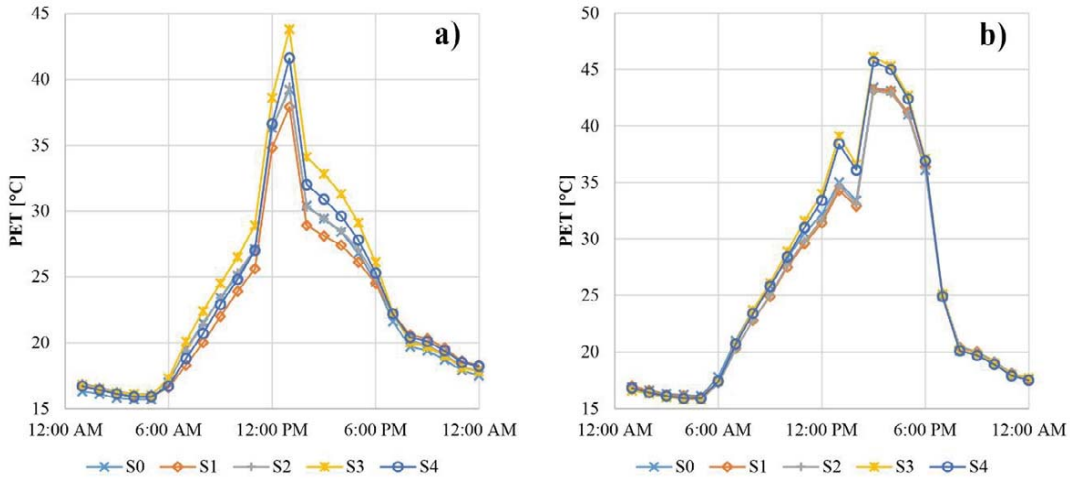

Fig. 7: PET daily trend in all simulated scenarios at (a) point 1 and (b) point 2 in the summer day

4.3. Winter analysis

Even if the proposed mitigation techniques are specifically designed to improve the outdoor thermal comfort conditions of the case study area during the hottest season (when the worst conditions in terms of outdoor thermal comfort are experienced at these latitudes), this section describes the results of the analysis of their effects during winter (January, 15th). The aim is to evaluate if the thermal comfort could be enhanced also in the cold season, or at least not reduced, and to quantify the potential benefits of the applied strategies, which are expected to be lower, compared to the summer ones.

In terms of air temperature, low improvements were detected in almost all the scenarios (Fig. 8). The only exception is registered in S3, i.e. in presence of high reflectance pavements, at point 2 from 12:00 to 4:00 p.m. However, a maximum decreasing of air temperature of only -0.06 K is detected at 2:00 p.m., meaning that paving surfaces are reaching lower surface temperatures even if subjected to the same direct radiation (as expected for cool materials). Nevertheless, S3 is globally the scenario where the higher air temperature increase is detected, with a mean daily variation, of +0.10 K at point 2 with respect to the reference scenario (S0). Instead, at point 1 the maximum mean daily variation, equal to +0.08 K, is registered in S1, i.e. where green facades are implemented. Moreover, higher air temperature improvements occur during the nighttime, when the lowest values of the parameter are reached.

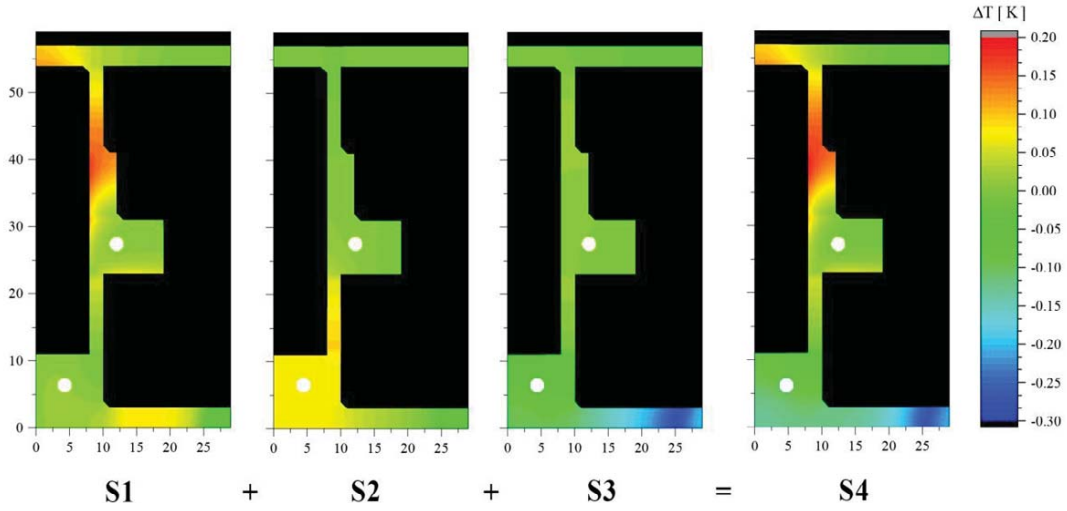

Fig. 8: Air temperature difference between reference (S0) and different mitigation scenarios in the winter day at 3:00 p.m.

Greater variations were found in terms of mean radiant temperature (Fig. 9), in particular at point 1, the one presenting the lower value of SVF (i.e 0.15). In fact, during winter both the selected points are never reached by direct solar radiation, due to the lower height of sun in this season. Therefore, in the absence of direct solar radiation, the effect of mutual reflectance between built surfaces has a stronger impact on the MRT. The highest values of the MRT occur in S3 (characterized by cool pavements) where a maximum difference of +3.41 K, compared to the reference scenario, is detected at 2:00 p.m., i.e. when the reflected radiation reaches its maximum. On the other hand, the introduction of greenery, i.e. S1, causes a drop in the MRT equal to -2.12 K in point 1, where the presence of the green vertical system is more perceived. After the sunset (i.e. at 5:00 p.m.) the effect of all mitigation strategies is almost the same and vary from +2.93 K (i.e. in S1) to +4.00 K (i.e. in S3) at point 1, and from +1.54 K (i.e. S1) to +2.32 K (i.e. S3) at point 2.

As regards the outdoor comfort assessment, the PET (Fig.10) was evaluated also in winter conditions by imposing a cloth resistance of 1.2 clo. In general, although the improvements are detected to be low, apart for S3, it is interesting to notice that the PET gap between the improved scenarios and the reference one is more significant in the nighttime rather than during the day. It means that the applied strategies induce an increment in terms of PET especially in the coldest hours. Therefore, even if the proposed solutions were specifically designed to fight discomfort conditions during the hot season, their effect is non-negligible also during winter, even if less significant.

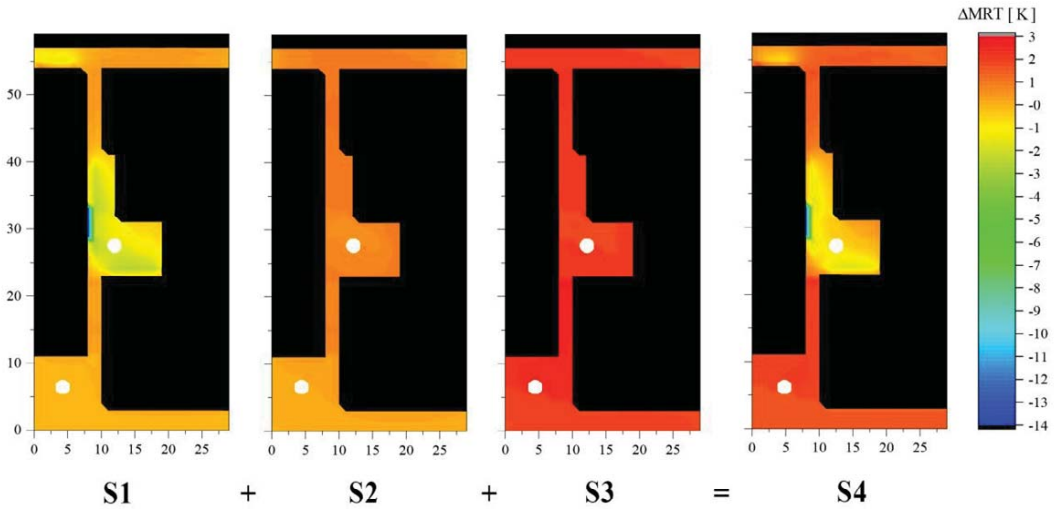

Fig. 9: Mean radiant temperature difference between reference (S0) and different mitigation scenarios in the winter day at 3:00 p.m.

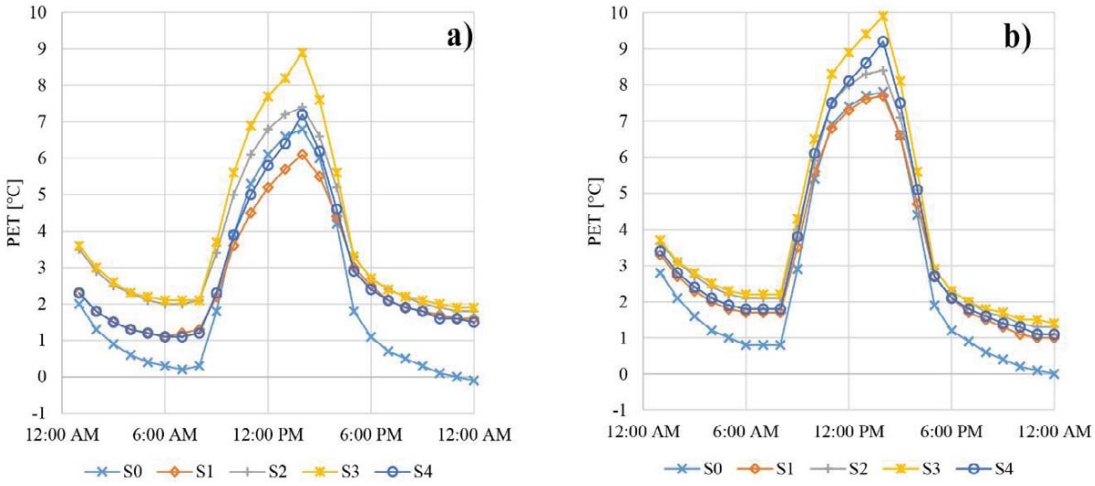

Fig. 10: PET daily trend in all simulated scenarios at (a) point 1 and (b) point 2 in the winter day

5. Conclusions

Urban microclimate has a strong influence on many aspects of human life in the cities. In dense urban environments, the Urban Heat Island phenomenon is a threat to the quality and the livability of the outdoor built environment. In this work, the impact of different UHI mitigation strategies implemented within a real historical precinct was assessed through calibrated numerical analysis, i.e. by using ENVI-met V4. Four possible mitigation scenarios were evaluated under both summer and winter conditions, i.e. the implementation of (i) greenery on building facades, (ii) cool roofs, (iii) cool pavements, and (iv) the combination of these three strategies. The possible thermal benefits deriving from their application were quantified in terms of microclimate parameters and outdoor comfort index, i.e. PET.

Generally, results showed improvements in terms of air temperature for all the solutions both during a summer and a winter day. The implementation of greenery led to the greater temperature gaps in summer, with respect to the reference scenario, i.e. an average daily difference (calculated for the whole analyzed area) of -0.25 K (at 1 m height) compared to the -0.05 K and -0.18 K obtained by implementing cool roofs and cool pavements, respectively. Whereas in winter, when lower effects were registered, no strong differences were noticed among the different scenarios. Furthermore, greenery was the only solution that improved the radiative balance of the outdoor environment in summer. On the contrary, the implementation

of cool materials, and in particular of cool pavements, caused a huge increase of the mean radiant temperature, which negatively affected the human thermal perception of the outdoor space in summer.

Future developments of this work will analyze the effects of such mitigation strategies applied diffusely within the city, enlarging the area of study. The final aim will be to provide reliable information to support both designers and urban planners in the design and development of policies to improve dwellers and pedestrians' quality of life.

Abstract

Energy saving and the integration of renewable energies are critical issues in Net Zero Energy Buildings (NZEB). In this context, the availability of methods for the prediction of the Electrical Load Demand (ELD) is extremely important mainly due to its relevance for an appropriate energy management, sizing of NZEB energy systems, and, especially, for the implementation of suitable energy control strategies, such as energy storage. This paper describes the development and assessment of an electricity demand short-term predictive Artificial Neural Network (ANN) model for a characteristic laboratory within an NZEB located at Almería (Southeastern Spain). As the model is aimed to be used as part of advanced building energy control schemes, some specific requirements, as a tradeoff between accuracy and simplicity, have been considered. The work presented in this paper contains both a description of the algorithms and reference data for an appropriate development of this kind of models. Moreover, a detailed discussion of the obtained ANN model which has been validated using real data obtained from the NZEB used as case-study has been included.

Keywords: *Net Zero Energy Buildings, Electrical Load Demand, Artificial Neural Network, Radial Basis Functions.*

1. Introduction

Nowadays, the concept of NZEB and energy efficiency measurement applied to buildings are receiving an extensive attention all around the world mainly due to their huge contribution to reduce climate change (Kolokotsa et al., 2001). Therefore, the prediction of ELD within the scope of NZEB is presently being widely studied since the optimization of the use of renewable energy sources by means of specific control systems requires an accurate knowledge of building energy consumption patterns, both for the peak and average loads and for the short and medium-term building rooms use dynamics (Castilla et al., 2014).

In this work, a bioclimatic building has been considered as a case of study. More specifically, this building is located at Almería (Spain) and it has been built to take advantage of the benefits provided by solar energy and natural ventilation for passive heating and cooling. In addition, it has a Heating, Ventilating and Air Conditioning (HVAC) system which uses solar thermal energy for active cooling of the rooms. Furthermore, a grid connected photovoltaic (PV) installation completes the building energy infrastructure to cope with the building electricity demands.

In literature, there are many studies that take into account the consumption of the whole building (Khosravani et al., 2016; Mena et al., 2014), several buildings or even the whole city (Ferreira et al., 2010), others are related to the power demand, wind speed, power forecasting and solar irradiance forecasting with different

doi:10.18086/eurosun.2016.01.20 Available at http://proceedings.ises.org

range of parameters (Ren et al., 2015). The approach presented in this paper takes into account one room (a laboratory) which can be observed in Fig.1, as a representative environment of the building. In this case, there are several factors that influence energy consumption such as weather variables, building's construction, building's occupants and their behavior, the use of artificial lighting, the use of the HVAC system, etc.

Artificial Neural Networks (ANNs) have been used to obtain predictive models for the power consumption. In addition, the modeling capabilities of Radial Basis Functions (RBFs) are influenced by the shape of basis functions, the number and placement of the centers, and the width (spread) of the basis function (Ferreira et al., 2012). The using of ANNs for forecasting has led to a tremendous increment in research activities in this field in the past years. As the interesting reader can check in the following works (Zhang el at, 1997; Mena et al, 2014).

In this work, an ANN for the prediction of the energy consumption of the laboratory has been considered. More specifically, it takes into account the energy consumption of artificial lighting, computers, and other equipment in the laboratory.

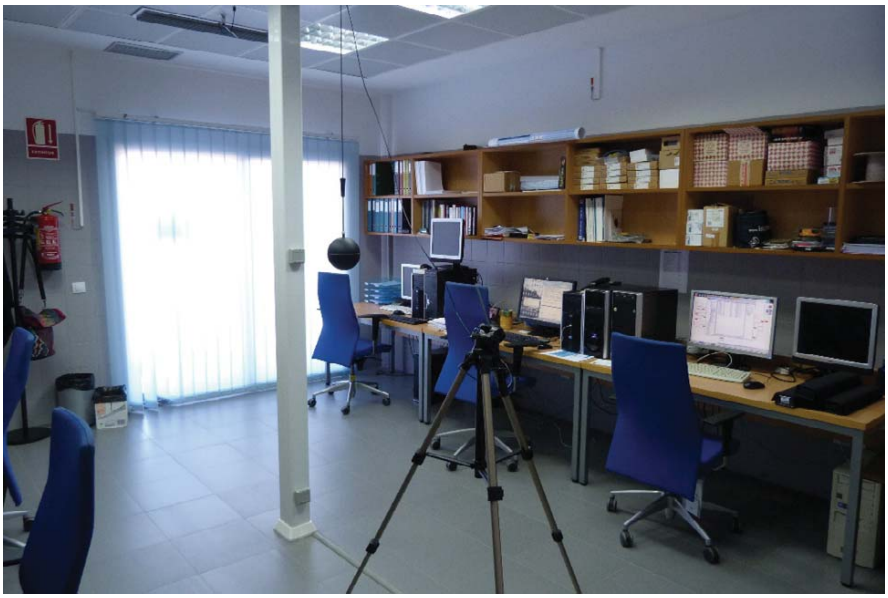

Fig. 1: Representative environment of the CIESOL building

The paper is organized as follows: Section 2 describes the scope of the work. The methodology used to obtain the ANN is presented in Section 3. In Section 4 the obtained results are briefly discussed. Finally, Section 5 includes the main conclusions and future works.

2. Scope of the work

The CIESOL building (http://www.ciesol.es) is a solar energy research center, see Fig. 2, which is located inside the Campus of the University of Almería in the southeast of Spain. This geographic location is characterized by having a typical desert Mediterranean climate, with an annual average number of 2965 hours of sunshine (climate values registered at the meteorological station of the Almería airport, located 3.5 kilometers far from CIESOL). This building is distributed into two different floors with a total surface of 1071.92 m^2. In addition, it was built following several bioclimatic criteria that affect to its architecture, as the use of photovoltaic panels to produce electricity and an HVAC system based on solar cooling.

This HVAC system makes use of a solar collector field, a hot water storage system, a boiler and an absorption machine with its refrigeration tower in order to produce heat or cold air as a function of the demanded necessities. Moreover, it has a wide network of sensors and actuators, and an appropriate data acquisition and measurement system. The availability of these data will allow to understand the behavior of each one of the

bioclimatic strategies which are implemented in this building, the energy saving and CO_2 emissions reduction which can be obtained with them, and also, to perform energy scheduling tasks to optimize the use of renewable energies against conventional energy sources.

Fig. 2: CIESOL building

3. Methodology and experiments

ANNs can be seen as weighted directed graphs where the neurons are nodes and the directed edges (with weights in each) are connections between input and output neurons. They are used for non-linear mapping between the input data $\boldsymbol{X}$ and the output vector $\boldsymbol{Y}$ in order to model relations or detect patterns among them. ANNs are black-box models and, thus, their parameters and structure have to be determined from data.

3.1 Architecture and structure selection: RBF Neural Network

The ANN is an artificial intelligence technique that mimics the human brain's biological neural network in the problem solving processes. As humans solve a new problem based on the past experience, a neural network takes previously solved examples, looks for patterns in these examples, learns these patterns and develops the ability to correctly classify new patterns. In addition, the neural network has the ability to resemble human characteristics in problem solving that is difficult to simulate using the logical, analytical techniques of expert system and standard software technologies (Daosud et al., 2005). In this work an RBF neural network is used. As it can be observed in Fig. 3, an RBF ANN has three layers. The first layer represents the inputs to the network from the outside environment. The second layer, also denominated hidden layer, applies a non-linear transformation on the input set. This layer usually has a large number of neurons to achieve better results. Finally, the third layer, which usually has a single neuron, performs a linear combination over the outputs of the neurons from the previous layer, that is, the hidden layer. Hence, the output of this layer is the result provided by the neural network.

Therefore, the output of an RBF ANN can be expressed as:

$$y = \sum_{i=1}^{n} w_i f_i \cdot (\|c_i - x\|_2) \qquad \text{(eq. 1)}$$

where w_i is the weight associated with the i^{th} hidden layer node, f_i is the radial function, c_i is the center location and x is the input point. The modeling capabilities of this network are determined by the shape of the radial function, the number and placement of the centers, and the width (spread) of the function. Moreover, different

options can be selected as radial function, such as radial linear function, radial cubic function, Gaussian function, thin plate spline function, multi-quadratic function, inverse multi-quadratic function or shifted logarithm function. However, the most used radial function is the Gaussian, see (eq. 2):

$$f_i(x) = e^{\left(-\frac{\|c_i - x\|_2^2}{2\sigma_i^2}\right)} \qquad \text{(eq. 2)}$$

where σ is the standard deviation, c_i is the center of the distribution, and x is the input point.

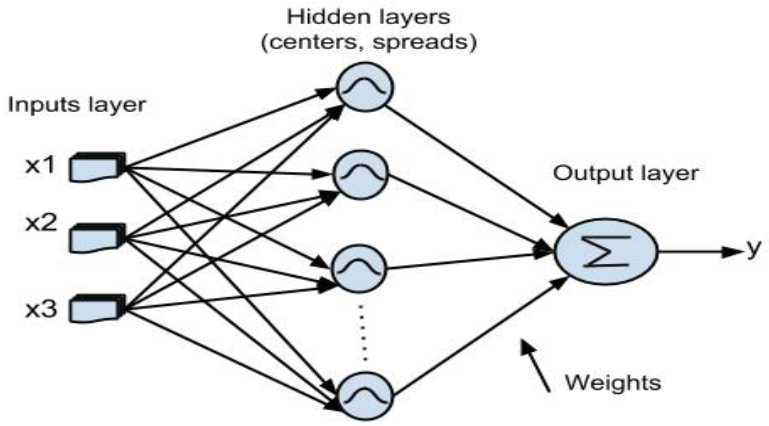

Fig. 3: RBF ANN simple diagram

In general, during the training process, the training error decreases. However, generalization error, that is, the accuracy of the used algorithm to predict the output for previously unseen input values, evolves as it is shown in Fig. 4. This problem is known as overfitting. Typically, the generalization error is estimated as the difference between the expected and the empirical error over a generalization data-set, which is a fixed set of data samples not from the training data-set. Therefore, the initial data-set should be partitioned into a training data-set and a testing data-set. Afterwards, the training data-set is split into two different data-sets: one to estimate the model, and the other to its validation. Hence, three different data-sets are used: training, generalization, and testing (Haykin 2005).

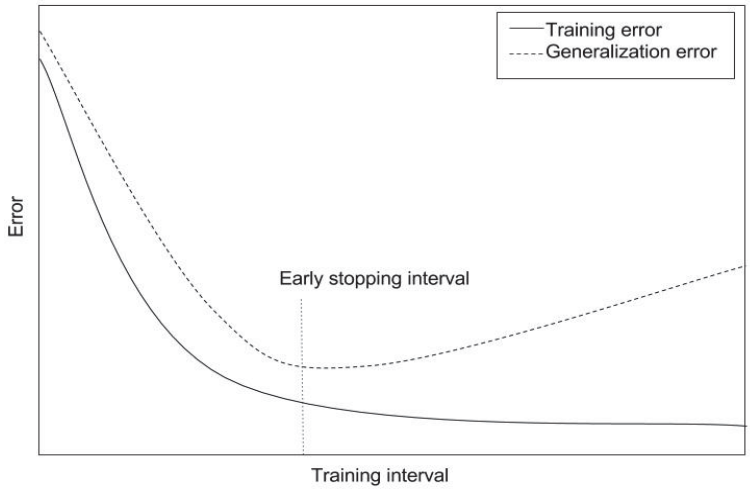

Fig. 4: Training error versus generalization error: early stopping interval (Haykin 2005)

3.2 Data-sets construction

To obtain the RBF ANN proposed in this paper, a set of historical data from the CIESOL building has been used. Concretely, the historic data-set comprises since the 11th of December 2013 to the 11th of February 2014, so it has a total length of 63 days, with a sample time of 1 minute, that is, 90720 points. These points were obtained from different measurement systems. Hence, to synchronize both of them, 60 points (1 hour) were removed from the historic data-set. Therefore, the final number of points was 90660 points.

Due to the sample time of the historic data, the power consumption signal had a random noise in it. Therefore, to remove this noise a smooth filter has been used. More specifically, the MATLAB *smooth* function has been applied to the data. This function smooths data using a 5-point moving average, that is, the

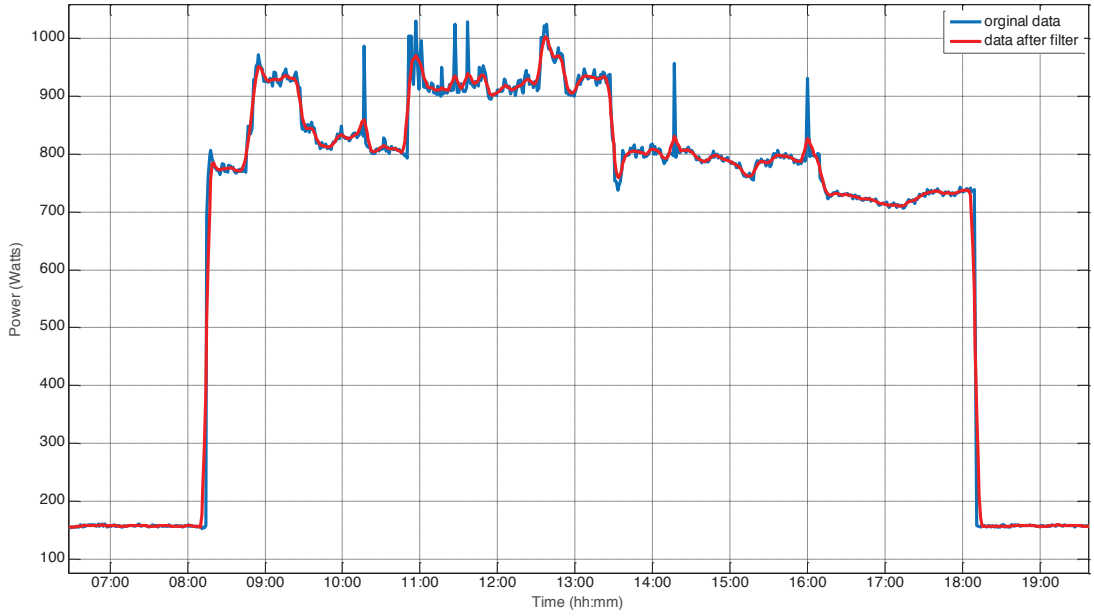

Fig. 5: Results provided by the smooth filter over the power demand signal

moving average filter smooths data by replacing each data point with the average of the neighboring data points defined within the span. This process is equivalent to a low pass filter. Hence, the response of the smooth function is given by the following difference equation:

$$y_s(i) = \frac{1}{2N+1}\left(y(i+N) + y(i+N-1) + \ldots + y(i-N)\right) \quad \text{(eq. 3)}$$

where $y_s(i)$ is the smoothed value for the ith data point, N is the number of neighboring data points on either side of $y_s(i)$, and $2N+1$ is the span (MathWorks Website, 2016). Fig. 5 shows a fraction of the data before and after the filter process has been applied.

3.3 ANN inputs and size

As has been pointed out within the Introduction Section, the output of the ANN model presented in this paper is the prediction of the power demand (excluding the HVAC system) of a representative laboratory of the CIESOL building, see Fig. 1. The original data-set has a total length of 63 days but, after removing the mistaken, unavailable, and unwanted data the size is reduced to 40 acceptable days that can be useful for modeling purposes, see Fig. 6. Figure. 7 shows the power demand of these 40 days in cyan color, and the average power demand in blue color. Finally, from this subdata-set only 23 days have been selected to be used for design the ANN.

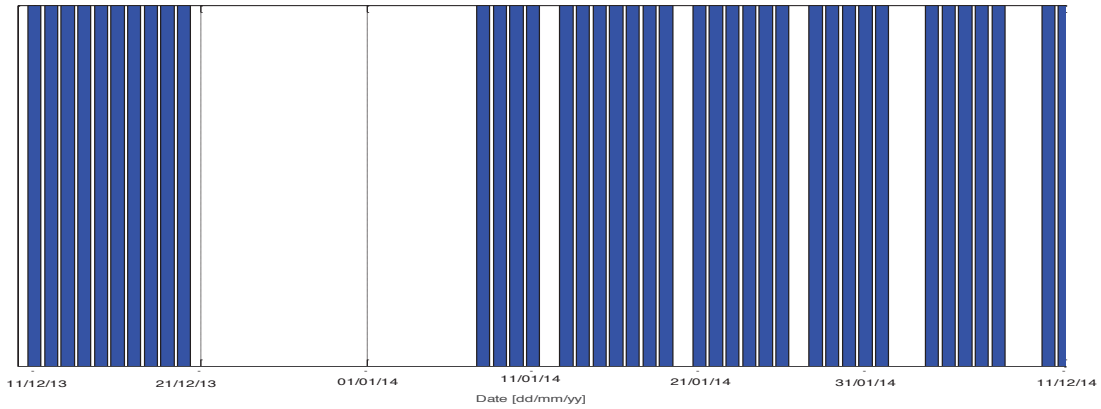

Fig. 6: Data used from the period

This subdata-set of 23 days has been divided into three different data-sets: training, generalization, and testing data-sets which contains the 12%, 8%, and 80% of total points respectively. These points have been selected randomly from the subdata-set of 23 days and, thus, the final size of training, generalization and testing data-set are 3974, 2650 and 26496 points respectively.

The ANNs proposed in this paper uses as inputs 2 lags of the power demand [W] of the laboratory, the CO_2 concentration inside the laboratory [ppm], the outside direct irradiance [W/m^2] and the number of people inside the modeled room [-]. The behavior of occupants have a major effect on the power consumption in the building (Virote and Neves-Silva, 2012). More specifically, they have a direct effect from their physical presence in the space, and an indirect effect derived from their social behavior and awareness of the power saving aspect (Oikonomou et al., 2009).

Moreover, the output of the ANNs is the prediction of the power demand in the laboratory. In Fig. 8 the three exogenous inputs data and the power demand of the period considered in this study are shown. The structure of the proposed ANN can be observed in Fig. 9.

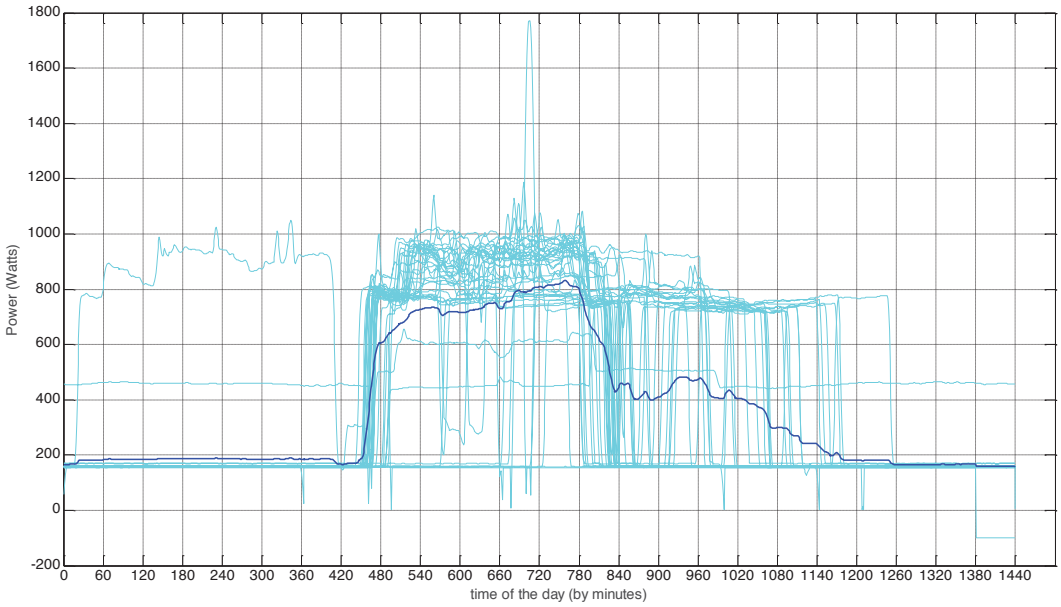

Fig. 7: Daily power of Laboratory with average of the period

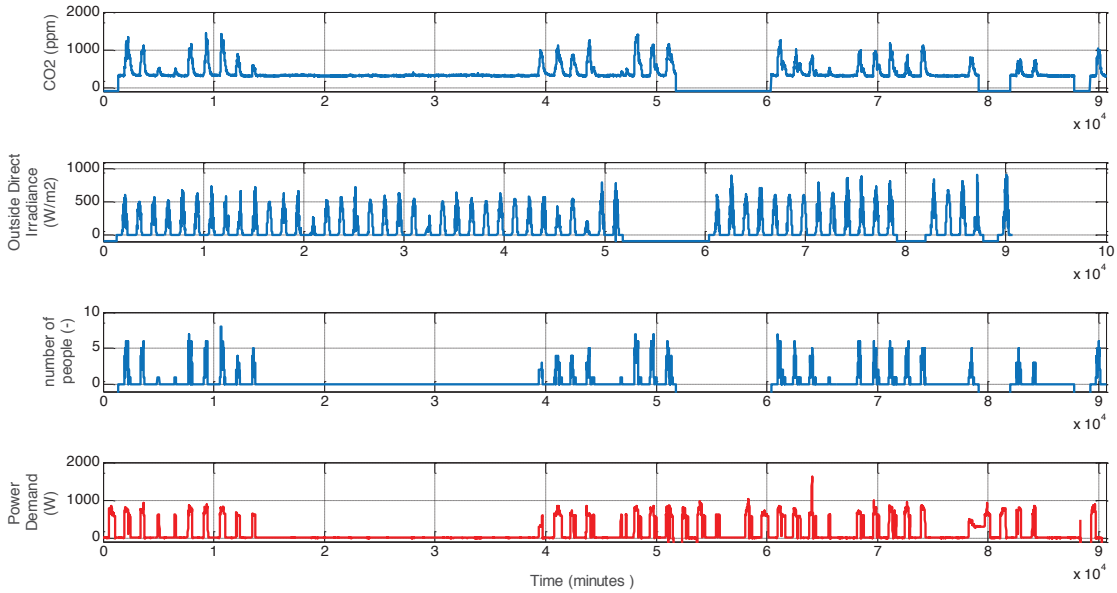

Fig. 8 The inputs and the output data

As different ANNs to predict the power demand of a representative laboratory have been obtained, each of them with different configurations, it is necessary to determine which of the proposed ANNs is the best one. For this aim, the Normalized Root Mean Square Error (NRMSE) has been used. This index is the percentage of the Root Mean Square Error (RMSE). In addition, this index has also been used to validate the proposed ANNs as a function of the prediction horizon (from 1st step and 16th step), see eq. 4, where λ is a weighting factor for each NRMSE:

$$rmseF = \frac{\lambda * NRMSE_{v-1st} + (1-\lambda) * NRMSE_{v-16th}}{2} \quad \text{(eq. 4)}$$

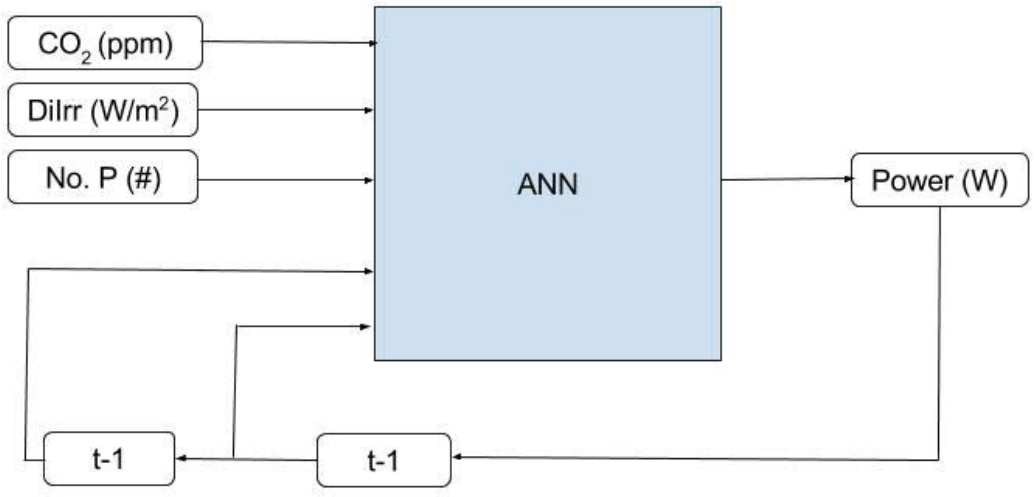

Fig. 9: Structure of the ANN proposed in this paper to predict the power demand in a laboratory of the CIESOL building

In the previous equation $NRMSE_{v-1st}$ and $NRMSE_{v-16th}$ are the NRMSE of the validation data-set for 1st step and 16th step prediction horizons respectively, and λ, in this case, has been fixed to 0.5.

The experiments had been run for all the combinations of these parameters:

- The number of the centers can be 3, 6, 9, 12 and 15.
- The τ parameter with values of 0.05, 0.01, 0.005 and 0.001, which is the termination criterion with early stopping, since an early stopping method with generalization data-set has been used.

In this work, the RBF ANN used to predict the power consumption of the laboratory has been trained using the Levenberg–Marquardt (LM) algorithm (T. Olofsson, 1998; D.W. Marquardt, 1963) which minimizes a modified training criterion (A. Ruano, et al, 1991; P.M. Ferreira and A.E. Ruano, 2000). This method has been successfully used in (P.M. Ferreira, 2012).

4. Results and discussion

In Table 1 a summary of the different models which have been obtained from training the ANN with real data from the bioclimatic building are shown. More specifically, the NRMSE index has been used to assess the performance on the different models. Moreover, validation results for one step ahead (using 1 minute interval) show an appropriate performance with a NRMSE less than 5% in the worst case. However, it does not happen with the worst case for 16 step ahead, which is higher. Thus, a final RMSE, which is the mean of the previous ones (1 and 16 steps ahead), has been calculated to select the most suitable model in both cases.

Finally, the results of the power demand for these 5 models in Table 1 are shown in Fig. 10, and the prediction of the 16 steps of the first model are shown in Fig. 11. In addition, the validation results of the 1st and 16th step prediction ahead for model number 1 can be observed in Fig 12.

The number of neurons that compose the hidden layer of the ANN, the small size of the data window and the parameters of the training algorithm for the experimental works carried out in this paper suggest that these values should be carefully studied, but anyway, many neurons were not needed to get satisfactory results.

5. Conclusions and future work

The obtained RBF ANN shows optimistic results with a simple structure as a method for the prediction of electric load in one room. The main virtue of this ANN model is its simplicity, which is based on the fact that the developed tool is very simple and the resources for its application are tiny and available at modern automation systems. In particular, in order to apply it to a control system, only data from simple sensors and electric power measurements are required.

As a future work, another ANN will be developed in order to predict the HVAC power consumption used for cooling/heating the laboratory. Moreover, other future research line is the use of the ANN as the basis of a control system which, through the ANN model, will be able to maintain the thermal comfort of the users of building whereas the energy consumption necessary to reach this thermal comfort situation is minimized.

Abstract

Buildings generating more energy than they require are a promising possibility to increase the share of renewable energies in the energy matrix. The German Federal Ministry for the Environment, Nature Conservation, Building and Nuclear Safety funded projects that provide a proof of concept of residential buildings producing energy beyond their own requirements, the so called "Efficiency Houses Plus" (EHP). The present work builds up on data of one of these buildings to propose an optimization model that minimizes the energy provision costs for a building while achieving the EHP standard. The model considers solar energy systems, a heat pump as well as electric and thermal storage systems. The model is used to determinate system configurations able to achieve the EHP standard under seven different scenarios. The results serve to discuss the relevance of each of the considered technologies for EHPs in the near future.

Keywords: *photovoltaics, solar thermal, heat and electric storage systems, energy plus house, net zero energy building, monitoring, MILP*

1. Introduction

The European Union (EU) has set the goals of a 20% share of renewable energy sources (RES) in the gross final energy consumption and a reduction of 20% of greenhouse gas emissions in comparison to the levels of 1990 by 2020 (Commission of the European communities, 2007). The EU long term aspirations include a decrease in greenhouse gas emissions of at least 80%, which would imply a share of RES of 75% by 2050 in the gross final energy consumption and 97% in electricity consumption (European Commission, 2011). The building sector has one of the highest potentials to contribute to this goals due to the fact that energy requirements for buildings account for 40% of the total energy consumption in the EU (European Commission, 2010, 2003). The largest share of this energy requirements (66%) can be attributed to energy demand for heating and cooling (Institute of Communication and Computer Systems of the National Technical University of Athens, 2008). Retrofitting measures for the existent building stock and high energy standards for new buildings can contribute to reduce these energy requirements considerably. However the strategy of the EU goes beyond that and the directive 2010/31/EU of the European parliament sets the 31st of December 2020 as the deadline when all new buildings shall be Net Zero Energy Buildings (NZEB).

The general idea behind the NZEB is a highly efficient building that produces as much energy as it would require from the grid or fossil sources to cover its demand over a certain period of time (Good et al., 2015). This is, however, a definition that can be interpreted in several ways and therefore, there is no consensus on the NZEB concept. Sources of discrepancy are, among others, the system boundaries and the weighting factors for the different used energy sources. Extensive discussions on this issue can be found in Marszal et al. (2011) and Sartori et al. (2012). One step ahead NZEBs are the so called "Energy plus houses" or "Positive Energy

doi:10.18086/eurosun.2016.01.08 Available at http://proceedings.ises.org

Buildings" (Ionescu et al., 2015). The German Federal Ministry for the Environment, Nature Conservation, Building and Nuclear Safety describes the "Efficiency House Plus" (EHP) as a building, which produces energy from renewable sources beyond its final and primary energy needs in a balance period of a calendar year (Bundesministeriums für Umwelt, Naturschutz, Bau und Reaktorsicherheit, 2012). The balance includes the energy need for space conditioning, building operation and equipment (Bockelmann et al., 2015). This definition has been used to fund several projects across Germany. These projects serve to show that technologies are already available, which allow the construction of EHPs. In the present paper hourly data from one of these EHPs are used to calibrate an optimization model that aims at conceiving energy generation systems, which allow buildings to achieve the EHP standard at the minimum possible cost. The model is applied to generate system configurations in scenarios where the system boundaries and assumptions are changed compared to the reference building. These scenarios serve to discuss the relevance of every one of the considered technologies for energy plus houses in the near future.

The paper is structured as follows: In the next section the main characteristics of the studied EHP are presented. Section 3 describes the optimization model and section 4 the case studies. Section 5 is devoted to results. Finally, in the last section of the paper conclusions are drawn.

2. The Schlagmann-BayWa EHP, monitoring concept and data

The investigated building is a family house located in Burghausen, Upper Bavaria, Germany. The building was inhabited by a three-person household during the entire study period. They were allowed to use the house for residential purposes without any restrictions. The house has two storeys, 176 m² of heated living area, a cellar and an external garage. It was built with massive single-shell brick filled with heat-insulating perlite. The energy certificate estimates that the energy demand for heating corresponds to the German Energy Savings Regulation (EnEV) 40 standard. The EHP is equipped with 10.76 kWp of photovoltaics (PV) (4.28 kWp on the main building's roof that is oriented towards south and has a 44° inclination as well as 6.48 kWp on the roof of the garage oriented towards east and west with half of the capacity in each direction and a 30° inclination). A 10.8 kWh electric storage system, a 51 m² solar thermal system, an electric car and an automatic steering system are also part of the concept. One additional feature of this EHP is a seasonal warm water storage able to store up to 4000 kWh with a volume of 48,000 L. It is dimensioned to cover the energy need for heating and warm water of the house during winter with solar energy harvested during summer.

The EHP was equipped with monitoring and optimal operation systems. All nodes of the energy system were monitored considering also environmental data inside and outside of the building. Data of more than 120 measuring nodes were stored continuously over two operation years (February 1st 2014 to January 31st 2016). The energy production and consumption of PV, solar thermal systems, heat pump, input and output of the storage systems as well as the energy demand for lighting and appliances, room conditioning, warm water, house operation equipment and the electric car were logged. Afterwards data processing, analysis and visualizing were carried out. Monthly amounts of the measured yields and consumptions (see Fig. 1) as well as the hourly averages and sums of the days per month (see Fig. 2) were investigated.

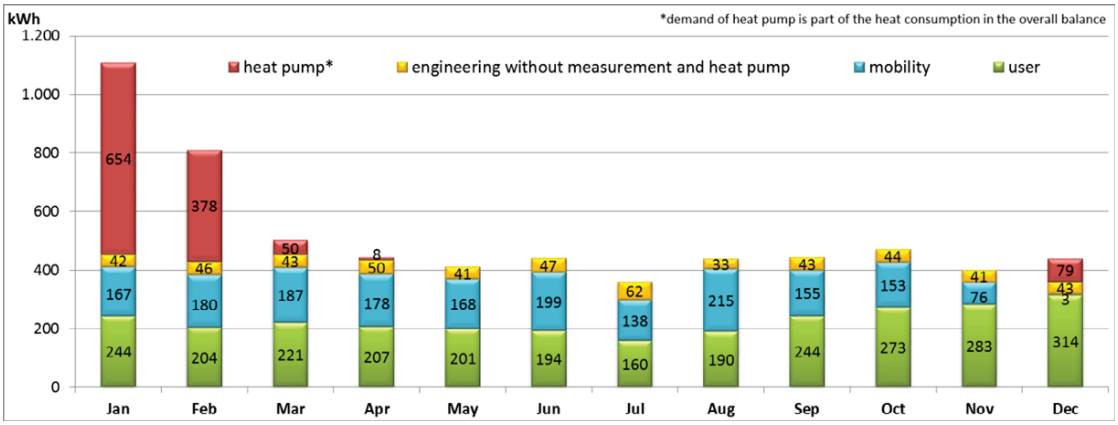

Fig. 1. Electric demand and mobility per month, measured in 2015

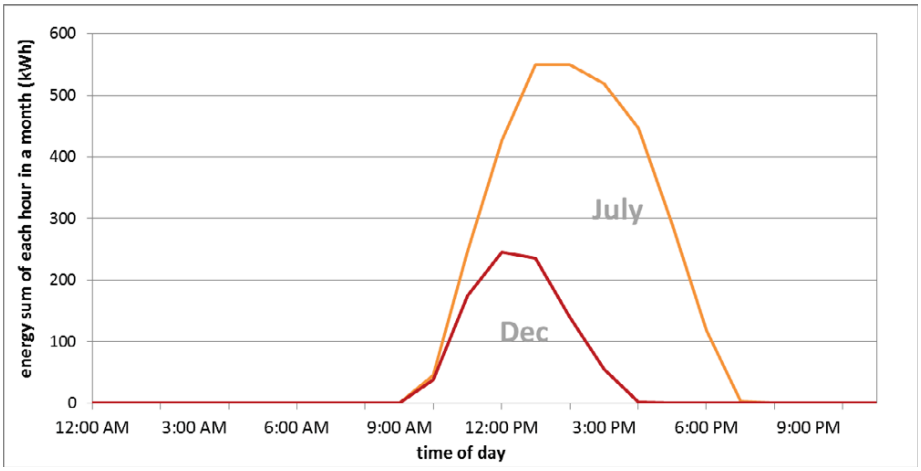

Fig. 2. Energy input into the warm water storage from the solar thermal system. Sum per hour of all days in a month for July and December 2015

The monitoring enables an evaluation of the energy standard and efficiency of technologies, the comparison with the predicted values and the analysis of the temporal development of energy production and consumption. Hourly data of 2015 from the monitoring are the reference for the proposed optimization model, which is described in the next section.

The evaluation of these data provided the evidence that the house of Schlagmann and BayWa fulfill the EHP – standard. On the one hand, the building required in 2015 13,084 kWh for room and hot water heating (incl. heat pump) and 6,464 kWh of electrical energy for the household itself (lighting, cooking and electrical equipment), installation engineering, other heating techniques, battery, other losses and also for the electric car (Fig. 3). On the other hand, the solar system had a yield of 20,675 kWh (solar thermal) and the PV installation generated 10,562 kWh of electric energy (Fig. 3). In total, the energy production exceeded the energy requirements by 11,689 kWh and the balance of primary energy was -14,060 kWh in 2015.

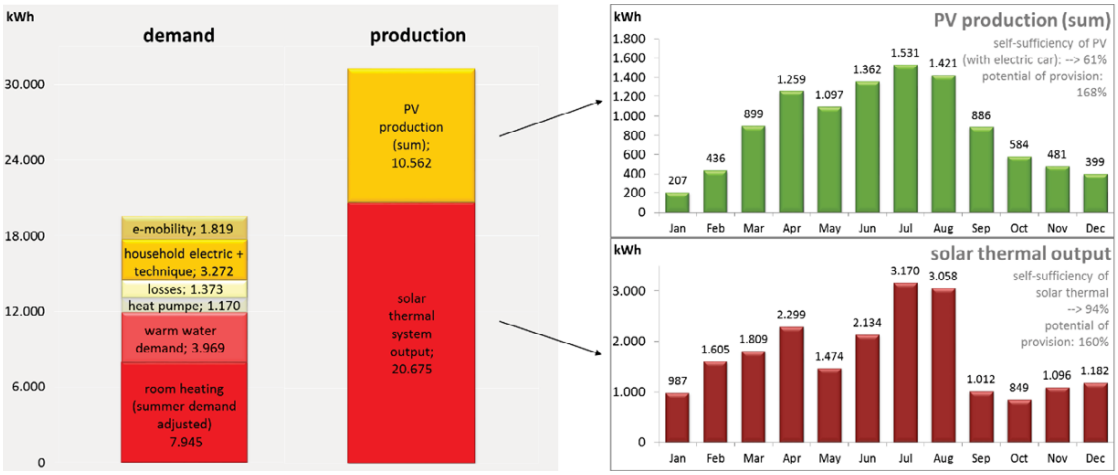

Fig. 3. Overall balance of the monitoring of the EHP of Schlagmann for the year 2015

The data confirm the functional interaction between the warm water system, the heat pump and the input from the solar thermal system. Fig. 4 presents the hourly progress of the heating system over the year 2015. The state of charge (SOC) was accounted on the basis of temperature variations in the warm water storage (sum of the average temperature of the low and the high temperature tanks; every tank has 10 measurement points distributed evenly). Higher solar thermal yields in summer raised the SOC of the warm water storage to a maximum in September and October. Afterwards, the SOC decreased in the winter days until the heat pump was necessary to produce additional heat. The different SOCs at the beginning and end of the year correspond to manual adjustments in the steering system.

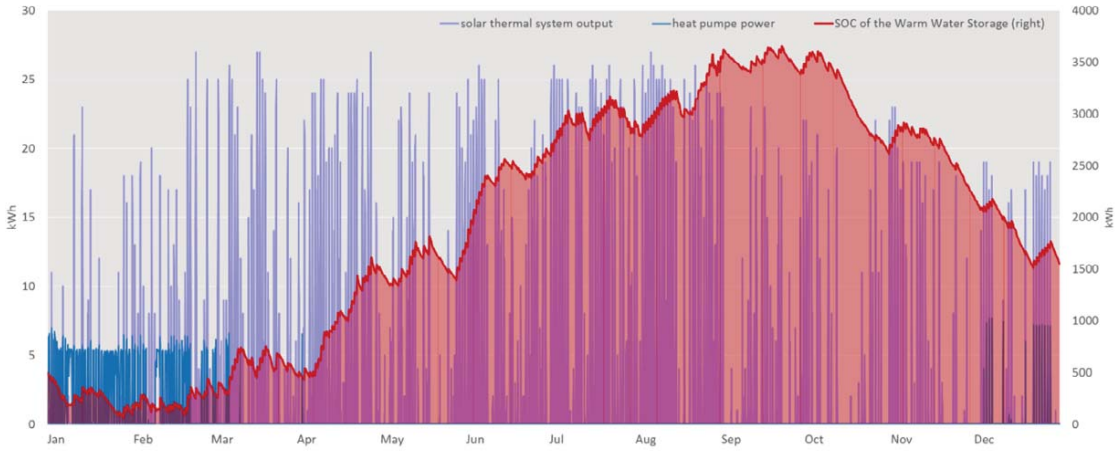

Fig. 4. Results of the monitoring for every hour in 2015 for the State of charge (SOC) of the warm water storage, the usable solar thermal system output and the heat pump output

3. A mixed integer-linear program for minimizing energy provision costs of EHPs

Design optimization of hybrid renewable energy systems for buildings is a research field that has gained significant attention in the last years (Lu et al., 2015a). A multitude of approaches and tools have been developed and some of them, such as the Hybrid Optimization Model for Electric Renewables (HOMER), have been used in dozens of projects all around the world (Erdinc and Uzunoglu, 2012). One of the most common approaches is mathematical programming, where the optimal sizing of hybrid renewable energy systems is reduced to linear, MILP or non-linear optimization problems (Evins, 2013). A MILP is for example the basis of the RED-CAM tool, which has been under development since 2000 and serves to optimize system configurations from a wide range of technologies based on minimum costs or minimum CO_2 emissions (Stadler et al., 2014). The model presented in this paper is also a MILP, but is a tailor-made model since widely used tools such as HOMER or RED-CAM and further tools, reviewed by Lu et al. (2015a), do not address at the same time three characteristics that are important when sizing a system for an EHP: 1) Space constraints for active solar energy generation technologies: The optimal use of space is a critical issue when deciding between technologies that could deliver the same type of energy. Furthermore, the energy input profile of active solar systems depends on geometric and location related characteristics that should be considered (Lang et al., 2015). In an optimal system configuration the right technologies should be installed in the right parts of the building's roof; 2) Use of the full length of data: in order to decrease the computational requirements for finding optimal solutions most of the existent tools rely on typical days or weeks per month to describe energy demand and energy generation yearly profiles. This strategy does not allow to account e.g. for entire weeks of snow coverage of PV systems, which are decisive when dimensioning storage systems. The proposed model uses as input time series of at least one entire year in the highest available temporal resolution. 3) Interdependences in the energy demand of energy generation systems: This is one of the most well-known limitation of HOMER. The tool is unable to account for the electric energy demand of a heat-pump unless this is known apriori and is entered in the model as an input (Lu et al., 2015b). The proposed model accounts for the energy demand profile of every system component that is part of the solution set.

The energy provision costs of the EHP are defined as the sum of the total installation costs, the operation and maintenance costs of the system and the costs of the energy requirements from the grid discounting the earnings of the energy surplus feed into the grid. The objective is to minimize the following problem:

$$\text{Min}((pvCost * \sum_a pvSize_a) + (stCost * \sum_a stSize_a) + (esSize * esCost * esReplace) + (hsSize * hsCost) + (hpSize * hpCost) + (opCost * lt) + (lt * eB * \sum_t eGrid_t) - (lt * eS * \sum_t pvSurplus_t)) \quad \text{(eq. 1)}$$

where $pvSize_a$ is the amount of kWp installed in every roof part and $pvCost$ its corresponding cost per kWp. $stSize_a$ is the size in square meters of the solar thermal system to be installed in every roof part. $stCost$ is the

cost per square meter of installed solar thermal system. $esSize, esCost$ and $hsSize, hsCost$ are the size and related cost per unit of the electric storage and heat storage systems. Both $esSize$ and $hsSize$ are given in kWh. For the electric energy storage an additional replacement factor, $esReplace$, is added to account for the short system life expectancy of current storage systems compared with the life time expectancy of components as PV installations. This factor depends on the expected life time of the storage system and lt, which is the expected operation time of the whole system. $hpSize$ is the maximum electrical input of the heat pump in kW and $hpCost$ is the corresponding cost per kW installed capacity. $opCost$ are the yearly maintenance costs of the system. $eGrid_t$ is the amount of electricity that must be consumed from the grid in every period of time in kWh and eB the electricity tariff per kWh. The surplus energy from the PV systems that cannot be used or stored in a certain time step, $pvSurplus_t$, is sold to the grid at a rate eS per kWh.

Several balancing conditions applied. First, the total PV generation per time step is to be divided in three possible uses; PV electricity can be directly used ($ePVUse_t$), it can be stored ($ePVStore_t$) or it can be sold to the grid ($pvSurplus_t$):

$$\sum_a pvSize_a * pvOutput_{t,a} = ePVUse_t + ePVStore_t + pvSurplus_t, \forall t \quad \text{(eq. 2)}$$

where $pvOutput_{t,a}$ is the output of one kWp PV in t. This depends on weather conditions and the geometric and shadowing conditions of every PV system. The calculation of $pvSurplus_t$ relies on the assumption that all electricity generation surplus can be sold to the grid and no curtailment is required.

Second, the solar thermal systems are assumed to work analogically to the PV systems but the surplus ($stSurplus_t$) cannot be sold to a grid and the energy output cannot be directly used but works depending on the warm water storage system and the heat pump i.e. for energy from the solar thermal systems there are not three but two possible uses:

$$\sum_a stSize_a * stOutput_{t,a} = hSTStore_t + stSurplus_t, \forall t \quad \text{(eq. 3)}$$

Third, the electric energy supply has to meet the demand, which includes the electricity demand of all appliances in the house ($eDemand_t$), the heat pump ($hpeDemand_t$) and the amount of energy required to operate the heat distribution system ($peDemand_t$):

$$eDemand_t + hpeDemand_t + peDemand_t = ePVUse_t + eStorDischarge_t * eStorDischargeEff + eGrid_t, \forall t \quad \text{(eq. 4)}$$

The electricity supply includes not only the part of the PV output for direct use and the amount of electricity that must be consumed from the grid but also the output of an electric storage system ($eStorDischarge_t$) decreased by the discharge efficiency of the storage system ($eStorDischargeEff$), which is assumed to be linear.

Fourth, in a similar way the energy demand for heating and warm water ($hDemand_t$) has to be met by the supply. The latest is assumed to be completely delivered by the heat storage system, which also has a discharge efficiency ($hStorDischargeEff$) that is assumed to be linear:

$$hDemand_t = hStorDischarge_t * hStorDischargeEff, \forall t \quad \text{(eq. 5)}$$

The variables $eStorDischarge_t$ and $hStorDischarge_t$ are bounded by the state of charge of the corresponding storage systems in $t-1$.

Fifth, the state of charge of the electric storage system $eSOC_t$ is calculated with the following equation, taking into account linear charging efficiency $eStorChargeEff$ and energy storing efficiency $eStoringEff$:

$$eSOC_{t+1} = eStoringEff * eSOC_t + eStorChargeEff * ePVStore_{t+1} - eStorDischarge_{t+1}, \forall t \quad \text{(eq. 6)}$$

The $eSOC_t$ is never negative and the first and last time steps in a year are assumed to be equal. The latest condition ensures the continuous operation of the system during winter days from one year to the next.

Sixth, the state of charge of the heat storage system ($hSOC_t$) is calculated in the same way as $eSOC_t$ with the corresponding storing and charge efficiencies ($hStoringEff$, $hStorChargeEff$), the part of the solar thermal output to be stored, the heat pump output to be stored $hHPStore_t$ and the discharge of the heat storage system $hStorDischarge_t$:

$$hSOC_{t+1} = hStoringEff * hSOC_t + hStorChargeEff * hSTStore_{t+1} + hHPStore_{t+1} - hStorDischarge_{t+1}, \forall t \quad \text{(eq. 7)}$$

Seventh, $hpeDemand_t$ is determined by the coefficient of performance of the heat pump $hpEff$ and the part of $hStorable_t$ that is not directly covered by the energy generation of the solar thermal system $hHPStore_t$:

$$hpeDemand_t * hpEff = hHPStore_t, \forall t \quad \text{(eq. 8)}$$

$$hStorable_t = hHPStore_t + hSTStore_t, \forall t \quad \text{(eq. 9)}$$

The highest $hHPStore_t$ serves to determine the size of the heat pump:

$$hHPStore_t \leq hpEff * hpSize, \forall t \quad \text{(eq. 10)}$$

The storage sizes are defined by the highest state of charge of each system:

$$eSOC_t \leq esSize, \forall t \quad \text{(eq. 11)}$$

$$hSOC_t \leq hsSize, \forall t \quad \text{(eq. 12)}$$

Additional constraints for $ePVStore_t$, $eStorDischarge_t$, $hSTStore_t$ and $hStorDischarge_t$to the capacities of the corresponding storage systems $eCapLimit$ and $hCapLimit$ are also necessary:

$$ePVStore_t \leq eCapLimit, \forall t \quad \text{(eq. 13)}$$

$$eStorDischarge_t \leq eCapLimit, \forall t \quad \text{(eq. 14)}$$

$$hSTStore_t \leq hCapLimit, \forall t \quad \text{(eq. 15)}$$

$$hStorDischarge_t \leq hCapLimit, \forall t \quad \text{(eq. 16)}$$

The size of the PV system in m² is calculated multiplying the required installed capacity in kWp by the amount of square meters necessary to fit one kWp ($AreaPV$) and the solar thermal and PV total systems size is constrained by the available area of every roof part ($roofArea_a$):

$$pvSize_a * AreaPV + stSize_a \leq roofArea_a, \forall a \quad \text{(eq. 17)}$$

Finally, the system configuration should be able to generate sufficient energy to allow the building to achieve the EHP standards. To comply with this, two balance equations are included. One for the final energy balance and one for the primary energy balance of the house, which correspond to the calculation method described in the DIN 18599-1 (Europäisches Komitee für Normung, 2011):

$$\sum_t (eDemand_t + hpeDemand_t + peDemand_t + eGrid_t) \leq \sum_t \sum_a pvSize_a * pvOutput_{t,a} \quad \text{(eq. 18)}$$

$$eGridFactor * \sum_t (eDemand_t + hpeDemand_t + peDemand_t + eGrid_t) \leq eDisplacementFactor * \sum_t \sum_a pvSize_a * pvOutput_{t,a} \quad \text{(eq. 19)}$$

These equations include the assumption that the only external energy input for the EHP comes from the grid. The last equation corresponds to the primary energy balance where $eGridFactor$ accounts for the energy sources mix of electricity delivered by the grid and $eDisplacementFactor$ is the displacement factor of PV electricity when replacing other energy sources.

4. Scenarios

Seven scenarios with different system restrictions are studied. These scenarios range from the case of a building that represents the current state of the EHP described in Section 2 to the case of a building, which is able to achieve the EHP standard while assuming that there is no energy input from the grid and no feed-in tariff (full auto-sufficient building). These serve to calibrate the model, calculate the limits of auto-sufficiency of domestic buildings and discuss the relevance of every one of the considered technologies for EHPs in the near future. The description of the scenarios is presented in Tab. 1.

Tab. 1. Scenario description

Scenario	Description
Scenario 1 - Current state of the Schlagmann-BayWa EHP	The lower and upper boundaries of the PV, solar thermal, heat pump, and storage systems sizes variables are set to the values of the currently installed systems. The parameter roof area is equal to the real available area of every roof part where a PV or a solar thermal system is installed.
Scenario 2 - minimum system size that would achieve the EHP status under current constraints	Differently to the scenario 1, the lower boundaries of the PV, solar thermal, heat pump, and storage systems sizes are not defined apriori. The objective of this case study is to determine the minimum system sizes that would be necessary to achieve the EHP standard assuming that the maximum installation size of a certain system is the current system size.
Scenario 3 - minimum system size that would achieve the EHP status with flexible sizes	Differently to the scenario 2, the upper boundaries of the PV, solar thermal, heat pump, and storage systems sizes are not defined apriori. The only system size boundary for the PV and solar thermal systems are the roof part sizes.
Scenario 4 - minimum system size that would achieve the EHP status under current constrains without feed-in tariff	This Scenario is equal to scenario 2 except that the feed-in tariff value is set to 0 EUR.
Scenario 5 - minimum system size that would achieve the EHP status with flexible sizes without feed-in tariff	This scenario is equal to scenario 3 except that the feed-in tariff value is set to 0 EUR.
Scenario 6 - EHP standard without electric energy input from the grid	The starting point of this scenario is scenario 3. It is additionally assumed that no electricity energy input from the grid is allowed and that the size of the roofs is three times the current one of the Schlagmann-BayWa EHP. The first additional constraint is equivalent to the assumption that the EHP standard is achieved at every time step.
Scenario 7 – EHP standard without electric energy input from the grid and without feed-in tariff.	In this scenario the impact of no feed-in tariff is studied for the system with the boundaries assumed in scenario 6.

The common parameters for all scenarios include the energy demand for heating, warm water and electricity that have been measured in the house during 2015. The electricity demand includes the residential use and the electric car. The energy generation profiles of the PV and solar thermal systems per unit of installed capacity (kWp and m² respectively) correspond to the hourly time series of measurements from the installations in 2015. $peDemand_t$ ranges from 0.04 kWh when there is no energy demand for heating or warm water to 0.18 when the pumps for the heating system must be activated (This values are based on the measurements of the electricity demand of the corresponding pumps). $hpeDemand_t$ depends on the size of the system to install, the profile of the energy demand for heating and warm water and the output of the solar thermal system. $hpEff$ has been defined as 300% based on the average of the measurements when the only input for the heating system was coming from the heat pump. The efficiency of the storage systems is defined as a round trip efficiency (Solomon et al., 2012), where the charging efficiency is equal to average efficiency of storage systems (75%

for the electric and 85% for the warm water storage systems) and the discharging efficiency is 100%. The hourly self-discharge ratios of the storage systems are set to 0.01%. The final price per kWh of electric energy from the grid is assumed to be 0.28 EUR and the feed-in tariff (in case it is considered in the scenario) is 0.12 EUR. The assumed lifetime of the system is 20 years and $esReplace$ is equal to 2. The installation prices per unit are rounded average prices from multiple vendors presented in Tab. 2. $eGridFactor$ and $eDisplacementFactor$ are taken from the DIN 18559 in its official version of 2012, in that year (when the house EHP was planned) these values where 2.4 and 2.8 respectively.

Tab. 2. System prices per unit (Average from multiple vendors)

System	Price in EUR
PV (kWp)	2100
Solar thermal (m^2)	350
Heat pump (kW)	5000
Warm water storage (kWh)	10
Electric energy storage (kWh)	1000

5. Results

A summary of the results for the seven case studies and the monitoring data of the EHP for 2015 for comparison is presented in Tab. 3. It includes the resulting system sizes, the sum of the results for one year of seven further variables and the minimum energy provision costs for the 20 years lifetime of the system.

The results of scenario 1 show differences to the measured data that have an explanation in the optimal operation under perfect forecast that takes place in the optimization model. While the steering system in the actual EHP operates demand driven and based on current data, the optimization model generates a solution relying on data for the whole year. In the optimization model operation decisions are taken knowing exactly which will be the demand of the building and which is going to be the resources availability for every single time step. As a consequence, the final total output of the PV and solar thermal installations remains equal to the reference building but the internal use of the energy changes. The direct use of PV electric energy is higher while the requirements for energy from the grid and the energy surplus sold to the grid are lower. These differences between the actual EHP and the optimization model show that there is place for improvement in the operation of the energy generation and storage system of the building. Furthermore, despite of its simplicity, the model is able to reproduce the behavior of the warm water storage and the heat pump during the year. As it is presented in Fig. 5, in the scenario 1 the warm water storage stores energy from the solar thermal system in summer in order to meet the energy demand for heating and warm water during the beginning of winter. Consistently, the heat pump is in operation only during the winter months and the first half of spring. The major differences between the model and the actual system are presented at the end of the year (see Fig. 4). These can be explained by the (perfect forecast) information available for the optimization model and the restriction that obligates the model to finish the year at the same level that it starts with.

Scenario 2 shows that less installed capacity would also have been sufficient to achieve the EHP standard. The same PV installed capacity, a heat pump with a third less capacity, considerably smaller solar thermal and warm water storage systems would have been sufficient to produce energy beyond the final and primary energy requirements. Moreover, the electric storage system is not part of the system configuration even though the energy input from the grid is considerably larger than in scenario 1. Due to the considerable system size reduction in scenario 2, the energy provision costs are less than half of the costs of the reference scenario.

When the roof parts can be used without restrictions for every technology (Scenario 3), the solar thermal system is considerably smaller, the available area is covered by a larger PV system and no PV system is required on the roof of the garage. These changes mean an increment in the total energy yield of the PV system, in the PV electric energy direct use, the amount of energy injected into the grid, the energy demand of the heat pump and the energy requirements from the grid. Nonetheless, this system configuration presents lower energy provision costs than the resulting configuration of scenario 2.

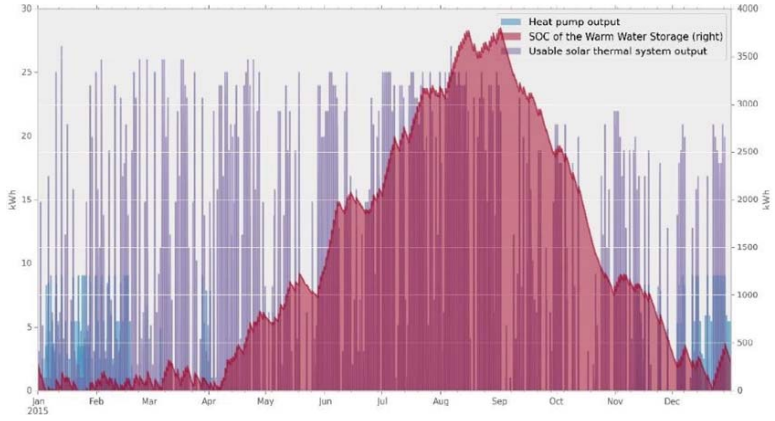

Fig. 5. Results of the scenario 1 for the State of charge (SOC) of the warm water storage, the usable solar thermal system output and the heat pump output for every hour in 2015.

In absence of feed-in tariffs (scenarios 4 and 5) solar thermal systems play an important role covering part of the energy demand for heating and warm water and therefore reducing the electric energy demand of the heat pump. Since surplus electric energy from the PV systems does not generate any income, it is more cost effective to install cheap solar thermal systems to cover part of the energy demand for heating and warm water than to install relatively expensive PV systems to supply the heat pump. This shows that mechanisms for promoting the adoption of renewable energies should be designed while taking into account interactions between technologies. If the interactions are not considered, the final system configurations would not only be more expensive for the system owner but also for the public treasury. It is important to note that even in the absence of feed-in tariffs, the electric energy storage does not appear as part of the solution system configuration.

A totally self-sufficient EHP is unfeasible under the actual system constraints. It would be necessary to have a building with at least three times as much roof space for accommodating active solar energy generation systems (scenarios 6 and 7) to conceive a 100% self-sufficient EHP. Only with PV installations several times larger than in the actual EHP and with an electric energy storage almost eight times larger than the currently installed ones, it would be possible to cover the energy demands of the building during the whole year. The most relevant factor for the large electric storage requirements is a series of consecutive days in winter when there is only little or no PV energy yield (due to snow covering the panels). An example for most part of January is presented in Fig. 6. If the PV yield between 24th and 28th January would be similar to the one of the previous weeks only half of the electric energy storage would be necessary to cover the system's requirements. This situation cannot be observed in optimization tools that rely on average or typical data to represent a whole year of data. Concerning the solar thermal system, this would be only slightly smaller in scenario 6 and a fifth larger in scenario 7 than the one that is currently installed. The warm water storage could be a third of the actual size. Finally, in the absence of feed-in tariffs (scenario 7) the PV system is smaller, the electric energy storage is used more intensely and the solar thermal system is larger than in scenario 6.

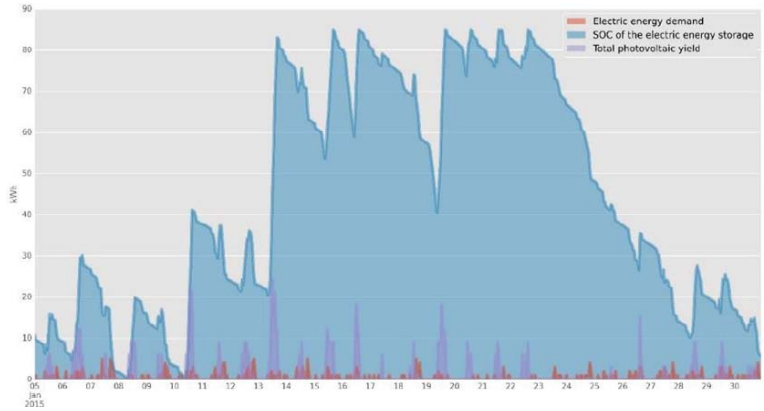

Fig. 6. Results of the scenario 6 for the state of charge (SOC) of the electric energy storage, the total PV yield and the electric energy demand for every hour of the period 05/01/2015-30/01/2015

Tab. 3. Scenario results summary

Variable	Actual EHP	Scenario 1	Scenario 2	Scenario 3	Scenario 4	Scenario 5	Scenario 6	Scenario 7
Electric energy storage (kWh)	10.8	10.8	0	0	0	0	84	86

6. Conclusions

State of the art technology can transform a residential building into a power plant. The data of the Schlagman-BayWa EHP show that a single family house can produce energy beyond its own final and primary energy requirements. In fact, to reach the EHP standard considering a yearly balance it would have been sufficient to install a significantly lower capacity, regarding not only the solar thermal, but also the electric and warm water storage systems. In contrast to the first five scenarios, the sixth and seventh scenario, which describe a building without energy input from the grid (equivalent to a building achieving the EHP standard in every time step), are unfeasible considering the available roof areas for installation of PV and solar thermal systems. The proposed MILP can only find a solution for these scenarios when the roof areas are assumed to be three times larger than the current size. The realization of such complete self-sufficiency scenarios would require not only larger energy generation systems, but also electric storage capacities several times higher than the one currently installed in the Schlagmann-BayWa EHP. Self-sufficiency seems to be hardly realizable even for the small demand of a single family house.

The use of the full length of data serves to identify that the main reason for the high electric storage requirements in these scenarios are series of consecutive days where only very little energy can be generated by the PV installations. Furthermore, the modelling showed that even in absence of feed-in tariffs for the PV energy surplus sold to the grid, electric storage systems are only part of the optimal solution when no input from the grid is allowed. It is also only in absence of a feed-in tariff for the surplus PV energy production that the solar thermal systems gain relevancy in the solution system configurations.

Finally, the EHP standard can be achieved in numerous ways, but the economic viability of such buildings requires the selection of the appropriate system configuration, which can be determined using the proposed MILP. It is also important that the design of economic mechanisms to promote certain renewable energy technology takes into account the interactions between technologies, otherwise energy generation systems installed by house owners would be more expensive not only for the owner but also for the public that is paying for these promotion mechanisms.

7. Acknowledgement

The authors would like to thank the consortium of the Schlagmann-BayWa EHP project for providing the monitoring data used in this study.

Control strategies and user acceptance of innovative daylighting and shading concepts

Michaela Reim[1], Werner Körner[1], Daniel Gerstenlauer[1], Stephan Weismann[1], Detlev Kranl[1], Helmut Weinläder[1]

[1] Bavarian Center for Applied Energy Research (ZAE Bayern), Wuerzburg (Germany)

Abstract

At the last Eurosun in Aix-les-Bains 2014 the daylighting and shading concept of the Energy Efficiency Center was presented (*Reim et al. 2014*) – a translucent membrane roof with subjacent translucent aerogel modules improves the daylighting especially in the room depth, highly innovative solar blinds guide the visual spectrum of the sunlight only into the rooms while blocking the infrared parts. Roller blinds for glare protection with special low-e-coatings improve thermal comfort in the offices. A high-level building automation system controls the different systems. After these measurements surveys were performed to determine the effect of the different daylighting and shading systems on the users in the different offices. The results of the conducted surveys with the users of the EEC in the offices will be assessed and the consequences for the optimization of the control strategy will be discussed. Finally, the influence of the aerogel glazing on the energy consumption will be discussed.

Keywords: *daylighting, shading, artificial lighting, user acceptance, aerogel glazing, control strategies,*

1. The Energy Efficiency Center

The Energy Efficiency Center (EEC) is a combined office (1st floor) and laboratory (ground floor) building with a function room attached to the north side, shown in Fig. 1. It is located in Würzburg, Germany, and was finished in June 2013. The overall aim of the project was to create a reference building which implements innovative techniques, serves demonstrational purposes, and sets new standards (*Weismann et al. 2016* and *Römer et al. 2016*).

Fig.1: Energy Efficiency Center viewed from north-east, the north-orientated rooms on the first floor and the roof of the technical center. Clearly visible is the textile roof with translucent PTFE-glass membranes and partially transparent ETFE films in the ridge of the roof.

doi:10.18086/eurosun.2016.01.13 Available at http://proceedings.ises.org

2. Lighting and shading concept

The goal of the lighting and shading concept is to minimize the energy consumption of the artificial lighting system by maximizing the daylight input into the rooms while, at the same time, reducing the heating/cooling loads by maximizing/minimizing the solar energy input into the offices as applicable. Depending on the heating or cooling demand of the office the solar energy input can be varied by using either the outside (low solar energy input) or inside (high solar energy input) shading device.

The roof of the main building consists of translucent PTFE-glass-membranes and partially of transparent ETFE films. The membrane acts as a climate interlayer above the thermal insulation level, the ceiling of the 1st floor which is partly transparent or translucent. Some ceiling areas of the office rooms away from the façade consist of translucent double skin sheets filled with Lumira-aerogel thus enabling a high room illumination in the depth. The roof of the function room to the north consists of translucent, double-layered, air filled PVC-membrane cushions.

The sun protection system on the south façade consists of outside blinds from WAREMA Renkhoff SE with spectrally selective lamellae. The solar reflectance of the lamellae in the visible spectral range is significantly higher than the reflectance in the solar spectral range. The result is a total solar energy transmittance which is lower than that of non-selective lamellae with the same visual transmittance. Additionally, all rooms are equipped with an inside glare protection system, a roller blind with a low-emissivity coating on the inner surface to improve thermal comfort of the inhabitants. The luminaries are switched and dimmed automatically based on combined occupancy and illuminance sensors in each room. Depending on the heating or cooling demand of the room, the solar energy input through the facade can be varied by using either the outside (low solar energy input) or inside (high solar energy input) shading device. The operation of the lighting and sun protection system was tested for all weather conditions. When the correct operation of the control system was verified the interaction of the users with the control system was investigated by surveying the user interventions with the building control system during winter conditions (*Reim, M.,* et al., 2014). Other surveys to optimize control strategies will follow.

2.1. Control of lighting and sun protection system

Each room is equipped with a ceiling-mounted combined occupancy and illuminance sensor. The occupancy sensor selects a low-power mode for the room when nobody is present. This includes switching off the light and operating the external sun protection system depending on whether there is heating or cooling demand (completely open or completely close the sun protection system) for the room.

When occupied, a default illuminance level of 500 lx (*EN 12464-1, 2011* for office rooms) at the work places is maintained using dimmable artificial lighting if necessary. The position of the shading system (open or closed) depends on the outside illuminance on the respective façade:

- It is closed at an outside illuminance higher than 45 klx. The lamellae angle is set depending on the position of the sun and the heating or cooling demand of the room. When heating demand is present the lamellae are closed just a few degrees more than the cut-off-angle, which ensures that no direct irradiation passes the sun protection system. The cut-off-angle is the angle to which the lamellae have to be closed in order to completely prevent direct radiation to pass through the sun protection system depending on the solar height. When cooling is needed the lamellae angle is set 10° higher than the cut-off-angle or a minimum of about 20°, further reducing the solar energy input to the room.
- It is opened when the outside illuminance is lower than 20 klx for some time.
- When the outside illuminance is higher than 30 klx the sun protection system is closed with a lamellae angle of 0° (horizontal). The same state is reached when the system is closed and the outside illuminance is lower than 30 klx.

All automatic settings for lighting and outside sun protection system can be overruled by the user; the control system is reset to automatic mode after 30 minutes without occupancy. The roller blinds used as inside glare protection are controlled manually.

Following a survey from spring 2015 the control strategy for the building was optimized as follows:

- The starting time for the room heating on Mondays after the weekend setback was changed from 6 am to 4 am to increase the room temperatures in the morning, especially in the corner offices.
- The maximal closing angle of the sun protection system of 50° was too big. Most of the users felt uncomfortable with the nearly fully closed shading system and artificial lighting switched on, so we set the maximum closing angle to 45°.
- At outside temperatures above 8°C, heating demand for the room and illuminance at the south façade above 45 klx the sun protection system was fully closed so far. In the rooms with room-high glazing we changed the control so that the sun protection system stops at a façade height of 40 % for the case of heating demand in the room. This improves the user acceptance, allows better visual contact to the outside and additionally increases the solar gains during the heating period.

After these changes, we performed new surveys to check if the changes really improved the situation in the offices. These results were presented in *Reim et al. 2015*. In nearly every room the number of the interventions by the users was reduced after the optimization of the control strategy of the sun protection system. Even in the rooms, where the users often intervene with the building control, the number of interventions was reduced after the optimization.

2.2 Daylight input through aerogel glazing

The ceilings in the back of the offices are equipped with aerogel glazing, shown in Fig.2. The aerogel glazing should improve the illumination in the room depth by daylight that is transmitted through the translucent textile roof. This should reduce the electric consumption needed for artificial lighting. To quantify this effect, measurements were made in two comparable rooms, one with and one without aerogel glazing (the aerogel glazing was covered for the measurements in this room) and the power signal for the artificial lighting was detected and analyzed.

Fig.2: Aerogel glazing in the back of the offices

3. Results

3.1 User surveys

After the control strategy of the sun protection system was changed as discussed in section 2.1, the efficiency of the changes was investigated. Assuming that the more comfortable the user feels the less he is intervening with building control, we compared the user interventions before and after the optimization, see Fig.3. The number of user interventions decreased, especially the cases when the sun protection system was manually opened fully (case "open") or partially (case "middle").

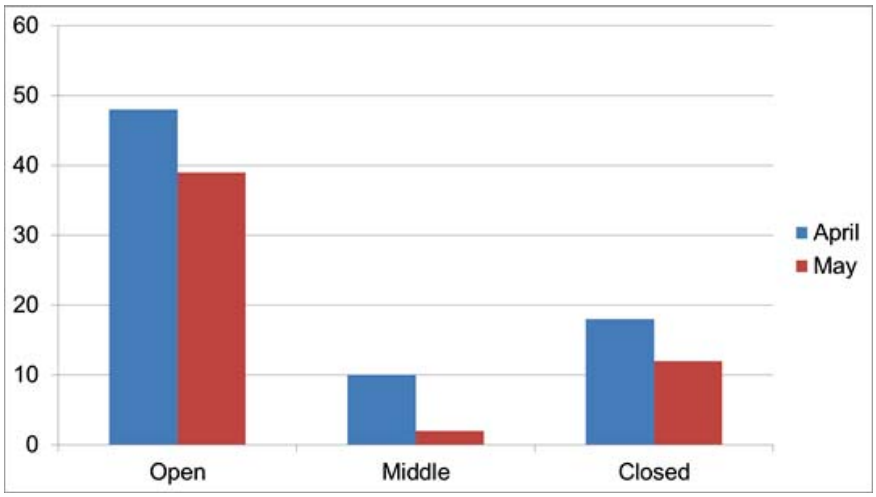

Fig.3: Number and sort of user interventions with the shading system before (april) and after (may) optimization of the control strategy.

After these changes, we checked the number of user interventions (see table 1) and additionally performed new surveys to check if the changes really improved the situation in the offices.

Table 1: Number of user interventions with the building control for different rooms before (april) and after (may) optimization of the control strategy.

Room Intervention	1	2	3	4	5	6	7	8	9	10	Total	Mean per workday
april	12	11	-	2	3	2	4	4	14	6	58	2.9
may	6	9	-	3	3	-	1	2	8	5	37	2.1

In a ‚pop-up' survey we asked users about their satisfaction with their working environment (happy/unhappy). After this window a second pop-up window opened asking for reasons for satisfaction/dissatisfaction (temperature/ light/ other reasons). In order to keep the user from choosing the shorter version of answering the survey, the number of windows and the number of clicks had to be similar. This was discussed with a psychologist in advance. In the course of the survey a problem became obvious: one can easily determine whether the office is too warm, cold, dark or bright, but it is difficult to decide if the office is just as warm or cold as one would like it to be. Many users got put off by the number of clicks needed (3 - 6). Hence the survey was reduced to one window with 2 clicks,Fig 4.

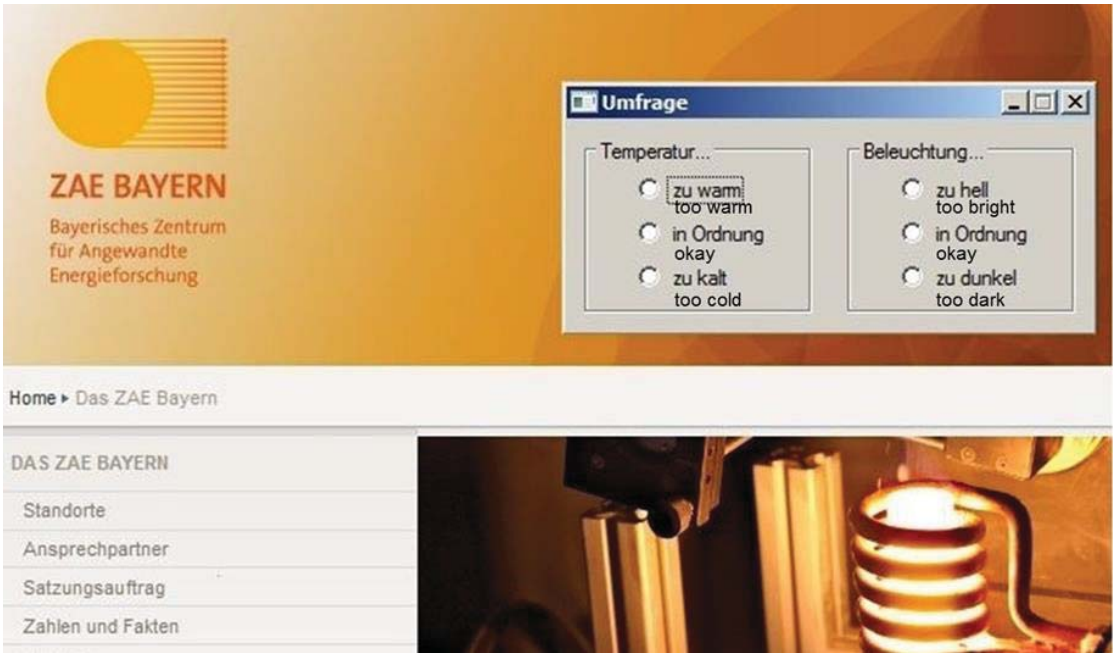

Fig.4: Optimized Pop-up window.

Evaluation of the survey between 16/08/2016 and 16/09/2016 is depicted in table 2 and table 3. In this timeframe the weather was very warm and sunny. In table 2 the user satisfaction in south- and north-facing as well as corner offices is depicted.

Table 2: Comparison of user satisfaction in south- and north-oriented as well as corner rooms

	South orientated	North orientated	Corner
too warm	1.6 %	3.8 %	8.1 %
okay	90.3 %	90.9 %	90.4 %
too cold	8.1 %	5.3 %	1.5 %
too bright	0.9 %	3.4 %	5.6 %
okay	95.3 %	90.0 %	92.1 %
too dark	3.8 %	6.6 %	2.3 %

With an overall satisfaction over 90 % we conclude, that for all offices – independent of their direction – the sun-protection and artificial light regulation is working very well at least for summer conditions.

In table 3 the user satisfaction as a function of daytime is depicted.

Table 3: Comparison of user satisfaction depending on daytime

	too cold	too warm	too dark	too bright
before 10 am	10.0 %	1.5 %	4.9 %	3.8 %
10 am – 2 pm	7.3 %	2.6 %	3.3 %	2.5 %
after 2 pm	2.0 %	5.5 %	5.2 %	2.0 %

There is neither a correlation between daytime and sensitivity of light, nor for perception 'too dark' (average 4.5 %) or too bright (average 2.8 %).

However, there seems to be a tendency in perception of temperature. During morning hours it is often too cold, in the afternoon often too warm.

One important change to the control was the last point mentioned in section 2.1, where the sun protection system was not closed completely any longer at outside temperatures above 8°C and heating demand as well as illuminance levels at the south façade of more than 45 klx but instead stopped at a façade height of 40 % thus shading only 60 % of the façade area instead of 100 %. This should lead to a reduced heating demand due to increased solar gains. In order to estimate this effect, we investigated the control log of the sun protection system and looked how long the sun protection system was in this optimized mode from September 1st 2015 to September 1st 2016. During the whole year, twelve office rooms stayed in this optimized mode for a total of 1891 hours in which the solar energy input was increased by 40 %, which equals a mean value of 158 hours per year and room.

In case of high irradiance on the south façade, which causes the mode of maximal shading angle this adds up to 2271 hours per year, which equals a mean value of 189 hours per year and room, in which most users switched on electric light, since it was too dark for them. Therefore, some energy savings should be achieved in this mode, however it is difficult to estimate how much.

3.2 Energy savings potential of aerogel glazing

Finally, we compared the illuminance and the lamp control signal for two similar rooms – one with and one without aerogel ceiling panel, see Fig. 5.

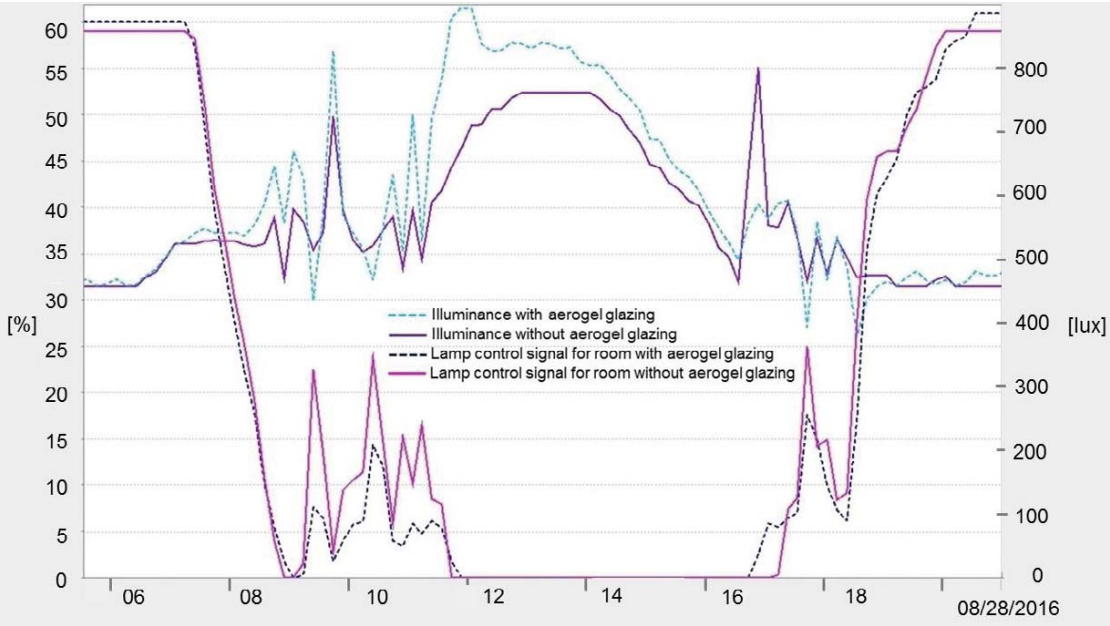

Fig.5: Comparison of illuminance in a room with (dotted line) and without (single line) aerogel glazing as well as the signal for lamp control; illuminance right axis [lx], lamp control signal left axis [%].

On the August 28th depicted in Fig. 5 the amount of daylight between 11:30 am and 4:30 pm is sufficient to illuminate the offices with 500 lx without any artificial lighting (lamp control is off). Here the illuminance during midday hours of a room with aerogel glazing exceeds that of a room without aerogel glazing by 100 lx. During morning (8:30 – 11:30 am) and evening hours (4:30- 6 pm) artificial lighting is added by the control strategy to guarantee a working place illuminance of 500 lx. In order to conduct measurements with defined boundary conditions, the control of the sun protection system was identical for both rooms and the presence was turned on all day without any user influence.

An overview of the measured electrical energy consumption in the two rooms with and without aerogel glazing is depicted in Fig. 6 for some days in May and August 2016. If we ignore the first measurement day on May 14th because of the very low consumption values with a corresponding high measurement error, typical energy savings of 10 % – 50 % can be achieved with the aerogel glazing as headlight. The mean value for all five measurement days yields energy savings of 30 %.

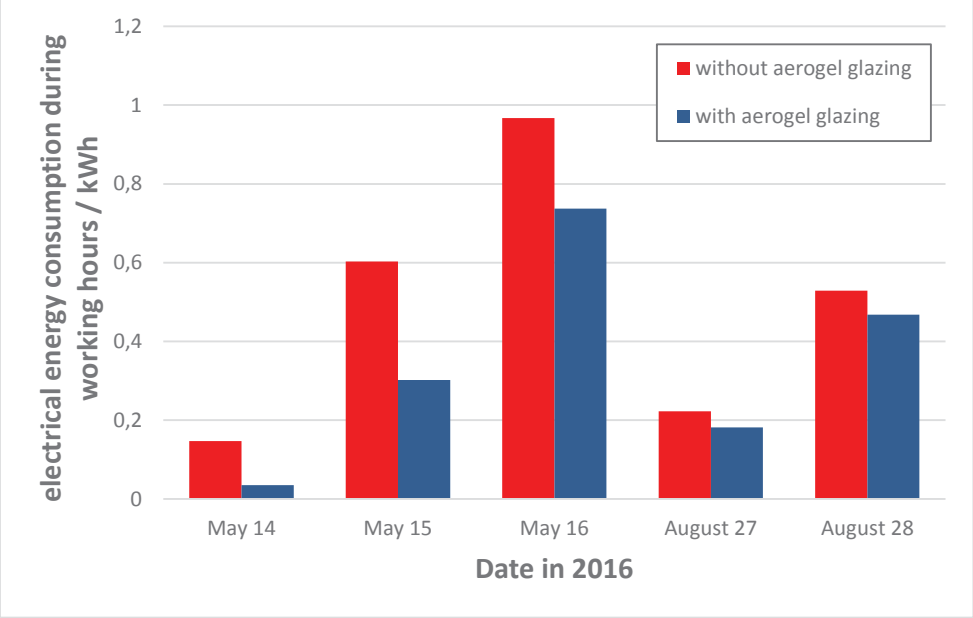

Fig. 6: Electrical energy consumption for artificial lighting in two rooms with and without aerogel glazing as headlight.

4. Summary and Outlook

During recent work, the building control of the Energy Efficiency Center with its innovative daylighting and sun protection concept was investigated and optimized. The various optimization measures were controlled and confirmed by user surveys. In addition, we started to evaluate the electrical energy savings potential of aerogel glazing as headlight in the offices to reduce artificial lighting. First measurement results are presented here that show an electrical energy savings potential of about 30 %.

Further surveys will be made to continuously check the quality of the building control. Measurements of the electrical energy consumption due to artificial lighting in the two offices with and without aerogel glazing will also continue.

Abstract

Passive systems and bioclimatic architecture principles applied to modern architecture are able to reduce the energy demand of the building sector, and to meet the Nearly Zero-Energy Building goals. The aim of this research is to reduce the discomfort time of buildings located in tropical climate, by using passive systems taken from vernacular architecture and bioclimatic modern buildings. For this purpose, a model building has been designed, meeting the tropical climate requirements. Energy simulation has been done to compare the thermal behavior and thermal comfort conditions of the model building, under different passive systems cases: thermal mass, solar protections, crossed ventilation, and dehumidification. The results reveal that a combination between high thermal inertia with nocturnal ventilation, the use of solar protections on the north facade, dehumidification, and the use of thermal insulation in the roof is fundamental for achieving the thermal comfort in buildings located in tropical weather.

Keywords: *Energy simulation, bioclimatic strategy, passive design, thermal comfort, office building.*

1. Introduction

Building sector consumes 40% of the final energy consumption (Economidou 2011). Half of this energy consumption is due to the use of active systems for heating and cooling (Meijer et al. 2009). For these reasons, the greatest energy savings potential is associated to the building sector, and to the reduction of the energy demand from heating and cooling systems (Economidou 2011). To reduce buildings energy consumption, it is created the concept Nearly Zero-Energy Building (NZEB). This concept has become part of the energy policies of many countries, to make possible the reduction of emissions of CO_2 generated by the building sector (COM 2011; Crawley et al. 2009). Passive systems and bioclimatic architecture principles applied to modern architecture are able to reduce the energy demand of the building sector, and to significantly contribute to the NZEB goals. These strategies were broadly used in vernacular architecture (Manzano-Agugliaro et al. 2015). However, the major part of contemporary architecture does not use them. Most of modern buildings are not designed in adaptation to their climatic conditions and, therefore, they require active systems for achieving the indoor thermal comfort.

The aim of this paper is to reduce the number of hours not meeting thermal comfort criteria of buildings located in tropical climate. This is done by using passive systems taken from vernacular architecture and bioclimatic modern buildings. For this purpose, this paper analyses the thermal behavior of a model building that incorporates different cooling passive systems, by using energy simulation. The building is located in Goiânia, a city of the interior of Brazil, with tropical climate (Aw according to Köppen). This research is part of an initiative that aims to build a prototype with the NZEB concept, named Model House, to realize experimental researches about thermal comfort and energy efficiency.

2. Passive systems for tropical climate

2.1 The climatic conditions of the location

The analyzed building in the simulation is hypothetically located in Goiânia, the capital of the State of Goiás, Brazil (Latitude -16.7º, Longitude -49.3, Elevation 741 m). The region of Goiás is within the Tropical savanna climate area (Aw), according to Köppen climate classification (Kottek et al. 2006). This climate is characterized by two main seasons: wet -from October to April- and dry -May to September- (Tab. 1). In Goiânia, the predominant winds are; north (16% of the time), south east (16% of the time), east (14% of the time), and north west (13% of the time).

Tab. 1: Climatic conditions of Goiânia, Brazil (World Climates 2016).

Month	Average Air temperature*	Relative humidity*	Daily solar radiation		
			Roof	South Facade	North Facade
	ºC	%	kWh/m^2·d	kWh/m^2·d	kWh/m^2·d
January	23.8	75	5.13	1.03	-
February	23.8	76	4.67	0,14	0,27
March	23.9	74	4.69	-	1,10
April	23.6	71	5.50	-	3,00
May	22.1	65	4.66	-	3,77
June	20.7	60	4.47	-	4,36
July	22.9	53	4.67	-	4,25
August	24.6	47	5.04	-	3,29
September	24.6	53	5.68	-	1,96
October	24.6	65	4.74	0,14	0,35
November	24.0	73	5.58	0,88	-
December	23.5	76	4.58	1,18	-

**Climatological average (1961-1990)*

In this latitude, the North facade is exposed to winter insolation. For this reason, it should be well protected from solar radiation and should have a reduced glass surface (Fernandes 2006). The south facade can have a wider glass surface, but still requires solar protections in summer period, when solar radiation can reach it. Along all the year, the roof is the part of the building which receives the highest solar radiation (Tab.1).

2.2 Bioclimatic strategies

According to this climate conditions, the thermal comfort is achieved during 27.4% of the year (Fig. 1). The rest of the year, the recommended bioclimatic strategies are:

- Solar heating (15% of the year).
- Thermal inertia for heating (13.4% of the year).
- Ventilation (13.8% of the year).
- Night ventilation (10.1% of the year).
- Thermal inertia for cooling (10.1% of the year).
- Evaporative cooling (10.1% of the year).

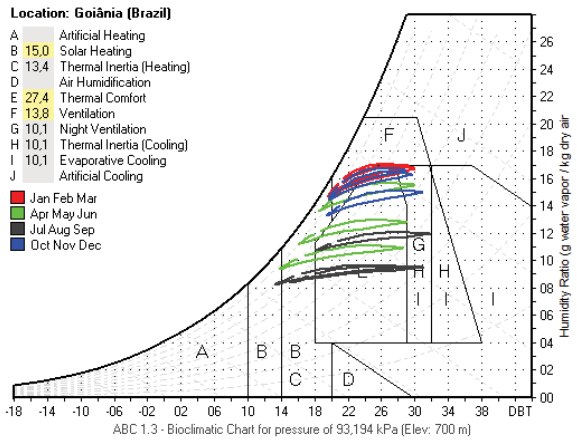

Fig. 1: Architectural bioclimatic classification according to psychometric abacus. Source: Roriz (1992).

The bioclimatic strategies for tropical climate are identified, selected, and applied to the building model. They are presented in Tab. 2.

Tab. 2: Bioclimatic strategies for tropical climate, based on Manzano-Agugliaro et al. (2015).

Bioclimatic strategy	Temperature	Relative Humidity	Operation	Architectural implementation
1. Solar protection	>20ºC	-	Avoiding heat gains through solar radiation. Avoiding temperature increases to remain in the comfort zone. Protection is focused on all building openings but can also be generally applied to the building envelope.	• Pergolas with deciduous vegetation • Porches • Awnings • Interior store • Exterior (sunblind) blinds • Exterior brise soleils.
2. Cooling through a high thermal mass	20-35 °C	-	The thermal mass of the building envelope that receives and subsequently transmits radiation to the interior with a phase difference to achieve climate uniformity throughout the day.	• Capacitive materials help to create a phase difference in the daily energy transmission and temper the intensity. Nocturnal dissipation by the facade and roof is necessary. • It is ideal to place a mobile daytime protection device to avoid gains and promote nocturnal dissipation
	From 24 ° C	80–50%		
	Up to 35 °C	30%		
3. Cooling by high thermal mass with nocturnal renovation	20 °C- 44 °C	-	Creating a phase difference between the effect of the daytime and night time outside temperatures to conduct a nocturnal renovation It is effective when the climate exhibits significant thermal differences between the day and night periods.	• The building envelope should comprise capacitive materials that transmit energy with the largest phase difference possible (approximately 12 h) with some damping. • At night, dissipation and renovation should be conducted through openings, patios and roofs.
	44 °C	5%		
	31.5 °C	32%		
	24 °C	80%		
4. Cooling through natural ventilation	20 °C - 31.5 °C	95% - 20%	A greater thermal sensation is achieved while the indoor air is simultaneously cleaned.	• Cross-ventilation from north to south facades or dominant winds • The chimney effect • A solar chamber • Subterranean ventilation • Wind towers • Evaporative towers • Vertical spaces within a building • Patios
	From 31.5 °C	50%		
	Up to 26.5 °C	95%		
5. Conventional dehumidification	> 25 °C	> 80%	The objective is to incorporate strategies to absorb water from the environment in order to achieve the comfort zone.	By using absorbent salts and saline cells and requires complementation with other strategies.
6. Thermal insulation in the roof	-	-	Avoid heat gains from solar radiation (perpendicular to the roof in tropical latitude)	Incorporation of thermal insulation in the roof.

3. Building design

This research is part of an initiative that aims to build a prototype with the NZEB concept, named Model House. This building will be used to realize experimental researches about thermal comfort and energy efficiency. In this paper energy simulations will be carried out to quantify and compare the benefits of the proposed bioclimatic strategies and to improve the building design. Once built, the building will be monitored to validate experimentally the simulation results.

The Model House is designed according to bioclimatic criteria, based on the tropical climate conditions and latitude. These criteria take into consideration the optimum shape factor in plan and volume, window size, surface façade and roof color, solar protection, and indoor natural daylighting (Fig. 2).

Moreover, the building is designed for meeting both requirements; experimental research and office use. For this reason, the building has two identical office rooms; the first one will be the reference case, and the second one the case of study. Both rooms share a common patio. This patio has local vegetation ("Cerrado") and a fountain to generate shadow and evaporative cooling. The mobile facades allow the connection of the offices to the patio, depending on the experiment.

According to Olgyay (1963), the optimum shape in plan of a building in tropical climate is 1:1.7, with a range to 1:3. Therefore, the shape plan 1:2 of the designed office space is between this range.

The net floor area of each office is 32.80 m^2 (8.20 m x 4.00 m). The interior height is 2.70 m. The building facilities (toilette, kitchen and storage) are located separately, in the east and west part of the building.

The roof is designed for projecting shadow over the building. This double roof protects the building from temperature variations due to solar radiation.

The east and west facades are highly insulated. The north and south facades are removable to make possible the change of experiments. Prefabricated construction systems are used to make possible the removal of materials.

Windows are the 30% of the total facade, according to Rizki et al. (2016), who determined three optimum solutions of window size, orientation and wall reflectance with regard to various daylight metrics and lighting energy demand in simple buildings placed in the tropical climate. They determined that the most optimum solution is the combination of window-to-wall ratio 30%, wall reflectance of 0.8, and south orientation (in the North hemisphere).

Fig. 2: General view of the Model House, a building designed with bioclimatic principles for experimental purposes in tropical climate.

The building also meets the Brazilian habitability and construction regulations (NBR 9050/2004, NBR 15220/2003, NBR 15575/2013). According to these regulations (ABNT NBR 15220-3), the maximum overall heat transfer coefficient (or U-value) for facades is 2.2 $W/m^2 \cdot K$, for the roof is 2.0 $W/m^2 \cdot K$. The physical characteristics of the materials used are shown in Tab. 3. The U-values are calculated for each construction system, according to their construction materials.

Tab. 3: Physical characteristics of the materials used in the building envelope.

Part of the building	Construction system	U-value [W m^{-2} K^{-1}]	Material	Thickness [cm]
Roof	Insulated roof	0.441<2.0	Gravel	6

**Used in the four facades in experiment #3.*

The space type for both offices is defined by regulation EN 16798, as well as the occupancy schedule. This means that it is stablished 17 m^2/person, or 2 people in each office space. The occupancy will be distributed from 8-12 AM and 1-7 PM.

No heating or cooling device is simulated, only free floating temperatures, because bioclimatic strategies are evaluated.

4. Energy simulation experiments

The thermal behavior of the Model House is simulated before its construction. This simulation is done with Energyplus software, by using Opens Studio (Fig. 3). The simulation results will be validated with the monitoring of temperature, humidity, and air flow in the constructed building. The experiments will take place under hot and humid, and hot and dry weather conditions for the tropical climate. The experiments held in the building model are:

- **Solar protection:** Comparison of a window with solar protection (horizontal brise soleils) versus a window with no solar protection (Fig. 3).
- **Cooling through a high thermal mass:** Comparison of two different materials in the facade; high thermal mass (concrete panel) versus low thermal mass material (ceramic brick), and different wall resistance (Tab. 3).
- **Cooling through a high thermal mass with nocturnal renovation**: Comparison of the use of night ventilation and no ventilation, with concrete panel in the four facades (Tab. 3).
- **Cooling through natural ventilation:** The effect of ventilation in the thermal comfort, comparing a ventilated office by using infiltrations through the window area (4 renovations per hour) and a no ventilated office.
- **Conventional dehumidification:** The use of absorbent salts for decreasing the humidity of the air of the test office (simulated by using a HVAC Dehumidifier) compared to a non-dehumidified office.
- **Thermal insulation in the roof** (Fig. 3): Comparison of the effect of thermal insulation in the roof without solar protection, comparing a roof with and without insulation (Tab. 3).

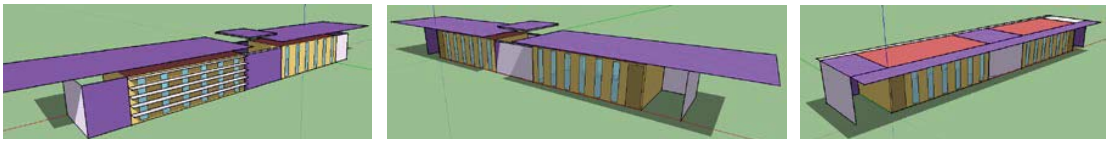

Fig. 3: Views of the office building (Model House) energy simulation done with SketchUp and Open Studio. From left to right: Solar protections, Cooling through natural ventilation, Thermal insulation in the roof.

Because of the latitude, the North facade receives solar radiation mainly in the winter season (Tab. 1). For this reason, the experiment #1 “Solar protections” will be done during solstice of June.

June is the month with wider thermal lag, reaching the coolest temperatures of the year during the night (Tab. 1). For this reason, winter solstice (the week around June 21st) is the selected period for the experiment #2 “Cooling by high thermal”.

The same experiment will be done with and without nocturnal renovation #3 “Cooling through a high thermal mass with nocturnal renovation”. Previous simulation with AnalisisBio (Albano 2013), points out this month as the optimum to reach the Nearly Zero Energy consumption.

The experiment #4 “Cooling through natural ventilation” will be done in both, dry and wet season. For this reason, the driest month, September, and the more humid month, December, are selected (Tab. 1).

December is the month with higher requirements of thermal comfort, due to the high relative humidity combined with the high air temperature (Tab. 1). This discomfort can be corrected by using natural ventilation (Albano 2016). It is in December, during the wet season, when will be done the experiment #5 “Conventional dehumidification”.

Finally, the experiment #6 “Thermal insulation in the roof” will be done during both solstices and the equinox in September, to test the differences in solar radiation along the key moments of the year (Tab. 4).

Tab. 4: Experimentation cases and timing.

Bioclimatic strategy to be tested	Reference Case A	Evaluated Case B	Period of time of the experiment
1. Solar protection in the north facade	No solar protection	Brise-soleils	14th – 28th June
2. Cooling through a high thermal mass	Ceramic brick	Concrete facade	14th – 28th June
3. Cooling by high thermal mass with nocturnal renovation	No nocturnal ventilation	Nocturnal ventilation	14th – 28th June
4. Cooling through natural ventilation 4.1. Dry season 4.2. Wet season	No Ventilation	All day ventilation	• Dry season: 1st-15th September. • Wet season: 14th – 28th December
5. Conventional dehumidification	No dehumidification	HVAC Dehumidifier	14th – 28th December
6. Thermal insulation in the roof 6.1. Solstice in June 6.2. Solstice in December 6.3. Equinox in September	No insulation	Insulation	14th – 28th June 14th – 28th December 14th – 28th September

5. Results

The thermal behavior of each office is evaluated by using the number of hours of discomfort in the office per the period of the experiment. Fig. 4 shows the "Time Not Comfortable" based on the ASHRAE Standard 55 Adaptive Comfort model, within the 80% acceptability limits. The ASHRAE Standard 55 Adaptive model is especially suited for naturally ventilated buildings with no mechanical cooling systems, and occupants have better control over their thermal comfort. More details about the requirements and features of the method are explained elsewhere (ASHRAE 2010). For the dehumidification case 5, the Fanger's Comfort model has been used instead, to be able to consider the effect of humidity on human comfort. The results are presented for the period of 2 weeks, during the time of occupation.

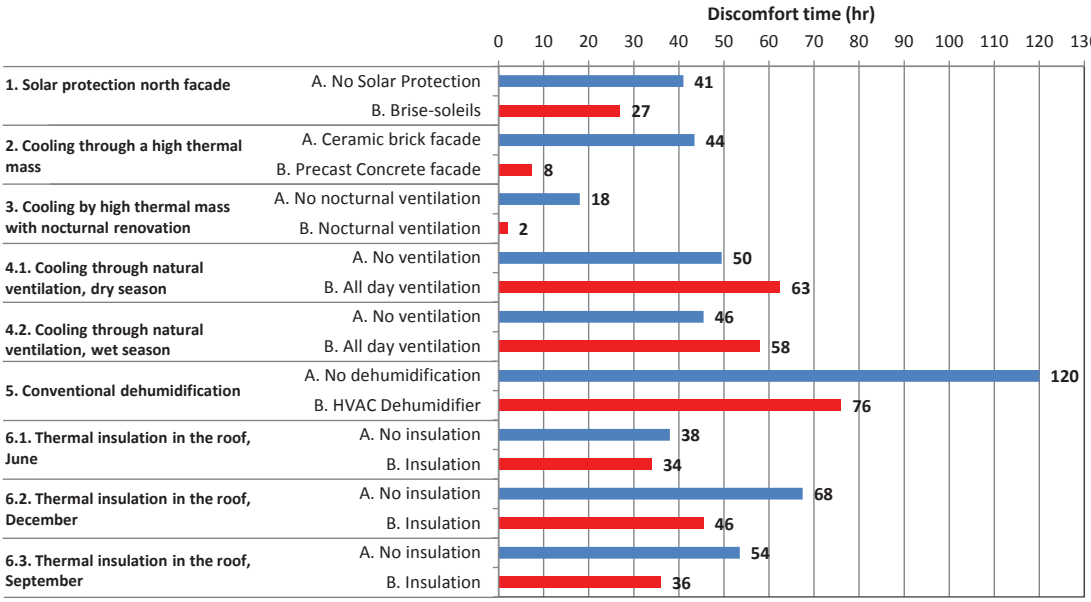

Fig. 4: Time Not Meeting the ASHRAE55 Adaptive Comfort Model with 80% Acceptability Limits during Occupied Hours. Units: hr.

The graphics of temperature, humidity, occupation, and air change rate for the selected period and each experiment are presented in Fig. 5: Outdoor temperature (black), indoor temperature in reference office (dark blue), test office (light blue), and occupation or ACH (pink dotted lines).

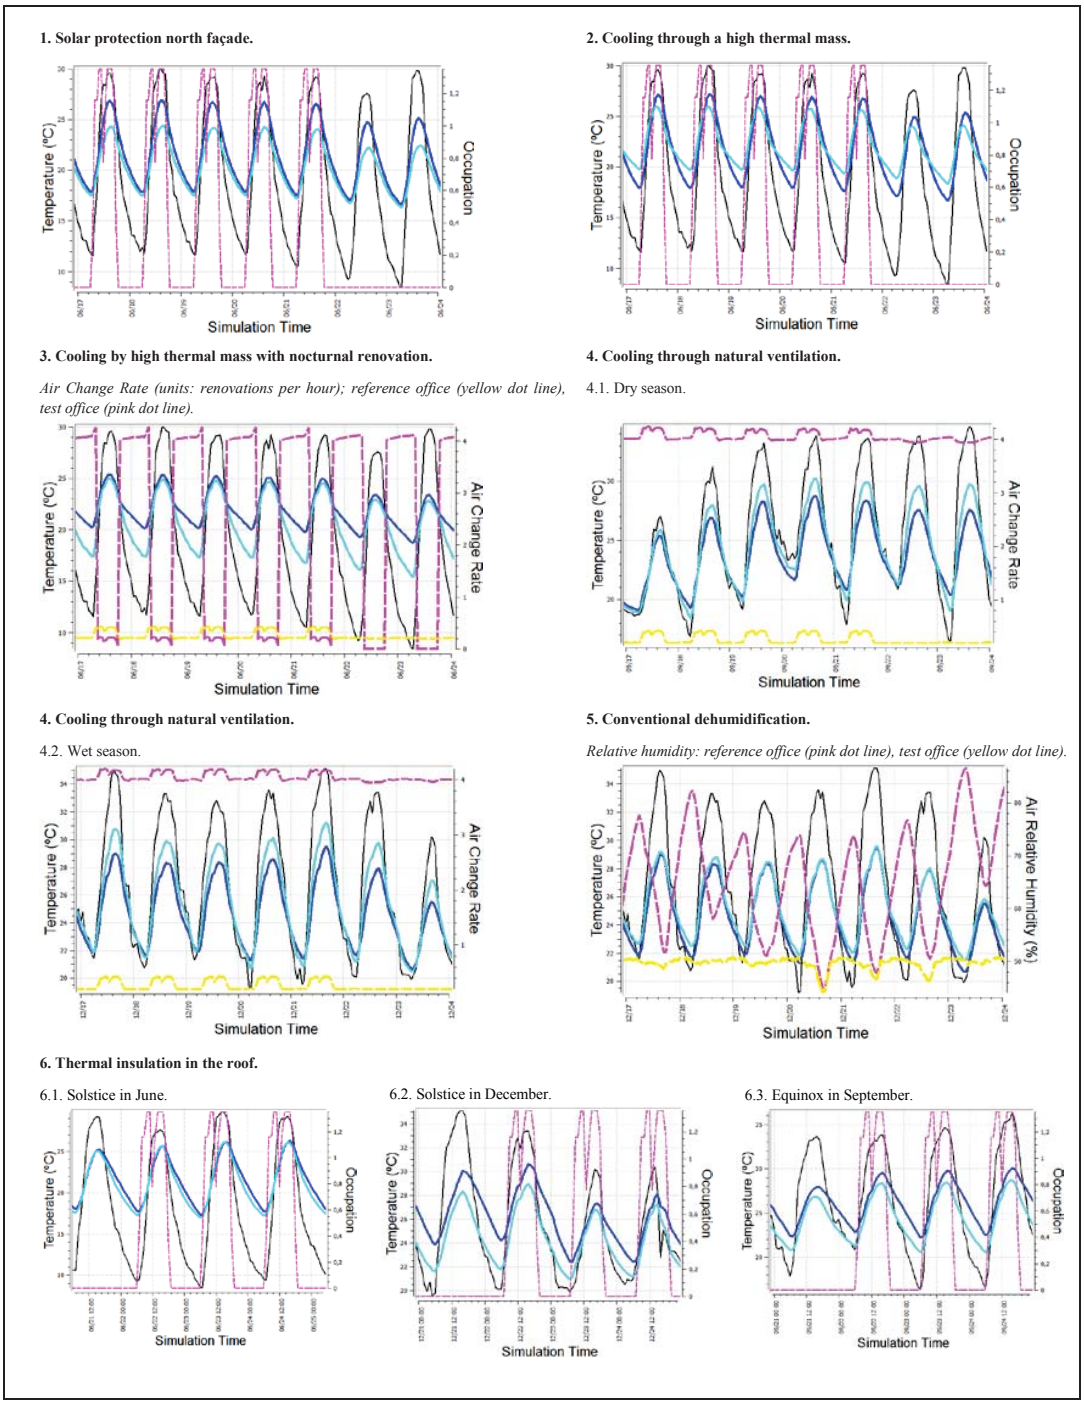

Fig. 5: Results for each experiment in the selected period: outdoor temperature (black line), reference office (dark blue line), test office (light blue line), occupation or Air Changes Rate (pink dot line).

6. Discussion

The more significant improvement performances were found in the following strategies:

- 1st: Cooling by high thermal mass with nocturnal renovation: 89% improvement.
- 2nd: Cooling through a high thermal mass: 83% improvement.
- 3rd: Solar protection on the north facade: 34% improvement (and even better, 52%, if we take the

90% acceptability limits.

- 4th: Thermal insulation in the roof during the Solstice of December and the Equinox of September: 33% improvement.

The implementation of materials with high thermal mass on the facade, such as the precast concrete panel, provided a more stable inner temperature in the office compared to the brick facade, despite the lower thermal transmittance of the concrete panel (Tab. 3). In the 2nd experiment, the thermal amplitude in the test office was 3 ºC lower than the reference office, reaching a maximum indoor air temperature between 1 ºC and 1.5 º lower than the reference office (Fig. 5). This temperature, together with the radiant mean temperature, yielded comfort conditions in most of the hours of occupation.

Night ventilation can help to decrease the day maximum air temperatures as long as there is high thermal mass in the building. In the 3rd experiment, a higher thermal mass was incorporated in the building by constructing the 4 facades with precast concrete panel. In this case, night ventilation was added. As a result, the maximum temperature was 1 ºC lower in the test office compared to the reference office. The minimum air temperature in the ventilated office decreased substantially during the night, a period with no occupation.

All day ventilation provided more hours of discomfort to the test office because it allowed the inlet of warm air from the hottest moment of the day. In both cases, dry hot and wet hot weather, the discomfort time in the ventilated office was around 26% higher than in the not ventilated office (Fig. 4). The maximum temperature in the ventilated office was around 2 ºC higher than in the non-ventilated office (experiments #4.1 and #4.2 in Fig. 5).

The use of horizontal brise soleils on the north facade was found to be an effective solar protection. The solar protection improved the temperature comfort during the afternoon, period with the maximum occupation. The maximum temperatures in the test office were 3 ºC lower than in the reference office (experiment #1, Fig. 5).

The incorporation of 12 cm of XPS in the roof, provided a significant improvement in the thermal comfort during the Solstice of December and the Equinox of September, when the solar radiation is more perpendicular to the roof, in tropical latitude (Tab. 1). In December, the maximum day temperature was around 2 ºC lower in the insulated roof office than in the non-insulated roof one.

The presence of a dehumidifier in the building simulation, maintaining the relative humidity below 50%, increases slightly the night minimum air temperatures (0.5 ºC), but helps achieving a 37% increase in thermal comfort hours, according to the Fanger's Comfort model, which takes into account, among others, the effect of the relative humidity in human comfort.

7. Conclusions

The use of passive systems in tropical climate contributes to reduce the discomfort time of buildings, in both wet and dry hot climate conditions. A combination between high thermal inertia with nocturnal ventilation, the use of solar protections on the north facade, dehumidification, and the use of thermal insulation in the roof is fundamental for achieving the thermal comfort in buildings located in tropical weather. However, the use of natural ventilation in the office has to be limited to the night, when it is effective due to the outdoor lower temperatures, but not to all the day. Daily crossed ventilation produce the increase of the maximum day temperatures in the office. For this reason, crossed ventilation can be only recommended when outdoor temperatures are below the maximum comfort temperature.

The implementation of these passive systems depends on the early stages of the design building process. This requires the knowledge of the architect and designers on bioclimatic strategies and passive systems. Technicians and designers need firstly to do a deep analysis of the climate and micro-climate conditions of the building site. Therefore, Nearly Zero Energy Buildings would require the implementation of passive systems in the design phase of new and renovated buildings and the spread of passive systems knowledge among technicians.

Quality management as a key for efficient building performance

Oliver Rosebrock, Franziska Bockelmann and Univ. Prof. Dr.-Ing. M. Norbert Fisch

Institut für Gebäude- und Solartechnik, TU Braunschweig, Mühlenpfordtstraße 23, 38106 Braunschweig, Germany

Abstract

The use of complex building services opens up many possibilities to gain an increase of energy efficiency in buildings. On the other hand there are also threats that ecologically and economically planned energy concepts for buildings do not work as proposed. To reduce this risk a procedure was developed, based on so-called "active functional specifications". It covers the time span from planning phase up to building operation and allows, by running a digital test to verify whether the building services work as planned and whether the building's owner received what he has ordered.

In this paper the procedure is explained and results for an energy plus multi-family home are shown. The building's energy supply is based on electricity only. A heat pump using an ice storage and solar thermal collectors as heat source provides the energy for heating and domestic hot water.

Keywords: *quality management, building services, test stand, monitoring, energy efficiency*

1. Introduction

The application of complex building services with integrated measurement technology holds the prospect of grand increase in energy efficiency. Securing the actual utilization of these potentials in the building's operation is therefore becoming a significant challenge. Discrepancies between energy demand and consumption can turn economical concepts originating from the planning phase into cost-pushers in operation.

Past research projects and experiences from building service operation show the importance of quality management for reaching the desired efficiency and complying with energetic specifications, stipulated in the planning, in practical application. One of the principal problems is based on the non-standardized specification of the systems' functionalities.

"Active functional specifications" (AFS) present an innovative technique for effective and economical quality management. The definition and review of system functions is executed in the form of so called operating rules, e.g. for mass flows or powers, on a digital test bench. These rules must be fulfilled during operation. They therefore can be used as setpoint states for the construction and are being monitored during operation.

Within the frame of the research project "Effizienzhaus Plus, FFM Riedberg – EnergiePLUS im Geschosswohnungsbau" the ordinary energetic monitoring is supplemented by the newly developed method for assuring quality – the "active functional specifications". The research project is part of the research initiative "Zukunft Bau" funded by the BBSR.

2. Multi-family house Riedberg

A multi-family house (MFH) with 17 accommodation units from two to five rooms is located in Frankfurt am Main in the district of Riedberg. It has four full stories and an attic floor (Fig. 1). The building is in use since August 2015. The standard of "Effizienzhaus Plus" is to be achieved with the help of a high-quality thermal building shell and optimal utilization of renewable energies.

The "Effizienzhaus Plus" standard demands that both the building's primary and end energy production exceed the consumption in the annual balance. In contradiction to the EnEV certificate the users' electricity consumption is also included into the balance.

The essential building characteristics are summed up in Tab. 1.

Fig. 1: Front view multi-family house Riedberg (source: egs-plan)

Tab. 1: Characteristics of the building in Riedberg

Year of construction	2015
Living area	1.600 m²
Number of accommodation units	17
Heated building volume	8.517 m³
Heated usable floor area A_N	2.407 m²
Annual heating energy demand	19 kWh/(m²$_{A_N}$a)
End energy demand electricity incl. household	25 kWh/(m²$_{A_N}$a)
Electricity production through photovoltaics	36 kWh/(m²$_{A_N}$a)
Electricity surplus (annual balance)	ca. 25.000 kWh/a

3. Energy concept

The MFH in Riedberg is an "electricity only building", meaning all energetic processes are driven by electricity.

The heat demand is supplied solely by an electrical brine/water heat pump with a thermal power of 50 kW. The building contains two distribution grids – a low-temperature grid of approximately 35 °C and a high-temperature grid of about 55 °C. The low-temperature grid serves the floor heating. The high-temperature grid is connected to the heating unit of the ventilation system, the bathroom radiators, and the preheating of the hot water in the fresh water stations of each flat. The additional heating of the hot water within the flats is realized electrically, too.

The building is ventilated mechanically. A heat recovery to reduce ventilation losses is implemented. Additional natural ventilation by opening of the windows is also possible.

The heat pump has two different heat sources, an earth-bound ice storage and solar thermal absorbers.

The solar thermal absorbers (11 modules, ca. 85 m²), which are located on the roof underneath PV panels, are used primarily to provide low-temperature environmental heat for the heat pump.

Additionally, an earth-bound ice storage of 98 m³ serves as an innovative heat source for the heat pump. The ice-storage uses the melting enthalpy (latent heat) of the phase change von liquid (water) to solid (ice). The latent heat per kg is nearly the same as the sensible heat provided by a temperature change of 80 K of a kg of water. When the amount of heat by the solar thermal absorbers is not sufficient, the heat source for the heat pump changes to the ice storage. The water in the storage cools down to 0°C and starts to freeze due to the heat extraction.

To maintain the functionality of the system the ice storage has to be regenerated, i.e. melting and heating up the water. The regeneration is done with natural heat from the surrounding soil and with the solar thermal absorbers when no heat is needed in the building and the temperature provided by the absorbers is higher than the temperature in the ice storage. The third option for regeneration of the ice storage is cooling of the building in summer.

The building is equipped with a cooling system. The floor heating system can be used for cooling in summer. The system works with free cooling and the ice storage is the heat sink, i.e. it provides the cooling energy.

PV modules on the roof (ca. 84 kW_p) and in the façade (ca. 15 kW_p) are planned to achieve a surplus of energy in the annual balance. The annual production of electricity exceeds the total electricity demand by approximately 40 % (ca. 25.000 kWh/a). The surplus is to be used for e-mobility. In addition to the electrical cars, a lithium-iron-phosphate battery (60 kWh) is used to increase the self-consumption of the produced electricity (Fig. 2).

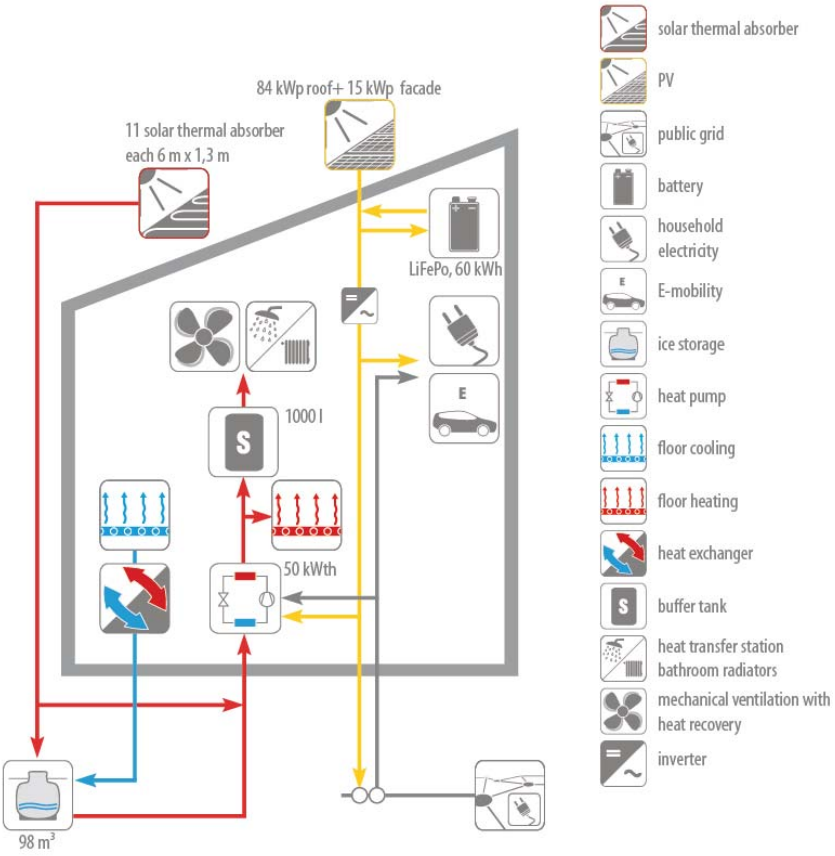

Fig. 2: energy concept multi-family house Riedberg

4. Active functional specifications

Within the scope of the active functional specifications operating modes and corresponding functions are already defined during the planning. These specifications, so called operation rules e.g. temperatures or valve positions, need to be fulfilled in the respecting operating mode.

Based on a simplified scheme the operating modes are being defined. Examples for different operating modes, rules, and definitions are presented in this paper. They are excerpts from the complex monitoring process.

The operating modes and rules are:

Operating mode BZ0 – OFF

All circulation pumps and the heat pump are inactive. All mass flows in the heat meters are equal to zero. The electrical power does not exceed standby needs.

Operating mode BZ1 – heating with heat pump - source ice storage

The heat pump (WP) is active due to a demand signal from the high- or low-temperature grid. The ice storage (ESp) serves the heat. The solar thermal absorber is inactive. The heat pump must be active for the correct operating mode 1. Heat meters WMZ3 and WMZ4 need to register mass flows, while the mass flows in WMZ1 and WMZ2 must be zero (Fig. 3, active circuits are coloured).

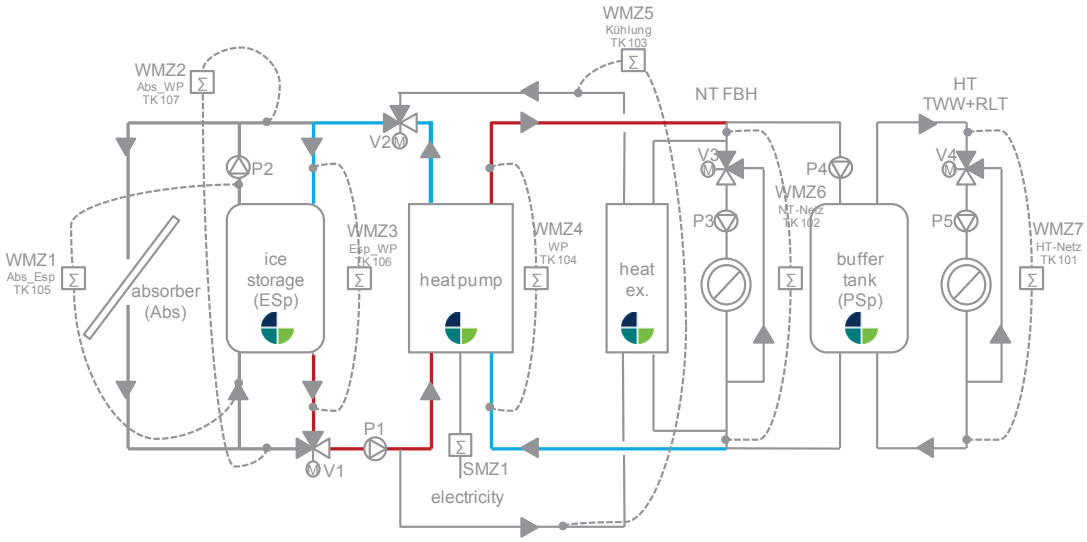

Fig. 3: operating mode BZ1 - source ice storage

Operating mode BZ2 – heating with heat pump - source absorber

In operating mode 2 the solar thermal absorber serves as the heat source. The ice storage is neither being charged nor discharged. For the correct execution operating mode 2 the mass flows at WMZ2 und WMZ4 are greater than zero and the heat pump is active (Fig. 4, active circuits are coloured).

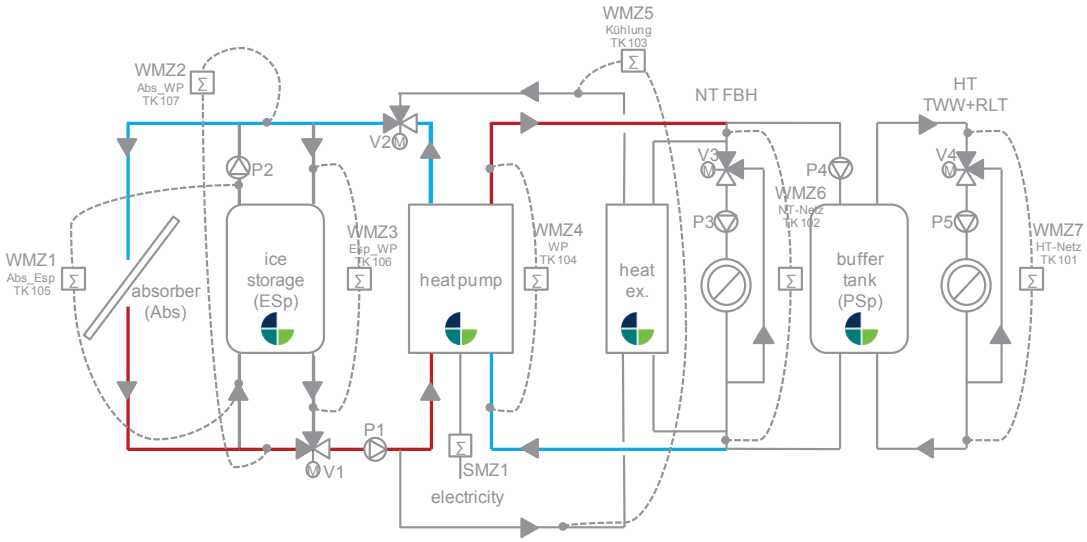

Fig. 4: operating mode BZ2 - source absorber

Operating mode BZ3 – regeneration of the ice storage

While the solar thermal absorber regenerates the ice storage, the WMZ1 must register a mass flow. The activity state of the heat pump can be either one, as it can operate during the ice storage regeneration, but does not need to (Fig. 5, active circuits are coloured).

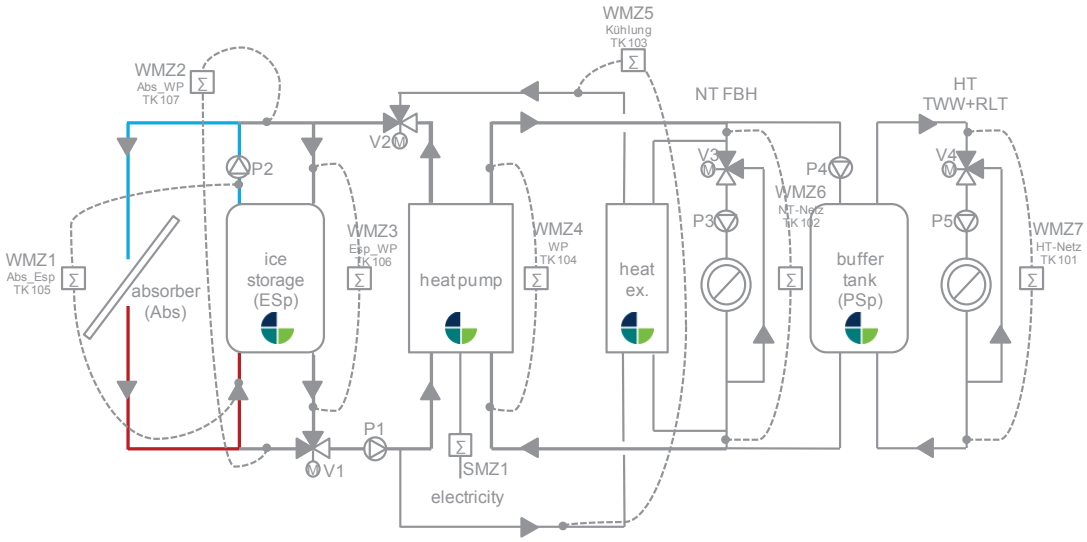

Fig. 5: Operating mode BZ3 – absorber to ice storage

Fig. 6 gives an overview about the operating rules that need to be fulfilled during the four operating modes. With all operating modes and rules defined, the monitoring and evaluation can be executed both during start-up and ordinary operation.

operating rule	BZ0 Off	BZ1 ice storage heat source	BZ2 absorber heat source	BZ3 absorber to ice storage
$\dot{m}_{WMZ1}$	0 kg/h	0 kg/h	0 kg/h	> 0 kg/h
$\dot{m}_{WMZ2}$	0 kg/h	0 kg/h	> 0 kg/h	0 kg/h
$\dot{m}_{WMZ3}$	0 kg/h	> 0 kg/h	0 kg/h	0 kg/h
$\dot{m}_{WMZ4}$	0 kg/h	> 0 kg/h	> 0 kg/h	0 kg/h
E_{SMZ1}	≤ 1,5 kWh	> 1,5 kWh	> 1,5 kWh	-

Fig. 6: overview operating rules

5. Operation and quality control

Only if all operating rules are satisfied, an operating mode (OPM) is being executed correctly. If not all rules are complied with, the operating mode is not active or incorrectly executed. Regulations like a set-point temperature comparison for the ice storage can be implemented to determine, whether an operating mode is supposed to be active.

The rate of correctly working OPM is transformed into the operating quality of the system. The operating quality describes the degree of conformity of the planned and the realised system. The automatic import of operating data from the building management system can be implemented to enable an automated control of the operating modes.

Fig. 7 displays the procedure for evaluating the operating quality. The monitoring data is assessed for every time step in the course of the year. The result of the analysis is stored as Boolean value (true/false, upper part of Fig. 7). The numbers of true and false values are compared to the overall number of assessment steps and form the operating quality (lower part of Fig. 7).

On the basis of a minimum ratio of true values the necessary conformity between planned and real operation can be defined.

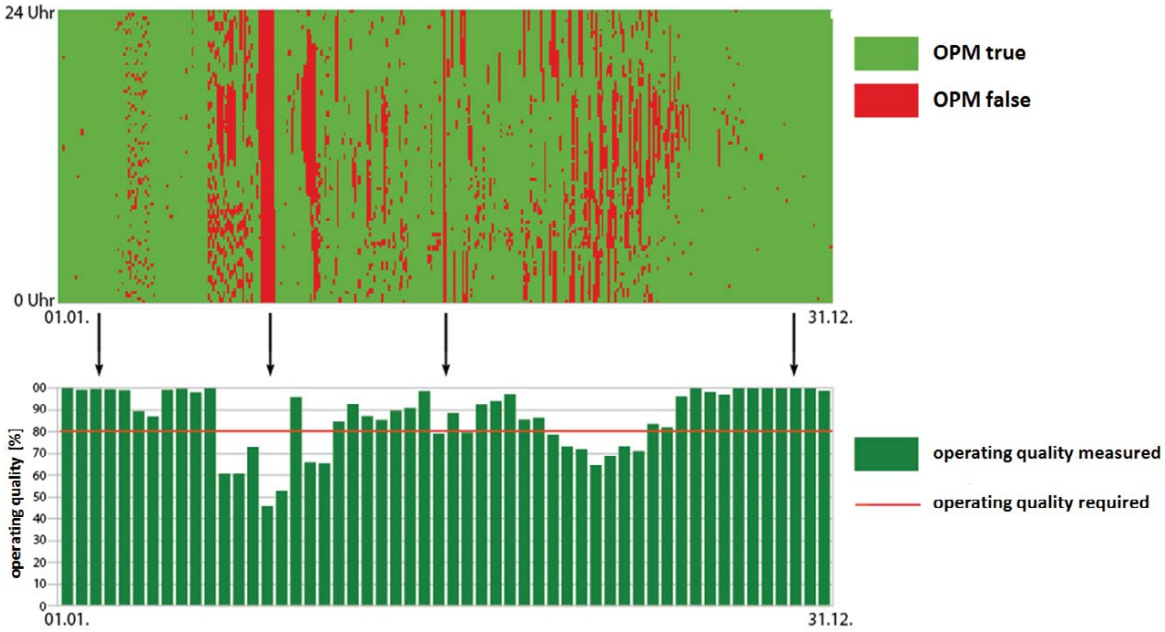

Fig. 7: Operating quality of the system (dummy values)

6. First monitoring results from MFH Riedberg

Measured data from the installed heat meters are available from November 2015 on. The analysis of the active functional specification (Fig. 8) shows that the system has been in OPM 1 (heating from ice storage) for most of the time. It is further visible that planning-conform operation has taken place in the beginning of the monitoring (green dots). From the middle of December on, the planned operation of the heat pump was not met (red dots). Where there is no point, the respective OPM was not active.

The problems in operation related to the heat source are easily visible in the operating quality (Fig. 9).

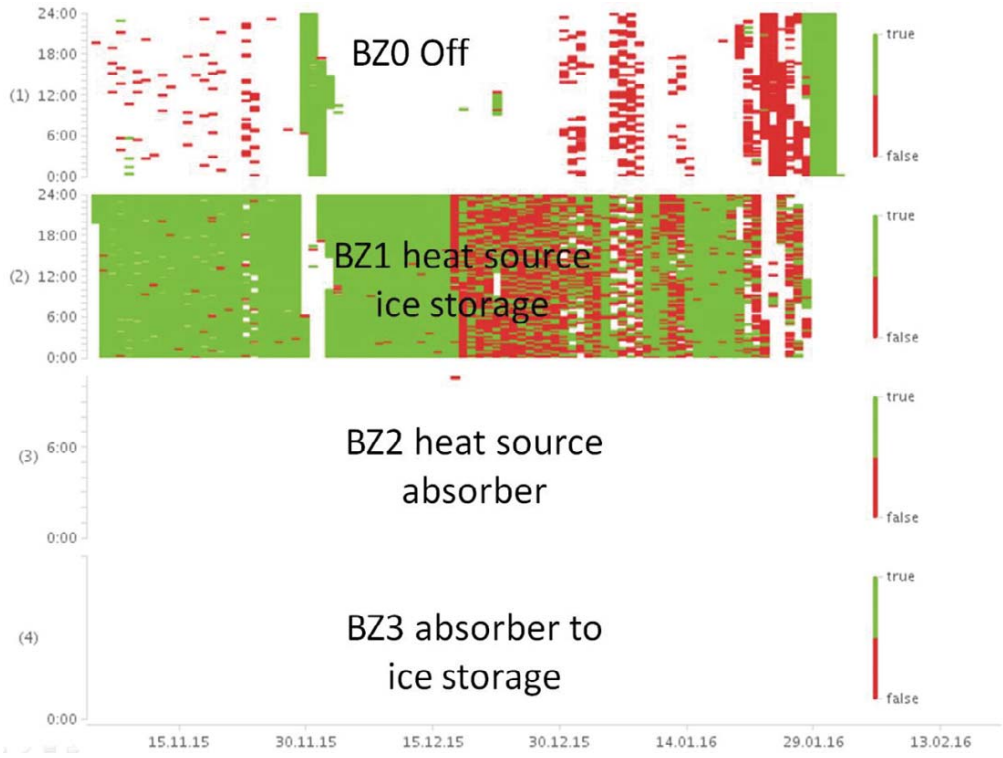

Fig. 8: Evaluation active functional specification - operating modes MFH Riedberg, November 2015 to January 2016

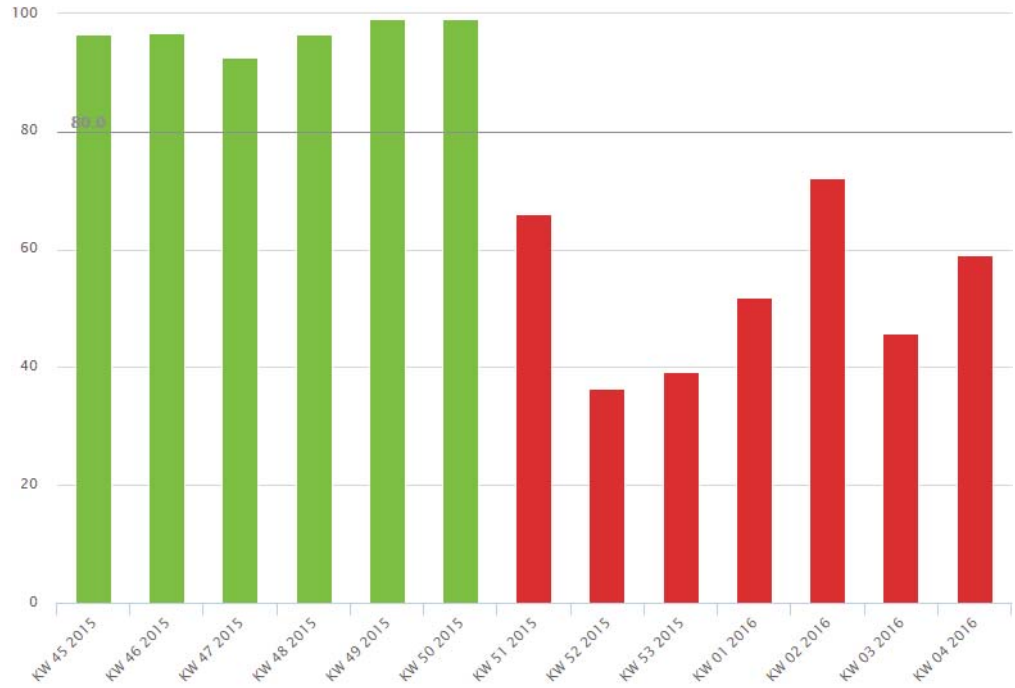

Fig. 9: Evaluation weekly operating quality MFH Riedberg, November 2015 to January 2016

Within the frame of the monitoring the inability of the absorber to deliver thermal power and the optimization need for the hydraulic system, especially regarding the control system, have been detected.

From February 2016 on, the system has been adjusted and altered to solve the problems of the hydraulic system. Among the solutions a buffer storage has been integrated into the low-temperature grid and the controls have been changed accordingly.

In the middle of June 2016 the last changes in the control system have been executed. The assessment of the operating quality shows planning-conformity since then (Fig. 10).

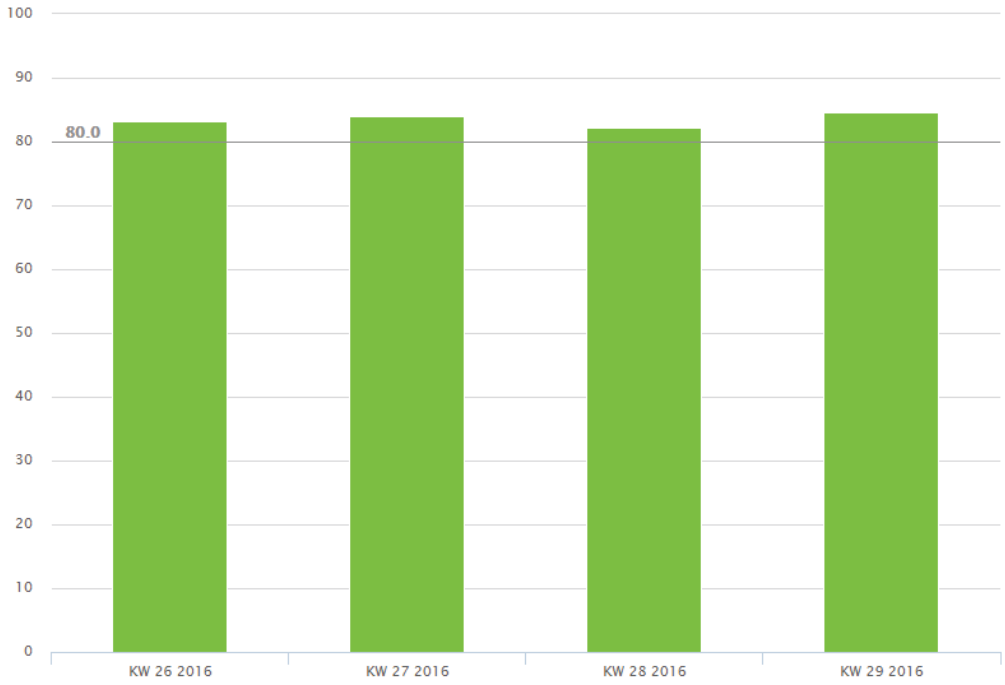

Fig. 10: Evaluation weekly operating quality MFH Riedberg, end of June 2016 end of July 2016

7. Conclusions and outlook

The assessment of the operating quality has made the early and easy detection of operating deviations from the planned design of the system possible. The active functional specification enables the efficient identification of errors. The scope of the detection goes from the broad view to the detail. In the first step the operating quality (Fig. 9) serves as an overview over the accordance to the planning. In case of deviations the operating modes are analyzed in detail. The singular operating rules are being evaluated and the source of trouble identified.

The combination of monitoring and the active functional specification have successfully detected the faulty operation of the heating system (absorber - ice storage - heat pump) and initiated the correction of the system.

First assessments after the reconstruction work show that the system has been in orderly operation since the beginning of the summer 2016. In the further course of the monitoring, the system functions are constantly being scrutinised and optimized.

A full evaluation of the system's performance is not yet possible because system was in irregular operation during the heating period 2015/16.

8. Acknowledgements

The monitoring of the MFH Riedberg is being funded with resources from the research initiative ZukunftBau of the Bundesinstitut für Bau-, Stadt- und Raumforschung (file reference PEH – A3-12 10 01/12.19).

The MFH Riedberg has additionally been included into a field test for the active functional specification (research project GA Spec&Check). Towards a nearly zero-emissions dwelling in Mallorca

Beatriz Rosselló-Batle[1] and Andreu Moià-Pol[1]

1 University of Balearic Islands, Physics department, Mechanical Engineering Area (ME)

Palma de Mallorca (Spain)

Abstract

Concern about climate change and its impact on the environment has become a problem of vital importance nowadays. New regulations have been approved and nearly zero-energy buildings have been defined as a target for the State Members in the European Union (EU). In this study the assessment of a nearly zero-emissions dwelling was shown in the Balearic Islands. The use of a system composed by different renewable energies in the building allowed getting a negative indicator both for primary energy consumption as well as for the CO_2 emissions per year.

Keywords: *Nearly zero-energy buildings, nearly zero-emissions buildings, dwelling, energy consumption, renewable energy.*

1. Introduction

More than 40% of European Union (EU) energy consumption and about 36% of CO_2 emissions comes from the construction sector and services, mainly composed of buildings (Nuij, 2013). New regulations have been approved in order to achieve the Kyoto Protocol compliance. The Energy Performance of Buildings Directive (EPBD) had as final objective the increase of the energy efficiency of buildings in the EU as well as the establishment by Member States of minimum requirements for energy efficiency, periodical inspection of energy systems and the creation of a methodology for the energy certification (The European Parliament and the Council of the European Union, 2002). The EPBD recast included the concept of a nearly zero-energy building (NZEB) as a building with a very high energy performance, in which the low amount of energy required should be covered mainly by energy from renewable sources with a very high level of energy efficiency (The European Parliament and the Council of the European Union, 2010). The Directive established all new buildings to be nearly zero-energy buildings before 2021, and two years earlier in the case of public buildings.

Ferrante and Cascella (2011) presented a study based on the design of a prototype dwelling in Italy. The authors highlighted the fact that zero balance both for energy and CO_2 emissions could be easily obtained in the Mediterranean area. Attia et al. (2012) presented a simulation tool as a support in the design phase of a NZEB in the residential sector in warmer climates. Zeiler and Boxem (2013) assessed the first school designed according to the principles of NZEB in the Netherlands and compared the results obtained with traditional schools. The present study arises from the current need to obtain effective reduction of CO_2 emissions and lower energy consumption patterns. The main objective is to assess the conversion of a conventional dwelling to a nearly zero-emissions dwelling in the Balearic Islands.

2. Methodology

In this study, an assessment to convert a single-family detached house to a nearly zero-emissions dwelling was proposed. For the energy demand assessment the "Unified Tool LIDER-CALENER" (Ministry of Development, 2013) was used. It is one of the official energy certification tools in Spain, and it comes from the unification of the tools LIDER and CALENER (already used in Spain previously) in the same platform. This tool includes a graphical interface for a 3D representation of the building and performs an hourly simulation

Selection and/or peer review under responsibility of Scientific Committee

considering a transitional regime, taking into account thermal coupling between adjacent zones and thermal inertia (Instituto para la Diversificación y Ahorro de la Energía (IDAE) y Asociación de Investigación y Cooperación Industrial de Andalucía (AICIA), 2009). The validation of LIDER tool was made through Building Energy Simulation Tests (BESTEST) by the International Energy Agency (IEA) (Instituto para la Diversificación y Ahorro de la Energía (IDAE) y Asociación de Investigación y Cooperación Industrial de Andalucía (AICIA), 2009), where a great number of cases were evaluated under specific conditions and the results were compared with those obtained by other internationally known tools, such as TRNSYS or DOE2. Results were presented in per kWh/m^{2}year (1 kWh=3,6 MJ).

2.1. Case study building

In this study a single-family detached house located in Mallorca with two floors and sloping roofs was used for the assessment. Facades composition is shown in Tab. 1. An image of the building represented in the HU-tool is shown in Fig. 1. The system in the original building was composed by a heat pump air to water (10 kW) for hot water, a heat pump air to water (16 kW) for a multizone water heating system and a direct expansion air conditioning (3 kW) for cooling the living room. As it will be seen in the Results section a new system composed by renewable energies was proposed and evaluated in the building.

Tab. 1: Facades composition in the case study building

Facades composition	U-value (W/(m^{2}K))	Thickness (m)
Cement mortar (1.5 cm)/polyurethane panels (PUR panels) (12 cm)/concrete blocks (24 cm)/plaster(1.5 cm)	0.19	0.39

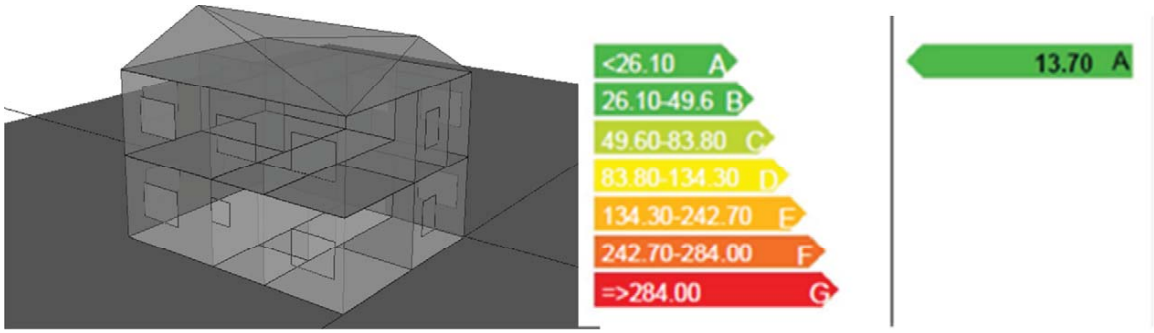

Fig. 1: Case study building represented in the HU-tool

3. Results

In this study a single-family detached house insulated with 12 cm of polyurethane panels and sloping roofs was used as a base case. Final thermal energy demand values obtained for the building were -12,97 kWh/m^{2}year for heating and 14,31 kWh/m^{2}year for cooling, under the limit established by the Spanish Building Technical Code for the Balearic Islands (15 kWh/m^{2}year). Heating and cooling energy demands per month are shown in Fig. 2. Heat losses and gains were evaluated per building component and results are shown in Fig. 3 and Fig. 4.

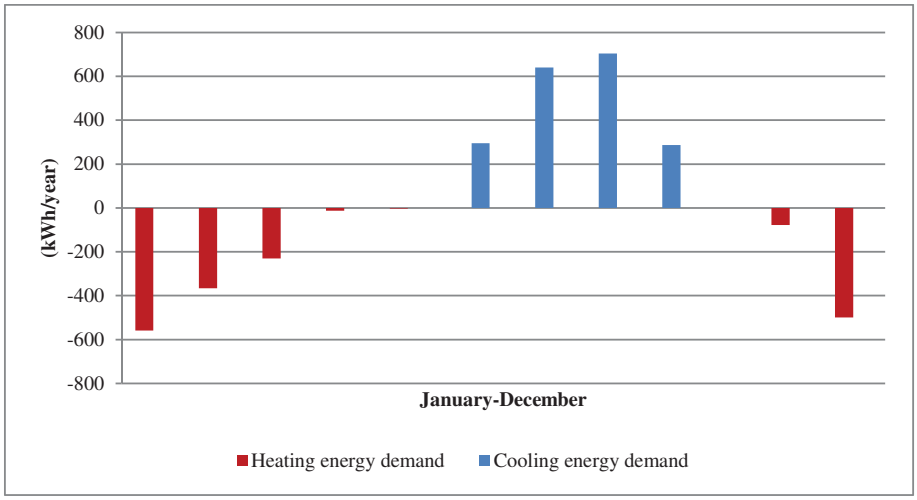

Fig. 2: Heating and cooling energy demands per month

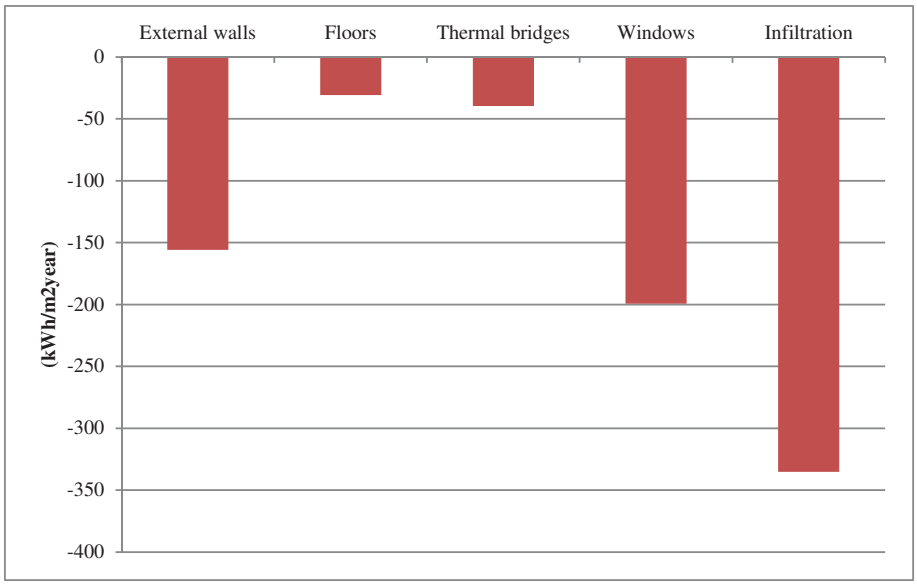

Fig. 3: Heat losses per building component

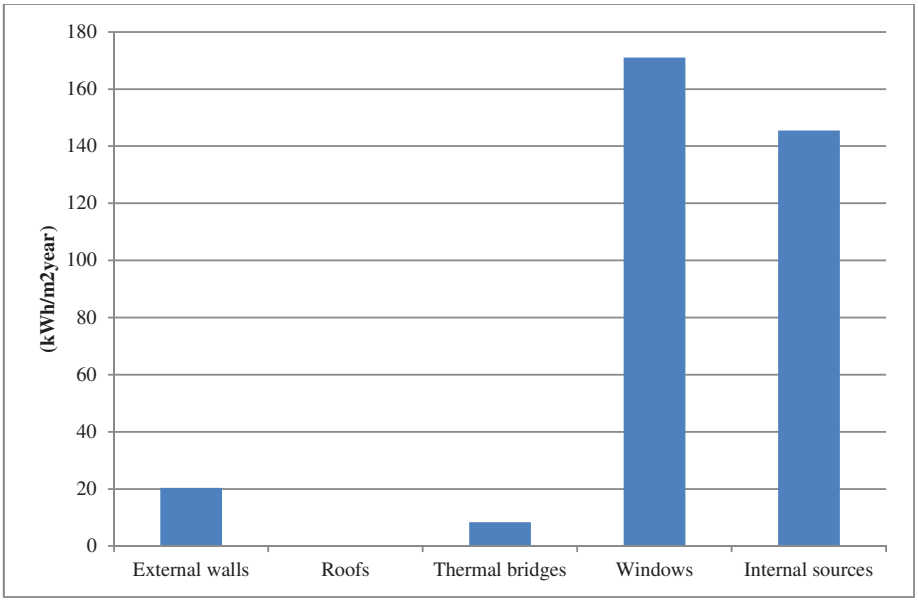

Fig. 2: Heat gains per building component

The results obtained for the base case taking into account the initial energy system of the building were 13,7 $kgCO_2/m^2year$ for the CO_2 emitted and a value of 46,8 kWh/m^2year for the non-renewable primary energy consumption. Specific primary energy consumptions for heating, cooling and hot water and specific CO_2 emissions are shown in Fig. 6.

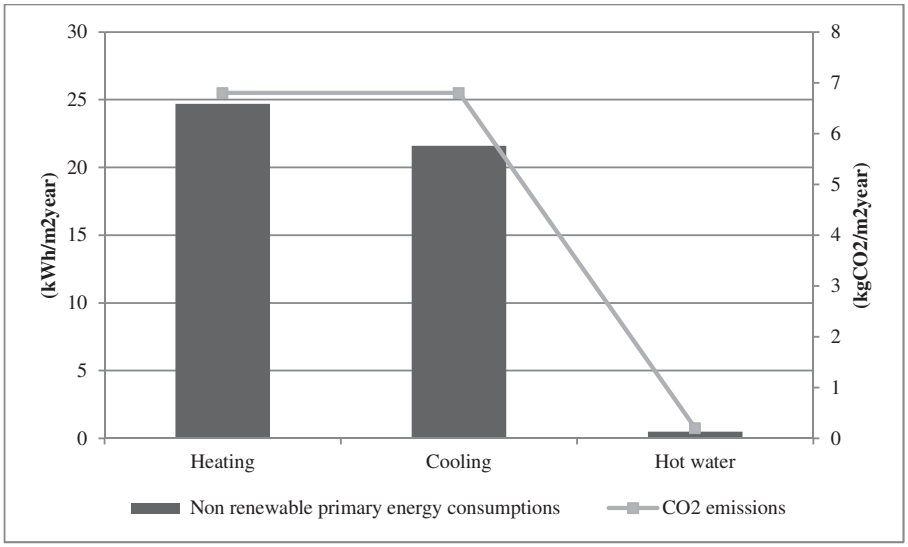

Fig. 6: Non renewable primary energy consumptions and CO_2 emissions for heating, cooling and hot water with the initial energy system

The alternative system proposed for the building was composed by a condensing biomass boiler (10 kW) and a solar water heating (SWH) covering the 95% of demand for hot water, a condensing biomass boiler (20 kW) for heating, a direct expansion air conditioning (3 kW) for cooling a single zone and a photovoltaic installation (1500 kWh/year). An indicator of -1,42 $kgCO_2/m^2year$ for the CO_2 emitted and a value of -1,12 kWh/m^2year for the primary energy consumption were obtained using the Unified Tool LIDER-CALENER. Specific primary energy consumptions for heating, cooling and hot water and specific CO_2 emissions are shown in Fig. 7. Self-consumed power is deducted from the global indicator and it is not shown for specific consumptions.

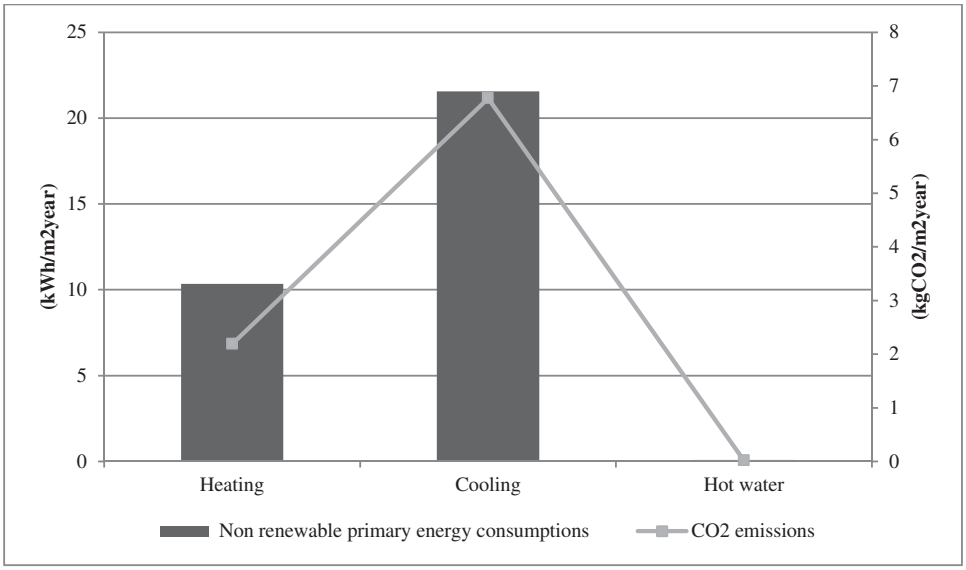

Fig. 7: Non renewable primary energy consumptions and CO_2 emissions for heating, cooling and hot water with the proposed alternative energy system

The label of the house will be A, with a few over cost of the solar thermal system and the PV system, only adding 2 m^2 more to the house and 1 kWp we can have almost zero energy buildings. In Spain the new buildings will be almost zero emissions in 2020, according to the EU law.

4. Conclusions

In this study, the conversion of a single-family detached house to a nearly zero-emissions dwelling was assessed in the Balearic Islands. Final thermal energy demand values obtained for the building were -12,97 kWh/m^2year for heating and 14,31 kWh/m^2year for cooling. It was observed that the greatest heat losses per building component were due to infiltration, windows and external walls. Whereas the greatest heat gains came from windows and internal sources.

The initial energy system for the building was composed by two heat pump air to water and a direct expansion air conditioning for cooling. The results obtained were 13,7 kgCO_2/m^2year for the CO_2 emitted and 46,8 kWh/m^2year for the non-renewable primary energy consumption. An alternative system composed by two biomass boilers, a solar water heating, a direct expansion air conditioning for cooling and a photovoltaic installation was proposed for the building. The results obtained were -1,42 kgCO_2/m^2year for the CO_2 emitted and -1,12 kWh/m^2year for the primary energy consumption.

Switchable Thermal Insulation for increasing energy efficiency of building façades

Constantin Römer[1], Helmut Weinläder[1], Stephan Weismann[1], Stephan Vidi[1] and Johannes Wachtel[1]

[1] Bavarian Center for Applied Energy Research (ZAE Bayern), Würzburg (Germany)

Abstract

A Switchable Thermal Insulation (STI) for using solar energy in winter was developed and evaluated at a test façade. As opposite to STI developed in previous research which was sealed by expensive and thermally inefficient stainless steel sheets, the new device with a switching function based on hydrogen and getter materials was sealed by high barrier foils. The results show a high energy input of about 67 kWh m^{-2} by using solar energy at the façade during one heating period. With a combination of STI and a massive wall the captured solar heat is transported through the façade with a time offset. Thus, nightly inside wall heating is possible.

Keywords: *building façade, switchable thermal insulation, vacuum insulation panel, hydrogen getters, high barrier foil, wall heating*

1. Introduction

Switchable thermal insulations (STI) based on hydrogen and getter materials were researched at ZAE Bayern in the end of the 90s (Horn et al., 2000; Meister et al., 1997). In the context of this research a demonstrator was built, which showed an excellent performance in using solar energy at building façades. During a heating period (October to April) a building energy input of 88 kWh m^{-2} through the demonstrator was reached by using solar energy (Horn, 2001). The demonstrator shell was realized by stainless steel sheets to avoid gas exchange with the environment. The research was continued in the funded project "Enotec" (Ebert et al., 2014). In this context a demonstrator shell was developed based on high barrier foils to reduce the thermal bridge at the demonstrator edges and to lower the costs of the element in contrast to a stainless steel STI.

2. Functional principle

The developed STI affords the opportunity to switch its thermal conductivity between a highly conductive and an insulating state on demand. Therefor a highly heat-insulated function block consisting of a getter material and an electric heater is placed in an evacuated porous insulation layer which is surrounded by a gas barrier such as a metallic shell. In case of the heat-insulating state of the STI the (cold) getter and hydrogen are ligated chemically. Due to the evacuated state of the porous insulation layer the gaseous thermal conductivity is compensated and the thermal conductivity of the insulation layer material dominates the effective thermal conductivity. In this state the thermal insulation is similar to the thermal insulation of a standard vacuum insulation panel (VIP). To get in a highly conductive state the function block is heated to a fixed temperature by low electric power. Thus, hydrogen is released by the getter and distributes in the porous insulation layer. Hydrogen has a high thermal conductivity about $186 \cdot 10^{-3}$ W m^{-1} K^{-1} and causes a significant rise of the effective thermal conductivity (see Figure 1). As shown in Figure 1 the thermal conductivity in the high-conducting state ($\approx 170 \cdot 10^{-3}$ W m^{-1} K^{-1}) is about 40 times higher than that in the insulating state ($\approx 4 \cdot 10^{-3}$ W m^{-1} K^{-1}) due to the increased hydrogen pressure.

doi:10.18086/eurosun.2016.01.04 Available at http://proceedings.ises.org

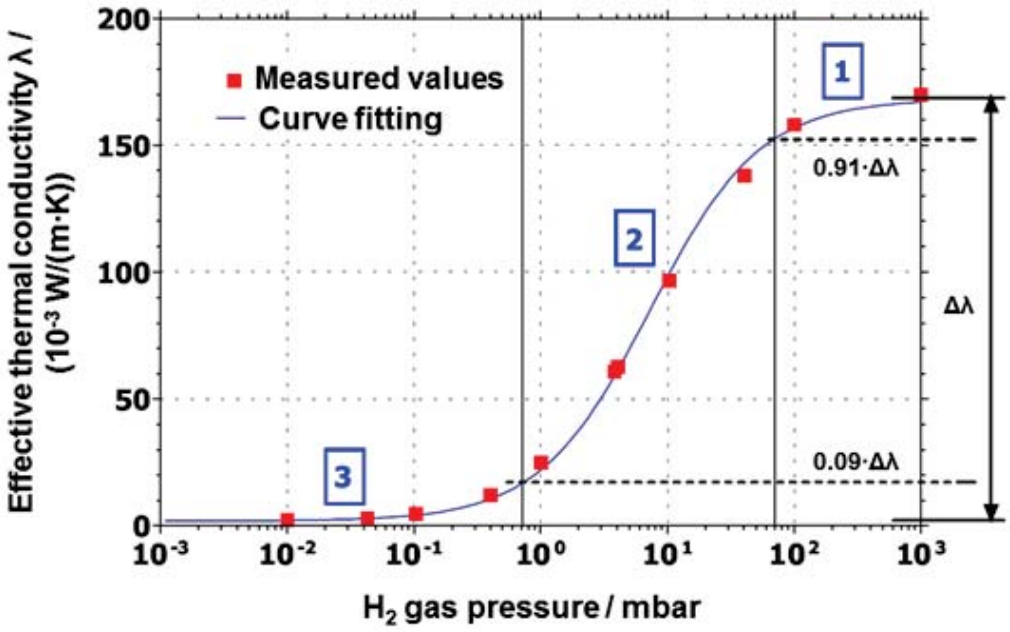

Figure 1: Thermal conductivity for a porous glass fiber system as a function of hydrogen gas pressure (Horn, 2001).

3. Use of solar energy

The STI setup shown in Figure 2 is used for capturing solar energy at the façade during a heating period. For the integrated STI a switching factor of 24.5 between high-conducting and high-insulating state was measured. The sand-lime brick wall behind the STI with a thickness of 0.24 m provides a good thermal storage so that heat is released indoors even during the night or during overcast sky. On the STI a metal sheet was installed to absorb solar radiation on the one hand and to press the STI on the sand-lime brick wall with a metal frame on the other hand. In order to prevent the heated absorber from cooling by outside air convection in winter, a glass panel was installed at a distance of about 40 mm from the absorber and was sealed at the edges. For the heating period 2014/2015 a monitoring of heat flux (inner surface), temperatures and switching states in the STI was initialized.

Figure 2: STI demonstrator with dimensions 80 cm x 50 cm, installed at a massive test façade. Left figure: Real STI demonstrator setup without surrounding insulation and plaster. Right figure: Real STI demonstrator setup after thermal insulating (black coloured) and plastering (white coloured).

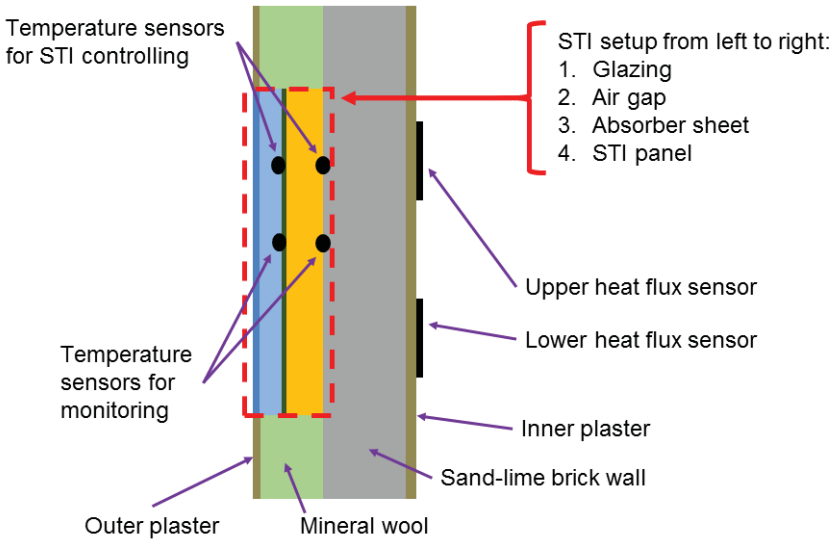

Figure 3: Sketched cross-section of the real STI setup with massive wall and surrounding thermal insulation and plaster.

4. Results

While conventionally insulated façades without STI show a negative energy input (heat losses), the measured heat flux on the test façade resulted in a (positive) energy input of about 67 kWh m^{-2} during the heating period 2014/2015. It should be noted, that the heat flux meters did not sense lateral heat fluxes to the sides, the top and the bottom of the sand-lime brick wall (see figure 3). Thus, the actual energy input probably will be significantly higher. Figure 4 shows this behavior. The one-dimensionally simulated heat flux values represent an ideal behavior of the STI test façade without lateral heat fluxes. For these calculations, a self-developed validated one-dimensional numerical simulation model for heat transfer was applied. The heat equation is therein solved by means of the finite volume method considering the switchability of the STI's thermal conductivity, convection and thermal radiation in the air gap as well as heat conduction (not in air gap), of course.

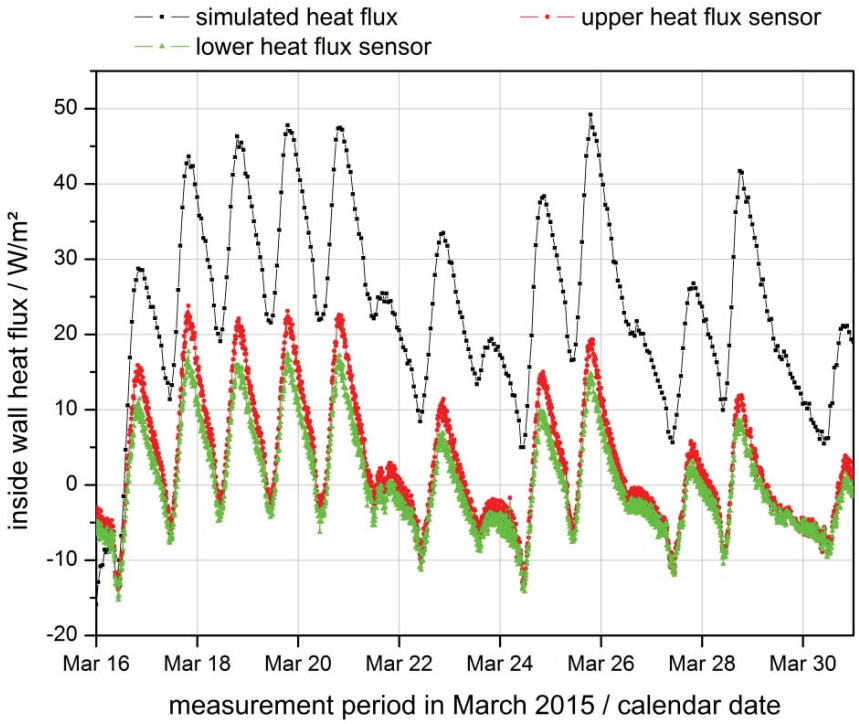

Figure 4: Measured and simulated heat flux of the STI test façade.

Meteorological data such as solar irradiance and air temperature recorded during measurements of the heat flow meters was used as boundary conditions for the simulations. While the simulation data show a very good agreement, regarding the curve progression the measured heat flux is significantly lower. The difference between measured and simulated heat flux mainly is due to already mentioned lateral heat fluxes in the sand-lime brick wall. However, in the one-dimensional simulation model the considered system boundaries are at the edges of the STI setup. Thus, heat is only possible to flow through the area behind the STI setup – in contrast to the real demonstrator setup.

The high thermal capacity of the sand-lime brick wall behind the STI causes a time offset to the heat input into the room. The time offset between absorber temperature peaks and inside wall heat flux peaks in Figure 5 is about 5 to 6 hours and shifts the heat gains into the room to the night hours. The higher the density, specific heat capacity or wall thickness the higher the time offset will be.

For comparison the heat transfer of a conventional façade with the same heat transfer coefficient as the STI setup in heat-insulating state (U = 0.22 W m^{-2} K^{-1}) was numerically simulated in WUFI (Künzel, 1994) for one heating period. Initial and boundary conditions as well as climate data were adapted to measured monitoring data. The simulation revealed an energy input of about -18 kWh m^{-2}. Taking the measured energy input of the STI of about 67 kWh m^{-2} into account the energetic benefit of the STI yields 85 kWh m^{-2}. During the heating period, a small maximum electrical power consumption of 1.5 kWh m^{-2} is necessary to switch the STI.

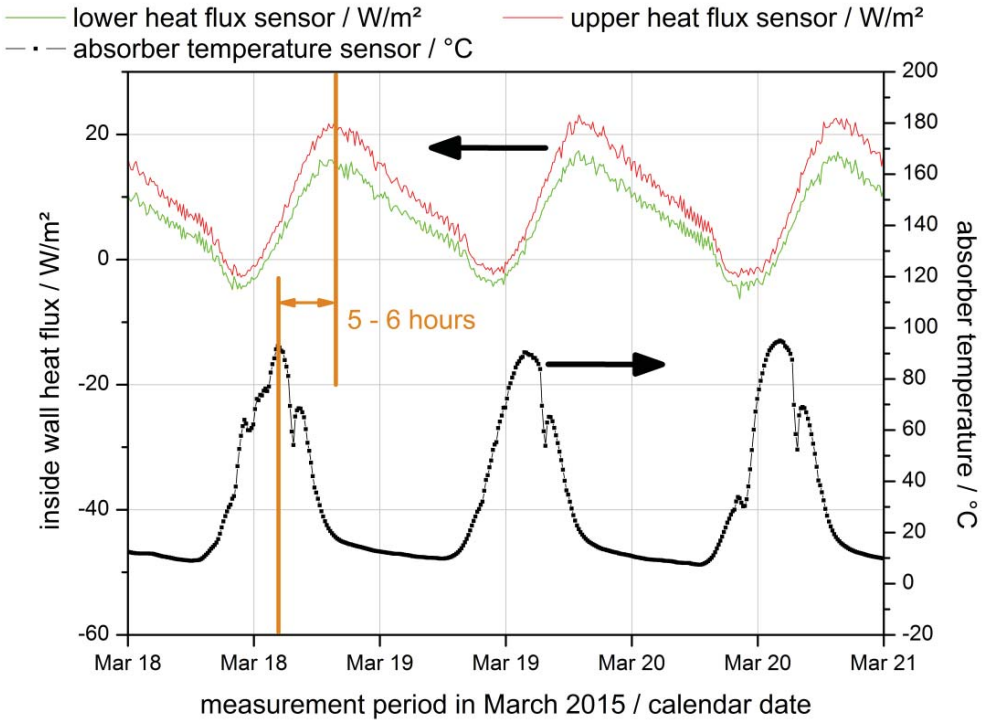

Figure 5: Time offset between absorber temperature peaks and inside wall heat flux peaks due to the thermal capacity of the sand-lime brick wall behind the STI.

5. Outlook

To raise the energy input of the STI during a heating period the thermal conductivity in the high-conducting state – respectively the switching factor – has to be increased by optimizing the function block. The getter material amount in the STI needs to be adapted to an ideal hydrogen filling so that costs for the expensive getter material are minimized while a high thermal conductivity is assured in the high-conducting state. Moreover, the STI can be used as a nightly summer cooling device by using low outdoor temperatures in combination with the high-conducting state.

Abstract

During the last years, the rapid increase of cloud computing, high-powered computing and the vast growth in internet use have aroused the interest in energy consumption and carbon footprint of data centres. The paper presents the results of an environmental and economic analysis to explore the path towards Net Zero Energy data centres. The economic and environmental assessment is presented for different data centre sizes (120 and 400 kW_{IT} of design IT power) and climate locations (Barcelona and Stockholm). It is the result of detailed TRNSYS simulations which have been developed in the framework of the European project RenewIT. Total cost of ownership and non-renewable primary energy consumption are used as main metrics to evaluate the performance of different energy concepts, energy efficiency strategies and the implementation of renewables, in particular PV and wind energy. Parametric analyses are presented to evaluate the influence of some of the main sizing variables for each concept.

Keywords: *Net Zero Energy Data Centres, renewable energy, energy efficiency, cost-benefit analysis*

1. Introduction

Data centres are unique buildings or dedicated spaces in other buildings which houses information technology (IT) rooms. The IT room is an environmentally controlled space that houses equipment and cabling directly related to computing and telecommunication systems which generate a considerable amount of heat in a small area. In the last years, the total energy demand of data centres has experienced a dramatic increase. This is why data centre industry and researchers are undertaking efforts to implement energy efficiency measures and to integrate renewable energy into its portfolio to overcome energy dependence and to reduce operational costs and CO_2 emissions (Salom, 2016). Oró et al. (2014) presented a comprehensive overview of the current data centre infrastructure and summarized a number of currently available energy efficiency strategies and renewable energy integration into the data centre industry together with the recent efforts for its characterization using numerical models. Shuja et al. (2016) presented a survey of case studies and enabling technologies to make cloud data centres more sustainable. In the framework of the European funded RenewIT project (Salom, 2016) holistic and dynamic energy models have been developed in TRNSYS (TRNSYS, 2012) to characterize the overall energy performance and the life-cycle economic impact of data centres after the implementation of energy efficiency strategies and renewables. This paper presents the economic and environmental results for different energy concepts as function of the data centre size (120 and 400 kW_{IT} of design IT power, being IT power the electrical power that must be supplied to the IT devices to work) and climate location in Europe (Barcelona and Stockholm).

2. Methodology

Selected energy concepts which implement cooling and power supply of data centres with renewable energy systems are evaluated using detailed TRNSYS simulation. A set of TRNSYS projects to model the energy behaviour and compute the investment and running costs of different data centre concepts have been built in the framework of the RenewIT project. The different models are based on the combination of subsystems of a data centre facility using TRNSYS' macros capabilities and they have been run with a 15-min time step to derive the results presented in the current paper. Due to limited space, only a brief description of the modelled concepts (Shrestha et al., 2015; Rudolf et al., 2016) is presented in section 3 which have been validated with real life case studies (Salom et al., 2015; Oró et al, 2015) and lead to the development of the RenewIT tool (2016) (Garcia et al., 2016).

To evaluate the economic and the environmental impact of the use of advanced energy solutions in data centre portfolio different metrics have been evaluated. The total cost of ownership (TCO) is the main metric to evaluate the economic benefits of an applied solution. The TCO is the addition of the initial investment costs (CAPEX), the operational expenditures (OPEX) and the replacement cost minus the residual value of components, based on the methodology proposed by CEN (2008). The TCO is used to assess the true total costs of building, owning, and operating a data centre energy facility during a certain amount of years. In the present study, the assessment period is equal to the components life time span which is 15 years; therefore the cost of replacement of the components is neglected in the economics calculations and the residual value is zero. The OPEX is the net present value of the costs for running a data centre facility. It includes the energy costs ($OPEX_{EC}$), both electricity and/or other energy carrier costs as well as the costs derived from the data centre water consumption, the maintenance costs ($OPEX_{MC}$) and the environmental costs ($OPEX_{CO2}$), i.e. the cost of the CO_2 emissions. The energy costs are calculated for each energy carrier and prices are temporary dependent.

$$TCO = CAPEX + OPEX \quad \text{(eq. 1)}$$

$$OPEX = OPEX_{EC} + OPEX_{MC} + OPEX_{CO2} \quad \text{(eq. 2)}$$

The annual non-renewable primary energy consumption of the data centre (PE_{nren}) is used as main metric to evaluate the environmental performance although other metrics are widely used in the industry to evaluate the energy efficiency measures such as the well-known power usage effectiveness (PUE) or the data centre water consumption and CO_2 emissions. The non-renewable primary energy means energy from non-renewable sources which has not undergone any conversion or transformation process. The calculation of PE_{nren} is based on equations 3 and 4 (being equation 4 the evaluation of Pe_{nren} at each time step) and the energy fluxes through the data centre boundary depicted in Fig. 1, where both delivered and exported energy carriers are weighted using the non-renewable primary energy weighting factors.

$$PE_{nren} = \int_{year} Pe_{nren}(t) \cdot \mathrm{dt} \quad \text{(eq. 3)}$$

$$Pe_{nren} = \left[(e_{del,el} \cdot w_{del,nren,el}) + (e_{del,fuel} \cdot w_{del,nren.fuel}) + (e_{del,Dheat} \cdot w_{del,nren,Dheat}) + (e_{del,DCool} \cdot w_{del,nren,DCool}) \right] - \left[(e_{exp,el} \cdot w_{exp,nren,el}) + (e_{exp,heat} \cdot w_{exp,nren,heat}) \right] \quad \text{(eq. 4)}$$

where $e_{del,i}$ and $e_{exp,i}$ are the energy entering to and exported from the data centre boundary respectively for energy carrier i; $w_{del,nren,i}$ and $w_{exp,nren,i}$ are the non-renewable weighting (or conversion factor) for each energy carrier delivered or exported. About energy carriers, *el* means electricity; *fuel* can be natural gas, biogas or biomass; *Dheat* and *DCool* means thermal energy coming for a district heating and cooling infrastructure and *heat* means exported heat to a district heating or surrounding buildings. The renewable energy ratio (RER_{EP}), equation 5, is the metric that allows calculating the share of renewable energy use in a data centre. The renewable energy ratio is calculated relative to the total primary energy used in the data centre facility.

$$RER_{EP} = \frac{\sum_i e_{ren,i} + \sum_i [(w_{del,tot,i} - w_{del,nren,i}) \cdot e_{del,i}]}{\sum_i e_{ren,i} + \sum_i (w_{del,tot,i} \cdot e_{del,i}) - \sum_i [(w_{exp,tot,i} \cdot e_{exp,i})} \quad \text{(eq. 5)}$$

Notice that in order to compare the results between data centres of different size, both, PE_{nren} and TCO are normalized by the design IT power capacity of the facility [kW_{IT}]. Therefore, normalized PE_{nren} is expressed in [$kW \cdot h_{PE,nren}/kW_{IT} \cdot year$] while normalized TCO is expressed in [€/kW_{IT}]

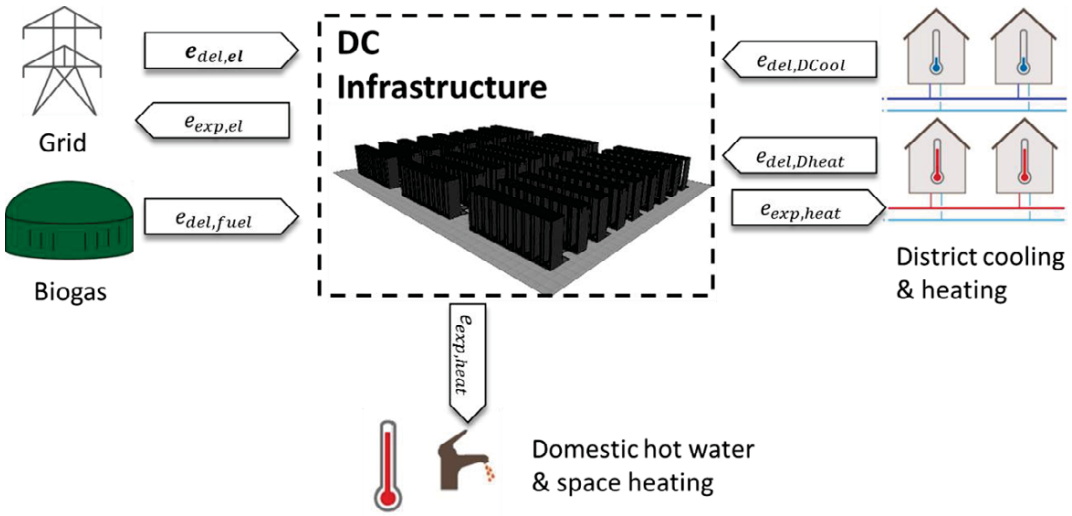

Fig. 1: Delivered and exported energy fluxes in a data centre facility

3. Concepts and scenarios

The present section describes briefly the different energy concepts, which have been simulated as well as the main characteristics of the four scenarios analysed: two sizes in two locations.

The concept 1, shown schematically in Fig. 2, is based on a conventional system where vapour-compression chillers along with dry coolers are used to produce cooling energy when it is required. Fig. 2 depicts the thermal and electric scheme of this concept. The electrical power required to drive the chiller and to run the IT hardware can be generated by a photovoltaic system and/or wind turbines installed in the building footprint; additional power is purchased from the grid. In winter, indirect air free cooling can be activated for efficient cooling supply to the data centre.

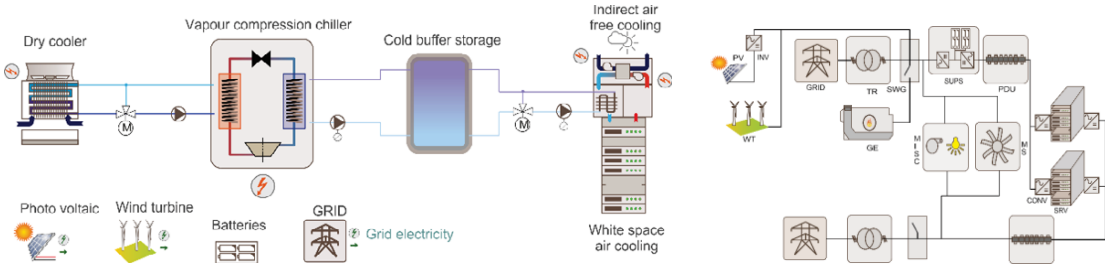

Fig. 2: Thermal scheme (left) and electric scheme (right) of concept 1 (conventional data centre concept with on-site PV and/or wind power systems)

Concept 2 is aimed for those data centres with liquid cooled servers. Depending on the technology used and implemented, part of the infrastructure will demand air cooling while other liquid cooling. Therefore, in this solution, chilled water for air-cooling is supplied by a district cooling system while heat from direct liquid cooling is reused for space heating and domestic hot water by means of a heat pump. A dry cooler could be used if there is no heat demand. Fig. 3 shows the thermal and electric scheme of this concept. Notice that during summer, chilled water from the district cooling system is used to cool the air flowing into the data centre but during winter, mostly indirect air free cooling can be conducted. With the objective to increase the use of renewables in the facility, this concept makes sense if the district heating and cooling system is fed by renewables at least to some extent. This is represented by the value used in the simulations of $w_{del,nren,DCool}$, which is 0.6, with the hypothesis of a district cooling system based on a biogas CHP system with absorption chillers.

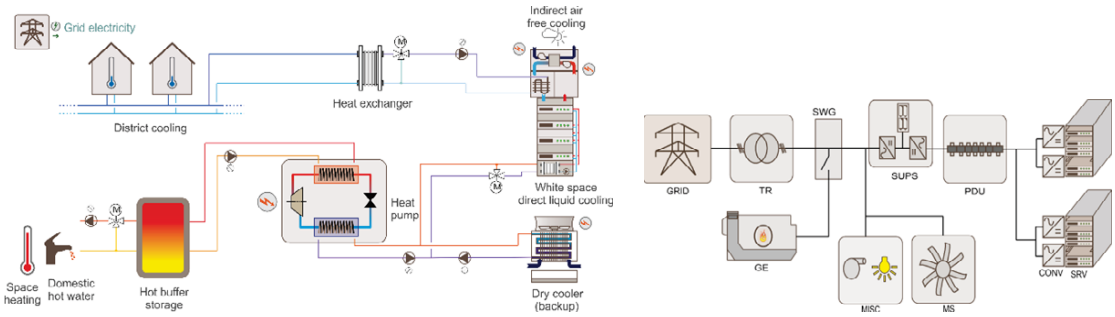

Fig.3: Thermal scheme (left) and electric scheme (right) of concept 2 (District cooling and heat reuse)

In concept 3, wet cooling towers (without the use of mechanical chillers) are used to produce cooling energy. Fig. 4 depicts the thermal and electric scheme of this concept. In winter, direct air free cooling is performed for efficient cooling supply to the data centre. When the evaporative free cooling is not possible, backup vapour-compression chillers along with the cooling towers are used. The electrical power required to drive the cooling towers and the backup chillers are purchased from the national grid.

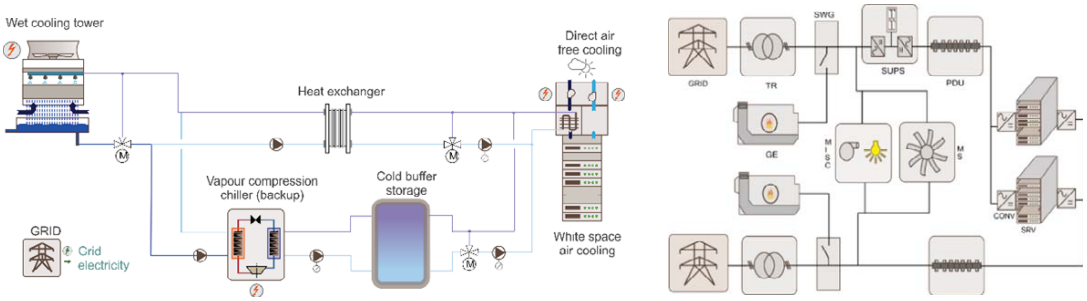

Fig. 4: Thermal scheme (left) and electric scheme (right) of concept 3 (Grid-fed wet cooling tower without chiller)

In concept 4, a biogas-fed fuel cell is applied for generating both power and heat, which is used for driving an absorption chiller during summer which produces cool (Fig. 5). In winter, indirect air free cooling avoids the operation of the chillers if it is activated. Then, the waste heat from the fuel cell can be recovered for space heating or might also be dissipated by a wet cooling tower. Because of the high temperature and pressure of the hot water, shell and tube heat exchanger are used for transferring the heat between the cooling tower and the fuel cell hot water circuit.

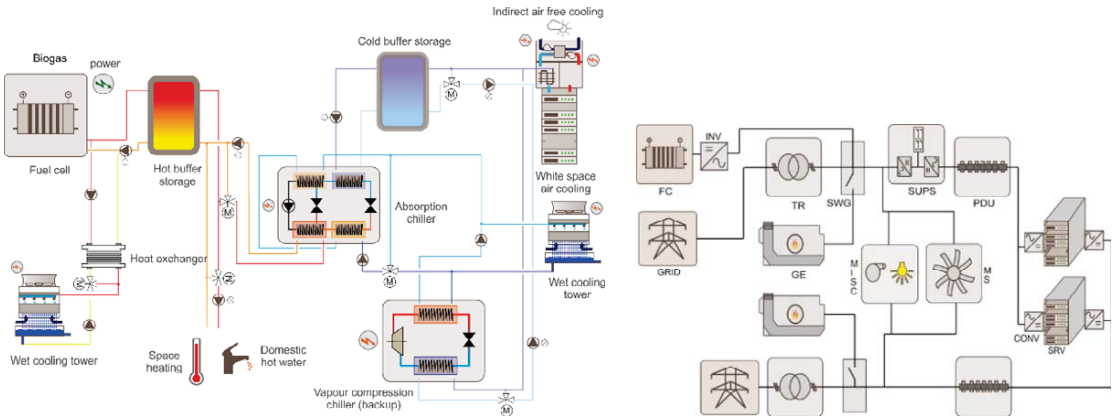

Fig. 5: Thermal scheme (left) and electric scheme (right) of concept 4 (Biogas fuel cell with absorption chiller)

The concept 5 shown schematically in Fig. 6 is based on biogas-fed tri-generation by means of a reciprocating engine combined heat and power (CHP) plant. The heat from this plant is used for driving a single-effect absorption chiller during summer and supplying space heating for offices or buildings close to the data centre during winter. Additionally, indirect air free cooling is implemented for efficient cooling

supply to the data centre especially during winter. Then, the heat from the CHP plant is used for space heating and producing domestic hot water if required.

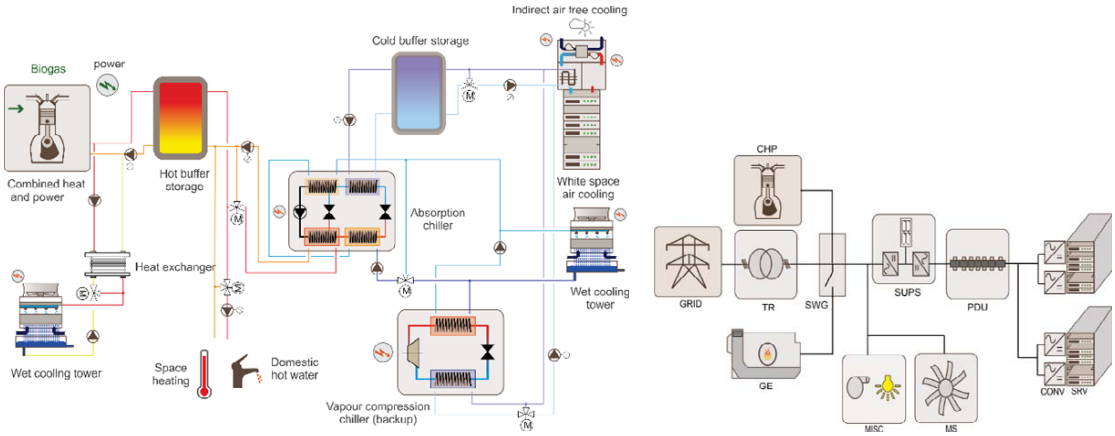

Fig. 6: Thermal scheme (left) and electric scheme (right) of concept 5 (Reciprocating engine CHP with absorption chiller)

Two different IT power capacities (120 kW and 400 kW) are analysed for each of the locations (Barcelona and Stockholm). In each of the scenarios, the main other parameters such as the rack density, the occupancy ratio (1.0 meaning fully occupied), the safety margin factor (1.0 meaning no safety margin), and the load profile are fixed as shown in Table 1. Safety margin factor indicates how much the data centre facility is oversized referred to the expected maximum IT Power, meaning 0.8 that the facility is 25% oversized. The white space area depends of the nominal IT Power capacity and the rack density and it was estimated using average ratios in the industry to determine the amount of floor occupied by a rack. In the present study the IT load profile used is a combination of the most standard/homogeneous IT workload profiles: Web, HPC and Data. In particular, the workload profile used is composed of 35% HPC, 30% Data and 35% Web based on Carbó et al. (2016). Table 2 shows some of the basic parameters used to define the sizing of the main elements in the different energy concepts. These parameters are used in the base cases scenarios for each of the concepts.

Table 1: Data Centre Scenarios

		Name of the scenarios			
Parameter	**Unit**	**BCN-120**	**BCN-400**	**STO-120**	**STO-400**
Location	[-]	Barcelona	Barcelona	Stockholm	Stockholm
IT power capacity	[kW]	120	400	120	400
Rack density	[kW/rack]	4	4	4	4
Occupancy ratio	[-]	1	1	1	1
Safety margin factor	[-]	0.8	0.8	0.8	0.8
White space area	[m^2]	90	300	90	300
IT Load profile	[-]	Mixed	Mixed	Mixed	Mixed
Average electricity price	[€/kW·h_{el}]	0.10	0.10	0.11	0.11
Biogas price	[€/kW·h_{biogas}]	0.08	0.08	0.08	0.08
District cooling price	[€/kW·h_{DCool}]	0.035	0.035	0.035	0.035
Exported heat price	[€/kW·h_{heat}]	0.025	0.025	0.025	0.025
CO_2 price	[€/tCO_2]	8.99	8.99	8.99	8.99
$w_{del,nren,el}$ (average)	[kW·h_{PE}/kW·h_{el}]	1.83	1.83	1.30	1.30

Table 2: Specific assumptions for the investigated concepts. Base case scenarios

#	Description	Basic parameters
1	Vapour compression chillers with dry cooler. Additional on-site PV/Wind power system can be added	VCCH Nominal power • 180 kW (120 kW_{IT}) • 600 kW (400 kW_{IT})
2	District cooling and heat reuse	Heat reuse ratio = 1.0; Efficiency of liquid cooling = 0.65; Ratio of heat pump cooling power and max. liquid cooling demand = 0.50
3	Wet cooling tower	Wet cooling tower nominal power: • 225 kW (120 kW_{IT}) • 750 kW (400 kW_{IT})
4	Biogas fuel cell and absorption chiller	Heat reuse ratio = 1.0; Ratio of absorption chiller size related to the total cooling power of data centre = 0.3; Ratio of fuel cell size related to absorption chiller size = 1
5	Reciprocating engine CHP with biogas	Heat reuse ratio = 1.0; Ratio of absorption chiller size related to the total cooling power of data centre = 0.3; Ratio of biogas engine size related to absorption chiller size = 1

The simulation models developed allow the introduction of a set of energy efficiency measures individually or combined. The energy efficiency strategies are technical solutions that can be applied in almost all the data centres and combined with any system to supply cooling and power with or without renewable energy sources (RES). Therefore, first the strategies that allow to reduce the load demand as much as possible have been analysed before studying the use of the renewable resources available in the data centre's location. Further details about the energy efficiency measures can be found in Shrestha et al. (2015) which can be grouped in several categories:

- Advanced measures for building design. The building design may affect the cooling demand of the data centre.
- Advanced measures for electrical supply. Some well-known strategies are modular UPS and bypassed UPS which achieve a reduction of electrical losses in the power distribution lines. In the results presented in this paper, modular UPS have been applied when energy efficiency measures are mentioned.
- Advanced measures for cooling supply. These measures include the use of free cooling, hot/cold aisle containment for a better air management, variable air flow and the increase of allowable IT working temperatures. Using highly energy efficient components, in particular vapour compression chillers, can also lead to a significant reduction of the total energy demand.
- Advanced measures for IT management. Consolidation aims to concentrate IT workloads in a minimum number of servers to maintain the inactive servers in idle state. Then also those servers in idle state can be turned off. Finally, IT scheduling aims to move IT jobs according to the availability if RES when it is possible.

4. Results and discussion

4.1. Concepts comparison and impact of energy efficiency measures

Figure 6 presents the results of the different concepts proposed for the four scenarios analysed. In the same graph the results for each of the concepts applying the complete set of energy efficiency measures are presented and compared with the results of the base case where none of these energy efficiency measures are applied. Normalized TCO and normalized PE_{nren} are presented in Fig.6-left for Barcelona and in Fig. 6-right for Stockholm.

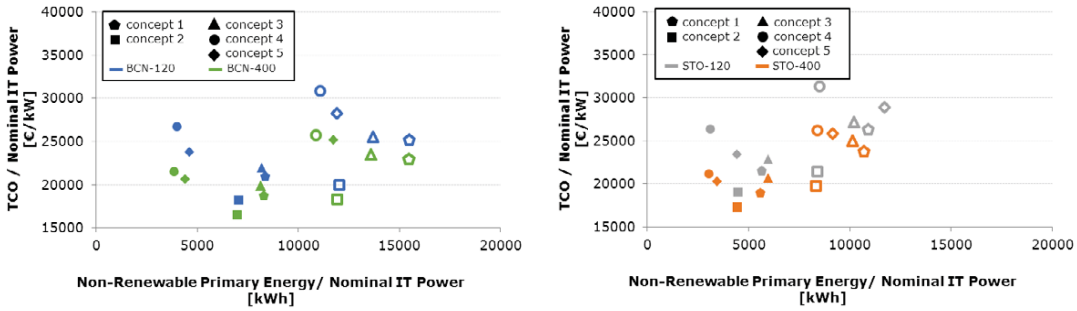

Fig. 6: Normalized TCO vs. normalized PE_{nren} for the location of Barcelona (left graph) and Stockholm (right graph). Results of no applying energy efficiency measures (unfilled shapes) and applying energy efficiency measures (filled shapes) are shown for all the concepts.

Analysing the influence of different sizes of the data centre for each of the concepts, the results show that the normalized PE_{nren} is similar for each concept independently of the size but there exists significant differences on the data centre cost. On average building and operating a data centre of 400 kW compared to one of 120 kW costs 13% less when energy efficiency measures are applied and 11% less for the base cases.

Talking about costs, one can observe that for the same concepts and the same sizes there are no significant differences between operating a data centre in Barcelona or in Stockholm under the hypothesis used in this study. TCO costs are mainly driven by the sizes of the main elements and labour costs of building a data centre to determine the CAPEX (which is not influenced by the location since average European prices have been used) and for the energy prices that influence the OPEX (which differences come from the differences in the electricity prices). The average difference of TCO between having a data centre in Stockholm or in Barcelona is 3%. However, the two locations present significant differences in the absolute values of PE_{nren} between the locations. As PE_{nren} considers the amount of non-renewable primary energy in the electricity network through the appropriate weighting factors there is a difference between the locations as well as in the influence of other climatic conditions: for example there are more hours of free cooling available in Stockholm than in Barcelona. Table 3 shows the results for concept 1 and concept 4, where differences between locations in normalized PE_{nren} are reduced because concept 4 is mainly based on biogas which has the same conversion factor for the two locations.

Table 3: Normalized PE_{nren} consumption [$kW \cdot h_{PE,nren}/kW_{IT} \cdot year$]

	BCN-400	STO-400
Concept 1- Conventional system: VCCH with dry coolers		
Without energy efficiency measures	15 314	10 711
With energy efficiency measures	8 194	5 541
Concept 4 - Biogas fuel cell with absorption chiller		
Without energy efficiency measures	10 884	8 415
With energy efficiency measures	3 846	3 033

For all the concepts and the locations, there is a significant benefit of applying as much energy efficiency measures as possible which will produce savings in the total costs and in the primary energy consumption. IT management strategies are the most beneficial ones, together with some measures which allow increasing the number of free-cooling hours or improving the efficiency in the electrical distribution. For the case studies presented here the impact of applying energy efficiency measures are 50% (in Barcelona) and 52% (in Stockholm) of reduction on PE_{nren} as well as 15% (Barcelona) and 17% (Stockholm) of TCO savings.

According to the results of the current study operating a conventional data centre (concept 1) without renewables can cost around 24450 €/kW_{IT} (± 7%) and consuming about 15383 $kW \cdot h_{PE,nren}/kW_{IT} \cdot year$ (± 0.5%) in Barcelona and 10750 $kW \cdot h_{PE,nren}/kW_{IT}$ (± 0.4%) in Stockholm. Although, it was commented that a significant reduction of TCO and PE_{nren} is possible applying different energy efficiency strategies, a reduction of primary energy resources is possible with different concepts to run a data centre. Among the ones presented in section 3, the concept 4 based on biogas fuel-cells gives the best results in terms of PE_{nren} reduction although it is an expensive concept compared with a conventional data centre. Having a CHP with

a biogas engine, concept 5, gives also promising PE_{nren} savings but is less expensive than concept 4 although still having TCO higher than a conventional data centre. Both concepts 4 and 5 rely also on the availability of biogas as local and/or imported resource. The most cost effective concept, i.e. the one that combines more PE_{nren} and TCO savings, is concept 2 which connects the data centre to a district cooling system and heat from the data centre can be used for heating purposes. The reduction of TCO can reach up to 21% and the PE savings up to 22% when no energy efficiency measures are applied. Concepts 2, 4 and 5 rely on a 100% reuse of the heat produced by the facility. Finally, the implementation of concept 3 based on wet cooling towers show slightly higher economic figures than the conventional case and moderate PE savings compared to other concepts which also dependent on the location and if free-cooling strategies have been applied.

4.2. Analysis of concept 1 adding on-site renewable energy systems

Fig. 7 depicts graphically the results of applying on-site renewable power systems to a conventional data centre: PV and wind turbines systems. On one hand, different sizes of on-site PV systems, which are characterized by their PV peak power, have been simulated. For the scenarios of 120 kW_{IT} and 400 kW_{IT}, PV systems are varied from 0 to 50 kW_p and from 0 to 100 kW_p, respectively (see Table 4). PV simulation which is integrated as part of the overall TRNSYS data centre models neglects the shadows effects of surrounding buildings and the own shadows of a large flat roof mounted PV field. The PV field is considered oriented south with an inclination slope of 32.2º for Barcelona and 44.6º for Stockholm. On the other hand, the use of small wind power systems has also been studied. For the 120 kW_{IT} data centre a unique 50 kW rated power wind turbine (Aeolos, 2015) is considered; while, for the 400 kW_{IT} data centre, the impact of having one and two identical wind turbines has been calculated.

Table 4: Specific assumptions of on-site PV and wind power systems for the investigated concept 1

Parameter	Unit	BCN-120 / STO-120	BCN-400 / STO-400
Total PV peak power	[kWp]	0, 10, 20, 30, 40, 50	50, 60, 70, 80, 90, 100
Total Wind rated power	[kW]	0, 50	0, 50, 100

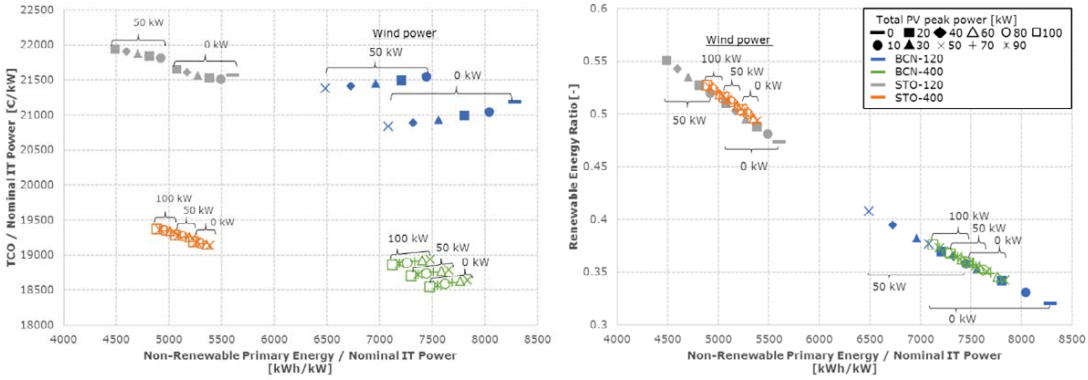

Fig. 7: Normalized TCO (left) and RER (right) vs. normalized PE_{nren} for different scenarios when adding on-site renewable power systems to concept 1

As expected, adding on-site PV and wind power systems implies an increase of the RER, as well as a decrease of the PE_{nren}. However, when analysing the economic and the energetic impact, it is shown that on-site PV systems are cost-effective when they are implemented in data centres located in Barcelona (south Europe) under the hypothesis of this study. PV systems in Stockholm are not cost-effective due to investment and the electricity prices considered and the low solar radiation over the year. Renewable electricity produced by on-site wind power systems in Barcelona and in Stockholm, which is based on wind availability in Meteonorm data files, is not enough to compensate the investment needed for such a systems. Using on-site wind power systems needs to be installed in locations where wind resource is available, which strongly depends on local conditions.

Table 5 shows the required roof space for a 50 kW_p and 100 kW_p PV field under the hypothesis that the PV field is mounted in a flat roof by tilted modules with a distance between rows based on rules which optimally minimize the occupancy of the roof and maximizes the PV production (RenewIT tool, 2016). The required

roof space depends on the size of the PV system and on the location. Although different types of data centre buildings exists and whitespace rooms can be part of large corporate buildings, available roof space (A_{roof}) is estimated in relation with the whitespace area ($A_{DC,room}$) as shown in equation 6 and based on information available from the industry. The required roof space for the PV field exceeds the available space. Results of the load cover factor, which represents the ratio between the power produced by PV and the overall electrical data centre consumption, are also presented in Table 5. Load cover factor is very low (less or equal to 10% in most of the cases) even with PV systems that go beyond the available roof space in all the cases analysed. This means, that under grid parity conditions having an on-site PV system is a good solution to reduce the environmental impact of a data centre. Although this will be very dependent on the case, conventional roof mounted PV fields are limited by the available roof space covering a small portion of the electricity consumption of a data centre. Using PV to have larger load cover factors would require to use additional space available in the data centre footprint or explore BIPV (Building Integrated PV) solutions.

$$A_{roof} = f_{roof\text{-}ws} \cdot A_{DC,room} \quad \text{where} \quad f_{roof\text{-}ws} \cdot = 2.2\ m^2_{roof}/m^2_{DC,room} \qquad \text{(eq. 6)}$$

Table 5: Required roof space, available roof space and load cover factor for different scenarios with on-site PV power system for the investigated concept 1

		Name of the scenarios			
Parameter	**Unit**	**BCN-120**	**BCN-400**	**STO-120**	**STO-400**
Required roof space – 50 kWp	[m^2]	796		1570	
Required roof space– 100 kWp	[m^2]	1593		3140	
Available roof space	[m^2]	198	660	198	660
Load cover factor – 50 KWp	[%]	16	5	10	3
Load cover factor – 100 KWp	[%]	-	9	-	6

4.3. Analysis of concept 2 for different liquid cooling solutions and amount of heat reuse

Fig. 8 presents the results of the parametric analysis for concept 2 (data centre connected to a district cooling and heating system with reuse of heat from direct liquid cooled servers) for data centres of 400 kW_{IT} in both locations (BCN-400 and STO-400). Only results for 400 kW_{IT} are presented to contribute to readability of the graphs. Maintaining the hypothesis that 100% of the heat extracted from the data centre can be reused, the sensitivity analysis for two parameters has been performed. On one hand, there is the type of liquid cooling system which is characterized by its efficiency: 0.65 for on-chip liquid cooling and 1.0≃0.99 for immersed liquid cooling system. This parameter means that for on-chip liquid cooling, 65% of the heat is extracted by water while the other 35% by air, while for immersed liquid cooling system, 100% of the heat is extracted by water. On the other hand, the size of the heat pump is varied which is characterized by the ratio between the heat pump cooling power and the maximum liquid cooling demand of the data centre. This ratio is varied from 0.1 to 0.5. The results shows that as the type of liquid cooling system allows extracting higher amount of heat from the servers, PEnren decreases as well as RER increases. As the ratio determining the size of the heat pump increases there is a reduction of the PE_{nren}, too. Having an immersed liquid cooling system with the capability to extract more heat is a bit more expensive, but with optimum sizes of the heat pump differences between different liquid cooling technologies are minimized both in terms of TCO and PE_{nren}. As it is shown in Fig. 8, the size of the heat pump has an important effect on the indicators having an optimal value between 0.4 and 0.5, while the differences between these two values of the parameter are negligible.

4.4. Analysis of concept 3 adding on-site PV power systems

Fig. 9 shows the results of applying on-site PV power sytems to concept 3 for the different scenarios. Results are in coherence with the findings of adding PV to concept 1 already explained in section 4.2. PE_{nren} decreases and RER increases as the size of the PV system increases, being cost-effective in Barcelona and not economically feasible for Stockholm in terms of TCO.

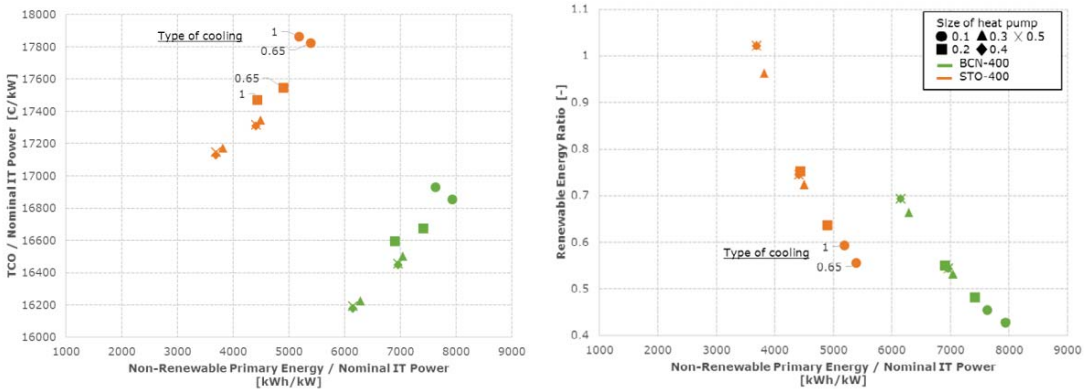

Fig. 8: Normalized TCO (left) and RER (right) vs. normalized PE_{nren} for different scenarios, types of cooling (On-chip/ Immersed) and sizes of the absorption chiller for concept 2

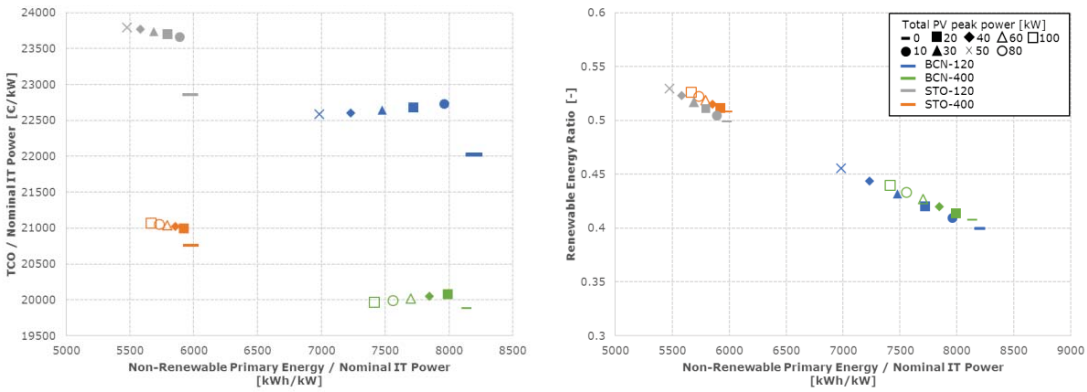

Fig. 9: Normalized TCO (left) and RER (right) vs. normalized PE_{nren} for different scenarios when adding on-site PV power systems to concept 3

4.5. Analysis of concept 4 with different sizes of absorption chiller and amount of heat reuse

Fig. 10 presents the results of a parametric analysis for concept 4 (data centre based on biogas fuel-cell driving an absorption chiller) for all the scenarios. Figure 10-right only shows results for 400 kW_{IT} data centre to improve the readability. The variation of two parameters has been analysed. One is the amount of heat produced by the facility which can be reused for other purposes outside the data centre: this is characterized by a ratio between 0.2 and 1.0, meaning 1.0 that 100% of the heat can be reused outside the data centre. The other parameters is the size of the absorption chiller which is characterized by a parameter from 0.2 to 0.5 which is the ratio between absorption cooling capacity and the total cooling power of the data centre. The results in Fig. 10 show that an increase of the absorption chiller size is not a cost-effective measure although it has an important effect on the reduction of the PE_{nren} and the increase of RER. For a ratio of the absorption chiller greater than 0.3, RER values are close to or great than 1.0 which indicates that the data centre facility is becoming a positive producer of primary energy even with low ratios of heat reuse. When the potential heat reuse is being reduced, the TCO increases as well as the PE_{nren} as consequence of the reduction of the exported heat.

4.5. Analysis of concept 5 with different sizes of absorption chiller and amount of heat reuse

Fig. 11 presents the results of a parametric analysis for concept 5 (data centre based on CHP – biogas engine driving an absorption chiller) for all the concepts. As in concept 4, the variation of two parameters has been analysed. One is the amount of heat produced by the facility which can be reused for other purposes outside the data centre; the other parameter is the size of the absorption chiller. The results in Fig. 11 show the same tendency than the ones for concept 4. An increase of the absorption chiller size is not a cost-effective measure although it has an important effect on the reduction of the PE_{nren} and the increase of RER. As well, as the amount of heat that can be reused is reduced (lower values of heat reuse ratio) the facility becomes more expensive to operate and PE_{nren} increases.

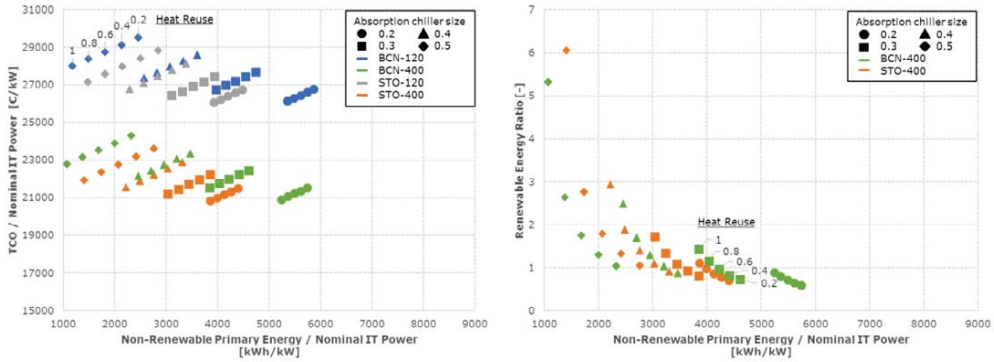

Fig. 10: Normalized TCO (left) and RER (right) vs. normalized PE_{nren} for different scenarios, relative absorption chiller sizes and amount of heat reuse ratio for concept 4

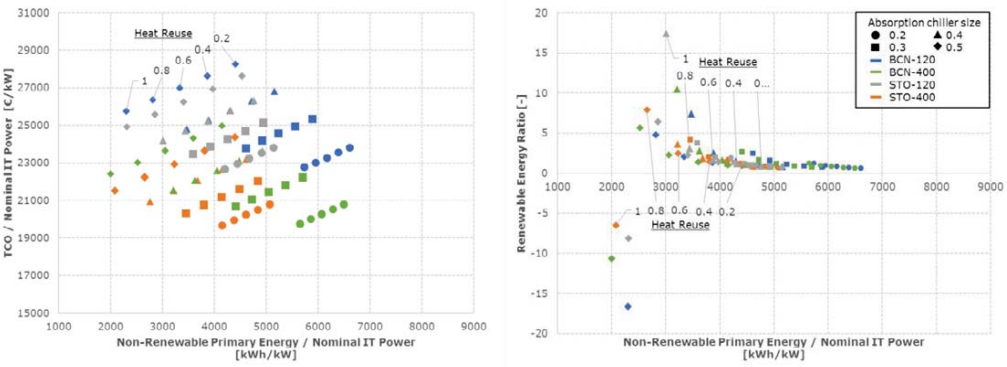

Fig. 11: Normalized TCO (left) and RER (right) vs. normalized PE_{nren} for different scenarios, absorption chiller sizes and amount of heat reuse ratio for concept 5

5. Conclusions

The extensive use of internet and cloud computing has increased the energy used for data centre industry. Thus, this paper studies the economic and environmental performance of different energy efficiency and renewable energy concepts in these unique facilities. Detailed TRNSYS simulation models developed in the European project RenewIT have been used to analyse the impact of those strategies in different data centre sizes and locations. In particular, the analysis has been performed for 120 and 400 kW_{IT} data centres in two climate locations: Barcelona and Stockholm. The aim of the different energy concepts analysed is to reduce the non-renewable primary energy consumption (PE_{nren}) as well as to explore how cost-effective each solution in terms of total cost of ownership (TCO) can be. Applying the most well-known energy efficiency measures such as free cooling, hot and cold aisle containment, the use of modular UPS, etc. lead to important reductions in PE_{nren} (about 50%) and in TCO (about 17%) and it should always be a must to explore energy efficiency measures alongside applying renewables. The concepts have also been compared to each other and the results show that the location has an influence on the absolute values of PE_{nren} due to climatic conditions and the differences between the shares of renewable in the national power grid, but there is not a lot of differences in TCO between the locations regarding the hypothesis about energy carrier prices considered in this study.

Data centres are very complex energy facilities and detailed optimization using the developed energy models is recommended together with information of local constraints, as energy prices or available space for renewables, to seek for a cost effective option. Together with the overview of the different energy concepts, basic parametric analysis have been performed in this paper varying some of the main parameters which characterizes the behaviour of each of the energy concepts. Concepts based on biogas CHP systems (with fuel cells or reciprocating engine) present promising numbers of PE_{nren} reduction but are not cost effective. These concepts rely on the availability of biogas as fuel resource as well as on reusing the heat which is not used by the absorption chiller outside the data centre whitespace. Small relative sizes of absorption chillers

give better values of TCO but PE_{nren} increases. The connection of a data centre to a district cooling and heating grid and reusing the heat from liquid cooled servers is a very promising solution and cost effective. Parametric analysis have been presented considering different heat pump sizes and different liquid cooling technologies and the reduction of PE_{nren} can be up to 22% compared to a conventional data centre. Using on-site PV or wind power production can be an interesting option towards Net Zero Energy data centres, but is dependent on the location: the local availability of wind resource for wind production and the availability of free space to integrate PV panels. In locations with grid parity situation PV is a feasible solution and load cover factor is limited by the availability of space for the PV panels.

ENERGYbase office building:

A reality check by seven years of monitored energy system performance

Tim Selke[1], Werner Wiedermann[2]

[1]AIT Austrian Institute of Technology GmbH, Donau-City-Str. 1, 1220 Vienna, Austria

[2] Siemens Gebäudemanagement &-Services G.m.b.H.

Abstract

The architectural design and the energy system concept of the ENERGYbase office building in Vienna / Austria fulfils the requirements of the *'Passivhaus'* standard. The use of ecological construction materials, high insulation and air-tightness of building envelope, advanced and energy efficient technologies - like solar-assisted air-conditioning, heat pump technology, photovoltaics - as well as innovative systems in terms of high quality of indoor comfort reduces the energy consumption. Since August 2008 the ENERGYbase office building is in operation and a monitoring campaign was carried out. This publication reports on seven years energy building performance based on measurement data from 2009 till 2015. Key findings are drawn and finally the ENERGYbase office building exceeds its ambitious targets related to energy and high indoor comfort in reality.

Keywords: *Nearly zero energy office building, local renewable energy use, energy monitoring, reality check*

1. Introduction

According the recast of the EU-Directive [1], future buildings are 'Nearly Zero Energy Buildings' and technically a bright variety of future building concepts exists. Two essential measures lead to such high energy performing buildings: high energy efficiency for both a) the building envelope and the energy systems and b) the use of renewable energy sources on-site. In Europe 'Nearly Zero Energy Buildings' have to be built in 2021, thus there is a need of successful pilot-projects demonstrating the feasibility of such future building concepts. The ENERGYbase [2] office building, owned by the Vienna Business Agency and located in the 21st district of Vienna, was built to show up cutting-edge office designs, energy efficient technologies and the use of renewable energy gained from on-site resources with the goal of stimulating further use and development of these techniques. The contracted planning team achieved these ambitious energy targets by complying the energy requirements of the '*Passivhaus*' standard [3]. For designing the ENERGYbase technical solution further measures had high priority; the use of a) environmentally friendly materials, b) high quality insulation, c) a well-sealed building envelope and d) innovative energy technologies (e.g., photovoltaics, solar-assisted air-conditioning, and advanced heat pump technology) as well as e) the development of an innovative control strategy to provide a high quality indoor air and comfort. The architectural design and the applied technology mix lead to a significantly reduction of the energy demand for heating, cooling and artificial lighting in comparison to the existing building standard. The ENERGYbase building and its energy features where already presented on the EUROSUN 2008 -1st International Conference on Solar Heating and Cooling in Buildings eight years ago [4].

Building facts are listed in Table 1. Figure 1 shows two photos of the ENERGYbase, one shows the south and west façade and the other one north and east façade. The geographical position of the ENERGYbase

location and some selected weather parameter are presented in Table 2.

2006 during the planning phase of the ENERGYbase building project the energy demand values were calculated by applying the method of the Austrian energy performance certificate. Based on this data and simulation results experts indicated a total electricity demand for heating, cooling, air treatment and artificial lighting of one year ENERGYbase operation of 25 kWh_{el} per useful area and year. With the current Austrian conversion factors [5] for primary energy (PE, nonrenewable part) and CO_2-Emissions the ENERGYbase consumes 33 $kWh_{PE,nr}$ primary energy per useful area and year and emits 69 kg_{CO2} per useful area and year.

Table 1: Building facts of ENERGYbase

Type of building	Office
Location	1210 Vienna / Austria
In operation since	2008
System operated by	Siemens Facility Management
Area (Gross/ Useful/ Air-conditioned)	9,430 m²/ 7,544 m² / 5,000 m²
Use of solar energy	Photovoltaics 48.2 kW_p (peak) power
Use of shallow geothermal energy	Ground water coupled heat pump
Other innovation	Green ventilation (i.e., biological supply air treatment in wintertime for pre-humidification and filtering)
	Costume-made south façade oriented to the South and 7° to West
	Thermal mass activation for sensible heating & cooling

Table 2: Climate

Located	48°12’ N/ 16°22’ E
Tmean (Tmax / Tmin hourly)	9.5°C (28.9 / -14.6°C)
Global radiation on horizontal	1,122 kWh/m² year
Global diffuse on horizontal	627 kWh/m² year
Global direct on horizontal	495 kWh/m² year

2. Heating, Cooling and Ventilation System

The ENERGYbase office building is fulfils the requirements of the ‘Passivhaus’ standard. The heating, cooling and ventilation system is designed to use both a) water and b) an air based energy distribution systems. The air temperature of the office rooms in the ENERGYbase is controlled by thermally activated building construction elements. The concrete core activation (CCA) covers the sensible load for heating and cooling; due to the controlling of the water inlet temperature into CCA and the different air temperature levels in the office rooms heat is extracted from or delivered to the building construction mass. For controlling the indoor air humidity and for supplying fresh air, a solar heat driven Desiccant Evaporative Cooling (DEC) system is put into operation, which is an air-conditioning system without using conventional vapor compression chiller for cooling and dehumidification purposes. The assessment of the energy performance of the solar heat driven DEC system is already published [6].

Geothermal energy is exploited by means of ground water in the ENERGYbase building. Two heat pumps coupled to the ground water temperature levels raises the water temperature up to 45 degree Celsius in winter and the hot water is supplied on one hand to the CCA and on the other the hand to several heating coils of the air treatment system. In summer the ENERGYbase is cooled by extracting heat from CCA with the help of water circulated through the building construction. Finally a water to water heat exchanger transfers the extracted heat to the ground water. The ground water temperature in summer time is approx. 14 degree Celsius and is raised by around 4 Kelvin. In summer high ambient air temperature and humidity values are treated by the DEC system using solar heat. The collector area is around 285 m² and mounted on the upper part of the south façade – see scheme in Table 8. First of all the solar heat is used for the regeneration process of the loaded sorption material used in the DEC system and additionally for covering partly the heating demand of the CCA and the heating coils. Table 3, Table 4 and Table 5 list technical design data of the heating, cooling and air treatment system of ENERGYbase.

Table 3: Ventilation and air treatment system

Technology	Desiccant and evaporative cooling
N° of DEC systems	2 DEC system (twins)
Nominal volumetric flow rate	2 x 8,240 m³ per hr
Nominal capacity	~ 40 kW_{th} per DEC system
Brand of cooling units	robatherm
Cooling load subsystem	Central AHU
Dehumidification	Sorption wheel (Klingenburg SECO 1770)
Regeneration power	80 kW_{th} per DEC system

Technology	Air treatment system
N° systems / components	1 system, 1 heating & 1 cooling coil, 2 speed controlled fans, 1 heat recovery wheel
Nominal volumetric flow rate	6,000 m³ per hr
Set supply temperature	22°C (Winter & Summer)
Heat recovery efficiency	~ 0,66
Brand of cooling units	robatherm
Nominal motor el power for fan	4 kW_{el}
Dehumidification/ Humidification	No humidity treatment

Table 4: Heat generation

Heat pump system

Technology	Heat pump
Brand / Type	Climaveneta
Nominal heating capacity	2 x 160 kWth
Evaporator circuit temperatures	10/6°C
Evaporator circuit volume flow	36 m³ per hr
Condenser circuit temperatures	40/35°C
Condenser circuit volume flow	27.4 m³ per hr
Nominal electric power	38.1 kW_{el}

Solar collector system

Collector type	Flat-plate collectors
Brand of collector	Sonnenkraft /MEA DESIGN
Collector area	285 m² aperture area
Tilt angle/ orientation	32° / South and 7° to West
Collector fluid	Water/propylene-glycol (70/30)
Typical operation temperature	80°C
Mass flow operation mode	Low flow
Integration	Roof top mounted
Storage technology	Solar hot water tank
Storage volume	15,000 l

Table 5: Ground water / water heat exchanger design data

Nominal heat transfer capacity	270 kW_{th}
Primary circuit - Ground water	
Delta T	6 Kelvin
Nominal mass flow	38,700 kg per hr
Secondary circuit	
Delta T	4 Kelvin
Nominal mass flow	68,500 kg per hr
Ground water data	
Ground water temperature (min/max)	9°C / 14°C
Max volume flow	20 l per sec
Limited temperatures of fed in water (min/ max)	5°C / 18°C

3. Energy Performance Assessment

3.1 Annual Overall Energy System Performance

Since August 2008 the ENERGYbase office building is in operation and a monitoring campaign was permanently carried out. This publication reports on seven years energy building performance based on measurement data from 2009 till 2015. Table 6 lists selected annual amounts of energy of consumed and delivered electricity and heat generated and extracted from the building. Line I of Table 6 displays the percentage of rented office areas in the observation period. The displayed data are essentially registered by the facility management and cross checked by Austrian Institute of Technology. Monthly accumulated energy fluxes are regularly taken from different kinds of sources; a) building automation system, b) energy meters implemented in systems devices like inverters, heat meters etc., and c) energy data registered by meters of the energy supplying company. In most cases the figured monthly energy data are adjusted in consequence of different time intervals. The annual total electricity consumption indicated in Table 6 – see line A - represents annual consumed electricity for operating all technical devices for heating, cooling, ventilation, artificial lighting of general areas and all other building equipment, like permanent emergency lighting. The electricity consumed by the office usage of tenants is not included.

Table 6: Annual energy performance data from 2009 till 2015 (Source: FM Siemens)

			2009	2010	2011	2012	2013	2014	2015

Due to the fact the ENERGYbase is only externally powered by the electric grid, i.e. there is no connection to district heat or gas network, the assessment of the consumed electricity is key. In the observation period of seven years the ENERGYbase was operated by electricity in a range from 141 MWh_{el} till 166.7 MWh_{el} per year, this corresponds to specific values from 18.7 kWh_{el} till 22.1 kWh_{el} per useful area and year. High ratio of the electricity consumption are achieved by the operation of the air handling unit, heat pump system and all other electric driven devices - see line J till N of Table 6. The south façade attached photovoltaic system delivers 23% up to 33% of the total consumed electricity for operating the heating, cooling, ventilation systems and all other general building service devices.

3.2 Monthly Energy System Performance in 2015

Figure 2 shows an energy flow chart displaying annual heat and electricity fluxes of the ENERGYbase without users' electricity consumption in 2015. The annual heat delivered to both the CCA and as well to the numerous heating coils (excl. the heat transferred to the regeneration coils of the air treatment system) is calculated to value of 19.7 kWh_{th} per useful area and year. In cooling mode the heat is extracted from CCA and transferred to the ground water, here the specific heat extracted from the building is 23.6 kWh_{th} per useful area and year. In 2015 the heat pump system delivered around 121.4 MWh heat per year with an electricity input of 32.2 MWh_{el} per year including the consumers a) control system, b) compressors and c) the pumps of the water circuits of condenser and evaporator part. This quantified energy fluxes result into a seasonal energy efficiency ratio $SEER_{HP}$ of the heat pump system of 3.77, which is calculated according to the formula expressed in Equation 1. The ratio of the used solar heat generated by the collector in relation to the cumulated heat transferred to the CCA, heating and regeneration coils of the air treatment system is around 38% und the formula of the solar fraction is expressed in Equation 2.

[1] Data source; Zentralanstalt für Meteorologie und Geodynamik, weather station ‚Hohe Warte' in Vienna

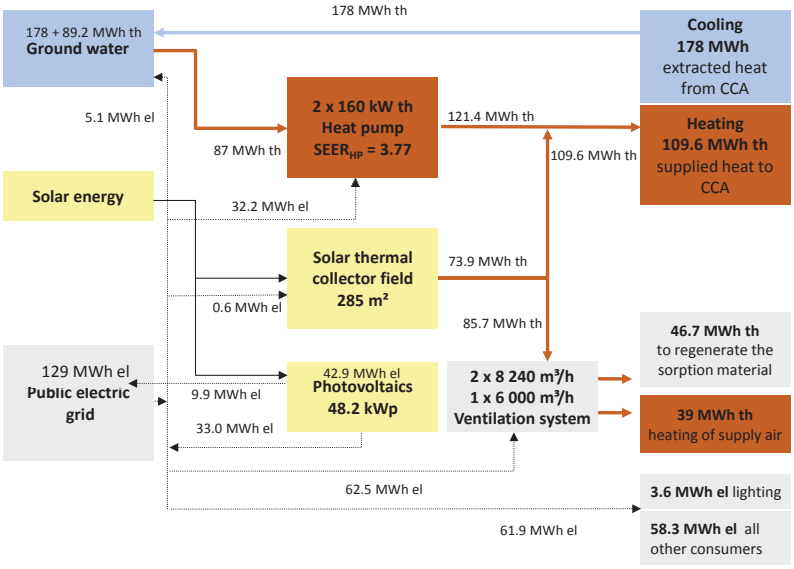

Figure 2: Annual energy fluxes (heat and electricity) of ENERGYbase in 2015 (Source: AIT)

Table 7 contains monthly values of electricity consumed by different energy systems. Furthermore the monthly values of heat transferred by circulated water to a) the CCA, b) the heating coils of the air treatment system and c) regeneration heating coil of the DEC system – see lines g, i and h of Table 7. As mentioned above the ENERGYbase is equipped with two heat pumps and one solar thermal collector field delivering hot water to heat distribution system described above. In 2015 the monthly calculated energy efficiency ratio $SEER_{HP}$ of the heat pump system operation is in range from 2.67 up to 3.87 – see line k of Table 7. The share of the solar heat used in the ENERGYbase can be calculated according to Equation 1. From May till September 2015 the solar heat covers fully the demand for the regeneration process of the sorption material in the DEC system, i.e. the solar fraction is accounted to 100%. Due to the lower availability of solar radiation in winter monthly values of the solar fraction decrease dramatically – see line m in Table 7.

$$SEER_{HP} = \frac{Q_{HP,\,Heat}}{E_{el,\,HP}} \left[\frac{kWh_{th}}{kWh_{el}} \right] \qquad \textbf{(eq. 1)}$$

Where:

$SEER_{HP}$	Seasonal energy efficiency ratio of the heat pump system [kWh_{th}/kWh_{el}]
$Q_{HP,\,Heat}$	Heat generated by the heat pump condenser, water cycle [kWh_{th}] – see line j in Table 7
$E_{el,\,HP}$	Electricity consumed by the heat pump components, i.e. motor for compressor and pumps of both circuits and the control unit [kWh_{el}] – see line j in Table 7

$$SF_{solar\,heat} = 1 - \frac{Q_{Heat\,Pump}}{Q_{CCA} + Q_{Heating\,Coil} + Q_{Reg.,Coil}} \left[\frac{kWh_{th}}{kWh_{th}} \right] \qquad \textbf{(eq. 2)}$$

Where:

$SF_{solar\,heat}$	solar heat fraction [-]
$Q_{Heat\,Pump}$	heat delivered by heat pump [kWh_{th}] – see line j in Table 7
Q_{CCA}	heat delivered to concrete core activation for heating purposes [kWh_{th}]
$Q_{Heating\,Coils}$	heat delivered to heating coils of the air treatment system [kWh_{th}]
$Q_{Reg.,\,Coil}$	heat delivered to heat coil of DEC system for regeneration purposes [kWh_{th}]

In 2015 the cooling season of the ENERGYbase started from April and ended in September. Monthly amounts of heat that has been extracted from the CCA are in the range from 14.92 MWh_{th} up to 43.64 MWh_{th} per month. The seasonal energy efficiency ratio $SEER_{Cool,\,Sys}$ of the water based cooling system can be expressed by eq. 3. According to line p in Table 7 the ENERGYbase ground water cooling system operates energy efficient and $SEER_{Cool,\,Sys}$ values are higher than 30.

$$SEER_{Cool,\,Sys} = \frac{Q_{Heat\ extr\ by\ CCA}}{E_{el,\,cold\ water\ pumps}} \left[\frac{kWh_{th}}{kWh_{el}} \right] \qquad \textbf{(eq. 3)}$$

Where:

$SEER_{Cool,\,Sys}$	Seasonal energy efficiency ratio for the cooling system [kWh_{th}/kWh_{el}]
$Q_{Heat\ extr\ by\ CCA}$	Heat extracted by the water cycle of CCA [kWh_{th}] – see line j in Table 7
$E_{el,\,cold\ water\ pumps}$	Electricity consumed by all cold water pumps [kWh_{el}] see line o in Table 7

Table 7: Monthly energy fluxes and key performance indicators for operating the air treatment system, heating and cooling system of ENERGYbase in 2015 (Source: FM Siemens)

Where:

a – Total: Overall electricity consumed by the technical equipment of the heating, cooling, ventilation system, lighting and other services

b - AHU: Electricity consumed by the fans, control unit and other devices of the Air Handling Units

c - HP: Electricity consumed by the heat pump by means of the a) control system, b) compressors and c) the pumps of the water circuits of condenser and evaporator part.

d - GWP: Electricity consumed by a) motors for ground water and cold water distribution pumps

e - AL: Electricity consumed by artificial lighting for general area

f – Others: All other electricity consuming devices

g – Heat to SDEC: Heat transferred to the two regeneration heating coils implement in the return air stream of the DEC system in dehumidification mode

h – Heat to HC: Heat transferred to all heating coils implemented in the air treatment system

i – Heat to CCA: Heat transferred to concrete core activation in order to lift the indoor air temperature

j – Heat from HP: Heat delivered by the heat pump systems, i.e. condenser water circuit

k – $SEER_{HP}$: Seasonal energy efficiency ratio of the heat pump according to eq. 1

l – SH: Used solar heat taken from the hot water storage

m – SF: Solar fraction expressed according eq. 2

n - Heat from CCA: Heat extracted from concrete core activation for lowering the indoor air temperature

o - El. CWP: Electricity consumed by motors of all required cold water pumps

p - $SEER_{Cool,Sys}$: Seasonal energy efficiency ratio of the cooling system according to eq. 3

q – Sp. heat to sys: Heat transferred to the energy system divided by useful office area (7.544 m²)

r – Sp. heat extr.: Heat extracted from concrete core activation divided by useful office area (7.544 m²)

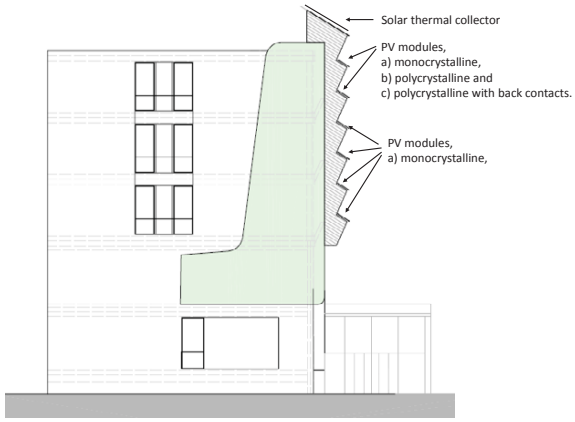
3.3 Energy Performance of the Photovoltaics (PV)

The photovoltaic system with a nominal capacity of 48.2 kW_p is attached to a custom-made stepped south façade. Six module lines with three different kinds of cell and module technologies are attached to the façade. In order to maximize the solar electricity yield the modules are naturally ventilated by ambient air and tilted with an angle of 31.5 degree – see scheme in Table 8.

In addition the façade added photovoltaic systems was designed and planned as well for research purposes and a scientific monitoring system is implemented beside other measurement equipment of the inverter. The upper two PV module lines are designed and installed for research activities and three different kinds of cell technologies are integrated; namely a) monocrystalline, b) polycrystalline and c) polycrystalline with back contacts. These different modules can be investigated with regard to their different long-term performance. The other four modules strings configured only with modules using polycrystalline cells and investigation of the inverter performances are foreseen. The technical data of the photovoltaic system are listed in Table 8. Since February 2009 the PV system is in operation. Annual energy performance indicators like a) delivered electricity from the all 366 PV modules, b) self-consumed electricity from PV system and c) PV electricity fed to the public grid are quantified in Table 9.

Table 8: Technical data of the PV system (Source: ATB-Becker 2008)

Type of	Attached to façade/ natural
Orientation / tilt	South and 7° to West / 30°
Total nominal	48.2 kW_p
Total PV module	400 m²
Module type 1	Solarwatt M135-55 GEG LK
Cell type	monocrystalline
number of pieces	286
Nominal power	134 W_p
Module type 2	Solarwatt P 125-55 GEG
Cell type	polycrystalline
number of pieces	40
Nominal power	122 W_p
Module type 3	Solarwatt M135-55 GEG
Cell type	polycrystalline
number of pieces	40
Nominal power	127 W_p
Inverter	10 x Sunways, 2 x SMA



During the observation period from January 2009 till December 2015 the annual electricity delivered by the PV system is in the range from 36,038 kWh per year (2009) to 47,430 kWh per year (2011), this corresponds to specific solar electricity yields from 748 and 984 kWh per kW installed peak capacity. In the beginning of the building operation some outages of the inverters occurred. The ratio of the PV electricity used in house and the total annual electricity consumed by the operation of the ENERGYbase energy systems is in range from 0.17 up to 0.22. In 2011 the PV system fed 14,024 kWh into the public grid and 33,406 kWh were directly used to operate the office building, this corresponds to approx. 70% of direct used solar electricity on site.

Table 9 lists monthly energy fluxes and key performance indicators from January till December 2015. Due to the specific shape of the solar façade the PV system achieved maximal yields in March with 112 kWh per kW installed peak capacity and in July with 126.4 kWh per kW installed peak capacity. Based on this measured data the predicted high yields for May, June and July cannot be confirmed. Demonstrably there is shading effect from the upper cell string on at least one of the lower module line occurring in June. Figure 3 illustrates monthly solar electricity a) delivered by the PV system, b) used in house and c) fed to the public grid from January till December 2015.

4. Key findings

Since August 2008 the ENERGYbase office building is in operation and a monitoring campaign was carried out. With this paper numerous annual energy fluxes and key performance indicators are presented from 2009 till 2015. Monthly energy system performance data are presented for 2015. The long-term observation allows an energy system performance assessment over seven years of the ENERGYbase office building operation. The electricity consumed by the office usage of the tenants, like using computers etc., is not part of this investigation. By analyzing the energy and key performance indicators following key findings are drawn:

- The ambitious energy targets stated in the initial ENERGYbase project phase were exceeded by the acquired energy data of seven years. From 2009 till 2015 the total electricity consumption for heating, cooling, air treatment, artificial lighting and other devices of the ENERGYbase is quantified from 141.1 MWh_{el} (2012) up to 166.7 MWh_{el} (2013), this corresponds to a range of specific values from 18.7 kWh_{el} up to 22.1 kWh_{el} per useful area and year. The allows the conclusion that the architectural design, the applied 'Passivhaus' standard and the implemented technology mix with a significant use of local renewable energy sources lead to a robust, reliable and predictable building energy performance.
- The convincing energy efficient performance is a result of a fruitful cooperation between the facility management and researchers on-site. The facility manager has carried out and investigated numerous measures achieving improvements in terms of energy efficiency, for instance permanently running pumps and fans have been operated in part load when motors are driven by frequency converters. AIT researcher performed several research projects focusing the optimization of subsystems of the ENERGYbase energy system. These activities are always a tradeoff between lowering the energy input and keeping the required high indoor comfort.

- The façade attached photovoltaic system delivered solar electricity in the range from 36 MWh_{el} up to 47.4 MWh_{el} per year. 69% up to 77% of the delivered solar electricity was self-consumed by the building operation and 17% up to 23% of the total electricity consumed was provided by PV system. Unfortunately self-shading effects of the shaped south façade result into relevant losses of solar electricity generation of the PV system when the solar altitude angle of the sun is near to its local maximum of $\alpha S \approx 65°$.

Solar Decathlon Europe and the Energy Endeavour Initiative

Karsten Voss [1], Susanne Hendel [1], Peter Russel [2]

1 University Wuppertal (Germany) 2 Technical University Delft (Netherlands)

Abstract

The Solar Decathlon is a prominent student competition on the topic of net zero energy and energy plus buildings. This competition has already taken place 12 times worldwide, three times in Europe and is under preparation for its next European edition. The unique feature is the triple of "design, build and operate" in an educational showcase addressing building designers, the industry and the general public. Over the course of the European editions, the participating teams have expressed the need for a platform to assist future competition organizers to further develop the format to confront renovation and dense urban living issues. This paper summarizes the ongoing process to establish such a platform: it is called the Energy Endeavour. It's aim is to further the continuation of the event and its evolution aimed to increased impact related to education, communication, energy policy and building science. One major element is a publicly accessible knowledge platform for the documentation and analysis of past events. The paper describes the structure and capabilities of this platform together with some analysis examples.

Keywords: *Student Competition, Zero Energy Building, Building Grid Interaction, Knowledge Platform, IEA*

1. Introduction

The Solar Decathlon (SD) is an international competition based on the initial idea of founder Richard King from the U.S. Department of Energy (DOE) in 2000. In this competition, universities from all over the world are challenged to design, build and operate solar powered houses. It is the only student competition worldwide addressing the performance assessment of realized buildings. During the competition's final phase, each team assembles its house in a common Solar Village. The final phase includes exhibition, monitoring and 10 contests, the reason why the competition was named a "Decathlon". Twelve competitions have been conducted up to 2016 (link 1,2), three of these took place in Europe (Solar Decathlon Europe, SDE), the last one being in Versailles, France, 2014. The European interest in the competition was stimulated by the award winners in the US from the universities in Darmstadt (2007, 2009) and Vienna (2013). With the background of the 2012 restructuring of the European Energy Performance of Buildings directive and the ongoing national efforts to improve national building codes for new buildings towards "nearly zero energy buildings", the Solar Decathlon Europe's importance as part of the European energy policy is raised as is its public visibility.

Tab. 1: Past and currently planned Solar Decathlons worldwide. Status October 2016

Region	Country	City	Past Events	Planned
North America	USA	Washington DC (5), Irvine (2)	2002/5/7/9/11/13/15	2017

2. Analysis & Evolution Examples

Due to its concept, the competitions all address so called "all-electric-buildings" only. Heating and cooling are - partly assisted by ambient and solar heat - supplied by heat pumps, electricity is generated by the photovoltaic systems. The houses thereby demonstrate the ongoing European trend of the decarbonisation of the heat supply by using heat pumps instead of gas or oil boilers and a power grid based on a high saturation with renewables. Due to the small size of the houses and thereby the high surface to volume ratio (above 1 m^2/m^3) they offer much more roof space per floor area than conventional, detached, terrace and in particular apartment houses. The installed PV power per floor area for the houses in the three European competitions is in the range of 150 W_p/m^2 compared to 69 W_p/m^2 on average for detached homes in the German demonstration program for energy plus buildings (BMUB 2014) and even 45 W_p/m^2 on average for net zero energy buildings investigated within the framework of the IEA research on net zero energy buildings (Voss 2012). Due to these large installations the visual impact is high. It is much higher than in usual net zero energy building practice. The 2014 competition rules limit the PV installation to 5 kW_p per house (2010: 15 kW_p, 2012: 10 kW_p) and illustrate the development from building sizes like small cottages to more usual layouts: the rules allow for up to 70 m² floor area, and up to 110 m² for 2-storey buildings respectively (resulting in max. installed power of 70 or 45 W_p/m^2), see Fig. 1. On the one hand this increases the practical relevance of the prototypes, and on the other hand the realization process with the students is becoming more complex due to the construction efforts. Innovations for smart living on less space are becoming less important. Due to the limited roof space available it is of major importance in the early design phase of multi-story net zero energy buildings to decide upon the integration of solar thermal systems as well as a combined PV/thermal approach (hybrid installations). Solar fades are another option but are hardly brought into practice due to increased system costs, strong design implications and shading losses in dense urban environments. Fig. 3 illustrates the distribution of the active solar systems within the three European competitions. Hybrid systems are an example for the link of the Solar Decathlon to solar system research.

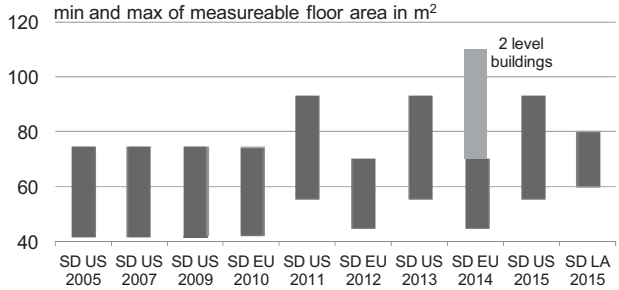

Fig. 1: Evolution of the allowable net floor area in the Solar Decathlon competition between 2005 and 2015, Source: University Wuppertal

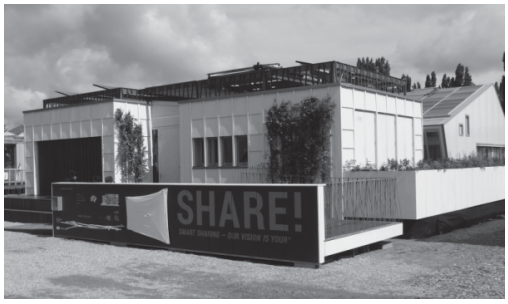

Fig. 2: The team Luzern contribution in Versailles 2014 addresses shared spaces to decrease the individual space needs per person. Source: University Wuppertal

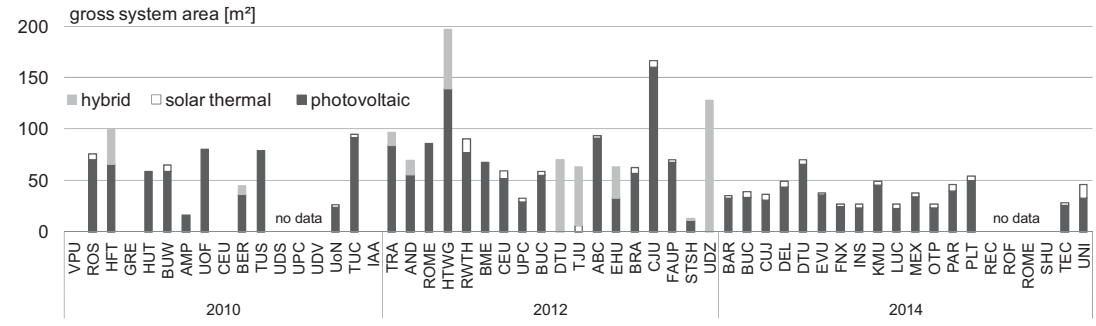

Fig 3: Distribution of the solar system gross area between solar thermal, photovoltaic and hybrid systems within the three European competitions. Source: University Wuppertal

The planned occupation of the buildings in the competitions is denser (30 m² per person) compared to real buildings in Europe (45 m² per person, Germany 2015). This addresses the enormous increase of today's life style in many countries: 3 times increased living area per person since 1950 (example Germany) is only partly compensated by the energy savings of more energy efficient buildings. Keeping this in mind, teams in the latest competitions addressed the topic of shared spaces as part of a more general shared-economy approach (Fig 2.).

Within the competition, the increased occupancy combined with energy efficient buildings resulted in an important role of appliances in the overall energy figure, Fig 4. The temporal correlation of demand and generation becomes an issue together with advanced energy storage and controls (Fig. 5 and section 3.).

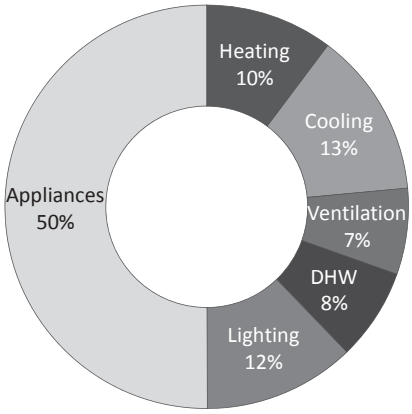

Fig. 4: Typical Distribution of the electricity demand of the solar houses presented at the Madrid competition 2012,
Source: University Wuppertal

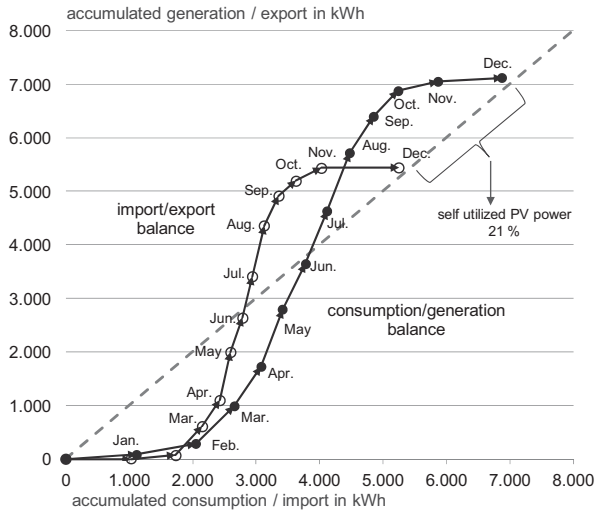

Fig. 5: The annual development of the electricity balance of the Team Wuppertal solar house during full year monitoring. The house was continuously occupied by a 2-person household (Arbach 2014).
Source: University Wuppertal

The competition is made up of 10 contests and generally: five are addressed by measurements and five judged by juries, Fig. 6. As the competition constellation varies between the events, the contest evolution is illustrated by the grouping of topics to 7 main ambitions. Fig. 7 illustrates the evolution of the weighting of these ambitions over the years. Starting with a relevance of 46%, the energy contest has lost half of its importance. This is mainly affected by introducing new contests, such as "affordability" and "sustainability". Whereas in the US the organizers tried to simplify und condense the competition rules (2002: 177 pages → 2015: 62 pages), the European edition of the rules has consistently contained about 150 pages.

The latest events in Europe and China already deal with renovation of existing buildings, mainly on the level of small homes, Fig. 8. This was not the effect of changes in the rules but individual decisions of the participating teams. Some teams work on dense urban structures although building small units in the competition by adding roof top apartments on existing apartment buildings, Fig. 9. A deeper relevance of building renovation and transformation is to be increased in future competition concepts within the new Energy Endeavour initiative (section 5).

The experiences with the large efforts to set up the infrastructure for the solar village together with the request for more intensive events, communication activities and research have stimulated the organizers of the upcoming competitions in China and Dubai to extend the operation of the solar village from two weeks to about three months and connect it to a series of further events.

Usual practice after the competition is the disassembly of the houses and the transport to the home countries of the participating teams. Many of the houses are exhibited on the home university campus and used for research or as office space extensions. This is already well documented for the US competitions, Fig. 10 (link

1). The post competition activities allow to extent the impact of the efforts at the home university in interdisciplinary research and education as well as communication. The joint project "10 Action" within the EU Intelligent Europe program, the summary books edited by the organizers of the two Spanish events (Vega 2011, 2013) or the German language book publication "SolarArchitektur [4]" following the SDE 2010 serve as successful examples of a coordinated after competition publicity in Europe (BUW 2011). The post competition activities at each participating university mean further work and a local budget allocated to it. Experiences from the German teams underline the big challenge in keeping the student teams alive and securing further financial support (Voss 2014). A convincing example from SDE 2010 is the utilization of the house of the Applied University Rosenheim: After two times presentation on large public fairs it was finally placed as part of a hotel development within a zero energy district development (link 3). The house can be regularly booked and experiences with the innovative building concept can be shared. A monitoring is running. A further convincing example is placing the award winner house of the US competition 2013 from the Team Austria in a commercial exhibition site for prefabricated houses near Vienna (link 4).

3. Scientific Liaison

Past Solar Decathlons focused on communicating innovative energy saving solutions and solar energy utilization in buildings to the general public. A special issue of the Energy & Buildings Journal 2014 was the first set of SD publications addressing the scientific value of the event (Vega 2014). A consequent analysis of the monitoring data from the competition week was not in the focus up to now. Some teams addressed building science questions by operating the solar houses as living labs back at home, Fig. 5 (Arbach 2014).

Within the competition, each building is designed for extremely low energy use according to the competition rules. All buildings together form a temporary solar village of all-electric-homes partly linked with electric vehicles, e.g. in Irvine, USA, 2015. Beside low energy consumption and solar energy generation, the correlation of demand and supply becomes a major issue in future energy systems, Fig. 11,12. Based on former research on net zero energy buildings within the framework of the International Energy Agency (IEA Task 40 SHCP / Annex 52 EBC) a new activity was started focusing on "energy flexible buildings" (Annex 67 EBC, link 5). The solar village of the next Solar Decathlon Europe is dedicated as a case study. The energy systems will be designed under consideration of performance indicators for energy flexibility. Heat and power storage together with advanced building automation systems will play a major role. An intelligent link between buildings and electric mobility has to considered. The measurements of the solar village´s smart grid will allow the comparison with the predictions as the basis for a scientific analysis.

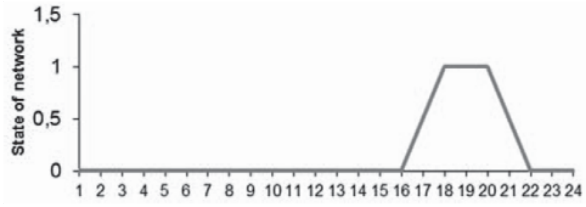

Fig. 11: Example of the energy contest rules in SDE 2014: To assess a house's energy consumption management ability at a certain time of day, the network maximum load period is simplified to a single consumption peak from 5 to 9 pm. If energy is sent to the network between 4 and 10 pm, points are won, proportionally to the amount sent. If energy is taken from the network between 4 and 10 PM, points are lost in proportion to the amount called.

4. Documentation & Analysis - The Knowledge Platform

Currently it is an extensive effort to gain precise information from past Solar Decathlons outside the US. As the competition concept spreads worldwide and has various national organizers, the information is presented on different web portals, in different forms, with different intensities and often disappears shortly after the competition. The SD knowledge platform is a major task to secure the information, experiences and data from past events as well as to feed in the information of new competitions in one place, Fig. 13,14. The web-based platform is currently under preparation at Wuppertal University and is planned for public accessibility in early 2017.

The audience for the information stored is made up of mainly the organizers as well as the participating teams of new events. The available information may stimulate scientific work and the utilization for education. The knowledge platform also will allow the user to do efficient research by using extensive filter possibilities and the full text document search. An interactive map will show all team origins and competition sites. The language of the knowledge platform is English. There will be also the possibility to use a browser built-in translator and filter documents for the language they are written in. After a test phase the teams of the Solar Decathlon China in 2017 and Solar Decathlon Middle East in 2018 will deliver their project manuals, project drawings, pictures and other media data as well as detailed information about their house directly to the knowledge platform.

5. The "Energy Endeavour" Evolution

Contrary to the US competition, which is centrally managed by the Federal Department of Energy (DOE), the Solar Decathlon in Europe is an independent organization for each location. The hosting organization individually works on a memorandum of understanding (MOU) with the DOE. Starting already in 2010 with the "Proclamation of Madrid" (SDE 2010) the participating teams of the Solar Decathlon Europe called for a European profile of the competition and an evolution with regard to form and content. A small team of former SDE organizers and participants was establish to develop an improved European platform for the competition with a link to the DOE (Rollet 2014). This was followed by a series of meetings with European Commission representatives to ask for political and financial support. The European Commission included a small budget for communication of the SDE in the Horizon 2020 2016/2017 budget (EC 2016, link 6). In early 2015 an organizational and financial structure was proposed including the creation of a nonprofit organization (Russell 2015). A central web portal was also created in 2016 to link all SDE events and connecting them to the worldwide movement, Fig 15.

The participating teams formulated in the proclamation of Madrid the need for an evolution of the competition to also address existing buildings and dense urban living (SDE 2010). This was readdressed in a symposium in Madrid 2012 and in the Versailles Declaration of 2014 (SDE 2014). As starting point of a discussion process, an analysis of the strengths, weaknesses, opportunities and threats of the past SDE events was compiled (Tab. 2). The analysis indicates strong potentials in the evolution of the competition itself but also in the link to other events and competitions. Not every need can be covered by the SD format itself but a wider set of competitions including the SD as its currently prime event may improve the impact of all of the events considerably. The name for this framework of sustainability competitions was coined the "Energy Endeavour" by Louise Holloway. The Energy Endeavour is being assisted by the non-profit foundation. The foundation is also negotiating the MOU with the U.S. DOE as their partner in Europe to steward the values, message and content of the Solar Decathlon in Europe.

Tab.2: SWOT analysis focusing on the three European competition editions.
Source: University Wuppertal

Strengths	Weaknesses
• topic of high relevance in society, policy, economy & building science • innovative show cases for communication of ZEB to the general public • unique "design-build-operate" approach for educating students • interdisciplinary work stimulates cross boarder education at the universities	• „insider event“, lack of links • no strong & harmonized communication outside the event weeks • limited market relevance by focus on new and small buildings • lack of links to building energy policy • missing scientific approach & relevance
Opportunities	**Threats**
• collaboration of all actors in the building sector • link to e-mobility • linking craftsmen and academic education • increased impact in research and energy policy • focus on existing buildings and dense urban structures • continuous evolution of topics, rules and form • continuous, harmonized communication and networking	• lack of interest of the general public, depending on location • decreasing degree of innovation (copy & paste) and interest • loss of organizational know-how from one event to the next • non secured financial foundation • risk of sufficient industry support

All past Solar Decathlon events underline the professional approach needed for the success of such an event. If the organizer cannot benefit from previous experience, even minor details can jeopardize success. The essential infrastructure for the competition phase demands considerable effort, from shuttle bus services to measurement technology. This in turn requires an adequate budget (in Europe about 10 million €). In many ways, in form, content and financially as well, new competitions profit from a certain continuity of know how. The Energy Endeavour network will serve as a know-how platform linking the experiences worldwide. This requires a certain financial foundation itself. On the other hand, the network service reduces the budget needed per event.

6. Outlook

An IEA annex addressing the Energy Endeavour initiative will be formally proposed within the program on Energy in Buildings and Communities (EBC) and discussed at its board meeting until the end of 2016. It will depend on the international support with regard to the content and shared funding, whether this new network can start work in 2017. The discussion on a follow up Solar Decathlon in Europe is still ongoing. In the case of successful installation of the Energy Endeavour network, it is intended that the location will be selected by a call for cities in 2017.

Acknowledgements

The work on the competition documentation and analysis as well as the knowledge platform is supported by the German Federal Ministry of Economy and Energy within its funding initiative for Energy Optimized Building (EnOB). The Energy Endeavour Foundation and its initial funding for setup, outreach and communication has been supported by the Faculty of Architecture and the Built Environment, TU Delft.

02. Solar Heat for Industrial Processes

Conference Proceedings

EuroSun 2016
Palma de Mallorca (Spain), 11 - 14 October 2016

Solar thermal energy use in lead acid batteries recycling industry: A preliminary assessment of the potential in Spain and Chile.

Abstract

Lead acid batteries recycling industry has a significant heat demand, including processes at around 500 and 1000 ºC. Due to it, this work faces a preliminary approach to the integration of CSP technology with such an industry. A general description of the recycling process is presented as well as the thermal requirements of the different stages. Smelting and refining are retained among them and they are proposed to be provided with concentrated solar energy as source of heat. Two different locations are evaluated: Murcia, in Spain and Calama, in Chile. Combining the two processes and two locations, four cases are presented. Heliostat field and central receiver dimensions are estimated for each case and the percentage of annual solar fraction is obtained according to the energy demand. A solar multiple is considered in order to include thermal storage and to provide a constant heat demand. While in Spain the proposed solar plants are able to supply 68 and 76 % of the smelting and refining respective annual demands, in Chile the solar fraction achieves 90 and 94 %.

Keywords: *Lead-acid batteries recycling, Solar process heat, Central receiver, Spain, Chile*

1. Introduction

Industrial sector accounts a significant fraction of the global heat demand. For instance in the European Union the total useful heat demand in industry overpasses 4000 PJ/year and covers about 28% of the total primary energy consumption for final uses (Pardo et al., 2012). According to IEA and SolarPACES this consumption can be separated into three temperatures intervals: below 100 ºC, 100-400 º C and above 400 ºC (SHC IEA and SolarPACES, 2008) and concerning European countries, 30 percent of industrial processing requires heat below 100 ºC, 27 percent of industrial heating needs can be met with heat between 100-400 ºC, and 43 percent requires heat over 400 ºC.

The use of solar energy to supply thermal requirements in industrial processes is an environmental friendly alternative applicable to different industrial sectors. However, there is still much room for innovation which has been largely unexploited. In several countries, chemical, petrochemical, textile, food and beverage industries have been considered to assess the substitution of conventional fuels by solar energy, although such a development is still in research stage (Baniassadi et al., 2015). Other promising sectors considered in literature include paper, mineral products, wood, tobacco and machinery among others (Lauterbach et al., 2012). Most studies aimed to integrate thermal solar energy as industrial heat process have been done on below 100 ºC and 100-400 ºC temperature ranges (Calderoni et al., 2012; Frein et al., 2014). Nevertheless, the feasibility of using solar industrial process heat at high and extremely high temperatures has been studied only for small scale processes such as synthesis of chemicals and materials treatment (Steinfeld et al., 2001). (Calderoni et al., 2012). The latest developments in concentrating solar energy technologies tend to increase

doi:10.18086/eurosun.2016.02.17 Available at http://proceedings.ises.org

the operation temperature in order to improve thermal conversion efficiency. If temperatures higher than 1000 ºC are reached in large scale systems, other industrial processes such as some metallurgical reactions can be considered to be addressed with solar thermal energy.

The general challenge in the field is a proper integration of state of art solar thermal technologies according to the heat, temperature and transfer medium requirements. Economic arguments must be also taken into account: due to relatively low energy prices for industrial customers in several countries worldwide, solar thermal systems do often have pay-back times higher than their lifetime. In general, the heat is transferred through a heat transfer medium (water, steam, air, etc.). For those processes that need constant loads, thermal storage and/or fossil hybridization have to be considered.

The lead–acid battery (LAB) is one of the most recycled products throughout the world with a recycling rate in most countries exceeding 95%. Because LAB dominates consumption of the element, around 80% of world lead output, secondary lead sourced from batteries is the major contributor to the world's annual lead production of around 8.4 million tons (Stevenson, 2009). Recycling contributes to the minimization of environment pollution and the conservation of natural lead resource. Moreover, it is considered a profitable business because of the value of lead as a commodity ("Lead Recycling Sustainability in action," 2014) and currently is cleaner and safer thanks to the lasts regulations.

Although the traditional high pollution associated to LAB recycling plants is being decreased with the more recent developments, their high energy consumption is still environmentally harmful. Frías et al. (year not available) presented an innovative process to reduce global pollution in LAB recycling (Frias et al., year not available.). Although their proposal is cleaner than more conventional technology, it still consumes 1 MWh/t Pb. As with other industrial processes, thermal solar energy could be employed to provide heat to several stages of the recycling plant. Thus, the objective of this work is to carry out a preliminary assessment of the potential to integrate central receiver solar thermal technology as heat source for the recycling process, considering two different scenarios: Spain and Chile. More than 350000 tons of LAB are processed in Spain annually what means more than $1.40 \cdot 10^{11}$ kJ of heat consumption in the form of natural gas. On the contrary, the industry in Chile is much smaller, with around 25000 tons of batteries annually recycled. The availability of solar resource is also quite different in both countries, as shown in the corresponding section below.

2. Methodology for the potential assessment

In order to assess the potential use of thermal solar energy in the LAB recycling industry, a general description of the process is presented based on different sources of bibliography and several visits to the plants of Exide Technologies (San Esteban de Gormaz, Soria) and Recobat-Lyrsa (Albate del Arzobispo, Teruel) in Spain, as well as personal communications from the qualified staff of these companies.

A simplified scheme of the operations retained for the study is presented. Typical operation temperatures and distribution of heat demand per ton of produced lead are stablished. The medium through which the heat is supplied is also informed. Those processes that occur at high temperature are selected and solutions are proposed based on the integration of solar central receiver technology. Different thermal storage technologies are also taken into account for the analysis.

An overview of the LAB recycling industry situation in Spain and Chile is also presented. Because the volume of processed LAB is very different in the two countries, two different plant sizes are selected for the study according to both scenarios. Situation of the plants in Chile and Spain are selected among the locations of existing plants, taken into account the isolation conditions.

Assuming that the industries have a portion of available land in their neighborhood, where a solar plant could be installed, a solar field is dimensioned to supply heat to the recycling process. To do that, DNI data of Spain are taken from Meteonorm. Because such a database does not include some areas of Chile, DNI data of Chile are taken from measurements published by the Energy Ministry of Chile. Once the heliostat field and the receiver are dimensioned for the established cases, including a certain solar multiple and a storage capacity, the energy production is monthly calculated. Then, the annual solar fraction is also given.

3. Description of the industrial process

Recycling of spent LAB to obtain secondary lead involves several stages of a global process from the reception of the batteries to the final production of the lead. In general, recovery of the lead and other components is not difficult because the batteries are easily broken and divided into their various fractions. Thus, the recycling of LAB is well established practice throughout the world (Stevenson, 2009).

Although there is not a unique scheme but a combination of different alternatives, many countries have implemented similar recycling technologies able to maintain recycling rates greater than 90%. Stevenson (2009) offers an overview of the most common procedures. Once received at the recycling plant, a LAB undergoes several breaking operations. Free sulfuric acid is drained and pumped to a neutralization plant. The battery itself is dismantled through a hammer mill or roller crusher. The plastic fractions are usually separated by floatation. Other processes exit to separate the components of a LAB, such as using a saw to remove the plastic top and a trommel to extract the internal metallic fractions. The internal parts of a LAB are composed of small fractions of metals and other materials and mainly of the so-called paste, which is formed by the positive (lead oxide, 30-35 %) and negative (lead sulfate 55-60 %) active materials of the battery. The plastic fraction is composed of polypropylene and polyethylene and, to be recycled, it is required their melting at temperatures that varies between 150 and 200 ºC, depending on the fraction composition. Hot air is usually employed as heat transfer medium. Some batteries recycling plant do not include this process but they send the plastic to be recycled elsewhere. Two methods exist for the recovery of lead from battery paste, grid and other lead components; pyrometallurgical and hydrometallurgical. Pyrometallurgical are the dominant methods for both recovery and refining and they are particularly taken into account in this analysis because of their high demand of heat. Main pyrometallurgical operation is the smelting of the grids and active materials, which usually takes places in rotary kilns that are also loaded with iron, coke and other compounds as silica and sodium carbonate (Zabaniotou et al., 1999). The exact composition of kilns load depends on the desired composition of the final product. In general terms, two types of finished lead can be differentiated: one of higher purity (99.98%) that will be further employed to produce lead oxides for cathodes and another one, of lower purity, called hard lead (~97%) that will give rise to grids and the production of lead sulfates for anodes (Zhang et al., 2016). Furnaces temperature can vary in a range of 950-1100 ºC depending on the load. Exhaust gases are employed to preheated air that enters in the kiln at 400-500 ºC. Then, internal temperature of the kiln is increased through natural gas driven burners. After the smelting, lead is separated from the slag and conducted to refining stage. A kettle is operated at maximum temperature of 650 ºC although its temperature varies depending on the consulted source and the finished product composition. Different substances are also added in this stage, such as NaOH, NaCl or NH_3NO_3. The result from the refining operation is the commercial pure or hard lead. A general flowsheet of the recycling processes is shown in Figure 1. Although the plants usually operate 24 hours a day, the process is not always continuous. Thus several intermediate storages can be found between one stage and the next.

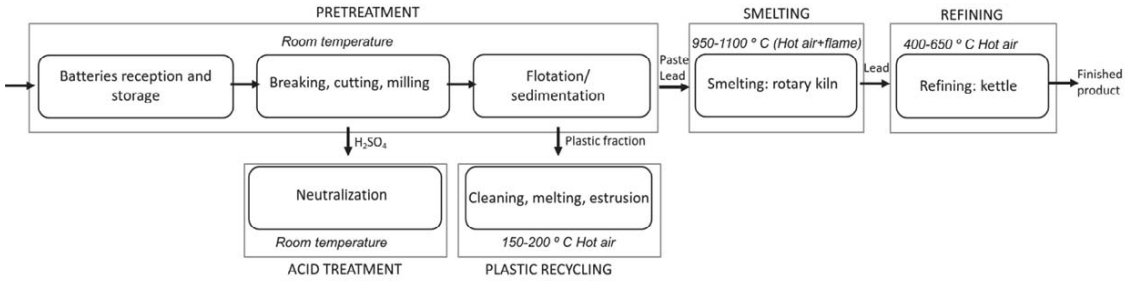

Fig. 1: Flowsheet of a typical lead-acid batteries recycling plant including the most common operations and working conditions.

4. Definition of the study

4.1. Heat demand

Because plastic fraction is usually send elsewhere for its recycling, it is not considered in this analysis. Then, the operations retained for this assessment work at temperature ranges characteristic of solar tower CSP systems.

Smelting temperature can vary between 950-1100 ºC and it is assumed as the average in this case: 1025 ºC. Rotary kilns employ natural gas burners and the heat consumption can be estimated in 43 m^3 per ton of finished product. Refining temperature can be also variable in a significant range but it is considered of 525 ºC for this preliminary analysis. Gas natural consumption of a typical kettle can be estimated in 18 m^3 per ton of finished product. Considered net lower calorific value of natural gas is 10.83 kWh/Nm^3. Note that the furnaces, both rotary and kettle, usually perform in batch mode, what implies the need of storing the material before each operation. Nevertheless, the furnaces are expected to operate also during nights, so for a preliminary analysis it can be considered a constant heat demand 24 hours a day all year round. Thus, thermal storage must be included in the analysis. These definitions are particularly stablished to carry out this work. Although they do not correspond with realistic data of any particular plant, they are based on the information provided by Exide Technologies and Recobat-Lyrsa.

4.2. Location, plant size and solar resource

LAB recycling is an extended practice in Spain with more than 350000 tons of batteries annually processed. (Gallardo Gómez, 2014). This represents a recycling rate over 95% but involves more than $1.40 \cdot 10^{11}$ kJ of heat consumption in the form of natural gas. It is important to note that primary lead production is null in Spain. Four important recycling plants are distributed in different locations of the country and they are indicated in Figure 2 together with their capacity in tons of lead annually produced. Other plants of less capacity are located around the country. The present study is based on a plant located in Murcia which capacity is defined in 30000 tons of lead per year. Murcia is one of the locations of higher DNI as it can be observed in Figure 2 (Geomodel, 2014, 2015).

The LAB recycling industry in Chile is much smaller, with around 25000 tons of batteries annually recycled. Many of the Chilean spent LAB are exported to other countries, mainly to Peru. For instance, 14000 ton of spent batteries were exported in 2008 to several countries. Moreover, there are a significant number of non-authorized recyclers that process batteries outside the law (Gobierno de Chile and GTZ, 2009). Figure 2 shows the location of the only authorized plant that currently operates in Chile whose capacity is about 8000 tons of end lead per year. It is placed in Calama, in the middle of the Atacama Desert where the insolation is the highest measured in the world. This plant is the reference for the definition of the Chilean cases.

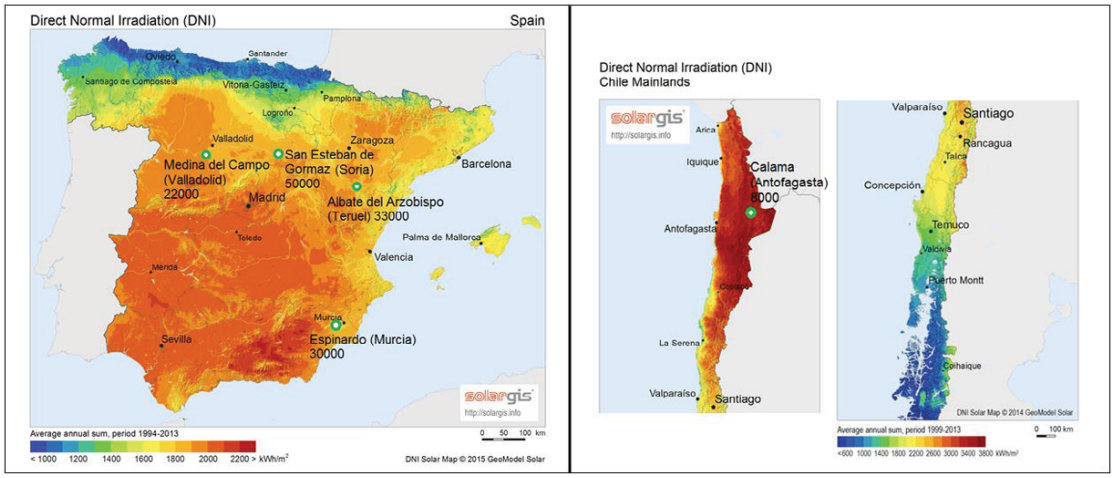

Fig. 2: DNI maps of Spain and Chile provided by SolarGis. Location of the main plants of lead-acid batteries recycling in Spain and Chile (indicated with a green circle) and their approximate capacities in produced tons of end lead per year.

4.3. Cases of study

Smelting and refining operation in both countries, Spain and Chile, have been selected as cases of study. Central receiver technology could be coupled with the processes according to the temperature values. Refining operation could be also coupled with a parabolic through plant but it is not analyzed in this work. Table 1 compiles the specific problems that are approached in this study. Combinations of different plant size, location and point of application in the industrial process leads to four cases of study. Heat demands are estimated for each case taken into account the selected plant capacity and the consumption previously defined for each operation.

Table 1. Definition of starting conditions for the present study. Four cases have been selected by combining different applications, location and plant size.

Case	Location	Operation	Heat demand (GWh/y)	Temperature (ºC)
1	Murcia (Spain)	Smelting	14	1025
2	Murcia (Spain)	Refining	5.8	525
3	Calama (Chile)	Smelting	3.7	1025
4	Calama (Chile)	Refining	1.6	525

5. Analysis of proposed cases

5.1. Case 1

A field of heliostats with an air central receiver can be considered for this case. Since the heat demand is 14 GWh/y and a constant demand is assumed, the required net thermal power is 1.6 MW. A high solar multiple has to be considered in order to overproduce a considerable amount of energy to supply such constant demand. A 3.5 is the selected value for this case and the following for comparative purposes. A storage capacity of 18 h is considered for calculations. Note that the storage capacity will be decreased according to the thermal storage system efficiency, which will depend on the TES system, but it is neglected for this analysis. This solar multiple lead to a receiver useful power of 5.6 MW and this value defines the plant size. For this power, one side oriented heliostats field coupled with a volumetric receiver could be used. In volumetric receivers airs flows through a porous structure and it is heated to high temperature. Ceramic volumetric are suitable to achieve up to 1200 ºC. The system may require a CPC when the peak concentrated solar flux is not sufficient to reach the process temperature. A typical efficiency of a ceramic volumetric receiver is taken from the average of the examples published by (Ávila-Marín, 2011) and it is 64%. Considering an efficiency of the heliostat field of 70 % (Falcone, 1986) for a conservative estimation, the required area of collection would be 12537 m^2. For this calculation, the maximum annual DNI of Murcia (997 W/m^2) was used. Advanced TES systems should be taken into account to be coupled with this type of solar plant. High temperature thermochemical storage (TCS), which is still in development stage, would be suitable to storage and release heat at temperatures ranges of 800-1200 ºC, depending on the employed material. Many works on such a topic can be found on literature (Agrafiotis et al., 2015; Alonso et al., 2015; Pardo et al., 2014)

5.2. Case 2

For this case, a one side oriented heliostat field combined with a central receiver is also selected. Because of the temperature range, this application can be easily coupled with more developed technologies: a cavity with a tubular receiver and the so called Solar Salt (60 % $NaNO_3$, 40% KNO_3) as thermal fluid. The heat demand is 5.8 GWh/y and for a constant demand, the required net thermal power is 0.74 MW. The efficiency of the receiver belonging to PS10 plant (Spain) is taken as a reference, which is close to 90% (Siva Reddy et al., 2013). Although this plant works with water as thermal fluid, the type of receiver can be coupled with the here exposed case. The considered heliostat field efficiency is 70%. A solar multiple of 3.5 is also included in this case as well as 18 hours of thermal storage, using for that a two tanks molten salts storage system, which is the most commercially developed currently. Thus, receiver power is set in 2.6 MW. The required collection area, calculated with the maximum DNI in Murcia results of 4139 m^2.

5.3. Case 3

Case 3 can be analyzed in a homologous form than Case 1. A one side oriented field of heliostat and a volumetric air central receiver are the technologies suitable to be integrated with the smelting operation. Constant heat demand is 3.7 GWh/y, that is, a power requirement of 0.4 MW. Assuming the same criterion to select the solar multiple, the receiver size would be 1.5 MW. The system may require a CPC when the peak concentrated solar flux is not sufficient to reach the process temperature. In comparison with the plant proposed in Case 1, better efficiencies of the heliostat field and volumetric receiver could be assumed due to the favorable climatic conditions of the plant location. A deeper analysis on the design parameters would be required to achieve a relevant evaluation. However, for this preliminary assessment, 70% and 64% are considered as heliostat field and receiver efficiencies respectively. The resulting collection area, for the maximum annual DNI in Calama (1132 W/m^2) is 2958 m^2.

5.4. Case 4

Case 4 would be equivalent to Case 2 in the employed technology and to Case 3 in the location and therefore, the climatic conditions. Proposed technology is a cavity with a tubular receiver coupled with a one side oriented field of heliostats. Thermal fluid would be molten salts (Solar Salt) as shown in Case 2 and it would be included a two-tanks thermal storage system able to take profit of the sensible heat of such molten salts. Constant heat demand is 1.6 GWh/y, that is, a power requirement of 0.18 MW. With a solar multiple of 3.5, the receiver power would be 0.63 MW. Receiver and heliostats field efficiencies taken for this case are 90% and 70% respectively. Then, the required collection area, calculated with the maximum DNI in Calama results of 918 m^2.

6. Annual energy supply

In this section, the annual energy supply estimated to each one of the previously analysed cases is presented. Figure 4 depicts the energy monthly produced according to the designs proposed in section 5. In Case 1, 68 % of the annual energy demand could be supplied by the solar plant, while 32 % should be provided by means of a fossil fuel source of energy. Thus, a hybrid installation will be required despite the use of thermal storage. A re-dimensioning of the plant could be interesting taking into account the cost of both the thermal storage and the fossil fuel back-up. Similar analysis can be done for Case 2 where 76 % of the annual demand could be covered by the solar plant. On the contrary, because of the favourable climatic conditions, those plants located in Calama would have a production close to the annual heat demand of the proposed industrial process. Calculations for Case 3 indicated the plant produce 90 % of the annual required energy, while result for Case 4 is 94 %. The production of a solar plant in Calama is more constant than in Murcia, which is favourable to be combined with a constant demand industrial process.

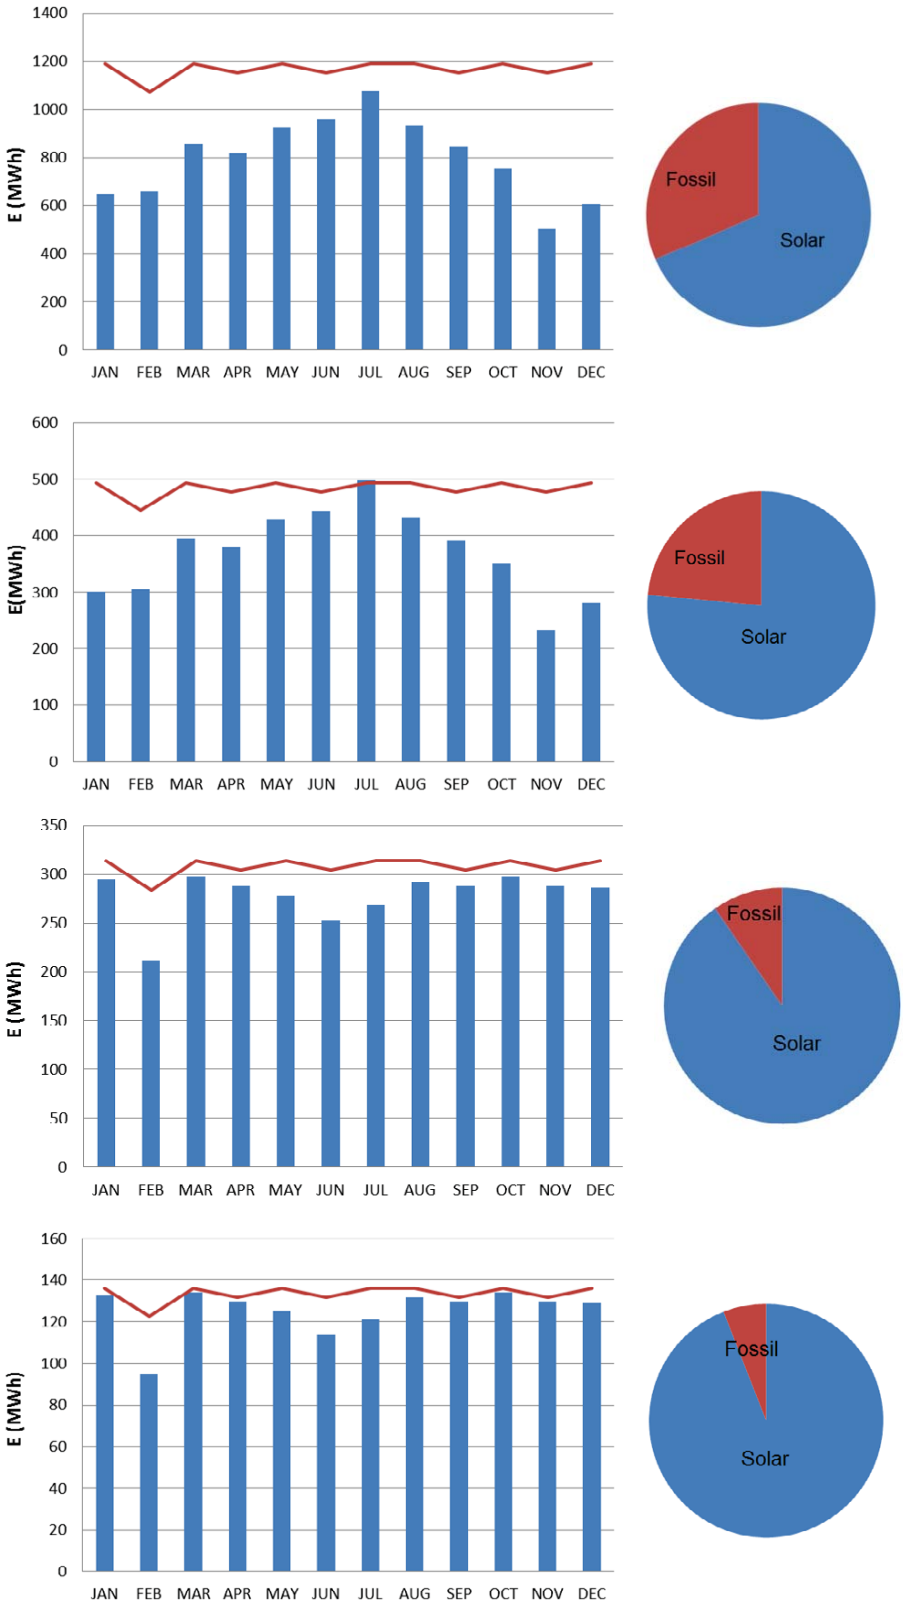

Fig.3. Energy production by the plants dimensioned to the cases described in section 5 per month during a typical year (case 1, 2, 3 and 4 respectively). Red line indicates the monthly heat demand. Fraction of the heat demand that should be provided by conventional fuels, according to the proposed designs.

7. Conclusions

Lead acid batteries (LAB) recycling industry is a strong sector all over the world and the associated heat demand is very significant. A preliminary analysis of the opportunities to integrate CSP technologies in the LAB recycling industry is presented in this work. Two operations, smelting and refining are retained for a concrete analysis and they are couple with central receiver technology. Two different locations are studied: Murcia (Spain) and Calama (Chile), with different climatic conditions. Thermal storage is considered by giving a solar multiple and a storage capacity. Using typical data of literature for plant dimensions estimation, the annual solar fraction of energy demand is obtained for the four proposed cases. While in Spain the proposed solar plants are able to supply 68 and 76% of the smelting and refining respective annual demands, in Chile the solar fraction achieves 90 and 94 %. The production of a solar plant in Calama is more constant than in Murcia, which is favourable to be combined with a constant demand industrial process. Economic aspects as well as daily energy supply management must be taken into account in a further stage for a more complete analysis.

Abstract

After the construction of the first commercial solar power plant with direct steam generation in Thailand, a new horizon will be open for this technology. In this industrial application for electricity generation, financing directly depends on the expected electricity production and corresponding financial revenues. The development of a simulation model for this technology will help reduce costs and hence increase plant output. The simulation model applied in this study reproduces the thermal and hydraulic behaviour of the solar field, including parabolic-trough collectors and connecting pipes. This quasi-dynamic model is able to address transient conditions with low computational resources. In addition, a power block suitable for a 35 MW_e solar plant is defined and analysed, allowing its implementation into the whole solar plant model. An economic optimization of the solar field size has been performed considering standard economic parameters. The main results of thermal and electrical energy obtained from the annual simulation of the optimized plant are presented in this paper.

Keywords: *direct steam generation, parabolic-trough collector, yield analysis, simulation model*

1. Introduction

At this moment, electricity generation is the most extended application of solar heat in industrial processes. Parabolic-trough systems, central towers and Fresnel linear collectors are the main technologies used in industrial applications. Solar thermal power plants based on parabolic-trough collectors are nowadays a successful technology with more than 4,000 MW_e installed and in operation around the world. Most of them operate with synthetic oil as heat transfer medium in receiver tubes, but recently other working fluids, such as water, are being investigated in order to improve the performance of parabolic-trough technology and avoid the environmental issues of synthetic oils. In direct steam generation (DSG), water is heated and evaporated through the solar field to feed a steam Rankine cycle or an industrial process, such as cleaning, heating or distillation in the food and beverage sector (Fernández-García et al., 2010), avoiding the need for heat exchangers and hence increasing the efficiency of the whole system (Eck et al., 2003).

A 5 MW_e solar power plant (Krüger et al., 2012) built in Kanchanaburi (Thailand) and connected to the grid in 2012 is the only commercial plant with parabolic-trough collectors and DSG in the world. This is a first step in the commercialization of this technology. At this point, a flexible simulation model of this technical concept can help calculate the energy production and perform viability studies of solar power plants with DSG in different places, with different collectors and solar field configurations.

This work addresses the simulation of a hypothetical 35 MW_e solar thermal power plant using DSG in parabolic-trough collectors, including the definition of a suitable power block. The simulation applies a quasi-dynamic model able to calculate annual results of thermal and electrical energy with low computational resources. In addition, a brief economic analysis is performed to optimize the size of the solar

doi:10.18086/eurosun.2016.02.05 Available at http://proceedings.ises.org

field considering expected electricity costs.

2. Plant model

The simulation model reproduces the thermal and hydraulic behaviour of each component of the plant including the main elements of the solar field and the performance of the power block. The model has been developed with the TRNSYS software tool (Klein et al., 2007), a graphically-based environment used to simulate transient systems. Models are created by connecting different components, providing a flexible tool that allows different configurations and sizes of the plant and an easy modification of details such as collector type, location, etc.

The solar plant is composed of two main systems: the solar field with collectors' loops of 1,000 m of effective length (20 collectors of 50 m length per loop) with North-South orientation and the power block with a steam turbine of 35 MW_e. Each loop of the solar field works as a preheater, evaporator and super-heater of the feed water, using the solar energy as primary source of energy. In nominal conditions the feed water enters at 206 ºC and 70 bar in each loop to be preheated, evaporated and super-heated in once-through operation mode. The super-heated steam generated in the solar field (450 ºC) is led to the turbine to complete the Rankine cycle, which can operate either in nominal or part-load conditions.

The following sections describe the model of collectors' loop developed to simulate the solar field, the definition and modelling approach of the power block and, finally, the integration of these subsystems in the whole solar plant model.

2.2. Model of collectors' loop

The model of each loop is developed by joining components such as solar collectors, connecting pipes and accessories to compose a whole arrangement. The TRNSYS model of the proposed collectors' loop for the solar plant is shown in Fig. 1, including components for parabolic troughs (type218), connecting pipes (type214) and injector (type228) which have been implemented in the Fortran programming language.

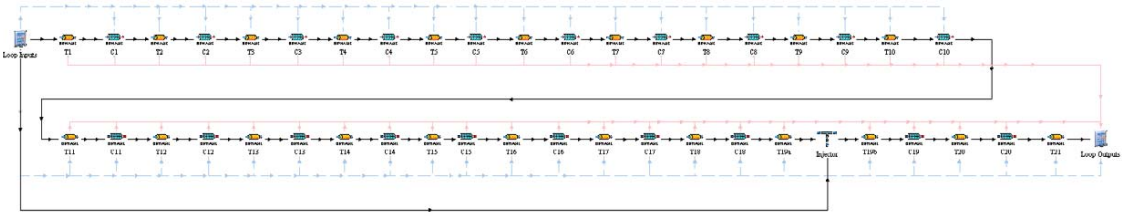

Fig. 1. Screenshot of the TRNSYS model for the collectors' loop

In general terms, the thermal model of parabolic-trough collectors is performed by evaluating the useful power gained by the fluid, $\dot{Q}_u$, with an energy balance between solar power absorbed by the system and thermal losses to the environment:

$$\dot{Q}_u = \eta_{opt,0^\circ}\, \eta_{clean}\, \eta_{sh}\, K(\theta)\, G_b\, cos(\theta)\, A_c - \dot{Q}_{loss} \qquad \text{(eq. 1)}$$

In this equation, G_b is the direct normal irradiance, A_c the net collector aperture area, θ the incidence angle, $K(\theta)$ the incidence angle modifier, $\eta_{opt,0^\circ}$ the peak optical efficiency, η_{clean} the cleanliness factor and η_{sh} the shadowing factor.

In this case, the expression applied to calculate the incidence angle modifier is based on the equation estimated for SkyFuel® concentrators (McMahan et al., 2010) from experimental data. However, SkyFuel® concentrators have 115 m length instead of the length of the foreseen collectors, 50 m. Hence, a correction with the ratio of end-losses factor for 115 m to end-losses factor for 50 m is applied. The resulting expression for incidence angle modifier is given by eq. 2, where θ is given in degrees.

$$K(\theta) = (1 - 2 \cdot 10^{-4} \cdot \theta + 3 \cdot 10^{-5} \cdot \theta^2) \cdot \frac{\eta_{end\ loss\ (50\ m)}}{\eta_{end\ loss\ (115\ m)}} \quad \text{(eq. 2)}$$

Regarding thermal losses in collectors, standard receiver tubes SCHOTT PTR®70 will be considered. The expression for thermal losses has been obtained (Valenzuela et al. 2014) from outdoor tests at PSA:

$$\dot{Q}_L = 0.342 \cdot \Delta T + 1.163 \cdot 10^{-8} \cdot \Delta T^4 \quad \text{(eq. 3)}$$

Where $\dot{Q}_L$ represents thermal power losses per unit length [W/m] and ΔT is the difference between average fluid temperature and ambient temperature [K]. Besides, the main parameters of the collectors and receiver tubes considered for the simulation are summarized in Table 1.

Tab. 1: Main parameters considered for solar collectors

Parameter	Value
Aperture length, m	6
Net collection area, m^2	272.7
Focal length, m	1.5
Peak optical efficiency, %	76.58
Cleanliness factor, %	97
Absorber tube length, m	48
Outer diameter of steel absorber tube, m	0.07
Inner diameter of steel absorber tube, m	0.0588
Inner roughness of absorber tube, m	$4 \cdot 10^{-5}$

During transient conditions, the model performs an energy balance taking into account the effect of thermal inertia due to the mass of fluid, m_{fluid}, and pipe, m_{pipe}, in a time step Δt. The useful energy absorbed by the fluid, $\dot{Q}_u \Delta t$, can be expressed as a sum of energy interchanged in each component. The specific enthalpy of the fluid at the collector's outlet, h_{out}, can be thus obtained knowing the rest of the elements in the following equation, where $\dot{m}$ is the mass flow rate, $\Delta \bar{T}_{pipe}$ and $\Delta \bar{h}$ the increase in average temperature of the pipe and average enthalpy of the fluid, respectively, since the previous time step, c_p the specific heat capacity of the pipe and h_{in} the specific enthalpy of the fluid at collector's inlet:

$$\dot{Q}_u \Delta t = m_{fluid} \Delta \bar{h} + m_{pipe}\, c_p \Delta \bar{T}_{pipe} + \dot{m}(h_{out} - h_{in}) \Delta t \quad \text{(eq. 4)}$$

In steady-state conditions, the two first terms of this equation are neglected ($\Delta \bar{h} = 0$ and $\Delta \bar{T}_{pipe} = 0$) and hence this expression is simplified.

The calculation of the temperature difference between fluid and absorber tube requires the estimation of the heat transfer coefficient by convection, which depends on the fluid phase. For one-phase flow, either liquid water or steam, the heat transfer coefficient is calculated by means of the Dittus-Boelter equation; for two-phase flow the heat transfer coefficient is obtained by means of the Kandlikar (1990) correlation.

On the other hand, thermal losses in connecting pipes are calculated by means of a model of thermal nodes composed of metal pipe and thermal insulation whose properties are known. Then, an energy balance is applied to calculate thermal losses to the atmosphere due to convection and to the sky due to radiation.

The hydraulic model is basically the same for both receiver pipes and connecting pipes between collectors and is based on the calculation of pressure drop through each component of the circuit. If the contribution of pressure losses due to change in kinetic energy is neglected, the calculation can be expressed in terms of pressure losses due to differences in height and friction in straight pipes and accessories. The pressure drop of a two-phase flow of water through a straight section of pipe is estimated from the pressure drop of liquid water by applying the Friedel (1975) proportionality factor; and the pressure loss of liquid water flowing through this pipe is calculated using the Darcy-Weisbach equation.

A detailed description of the TRNSYS model of collectors' loop developed for direct steam generation, together with its validation using the configuration and real data of the DISS loop at PSA, can be found in a previous work (Biencinto et al., 2016).

2.2. Description and model of the power block

A 35 MW_e power block suitable for the proposed DSG solar plant has been defined. This section describes and analyses the behaviour of this power block both at nominal and part-load conditions.

The power block proposed is based on a non-reheat Rankine cycle and includes a steam turbine with three extractions, a wet-cooling condenser, a deaerator, two surface heat exchangers for feed-water preheating and two water pumps. In nominal conditions, the steam produced by the solar field is driven to the turbine inlet at 450 ^{o}C of temperature and $6{\cdot}10^{6}$ Pa. The condenser pressure will be $6.6{\cdot}10^{3}$ Pa. Besides, standard values have been selected for the rest of parameters of the power block.

The analysis of the behaviour of the power block at nominal conditions has been performed with the IPSEpro (2016) software. Fig. 2 shows the basic diagram of the system obtained from this software tool including fluid conditions in relevant points of the system.

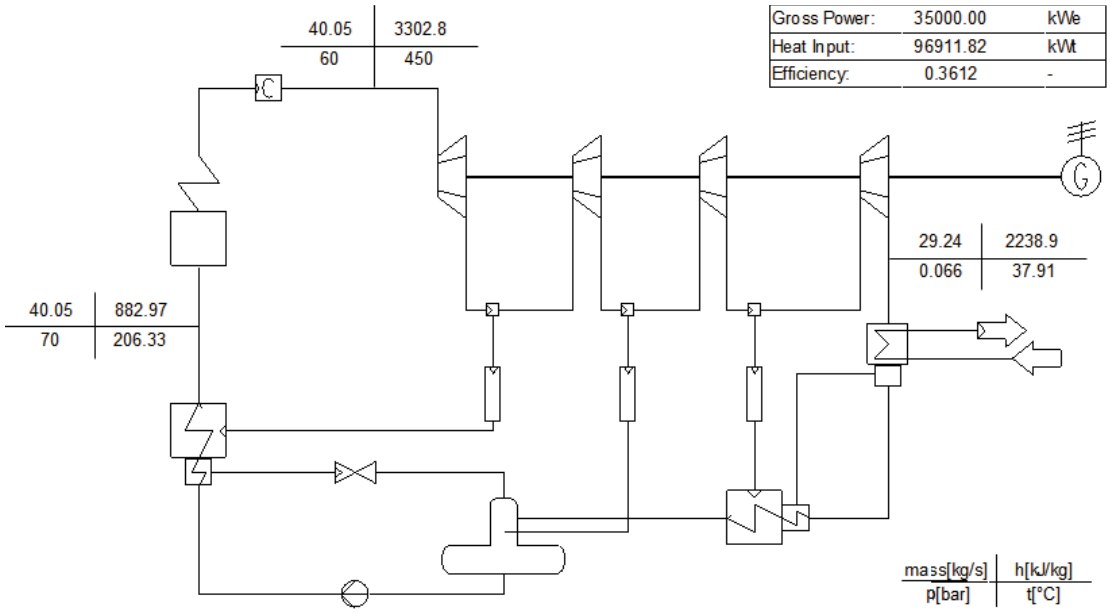

Fig. 2. Diagram of the power block design at nominal conditions in IPSEpro

Equal-enthalpy steps have been assumed for the selection of extraction pressures because this strategy is supposed to lead to an optimum efficiency (Kostyuk and Frolov, 1988). The analysis at nominal conditions in IPSEpro has been applied to determine the most relevant results of the power block that will be useful for the modelling, summarized in Table 2.

Tab. 2: Main results of the power block analysis at nominal conditions

Parameter	Value
Inlet water temperature for the solar field, °C	206.3

Inlet water pressure for the solar field, MPa	7
Steam quality at turbine outlet, %	86.3
Gross efficiency of the power block, %	36.12
Mass flow rate required from solar field, kg/s	40.05
Thermal power required from solar field, MWth	97
Parasitic consumption for water pumping, kWe	416.9

The methodology applied for part-load analysis is based on similar studies for typical Rankine cycles used in solar thermal plants (Montes et al., 2009). However, given the uncertainties associated to the regulation of the working pressure of the solar field in DSG, the control strategy will be based on fixed pressure instead of sliding pressure. Nevertheless, the regulation of part-load behaviour with fixed inlet steam pressure of the turbine by nozzle section control implies an efficiency reduction related to valves throttling and aerodynamic losses. In this way, an additional efficiency losses factor, taken from previous studies (Eck et al., 2008), has been applied for part-load regulation. The resulting isentropic efficiencies at part-load conditions including both conventional reduction and fixed-pressure regulation is shown in Fig. 3 for each turbine stage.

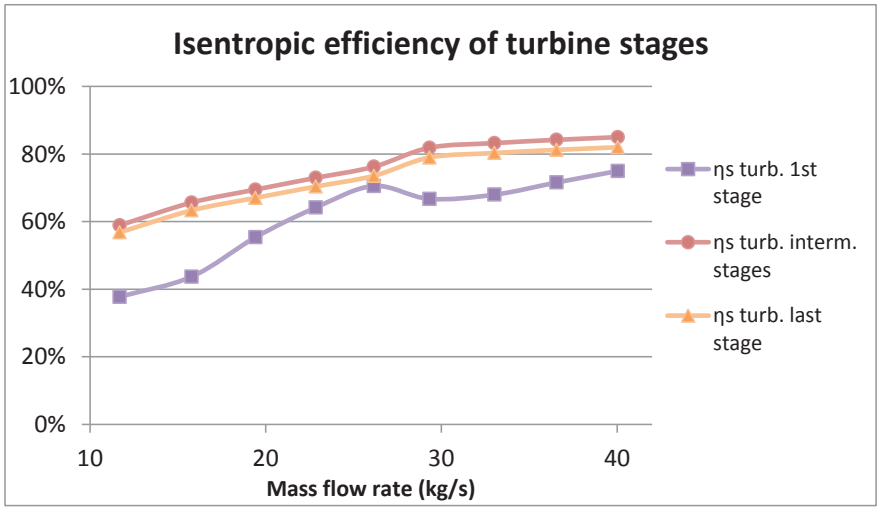

Fig. 3. Isentropic efficiencies for each stage of the turbine obtained at part-load behaviour

An efficiency-load curve has been obtained taking into account the above-mentioned assumptions and methodology. As a result, the evolution of gross efficiency of the power block at part load is shown in Fig. 4.

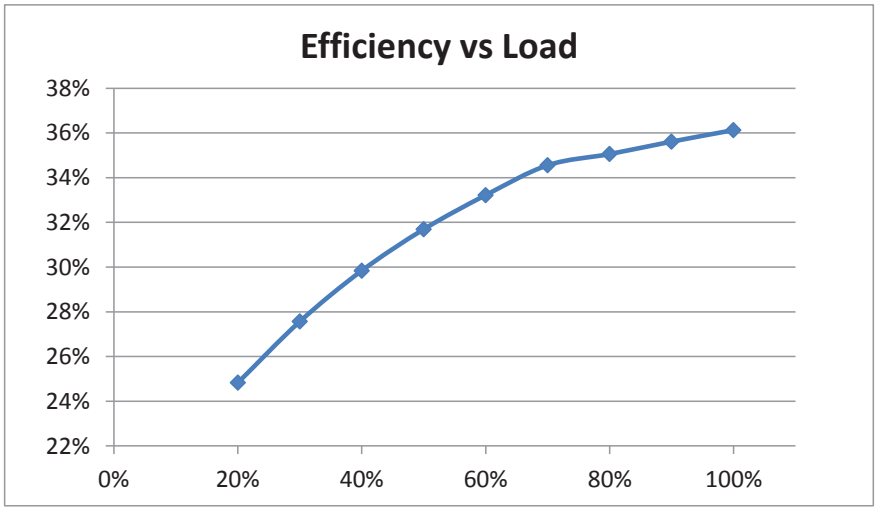

Fig. 4. Gross efficiency vs load curve obtained for the power block

Based on previous works (Eck et al., 2008), 10% overload will be allowed for the power block, leading to a maximum power of 38.5 MW_e. In this case, the nominal gross efficiency will be also applied.

Analogous curves have been obtained for inlet water temperature of the solar field and pumping consumptions. As a result, polynomic expressions relating gross efficiency, inlet temperature of the solar field and electrical losses with mass flow rate have been inferred. In addition, a quadratic curve has been included to simulate the start-up & preheating process of the turbine taking into account metal temperatures.

Finally, the approach explained in this section has been applied to implement a suitable model for the power block at part-load behaviour to be integrated with the proposed DSG solar field.

2.2. Solar plant model in TRNSYS

The general layout of the TRNSYS model for the whole solar plant is shown in Fig. 5, including equation editors, components from the TRNSYS standard library to read input data (Type9a) and determine solar angles (Type16g) and components specifically developed to retain values from the previous time step (type293) and to obtain thermo-physical properties of water/steam (type221). This overall model also includes macro-components that represent several subsystems of the plant: 'Collectors Loop', 'Distribution Pipes' and 'Solar Field Control'.

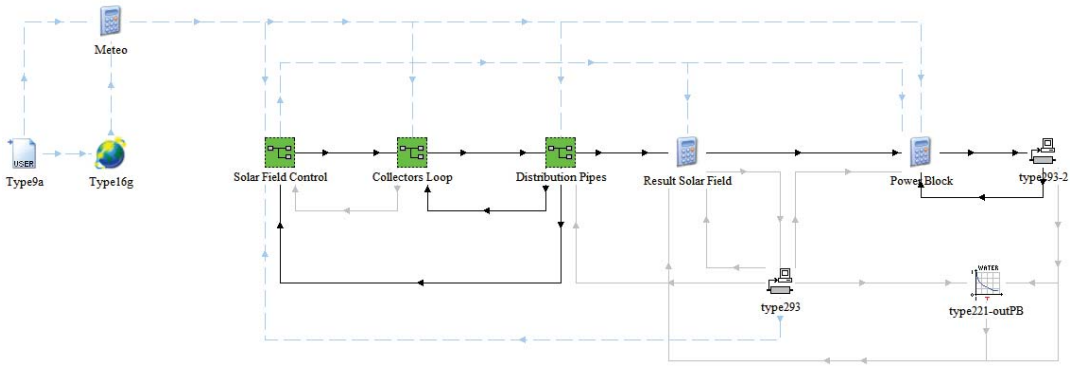

Fig. 5: Screenshot of the TRNSYS model for the solar power plant

The 'Collectors Loop' subsystem (seen in Fig. 1) simulates the behaviour of one loop with 20 collectors. Since all loops in the solar field are equal and they receive the same solar irradiance, the values of mass flow rate and thermal power of one loop are multiplied by the total number of loops to obtain the total results of the solar field.

Besides, the 'Solar Field Control' subsystem implements the corresponding control strategies to determine mass flow rates (loop and injection) and pressure, based on ideal schemes for once-through mode (Valenzuela et al., 2005). This subsystem also handles strategies for plant operation, such as mass flow rate assignment during start-up process, shutdown mechanisms, etc.

The 'Distribution Pipes' subsystem simulates the behaviour of the piping circuit (both hot and cold) between collectors' loop and power block for a solar field composed of two subfields with East-West orientation by means of the pipe component. Since the geometry of distribution pipes may strongly vary throughout the solar field, average diameters for pipe and insulation are applied to allow a simplified approach.

Finally, an equation editor is used to implement the power block model described in section 2.2, both at nominal and part-load conditions, giving as outputs the gross and net electric power generated, pumping consumptions and parasitic losses.

3. Solar field optimization and annual yield analysis

The solar plant model described in section 2 has been applied to perform annual simulations aimed at both optimizing the number of loops in the solar field and obtaining the electricity production of the optimized plant. The location selected for the plant is Plataforma Solar de Almería, Spain (37º05'30" N, 2º21'19" W),

and the input data used for the simulation is a typical meteorological year (TMY). This TMY file contains the record of direct normal irradiation (DNI) and ambient temperature every five minutes from the same site, yielding a yearly DNI balance of 2,071.46 kWh/m^2 and 3,658 hours of sunlight. The time step of every simulation is the same as the time step of input data, 5 min.

3.1. Economic optimization of solar field size

The solar field size needed to match the nominal thermal power required by the power block (97 MWth) will be given by the thermal power gained by the fluid in a collectors' loop at the design point, which is expected to be around 3.3 MWth. The resulting calculation leads to 30 loops in the solar field.

Besides, an important figure to assess the solar field size is the Solar Multiple (SM) of the plant, which is the ratio of thermal power gained by the fluid in the solar field at nominal conditions to nominal thermal power required by the power block. Hence, a number of loops of 30 will represent a SM = 1. However, a Solar Multiple of 1 may involve a limited production, mainly in winter, because low solar irradiances imply that the power block works at part-load condition and therefore at reduced efficiency. In this way, it is recommended to oversize the solar field to avoid part-load operation as much as possible. Nevertheless, the oversizing of the solar field will imply that in certain conditions with high solar radiation the thermal power that is able to produce the solar field will be higher than the maximum thermal power allowed by the power block. These situations will require a partial defocusing of the solar field, thus causing energy dumping.

To assess the effect of solar field oversizing, annual simulations for several solar multiples have been performed using the DSG solar plant model described in section 2. Fig. 6 shows the annual results of net electricity production and thermal energy dumped for the proposed plant, using solar multiples from 1 to 1.47. This range of solar multiples represents 30 to 44 collectors' loops in the solar field, respectively.

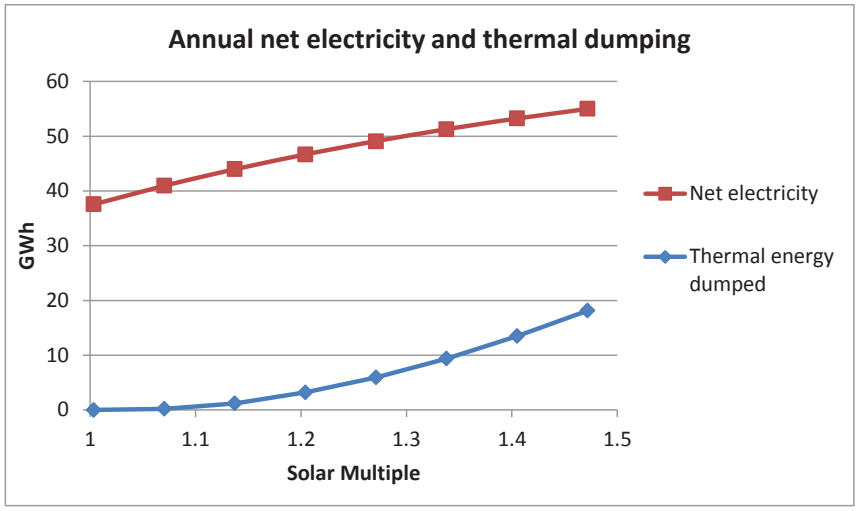

Fig. 6. Annual results of net electricity production and thermal energy dumped as function of the solar multiple for the DSG solar plant considered

In order to obtain the optimum value of the solar multiple (and therefore the number of loops in the solar field), a basic economic analysis has been performed taking into account a rough estimation of electricity costs. According to current definitions (AENOR, 2013), levelized electricity cost is given by the following expression:

$$LEC = \frac{CRF \cdot K_{invest} + K_{O\&M} + K_{fuel}}{W_{net}} \qquad \text{(eq. 5)}$$

Where K_{invest} is the total investment cost of the plant, $K_{O\&M}$ the annual cost of operation and maintenance, K_{fuel} the annual cost of fuel, W_{net} the annual net electricity production and CRF the capital recovery factor.

The economic parameters and specific costs considered for the *LEC* calculation are summarized in Table 3.

Tab. 3: Economic parameters and specific costs considered for the LEC analysis

Parameter	Value
Specific cost of solar field, €/m^2	190
Specific cost of power block, €/kW	350
Land specific cost, €/m^2	2
Engineering & building, % of K_{invest}	20
Annual O&M specific cost, €/(kW·SM)	56
CRF (Capital Recovery Factor), %	10.37

Fig. 7 represents the *LEC* values calculated for the above-mentioned range of solar multiples, together with the dumping factor. For this analysis, we define dumping factor F_{dump} as the ratio of thermal energy dumped to useful thermal energy to the power block.

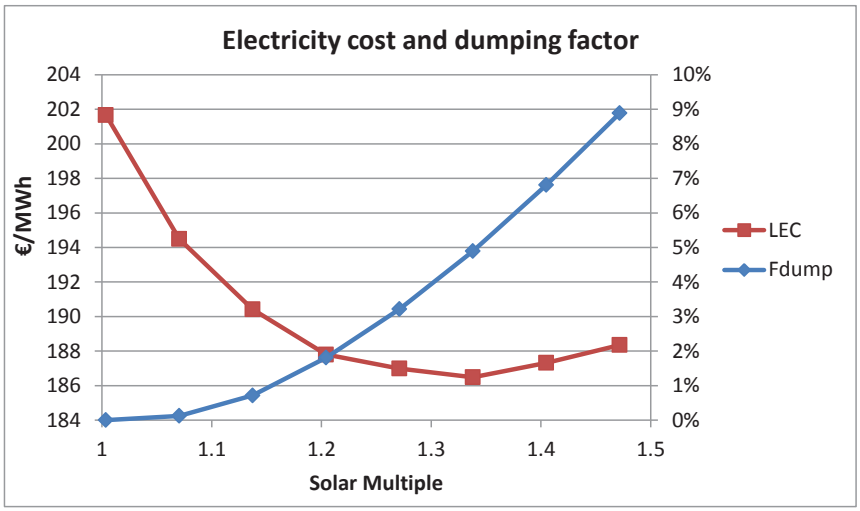

Fig. 7. Results of levelized electricity cost (*LEC*) and dumping factor (F_{dump}) as function of the solar multiple for the DSG solar plant considered

As seen in Fig. 7, the solar multiple that provides a lowest electricity cost is 1.338, which corresponds to a solar field with 40 loops of collectors, leading to a net collection area of 217,760 m^2. The resulting solar field lay-out proposed for this plant is shown in Fig. 8, with the power block in central location and 40 collector loops distributed in two subfields, West and East. Considering an extra space for access and maintenance purposes, the land area required for this arrangement would be around 1,100,000 m^2.

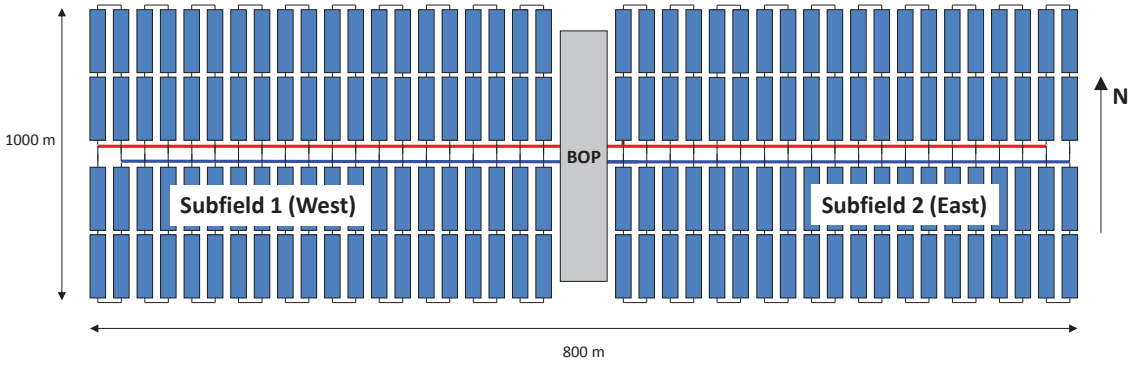

Fig. 8. Solar field lay-out proposed for the DSG solar plant

3.2 Annual yield results

Once defined the optimum solar field size and plant lay-out, an annual simulation has been performed to obtain either the thermal or electrical energy involved through each subsystem. As a result, Fig. 9 shows the monthly values of thermal energy gained by the fluid in the solar field and thermal energy useful to the power block.

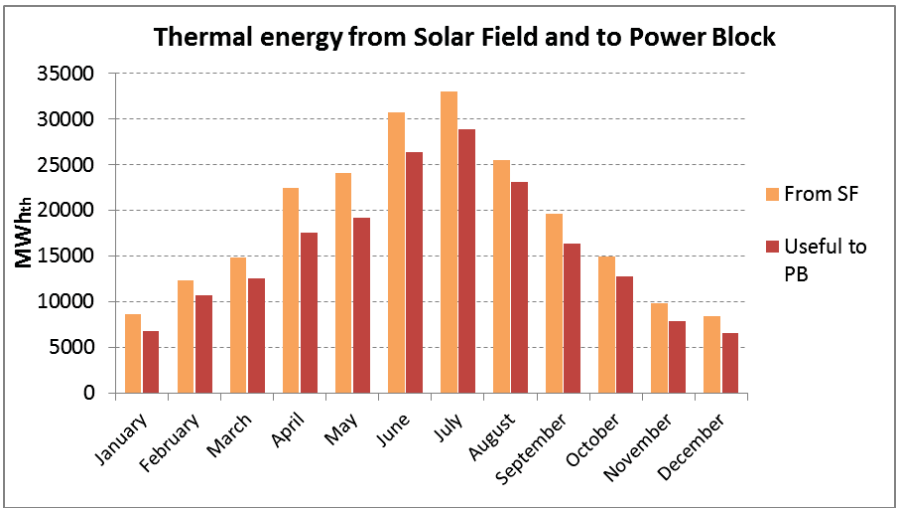

Fig. 9. Monthly results of thermal energy obtained from the solar field and useful to the power block for the DSG solar plant considered

As seen in Fig. 9, thermal energy results show a strong variation between summer and winter months, both from solar field and to the power block. The thermal energy obtained from the solar field in the worst month, December, is 25.6% of the result for the best month, July. In terms of thermal energy useful to the power block, this ratio is 22.6%.

The differences between both magnitudes are related to two main effects. On the one hand, some of the thermal energy obtained from the solar field cannot be used by the power block because the steam has not the required conditions of temperature, pressure or mass flow to feed the turbine. On the other hand, when thermal power produced by the solar field exceeds the maximum thermal power allowed by the power block, the remaining thermal energy is discarded as energy dumping. The monthly breakdown of these two effects is represented in Fig. 10. From this figure, we can point out that energy dumping becomes relevant from April to July.

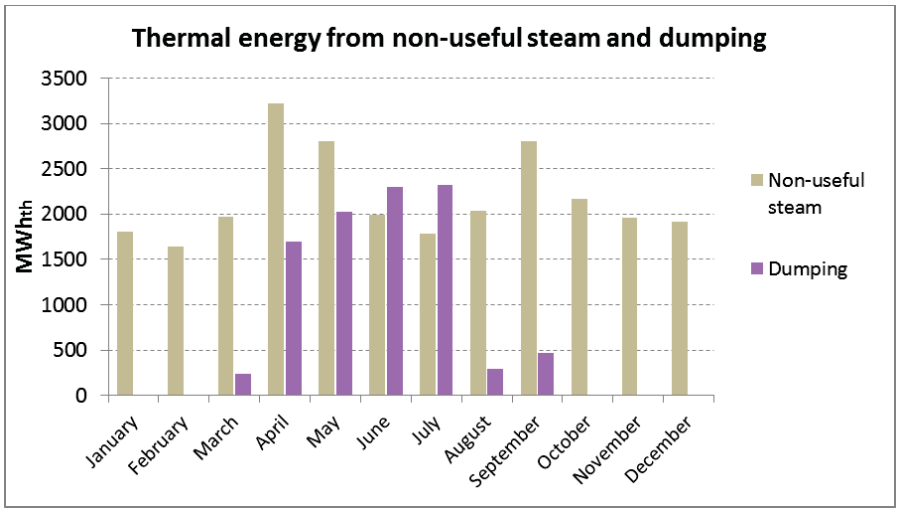

Fig. 10. Monthly results of thermal energy from non-useful steam and thermal energy dumping for the DSG solar plant considered

Fig. 11 shows the monthly results of gross and net electricity produced by the plant.

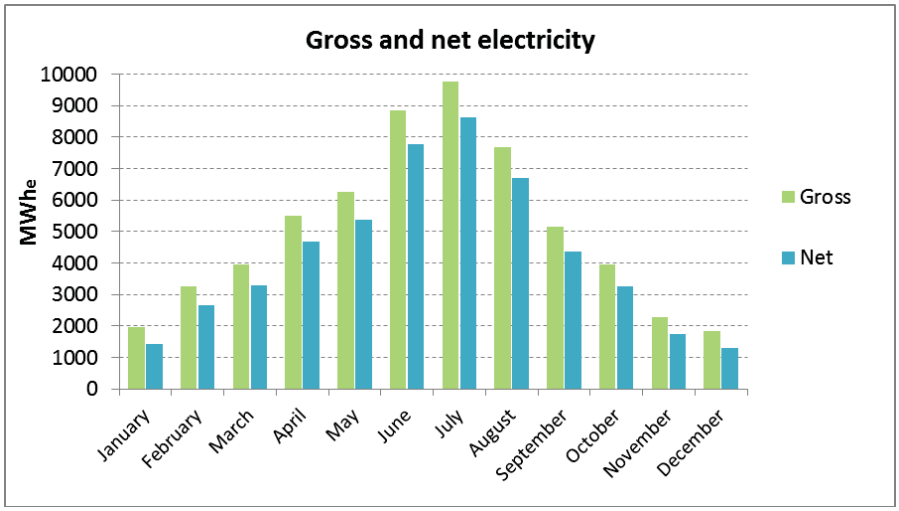

Fig. 11. Monthly results of gross and net electricity production for the DSG solar plant considered

In the same way as for thermal energy, a strong variation can be observed between summer and winter months. The ratio of worst month (December) to best month (July) production is 18.8% in the case of gross electricity and 15% in the case of net electricity. As inferred from these figures, this ratio decreases with each subsystem due to either thermal or electrical losses. In order to illustrate the evolution of energy losses, including optical losses in the solar field, the monthly results of available and useful radiant solar energy, thermal energy from solar field and useful to power block, gross and net electricity production is depicted in Fig. 12.

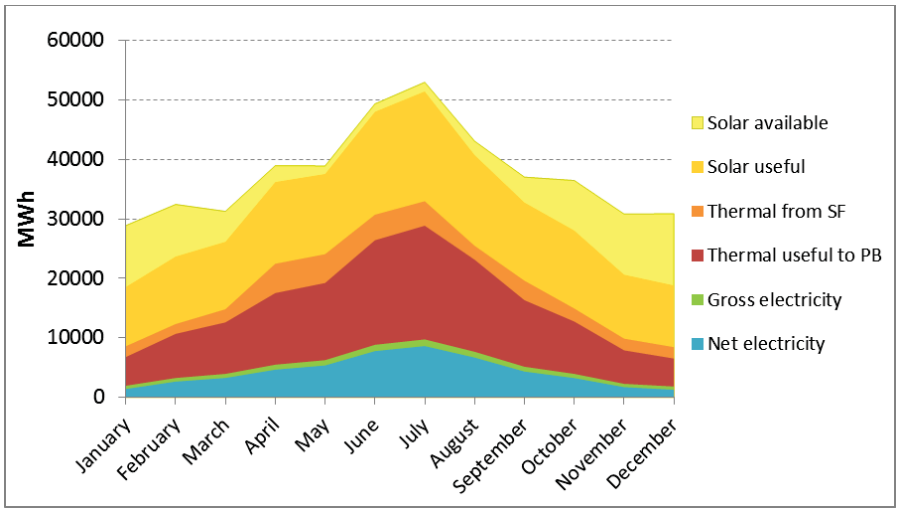

Fig. 12. Monthly results of available and useful radiant solar energy, thermal energy from solar field and useful to power block, gross and net electricity production for the DSG solar plant considered

Finally, Table 4 summarizes the main results obtained from the annual simulation of the plant. The efficiency values included in this table are obtained by dividing thermal or electrical energy results by available radiant solar energy (for plant and solar field efficiencies) or thermal energy useful to power block (for power block efficiencies). Besides, the equivalent operating hours are obtained as the ratio of net electricity production to nominal power (35 MW_e); and the annual capacity factor is the equivalent operating hours divided by the annual total hours (8,760 h).

Tab. 4: Main annual results obtained from the simulation of the DSG solar thermal power plant

Result	Value
Available radiant solar energy, MWh	451,081.56
Useful radiant solar energy, MWh	382,811.24
Thermal energy from solar field, MWh_{th}	224,330.91
Thermal energy dumped, MWh_{th}	9,357.30
Thermal energy in non-useful steam, MWh_{th}	26,107.33
Thermal energy useful to power block, MWh_{th}	188,866.28
Gross electricity production, MWh_e	60,469.84
Net electricity production, MWh_e	51,172.67
Solar field efficiency, %	49.73
Gross power block efficiency, %	32.02
Net power block efficiency, %	27.09
Gross plant efficiency, %	13.41
Net plant efficiency, %	11.34
Dumping factor, %	4.95
Equivalent operating hours, h	1,462.08
Annual plant capacity factor, %	16.69
LEC (Levelized Electricity Cost), €/MWh	186.5

4. Conclusions

Direct steam generation in parabolic-trough collectors may be an interesting solar technology both for industrial applications and electricity production. In this way, this work describes and analyses a 35 MW_e solar thermal power plant with DSG in parabolic troughs using a quasi-dynamic simulation model developed in TRNSYS. A solar field with North-South oriented loops of 1,000 m with 20 collectors of 50 m length, together with a suitable power block based on a steam Rankine cycle, has been defined for this plant. An economic optimization of the solar field size leads to a solar multiple of 1.338, which represent 40 collector loops. The annual simulation of this plant yields a net electricity production of 51,173 MWh_e and a capacity factor of 16.7%. Additionally, a brief economic analysis for this plant gives a levelized electricity cost of 186.5 €/MWh.

Avenue des Sports 20, CH-1400 Yverdon-les-Bains, Switzerland

Abstract

The analysis and optimisation of a medium temperature solar thermal installation for bitumen storage is presented in this article. Coupled with a gas boiler, a solar thermal installation was designed to provide heat to an onsite building, a bitumen tank and two bitumen emulsions tanks The behaviour and performance of this medium–temperature solar system for industrial process have been investigated based on measurements and simulations for subsequent optimisation of the process. A number of anomalies of the system have been identified, corrected and the impact on its performance evaluated. Results show that, on an annual basis, solar energy is mainly delivered to the water storage tanks. Simulations show that there is room for improvement and that the solar production could be roughly doubled if the system operates as designed. The life cycle impact assessment of the solar installation showed that the infrastructure impacts predominate over the entire life cycle. Environmental return on investment periods were found quite interesting in the case of an optimised solar bitumen storage system.

Keywords: *industrial application, solar thermal collectors, thermal storage, bitumen, simulation, measurements, LCA*

1. Introduction

In Europe, the industrial sector is responsible for 26% of the final energy consumption (Eurostat, 2013) which makes it an important player in the energy consumption and greenhouse gas emissions debate. Moreover, (Krummenacher and Muster, 2015) showed that 26% of the industrial process heat demand is lower than 100°C and 19% is between 100 and 400°C. A huge potential exists for these low to medium temperature heat demands to be delivered using existing conventional and advanced collector technologies. It is, therefore, very important to capitalise on this potential as today less than 0.1% of the heat demand in industry is supplied by solar energy (Mauthner and Weiss, 2015). The purpose of this study is to investigate the use of solar energy for bitumen and emulsion (mixture of water and bitumen) storage applications for a subsequent optimisation of the process.

Low temperature processes up to 100 °C are very suitable for using well-established conventional solar thermal systems. For processes in the medium temperature range up to 250 °C, several new types of collectors have been developed recently. Recently, within the framework of the International Energy Agency (IEA) Solar Heating and Cooling (SHC) Task 49 (IEA-SHC, 2014) 134 solar thermal installations supplying process heat were reported worldwide, with a total capacity of about 100 MW_{th} representing a very small fraction (less than 0.1%) of the total solar thermal capacity installed. Those figures demonstrate that there is a considerable untapped potential for solar thermal energy in the industrial sector.

doi:10.18086/eurosun.2016.02.18 Available at http://proceedings.ises.org

Bitumen and emulsions are used in road construction, an industry based on fossil energy with medium temperature heat demands. The operating temperature for bitumen emulsion ranges from 60 to 75°C while for bitumen it ranges from 160 to 200°C. These hot products must be stored, transported and used hot to maintain their workability. Conscious of the important potential of solar heating in the industrial context, but also of the economic and environmental issues related to fossil energy use, COLAS Switzerland, has implemented a medium temperature solar thermal system to maintain its bituminous products tanks at the required temperature.

A first pilot project was launched on an asphalt production site in Geneva in 2011. The solar thermal installation was designed to reduce energy consumption related to bitumen heating and implicitly, reduce emissions of greenhouse gases (Maranzana and Bornet, 2011). This first experience has shown the significant potential to cover the useful heat demand of bitumen heating. On the other side, simulations showed that the annual performance of the solar thermal system could be significantly improved with a better orientation and tilt, lower operating temperature or shorter distance between solar collectors and bitumen tanks. Based on this experience, COLAS Switzerland has integrated an improved and more flexible solar thermal system in its bitumen storage site in Yverdon-les-Bains (Switzerland). In both installations, the solar thermal heat was delivered using ultra high vacuum flat plate collectors.

This paper reports the findings of the R&D project funded by the Swiss Federal Office of Energy aimed to analyse and optimise the thermo-economic and environmental performance of this medium temperature solar thermal installation. (Bunea et al., 2013).

1.1 Description of the facility

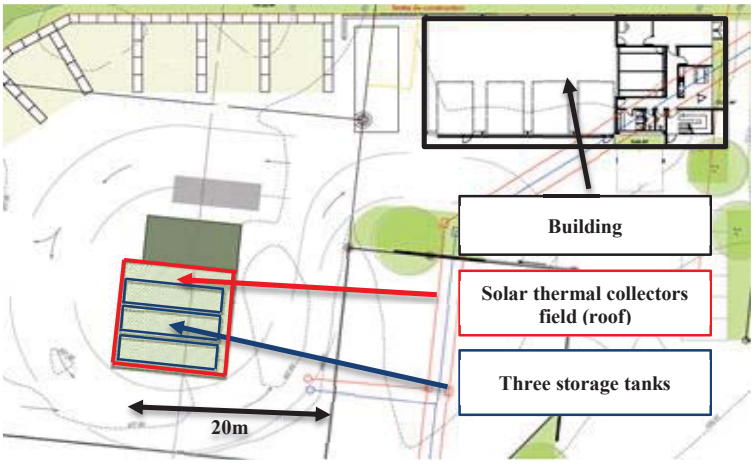

Fig. 1 : Bitumen storage site at Yverdon-les-Bains

In Yverdon-les-Bains, COLAS stores bitumen and its emulsions to be used in road construction. The products are delivered hot from the production plants and stored in three thermal insulated tanks. An ultra-high vacuum flat plate solar collector field backup by a gas boiler are used to heat the bituminous products to temperatures between 160 and 200°C for bitumen and between 60 and 75°C for emulsions. In addition, the heating system delivers energy for space heat and domestic hot water (DHW) for a building located next to the facility. Fig. 1 shows the location of the various components on the site.

There are two operating seasons:

- April to September: “Summer season” - bitumen and emulsions have to be permanently available at operating temperatures. Furthermore, DHW has to be provided to the office and workshop buildings on the site.
- October to March: “Winter season” - Bitumen or emulsions generally not stored, with an exception for dry winters where storage could be extended a few months. In the general case, only heat for space heating and DHW has to be provided.

1.2 Solar collectors

The solar thermal collectors are manufactured by SRB Energy and were developed at the European Centre for Nuclear Research (CERN). The SRB Ultra High Vacuum (UHV) collector (Benvenuti, 2013) uses a technology based on evacuated flat plate collectors. This collector can be combined with cylindrical mirrors, which are a cost-effective way to increase the aperture area and to improve performance at high temperatures.

These collectors are characterised by excellent thermal insulation provided by the ultra-high vacuum (10-8 mbar at ambient temperature) achieved and maintained using a Getter pump. This pump is activated by solar energy and it has the ability to remove air or any other gas molecules inside the collector through chemical reaction. This insulation combined with solar concentration allows the solar collector to reach a stagnation temperature of 400°C, significantly greater than conventional solar thermal collectors. Moreover, compared to the "classic" concentration collectors that only use direct solar radiation, these collectors take also advantage of the diffuse solar radiation, due to a larger absorber area. In Switzerland, the diffuse radiation is an important part of global solar radiation, accounting for more than 50% in Yverdon-les-Bains (Bunea et al, 2013).

The solar thermal field in Yverdon-les-Bains consists of 35 SRB UHV Type C2 solar collectors spread over 7 rows of 5 collectors in series for a theoretical peak power of 96.1 kW with a solar irradiation of 1000W/m^2. They are placed on a specially designed metal frame above the storage tanks, with an orientation of 50° West and 20° tilt. The heat transfer fluid (HTF) used in the system is a Shell mineral oil of type Thermia B supporting over 300°C, without chemical or physical degradation.

1.3 Storage tanks

The bitumen storage site contains four insulated storage tanks, see Fig. 2. Two of the tanks are used for emulsion storage, one for bitumen storage while the fourth is filled with water and serves as heat storage to meet the energy demand of the building but also for emulsion operating needs. The water, emulsion and bitumen storage tanks have a capacity of 23, 50 and 70 m^3, respectively.

The water and bitumen storage heat demand is provided by solar energy and a backup gas boiler whenever solar energy is no available. Emulsion storages heat provision is either through the water storage by means of a heat exchanger or with electric heaters for night operation.

Fig. 2 : Storage tanks of the installation

The bitumen storage site was designed to store solar heat at two temperature levels:

- Water tank: between 60 °C and 90 °C depending on the weather conditions, but also on the building and emulsion heat demand.
- Bitumen tank: between 160 °C (for viscosity reasons) and 200 °C (thermochemical decomposition of bitumen beyond this temperature).

1.4 Building

The building was built in 2012 and comprises a mechanical workshop with a heated volume of about 1500 m^3 and offices over two floors with a total volume of ~1200 m^3.

The building annual heating demand was measured to be 42'370 kWh and includes space heating during winter and DHW for office employees and mechanics who take daily showers.

1.5 Gas Boiler

When solar energy is insufficient, heat provision for the building or to compensate the bitumen tanks losses is supplied by a 350 kW gas boiler. This backup system was installed in 2013 and replaces an old 1000 kW oil boiler.

The boiler contains an important thermal oil storage (~2000 l) which gives a large thermal inertia to the boiler. Although this energy stock generates heat losses, the burner operates mostly at reduced power and provides better overall performance compared to the old oil boiler. In addition, the natural gas operation will reduce the system emissions of greenhouse gases.

1.6 System integration and regulation

The solar pump is switched on when the solar irradiation is larger than 300 $W \cdot m^{-2}$. It circulates the HTF through the solar collectors until the field temperature is above the storage tank temperature, see Fig. 3. In order to improve the solar collector's efficiency, solar heat is delivered priority to the water tank - at lower temperature range. If the water storage tank has reached the set point temperature, then the extra solar energy is delivered to the bitumen tank. Inflow and outflow pipes of the bitumen tank must always be kept at a temperature of 200°C by the gas boiler, to ensure a good consistent flow through loading and unloading periods.

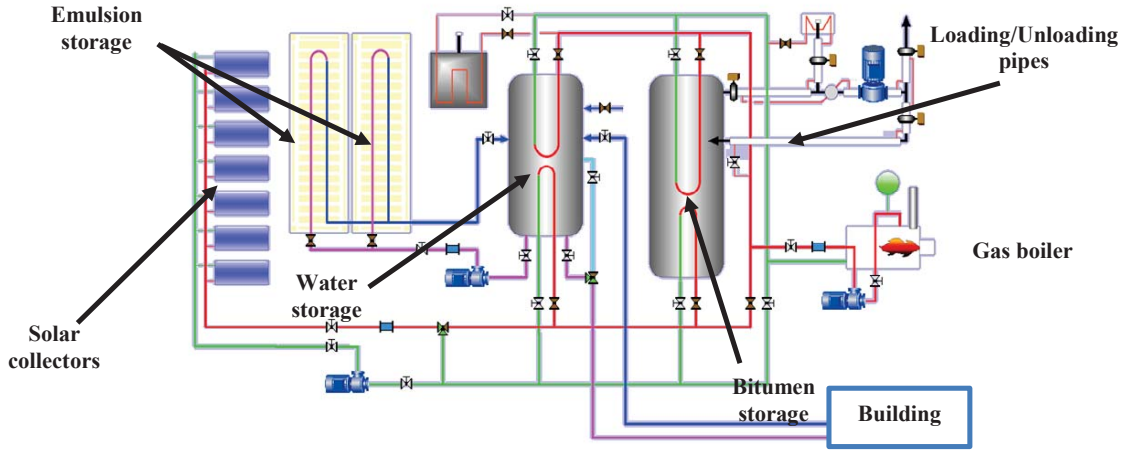

Fig. 3 : Schematic representation of the bitumen storage system.

2. Anomalies and failure analysis

In order to investigate the facility real behaviour and possible anomalies and failures to the expected operation, the facility was instrumented with sensors in the system lines to measure fluid temperatures and flow rates. Troubleshooting of this particular solar thermal system has revealed the following problems:

- The internal heat exchangers of the storage tanks are improperly sized, with a value 3 times lower when compared to the general rule of thumb (e.g. Jobin et al., 1994) for conventional solar collector applications. This causes performance of the system to be reduced.

- Estimation of the heat loss from tanks have shown that the insulation around the bitumen tank is probably improperly installed. For simulation purposes, the measured thermal insulation had to be reduced 10 times in order to have the same thermal loss as the measurements.

- Measurement of the collectors' efficiency have shown an important discrepancy between the accredited test values and the measured ones, see Fig. 4. Differences observed for the optical efficiency (15%) can be partly explained by eventual dust or bituminous particles deposits on the collector glasses and mirrors. A thermographic analysis of the solar collectors' field has further suggested that the thermal insulation of the UHV is also not fully ensured for some of the collectors. Consequently, global efficiency of the collector field is compromised, see Fig. 4. For high operating temperatures, the difference with the theoretical efficiency of the collector exceeds 50%. This highlights the fact that extrapolation of certified tests results beyond 100°C is not appropriate for evaluating these solar thermal collectors.

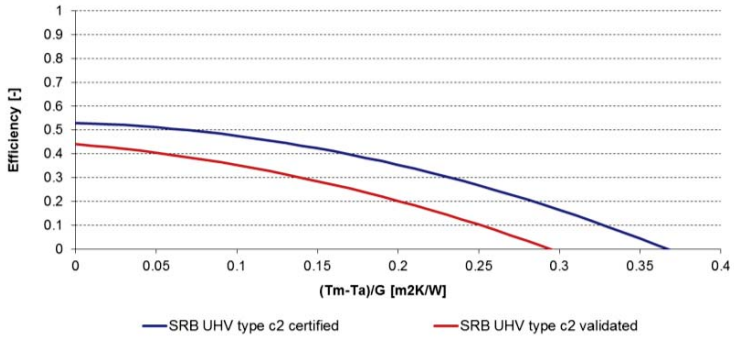

Fig. 4 : SRB UHV type C2 collector efficiency curve

3. Measurement campaign

The described system has been monitored continuously since 2014. This article presents the measurements performed between April 2015 and March 2016 following the modifications implemented from the preliminary study (Bunea et al., 2015). This period includes all improvements made to the system and a full year of measurements showing summer and winter periods.

Fig. 5 shows the weather conditions measured on the site during the investigated period (monthly values):

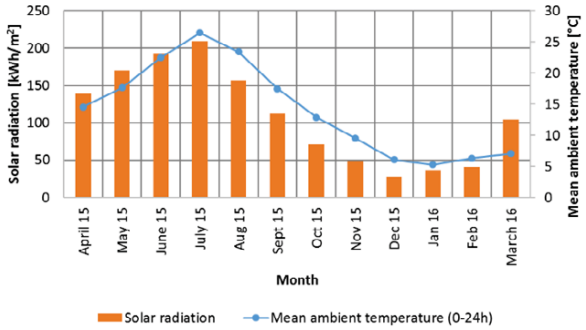

Fig. 5 : Monthly average solar radiation and ambient temperature for Yverdon-les.Bains from April 2015 to March 2016

Results for the period considered show an uncommon evolution during the year, see Fig. 6.

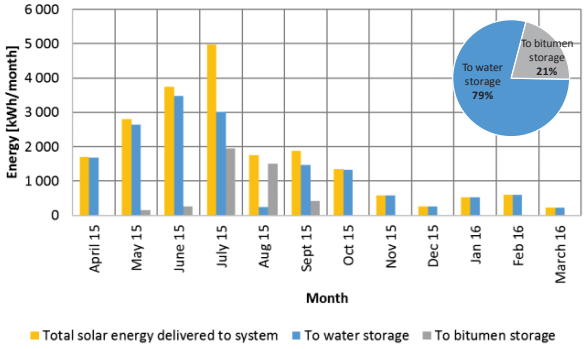

Fig. 6 : Monthly solar energy delivered to the system, 2015

From April to July, an increase almost linear of the solar energy production was observed, with a peak of about 5000 kWh in July. From August onwards, the total solar energy delivered to the system decreased substantially due to a hydraulic problem found in the water storage tank that was taken out of service for two months. Under this configuration, solar collectors delivered energy mainly to the bitumen storage, operating at higher temperatures, which greatly reduced the efficiency of the solar thermal system. The breakdown of solar energy

delivered to the bitumen and the water storage tanks on an annual basis was found to be 21 and 79%, respectively.

During the winter season, it can also be seen that solar energy is only delivered to the water storage tank for space heating and DHW purposes. This amount of solar energy is, nevertheless, low because the combination of shorter days and more diffuse radiation (Yverdon-les-Bains tends to be often overcast) means less solar radiation than in the summer season.

Switzerland's 2015-2016 winter season was an exceptionally dry and warm winter. For this reason, road construction activities kept going beyond de normal summer season and storage of bitumen carried forward until December. The required energy for the bitumen storage site, in this exceptional period, was supplied by the backup gas boiler. Fig. 7 shows the breakdown of the thermal energy delivered to the water tank, bitumen tank and the bitumen loading/unloading circuit, this latter heated exclusively with the gas boiler.

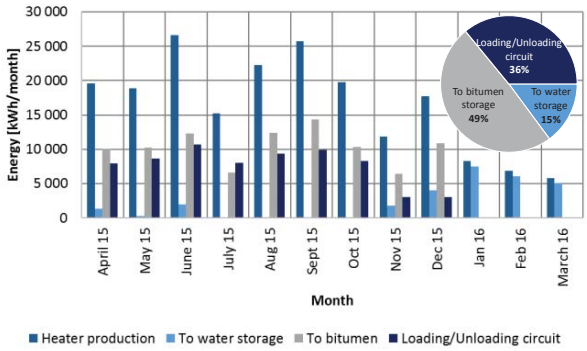

Fig. 7 : Breakdown of the energy delivered by the gas boiler

It can be seen that the gas boiler supplies energy to the water tank primarily during periods where bitumen is not stored. The maximum monthly energy from the gas boiler is found to be over 25000 kWh but the average monthly value for the summer season is about 20000 kWh. This value falls to about 10000 kWh in the winter period. The breakdown of energy delivered by the gas boiler shows that a significant part, 36%, is used to heat the bitumen loading/unloading circuit to enable sufficient fluidity and proper workability of the bitumen. Heating of the emulsion tanks were found to be 98% supplied by electricity and only 2% by the water tank.

Based on this information, it is possible to calculate the solar fraction of the installation, a key factor to evaluate the performance of the solar thermal system. The solar fraction is the ratio between the solar energy supplied to the water and bitumen tanks and the total energy required by the system, including gas and electricity energy consumptions.

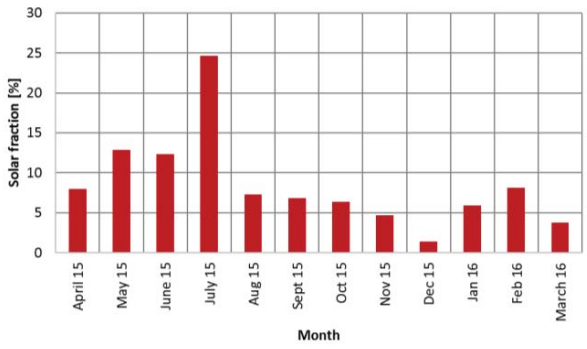

Fig. 8 : Average monthly solar fraction of the system

Fig. 8 presents the solar fraction of the installation on a monthly basis. It can be observed that for the entire year, solar fractions are generally quite low, with a majority less than 10%. The high value of ~25% solar fraction observed in July is due to the good climatic conditions, see Fig. 5, but also because of a low activity in the road surface construction sector and implicitly on the industrial site for this specific month.

The low values mean that for this particular application under current operating conditions, solar energy is not fully maximised. The operational problems encountered with the water tank in August have significantly contributed to this poor performance. However, an overall analyse of the system operation revealed a poorly use of the solar energy in the bitumen storage site to meet their specific energy saving goal. This is the case of the emulsion tanks that are mainly heated with electricity even when the water tank is able to provide the required energy. Furthermore, the real efficiency of the solar collectors was found to differ considerably from the theoretical values. Differences between these values are probably due to dirt accumulation on the glass cover and a potential vacuum loss, factors that were investigated in the simulation, see 4.2.

As the solar collectors supply energy to the water tank, their performance changes from that when energy is delivered to the bitumen tank due to their different operating temperature. To illustrate this Fig. 9 shows a comparison of the performances under these two supply configurations against the daily radiation.

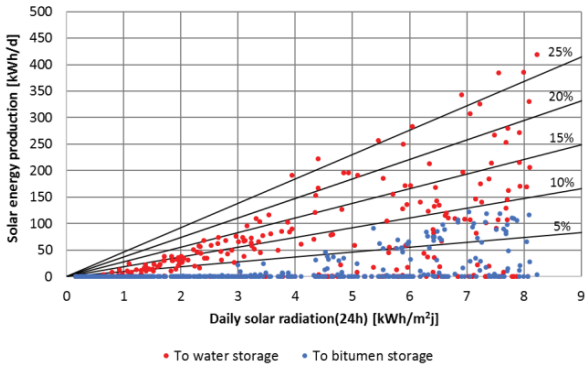

Fig. 9 : Performance distribution of solar collectors

Overall, the performance is low under all operating modes. The distributions indicate that the collectors' performance decrease when charging the bitumen tank (blue dots) with values below 10%. However, when delivering energy to the water tank (red dots) the performance is better and could reach 25%. In this case, scattering of the data is more pronounced because of the different utilisation modes of the water tank. Data points at 0% performance correspond to days where the collectors' pump was operating but no heat was delivered to any of the two tanks. This happens because the operating temperature is not higher than the storage tanks temperature. Consequently, 35% of the total energy used by the solar pump was spent for circulation only, clearly revealing a controller malfunction.

4. Numerical simulation

A simplified numerical model of the heating system was designed using the Polysun software, version 9.0.9. The complexity of the installation does not allow the use of Polysun current implemented models. Hence, a specific model was designed to reproduce the behaviour of the installation in Yverdon-les-Bains and to simulate its annual performance. This model will be further used in this project to optimise the solar thermal control system. Fig. 10 gives an overview of the simulation model and its different components.

4.1 Assumptions and simplifications

The gas boiler and its hydraulic system were modelled as integrated gas boilers placed within the storage tanks (see Fig. 10). This means that the pump and piping components connecting the gas boiler to the storage tanks were not taken into account. However, thermal losses due to fluid transport and the gas boiler oil storage were considered.

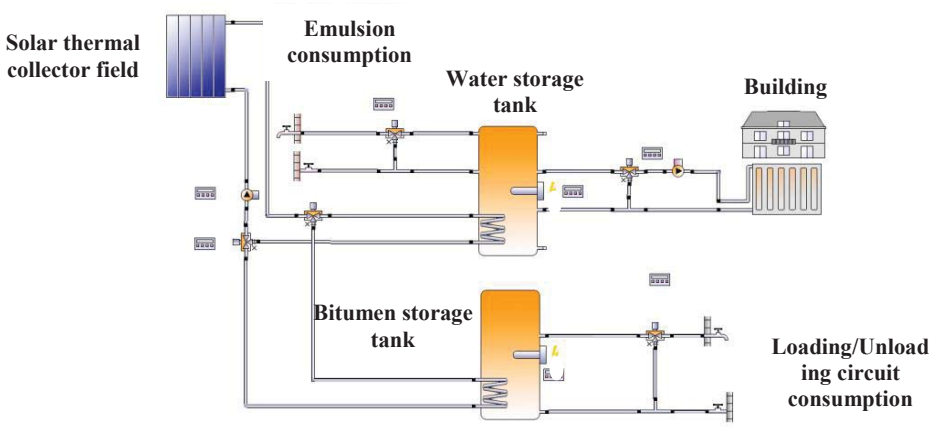

Fig. 10 : Schematic diagram of the simulation model of the bitumen storage installation in Yverdon-les-Bains.

Polysun is not designed to deal with tanks that are partially filled. Consequently, the energy consumed by the loading and unloading of emulsion and bitumen was taken similar to a DHW loading profile. A constant inlet temperature was fixed while the outlet storage tank temperature was set to 155°C for bitumen and 55°C for emulsion. The daily quantity of extracted fluid from the tanks was adapted in order to have the same amount of monthly energy consumption as measured for the given period. The electric heating elements for emulsion tanks were not included here, because in an ideal system, the emulsion should only be heated by the water tank.

Both storage tanks numerical models were validated against measurements taken when the tanks were turned off for several hours. This prevented any energy going in and out of the tanks, leaving heat loss from the tanks as the only driver. The collector model was provided by SRB Energy as it is not available in the Polysun database. The performance coefficients were estimated considering the certification test results.

4.2 Simulation results

To validate the overall operation of the system, measured monthly consumptions of the building, bitumen and emulsion tanks were introduced in Polysun. Fig. 11 compares the predictions of the annual energy consumption with the measurements and acceptable agreement is obtained. For the analysed period, heat supplied to the emulsion tanks was mainly by electricity. This working procedure leads to reduced energy consumption from the water storage in summer season and implicitly less solar energy production at lower temperatures.

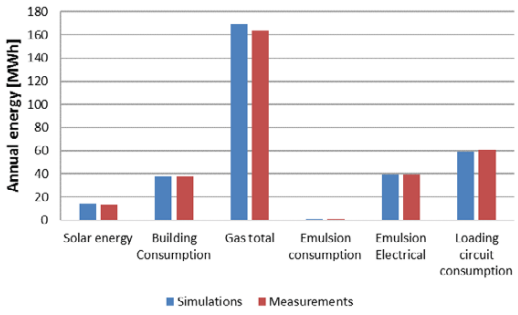

Fig. 11 : Simulated and measured annual energy flows

Based on the observed failures and improper operating practices, several simulations were performed to estimate the potential of this system operating under ideal conditions, namely: solar collector field performance as certified, well-insulated bitumen tank and improve control system operation. The latter allowing heat for emulsions to be supplied either by solar energy or by the gas boiler through the water storage.

Fig. 12 shows an increase of over 75% of the annual solar energy production when the collector performance is based on the certified values.

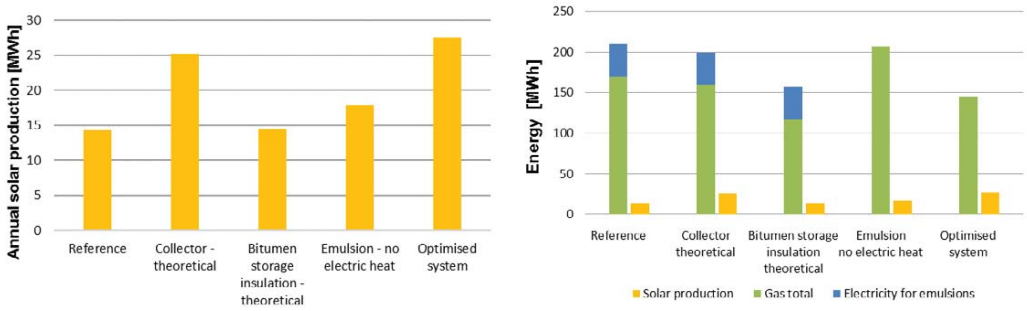

Fig. 12 : Predicted annual solar energy production and heat consumption for different system configurations

Improved insulation of the bitumen storage is found to have a significant impact on the gas consumption of the system (31%), but not on the solar production. The optimised system taking into considerations all enhancements presented above, while keeping the original heat demand, shows very promising results with an increase of over 90% for the solar energy production, no electric heating consumption and 15% less gas consumption when compared to the actual measured system. Nevertheless, in all cases, the overall share of solar energy contribution remains low (e.g. 19% for the optimised case).

The effect of different operating conditions on the performance of the optimised system was further investigated as a measure of the overall solar thermal efficiency. The effects of changing dimensions of the internal heat exchanger, collector field surface area as well as the collectors' orientation and tilt were studied, see Fig. 13.

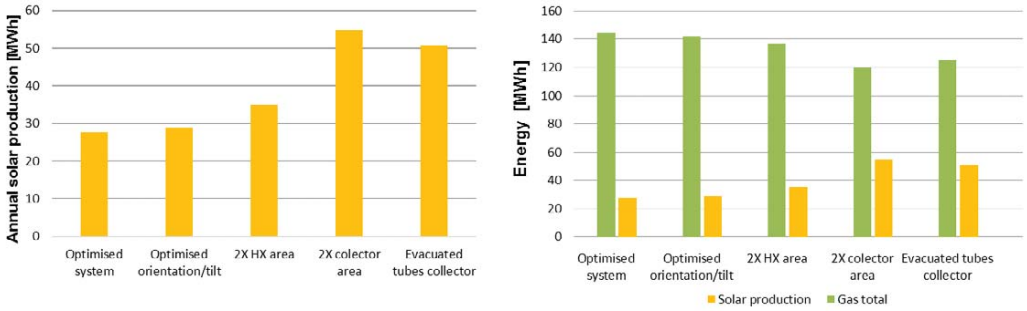

Fig. 13 : Predicted annual solar energy production and heat consumption for different operating conditions – optimised system

Collectors tilted 35°and south-oriented seem not to significantly increase solar production. In contrast, with larger heat transfer surface areas, high solar production is achieved due to a higher thermal performance of the heat exchangers and consequently lower inlet collector temperatures. Large solar thermal collector fields will certainly improve the annual solar energy production, but, because heat in summer is also supplied to the high temperature bitumen tank, collectors will present a low degree of efficiency.

As observed in Fig. 6, the large energy demand of the water storage results in a low solar energy supplied to the bitumen tank even with larger collector fields. The effect of replacing the SRB UVH C2 collectors by evacuated tube collectors for heating the water storage while bitumen was heated with gas revealed that it is possible to double the solar energy production while decreasing the gas consumption.

5. Life cycle analysis

An environmental assessment was conducted taking into account the environmental impacts of the installation materials as well as the energy consumed by the solar installation. The methodology applied in this study is conforming to standards ISO 14'040 series (ISO, 2006). The functional unit considered the impacts generated by the solar installation including the energy and materials consumption over an operational period of 20 years. The system boundaries include manufacturing and disposal of the materials used in the solar installation and the energy consumption throughout the use phase. Transport between the assembly site and the installation site is excluded from the analysis. All impact values were taken from KBOB database (KBOB, 2014) or Ecoinvent database v2.2 (Frischknecht et al., 2004). The indicators considered in this study are:

- *Cumulative Energy Demand NRE (CED_{NRE})* in MJ-eq considers non-renewable energy only. This indicator includes fossil, nuclear and biomass from primary forests (i.e. biomass consumption that contributes to deforestation or forest/woodland degradation)
- *Global Warming Potential (GWP)* in kg CO_2-eq

The analysis aims to estimate the environmental impact of the solar installation (solar collectors, pipework components and supporting structure) to compare to the potential energy savings it could possibly bring. Energy consumption of the installation was defined based on monthly simulations. The analyse considers the solar installation as operated between August 2015 and July 2016 (reference case) and the optimised system.

5.1 Impact of the solar installation

Data on material constituents of the solar installation, including the supporting structure of the solar collectors, was determined by the industrial partner or based on experience. Fig. 14 shows the environmental impacts of the main components of the solar installation. It can be seen that impacts due to the supporting structure predominate and are responsible for over 60% of the total CED_{NRE} impact because of the large number of components. Impact of solar collectors represent nearly 30% while pipework circuits 9%. A similar distribution is found for GWP indicator.

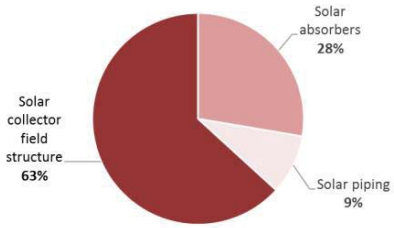

Fig. 14 : CED_{NRE} impact of main components of the solar installation

5.2 Assessment of the solar installation

The measurements and predictions have clearly demonstrated that the use of solar energy in bitumen storage can lead to energy savings. Thus, the solar energy used was converted into gas and electricity savings. Two cases were considered:

- Case 1: reference case where all supplied solar energy corresponds to gas savings as the emulsions were essentially electricity heated.
- Case 2: optimised installation according to simulations where all supplied solar energy corresponds to gas and electricity savings as the emulsions are only heated by the water storage.

In both cases, energy from the different pumps in the system (solar, boiler and emulsions) was taken into consideration.

The measured useful energy was converted into final energy by considering a thermal efficiency of 80% for the gas boiler (value from practice) and a 100% efficiency for conversion into electrical energy. The annual solar energy production for case 1 was predicted to be over 14000 kWh while for case 2 was above 27500 kWh. Fig. 15 shows the impacts of the solar installation due to infrastructure components and pump electricity

consumption and the gas and electricity savings that could be made over the entire life cycle span.

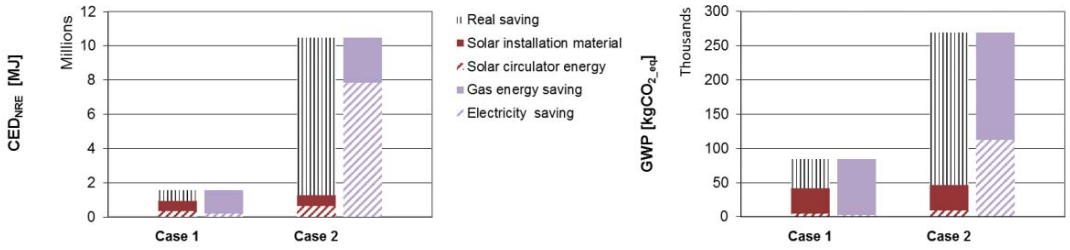

Fig. 15 : CED_{NRE} and GWP impacts of the solar installation and derived real savings

In both cases and for both indicators, the solar installation related impacts are lower than the derived savings of primary energy or emissions of greenhouse gases. This means that the use of solar thermal for this particular application is still interesting in terms of energy savings despite the strong impacts of the supporting structure.

An important difference of impacts is also observed between case 1 and case 2. Indeed, the operating problems observed during the investigated period strongly penalise case 1. In the optimise configuration (case 2), replacing emulsions electric heating by the water heating, contributes to significantly increase energy savings and consequently, decrease impacts.

The evolution of these impacts and potential savings over time has allowed defining the return on the investment this solar installation offers, see Fig. 16.

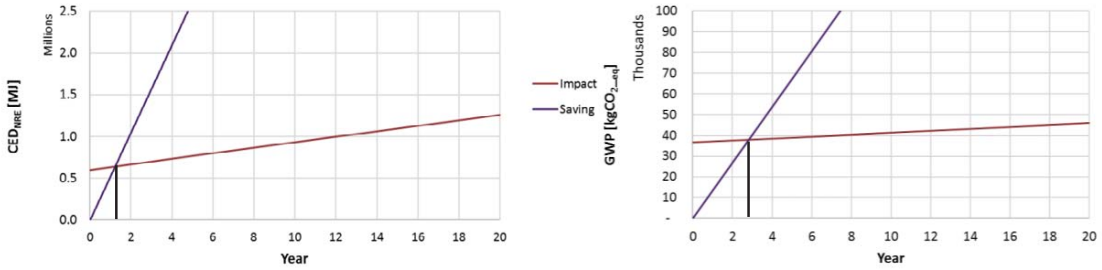

Fig. 16 : Return on investment for case 2

It can be seen that for case 2, the solar installation offers 1 and 3 years return on investment for CED_{NRE} and GWP, respectively. Longer return on investment times, approximately 10 years, were found for case 1. Thus, improving the bitumen storage system and in particular replacing emulsions electricity heating by gas and solar is not only environmental but economically interesting.

6. Conclusion

The behaviour and performance of a medium–temperature solar industrial process for bitumen storage have been investigated based on measurements and simulations for subsequent optimisation of the process. Important differences, up to 50% at 220°C, between the certified performances of the solar thermal collectors and measured were observed during this project. The low solar fractions (~10%) observed for this installation are a result of combining low and medium temperature applications with a variety of operating modes into a single solar installation.

Simulations show that there is room for improvement and that the solar production could be roughly doubled if the system operates as designed. Furthermore, simulations prove that the heat exchangers designed for both thermal storages are undersized. Increasing solar collector area results in higher solar productivity, but still relatively low annual collector field efficiency.

Supplying water storage with solar energy from evacuated tubes collectors for emulsions and building heating

needs, proved to be a cost-effective configuration for this industrial site.

The life cycle impact assessment of the solar installation showed that the infrastructure impacts predominate over the entire life cycle, accounting for over 60% of the total CED_{NRE}. Energy savings brought along by the solar installation more than compensate the additional material and energy related impact of integrating such a system. Less than 3 years environmental return on investment periods were found in the case of an optimised solar bitumen storage system.

Abstract

An agricultural greenhouse is thermally analyzed using the simulation program TRNSYS 17. The thermal loads resulting from the heating and cooling are calculated to maintain the greenhouse temperature within the range of crop development. Construction materials, geographical location and the optimal development characteristics of the Saladette tomato and its different growing stages are also reported. The thermal performance inside and outside the greenhouse with and without air conditioning is also described. The heating and cooling loads are shown for an idealized air conditioning system considering the number of heat exchangers, temperatures required by the crop and the hot/cold water temperature available in the system. The results of a thermal analysis for a three day in June is described in detail. The temperatures inside and outside of the greenhouse, including the thermal load for the most critical day of the year are shown. Simulation results show that 4,231,966 GJ and 39,324,140 GJ are being demanded for heating and cooling respectively along a typical meteorological year. A case of study is presented in order to analyze the greenhouse in which energetic requirement is partially provided using solar energy. The simulation shows that in order to achieve a solar fraction of 72% for heating and 30% for absorption cooling, 300 solar collectors are needed.

Keywords*: Agricultural greenhouse, Solar heating and cooling, Trnsys simulation, Solar heat for industrial processes.*

1. Introduction

In Mexico tomato production in greenhouses with controlled environments is taking great importance. The use of highly automated greenhouses allows to control the necessary variables for tomato growing and thus significantly increase the volume of annual production in continuous operation (Kolokotsa et al., 2010). The main variables for a greenhouse are temperature, humidity, CO2 and the plagues (Attar et al., 2013), (Chargui and Sammouda, 2014), (Kamel and Fung, 2014). It is necessary to have a closed greenhouse in order to control the variables as proposed by Vadiee and Martin (2013 a). However, in extreme climates with low relative humidity, cold but sunny winters and hot summers, it is possible to get temperature variations up to 25 °C in a day. For a greenhouse under these conditions and continuous operation throughout a year, requires a high power supply so huge that become unaffordable for commercial operation. Currently, for a greenhouse optimum design it is necessary to calculate the heat transfer rates to and from the envelope, required to maintain the optimum temperature for the crop. Quantification of a greenhouse energy demand is a challenging task, due to the continuous variation of atmospheric variables. Therefore it is also uncertain to

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/eurosun.2016.02.15 Available at http://proceedings.ises.org

develop a reliable economic analysis that allows to determine whether the obtained production profit justifies the initial investment and operating costs (Souliotis et al., 2009). Nowadays, there is specialized software such as TRNSYS that analyze different design scenarios, in order to compare the thermal performance of different configurations, sizes and types of technology used, delivering results with less than 6% of uncertainty (Almeida et al., 2014) (Attar and Farhat, 2015). TRNSYS has been used to model and analyze greenhouses, in places like Zimbabwe (Mashonjowa et al., 2013), Nepal (Seona et al., 2012) and Australia (Lu Aye et al., 2010), nevertheless studies for the northern part of Mexico has not yet been developed.

No papers were found for the energy performance and the economic analysis of greenhouses. Developed in this paper, is the analysis of the interaction of an agricultural greenhouse with the climatic conditions of the semi-arid region of northern Mexico, specifically in the proximity of 28° N latitude. An air conditioning system is proposed, based on the circulation of hot/cold water through heat exchangers located inside the greenhouse. The aim of this paper is to demonstrate that the amount of energy, and thus the air conditioning equipment required for a greenhouse throughout a year are enormous on its original architecture, resulting in low profitability. It is therefore proposed, a detailed analysis of technical alternatives to reduce the thermal loads of a greenhouse. Thermal insulation and shading are mainly considered to reduce as much as possible the investment needed for air conditioning operation. These will lead to an optimal design of the air conditioning system, including construction materials, shading system and a combination of heating and cooling equipment assisted with solar energy, that together aim to reduce the project cost and thus maximize production profit.

1.1. Crop Information

1.1.1. Tomato Variety

The greenhouse used as a case of study produces organic Saladette tomato in a variety called “Moctezuma and Cuauhtémoc” (Figure 1).

Fig. 1: Saladette tomato inside the greenhouse of this case of study

1.1.2. Requirements for temperature, humidity and CO_2

The requirements of temperature, relative humidity and CO_2 concentration of Saladette tomato are found in the following table.

Tab. 1: Required environmental specifications for the crop (Castellanos, 2004)(León, 2006).

Requirement	Values
Temperature for all production stages (°C)	15 – 30
Humidity (%)	70 – 85
CO_2 concentration (ppm)	700 - 800

1.2. Greenhouse information

1.2.1. Geographical location

The greenhouse analyzed in this work is located within the Agroindustrial Park Naica, Saucillo Municipality, Chih., Mexico. Its geographical coordinates are 28.062543 N, 105.534867 W.

1.2.2. Design and type of technology

The greenhouse is a multi-chapel type (greenhouse technology developed in Canada), designed for medium and highly automated operations. It has 9 chapels spread over a surface area of 1.6 hectares and an approximate volume of 100,000 m^3. The double-walled polyethylene cover is supported by metallic structures represented by dots in Figure 2.

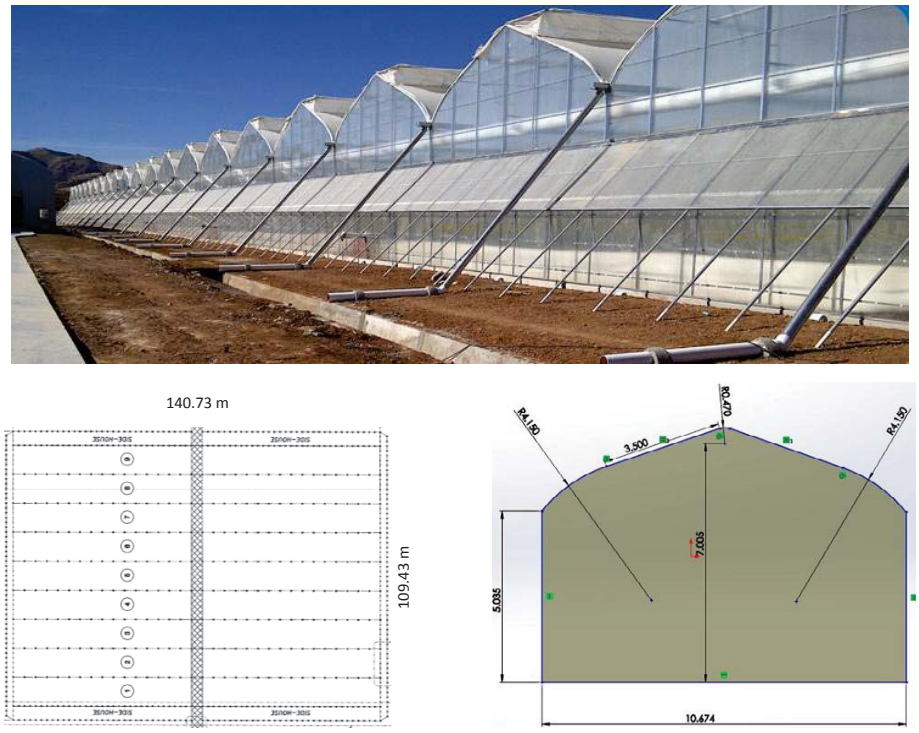

Fig. 2: Multi-chapel Greenhouse type

1.2.3. Current Climate Control

Currently the greenhouse has no air conditioning system. Instead, it has a double walled cover, and a natural ventilation induced by a vent system with a mechanized aperture, located at the top of the structure.

2. Proposed air conditioning system

The greenhouse air conditioning system proposed and its main components are shown in Figure 3. The system use a heat exchanger (water-air) network distributed in the greenhouse to cool or heat the air inside, without introducing external air that contaminates and dilute the CO^2 concentration. The heating system is mainly composed by a field of solar thermal collectors, a storage tank and an auxiliary heating system based on LPG. It also has a refrigeration equipment to produce cold water during summer.

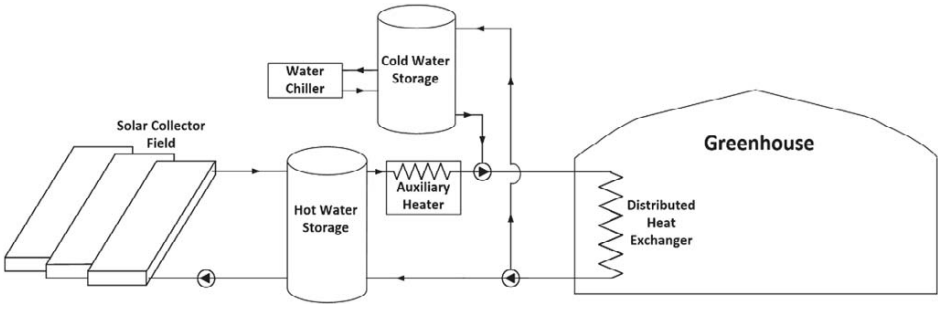

Fig. 3: Greenhouse air conditioning system proposed.

3. Simulation

3.1. Simulation tools

The software packages required for the proposed analysis, were among others, SketchUp Pro, Simulation Studio, TRNBuild, TRNEdit, Meteonorm, Berkeley Lab Window 7.2, MS Excel and TRNSYS 17. The greenhouse geometry was first modeled, then the materials physical properties of the envelope and the translucent cover were incorporated, after that, the thermo-mechanical components were simulated. In Figure 4, the type of greenhouse technology and its implementation in the SketchUp Pro software is displayed.

Fig. 4: Greenhouse technology type and SketchUp schematization.

The main components of the air conditioning system and its interaction is shown schematically by means of TRNSYS 17 Icons as shown in Figure 5.

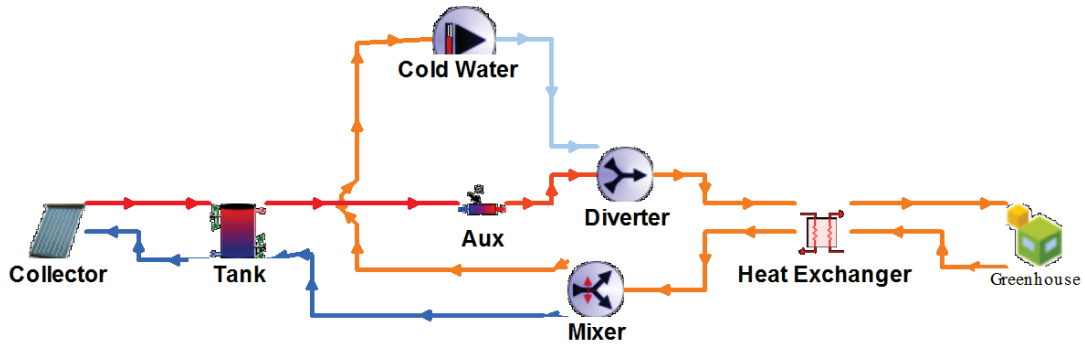

Fig. 5: TRNSYS system setup.

3.2. Simulation remarks

System operation was simulated throughout a typical year, in a 15 minute (step) based calculation. Parametric variation was performed using the climatic information (TMY) of the city of Delicias, Chihuahua. Instantaneous flow rates were integrated over periods of a day and a year to get the daily and annual cumulative.

4. Results

4.1. Thermal Performance

In Figure 6 the environment temperature behavior is shown for a typical meteorological year (TMY) in the specified greenhouse location. The temperature range recommended for a good development of a tomato crop at all stages is also displayed.

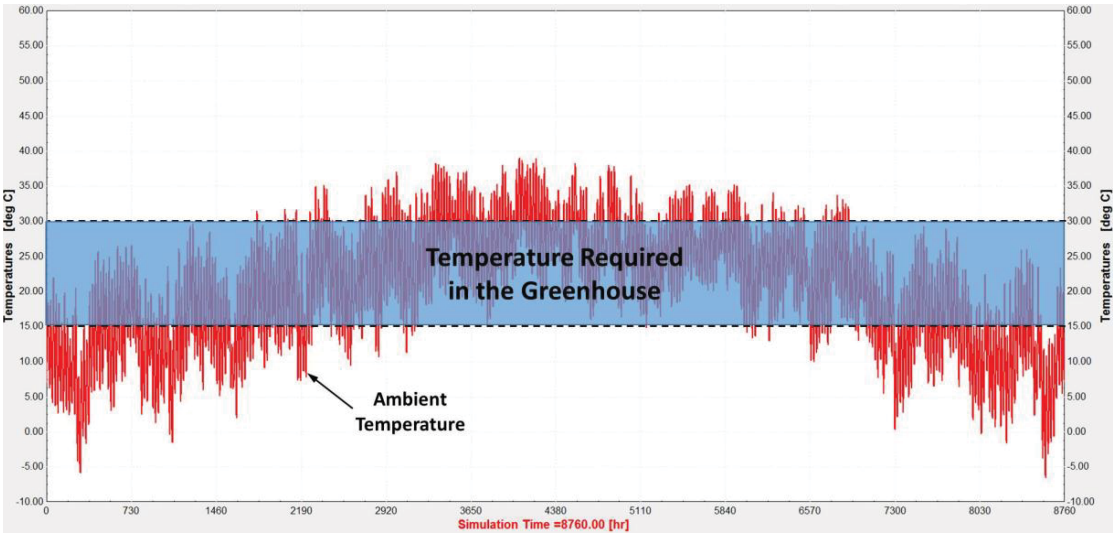

Fig. 6: Environment temperature and range required inside the greenhouse.

The air temperature performance inside the greenhouse is shown in figure 7, when operating closed and without air conditioning. The temperature range required for the crop development is also shown. In this case the greenhouse is performing closed in order to maintain relative humidity and CO2 concentration under control, however, the temperature remains within the comfort zone for only a few weeks a year.

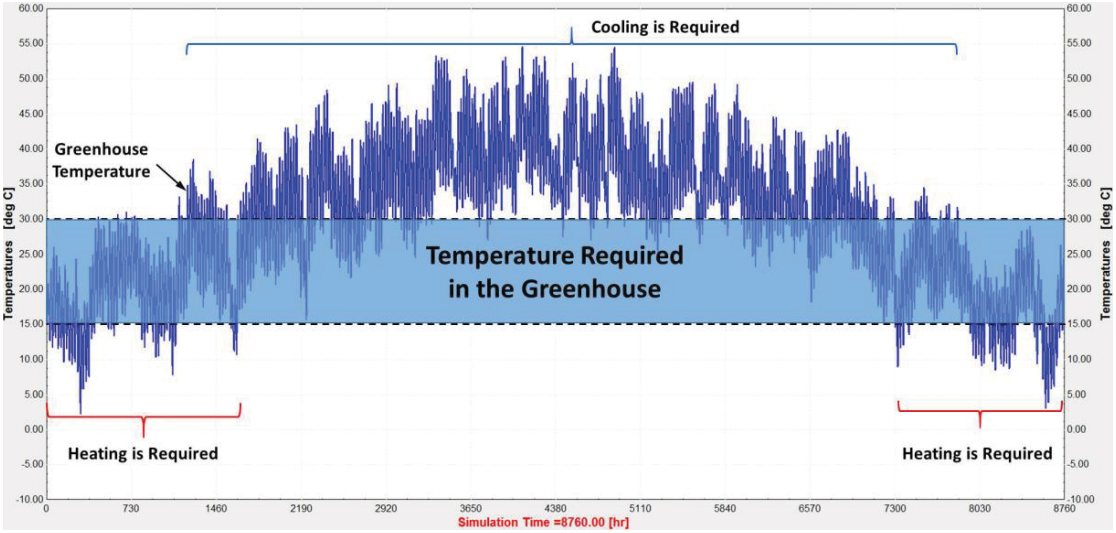

Fig. 7: Air temperature behavior inside the greenhouse without air conditioning, and the crop thermal comfort zone.

The time periods when heating or cooling is required are shown in figure 7. It is noted that for this climate conditions, cooling requirements during the summer season are significantly higher than those of heating in winter, due to the natural greenhouse effect. It can be observed that without air conditioning, the vast majority of time throughout the year, the air temperature inside the greenhouse is above the comfort zone, reaching lethal to plants temperature values, this makes not only impossible to harvest in summer, but necessary to replace dead plants at the end of the hot season.

4.2. Theoretical thermal loads for Heating and Cooling

To achieve a perfectly controlled climate within the greenhouse, it is required to supply heating and cooling to counteract the external thermal loads, at the same rate as they occur. In the simulation this is achieved assuming that there is an unlimited hot or cold water supply, and energy is transferred to or from the air instantly. This indoor ideal temperature control is obtained and the instant energy consumption is

determined. The greenhouse thermal simulation for the previously described is shown in Figure 8. The graph shows that for the coldest day, heat must be supplied at a rate of 1,370 kW to the greenhouse and for the warmest day heat needs to be extracted at a rate of 2,490 kW from the greenhouse.

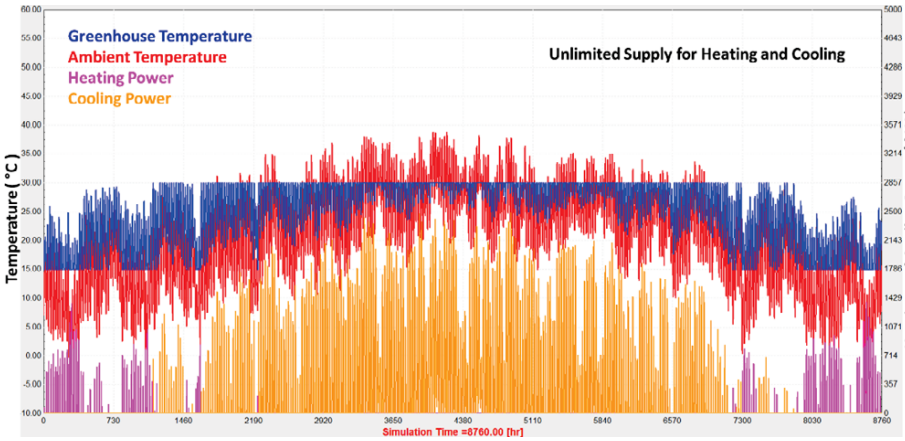

Fig. 8: Greenhouse inside and outside temperatures and the heating/cooling power.

However, by introducing the physical performance of the required equipment, the type and number of devices used for air conditioning are obtained, additionally an estimate of the cost is also obtained. Physical and economic data of real devices, available in the local market were used in this work to obtain an initial estimate of the economic impact of the greenhouse air conditioning.

4.3. Heat transfer equipment

To maintain the previously mentioned comfort zone inside the greenhouse, the effect on the use of different number of heat exchangers was analyzed. Figure 9 shows the behavior of the air temperature within the greenhouse based on the number of heat exchangers used for air conditioning. Commercially available fan and coil heat exchangers of an overall heat transfer coefficient of 400 W / ° C were simulated. The greenhouse performance using 0, 85, 145 and 180 exchangers is shown.

It is noted that in order to control the indoor temperature in winter using 85 heat exchangers is easily achieved, however cooling in summer requires more equipment. It is also noted that even when using 145 heat exchangers, there are periods at temperatures above the desired maximum level. Increasing the number to 185 it improves only marginally. This illustrates that the problem is no longer technical but economical and it is compulsory to determine how far it is appropriate to add equipment for an overall economic feasibility.

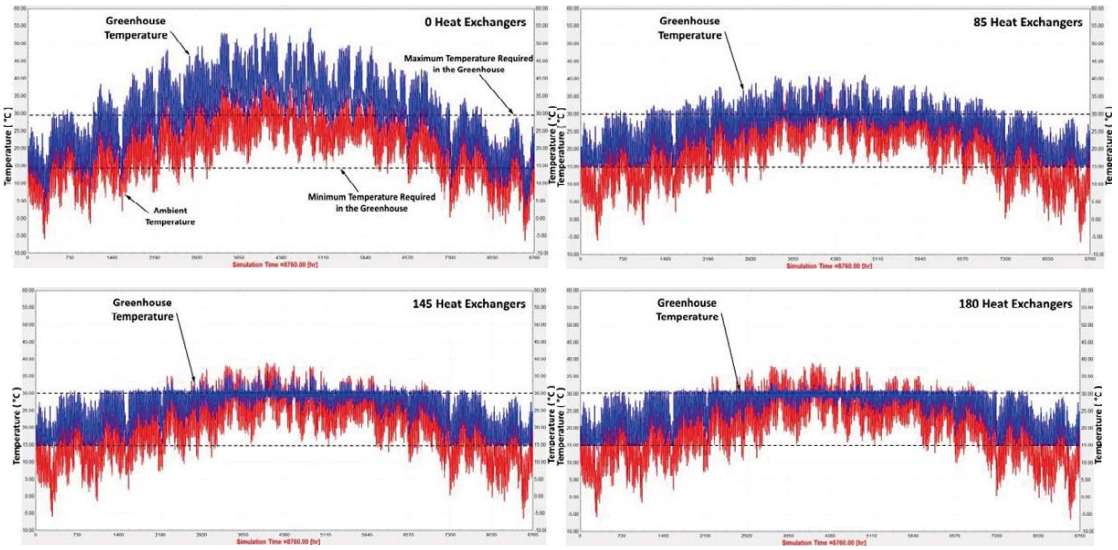

Fig. 9: Thermal performance in the greenhouse using 85, 145 and 180 heat exchangers.

From the technical point of view in the previous graphs, it can be concluded that the required number of heat exchangers for the air conditioning of the greenhouse should be 180 in order to ensure that the internal temperature will partially not exceed the maximum level in the year.

4.4. Actual thermal heating and cooling loads

To analyze the greenhouse thermal loads using the locally available heat transfer equipment, considerations shown in Table 2 were made.

Tab. 2: Considerations for the analysis of thermal heating and cooling loads.

Parameter	Value
Heat exchangers amount	180
Available hot water temperature (°C)	60
Minimum allowed temperature inside the greenhouse (°C)	15
Available cold water temperature (°C)	2
Maximum allowed temperature inside the greenhouse (°C)	30

Based on the limitations imposed in the table above, simulation shows that to maintain the greenhouse interior temperature within the comfort zone it is necessary to insert and remove the heat rate amount shown in Figure 10. The heating and cooling power values are of around 3,700 kW and 1,800 kW respectively.

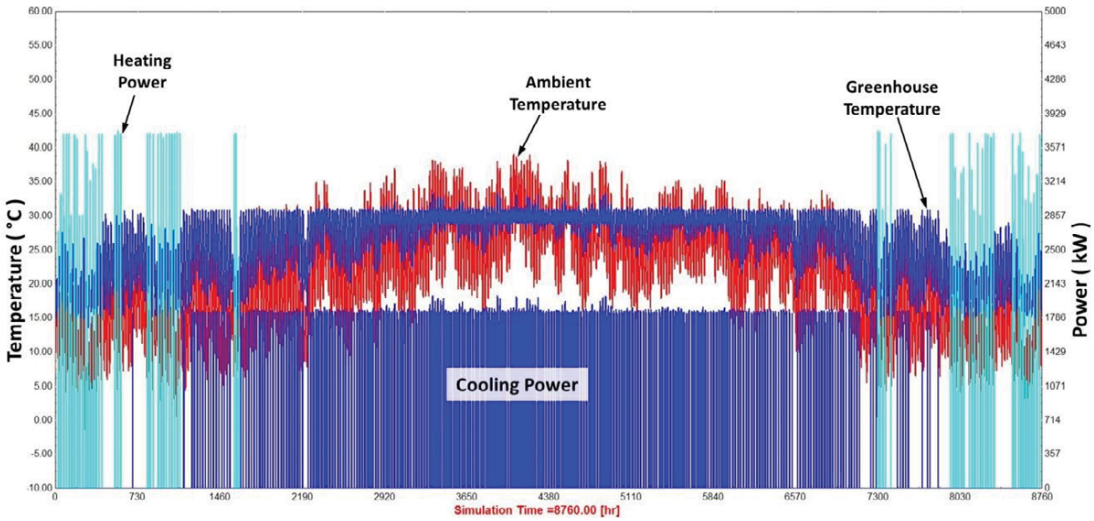

Fig. 10: Necessary heat transfer rate.

4.5. Greenhouse daily thermal performance

To analyze in detail the thermal performance outside and inside the greenhouse without air conditioning, simulation results on June 19th, 20th and 21st are shown in Figure 11. This figure shows that the temperature inside the greenhouse is above the maximum allowed temperature. Even the exterior temperature is generally above that temperature.

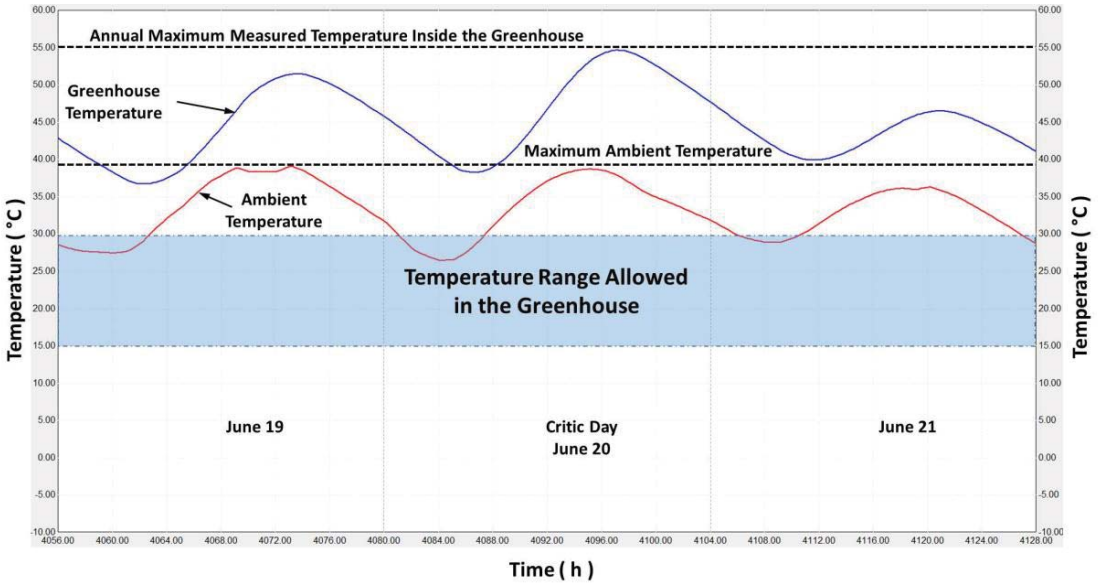

Fig. 11: Temperatures reached inside and outside the greenhouse on June 19th, 20th and 21st.

Figure 12 presents the thermal performance inside and outside the greenhouse when the air conditioning system is used. The power required for the three day cooling is also displayed, additionally the energy required on June 20th is included. The simulation showed that the highest cooling demand of the year is on that day.

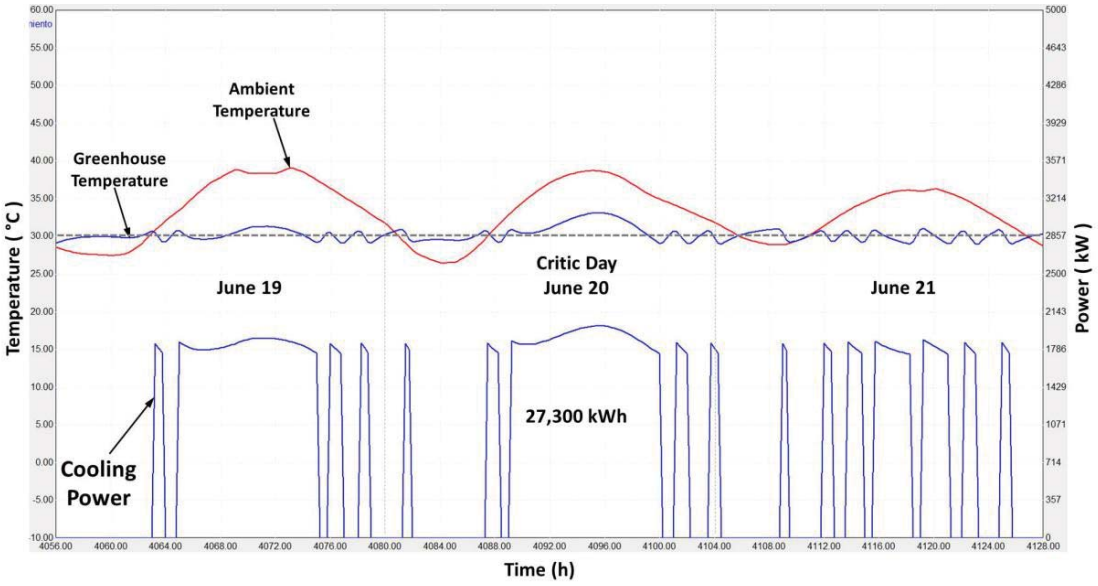

Fig. 12: Thermal performance inside and outside the greenhouse using air conditioning on June 19th, 20th and 21st.

Figure 13 shows the thermal performance inside and outside the greenhouse using air conditioning along with the power and energy inputs to achieve this. However, the necessary energy to extract heat from the greenhouse is 27,300 kWh and it can be supplied by a device with an output of 325 tons of refrigeration.

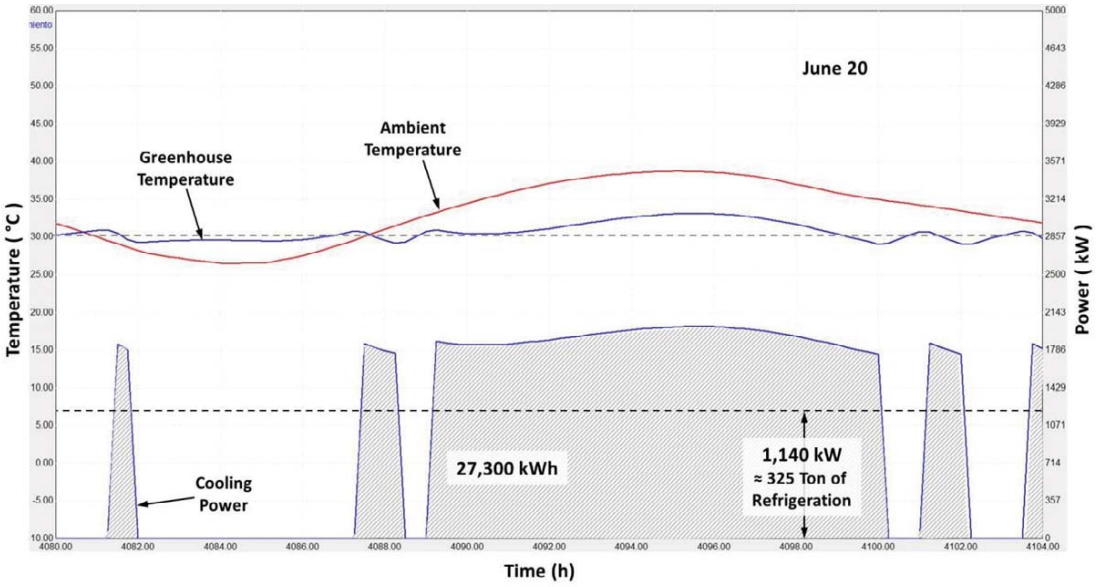

Fig. 13: Power, energy and thermal performance of the air conditioned greenhouse on June 20th.

4.6. General results

The simulation results allows to observe that the energy required for the greenhouse heating and cooling to keep the temperature within the optimum thermal zone for the crop development throughout the year is 4,231,966 and 39,324,140 GJ GJ respectively.

Once the number of heat exchangers is determined and the temperature considerations are set, the power calculated for heating and cooling results in 3,700 kW and 1,800 kW respectively.

This huge energy consumption can be supplied by several sources such as oil, LP gas, natural gas, electricity, biomass, and solar (Vadiee and Martin, 2013 b), (Vadiee and Martin, 2014).

The following case of study allows to analyze the system performance when part of the energy is met by a solar source. The simulation results show that in order to achieve a solar fraction of 72% for heating and 30% for absorption cooling, the equipment required is shown in Table 3.

Tab. 3: Required equipment to supply a specific solar fraction.

Equipment	Amount	Unit Price ($USD)	Total Price ($USD)
Evacuated tube solar collector (heat pipe)	300	500	150,000
Thermal storage @ 60 L/m^2	75 m^3	5,000 / 25 m^3	15,000
heat exchanger overall heat transfer coefficient (400 W/°C)	180	2,433	437,940
Auxiliary heater (1,000 kW)	1	53,552	53,552
Absorption refrigeration system (1,140 kW)	1	325,000	325,000

5. Conclusions

Energy requirements have been studied in order to maintain the greenhouse air temperature in an optimal range for the crop development, as well as the heat exchange equipment required for the air conditioning throughout the year.

It was found that the thermal loads for both heating and cooling are very high, thus making the technology implementation unfeasible either for conventional or solar energy supply in the crop production throughout a year.

Consequently, all of the above encourage to propose a detailed analysis of the technical alternatives applied to reduce the thermal loads in the greenhouse, mainly by means of the analysis of thermal insulation and shading and thereby predicting lower operation costs by heating and cooling.

After an energy efficiency analysis it is possible to propose the use of solar energy for the heating and the cooling of the greenhouse.

Abstract

Solar thermal energy and heat pumps are key technologies to increase the share of renewable energy in industry. In order to spread these technologies, integration barriers should be reduced, such as high investment costs, lack of experience, missing integration schemes and planning guidelines or lack of knowledge about technological developments. Within the Austrian research project EnPro appropriate guidelines for manufacturers, users and planners are being developed. Therefore, in total 12 case studies in food, paper, metal production and processing, laundries and insulation industry have been performed, three of them selected and presented in this paper. Based on a detailed assessment of the processes, their process parameters and energy demand as well as the energy supply of the industry, integration concepts of solar thermal and heat pump systems and their combinations have been developed. Possible integration concepts include the parallel use and three different variations of serial integration of solar thermal and heat pumps. As variation I solar thermal is integrated first in the supply cascade (heating demand of a process or the supply system), followed by the heat pump. Variation II is the reversal of the order while as variation III solar thermal is used as source for the heat pump. Integration points for all possible combinations have been detected in the assessed companies. The concepts will be economically evaluated. The focus is set on generalized integration schemes for solar thermal and heat pump systems and the combination of both followed by the identification of upcoming R&D topics to push the implementation of identified solutions.

Keywords: *solar thermal, heat pumps, combined integration, industry, energy efficiency, process heat, renewable energies*

1. Introduction

In order to address the challenge of climate change and global warming the European Union agreed on the ambitious targets to reduce greenhouse gas emission by 40 % and to increase energy efficiency and renewable energy by 27 % by 2030. Special emphasis is placed on energy efficiency and renewable energy in industrial processes as industry accounts for 30 % of the final energy demand in Austria (Statistics Austria, 2014). Solar thermal energy and heat pumps are considered as important measures to reach these targets. Therefore they play an important role in European guidelines as well as in national regulations (European Parliament, 2009).

Solar thermal systems and heat pumps are state of the art for covering heating and hot water demand in the building sector. Combined systems including solar thermal and heat pumps also play a considerable role

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/eurosun.2016.02.02 Available at http://proceedings.ises.org

within this sector. However, these technologies are not yet wide spread in industry, as there are still significant barriers although the potential is high. The main reasons for these barriers are high investment costs, lack of experience or skepticism regarding the reliability of these technologies, lack of planning guidelines and integration concepts, as well as lack of users' knowledge of ongoing technological developments, such as high-temperature heat pumps or advanced solar collectors. Several studies and projects have proven that the required temperature range of industrial processes with a heating demand is suitable for the integration of solar thermal systems, heat pumps and the combination of both technologies. These industry sectors include for instance food and beverage, insulation, paper, metal processing and laundry (Hummel et al. 2013; IEA Heat Pump Centre, 2014; Wolf et al. 2014). The Austrian research project EnPro[1] aims to reduce these barriers, hence appropriate guidelines for manufacturers, users and planners are being developed. The bases for the guidelines are twelve case studies that are carried out in the project in different industrial sectors.

The choice of sectors ensures high potential for application of solar thermal energy and heat pumps and guarantees a high degree of replicability. In the companies, the current situation of energy supply and consumption is analyzed based on the European standard EN 16247. The aim is to identify and classify processes, that are suitable for the integration of solar thermal energy and heat pumps and their combination and to detect available waste heat streams and other suitable heat sources for heat pumps. Based on the energy demand of the respective process, integration concepts for solar thermal energy and/or heat pumps are developed to reach more energy efficiency and to increase the amount of renewable process energy. Special focus is set on efficient and cost effective integration concepts for solar thermal energy, heat pumps and the combination of both technologies. Within the framework of the project four different integration concepts for the combination of solar thermal energy and heat pumps are considered as basis for specific adaptions. The EnPro guidelines will consist of generalized concepts for the studied industrial sectors and a calculation tool that allows for basic planning of solar thermal and heat pumps for industrial use.

1.1 Solar thermal systems

Solar thermal systems use solar radiation for the supply of process heat, mainly hot water, but also process steam. Process heat collectors and their application can be divided into three temperature ranges: low temperature (<100 °C), medium temperature (100-250 °C) and high temperature (>250 °C) (Frank et al. 2012). The available technologies can be subdivided into concentrating and non-concentrating collectors, which show differences in design and in optimal operating temperatures. With increasing collector temperature, the efficiency of concentrating systems does not decrease as strongly, compared to non-concentrating collectors. Therefore flat plate collectors and vacuum tube collectors with reflectors are used to provide low temperature levels, vacuum tube collectors and low concentration systems are used for medium temperature levels, while stronger concentrating systems are used for high temperature levels.

1.2 Heat pumps

Heat pumps use low temperature streams to provide heat at a higher temperature level. In the building sector ambient air, ground water or the ground are commonly used as heat source for heat pumps, they usually supply hot water for domestic heating.
In industrial processes, waste heat streams often cannot be reintegrated into the production process or the energy supply of the process because of the inadequate low temperature levels. Therefore low temperature waste heat is released to the environment in many cases. This often goes along with additional cooling demand. Heat pumps allow for re-integration of waste heat streams into the production processes at a higher, useful temperature level and thereby increase energy efficiency. Currently heat pumps that provide temperatures from 90 to 125 °C are available on the market (IEA Heat Pump Centre, 2014; Wolf et al. 2014). Heat pumps that provide temperatures up to 160 °C have been in scope of research since several years. The mentioned temperatures can already be reached in experimental heat pumps and it can be assumed that heat pumps providing temperatures up to 160 °C reach market maturity in the next few years (Fukuda et al. 2014; Fleckl et al. 2014).

[1] The project EnPro (project number 848818) is an R&D service on behalf of the Austrian Climate and Energy Fund, financed by the Energy Research Programme 2014.

2. Problem statement, methodology and project introduction

2.1 Problem statement

There are different integration barriers for solar thermal energy, heat pumps and the combination of both technologies to increase market penetration. The most important barriers are high investment costs, lack of experience, missing best practice examples, missing integration schemes and planning guidelines and lack of knowledge about technological developments. When evaluating the technical integration of the technologies in an industry, several challenges related to the process and energy supply system can be identified such as:

- Heat supply of production sites are often grown structures (based on steam or hot water…) that do not allow a standardized integration
- Due to different used technologies the heat demand varies significantly:
    - Batch or continuous processes
    - Different load profiles and operating hours
    - Different requirements in process parameters (e.g. temperature…)

Another challenge is the choice of the suitable integration point and the development of an integration concept, defining how renewable energy is integrated in the production site. There are different levels for the integration of solar thermal and heat pump systems, on process level (direct supply of one selected process) or on supply level (integration in existing system). Requirements concerning storage and heat exchanger systems result from the defined integration concept. It has to be emphasized that not only the integration concept is important. With regard to the selection of the type of solar collector and the hydraulic connection (charging and discharging strategies of the solar storage), the needed temperature in the collector loop is essential aside from the chosen integration concept and the control strategy. Furthermore, the location of the production site (solar irradiation), its available areas (ground or roof), and static requirements to carry collector weight, orientation or shading are important to gain a maximum solar yield. (Muster et al. 2015) Regarding the integration of heat pumps also the required temperature of the process is an important parameter, as it relates to the refrigerant agent of the heat pump, the temperature of the heat sources, as it has a strong influence on the efficiency of the heat supply, the simultaneity of heat source and demand, as it decides whether storage is necessary. The available space to erect the heat pump and the distances to available heat sources also have to be considered.

Based on the results of IEA Task 49/IV, the main challenges for solar process heating systems are the achievement of a high solar cover ratio and the close alignment with process demands up to the development of "solar process technologies". Also the best possible combination of solar thermal systems with other technologies gets more and more important. This is precisely where the potential of combined solar thermal and heat pump systems can be seen: for example, the achievable temperature of the solar thermal system could be increased with a heat pump to meet process demands.

2.2 Methodology and project introduction

In order to identify and evaluate possible integration concepts in industrial sectors, a total of twelve production sites from different industrial sectors were chosen within the project EnPro. For the selection of the sectors, branches identified in a preceding project were considered and ranked based on high replicability (Hummel et al. 2013) Especially branches with a high number of companies and a high energy demand were selected. The chosen sites were analysed based on the European standard EN 16247. The current situation of energy supply and consumption of the industrial sites were evaluated and the thermally relevant unit operations were identified. The unit operations were classified to ensure high replicability of the integration concepts. The mentioned classification provides information concerning process technology, process and supply temperatures, process medium, load profiles and operating hours.

Also optimization potentials on process and system level were evaluated as basis for the integration of renewable energy. Pinch analysis was used as methodology to identify heat recovery potentials.

This was followed by the identification of processes that are suitable for the integration of solar thermal energy, heat pumps and their combinations to reach more energy efficiency and to increase the amount of renewable process energy in the industry. The basis was the classification of the unit operations and the evaluated parameters. Within this step, concepts and different schemes for the combined usage of the technologies were created, accompanied by site-specific simulations. Considering the classified processes and the integration concepts the achieved information are generalized resulting in general applicable integration

points for the different branches and general combination schemes. A main focus of the project EnPro is the development of guidelines and a basic planning and calculation tool.

The final guideline and tool will be designed as a basic planning instrument consisting of a decision tree that compares the different possible combinations for a specific case study. By the combined use of tool and planning guideline recommendation on the implementation of solar thermal energy and or heat pump technologies can be made. The tool includes the following features:

- stop/go criteria – pre-assessment of the integration potential
- definition and evaluation of the energy related status quo
- branch specific process definition possibilities and process optimization suggestions
- systems optimization including pinch analysis for the deduction a heat exchanger network
- generic integration concepts and
- assessment of solar thermal energy, heat pumps and the combination of both technologies

As a final step, based on the assessments and the developed integration concepts the project EnPro is defining upcoming R&D advices, taking also existing international R&D advices and roadmaps into account (e.g. "renewable heating and cooling technology platform" roadmap or results from IEA networks).

3. Case studies

In this paper, three of the twelve performed case studies are presented. A special focus is set on integration concepts for solar thermal and heat pump systems and the combination of both technologies.

3.1. Bakery

The audited production site is a large scale bakery. The main products are typical Central European bakery goods (i.e. bread, rolls, fine pastry…). Typical process steps for all products are shown in Fig. 1. First, the ingredients are processed followed by the fermentation step. There are different operation modes for the fermentation step in a bakery. For direct fermentation the step is finished before baking. The other way is to cool the piece of dough and process it later on. In this case a controlled heating step is necessary before the fermentation step. Rack ovens (batch-mode) or continuous baking machines (conveyer) are used for the baking process. Depending on the type of product the baking step is finished, the product gets packaged, stored (cooled) and distributed or it is pre-baked, deep frozen and distributed.

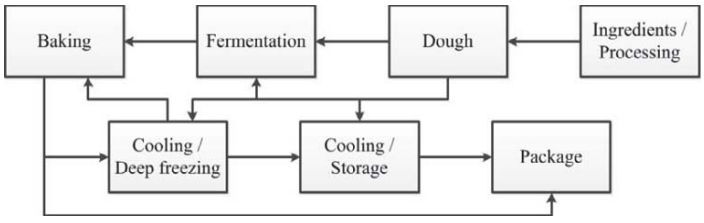

Fig. 1: Process steps with high energy demand in bakery

3.1.1 Energy supply and energy demand

The energy supply of the company is based on fuel oil, natural gas and electricity. Electricity is used by the cooling devices (approx. 40 %) and the bakery ovens (26 %). The rest is consumed by small consumers, pressurized air and the ventilation system. Natural gas is consumed by four boilers supplying the baking ovens as well as for supplying steam (process steam and heating system). The fuel oil is partly consumed by a thermal oil boiler and a steam boiler and partly distributed to directly fired baking ovens in the production hall. A detailed analysis of the last years shows a significant shift from fuel oil to natural gas.
Process steam is needed beside the demand of process heat (160 – 270 °C) during the baking process depending on the product type. Humidification of the baking goods ensures good heating transfer within the baking step. Simultaneously quality and taste of the product are influenced. The steam, provided by the steam boilers is also used for covering the space heating demand.

The cooling demand is a large part of the total energy demand of a bakery. Firstly the unbaked pieces are deep frozen (-4 to -23 °C) to stop the fermentation process. Secondly the ingredients (before the dough-

making-process) and the finished products have to be stored (deep) frozen. Hot water for cleaning is needed at a temperature level between 40 and 60 °C. Hot water storages support the heat distribution.

3.1.2 Optimization potentials and integration of solar thermal systems and/or heat pumps

Within the energy audit short term optimization measures have been identified. Partly due to the age of the baking ovens and due to the high energy demand high potential for process optimization has been identified. The primary direct fired baking ovens (including internal heat recovery) will be substituted by more efficient and central supplied (thermal oil) baking ovens step by step in the next years. High losses (mainly space heating and cooling) caused by high flow temperatures could be reduced by the integration of a central distribution system. The biggest potential was identified within heat recovery of cooling devices. The fuel oil boilers could be substituted step by step by optimizing the existing heat distribution network and integrating thermal energy in existing storages for the preparation of hot water for cleaning.

The baking process is suitable for the integration of solar thermal energy only to a limited extent due to the demand of high temperatures. Nevertheless two potential integration points have been identified. Firstly, the supply of hot water for cleaning in combination with the heat recovery from the cooling devices shows potential. The needed temperature of 60 °C is optimal for supplying the demand via flat plate collectors with a high efficiency. The existing storage infrastructure also supports the integration of a solar thermal system. Secondly, solar thermal energy could be integrated on system level for pre-heating of boiler feed water and for pre-heating of thermal oil.

There are two possibilities for the integration of heat pumps. The first possibility is to use the waste heat from the cooling devices as a heat source and to heat the cleaning water instead or in parallel to solar thermal system. The second possibility is a combination of solar thermal and heat pump system. Within this combination the solar thermal energy is used first for heating the cleaning water and a heat pump is used for increasing the temperature level provided by the solar thermal system using waste heat from the cooling devices as the heat source.

3.2. Metal surface treatment

The metal company analysed in the project produces hardware for windows and doors. The audit focuses on the thermal energy demand and was mainly done for the production area of metal surface treatment which consists of a barrel plant and a rack plant (rotating barrels or racks are used for the transportation of work pieces between different process baths). The process temperatures are in a range between 40 and 80 °C. This offers a potential for the integration of solar thermal and heat pump systems.

The surface treatment process steps can be divided into pre-treatment, main treatment and post-treatment as shown in Fig. 2.

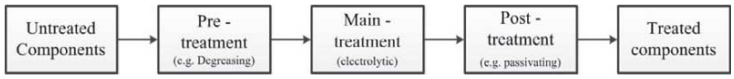

Fig. 2: Main process steps in metal surface treatment

The work pieces are pretreated to be clean from dust, grease and oil and to ensure uniform application and permanent adhesion of the surface treatment. Furthermore oxides are removed to ensure a chemically active surface. Pretreatment processes applied in the assessed company are degreasing, electrolytic degreasing, pickling and descaling. Rinsing is carried out between the processes steps with varying temperatures. For degreasing temperatures of 70 °C are necessary. The other pre-treatment steps do not have any heating demand. After pretreatment the core activities follow. In the audited company zinc coatings are used for the electrolytic surface treatment. During the exothermal electrochemical reaction, heat is released. It is necessary to cool the solution in order to keep the process baths within the required temperature range (23 to 26 °C) to ensure high quality of the products and minimize the breakdown of chemicals in the process bath. Afterwards the work pieces are post treated by brightening, passivation and sealing. Finally the work pieces are dried in order to avoid staining and corrosion. In the barrel plant centrifugal drying is used, whereas in the rack plant the dryer operates with circulatory air. The temperatures of the post-treatment are in a range from 40 to 80 °C. For centrifugal drying a temperature of 130 °C is provided by electric heating.

3.2.1 Energy supply and energy demand

The energy supply of surface treatment is based on natural gas (53 %) and electricity (47 %). Natural gas is consumed by a thermal gas boiler supplying heating process baths (25 %) and dryers (28 %), heating of production halls (46 %) and domestic hot water (1 %). During summer less natural gas is consumed as a result

of increasing ambient temperatures. The process baths have to be heated up before the process starts and a constant process temperature (cover also heat losses) has to be kept to ensure the product quality. Two chillers are operated in the area of surface treatment to provide cooling water for the zinc baths.

3.2.2 Optimization potentials and integration of solar thermal systems and/or heat pumps

Within this energy audit process optimization measures have been identified mainly in the field of the heating of production halls. There air curtains are an effective way to prevent the intrusion of cold outdoor air. In order to reduce energy losses of the process tanks, insulation can be applied at the tanks. Furthermore the surface of the process baths can be covered with a blanket of plastic floating spheres which reduce evaporation without restricting the access of work pieces, jigs or barrels.

For integration of solar thermal energy and heat pumps potential processes have been identified. First of all, solar thermal energy can be used on process level to heat up the process baths at temperatures between 40 and 80 °C. Flat plate collectors and vacuum tube collectors reach high efficiency in this temperature range. Secondly, solar thermal energy could supply the heating demand of domestic hot water.

For integration of heat pumps especially the process baths have been identified as appropriate integration points on process level. The return flow of the cooling water from the process baths could be used as a heat source for heat pumps. The upgraded energy can heat up other process baths. The advantage arising from this integration point is that heat sink and source occur at the same time, so far not used heat streams are utilized and the processes operate constantly over the whole year.

A combination of solar thermal and heat pump systems can be implemented on the one hand in a parallel integration in one storage tank supplying the above mentioned processes 24 hours a day. Furthermore, the decreasing solar thermal energy yield in winter months could be compensated by the heat pump. On the other hand, a possibility is rising up the temperature level provided by the solar thermal energy system with a heat pump using the waste heat from cooling the process baths as a heat source.

3.3. Laundry

This laundry is specialized on the cleaning of work wear. Fig. 3 shows the most important process steps concerning energy demand. The dirty laundry is delivered, sorted, manually loaded into washer extractor machines and washed. Depending on the type of fabric the clothing gets pre-dried via gas- or steam heated driers. Afterwards the clothing is straightened in a gas heated tunnel dryer (finisher) or pressed and dried. The dried clothes are sorted, packaged and delivered to the customers.

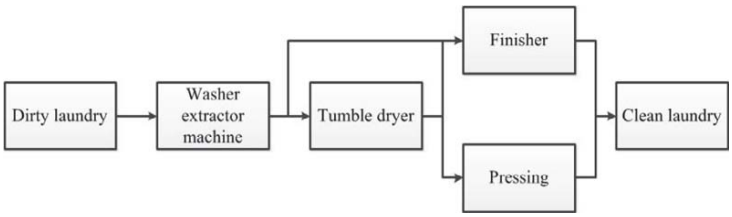

Fig. 3: Process steps in the laundry

3.3.1 Energy supply and energy demand

The energy supply of the company is mostly based on natural gas (83 %) that is used for steam generation. A total of 17 % of the energy demand is covered by electricity. The gas supplied steam generator provides up to 2 t/h of steam with 11 bar (saturated steam, 185 °C).

The most important consumers of thermal energy are the washer extractor machines, the driers and the finisher. The fresh water is preheated via heat recovery from waste water. Steam is injected directly to increase rapidly the temperature of the fresh water to the required washing temperature. The temperature range of the prewashing (30-70 °C) and the main washing step (40-70 °C) depends on the material and the degree of soiling. Two steam heated drum dryers and a gas heated drum dryer are used for the pre-drying step. Concerning the steam heated drum dryers steam increases the temperature of the air via heat exchanger up to 160 °C and is drained as condensate. The dryer operates with circulatory air. The drying air absorbs the moisture of the clothing and leaves the dryer as waste air with a temperature of around 70 °C. Concerning the gas heated dryer the hot exhaust gas of the burner is used for the drying process. The finisher is a continuous tunnel dryer. First, the clothing is sprinkled with steam. The following drying zones are heated with three gas burners to ensure an air temperature of around 130 to150 °C. Circulating fans ensure the circulation of air for

straightening the clothes. The saturated air passes an exhaust air system and is replaced by fresh air. The exhaust air has a temperature level of about 80 °C and is not used any further.

3.3.2 Optimization potentials and integration of solar thermal systems and/or heat pumps

The exhaust gas of the boilers has a temperature level of 140 °C. A further exhaust gas heat exchanger could be integrated to lower the exhaust gas temperature. In order to maintain the induced draft effect the described measure has to be coordinated with the boiler manufacturer. About 40 % of steam in the washer extractor machines and the finisher are used directly are replaced by fresh water. Preheating of the boiler feed water also increases the efficiency of the steam boiler

An integration potential of solar thermal energy could be the preheating of the boiler feed water or the process water for the washing machines. Integration for space heating is not possible in this laundry due to the existing heating system.

For the integration of heat pumps several waste heat streams were identified as possible heat sources that are currently released unused. Exhaust air streams of the dryers and the finisher are relevant streams for this concept. Possible heat sinks are preheating of the dryer air or preheating of the boiler feed water. The advantage of preheating the dryer air is that waste heat and heat demand occur at the same machine at the same time. The steam boiler is also an interesting heat sink as it has the longest operation time per day compared to the other processes. However, the distances between source and sink are significantly higher.

4. Integration concepts of combined solar thermal systems and heat pumps

Based on the case studies the following simplified integration schemes have been developed. Although ambient heat is a potential source for heat pumps supplying industrial processes on low temperature level, the focus was set on available waste heat streams from processes or utilities supplying heat pumps. The chosen combination possibilities and integration schemes are inspired by the IEA SHC Tasks 44 (system combinations of solar thermal systems and heat pumps for residential buildings) and IEA SHC Task 49 (different integration schemes and systems for solar thermal in industry). Within this paper only schemes for integration of combined solar thermal systems and heat pumps systems are presented. For the combination of the technologies, it is crucial to have a significant process heat demand that can be supplied with available solar irradiation and a suitable waste heat source.

The following four combination concepts have been identified within the project:

- Parallel combination - heat pump and solar thermal system supply in parallel
- Serial combination
    - Serial variation I - the process stream is heated first by the solar thermal system and then by the heat pump
    - Serial variation II - the process stream is heated first by the heat pump and then by the solar thermal system
    - Serial variation III – the solar thermal system is used as heat source for the heat pump supplying the process stream

4.1 Parallel combination

Solar collector and heat pump provide heat independently from each other as shown in Fig. 4. The combination can be operated with storages or the heat can be transferred directly to the process. Available waste heat (from processes or energy supply devices) is used as heat source for the heat pump. This combination is able to balance the lower yield of a solar system in winter and vice versa the operating time of the heat pump is reduced in summer because of the high solar yield. By an optimized system design the efficiency of both technologies van be optimized having also positive effects on the lifetime of the systems. (Hadorn, 2015a, 2016b)

Examples for possible integration points have been identified in the three case studies. Generally, the solar thermal and heat pumps systems supply the processes via an optional storage. The source for the heat pump is defined:

The parallel combination of both technologies offers the individual optimization of each system without any influence on the other. One option is that the heat pump provides heat when the collector does not deliver

due to seasonal or time of day. The other option is that the heat pump valorizes a waste heat stream that is available all the time and the solar collector adds more heat and by this fossil fuel consumption is further reduced. Which option is the most suitable has to be determined by a technical and economical evaluation for the specific industrial site. A disadvantage of this combination is that the provided maximum process temperature is limited by the technologies itself. This integration might be seen comparably easy concept and the R&D demand has to focus on maximum achievable temperatures of both technologies.

An example for this integration concept can be found in the bakery evaluated. A solar thermal collector and a heat pump supply heat via a storage for space heating and cleaning water demand. The source for the heat pump is the waste heat from a chiller.

Further examples - the source for the heat pump is defined:

- Metal surface treatment – heat pump source: return flow of cooling water
  - Heating of process baths
- Laundry – heat pump source: exhaust air streams
  - Space heating
  - Fresh water for washing machine

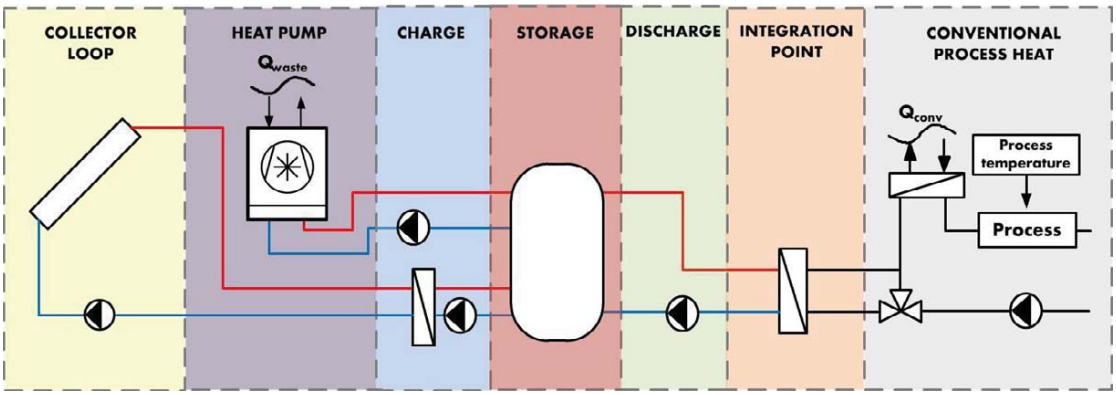

Fig. 4 Parallel combination of solar thermal systems and heat pump

4.2 Serial combinations

4.2.1 Serial variation I

In this combination first the process stream is heated by a solar system followed by the heat pump to reach higher temperatures (shown in Fig. 5). Available waste heat is used as heat source for the heat pump. Storages can be integrated to balance temporary deviations between heat supply and heat demand. If the solar thermal system supplies the total heat demand at necessary temperature, the heat pump is bypassed and the process is supplied only by the solar thermal system.

A clear advantage of this integration concept is the significant higher temperatures provided by the serial combination of the technologies. The solar thermal collector is operated in a suitable temperature range for flat plate and vacuum tube collectors offering high efficiencies. Heat pumps are able to provide temperatures up to 120 °C. To achieve high efficiency, a comparable warm heat source exceeding 40 °C is preferable. This waste heat has to be mentioned as a challenge. The upcoming R&D demand has to focus on the further development of heat pumps providing heat up to a temperature of 160 °C.

An example for this concept can be found in the metal surface treatment company. There the solar thermal collector could preheat the process baths or the air needed for heating the dryer up to a temperature of 70 °C. The heat pump, using the waste heat from the cooling system can further increase the temperature of this process stream up to a level of 100 – 120 °C.

Further examples - the source for the heat pump is defined:

- Bakery - heat pump source: waste heat chiller
  - Hot water for cleaning
  - Heating of thermal oil
- Laundry – heat pump source: exhaust air streams
  - Preheating of the dryer air

- Preheating of the boiler feed water
- Potentially space heating in case of hot water based heating system

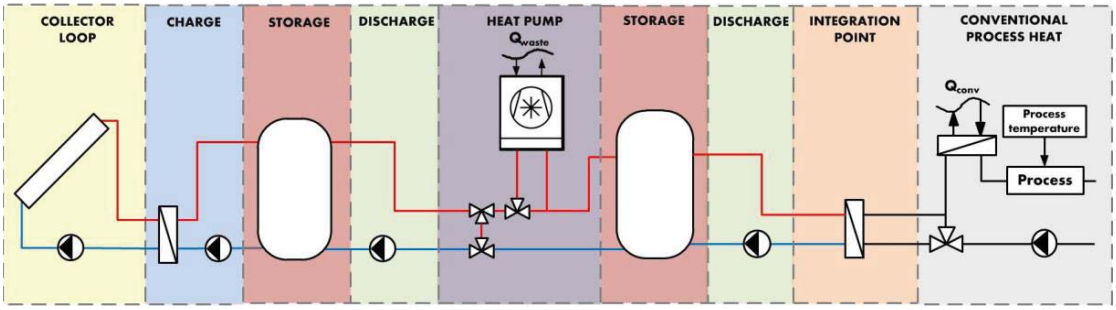

Fig. 5 Serial variation I of solar thermal system and heat pump

4.2.2 Serial variation II

First the process stream is heated by the heat pump followed by the solar system to reach higher temperatures (shown in Fig. 6). The heat pump uses available waste heat as heat source. If a process stream, that has to be cooled, can be used as heat source, a double benefit of the system occurs. Storages can be integrated to balance temporally deviations between heat supply and heat demand.

This serial integration concept is more suitable for low temperature heat sources from process waste streams or if available ambient air or ground water. A disadvantage is the demanded supply temperature (> 100 °C) of the solar thermal system and following low efficiencies of the flat plate and vacuum tube collectors. Furthermore, especially in Central European regions the direct solar irradiation is not sufficient to supply concentrating collectors and the limited maximum temperature is by this a challenge for this concept that has to be part of upcoming R&D activities.

An example for this combination concept can be found in the assessed laundry. There, the spent and cooled water from a washer can be used as heat source for the heat pump. An advantage is that the waste water is further cooled before charged into the sewage system. The process supplied is the fresh water for the steam boiler, which is preheated first by the heat pump followed by a suitable solar thermal system up to 80 – 110 °C to further decrease the fossil fuel demand of the boiler.

Further examples - the source for the heat pump is defined:

- Bakery - heat pump source: waste heat chiller
  - Heating of thermal oil
- Metal surface treatment – heat pump source: return flow of cooling water or chiller
  - Hot water for cleaning

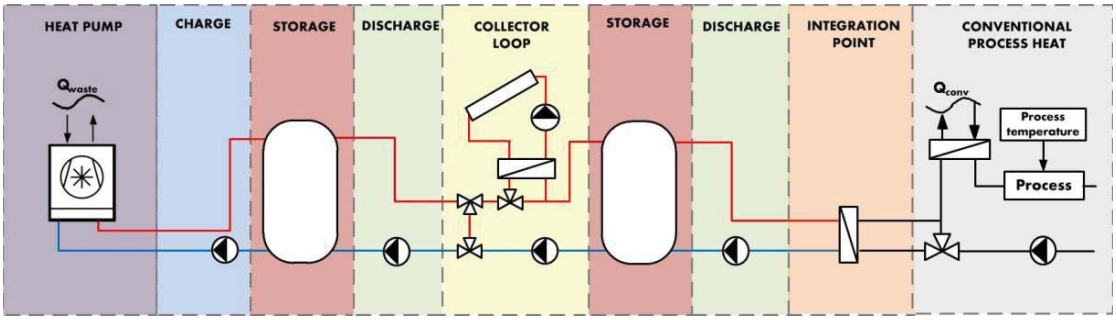

Fig. 6 Serial variation II of solar thermal system and heat pump

4.2.3 Serial variation III

In this integration concept the heat pump uses solar heat as heat source (shown in Fig. 7). Solar heat can be used directly by the heat pump or via storage. As the solar thermal system is used to provide temperatures up to 50 – 80 °C, flat plate and vacuum tube collectors operate at high efficiencies.

An advantage of this concept is that the solar thermal system provides heat for the heat pump at a higher temperature than ambient sources in case that no waste heat streams are available. Additionally available waste heat streams above 50 °C in the assessed industry were limited and this concept could overcome this challenge. By this the demanded temperature lift of the heat pump is reduced and the efficiency (also for higher temperatures) increases. In this concept a storage can be seen as mandatory. An upcoming R&D focus should be set on the further development of heat pumps providing heat above 120 °C.

An example for this concept can be found in the bakery. Available waste heat streams are already well integrated in the heat recovery system with only limited access for a heat pump concept. The integration of this stream as source for the heat pump is competing with this solution (a disadvantage in serial variation I). The solar thermal source for the heat pump addresses this challenge- A possible integration of the concept would be in the existing thermal oil based supply system. The solar thermal system supplying the heat pump that is providing heat above 100 °C.

Further examples:

- Metal surface treatment
  - Heating of process baths
- Laundry
  - Preheating of the dryer air
  - Preheating of the boiler feed water
  - Potentially space heating in case of hot water based heating system

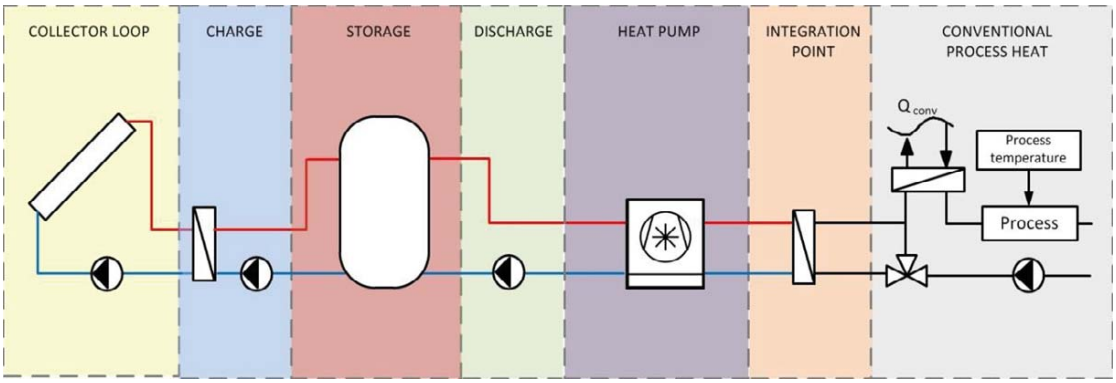

Fig. 7: Serial variation III of solar thermal system and heat pump

5. Conclusion

For assessing the energy supplies of an industrial company the energy demand on process level and its specific parameters (load profiles, temperature levels, etc.) as well as the type of supply system (media) have to be considered. Considering identified integration criteria different integration possibilities on process and supply level for solar thermal system and/or heat pumps were evaluated from a technical point of view. Examples for integration criteria are load profiles, temperature levels, temporal correlation between demand and supply, efficiency factors, solar yields, quality grades, payback periods or needed storages.

In the assessed industry examples for the single integration of solar thermal or heat pump systems have been identified. In bakeries for example hot water for cleaning is needed on process level, typical for the food and beverage sector with a significant cleaning demand. Hot water is also needed in laundries for the washing

process. This demand can be easily supplied by solar thermal system or heat pumps. Especially flat plate collectors are suitable for covering hot water demand with a temperature level of 60 °C (typical for cleaning processes), because of the high efficiency of flat plate collectors in this temperature range. Heat pumps are also suitable for supplying this hot water demand. Available waste heat streams as source are the waste heat of cooling machines (bakery and metal surface treatment) and humid exhaust air streams (laundry). The advantage of integration on process level is that heat sink and source occur at the same time, so far not used heat streams are utilized and the heat source is available at the same time the demand occurs.

An example for an integration of solar thermal system and heat pumps on system level is the integration in steam boiler systems as identified in the case studies bakery and laundry. The usage of direct steam leads to a fresh water demand. Both, solar thermal system and heat pumps could be used for pre-heating the fresh water/boiler feed water. Another option could be the production of steam but only with limited potential due to existing technical constraints further supported by regional difficulties (limited solar irradiation in Central Europe needed for concentrating solar thermal system providing steam). In many cases the needed integration concept for the integration on system level is easier compared to a direct integration on process level, which comes along with several research questions.

Besides the single integration of solar thermal system and heat pump systems, the combination of these offers a huge potential for an optimized system and a further boost of the technologies. The first technical assessment highlights four options as mentioned above parallel operation of solar thermal and heat pump system and three different serial connections.

Parallel combinations could be used for balancing seasonal differences in the solar yield as e.g. for heating of process baths in the metal surface treatment site. This concept offers the individual optimization of each system. One option is that the heat pump provides heat when the collector does not deliver due to seasonal or time of day. The other option is that the heat pump valorizes a waste heat stream that is available all the time and the solar collector adds more heat and by this fossil fuel consumption is further reduced.

Within the serial combination (variation I) first the solar thermal system is used supplying the demand (e.g. for heating the boiler feed water or other streams) and the heat pump technology is used for further increasing the temperature level. Depending on the used collector types and needed temperature level a possibility is also first going through the heat pumps followed by the solar thermal system (variation II). Finally as variation III the solar thermal system can operate as source for the heat pump. In all variations the provided temperature is higher compared to the parallel combination.

In variation I the solar thermal collector is operated in a suitable temperature range for flat plate and vacuum tube collectors offering high efficiencies. Heat pumps use waste heat streams as source in a temperature range between 50 – 70 °C and the system is by this able to provide temperatures up to 120 °C. The demand of a suitable waste heat stream (temperature range > 50 °C) has to be mentioned as a challenge. The serial variation II concept is more suitable for low temperature heat sources from process waste streams or in some cases ambient air or ground water. A challenge is the demanded supply temperature (> 100 °C) of the solar thermal system and following low efficiencies of the flat plate and vacuum tube collectors. In variation III the solar thermal system provides heat for the heat pump at a higher temperature than ambient sources in the case no waste heat streams are available. By this the demanded temperature lift of the heat pump is reduced and the efficiency, also for higher temperatures, increased.

6. Outlook

The case studies show the high potential for the integration of solar thermal system, heat pumps and the combination of both in industrial companies. Due to the fact that the considered process steps and supply structures are typical for each sector the possibilities for the integration can be multiplied and are supposed to be applicable for other companies. Based on the results of the case studies, generalized integration schemes were developed and will be further evaluated. By this, clear recommendations considering technical, ecological and economic evaluations of identified integration concepts will be available.

Further steps will be the definition of selection criteria for the different combinations and based on that the creation of a decision tree. The decision tree will lead the user to the most suitable technology or combination for a certain integration point. For the definition of selection criteria the detailed simulations of the case studies are the basis to identify efficiency ratios, performance numbers, solar yields and quality grades as

well as gained energy form heat pumps. Based on that, optimized integration concepts on process- and supply level for the case studies and derived conclusions for the industry sectors will be developed.

Furthermore the derived results will be integrated in an optimized version of a planning and calculation tool. Moreover the sectors and branch specific processes of the tool will be extended and linked to a planning guideline.

One of the main barriers for a market penetration of the technologies is the lack of best practice examples. Based on the selected case studies and developed concepts and a positive economic evaluation this obstacle is targeted to be addressed. Implemented integrations have to act as best-practice examples for other industrial companies. Hence the applicability of solar thermal system, heat pumps and the combination of both technologies is demonstrated.

In correlation with the described actions the need for research and development will be defined. One key aspect is the technological optimization of solar thermal and heat pump technologies. The optimization as well as the development of new refrigerating agents and compressors to increase the maximum condenser temperature of heat pumps is currently part of R&D. For solar thermal systems and components further development is necessary in order to simultaneously increase the efficiency and reduce the costs. Several studies show the need for technologies that supply energy demand at higher temperatures or even supply steam. The efficiency of concentrating solar systems for the supply of steam strongly depends on the regional solar radiation. Heat pumps that supply steam at typically required steam parameters of 5-10 bars are not available on the market yet. A strong need for research has to be seen in this field. The definition of research demand will be carried out after the detailed simulation of the case studies.

Abstract

In this work, technical considerations and a comprehensive discussion on solar rotary kilns are reported. Rotary kilns permit to obtain well-mixed particles in a broad range of temperatures (up to 2000°C), and, for this reason, they are widely used for treating solid particles in several industrial sectors. In solar research field, they have been employed for processing materials in solar furnaces and, in some cases, they have also been proposed as receivers in solar tower plants. The aim of this work is to investigate the potential of solar rotary kilns as thermal receivers in solar tower plants, taking into account the constraints that limit their use. In particular, because of the shape of these reactors, circular heliostat fields are not allowed and the maximum power of the receiver is limited to less than 100 MWth. Thus, the reference case of a 50-MW_{th} central tower plant for the heating of sand as heat transfer medium is reported. Residence time and receiver thermal efficiency are evaluated using an analytical method. In addition, two possible heliostat fields with different size of mirrors are also proposed.

Keywords:*Concentrating solar heat, rotary kilns, industrial applications, scaling-up, thermal storage*

1. Introduction

Fossil fuels are currently the main energy source for heat-demanding industrial processes. However, solar thermal technologies can replace them offering an environmentally friendly and widely available solution. Different solar thermal technologies operate at low, medium and high temperature and can be considered to provide heat for industrial processes of variable requirements (Calderoni et al., 2012; Fuller, 2011; Lauterbach et al., 2012). Concentrating systems employ reflectors in order to collect the solar beams on a small area where the power levels are intensified (Liu et al., 2016). With concentration ratios of around 1000, systems efficiencies are maximized at high temperatures (700-1500 ºC). This represents a relevant advantage concerning the use of concentrating solar heat to drive high-temperature industrial processes (Romero and Steinfeld, 2012). Some of the most studied applications of concentrating solar energy, apart from electricity generation, focus on the production of solar fuels, including hydrogen, which is based on H_2O/CO_2 splitting and decarbonization processes (cracking, reforming, and gasification of carbonaceous feedstock) (Steinfeld, 2005). Other industrial applications are extractive metallurgy, ceramic material processing and calcination (Halmann et al., 2012; Meier et al., 2004; Nikulshina et al., 2009).

Concentrating solar energy can be coupled with thermal energy storage (TES) systems, representing an important advantage with respect to other renewable energy technologies as photovoltaics and wind. In the last years, efforts have been focused on developing more efficient TES with higher storage capacity in order to make concentrating solar energy more cost effective. Molten salts able to storage sensible heat are currently the more commercially exploited TES system but many other solutions are also under development (Kousksou et al., 2014; Mahlia et al., 2014; Pardo et al., 2014). Concerning the present work, the solar heating of solid materials, normally in form of particles, has been previously used to storage the energy as sensible heat (Gallo et al., 2015; Jemmal et al., 2016; Zhang et al., 2016) or as a combination of sensible and thermochemical heat (Alonso et al., 2015; Aydin et al.,

doi:10.18086/eurosun.2016.02.04 Available at http://proceedings.ises.org

2015; Block and Schmücker, 2016).

Receptors/reactors design plays an important role for increasing the efficiency of high temperature processes driven by concentrated solar energy. In direct absorption devices, there is not opaque barrier between the radiation and the absorber material. This material is usually the one that have to be heated as the final purpose of the tested process, such as an industrial reactant or a storage material. Direct absorption particles in solar receivers or reactors are commonly employed where the objective is to increase the temperature of such particulate material. Different types of particles can be found in literature according its configuration and performance (Alonso and Romero, 2015). Some authors have tried to innovate and to design novel engineering concepts. Many others have readapted classical technologies to integrate the direct solar radiation.

Rotary kilns have a long history of use in metallurgical and chemical industries, their performance is well known and they are able to operate at a very wide range of high temperatures (up to 2000 ºC) with greater thermal efficiencies than other reactor types. Since it is a well-known technology, several authors have developed prototypes of solarized rotary kilns that have been successfully demonstrated for different applications (Alonso et al., 2015). This work tries to analyze some relevant aspects of applying such a technology for industrial processes. A preliminary design of a 50-MW_{th} plant coupled with a rotary receiver is presented. Particles of sand are considered to be heated up until 750 ºC. With this assumption, an estimation of the kiln dimensions, residence time and particles flow-mass is given. A heliostat field design is optimized in order to reduce optical losses on the receiver aperture. The possibilities for integrating thermal storage within the solar plant are also discussed in this work.

2. Methodology for the preliminary design

The proposed methodology for the scale up of a solar tower plant based on a rotary kiln as central receiver consists of three main parts. In the first part, a simplified sizing of the kiln was carried out. Calculations were based on kilns working in a continuous mass-flow mode. In the second part, in order to calculate the receiver efficiency and to predict the thermal load, a thermal model was developed. This model was applied to a rotary kiln for the heating of sand without a quartz window at the aperture. Finally, in the last part, two heliostat fields based on different heliostat sizes were designed for such a receiver.

2.1. Receiver sizing

2.1.1. Industrial rotary kiln

Rotary kilns are widely utilized for several industrial processes because they supply well-mixed particles. In this way, uniform temperatures are obtained in the products. These reactors can be considered as a sort of cylindrical heat exchanger in which a gas phase transfers the heat to a solid phase. Generally, rotary kilns operate in continuous mode. In this system, particles are introduced at one of the ends and are extracted at the other one. The kiln usually presents a slight slop s to favor the particles axial movement. In the radial directions, particles movement depends mainly on both the rotational speed N and the Fill Ratio FR (percentage of reactor volume occupied by the particles). Different “bed-motions”, which depend on the kind of particles (size, shape, density) and wall-particle friction coefficient, can be achieved. Usually, rolling and cascading modes are the most used behaviors for industrial applications. The residence time τ is a measure of the particle permanence inside the reactor and it depends only on geometrical and operation parameters. Differently, a solar rotary reactor presents an aperture at one end of the kiln. In this way, the solar radiation can enter inside the device and impinges directly on solid particles. In some cases, a transparent quartz window is needed to work in established environments.

2.1.2. Residence time analysis

In the last decades, several models have been carried out to predict the residence time of particles in classical rotary kilns. Most of the authors proposed correlations based on few parameters. Usually those parameters were geometrical characteristics of the reactor or particles and a combination of some of them was normally used. Main parameters were the angle of repose of the particles, mass flow, reactor size, reactor slope, rotational speed, diameter, length, height of the dam, among others.

Normally, those correlations were based on laboratory rotary kilns whose dimensions were considerably smaller than industrial ones. Renaud et al. (2000) realized a comparative of some of these correlations with the experimental results obtained from an industrial rotary kiln. They observed most of the equations, when applied to larger reactors, underestimated the residence time from four to eight times, which means that most of the

correlations proposed were not applicable for the scale up of such devices. Hence, they suggested some improvements to the quite complex model developed by Cholette and Cloutier (1959) to predict the residence time, obtaining a good approximation with experimental results (lower than 9%). Nevertheless, one of the simplest correlation was the Sai's one which underestimated the experimental residence time less than 1.2 times. Hence, for the sake of simplicity this equation was used in the present work to estimate the residence time of a scaled up solar reactor. Sai's correlation is the following (Sai et al., 1990):

$$\tau = 60 \cdot \frac{1315.2 \cdot {h_{dam}}^{0.24}}{s^{1.02} \cdot N^{0.88} \cdot F^{0.072}} \quad (1)$$

where s is the slope of the reactor in degree, N is the reactor rotational speed in rpm, F is the mass flow in kg/h, and h_{dam} is the height of the dam in m. The dam allows maintaining the particle bed inside the reactor with an almost constant height along the axial directions to favor particle mixing and to increase the residence time.

2.1.3 Mass flow

In order to calculate the proper height of the reactor dam, a design mass flow has to be defined. Because of the characteristics of rotary kilns, the mass flow is estimated from the fill ratio (FR). As mentioned above, the fill ratio corresponds to the percentage of the reactor volume occupied by the particles. If the reactor cross section A_{RR} is assumed constant, it is possible to evaluate the area (A_p) and the height of the bed (h_{bed}) for a specific fill ratio. For a determined design conditions, the dam of the reactor has to be lower or close to the predicted bed height. In following equations, bed height was employed because it was considered the maximum limit for dam height ($h_{dam} \approx h_{bed}$). Equations 2, 3 and 4 show the formulae to evaluate the fill ratio, particle area and bed height:

$$FR = \frac{\dot{m} \cdot \tau}{V_{RR} \cdot \rho_b} \quad (2)$$

$$A_p = A_{RR} \cdot FR = \frac{1}{2} \cdot R^2 \cdot (\alpha - \sin\alpha) \quad (3)$$

$$h_{bed} = R \cdot (1 - \cos\frac{\alpha}{2}) \quad (4)$$

where $\dot{m}$ is the mass flow in kg/s, V_{RR} is the volume of the reactor, ρ_b is the bulk density of the particles, R is the radius of the reactor cross section, and α is the central angle determined by the particle bed.

Typical values for the fill ratio are limited in a range from 10 to 25% to achieve a good mixing of particles and they generally correspond to rolling and cascading subtypes of bed-motion in Mellmann classification (Mellmann, 2001). In the rolling mode, the solid material lines the bottom of the inner wall of the reactor up to a certain height and then the particles roll down on the upper surface of the bed. Thus, the particles that roll down constitute the active layer, while the particles that rotate as rigid body with the wall of the cylinder form the passive layer. From a certain fill ratio, a core of static particles appears in the central region of the bed, where mixing is not achieved. Analogously, when particles with different size or density are introduced inside the reactor, smaller and more dense particles segregate and form a static core (Boateng and Barr, 1996).

Moreover, the equation that links the absorbed power with the inlet and outlet temperatures was added to the previous ones (see equation 5). In this way, the proper residence time, the mass flow, the fill ratio and the height of the bed were calculated.

$$Q_p = \dot{m} \cdot (c_p^{T_{out}} \cdot T_{out} - c_p^{T_{in}} \cdot T_{in}) \quad (5)$$

where c_P is the specific heat of the treated material at the inlet (T_{in}) and outlet temperature (T_{out}).

2.2. Thermal Model

Heat transfer mechanisms are different in solar rotary reactor from traditional industrial kilns. In solar reactor, radiation is the main mechanism, while in classic kilns, particles heating is due to a combination of convection and radiation from the hot gas. Hence, in order to calculate the efficiency of the rotary kiln, a thermal model based on a particular cavity receiver was carried out. In the model, each kind of thermal losses was estimated following correlations found in literature. The gross power required (Q_{RR}) by the rotary receiver was calculated as the sum of the power absorbed by the particles (Q_p) and the total thermal losses (Q_l), see equation 6. In addition, kiln efficiency (η_{RR}) was obtained from equation 7.

$$Q_{RR} = Q_l + Q_p \quad (6)$$

$$\eta_{RR} = \mathrm{Q_p}/\mathrm{Q_{RR}} \quad (7)$$

Thermal losses were divided in radiative, convective, conductive, and reflection losses (see equation 8). Since conductive losses in solar receivers are more than one order of magnitude lower than other contributions, they were neglected in this work.

$$Q_l = Q_{l_{rad}} + Q_{l_{cv}} + Q_{l_{cd}} + Q_{l_{refl}} \quad (8)$$

2.2.1. Radiative losses

Radiative losses ($Q_{l_{rad}}$) were calculated with Stefan-Boltzmann law (see eq. 9) considering the effective emissivity ε_{eff} of a cylindrical cavity. In equation 9, $\sigma = 5.67 \cdot 10^{-8}$ W m^{-2} K^{-1} is the constant of Stefan-Boltzmann, A_{ap} is the aperture area of the rotary kiln, T_{amb} is the environment temperature, T_{cav} is the average temperature inside the reactor calculated with equation 10 and A_{cav} is the total area of internal surfaces of the reactor. T_i represents the average temperature of each surface that composes the cavity. In this case, the average bed temperature and the average wall temperature (T_w) were used. T_w was considered equal to stagnation temperature obtained from the average heat flux (q'') received by the internal cavity surfaces, see equation 11.

$$Q_{l_{rad}} = \varepsilon_{eff} \cdot \sigma \cdot \mathrm{A_{ap}} \cdot (T_{cav}^4 - T_{amb}^4) \quad (9)$$

$$T_{cav} = \frac{\sum_i T_i \cdot A_i}{\sum_i A_i} = \frac{\sum_i T_i \cdot A_i}{A_{cav}} \quad (10)$$

$$T_w = \sqrt[4]{\frac{q''}{\sigma \cdot \varepsilon_w}} = \sqrt[4]{\frac{Q_p}{A_{cav} \cdot \sigma \cdot \varepsilon_w}} \quad (11)$$

ε_{eff} was calculated following the methodology indicated in Bergman et al., (2011) applied to a cylindrical cavity with an aperture in one base (see equation 12). ε_{cav} corresponds to the average internal cavity emissivity, and the view factor ($F_{cav \to ap}$) was defined with equation 13. The radius of the aperture was assumed equal to the difference between the internal radius of the reactor and the dam height (see equation 15).

$$\varepsilon_{eff} = \frac{1}{F_{cav \to ap} \cdot \frac{1-\varepsilon_{cav}}{\varepsilon_{cav}} + 1} \quad (12)$$

$$F_{cav \to ap} = \frac{R_{ap}^2}{2 \cdot \mathrm{R}^2 - \mathrm{R_{ap}^2} + 2 \cdot \mathrm{R} \cdot \mathrm{L}} \quad (13)$$

$$A_{ap} = \pi \cdot \mathrm{D_{ap}^2}/4 \quad (14)$$

$$D_{ap} = 2 \cdot \mathrm{R_{ap}} = 2 \cdot (R - \mathrm{h_{dam}}) \quad (15)$$

2.2.2. Convective losses

In case of an open cavity rotary kiln, convective losses $Q_{l_{cv}}$ were expected similar to the losses of a static solar cavity receiver. Because rotational speed were not high and it was supposed the reactor/receiver was protected by a well-insulated static case, losses from the external walls of the reactor were neglected. Otherwise, convective losses in the interior of the cavity are not easy to calculate and a specific study has to be done on a case by case basis. However, several correlations have been proposed and used by many authors (Li et al., 2010; Ma, 1993; Mcdonald, 1995; Siebers and Kraabel, 1984). In this work, the methodology proposed by Siebers and Kraabel (1984) was followed. Convection losses were separated in forced $Q_{l_{cv}}^f$ and natural $Q_{l_{cv}}^n$ contributions as indicated in equation 16 and 17. Where *Nu* is the number of Nusselt, *K* the conductivity of the air and *D* the diameter of the reactor.

$$Q_{l_{cv}} = Q_{l_{cv}}^f + Q_{l_{cv}}^n = h_{conv} \cdot (T_{cav} - T_{amb}) \cdot A_{cav} \quad (16)$$

$$h_{conv} = h_{nc} + h_{fc} = \frac{Nu_{nc} \cdot K}{D} + \frac{Nu_{fc} \cdot K}{D} \quad (17)$$

Stine and Mcdonald indicated *Nu* for natural convection can be calculated by equations 18, 19 and 20, where *Gr* is the number of Grashof ($10^5 < \mathrm{Gr} < 10^{12}$); β, the coefficient of volumetric expansion; ν, the cinematic viscosity of the air at the ambient temperature, and *g* is the gravity acceleration (Mcdonald, 1995).

$$Nu_{nc} = 0.088 \cdot Gr^{\frac{1}{3}} \cdot \left(\frac{T_{cav}}{T_{amb}}\right)^{0.18} \cdot (\cos s)^{2.47} \cdot \left(\frac{Dap}{D}\right)^{S} \quad (18)$$

$$Gr = \frac{g \cdot \beta \cdot (T_{cav} - T_{amb}) \cdot D^3}{\nu^2} \quad (19)$$

$$S = 1.12 - 0.982 \cdot \left(\frac{D_{ap}}{D}\right) \quad (20)$$

To calculate *Nu* for forced convection, the following correlation from Ma (1993) was used:

$$h_{fc} = 0.1967 \cdot v_{wind}^{1.849} \quad (21)$$

where v_{wind} is the wind speed.

For the treatment of reactive particles or direct treatment of materials, a controlled atmosphere inside the reactor is required. Therefore, a window at the kiln aperture must be employed. In these cases, similar to industrial rotary kilns, convective heat losses are mainly due to the forced fluid flow inside the reactor. Nevertheless, gases in solar kilns are at relatively low temperatures and the heat passes from the wall and particles to the gas. On the contrary, in industrial devices, the heat passes from the hot gas to the particles and to the kiln walls. For this configuration, no specific equations have been developed so far, neither for solar rotary kilns nor for industrial rotary kilns. For instance, Brimacombe and Watkinson correlation underestimated convective heat losses for their classical rotary kiln (Brimacombe and Watkinson, 1978; Watkinson and Brimacombe, 1978). Yang and Farouk correlation was also discarded for the same reason (Yang and Farouk, 1997).

2.2.3. Reflection losses

In solar plants, part of the radiation impinging on the receiver is reflected by the receiver surface towards the environment. Cavity receivers reduce these losses, which can be calculated with equation 22. ρ_{cav} is the reflectivity of the internal surfaces of the cavity and it is calculated through equation 23 as the weight average reflectivity for the different constituent materials.

$$Q_{l_{refl}} = F_{cav \to ap} \cdot \rho_{cav} \cdot Q_{RR} \quad (22)$$

$$\rho_{cav} = \frac{(1-\varepsilon_w) \cdot A_w + (1-\varepsilon_p) \cdot A_{bed}}{A_{cav}} \quad (23)$$

2.3. Heliostats fields design

Solar tower plants consist of a receiver mounted on the top of a tower and a heliostat field. The distribution of the heliostat field can be either circular (around the tower), or at one side of the tower (north or south field, depending on the hemisphere where the plant is located). Because solar rotary kiln shape is similar to cavity receiver, only one-side configuration is suitable for these thermal processes. For this reason, the power range of such a solar tower plant is limited to 1-100 MWth, approximately.

In order to define the heliostat field for the plant, the software WinDelsol was used. WinDelsol is based on the original Delsol3 code from SANDIA National Labs. The software can design and optimize heliostat fields and determine the radiative flux on cavity, external or flat receivers. In this case, a tilted flat receiver was employed in order to reproduce the flux that reaches the aperture of the reactor. The location of the plant was supposed in the Tabernas Desert, Almeria (Spain) for which atmospheric attenuation parameters were known. Detailed characteristics of heliostats, aiming strategies and the required power on the receiver were introduced in the software as inputs for the calculation. With this information, WinDelsol could estimate the flux distribution on the selected receiver and at the same time, it delivered the optimized heliostat field, considering thermal losses due to cosine factor, shadowing, blocking, spillage and atmospheric attenuation. WinDelsol delivered also the number of heliostats (N_{HS}), the efficiency (η_{HS}), the total area ($N_{HS} \cdot A_{HS}$) and the reflected power (Q_{HS}) by the heliostat field. Alternatively, knowing the number of heliostats and the reference direct normal irradiation (DNI_{ref}), the power reflected by the heliostat field could be obtained with equation 24 and the efficiency with 25. A_{HS} is the reflecting surface of one heliostat. In this study, a minimum efficiency of 70% for the heliostat field was considered acceptable.

$$\mathrm{Q_{HS}} = N_{HS} \cdot A_{HS} \cdot DNI_{ref} \quad (24)$$

$$\eta_{HS} = \mathrm{Q_{RR}}/\mathrm{Q_{HS}} \quad (25)$$

Finally, the total efficiency of the plant can be calculated with equation 26.

$$\eta_{tot} = \mathrm{Q_p}/\mathrm{Q_{HS}} = \eta_{HS} \cdot \eta_{RR} \quad (26)$$

2.4. Storage system considerations

In this work, the kiln was treated as a thermal rotary receiver for sand or particles. Depending on the requirements, the system can store or not the absorbed solar energy. As previously explained, the shape of the reactor limits the maximum power available and, when the thermal demand is high, a plant without storage could result more advantageous to produce hot air, water or steam in a heat exchanger with the integration of an auxiliary heater. In other cases, when the heat demand of the process is considerably lower than the maximum power of the solar plant, a storage system should be considered. Thus, a specific solar multiple has to be defined for the plant, taking into account the requirements of each case. Finally, in plants working with direct treatment of material, a batch reactor could be more appropriate than a continuous one.

As mentioned, the plant can operate with or without thermal storage. If the plant is provided with an insulated hot tank, when the heat demand decreases or is null, the sand can be stored in it. In this way, the control of sand energy could be easier. However, residence time could not be sufficient to heat up the sand because of the intermittency and variations of solar energy. Although residence time can be varied by changing the rotational speed of the reactor, recirculation of sand in the reactor or an auxiliary heating system inside the hot storage should be implemented in order to achieve the desired particle temperature when weather conditions are not ideal. A schematic representation of a plant with thermal storage and with direct treatment of material is shown in figure 1.

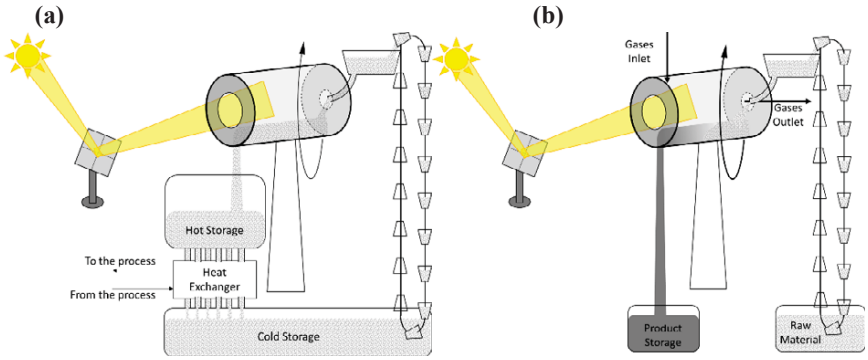

Fig. 1: Configurations of a plant a) with thermal storage and b) for direct treatment of material in the receiver.

3. Results

3.1. Receiver sizing, residence time and mass flow

A reference case based on PS10 solar tower plant is presented for which a thermal power (Q_p) of 50 MW was considered. Kiln size was determined in order to be similar to PS10 receiver. Furthermore, a rotational speed of 5 rpm and a receiver slope of 5° were assumed. Those values are within the typical range for industrial rotary kilns and they assure a bed motion in rolling or cascading mode. As mentioned, sand was the material designated for the study with a design outlet temperature of 750 °C. The considered sand properties were bulk density (1560 kg/m^3) and the specific heat, which was calculated at the entrance and at the outlet of the reactor according to equations 27 and 28 (Perry, 1997). In the case of a plant without storage, in which the particles are directly irradiated, the specific heat of sand has to be changed with the treated material's one (this case is not reported here). Sand properties used in the calculation are resumed in table 1.

$$C_{p_{SiO2,\alpha}} = \frac{4.187}{0.06} \cdot \left(10.87 + 0.008712 \cdot T - \frac{241200}{T^2}\right) \quad \text{for } 273 < T < 848 \text{ K} \quad (27)$$

$$C_{p_{SiO2,\beta}} = \frac{4.187}{0.06} \cdot (10.95 + 0.0055 \cdot T) \quad \text{for } 848 < T < 1873 \text{ K} \quad (28)$$

Table 1: Main physical properties of sand used for calculations.

Property	bulk density	Specific heat at 20 °C	Specific heat at 750 °C
Unit	kg/m^3	$J\ kg^{-1}\ K^{-1}$	$J\ kg^{-1}\ K^{-1}$
Sand	1560	740.9	1156.8

An iterative process was adopted in order to determine the proper size of the receiver. According to Mellmann classification, a fill ratio higher than 10% assures the achievement of a rolling bed motion inside the kiln. Nevertheless, increasing the fill ratio, segregation can arise inside the core of the particle bed. Another constraint is related to kiln aperture. As indicated above, aperture diameter depends on the height of the particle bed that defines the height of the kiln dam. A small aperture can reduce receiver heat losses; however, if it is too small, part of the flux reflected by the heliostat field could not enter and, as a consequence, spillage losses increase. Taking into account this consideration, an internal diameter of 9 m and an axial length of 8.7 m were selected for the receiver.

Table 2: Rotary kiln geometrical and operational characteristics.

Parameter	Internal Diameter	Length	Dam Height	Aperture Diameter	Fill Ratio	Residence Time	Mass Flow	Central Angle α
Unit	m	m	m	m	%	min	kg/s	degree
Value	9	8.7	1.4	6.2	10	28	51.7	93.3

3.2. Thermal model results

For the calculations, it was assumed that the rotary kiln had been heated before the addition of the particles. Once the size of the receiver was fixed and mass flow and temperature range were known, thermal losses were calculated. Air parameters used in the equations are shown in table 3. To evaluate radiative losses, a wall and a particle emissivity of 0.8 (Zhou et al., 2006) and 0.76 ("Engineering Toolbox," 2016) respectively, were assumed.

Table 3: Main physical properties of air used for calculations.

Property	Cinematic viscosity	Volumetric expansion	Conductivity	Wind speed
Symbol	ν	β	K	v
Unit	m^2/s	1/K	$W\ m^{-1}\ K^{-1}$	m/s
Air	$15.11 \cdot 10^{-6}$	$3.43 \cdot 10^{-3}$	0.0515	10

With these values, the results shown in table 4 were obtained. In case 1, convective losses were calculated considering an open cavity receiver, following the methodology proposed by Siebers and Kraabal with the correlation of Stine and Mcdonald for the natural convection and Ma´s correlation for the forced convection.

Table 4: Thermal results for the rotary kiln without transparent windows at the aperture.

	Inlet temp.	Outlet temp.	Absorbed Power	Radiative Losses	Convective Losses	Reflection Losses	Efficiency
Unit	°C	°C	MW	MW	MW	MW	%
Value	750	20	50	3.42	5.45	1.12	83

3.3. Heliostat field results

Two heliostat fields were calculated, assuming Tabernas Desert conditions, a tower height of 110 m and a minimum efficiency of 70%. The first field was based on PS10 heliostats. Those mirrors had a large size and a reflecting surface of 121 m^2 each one. Field with larger heliostats had the advantage to be cheaper, mainly because a minor number of elements is needed. With 713 heliostats, it was possible to concentrate 60 MW of solar radiation inside a circular area of 8 m in diameter placed at the receiver aperture plane. A maximum flux of 2320 kW/m^2 and an average flux of 994 kW/m^2 at the aperture were predicted. A secondary concentrator at the entrance of the kiln was needed because the calculated aperture of the kiln was smaller than the achieved flux distribution. Moreover, a second heliostat field was designed, considering a smaller heliostat size (13.5 m^2). In this case, it was predicted a heliostat field of 6622 elements, a maximum heat flux of 3620 kW/m^2 and an average one of

1656 kW/m^2. For this case, the flux fitted inside the kiln aperture of 6.2 m. In Fig. 2 both heliostat fields are shown.

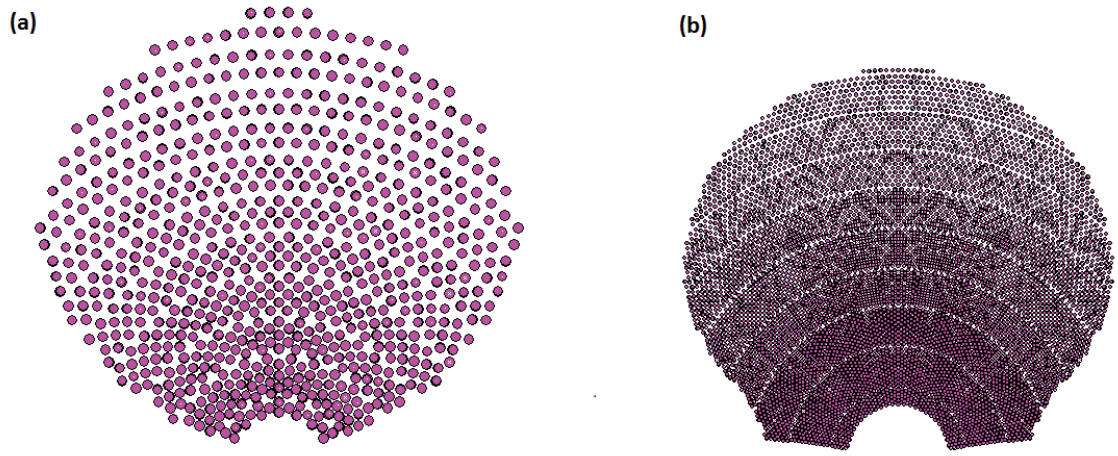

Fig. 2: Heliostat field a) with large heliostats and b) with small heliostats.

4. Discussion and further considerations

The design of the rotary receiver required the selection of several parameters. Geometrical parameter were based on the existing PS10 tower plant and solar rotary kilns proposed so far. In the analyzed example, the mass flow through the kiln was determined by the design power of the receiver and temperature conditions at the inlet and outlet. Working with solid particles at ambient temperature avoids freezing problems of conventional thermal fluids and reduces storage costs in comparison with other heat transfer fluids (i.e., molten salts). Moreover, because of the wider working temperature range, lower mass flows are needed to obtain an equal absorbed power. The outlet temperature of 750 °C was selected because it was higher than the limit of current commercial heat transfer fluid, but it was low enough to avoid a considerable increase of material cost, in particular, the cost of the transport system of the particles, heat exchanger and hot storage tank. Moreover, working with higher temperatures implies reducing the mass flow and as consequence the fill ratio or the kiln aperture. For the proposed example, those parameters were close to their lower limits.

Residence time estimation are quite complex for rotary kilns and in most cases, they are not applicable for scaling up from lab devices. Residence time presented in this work is a rough evaluation of the experimental residence time of an industrial rotary kiln. In the future, a detailed model for the rotary kiln will be developed with the aim to achieve more reliable results and to improve the scale up of such a device. Nevertheless, the estimation of the residence time presented in this work could be assumed as an initial information for the scale up of the plant. A calculated time of 28 min is a reasonable time for the operation in a solar device. An important issue for this solar systems is the control of particle temperature and because of variation in weather conditions, higher residence time could make it complex.

For the thermal model, the rotary kiln was considered similar to a cavity receiver and calculations were based on the existing models for this kind of elements. Therefore, calculated efficiency resulted close to typical efficiencies of these receivers. One of the greatest challenges for both, cavity receivers and rotary kilns, is a good prediction of convective losses. Moreover, an important difference consists in the heat transfer mechanisms for those technologies. In particular, for cavity receivers and solar rotary kilns, radiation is the principal mechanism, while for rotary kilns a combination of convection and radiation from the gas to the solid particles and the walls is the main one. In this work, a simplified model for convective losses was used for the case of a rotary receiver with an open aperture. The proposed thermal model indicates convective losses are the most relevant, corresponding to more than 5 MW. Radiative and reflective losses are 3.42 and 1.12 MW, respectively.

Heliostat fields obtained with the software WinDelsol present higher fluxes than those used in solar tower plants for electricity production. However, they are in an acceptable range for this kind of technology. For both heliostat fields the efficiency was 70% and, as it can be seen in figure 2, a more compact field can be obtained if smaller heliostats are used. Second field allows to fit the flux inside the reactor aperture without the need of a second concentrator. As a drawback, a considerable higher number of heliostats is needed and that could increase the

cost of the plant.

As future work, studies on a solar rotary kiln, which operates in batch mode, will be carried on. This operational mode could facilitate control of the temperature inside the receiver/reactor, but it needs time for charge and discharge phases. As a consequence, during these phases, part of the daily solar radiation cannot be used.

5. Conclusions

Considerations on central receiver plants with rotary kiln for production of process heat with or without storage have been analyzed and discussed in this work. In particular, the case of a 50 MW_{th} plant is presented. Because of the shape of rotary kilns, only one-side heliostat field can be suited in this kind of solar tower plant. A rotary kiln with sand particles is analyzed. A simplified thermal model was carried on and a receiver efficiency of 83% was calculated. A sand residence time of 28 minutes was also predicted. Finally, two heliostat fields are proposed. The first one consists of 713 large heliostats which focus solar energy on a secondary concentrator of 8 m in diameter. With the second one, it is possible to concentrate the required power by the receiver on the aperture of the kiln without the use of a secondary concentrator. As a drawback, more than 6600 small heliostats are needed. To conclude, a first analysis of central tower plants with rotary receiver was conducted. Initial results show the possibility to realize solar plants with these characteristics in future developments. However, more detailed models must be studied in order to more accurately predict the performance of such systems.

SOLAR HEAT FOR INDUSTRIAL PROCESSES (SHIP): MODELING AND OPTIMIZATION OF A PARABOLIC TROUGH PLANT WITH THERMOCLINE THERMAL STORAGE SYSTEM TO SUPPLY MEDIUM TEMPERATURE PROCESS HEAT

María V. Guisado[1], Fritz Zaversky[1], Irene Santana[1] and Ana Bernardos[1]

[1] National Renewable Energy Centre (CENER), Navarra (Spain)

Abstract

This paper presents the development of a simulation tool for a Solar Heat for Industrial Processes (SHIP) plants, based on Parabolic Though technology and equipped with direct thermocline Thermal Storage System (TES). The model developed is a one–dimensional model, based on the Modelica language, which allows the transient performance evaluation of the plant.

Key-words: Solar heat, Industrial process heat, Transient simulation, Modelica, Thermocline.

1. Introduction

This work have been carried out within the project ANTHOPHILA, a project of the Call RETOS-COLABORACIÓN 2014 of the R&D National Program of Research, Development and Innovation, funded by the Ministry of Industry, Energy and Tourism and with Ingeteam and CENER as partners. The main objective of this project is the research and development of new technologies that allows the procurement of a new concept of a hybrid solar thermal for industrial heat application.

Globally, industrial process heat accounts for more than two-thirds of total energy consumption in industry, and half of this demand is low-to-medium temperatures (<400ºC) (Kempener et al., 2016). This means that there is a big potential market for the application of solar thermal energy. Currently there are already installed 188 plants worldwide (AEE-INTEC, 2016) providing solar heat to industrial processes.

Due to the diversity of industrial processes and solar heat supply options, more detailed and accurate models for each of the plant components as well as transient simulation of the plant as a whole are required, in order to achieve efficient configurations.

This paper is focused on the application of a well-structured and flexible model, able to satisfy the requirements of the different industrial heat process plants. The model applies Modelica (Elmqvist and Mattsson, 1997) as modeling language and Dymola (Dassault-Systèmes, 2012) as simulation environment. The model has been applied in a small scale thermal plant for the hybridization of solar thermal and conventional combustion process for SHIP plants. The solar thermal process includes as TES a thermocline single-tank option, proposed by various authors in order to reduce costs, and which is hardly analyzable using the conventional quasi-steady state models.

2. Modelica Description and in-house model library

Modelica is a multi-purpose physical system modeling language which models the dynamic behavior of technical systems and it has been developed in an international effort in order to unify already existing

doi:10.18086/eurosun.2016.02.22 Available at http://proceedings.ises.org

similar modeling approaches and to enable developed models and model libraries to be easily exchanged. The concept is based on non-causal models featuring true ordinary differential and algebraic equations, i.e. differential-algebraic equation (DAE) systems (Elmqvist and Mattsson, 1997).

The object-oriented approach, the possibility of multiple inheritance and the re-declaration feature lead to a clear model structure, avoid multiple definitions of frequently used code and offer an incredible model flexibility. The code syntax and application guidelines are defined in the regularly updated Modelica Language Specification (Modelica-Association, 2012). Furthermore, the use of Modelica clearly decouples the modeler from the equation system solving. Instead of developing a specific solving algorithm for each modeling task, the Modelica tool reads the developed Modelica code, performs symbolic manipulations of equations and translates the Modelica model into numerical simulation code, using state-of-the-art algorithms developed for general application. Thus, developed models and model libraries are exchangeable, i.e. can be read and simulated using different Modelica environments. Today, commercial, as well as open-source Modelica environments are available (Dassault-Systèmes, 2012; Open-Source-Modelica-Consortium, 2013).

Based on the Modelica Standard Library (MLS), the Solar Thermal Energy Department of the Spanish National Renewable Energy Centre (CENER) has developed an in-house model library for the simulation of Concentrating Solar Thermal Plants (CSTLibrary).

The library is based on a one-dimensional fluid flow modeling approach, implemented according to the finite volume method (FVM) (Franke et al., 2009). The library includes a variety of components of thermal solar systems such as, solar collectors with different geometry and thermal loss models, several thermal energy storage solutions, including indirect and direct storage systems with two tanks and thermocline single-tank options, as well as heat exchangers and other thermo-hydraulic components: pipes, pumps, valves, etc., needed for a whole plant simulation. The transient models allow a detailed analysis of the components. Besides, any operation strategy can be integrated.

The modeling approach and the validation of single component models have been previously published in several works, e.g. (Zaversky et al., 2013; Zaversky, 2014; Hernández Arriaga et al., 2015).

3. Industrial Process Description and Model Implementation

The great flexibility of the models allows analyzing a wide variety of industrial heat processes. Concretely, in this work, the model has been applied to an industrial process consisting of a drying unit for the agricultural sector, whose heat is provided by a solar thermal system with parabolic trough technology working at medium temperature (100-250 °C), and an auxiliary fossil fuel boiler. The solar thermal plant also incorporates a storage system, whose size has been optimized considering the number of loops, with the objective to cover as much as possible the heat required by the process.

In order to demonstrate the flexibility of the model and at the same time, to analyze the technical feasibility of the industrial process, two types of thermal storage have been tested, the conventional two-tank storage system and a thermocline storage tank, which can provide a costs reduction but is hardly analyzable using the conventional quasi-steady state models. In addition, two absorber tubes of the same dimensions but different degrees of vacuum have been also analyzed in this work.

Fig.1 shows a basic scheme of the plant, which can be divided into three main systems: solar field, storage system and steam generator. The plant includes an auxiliary gas boiler in order to cover the thermal demand of the industrial process when the solar energy is not available.

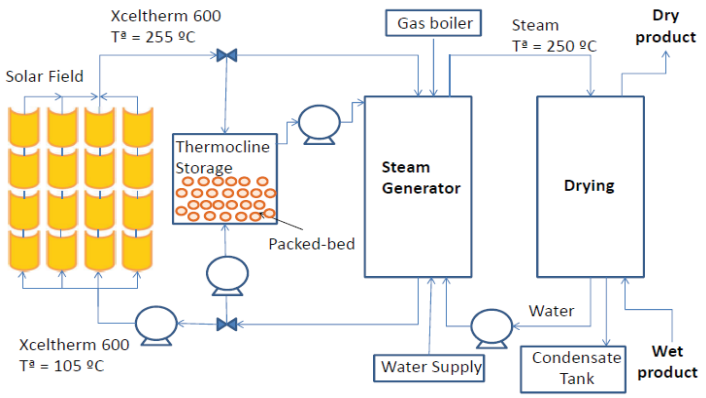

Fig. 1: Diagram of the reference plant with thermocline packed-bed storage

The following sub-sections show a brief description of the models used for each of the main systems mentioned above. They are described detailed in Zaversky (2014).

3.1. Solar Field

The solar field of a parabolic trough collector plant is composed of a number of solar collector loops of identical characteristics. A cold header pipe supplies the thermal fluid to the loops where the thermal fluid is heated by the solar energy and it drains into the hot header pipe. Each loop consists of solar collector assemblies (SCAs) connected in series and each solar collector assembly is composed of the basic solar collector components, as the parabolic mirrors and the solar absorber tubes, i.e. the heat collector elements (HCEs).

Fig. 2 shows a scheme of the solar field model used in this work. It consists of one representative solar collector loop, tow mass flow gains, and two additional dynamic pipe models that represent the cold and the hot header. Basically, the model is based on a 1-D approach according to Forristall (2003),and it discretizes the solar collector loop into a certain number of control volumes according the finite volume method. To correctly reproduce the dominant dynamics and the steady-state behavior, a certain minimum number of control volumes per loop are required.

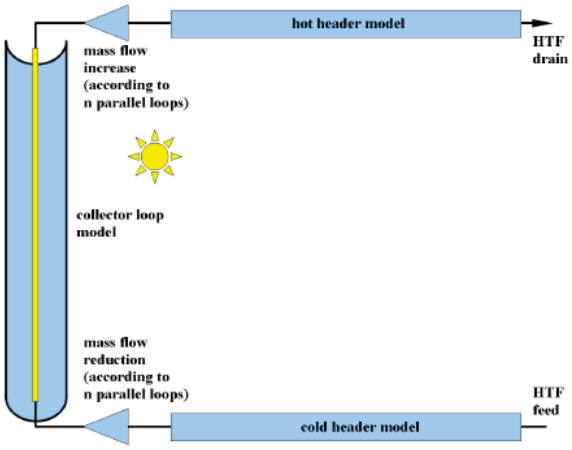

Fig. 2: The end-loop model of the parabolic trough collector field (Zaversky, 2014)

The total thermal power of the solar field is simply achieved via multiplying the mass flow of one loop by the number of total parallel loops.

The number of collectors per loop, and thus the final length of one loop, is defined by the plant´s operating conditions, such as the solar field´s nominal inlet and outlet temperature and the desired HTF mass flow rate for a given solar irradiance level.

Regarding the linear absorber of a parabolic trough collector, it is modeled as a straight steel pipe featuring a selective coating at the tube´s outer surface. It is discretized into a number of finite control volumes, and for each of them, the basic equations for mass and energy conservation are solved (see Fig. 3).

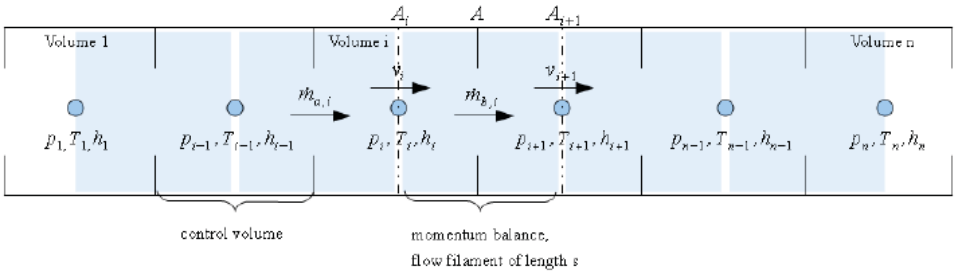

Fig. 3: Finite volume discretization scheme (Tummescheit, 2002)

In order to simplify the model, some assumptions are taken into account. Thus, the absorber tube as well as the glass envelope is assumed to have uniform circumferential temperatures and a uniform circumferential solar heat input. The glass envelope is considered opaque to infrared radiation (Forristall, 2003).

All solid material properties, thermal conductivity, density, and specific heat capacity are assumed to be constant and homogeneous. The heat conduction in longitudinal direction within the absorber tube and the glass envelope is neglected.

Finally, regarding the solar field sub-model, the thermal oil used is not yet available in open Modelica libraries, so these features have been newly implemented. It is modeled as incompressible fluid according to Radco-Industries-Inc. (2014).

Within the MSL, all specific media property functions are decoupled from the library components by defining a replaceable "medium package" in each of them. Basically, all fluid property function names and interfaces are defined within the base class "partial medium". In order to allow a full replaceability, each specific medium model extends from this base class the "partial medium" and defines the specific media related relationships by re-declaring each necessary medium property function. Thus, every single component of the library can easily be adapted for the use of different fluids, by simply replacing the default medium package when instantiating the final model.

3.2. Thermal Storage System

Regarding the thermal storage system, as it has been indicated previously, two types of systems have been analyzed, a conventional two-tank storage system and a single-tank thermocline with filler material. In both cases, the storage is a direct system in which the heat transfer fluid, thermal oil, is used as thermal storage fluid too.

Following sub-sections show a brief description of the main characteristics of each thermal storage system model.

3.2.1 Direct two-tank storage system

The active direct two-tank thermal energy storage system is composed of two tanks, physically separated such that the cold fluid is stored in one of them and the hot fluid in the other one. During charging, the thermal oil leaves the cold tank and it absorbs the energy provided by the solar field increasing its temperature and then it is stored in the hot tank. During discharging, the thermal oil from the hot tank provides heat to the steam generator when the energy from the solar field is not enough and the cold thermal oil is returned to the cold tank.

The basic components of a typical active direct two-tank system are the storage tanks (the hot tank and the cold tank).

The storage tank model is based on the assumption of having one representative thermal oil temperature. Hence, the thermal oil within the tank is modeled as a single control volume, defining an ideally mixed energy balance.

3.2.2 Direct thermocline storage system

Unlike the conventional two-tank storage system, in which the hot and cold fluid are stored in two different tanks, the thermocline storage system uses a single tank of slightly large dimensions in which the hot oil remains in the top of the tank and the cold fluid remains in the bottom, due to the thermocline effect.

The strongest temperature variation between these stratified layers occurs in a limited zone within the total thermal oil level height. For this reason, it is possible to provide almost constant thermal oil outlet temperatures, during a reasonable part of the discharging process. And vice versa, the cold thermal oil outlet temperature is almost constant during charging mode. About 69% of the total maximum thermal oil level height can be used for the actual storage capacity. Hence, about 31% of the thermal oil level height is required by the temperature gradient.

Furthermore, a packed bed is used in the thermocline tank as filler to increase the thermal capacity. The filler material avoids the convective mix and reduces the amount of fluid required for the storage system. The filler must have a high specific heat capacity, a minimal interstitial space, must be compatible with the storage fluid, and one should avoid toxic or hazardous materials.

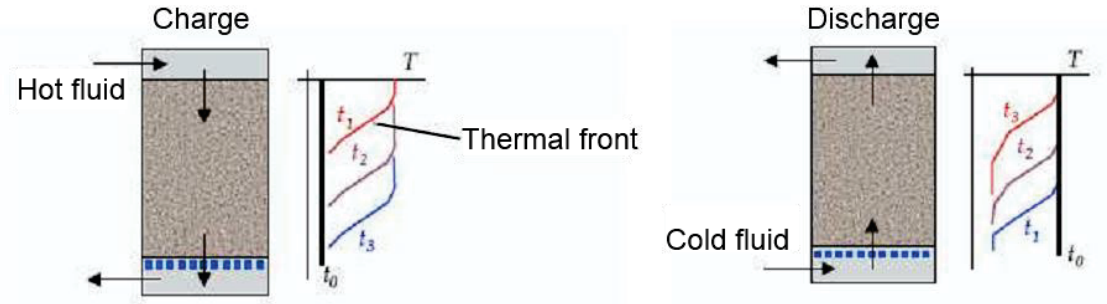

Fig. 4: Operation of a thermocline storage system with bed packed

The thermocline storage space can be divided into three zones. Starting from the bottom, the first zone is a rather constant low temperature zone (i) ranging from the bottom area of the tank up to the beginning of the pronounced temperature gradient zone. This temperature gradient zone (ii) is characterized by significant temperature changes of the storage fluid and the filler material. Finally, the temperature gradient zone is followed by the rather constant high temperature zone (iii) at the top of the tank (Yang and Garimella, 2010).

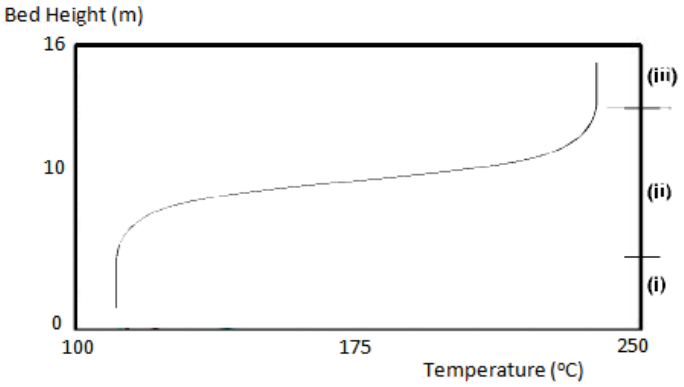

Fig. 5: Thermocline zones (i, ii, iii)

While discharging and charging, the temperature gradient zone moves towards the exit piping, leaving behind an expanding constant low temperature zone (discharging), or high temperature zone (charging), respectively.

In the constant temperature zones, the filler material is completely cooled or heated, providing a thermodynamic equilibrium between the thermal oil and the filler material. In the temperature gradient zone, the thermal energy is either transferred to the filler material (charging), or, in the case of discharging, to the thermal oil.

The thermocline problem can be described by the following set of coupled partial differential equations (PDEs), based on the pioneering work of Schumann (1929).This set of PDEs has to be discretized in order to obtain a set of ordinary differential equations (ODEs) suitable for the model formulation in Modelica. This has been done according to the finite volume method (FVM). In particular, the developed model is based on well-proven and freely available model structures and base classes, as provided by the Modelica Standard Library (MSL) (Modelica-Association, 2010). For a detailed model description, the interested reader is referred to Hernández Arriaga et al. (2015).

$$M_f c_f \frac{\partial T_f}{\partial t} + M_f c_f v \frac{\partial T_f}{\partial x} = h_{fs} P_{fs}\left(T_s - T_f\right) + k_{fe} A_c \frac{\partial^2 T_f}{\partial x^2} - U\, P_w\left(T_f - T_a\right) \quad \text{(eq. 1)}$$

$$M_s c_s \frac{\partial T_s}{\partial t} = h_{fs} P_{fs}\left(T_f - T_s\right) + k_{se} A_c \frac{\partial^2 T_s}{\partial x^2} \quad \text{(eq. 2)}$$

where

$$M_f = \epsilon\, A_c \rho_f \quad \text{(eq. 3)}$$

$$M_s = (1-\epsilon) A_c \rho_s \quad \text{(eq.4)}$$

$$v = \frac{\dot{m}_f}{\rho_f\, \epsilon\, A_c} \quad \text{(eq.5)}$$

3.3. Steam generator

The steam generator is modeled in quasi-steady manner, applying steady-state heat exchanger models implemented according to the logarithmic mean temperature difference method (Shah and Sekulic, 2003). The water medium model is implemented according to Wagner and Kruse (1998).

3.4. The transport system model, the control model and operation strategies

All sub-models for different systems of the plant are connected by the transport system model. The transport system model has the task to correctly distribute the mass and energy flows between the solar thermal plant's components. Further-more, the pumping power for the HTF circuit has to be estimated.

Basically, the transport system model consists of a steady-state pump model, an expansion vessel model, instances of a T-junction model and the corresponding connecting equations between the power plant components.

Next, the control of the plant model will be roughly outlined. Transient Modelica models of thermal processes where certain process variables need to be controlled, typically feature continuous feedback proportional-integral (PI) control. The solar field model´s mass flow control additionally features a feedforward term that uses a simple steady-state model of one representative loop, in order to predict a reasonable mass flow signal depending on the current direct normal irradiance.

Furthermore, besides the control loops for the nominal solar field outlet temperature, a defocusing control loop is implemented as well, in order to avoid overheating of the heat transfer fluid. In this work, this defocusing control is implemented using a simple PI feedback structure. Thus, whenever the HTF temperature exceeds a maximum value of 260°C, the loop is defocused in the model. Not that the set point for the solar field outlet temperature is 255ºC.

In a solar thermal system with thermal energy storage, the current solar field mass flow rate does not automatically define the thermal load of the steam generator, since a fraction of the solar field mass flow can either be used for storage system charging, or, in storage system discharging mode, a certain mass flow top-up can be supplied to the power block by the thermal energy storage system. Thus, for a solar thermal plant with storage, the desired thermal load of the steam generator is controlled via charging or discharging of the thermal energy storage system, of course, if the current state-of-charge of the storage system allows the desired operation. The solar field will be defocused if the storage system is full and the solar field provides more power than the steam generator is able to handle.

The top-level control block implements the operating strategy of the plant model, i.e. it acts as a virtual operator of the plant that defines allowed minimum and maximum mass flow rates, the solar field recirculation mass flow, the thermal load set point of the steam generator as well as the thermal energy storage system´s operation.

An important point of the operation strategy control block is that it features discrete time variables that change their values at certain events during simulation, so, any arbitrary operating strategy can be implemented that defines certain variable set points according to specific operating directives.

4. Results and Conclusions

4.1. Plant Description – Technical parameters

The solar field of parabolic trough collectors consists of loops of 300 m. Each loop is composed of 74 collectors of 4 m length each of them. The thermal oil used as heat transfer fluid and thermal storage fluid is XCeltherm 600, which is an adequate fluid for the working temperatures. The absorber tubes are tubes of 2 meters length and have an inner diameter of 37 mm. The number of loops of the plant is a parameter which is going to be optimized.

In the case of the thermocline single-tank, the storage system includes a filler material in order to improve the thermal efficiency. After analysis of several materials, Cofalit has been selected for this study. It is a post-industrial commercial ceramic obtained from industrial processing of asbestos and waste. It shows good properties for the storage of thermal energy in the form of sensible heat up to 1100 °C. It has a specific heat of 0.860 kJ / kg K and its cost is very low.

The storage size, analyzed in a range of 1-8 hours, has been technically optimized during the design process in order to cover the thermal demand of the drying process as long as possible. An initial objective is that at least in the months of June, July and August, the auxiliary boiler should not be necessary.

The auxiliary boiler with fossil fuel is used to provide heat to the drying process when the thermal power provided by the solar field and/or storage system is not enough to cover the thermal demand.

The operation strategy consists of an annual demand of 3170 MWh distributed hourly such as is shown in Table 1 knowing that 100% of the demand is 1.5 MWt. It has been stablished as an initial target that at least in the months of June, July and August it is not necessary to start-up the boiler.

The model has been run over a year at Valladolid in Spain (Latitude 41.65^{o}) with a specific weather input file.

4.2. Results

The detailed transient analysis carried out by this software allows extracting and analyzing a large number of variables for the different systems and connections of the plant. The output variables such as power, energy, temperature, enthalpy, pressure, mass flow or charge states of the storage systems can be obtained for any instant of simulated period.

Results from these detailed simulations allow an accurate evaluation of the annual performance of the different alternatives, thereby providing a powerful and reliable tool for heat process plant designers.

Fig. 6 shows some of these variables for a clear day.

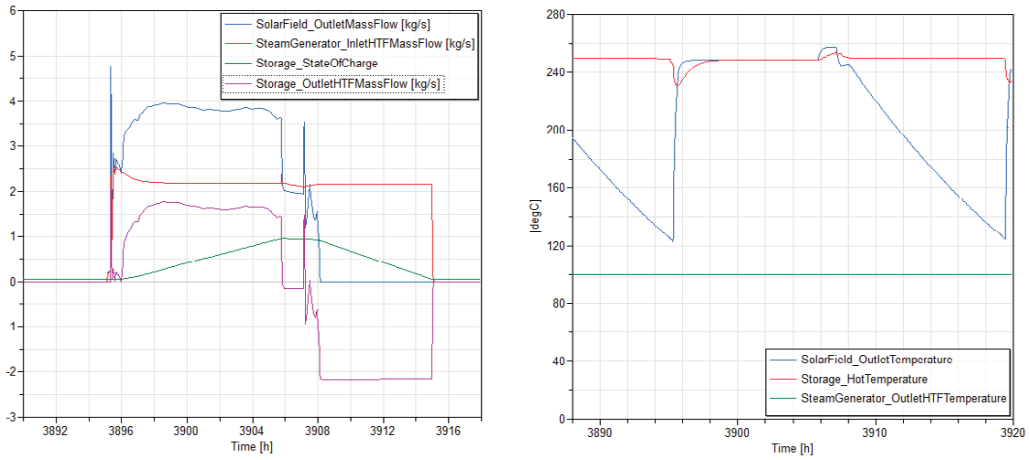

Fig. 6: Some variables provided by the software

During the optimization process, solar fields of 3-6 loops (1-1.5 MWt) and storage sizes of 1-8 hours have been analyzed, establishing as main aim to cover the demand of June, July and August. From this process, it can be concluded that, in order to cover that demand and due to that most of energy is required during the night, it is more profitable an increase of the storage size than an increase of the number of loops. So, among the options studied, a solar field with 3 - 4 loops and 8 hours of storage has been chosen as a technically optimal option. An increase in the number of loops would increase the defocusing and thus, would decrease the net plant performance but, it wouldn´t improve the coverage of the heat demand.

So, from the previous optimization process, several options have been analyzed including the different types of absorber tubes (Tube A and Tube B, which has a lower vacuum degree) and storage systems previously described.

The following tables show the main results for the options analyzed, from which can be observed that with a solar field of 4 loops, despite the annual energy generation decreases around 10-12% using the Tube B and a thermocline TES system, the power demand of June, July and August can be achieved.

So, in a next optimization stage, not included in the scope of this work, a detailed cost analysis for all components must be included in order to perform the techno-economic optimization of the complete plant and to confirm the potential feasibility of this TES system and the each type of tube for an industrial heat process.

Tab. 2:Results

	Two Tanks				Thermocline			
	Tube A	Tube B	Tube A	Tube B	Tube A	Tube B	Tube A	Tube B
Number of loops	3	3	4	4	3	3	4	4
Storage (h)	8	8	8	8	8	8	8	8
Energy Generation (MWh)	941	895	1072	1039	772	730	966	910
Annual Demand Coverage (%)	29.7	28.2	33.8	32.8	24.4	23.1	30.5	28.7
June, July and August Coverage (%)	100	96	100	100	89	87	98	98

Subsequently, in order to show the detailed analysis that the software can provide for each one of the

systems, several figures of the storage systems and the absorber tube behavior are included.

Fig. 7 shows the behavior of the thermocline storage system for two different days. For one of them, the storage is partially filled and for the other one, it can be completely filled. To carry out the simulations, the thermocline tank has been divided on 40 nodes and the full storage graph shows that, as described in the thermocline sub-model, about 69% (28 nodes) of the total maximum thermal oil level height is in the hot zone and can be used for the actual storage capacity.

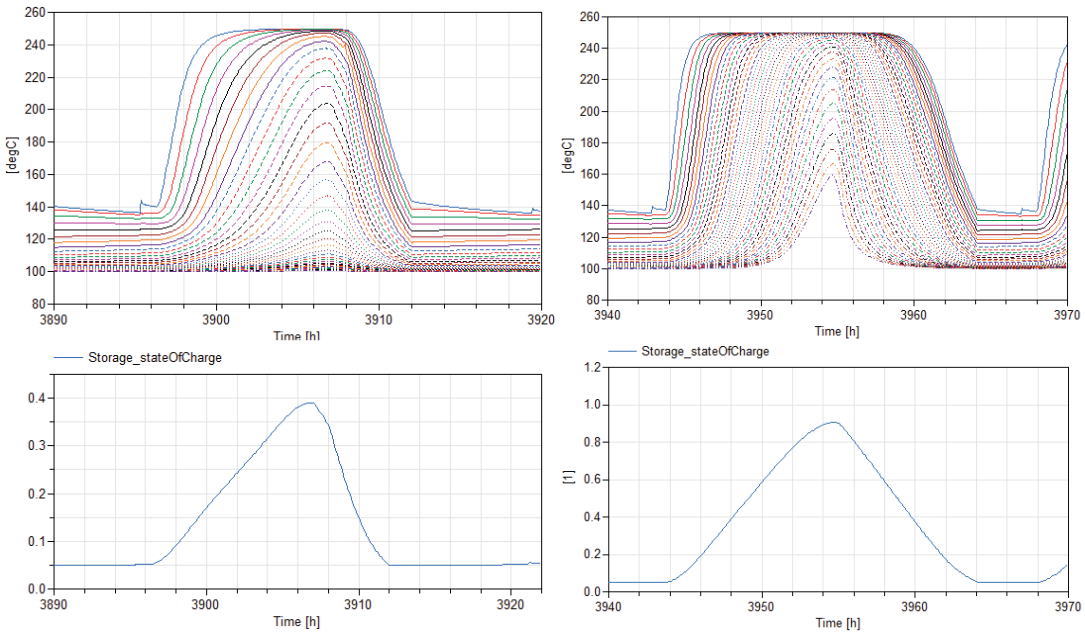

Fig. 7: Thermocline behavior

Finally, Fig. 8 shows the behavior of each type of absorber tube analyzed. It can be seen that the absorber tube B, which has higher thermal losses due to the lower vacuum degree, needs more time to achieve the output temperature (250ºC). Furthermore, nocturnal losses are bigger in this tube.

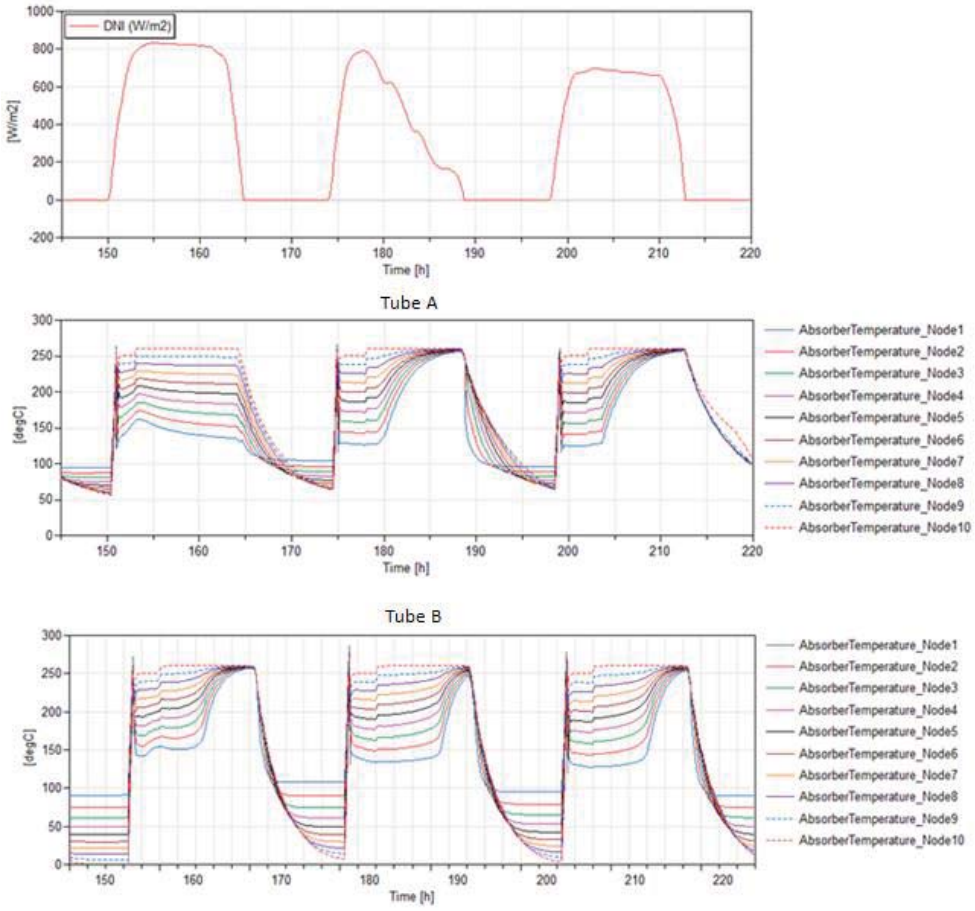

Fig. 8: Absorber tubes behavior

4.3. Conclusions

This work presents a well-structured and flexible model of a solar powered industrial process heat plant. In particular, the model has been applied on a small-scale hybridized SHIP plant, providing thermal power to a drying unit for the agricultural sector. The model applies Modelica as modeling language and Dymola as simulation environment. CENER's in-house model library (CSTLibrary) has been applied to model the system.

The transient analysis allows the evaluation of systems such as a thermocline single-tank storage, which has been proposed by various authors in order to reduce costs, and which is hardly analyzable using the conventional quasi-steady state models for process simulation.

Two types of thermal energy storage, the conventional two-tank concept, and the innovative single-tank thermocline option have been evaluated. Additionally, two types of solar collectors with different levels of vacuum have been analyzed.

The results of the simulations carried out show that with a solar field of 4 loops, despite the annual energy generation decreases around 10-12% using the Tube B and a thermocline TES system, the power demand of June, July and August can be achieved.

Future work will have to continue the optimization process also including costs to perform a techno-economic optimization.

Abstract

Solar thermal (ST) systems for the South African (SA) sugar industry could reduce coal consumption in the boilers and partly replace bagasse (pressed sugar cane fibres) as a heating fuel. Based on the heat and mass balance of a representative sugar mill, the most promising solar heat integration points were identified and pre-ranked according to their potential energetic and economic benefits.

The identified opportunities for solar process heat (SPH) are the generation of live steam and exhaust steam, the pre-heating of boiler feed water, the drying of bagasse and raw sugar, and the heating of clear juice. Without additional thermal storage, ST systems can supply between 12 and 27 % of the heat demand of these processes. The estimated levelized costs of heat (LCOH) for the SPH systems range from 2.57 Eurocent/kWh (0.42 ZAR/kWh) for solar drying of raw sugar during the crushing season (CS) to 4.57 Eurocent/kWh (0.75 ZAR/kWh) for all-year solar live steam generation.

This study assumes that SPH has to compete with coal, which is the cheapest energy source in SA, to replace bagasse. Using current coal prices and past price increase rates, the estimated achievable internal rate of return (IRR) for solar live steam generation is 4.6 % if the steam can be used during the whole year, e.g. for electricity export. The highest IRR of 9.1 % is expected for sugar drying during the crushing season.

Keywords: *solar process heat, energy efficiency, sugar production, electricity export, feasibility study*

1. Introduction

South Africa (SA) produces about two million tons of raw and refined sugar per year as well as a wide range of sugar by-products. Six milling companies operate 14 sugar mills. The vast majority of 12 mills are located in the KwaZulu-Natal province with the remaining two in Mpumalanga. The industry employs 79 000 people directly. SA is one of the leading exporters of sugar, competing with, among others, Brazil, Australia and India (DAFF, 2013). The crushing season usually stretches from March/April to November/December, depending on the amount of cane available in a particular year. On average, about 22 million metric tons of sugarcane are being processed per year (Wienese and Purchase, 2004, p. 41). The capacities of the SA sugar mills vary between 90 and 550 tons of cane per hour (t/h), with an average of about 300 t/h (Smithers, 2014, p. 917). The average length of the 2012/13 crushing season was 254 days and the overall time efficiency (OTE) was about 75.7 % (Smith et al., 2013, p. 30).

A decrease in coal consumption due to improved process management and energy efficiency directly reduces running costs. New income streams can be accessed if a share of the bagasse can be utilized for purposes other than energy generation for the sugar mills. This bagasse can be used to produce fertilizer, animal feed, or paper. It can also be used as feedstock for bio-ethanol production. Particularly interesting in the context of solar process heat (SPH) utilization is the use of steam from bagasse boilers to generate electricity for export to the SA national grid.

2. Sugar Production und Current Energy Supply

To provide a background for the SPH integration analysis to follow, this chapter gives a short introduction to the production of sugar from sugar cane, and on the energy supply to the different processes involved. The descriptions are all based on Rein (2007), unless otherwise stated.

doi:10.18086/eurosun.2016.02.14 Available at http://proceedings.ises.org

2.1 Sugar production process

A simplified representation of the main processes, the intermediate product streams, and the energy supply is given in Figure 1.

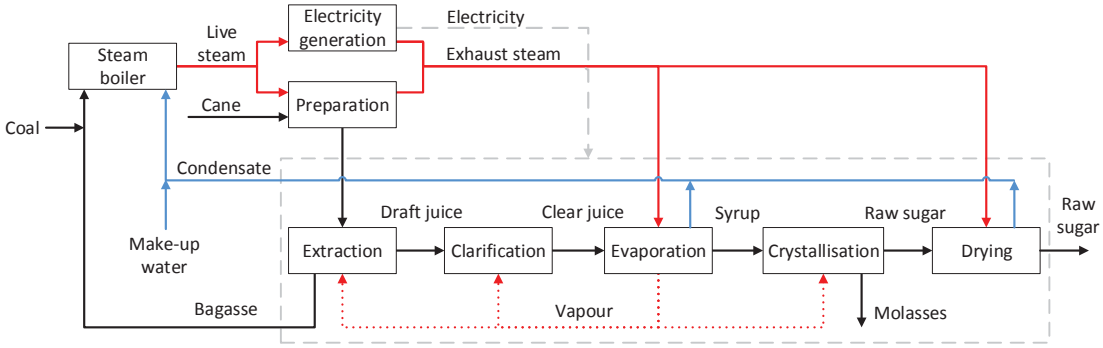

Figure 1: Processes and energy supply of a South African sugar mill

In SA, the cane is usually burned on the field to simplify manual harvesting even though this results in some of the biomass from the leaves being lost. The cane is cut, bundled and transported to the mills. It has to be processed as soon as possible to avoid a loss in sucrose.

Cane preparation refers to the removal of dirt and rocks, the cutting of the cane, and the fiberization of the cane by shredders. Modern sugar factories no longer mill the cane but use diffusers for the extraction of sucrose. In the diffuser, the sucrose is leached by repeatedly spraying heated juice onto a bed of cane fiber moving in counter-flow direction. The bagasse exiting the diffuser is pressed in roller mills to reduce the moisture content and to extract the maximum amount of sucrose. Cane knives, shredders and roller mills are referred to as 'prime movers'. They are usually run by live steam. In the clarification process, the impurities in the juice are removed. Therefore, the juice is pre-heated, flashed, and chemicals such as milk of lime are added.

By evaporation, the clear juice is concentrated to syrup by increasing its sucrose content. This is done in multiple effect evaporators, which have four or five heat exchangers that utilize low-pressure steam as a heating medium. The operating pressure is reduced in each consecutive effect to lower the saturation temperature of the vapor and the boiling point of the syrup. The first effect consumes exhaust steam, after which each successive effect consumes vapor bled from the preceding effect. Additionally, vapor is bled from the evaporators to serve as a heating medium for most of the other processes within the factory (cp. red dotted lines in Figure 1). To achieve crystallization, the syrup is boiled under vacuum in order to concentrate it to saturation. This is usually done by three different batch or continuous boiling pans, referred to as pans A to C. At the outlet of each pan, crystallizers cool the syrup and a centrifuge splits the mass in sugar and molasses. The molasses from the centrifuges of pans A and B is fed into the following pans, while the molasses from the pan C centrifuge is sold as a by-product, used for the production of ethanol, yeast, fertilizer or animal feed.

In the final drying process, the surface moisture content of the raw sugar is reduced by evaporation. For this, usually rotary cascade drums with counter flow hot air are used. After the sugar is dried, it is cooled with ambient air. Raw sugar can be sold directly, or be further refined at a refinery.

2.2 Current energy supply of SA sugar mills

For this study, the steady-state energy and mass balance of a theoretical South African sugar mill without energy efficiency measures is used. Temperatures, pressures and flow-rates are simulation results from the Biorefinery Techno-Economic Modelling project (BRTEM, Starzak and Zizhou, 2015). The BRTEM sugar mill represents the current practice in SA and assumes a throughput of 250 tons cane per hour.

Figure 2 shows besides a first SPH integration concept also the energy supply of the BRTEM sugar mill. The main energy source is bagasse from the roller mills after the extraction process. Live steam is used to perform mechanical work by driving the three prime movers, but it also drives a turbine, which runs a turbo alternator to generate the electricity needed in the production processes. The resulting exhaust steam is used to run the thermal processes of the plant with the highest exergy requirements.

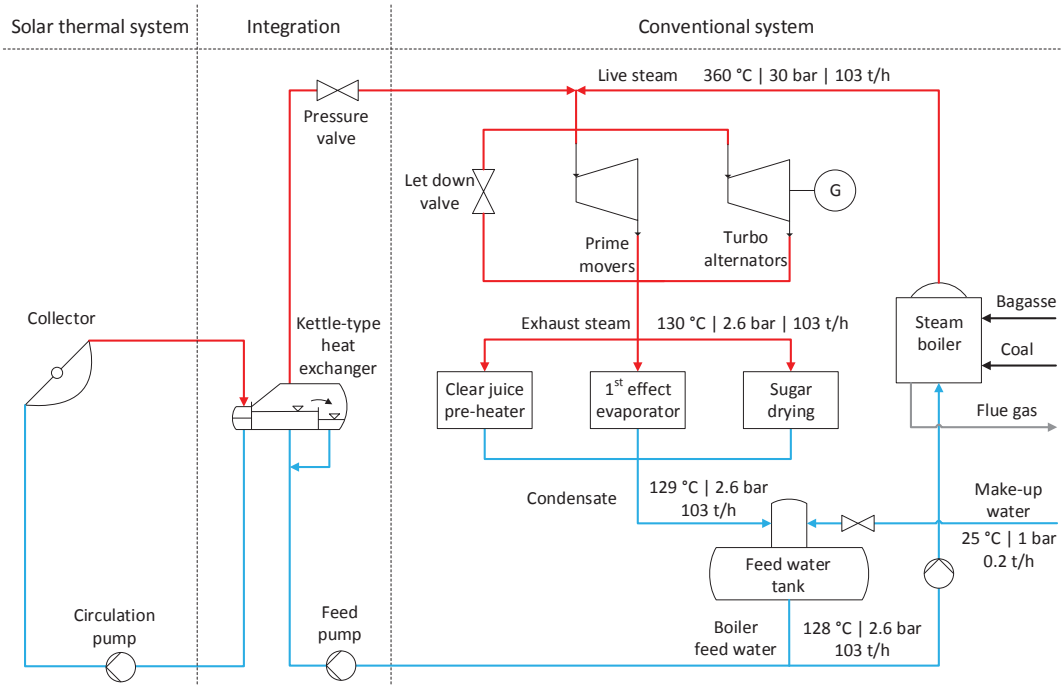

Figure 2: Integration scheme for indirect solar live steam generation (process values from Starzak and Zizhou, 2015)

Raw-sugar factories could be energy self-sufficient as the energy content of the bagasse is higher than their thermal and electrical energy demand. However, in SA, coal is used as an auxiliary fuel to supplement the bagasse. Factories without bagasse-export, electricity-export or a back-end refinery usually only need supplementary coal for abnormal occurrences. In the 2012/13 season, the SA mills had an average coal consumption of approximately 11 t per 1 000 t of cane. The industry consumes roughly 200 000 t of coal per season (Reid, 2006; Smith et al., 2013). The calorific value of 1 t coal equals that of 4 t of bagasse (Smith et al., 2013, p. 48).

3. Solar Heat Integration

3.1 Available solar resource

Figure 3 shows the annual variation of the mean daily global tilted irradiation (GTI) and direct normal irradiation (DNI) at characteristic sugar milling locations in KZN and Mpumalanga. The available irradiation in the KwaZulu-Natal (KZN) coastal region is about twice as high as in Central Europe and similar to other sugar milling locations in Brazil or India (Solar GIS, 2015).

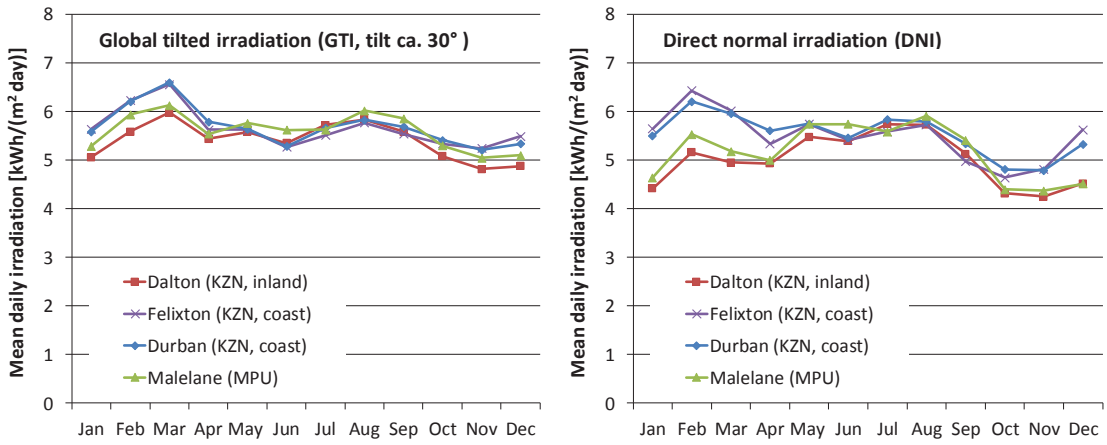

Figure 3: Mean daily GTI and DNI at sugar mill locations (values from PVGIS, 2015)

The GTI in Figure 3 is valid for a surface of 1 m^2 tilted approximately 30° towards the equator, i.e. orientated north. The DNI is the beam irradiance onto a surface of 1 m^2 tracking the sun. The annual sums of irradiance for the four locations in Figure 3 are shown in Table 1.

Table 1: Annual solar irradiation at sugar mill locations in South Africa (values from PVGIS, 2015)

Location	GHI [kWh/(m2 a)]	GTI [kWh/(m2 a)]	DNI [kWh/(m2 a)]	Optimal slope for GTI [°]	Fraction of diffuse [%]
Durban (KZN, coast)	1 825	2 077	2 018	32	34
Felixton (KZN, coast)	1 840	2 062	2 008	31	34
Malelane (MPU)	1 854	2 044	1 883	29	37
Dalton (KZN, inland)	1 737	1 975	1 825	33	37

Figure 3 and Table 1 show that the annual GTI varies by only 5 % between the SA milling locations; DNI varies by 10 %. The irradiance in Mpumalanga is very similar to KZN inland. For a first assessment, Durban can be used as a representative location for the SA sugar mills.

3.2 Integration point assessment

By analyzing the mass and energy flows of the BRTEM model (Starzak and Zizhou, 2015), 23 potential solar heat integration points (IPs) within the model sugar mill were identified. IPs are physical locations, e.g. heat exchangers, in the mill at which solar heat can replace conventional heating media. The potential SPH integrations points were evaluated considering the methodology discussed in the SPH Integration Guideline of Muster et al. (2015). The most relevant criterion was that the support of a heat sink with solar heat would result in direct savings of bagasse or coal. The next priority was saving live steam and then saving exhaust steam. In this first study, the potential integration points saving bleeding vapor were not considered further as the internal value of this steam is lower than that of live steam, and the reduction of bleeding vapor consumption would, without modification to the processes, not directly result in overall energy savings in the mill.

Other ranking criteria were a significant heat demand at the integration point, a sufficient temperature difference to transfer solar heat, and no interference of solar heating with present or future efficiency measures, e.g. the economizers of the boilers. This resulted in the selection of six integration points for further consideration. On supply level these are live steam generation, pre-heating of boiler feed water, exhaust steam generation, and the drying of bagasse. On process level, it is raw sugar drying and clear juice heating.

For each of these processes, integration schemes were developed following the scheme suggested by Helmke and Hess (2015). These schemes were published in Hess et al. (2016). The two most promising integration schemes are discussed in the following.

3.3 Solar live steam generation

Figure 2 above already showed a potential integration scheme for solar live steam generation. According to the BRETM model, the processing of 250 t cane per hour requires about 103 t/h of live steam, as indicated. The boiler in this reference sugar mill provides a power of 74.4 MW_{th}, calculated from the enthalpy difference between feed water and live steam. This is equivalent to the total power demand of the factory. Thus, solar generation of live steam parallel to the existing boiler is a way to utilize very high amounts of solar heat. From Smith et al. (2013) it can be calculated that every ton of solar generated live steam has the potential to offset approximately 0.5 t of bagasse or about 0.125 t of coal.

If we consider a value of 700 W_{th} peak power per square meter of solar collector area (Mauthner, 2015, p. 5), an area of 106 336 m^2 could at peak performance supply the whole power demand of the reference mill (neglecting the heat exchanger efficiency). However, since the SPH is normally only off-setting the fuel consumption of the existing bagasse boiler, the ability of this boiler for power modulation also has to be taken into account. In this paper, we assume that the boiler can only maintain its current efficiency if it produces 37 MW^{th} or more, i.e. more than 50 % of its BRTEM power. To maintain this condition, maximally 37 MW_{th} of solar steam power could be added without solar heat storage. This corresponds to a collector field of about

53 168 m^2. In Durban, high-temperature PTCs producing the required live steam parameters would yield approximately 1 110 $kWh_{th}/(m^2\,a)$, as shown in Table 2. If the collector field is only operated during the crushing season, the specific yield reduces to 768 $kWh_{th}/(m^2\,a)$. The field size mentioned above could substitute 12 % of the boilers' annual energy production if it operated throughout the crushing season, not considering OTE, and 17 % if operated all year. Collector field size and solar fraction can be further increased if a solar heat storage is installed.

By 2012, in India a total capacity of approximately 5 GW_{el} of bagasse-fueled power stations was installed (Tongaat Hulett, 2013). In Mauritius, 90 % of the sugar factories export electricity to the grid (Smithers, 2014). In Brazil, in 2013 a total amount of 15,067 GWh_{el} was produced by bagasse-fueled power plants for the national grid, and this shall be increased by a factor of 13 until the year 2022 (Burin et al. 2015).

Tongaat Hulett (2013, p. 12) estimates that the 14 SA sugar mills could generate about 800 MW_{el} to 1 000 MW_{el} for export to the SA grid. Tongaat Hulett's eight sugar mills in Mozambique, SA and Zimbabwe, in some instances, already feed electricity back to the grid. In the 2014/2015 season, Tongaat Hulett exported 32.65 GWh_{el} (Tongaat Hulett, 2015). Smithers (2014) estimated that the South African sugar industry could potentially produce a total of 600 MW of electricity by the end of 2016, accounting for approximately 1.5 % of the country's total generation capacity. In a financial viability and macro-economic impact analysis, Conningarth Economists (2013) strongly advocate for export of electricity by SA sugar mills. However, no large scale projects with electricity export are in place at SA sugar mills yet. The prices offered by the national SA power grid operator for electricity from sugar mills are all negotiated individually. The revenue being offered is apparently currently not making it viable to invest in equipment for increased export.

3.4 Solar drying of bagasse

An integration scheme for solar drying of bagasse is shown in Figure 4. The typical moisture content of bagasse after the dewatering mills in the juice extraction unit is approximately 50 % of weight. In the 2012/13 season, the average bagasse moisture content ranged between approximately 46 % and 52 % (Smith et al., 2013).

According to Rein (2007), the advantages of bagasse drying include improved boiler efficiency, reduced fuel consumption, higher flame temperature and reduced excess air requirements. Rein (2007) further states that the technical lower limit for the moisture content of bagasse is in the order of 30 %. According to Loubser (2015), however, the moisture content should not be reduced to below 40 % because of the risk of spontaneous combustion. It is expected that the gross calorific value of bagasse can be increased by approximately 20 % by reducing the moisture content from 50 % to 40 %.

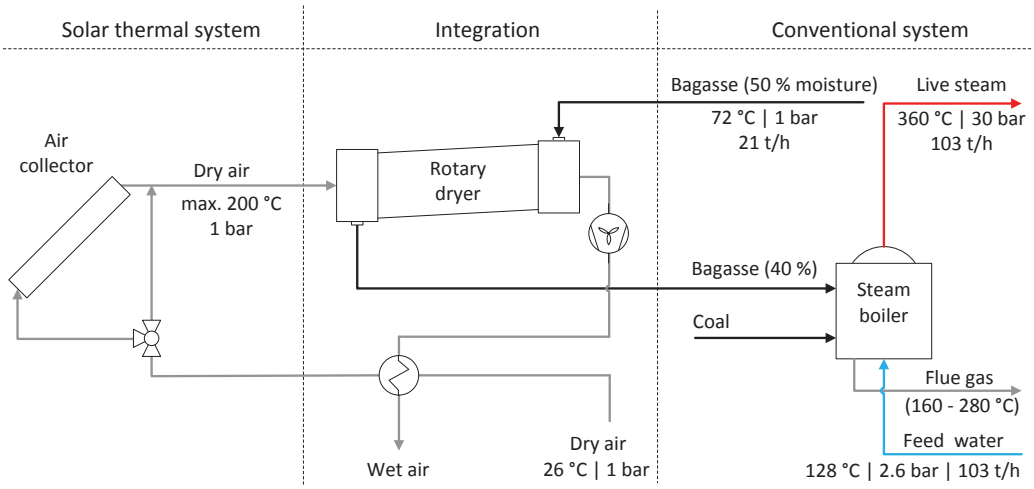

Figure 4: Integration scheme for solar drying of bagasse with air collectors (process values from Starzak and Zizhou, 2015)

Solar air collectors have already for long been applied for drying, e.g. of wood chips or fruit. Direct solar pre-heating of ambient air has the advantage of low collector absorber temperature to achieve high efficiencies. For bagasse drying, a fan would suck ambient air through an air collector field and into the rotary dryer. If a constant dryer inlet temperature is needed, or the dryer inlet temperature is controlled automatically depending

on output bagasse moisture, a mixing device can add some ambient air into the collector outlet stream. The drying air cannot be recirculated as the relative air humidity at the dryer inlet must be low. However, heat recovery can be implemented to pre-heat the collector air inlet from the dryer outlet air.

A first rough dimensioning of a rotary dryer for the task of evaporating a water amount of about 2 t/h resulted in an energy demand of approximately 6 GJ_{th}/h to achieve such an evaporation rate (based on Bruce and Sinclair, 1996). For heating of ambient air to a maximum dryer inlet temperature of 200 °C, the mean load of the dryer system without heat recovery would be 1.67 MW_{th}. The simulation results given in Table 2 indicate that the specific solar gains at the bagasse drying temperature level can reach 779 $kWh_{th}/(m^2\ a)$ during the crushing season. About 24 % of the overall bagasse drying heat demand during the crushing season could be supplied by a SPH system without storage. If the dryer could operate throughout the year, the solar gain would increase to 1 058 $kWh_{th}/(m^2\ a)$ and the solar fraction for drying the same amount of bagasse would increase to 33 %.

A pilot plant test for solar drying of bagasse in a sugar mill in the Dominican Republic showed a reduction in moisture from 50 % to between 36 % and 44 %, but it was noted that on a large scale the results could vary considerably (Rein 2007, p. 610). In his overview on bagasse drying technologies, Sosa-Arnao (2006) points out that a study on the trade-off between combustion air pre-heating, the economizer in the boiler and the drying of bagasse is still to be done. The option of solar drying could be included in such a study.

4. Solar Gains and Performance Indicators

Table 2 shows the heating power demand of each heat sink and the performance indicators that were estimated from literature (Live steam) or simulated (all other).

The heat demand is the maximum solar energy that could be fed in at this point. It is calculated from the mass flow at the integration point and the enthalpy difference between heat exchanger inlet temperature and pressure (process return), and heat exchanger outlet temperature and pressure (process feed). The maximum field size for all variants results from dividing the heating power demand by 700 W/m^2 peak power by 1 m^2 of collector area. This ensures that the solar heat generated is always below the demand (no storage). For live steam generation, the maximum area is additionally limited by the capability of the boiler for power modulation.

Table 2: Solar collector field dimensions with annual (A) and crushing season (CS) performance estimation in Durban without thermal storage

Heat sink	Heating power demand [MW_{th}]	Max. field size [m^2]	Process return temp. [°C]	Max. feed temp. [°C]	Collector type*	System efficiency on GHI [%]		Specific gains [kWh/m^2]		Solar fraction [%]	
						A	CS	A	CS	A	CS

* parabolic trough collectors (PTC) for high temperature (HT) and medium temperature (MT) applications, evacuated tube collector (ETC), and flat-plate collector (FPC) with water as collector fluid

For the simulations, the software Polysun V8.011.21 (Vela Solaris 2014) was used. Since the objective was only to calculate realistic estimates of potential energy gains, very simple system hydraulics and control principles were used (cp. Figure 5). This was based on existing schemes in the Polysun library for the simulation of solar process heat systems.

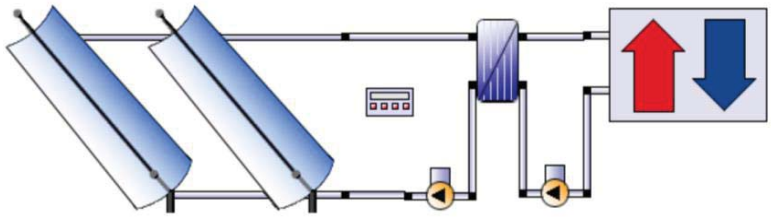

Figure 5: Simple hydraulic scheme in Polysun to estimate annual gains for solar feed water pre-heating with medium temperature parabolic troughs (PTC-MT)

On the right hand side of Figure 5 is a heat sink. In the simulations for the solar heating of feed water with PTC-MT collectors, the process return temperature was 128 °C, as given in Table 2. The mass flow of the process loop pump was constant and set to a value at which 200 °C is achieved if a power of 9 MW_{th} can be provided. The solar loop pump was speed controlled to ensure that a positive temperature gradient is always maintained between the solar loop and discharging loop of the heat exchanger. For a PTC-MT, for example, the parabolic trough of the company NEP (NEP, 2015) was used in Polysun. The receiver tube of this collector is not evacuated. It therefore has significant thermal losses at higher temperatures. For a highly efficient ETC, for example, the Ritter Aqua Plasma collector (Ritter, 2015) was used. The selected FPC is the Solid Gluatmugl HT (Solid, 2013). The solar drying processes should ideally be realised with air collectors. Since these collectors cannot be simulated in Polysun, the two drying processes were also simulated with the Gluatmugl HT flat-plate, ensuring that the air heating demand was correctly represented on the secondary side of the heat exchanger. However, for the case of applying air collectors (FPC-Air), the given gains have to be seen as a maximum value as this technology usually has higher heat losses than flat-plates with water as collector fluid, especially at higher working temperatures.
The annual gains of the high-performance parabolic trough collectors (PTC-HT) were also not simulated, but roughly assessed as follows: The average annual thermal solar field efficiency of concentrating solar power (CSP) PTC fields is in the range of 50 % to 60 % for DNI, according to Geyer et al. (2002, p. 6), Sargent and Lundy Consulting Group (2003, p. D 17), and Günther et al. (2012, p. 80). For this study, an efficiency of 55 % is used. The system efficiencies given in Table 2 all relate to GHI in Durban (GHI = 1 825 kWh/(m^2 a), DNI = 2 018 kWh/(m^2 a)). Thus, in Table 2 an annual system efficiency of 61 %, to allow for comparison to the other technologies, is given.

The *system efficiency* indicates which share of the global horizontal irradiance can be converted to useful solar heat for the process. The annual (A) efficiency considers the mean efficiency during the whole year; the efficiency during the crushing season (CS) considers only 1 March to 30 November. The efficiencies differ slightly due to varying irradiance and ambient temperatures. It is assumed that all solar heat can be used (no OTE influence on solar field operation). The *specific solar gains* per square metre of collector gross area give the useful heat produced per year (A) and during the crushing season (CS). Again, it is assumed that there is no OTE effect on the solar field operation. The *solar fraction* is the share of the annual heat demand of the heat sink, which can be covered by solar heat. It is valid for systems without heat storage. The solar fraction can be increased significantly when storage is installed, but this would also mean an increase in the solar thermal system costs. For this pre-condition, the *overall annual solar energy gains* can be calculated from Table 2. The PTC-HT field of 53 168 m^2 would yield 40 833 MWh_{th} during the crushing season, and about 59 016 MWh_{th} if it could be operated throughout the year. As explained above, the CS duration used is 254 days, with an OTE of 75.70 % (cp. season 2012/2013, Smith et al., 2013), so the boiler operates 4615 h/a. This results in an overall boiler steam energy generation of 343 356 MWh_{th}.
With these assumptions, the solar fraction would be 12 % if the solar field operates during the whole CS (not considering OTE), and 17 % if it operates the whole year. To roughly assess how the specific solar gain would be affected if the collector loop only operated at times of boiler operation, the specific gains during the crushing season can be multiplied by the OTE.

5. Economic Assessment

5.1 Solar heat as an alternative to coal

As outlined above, the heat demand of SA sugar mills is covered by steam from burning bagasse, in some cases supported by coal. Since bagasse is a by-product of sugar production, the costs of this steam are obviously very low. However, the true value of bagasse is determined by the opportunity costs. Integration of solar heat will only be considered if such an opportunity is pursued, i.e. if the heat demand of the mill increases e.g. from production of bio-ethanol, or export of electricity), or if bagasse is used for purposes other than heating e.g. the production of animal feed, fertiliser, or paper. In all scenarios, the cheapest alternative energy source in SA would be coal. Thus, this assessment of SPH for SA sugar mills compares solar heat to the heat from coal.

The price paid for coal by the different SA sugar mills varies as it includes the price for mining ('ex mine'-price) and the costs of transport to the respective mills. To estimate the costs of life steam from coal, a coal price of 1100 ZAR/t, an energy content of 27 GJ/t and a boiler efficiency of 75 % can be assumed (Peacock, 2016a). Thus, this work uses a current value of life steam from coal of 0.20 ZAR/kWh (1.2 EUR-ct/kWh) for comparison[1]. Since one ton of live steam can be let-down to approximately 1.2 tons of exhaust steam (Rein, 2007, p. 666), the current value of exhaust steam is considered to be 0.16 ZAR/kWh (1.0 EUR-ct/kWh). An analysis of annual coal prices for a large SA sugar producer provided by Peacock (2016b) revealed that the price after delivery increased on average by 12.3 % p.a. from 2004 to 2014.

5.2 Investment costs for SPH systems

In order to obtain reference values for the costs of SPH systems, the SHIP Plants (2015) database was analysed. By mid-April 2016 it included ca. 190 systems, but for many entries no cost data were given. However, it could be observed that the system costs per m^2 of collector gross area depend highly on the collector technology, the system size, and the country of installation.

The systems to consider for the SA sugar industry would be of several hundred or several thousand square metres (cp. Table 2), and for this first assessment have no thermal storage. Thus, to get a more realistic cost estimate, the database was filtered for systems above 200 m^2, and installation dates from the beginning of the year 2000 to end 2015. Since the number of systems without storage was too small, systems both with and without storage were included. For each technology, the median value of the investment costs per m^2 was determined. This resulted in 183 EUR/m^2 for installations with FPCs with air as collector fluid (based on data of only two plants), 188 EUR/m^2 for ETCs (10 plants), 388 EUR/m^2 for FPCs with water as collector fluid (16 plants), and 445 EUR/m^2 for PTCs-MT (nine plants).

The SPH plant database does not contain examples with CSP technology so for the PTC-HT troughs the costs had to be assessed from literature. According to Turchi et al. (2010, p. 6), the installed costs of a large PTC-HT field in the United States operating at 391 °C are expected to be 335 USD/m^2, including heat transfer fluid, in 2015. The authors give similar costs for a heliostat field with central receiver (HCR).

It must be noted that within each collector technology group, very high variances, even between similar installations, were found both in the SHIP Plants database and in the literature. Many of the SHIP plants have thermal storages included so that installed costs for the investigated systems in SA could be lower. To conclude, the costs used for this study are only a rough estimate. They cannot replace quotes for specific cases in future feasibility studies.

5.3 Levelized cost of heat (LCOH)

The levelized cost of energy LCOE is a common measure to assess and compare the financial feasibility of renewable energy projects. In this work, this measure is referred to as LCOH to stress that it reflects the levelized costs of heat, not of electricity. Note that the LCOH is the average heat price per unit of energy generated throughout the lifetime of a heating project; it is independent of the value of the energy replaced. Equation 1 gives the LCOH (NREL, 2014).

$$LCOH = \left. \sum_{n=0}^{N} \frac{C_n}{(1+d)^n} \right/ \sum_{n=1}^{N} \frac{Q_n}{(1+d)^n} \quad [\text{EUR/kWh}] \qquad \text{(eq. 1)}$$

[1] In this work, the exchange rates of 1.128 USD/EUR and 16.46 ZAR/EUR as of 13 April 2016 are used.

The LCOH compares the annual project costs (C_n) to the annual yield (Q_n) for each year n over the lifespan of the system in years (N). Costs and yields are discounted with the rate d to account for the time value of money. Figure 6 below shows the calculated LCOH from coal and solar thermal energy over 20 years.

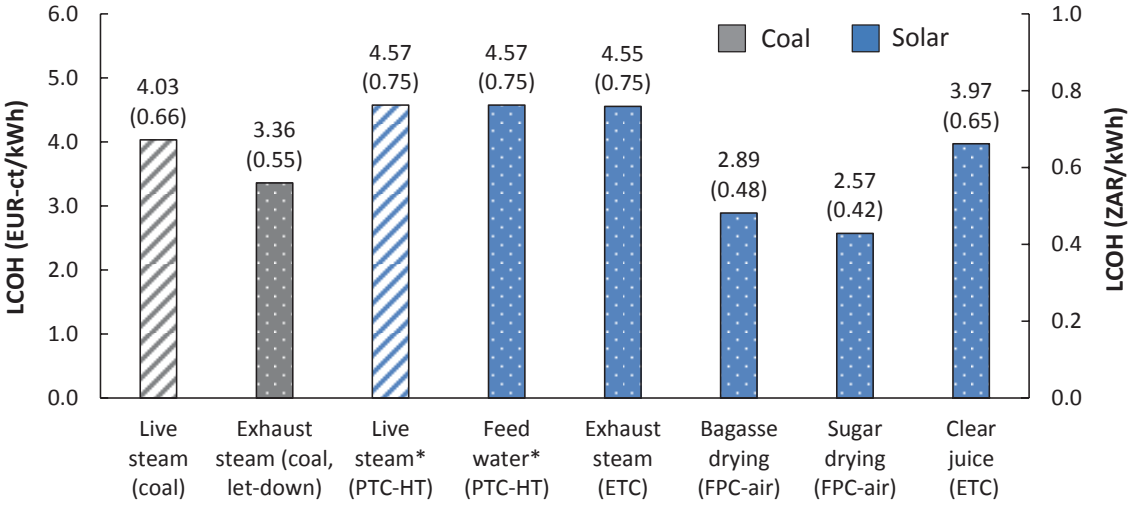

Figure 6: Estimated levelized costs of heat (LCOH) for SA sugar mills from coal and from solar thermal energy (*SPH systems for live steam and feed water operate for the whole year and the others only from March to November)

The PTC-LT variant, for both feed water and exhaust steam generation, had higher LCOHs than the technical alternative (cp. Table 3). In Figure 6, for each integration point only the variant with the lowest LCOH is indicated. In addition to the investment costs, annual operational costs were taken into account. These include maintenance and auxiliary energy consumption. For the annual maintenance, including replacement, of the large-scale non-tracking ST systems in this study, a value of 1 % of the capital expenditure was used (VDI, 2004, p. 65). For the annual auxiliary energy consumption of these systems, 2 % of the yearly energy yield was considered (VDI, 2004, p. 65), with a constant auxiliary energy tariff of 0.50 ZAR/kWh$_{el}$ (3.04 EUR-ct/kWh$_{el}$). The annual operational costs increase with the consumer price index (CPI) of South Africa of 6 % per annum (inflation). For the two parabolic trough systems, combined maintenance and auxiliary energy costs of 2 % of the capital costs are used, as is common for CSP power plants (Hernández-Moro and Martínez-Duart, 2012, p. 186). This was annually increased by the CPI as well.

To calculate the LCOH of the solar heating projects, a nominal discounted rate of 10 % has been used. This corresponds with the expected weighted average cost of capital (WACC) of the SA sugar industry (for 30 % equity with a return of 14 %, and 70 % debt with an interest rate of 8 % and a loan period of 10 years) (Foxon, 2015). A financial project life of 20 years was assumed, even though the service life of SPH systems may well exceed this. The LCOH for solar live steam and feed water generation was calculated from specific system yield Q_n of whole-year operation (cp. Table 2) as in this case an electricity export scenario independent from the sugar mill operation was assumed. The other four SPH systems operate during the crushing season only so the theoretical gains from November to January were not taken into account.

For comparison, the estimated LCOH from coal within the potential duration of a SPH project of 20 years is also given. For this, it is assumed that an existing boiler can burn variable amounts of coal without additional costs. Thus, for comparison with solar heat, only the fuel costs are considered. The levelized costs per kWh steam were calculated from current costs of 1.2 EUR-ct/kWh for live steam and 1.0 EUR-ct/kWh for exhaust steam, both increasing by 12.3 % annually. The LCOH was then calculated by using the CPI discount rate of 6 %.

Comparing the LCOH values of the six different SPH integration variants suggests that the solar drying of sugar and bagasse is possible at lower levelised costs than exhaust steam generation from coal. Note that for this first assessment equal gains of air flat-plates and water flat-plate collectors within the working temperature range were assumed (cp. comment above on flat-plate gains).

5.4 Internal rate of return (IRR)

Contrary to the LCOH, the internal rate of return (IRR) can be used as an indicator for the financial viability of a project because it takes the value of the conventional energy, which is replaced by SPH, into account. The IRR is an estimation of the discount rate that would result in a zero net present value (NPV). Table 3 summarises the results of the economic assessment of the most promising SPH variants. The estimated capital expenditure of the different collector fields is given under the premise that the maximum area possible without solar heat storage is installed.

Table 3: Estimated economic figures of the six SPH integration variants

Integration Point	Collector type	Heat demand [MW_{th}]	Max. field size [m^2]	System costs [EUR/m^2]	Capital expenditure [Mio. EUR]	LCOH [EUR-ct /kWh]	IRR [%]
Live steam*	PTC-HT	74.4	53 168	378	20.10	4.57	4.6
Feed water*	PTC-HT	9.0	12 880	378	8.46	4.57	2.6
Exhaust steam	ETC	62.5	89 238	188	16.78	4.55	3.3
Bagasse drying	FPC-Air	1.7	2 381	183	0.44	2.89	7.8
Sugar drying	FPC-Air	0.6	899	183	0.16	2.57	9.1
Clear juice	ETC	4.7	6 739	188	1.06	3.97	4.6

* Solar live steam generation and feed water heating for whole year operation (electricity export scenario), other SPH integration points operate during crushing season only (March to November)

The NPV is obtained by discounting all net cash flows (C_n) of each year (n) over the lifespan of the project (N) (NREL, 2014). Solving the NPV equation for the discount rate d gives the IRR. The income cash flows depend on the internal value of the energy, and thus the heating fuel, that is being substituted by SPH. In this first assessment it was assumed that only live steam from SPH replaces the actual internal live steam value from coal; all other integration variants replace the exhaust steam value (cp. hatched and dotted bars in Figure 6). The hurdle rate for projects or investments by the SA sugar milling industry is in the range of 10 % to 15 % (Foxon, 2015). A project is feasible if the IRR exceeds this hurdle rate.
The formula for the calculation of the NPV is provided in equation 2.

$$NPV = \sum_{n=0}^{N} \frac{C_n}{(1+d)^n} \quad \text{[EUR]} \qquad \text{(eq. 2)}$$

The results in Table 3 indicate that currently none of the prioritised six SPH integration schemes offers the expected return. The two solar drying applications are closest to financial viability and should be investigated in more detail. Their IRR would increase to 11.7 % for bagasse drying and 13.1 % for sugar drying if they could be operated the whole year.

6. Conclusions

For an electricity export scenario, *solar live steam generation* should be considered as an option if solar steam can also generate electricity independent of the mill operation, i.e. outside the crushing season. This SPH variant can cover a significant share of the heat demand of a mill. The feasibility here depends highly on the price received for export electricity.
Solar *drying of bagasse* is the only solar technology that has been demonstrated in sugar mills. To determine financial feasibility, the effect of dried bagasse on boiler efficiency must be studied in more detail, an energy balance of the solar drying process itself must be worked out, and the investment in a suitable dryer must be taken into account. LCOH and IRR of both drying applications have high uncertainties because the estimated system costs are based on data of two plants only, and the gains were simulated with FPCs with water as collector fluid. In addition, the drying processes seem well-suited for waste heat recovery.

With the framework conditions used for this first study, none of the six SPH integration variants achieved an IRR of the required 10 % to 15 %. The main reason for this is the very low coal price, even though a price increase of 12.3 % p.a. was taken into account. Another factor is the limited duration of the crushing season which limits the time of the year that solar heat can be used for processes within the mill. At more beneficial framework conditions, e.g. with government subsidies for SPH or a fixed minimum feed-in tariff for power export from cogeneration, including ST collectors, financial viability would be possible.

Further work on SPH for sugar mills must be based on the energy balance of a mill with all feasible heat recovery measures implemented. For such a mill, different scenarios like the implementation of high pressure boilers with condensing extraction steam turbine, or the production of bio-ethanol on site, have to be described so that more detailed SPH feasibility assessments can be performed.

Acknowledgements

This study was funded within the framework of the Sugarcane Technology Enabling Programme for Bio-Energy (STEP-Bio), which is co-funded by the SA Department of Science and Technology (DST) and the South African sugar industry under the DST Sector-specific Innovation Fund.

Solar Process Heat Potential in California, USA

Parthiv Kurup[1], Craig S. Turchi[1] and Guangdong Zhu[1]

[1] National Renewable Energy Laboratory (NREL), Golden, Colorado (USA)

Abstract

The cost for solar industrial process heat (SIPH) is quantified by defining the levelized cost of heat (LCOH). The state of California, in the United States offers a favorable environment for SIPH given its excellent insolation, industrial gas prices typically higher than the national average, and policies promoting solar-thermal deployment. Given historically low gas prices, competing with natural gas remains the primary challenge to deployment. However, this study finds that the solar LCOH from Concentrating Solar Power (CSP) collectors for many regions in California is expected to be lower than the LCOH from natural gas, using a representative installed solar hardware price and the average price for industrial natural gas in California. Lastly, modifications are in progress to the parabolic trough and Direct Steam Generation (DSG) trough and Linear Fresnel models within NREL's System Advisor Model (SAM) to allow users to more easily predict performance for these industrial heat and steam-generation applications.

Keywords: *solar industrial process heat, SIPH, IPH, parabolic trough, CSP, LCOH, California*

1. Introduction

In 1977 the International Energy Agency (IEA) established the Solar Heating and Cooling (SHC) program to create an environment for the development and progression of SHC (IEA, 2016). An EU-led collaborative project between the SHC program and the SolarPACES program known as Task 49/Task IV was created specifically to establish and help meet the potential of solar Industrial Process Heat (SIPH) (IEA, 2016; SolarPACES, 2016a). (Note that the IEA uses the acronym "SHIP" for solar heat for industrial processes. The term "industrial process heat" is recognized in the United States, and this paper will refer to these applications as solar IPH or "SIPH"). Much of the initial work in the IEA program dealt with the potential of nonconcentrating, flat-plate collectors. Flat-plate solar collectors are common in many countries, including the United States, where the overwhelming majority is applied to domestic home heating or water heating for swimming pools (SHIP, 2016). While these are excellent applications for low-temperature collectors, this paper deals with the growing interest in the deployment of concentrating parabolic trough collector technologies that can achieve temperatures needed within the industrial sector.

Thermal energy and steam are ubiquitous needs in industrial processes. From the extraction of raw materials to food processing, heat is a vital part of the processing and manufacturing sectors. In the 1970s and 1980s there was great interest in collection of solar-thermal energy for buildings and IPH applications (Kutscher et al., 1982). Despite significant effort, very few projects came to fruition, mainly due to high solar collector costs and an associated inability to effectively compete with natural gas (Carwile and Hewitt, 1994). In recent years, the improvement and proliferation of solar collectors for electricity generation and the development of sophisticated solar collector modeling tools has regenerated interest in solar process heat applications.

Despite great potential, the worldwide adoption of concentrating collectors for SIPH generation is modest. For example, as of Sept. 2016, of the 191 SIPH plants listed in the "IEA SHIP Plants" database, only 25 involve concentrating collectors of either parabolic trough or Linear Fresnel technologies (SHIP, 2016). The

doi:10.18086/eurosun.2016.02.07 Available at http://proceedings.ises.org

25 SIPH plants in operation are for industries such as food and dairy production (e.g., heat for sterilization of milk) (SHIP, 2016). Due to the excellent solar resource conditions in the United States (especially in the Southwest) and the ubiquitous need for IPH, the United States has a sizeable opportunity for greater deployment of concentrating solar-thermal collectors with the associated benefits of increased solar jobs and lower carbon emissions. For example, within the industrial sector in the United States the estimated consumption of energy for heat for applications such as washing, sterilization, and preheating was approximately 24,000 trillion Btu (TBtu, or 7,000 TWh_{th}) in 2014 (EPA, 2016). Depending on the specific industry in question, between 35% and 50% of the total energy consumption can be for IPH applications (EIA, 2013).

Linear-focus collectors, such as parabolic troughs and Linear Fresnel reflectors, can reach temperatures up to about 550°C (SolarPACES, 2016b). For solar hardware developers, expansion into IPH offers access to new markets for already well developed CSP collector technologies. For policy makers and businesses concerned about greenhouse gas emissions, solar-thermal energy is a potential valuable substitute for natural gas used for process heat in the industrial sector. This paper evaluates the installed cost of a modern parabolic trough collector and re-examines the potential for solar-thermal technologies to supply IPH in light of the demonstrated reductions in technology cost. The state of California is used as a prime example of where this application may grow in the United States.

2. Current Cost Of Parabolic trough Collectors

NREL recently completed a cost analysis of two different state-of-the-art parabolic trough solar collector assemblies (SCAs) (Kurup and Turchi, 2015a). The effort first developed a bill of materials (BOM) for the subject designs based on published literature and discussion with the system developers. A key tool in the analysis was a suite of software tools called Design for Manufacture and Assembly (DFMA). The DFMA software package is used industry-wide and has two parts: Design for Manufacture and Design for Assembly (Boothroyd Dewhurst, 2016). The DFMA tool has detailed databases and allows the user to calculate a primary manufacturing cost for each component and then assemble it within the overall product/assembly. Design for Manufacture was used for the majority of the components within the BOMs to model the SCA as if it were to be manufactured in commercial quantities. As such, the material, manufacturing processes, key dimensions, and machining steps were estimated.

A SCA is built of a string of trough modules controlled by a single drive and represents the smallest unit of a functional parabolic trough solar field. The DFMA methodology was applied to the trough structural assembly, i.e., frame, foundation and pylons. The cost of specialty components such as receiver tubes, drive systems, and glass mirror panels were based on quotes from representative suppliers.

Of the two trough modules examined—SkyFuel's SkyTrough and FLABEG's Ultimate Trough—the former is more amenable to deployment in small solar fields due to its smaller size and ability to be fabricated onsite without a specialized assembly jig or facility. These are important factors for SIPH, which is expected to use much smaller solar fields than systems for electric power generation. It is important to note, that the SkyFuel SkyTrough has already been used for solar heat addition to the overall process at the Stillwater hybrid solar-geothermal plant and is considered suitable for SIPH applications (NREL, 2016; Wendt et al., 2015).

The key subsystems for the SkyTrough module and SCA analysis were the receivers, receiver supports, mirror panels, parabolic ribs, space frame, torque plates, drives and control, drive pylon and regular pylons, and the foundations. The main subsystem categories for NREL's SkyTrough BOM and analysis are seen in Figure 1. The SkyTrough SCA consists of 8 modules and has a total length of 115 m and aperture width of 6 m. Details on the SkyTrough SCA can been viewed in the default *CSP Physical Trough* model within NREL's free System Advisor Model (SAM, https://sam.nrel.gov/), version 2016 release.

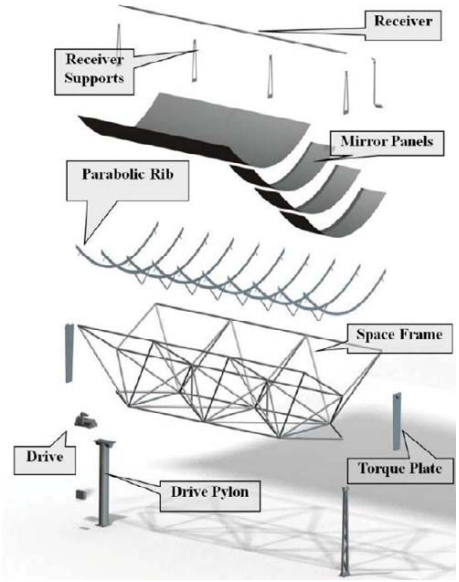

Fig. 1: Main components of the SkyTrough module and picture of regular pylon. (Illustration from SkyFuel)

Within each subsystem NREL estimated dimensions and costs using manufacturing analysis for the subsystems (including the manufacture of the drive and nondrive support pylons). Construction activities were estimated for the digging and placement of the foundations.

Each subsystem was broken down into the specific components that would make up a module and an individual SCA. From that point the BOM and the manufacturing, assembly, and installation analysis per SCA followed. Other troughs have been used for SIPH, e.g., Abengoa Solar's PT1 (California Energy Commission, 2010). Unlike the PT1 which uses silvered glass mirrors, the SkyTrough uses a polymer-film reflector. The vendor's quoted prices were used for capturing the cost of this component.

The NREL analysis on the manufacturing, assembly, installation equipment, and construction activities assumed a production volume of 1500 SCAs. The Installed Cost/m^2, as seen in Figure 2 for 1500 SCAs was found to be \$170/m^2. Hence, the assumption is made that a central manufacturing factory is making sufficient parts for 1500 SCAs per year, for combined SIPH or CSP applications, while the number of SCAs assembled on-site varies with project size. Given the thermal capacity of a SkyTrough SCA is about 2.2 SCAs/MW_{th}, and assuming a SIPH project size of 5 MW_{th}, 100 SCAs would represent about nine projects per year. For comparison, only two of the 25 concentrating solar projects in the SIPH database are ~5 MW_{th} (SHIP, 2016).

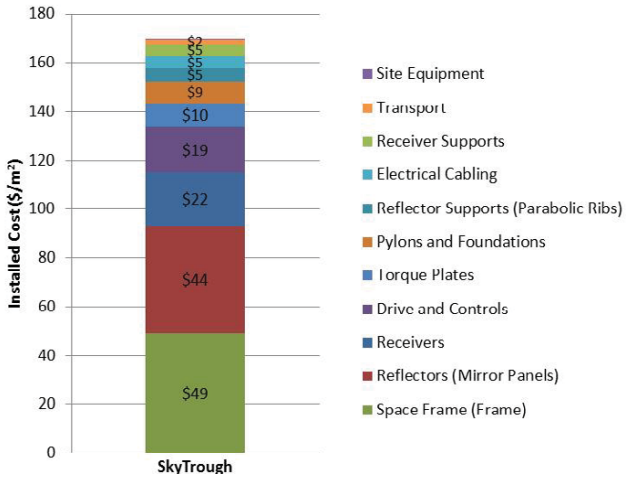

Fig. 2: Installed cost for the SkyTrough assuming 1500 SCAs. Total installed cost is estimated at \$170/m2. (Kurup and Turchi, 2015a)

3. Overall IPH Usage in the United States

In the present paper we have highlighted the results from a specific "top-down" methodology and analysis approach that first examined the regional solar resource potential and the thermal energy demand characteristics of potential user industries (Kurup and Turchi, 2015b). The work focused on specific industries that have the largest thermal energy requirements in the appropriate temperature range for concentrating solar collectors. This method provides an initial, high-level assessment of the SIPH potential (which was then focused on California). Full details of the methodology and its development are outside the scope of this paper. Understanding the conventional energy source (e.g., natural gas, waste heat, or electricity) is also examined to assess the economic potential.

The U.S. Manufacturing Energy Consumption Survey (MECS) is a national sample survey that collects information on the U.S. manufacturing establishment, their energy-related building characteristics, and their energy consumption and expenditures (EIA, 2010a). Based on MECS data, the U.S. manufacturing sector has three primary energy sources: fuel, steam generation, and electricity generation. Considering the direct and indirect (e.g., onsite steam production) use of all energy sources, process energy consumed approximately 10,000 TBtu (as in Figure 3). This represents approximately 42% of the total primary energy consumption in the U.S. manufacturing sector. (Note 1 TBtu ≈ 0.3 TWh_{th}.) From Figure 3, the importance of process heating within process energy as a whole is clear. For 2010, the MECS industries utilized 7,204 TBtu/yr (2,100 TWh_{th}/yr) for process heat—or approximately 29% of the total primary energy in the U.S. manufacturing sector.

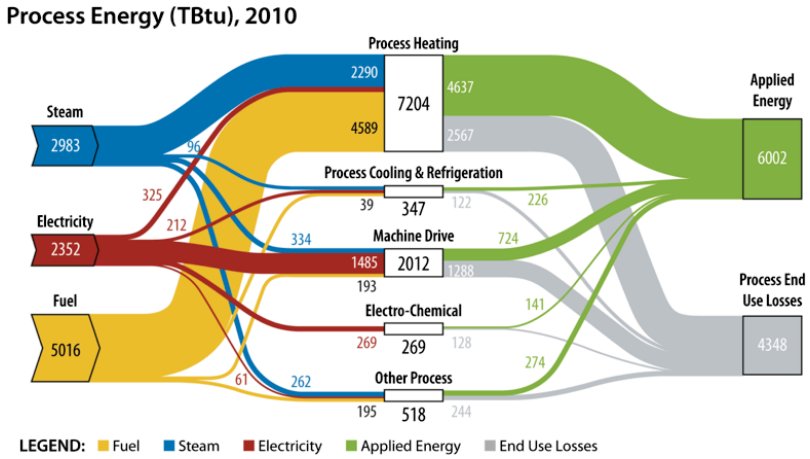

Fig 3: Sankey diagram of process energy flow in U.S. manufacturing sector in 2010 (EERE, 2016). Values are shown in trillion BTU

Figure 4 shows the fully compiled MECS 2010 end-use subcategories for natural gas, which is the fuel most often used for process heating, conventional boiler use, and combined heat and power (CHP) or cogeneration. In contrast, electricity is most commonly used for direct machine drive with some use in process heating. Data indicates that natural gas replacement is the biggest opportunity for SIPH. Situations where electricity can be offset will be rare although they may present favorable economics.

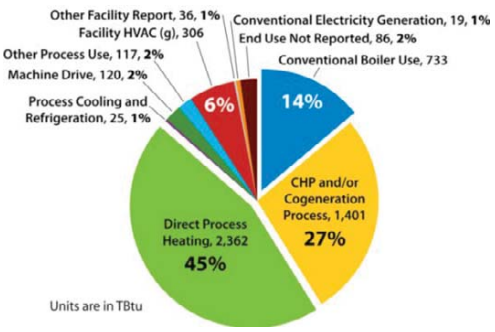

Fig. 4: 2010 United States MECS overall natural gas breakdown by end use (EIA, 2010b)

The U.S. industrial and manufacturing sectors are the largest consumers of natural gas and electricity for process heat either directly or indirectly through steam production via a conventional boiler (EIA, 2010b; Fox et al., 2011). A representation of the potential U.S. IPH market size for steam is provided in Figure 5, which depicts annual steam consumption for the manufacturing sectors of Food, Paper, Petroleum and Coal Products, Chemical and Primary Metal Manufacturing – the five sectors that have the greatest usage of natural gas. The total consumption in the range between 100ºC and 260°C amounts to about 1700 TWh_{th}/yr. To put this in perspective, the 64 MW_e Nevada Solar One CSP plant produces about 0.35 TWh_{th}/yr so the thermal energy potential depicted in Figure 5 represents the equivalent of about 4,800 such plants if all the sites were suitable for SIPH. All the sectors listed in Figure 5 utilize steam in temperature ranges suitable for solar generation; however, the food industry presents a particularly appealing target. As noted previously, the food sector has been the application of choice for many international SIPH plants.

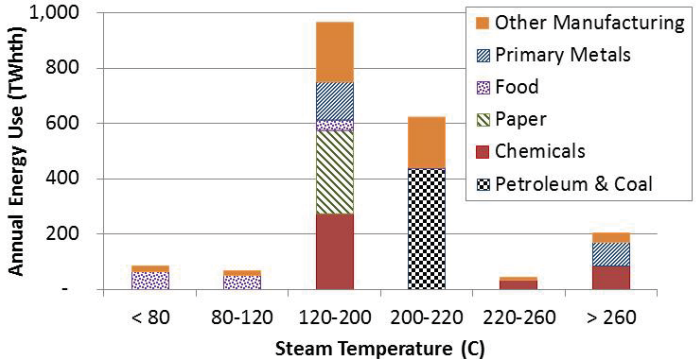

Fig. 5: IPH annual energy use for steam generation for the industries utilizing the greatest amount of natural gas (Fox et al., 2011)

4. Focus on California Industrial Natural Gas and Solar Potential

4.1 Industrial Natural Gas consumption in California

A 2014 California Energy Commission (CEC) study listed natural gas consumption for industries in California (Schrupp, 2013), and according to the MECS 2010 data, the food industry in the United States consumed approximately 59% of its total natural gas consumption for applications of direct process heating and conventional boiler use (EIA, 2010b). Assuming this percentage holds for the food industry in California, it can be estimated that about 10 TWh_{th}/yr were consumed for direct process heating and conventional boiler use in the state in 2014 (Schrupp, 2013), which is the thermal equivalent of about 30 solar fields as big as Nevada Solar One (NSO).

This methodology was continued across all MECS sectors listed in Table 1 below. Table 1 shows the GWh_{th} used by the MECS industries identified as the biggest consumers of steam at less than 260°C in California (i.e. for Food, Paper, Petroleum and Coal Products, Chemical and Primary Metal Manufacturing). The CEC concluded industries in California such as food processing, chemicals, petroleum, and primary metals manufacturing "represent prime areas of opportunity for reducing natural gas use" (Schrupp, 2013).

Tab. 1: Estimated natural gas consumption for direct process heating and boiler use in California for select MECS industries

MECS sector with North American Industry Classification System code	Natural Gas Consumption for Process Heating (GWh_{th}/year)
Food Manufacturing (311)	10,200
Paper Manufacturing (322)	1,244
Petroleum and Coal Products Manufacturing (324)	31,211
Chemical Manufacturing (325)	3,526
Primary Metal Manufacturing (331)	2,134
	48,100

4.2 Solar Industrial Process Heat Potential in California: A look at the Food Industry

In the present paper as mentioned, the results from a specific energy analysis are presented (Kurup and Turchi, 2015b). The full method and derivation of the results is outside the scope of this paper. When the Direct Normal Irradiance (DNI) resource and available land area at a 10-km by 10-km resolution are looked across California, the estimated Technical Thermal Energy Potential for California from using parabolic troughs was 23,000 TWh_{th}/year (Kurup and Turchi, 2015b). As can be seen, the Technical Thermal Energy Potential of California at ~23,000 TWh_{th}/year is orders of magnitude beyond the demand of 48 TWh_{th}/year shown in Table 1.

An objective for this paper is to highlight specific industries known for high use of natural gas or electricity for IPH to their local solar thermal energy potential. For this study, the Food industry and sample sub-industries in California were considered prime candidates. These include the MECS food sub-industries of animal-food manufacturing, breweries, dairy product manufacturing, and fruit and vegetable producers. To highlight that the thermal demand of these industries can be theoretically met with the SIPH potential found for California, maps have been created overlaying the location of the industries in California and the estimated Technical Thermal Energy Potential. Figure 6 shows the co-locations of known animal-food processing plants, breweries, and dairy products along with the Technical Thermal Energy Potential by county in California. These 3 sub-industries were selected as they were considered representative of the Food industry of California.

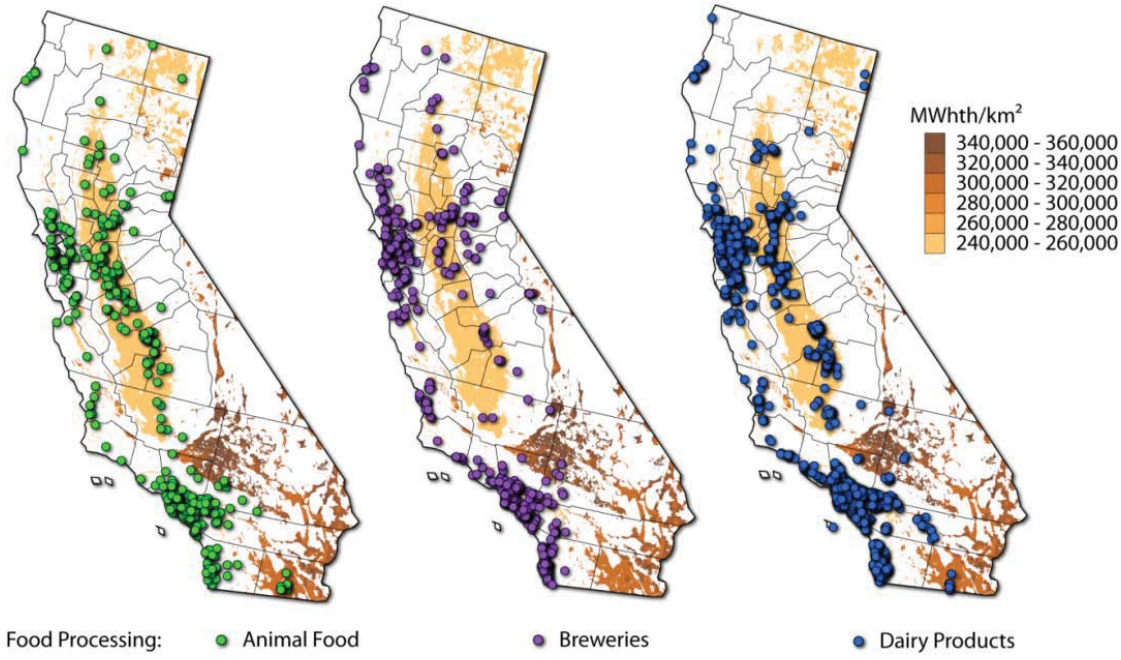

Fig. 6: Locations of animal-food manufacturing, breweries, and dairy products plants across California along with annual solar Technical Thermal Energy Potential (MWhth/km²/year) (Kurup and Turchi, 2015b)

Figure 7 zooms in on Fresno, California and shows the locations of the animal-food manufacturing, breweries, dairy product manufacturing, and fruit and vegetable producers overlaid with the solar thermal energy supply. Developed city areas and other exclusion zones are shown in white. While the majority of sites are within the Fresno city limits, there are clusters of specific industries that could potentially benefit from SIPH plants. As can be seen, clusters A, B, and C of fruit and vegetable manufacturing plants potentially have available land for solar developers to install SIPH facilities and provide heat to augment steam production processes. Clusters of multiple users near a potential SIPH plant site increase the likelihood of favorable economics.

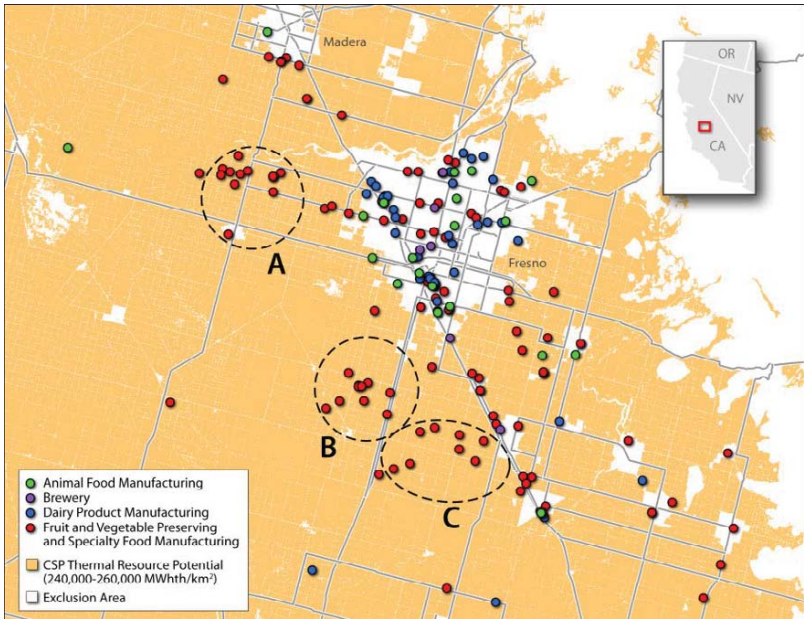

Fig. 7: Close-up of Fresno, CA showing the solar thermal generation potential and potential user industries. (Kurup and Turchi, 2015b)

4.3 Selection Of Heat Transfer Fluid (HTF) For SIPH

Different solar thermal collectors have different temperature capabilities (IRENA, 2012). Table 2 lists different temperature ranges and the likely solar collectors and HTFs to supply IPH at those conditions.

Tab. 2: Temperature regions and recommended HTFs for SIPH

Temperature Range	Solar Collector Type	HTF of Choice
< 80°C	Flat plate Non-tracking compound parabolic Solar pond	Water
80 to 200°C	Parabolic trough Linear Fresnel	Water/steam
200 to 300°C	Parabolic trough Linear Fresnel	Mineral oil or steam
300 to 400°C	Parabolic trough Linear Fresnel	Synthetic oil
400 to 550°C	Parabolic trough Linear Fresnel	Steam or Molten salt

Temperatures below about 80 °C can be achieved with non-tracking, non-concentrating devices such as solar ponds and flat-plate collectors to supply hot water, swimming pool heating, or space heating. While such applications are excellent matches for solar energy, the development and deployment of these systems are outside the scope of this study, which is dedicated to concentrating solar collectors.

At the other end of the spectrum, temperatures above about 550 °C exceed the limit of linear-concentrating systems and require the use of point-focus systems such as parabolic dishes and central receivers. These units most often deploy molten salt or high-pressure steam as the HTF, although some designs have been tested with air.

The region of interest for the present study is the realm of temperatures that can be achieved with tracking, linear-focus concentrating collectors. These collectors have a proven track record, utilize simple one-axis

tracking, and can be deployed in a modular fashion by adding additional collector length. The optics of linear-focus systems can achieve temperatures up to about 550°C. However, as one moves to higher temperatures, the requirements for the HTF and the receiver become more restrictive, which generally means more expensive hardware and fluids are required. Per Figure 5, it is anticipated that the majority of SIPH applications will target temperatures below about 220 °C.

4.4 Estimated Cost of Solar Thermal Heat

The levelized cost of heat (LCOH) is a convenient metric for estimating lifetime cost of a solar collector system for process heat applications. LCOH is defined analogously to LCOE, which conventionally refers to levelized cost of electric energy. In its simplest form, LCOH is defined as:

$$LCOH = \frac{(TIPC) * (FCR) + (Annual\ O\&M)}{Annual\ thermal\ generation} \qquad \text{(eq. 1)}$$

where TIPC is the Total installed project cost, FCR is the fixed charge rate, and annual O&M includes both fixed and variable operating costs. The FCR depends on a range of financial parameters that can have a significant influence on LCOH. NREL's SAM model includes various ways of estimating LCOE. The latest release includes a procedure for estimating and using the FCR method that is used in this study. Additional details on SAM's LCOE options can be found in the SAM Help Menu (NREL, 2015).

Figure 8 shows the LCOH for a range of installed solar costs and three different solar resource levels that are representative of California. For an installed solar field cost of about \$160/m^2, solar thermal energy is competitive with natural gas (i.e., has a lower LCOH) at its 2015 average California price of \$6.35/MMBtu (EIA, 2016) in California where DNI > 6 kWh/m^2/day. DNI > 6 kWh/m^2/day corresponds to all shaded regions shown in Figure 6. Note that Figure 8 shows the installed solar field cost and the assumed total project cost based on a multiplier for balance of plant and indirect costs. Total installed project cost includes solar field, site preparation, heat transfer fluid piping, heat exchanger, and other project costs. Added to these direct costs is a 7% contingency and 25% indirect costs. Like LCOE, the LCOH is sensitive to the financial assumptions. In this scenario the fixed charge rate is set at 0.101, which corresponds to a weighted average cost of capital of 6.2%.

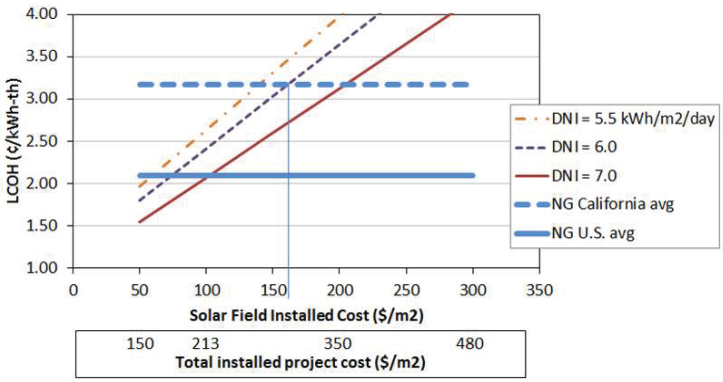

Fig. 8: Estimated LCOH for different solar resource and solar field costs compared with two natural gas (NG) prices from 2015. Total installed project cost includes solar field, site preparation, HTF piping, heat exchanger, and other project costs. No solar incentives are included. Gas costs include \$200/kW burner cost and 80% efficiency. Based on FCR = 0.101, WACC = 6.2% (updated from Kurup and Turchi, 2015b)

The data suggests that economic SIPH applications can be found in California at existing solar hardware costs and market gas prices, with incentives in the marketplace further expanding the range of feasible projects. For example, the California Solar Initiative–Thermal Incentive Program offers industrial sites up to \$800,000 to set up an SIPH plant for the displacement of natural gas (CPUC, 2016). Solar technology developers estimate that under this program, even with the relatively low gas prices of today, payback period on these projects could be less than three years. In summary, project viability will be strongly dependent on the specific solar project costs—including any incentives—and the specific gas pricing contract in place. The deployment of a few successful pilot projects would be expected to spur further utilization of SIPH with a concomitant decrease in project development costs.

5. Modifications to SAM to Facilitate SIPH

The solar-thermal models in SAM were developed to estimate the performance and cost of electric power generation. The first stage of the modeling is estimating the solar resource and the efficiency of the solar collectors. Operation of the system, however, is dependent on the demands of the integrated steam-Rankine power cycle. For users whose concern is thermal energy production, not electricity, there is no easy way to avoid interference from the power cycle constraints. In 2015 NREL showed that retention of the power cycle caused a 6% underestimation of performance from what should have transpired had the model been freed of the power cycle constraints (Turchi and Neises, 2015). This was after making changes to the SAM input values to minimize cycle impacts. In the absence of those changes, the underestimation was at least 14%.

NREL are currently modifying the SAM code to create a model set that does not require a power block and is suitable for SIPH modelling. The technologies chosen currently include: Parabolic trough with oil/water as the HTF; Direct Steam Generation (DSG) trough; and DSG Linear Fresnel. These changes are being applied exclusively to the *Physical Trough* and *Linear Fresnel* models within SAM, as these are the technologies expected to be most useful for SIPH applications. Initial validations of the new SAM code have been undertaken, with further testing and iteration expected.

6. Conclusions and next steps

Recent advances in parabolic trough design and manufacturing has led to reduced cost per square meter of aperture area. Analysis of the SkyTrough—a design that is suited for use in relatively small SIPH applications—predicts that the installed solar field cost can be as low as $\$170/m^2$. Collector designs that are tailored for efficient construction and deployment at small plant capacities are essential for viable SIPH systems. Inclusion of balance of system and indirect costs brings this total to about $\$350/m^2$ (Kurup and Turchi, 2015b).

An examination of solar resource and natural gas use for IPH in California indicates a Technical Thermal Energy Potential that far exceeds the appreciable demand in the state and highlights the food and dairy sectors as good candidates for early adoption of SIPH systems.

Three general application temperatures between 80°C and 400°C are defined for linear concentrating collectors based mainly on the preferred HTF. The low-temperature region of 80-200°C is best suited for use of water or steam, the intermediate region of 200-300°C can utilize DSG or mineral oils, and the high-temperature region of 300-400°C must use DSG or more costly synthetic oils. It is noted that the industrial demand for steam is dominated by temperatures in the range of 120 to 220°C; thus, the best SIPH market target is believed to be systems using pressurized water or steam in the range of 120 to 220°C.

California offers a favorable environment for SIPH given its good insolation, gas prices typically higher than the U.S. national average, and policies promoting solar-thermal deployment. Given historically low gas prices, competing with natural gas remains the primary challenge to deployment. However, this study finds that the solar LCOH for many regions in California is lower than the LCOH from natural gas, using a representative installed solar hardware price and the average price for industrial natural gas in California. The economic case for SIPH only improves as gas prices climb or if a price is leveed on carbon emissions.

Lastly, modifications underway to the *Physical Trough* and *Linear Fresnel* models within SAM which will allow users to more easily predict performance for these industrial heat and steam-generation applications. These changes will remove the requirement of having a steam-Rankine power cycle in the SAM model and allow users to design for steam as the final product. These modeling options are expected to debut in the parabolic trough and Linear Fresnel models in SAM 2017.

Abstract.

A exergoeconomic and techno-economic analysis of integrating multi-effect distillation, absorption refrigeration and process heat plants in a concentrated solar power plant is carried out. A solar multigeneration plant is modeled to simultaneously produce electricity, desalinated water, cooling, and process heat. The methodology considers modeling a multi-generation plant, applying exergoeconomic method and levelized cost method. The solar multi-generation plant is simulated in a typical meteorological year, with one hour time-step and a yearly total DNI of 3,389 kW h/m^2/year, considering the demand of a specific mining company located in northern Chile. The analysis of simulation shows that the levelized cost method overcharges electricity and undercharges water, cooling and process heat with respect to the exergoeconomic method. The exergoeconomic method is a robust method of cost allocation for applying in a solar multi-generation plant.

Keywords: *multi-generation, exergoeconomic, CSP, multi-effect desalination, absorption refrigeration.*

1. Introduction

The demand for electricity, water, cooling and process heat has been growing increasingly in Chile [1], especially due to the mining requirements. Consequently, electricity, water, and fuel prices have reached high levels, which negatively impact the competitiveness of companies. According to Chilean Energy Ministry [2], in 2014, 37% of electricity generated in Chile was consumed by the mining industry, other industries consumed 31%, the residential sector 17%, while the commercial and public sectors accounted for 14% of the electricity consumption. On the one hand, Chile has high availability of renewable energy resources, such as solar, wind, hydro, biomass and geothermal energy. Within these sources, solar energy is an important resource due to high rates of radiation existing in northern Chile, considered as the highest worldwide [3]. On the other hand, in the north of Chile there are several mining facilities, which demand a large amount of electricity, fresh water, heat process, and cooling [1], [4], utilities that are feasible to be delivered by multi-generation systems or stand-alone systems.

Multi-generation or polygeneration is defined as the concurrent production of two or more energy services and/or manufactured products that, benefiting from the energy integration of the processes, extracts the maximum thermodynamic potential of the resources consumed [5]. A multi-generation scheme has comparative advantages over stand-alone systems, since it allows reducing both primary energy consumption and emissions of greenhouse gasses displacing fossil fuels, as well as decreasing energy dependency at the country level, contributing to the diversification of energy sources. Multi-generation scheme is a process of

doi:10.18086/eurosun.2016.02.03 Available at http://proceedings.ises.org

integration of different technologies by which is possible to increase the thermodynamic efficiency and decrease the consumed resources [5]. This integrated process can be evaluated either by an levelized cost analysis or exergoeconomic analysis. Levelized cost analysis considers the first law of Thermodynamics and economic principles to determine the present value of the total cost of building and operating of a productive plant over its economic life, converted to equal annual payments. Costs are levelized in USD per unit of annual production. Key inputs to calculate levelized cost include capital expenditure, operational expenditure, fuel costs, and revenues from the sales of by-products, such as, carbon credits [6]. However, a conventional economic analysis, as levelized cost, does not provide criteria for apportioning the carrying charges, fuel costs, and operational expenses to the various products generated in the same system [7]. On the other hand, exergoeconomic or thermoeconomic analysis considers the second law of Thermodynamics and economic principles for determining the unit exergy costs and exergy cost rate of each product. According to Tsatsaronis [8], exergoeconomics is defined as the branch of engineering that appropriately combines, at the level of system components, thermodynamic evaluations based on an exergy analysis with economic principles, in order to provide the designer or operator of a system with information that is useful to the design and operation of a cost-effective system, but not obtainable either by regular energy, or exergy analysis, or economic analysis. Exergoeconomic assesses the cost of consumed resources, money and system irreversibilities in terms of the overall production process [5].

For the reasons mentioned above, a solar multi-generation system is configured and simulated in order to produce electricity, desalination water, industrial cooling and process heat required by the mining sector in northern Chile. The solar multi-generation plant proposed herein consists of a concentrated solar power (CSP) parabolic trough collector (PTC) field with thermal energy storage (TES) and backup system (BS), a multi-effect distillation (MED) plant, a single-effect absorption refrigeration system (Ref), and a countercurrent heat exchanger as process heat plant (PH), the last three plants use thermal energy to drive the processes.

CSP-PTC could be integrated into multi-generation system so as to deliver different products, such as electricity, fresh water, process heat and refrigeration [9], different studies have focused on cogeneration configurations [10]–[16] and trigeneration schemes [14], [17], [18]. However, there are studies which considered the levelized cost method and others the exergoeconomic one to evaluate the benefits of the integration, but both methods are unlike and produce different results. For this reason, the aim of the present work is to apply an exergoeconomic method and levelized cost method in a multi-generation plant to compare the unit costs of each product.

2. Materials and methods

The methodology considerers modeling a solar multi-generation plant and applying an exergoeconomic method and levelized cost method.

2.1. Multi-generation plant

The solar multi-generation plant is depicted in Figure 1, the CSP-PTC plant is configured and modeled considering a typical CSP plant as Andasol-1 power plant [19], [20]. The solar field (SF) consisting of EuroTrough collectors (ET-150), Schott PRT-70 absorber tubes, Dowtherm A as heat thermal fluid (HTF). The design temperature of SF is 393 ºC and the outlet temperature is 293 ºC. The irradiance and solar efficiency at design point are 1,010 W/m^2 and 0.72, respectively. The solar multiple (SM) is defined as 2.56 with 614,014 m^2 of aperture area. The solar multiple is a measure of the solar field aperture area as a function of the power block's nameplate capacity, and it is expressed as:

$$\mathrm{SM} = \frac{\dot{Q}_{\mathrm{th,solar\ field}}}{\dot{Q}_{\mathrm{th,power\ block}_{\mathrm{design\ point}}}} \qquad \text{(eq. 1)}$$

where $\dot{Q}_{\mathrm{th,solar\ field}}$ is the solar thermal energy produced by the solar field at the design point, $\dot{Q}_{\mathrm{th,power\ block}}$ is the solar thermal energy required by the power block at nominal conditions.

The power block (PB) consists of a regenerative Rankine cycle with reheat and six extractions, as suggested in Blanco-Marigorta et al. [21]. The TES is assumed as a two-tank indirect system using molten salts (60% $NaNO_3$, 40% KNO_3) as storage media, 95% of annual storage efficiency, and the design temperature in the hot tank is 386 ºC and 292 ºC for the cold tank. TES_{th} is the equivalent thermal capacity of the storage tanks, it is defined as:

$$TES_{th} = \frac{\dot{W}_{des.gross}}{\eta_{des}} t_{full\ load} \qquad \text{(eq. 2)}$$

where, $\dot{W}_{des.gross}$ is gross power, η_{des} is efficiency of Rankine cycle in design point, and $t_{full\ load}$ is the number of hours of thermal energy delivered at the power block's design thermal input level. It is assumed 12 hours of full load capacity.

The BS supplies thermal energy directly to the HTF in the PB. Other assumptions are made: SF outlet temperature has been kept constant [22]; startup and shutdown are not evaluated; the capacity factor is assumed as 96%; and CSP plant is a base load power station.

In the CSP plant, the point of coupling of MED, Ref and PH plants is selected according to the operating temperatures constraints imposed by each technology and to cause the minimum penalty for power production. Therefore, the MED plant replaces the CSP plant condenser, the Ref plant is coupled to the fifth turbine extraction, and the PH plant is coupled between feed water preheaters (FWP). It is not possible to regulate the amount of water produced because the MED plant is driven by the heat rejected from the power cycle. The production from Ref plant and PH plant can be regulated per the demand.

The desalination plant is modeled with 12 effects parallel-cross feed MED plant with 11 feed preheaters, as suggested in Zak et al. [23]. The fresh water production is 37,341 m^3/day and 9.1 of Gained Output Ratio (GOR).

The refrigeration plant is configured with a single-effect LiBr-H_2O absorption chiller, as suggested in Herold et al. [24] with 5 MW_{th} of cooling capacity and 0.7 of nominal coefficient of performance (COP).

Finally, a counter current heat exchanger is configured to produce process heat, with 7 MW_{th} heating.

The sizing chosen for each plant was selected according to the demand of a specific mining company located in northern Chile.

Each stand-alone system is modeled and validated. Then, the multi-generation plant is the combination of the validated stand-alone systems. The CSP-PTC stand-alone plant is validated from Blanco-Marigorta et.al [21] and SAM software [19]. The MED plant is validated from Zak et al. [23] and El-Dessouky et al.[25], and the cooling plant is validated from Herold et al. [24].

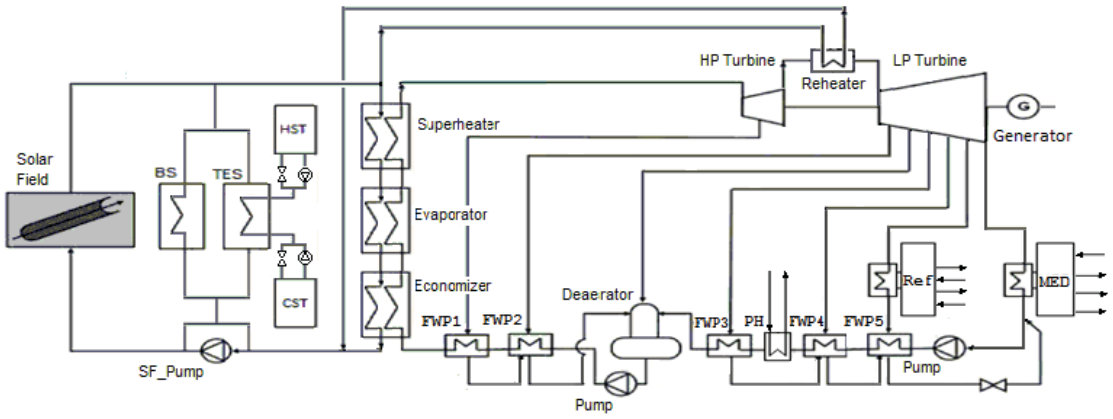

Fig. 1: Multi-generation plant configuration. CSP/TES + MED + Ref + PH.

Table 1 shows the main parameters of solar multi-generation plant.

Tab. 1: Main parameters of multi-generation plant at design point.

Property	Value Unit
TES	
Type / Storage fluid	2-tank / Molten Salt
Tank temperature (cold/hot) / Annual Storage Efficiency	(292 °C / 386 °C) / 95%
Full load hours of TES	12 h
Solar field (SF)	
Parabolic trough collector model	EuroTrough collector (Skal-et)
Solar Field inlet/outlet temperature	293.0 °C / 393.0 °C
Aperture area	614,014 m^2
Solar Multiple	2.56
Power block (PB)	
Gross power production	55.0 MW_e
HP turbine inlet pressure/temperature	103.57 bar / 373 °C
LP turbine back pressure/temperature	0.37 bar / 73.9 ºC
HP turbine / LP turbine isentropic efficiency	85.2% / 85.0%
Generator /motor / pumps efficiency	98.0 % / 98% / 70%
Multi-Effect Desalination (MED)	
Feed seawater intake temperature / salinity	25.0 °C / 0.042 kg/kg
Feed seawater after down condenser temperature	35.0 °C
Maximum salinity in each effect / Top Brine Temperature	0.072 kg/kg / 65.0 °C
GOR / Concentration factor	9.07 / 1.71
Single-effect absorption chiller (Ref)	
Cooling power	5.0 MW_{th}
Chilled water inlet / outlet temperature	10.0 °C / 6.0 °C
Cooling water inlet/outlet temperature	25.0 °C / 35.0 °C
Inlet temperature desorber / COP	108.5 °C / 0.70
Process Heat (PH)	
Process heat capacity	7.0 MW_{th}
Heat exchanger temperature inlet / outlet	63.0 °C / 90.0 °C

The software IPSEpro [26] was used for the modeling and simulations of the multi-generation plant and each stand-alone plant. IPSEpro can calculate mass and energy balances and simulate different kind of processes. IPSEpro solves the flowsheet of the process using Newton-Raphson method. IPSEpro provides only steady state solutions. In order to obtain the dynamic system behavior, IPSEpro has to be linked to Microsoft Excel by IPSEpro-PSExcel, where the solar multi-generation plant is simulated over a one-year period in time steps of one hour. Finally, MATLAB software is used for modeling and simulating TES behavior and for thermoeconomic and techno-economic assessment.

The multi-generation plant was evaluated to be installed in northern Chile, in Crucero, latitude -22.14°, longitude -69.3° and 3389 kW h/m^2/year of DNI [3].

In the model, variations of kinetic energy, potential energy, and pressure drops in the lines were disregarded.

2.2. Exergoeconomic method

A exergoeconomic evaluation is applied using Bejan et al. method [7]. Figure 2 depicts the delimitation of the boundaries analysis. The fuels and products are established, and mass, energy and exergy balances are applied. The exergy balance equation take the form:

$$\sum(\dot{Q}\left(1-\frac{T_0}{T}\right))-\dot{W}+\sum(\dot{m}_{in}e_{in})-\sum(\dot{m}_{out}e_{out})-\dot{E}_D=0 \quad \text{(eq. 3)}$$

where, $\dot{Q}$ is the heat power, T_0 is the temperature of reference, in K, $\dot{W}$ is exergy rates of work, $\dot{m}$ is the mass flow rate, e is the exergy specific, and $\dot{E}_D$ is the rate of exergy destruction.

The exergy rates from sun [27] is defined as:

$$\dot{E}_{sun}=A\cdot DNI\cdot(1+\frac{1}{3}\left(\frac{T_0}{T_{sun}}\right)^4-\frac{4}{3}\left(\frac{T_0}{T_{sun}}\right)) \quad \text{(eq. 4)}$$

where A is the solar field aperture area, and T_{sun} is the sun's surface temperature, taken as 6000 K.

For each system component is applied the economic balance in order to determine the unit exergy cost c_j and exergy cost rate $\dot{C}_j$ of each stream. The economic balance is expressed by:

$$\sum_{j=1}^{n}(c_j\dot{E}_j)_{k,in}+\dot{Z}_k^{CI}+\dot{Z}_k^{OM}=\sum_{j=1}^{m}(c_j\dot{E}_j)_{k,out} \quad \text{(eq. 5)}$$

where, c_j is the exergy unit cost, $\dot{E}$ is the exergy rate, $\dot{Z}_k^{CI}$ is the non-exergy-related cost rate associated with an investment cost (or capex), $\dot{Z}_k^{OM}$ is the non-exergy-related cost rate associated with an operation and maintenance cost (or opex).

The exergy cost rate is expressed as function of unit exergy cost by:

$$\dot{C}_j=c_j\dot{E}_j=c_j\left(\dot{E}_{ph}+\dot{E}_{ch}+\dot{E}_p+\dot{E}_k\right) \quad \text{(eq. 6)}$$

where the subscripts ph, ch, p, and k are physic, chemical, potential and kinetic, respectively.

The total cost rate of product $\dot{C}_p$ is the sum of total cost rate of fuel $\dot{C}_f$ and non-exergy-related cost rate $\dot{Z}$.

The exergy analysis considered a reference temperature of 25°C, a reference atmospheric pressure of 1.013 bar, a reference mass fraction of LiBr of 0.5542 kg/kg, and a reference mass fraction of water salinity of 0.042 kg/kg.

Investment cost in MUSD, and operating and maintenance cost in MUSD/year considered are: 397.3 and 17.8 in CSP [11], [19], [28], [29]; 59.5 and 1.8 in MED plant [25], [30]–[33]; 2.7 and 0.006 in Refrigeration plant [16], [34]; and finally 0.3 and 0.0006 in process heat plant [35], respectively. The fossil cost fuel is 0.0324 USD/kWh [36]. It has been considered a horizon of 25 years and a discount rate of 10%.

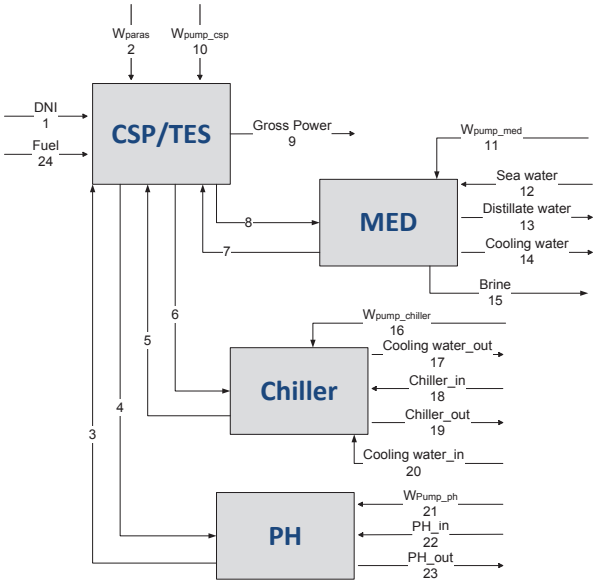

Fig. 2: Aggregation level for exergoeconomic assessment in multi-generation plant.

2.3. Levelized cost method

The levelized cost is the total cost of installing and operating expressed in USD per unit of product generated by the system over its life [11], [22], [37].

The levelized electricity cost (LEC), in USD/kWh, is defined by:

$$LEC = \sum_{j=0}^{n} \frac{capex_j crf + opex_j + C_{fuel\,j}}{(1+i)^j} / (E_{elect\_an\_j}) \quad \text{(eq. 7)}$$

where $capex$ is the capital expenditure, $opex$ is the operational expenditure, crf is the capital recovery factor, C_{fuel} is the annual fuel cost, i is the discount rate, n is the number of time periods, $E_{elect\_an\_j}$ is the annual production of electricity provided by the generator minus the parasitic loads of CSP plant. Fuel cost is calculated by:

$$C_{fuel} = c_{ff} \frac{Q_{\text{th,power block\_BS}}}{\eta_{\text{boiler}}} \quad \text{(eq. 8)}$$

where c_{ff} is the fossil fuel cost, in USD/kWh, $Q_{\text{th,power block\_BS}}$ is the thermal energy required by the power block from BS, in kWh/year, and η_{boiler} is the boiler efficiency, assumed as 0.9.

A similar procedure was used for the other levelized costs estimation. The levelized water cost (LWC), in USD/m^3, is defined by:

$$LWC = \sum_{j=0}^{n} \frac{capex_j crf + opex_j + C_{fuel\,j}}{(1+i)^j} / (V_{water\_an\_j}) \quad \text{(eq. 9)}$$

where $V_{water\_an\_j}$ is the annual production of water, in m^3/year, and C_{fuel} is the fuel cost, in USD/year. Fuel cost in the case of MED, refrigeration and process heat plants is the cost associated with electric consumptions, and it is calculated by:

$$C_{fuel} = LEC\ \text{En}_{\text{pumps}} \quad \text{(eq. 10)}$$

Where En_{pumps} is the annual energy consumption from pumps, in kWh/year.

The levelized cooling cost (LCC), in USD/kWh, is defined by:

$$LCC = \sum_{j=0}^{n} \frac{capex_j crf + opex_j + C_{fuel\,j}}{(1+i)^j} / (E_{cooling\_an\_j}) \quad \text{(eq. 11)}$$

where $E_{cooling\_an\_j}$ is the annual production of cooling, in kWh/year.

The levelized process heat cost (LHC), in USD/kWh, is defined by:

$$LHC = \sum_{j=0}^{n} \frac{capex_j crf + opex_j + C_{fuel\,j}}{(1+i)^j} / (E_{heat\_an\_j}) \quad \text{(eq. 12)}$$

where $E_{heat\_an\_j}$ is the annual production of process heat, in kWh/year.

3. Results and discussion.

3.1. Production and cost in the base case.

The monthly production of electricity, fresh water, cooling and process heat, in the solar multi-generation plant without BS, is presented in Figure 3. At the location, there is a seasonality of DNI, with shorter days and lower values of DNI in the winter season. Hence, the solar multi-generation plant shows a seasonal variation, presenting a lower production of electricity, fresh water, cooling and process heat during the winter (June and July). However, in February, the production decreases by the Altiplanic Winter which moistens the air coming from the east (where Bolivia is located) bringing unsettled weather and clouds.

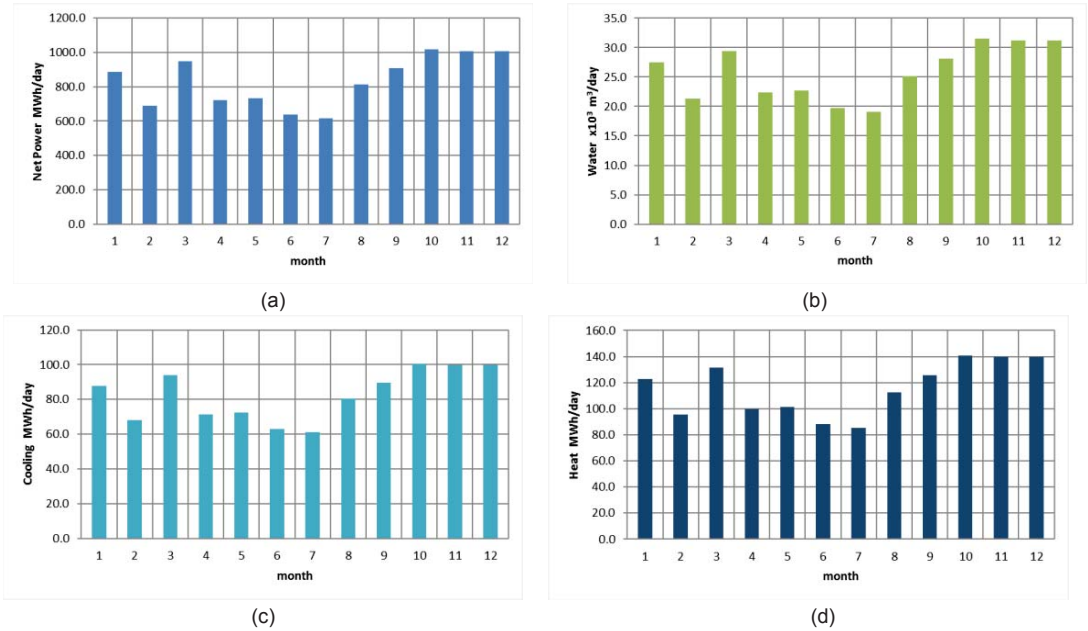

Fig. 3: Monthly productions from the solar: a) Net power. b and water. c) Cooling. d) Heat.

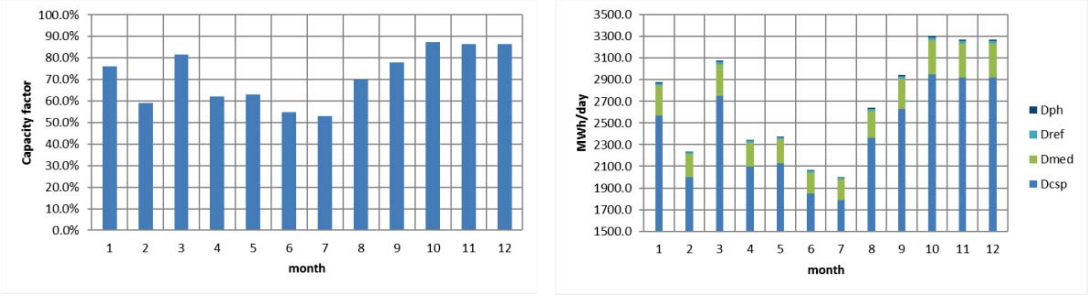
Figure 4a depicts the monthly capacity factor without BS, which is largest in the summer due to the seasonal variation in DNI available for collection. Figure 4b shows the monthly exergy destruction, which is greater in the CSP plant with an 89.4%. In the CSP plant, the SF is the most critical component in terms of exergy destruction. It is important to point out that exergy input of SF is derived solely from the sun which does not affect the consumption of fossil fuel. The second largest exergy destruction is in the MED plant with 9.6% of the total exergy input. In the case of cooling and process heat plants, the exergy destruction is less than 1%.



(a) (b)

Fig. 4: a) Monthly capacity factor without BS. b) Monthly exergy destruction without BS.

The annual productions in base case are: 463.1 GWh/year of gross power, 408.2 GWh/year of net power, 13.2 Mm^3/year of fresh water, 42.0 GWh/year of cooling, and 58.9 GWh/year of process heat.

The unit exergy costs (UEC) and levelized costs (LC) are presented in Figure 5. Two cases are considered in the case of water cost, without and with the cost of pumping the seawater to the plant location (about 70 km). The difference in value between UEC and LC is due to the form of cost allocation. Exergoeconomics uses the exergy as criterion to allocate the costs, and it is considered as a rational cost allocation. The levelized cost method overcharges electricity and undercharges water, cooling and process heat.

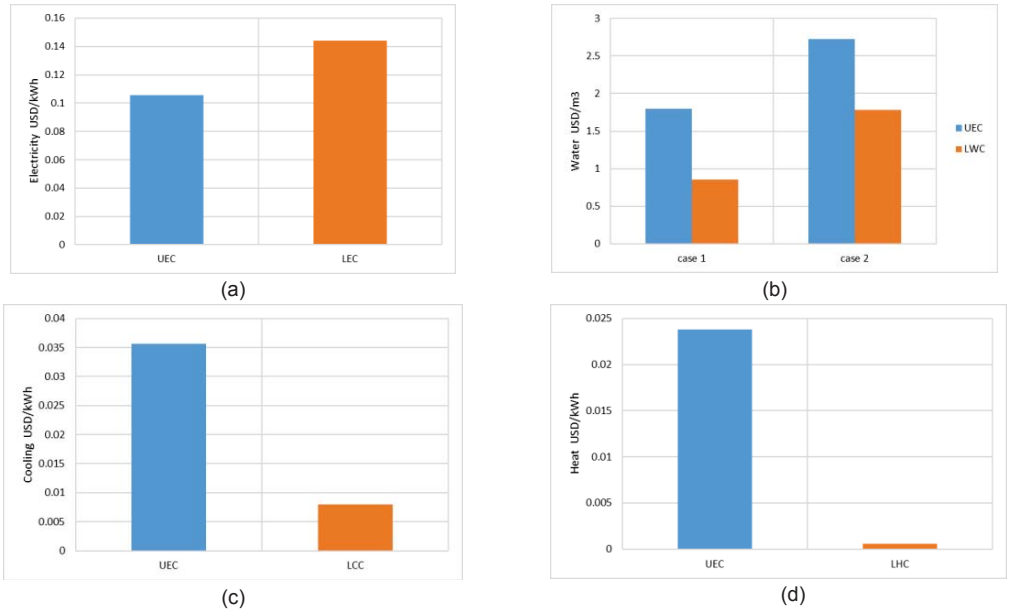


Fig. 5: Comparison between the levelized cost method and exergoeconomic method. Specific cost (UEC and LC) of: a) electricity, b) water, c) cooling, d) process heat.

If a system produces only one product, there are no problems to calculate the levelized cost because it is not necessary to use an allocation criterion of costs. However, if a system produces more than one product as in a multi-generation system, then, it is needed to establish an allocation criterion of costs in order to calculate the products cost. Conventional economic analysis does not provide criteria for apportioning the carrying charges, fuel costs, and opex to the various products generated in the same system [7]. Exergoeconomics provides criteria for apportioning the costs, therefore, exergy is the appropriate variable to use in this case.

On the other hand, the total exergy cost rate of products is 8,988.4 USD/h, which is distributed in 64.7% in electricity, 31.3% in fresh water, 2.2% in cooling, and 1.8% in process heat. In a process of optimization, the variable to be minimized is the total exergy cost of products.

3.2. Production and cost as functions of sizing SM and TES.

The solar multi-generation plant was hybridized with fossil fuel in order to fix the capacity factor in a 96%. Chile does not have restrictions to use fossil fuel in CSP plants. In contrast, Spain limits the use of fossil fuel in CSP plants. A solar multi-generation plant will be more dispatchable by coupling the solar multi-generation plant with BS. This also allows a more flexible generation strategy to maximize the value of the products generated. Figure 6 shows the capacity factor in the multi-generation plant without BS in which the capacity factor is increased with the SM and the hours of TES. This latter one allows storing excess energy collected by the SF when it is not used in the PB, and discharges that energy later when the DNI is lower, such as in cloudy days or at night. Consequently, the annual production of each product is increased too, as seen in Figure 7.

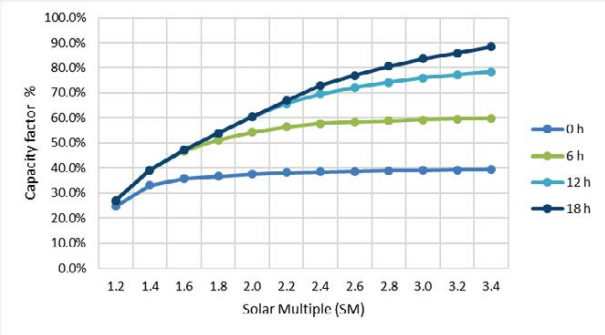

Fig. 6: Capacity factor in the multi-generation plant without BS.

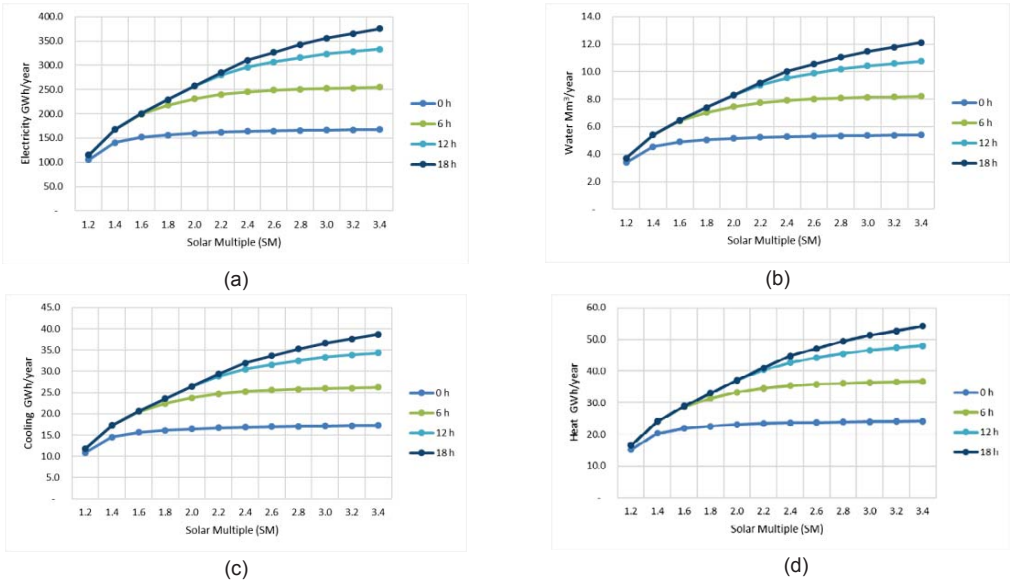

Fig. 7: Annual production of: a) electricity, b) water, c) cooling, d) process heat.

Figure 8 presents the unit exergy cost (UEC) and levelized cost (LC) of each product (electricity, fresh water, cooling, and process heat) as a function of SM, and with a TES of 12 hours. It is observed that UEC and LC are different, but the minimums UEC and LC are produced at the same SM, with an SM of 2.2. In a multi-generation plant, there are common costs associated with the products concerned, and it is necessary to determine the share of costs attributable to one or another product. So, the allocation cost needs an additional rational analysis to prevent allocation from being arbitrary. Regarding the levelized cost method, the fuel cost for MED, refrigeration and process heat plants only corresponds to the cost associated with electric consumptions and does not consider the steam cost because this latter one is assumed as an internal cost. On the other hand, allocation of costs based on exergoeconomic method equitably charges each product with the appropriate share of capex and opex that are involved in operating such component according to its exergy rate. Hence, the exergoeconomic method is more appropriate to multi-generation plant than levelized cost method.

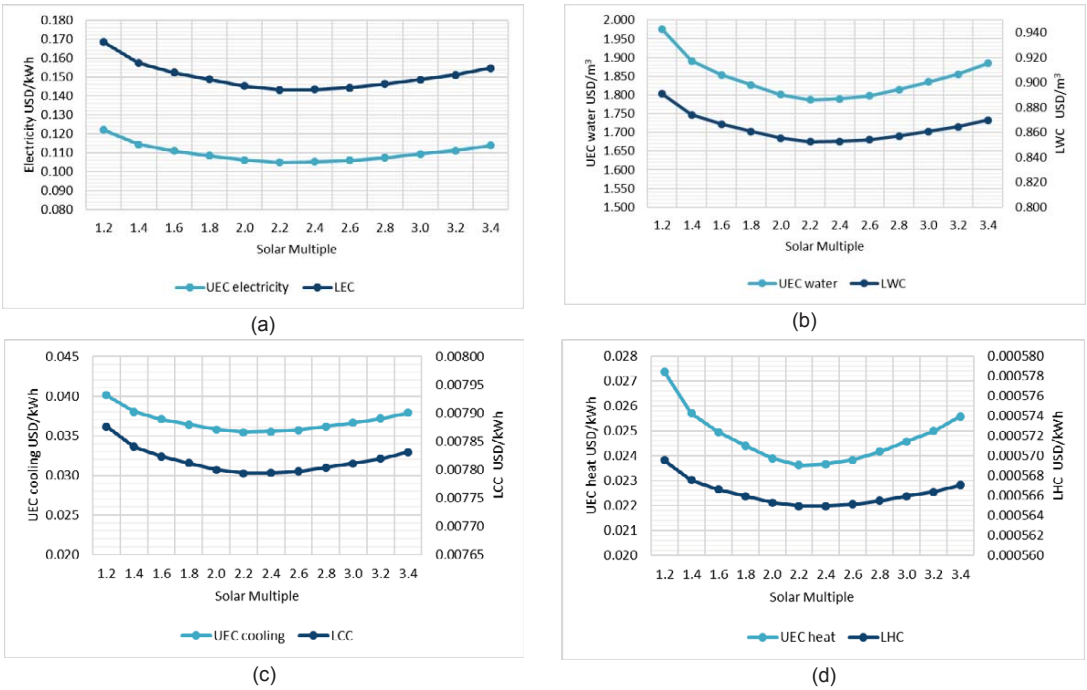

Fig. 8: Specific cost (UEC and LC) as a function of SM. a) electricity, b) water, c) cooling, d) process heat.

An optimal sizing of SF and TES should minimize installation and operating costs, and maximize the amount of time in a year to drive the power cycle at its nominal capacity. This point is reached with the minimum levelized cost and unit exergy cost. The unit cost in the solar multi-generation plant is dominated by the investment cost of CSP plant. The unit cost varies significantly, depending on the capacity factor, which in turn depends on the DNI, hybridization (BS) levels, and sizing of SF and TES.

4. Conclusions

The levelized cost method and the exergoeconomic method were applied to a solar multi-generation plant to compare the unit costs of each product. The solar multi-generation plant was made up of concentrated solar power plant, multi-effect distillation, absorption refrigeration, and process heat plants. The solar multi-generation plant was simulated hourly during a typical meteorological year.

The levelized cost method overvalues the electricity cost and undervalues the water, cooling, and process heat costs because the allocation cost does not charge all internal cost to MED, Ref and PH plants.

The exergoeconomic method is more appropriate than levelized cost method since the allocation cost is based on the second law of Thermodynamics and economic principles. Then, there is an equitable distribution of the appropriate share of non-exergy-related cost rate and exergy cost rate in each product.

The minimums UEC and LC happened at the same sizing of SM and TES, however, the unit costs have different values. Hence, independently of the method used, in a process of optimization of sizing of SM and TES, it is obtained the same sizing.

In terms of exergy destruction, the highest exergy destruction of the CSP plant is produced in SF and PB. The second highest is produced in the MED plant, but in the case of Ref and PH plant, the exergy destruction is about 1%.

In future studies, it is recommended that an exergoeconomic analysis and life cycle analysis be done in the solar multi-generation plant in order to use the cost accounting in the environmental evaluation. Likewise, another research line could be to evaluate different schemes of solar multi-generation plant coupled with other technologies, such as reverse osmosis desalination and vapor compression refrigeration systems.

Finally, an exergoeconomic evaluation with low aggregation level in CSP plant should be done at the level of individual components, such as the turbine, pump, solar field, and so on.

Competitive Assessment between Solar Thermal and Photovoltaics for Industrial Process Heat Generation

Steven Meyers, Bastian Schmitt, and Klaus Vajen

[1] Institute of Thermal Engineering, University of Kassel, Kassel, Germany

Abstract

The interest in photovoltaic heating has grown in recent years due to falling technology costs and ease of installation, though mainly in the residential sector. A study was conducted to determine under which conditions photovoltaic heating may become less expensive than solar thermal in low temperature industry (e.g. food and beverage). A broad parametric simulation study was conducted in TRNSYS which determined specific energetic yields for solar thermal and photovoltaic heating systems. A comparative analysis followed suit, conducted in a way to generate an assessment tool which functions for nearly every industrial, climatic, or economic setting. Results indicated that for lower temperature applications, solar thermal will remain a preferred choice in most climates. For higher temperature industrial process heat requirements, photovoltaic heating may already provide a lower cost solution in low and medium solar irradiation climates.

Keywords: *renewable heat, solar thermal, photovoltaic, process heat*

1. Introduction

In the wake of COP 21, nations across the world agreed to begin reducing their carbon emissions, namely through renewable electricity and lower carbon transport. While important, it overlooks an equally relevant carbon emitting sector, industrial manufacturing, which consumes mainly thermal energy. Lower carbon heat can be achieved through a few mechanisms, but solar offers the nearest term and most complete solution for the quickest reduction. Solar thermal (ST) collectors are an obvious choice for obtaining thermal energy, but in some niche markets photovoltaic (PV) heating systems are now being offered. While their focus is primarily on the domestic hot water sector, it provides an example where PV electrical resistance heating may be more cost effective than solar thermal.

The choice for PV resistance heating is easy to understand. The costs continue to drop year after year, installation is nearly fail proof, and its thermal energy generation capability is nearly independent of the process temperature level. Until now, minimal research (Fanney and Dougherty, 1997; Le Berre et al., 2014) has been done to compare the thermal energy generation costs of ST and PV at various temperature levels. Therefore, an assessment was conducted to determine their specific energy generation capabilities, paying close attention to their cost competitiveness for various climates, industrial process temperatures, load profiles and storage tank sizes.

2. Methodology

Two simulation decks were constructed in TRNSYS 17 to obtain the energetic yield potential of solar thermal and solar photovoltaic heating systems under various boundary conditions. Specific energy yields (per m^2 for ST and per W_p for PV) were then used to calculate the Levelized Cost of Heat (LCOH),

doi:10.18086/eurosun.2016.02.01 Available at http://proceedings.ises.org

subsequently used to determine the Cost Ratio (CR), an inflection point which indicated a preferred heating technology.

2.1. Solar Thermal Heating Model

The TRNSYS thermodynamic model was constructed around the popularly used collector model Type 832 (v5.01), developed by Haller et al. (2013), shown in Fig. 1. A constant speed pump in the solar loop operated between an upper and lower deadband of 7 K and 3 K between the collector (T_{coll}) and the bottom storage tank temperature ($T_{0.1}$), respectively. Connected pipes, insulation, charging/discharging heat exchangers and pump flow rates in the loops were sized in accordance to VDI 6002 (VDI, 2014). A storage tank was included (Type 534) to allow for flexibility in heat storage and delivery. For the charging loop, the storage tank had two inlet valves, located at a relative height of 0.9 and 0.6 from the bottom, allowing for stratification, as well as an outlet at 0.1. A constant speed pump in the charging loop was activated using the same deadband as the solar loop, though comparing temperatures between the heat exchanger ($T_{solarHX}$) and the bottom storage tank temperature ($T_{0.1}$). The process discharge loop was activated when the temperature difference between storage tank ($T_{0.9}$) and process return ($T_{process\ return}$) was greater than 10 K and deactivated at 5K. Temperature controls were put into place for the collector and storage tank, protecting both from stagnation and overheating. The discharge flowrate ($\dot{m}_{discharge}$) was regulated by a Type 805 heat exchanger (Heimrath and Haller, 2007), controlling the process flow temperature ($T_{process\ flow}$) to its set temperature when possible. If not achievable due to insufficient stored energy, the pump was operated at its maximum flow rate, which was set at 90% of the maximum flow rate of the process. The process was defined in section 2.3.

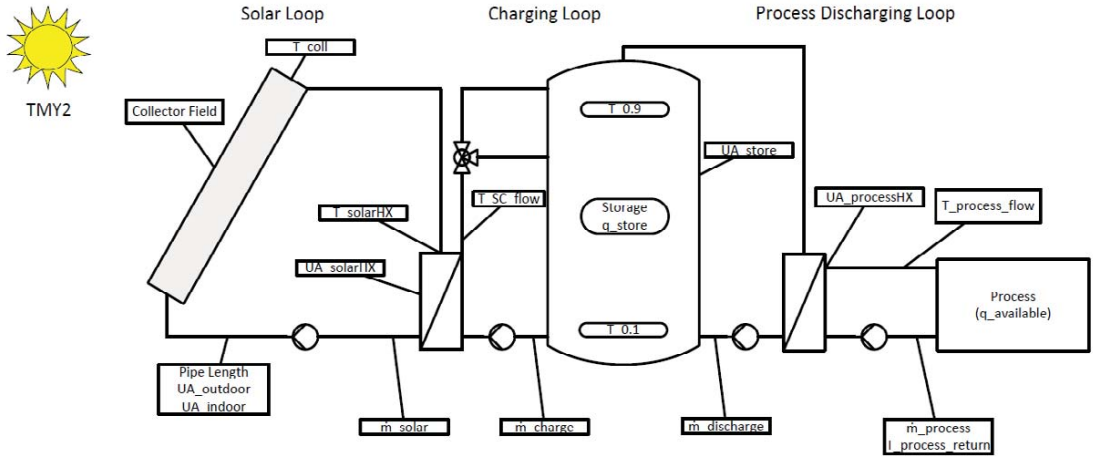

Fig. 1: The design of the solar thermal heating model in TRNSYS

2.2. Photovoltaic Heating Model

The solar loop for the PV heating model was built using Type 562, with inputs modelled after a high efficiency mono-silicon module, shown in Fig. 2. Two resistance heaters were implemented to directly heat the process fluid or water in the storage tank with an assumed efficiency of 98%. If the process load heating requirement ($q_{available}$) was greater than the available energy produced by the PV solar loop (q_{pv}), all electrical energy was directed to the process resistance heater. If excess energy was available, it was sent to the charging loop (storage) resistance heater. The charging loop variable speed pump adjusted the flow rate ($\dot{m}_{charge}$) to store the heat (Type 534) with high stratification. The discharge mass flow rate ($\dot{m}_{discharge}$) of the storage tank was controlled by determining the difference between $q_{available}$ and q_{pv}. If there was a deficit, the mass flow rate was calculated to heat the difference. This only occurred when there was a 10 K or greater difference between the upper storage tank temperature ($T_{0.9}$) and the process return temperature ($T_{process\ return}$). If the storage tank ever became full while the process load was completely heated by the PV system, any excess energy produced was considered wasted or sent to the local grid.

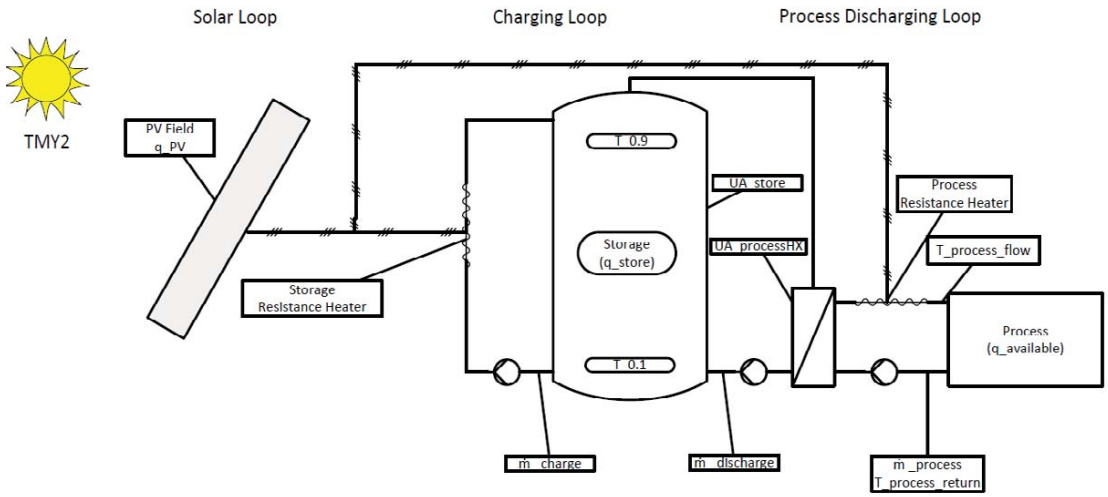

Fig. 2: The design of the solar PV heating model in TRNSYS

2.3. Simulation Parameters and Cases

A large parametric study was conducted to include geographical and industrial manufacturing conditions found all over the world. Quantities have been normalized to allow for easily scalability for specific conditions. For each parametric case, both a ST and PV simulation was conducted and subsequently compared.

Process Load and Profile

The process load quantity and temporal (daily, weekly) profile are two key parameters which have a significant influence on the overall performance of the industrial solar heating system. The load was defined as the daily energetic demand of the process divided by the gross area (A_g) of installed solar collector area (eq. 1). For instance, if the process has a daily flow of 30 m^3 from 45..75 °C with 125 m^2 of installed collectors, the specific daily load was calculated at 8.2 kWh/m^2d. Three various load quantities were simulated for this study, at 4, 6, and 10 kWh/m^2d, which represent a low, medium and high load demand. A load of 20 kWh/m^2d was also simulated to determine an ideal case which all thermal energy was immediately transferred to the load, thus eliminating the need for a storage tank.

$$q_{available} = \dot{V}_{process} \cdot \rho \cdot c_p \cdot \Delta T / A_g = 8.2 \ \frac{kWh}{m^2 d} \qquad \text{(eq. 1)}$$

Multiple daily and weekly load profiles have been recommended by Lauterbach (2014) for various cases found in industry. The best case scenario (highest efficiency) for a solar plant was a constant daily load profile which operates seven days a week (minimal heat losses). The mentioned load profile was partitioned into hourly sections, shown in Fig. 3. The hourly energy load, used in the TRNSYS simulations, was then determined by multiplying the hourly share of daily demand (Fig. 3) by specific daily load ($q_{available}$).

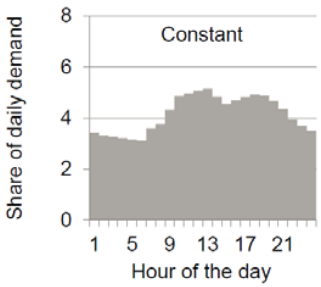

Fig. 3: Simulated daily load profile (Lauterbach, 2014)

Storage Tank Size

The available specific storage tank capacity (q_{store}) was defined by the stored thermal energy between the maximum rated storage tank temperature and the process load return temperature divided by the gross area of the ST system. Lauterbach (2014) recommended a specific storage tank capacity between 3 and 9 kWh/m^2 for low temperature solar thermal systems in central European climates. Due to higher process temperatures

and simulations conducted in higher solar resource regions, the specific storage tank sizes were 3, 5, 7, 9, and 11 kWh/m^2. The storage tank specific volume (v_{store}) was subsequently calculated (eq. 2), which determined the storage tank size capacity, in l/m^2. A typical non-pressurized storage tank had a $T_{0.9max}$ of 95 °C. If the $T_{process\ return}$ was 25 °C and a large q_{store} was desired (9 kWh/m^2), the calculated storage tank specific volume was 112.6 l/m^2.

$$v_{store} = q_{store}/c_p \cdot \rho \cdot \left(T_{0.9max} - T_{process_{return}}\right) = 112.6\ \frac{l}{m^2} \quad \text{(eq. 2)}$$

At higher temperatures, less energy was stored due to the storage tank thermal limitations. As a reference, the maximum storage tank temperatures were as followed (Tab. 1), based upon the process flow temperature.

Tab. 1: The relationship between process flow temperature and maximal allowed storage tank temperature

$T_{process\ flow}$ (°C)	$T_{0.9max}$ (°C)
< 90	95
< 120 and >90	130
>120	$T_{process\ flow}$ + 30

Collectors and Process Temperatures

Four solar thermal collectors (Flat Plate [FPC], Evacuated Tube [ETC], Compound Parabolic Concentrator [CPC], Parabolic Trough [PTC]) and one photovoltaic collector were selected for simulation. Each thermal collector was simulated at three temperature ranges, fitting for their potential applications in industry while the single PV collector covered all noted temperature ranges, as is the nature of electric heating. The ST collector model (Type 832V5.01) implemented the quasi-dynamic testing method (EN 12975-2 and ISO 9806:2013) for the parameters used by TRNSYS (Tab. 2). The PV model parameters (Type 562) were provided by the manufacturer (Tab. 3). All parameters are in terms of gross area, A_g. Incident Angle Modifiers (IAM, transverse, longitudinal, and diffuse) were also implemented.

Tab. 2: Solar thermal collector simulation parameters and load temperatures

		FPC	ETC	CPC	PTC
η_o (-)		0.77	0.48	0.56	0.59
c_1 (W/m^{2}K)		3.25	1.21	0.78	0.21
c_2 (W/m^{2}K^2)		0.0150	0.0038	0.0009	0.0013

Temperature Efficiency Modifier (1/C)	-0.0038
Radiation Efficiency Modifier (%)	$0.0502 \cdot \ln(G_T)+0.6833$

Locations

It was critical to select simulation sites whose results can provide analysis for nearly every location in the world. The two main factors which affected the performance of ST and PV systems were the daytime ambient temperature ($T_{amb,day}$) and diffuse ratio ($DR=H_d/H_t$). Given three levels (low, medium, and high) of both, nine sites were selected from the extended weather database in TRNSYS to conduct the parametric study, shown in Tab. 4. Fig. 4 included these nine sites, plotted in a line by similar diffuse ratios (indicated in Tab. 4), along with 1079 other sites within the TRNSYS database, which indicated how these nine sites provided representation for nearly all global climate conditions.

Tab. 4: The selected sites for simulation analysis, detailing their solar irradiation, average daytime ambient temperature, diffuse ratio, and latitude

Site	GHI (kWh/m²a)	DNI (kWh/m²a)	$T_{amb,day}$ (°C)	DR	Latitude (°)
Dongola, Sudan	2476	2843	29.8	0.22 (low)	19.17
Jerusalem	2093	2404	18.3	0.26 (low)	31.78
Eagle, Colorado, USA	1715	2031	9.6	0.33 (low)	39.65
Abu Dhabi, UAE	1957	1605	29.2	0.45 (mid)	24.43

Simulation Setup and Key Results

The ST model was validated by comparing results to a similar model created by Lauterbach (2014) (validated on a solar process heat plant at a brewery in Germany), which yielded a system utilization ratio difference of less than -2%. The PV model used the same main components (pipes, storage tank, insulation, heat exchangers), only replacing the solar heating source. While not directly validated, it serves as a good approximation as what may be installed in the future, as no PV process heat plant is currently in operation.

The ST and PV parametric simulations were conducted using TRNEdit, once the TRNSYS simulation deck was finalized. Completed annual simulations recorded key variables such as the specific annual system yield (eq. 3), the annual system utilization ratio (eq. 4), and the solar fraction (eq. 5). The specific annual system yield was defined by the total energy delivered to the process load from the ST or PV system, taking into

account thermal losses of the hydraulics and storage tank. The annual utilization ratio was determined by dividing the specific annual system yield by the quantity of useable solar irradiation on the collector surface during the year (total or beam). The solar fraction was calculated by the dividing the specific annual system yield by the annual specific load.

$$Q_{yield}^{ST,PV} = \sum_{0}^{8760} \Delta Q_{process} \quad \text{(eq. 3)}$$

$$\eta_{system}^{ST,PV} = Q_{yield}^{ST,PV} / H_{t,b} \quad \text{(eq. 4)}$$

$$f_{sol}^{ST,PV} = Q_{yield}^{ST,PV} / \sum_{0}^{8760} q_{available} \quad \text{(eq. 5)}$$

There was an inherent mismatch between the standard units of ST and PV systems, as ST specific performance and costs are commonly per square meter and PV per watt peak (W_p). While these respective units are used in subsequent comparative analysis, a conversion was made between the two to ensure that both thermal systems have the same parameters (i.e. $q_{available}$, q_{store}) while being simulated. The peak specific energy yield by the ST system was estimated using the simulated collector parameters and expected mean collector temperature (Tab. 2). A similarly sized (by energy) PV system was then determined by dividing the ST peak specific energy yield by the nominal PV efficiency. For example, if a ST system generated 0.6 kW/m^2 for a given process temperature while assuming a 19% nominal efficiency of the PV system (0.19 kW/m^2), the simulated PV system must have gross surface area 3.15 times lager to yield the same peak thermal energy (input into TRNSYS). Through this, the previously mentioned specific simulation parameters can be used by both the ST and PV models, allowing for an equal comparison.

2.4. Energetic and Cost Comparisons

The Levelized Cost of Heat (LCOH) is a standard metric used when comparing two or more technology types to determine which has the lowest heat generation cost over a certain time period. Absolute LCOH values are important to determine when building solar systems, but for a comparison study relative costs are more insightful and allow for flexibility for multiple cost conditions.

The LCOH for both the ST and PV systems is shown in (eq. 6) with key parameters listed in Tab. 5.

$$LCOH = \frac{CapEx_{ST,PV} + \sum_{n=1}^{20} \frac{OM_{ST,PV}}{(1+DR)^n}}{\sum_{n=1}^{20} \frac{Q_{yield}^{ST,PV} * (1-SD)^n}{(1+DR)^n}} \quad \text{(eq. 6)}$$

Tab. 5: The input parameters to calculate the Levelized Cost of Heat

Parameter	Definition	ST Value	PV Value
$CapEx_{ST,PV}$	Capital Expenditure (€/m^2 or €/W_p)	Variable	Variable
$OM_{ST,PV}$	Operation and Maintenance (€/m^2 or €/W_p)	2% of CapEx	1% of CapEx
DR	Discount Rate	3.50%	3.50%
SD	Degradation Rate	1.0%	0.5%
n	Years of Operation	20	20

The LCOH Ratio was defined by the division of the LCOH of the ST system by that of the PV system for the same simulation case (eq. 7). This value was required to help calculate the Cost Ratio and also serves as an indicator to the lower cost solar heat system. When this value is greater than one, the heat generated from the PV system is less expensive, and when less than one, the heat from the ST system is.

$$LCOH_{ratio}(LHR) = \frac{LCOH_{ST}}{LCOH_{PV}} \quad \text{(eq. 7)}$$

If the $LCOH_{ratio}$ is set to one, it can be rearranged ($LCOH_{ST} = LCOE_{PV}$) and reformulated to determine the Cost Ratio (CR) (eq. 8), which is the $CapEx_{ST}$ divided by $CapEx_{PV}$. To do this, an assumed $CapEx_{PV}$ was input into the equation, along with the known annual ST and PV system yields. An iterative loop was written

in Matlab to determine the $CapEx_{ST}$ which makes $LCOH_{ST}$ = $LCOE_{PV}$ true, providing both inputs to determine the Cost Ratio, which was calculated for every parametric run.

$$CR = \frac{CapEx_{ST}}{CapEx_{PV}} \left(\frac{W_p}{m^2}\right), when\ LHR = 1 \quad \text{(eq. 8)}$$

For example, in a particular simulation the specific ST yield was 452 kWh/m^2 and the PV 1001 kWh/kWp. Using (eq. 6) with parameters from Tab. 5 and an assumed $CapEx_{PV}$ of 1.5 €/W_p (Shah and Booream-Phelps, 2015), the iterated $CapEx_{ST}$ was 576 €/m^2, leading to a CR of 384 W_p/m^2. When doing the same iteration under various $CapEx_{PV}$, the same CR was calculated.

The advantage of the CR is that it allows the comparative analysis in any currency to be flexible for the ever changing $CapEx_{ST,PV}$, whether it is from technology/system improvements or changes in local subsidies. It is used in two ways: either one CapEx is known and the other is determined using the simulated CR; or both $CapEx_{ST,PV}$ are known and are compared against the simulated CR. For the first case, the $CapEx_{PV}$ tends to be less variable than that of ST, due to the commoditization of PV panels and is for example purposes, set at 1.3 €/W_p. Assuming a simulated CR of 384 W_p/m^2, these two values are multiplied together to determine the maximum cost of a comparable ST system (eq. 9) for it to be financially competitive with the PV system. For the second case, if both CapExs are known (450 €/m^2 and 1.6 €/W_p), the CR is calculated to be 281 W_p/m^2 (eq. 10) and when less than simulated CR, ST produced heat at a lower cost.

$$1.3 \frac{€}{W_p} \cdot 384 \frac{W_p}{m^2} = 499 \frac{€}{m^2} \quad \text{(eq. 9)}$$

$$450 \frac{€}{m^2} / 1.6 \frac{€}{W_p} = 281 \frac{W_p}{m^2} \quad \text{(eq. 10)}$$

Graphical representation of the CR as a function of solar irradiation and ambient temperature were constructed per simulation case to serve as an easy to use guide to determine which industrial solar heating system has the lowest cost.

3. Simulation Results

3.1. Energy Yields and Cost Ratios

Three simulation sites are shown to illustrate the type of results obtained from the parametric study with indicated process temperatures and selected ST technology. The first site was Copenhagen (FPC), the second Sydney (CPC), and the final Abu Dhabi (PTC) (Fig.5). For this example, the process load ($q_{available}$) was 6 kWh/m^{2}d and storage tank size (q_{store}) 9 kWh/m^2, indicating a medium load and large store. The process temperatures for each case are noted on the x-axis. The primary y-axis shows the system utilization ratio (η_{system}) and the secondary the associated Cost Ratio (CR).

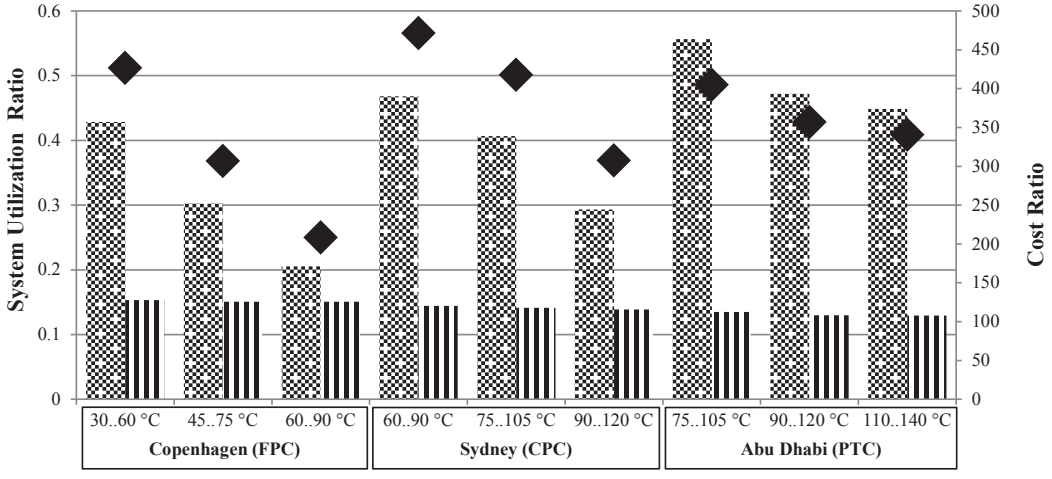

Fig. 5: Three exemplary sites showcasing the ST and PV system utilization ratios and Cost Ratio for three temperature levels and ST technologies

3.2. Comparison Graphs

To graphically compare ST and PV heating systems, new plots were constructed with the CR on the x-axis and the respective available solar irradiation on the y-axis for the nine sites during one parametric simulation (one collector, process temperature, load, and storage tank size). Sites with similar ambient daytime temperatures (Low~10°C, Medium~18°C, High~28°C) were connected with lines, which represent LHR lines. The CR and GHI cases above this line represents situations when the LHR<1, indicating that heat generated by a ST system is less expensive, and the contrary below said line. Fig. 6 shows a lower temperature case with FPC while Fig. 7 was for a higher temperature case with PTC. The previously mentioned sites are circled in each figure as a reference.

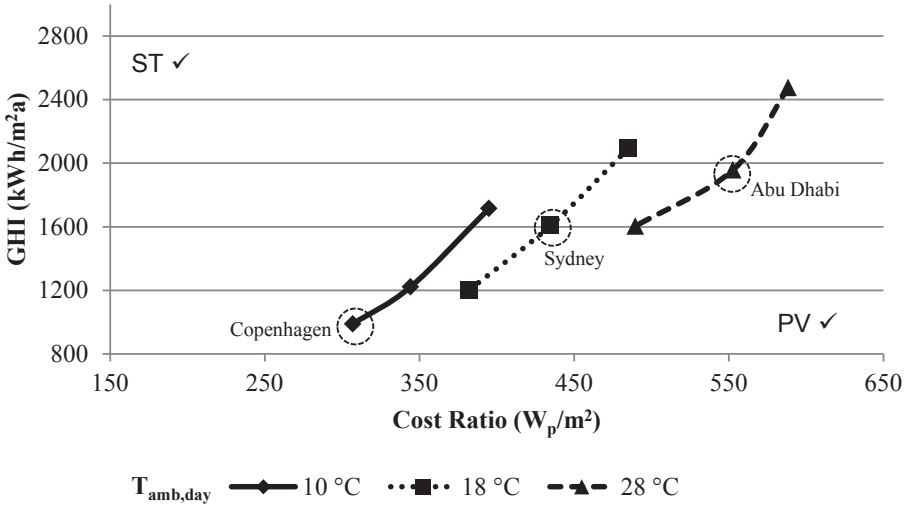

Fig. 6: Solar Thermal and PV comparison graph for a FPC with a process of 45..75 °C, specific load of 6 kWh/m²d, and specific store of 9 kWh/m²

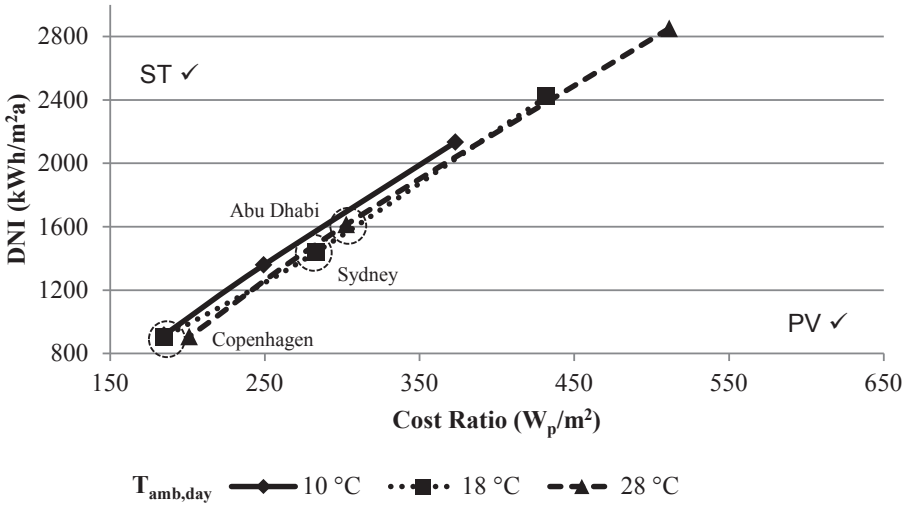

Fig. 7: Solar Thermal and PV comparison graph for a PTC with a process of 110..140 °C, specific load of 10 kWh/m²d, and specific store of 9 kWh/m²

3.3. Example Application of Comparison Graphs

The use of the comparison graphs provided a powerful yet easy to understand tool to determine which industrial solar heating technology can provide a lower cost of heat. As an example case, Fig. 8 detailed two ST collectors (FPC, CPC) for one case (process temperatures 60..90 °C, load 6 kWh/m²d, store 7 kWh/m²);

something which may happen in reality when deciding between different collectors for a system. Tab. 6 highlighted four technology comparisons for two different locations along with the determined CR by using Fig. 8. This was done per site by drawing a horizontal line from the y-axis at the corresponding GHI to the fitting temperature line (or interpreted between two lines) of the desired ST technology. From this point, a vertical line was drawn to the x-axis, which determined the CR for that case. The CR was then used, as in (eq. 9), to determine the competitive maximum cost of a ST system by simply multiplying the known PV cost (€/W_p) by the Cost Ratio (W_p/m^2) (Tab. 6). If a Cost Ratio was already known through local ST and PV costs, the comparison can be done in reverse. A vertical line could be drawn up from the x-axis and a horizontal line right from the y-axis (given the local solar irradiation). The intersection point of these two lines was compared to the local temperature line (the LHR line). If this point was above the line, ST was a better choice (indicated by the ST check mark in the upper left hand corner). If below the curve, PV was selected (PV check mark in the lower right hand corner).

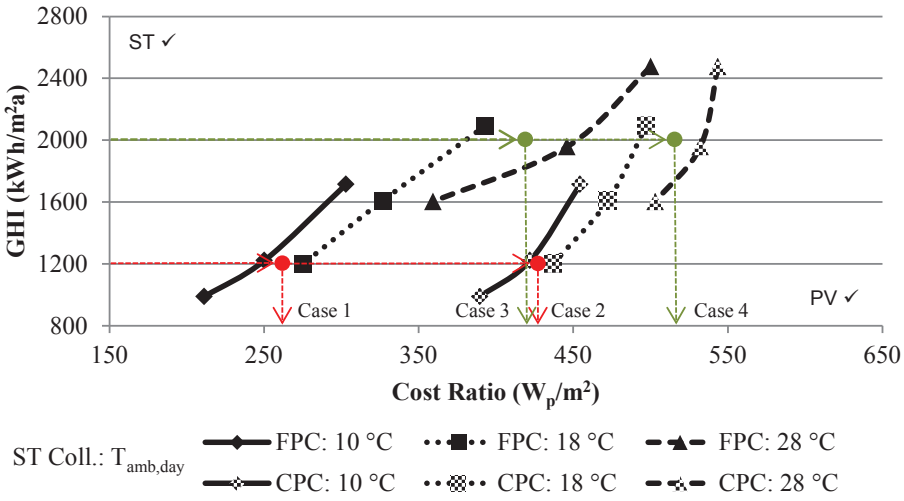

Fig. 8: An example of how to use the comparison graphs to determine the Cost Ratio for specific locations and system cases. These plots are valid for process temperatures 60..90 °C, load 6 kWh/m²d, and store 7 kWh/m²

Tab. 6: Input parameters and results for use in the comparison graph example in Fig. 8

Case	Site	GHI (kWh/m²a)	$T_{amb,day}$ (°C)	ST Technology	CR (W_p/m^2)	PV Cost (€/W_p)	ST Max. Cost (€/m²)
1	1	1200	14	FPC	265	1.2	318
2	1	1200	14	CPC	430	1.2	516
3	2	2000	23	FPC	420	1.5	630
4	2	2000	23	CPC	515	1.5	773

4. Discussion

The resulting energetic simulations in TRNSYS revealed the expected results for the both the ST and PV heating systems. For all three presented cases (Fig. 5), the ST system utilization ratio decreased as a function of process temperature, due to increased collector thermal losses. While three different technologies were used for Copenhagen, Sydney, and Abu Dhabi, it was clearly shown that ambient temperature plays a large role in the effectiveness of such collectors, as Abu Dhabi's showed the highest average system utilization factor and Copenhagen the lowest. The opposite was true for the PV systems, where a lower system utilization ratio occurred in the higher irradiation regions, namely due to greater ambient temperatures and the technology's negative temperature efficiency modifier. The higher process temperature PV systems showed a small decrease in performance due to larger thermal losses in the storage tank. Combining these two trends together, it was understandable that the Cost Ratio for all ST technologies decreased as a function of process temperature. The rate of decrease was less for the PTC and CPC, as both technologies had smaller thermal losses (c_1, c_2) and are more immune to reduced performance at higher process temperatures.

The results shown in Fig.6 and Fig.7 demonstrated the goals of this research, to create an easily understood graph which helps determine the preferred renewable solar heating technology; no matter where it is geographically located, when it may be built, and which currency is used. Analysis of this graph determined clear trends which are supported by other simulations not detailed in this paper. The best conditions for ST systems are exhibited in Fig. 6, for a lower temperature heating process load met using relatively inexpensive FPC. In higher temperature regions with high solar irradiation like Abu Dhabi, given present and future PV costs, it does not seem likely that PV would ever overtake ST. In lower temperature and solar regions like Copenhagen, PV heating may pose a near term threat. This was mainly due the location's numerous cold and cloudy days in which no energy was produced by ST while PV still could, actually benefiting from the colder temperatures and having a lower minimum solar irradiance requirement for energy production. The contrary was shown in Fig. 7, the situation where PV may soon, if not already, overtake ST as the preferred industrial solar heating choice. For higher temperature processes requiring a concentrating collector, all three temperature lines are shifted left towards the y-axis, indicating a decreased Cost Ratio and thus more competitive PV system. This can be a challenge, as concentrating collectors tend to be more expensive than other solar thermal technologies. If PV costs were assumed to be 1 €/W_p, then even in regions with a DNI resource of greater than 2000 kWh/m^2a, the installed cost of a PTC system must be less 400..500 €/m^2, difficult given their current estimated costs (Frank et al., 2013).

5. Conclusion and Future Work

This study was conducted in order to provide insight into the future of industrial process heating by solar energy. Traditionally, this has been done with solar thermal collectors. However, with the continued development of lower cost PV systems and their inherent ease of installation, this technology may prove to provide a lower cost source of low carbon heat. Through energetic simulations and comparative financial analysis, it was shown that for lower temperature process heat cases, solar thermal systems will most likely remain the preferred technology choice. The contrary was true for higher temperature applications, especially in colder, lower solar resource locations, where PV is already a competitive choice for heat generation. The exhibited results were crafted in such a way that they can be used for nearly any industrial process heat condition, global location, and present or future technology cost. The opportunity cost of not using PV energy for offsetting local electricity consumption was not considered. This is one avenue of future work, along with the assessment of industrial heat pumps working together with ST and PV to provide the lowest carbon emission heat source for industrial applications.

Modelling of a Solar Dryer for Food Preservation in Developing Countries

Joakim Olsson[1] and Henrik Davidsson[1]

[1] Lund University (Sweden)

Abstract

Food insecurity has proven to be a significant problem in many developing countries, which in some cases occurs due to the lack of adequate methods of preserving foods for longer periods of time. Solar drying of foods could be a feasible method for preserving foods in developing countries. To maintain a good product quality, the design of the solar dryer used needs to be considered. A faulty design will result in the foods being exposed to either excessive heat, which will degrade nutrients such as Vitamin C, or exposed to insufficient heat which could result in growth of mold or bacteria.

In this study a base scenario for a solar dryer design has been set up and mathematically analyzed to find ways of improving the design and identifying the most important parameters to consider. The study will serve as a part of an ongoing project at Lund University in Sweden, which will be implemented in Mozambique. The results of the study imply that the collector performance can be improved significantly if the most important parameters are optimized. For future work, more practical measurements would be required to verify the results, particularly regarding the evaporation rate of the drying products.

Keywords: *Solar drying, food preservation.*

1. Introduction

The malnutrition in developing countries has proven to be a persistent problem over the decades and appears to remain unsolved despite the economic growth that has occurred in some of the countries. Among these developing countries is Mozambique, which had a Human Development Index (HDI) positioned at rank 180 out of 188 countries and territories in 2014 by the United Nations Developing Programme, despite the HDI value being 75 % higher than in 1980 (UNDP, 2015). Almost one-third of Mozambicans, most of them living in the south and centre regions, suffer from chronic food insecurity and the country is prone and sensitive to natural disasters such as drought and flooding (World Food Programme, 2016).

Even if a major number of Mozambicans are suffering from malnutrition, it is not due to insufficient harvests. Previous studies have found that Mozambique suffer 25 % to 40 % post-harvest losses of crops, mainly due to inadequate preservation methods and infrastructure (Phinney et al., 2015). Since Mozambique currently is lacking the economical means and infrastructure to support conventional preservation methods of non-developing countries, improvement of the current drying methods is limited in terms of complexity. Having this problem in mind, an ongoing project at Lund University aims to find a simple and economical method for food preservation that can be implemented in Mozambique.

One method for preserving the fruit is using an indirect solar dryer consisting of a solar collector connected to a drying tower according to Fig. 1, which will be the main focus of this study. An indirect solar dryer uses a solar collector to heat air which is then transported to a drying unit which is protected from direct sunlight (Kumar et al., 2015). Since the sunlight doesn't directly irradiate the surface of the drying products, the risk of crust formation on the drying products, which tends to reduce the drying rate, is greatly reduced (Mills-Gray, 1994). Another benefit of an indirect solar dryer is the hygiene of the products as they are more protected from

doi:10.18086/eurosun.2016.02.19 Available at http://proceedings.ises.org

the environment. To further improve the hygiene, Solar Assisted Pervaporation technology (SAP) can be used in combination with indirect solar dryers. The SAP-technology involves a textile semi-permeable to water, being impermeable to liquid water while water vapor can pass freely through the textile. Using this textile, pouches can be made to hold various fruit juices for drying, which will be referred to as SAP-pouches. The liquid fruit juice will be kept inside the pouch, protecting it from contamination, while the evaporated water can still escape the pouch. The textile is also designed to prohibit any microorganisms from entering the pouches. This means that if the fruit juice becomes pasteurized inside the pouch, it will remain sterile and thus preserve the foods for longer (Phinney et al., 2015). The drying process of indirect solar dryers mainly depends on the drying conditions inside the drying chamber, being the air mass flow rate, airflow temperature and relative humidity (Blanco-Cano et al., 2016). In other words, if these three key parameters can be improved, the dryer performance will also be improved.

The aim of the study is to set up a mathematical model for an indirect solar thermal dryer that can be used to dry SAP-pouches containing fruit juices in developing countries such as Mozambique. Furthermore, the model was used to generate simulations to identify ways of improving the dryer performance. To perform the simulations, the model was implemented in a calculation tool which could also assist the project in Mozambique in the future. The calculation tool was programmed in Maple 2015, a software used analyse, visualise and solve mathematical problems (Maplesoft, 2016).

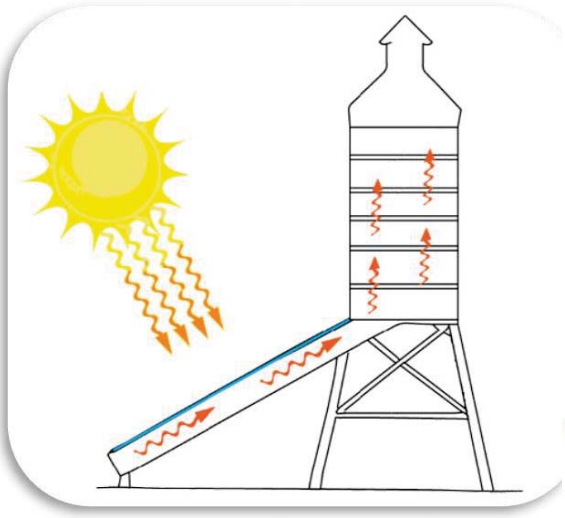

Fig. 1: Schematic figure of a solar dryer. The orange arrows inside the dryer are representing the air flow *(PAEGC & TH Cologne, 2016)*.

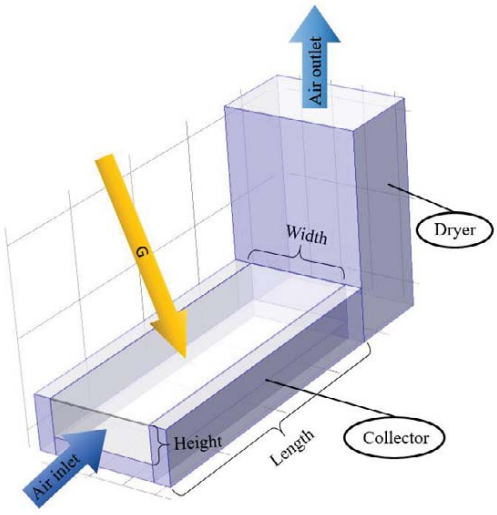

Fig. 2: Schematic figure of the model. The solar dryer is consisting of two parts: the collector and the dryer. The collector consists of a glass layer on the top, insulation on the sides and the bottom and an absorber plate on top of the bottom insulation layer. The dryer is insulated on the sides and contains shelves with SAP-pouches.

2. Method

To set up the model for the solar dryer, the solar dryer was divided into two sections according to Fig. 2; the collector and the dryer. This was essential since collector and the dryer are containing different conditions for setting up energy balances. The output air temperature of the collector will be used as an input temperature for the dryer air flow. The main idea for the model is to identify all flows of energy going in and out of the collector and the dryer in order to set up energy balances. The energy balances made for each surface of the collector and dryer respectively, i.e. the absorber plate, glazing and walls, will serve as equations that can be used in equation systems for the collector and the dryer. The equation systems are solved for relevant surface temperatures and the drying rate of the SAP-pouches is estimated from the drying conditions. To simplify the model, the following assumptions were made:

2.1. Assumptions

- The collector and dryer are in steady state for a constant solar irradiation. In reality the solar radiation will vary with time and weather conditions.
- No air leakages.
- The collector inner sides are assumed to have the mean temperature of the absorber and the glazing of the collector.
- The temperatures of the SAP-pouches are equal to the surrounding air temperature and the bags are not dried out. In practise the evaporation rate from the SAP-pouches will differ when the dryer is warming up since the pouch temperature will increase, absorbing heat.
- The parameters ρ (density), C_P (specific heat), μ (dynamic viscosity), λ_{air} (heat conductivity for air) and Pr (Prandtl number for air) have been assumed to be constant for 300 K and 1 atm.
- The inner sides of the collector will not reflect any radiation. Instead, all heat radiation is reflected between the absorber and the glass. Furthermore, the heat radiation from the absorber to the glass is also assumed to be normal to the absorber. In practise the heat will radiate in several directions from the absorber and the glass.
- Fully developed laminar air flow for Re (Reynold number) < 3000 and fully developed turbulent air flow for $3000 \leq Re \leq 5 \cdot 10^5$. For the turbulent interval, the characteristic length of the collector/dryer must be at least 10 times greater than the hydraulic diameter.
- No heat transfer between SAP-pouches.
- The ambient temperature is within the interval 0 °C < T_{amb} < 100 °C, the valid interval for using Antoine's equation for saturation pressure.
- The glass does not absorb any sunlight ($\alpha_{glass} = 0$).
- The collector sides and bottom and the dryer do not absorb any sunlight on the outside. Additional heat gains of the dryer will be added independently of the solar irradiation G.
- The convective heat transfer coefficient for all exterior walls $h_{con,\ out}$ is assumed to be a constant value of 20 W/(m²·K) (Sekhar et al., 2009) (Kumar Moningi, 2016).
- The outward heat radiation of the side areas of the collector and the dryer walls are assumed to radiate 50 % towards the sky temperature (T_{sky}) and 50 % towards the ground (T_{amb}).

2.2. The collector

For the collector, four different surfaces are identified: the glazing, the air flow, the absorber plate and the exterior walls of the sides and bottom. Each surface will have a certain temperature according to Fig. 3, dependant on the ambient conditions and the design of the collector. Energy balances for each of the four surfaces can be put together as an equation system for the entire collector and solved in Maple 2015. The energy balances will be set up with regards to the three possible ways of heat transfer; convection, conduction and radiation according to Fig. 3. Note that Fig. 3 displays the cross section of the collector and that the absorber will have absorbed some of the solar irradiation G, referred to as G_e. For explanation of all parameters used in the study, see the Nomenclature section of the appendix.

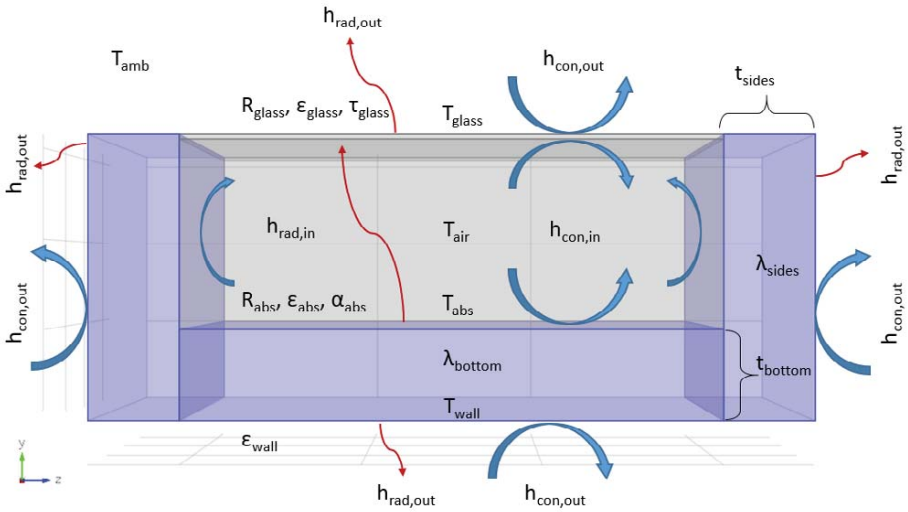

Fig. 3 : Schematic figure for all energy flows and temperatures that are included in the model for the collector. Energy balances for the glass, air flow, absorber and outer wall of the collector will be set up according to this figure. Blue arrows are representing convective heat transfer, red arrows are representing radiative heat transfer and lambdas are representing conductive heat transfer.

2.2.1 The glazing

The energy balance for the glazing consists of four energy flows according to Fig. 3. The warm absorber plate will radiate heat towards the glazing and the heated air flow will transfer heat to the glass by convection, which can be considered as the heat gains of the glazing. The heat losses of the glazing occur by radiation towards the sky and convection to the ambient air. Having identified the heat gains and losses of the glazing, the energy balance can be set up according to eq. 1.

$$h_{con,in} \cdot A_{abs} \cdot \left(\frac{T_{in}+T_{out}}{2} - T_{glass}\right) + h_{rad,in} \cdot A_{abs} \cdot \left(T_{abs} - T_{glass}\right) - h_{con,out} \cdot A_{abs} \cdot \left(T_{glass} - T_{amb}\right) - h_{rad,out} \cdot A_{abs} \cdot \left(T_{glass} - T_{sky}\right) = 0 \quad \text{(eq. 1)}$$

The external convective heat transfer coefficient $h_{con,out}$ is assumed to be a constant value of 20 W/(m²·K), but $h_{con,in}$, $h_{rad,in}$ and $h_{rad,out}$ needs to be calculated using relevant equations. Radiative heat transfer can be calculated according to eq. 2 for the heat radiating from the absorber and eq. 3 can be used to calculate the heat radiating from the glazing to the atmosphere (Incropera & Dewitt, 2002).

$$h_{rad,in} = \frac{\frac{1}{\frac{1}{\varepsilon_{abs}} + \frac{1}{\varepsilon_{glass}} - 1} \cdot \sigma \cdot \left(T_{abs}^4 - T_{glass}^4\right)}{T_{abs} - T_{glass}} \quad \text{(eq. 2)}$$

$$h_{rad,out} = \frac{\varepsilon_{glass} \cdot \sigma \cdot \left(T_{glass}^4 - T_{sky}^4\right)}{T_{glass} - T_{sky}} \quad \text{(eq. 3)}$$

The internal convective heat transfer coefficient for turbulent flows can be calculated using the definition of the Nusselt number according to eq. 4, where the definition of the hydraulic diameter of the collector can be found in eq. 5. For laminar air flows, $Re_{air} < 3000$, the Nusselt number is set to a constant value depending on the ratio between the height and the width of the collector (Incropera & Dewitt, 2002).

$$Nu = \frac{h_{con,in} \cdot D_h}{\lambda_{air}} \quad \text{(eq. 4)}$$

$$D_h = \frac{2 \cdot Height \cdot Width}{Height + Width} \quad \text{(eq. 5)}$$

To calculate the Nusselt number, eq. 6 can be used where the friction factor *f* is defined according to eq. 7. The Reynold number Re_{air} is calculated using the hydraulic diameter of the collector (Incropera & Dewitt, 2002).

$$\mathrm{Nu} = \frac{\left(\frac{\mathrm{f}}{8}\right) \cdot (\mathrm{Re_{air}} - 1000) \cdot \mathrm{Pr_{air}}}{1 + 12{,}7 \cdot \left(\frac{\mathrm{f}}{8}\right)^{\frac{1}{2}} \cdot (\mathrm{Pr_{air}}^{\frac{2}{3}} - 1)} \quad \text{(eq. 6)}$$

$$\mathrm{f} = (0{,}790 \cdot \ln(\mathrm{Re_{air}}) - 1{,}64)^{-2} \quad \text{(eq. 7)}$$

Using eq. 4 and eq. 6, the internal convective heat transfer coefficient can be calculated, resulting in all heat transfer coefficients of eq. 1 being identified as functions of various collector temperatures. Eq. 1 can now be used as one out of four equations of the equation system for the collector.

2.2.2 The air flow

Unlike the glazing, the air flowing through the collector will not absorb or emit any considerable amounts of heat radiation. The heat gains and losses of the air flow will thus only be convective heat transfer as well as the energy required to raise the temperature of the air. Since the air will contain moisture, especially in a sub-tropical country such as Mozambique, the water vapour passing through the collector should also be considered. Taking the water vapour into consideration will also be important for determining the drying rate.

The absorber and the inner sides of the collector will transfer heat to the air through convection, resulting in the first two terms of eq. 8, the energy balance of the air flow. At the same time, convective heat losses are likely to occur towards the glazing, resulting in the third term of eq. 8. Note that the absorber area and the glazing area are equally large. The fourth and fifth term of eq. 8 are representing the heat that is absorbed by the air flow, where the fourth term is dry air and the fifth term is water vapour.

$$\mathrm{h_{con,in}} \cdot \mathrm{A_{abs}} \cdot \left(\mathrm{T_{abs}} - \frac{\mathrm{T_{in}}+\mathrm{T_{out}}}{2}\right) + \mathrm{h_{con,in}} \cdot \mathrm{A_{sides}} \cdot \left(\frac{\mathrm{T_{abs}}+\mathrm{T_{glass}}}{2} - \frac{\mathrm{T_{in}}+\mathrm{T_{out}}}{2}\right) - \mathrm{h_{con,in}} \cdot \mathrm{A_{abs}} \cdot \left(\frac{\mathrm{T_{in}}+\mathrm{T_{out}}}{2} - \mathrm{T_{glass}}\right) - (\mathrm{T_{out}} - \mathrm{T_{in}}) \cdot \rho_{\mathrm{air}} \cdot \mathrm{C_{P,air}} \cdot \mathrm{u_{air}} \cdot \mathrm{A_{inlet}} - (\mathrm{T_{out}} - \mathrm{T_{in}}) \cdot \mathrm{C_{P,H2O}} \cdot \mathrm{m_h} = 0 \quad \text{(eq. 8)}$$

Using eq. 4-7, $h_{con,in}$ can be identified in eq. 8, resulting in the water mass flow m_h, being the only unknown parameter of eq. 8. The air velocity u_{air} is not considered as being temperature-dependent in the model and is set to a constant value. To determine the mass of water that passes through the collector each second, the relative humidity of the ambient air can be used. The relative humidity is defined as the ratio between the vapour pressure of the water and the saturation pressure of pure water at the same temperature (Alvarez H., 2006). This is shown in eq. 9.

$$\mathrm{RH} = 100 \cdot \frac{\mathrm{P_w}}{\mathrm{P_{ws}}} \quad \text{(eq. 9)}$$

To find the partial pressure of the water vapour, the saturation pressure needs to be calculated for a specific temperature. Using Antoine's equation, found below as eq. 10, the saturation pressure can be calculated where *A*, *B* and *C* are constants valid for a certain interval of temperatures (R.K.Sinnot, 2005).

$$\log(P_{ws}) = A - \frac{B}{T+C} \quad \text{(eq. 10)}$$

Combining eq. 9 and eq. 10 results in the partial pressure P_w being identified as a function of the air temperature. The water vapour in the air flowing through the collector can be assumed to be an ideal gas, meaning that the mass flow of water through the collector can be calculated according to eq. 11 (Atkins P. & de Paula J., 2002), resulting in all parameters of eq. 8 being identified as functions of various collector temperatures.

$$\mathrm{m_h} = \frac{\mathrm{P_w}}{\mathrm{R_V} \cdot \mathrm{T_{amb}}} \cdot \mathrm{A_{inlet}} \cdot \mathrm{u_{air}} \quad \text{(eq. 11)}$$

2.2.3 The absorber

The absorber plate contains one unique parameter, being the effective solar irradiation G_e. To calculate G_e, the optical properties of the glazing and the absorbers ability to absorb sunlight needs to be considered in terms of reflection, transmission and absorption. The resulting equation can be found in eq. 12. Note that expression contains no absorbance coefficient for the glazing, since the glazing is assumed to not absorb any sunlight.

$$G_e = \frac{G \cdot \tau_{glass} \cdot \alpha_{abs}}{1 - R_{abs} \cdot R_{glass}} \quad \text{(eq. 12)}$$

Having identified G_e, the full equation for the energy balance for the absorber is set up according to eq. 13. Note that the energy losses from the interior walls to the exterior walls of the collector have been included in the energy balance, where the interior walls are assumed to have the mean temperature of the absorber and the glazing.

$$\mathrm{G} - \mathrm{h_{con,in}} \cdot \left(\mathrm{T_{abs}} - \frac{\mathrm{T_{in}}+\mathrm{T_{out}}}{2}\right) - \mathrm{h_{rad,in}} \cdot \left(\mathrm{T_{abs}} - \mathrm{T_{glass}}\right) - \frac{\lambda_{\mathrm{bottom}}}{\mathrm{t_{bottom}}} \cdot \left(\mathrm{T_{abs}} - \mathrm{T_{wall}}\right) - \frac{\lambda_{\mathrm{side}}}{\mathrm{t_{side}}} \cdot \frac{\mathrm{A_{sides}}}{\mathrm{A_{abs}}} \cdot \left(\frac{\mathrm{T_{abs}}+\mathrm{T_{glass}}}{2} - \mathrm{T_{wall}}\right) - \mathrm{h_{con,in}} \cdot \frac{\mathrm{A_{sides}}}{\mathrm{A_{abs}}} \cdot \left(\frac{\mathrm{T_{abs}}+\mathrm{T_{glass}}}{2} - \frac{\mathrm{T_{in}}+\mathrm{T_{out}}}{2}\right) = 0 \quad \text{(eq. 13)}$$

The parameter $h_{con,in}$ is calculated using the same method as for the glazing and the parameter $h_{rad,in}$ is calculated using eq. 2.

2.2.4 The external walls of the collector

The external walls of the collector include the bottom and the sides of the collector. The amount of heat being transferred from the external walls to the ambience are important to acknowledge, since these will correspond to the amount of heat that is lost through the insulation. All heat gains to the exterior walls will be heat being conducted from the interior or the collector through the insulation layer, as shown in first two terms of eq. 14.

$$\frac{\lambda_{\mathrm{bottom}}}{\mathrm{t_{bottom}}} \cdot \left(\mathrm{T_{abs}} - \mathrm{T_{wall}}\right) + \frac{\lambda_{\mathrm{side}}}{\mathrm{t_{side}}} \cdot \frac{\mathrm{A_{sides}}}{\mathrm{A_{abs}}} \cdot \left(\frac{\mathrm{T_{abs}}+\mathrm{T_{glass}}}{2} - \mathrm{T_{wall}}\right) - \mathrm{h_{con,out}} \cdot \frac{(\mathrm{A_{abs}}+\mathrm{A_{sides}})}{\mathrm{A_{abs}}} \cdot \left(\mathrm{T_{wall}} - \mathrm{T_{amb}}\right) - \mathrm{h_{rad,out1}} \cdot \left(\mathrm{T_{wall}} - \mathrm{T_{amb}}\right) - \mathrm{h_{rad,out1}} \cdot \frac{\mathrm{A_{sides}}}{2 \cdot \mathrm{A_{abs}}} \cdot \left(\mathrm{T_{wall}} - \mathrm{T_{amb}}\right) - \mathrm{h_{rad,out2}} \cdot \frac{\mathrm{A_{sides}}}{2 \cdot \mathrm{A_{abs}}} \cdot \left(\mathrm{T_{wall}} - \mathrm{T_{sky}}\right) = 0 \quad \text{(eq. 14)}$$

The heat losses of the external walls will occur by convection affecting the sides and the bottom, but also by radiation. The sides have been assumed to radiate 50 % towards the atmosphere and 50 % to the ground and the bottom of the collector will radiate towards the ground. This can be seen in eq. 14 as the last three terms, where $h_{rad,out1}$ and $h_{rad,out2}$ are calculated according to eq. 15 and eq. 16 respectively. The ground is assumed to have the same temperature as the ambient air, T_{amb}.

$$\mathrm{h_{rad,out1}} = \varepsilon_{\mathrm{wall}} \cdot \sigma \cdot \frac{\mathrm{T_{wall}^4} - \mathrm{T_{amb}^4}}{\mathrm{T_{wall}} - \mathrm{T_{amb}}} \quad \text{(eq. 15)}$$

$$\mathrm{h_{rad,out2}} = \varepsilon_{\mathrm{wall}} \cdot \sigma \cdot \frac{\mathrm{T_{wall}^4} - \mathrm{T_{sky}^4}}{\mathrm{T_{wall}} - \mathrm{T_{sky}}} \quad \text{(eq. 16)}$$

After identifying equations for energy balances for the glazing, the air flow, the absorber and the external walls of the collector, an equation system for eq. 1, eq. 8, eq. 13 and eq. 14 can be set up and solved for T_{out}, T_{abs}, T_{glass} and T_{wall}. To create more accurate results, the equation system can be solved multiple times after dividing the collector into segments, also known as the finite element method. The segments are distributed over the length of the collector and the equation system is solved individually for each segment. The calculated outlet air temperature of the first segment can then be used as the input temperature for the air flow of the next segment. As an example, if a 1 m long collector is divided into two segments the first segment will include the first 0,5 m of the collector and show the mean temperatures for that length. The reason why more segments enhance the accuracy of the simulation is because the radiative heat transfer

coefficient will vary from segment to segment in a non-linear manner.
The number of segments that can be used are unlimited using Maple 2015, but a higher number of segments (a higher resolution) will result in a slower simulation speed. The resolution used to generate the results of the study was set to 250, which can be regarded as more than sufficient for solar collectors since they are generally rather short.

2.3 The dryer

Once the air has been heated up in the solar collector, it will enter the dryer containing the SAP-pouches. The dryer is modelled according to Fig. 4, where three surfaces can be identified; the dryer air flow, the internal- and the external walls of the dryer. Unlike the collector, the dryer will be split up in segments according to the number of shelves within the dryer, where each shelf will hold a certain number of SAP-pouches from which water will evaporate. Note that Fig. 4 is an example of a dryer section for a dryer holding one SAP-pouch per shelf. The released water from the shelves will accumulate from shelf to shelf, which will increase the resistance for evaporation of the bags further up in the dryer.

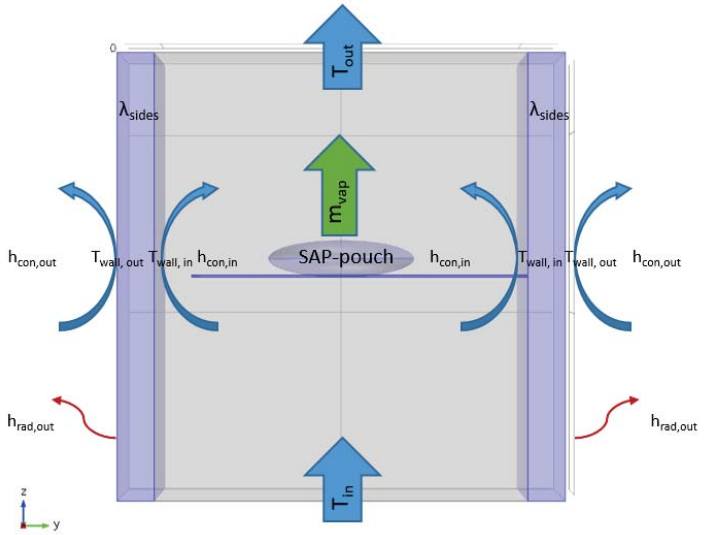

Fig. 4 : Schematic figure for all energy flows and temperatures that are included in the model for the dryer. Energy balances for the air flow, inner and outer wall of the collector will be set up according to this figure.

2.3.1 The internal walls of the dryer

The energy balance for the internal walls of the dryer include convective heat transfer from the dryer air flow as well as conductive heat transfer through the dryer insulation layer, shown in eq. 17.

$$h'_{con,in} \cdot \left(\frac{T_{in}+T_{out}}{2} - T_{wall,in}\right) - \frac{\lambda_{dryer}}{t_{side}} \cdot \left(T_{wall,in} - T_{wall,out}\right) = 0 \qquad \text{(eq. 17)}$$

Note that $h'_{con,in}$ is calculated using the same method as for the collector, but the air velocity in the dryer could differ from the collector. If the cross section area of the dryer is larger than the cross section area of the collector, the air velocity will be lower in the dryer than in the collector. A different air velocity and a different cross section will result in a new Reynold's number, meaning that the flow characteristics of the collector and the dryer could be different. For this reason, the Reynold's number for the dryer needs to be calculated.

2.3.2 The external walls of the dryer

The energy balance for the external sides of the dryer is set up according to the same method used for the collector sides in section 2.2.4, meaning that half of the heat radiation will radiate towards the ground and half will radiate towards the sky. The resulting equation can be found in eq. 18, in accordance with Fig. 4. One parameter that has been added to the energy balance for the external walls of the dryer is the additional heat gain z. The additional heat gain represents the average solar irradiation of all four outer walls of the dryer. The additional heat gains will increase the outer wall temperature of the dryer, which will reduce the heat losses through the walls or, if the outer walls are warmer than the inner walls, add heat to the air.

$$\frac{\lambda_{dryer}}{t_{side}} \cdot \left(T_{wall,in} - T_{wall,out}\right) - h_{con,out} \cdot \left(T_{wall,out} - T_{amb}\right) - \frac{1}{2} \cdot h_{rad,out1} \cdot \left(T_{wall,out} - T_{amb}\right) - \frac{1}{2} \cdot h_{rad,out2} \cdot \left(T_{wall,out} - T_{sky}\right) + z = 0 \quad \text{(eq. 18)}$$

2.3.3 The dryer air flow

For the dryer air flow, the same method used in section 2.2.2 for the collector air flow is used with the addition of a mass flux of water vapor from the SAP-pouches. This means that the calculations need to include an accumulation of the water molecules from shelf to shelf. For the first shelf, the inlet mass flux of water will be according to the absolute humidity which was calculated in the collector, m_h, while the outlet mass flux will also have gained water vapour from the SAP-pouches of the first shelf. The outlet mass flux of water from the first shelf will then be used as input for the inlet mass flux of water for the second shelf. Also note that the shelf is placed in the center of the dryer section, meaning that the SAP-pouch will have the section mean air temperature at steady state. The full expression used for the dryer air flow can be found in eq. 19, where E_{vap} corresponds to the amount of energy absorbed by the SAP-pouches, see eq. 20.

$$\left(T_{in} - T_{out}\right) \cdot \rho_{air} \cdot C_{P,air} \cdot u_{air} \cdot A_{inlet,dryer} - h'_{con,in} \cdot A_{sides} \cdot \left(\frac{T_{in}+T_{out}}{2} - T_{wall,in}\right) + \left(T_{in} - T_{out}\right) \cdot Cp_{H2O} \cdot m_h + \left(\frac{T_{in}+T_{out}}{2} - T_{out}\right) \cdot Cp_{H2O} \cdot m_{vap} - E_{vap} = 0 \quad \text{(eq. 19)}$$

$$E_{vap} = m_{vap} \cdot \Delta h_{vap,H2O} \quad \text{(eq. 20)}$$

Combining eq. 19 and eq. 20, the only unknown parameter is m_{vap}, which can be regarded as the drying rate of the SAP-pouches. For this reason, finding a good way to calculate m_{vap} is essential to evaluate the solar dryer performance. Since SAP-pouches can consist of various materials, the drying rate will differ depending on the pouch material (Phinney et al., 2015). For this study, measurements were provided from a separate study[1] where the drying rate of a specific type of SAP-pouch was measured for different temperatures, air flow rates and relative humidity. The data provided from the measurements were used to create a mathematical expression for the drying rate as a function of relative humidity and air velocity, shown in eq. 21.

$$m_{vap} = \frac{A_{bags}}{3600} \cdot \left(-1{,}0015 \cdot u_{bags} - 0{,}9565\right) \cdot RH + 0{,}3088 \cdot u_{bags} + 0{,}6297 \quad \text{(eq. 21)}$$

Note that the SAP-pouches will obstruct the air flow, reducing the effective cross section area of the dryer. To take this into consideration, the air velocity used to calculate the drying rate u_{bags} is calculated for the effective cross section area of the dryer. In other words, placing more SAP-pouches per shelf results in a higher u_{bags}.
The relative humidity *RH* of eq. 21 is calculated for the conditions around the SAP-pouches, i.e. the absolute humidity and the dryer air temperature.

3. Results

The main aim of the study was to create a calculation tool in Maple 2015 which can be used to generate approximate values for the drying rate and various temperatures for a user defined design of a solar dryer. Using the method described a calculation tool was built capable of simulating temperatures for the absorber, the glazing, the air flow and the external walls of the collector as well as the drying rate and temperatures of the air flow, internal- and external walls of the dryer. However, it was also decided to include a parametric study to find ways of improving the solar dryer performance. Several parameters were examined, where the most important ones will be presented in this paper with regards to temperature increase, drying rate how and suitable the solution would be to a developing country.

[1] Phinney, R. Unpublished data. Department of Food Technology, Engineering and Nutrition. Lund University

3.1 Adding fins to the absorber plate

To simulate fins being added to the absorber plate, a factor was added to the second term of eq. 13, being the convective heat transfer from the absorber plate to the air flow. As an example, a convective heat transfer factor of 2 means that fins with a total area equal to the absorber plate have been installed. A factor of 3 means that the area of the fins is twice as large as the collector plate and so on. The outlet air temperature of the collector, i.e. the inlet air temperature for the dryer, for various convective heat transfer factors can be found in Fig. 5. A schematic example of a collector with fins can be found in Fig. 7.

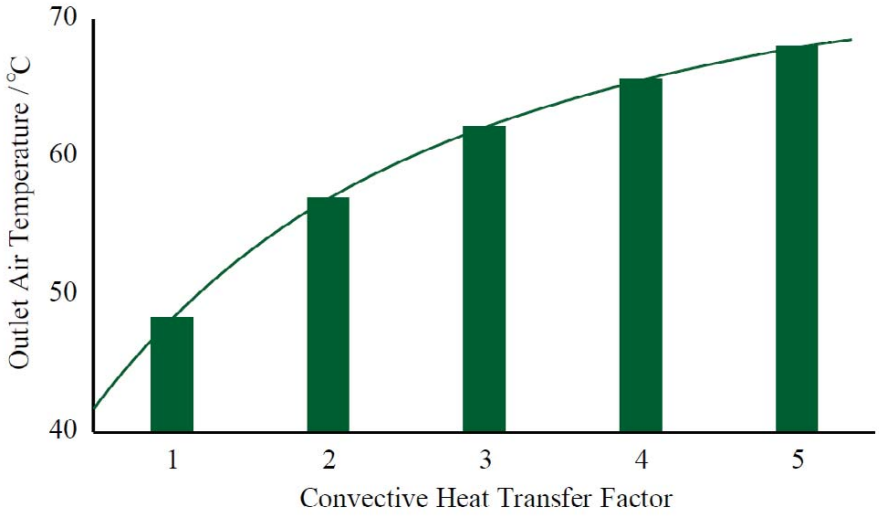

Fig. 5 : Calculated outlet temperatures of the collector for the base scenario for different convective heat transfer coefficient factors of the absorber.

3.2 Varying the number of SAP-pouches in the dryer

The number of SAP-pouches placed in the dryer is likely to affect the drying rate, since more bags per shelf will cause greater accumulation of water vapour from shelf to shelf. Varying the number of pouches placed per shelf is also a way of simulating the effects of uncertainties of the equation used for the drying rate, eq. 21. For the results of the study, simulations were made for 1, 2 and 3 pouches per shelf for a dryer with 8 shelves. The results for the drying rate per shelf can be found in Fig. 6.

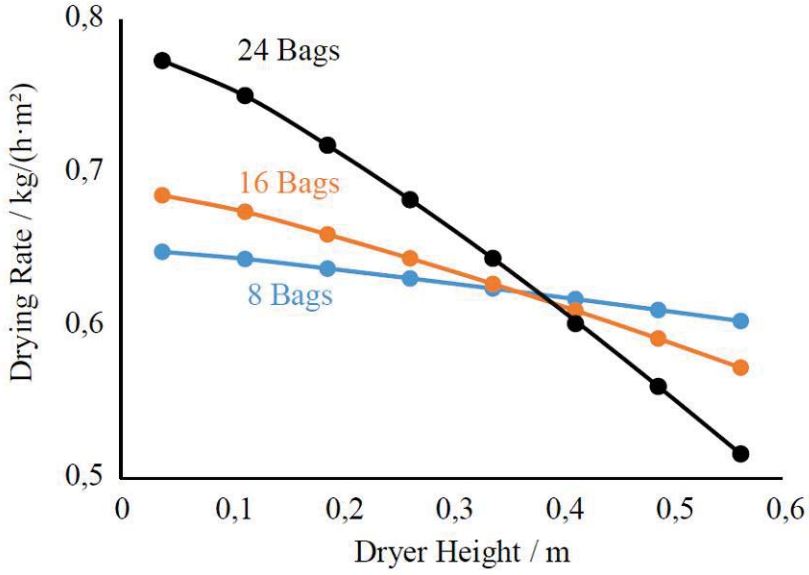

Fig. 6 : Simulated values for the drying rate for one (blue), two (orange) and three (back) SAP-pouches per shelf. Each dot represents one of the eight shelves inside the 0,6 m high dryer.

4. Discussion

4.1 Adding fins to the absorber

Increasing the outlet air temperature of the collector is a good method for increasing the drying rate. For the model used in this study, a higher air temperature results in a lower relative humidity inside the dryer, which increases the drying rate in eq. 21. Several different methods can be used to increase the air temperature of the collector, but it's important to consider which methods that are applicable in a developing country.

To avoid potential problems with complex materials unsuitable for developing countries, fins can be built using cheap materials with sufficient heat conductivity, see Fig. 7. The fins will conduct heat from the absorber, practically resulting in the contact area between the air flow and the absorber to be increased. As shown in Fig. 5, adding fins has good potential of increasing the collector air temperature and thus the drying rate. The air temperature gains from adding fins appears to decrease exponentially with increased convective heat transfer coefficients. This indicates that fins are most efficient for low convective heat transfer coefficients, as the temperature gains from adding excessive amounts of fins may not justify the material costs.

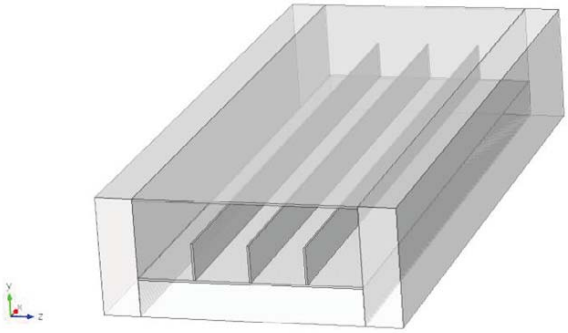

Fig. 7 : Schematic picture of a solar collector with fins attached to the absorber.

4.2 Potential problems with overloading the dryer

As shown in Fig. 6, the drying rate of the SAP-pouches will differ from the entrance to the outlet of the dryer. The pouches placed on the first shelf, closest to the entrance, will be exposed to a lower relative humidity than the pouches placed further up in the dryer. This occurs due the absolute humidity being higher further up in the dryer as well as the temperature being lower, since heat will be absorbed by the pouches and lost through the walls. Both the lower air temperature and the higher absolute humidity will result in a higher relative humidity, which reduces the drying rate. Also, if the SAP-pouches are obstructing a large portion of the dryer cross section area the air velocity surrounding the pouches will be higher, which according to the model will result in a higher drying rate. This can be seen in Fig. 6, where the drying rate for the first shelf is considerably higher when placing three pouches per shelf compared to placing one pouch per shelf.
Bearing the variations of the drying rate this in mind, it's important to acknowledge that every pouch placed in the dryer is required to have a sufficient drying rate. If the drying rate variation is too great, it could result in only the pouches placed on the first shelf to dry out completely. The lower drying rate of the remaining shelves could also cause the drying process to become too slow, resulting in the contents of the pouches becoming spoiled.

To avoid the problem described, there are two parameters worth considering; the volumetric air flow of the dryer and the number of SAP-pouches placed in the dryer. Increasing the volumetric air flow in the dryer results in better ventilation of the vapour generated by the pouches. To increase the volumetric air flow, the air velocity in the dryer could be increased. This will have two positive effects according to eq. 21, as the air velocity is increased and the relative humidity is decreased.
But increasing the volumetric air flow also has negative effects on the drying rate. Since the dryer is connected to the collector, the volumetric air flow will also be increased inside the collector. This will result in lower air temperatures in the collector and thus in the dryer.
Furthermore, increasing the air flow could require installations of fans. While fans are very likely to improve the solar dryer performance, they may not be a suitable solution in a developing country since a source of electricity is required. As a conclusion, finding a good balance between the collector outlet temperature, the dryer air velocity and the number of pouches placed in the dryer is the key to designing a good solar dryer.

POTENTIAL APPLICATION OF SOLAR PROCESS HEAT IN THE MEAT SECTOR CONSIDERING HEAT RECOVERY AND INDUSTRIAL HEAT PUMPS AS COMPETING TECHNOLOGIES

Felix Pag[1], Bastian Schmitt[1] and Klaus Vajen[1]

[1] Institute of Thermal Engineering, Kassel University, Kassel (Germany)

Abstract

Food industry, specifically the slaughter and meat processing industry, is a promising field for solar process heat. Several processes, such as scalding or hot water generation for washing and cleaning, offer feasible integration points due to the low temperature level and conventional heating equipment. For the German meat sector, a technical potential of one million square meters of collector area was estimated. However, heat recovery systems can reduce this potential significantly, especially if they are installed in combination with industrial heat pumps. Thus, the questions arise how heat recovery systems can be operated most economically with respect to the condensation temperature of compression chillers and which influences have to be expected for the integration of solar heat and industrial heat pumps.

Keywords: Solar process heat, Slaughter and meat processing industry, Heat recovery, Industrial heat pumps

1. Introduction

Based on the temperature level and constant high heat loads, the food and beverage industry hast the highest potential for solar heat in industrial processes (Schmitt et al., 2015). However, the market penetration of solar process heat failed to meet the expectations in this field of application based on several reasons. One crucial point is the identification of a feasible integration point which can be very complex. Due to a high hot water demand for washing and cleaning purposes, the German slaughter and meat processing industry has been analyzed regarding that fact. Based on the high cooling demand for preserving the meat products, low temperature waste heat from compression chillers plays a particularly important role for the evaluation of solar heat integration. Additionally, the waste heat offers the opportunity to install industrial heat pumps using it as heat source ending up in an improved efficiency.

2. Suitable applications and technical potential of solar process heat in the German slaughter and meat processing industry

In contrast to other branches of the food industry the diversity of heat consuming processes in the slaughter and meat processing industry is rather limited as a literature research has proven. Additionally, the heat demand is mostly limited to process temperatures below 100 °C. This demand is dominated by the preparation for hot water which is especially used for washing and cleaning processes. To reduce the bacteria load, the carcasses as well as any utility that have been in contact with the carcasses has to be cleaned regularly. Especially the cleaning of animal transporters, which is done after unloading on site, guarantees a constant warm water demand. At least once a day, all production rooms have to be lathered and cleaned.

The slaughter processes of pigs and poultry are very comparable. After several prewashing steps with warm and cold water, the carcasses have to be scalded at temperatures between 50..65 °C, making the subsequent step of bristle removing and de-feathering much easier. Therefore, the carcasses are moved through one or

doi:10.18086/eurosun.2016.02.20 Available at http://proceedings.ises.org

several warm water baths. These baths have to be kept at temperature during all time which is ensured by external heat exchangers or steam injections. However, due to the high bacteria load and the carryover by the carcasses, fresh water has to be fed constantly. But, the bacteria load can only be reduced to a certain extent by feeding fresh water. Consequently, the whole bath capacity has to be changed at least once a day. In alternative to these baths, the carcasses can also be sprayed with warm water which ensures a reduced water and energy demand in addition to a reduced bacteria load on the carcasses. The bristles and feathers are removed by scrapers and rollers, partially supported by valves which spray warm water on the carcasses. Pigs have to be processed in a gas oven additionally, where any remaining bristle is burned at temperatures above 200 °C. The carcasses of cattle don't have to be scalded, because the skin is peeled off. In summary, there are several integration points for the use of solar process heat in the slaughter industry: The integration on the supply level using the hot water network is just as feasible as the integration on the process level, for example maintaining the bath temperature in scalding processes in the set temperature range.

Beside the supply of hot water for cleaning, it is more complicated to integrate solar heat in processes in the meat processing industry. The filling of kettles and other machineries in cooking and pasteurizing processes at the beginning of every day or batch can be done with solar heated water. In contrast, the use of solar heat for the continuous heat demand to maintain or increase the process temperature is very often restricted by technical reasons and the conventional heating equipment.

Other processes such as smoking and maturing are conventionally heated by steam, gas burners, or electrical heaters. Although the products are processed at relatively low temperatures, the integration of solar heat is difficult due to the conventional heating equipment. Depending on the product, the temperature range of smoking can vary between 10 to 100 °C while the process time is inversely proportional to the temperature. Often steam is used directly to generate smoke, which makes it almost impossible to replace it by solar heat. In these cases, the limited space does not allow the retrofit for a water based heating system which is necessary for the utilization of solar heat. However, in case of a significant amount of direct steam consumption, the required make-up water can be supplied with solar heat easily.

Whereas in smoking chambers it is not possible to integrate solar heat, maturing halls, for example for sausages, is more promising instead. The maturing process can take up to several days or even weeks. During this time, the products are placed in big halls which are temperature- and humidity-controlled. Steam injections for heating and humidification on the one hand and cooling machines for cooling and dehumidification on the other hand try to control temperature and humidity in a very small range, which is necessary for an optimal maturing result. If the control is not balanced here, there is a relevant potential for energy savings. Since maturing halls typically have a lot of available space and a relative continuous load profile, it can be possible to replace the conventional heating by steam injections to water heating surfaces here. Such modification would allow the efficient use of solar heat at a low temperature level here.

There are several processes, especially for a dry heat treatment as baking or roasting, where the use of solar heat is impeded– on the hand due to the temperature level and on the other hand due to the fact that the conventional heating is based on direct electrical heating.

To sum up, there are several promising integration points in heat consuming processes within the slaughter and meat processing industries as shown in Tab. 1. In both industries the majority of the heat demand is used for hot water preparation, which makes it generally easy to identify a suitable integration point for solar heat on supply level. The use of solar process heat in maturing halls is a very promising application on process level due to the very low temperature level and the constant heat demand due to dehumidification.

Tab. 1: Heat consuming processes in the slaughter and meat processing industries regarding the potential for the use of solar process heat; The solar potential is evaluated with respect to the climate in Central Europe

Process	Temperature level	Annotations	ST Feasibility
Both sectors			
Cleaning and Washing Processes	50..60 °C	High and constant hot water demand, simple integration at supply level	+
Make-up water	15..95 °C	Material use of steam requires constant replacement of feed-water	+
Slaughter Industries			
Scalding	50..65 °C	Bath filling and refilling with solar heated water and continuous bath heating	+
Singeing	> 200 °C	No potential due to conventional heating equipment	-
Meat Processing Industries			
Scalding and Cooking	60..100 °C	Bath filling with solar heated water. Continuous heating not feasible	0
Pasteurizing	80..100 °C	Possible use of solar heat depends on heating equipment	0
Sterilizing	> 100 °C	Temperature level and heating equipment impede the use of solar heat	-
Smoking	10..100 °C	No potential due to conventional heating equipment	-
Maturing	15..25 °C	Promising application, needs modification of heating equipment	0
Baking, Frying, Roasting	> 200 °C	No potential due to conventional heat supply and heat transfer	-

Based on the process analysis, a technical potential for use of solar process heat in the German meat sector has been calculated. The overall energy demand in the German slaughter and meat processing industry was 7.3 GWh in 2011 (BMEL, 2013), whereby 58 % of the energy was consumed for heat generation by fossil fuels[1] (excluding heat generated by electricity). Almost 60 % of the heat demand is eased by the meat processing industry, whereas 40 % are consumed in slaughter houses. The heat supply is dominated by the central combustion of natural gas feeding steam or hot water networks distributing the process heat.

In slaughter houses for cattle and poultry, all heat demand, as shown before, is needed at a temperature level below 100 °C which makes it very feasible for solar heat. During the slaughter process of pigs, there is also a heat demand at a higher temperature level for the bristle burning which accounts for 30 % of the heat demand in the pig slaughter process (Rosenwinkel, 2014). Taking into account the average heat demand per carcasse (weight) (VDI, 2009) and the absolute slaughter figures (Maennel, 2014), the heat demand can be distributed to heat which is needed below 100 °C (78.4 %) and above (21.6 %). Using the methodology of Lauterbach et al. (2012), taking into account a potential for efficiency measures, competing technologies and a limited solar fraction as well as suitable roof areas, there is a technical potential for solar heat of 172.4 GWh_{th} (383,000 m^2[2]) in slaughterhouses.

For the meat processing industry, it has to be relied on cross-sectoral data for the food industry presented by Nast et al. (2010), whereas 43 % of the heat demand is needed below 100 °C, 41 % between 100..150 °C and 16 % above. This results in a technical potential of 239.5 GWh_{th} (532,000 m²) with respect to a feasible

[1] Electricity which is used for heat generation, for example in baking processes, is not included here.
[2] Assuming a solar yield of 450 kWh/m²a.

temperature level up to 150 °C.

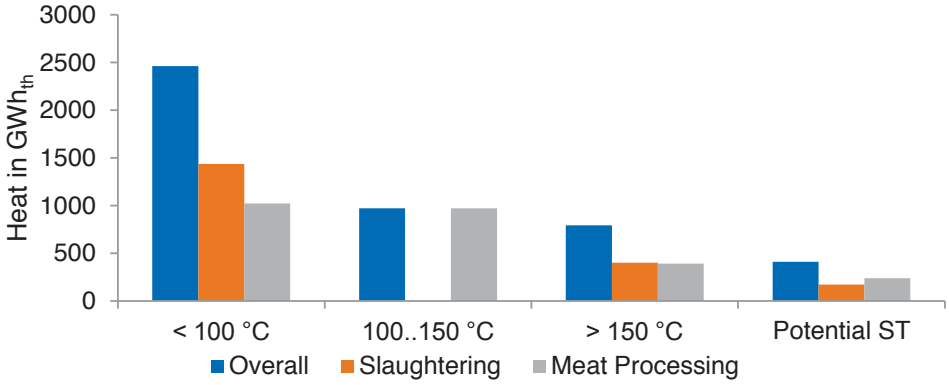

Fig. 1: Distribution of the heat demand and technical potential for solar process heat in the German slaughter and meat processing industry

In total, referring to Fig.1, there is a technical potential for solar process heat of almost 412 GWh$_{th}$ (< 150 °C) in the German slaughter and meat processing industry which is corresponding to a collector potential of almost 1,000,000 m².

However, this potential has to be seen in relation to the massive potential for low temperature waste heat due to the widespread application of compression chillers. Here, it is estimated that more than 114,000 cooling systems are operated up to a cooling capacity in the megawatt range (Steimle et al., 2002). Following Preuss (2011) this potential can be calculated assuming an average COP (Coefficient of Performance) depending on the cooling temperature[3], operational time and installed cooling capacity with respect to the size of the company. Using eq. 1, a theoretical potential for heat recovery (hr) from compression chillers can be calculated.

$$\dot{Q}_{hr} = P_{el} \cdot (COP + 1) \qquad \text{(eq. 1)}$$

Theoretically, there is a potential for low temperature waste heat from compression chillers of 5.2 TWh$_{th}$ in the German meat sector, whereby this potential exceeds twice heat demand below 100 °C in this sector and the technical potential for solar process heat by the factor 10. Still, only a share of this heat recovery potential can be exploited due to the low temperature level (20..40 °C), the lack of storage possibilities and other technical limitations. Still, this comparison shows that waste heat can massively reduce that potential of solar heat using it for example for water preheating.

3. Heat generation costs of industrial heat pumps

Industrial heat pumps have a great potential to cover the low temperature process heat demand in industrial applications, especially if waste heat with a temperature about 30 to 40 °C can be used as heat source in the evaporator. Still, there are only a few industrial heat pumps (approx..80 in 2011) installed in Germany so far (Preuss, 2011) but the market development is positive. In the meantime heat pumps with a thermal capacity up to a double-digit MW$_{th}$ range are available. Supply temperatures with single-stage heat pumps can reach up to 75 °C. Beyond that, the heat pump has to be operated two-staged. There, even supply temperatures above 100 °C can be provided. In general, heat pumps and solar thermal systems have in common that they can work most efficiently if they produce heat at a low temperature level. Thus, even if they can be installed in combination with solar thermal systems they are a concurrent technology to solar process heat.

To evaluate the competitive situation, the heat generation costs of single-stage industrial heat pump systems are calculated with fixed parameters in a reference scenario for the design data. Part-load performance or a

[3] For this calculation, it is assumed that normal refrigeration accounts for 40 % and deep freezing accounts for 60 %.

certain load profile have not been respected. The parameters of this scenario are given in Tab. 2.

The heat generation costs are calculated over a period of 20 years with the annuity method. The investment and installations cost are taken from Lambauer et al. (2008). As it can be seen in fig. 2, the specific costs per installed capacity are heavily decreasing with the thermal capacity of the heat pump system until a capacity of 500 kW_{th}. Beyond that, the specific investment costs are more or less the same. Regarding the investment costs, the conditions of German subsidies are taken in to account[4] for the calculation of the heat generation costs. The supply temperature, the heat pump has to provide, is 65 °C (hot water generation) whereas the source temperature is 30 °C. This source temperature can easily be provided by the compression chillers' waste heat referring to a condensation temperature of 35 °C considering a temperature difference of 5 K for the heat exchanger.

Tab 2: Parameters of the reference case for the calculation of the heat generation costs of an industrial heat pump

Parameter	Value
κ_{el}	0.15 ct/kWh_{el}
$T_{E,HP}$	30 °C
$T_{C,HP}$	65 °C
$\dot{Q}_{HP}$	300 kW_{th}
Full Load Hours	1530 h/a
j_{el}[5]	1 %/a
Refrigerant	R134a

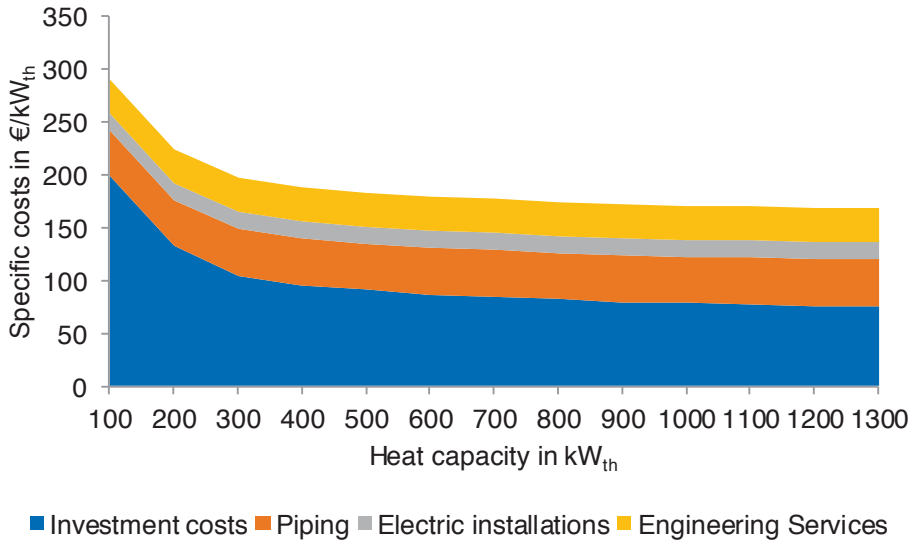

Fig. 2: Investment and additional cost for the installation of an industrial heat pump from Lambauer et al. (2008)

With the given parameters, the heat generation costs are 3.9 €-ct/kWh_{th}.

Subsequently, the sensitivity of these parameters is analyzed to quantify their effects on the heat generation costs. The results of the sensitivity analysis with a variation of the parameters by 50 % are given in Fig. 3

[4] Heat pumps with a heating capacity of > 100 kW_{th}, 30 % of the total investment cost can be funded.
[5] Increase of electric costs in %/a

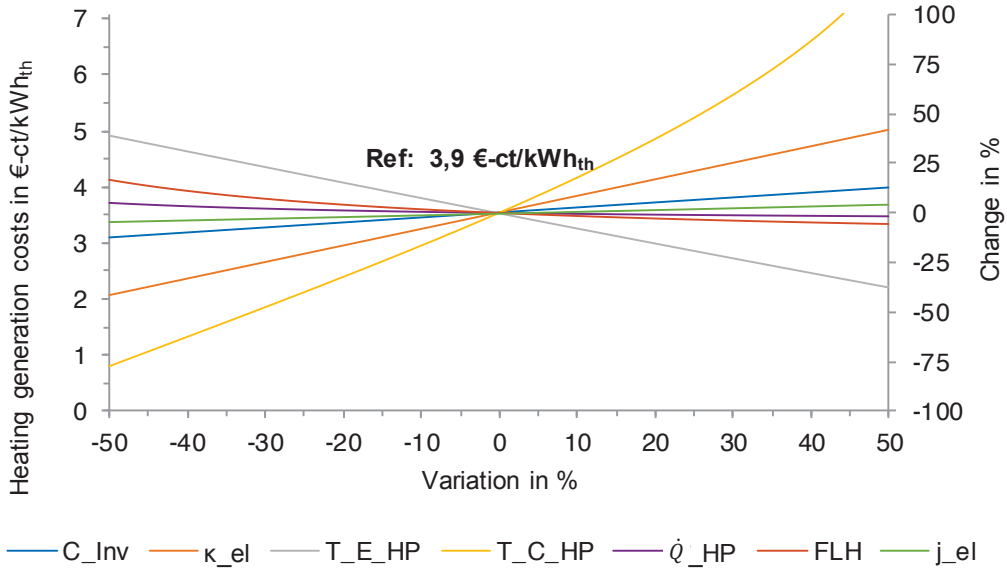

Fig. 3: Results of the sensitivity analysis with the absolute heat generation costs (left axis) and the change in percentages (right axis)

The sensitivity analysis underlines that the main determining parameters for the heat generation costs are on the one hand the temperatures of the low temperature heat source (TE,HP) and the heat sink (TC,HP) and on the other hand the price for electric energy (κel). The influence of the total investment costs (CInv), in contrast, are less relevant. Here, an increase of the investment costs by 50 % only results in an increase of the heat generation costs of 12 %. Such an increase of the price for electric energy would lead to heat generation costs of about 5 €-ct/kWh$_{th}$ (+ 41,7 %). The operational time and the amount of delivered heat does also only play a minor role due to the fact that the investment costs are less relevant. Decreasing the operation time does only result in higher investment costs per delivered heat. But this change in the heat generation costs secondarily in relation to the operation costs for electricity.

As the price of electricity and the operation temperatures of the heat pump has been determined as the key factors for the heat generation costs of an industrial heat pump, several simulations has been carried out with varying parameters. The results are given in fig. 4. There, the heat generation costs are given in dependence of the temperature lift of the heat pump (x-axis) and the price of electricity (y-axis) for a process temperature of 60 °C (e.g. hot water preparation). The temperature loss which has to be taken into account due to the use of heat exchangers is already respected. Thus, if the waste heat temperature, which is used as heat source for the heat pump, is about 30 °C and the process temperature 60 °C, a temperature lift of 30 K has to be used in the diagram. The efficiency of the heat pump is calculated with additional 10 K, resulting in a temperature lift of 40 K. As it can be seen, quite low heat generation costs can be achieved by a heat pump if waste heat at a suitable temperature is constantly available. With the given example (ΔT_{HP}=30 K), the heat generation costs would be in the range of less than 3 ct/kWh$_{th}$ up to 5 ct/kWh$_{th}$ depending in the price of electricity. These costs can be very different, even in industries, especially if there is a high electricity demand. Obviously other waste heat sources apart from compression chillers might be used as well.

$\dot{Q}$

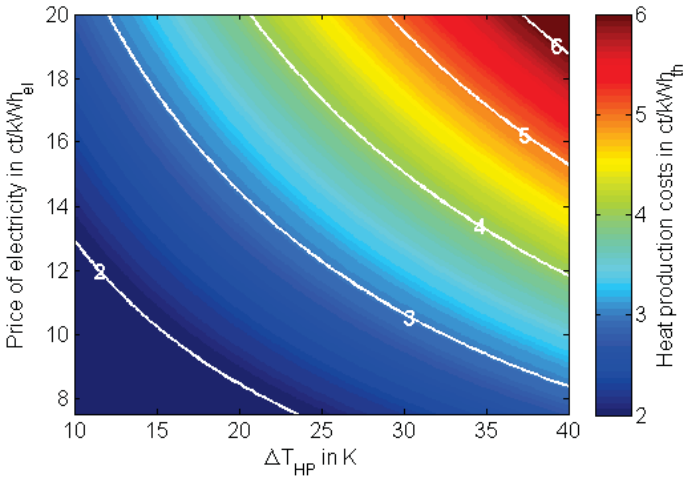

Fig. 4: Heat generation costs in €-ct/kWh$_{th}$ of industrial heat pumps in dependence of the temperature lift the heat pump has to provide (x-axis) and the price of electricity (y-axis) for a process temperature of $T_{Process}$=60 °C

4. Optimized operational mode of compression chillers with respect to the condensation temperature

As shown in Section 2, there is a huge theoretical potential for the use of waste heat from compression chillers. The subsequent technical potential is mainly dependent on the temperature level in the condenser (T_C) which can be varied according to the system and the temperature in the evaporator (T_E). Generally, this condensing temperature has to be chosen as low as possible, operating the compression chiller as efficient as possible (high COP) according to Eq. 2, whereas the evaporating temperature (T_E) is typically limited by the transfer and distribution of the cooling energy in the cooling room. Calculating the COP via the temperatures T_C and T_E, only gives the theoretical optimum. In practice, the COP is much lower due to technical reasons.

$$COP = \frac{\dot{Q}_c}{P_{el}} = \frac{T_C}{T_C - T_E} \qquad \text{(eq. 2)}$$

However, there is also a minimum for the condensation temperature, which is given by the installations for recooling and the ambient conditions. It has to be guaranteed, that the waste heat from the compressor can always be dissipated by air or water cooling. For air cooling, the condensation pressure has to be chosen to result in a condensation temperature which is about 10 K above the ambient air. So, the chiller works with a floating condensation temperature over the year in dependence of the air temperature resulting in a changing efficiency (COP), too. In case of water cooling, the wet-bulb temperature, which is always below the ambient air temperature, determines the condensation temperature. Very often, especially with outdated chillers constant condensation levels over the year can be found in industry, resulting in inefficient operation during the majority of the year.

As shown before, a low condensation level results in an efficient cooling system. In contrast, a higher condensation temperature might result in a higher amount of heat that can be used. Thus, the operator ends up in a target conflict between an efficient cooling system and an increased waste heat potential. To find the optimal solution, simple considerations were made with respect to the design values. As before, regarding the consideration of the heat pump, neither a part-load behavior of the compressor or the whole chiller nor any specific cooling load were considered. On the one hand, the additional amount of waste heat energy (ΔQ_{hr}), that can be used for water preheating by increase of the condensation temperature by 1 K can be determined with Eq. 3 if the daily hot water demand ($V_{HW,d}$) is known.

$$\Delta Q_{HR} = V_{HW,d} \cdot c_{p,HW} \cdot 1K \qquad \text{(eq. 3)}$$

On the other hand, you have to take into account the additional amount of electric energy per day, you have to use for the less efficient cooling system (Eq.4). Here, the factor f is used to approximate the decline of efficiency.

$$W_{el,d,new} = f \cdot W_{el,d,old} \qquad \text{(eq. 4)}$$

Afterwards, the relation of saved costs by the surplus of recovered heat to the extra costs for electricity has to be considered with the specific costs for heat (κ_{th}) and electricity (κ_{el}). K_{hr} represents the saved costs by increasing the condensation temperature. Subsequently conventional energy needed for heating the water can be saved. K_{el}, however, represents the additional cost for electricity which have to be paid due to the less efficient cooling system.

$$\frac{K_{hr}}{K_{el}} = \frac{V_{WW,d}}{W_{el,d,old}} \cdot \frac{\kappa_{th}}{\kappa_{el}} \cdot \frac{c_{p,W} \cdot 1K}{f} \qquad \text{(eq. 5)}$$

As shown in Eq. 5, there are two ratios which determine the most cost efficient mode of operation. At first, this is the ratio between the amount of water that can be preheated by the heat recovery system. The more water can be heated, the more interesting it can be to use the chiller as a heat pump, whereas this is less attractive if there is a lot of electric energy demand for cooling. The second ratio is the relation between the costs for heat and electricity which play an important role. In case of a company that has to pay high prices for electricity in relation to the costs for heat generation, it is energetic and economical more efficient to operate the chiller with the lowest condensation possible. This should be the case in most companies. But in turn an institution has to pay relatively low prices for electricity and a relevant amount of the waste could be used, for example for water preheating, it might be profitable to increase the set temperature of the condensation.

Finally, the factor f has to be determined. Therefore, a model has been built in Matlab (MATLAB, 2010) using the database CoolProp (Bell et al., 2014), which offers the possibility to calculate compressor load and the amount of waste heat from the condenser in dependence of the cooling load and the ambient temperature. The parameters of the model are given in Tab. 3.

Tab. 3: Models Parameter

Parameter	Value
Refrigerant	R134a, R404A, R407C, NH_3
Cooling load	200 kW_{th}, constant
T_E	-20..0 °C
T_C	35..45 °C
$\Delta T_{overheating}$	5
$\Delta T_{subcooling}$	3
$\eta_{isentropic,comp}$	0.7
$\eta_{el,comp}$	0.9

As shown in Fig. 5, the factor f is dependent from the temperature level in the evaporator as well as from the refrigerant. In deep freezing applications the effect in the decrease of the COP is less relevant (approx. 2.2 %/K) than for normal refrigeration (approx. 3 %/K). Additionally, there are differences in the performance dependent on which refrigerant is used. Cooling systems which are filled with Ammonia (NH_3) are more attractive to use as heat pump, generally. In contrast, if R404A is used, the decrease of the efficiency of the cooling system is stronger.

Having determined the factor f, the target conflict can be solved with respect to the ratio of energy costs and the demand supply ratio which can be calculated easily. The range of the realistic ratio of energy costs is from 0.2 to 0.55 (ct/kWh_{th})/(ct/kWk_{el}). Fig. 6 shows the ratio of cost savings for a factor f of 2.2 % (left) and 3 % (right). The white line is marking the inflection line, where a change of the condensation temperature would have no cost saving effect. Below this line, the company should decrease the condensation temperature as far as possible to benefit from savings. Since, the saved conventional heat generation costs cannot be amortized by the heat recovery system. Here, the costs for electricity outweigh the savings. Otherwise, if the demand-supply-ratio and the ratio of energy cost result in an intersection point above the white line, the operator of the cooling system can save costs by increasing the condensation temperature and use the chiller as a heat pump.

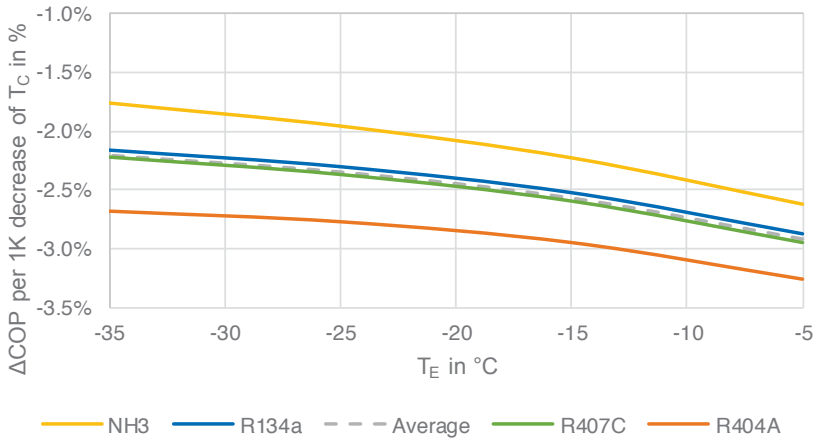

Fig. 5: Change of COP (factor f) per 1 K decrease of T_C in dependence of the evaporation temperature and common refrigerants

As an example, a company of the meat processing industry is considered. The daily hot water demand is approx. 45 m³/d, whereas 375 kWh_{el}/d are consumed for normal refrigeration and the same amount for deep freezing. Assuming that for each cooling application, there is an own heat recovery system, 22.5 m³/d can be preheated by each system. This results in a demand-supply-ration of 0.06 (m³/d)/(kWh_{el}/d).

Here it is assumed, that ratio of the meat processing factory has a value of 0.4. As it can be seen in Fig. 3 in case of normal refrigeration and a factor f of 2.2 %, the cooling system can be used as a form of heat pump since an increase of the condensation temperature is interesting from an economical point of view. Here, the savings in heat generation account for up to 30 % in relation to the additional costs for the electric energy demand for cooling. In contrast, with a view to the deep freezing system on the right, the cooling system should be operated as efficient as possible with the deepest condensation temperature possible.

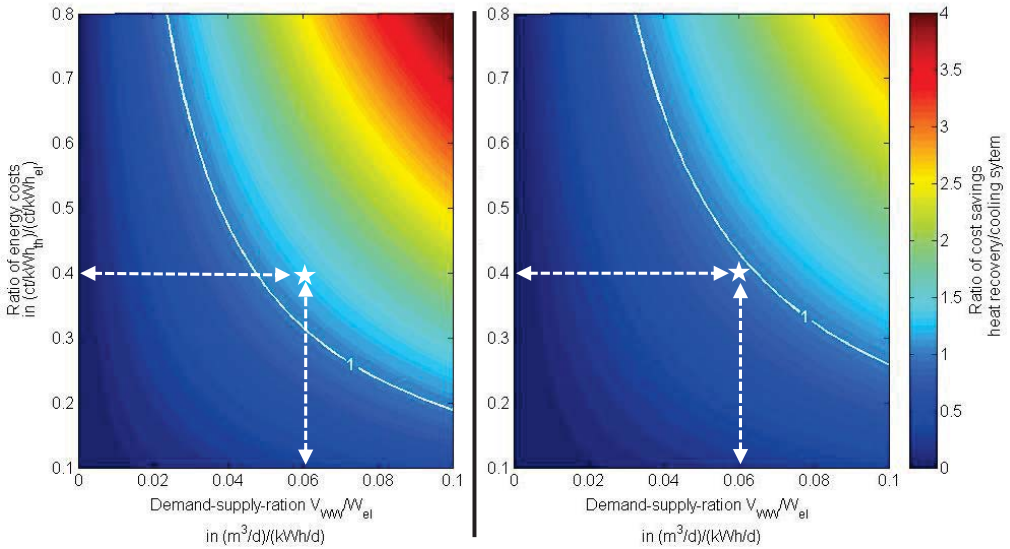

Fig. 6: Ratio of cost savings operating the cooling system most efficiently in dependence of the defined ratios, left: factor f=2.2 %, right: factor f=2.9 %

This calculation does only take the preheating of hot water into account. If there is another heat consuming process on a low temperature level (25..35°C) which can be fed by the heat recovery system, the savings due to an increase of condensation temperature can be even more relevant. Additionally, the costs for recooling the waste if not needed are not considered. This could make a use of the chiller as heat pump even more attractive, because the heat can be used and does not have to be recooled for which additional electricity for fans and pumps, as well as water in case of evaporative recooling, is needed.

Finally, it has to be discussed how to operate a cooling system if a heat pump system is installed downstream, using the chiller's condenser waste as heat source for its evaporator. Therefore, several simulations have been carried out. These simulations aimed at the increase of required electric energy demand for cooling by increasing the condensation temperature of the cooling system in relation to the decrease of the electric energy demand of a heat pump system by increasing the evaporator's temperature level. The results are given in Fig. 7. The change of electric energy is given in dependence of the temperature level of the condenser of the chiller (first x-axis) and of the evaporator of the heat pump (second x-axis). As before, it is assumed, that if the heat pump uses the chiller as heat source, there is a temperature difference between the two temperature levels of 10 K due to the two required heat exchangers. With the given figure and in knowledge of the electric energy demand for the cooling system as well as for the heat pump, it is possible to decide if is more profitable to decrease the condensation temperature of the cooling system and let the heat pump take this additional temperature lift or vice versa. As it can be seen, especially for normal cooling, for a lower condensation temperature level of the cooling system, the percentage reduction of the energy demand for cooling is higher than the percentage increase of the energy demand for the heat pump. In deep-freezing applications with lower evaporation temperatures, the temperature difference between evaporator and condenser in the compression chiller is already that big, that an additional increase does not affect the total energy demand significantly. The same effect can be seen for the heat pumps with the higher set target temperature, even though for higher evaporation temperatures the efficiency is increasing faster. For a better understanding, in the following, an example is given

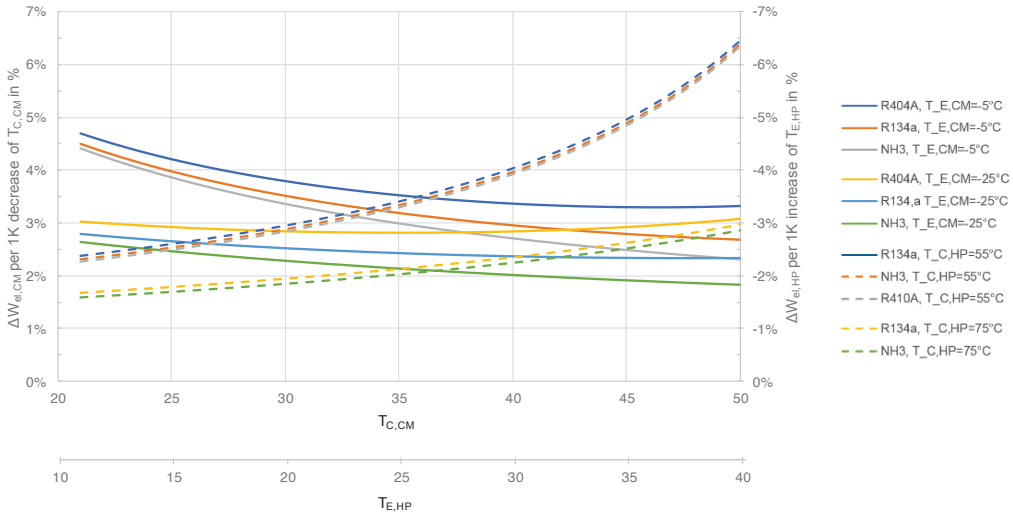

Fig. 7: Comparison between the increase of the electric energy demand per 1 K increase of the condensation temperature of the chiller (left axis, continuous line) and the decrease of the electric energy demand per 1 K increase of the evaporation temperature of a heat pump (right axis, dashed line). Valid for customary refrigerants and evaporation temperatures (chiller) and condensation temperatures (heat pump)

5. Conclusion

The process and energetic analysis has shown that there is a significant potential for solar process heat in the German meat sector. The technical potential is 1,000,000 m². The big amount of hot water simplifies the identification of a suitable integration points. Especially the maturing process is promising regarding the further use of solar heat. It has to be weighed if the retrofit to water heating is beneficial.

Due to the massive use of compression chillers for cooling the products, industrial heat pumps can reach low heat generation costs. The solar heat industry should focus on creating complementary systems of solar collectors and heat pump. If there is only a small temperature lift to provide. Heat pumps are going to be the favourable solution. As is could be shown, in general, cooling systems should be operation as efficient as

possible, resulting in a very low condensation temperature. If there is a significant demand for hot water in relation to the used electric energy for cooling, it can be beneficial to use the compression chiller as heat pump, enabling an intensified use of heat out of the condenser. The combination of heat pumps and compression chillers is very promising. But, finding the optimal combination heavily depends on the system. If all of the waste can be used in a heat pump it can be profitable to increase the condensation temperature of the cooling system making the heat pump even more efficient.

Abstract

Lineal Fresnel Reflectors (LFR) is a promising technology in the field of concentrating solar thermal collectors which presents several advantages in comparison with the widely used parabolic-trough collectors (PTC). A methodology to properly design a LFR is presented as well as several issues arisen out the study of a particular case. As first step, a brief review was performed to select the proper receiver configuration, resulting in a trapezoidal cavity with multitube absorber receiver. Secondly, several stages of the optimized process were followed using an in-house ray tracer computer code to simulate the optical behavior of the system. Different characteristics, as width of the mirrors, number of rows, mirror geometry profile, height, length and configuration of the receiver, were optimized setting the power impinging in the absorber tube surface as the objective function. According to the results obtained, the shape of the mirrors was stablished based on the optical advantages that parabolic mirrors have over flatted ones. The point strategy was focused on achieving a homogeneous flux in the receiver tubes surface. The height of the receiver over the mirrors plane was selected as the one that maximizes the impinging power. A practical analysis related with the facilities characteristics was carried out to set the number and width of mirrors. In addition, a thermal balance between the impinging power and the thermal energy gained by the heat transfer fluid (HTF) was performed to calculate the length of the receiver tubes. Finally, the results of the analytical model were cross checked with a ray tracer software (Tonatiuh), with satisfactory results.

Keywords: *Lineal Fresnel Reflector, ray tracer, multitube absorber, point strategy.*

1. Introduction

LFR is a promising technology in the field of concentrating solar thermal collectors (Singh et al. 1999). The operating principle relays on a set of long and narrow mirrors that might be flat or slightly curved, which reflect direct solar radiation by tracking the sun along the day. The reflected solar beams are absorbed by a fixed receiver, which is the key component of the system. The energy absorbed by the receiver is transferred to the HTF circulating inside it, which increases its enthalpy. Several designs of receivers are found in the literature (Zhu et al. 2014), including receiver tubes arranged individually or in group protected from the ambient by a cover in order to minimize heat loses.

PTC are the main technology in terms of number of plants installed and currently in operation (Fernandez-Garcia et al. 2010), mostly because of the optimum results of SEGS plants in Mojave Desert, California, which are being producing electricity since the 80's until now. It has been found that LFR technology presents some significant advantages compared with PTC (Sahoo et al. 2012; Sait et al. 2015). On one hand, the costs of the optical components is lower in LFR, according to the nearly flat shape of the mirrors (Boito & Grena 2016) and also the absence of metal-glass welds in the receiver tubes, because in most of the designs the receiver tubes are not directly exposed to the ambient and no vacuum is needed. On the other hand, as the receiver is fixed, they do not use ball joints, as PTC does, at the points where the distribution pipe meets the start and end of the collector. As a consequence of this, lower maintenance and operation costs for LFR plants is achieved (Haeberle et al. 2002).

doi:10.18086/eurosun.2016.02.21 Available at http://proceedings.ises.org

On the contrary, the main disadvantage of LFR compared with PTC, is the lower optical efficiency, explained by the longitudinal component of the radiation impinging the receiver's tubes, which increases when sun is far away from the zenithal position. Also, significant optical errors due to the large distance between the mirrors and the focal point contribute to decrease the optical performance (Boito & Grena 2016).

The receiver of a LFR may be considered as the most relevant component of the system because it is the place where the energy conversion process occurs. Its geometrical and optical configuration has changed, depending mainly on the application. Previously, the most common design was based on a single tube with a secondary reflector (see Fig. 1 left). This design could be conceived with a second glass tube surrounding the metal one and vacuum between both, or just a single steel tube with a glass flat cover sealing the receiver from outside climate conditions (Montes et al. 2016). Recent designs agree in using a trapezoidal cavity with a multitube absorber (see Fig. 2 right). The main advantages of trapezoidal cavity with multitube absorber are a higher efficiency in the transfer process and a more flexible design leading to simpler control of the flow through the tubes (Abbas et al. 2012).

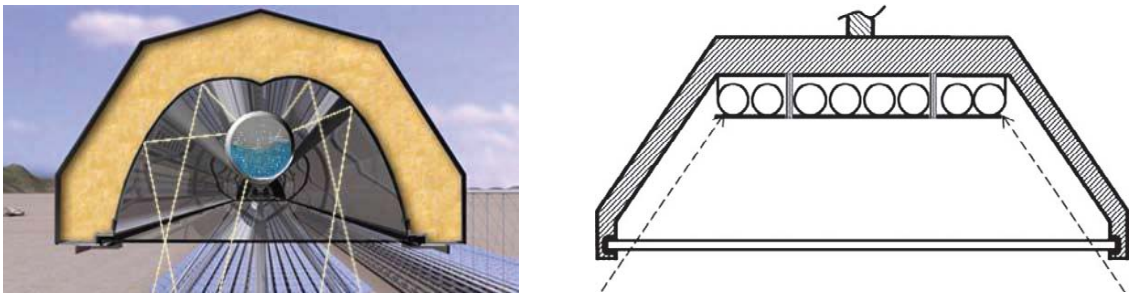

Fig. 1: Left: Single tube receiver configuration (source: Novatec Solar). Right: Trapezoidal cavity with multitube absorber receiver (source: Abbas et al. 2012).

Although the thermal energy consumption in industrial processes is significantly high (Kalogirou 2003) and LFR represents an economically feasible and clean solution, this technology is not as mature as expected. This paper presents a methodology to optimize the design of a LFR oriented to production of thermal energy for industrial process heat (IPH) applications at temperatures up to 200 ºC.

2. Methodology

This section includes the methodology followed in the design process of a LFR prototype for IPH applications. Different characteristics, as width of the mirrors, number of rows, mirror geometry profile, height, length and configuration of the receiver, were optimized, setting the power impinging in the absorber tube surface as the objective function.

2.1. Ray tracer

An in-house ray tracer computer code based on a Monte Carlo stochastic method developed in Matlab® was created (see the algorithm steps in Fig. 2), in order to study different configurations and geometries of the LFR prototype. This code gives the possibility to choose the Sunshape distribution from Buie, Neumann or Pillbox (Buie et al. 2003; Neumann et al. 2002). As a second step, an accumulated distribution function was obtained.

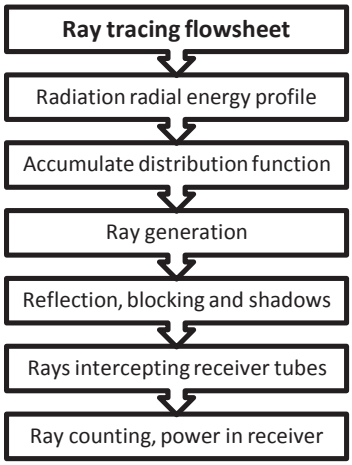

Fig. 2: Ray tracer flowsheet scheme.

A two-dimensional design was considered, in order to minimize the computing time of the simulations, folding the longitudinal coordinates into transversal plane and using a proper variable change. With this approach, the number of equations and variables was considerably reduced. This method does not disregard the longitudinal component of the impinging radiation, though. It involves a significant advantage because in case only the transversal component of the rays were considered, the path of the rays reflected from the mirror to the receiver would be considerably shorter than the path of those rays with longitudinal component.

In the rays path, reflection, blocking and shading are considered before the rays reach (or miss) the receiver surface. The rays that intercept the receiver tubes are then counted, given a power value assigned of each ray. Then, the concentrated flux profile on the receiver ($f(\theta)$) is calculated. The whole power impinging on the receiver is simply the sum of all of them, as indicated in equation (1).

$$q_t = \sum_{i=1}^{n} \int_{-\pi}^{\pi} r_{abs,i} \cdot f_i(\theta) \cdot d\theta \qquad \text{(eq. 1)}$$

where q_t [Wm^{-1}] is the sum of the power impinging in the n receiver tubes, $r_{abs,i}$ [m] is the radius of the tubes, and $f_i(\theta)$ [Wm^{-2}] is a function of the power received in every differential of the angular direction of the tube, θ.

Several simulations were done to develop an optimized design of a LFR. As base case, the code was run by using the meteorological data and the sun position of the *Plataforma Solar de Almería* (southern Spain). Five hours before and after noon were utilized for the simulations of one day from every month of the year. The power impinging in the receiver was maximized, and the geometry of the LFR that achieves this maximum was accepted as the optimal design.

2.2. Receiver configuration

The first step followed to select the receiver configuration for the LFR under design was to perform a literature revision, taking into consideration the operating conditions of the industrial process where the LFR designed will be used. The trapezoidal cavity with a multi-tube receiver was selected as the proper configuration (see section 3.1) and the number of tubes was set.

2.3. Shape of mirrors

Once the receiver configuration was chosen, the next step was to select the shape of the concentrating mirrors. The possibilities were restricted to flat shape or parabolic shape due to practical and economic issues. The analysis was made by simulating the power impinging in the receiver for both alternative shapes.

As shown in Fig. 3a, the image reflected by flat mirrors on the receiver, w_r, is approximately equivalent to the width of the mirrors, w_1 ($w_1 \approx w_r$). That is, the distance traveled by the reflected rays from the mirror to the receiver will not considerably increase the final width of the image at the receiver surface. For this reason, the optimal width for flat shaped mirrors should be close to the width of the receiver, w_R ($w_r \approx w_R$). If this condition was not stablished and wider mirrors were used (with a width of w_2, being $w_2 > w_1$ as displayed in Fig. 3b), the reflected image would certainly be wider than the receiver ($w_r > w_R$) and several rays will miss the target.

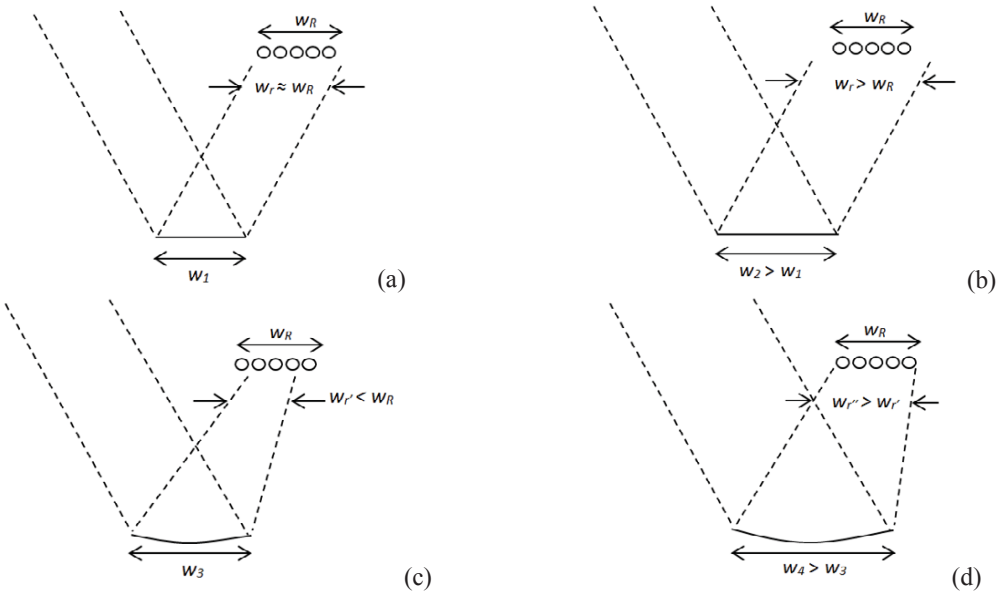

Fig. 3: Schemes representing the influence of the width in flat and parabolic shaped mirrors in the image reflected over the receiver.

In case of using parabolic mirrors (with a certain width, w_3), the image reflected by the mirrors will tend to converge to the focal point of the parabola, reflecting a beam of rays whose width ($w_{r'}$) is lower than the receiver width, $w_{r'} < w_R$ (Fig. 3c). In order to increase the power impinging into the receiver, wider mirrors ($w_4 > w_3$) could be considered without the limitation found in flat shaped mirrors. Wider mirrors imply more radiation in the reflector aperture ($w_{r''} > w_{r'}$), which leads to raise the concentration factor of the LFR (Fig. 3d). In addition, the height of the receiver over the lines of mirrors must be adjusted in order to fit the image reflected to the target.

2.4. Point strategy

The point strategy, i.e. the image that reflected rays form in the receiver transversal surface, has a significant relevance in the overall performance of LFR. Due to the fact that the receiver is not a singular aiming point, but a group of tubes, every tube should be lightened homogeneously. In other words, a homogeneous flux should be maintained so that hot spot which could lead to thermal stress in the tube material can be avoided. Several point strategies were analyzed with the in-house ray-tracing simulation code in order to address this issue along with the concentration ratio.

2.5. Height of the receiver

The distance from the mirrors plane to the receiver was established by maximizing the power delivered to the receiver. A set of calculations for different heights, fixing the rest of parameters, was carried out to study the relationship among the different geometrical parameters and to find the combination that yields an optimum height.

2.6. Number and width of mirrors

Having on goal the collection of maximum power, the selection of the number and width of mirrors is not a trivial issue. More and wider mirrors imply a larger reflecting surface which leads to more solar radiation collected in the aperture of the LFR. As a consequence, the power maximization cannot be the only design criterion to find the optimum number and width of mirrors. An economical approach combined with practical and technical aspects of the industrial facilities, where this system will be installed, is the best strategy to follow.

2.7. Length of receiver tubes

When the rest of the parameters explained in the previous sections were selected and the power in the receiver was obtained by the software developed, the next step was to simulate the thermal behavior of the receiver to calculate the tubes length required to achieve a certain increase of HTF temperature. In LFR technology,

thermal losses from tubes to ambient are mostly governed by radiation effect, having the convection mechanism a lower influence, and the conduction phenomena a negligible contribution (Pye et al. 2003; Singh et al. 2010). Different authors (Kumar et al. 2012; Reynolds et al. 2002; Sahoo et al. 2012) have developed experimental correlations for the same receiver configuration selected in this work. They consider the Nusselt number (see eq. 2) as the principal parameter to study the thermal losses due to both radiation and convection from the tubes to the glass cover window. The correlations given by these three studies mentioned were analyzed and compared among them.

$$Nu_{\sigma+h} = \frac{q_{\sigma+h} \cdot D}{k_f \cdot (T_{abs} - T_{cov})} \qquad \text{(eq. 2)}$$

where $Nu_{\sigma+h}$ [-] is the overall Nusselt number that regards radiation and convection effect, $q_{\sigma+h}$ [Wm^{-2}] is the overall heat flux, D [m] is the distance from the tubes to the glass cover window, k_f [$Wm^{-1}K^{-1}$] is the thermal conductivity of the fluid, T_{abs} [K] is the temperature of the tubes and T_{cov} [K] is the temperature of the glass cover window.

Additionally, a fourth correlation, in which a theoretical approach is made, was included in the study. This theoretical approach considers two flat parallel plates (Incropera, 2007). The hot one (simulating the tubes) is located above and facing down and the cold one (simulating the glass cover) is situated below. The equations ruling this condition respond to external free convection flows over horizontal plates.

3. Results

The results obtained in the LFR design process by using the in-house software developed in this work are presented in this section. This results belong to particular requirement stablished, however the process could be followed by any other set of conditions.

3.1. Receiver configuration

The final receiver configuration selected was based on the information collected from the literature along with the operating conditions of the industrial process to be supplied, i.e. thermal energy demand, fluid temperature and mass flow rate. A trapezoidal cavity with a multitube absorber design presents the best operation condition in terms of flow control alongside the simplicity of the receiver assembly. After considering several configurations (ranging from 2 to 8 tubes), the design option chosen incorporates 6 parallels tubes. This design is flexible and allows restricting the flow to central tubes, if radiation is lower than a certain value, in order to maintain a stable operation temperature.

3.2. Shape of mirrors

A comparison of the power impinging in the receiver was made between parabolic and flat shaped mirrors (see section 2.3). An increase in the width of the mirrors delivered similar results for both options until mirrors reach the same width of the receiver, w_R (see Fig. 4). For mirror widths higher than w_R, the increase of this parameter leads to directly enhance the power for the parabolic shape. However, the flat shape does not respond in the same way because of the overflow effect previously explained. According to these results, the parabolic shaped mirrors are preferred instead of flat shaped mirrors.

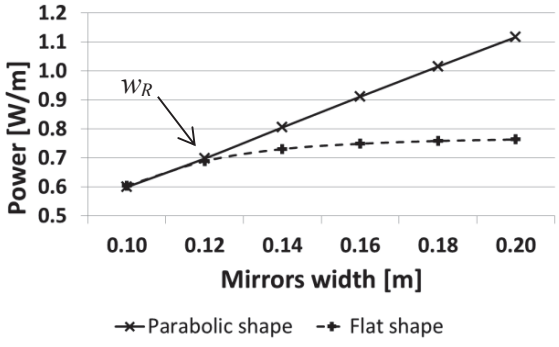

Fig. 4: Normalized power ($Power_{reference}$ = 1 Wm^{-2}) in the receiver according to the width of flat and parabolic shaped mirrors. For a configuration of 12 rows of mirrors.

Cylindrical shaped mirrors, which present quite similar optical behavior compared with parabolic shaped mirrors, are a suitable alternative solution from a practical and financial perspective because they involve an easier and cheaper manufacturing process. The main characteristic of cylindrical mirrors is the radius of curvature, which is twice the focal length of parabolic shaped mirrors for the same receiver height (Abbas et al. 2012). A higher radius of curvature implies a smoother geometrical profile, which entails a significant advantage for the manufacturing of the concentrator because it may be accomplished with thin glass mirrors glued over a cylindrical preformed pattern, which is easy to achieve.

In LFR systems, every mirror has a singular focal distance to the receiver, which leads to a different radius of curvature for each mirror. Manufacturing different preformed pattern with every radius of curvature certainly increases the cost of the LFR. An iteration process was performed with the goal of maximizing the power impinging in the receiver while using one single radius of curvature for all mirrors. At each iteration, a specific radius of curvature was employed for all mirrors, which was changing from the focal distance of the farthest mirrors from the receiver to the focal distance of the nearest mirror. It was established that the radius of curvature of the farthest mirror delivers the best results. In addition, it was concluded that the impinging power in the receiver for this particular configuration (i.e. the radius used for all the mirrors is the one corresponding to the farthest one) is similar to the power achieved when every mirror has its own specific radius.

3.3. Point strategy

Fig. 5 shows the image form by the rays if every mirror would point to the central position in the receiver. In this approach, the rays are concentrated in the central tubes, leaving the external tubes with no rays at all. As it was explained in section 2.4, this point strategy leads to generate hot spots that are prejudicial to the overall performance of LFR.

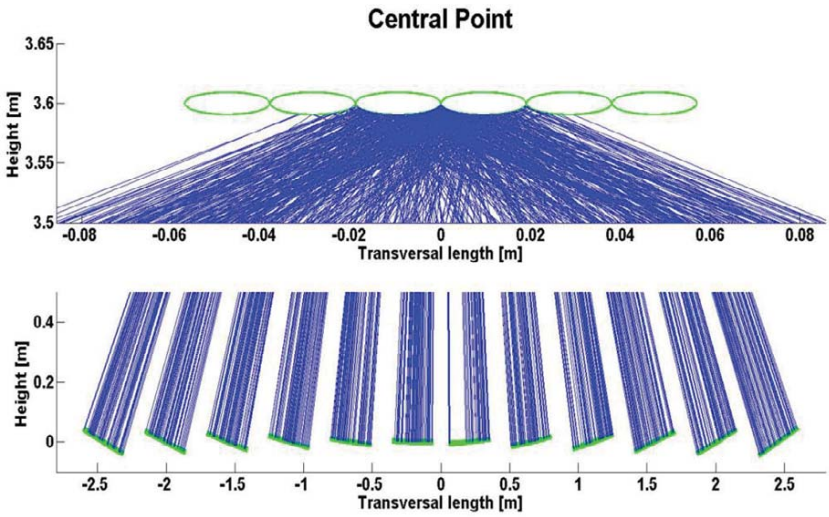

Fig. 5. Rays impinging in receiver following a central point strategy.

On the contrary, if an individual point strategy is taken into account, in which a group of mirrors aims exclusively at a specific tube, the image formed by the rays is much more homogeneously distributed, as expected. As it can be seen in Fig. 6, the power flux in the receiver is more uniform when this strategy is applied. In this figure, the red lines represent those rays missing the receiver.

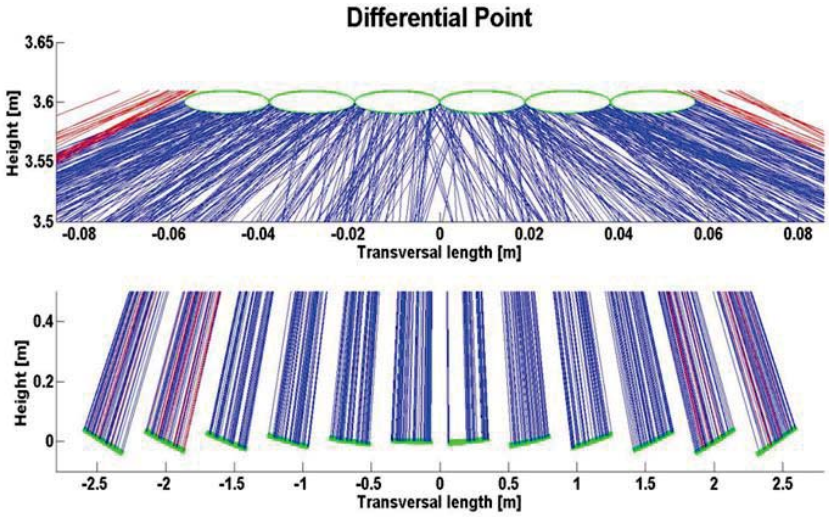

Fig. 6. Rays impinging in receiver following a differential point strategy.

The point strategy assumed in this case is based on a compromise between the concentration ratio and flux distribution.

3.4. Optimized height of receiver

Fig. 7 shows the power obtained when the height of the receiver is varied, for different number of mirror rows. Every number of rows presents one specific receiver height in which the power is maximized (indicated by the red circles in the graph). If the receiver is placed below the optimum height, blocking and shadows become predominant and consequently fewer rays reach the receiver, and therefore reducing the impinging power. On the contrary, in case of locating the receiver above the optimal position, it implies a higher rate of rays missing the target because the effect of sunshape becomes noticeable when the distance traveled by reflected rays increases. Additionally, a stochastic approach to model the deviation of rays caused by mirrors aberrations was included in the model. The longer distance traveled by the rays, the more noticeable this phenomenon is. If the receiver height is not increased after adding mirrors, the furthest one will present a pronounced tilt, which will lead to increase shadings on the neighbor mirrors and consequently a reduction in the power with respect to the corresponding optimum height for that number of mirrors. For this reason, the optimized receiver height is larger for a higher number of rows of mirrors. Finally, for the selected configuration with 12 rows of mirrors the optimal height of the receiver is 3.4 m.

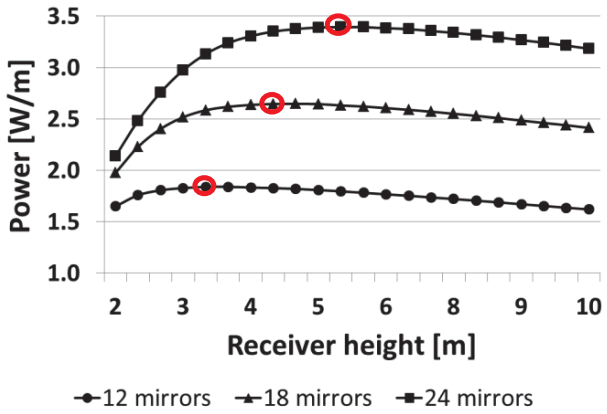

Fig. 7. Normalized power ($Power_{reference}$ = 1 Wm^{-2}) in receiver related with its height for different number of mirrors.

3.5. Number and width of mirrors

According to the methodology explained in section 2.6, the number and width of mirrors could be selected with the in-house code presented in this work, for every specific facility, by considering both the expected power and several technical, economical and practical aspects. For example, as shown in the previous section, every

mirror configuration involves an optimum receiver height, which must be suitable for the facility characteristics as well. The selected configuration is made up of 12 rows of mirrors of 0.28 m width.

3.6. Length of receiver tubes

The thermal energy model described in section 2.7 was applied. An increase of 20 ºC in the HTF temperature was set as the criterion to determine the absorber length. Such a high thermal gain was imposed in order to minimize the temperature relative errors when carrying out the experimental test campaign. The accuracy of the measurement instruments was also considered at the time of setting the temperature difference in the LFR. The length of the receiver that satisfied this condition is in the range of 10 to 12 meters.

The four heat loss correlations explained in section 2.7 were not in agreement among them. It was found a difference of up to 30% in the calculated length of the receiver. All the correlations regarded use different criterion for the definition of ΔT This disagreement could be the reason of such an inconsistent results.

3.7. Benchmarking of ray-tracing code

The optical model presented in this work was cross checked with a free ray tracer software, called Tonatiuh (Blanco et al. 2009). This software allows simulating a LFR with its geometrical and optical characteristic. The results of the comparison are showed in Fig. 8. Six charts can be seen in this figure, one for each tube in the receiver. In every chart, the normalized power impinging in the receiver is presented versus the angular coordinate around the tube perimeter (expressed in radians).

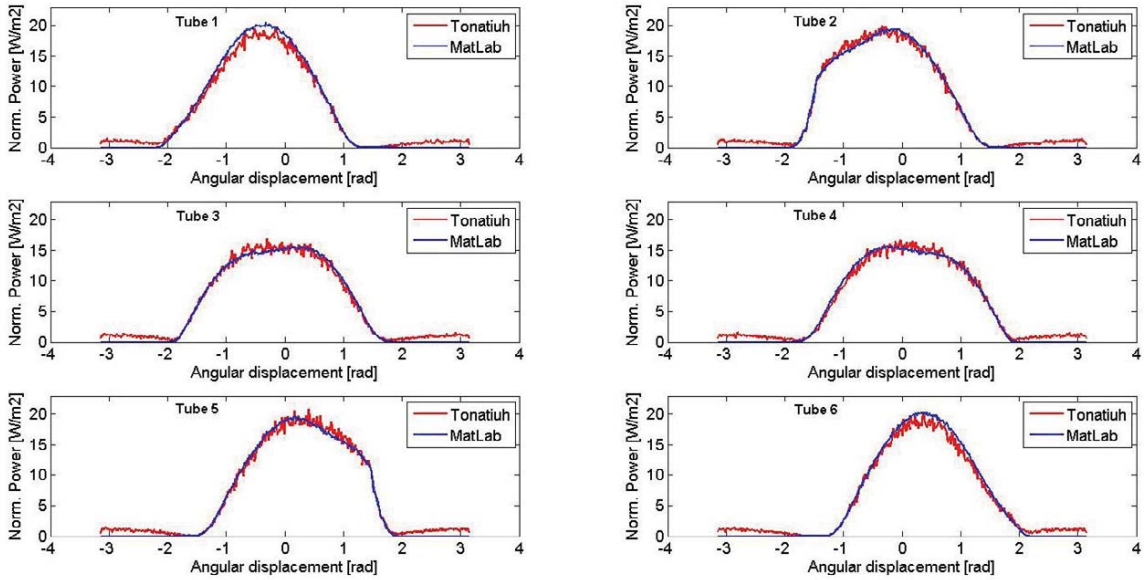

Fig. 8.Simulated normalized power impinging in receiver tubes from Tonatiuh software (red) and in-house Matlab code (blue). ($Power_{reference}$ = 1 Wm^{-2}, Location: Plataforma Solar de Almería, Spain).

For every single tube of the receiver, it was found that the curves profile and values of normalized impinging power match satisfactorily in both simulations.

4. Conclusions

A detailed design procedure for a Linear Fresnel solar collector was described. The collector was designed to provide thermal energy in IPH applications. The reflector configuration was determined by means of an in-house ray tracing code. The mirrors follow a cylindrical shape, the number of rows selected for the prototype to be built is 12 and the width chosen for each one is 0.28 m. The receiver configuration is a multitube cavity receiver composed of 6 parallel tubes and a trapezoidal cavity around 11 m long located 3.4 m over the mirrors plane. For mirrors tracking, a differential point strategy was analyzed with the objective of achieving a more homogeneous flux distribution on the multitube receiver panel. The next steps in the design process are optimizing the final design and building a prototype at the *Plataforma Solar de Almería*. Further work, can be

done from the current model, including the optimization of the mirrors shift value according to economical and technical restrictions.

Industrial Integration of Mid-Temperature Solar Heat – First Experiences and Measurement Results

Alois Resch[1], Rudolf Kraft[1]

[1] Fachhochschule Oberösterreich Forschungs & Entwicklungs GmbH, A-4600 Wels

Abstract

The integration of solar thermal energy at mid-temperature level (up to 200 °C) in industrial applications has an enormous potential. Developing a flexible simulation environment within the software MATLAB/Simulink for various kinds of industrial processes is therefore one of the main goals of the present project work. Furthermore, a modular hydraulic system has been developed and installed at the University of Applied Sciences Upper Austria, which provides the possibility to recreate processes on a laboratory scale in order to gain measurement data for verifying and adjusting the simulation environment. A centerpiece of the hydraulic system is a concentrating solar collector (Fresnel system) driven by thermal oil, which is currently being operated within a long-term measurement to achieve a comprehensive characterization at the location of Wels, Austria.

By the end of this project work a simulation environment with unique reliability will be available, which will highly support the integration of mid-temperature solar energy in industrial processes.

Keywords: *Fresnel, mid-temperature, solar thermal, industrial processes*

1. Introduction

Solar thermal energy is worldwide already well established for applications like domestic hot water generation, where temperatures of up to 100 °C are required. For temperatures beyond this limit there is still a huge potential for the substitution of fossil fuels by solar energy. Therefore, the present project was started to investigate the integration of mid-temperature solar thermal energy (up to 200 °C) for various applications in the industrial sector.

The centerpiece of this project is a modular hydraulic system consisting of several heat sources and heat sinks that can be combined in a very flexible way by a loop to be able to emulate different cases of application, like solar cooling, solar district heating or industrial process heat. One hydraulic loop works with water and can handle configurations up to 95 °C, whereas the second loop is driven by thermal oil for applications up to 200 °C. The central mid-temperature heat source is a Fresnel collector with an aperture area of 22 m², which provides the heat to the thermal oil loop by a plate heat exchanger. One of the heat sinks is an absorption chiller with a cooling power of 19 kW, driven by the water loop with temperatures up to 95 °C.

doi:10.18086/eurosun.2016.02.11 Available at http://proceedings.ises.org

In parallel to the hydraulic investigation of these applications another main task of this project is to develop a dynamic simulation of the entire hydraulic system using the software MATLAB/Simulink. After a deep verification of the simulation environment by matching the simulation results with the measurement results, it will be extended to a "hardware-in-the-loop" system, so that single hydraulic components can be characterized with a simulated environment.

By the end of this project work a verified and well tested simulation environment will be available to analyze and optimize the integration of solar thermal energy in industrial processes. Applications with a thermal power of up to 50 kW can also be demonstrated and measured on the modular hydraulic testing center.

2. Functional requirements

The designing phase of this system started with a definition of the functional requirements. The three main limitations in functionality are the following:

- Heat transfer medium only in liquid phase (steam or gas applications are not considered)
- Maximum application temperature: 200 °C
- Maximum thermal power: 50 kW

The required operation modes of this test stand were summarized in flow charts like the one that is displayed in Fig. 1.

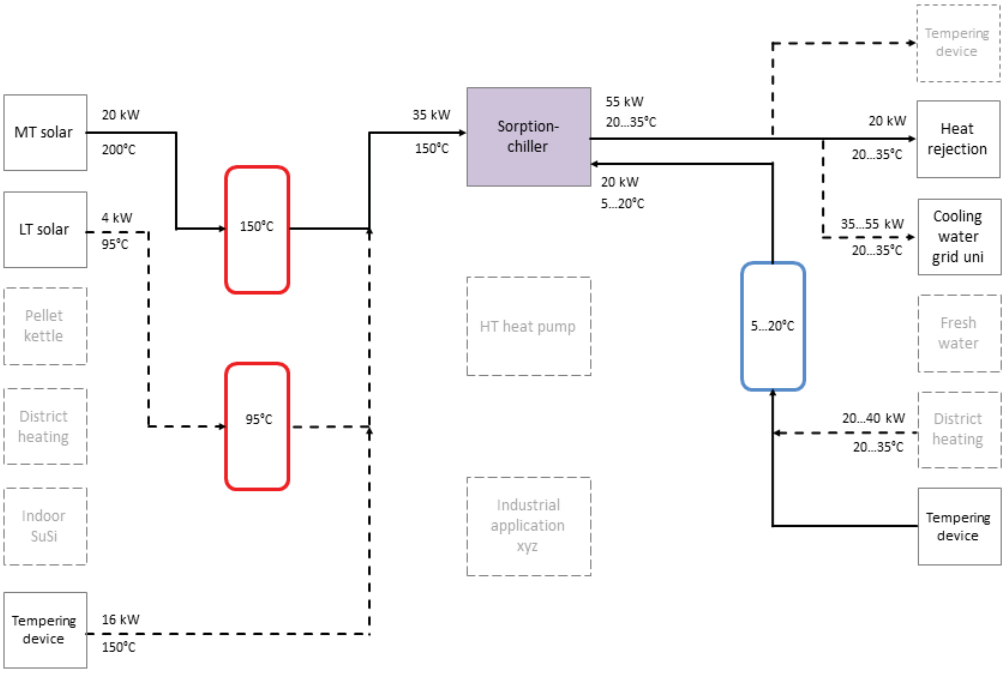

Fig. 1. Flow chart of operation mode "sorption chiller"

Using this kind of flow charts for describing the various configurations within the hydraulic system (heat sinks and heat sources) provides an appropriate overview of the thermal energy flow and shows the activated parts for each operation mode. The implemented components are the following:

- MT Solar: Mid-Temperature solar thermal collectors; 11 m² vacuum tube collectors + 22 m² Fresnel collector
- LT Solar: Low-Temperature solar thermal collector; optional flat plate collectors (up to 8 m²)

- Pellet boiler: 15 kW
- District heating: interface to the local district heating supplier (optional)
- Indoor SuSi: Connection to the available indoor sun simulator (optional)
- Tempering device: provides heating and cooling power at a precise temperature
- Heat rejection: optional connection of heat rejection for sorption chiller
- Cooling water grid uni: university´s internal cooling water for all kinds of heat rejection; constant temperature of 15 °C is provided
- Fresh water connection
- Thermal oil storage: two tanks with a volume of 1,300 liters
- Cold water storage: tank with a content of 1,000 liters; used as cooling load
- Hot water storage: tank with a content of 1,000 liters; used as storage for the low-temperature solar thermal collectors resp. as heat source for all water applications
- Sorption chiller: Cooling power of 19 kW

3. Hydraulic concept, simulation and engineering

The basic hydraulic concept of connecting the mentioned high number of heat sources and heat sinks by a loop is illustrated in Fig. 2. Depending on the required operation mode each branch of the loop (collector, district heating…) can be either activated or by-passed, providing the possibility to realize various combinations of the hydraulic components. This first loop is driven with silicon oil, so that all applications with temperatures between 100 °C and 200 °C can be operated without exceeding the boiling point of the fluid.

The second loop driven with water for low temperature applications is realized in a similar way, including a tempering device, water storage, the district heating interface and the absorption chiller.

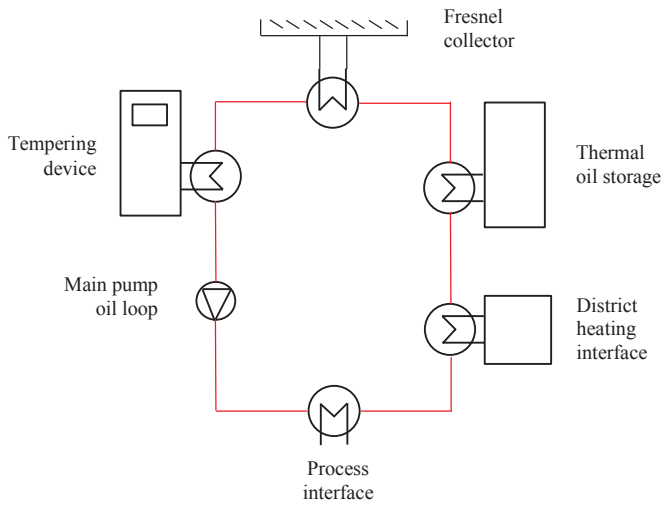

Fig. 2. Hydraulic concept of the thermal oil loop

All heat exchangers are equipped with temperature sensors on the inlet and outlet. In combination with a precise mass flow measurement in each separate hydraulic circuit all heat transfers (positive and negative) can be measured very exactly.

Basing on the hydraulic concept, first calculations of the system have been performed to quantify the main parameters like pipe dimensions, pressure losses, pump dimensions, mass flows etc. These first designing results have been used as initial information to set up the hydraulic circuits within the simulation software MATLAB/Simulink. The following Fig. 3 displays a segment of the simulation of the water loop with the collector circuit and its interface to the hydraulic ring (heat exchanger in red). With this detailed simulation the hydraulic engineering of the entire system could be finalized in a much more precise way. Furthermore, the simulation of different control strategies for all possible combinations of heat sinks and sources provided valuable information for a reliable and safe operation of the system.

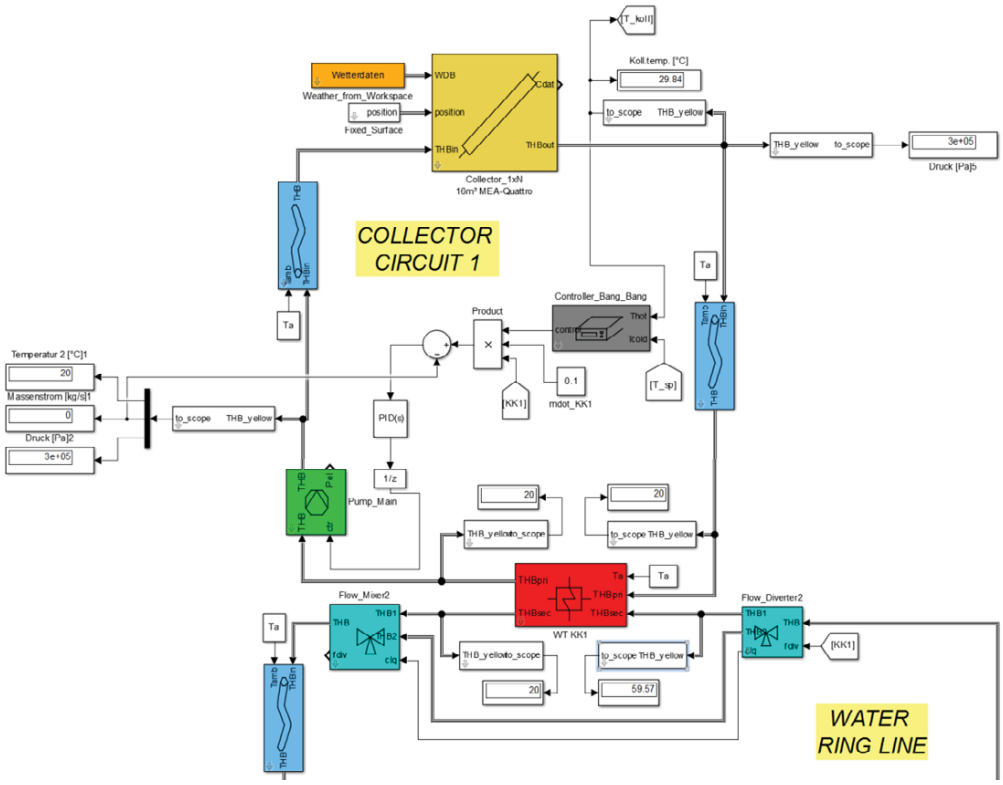

Fig. 3. Simulation segment of the water loop in MATLAB/Simulink

The basis for the final engineering of this test bench was the detailed hydraulic schematic, which cannot be illustrated within this paper due to its complexity and dimension. Nevertheless, the following numbers of implemented appliances and fittings shall demonstrate the scale of this hydraulic system:

- 14 pumps: speed-controlled
- 27 valves: 3-way, mainly motor driven
- 14 plate heat exchangers
- 300 m of pipes
- 10 mass flow meters
- 69 temperature sensors

4. Selected components in detail

4.1. Concentrating collector

The main solar heat source of this test stand is a Fresnel collector shown in Fig. 4. It works with 110 planar mirrors (dimension 70 mm x 2860 mm) reflecting the sunlight to the linear absorber, which consists of a steel pipe with selective coating, a glass cover and a secondary reflector. The collector has a total dimension of 5.8 m x 4.6 m (gross area 26.68 m², mirror area 21.68 m²) and a weight of 740 kg.

Fig. 4. Installed Fresnel collector [Fresnex, 2015]

4.2. Thermal oil storage

Two tanks with a volume of 1,300 liters each are used as mid-temperature storages. Mineral heat transfer oil serves as storage medium, whereas the oil is not stored stationary in the tanks. During each charging or discharging cycle the thermal oil is pumped from one tank into the other one, ensuring that the temperature at the heat exchanger to the loop is always constant for the cycle time. The empty volumes of the tanks are filled with Nitrogen to achieve a passivation of the oil surfaces.

As the implemented pump is not able to turn its direction of rotation, an external hydraulic solution had to be found to be able to change the flow direction between the two tanks. Therefore, two motor driven 3-way-valves (V901 and V902) were installed, see Fig. 5.

Temperature sensors and filling level sensors are also implemented in the construction of the tanks in order to guarantee a safe and well monitored operation of the mid-temperature storages.

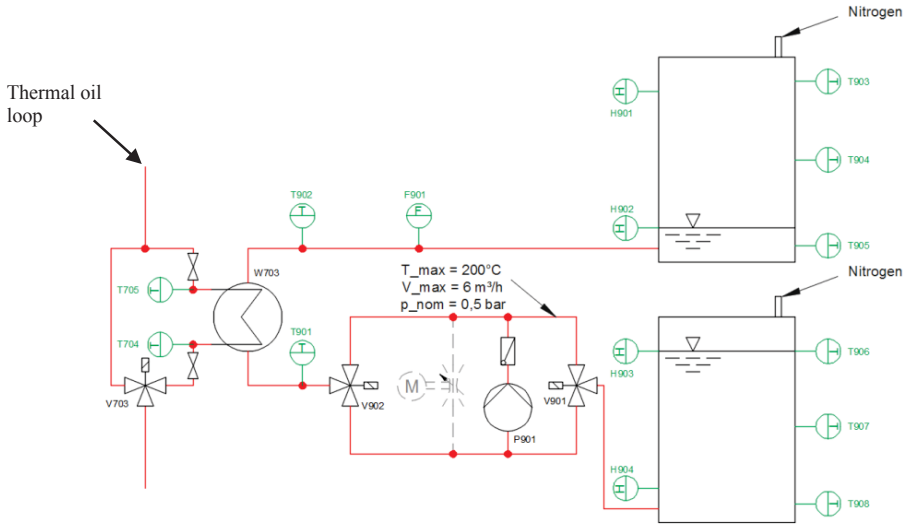

Fig. 5. Hydraulic implementation of thermal oil storages

4.3. Control and measurement equipment

The main goal of this test stand is to quantify the transfer of thermal power as precise as possible. The necessary information of mass flow and temperature difference is gained by using the following measurement equipment:

- Magnetic inductive flow meters for all water circuits: accuracy < 0.2 % of measured value
- Coriolis flow meters for all thermal oil circuits: accuracy < 0.1 % of measured value
- Temperature sensors PT100 1/10 DIN

The data of all sensors in the system are centralized by a programmable logic controller (PLC), which operates and controls all appliances and components of the test stand by applying appropriate control algorithms.

As the testing center will be used for research tasks as well as for demonstration and teaching purposes, operation and measurement of this complex system must be possible in a simple way. Therefore, the creation of full system visualization was mandatory. The visualized low temperature part can be seen in the following Fig. 6.

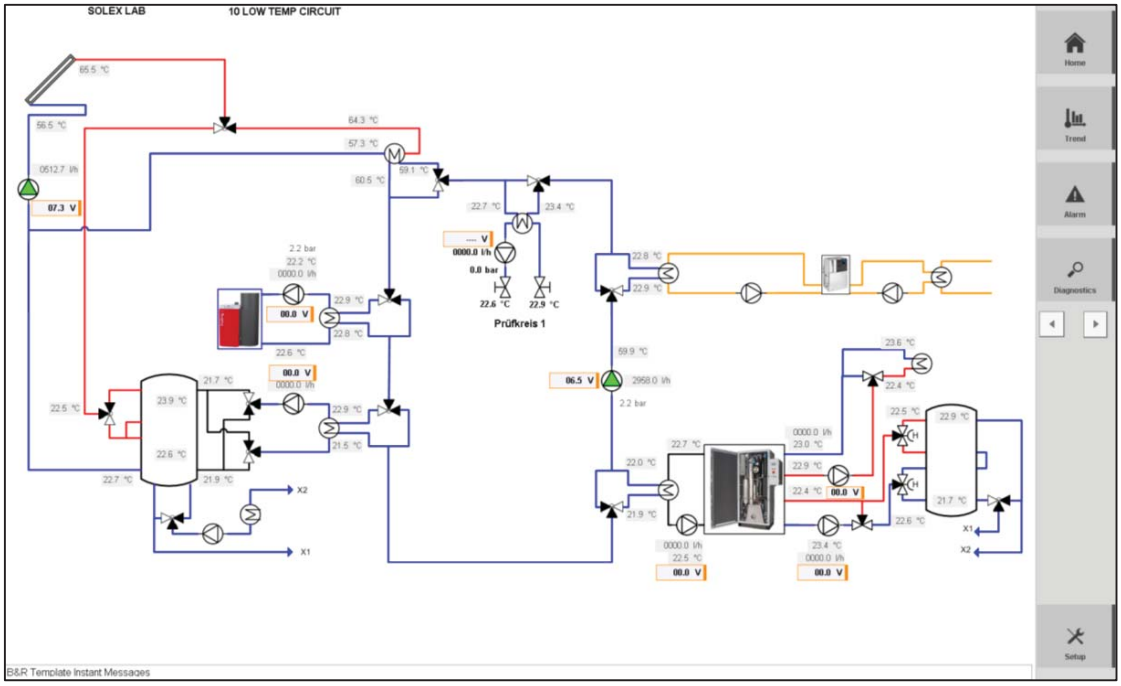

Fig. 6. Visualization of the low temperature part of the testing center

5. Start-up phase and first measurement results

During the start-up phase of the entire hydraulic system each branch and each hydraulic combination was tested thoroughly. Algorithms for the mass flow control had to be implemented, as well as various safety strategies to ensure reliable operation within the specified limits of the test stand.

Exemplary among all performed start-up measurements, Fig.7 illustrates the hydraulic configuration for the operation mode “pellet boiler characterization”. Only the components drawn in solid line are activated in this setup, whereas all other parts of the low temperature system are by-passed or inactive (dotted line). The pellet boiler provides its heat via the plate heat exchanger to the water loop, where the energy is transferred to the heat exchanger of the hot water storage by the main pump. Furthermore, the pump of the hot water storage circuit feeds the transferred thermal energy into the tank.

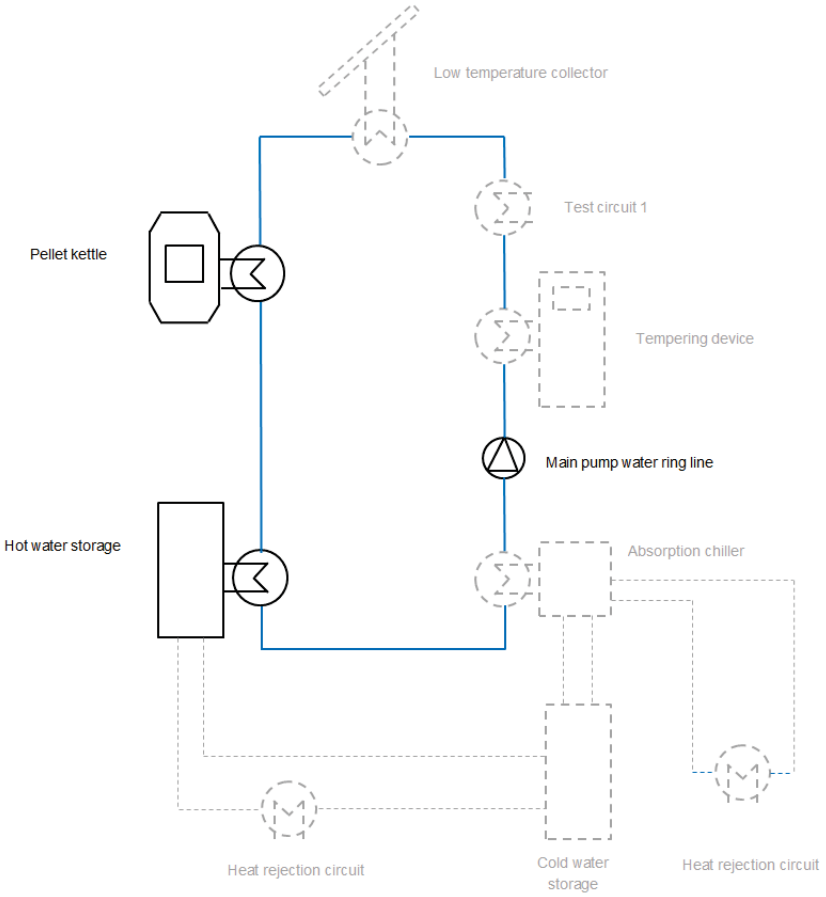

Fig. 7. Hydraulic setup for the characterization of a pellet boiler

Due to the mentioned speed-controlled pumps and the available tempering device, the pellet boiler can be driven with all possible thermal loads between 1 and 20 kW as well as a wide range of return flow temperatures between 10 °C and 95 °C.

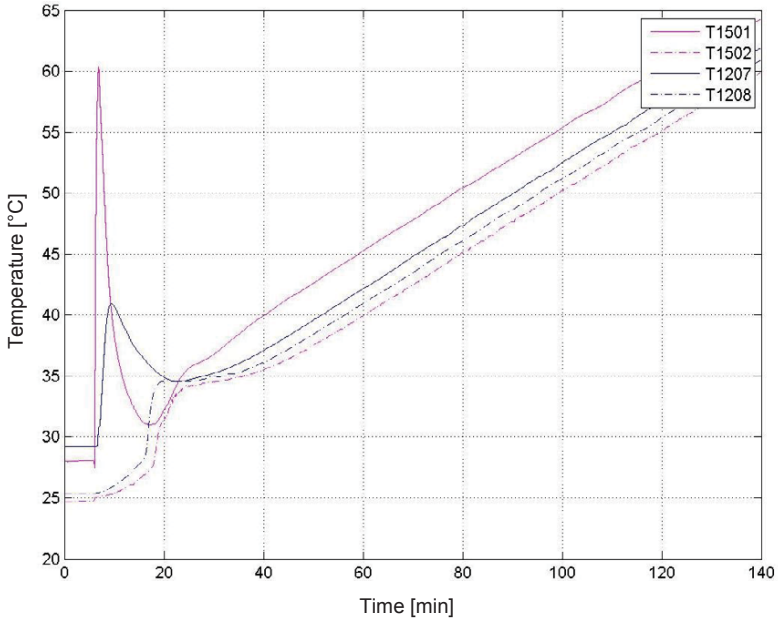

Fig. 8. Temperature rise during the characterization of a pellet boiler

For this described start-up measurement the hot water storage tank had an average temperature of 27 °C. The pellet boiler was pre-heated to an internal temperature of 67 °C. After starting the heat transfer from the boiler to the storage tank, the temperature rise displayed in Fig. 8 could be observed. After a stabilizing phase in the first 20 minutes of the measurement the temperatures rise constantly.

The temperature sensor T1207 is located in the storage tank at the height of the outlet connector. During the measurement period between “minute 30” and “minute 110” this sensor shows a temperature increase from 35 °C to 55 °C. Assuming that around 800 liters of the content of the storage is circulated in this configuration, the required thermal power can be calculated as follows:

$$P = \frac{m * c_p * \Delta T}{t} = \frac{800\ kg * 4.187\ \frac{kJ}{kg*K} * 20\ K}{80 * 60\ s} = 13{,}96\ kW \qquad \text{(eq. 1)}$$

The pellet boiler has a nominal power of 15 kW, meaning that the start-up measurement shows reasonable results.

6. Outlook and further work

The long-term aim of this entire project is to increase the use of mid-temperature solar energy to substitute fossil fuels in various industrial processes by providing a flexible and dynamic simulation environment. The basis for this simulation environment was already created during the engineering process for the hydraulic test stand, but further refining and extension has to be done. Moreover, new simulation models have to be created within the used CARNOT-blockset of MATLAB/Simulink to be able to apply the simulation environment for a large number of industrial processes.

In parallel to this simulation work all possible operation modes of the test stand have to be measured and characterized in a more detailed way and in long-term operation in order to gain statistical relevant amount of data. This experimental information will afterwards be used to verify and adjust parameters in the simulation environment, which provides the opportunity to realize a high precision and dynamic simulation tool for a substantial number of different industrial processes in the mid-temperature range.

7. Acknowledgements

The described work is carried out within the project “SOLEX – Solare Exergiebereitstellung”, which is partially funded by the program “COIN-Aufbau”, supported by the Austrian FFG (Forschungsförderungsgesellschaft).

RECOMMENDATIONS FOR THE REDUCTION OF FAILURESDURING THE PLANNING AND INSTALLATION PHASES OF SOLAR THERMAL PROCESS HEAT SYSTEMS

Dominik Ritter, Lennart Paape, Bastian Schmitt, Klaus Vajen
Institute of Thermal Engineering, University of Kassel, Kassel (Germany)

Abstract

Although several studies investigated failures in large solar thermal systems (STS) in the past, some of these failures still occur in recently built systems for solar process heat applications. Besides technical issues according to the long term reliability of components, which have to be addressed by the manufacturers, many problems lead back to insufficient planning or failures during installation. Such failures in STS can reduce the performance perceptibly and will continually impair the image and acceptance for solar thermal process heat systems. To support the market development of large individualized STS the "human caused failures" should be reduced significantly. Therefore, wide spread problems, especially those with a high impact on the performance, will be collected, analyzed and disseminated to the target groups to provide applicable failure prevention recommendations.
Keywords: *failure prevention, large solar thermal systems, individualized systems, solar process heat*

1. Introduction

Even if there is a large potential of 50 TWh/a for industrial and commercial applications up to a temperature of 250°C[1] for STS in Germany, the market uptake is rather slow. In fact the growth of market for solar process heat, that could be detected between August 2012 and the beginning of 2015, is declining at the moment. Besides the major influence of the dropped oil prices in the middle of 2014, some other barriers have to be addressed for a lasting increase of the number of newly installed solar process heat systems in Germany and other countries.

At first the relation between the high installation costs and the low operating costs of STS seem to be a barrier for many entrepreneurs. To address this barrier 50 % of the overall investment costs for solar process heat systems is subsidized in Germany, enabling investors to achieve an amortization time of seven to ten years in most cases. But these amortization times are still too long for many companies, although STS have a long operating life of 20 to 25 years.

The second problem is the missing knowledge of most entrepreneurs that solar thermal can be used to provide heat for processes. In addition, some of those who are aware of this fact fear a bad influence on the operational reliability, although there should be no risk if planned and installed correctly. Also, as solar thermal process heat systems should be realized after the implementation of obvious energy efficiency measures, there is an extra effort to realize such projects. In addition the systems have to face the competition to combined heat and power (CHP) and industrial heat pumps (HP). Perhaps in future even direct PV-heating could compete with solar thermal in industry, depending on the development of prices for PV and STS.

[1] including space heating and domestic hot water

doi:10.18086/eurosun.2016.02.06 Available at http://proceedings.ises.org

Another important factor that is slowing down the market is that only few companies deal with solar thermal process heat systems professionally and even fewer companies are offering the full projecting of planning, installation, start-up and if necessary also the operation of STS as a package. Besides, there are installers at the market with no trust and no will to deal with solar thermal process heat systems, as conventional oil and gas boilers as well as CHP and HP are normally less complex in planning and installation.

This complexity leads to the last point, the higher efforts for a precise planning and faultless installation of solar process heat systems, which are mostly individualized systems in contrast to the standardized systems for domestic applications. Especially in such a small market where new companies are trying to sell projects, the required high precision during planning and installation unveils a large potential for human caused failures that can be done.

Although there has been intense research on the performance of and failures in large scale solar heating systems, the resulting knowledge has not been condensed into applicable guidelines or tools as it was done e.g. for process heat specific knowledge on the pre-dimensioning and the definition of integration points [Schmitt et al. 2015, Muster et al. 2015]. This was one reason for the German Federal Ministry for Economic Affairs and Energy to fund the research project "Analysis and Development of the German Market for Solar Process Heat in Germany" (Ident. No. 03MAP286). This project has three work packages: The first one is the economic and technical analysis of planning documents that have to be handed in to apply for the 50 % investment grant. The second work package is the assessment of the solar yield of STS with a collector area larger than 100 m^2_{gross} and the detailed monitoring of three selected systems newly built within the funding program. The third work package is the preparation of gained knowledge out of the project as well as existing knowledge and the dissemination into the market by organization and conduction of regional roadshows and workshops for planners and installers. A very important part of the work package is the preparation and dissemination of specific knowledge as guides for planners and installers to reduce failures in large scale STS with the focus on solar process heat. The input for these guides are mainly failures detected within the technical analysis of the planning documents done in work package one and the identified problems in the three monitored systems. These failures are extended with the documented problems in literature. At the end the guides should cover common failures especially those with a large impact on the performance. They have to be provided in a compact but comprehensive way to both target groups – planners and installers. These guides for planning and installation will probably become a standard whose abidance planers and installers have to confirm as an indication on following the state of the art. The guides will be provided as additional information material together with the application form for requesting the subsidies.

2. Failures in Large Scale Solar Thermal Systems

Although several studies investigated failures in large scale STS in the past, a lot these failures still occur in recently built systems for solar process heat applications. Besides technical issues according to the long term reliability of components, which have to be addressed by the manufacturers, many problems lead back to insufficient planning or failures during installation. Such failures in STS can reduce the performance of the particular system perceptibly and will additionally lead to a continually impair of the image and acceptance for solar thermal process heat systems. To support the market development of individualized solar process heat systems, the "human caused failures" should be reduced significantly. Therefore, wide spread problems, especially those with a potentially high impact on the solar yield, were collected and analyzed to provide applicable failure prevention recommendations.

For the preparation of these recommendations, the failures detected in the three monitoring systems within the before mentioned research project as well as within over 260 planning documents and those out of literature were collected. The main used literature sources on failures in large scale STS are Peuser et al. (2009), Croy and Wirth (2006), Fink et al. (2006), Wiese (2006), Lanz et al. (2013), Remmers et al. (2001), Peuser et al. (2001), Lauterbach et al. (2012). Finally, a list of nearly 80 different failures could be prepared.

Out of these failures those that are not relevant anymore were deleted like the discoloration of the absorber or torn inner collector covers (material problems with the used foil) as well as leak absorber pipes. Afterwards failures that are not caused by inaccurate planning or installation but by quality problems according the long

term reliability of the components were identified, as they are disregarded for the recommendations for the planning and installation phases. These problems concerning material defects or production failures have to be addressed by the manufacturers. In addition, as such failures according the long term reliability can never entirely be prevented, the University of Kassel is starting a research project on the automated system evaluation and failure detection together with several partners out of solar industry. Applying the FSC method (fractional solar consumption) developed in IEA Task 32, which is used to compare the actual fractional energy savings of a system with the theoretical maximum of the actual systems configuration, manual analysis of measurement data will be redundant. Moreover, an algorithm-based fault detection method can be applied, which is able to determine in which subsystem or component a fault has probably occurred.

Having deleted the failures not relevant anymore and disregarded those occurring during several years of operation, a list of failures that can be caused by insufficient planning or poor installation remains. These failures can be referred to different parts of the solar system, as it can be seen in Figure 1 [in German language].

Figure 1: Example for the allocation of the detected failures to the different parts of the solar system

The first part of the system failures can occur in is the solar loop. Main source for potential failures are related to the collector field like an uneven flow distribution in the different collector rows. Also the dimensioning and installation of the expansion vessel and the pump seems to be a problem in some cases. The second part is the storage loop, here including the heat exchanger for charging the storage. Most problems emerge due to incorrect connections causing natural circulations. The dimensioning of the storage volume and the heat exchanger is also a common source for failures. Following, the process loop was defined, starting with the heat exchanger for the discharge of the storage. An example of failures for this loop is the underestimation of the peak load of the heat sink, leading to an undersized heat exchanger. Completing this classification failures were also allocated to the secondary heating loop (e.g. oil or gas burner) and the controller loop. Examples are fouling in the heat exchanger due to the wrong choice of the type or simply a wrong control strategy that could for example use the conventional boiler as primary heat source instead of the solar thermal process system.

In the following section some examples for failures made during planning or installation of recently built systems are named as well as a short description of the effect on the system.

3. Examples for Failures found in Solar Process Heat Systems

The analysis of planning documents and the detailed monitoring of three selected STS in industry and commerce within the project "Analysis and Development of the German Market for Solar Process Heat" (Ident. No. 03MAP286) showed that several failures were made during planning and installation. In addition, the University of Kassel had the opportunity to discuss with several planners and installers as well as with companies that invested into a solar process heat system, which could be used as an additional source of information. Following some examples of the failures that were found are given. Some of these failures appeared several times in different STS.

It was assessed that some planers do not choose the collector type according to the application with its necessary temperature levels. They typically use one specific collector type independent from the intended application (domestic hot water or process heat). Using this approach, systems were built with evacuated tube collectors heating up cold water to a desired flow temperature of only 40 °C. For this temperature level a single glazed flat plate collector would have been a more efficient choice compared to evacuated tubes additionally with lower costs at higher specific solar yields. Even unglazed collectors would reach a higher efficiency over a long period of the year. Such a poor choice of the collector type leads to unnecessarily high solar heat generation costs due to higher cost for the component and the lower solar yield.

Another failure that often occurs is the realization of the desired storage volume by connecting several small storages, often in parallel. The highest number of interconnected storages was 14, each with a volume of only 1 m³, realized as two storage batteries each with seven storages connected in parallel. Compared with a one single large storage, the interconnection of multiple storages leads to significantly increased costs for hardware and installation as well as increased heat losses due to the higher storage surface and multiple connections between the storages. In addition measurements in STS showed that storages connected in parallel always start interacting over the time, even if they were installed correctly hydraulically balanced. This leads to uncontrollable charge and discharge of the storages and therefore to a mixing of different temperature levels, reducing the useful solar yield. In general, the monitoring of several systems showed, that it is always preferable to use one single storage but never more than two in parallel or three in series (Peuser er al., 2001).

According to the realization of the storage, some systems were planned to be built with vacuum-insulated storages. As they are very expensive – prices between 3,000 and 3,500 €/m³ were found in the planning documents – it can only be reasonable to use them as mid or long term storages for systems with excess energy gains in summer or autumn. As the systems were designed to achieve a solar fraction of less than 50 % in the summer months, there is no need for such storage. The only effect is an increase of the solar heat costs. An exception for using a vacuum storage in such cases could be very little space at the installation site.

One point that came up during discussions with owners/operators and planners of solar thermal process heat systems was that the installing company used tap water instead of demineralized water for the storage. This resulted in a rapidly decrease of heat transfer from the primary to the secondary solar loop as the plates of the heat exchangers were calcified. This finally led to a lower utilization ratio as the heat produced by the collectors cannot sufficiently be transferred into the storage leading to higher temperatures in the solar loop and therefore to higher heat losses and lower collector efficiencies.

Another failure caused during the planning phase was the selection of incorrect pump combinations, leading to unbalanced capacity flows in the primary and secondary solar loop. Systems were found in which the capacity flows of the primary loop always exceeded the capacity flow of the secondary loop. In this case, the temperature of the storage was charged with heat very close to the solar flow temperature. As the solar loop fluid cannot be cooled down to the return flow temperature of the storage charging loop, the heat losses increase and the collector efficiency drops as its mean plate temperature is unnecessarily high. Once again, this failure leads to a lower system utilization ratio and higher solar heat generation costs.

It could be also found that single speed pump designed for medium irradiations on the collectors were selected for the primary solar loop. The utilization of these kinds of pumps causes inefficient operating conditions at low radiation as well as at times with high radiation. At low radiation, the volume flow is very high for heating up the solar loop fluid and only very low temperature differences between flow and return flow can be achieved. The result is a comparably long time until the storage can be charged with the desired minimum or set temperature. In contrast, at times with high solar radiation, the average temperature in the solar loop is very high as the produced heat cannot sufficiently be dissipated. Summed up, in the morning, evening and on days with a low radiation, there are unnecessarily high electricity costs for the pump and unfavorable operating conditions for the solar thermal system. On days with a high radiation the temperature in the solar loop is higher than required, causing higher heat losses, a lower collector efficiency and probably even unnecessary additional stagnation times.

An additional problem, planners have to take care of, is the determination of the daily load and the peak load of the chosen heat sink. As this data is usually not available in companies, it should be measured on a typical production day and not only be estimated. But as the measurement takes a little time and financial effort, the system dimensioning is often done using a rough estimation. The estimation of a higher daily load leads to lower solar yields compared to the simulation, as less heat is needed than expected. If the peak loads are estimated too low, it is very likely that an undersized heat exchanger will be installed, not able to heat up the process medium or fluid stream to the designed temperature, even if the storage is fully charged. This leads to a higher conventional heat demand than necessary and higher heat losses of the storage as the discharge is lower than expected. Both mistakes – overestimation of the daily load and underestimation of the peak load – were found within the project.

It also happened that the chosen gaskets in the solar loop were sufficiently temperature resistant for regular operation conditions but not for stagnation. The results were leakages at the connections of the solar loop making it necessary to drain the loop, dismount all connections close to the collector that could be affected during stagnation, and to renew the gaskets. At the end the solar yield that could have been gained between the time the leakages emerged and the resumption of operation were given away and additional costs for the reparation were caused.

Another failure that could be found is missing valves to reliably close different loops being used at different times at different temperatures providing several heat sinks. This is necessary to avoid fault forced circulation between the loops. The effect of missing valves is a mixing of flows and / or return flows with different temperatures making it nearly impossible to achieve the desired temperature in the different heating loops.

The last detected problem that will be mentioned here, is the inaccurate installation of the temperature sensors in the last collector of each collector row. In two systems the sensor was not correctly plugged in the collector causing an offset between the measured and real temperature. In addition the offset increased with higher temperatures. If this measured temperature is used as the solar flow temperature for the controller to control the pump, the result is again an unnecessary high temperature in the solar loop, causing additional heat losses and a lower collector efficiencies.

4. Concept for Failure Prevention Recommendations

To prospectively prevent the failures found within the analyzed systems as well as those found in literature, they have to be prepared in such way planners and installers are willing to consider within their daily routine. Therefore it had to be evaluated, which information at which extend is suitable for these two target groups. As these groups have different needs and duties, two varied designs of the failure prevention recommendations with diverging information are the result of this evaluation.

For both groups it has to be as short as possible without being inaccurate and the recommendations should only cover the most important points to reduce the paperwork that should be used by the target groups. As it cannot cover the whole planning and installation steps of a solar thermal system, it can only be used as an addition to the existing knowledge and tools to prevent the most common failures.

First draft of the recommendations for planners

The main steps the planner is responsible for, is collecting the necessary data to make a feasibility study and to submit an offer to the particular company. Afterwards a detailed system design and hydraulic scheme has to be prepared including all dimensions and specifications for the required components. In addition, a suitable control strategy has to be designed. After the realization of the solar process heat system an appropriate documentation of the system should be handed over to the operator.

As the planner should be used to deal with paperwork and formulas to design a whole system, it seems reasonable to provide recommendations of two to three pages for the components failures often occur including descriptions in continuous text or bullets together with schemes and formulas for the correct dimensioning. Figure 2 gives an example on the recommendations, in this case for the collector field [in German language].

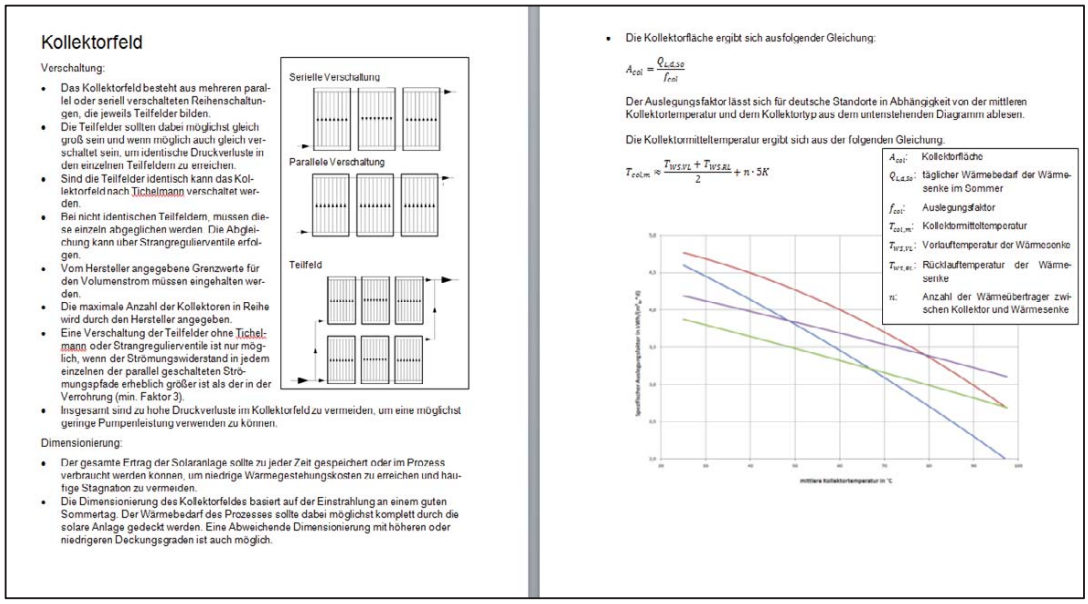

Figure 2: Example for the failure prevention recommendations for planners

The recommendations for the planners are not as standardized as the hints for installers, as the aspects are varying. They include short descriptions of the general requirements, advices on which aspects have to be considered for a suitable selection of the particular part of the system as well as formulas and graphs to support the correct dimensioning. If the failures found in literature and within the project indicated the necessity, there are also hints on how to integrate the particular part correctly into the whole system.

First draft of the recommendations for installers

The installers' job is to install the system according to the planners' specification and with respect to the state of the art. In addition he is responsible (sometimes together with the planner) for the start-up of the system, giving the owner of the system an introduction.

As installers are always dealing with one component or connection after another, they need specific hints regarding single components, not the whole system. In addition, during installation there is normally no time to deal with extensive paperwork. Therefore, very short but precise hints on how to prevent common failures are necessary, always dealing with one single installation step. To support a quick grasp of the information included in the recommendations, schemes are given. Figure 3 is an example of the first draft of the hints that should be considered to reduce failures made during installation [in German language]. The format of each hint is a half DIN A4 page.

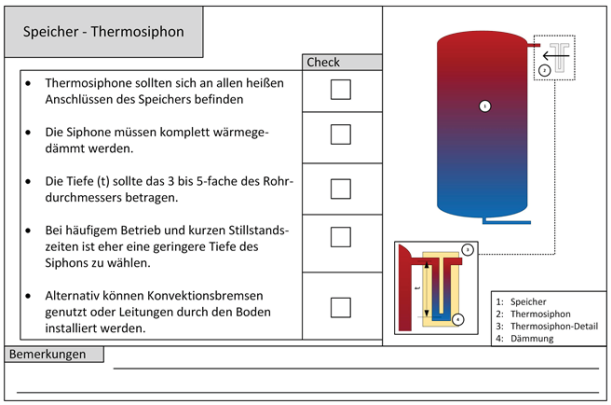

Figure 3: Example for the failure prevention recommendations for installers

The figure shows a few bullet points – here for the installation of thermos syphons at the hot connections of storages - with the information needed to prevent natural convection losses. Beside these bullet points are check boxes that can be used to confirm the observance of the given information. On the right hand side of the recommendations is a scheme with a short legend naming the parts visualized in the scheme. If necessary or helpful selected parts of the scheme are zoomed to capture more details. At the bottom of the hints an empty space is left where special circumstances, problems occurred or alternate solutions can be written down.

5. Outlook

As failures during the planning and installation phases were done in the past and will occur in the future there is a need to reduce them by giving guides like it is described in the previous sections.

The developed concept was discussed with a company mainly offering the planning, installation and if requested also the operation of solar process heat systems or other large scale STS, to confirm if the key aspects are covered in the recommendations and if they are short but still precise enough to be used by the target groups. As the feedback was positive and some additional input could be added, the recommendations seem to be suitable for the failure prevention.

Although the gathered recommendations can never cover every possible failure, a solid basis of identified failures occurring during planning and installation as well as hints to their prevention could be developed. In addition, the list of recommendations can easily be extended or revised if it is necessary.

The next steps are the final editing and dissemination of the hints and a definition on how to ensure, that planners and installers are aware of the content. To ensure that, one way of publishing the recommendations will be the download together with the application forms for the 50 % investment grant.

After publishing, the recommendations will become a defined document for the state of the art for realizing solar process heat systems. It is even possible that these recommendations will become a standard that have to be used if the planners and installers want to apply for the investment grant. This could be ensured by the need of signature that the system will be realized with respect to these failure prevention recommendations. With this approach a lot of failures could be prevented, supporting a market development on basis of systems delivering good performances.

A further module for supporting solar process heat systems to achieve constantly high yields even after several years of operation is the project on the automated evaluation of the fractional energy savings mentioned before.

Direct Radiation Measurements for the Evaluation of Process Heat Systems with Concentrating Solar Thermal Collectors

Mercedes H. Rittmann-Frank, Mattia Bataglia, Jana Möllenkamp, Matthias Rommel, Andreas Häberle

SPF Institute for Solar technology, Rapperswil (Switzerland)

Abstract

For the evaluation of the performance of thermal and photovoltaic concentrating solar systems a detailed determination and measurement of the Direct Normal Irradiance (DNI) is essential. The most accurate way of measuring this is with a bi-axial tracking pyrheliometer. However due to its high investment cost and need of maintenance, cost-efficient alternatives are of interest, especially for monitoring projects. This work presents an investigation of the performance and reliability of different alternative devices for the determination of the DNI, which are a sunshine pyranometer SPN1 device and a Rotating Shadowband Irradiometer (RSI). While the pyrheliometer directly measures the DNI via 2-axis tracking, the SPN1 and RSI determine the DNI through the measurement of the global and the diffuse irradiation and the information of the location and solar time. In order to investigate the suitability and reliability of these alternative instruments we have recorded data of about two years in 10 s resolution for the pyranometer SPN1 and pyrheliometer and of about 1 year in 1-minute resolution for the RSI and analyzed the data up to an irradiance of 950W/m^2.

Keywords: *Direct Normal Irradiance measurements, Pyrheliometer, Sunshine Pyranometer SPN1, Rotating Shadowband Irradiometer RSI*

1. Introduction

Accurate and reliable solar irradiance measurements of the global horizontal irradiance (GHI) and its fractions, such as the direct normal irradiance (DNI) and the diffuse horizontal irradiance (DHI), play an important role for solar resource assessments, either for short–term forecasting or for monitoring of solar plants. For solar power plants with concentrating systems, which can be photovoltaic or thermal collectors, the determination of the DNI is essential to evaluate their performance. Also solar thermal plants, which cover a lower temperature range (<300°C) compared to solar thermal power plants have been gaining a lot of attention for applications in industry and are becoming a promising source for process heat.

With the increasing awareness for the need of a more environmentally friendly and energy efficient industry, in the past few years several plants with solar thermal collectors have been installed in Swiss companies and are being monitored and evaluated by the SPF Institute for Solar Technology. For process temperatures between 100°C and 300°C concentrating collectors (parabolic trough and linear Fresnel collectors) are the most suitable technology and are used in three dairies in Switzerland. In order to evaluate the performance of these fields an accurate measurement of the DNI is essential. The most accurate way to do this is by a bi-axially tracking pyrheliometer. Collector developers and research institutes therefore use this instrument. However, a tracking pyrheliometer requires some maintenance and the costs are relatively high (approximately 15'000 Euros). For monitoring projects with field measurements of systems providing solar process heat such costs are in most cases too high.

In this study, we present our evaluation of two less expensive alternative instruments for the measurement of direct normal irradiation DNI: (1) the "Sunshine Pyranometer" SPN1 and (2) the "Rotating Shadow band

doi:10.18086/eurosun.2016.02.13 Available at http://proceedings.ises.org

Irradiometer" RSI in comparison to the bi-axial pyrheliometer for DNI and pyranometers for GHI and DHI measurements. For this, all devices are setup and evaluated at the test facilities at the SPF Institute of Solar technology in Rapperswil. In the case of the above-mentioned solar process heat plants, SPN1 devices are used for the measurement of the DNI. The here presented results are the basis for further studies on how to consider the deviation of the SPN1 or RSI devices to the pyrheliometer in the evaluation of solar plants when using these alternative instruments.

2. Materials and Methods

The evaluation of the radiation meters is carried out using the instruments and test stands at the SPF Institute for Solar Technology in Rapperswil, Switzerland. A bi-axially tracking pyrheliometer is used as the reference instrument for the DNI measurements (figure 1c). In Fig. 1 a (left) the pyranometer and a pyranometer with a shadow-ring are shown, which are used for the reference instrument for the GHI and DHI respectively. All instruments are cleaned daily.

While the pyrheliometer directly measures the DNI via 2-axis tracking and a view-limiting aperture of 5°, the SPN1 and RSI compute the DNI through the measurement of the global and the diffuse irradiation and the information of the location and solar time. In the SPN1 (Fig. 1a (center)) six sensors are placed on a hexagonal shape and one sensor in the center on a horizontal plane behind a complex shading mask. The shape of the shading mask ensures that at least one of the sensors is completely shaded and at least one is fully exposed to the solar irradiation, which allows measuring simultaneously GHI and DHI. The big advantage of the SPN1 is that no moving parts in need of continual accurate alignment are required, decreasing the maintenance cost. In the RSI instrument (Fig. 1b) two Silicon-based semiconductors sensor measure the GHI. Every 30s the shadow band rotates 360° around the sensors, which leads to a momentary shading. During the rotation phase of about 1s duration, data is collected in a frequency of 1kHz from which an internal algorithm computes the DHI after two cycles (about one minute).

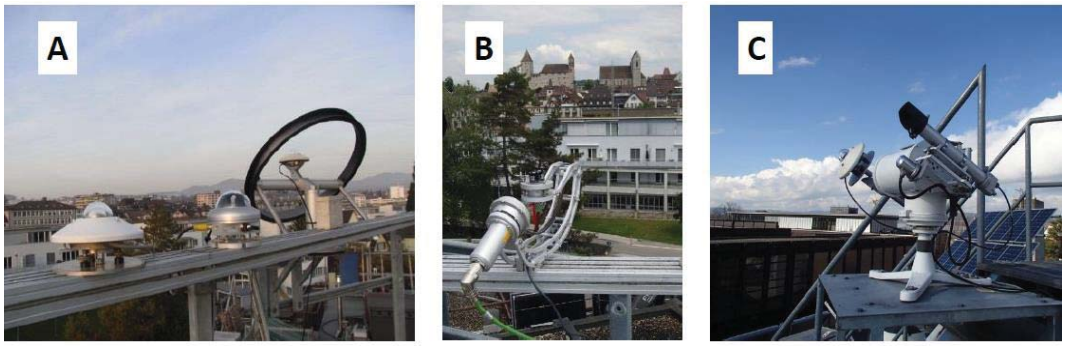

Fig. 1: (A) Pyranometer for the measurement of the horizontal global radiation (left), "Sunshine Prynometer SPN1" (center), pyranometer with shadow-ring for measurement of the horizontal diffuse radiation (right). (B) "Rotating Shadow band Irradiometer RSI". (C) Tracking pyrheliometer for DNI measurements used as reference. All instruments are installed at the SPF Institute for Solar Technology in Rapperswil, Switzerland

We have recorded data of about one year (8.8.2015-7.8.2016) in 10 s resolution for the SPN1, the pyranometer and pyrheliometer and in 1-minute resolution for the RSI and analyzed the data up to an irradiance of 950W/m^2. Data that showed obvious discrepancy due to operation failure was removed from the study. All data was evaluated using the recommended quality control test (Roesch et al., 2011)

The DNI value is calculated via

$$DNI = \frac{GHI - DHI}{\sin(\gamma_s)} \qquad \text{(eq. 1)}$$

where γ_s represents the elevation angle of the sun.

The evaluation of the measurements relative to the reference instruments and the quantitative criteria to describe the absolute and relative dispersion was done based on the publication of Badossa (2014). The slope

of the data was determined by a linear regression forced to zero. The standard deviation around the fitting line was calculated as follows:

$$STDE = \sqrt{\frac{\sum_{t=1}^{N}(I_{SPN1/RSI} - I_{ref} \cdot slope)^2}{N}} \qquad \text{(eq. 2)}$$

I stands for DHI, GHI or DNI. The index indicates the measuring device SPN1, RSI or by any of the reference instruments. N is the total number of values. The regression coefficient R^2 is calculated via:

$$R^2 = 1 - \frac{\sum_{t=1}^{N}(I_{SPN1/RSI} - I_{ref} \cdot slope)^2}{\sum_{t=1}^{N}(I_{SPN1/RSI} - \bar{I}_{SPN1/RSI})^2} \qquad \text{(eq. 3)}$$

$\bar{I}_{SPN1/RSI}$ Indicates the average value. Coefficient values larger than 0.99 indicate a high correlation.

3. Results for RSI and SPN1 vs Pyrheliometer and Pyranometer

In the following figures the deviation between the measurement values for DNI, GHI and DHI for the reference methods (pyrheliometer, pyranometer) and the alternative detectors SPN1 and RSI are shown.
An overview of all irradiance measurements during a day with clear sky conditions for all measuring methods is shown in **Error! Reference source not found.**. It can be seen, that the RSI measures lower values for DHI and DNI, while the SPN1 overlaps well with the reference measurements. The DNI line for the SPN1 shows a step around noon. This was observed for several days. One possible explanation is a mismatch of the different detectors with the SPN1 device or to dome lensing (Badossa (2014)). Further investigations are planned in order to resolve this issue.

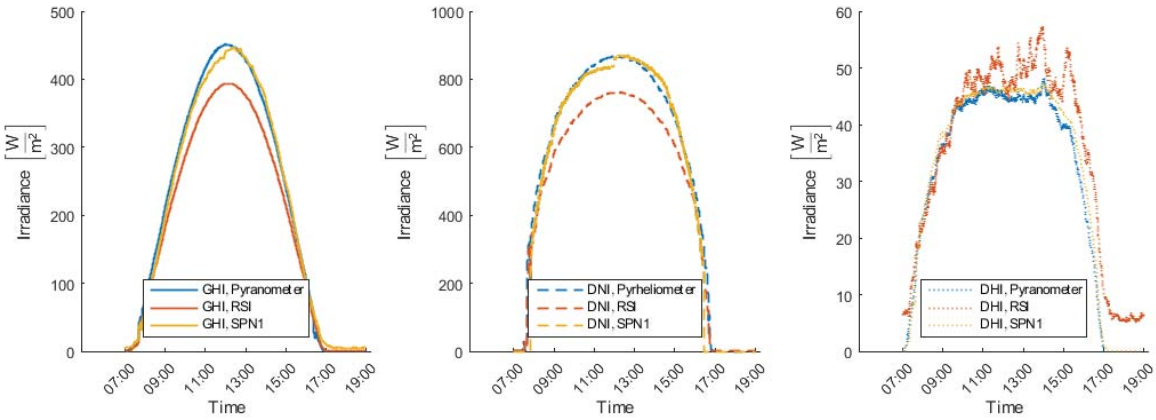

Fig. 2 Overview of GHI, DHI and DNI measurements with SPN1 and RSI and reference devices for one day with clear sky conditions at Rapperswil, Switzerland

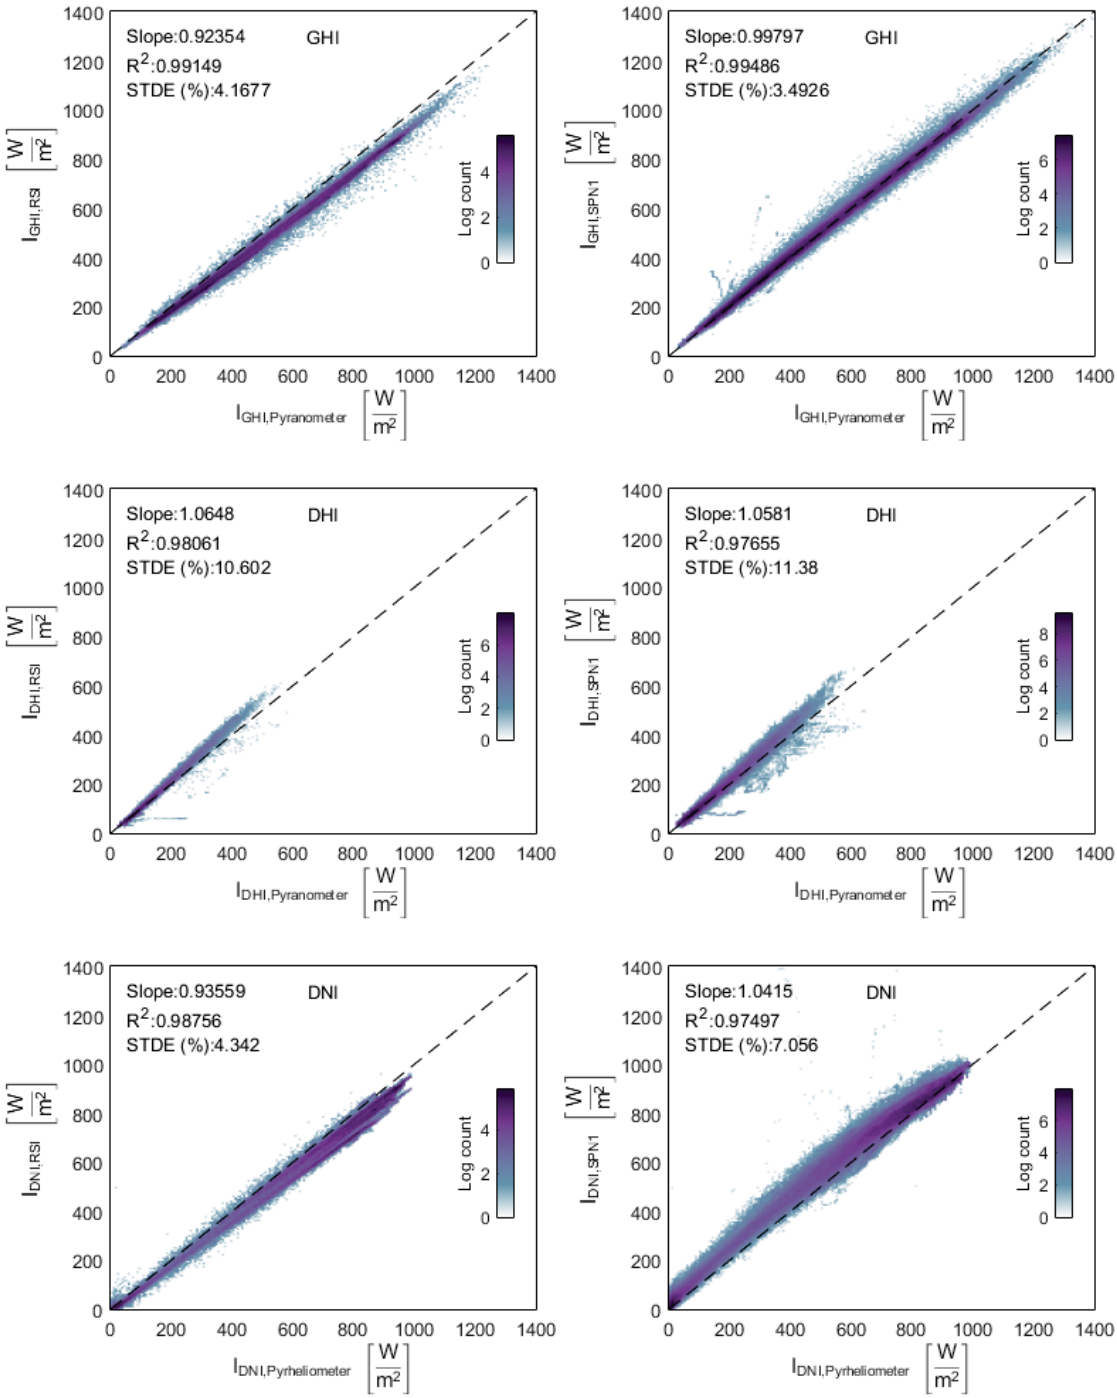

Fig. 3: Scatter plots of GHI, DHI and DNI for SPN1 and RSI in comparison to the pyranometer, pyranometer with shadow-ring and bi-axial tracking pyrheliometer, respectively. Measurements were performed at Rapperswil, Switzerland.

The scatter plots in Fig. 3 show the comparison between SPN1 or RSI vs the reference instruments, the pyrheliometer for the DNI and the pyranometers with and without shadow ring for the DHI and GHI measurements. The slope values indicated in each graph are obtained via a linear regression. The scatter plots show for both, SPN1 and RSI, the smallest spread of data points for the GHI and the largest spread (STDE 4.2% and 3.5%) for the DHI (STDE 10.6% and 11.4%). Furthermore, we see that the data spread becomes narrower for values above 800W/m^2. The slope values reflect well the previous observation done for **Error! Reference source not found.**. The slope value of 0.92 for the RSI measurement indicate an underestimation for GHI. While the slope of 0.998 confirms the good agreement between the GHI measured by the SPN1 and

the pyranometer. For the DHI comparison, both devices overestimate the values as indicated by the slope of 1.06. The SPN1 overestimates the DNI value, as indicated with the slope of 1.04. The RSI instrument underestimates the DNI value with a slope of 0.93. Furthermore, we observe for the RSI DNI several lines. Since those lines are not visible in the DHI and GHI measurements, we assume that they are an artifact caused by the internal algorithm that is used to determine the DNI.

In the following, we will focus on the relative deviation for the DNI between the values of the reference pyrheliometer and the SPN1 and RSI devices, since these values are the most important for the evaluation of the performance of concentrating collectors.

DNI : RSI vs Pyrheliometer

Fig. 4 shows the relative deviation for the RSI from the values measured by the pyrheliometer. The data shows a broad spread of data points for low irradiance values, due to the division by values near to zero at low sun elevation angles (eq. 1). For the evaluation of concentrating collectors the more interesting range of irradiance is above 600W/m^2, where the spread is also narrower and the maximal deviation is around 15%. For a better visualization, the histograms in Fig. 5 show the distribution for different irradiance values: (400 ±25)W/m^2, (600 ±25)W/m^2 and (800 ±25)W/m^2. For all three graphs we observe a negative deviation, which shows the underestimation of the DNI. Furthermore, two clusters at -5% and -12% are clearly visible. In Fig. 6 the relative deviation for the RSI from the values measured by the pyrheliometer for a restricted irradiance range between 700 W/m^2 to 900W/m^2 is shown. In addition, the data points are associated with the seasons. From this representation we discover clear lines for each season. Based on this, we can assign the two clusters observed in the histograms to the seasons. The lower deviation corresponds to summer and spring, while the higher deviation value can be attributed to winter and autumn. This is an indication of the dependency of the measurements and the solar altitude.

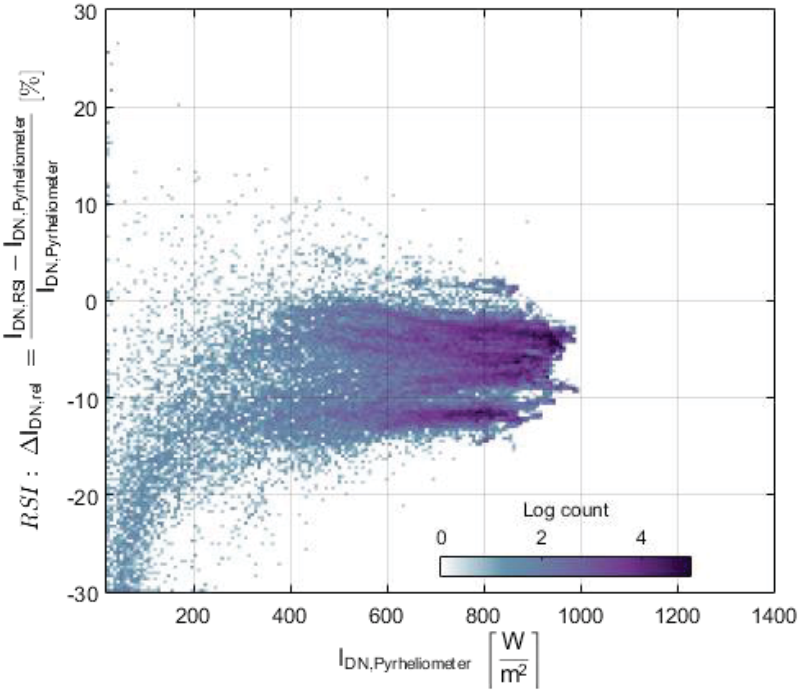

Fig. 4: Relative deviation of the calculated DNI for the RSI vs the values measured by the pyrheliometer.

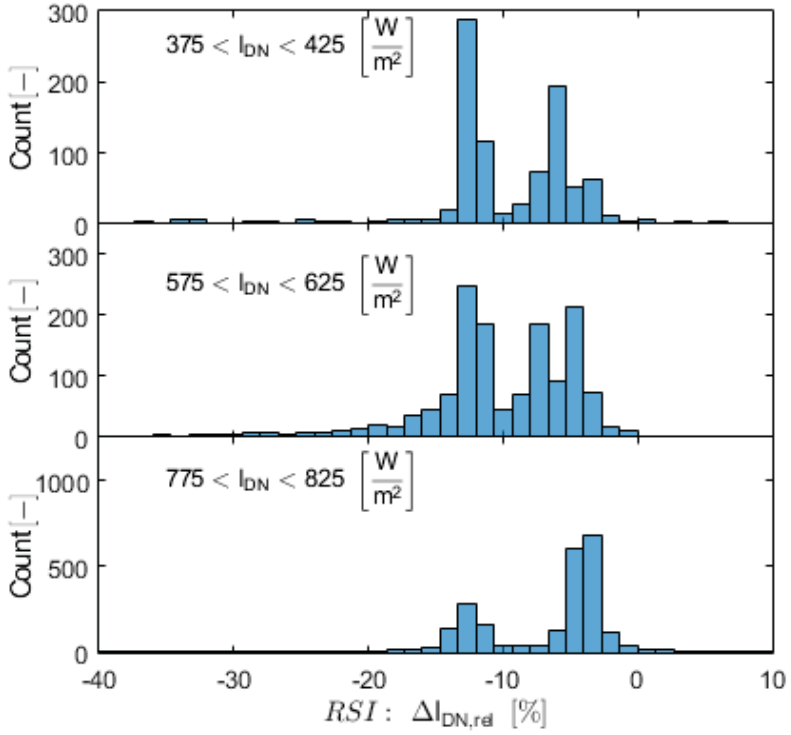

Fig. 5 Histogram indicates the distribution for the relative deviation of the calculated DNI for the RSI vs the values measured by the pyrheliometer at different irradiance values measured (400 ±25)W/m², (600 ±25)W/m² and (800 ±25)W/m².

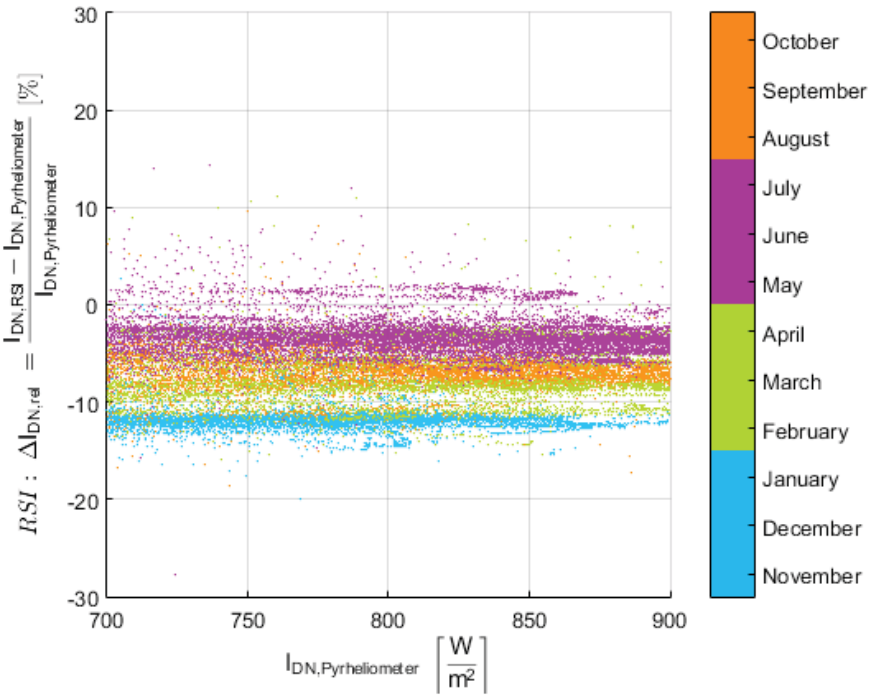

Fig. 6: Zoom of figure 4. Relative deviation of the calculated DNI for the RSI vs the values measured by the pyrheliometer. Color code indicates the seasonal correspondence of each data point.

DNI : SPN1 vs Pyrheliometer

Fig. 7 shows the relative deviation for the SPN1 from the values measured by the pyrheliometer. Similar to the data for the RSI in figure 4, the data shows a broad spread of data points for low irradiance values, due to the division by values near to zero at low sun elevation angles (eq.1). The positive deviation indicates an overestimation of the SPN1 in comparison to the pyrheliometer. The histograms in Fig. 8 show the spread of the data points at different irradiance values: (400 ±25)W/m^2, (600 ±25)W/m^2 and (800 ±25)W/m^2. In contrast to the RSI data, the data for the SPN1 show a more symmetric Gaussian shaped distribution around one center value, which moves closer to zero with increasing irradiance value. For (400 ±25)W/m^2 the mean value is at 16% , at (600 ±25)W/m^2 it is about 9% and for (800 ±25)W/m^2 it is around 3%. The variance μ and the STDE of the distribution also decreases with increasing irradiance values. The representation of the deviation in correspondence of the seasons (Fig. 6) shows no striking seasonal dependency, as could be observed for the RSI measurements in Fig. 9. Only for values lower than 800W/m^2 there is a slight difference visible between summer and winter months.

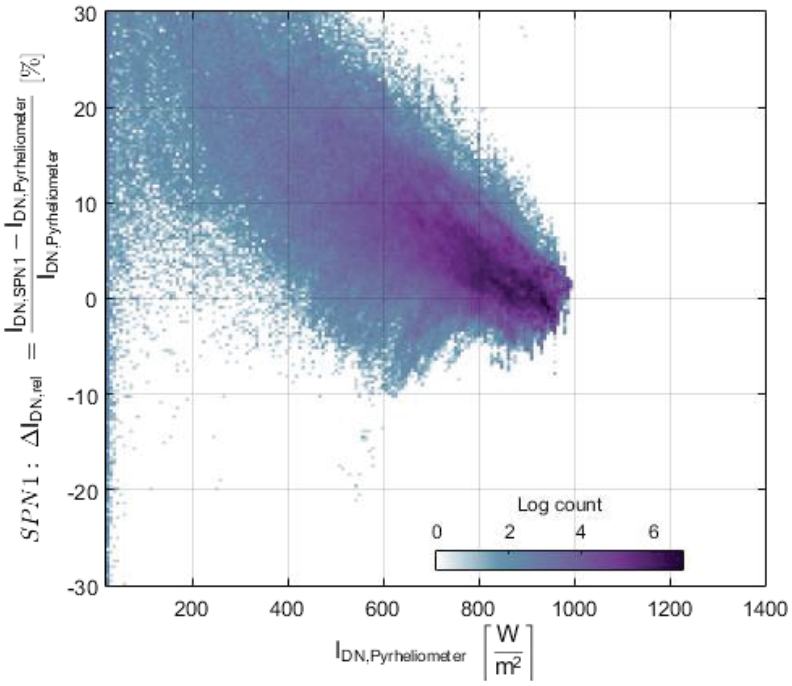

Fig. 7: Relative deviation of the calculated DNI for the SPN1 vs the values measured by the pyrheliometer.

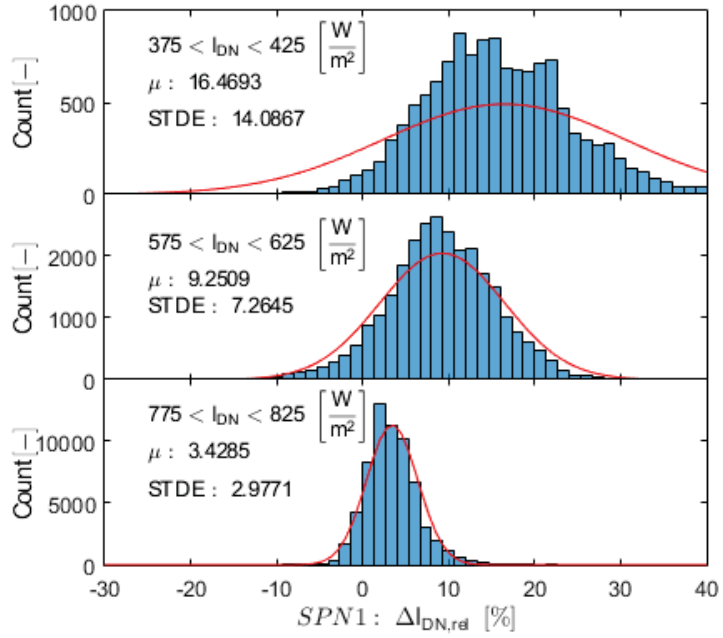

Fig. 8 The histograms indicate the distribution for the relative deviation of the calculated DNI for the SPN1 vs the values measur by the pyrheliometer at different irradiance values measured (400 ±25)W/m², (600 ±25)W/m² and (800 ±25)W/m².

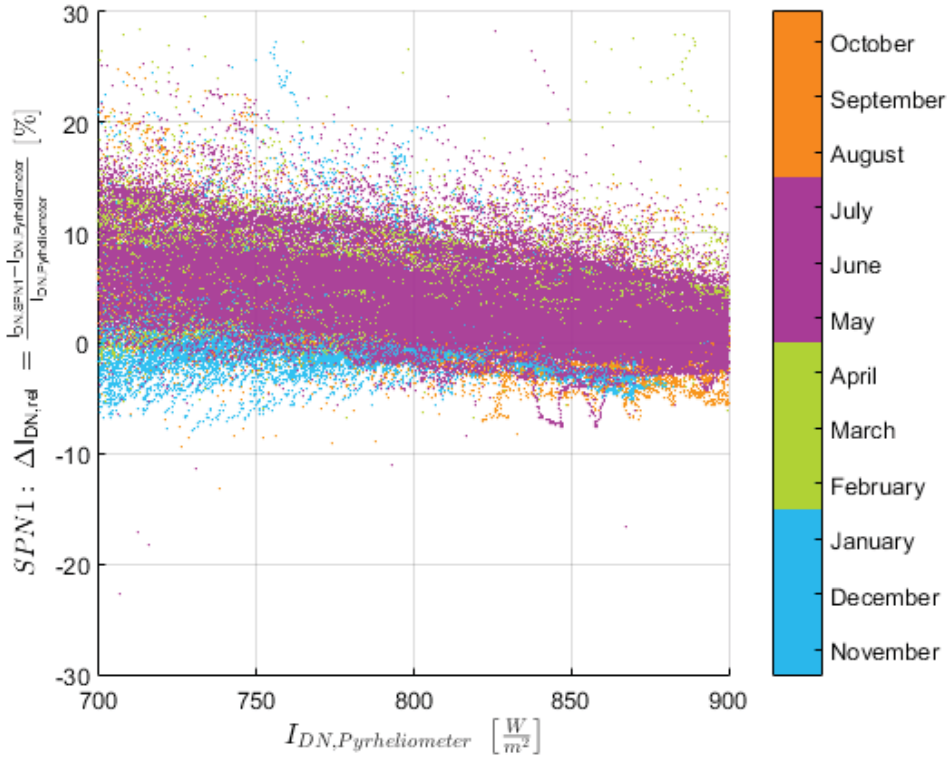

Fig. 9: Zoom of figure 7. Relative deviation of the calculated DNI for the SPN1 vs the values measured by the pyrheliometer. Color code indicates the seasonal correspondence of each data point.

4. Conclusion and Discussion

When comparing the RSI and the SPN1 it can be stated that the data for the RSI is less spread and shows the tendency to underestimate the DNI. The measurement for the SPN1 show a wider spread and indicate a slight overestimation of the DNI. The slope value for the SPN1 is in agreement with values obtained by Badosa et al. (2014), who determined a slope of 1.05 for Payerne, a location with similar conditions as Rapperswil. Both, the SPN1 and RSI device show a broad data spread for lower irradiance values below 400 W/m^2. The data shows a strong increase of the deviation for data points with very low irradiance values, due to the division by values near to zero at low sun elevation angles (eq.1). However, for the range above 600W/m^2, which is more relevant for concentrating collectors, the spread becomes narrower. The overestimation of the DNI by the SPN1 can be explained by the inclusion of a larger part of the circumsolar aureole at certain solar angles in comparison to the pyrheliometer, which has a limiting opening aperture (Badosa (2014)). For the SPN1 the results indicate a mean deviation of about 9% from the Pyrheliometer at 600W/m^2, which is in good agreement with previous studies (Badossa et al. (2014), D.R. Myers(2010), Rommel and Larcher (2015) and Rommel et al. (2016)). In addition, it only shows a deviation of 3.4% at an irradiance of 800W/m^2. For the RSI the deviation varies depending on the season, for summer 5% and 15% for winter season depending on the altitude of the sun.

We conclude that both alternative devices, SPN1 and RSI, show reliable measurements of the DNI at ranges above 600W/m^2 and are suitable for field monitoring of solar plants with concentrating collectors. These results are the basis for further investigations and detailed analysis of the accuracy and handling characteristics of these alternative devices with the aim to propose how to incorporate our findings into the evaluation of the performance of solar fields with concentrating collectors.

Direct steam generation for process heat applications in compound parabolic collector (CPC)

Madhavi V. Sardeshpande[1], Vishal R. Sardeshpande[2]

[1] Industrial Flow Modeling Group, Chemical Engineering Division, National Chemical Laboratory, Pune – 411 008 India

Abstract

In recent years, CPC (Compound Parabolic Collector) is gaining its acceptance for temperature range higher than non-concentrating stationery solar collectors like flat plate collectors but lower end of temperature range of concentrating solar collectors like PTC (parabolic trough concentrators). Generally, pressurized hot water or thermal oil is used as a working fluid in the CPC. The elimination of solar tracking in CPC provides flexibility for installation and lower price point compared to other concentrating technologies with tracking.

Steam is one of the universally accepted working fluid for process heat applications due to availability, non-toxic and high heat carrying capacity. Many industrial sectors such as food and beverages, textile, chemical processes etc utilize steam as a working fluid for process heat applications. Direct steam generation as a working fluid through a CPC has various operational, integration and cost advantages. The use of CPC for direct steam generation at saturation steam temperature range 105-145 °C (equivalent saturation pressure 0.5-3 bar (g)) can cater for low temperature process heat demand. Solar radiation intensity changes with the time of the day leading to change in heat flux for steam generation. There are challenges for handling two phase flow (steam generation) in 'U' shaped metal tubes due to pressure drop, flow instabilities and control of steam dryness fraction under varying solar heat flux.

The focus of the present research work is to analyze a CPC system for direct steam generation. This paper discusses an experimental setup and challenges for direct steam generation. The experimental measurements will be focused on behavior of the thermal flow pattern inside the inclined metal tube at various heat flux conditions throughout the day, measurement of local heat transfer coefficients and corresponding vapor quality. Experimental data analysis and understanding will be useful to develop direct steam generation engineering schemes and its integration approach with various end-use applications.

Keywords: *CPC, process heat, process steam, two phase flow*

1. Introduction

The fossil fuel is used for electricity generation and process heat applications. Considering adverse effects of fossil fuels such as air pollution and global warming, it is important to promote renewable energy technologies especially in industries (Garud and Purohit 2013). The process heat requirement in an industry typically varies from 80 ºC to 250 ºC. Steam is widely accepted working fluid to cater the temperature range of 80-180 ºC, thermal oil is a preferred choice above 180 °C.

Solar thermal technologies are of concentrating and non-concentrating type. Traditionally, the non-concentrating technologies are used for end-use temperatures less than 80 ºC, and the concentrating technologies are used for medium end-use temperature applications. The concentrating technologies track the Sun and reflect its radiation to the focal point of a concentrator. Medium temperature concentrating

doi:10.18086/eurosun.2016.02.09 Available at http://proceedings.ises.org

technologies provide temperatures in the range 80–400°C and are used mainly for process heat applications (Sukhatme & Nayak, 2008).

The major considerations for adoption of solar thermal technologies for process heat applications are existing working fluid, end-use temperature requirement, shadow free space available for solar installation and cost of solar thermal technology. The solar thermal technology providers are innovating to brake the conventional barriers for working fluid limitation, maximize system efficiency (reduce area and improve ability to cater higher temperature) and minimize cost of solar thermal system.

The CPC (Compound Parabolic Concentrator) technology is in the market from more than 25 years, it is combination of a stationery (evacuated tube) and a concentrating technology (reflector) with no tracking requirement, this also known as a non-imaging technology. The elimination of solar tracking provides ample flexibility for choice of installation areas and simple operation. Generally, single phase working fluids like pressurized hot water or thermal oil is used in the CPC for the temperature range of 80-130 °C. The use of CPC operating with single phase working fluid in steam system requires additional heat exchange devices and higher solar system operating temperature leading to increased capital cost and reduced thermal performance (due to high operating temperature).

This paper discusses the considerations and approach for the direct steam generation from the CPC. An experimental setup and measurement protocol for proposed for direct steam generation is also discussed in the paper.

2. Industrial process heat and solar thermal technologies

2.1 Industrial process heat

Process heating is an essential component in the manufacture of most of the industrial products, typically, the energy used for process heating accounts for 2% to 15% of the total production cost (U.S. Department of Energy 2001).

Share of industrial heat demand for different temperature ranges based on data from 32 countries is shown in figure 1. About 30% of the total industrial heat demand is required at temperatures below 100°C and 27% at temperatures below 400°C (IEA SHC Task 33 2008).

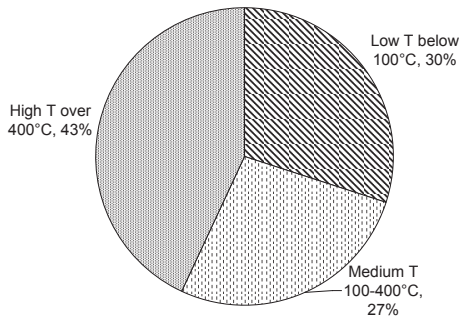

Figure 1: Share of industrial heat demand by temperature level. (IEA SHC Task 33 2008)

The majority of heat demand in industrial sectors, is at low and medium temperature. Saturated steam is generally a preferred working fluid for process heat demand below 180 °C. Steam system of a process plant has three major sections namely, generation, distribution and utilization. The steam generation is performed in a boiler (fired pressure vessel) and it is distributed using insulated steel pipes in the plant. Saturated steam has fixed pressure and temperature relationship; the desired temperature is achieved by adjusting the steam

pressure. A typical steam generation, distribution and utilization system is presented in figure 2. Steam is generated at a pressure close to the boiler design pressure, even if this is higher than is needed in the plant. The steam pressure is adjusted to desired end-use temperature using pressure reducing station.

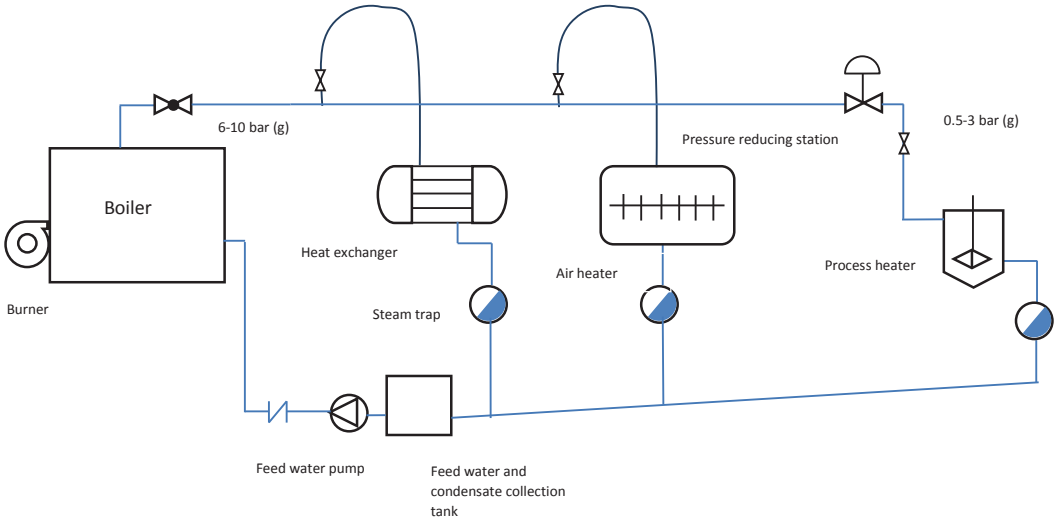

Figure 2 Typical steam system in a process plant

The key sectors utilizing industrial process heat are food (including wine and beverage), textile, metal, plastic, paper, dairy and chemical. The areas of application with the most suitable industrial processes, include cleaning, drying, evaporation and distillation, blanching, pasteurization, sterilization, cooking, curing, painting, and surface treatment. The typical temperature range for various applications is presented in table 1.

2.2 Solar thermal technologies

The popular concentrating and non-concentrating technologies for the process heat application is presented in figure 3. The temperature range for these technologies is presented in figure 4. There are different concentrating technologies suitable for different temperature ranges. There are two major types of concentrating technologies non-imaging (no tracking) and imaging (with tracking). The typical concentration ratio for non-imaging technologies is in the range of 1-10 and above this concentration ratio imaging technologies i.e. technologies with tracking are practiced (Rabl 1985).

Non-imaging concentrators have the capability of reflecting to the absorber all of the incident radiation within wide limits. The absence of tracking makes the CPC to accept incoming radiation over a relatively wide range of angles.

Imaging concentrators use tracking reflector systems to focus radiation onto a receivers (absorber) that is located at the focal point. Parabolic trough concentrators use parabolic trough reflectors to produce a linear focus on a receiver that moves with the trough as it tracks the Sun. Linear Fresnel systems use an array of smaller parallel reflectors that track individually onto a fixed linear receiver. Paraboloidal dish concentrators focus to a point focus receiver located at the focal point.

Table 1: Industrial sectors and processes with the greatest potential for solar thermal uses (Intelligent Energy, Europe 2006)

Industry	Process	Temperature ^{0}C

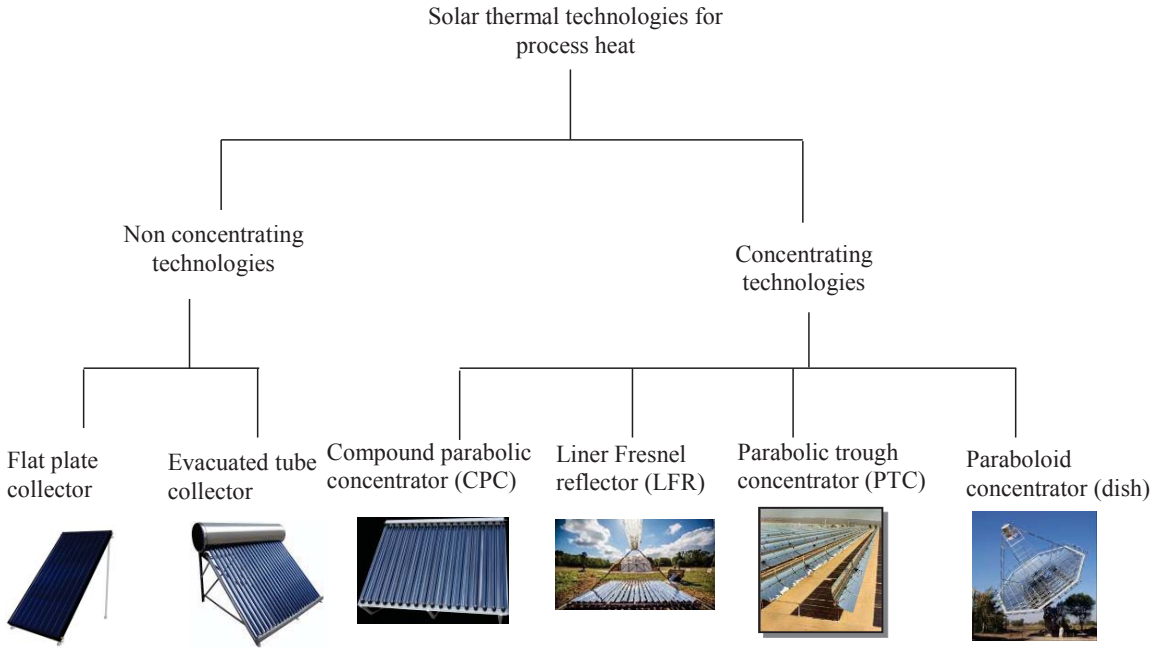

Figure 3 Popular solar thermal technologies for process heat applications

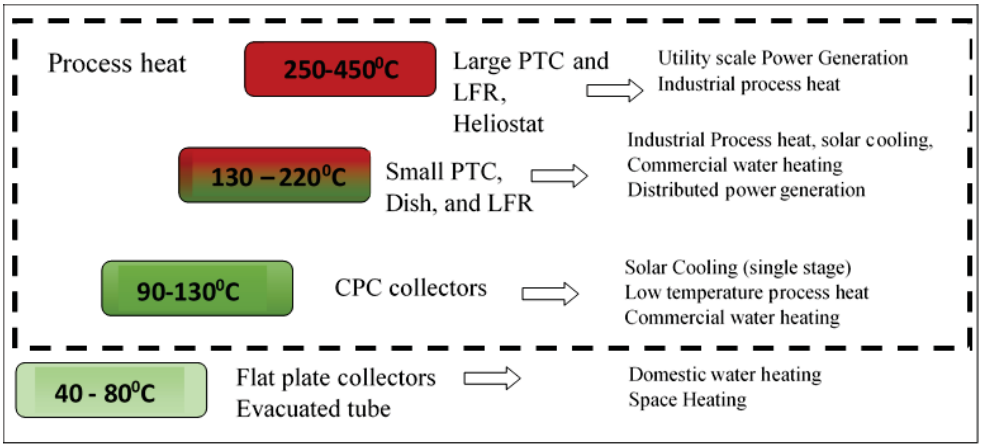

Figure 4 Solar thermal technologies and generation temperature range (ccilaportugal 2016)

It should be noted that quite often industrial processes utilize medium temperature heat in the form of steam even though for actual process lower working temperatures (below steam temperate in the range of 80-130 °C) would be sufficient. Performance of solar thermal system is better at lower operating temperature. Therefore, in order to assess correctly the feasibility of the solar thermal in an industrial process, one should look at the actual temperature needed by the process itself and not get driven by the utilization temperature of the heat carrier being used. Such an approach should be adopted to maximize overall performance of the solar thermal systems in process heat application.

Apart from temperature requirement, the other major consideration for solar thermal technology adoption is a system cost and suitability of an installation area. The CPC is non-imaging technology suitable to deliver heat at 90-130 °C temperature range at 20-40% lower system cost compared to imaging type technologies. The lower cost is mainly on account of no tracking requirement, no moving parts and simple installation structure. In addition to the system cost advantage, the CPC is flexible to install on a slanting roofs and has weight 18-22 kg/ m^2 aperture area compared to other concentrating technologies which have limitation for installation on the slanting roofs and the weight of such systems is in the range of 40- 80 kg/ m^2 aperture area

There are variety of applications like steam tracing, evaporation, boiling processes in cooking, essential oil extraction, pasteurization, sterilization etc. requires heat at 90-130 °C temperature range in the form of steam. In the process plants steam for such applications is supplied after PRS (pressure reducing station) in the pressure range of 0.5-3 bar (g) (shown in figure 2).

Generally, liner receiver systems use sensible heating working fluid either thermal oil or pressurized hot water for extracting heat from the solar thermal system. The sensible working fluid can be used for indirect steam generation using external heat exchanger and accessories. Indirect steam generation as process heat working fluid from concentrating solar system has various operational limitations and cost disadvantages captured as follows:

- Indirect steam generation requires additional steam generating system increase system cost, not very economical for small systems (below 100 m^2 aperture area)
- Lower solar thermal system performance as the sensible working fluid temperature needs to be 10 to15 °C higher than the steam generating temperature
- Continuous operation of sensible working fluid circulation pump leads extra energy cost for pumping
- Design of steam generating heat exchanger for varying sensible working fluid flow (30% -100%) on account of variation in the solar radiation during the day

3. CPC technology

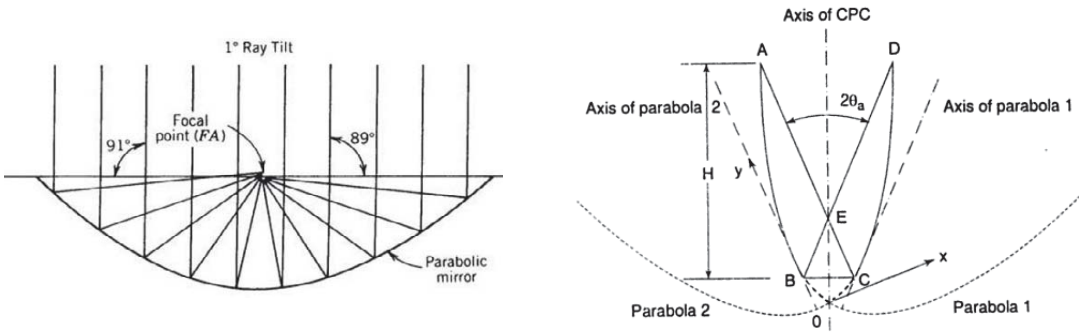
3.1 Basics of CPC

Compound Parabolic Concentrator (CPC) is a special type of solar collector fabricated in the shape of two meeting parabolas. It is a hybrid, non-imaging solar thermal system with high aperture area. The concentration ratio up to 10 can be achieved in the non-tracking mode easily (Rabl 1985). The geometry of a CPC is as shown in figure 5. It has two parabola sections AB and CD of parabola 1 and 2 respectively. AD is the aperture area with width ‘w’, while BC is the absorber area with width ‘b’. The axis is oriented in such a way that C is the focus of parabola 1 and B is the focus of parabola 2. Also the height of the collector is so chosen that tangents at A and D are parallel to the axis of the collector.

The acceptance angle of the CPC is the angle AED. It is obtained by joining the focus to the opposite aperture edge. In the CPC, reflector segments are oriented such that the focus of one segment lies at the base of the other segment which is in contact with the receiver. With this type of arrangement, the rays which falls in the central region reaches the absorber directly whereas those falling near the edges undergo certain reflections. The optical efficiency for a CPC is around 65%, which is 8% more as compared to a parabolic trough collector (Sukhatme & Nayak, 2008). The concentration ratio (CR) is given by w/b. For a

concentrating collector the amount of diffused radiation that can be collected is given by 1 /CR. Thus the advantage of a CPC is that it can collect diffuse radiation delivers partial heat output during cloudy atmosphere.

CPC are generally oriented in the East – West direction with south facing aperture area (for northern hemisphere), so that the maximum sunlight is utilized. However, for application where the concentration ratio is high or the acceptance angle is less, than tracking is to be provided to ensure that sunlight falls continuously on the CPC.

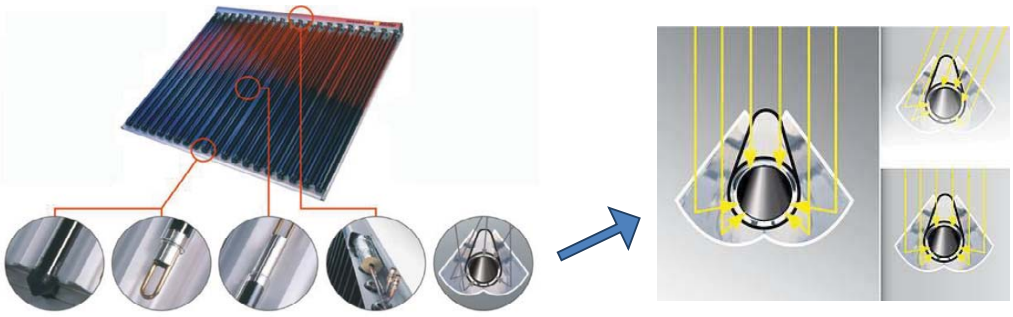


(a) (b)

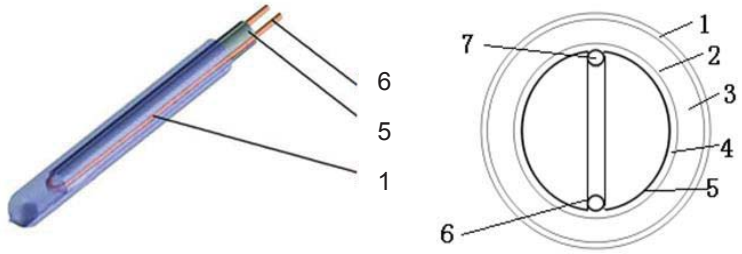
Figure 5: Construction of Compound Parabolic Concentrator (a) single parabolic mirror (b) two intersecting parabolas (Sukhatme & Nayak, 2008)

3.2 Construction of CPC

The main components of CPC technology are an evacuated tube, a compound parabolic reflector and a metal tubes (enclosed in the evacuated tubes) for transporting working fluid. The evacuated tube is a double sided selective surface coated glass tube receiver with vacuum envelop in the two glass surfaces. The evacuated tube is mounted inside the compound parabolic reflector. An 'U' shaped metal tube is enclosed in the evacuated tube, the metal tube is connected to the common headers for supply and return of working fluid. Pictorial view of CPC is as shown in figure 6.



(a)



(b)

1: Outer tube 2: Selective absorption coating 3: Vacuum gap 4: Inner tube 5: Transfer plate 6: U metal pipe 7: Working fluid

Figure 6: (a) Pictorial view of Compound Parabolic Concentrator (b) Internal 'U'tube (Linuo Ritter International 2014)

The evacuated tube receives direct solar radiation from upper surface (surface facing the sun) and receives reflected solar radiation from the bottom surface (surface facing reflector). The radiation received on the upper surface utilize both beam and diffuse component of solar radiation (global radiation) and the bottom surface utilizes only reflected beam component of solar radiation. Direct, diffuse and reflected solar radiation is received on the outer layer of a glass tube (evacuated tube); it is then passed through the vacuum, and is then absorbed upon a specialized coating on the inner layer of the glass tube. Heat is then radiated and conducted from the inner layer of the glass tube to a metal tube. Heat absorbed by the metal tube is transferred to a working fluid flowing inside the metal tube. Pressurized hot water or thermal oil is used as the working fluid to extract heat captured in the evacuated tube. The general arrangement for the sensible heating of working fluid using the CPC array is presented in figure 7. The major components of the system are CPC modules, a circulation pump, an expansion tank, a heat exchanger and piping accessories.

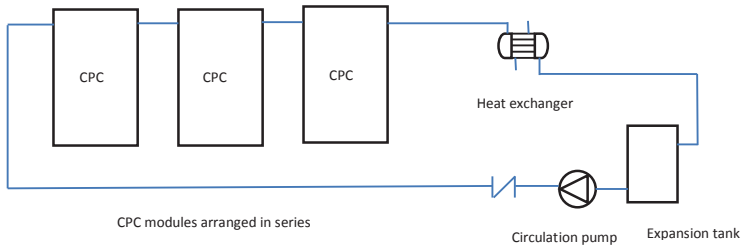


Figure 7: The general arrangement for the sensible heating of working fluid using CPC system

4. Steam generation from CPC system

Use of steam as a process working fluid for process heat has number of advantages like high heat carrying capacity, high heat transfer coefficient, constant temperature boundary condition during end-use heating, non-toxic, inexpensive, easily available etc.

There is limited literature about direct steam generation in a CPC in the recent past. Heinzel and Holzinger (1987) reported direct steam generation for process heat steam production from flat plate tubular collector. The steam generation from tubular collectors suffers from flow instabilities like steam blockage and flow pattern changes leading to vibration and unsteady release of steam (Heinzel and Holzinger 1987). The experimental setup of Heinzel and Holzinger (1987) was a natural circulating loop with heated riser glass tubes, release of the two phase flow in a steam drum and down comers to feed water back to the riser glass tubes. The experimental setup was operated with two modifications 1) use of orifice at the outlet of steam drum and 2) use of enlarge header for steam water separation at riser glass tube exist, both the modifications helped in curtailing flow instabilities.

El-Assy (1987) discussed the effect of a CPC thermal performance on steam exist condition (direct steam generation) using analytical equations. The effect of various parameters like concentration ratio, solar radiation, and mass flux on steam exit condition were predicted.

The challenges for direct steam generation in the CPC are as follows:

- Uniform water flow distribution in array of 'U' metal tubes enclosed in evacuated tube
- Steam lockout and flow instabilities in an array of the steam generating 'U' tubes
- High pressure drops for low pressure (low temperature) steam generation process
- Variation in solar radiation intensity leading to dry-out condition (100% steam dryness fraction) in individual tubes during operation

The challenges need detail investigations though experimentation for direct steam generation in the CPC system. The experimental measurements are expected to throw light on following aspects of direct steam generation from the CPC:

- Effect of variation in solar radiation on the different flow patterns in a tube boiling
- CPC solar collectors are generally mounted in an inclined position to maximize the intercept of solar radiation; the effect of inclination influences the transport processes in the bubbly and the intermittent flow regimes in two phase flow boiling.
- Two phase flow pressure drop, flow instabilities, wall temperature variations, control of dryness fraction under varying solar heat flux
- Source of two phase flow induced vibrations in the CPC system will be investigated
- The norms for acceptable water quality and steam exist dryness fraction will be studied to eliminate possibility of clogging of tubes

A suitable configuration for direct steam from the CPC will be developed considering various aspects investigated in experimental measurements

4.1 Experimental setup

CPC module mounted on the platform and integrated with supply line of water for direct steam generation will be the primary experimental setup. Schematic representation of experimental set up is as shown in Figure 8. The water at ambient temperature entering the CPC module will be heated from solar radiations. In order to study the steam generation in the CPC, there are two levels of measurement a) overall measurement of CPC module and b) local measurement of single tube

The overall measurement system consists of measurement of an inlet / outlet temperature to CPC modules, flow rate of water to CPC modules, heat flux incident on the CPC modules and dryness measurement of the

outlet steam. The flowrate of water is measured with the amount of condensate collected in the tank. The heat flux incident on the CPC module is estimated based on global and diffuse radiation measured with pyranometer. The measurement of dryness fraction is discussed by Sardeshpande et al (2011). The analytical equations for experimental measurements are given in Appendix-A.

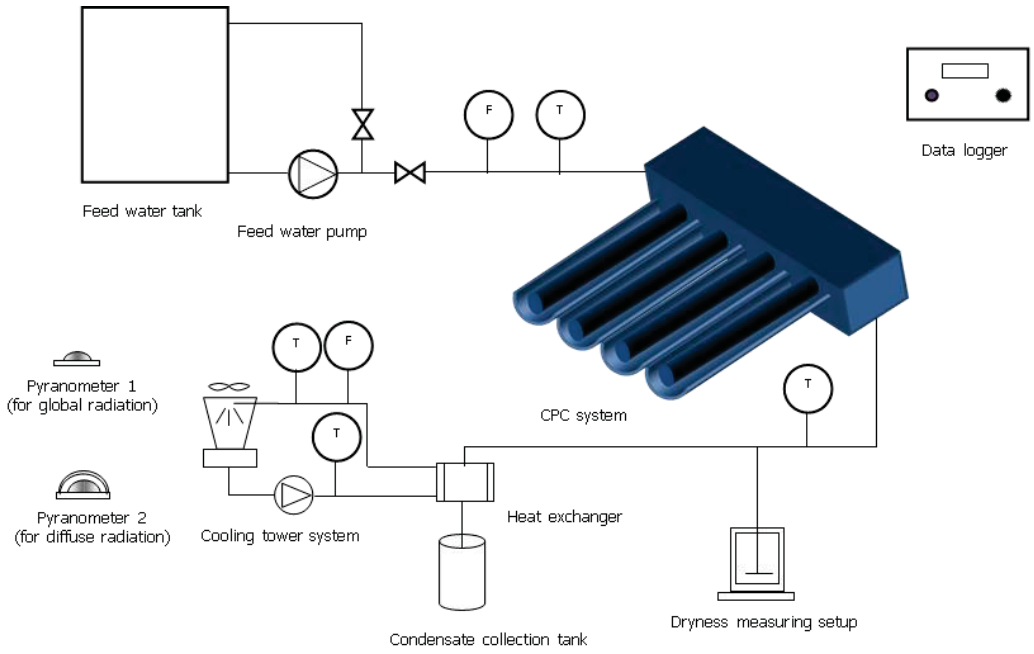

Figure 8: Schematic representation of proposed experimental set up

The local measurement consists of 10 temperature sensors installed along the length of a metal tube at an interval of 0.2 m distance. Along with this, two pressure sensors will be installed at the inlet and outlet of the tube to check the pressure fluctuations and overall pressure drop. The tube wall temperature as recorded by the temperature sensor will be the influenced by the heat transfer across the walls and formation of flow regimes inside the tube. The data generated by the temperature and pressure sensors will be recorded in data logger at suitable capturing frequency. The effects of solar radiation variations on steam dryness fraction and flow regimes in the tube will be investigated in this setup. The variation in tube wall temperature with solar radiation for constant mass flow rate indicates presence of different flow regimes. Schematic representation of local experimental plan is as shown in figure 9.

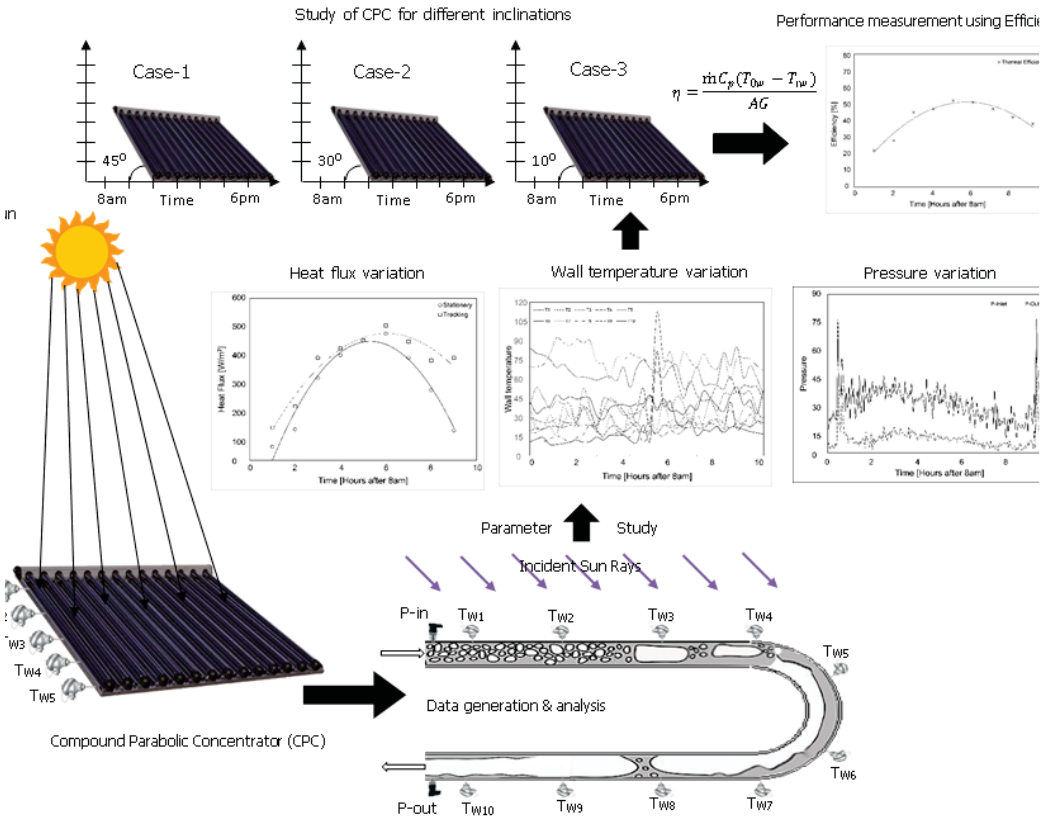

Figure 9: Schematic representation of Solar CPC and overall experimental plan

5. Conclusion

The direct steam generation from the CPC system has cost and operational advantages. However, it has many challenges on account of two phase flow in the metal tube enclosed in the evacuated glass tube. The two phase flow boiling patterns introduce flow instabilities and higher pressure drop. The present research work is focused on understanding and quantification of the direct steam generation in the CPC system.

The experimental setup proposed will undertake a) overall measurement of the CPC module and b) local measurement of single tube inside the CPC module. The overall measurement will be focused on the study of flow balances in various tubes, dryness fraction at the outlet of the CPC module for different solar radiation conditions and overall performance (thermal efficiency) of the CPC module. The local measurement of single tube will be focused on the wall temperature measurement along with mass flow rate of water and heat flux of solar radiation. The wall temperature will be used for the estimation of the boiling heat transfer coefficient. Experimental data analysis and understanding will be useful to develop direct steam generation engineering schemes and its integration approach with various process heat end-use applications.

Appendix -A: **EXPERIMENTAL MEASUREMENT ANALYTICAL EQUATIONS**

The experiments on CPC will be conducted for different combination of inclinations, flow rates and solar heat requirement and according to the results obtained it will be put to optimum use. The plot of efficiency of the CPC collector against time will reveal the optimum time for the use of CPC. The theoretical energy calculations about the quantity of steam or hot water required, the capacity of the CPC to handle this load will be investigated on daily basis as per the following.

$$Q_u = \dot{m}_w \times \left(h_{g,out} - h_{f,in}\right) \quad (1)$$

$$h_{g,out} = (1 - x) \times h_{f,out} + x \times h_{fg,out} \quad (2)$$

where Q_u = heat gain during the steam generation (kJ)
m_w = mass flow rate of water (kg/s)
x = dryness fraction of steam generated
$h_{g,in}$ = Enthalpy of steam at saturation outlet temperature (kJ/kg)
$h_{f,in}$ = Enthalpy of water at saturation inlet temperature (kJ/kg)
$h_{f,out}$ = Enthalpy of water at saturation outlet temperature (kJ/kg)
$h_{fg,out}$ = latent heat of evaporation corresponding to saturation outlet temperature (kJ/kg)
The total energy received by the CPC depends upon the average solar radiation normal to aperture and the aperture area. The total solar energy received by the reflecting surface of the concentrator is presented in equation 3.

$$Q_r = A_{ap} \times I_g \times t \quad (3)$$

where Q_r = solar energy received (kJ)
I_g = normal beam radiation (kW/m^2)
A_{ap} = aperture area of concentrator (m^2)
t = duration of test (s)
The thermal efficiency of CPC is ratio of useful heat recovered to the total heat received on the aperture area as presented in equation 6.

$$\eta_{th} = \frac{Q_u}{Q_r} \quad (4)$$

η_{th} = Thermal efficiency of CPC

$$Q_{u,st} = \frac{Q_u}{N} \quad (5)$$

Where, $Q_{u,st}$ = heat gain during the steam generation for single tube (kJ)
N= Number of tubes

$$Q_{u,st} = \varphi_{avg} \times A_{sa,st} \times \left(T_{w,avg} - T_{f,avg}\right) \quad (6)$$

φ_{avg} = Average heat transfer coefficient for single tube (W/m^{2}K)
A_{sa} = Surface area of metal tube (m^2)
$T_{w,avg}$ = Average wall temperature of sensors (°C)
$T_{f,avg}$ = Average fluid temperature (°C)

The instruments used for testing are listed in table 3. The test setup also includes a steam dryness fraction measuring setup where a small amount of steam is introduced into an insulated container. This setup is adapted from the method proposed for measuring steam quality[25]. The change in the temperature is measured along with increase in weight of the water in the container. The mass balance of the sample taken for steam moisture measurement is given in equation 7.

$$m_s = m_{w,f} - m_{w,i} \quad (7)$$

where m_s = mass of steam in the sample for dryness measurement (kg)
$m_{w,f}$ = final mass of water after steam is bled in the container (kg)
$m_{w,i}$ = initial mass of water before sample of steam is introduced (kg)
After the estimation of mass of steam introduced in the container of the moisture measurement setup, the moisture fraction in the steam sample is estimated using the equation 8.

$$x = \frac{\left[m_{w,f} \times C_{p,w} \times \left(T_f - T_i\right) - m_s \times C_{p,w} \times \left(T_{sat} - T_i\right) + m_c \times C_{p,c} \times \left(T_f - T_i\right)\right]}{\left(m_s \times h_{fg}\right)} \quad (8)$$

where x = dryness fraction of steam
$C_{p,w}$ = Specific heat of water (kJ/kgK)
T_f = Final temperature of water in container (°C)
T_i = Initial temperature of water in container (°C)
T_{sat} = Saturation temperature of water at the saturation pressure when test is conducted (°C)
m_c = mass of the container (kg)
$C_{p,c}$ = Specific heat of material of container (kJ/kgK)

Solar assisted production of expanded polystyrene with high efficiency flat plate collectors

Elisabeth Schneider, Jan Steinweg, Lukas Machelett, Federico Giovannetti

Institut für Solarenergieforschung Hameln, Emmerthal (Germany)

Abstract

The use of solar thermal energy for process heating in industry is a young field which has a high theoretical potential to reduce the consumption of fossil fuel, but also represents a high technical and economical challenge. In the framework of a running project we investigate the integration of a solar heating system into an existing production process of expanded polystyrene (EPS), through utilization of recently developed high efficiency flat plate collectors. For this purpose a detailed process analysis based on an extensive measuring campaign and a simulation study with different solar integration and efficiency strategies are conducted. The results should provide a basis for the development of a suitable integration concept. This paper features the results of the analysis and of the simulation study, showing different solutions for solar integration with reductions of fossil fuel consumption up to 11 %.

Keywords: *Process heat, high efficiency flat plate collector, industry, expanded polystyrene, EPS, efficiency*

1. Introduction

The use of solar thermal energy to support industrial processes is a young field which has a high theoretical potential to reduce the consumption of fossil fuel, but also represents a high technical and economical challenge.

In the context of a R&D project, which is supported by the Deutsche Bundesstiftung Umwelt (DBU) and in cooperation with the industrial partners Solvis GmbH and Kluth Dachbaustoffe GmbH we analyse the use of solar heat for the production of expanded polystyrene (EPS).

According to a first estimation based on market data (Sprengard et al., 2013) and extrapolated consumption data the current annual heat demand of the entire EPS-plants in Germany is around 150 – 200 GWh/a and will increase due to a rising market. This energy is required as process heat at temperature levels between 40 °C and 110 °C. The annual course of production, which depends on the typically seasonal intensity of activities at the building sites, shows a minimum in the winter months. These two aspects represent good prerequisites for the use of low-temperature solar heat.

The aim of the project is to develop suitable solar integration concepts for EPS-plants with new high efficiency flat plate collectors. These spectrally selective, double glazed collectors were developed in the context of a completed research project (Föste et al., 2013). In order to improve their cost effectiveness the size is increased (from 2 m² to 8 m²) and design modifications are implemented.

The article focuses on the integration of solar heat into the EPS-production process and on energy efficiency measures based on the existing plant configuration of the Kluth Dachbaustoffe company. After a detailed analyses of the production process, the plant is modeled with the simulation software TRNSYS and a simulation study with various kinds of system optimization and sizes of the solar system as well as different control strategies is carried out. The results provide a decision basis for the solar integration concept and for the system dimensioning.

doi:10.18086/eurosun.2016.02.10 Available at http://proceedings.ises.org

2. Analysis of the production process

In this section the foaming process of EPS is explained. Figure 1 shows the simplified process scheme of the production line.

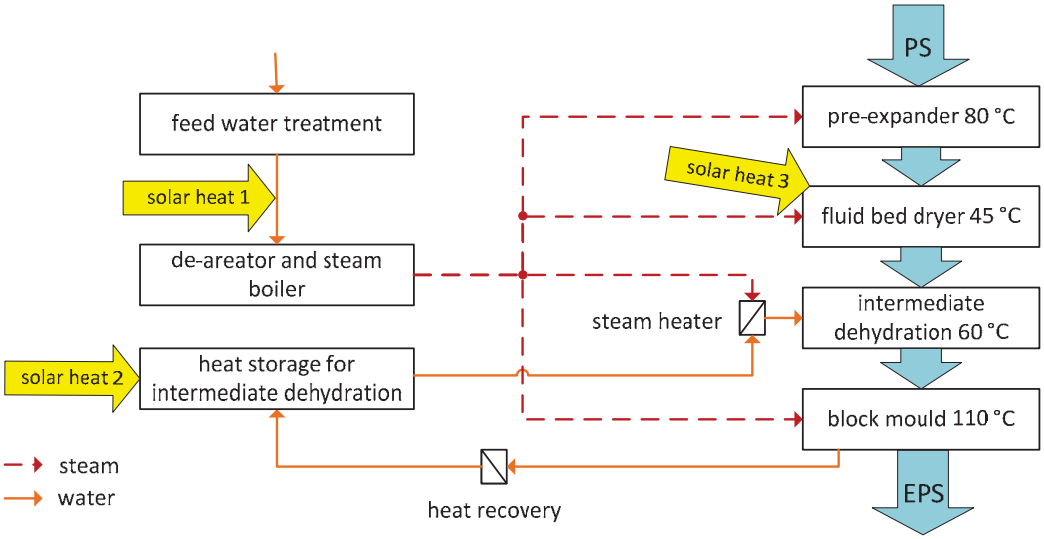

Figure 1: Simplified scheme of the foaming process and suggested integration points for solar heat.

The initial material is polystyrene granulate (PS), which contains of the main component polystyrene and the foaming agent pentane (Demacsek, 2016). This granulate first gets expanded in the pre-expander by steam at a temperature of around 80 °C, where it experiences a volume increase by about 5000 %. In the next step the pre-expanded and still in loose form existing polystyrene particles are pre-dried in the fluid bed dryer, which operates with steam heated air. Afterwards the EPS is stored in the intermediate dehydration. During the dehydration process the humidity, which has entered with the steam, is evaporated out to stabilise the EPS. Furthermore for the following processes the content of pentane has to be decreased to a defined percentage. The intermediate dehydration takes place in large silos and operates with an airflow heated by warm water from a heat storage tank (volume: 6 m³)[1]. This water gets thermal energy from a heat recovery of the block mould and, if necessary, receives an additional re-heating from a steam heater before it supplies the dehydration-process. In the current plant configuration the re-heating is conducted without a control strategy and the temperature in the silos ranges between 25 °C and 85 °C. According to the statement of the plant operator a provided dehydration temperature of around 60 °C would be optimal for a high quality product. When the material is ready for the next process, it is foamed in the block mould to blocks of 6 m³. The block mould operates with steam at a temperature of 110 °C. The EPS-blocks are then stored in a warehouse for further drying before they get cut and finished.

The production process runs during the day from Monday to Friday. The daily production time depends upon the seasonal demand, featuring a minimum during wintertime and a maximum in the late summer and in autumn. At night and on weekends there is no production. The yearly operation time amounts to approximatly 1000 hours. Currently the whole process plant of the company is supplied with heat from steam, generated by a natural gas-fired boiler. The annual energy demand of the boiler is about 1.6 GWh/a, the production volume is around 110.000 m³ EPS per year.

Following a pre-analysis of the production plant, an extensive measurement campaign has been started in July 2015, focusing on analysing the detail of heat flows and temperature levels at single plant sections. Through the data analysis three potential integration points for solar heat have been identified: the preheating of feed water before entering the boiler (solar heat 1), the intermediate dehydration (solar heat 2) and the fluid bed dryer (solar heat 3). These integration points are chosen because of their temperature levels (below 100 °C) and the fact, that steam is not directly needed as a process component.

To verify the potential for energy efficiency measures, additional measurements have been carried out. The waste

[1] The heating of the intermediate dehydration process is a specific feature of the considered EPS-plant.

heat flow of the pre-expander, the occurring condensate, waste heat from vacuum pumps and process-related radiant waste heat have been investigated. With the exception of the vacuum pumps, all analysed heat sources have a relatively low heat amount and/or a quite low temperature level making an useful and effective integration into the production process hardly possible. The cooling water of the heat pumps, which has an average temperature level around 50 °C at a flow rate about 7.2 m³/h and operates parallel to the block mould (circa 1000 h/a), is therefore taken into further consideration as heat recovery source. Additionally, the hydraulic interconnections of the single components were analysed with the aim of improving the process efficiency by considering the temperature levels of the available heat. This approach applies particularly to the heat recovery of the block mould and the intermediate dehydration.

3. Modelling the production plant

In order to evaluate the potential and possibilities of the considered efficiency measures and the implementation of the solar integration points in more detail, the relevant processes are modelled with the simulation software TRNSYS and a simulation study is carried out. Figure 2 shows the modelled components as well as their hydraulic interconnection schematically.

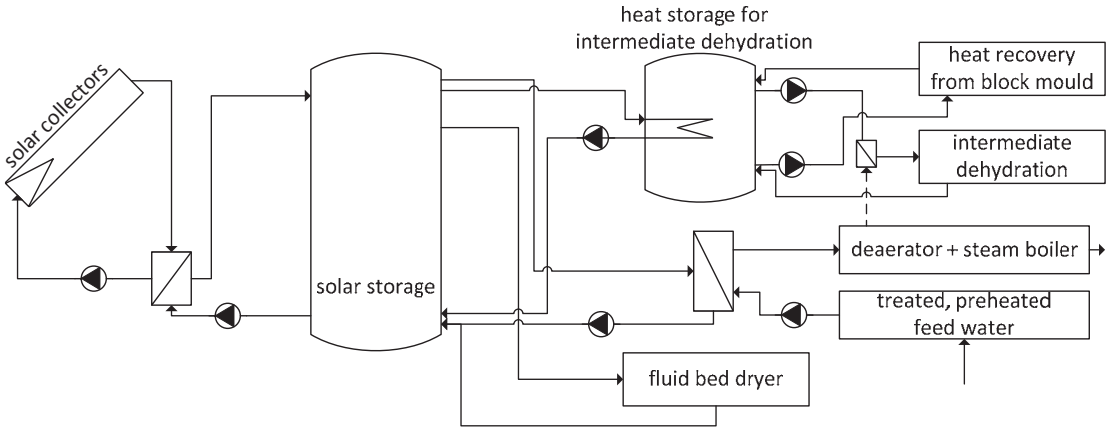

Figure 2: Schematic representation of the basic TRNSYS model for the current plant configuration supported by a solar thermal system.

The following components of the plant are modelled:

- Feed water supply (treated and pre-preheated by further heat recovery)
- Steam boiler
- Intermediate dehydration + associated steam heater
- Hot water tank for supplying the intermediate dehydration
- Heat recovery from the block mould (including the operation mode of the block mould)
- Fluid bed dryer

The single components are modelled considering the annual load profiles based on the measurement analysis.

The model for the solar thermal system includes the highly efficient solar collectors, a solar heat storage with an external heat exchanger for solar charging, a heat exchanger for pre-heating the feed water and a hydraulic connection between the solar storage and the heat storage for the intermediate dehydration.

Based on this model different simulation variations are calculated. Following parameters are varied:

- Solar system specific parameters:
  - Collector field area (given consideration of the available roof area)
  - Slope of the collectors
  - Construction of the collectors with its characteristic performance values
  - Volume of solar heat storage
  - Arrangement of the hydraulic connections at the heat storage
- Production plant specific parameters:
  - Hydraulic integration of the solar process heat

- Control strategy of the intermediate dehydration and its steam heater
- Hydraulic arrangement of system components (intermediate dehydration, heat recovery from the block mould)

4. Simulation results

The discussion is limited to the most significant findings of the simulation study. For the solar integration points, the following results are considered:

- Control strategies for the intermediate dehydration
- Integration of solar heat
  - Impacts of the hydraulic arrangement of intermediate dehydration and heat recovery: parallel connection vs. series connection
  - Integration of an additional heat recovery

All of the configurations are examined with different sizes of the solar thermal system. The collector parameters represent a highly efficient flat plate collector with spectrally selective air-filled double glazing (eta0 = 0.799, a1 = 2.45 W/m²/K, a2 = 0.101 W/m²/K², slope of the roof: 10 °).

4.1 Control strategies for the intermediate dehydration

As previously mentioned, in the current plant configuration the steam heater, which is responsible for the inlet temperature of the intermediate dehydration, runs uncontrolled. In order to ensure a high product quality, the ideal inlet temperature for the dehydration process is approximately 60 °C. Under this assumption, different control strategies are modeled and evaluated. Two exemplar configurations are considered here: System 1 - required temperature of 55 °C with continuous operation; System 2 - required temperature of 60 °C operating parallel to the plant operation.

The most significant differences of these two control strategies are shown in Figure 3.

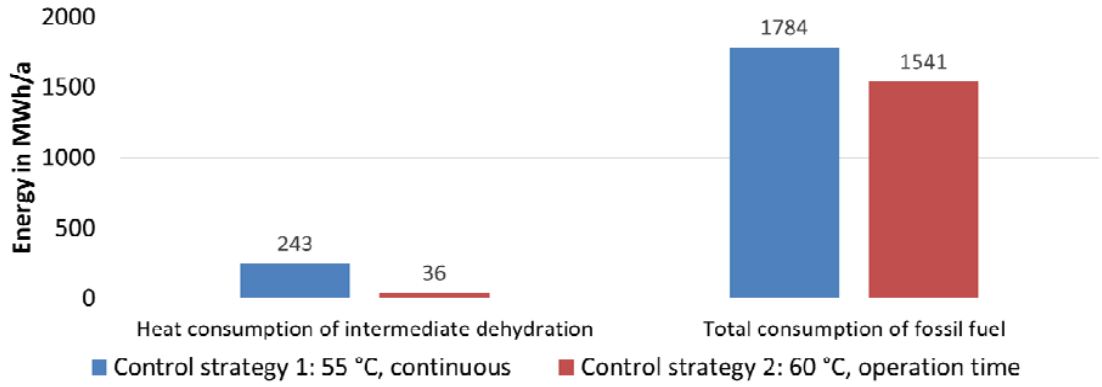

Figure 3: Calculated energy consumptions of the intermediate dehydration and in total for the considered control strategies without solar heat supply.

The energy consumption of the intermediate dehydration of system 1 is about 6 times higher than in system 2, mainly due to the different operation times. System 1 runs all over the year (except during the winter break), system 2 runs just about 1000 h/a, so nearly one-eighth of system 1. Because of the steam heater efficiency, the difference of 243 MWh/a between the total energy consumptions is a little higher than between the dehydration consumptions of 207 MWh/a.

To which extend the quality improvement of the product can compensate the significant increase of the energy demand, can only be evaluated by the plant operator on the basis of a comprehensive economic assessment.

In the following investigations both control strategies are considered. Since control strategy 2 has a lower heat demand for the intermediate dehydration, the control takes in case of available solar heat an additional heating for the dehydration beyond the operating periods into account.

4.2 Integration of solar heat

As previously mentioned, three solar integration points are considered. Based on the measured data of the current plant configuration, first estimations concerning the range of solar heat integration potential are done.

The theoretical potential for the feed water pre-heating (integration point 1) is defined by the temperature limitation in the solar storage tank, which amounts to 90 °C. On the assumption that the feed water can be pre-heated over the course of the year to 90 °C, the fossil energy savings are around 7 %. With the assumption that solar heat substitutes the complete supply of the steam heater, the theoretical solar heat integration potential of the intermediate dehydration (integration point 2) for the uncontrolled operation in the current plant configuration is about 8 %.

The estimated heat demand of the fluid bed dryer, therefore its maximum potential for the usage of solar heat is about 4 %. The current configuration features a heat exchange with steam supply. To ensure a sufficient heat supply by warm water laborious modifications of the existing supply system are necessary. Thus a solar heat supply for the fluid bed dryer is not taken into consideration for our simulations.

4.2.1 Impacts of the hydraulic arrangement of intermediate dehydration and heat recovery

In the current plant configuration the intermediate dehydration and the heat recovery from the block mould are parallel connected to the heat storage. To figure out if a series connection is more efficient than the existing one, both configurations are simulated, as shown in Figure 4.

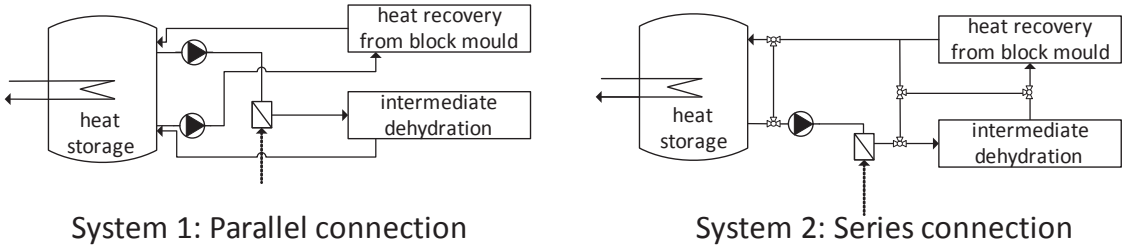

Figure 4: Sketch of the two different system configurations.

The simulation results for control strategy 1 and 2 are shown in Figure 5. The graph illustrates the reductions of fossil fuel as well as the additional heat supply of the intermediate dehydration for control strategy 2. The energy amounts are calculated in reference to the existing parallel plant configuration without the use of solar heat.

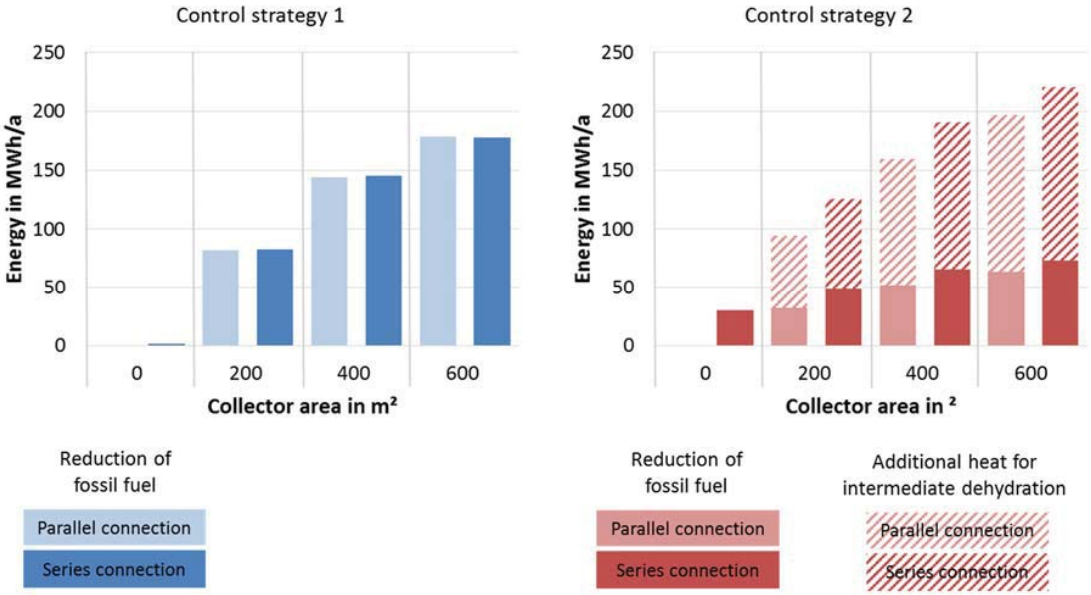

Figure 5: Calculated reduction of fossil fuel by changing the parallel connection into a series connection depending on the size of the solar thermal system.

As Figure 5 shows, for control strategy 1 the kind of interconnection has an insignificant impact on the consumption of fossil fuel. The main reason is that the system can take advantage of the series connection only when the two components are operating simultaneously. This occurs during approximately 12 % of the dehydration time, since the heat recovery only runs 1000 h/a. As a result most of the time the intermediate dehydration operates directly from and into the heat storage. Consequently there are no useful advantages with the change of this interconnection for control strategy 1.

On the contrary, for control strategy 2 a series connection leads to significant savings of fossil energy, due to a more efficient use of temperature levels of the available heat: The fluid, cooled down by the intermediate dehydration moves directly into the heat recovery where it can absorb more thermal energy at a lower temperature. Through a bypass these energy gains can be used directly for the intermediate dehydration. Compared to the parallel interconnection where the intermediate dehydration is supplied by a lower temperature from the heat storage, this series connection needs less steam for re-heating. This results in a significant reduction of fossil fuel. The difference of energy savings decreases by increasing the amount of solar energy production (size of the solar energy system). With a higher amount of solar energy the temperature of the heat storage in both systems rises. Therefore the advantage of using the heat recovery output directly for the dehydration decreases. Solar energy and heat recovery are partially in competition with each other.

The change from a parallel to a series hydraulic interconnection represents an energetically reasonable approach for control strategy 2 and is assumed for both strategies in the further simulation study.

In the next step, the theoretical maxima of fossil energy savings by the use of solar heat are calculated. For the feed water pre-heating fossil energy savings for both control strategies about 7 % of total energy demand were calculated, the same result as mentioned in the previous section. The fossil savings potential by heating the intermediate dehydration depends significantly on the control strategy. For control strategy 1 that results in a fossil energy reduction of 16 %, for strategy 2 in a reduction of 2 %. The theoretical total energy savings potential is about 23 % for control strategy 1 and about 9 % for control strategy 2.

The following figures present the achieved reductions of fossil fuel and the solar heat gains with collector fields up to 600 m² and as a function of the solar storage volume. Figure 6 shows the results for control strategy 1, Figure 7 for strategy 2.

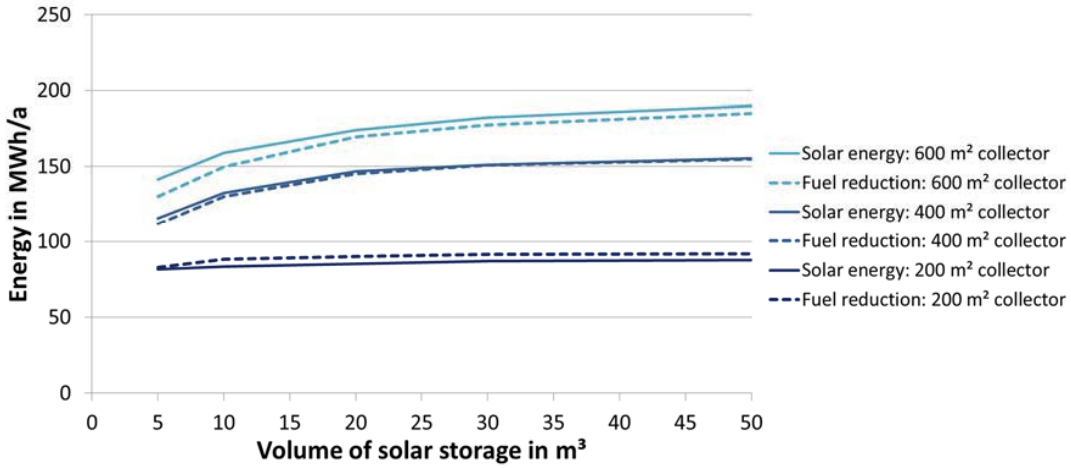

Figure 6: Control strategy 1: Calculated solar energy gains and fossil fuel reductions depending on collector area and storage volume.

Depending on the dimensions of the solar thermal system, control strategy 1 achieves solar gains up to 190 MWh/a. This corresponds to savings of fossil fuel up to 11 %. The amounts of solar heat gains and reductions of fossil fuel are approximately equal. The small deviations result from the boiler efficiency and heat losses of the solar thermal system. On the contrary, the results for control strategy 2 show significant differences between solar gains and fossil fuel savings. While the total solar gains are up to 200 MWh/a, the reductions of fossil fuel consumption reaches just 75 MWh/a, which correspondents to about 5 % of the total energy demand. The remaining solar heat gains up to 125 MWh/a are used to increase the process temperature for the intermediate dehydration, beyond the operation times, which is supposed to improve the quality of the EPS.

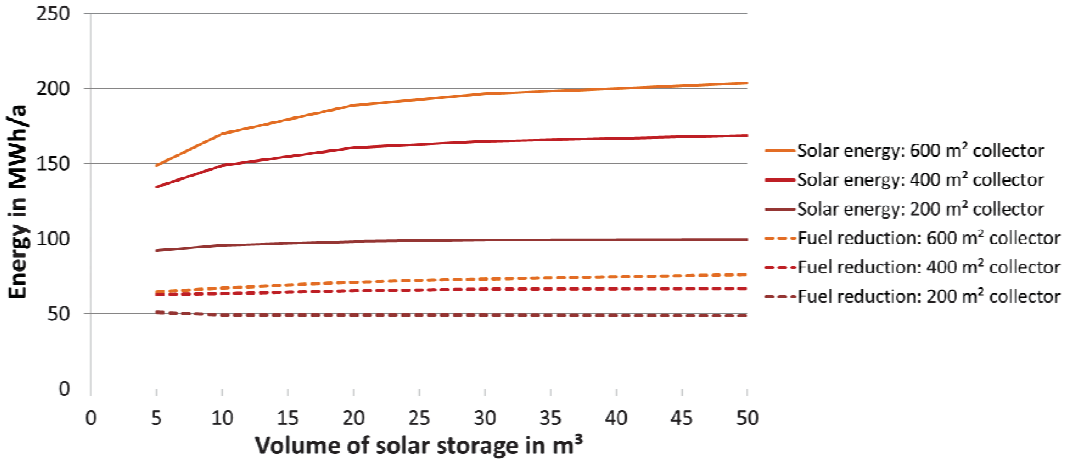

Figure 7: Control strategy 2: Calculated solar energy gains and fossil fuel reductions depending on collector area and storage volume.

Compared to the calculated theoretical fossil fuel savings potentials by the use of solar heat, control strategy 1 reaches 48 % with a collector field area of 600 m² and control strategy 2 reaches, at the same collector field size, 55 % of the potential energy savings.

4.2.2 Integration of waste heat from the vacuum pumps

As already noted, the cooling water of the block mould vacuum pumps could be used as a source for heat recovery. To analyse if this energy can be integrated usefully into the process, we carry out additional simulations. In the simulation model we assume that the heat from the recovery moves directly into the solar storage. Therefore, the potential heat sinks are the pre-heating of the feed water and the intermediate dehydration.

Figure 8 shows the savings of fossil fuel by heat recovery from the vacuum pumps for both control strategies and with different sizes of a solar thermal system with refer to the configuration without heat recovery and without solar heating supply.

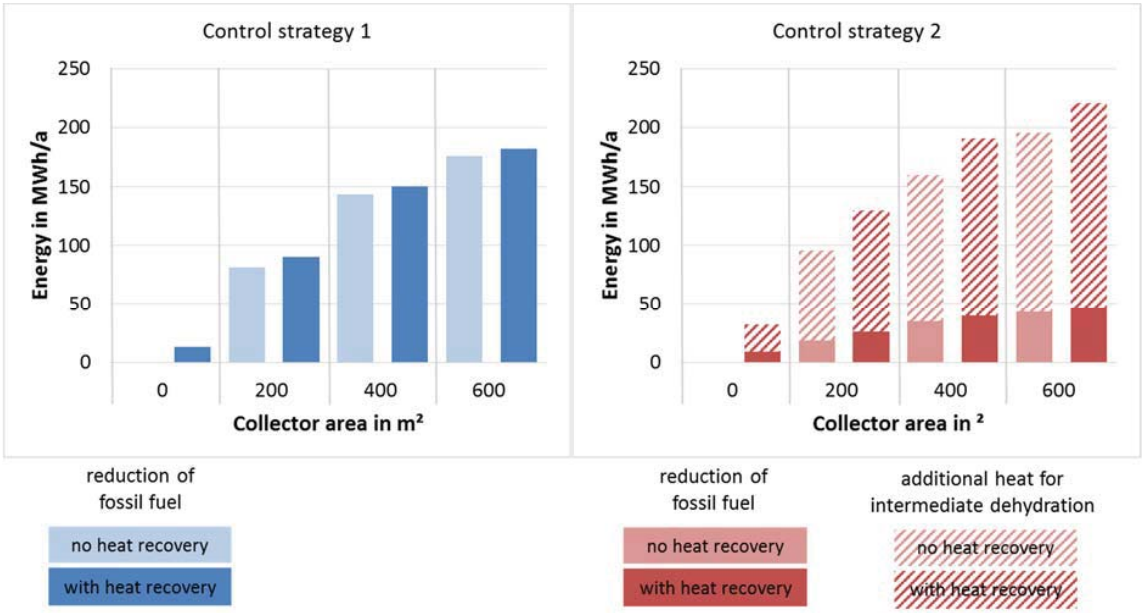

Figure 8: Calculated reductions of fossil fuel by using the heat recovery from the vacuum pumps depending on the control strategy and the solar thermal system.

The use of the heat recovery without a solar supply leads to fossil fuel reductions of 13 MWh/a and 9 MWh/a. The reason for the higher fuel reductions within system 1 is the higher energy demand for the dehydration and, thus, for pre-heating the feed water. In control strategy 2 additional heat for dehydration is available. In the

dehydration downtimes, when the steam heater is not operating, recovered heat even at relatively low temperatures can be used for the dehydration process. The amount of recovered heat decreases by an increasing solar heat supply. Consequently the use of solar energy and the recovered heat are partially in competition with each other.

To assess the reasonableness of this measure economic aspects should also be taken into consideration.

The final decision of which plant configuration is more appropriate to save fuel and to optimize the product quality has to be made by the EPS plant operator. For this purpose and also for dimensioning the solar plant an economical assessment and an analysis of the product properties should be carried out.

5. Conclusion and Outlook

We carried out a simulation study based on experimental data from a real plant to analyse the potential of solar heating for assisting the production of EPS. According to our simulation results, combining energy efficiency measures with the use of solar energy at the investigated EPS plant provide a potential for fossil fuel reduction up to 11 % are possible. The pre-heating of the feed water and the intermediate dehydration are identified as suitable heat sinks. The fluid bed dryer operates at a low temperature and could be qualified for solar assistance as well. The practical implementation requires a laborious modification of the existing supply system and was not taken into consideration for our analysis.

In the next step, both the solar system integration as well as the heat recovery measures should be evaluated under economic aspects.

The results should provide a basis for developing a solar integration concept for EPS-plants. The final aim of the research is not only to evaluate the suitability of solar process heating within this specific production facility but also to assess the transferability of the results to the broad EPS-industry.

Technical assessment of a concentrating solar thermal system for industrial process steam

Panagiotis Tsekouras, Rosie Christodoulaki and Vassiliki Drosou

CRES- Centre for Renewable Energy Sources and Saving, 19th km Marathonos Ave. Pikermi, 19009 Greece

Abstract

The aim of this study is to present a techno-economic assessment of a concentrating solar thermal system for steam production for a food industry located in Kalamata, Greece. The solar system mainly consists of the parabolic trough collectors, the steam generator and the thermal oil storage.

Initially, the potential hydraulic configurations of the system were demonstrated and evaluated. Following a thorough evaluation of a series of parameters, the most appropriate one was selected for analytical energy simulation. Energy simulation was performed with the Greenius software; the outcome of the simulations leads to measurable indicators of the overall system performance. The energy results of the selected system were presented in details followed by a parametric analysis modifying important system variables. The last section of this study provides technical conclusions accompanied with recent economic figures.

Present study aims to further assist the penetration of such systems to a market which is still under development in Greece.

Keywords: Concentrating solar thermal system, parabolic trough collectors, industrial process heat, solar steam

1. Introduction

Worldwide, 66% of heat is generated by fossil fuels and 45% of that is used in industry as process heat (European Union, 2013). At European level, 27% of total energy concerns heat consumed by industries. 30% regards temperatures below 100 ^{o}C, 27% temperatures in the range of 100 - 400 ^{o}C and the remaining 43% at higher temperatures (European Commission, 2009).

The efficacy of solar thermal systems in applications other than hot water production i.e. process heat and solar cooling has already been presented in former studies (Tsekouras et al., 2014; Tsoutsos et al., 2009; Drosou et al., 2009). However solar heat for industrial processes still presents a quite modest share of about 88 MWth installed capacity (0.3% of total installed solar thermal capacity, at European level) (Ecoheatcool, 2006). Solar thermal systems are considered to be cost effective mainly in low temperature applications. Moreover, at a European level there is intense research activity to broaden the applications of solar thermal systems beyond their established domains and to foster their participation in the energy maps of the EU-Member States.

The Concentrating Solar Thermal (CST) systems are expected to play a key role in this effort, especially for medium temperatures needed for industrial applications. The CST systems use a combination of mirrors or lenses to concentrate the direct irradiation radiation to produce heat. The most mature CST technologies are the parabolic trough collectors, the central receivers and the linear Fresnel collectors.

Greece is identified as one of the world-leading countries in the use of solar systems for hot water production presenting one of the highest ratios in the installed solar thermal collector area per capita. The main solar thermal product was, and still is, the thermosiphon water heater, comprising of flat plate collectors and

doi:10.18086/eurosun.2016.02.12 Available at http://proceedings.ises.org

storage tank. From the early 1990s to the present, several successful solar thermal systems for industrial process heating applications have been in operation in Greek industries; however, they are limited to flat plate solar systems, mainly due to the low level temperatures for hot water production. Among the industrial applications in Greece food industry, textiles, chemical industry and beverage industry are identified as presenting significant amounts of heat needs at a medium temperature level. As the industrial heat in Greece is produced by costly and polluting use of fuels (heavy oil, natural gas, fuel oil) this sector is ideal for solar thermal systems in terms of technical, environmental and economic feasibility. Apart from that, the climate change and the rising trend in energy costs require sustainable solutions that may use the domestic high solar potential.

2. Description of industrial user

For the purpose of the study, an existing industry was chosen, whereas the CST system will support the production steam needs. The industry is a food process industry situated in Kalamata, Greece. The production schedule requires energy throughout the year, seven days per week from 07:00 to 18:00, as depicted in Fig 1.

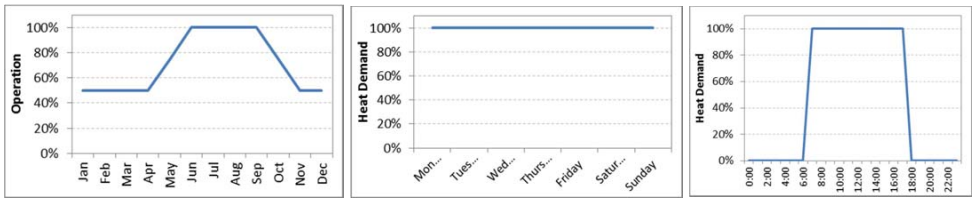

Fig 1: Time profile for year, week and day operation

Currently, the thermal energy requirements are covered by a conventional steam oil boiler with the technical characteristics summarised in Table 1.

Table 1 : Technical characteristics of the existent energy system

Description	Value
Steam temperature	170 °C
Steam pressure	7 bar
Steam supply	700 kg/hr
Annual energy consumption	1.554 MWh p.a.
Oil boiler efficiency	75 %
Annual oil consumption	207 tn p.a.

The meteorological data for the Kalamata site is extracted from the Meteonorm software, having a reference period from 1986 to 2005. The concenetrating solar collectors use only the Direct Normal Irradiation (DNI) which accounts for the specific site to 1,923 kWh/m^2 per year.

The DNI monthly distribution shows high mean daily values of approximately 8.7 kWh/m^2 during the summer period and low values of 3.1kWh/m^2. Fig 2 shows the distribution of DNI during a summer day.

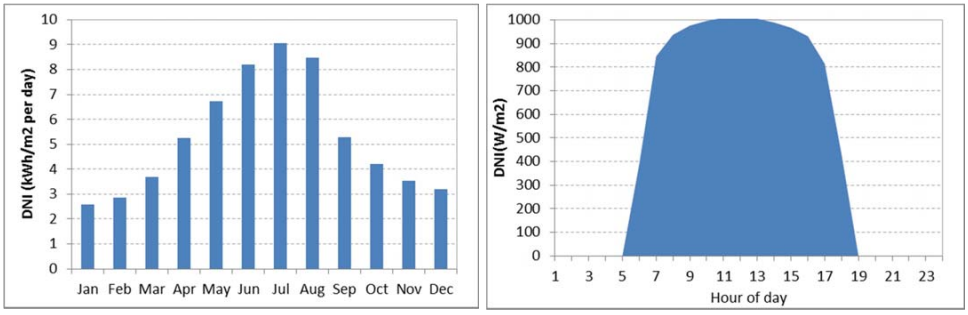

Fig 2: DNI distribution per month (left) and per hour of a summer day (right)

Fig 3 shows the number of hours during a calendar year when the irradiation exceeds a specific level. As such it can be noticed that, out of the annual 8760 hours the 1957 hours have DNI level higher than 500 W/m^2. This duration is a quite important factor for the annual system performance of a concentrating solar system considering that high radiation levels are provided during a significant part of the year. DNI of 500W/m^2 can be deemed as general threshold for CST plants operation. In this sense the optimum regions for CST plants are those with high levels of DNI occurred in long time in daily and yearly basis.

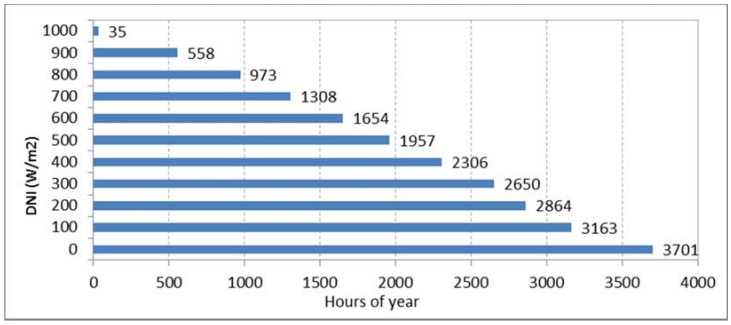

Fig 3: Annual distribution of hours for specific DNI irradiation levels.

3. Solar system configurations for industrial applications

In the following section, three suitable solar configurations for steam production using the solar system in parallel with the conventional one are examined. The parabolic trough collectors can operate either with thermal fluid (indirect steam production) or with two phase water (direct steam production).

3.1 Configuration C1: Indirect steam production via parabolic trough collectors with liquid thermal fluid and no storage

Starting from the concentrating solar collectors, the parabolic mirrors track the sun in one axis in order to concentrate the solar irradiation into the linear receiver located at the focal line. The receiver converts the concentrated irradiation to useful heat raising the temperature of the liquid thermal fluid which is circulated inside the receiver pipe. The thermal fluid, in higher temperature now, transfers its solar heat to the water in the steam boiler. When the produced steam reaches the required conditions, the steam is supplied to the thermal processes. If the solar system supplies less steam than the required amount, the conventional steam boiler covers the remaining requirements.

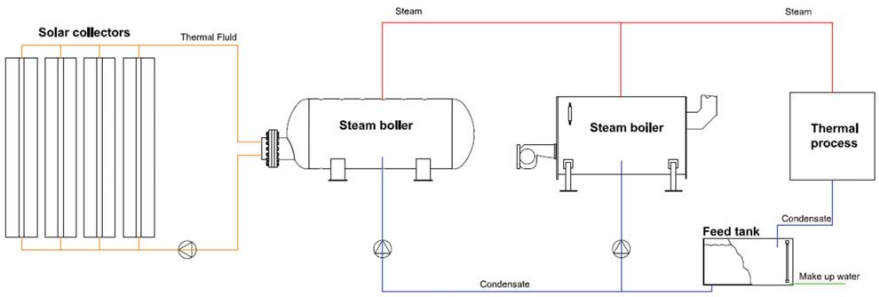

Fig 4: Configuration C1 -Indirect steam production via parabolic trough collectors with liquid thermal fluid and no storage

3.2 Configuration C2: Indirect steam production via parabolic trough collectors with liquid thermal fluid and thermal storage

This configuration is similar to C1, with only difference the integration of a thermal energy storage to the system which aims to exploit better the solar heat especially in cases when the solar heat flows are higher than the required. In this way, when appropriate sun conditions exist the thermal fluid is circulated at the parabolic trough collectors absorbing heat. Then the heated up thermal oil is stored at the thermal energy

storage. In case of steam demand, the thermal fluid from the storage drives the steam boiler. In this way the energy supply and demand are decoupled to some extent.

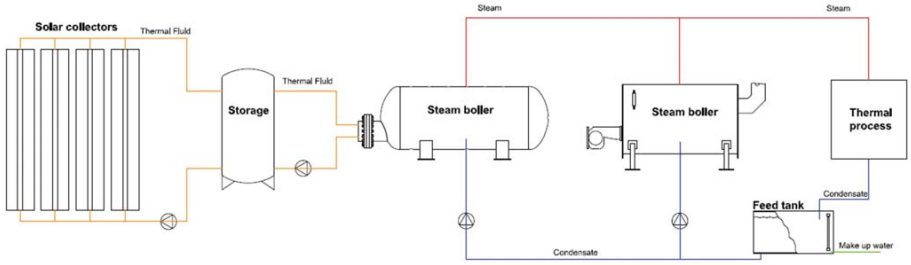

Fig 5: Configuration C2 - Indirect steam production via parabolic trough collectors with liquid thermal fluid with storage

3.3 Configuration C3: Direct steam production via parabolic trough collectors

This is the simplest configuration since it does not have additional steam boiler and storage system. Instead of a liquid thermal fluid, the two phase water is circulated inside the receiver pipes. In brief, the water passes through the first part of the solar collectors and it is heated up to the saturated liquid point. When it passes through the second part, the heated up liquid water starts boiling and being converted to steam and then to superheated steam. The produced steam enters directly the steam network and heads to the consumption.

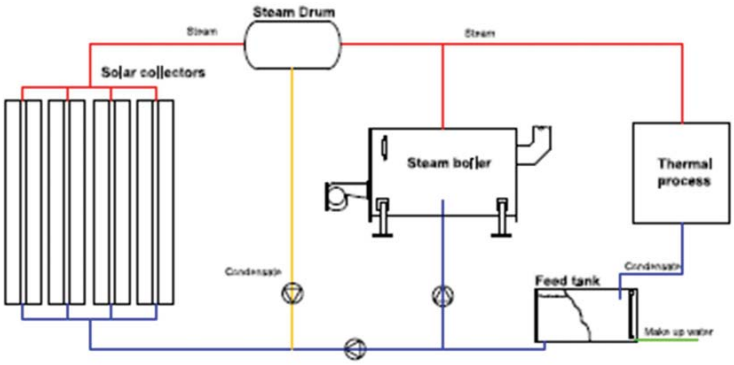

Fig 6: Configuration C3 - Direct steam production via parabolic trough collectors

4. Methodology

The initial scope of this study is present a proposal for implementation of a CST system in the industrial sector. Specifically, an integrated CST using parabolic trough solar collectors is discussed, used to support the steam production for a food industry located in Kalamata, Greece.

The Configuration C2 was selected for the purpose of this study as it combines the following advantages: good heat transfer characteristics, modest cost of heat transfer medium, lower operational pressure of solar system and commercial maturity. This section presents the technical characteristics of the major system components. In the present study, the below system case is used as the base scenario for the parametric analysis.

The technical characteristics and efficiency curves of the parabolic trough collector are summarized in Table 2 and Fig 7. The solar field consists of 80 solar collectors with reflective area of 1,056 m^2. The solar collectors are aligned in 8 parallel series with North – South orientation and 10 collectors in series. The optical losses due to dust in the mirrors are assumed to be 3% all year long, taking into consideration a regular cleaning and maintenance schedule.

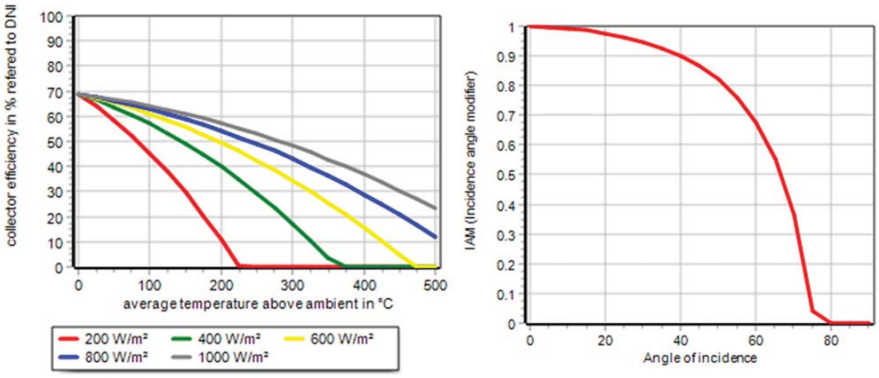

Fig 7: Efficiency curves of the parabolic trough collectors

Table 2 : Technical characteristics of the parabolic trough collector

Description	Value
Aperture width	2.3 m
Collector length	5.75 m
Effective mirror area	13.2 m^2
Receiver diameter	0.0508 m
n_o	0.689
a_1	0.36 W/(m^2K)
a_2	0.0011 W/(m^2K^2)
Number of collectors / rows / collectors per row	80 / 8 / 10
Orientation	North - South
Total effective mirror area	1056 m^2
Total absorber length	460 m

For the selected configuration, a specific type of thermal oil has been selected for the solar field that meets the following prerequisites: liquid state in the operational temperature range, low freezing point, good heat transfer, thermal stability, non-corrosive, low initial cost. As the parametric analysis included operation of the solar field in temperature up to 350°C the selected thermal oil has the following characteristics. In the base scenario the thermal oil supply temperature from the solar collectors is 250°C with returning temperature of 200°C.

Table 3 : Properties of the thermal oil

Temperature (oC)	Density (kg/m^3)	Heat capacity (Wh/kg.K)
65 / 255 / 355	1023.7 / 854 / 734	0.4725 / 0.6197 / 0.712

The thermal storage is a single tank with volume of 10 m^3 corresponding to thermal storage capacity of 250kWh in the range of 200-250°C.

Table 4 : Technical characteristics of the thermal storage

Description	Value
Thermal energy capacity	250 kWh
Operational temperature range	200 - 250 °C
Storage volume	10 m^3

Tank material	Stainless steel
Insulation material	Mineral wool 100kg/m^3
Insulation thickness	50 cm

5. Results and Discussion

5.1 Methodology

The energy study is conducted with the software Greenius (Greenius, 2016), considering the simulation algorithm as shown in Fig 8. . In brief, the simulation starts by reading the climate data (i.e. DNI, ambient air temperature, sun position) of the specific location. The climate data along with the characteristics of the parabolic trough collectors (i.e. solar module characteristics, efficiency coefficients, incidence angle modifier), the solar field (i.e. number of modules, orientation, series distance, operating temperature, piping characteristics) and the thermal storage result in the potential solar heat gains from the solar collectors. This heat is divided in the heat losses and the useful solar field heat. The later can be exploited by the end user (useful solar heat) in order to cover the energy requirements. Still, there is a small portion of the solar field heat that owing to time and load restrictions cannot be utilized (dump solar heat). The heat load is calculated based on the energy profile of the end user. When the solar system cannot meet the full energy demand, the auxiliary boiler is activated supplying the extra heat required.

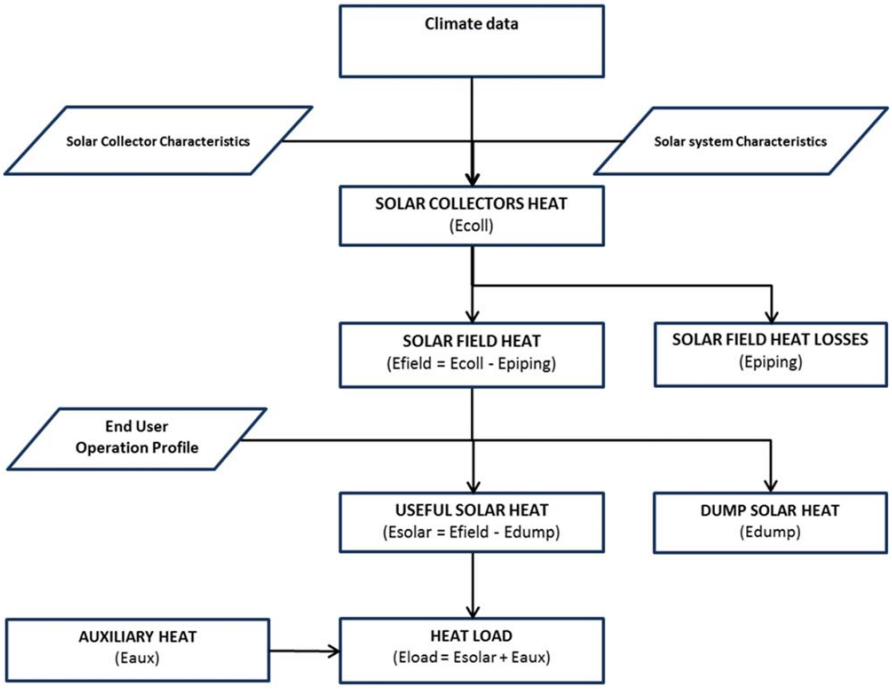

Fig 8: Algorithm for energy simulation of the system

5.2 Energy results

For the specific dimensioning and configuration that analyzed in the previous sections, the simulation energy results are presented below. The graphical representation of the direct normal irradiation (DNI) annual variation, the heat produced by the solar collectors (Ecoll), the solar collectors efficiency ($\eta_{\_coll}$), the solar heat produced by the solar field (Efield), the dump energy (Edump), the useful solar heat of the solar plant (Esolar = Efield – Edump), the solar field efficiency (η_field), the overall solar fraction (RF) and the heat load (Eload) variation are shown in Table 5, 6, 7 and Figure 9 & 10.

Table 5: Summary of energy simulation results

Parameter	Value
Direct Normal Irradiation (DNI)	2 031 MWh
Solar collector heat (Ecoll)	739 MWh
Solar collectors efficiency (n_coll)	36 %
Useful solar heat (Esolar)	655 MWh
Solar Fraction (SF)	42 %
Oil saving	87 333 lt
Reduction of CO_2 emmissions	213 960 kg

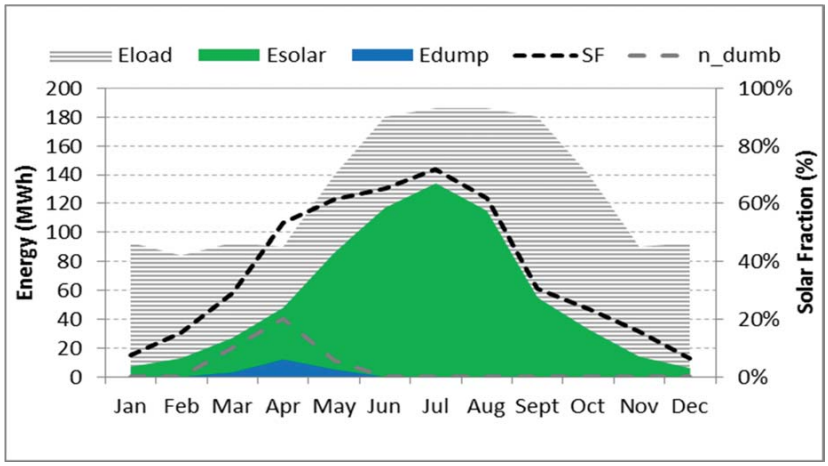

Fig 9: Overall system energy performance

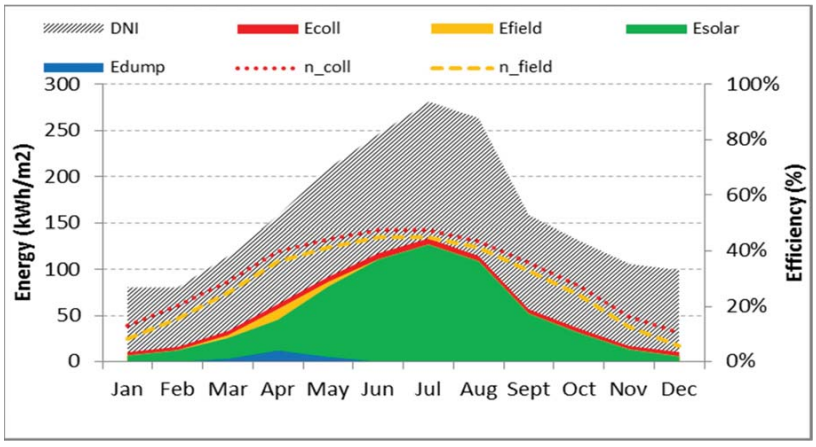

Fig 10: Solar field energy performance

The annual solar irradiation is 2,031 MWh (or 1,923 kWh/m^2), with the solar collectors being able to produce at maximum 739 MWh (700 kWh/m^2) of heat operating with an annual efficiency of 36%. Given the heat losses and the thermal inertia of the solar system, the available solar field heat (Efield) is at maximum 675 MWh (639 kWh/m^2). Moreover, owing to the mismatching of the supply and demand, a small portion of the solar heat cannot be exploited (Edump) and therefore the final heat supplied to the end user (Esolar) equals to 655 (620 kWh/m^2). The solar system achieves solar fraction (SF) of 42%, with the energy savings corresponding to oil savings of 87 tn per year and CO_2 emissions of 213tn.

Table 6 summarizes the energy results in monthly base.

Table 6: Energy simulation results in monthly basis (part I)

5.3 Parametric analysis

The solar system of the previous paragraphs has been used as the base scenario for each parametric analysis as a result of the 35 cases that were examined and analyzed in

Table 8.

Table 8: Variables of parametric simulations

Variable	Minimum	Maximum	Step	Number of simulations	Value of base scenario
Orientation of the parabolic trough collectors	0°	90°	10°	10	0°
Outlet temperature from the solar collectors with constant DT =50K	225 °C	350 °C	25°C	6	250°C
Outlet temperature from the solar collectors with constant inlet temperature of 200°C	225 °C	350°C	25 °C	6	250°C
Solar aperture area	500	2,000	250	7	1056 m^2
Series distance expressed in multiples of the collector aperture width	1	4	0,5/1	6	2.5

5.3.1 Variable 1 - Orientation of the parabolic trough collectors

In this parametric set, the effect of the orientation of the parabolic trough collectors at the system energy performance was investigated. In total 10 cases were simulated from the North-South orientation to the East - West with a step of 10° field rotation.

The optimum orientation is the North – South with annual solar field heat accounts for 639 kWh/m^2 and solar system efficiency of 33%. Deviations up to 20° in the orientation result in small reduction in the system efficiency up to 3%. The reduction is evident in cases with deviation from 30° up to 90° (East-West) in which there is 27% less heat production.

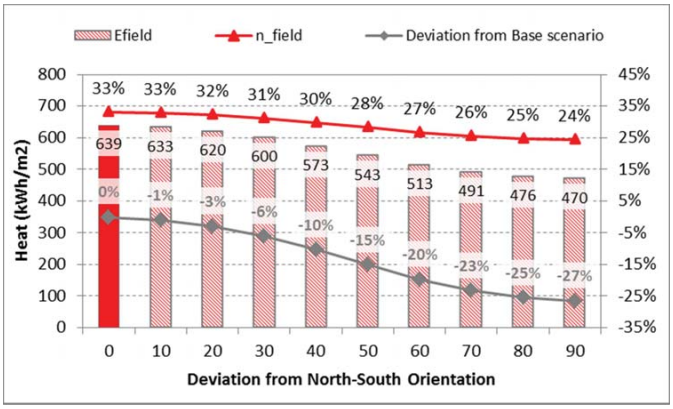

Fig 10: Effect of the orientation at the system energy solar field heat (Efield) production and the solar field efficiency (n_field)

5.3.2 Variable 2 - Outlet temperature from the solar collectors with constant temperature difference

In this parametric set, the effect of the outlet temperature from the solar collectors at the system energy performance was investigated, keeping constant the temperature difference (outlet and inlet in the solar field) DT =50K. In total 6 cases were simulated from outlet temperature of 225 to 350°C with a step of 25°C.

The outlet temperature of 225°C results in 8% increase in the energy production compared to the base scenario, whereas the outlet temperature of 275, 300 and 350°C results in less energy production by 8, 16 and 31% respectively. The significant decrease in the efficiency was expected as the specific parabolic trough model is optimized for operation at around 250°C and in higher operational temperature presents significant reduction in the solar heat production. In system level, the increase of the operational temperature leads to use of hydraulic equipment, pumps and thermal oil of higher temperature and this leads to increased system

cost. On the other hand, the increase of the operational temperature reduces the heat exchanger of the steam boiler and therefore its initial cost. Balancing the above reasons the outlet temperature of 250°C was selected as base scenario.

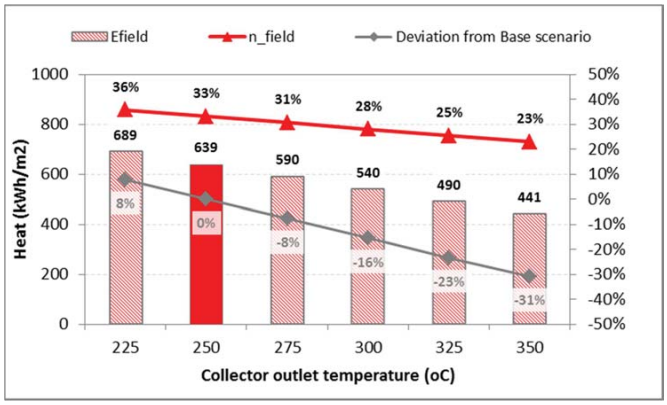

Fig 11: Effect of the Outlet temperature from the solar collectors with constant DT =50K at the system energy solar field heat (Efield) production and the solar field efficiency (n_field)

5.3.3 Variable 3 - Outlet temperature from the solar collectors with constant inlet temperature

In this parametric set, the effect of the outlet temperature from the solar collectors with constant inlet temperature of 200°C at the system energy performance was investigated. In total 6 cases were simulated from outlet temperature of 225 to 350°C with a step of 25°C.

On the contrary to the previous parametric set, the increase in the outlet temperature has limited effect on the system energy performance up to 5%. This is explained by the fact that the mean temperature is kept in lower levels owing to the constant inlet temperature.

Even though, there is limited effect in the energy yield, this case may have crucial effect on the systems economics especially in cases where high thermal storage volume is required in order to smooth high difference between supply and demand. The higher thermal oil operation temperature reduces the storage volume and consequently the system cost. Though, special care is required in the dimensioning of the solar field as the minimum required flow rate should be ensured. On the other hand, the gain from the thermal storage cost should counterbalance the extra cost of the more expensive equipment in the solar field including the thermal oil owing to the higher operation temperature.

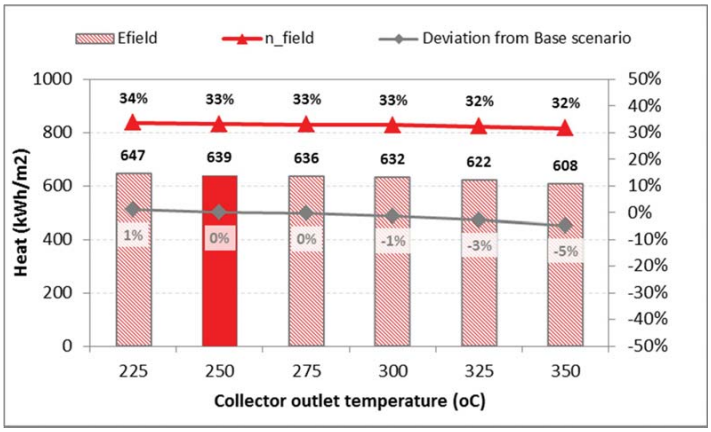

Fig 12: Effect of the Outlet temperature from the solar collectors with constant inlet temperature of 200oC at the system energy solar field heat (Efield) production and the solar field efficiency (n_field)

5.3.4 Variable 4 - Solar aperture area

In this parametric set, the effect of the solar aperture area at the system energy performance was investigated. In total 7 cases were simulated from area of 528 m^2 to 2,112 m^2 with a step of approximately 250 m^2.

Starting from the base scenario of 1,056 m^2, the decrease of the aperture area leads to almost equivalent reduction. For example area of 528m2 which is 50% less than the base scenario (1056m^2) leads to solar fraction of 22% which is reduced by 49%.

On the other hand, the increase of the solar aperture area offers limited increase of the solar fraction. For example the increase of the solar area by 40% (1,478m^2) leads to increase of solar fraction only by 21% (from 42 %to 51%).

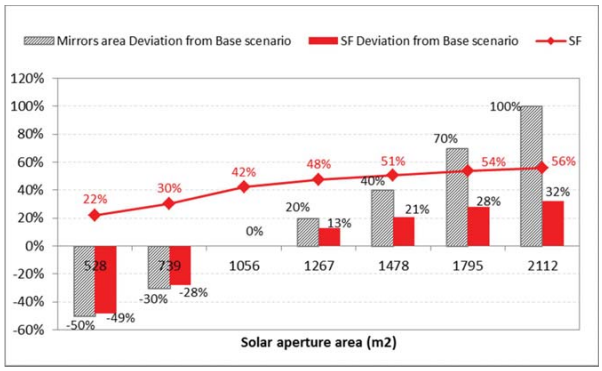

Fig 13: Effect of the solar aperture area at the system solar fraction (SF)

5.3.5 Variable 5 - Series distance expressed in multiples of the collector aperture width

In this parametric set, the effect of the series distance expressed in multiples of the collector aperture width (2.3m) at the system energy performance was investigated. In total 6 cases were simulated from series distance of 1 to 4 multiples with a step of approximately 0.5.

The series distance of 1 multiply (2.3m) leads to ground coverage of 100% but the energy production is reduced by 34% compared to the base scenario of 2.5 (5.75m). Series distances of 2 to 3 multiples have limited effect at the energy production (-4% to 2%) and the ground coverage lays between 33% and 50%. Respectively, the series distance of 4 multiples lead to increase of energy production only by 5% but the ground coverage is 25%.

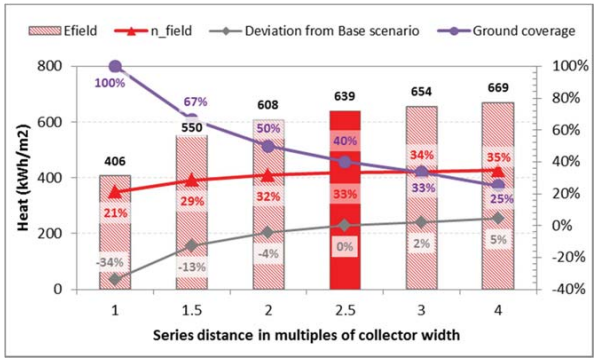

Fig 14: Effect of the series distance expressed in multiples of the collector aperture width at the system energy solar field heat (Efield) production and the solar field efficiency (n_field)

6. Economic assessment

The overall system budget accounts for 573 k€, with the solar collectors absorbing the highest percentage. The figures of the major system components are based on recent quotations while the rest are based on estimations from previous projects.

The main analysis assumptions are the following: 1% / year efficiency system reduction, 4% operation and Maintenance cost,75% conventional system efficiency, 1 €/lt oil cost and 10% increase rate of energy cost.

Based on the above considerations, the simple payback period time is calculated at 7 years.

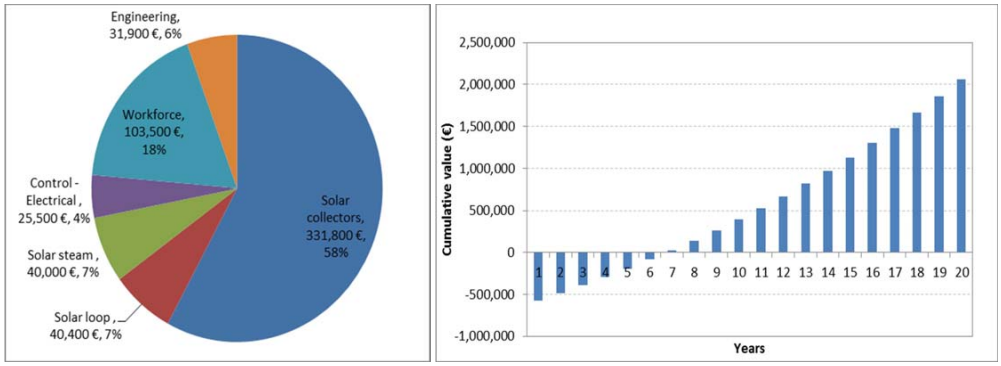

Fig 15: System economic figures

7. Conclusions

Present study attempted to present a techno-economic evaluation of a concentrating solar system for steam production at a food industry in Kalamata. The solar system consisted of the parabolic trough collectors (1 056m^2), the thermal storage (4.7tn of thermal oil) and the solar steam boiler (530kW). The field orientation was North – South, the series distance of the parabolic trough collectors was 5.75m and the thermal oil operation temperature was in the field is 200 - 250^{o}C. A parametric analysis of the above parameters was performed in order to investigate their effect in the system performance.

According to the energy simulation for the base scenario, the solar fraction (SF) was 42%, saving energy of 655MWh per year which corresponds to oil savings of 87.3 tn and 213tn CO_2 emissions. Of the 700kWh/m^2 heat production of the parabolic trough collectors 89% (620kWh/m^2) were actually delivered to the system. Regarding the economic potential of the system, the initial cost was 573 k€, the annual Operation and Maintenance cost was 4%, and the oil cost was 1 €/l, resulting to a simple payback of the system, without any subsidy, of 7 years. Considering the cumulative value at the end of the system lifetime (20 years) the present study indicates that the concentrating solar systems can play an important role at the energy saving in the sector of process heat in Greece.

Abstract

The objectives of this research was to study the efficiency of two para - rubber sheet drying methods; solar drying and solar drying combine solar pond. The solar energy house of 1.8 x 2 x 3 m^3 with the capacity of 100 sheets was constructed in Amphoe Mueang Khon Kaen district,Khon Kaen province Thailand, in conjunction with the solar pond which was 8 meters in diameter and 2.5 meters in depth. In order to evaluate energy using aspect, the energy using studies were divided to 2 systems. System I was only solar drying. System II was using solar drying at day time and solar pond at night time. The initial humidity of para-rubber sheet was about 29 - 33% respectively. The experimental results showed that the temperature distribution in the solar energy house was uniform. The night time average inside temperature solar energy house was higher than that outside 3°C, 10°C for system I, II respectively. The solar energy house was that system I required the longest time 120 hours while system II required the shortest time 84 hours. Moreover, it was found that, the humidity of para-rubber sheet range was about 0.5 – 1.25% after drying.

Keywords:*solar energy; parabolic dish; Thermoelectric,*

1. Introduction

Thailand is currently the largest natural rubber (NR) producing and exporting country in the world. Natural rubber is commercially produced in four forms: ribbed smoked sheet (RSS), block rubber, rubber concentrated latex, and miscellaneous other forms. The factors affecting the drying of rubber sheets are temperature, velocity and humidity of the drying air. The drying time can be reduced and the quality of the rubber sheets can be improved. (Prasertsan et al., 1991;Wattana et al., 2005)

Rubber sheet drying, which is one of the most important parts of the natural rubber industry, can be divided into two types according to the processes of drying (Office of Industrial Economics ., 2013) According to the survey of rubber sheet smoking factories, (Prasertsan et al., 1991;Wattana et al., 2005) in the southern part of Thailand, the quantity of rubber tree fire-wood used to smoke rubber sheets each year is approximately 229,994 m^3 (1 m^3 of firewood = 600 kg). In other words, such vast amount of firewood can generate heat to dry rubber sheets at 226.8 GJ. Therefore, it follows that costs associated with drying can be saved if energy consumption can be reduced. (Beymayer et al., 1993) introduced the solar air heater to the rubber sheet smoking system. It was found that the drying rate was faster; the normal smoking took process took 12 days, but only 5-6 days with the solar air heater. (Nilchuewong et al., 2012) studied rubber sheet drying with hot air and a conservatory. Their results showed that the drying rate of the hot air drying was better. However, the

doi:10.18086/eurosun.2016.02.16 Available at http://proceedings.ises.org

energy consumption of the hot air drying ranged from 8–20 MJ/kg of water evaporated. The quality of the rubber sheets from both experiment conditions passed the local market criteria (Grade 1–3) and the yellowness of dried rubber sheets proportionally varied with drying temperatures.

Many previous studies have used solar energy to dry raw rubber sheets during daytime but there has been no reports of harnessing solar energy for night time drying. This research has investigated a novel method of using solar energy to dry rubber sheets both day and night. The rubber drying plant is designed to combine heat from solar energy and a solar pond in order to reduce the amount of time required in the production process for rubber sheet drying. The drying plant has additionally provided good quality rubber sheets with low moisture contents and desirable appearance. The current paper presents the design and testing of the new system. Results are then discussed and interesting conclusions are made.

1.1 Solar pond

A solar pond is a device that collects and stores solar energy. It can operate continuously throughout the year. Solar ponds collect energy from solar radiation. The radiant heat is collected at the bottom part of the pond and this amount of heat can be used later. The temperature difference between the top and the bottom of the solar ponds can be as high as 50–60 °C. Thermal energy stored in the solar pond can be utilized for heating of buildings (hydrophonic), power production and desalination purposes (Akbarzadeh et al., 2005).

The structure of a solar pond is shown in Fig. 1**.** It is noted that the size of the pond depends on the aim of energy use such as water heating, crop drying, desalination and electrical power generation. There is an amount of saline inside the pond. Generally, the saline solution is sodium chloride or magnesium chloride solution. The pond can be divided into three regions namely the upper convective zone (UCZ),the middle non-convective zone (NCZ) and the lower convective (LCZ).

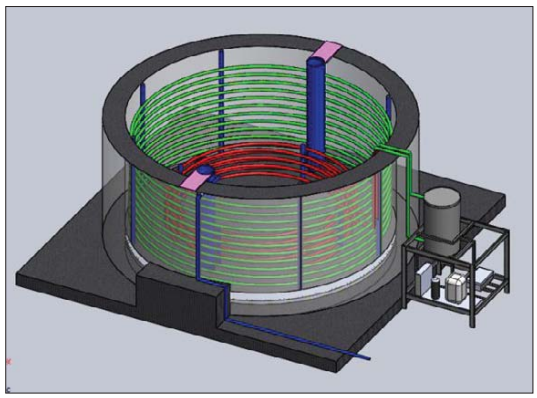

Fig. 1: Schematic of the solar pond

The upper convective zone is located at the top of the pond. The temperature of this zone is close to ambient temperature. The salt concentration is also near that of clean water. Due to the contact between the top layer of the UCZ and the ambient air, there is inevitable energy loss from convection and evaporation.

The middle zone, the NCZ, is sandwiched by the UCZ and the LCZ. In this zone, the salt concentration changes with depth measured from the interface of the upper convective zone and non-convection zone. An increase of depth from this interface results in an increase in salt concentration. The function of this zone is to inhibit heat convection away from the LCZ. However, there is an optimal thickness such that heat can be

transferred from the UCZ downwards without significant heat loss, yielding the high efficiency of energy storage inside the pond (Andrew et al., 2005).

The bottom zone, the LCZ, has the highest salt concentration which is also uniform. When the pond receives heat from solar radiation, the heat penetrates through the upper and non-convection zones to be stored at the LCZ. Thus, it is clear that heat energy is extracted from this zone for useful applications.. Two methods have been used to extract energy from solar ponds. Firstly, fresh water or glycol is circulated through a submerged heat exchanger in the pond. This method is limited by heat transfer by natural convection within the lower convective zone, and the surface area of the submerged heat exchanger can be determined accordingly. Secondly, brine from the lower convective zone is circulated through an external heat exchanger installed outside the pond. This brine-withdrawal method requires less heat exchanging surface, but the flow-distribution system must be carefully designed to avoid erosion of the non convective zone. In the present research it is shown that by combining thermosyphons and thermoelectric cells, it would be possible to utilize the temperature difference existing between the top and the bottom of a solar pond and produce electric power in a fully passive way, i.e. no moving parts. In such a scheme, the heat is transferred by the thermosyphon from the lower region of the pond to the 'hot' side of thermoelectric cells which maintains a good thermal contact with the top of the thermosyphon tube. The 'cold' sides of the cells are in contact with the cold environment of the top layer of the solar pond (Tundee et al., 2010; Randeep et al., 2011).

2. Experimental setup

The experimental setup was composed of a solar pond and a rubber drying plant as schematically illustrated in Fig.2. The solar pond, made of concrete, was a cylinder with a diameter of 800 cm, height of 250 cm and the pond's wall's thickness of 25 cm. Within the solar pond, two sets of heat exchangers (dubbed Set 1 and Set 2) were installed. Set 1was installed within the lower convective zone and Set 2 was installed at the inner wall of the solar pond 50 mm away from the wall. the temperature output had reached a steady state, K-type thermocouples ($\pm$0.5 °C accuracy) were also installed in the solar pond at an interval of 0.1 m from the bottom floor to the upper convection layer in order to measure the heat accumulated within the solar pond. Data is collected every 1 minute using a temperature recorder Yokogawa, DA100$\pm$0.1°C with 24 channels and subsequently stored in a data acquisition device for further analysis. 100 sheets of rubber were stored in the rubber drying plant which was 1.8 × 2 × 3 m in size. The tests were carried out three times by using three flow rates of water from the solar pond to the heat exchanger, which were 3, 2.5 and 2 litters per minute respectively.

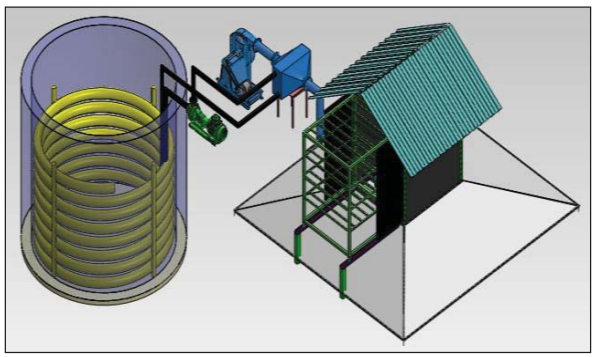

Fig. 2 : Schematic view of the solar pond and the heat extraction system.

3. Results and discussions

3.1 The effect of solar radiation

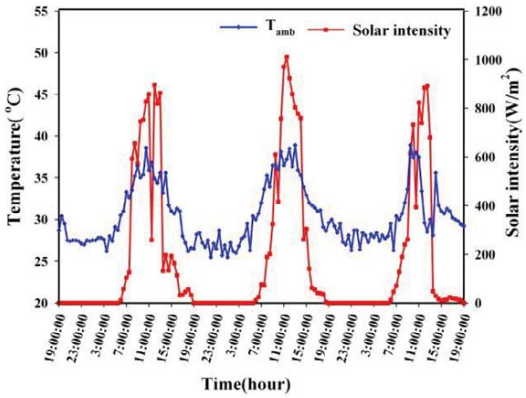

Fig. 3: Time variation of solar radiation on the test site over the three days of test duration.

Fig. 3 shows the time-varied solar radiation during the experiment using a pyranometer measuring the solar radiation in experiment area. The data logger was used to record radiation values every two minutes and average values were calculated every 30 minutes, as shown in Fig. 3 by collecting data over three days during the drying period . It can be seen that the thermal radiation values changed due to changeable day-to-day weather factors including cloudiness, sunlight or rain. Having many clouds in the sky on the third day of the experiment, the radiation value was noticeably reduced.

3.2 The density of solution in the solar pond

Fig. 4 shows the density of the solution in the solar pond, after salt had been added for 2, 30 and 60 days. The density value of the solution remained constant throughout the two-month period. The density profile shows is divided into three layers. The top layer, the UCZ has a thickness of 20 cm and the density of the solution is similar to water. It is followed by the NCZ. The density value of the solution increases steadily downwards and becomes constant at the onset of the LCZ. The thickness of the NCZ was 150 cm. The final layer, the LCZ, has a thickness of 80 cm. Its density is constant throughout the layer, similar to the saturation value of saline solution.

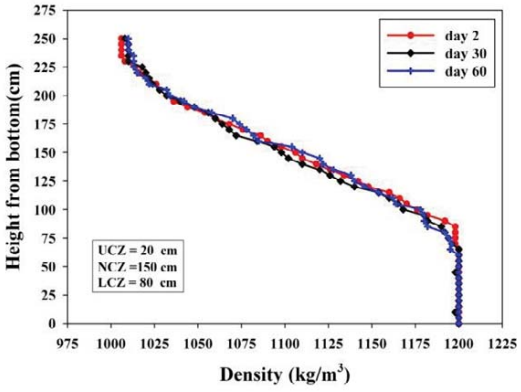

Fig. 4 : Density profile of the salinity gradient solar pond located at RMUTI Isan in Summer.

3.3 Internal temperature in the solar pond

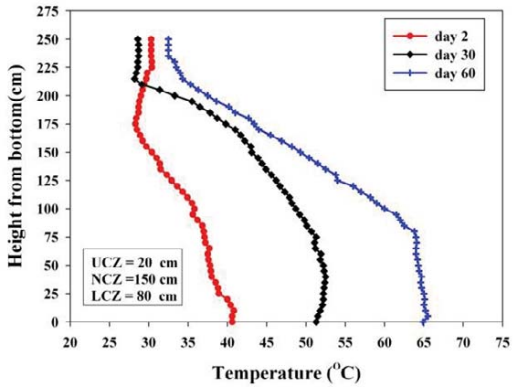

Fig. 5: Temperature profile of the salinity gradient solar pond located at RMUTI Isan in summer.

Fig. 5 shows the internal temperature of the solar pond, measured on the same day as the density profile in Fig.4. The temperature of the solar pond was measured at every 5 cm from the LCZ at the bottom of the solar pond to the NCZ and the UPZ. The figure shows that when the solution had been added to the pond for two days, the internal temperature of the solar pond in the layer of LCZ was approximately 41 °C, and the value decreases with the height from the solar pond's floor. The temperature in the UPZ was approximately 29 °C, close to ambient temperature and uniform through the entire layer. When the test duration of 2 months days had elapsed, the temperature in the layer of LCZ reached approximately 65 °C, which gradually reduced with height above 80 cm from the floor to the bottom boundary of the UPZ.

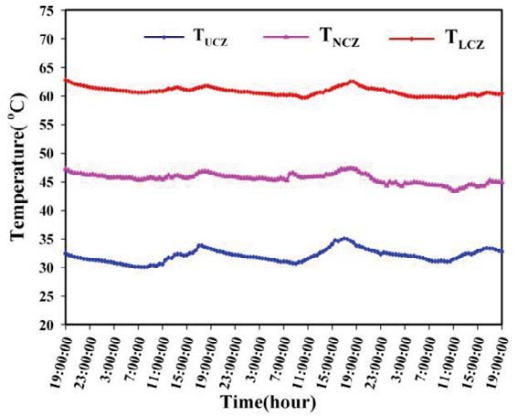

Fig. 6: Average temperature in the solar pond at the UCZ, NCZ and LCZ.

Fig. 6 shows average temperature in the solar pond at the UCZ, NCZ and LCZ. Thermocouples were installed in the solar pond with a distance of 5 cm from the bottom of the solar pond up to the upper layer. The average values were calculated from five measure points in the 20-cm-thick UCZ. . The temperature in the UCZ was similar to the ambient value. It can be seen that during daytime, when the temperature of the atmosphere was high, the three average temperatures increased accordingly. At night, when the atmospheric temperature dropped, the temperature in the UCZ dropped as a result. By contrast, the average temperature of the NCZ exhibited small reduction or increase during the night and daytime respectively. In the rubber drying experiments, during the period from 6:00 AM to 18:00 PM, thermal energy came from the sun directly. From 18:00 PM to 6:00 PM, stored energy in the solar pond is extracted for drying, hence a steady night time

temperature drop of the solar pond in Fig. 6. The temperature in the solar pond increased again upon receiving daytime solar energy.

3.4 The features of rubber sheet in the rubber drying plant

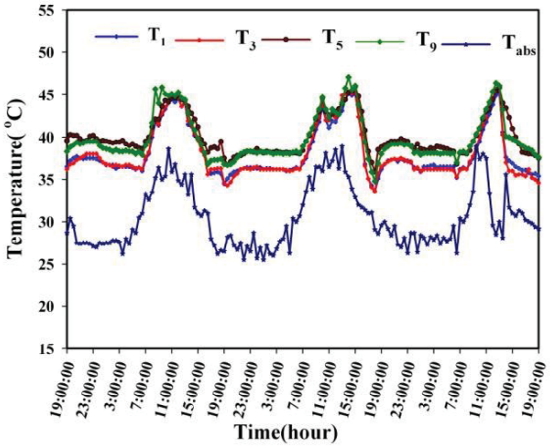

Fig. 7: Time-varied ambient temperature and temperature in the rubber drying plant measured at 4 locations T1, T3, T5 and T9.

Fig. 7 shows the temperature in the rubber drying plant at four points in the rubber drying plant. There were four measurement locations in the drying plant: T1 and T3 were installed at the top of the plant whereas T5 and T9 at the bottom. Ambient temperature was also recorded. The figure shows similar values amongst all the four locations, which changed in accordance with ambient temperature. Under sunlight, the temperature rise in the rubber drying plant above the atmosphere varied around 15-20 °C during the day, and around 10 °C during the night when the rubber drying plant was heated by the solar pond.

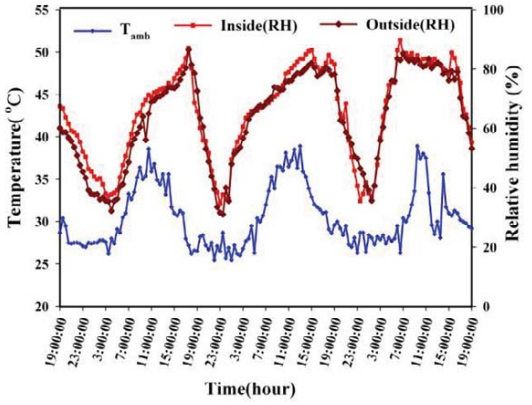

Fig. 8: The humidity values in the rubber drying plant.

Figure 8 shows humidity values in the rubber drying plant, It can be seen that humidity in the rubber drying plant follows the temperature outside. When the outdoor temperature increased, the indoor humidity increased. It can be observed from 15.30 PM, the humidity in the rubber drying plant was about 25-38 percent. During the day, the humidity outside the plant was about 23-35 percent. During the night, the humidity in the rubber drying plant increased because the temperature outside the plant decreased, thereby lowering the saturation level and consequently increasing relative humidity. Humidity in the drying plant at 04:30 AM was about 87-82 percent, but 80-84 percent outside.

Fig. 9: Features of the rubber sheets (a) before and (b) after 2 days of drying.

Fig. 9 shows the features of the rubber sheets before drying and after drying for 2 days. The rubber sheets were installed on the racks in the drying plant. The rubber sheets before drying were raw rubber sheets. They were pre-dried in the air to drain before loading into the drying plant. 100 rubber sheets (maximum capacity of the plant) were loaded in the experiment where they were placed on nine panels. Eight panel had 12 rubber sheets, but the ninth panel had four. The weight of a rubber sheet before drying was about 1 kg.

After drying for two days, the rubber sheets appear pale yellow, clear but with some white partially-wet patches.

Fig. 10: The features of rubber after drying for three days in solar drying chamber

Fig. 10 shows the features of rubber sheets after drying for three days in the drying chamber, the rubber sheets appeared clear, pale yellow and evenly-coloured which would have been difficult to achieve by smoking method. When subjected to further drying, the moisture contents of the rubber sheets were unchanged, rendering them suitable for discharge after only 3 days of drying.

4. Conclusions

The solar drying chamber for para rubber sheets that works in conjunction with the solar pond was investigated. During daytime, the drying plant uses solar energy for drying and then thermal energy extracted from the solar pond at night. The system has been shown to elevate the temperature of the rubber drying plant from ambient by 10 °C at night, and shorten the length of drying time by two days compared with drying without a solar pond, and faster by up to 6 days compared with typical sun drying in the open air. The rubber sheets that passed through the current drying process appeared light yellow, evenly-coloured and without any black dots or air bubbles which are desirable characteristics of high-grade rubber sheets.

Analysis of results of a parabolic concentrator's pipe receiver to heat air for drying process of black tea in Cusco, Peru

Sandra Vergara[1], Miguel Hadzich[1]

[1] Sección Ingeniería Mecánica, Pontificia Universidad Católica del Perú, Lima (Perú)

Abstract

The objective of the design is to solve the problem of shortage of fuel for drying process in a black tea conditioning factory, through the use of solar thermal concentration with the adaptation of the receiver tube of a linear parabolic concentrator for heating air. This is part of a pilot project to develop and implement in tea enterprise AGROINKA SAC a prototype cogeneration system with solar thermal energy, made of 6 lines of 10 concentrators (60 linear concentrators). The company AGROINKA is in a rural area of the region of Cusco. It has little access to other possibilities of thermal energy resources and technologies for different processes of his production chain of black tea. It is an area dedicated to the processing of tea to supply 80% of the market in the country and 750 families depend on tea production. This paper describes the behavior of hot air in the receiver pipe along a line of 10 concentrators. The results of this paper correspond the winning project of the National Fund for Research and Development Competition for Competitiveness – FIDECOM (for its acronym in Spanish); entitled "Development and integration of a cogeneration system with solar thermal energy for processing of black tea in the Cusco region" 210-FINCyT-FIDECOM -PIPEI-2012.

Keywords: thermal solar energy, drying, tea, Cusco, rural sector, productive use

1. Introduction

The Support Group for the Rural Sector (GRUPO PUCP) is an operating unit of the Department of Engineering at the Pontificia Universidad Católica del Perú (PUCP) founded in 1992. We work to develop appropriate technologies using renewable energy for the rural sector. The project "Development and integration of a cogeneration system with solar thermal energy for the processing of black tea in the Cusco region" was developed in partnership with the company AGROINKA of Cusco.

The processes for obtaining black tea from the Camellia sinensis's leaves are: withering, by leaving the leaves rest for a day in a dry and dark place; cutting, where the leaves are crushed to initiate the oxidation process; fermentation, which gives the black color to the black tea; drying, to remove the moisture and to stop fermentation; and classification.

For the drying process the enterprise uses industrial furnaces, which are fed with wood, in low energy efficiency, resulting the low productivity and high consumption of fuelwood. Then hot air is injected at a temperature between 80 °C and 90 °C to the drying chambers. It has been developed and implemented linear parabolic concentrators to replace a percentage of wood used in the drying process. This paper describes the behavior of hot air in the receiver pipe with 5" diameter along a line 10 concentrators.

2. Project

As mentioned, the project was developed in partnership between GRUPO PUCP and the company AGROINKA. Tea or Camellia Sinensis is originally from Asia but today it can be found in tropical and subtropical regions around the world. Depending on the processing of Carmellia Sinensis' leaves, many

doi:10.18086/eurosun.2016.02.08 Available at http://proceedings.ises.org

types of tea can be obtained with different scents and flavors.

The area has a diverse agriculture by the various ecological floors and microclimates. They can be found in a 2.5 hours' journey from the mountain "Veronica" (4316 m) up to the low jungle in the district of Quillabamba (1050 m). The town of Huyro, where the project took place, is located in the district of Huayopata in the province of La Convención. To reach the town you need to make a 3.5 hours trip from the city of Cusco. According to coordinates, the location is on the south latitude 12 ° 0'23 " S (-13.01), West Longitude: 72 ° 33 '. 25.8 "W (-72.56) and is located at an altitude of 1562 meters above sea level. This area has been identified with an excellent tropical climate for tea production, as well as other products like coffee, cinnamon, fruits, etc.

The company uses 400 truckloads of firewood per year, equivalent to 4000 m3 of wood at a cost of 5.00 soles (approximately $1.5) per kg. For the drying process they use 2 furnaces, which are fed with firewood for heating the air. Then this air is injected at temperatures between 80° C and 90° C to the drying chambers (one fluidized bed and one orthodox). This process reduces the moisture of the tea leaves and stops the fermentation process which gives the characteristic color to the black tea.

The company doesn't have access to other fuel for thermal energy. But they are also aware that its high consumption generates environmental impacts like pollution and deforestation, affecting the landscape, the biodiversity, soil fertility and by increasing the likelihood of landslides.

The design was implemented using a clean and sustainable technology that serves as an alternative to firewood. This prototype system consists of a solar thermal power cogeneration composed by 3 modules of 20 linear concentrators (60 linear concentrators in total). The system is integrated to one of the furnaces which permits the use of hybrid system. Unlike other solar thermal energy, this design does not use a heat exchanger and the air is injected directly into the oven. There's no need to storage the hot air, as the company works up to 3 shifts during the year.

Fig. 1: The solar concentrator's installation in Yanayaco, Cusco, Perú

Fig. 2: Panoramic view of the solar concentrator's installation in Yanayaco, Cusco, Perú

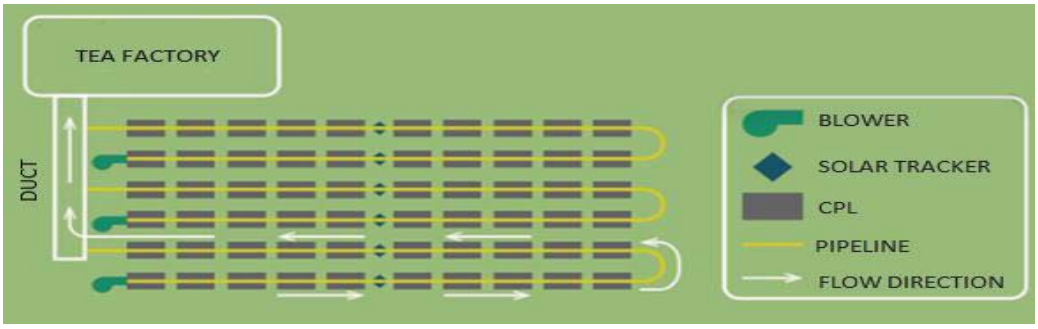

Fig. 3: The solar concentrator's diagram in Yanayaco, Cusco, Perú

Each linear concentrator used anodized aluminum for reflected material and has made with a specific geometry presented in showed in the next table. The 5" pipe was made of carbon steel with a matt black paint coating.

Tab. 1: Concentrator Geometry (Vergara Dávila & Hadzich Marín, 2014)

Description		Units
Semi straight side length	0.530	m
Concentrator Height	0.201	m
Diameter of the pipe	0.127	m
Concentrator length	2.4	m
Concentrator aperture size	2.544	m
Concentrator aperture angle	3.0639	rad
Semi-apparent angle of the sun equal to 16'	0.00465	rad
Pipe Height (different than focus line height)	0.2216	m

3. Methodology

To cover the demand of thermal energy, linear parabolic concentrators were used to generate hot air with the air flowing through the receiver tube making possible working without a heat exchanger. The innovative part of the system is that the air functions as the fluid that flows through the pipeline. However, this carries some difficulties, such as the size of the receiver pipe used which as being too big, it cannot work with a glass tube as insulation. The different air behaviors due to speed flow of the air is also a complication dealt with in this project.

We tested a line of 10 concentrators that reaches the approximate distance of 26 meters. We took data from the inside of the receiver pipe to obtain the temperature curve for the air at different speeds and these tests were repeated with and without insulation on the top of the pipeline.

To obtain information from the behavior of air in the receiver pipe without and with insulation, 11 holes were made along a line of 10 concentrators, where a bimetallic thermometer was introduced.

Additionally, during the test stage, 2 more holes were made in a second line or returned line from the receiver pipe (10 concentrators). The first one at the start point of second line's receiver pipe and the second one at the end of the second line receiver pipe or entry point to the duct to tea factory.

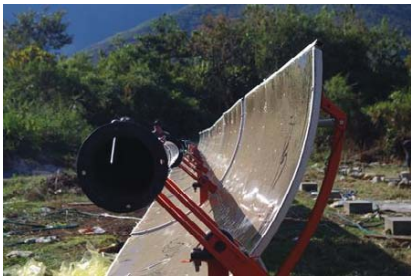

Fig. 4: Section view of the receiver pipe

The Weisz's bimetal thermometer was used. It has a temperature range of 10 ° C to 150 ° C.

Fig. 5: Weisz's bimetal thermometer

On parallel to the temperature's measurement, the beam irradiance was measured. This measurement was made using an irradiance measurer by the brand R & S Renewable Energy Systems. First, we measured global irradiance and subsequently diffuse irradiance. The difference between the two irradiances gives us as a result the beam irradiance.

Fig. 6: R&S Renewable Energy Systems's irradiance measurer

Kestrel brand equipment was used for measuring the air velocity inside the receiver pipe. This was placed at the end of the pipeline.

Fig. 7: Kestrel's air speed measurer

4. Results

Through data collection, temperature curves could be obtained and also the delta of temperature between each sampling point of the receiver pipe with and without insulating varying the air velocity.

Initially air measurement was performed with a speed of 3 m s-1 inside receiver pipe without insulation.

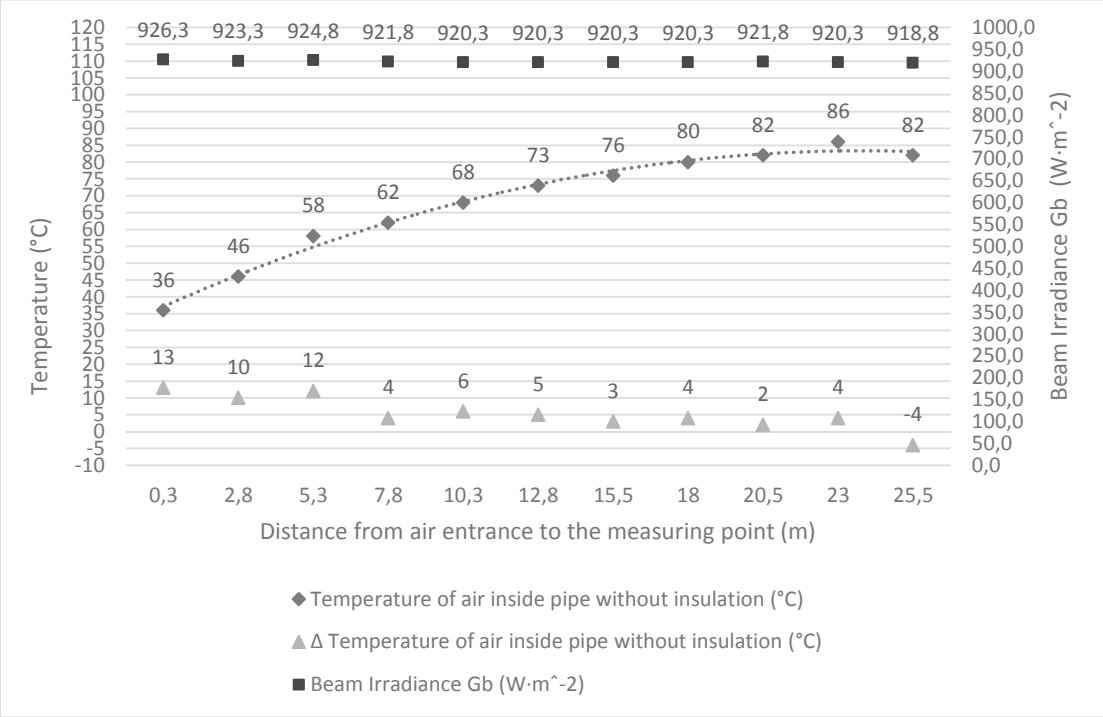

Fig. 8: Behavior of air into the receiver pipe without insulation to 3 m s^{-1}

It can be seen in Fig. 8, that in the first meters the delta of air temperature is higher subsequently it decreases. At 23 m in the receiver pipe the air temperature drops from 86 ° C to 82 ° C. The maximum temperature that air could reach was 86 ° C into the pipe.

Making use of a thermal imaging camera, images of the receiver pipe were taken. As shown in Fig. 9 the temperature is higher in the area where the receiver tube receives sunlight reflected by the concentrators, however, the temperature at the top reached around 60 ° C.

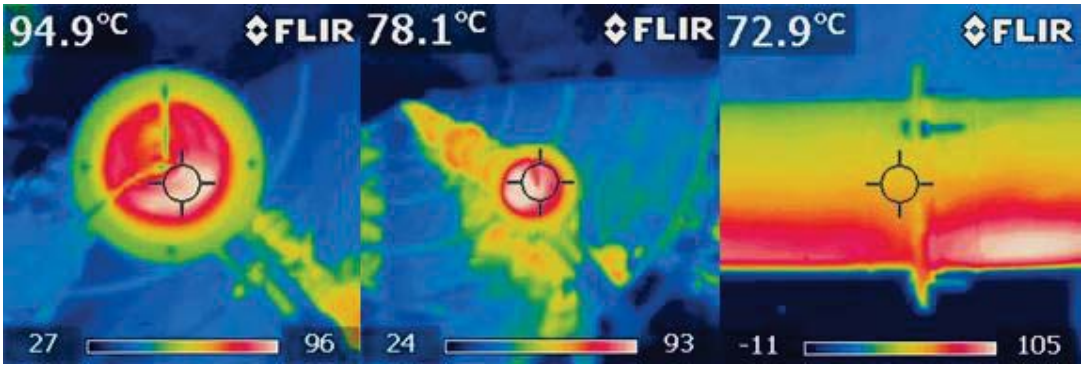

Fig. 9: a) sectional view of the receiver pipe without insulation; b) view of receiver pipe without insulation ; c) side view of receiver pipe without insulation

Afterward it was considered to place on the top of the receiver pipe of 5" diameter, a fiber insulation glass with a top cover in case of rain. The tests were repeated with a speed of 3 m s-1.

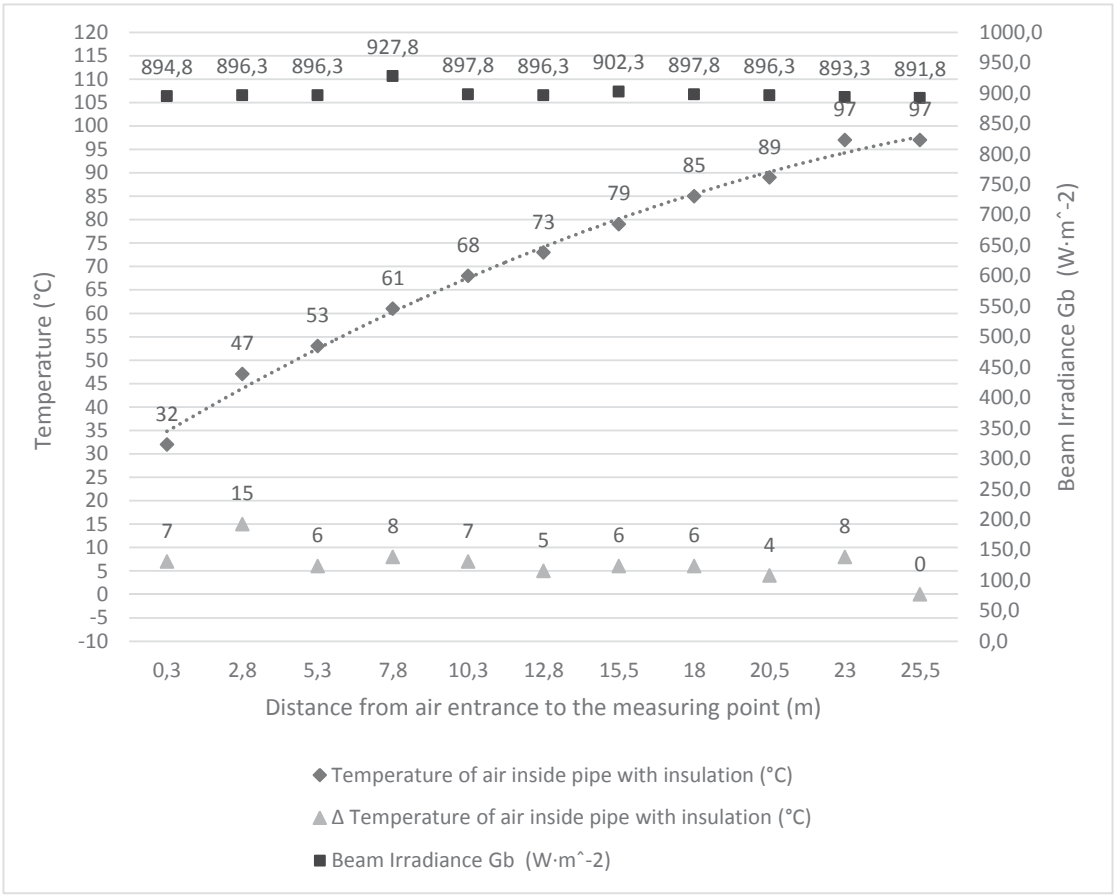

Fig. 10: Behavior of air into the receiver pipe with insulation to 3 m s^{-1}

Can be seen in Fig. 10 in the first meters, the delta of air temperature is higher. However delta of air temperature remains constant along the receiver pipe. As in the previous case, from 23 m of the receiver pipe, air temperature decreases. The maximum temperature that air reached was 97 ° C into the pipe.

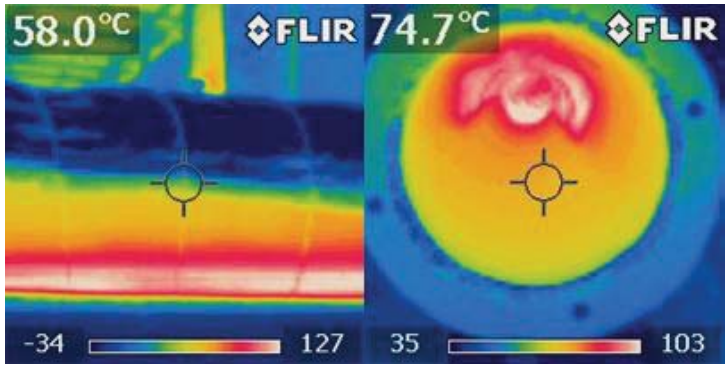

Fig. 11: a) lateral view of the pipe with insulation; b) sectional view of the receiver pipe with insulation

It can be seen in Fig. 11 the thermographic image of lateral and sectional view of the receiver pipe after fitting with insulation.

For better comparison of the behavior of air temperature, both insulated and non insulated receiver pipe were integrated in Fig. 12.

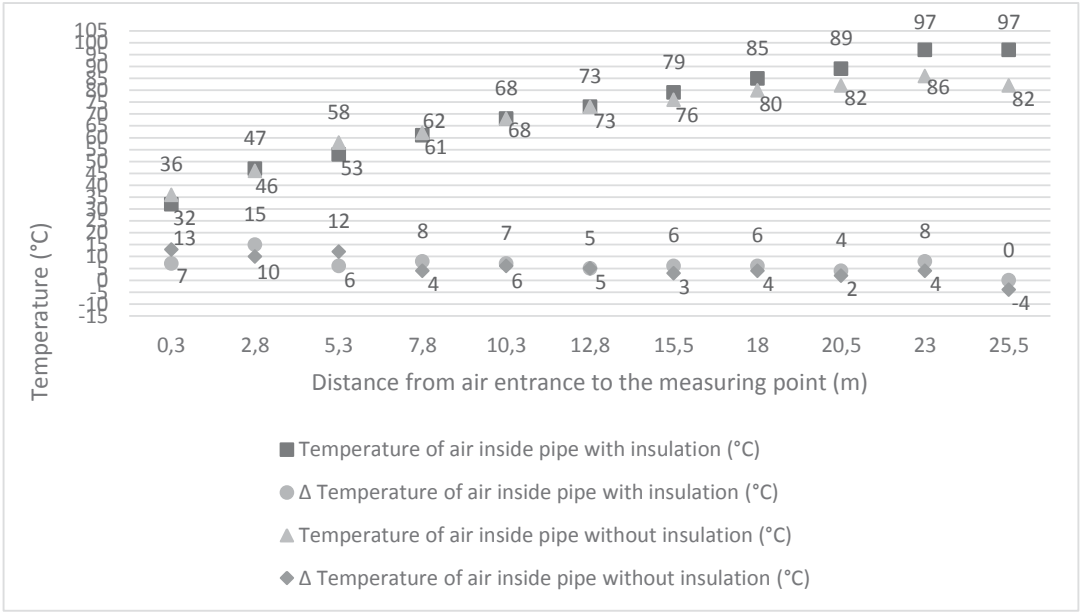

Fig. 12: Behavior of air into the receiver pipe receiver with and without insulation to 3 m s^{-1} air velocity

As shown in Fig. 12 from the 15.5 m of the receiver tube, the air in the insulation system reaches higher temperatures.

It's important to mention that in the second line, for a velocity of 3 m/s with insulation, we obtained in the start point of the second line's receiver pipe (first hole) a temperature of 88°C. This is because, the pipe curve that connect first line with second line has a heat loss of 10 ° C. Meanwhile, in the end of the second line receiver pipe (second hole) or entry point to the duct, we archived a temperature of 108°C.

This showed us, that total delta temperature of air on the first line with 3 m/s and insulation is around 65°C, meantime that total delta temperature of air on the second line with 3 m/s and insulation is around 20°C. In consequence, due to economic and financial viability the rest of testing stage was focused on the first line.

The same procedure was repeated with the receiver pipe insulated by varying the air velocity to 8.5m s^{-1}. This variation was conducted by opening the gate of the blower air flow.

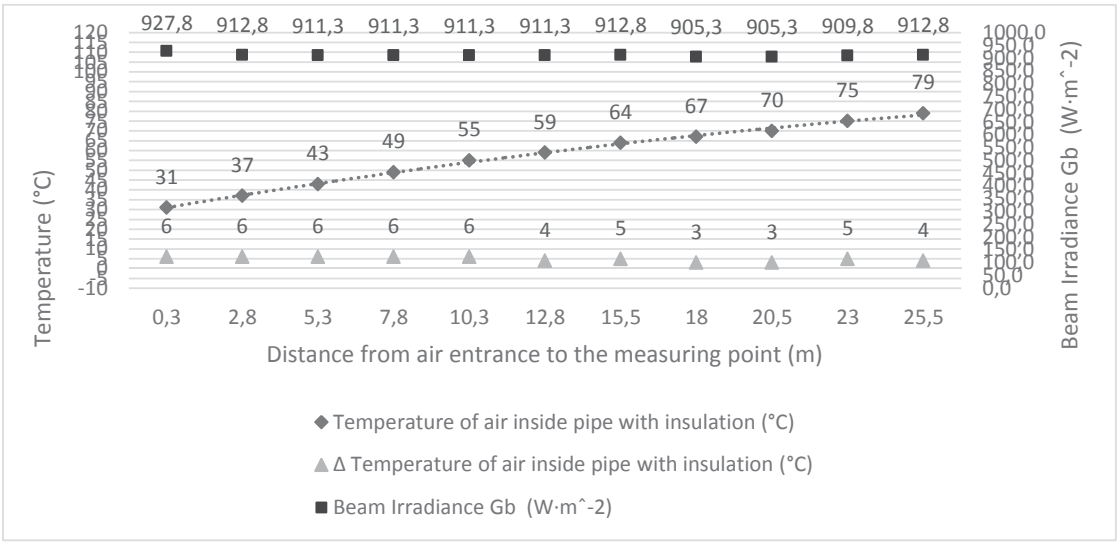

Fig. 13: Behavior of air into the receiver pipe with insulation to 8.5 m s^{-1}

It can be seen in Fig. 13 that the delta air temperature is constant from the start, along the receiver pipe. It could reach 79 °C of air temperature inside the pipe with a speed of 8.5 m s^{-1}.

Finally, the same procedure was repeated with the receiver pipe insulated varying the air speed to 14m s^{-1}. This variation was conducted by opening the gate of the blower air flow.

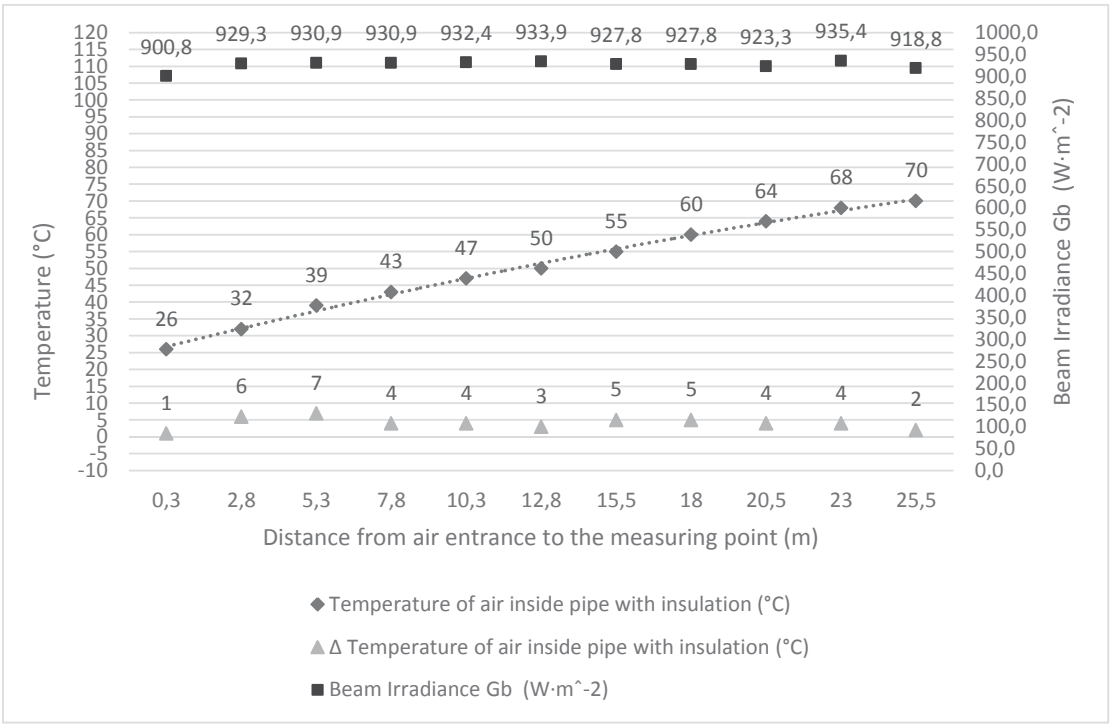

Fig. 14: Behavior of air into the receiver pipe with insulation to 14 m s^{-1}

It can reach 70 °C of air temperature inside the receiver pipe with a maximum speed of 14 m s^{-1}.

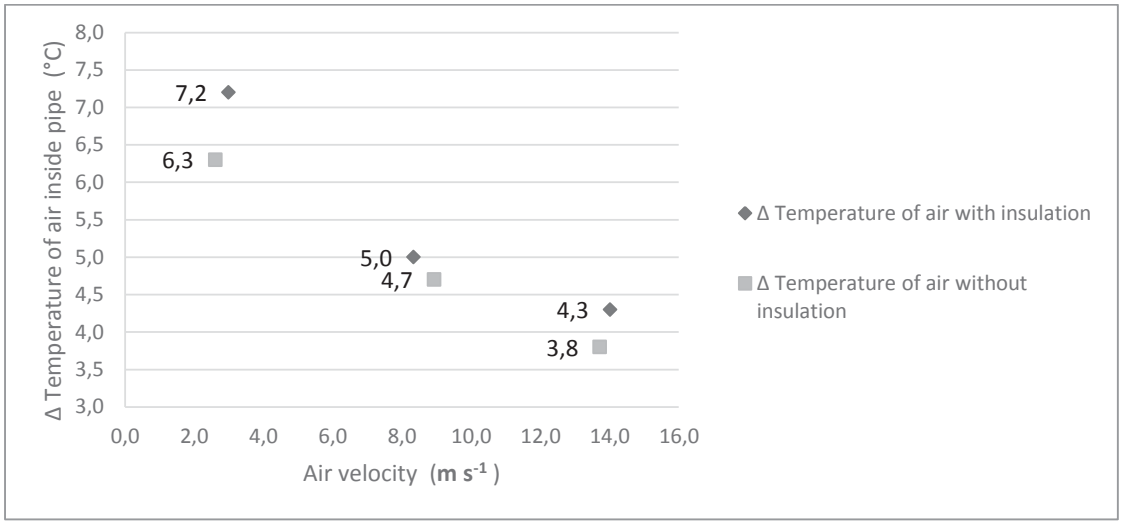

Fig. 15: Δ Temperature of the air in the pipe with and without insulation depending on the speed

It can be observed that the higher the air's velocity gets, the lower delta of temperature of air is obtained, and the delta of temperature of air in the receiver pipe with insulation is greater than without insulation.

5. Conclusions

It can be concluded that a large difference in temperatures can be reached when comparing receiver pipe with and without insulation. For example, in Fig. 12 we observe that at the last meters the receiver pipe with insulation has a difference of 15°C compared to the receiver pipe without insulation. In addition, the receiver pipe with insulation is better to reach higher temperatures spite of different speeds how we observe in Fig. 15

Likewise, depending on the speed with which the air is transported, a variation in the temperature delta is obtained, mainly because of heat losses depending on the flow characteristics.

It can also be concluded that using air as the carrier fluid with 3 m/s of air velocity, we can achieve a temperature of 97 °C at 25.5 meters inside the receiver pipe with 5 inches of diameter and insulation in Fig. 10.

THERMAL ENERGY STORAGE WITH CONCENTRATED SOLAR POWER FOR A MORE RELIABLE AND AFFORDABLE ELECTRICITY TO INDUSTRIAL APPLICATIONS

El Ghali Bennouna[1,2] and Abdelaziz Mimet[2]

[1] Institut de Recherche en Energie Solaire et en Energies Nouvelles, Benguerir (Morocco)

[2] Ecole Normale Superieure – Université Abdelmalek Essaâdi, Martil (Morocco)

Abstract

The implementation of Concentrated Solar Power for industrial applications has become a topic of high interest both for CSP plants developers and potential client industries. The integration of CSP for industrial processes can be done follow various needs ranging from power generation to steam generation, drying, heating and even cooling applications. Although the interest for the latter "less common" applications has gained more importance for researchers over power generation, this options has still a lot of interest for industrials especially when this power generation can be more flexible and cheaper thanks to a good Thermal Storage System integration and to encouraging market conditions and availability of the solar resource.

In this paper we studied the possibility for large industrial facilities to exploit small scale CSP plants as fossil fuel and grid saving mechanism considering the variable grid pricing and an appropriate TES integration.

Keywords: *Concentrated Solar Power (CSP), Thermal Energy Storage (TES), industrial application…*

1. Context

Since its creation, IRESEN has placed small scale CSP-ORC systems among the main priorities. Such systems are considered as possible solutions for small power consumers (below 5MW). In this regard a first demonstration and research pilot CSP-ORC plant of 1MW capacity is being commissioned at the green energy park in Benguerir, Morocco.

During the project planning period, the development of an appropriate thermal storage add-on to increase the dispatchability of the plant, and help demonstrate the benefits of storage for this package and the potential clients.

Fig. 1: Picture of the 1MW CSP-ORC plant under commissioning in Benguerir, Morocco

Industry is out of doubt one of the most energy intensive sectors, standard energy needs for industry cover electricity for machines supplying, electrolyze processes, cooling, lightning and others. On the other hand, various needs for heat at various grades and on various ways (hot air for drying, high pressure steam, furnaces, processes preheating…), this heat is mostly obtained via the combustion of fossil fuels but can also be produced by electricity at higher cost while many industrial processes based on fossil fuel are being supported by others based on electricity such as for steel industry.

doi:10.18086/eurosun.2016.03.17 Available at http://proceedings.ises.org

The costs of fossil fuel have decreased significantly during the last few years, this has put CSP for heating applications in a less comfortable position, although this can be regarded as a temporary situation which can change following geopolitical conjuncture.

On the other side, electricity prices are more or less constant in many countries regardless of fossil fuel prices. The price of electricity from the grid are generally linked to the power demand or load either at a national or regional level. In Morocco for example, electricity from the national grid (ONEE) follows a time dependent pricing approach for industrial consumers (middle and high voltages), the highest prices correspond to the hours of higher power demand (peak hours and also super peak hours for high voltage consumers).

Tab. 1: ONEE power pricing in Morocco for middle and high voltage consumers (ONEE, 2016)

Pricing options 60kV	Yearly capacity price per	kWh price (MAD/€)

Capacity Reduction Factor		1	0,8	0,6	0,4

In this configuration, the price of electricity during super peak hours can raise to more than three times the base price at off load hours. Peak and super peak hours are generally between 6:00 and 10:00 in the evening. This opens a large opportunity for large industries which have large power needs and whose processes are working continuously to integrate CSP with storage in order to use less electricity from the grid especially during the evenings.

By offering the possibility to extend a CSP plant production to the evening, thermal energy storage has then a double benefit if we consider a “grid saving” approach:

- Benefit of higher grid prices during the evenings allowing the operator to profit from a better competitiveness versus grid power;
- Benefit of generally lower ambient temperatures which contribute to a higher power cycle efficiency, hence a higher production and a better economic efficiency;

2. Methodology

The Noor-Ouarzazate 1 plant is seen as a breakthrough in terms of CSP competitiveness with a kWh price around 15 cents, nevertheless, this price might seem very high for basic Moroccan consumers which do not pay electricity on a time based pricing. For middle voltage and high voltage clients the variability of electricity price between peak and off peak hours offers a high potential for the integration of CSP with storage.

The aim of this paper is to study the impact of integrating a small CSP unit with thermal storage to supply an industrial installation. This can be achieved by simulating the CSP plant production with a home developed model at IRESEN based on the 1MW CSP-ORC plant of Benguerir. Although this model is very simple, it was successfully compared in many occasions with more proven tools such as GREENIUS (J. Dersch). The simulations will be integrated on an economical balance taking into account all consumers specifications and electricity pricing (V. Quaschning et al., 2011).

2.1. Plant simulation input

The simulations for production are based on three calculation modules:

- The solar field performance: the total heat production of the solar field is based on the weather conditions, mainly, the Direct Normal Irradiation or DNI, the ambient temperature and the solar angles (Azimuth and Elevation) combined with the solar collector performances (A. Soteris Kalogirou, 2004).
- Storage and heat dispatch: this module defines the amount of heat to be stored and the share to be dispatched, it also calculates the charging level of the storage system based on the solar field output and the dispatched heat (J. Pacheco, 2002).
- ORC module: the ORC performance is calculated using the supplier's correction curve, the ambient temperature and the amount of heat dispatched by the solar field and storage.

Among the available weather data sets, actual measurements data were preferred over satellite data, the data set used for the simulations contains a measurement value for each 10 second and was obtained with a high precision tracker based weather-station.

Concerning the solar field, the adopted configuration consists of 16 loops with 4 linear Fresnel collectors on each, the total surface area of the mirrors is 26500m^2, and the nominal solar field capacity is 11.3MW_{th} at a reference DNI of 750kWh/m^2 (A. Haberle et al., 2002). The heat transfer fluid enters each solar field loop at 185°C and exits at 315°C.

The storage technology is thermocline with Quartzite rocks bed, the heat capacity is 27MWh equivalent to 5 storage hours. Charging of the storage system is given priority over ORC operation, which is similar to a partial production shifting mode.

Discharging is oriented to the peak hours while the charging rates are based on the season and the average solar irradiation for the few hours preceding the calculated time slot, this means that during winter for example, a full production shifting occurs to the peak hours while in summer there is only a partial charging of the storage during the first hours of operation and depending on the amount of heat produced by the solar field.

The ORC set used on the simulations has a nominal net capacity of 1MW at an ambient temperature of 20°C and heat input of 4.8MW. The efficiency of the power cycle varies proportionally to the heat input and inversely to ambient temperature.

2.2. Economic configuration

The selected potential client for the simulated plant is an industrial unit connected to the national grid at high voltage with a medium/long consumption contract (3500 to 6000 hours per year). In this case the price of electricity will follow 4 different time slots as presented on figure.

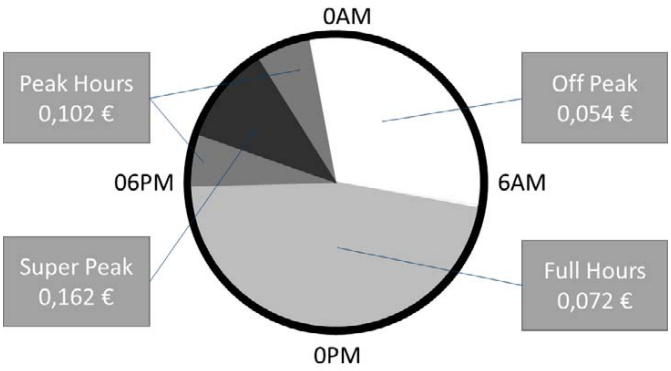

Fig. 2: Power pricing for middle/long consumption at high voltage connection (150 & 225kV)

For the following calculations we assume that the industrial client can sustain the full investment, meaning an equity ratio of 100% (this might be likely with small CSP units requiring relatively reduced investments). In addition, it is also assumed that the required land surface is owned by the client, hence land costs are not considered in calculations.

Tab. 2: Plant main properties and components cost

Plant main properties			Main components specific costs		
Solar field total mirrors area	26500	m²	Solar Field specific cost	240	€/m²
ORC nominal capacity	1000	kWe	ORC specific cost	1600	€/kWe
Thermal storage capacity	27000	kWh	Thermal Storage specific cost	35	€/kWh
Total required surface area	2.5	ha	Operation & Maintenance costs	0.01	€/kWh

The total investment is 9.15M€ based on the information in table 2. The economic assessment is done over a period of 20 years, followed by another 5 years with higher maintenance costs (+50%).

Operation and maintenance costs are generally close to 0.015$/kWh (IRENA, 2012), in the CSP-ORC plant case, a specific configuration and particular design requirements were set to allow for maximal automation and minimum operation leading to much lower O&M requirements.

3. Simulation results and conclusions

The simulations were done for one complete year using hourly data (average values from 10 seconds values). However, two representative days were selected to show the impact of an operation strategy specifically oriented to the peak hours.

4.1 Results for representative days

When observing figures 3 and 4 a slight difference can be noticed in terms of power production, although the sum of the daily production is comparable with both approaches.

Regarding the cash flow curve, a strong difference between the two figures can be noticed despite being representative of the same day. This is mainly due to the production being shifted with the peak oriented operation strategy, while the second strategy only focuses on smoothing the production. Hence, a large share of the power is produced during the day, which means out of peak hours, and does not occur during hours with the highest pricing.

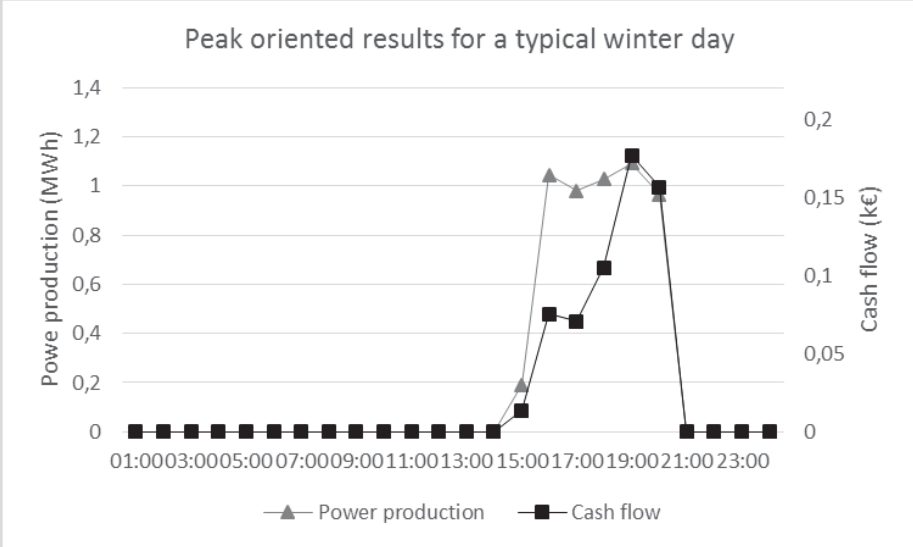

Fig. 3: Power production and cash flow results for a typical winter day with peak oriented operation

It is important to notice that the ORC efficiency increases with lower ambient temperatures until a certain limit, this is a reason not to shift the production beyond 11PM, as temperatures can go easily below 10°C which is a threshold for ORC operation. Moreover, the stored heat has to be completely discharged before 11PM as the pricing moves directly to off peak period leading to an intense drop of electricity pricing.

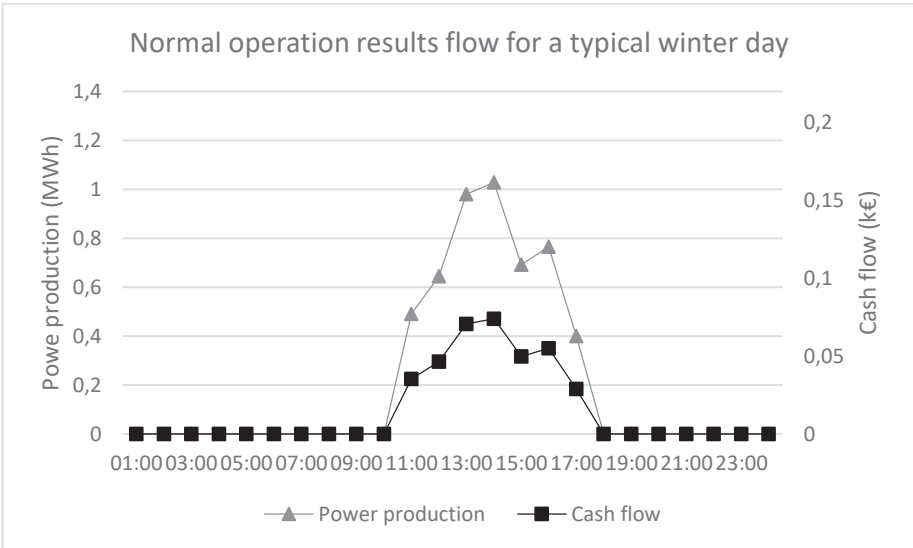

Fig. 4: Power production and cash flow results for a typical winter day with normal operation

During summer, the situation is quite different, when comparing figures 5 and figure 6, the overall shape of the power production curves of both figures is more or less the same. There is only a slight difference on the top of the curve (plateau shape), as the production is limited to 1MW before discharge and around 1.2MW after discharge for the peak oriented operation strategy, while the opposite happens with normal operation.

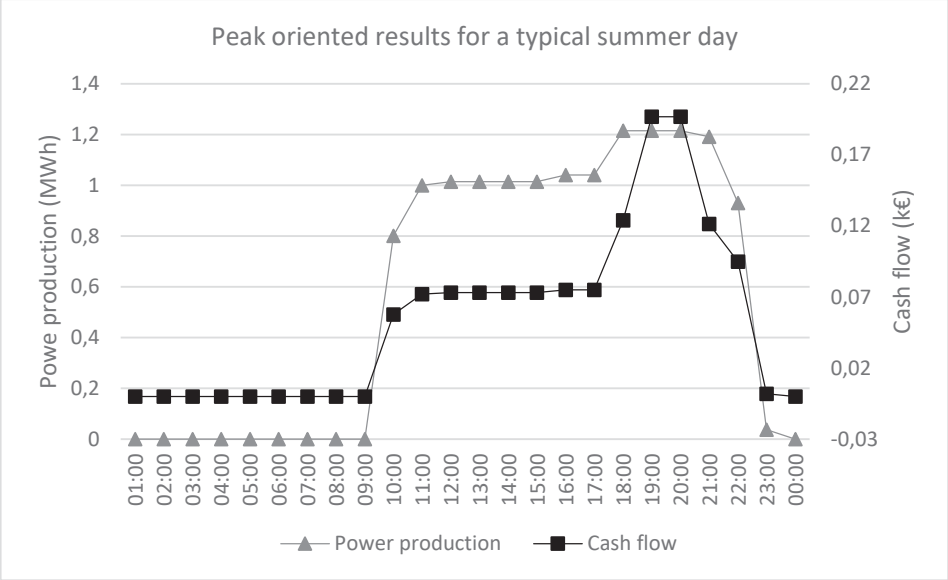

Fig. 5: Power production and cash flow results for a typical summer day with peak oriented operation

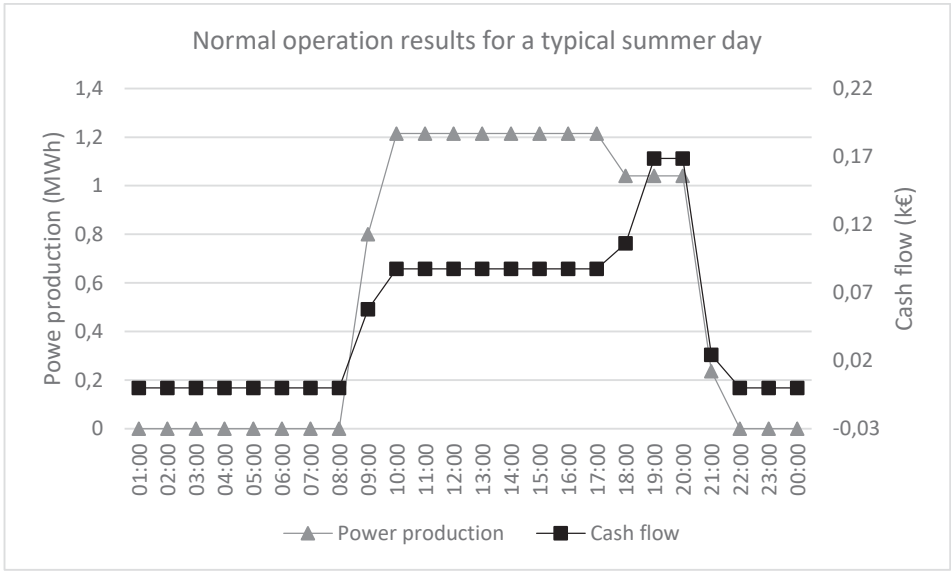

Fig. 6: Power production and cash flow results for a typical summer day with normal operation

In terms of cash flow, there is a certain difference between the two operation approaches, and this is due to the higher amount dispatched during the evening with the peak oriented operation. Nevertheless, this difference is not as important as for the winter example, simply because in this case both strategies tend to extend the production to the evening with different intensities.

4.2 Yearly results

Concerning the yearly simulations, there is slightly equivalent overall production. But when analyzing average values for the summer and winter period, it appears that there a larger increase of production in winter when applying the peak oriented strategy over the normal approach. This is due to the higher efficiency of the ORC with a controlled discharge at high ORC input over spread production with generally low heat input.

Tab. 3: Summary of the main simulation results

Simulated operation strategies	Yearly production		Average Summer day production		Average winter day production	
	Power generation (MWh)	Cash flow (k€)	Power generation (MWh)	Cash flow (k€)	Power generation (MWh)	Cash flow (k€)
Scenario with focus on peak hours	3637	356	15.09	1.34	5.3	0.59
Scenario with normal operation	3611	312	15.01	1.22	4.6	0.37

The cash flow results show an increase for both periods with respectively 10% for summer and 60% for winter, for an entire year the total cash flow gain is 14%.

The initial investment of the plant is set at 9,460,000€, over a period of 20 year, the total incremental costs are 10,020,000€, by extending the operation to 25 years, these costs reach 10,270,000€. In the studied case no debt financing was considered, otherwise, the total incremental costs would have largely exceeded the latter value.

After 20 years of operation, the plant should have produced 72GWh. With a normal operation, this production can generate 6,200,000€, while a peak oriented strategy can generate up to 7,100,000€ which represents 71% of the total incremental costs.

By extending the operation for further 5 years and increasing operation and maintenance costs by 50%, the figures can reach 8,900,000€ and 87%. A 10 years extension of the operation can drive the total revenues up to 10,680,000€ which exceeds the total costs (10,600,000€) including doubled operation costs for the last 5 years.

Such a plant operated with a classical approach would need 5 additional years for amortization, which tends to be difficult with the increasing O&M costs.

The objective of this work is not only to display applicability of small CSP units for industrial consumers, but also to demonstrate that the integration of thermal storage to such plants can help achieve better economic results. It is common to compare CSP projects LCOE with the base power pricing, however, in the case of systems with storage, the comparison is not as simple and must include some other parameters.

A plant with an LCOE of 0.18€ or 0.22€ (which is the average of small scale CSP units) might seem totally unfeasible with an average electricity price of 0.1€/kWh, it appears that such a plant when equipped with an appropriate storage system, can be amortized with a reasonably extended operation lifetime.

Although the approach followed in this study does not consider debt financing, no land cost and relatively long operation in comparison to average plants lifetime simulations, it is still sufficiently reliable to demonstrate the advantage of a peak oriented operation over normal production extension.

It also demonstrate the ability of CSP to supply reliable electricity during the peak periods and compensate for other energy sources especially with a high penetration of renewables on the grid (J. Jorgenson et al., 2014).

In any case, the obtained results show that a slight increase in electricity pricing in Morocco and the mastering of CSP technologies combined with economies of scale (when applicable) and with reasonably high fossil fuel prices can make small CSP applications able to enter the market within the coming few years.

Abstract

A pilot plant facility focused on testing thermal energy storage (TES) systems both at pilot and commercial scale was designed and built at the University of Lleida in 2008. This facility was designed and equipped with the measuring devices needed to measure and analyse the thermal behaviour of all the systems tested as a previous step to commercial development. The versatility of this facility has allowed simulating real working conditions and therefore testing different TES systems, mainly for solar thermal applications such as domestic hot water, solar cooling or solar power generation, but also for other applications such as industrial waste heat recovery or combined heat and power (CHP). In this paper the main characteristics of components of the pilot plant of University of Lleida as well as the main results of the tests performed with both sensible and latent TES are shown.

Keywords: *thermal energy storage; solar thermal applications; phase change material; sensible heat; pilot plant scale*

1. Introduction

In recent years, research on renewable energies has become an important issue to achieve the main goals established by the most important international agencies and governments in order to fight against global climate change and to ensure a sustainable development for the future generations (International Energy Agency, 2014).

The most promising renewable technologies are based on solar energy. However these technologies are extremely dependent on the climate, causing temporal differences between the energy supply and the energy demand. In recent years thermal energy storage (TES) has been widely studied and represents one of the possible solutions to overcome this mismatch. Chidambaram et al. (2011) reviewed the TES systems coupled to solar cooling technologies and stated that TES integrated in solar cooling systems increases the cooling availability and improves the overall performance of the solar field. Considering solar power generation, Gil et al. (2010) showed a classification of current storage systems for solar power generation. They divided these systems depending on the materials used and the different storage concepts. They highlighted that TES systems allow a better dispatchability of power plants and enhance their power capacity.

TES systems can be classified in sensible thermal energy storage (STES), latent thermal energy storage (LTES), sorption energy storage, and thermochemical energy storage (TCES) and they can be applied in a wide range of applications at different temperatures, such as domestic hot water (DWH), solar cooling, combined heat and power (CHP), industrial waste heat (IWH) recovery, and concentrated solar power (CSP) plants. TES materials are a key factor in the solar technology field to improve the techno-economic performance. Most of the current literature evaluates the performance of the TES materials at laboratory scale (Fernandez et al. (2010); Pereira and Eames (2016)). However, it is known that the behaviour of those materials could be size-dependant (Rathgeber 2014). Moreover, there are several aspects such as operation, instrumentation, compatibility of materials (dynamic and static corrosion), and the behaviour of the TES material under the real operation conditions which need to be improved before the commercial development of the TES system. This previous research allows providing solutions to technical problems and to reduce the

cost of commercial plant (Rodríguez et al. (2014); Prieto et al. (2016)).

With this purpose, a pilot plant facility was designed and built at University of Lleida in 2008 (Peiró et al (2016a)). Its design simulates a real CSP plant and allows testing different sizes and configurations of TES storage tanks. Moreover, it is equipped with many measurement devices which record the different parameters to analyse the thermal behaviour of the pilot plant and their components. Up to now, this facility has been used to analyse both STES and LTES systems with configurations such as shell-and-tube tanks and two-tank system. Thus, the objective of this article is to summarize and discuss the experimentation performed using this facility.

2. Description of the pilot plant facility

The pilot plant facility presented in this paper is mainly integrated by three systems:

- The heating system, which consists of a 24 kWe electrical boiler that heats up the heat transfer fluid (HTF) simulating the solar energy source in a real application. In this facility, two different fluids have been used as HTF, thermal oil Therminol VP-1 (T-VP1) and silicone fluid Syltherm 800 (S-800). Their flow rate is measured with a differential pressure transmitter and controlled by a proportional-integral-derivative controller.
- The cooling system, which consists of an air-HTF heat exchanger of 20 kWth to cool down the HTF. It simulates the energy consumption of the real application.
- The TES system, which consists of different storage tanks that store the thermal energy during the charging process and releases it during the discharging process. These tanks are equipped with several Pt-100 temperature sensors located strategically in order to obtain a proper map of temperatures of both the TES material and HTF.

Moreover, this facility has several auxiliary systems in order to ensure a proper operation, such as pumps, piping, valves, electrical system, and control and recording data system. All these components are suitably insulated to minimise the heat losses to the surroundings. Rockwool is used for the surfaces in contact with the ambient and Foamglass and refractory concrete for the surfaces in contact with the ground. Fig. 1 shows an overview of the different components of the previously described pilot plant facility.

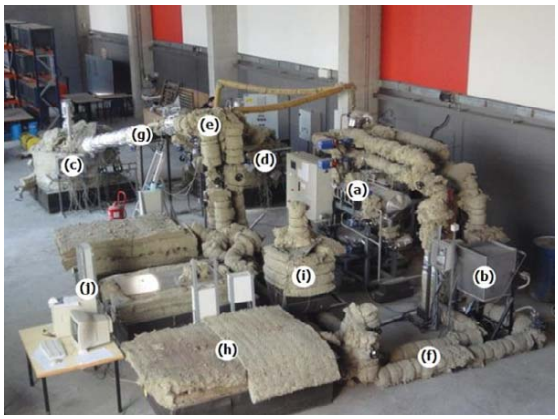

Fig. 1: Overview of the pilot plant facility available at the University of Lleida. (a) Electrical heater, (b) air-HTF heat exchanger, (c) molten salts hot tank, (d) molten salts cold tank, (e) HTF-molten salts heat exchanger, (f) HTF loop, (g) molten salts loop, (h) LTES system, (i) solid STES system, and (j) acquisition and recording system (Peiró et al. (2016a)).

3. Description of thermal energy storage systems

Different TES tanks and materials for both STES and LTES have been tested in this facility. The main characteristics of these systems are shown in this section.

3.1. Sensible thermal energy storage (STES) systems

Two different STES configurations were constructed and tested: a shell-and-tube STES tank and a two-tank TES system.

The shell-and-tube STES tank design consists of a vertical tube bundle with four tubes through which the HTF is circulated and a housing surrounding the tubes serves as storage material container. Fig. 2 shows a 3D view of the STES tank and Table 1 its design characteristics.

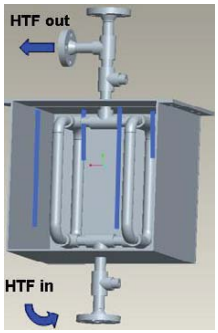

Fig. 2: Shell and tube STES tank: 3D view.

Table 1. Design characteristics of STES tank.

Dimensions of the tank	
width x height x depth	0.35 x 0.42 x 0.35 m
Packing factor	0.54

Material	Stainless steel 304L
Thickness	0.005 m
Tubes	
Material	Stainless steel 304L
Outer diameter (OD)	0.025 m
Total length	1.74 m

The two-tank STES system is composed of two identical storage tanks (called hot and cold tanks due to their thermal level). Both tanks are designed with the same aspect ratio (L/D) than commercial storage tanks. The design of the tank consists of a cylinder-shaped vessel, where the TES material is housed, which is closed with a Klöpper cover welded on the top. Fig. 3 shows a view of the storage tank of the two-tank molten salts TES system and Table 2 its main design characteristics. The walls and cover of the tank are manufactured with some openings in order to place the electrical heaters used to heat up the TES material, to place the different measuring devices, and to place the molten salts pumps. These pumps are responsible to move the molten salts from one tank to the other tank through a multiple pass plate heat exchanger. The heat exchanger is the component responsible to carry out the heat exchange between the molten salts and the HTF (Fig. 4 and Table 3).

3.2. Latent thermal energy storage (LTES) systems

Two storage tanks were designed and built in order to test the LTES concept with different phase change materials (PCM). The design of the tanks was based on the shell-and-tube heat exchanger concept. It consists of a rectangular-shaped vessel with a tubes bundle inside. The PCM was located in the housing of the shell part. The HTF circulated inside the bundle of tubes, which was integrated by 49 tubes bended in U-shape and distributed in square pitch (Fig. 5). One of these tanks was built with a 196 transversal squared fins assembled along of the tube bundle in order to enhance the heat transfer between HTF and PCM (Fig. 6). Table 4 shows the main design characteristics of the LTES tanks.

Packing factor	0.80
Material	Stainless steel 304L
Number of fins	196
Dimensions	0.25 x 0.25 m
Thickness	0.0005 m

4. Description of the storage materials

A total of six different TES materials have been studied at pilot plant scale for both STES and LTES systems. Regarding the STES, two different TES materials were tested: on one hand, granulated NaCl, a by-product from the potash industry, which was used in the STES tank; on the other hand, molten salts, which were used in the two-tank system. Regarding the LTES tanks, four PCMs have been used: RT58 (a paraffin), bischofite (a by-product from the mining industry), d-mannitol (a sugar alcohol), and hydroquinone (an aromatic compound). Table 5 shows the main characteristics of these PCMs, such as specific heat for materials used in STES and melting temperature and enthalpy for materials used in LTES tank. These characteristics were obtained with differential scanning calorimeter (DSC) tests.

Table 5. Main characteristics of the STES and LTES materials used for testing.

TES Material	Type of energy storage	Specific heat [kJ/kg·K]	Melting temperature [ºC]	Melting enthalpy [kJ/kg]
NaCl	Sensible	0.738 (solid)	-	-
Molten salts	Sensible	1.51 (liquid)	-	-
RT-58	Latent	-	53-59	120.0
Bischofite	Latent	-	100-110	115.0
d-mannitol	Latent	-	162-170	246.8
Hydroquinone	Latent	-	168-173	205.8

5. Experimental procedure

Based on the operation performance of TES material, the experimentation carried out at the pilot plant facility consisted of several charging and discharging processes. Different HTF flow rates and arrangements, and different temperature ranges were considered in order to simulate real application operation conditions. In the LTES and the STES tanks the experimentation procedure is the following: before starting the charging process a warming period is done in order to achieve the initial required conditions. Once the TES material reached the initial required temperature, the HTF is heated up outside the tank until charging temperature is reached. After that, the charging process is able to start. During the charging process, the inlet temperature of HTF is kept at desired temperature. The charging process is stopped when the average temperature of the main temperature probes of the TES material tanks reaches the same temperature than the inlet HTF temperature. Then, the HTF is cooled down outside the tank with cooling system until the discharging temperature is reached. After that, the discharging process starts and it is considered finished following the same criteria than in the charging process. In the two-tank molten salts system, the charging and discharging processes are carried out with a different procedure simulating the operation in a solar power plant. During the charging process, the molten salts are pumped from the cold tank to the hot tank through the heat exchanger system. In this system, the molten salts are heated up with the HTF, which has been previously heated with the heating system. The process is considered to be finished when the level of the molten salts at the cold tank reaches the minimum level for a proper performance of the molten salts pump. On the contrary, during the discharging process, the molten salts are pumped from the hot tank to the cold tank through heat exchange system. In this system, the HTF is heated up with the molten salts to be further cooled down at the cooling system, simulating the power block. The discharging process is considered to be finished when the level of the molten salts at the hot tank reaches the lowest level.

Table 6 shows a summary of the main working conditions of the different experiments carried out at the pilot plant facility. The temperature range was selected according to the materials characteristics and to the final application, while the flow rate was selected to study its influence on the charging and discharging processes.

Table 6. Summary of the characteristics of experimentation carried out at pilot plant facility.

System	TES material	Mass tested [kg]	HTF	HTF flow rate [l/h]	Temperature range [ºC]	Ref.
STES tank	NaCl NaCl + water	59	T-VP1	1000- 3000	100-200	Miró et al. (2014)
Two-tanks	Molten salts	1600	T-VP1	435	298-343 303-372	Peiró et al. (2016b)

6. Results

6.1. Sensible thermal energy storage systems

The experimental work with STES tank presented in Miró et al. (2014) was focused on comparing the thermal behaviour of granulated NaCl and NaCl compacted with water. Four thermal cycles (charge and discharge) were performed with temperature range of 100-200 ºC. The main differences between the thermal cycles were the HTF flow rate (1000 l/h and 3000 l/h) and the duration of the processes (4 h and 8 h).

Fig. 7a and Fig. 7b show the temperature profile of the HTF and average temperature of both granulated NaCl (salt A) and NaCl compacted with water (salt B). In the four thermal cycles performed, both salt A and salt B do not reach the fixed temperature set-point for charging (200 ºC) because the two proposed intervals of time were not sufficient to ensure a full charge. However, it can be observed that the temperature profile of the salt A and salt B are significantly different. Notice that at the end of the 4 h charging process (Fig. 7a) the salt B temperature is around 25 ºC higher than the temperature of salt B. The reason lies on the fact that the thermal conductivity of salt B (2.84 W/m·K) is 8.6 times higher than the salt A (0.33 W/m·K). From Fig. 7a, it also can be observed that there are not significant differences between the temperature profiles of the salts when the HTF flow rate was increased. Moreover, during this experimentation the energy accumulated or delivered by the salts was analyzed. During the charging process, salt A average accumulated energy was 0.63 kWh, while it was 0.75 kWh for salt B (the wetted compacted salt). This fact represented an increase of 19% in energy accumulated when using salt B. During the discharging process the average energy delivered by salt A was 0.40 kWh and 0.66 kWh for salt B. That represented an increase of 68%. The reason is because in the same period of time, the conductivity had a big impact. The average thermal efficiency was 63% for salt A and 88% for salt B, which represented an increase of 40%. It was also observed that there was no influence in the energy accumulated with an increase of the HTF flow rate. As expected, when the duration of experiments was doubled, an average increase of 27.8% (salt A) and 16.3% (salt B) of the energy accumulated during the charging process, and an increase of 30.6% (salt A) and 22.3% (salt B) of the energy delivered during the discharging process. With these results, the main conclusion reported in the study performed by Miró et al. (2014) is that NaCl compacted with water represents a better and cheaper option than other STES materials for TES due to the reduction of air gaps inside the solid.

The two-tank molten salts TES system experimentation presented in Peiró et al (2016) represents the first study in the literature at pilot plant scale with molten salts as TES material and thermal oil (Therminol VP-1) as HTF operating in a plate heat exchanger. The main objective of this work was to study the effects of varying the flow arrangement (parallel and counter flow) in the plate heat exchanger and the effects of modifying the temperature gradient between the HTF and the molten salts (46 ºC ± 3 ºC and 68 ºC ± 1 ºC).

From the results of the experiments carried out, it was observed that for the same temperature gradient, counter flow arrangement performed better than parallel flow. Higher values of power were obtained with counter flow arrangement in both charging and discharging processes (from 65.5% to 78.8% higher). The reason of this behavior lies on the fact that in counter flow arrangement a more constant thermal gradient between the hot and the cold fluid at the heat exchanger is obtained during the whole process. On the other hand, it was observed that with the same flow, the experiments carried out with a higher thermal gradient provided values of power from 12.9% to 35.5% higher in both charging and discharging processes as a result of an increase in the driving force for the heat transfer.

Fig. 7c and Fig. 7d show the temperature evolution of both HTF and molten salts during the charging and discharging processes at inlet and outlet of the heat exchanger of two-tank system for the best working conditions (counter flow arrangement with a temperature gradient between 305 ºC and 370 ºC). The shaded areas represent the periods used to achieve the operational conditions required for the experimentation. The HTF temperature is represented in dotted lines while the molten salts are represented in straight lines. Moreover, in both charging and discharging processes, the hot fluids are plotted in red while the cold fluids are plotted in blue. During the charging process (Fig. 7c), the energy released by the HTF (7.8 kWh with an average thermal power of 13.0 kW) is higher than the energy absorbed by the molten salts (6.8 kWh with an average thermal power of 11.6 kW), which gives a process efficiency of 89%. On the contrary, during the discharging process (Fig. 7d), the energy released by the molten salts (7.5 kWh with an average thermal

power of 11.75 kW) is higher than the energy absorbed by the HTF (7.09 kWh with an average thermal power of 11.12 kW), which gives a process efficiency of 94.53%. The differences between the energy of HTF and salts are due to the heat losses of heat exchanger. Notice that the energy released by the salts during the discharge is higher than the energy absorbed in the charge process, due to the salts temperature difference between the inlet and outlet, which is slightly higher in discharge than in charge as a result of the electrical resistances placed inside the hot storage tank.

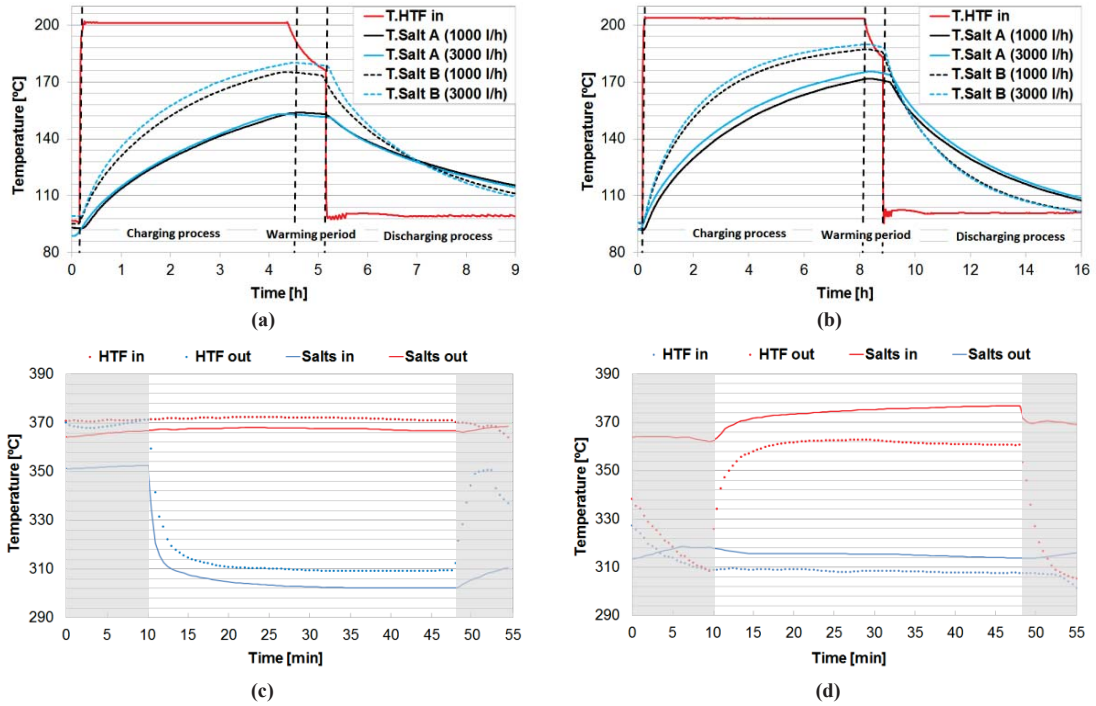

Fig. 7: STES systems temperature profiles. STES system: (a) thermal cycle of 4h and (b) thermal cycle of 8h. Two-tank molten salts TES system: (c) charging process and (d) discharging process.

6.2. Latent Thermal Energy Storage systems

The LTES systems, with the four above-mentioned PCMs, were analyzed under different HTF flow rates and working temperatures in order to test different operational conditions. Moreover, the effect of adding extended surfaces and the arrangement in series of different PCM's with different melting temperature and melting enthalpies were also studied.

The first PCM presented in this paper is RT58. This material was selected for DWH taking into account its melting temperature range (Table 5). The experimental work with RT58 presented in Gasia et al. (2016) was carried out with the objective of characterizing this material as PCM. Several charging and discharging processes were performed with a temperature range of 48-68 ºC for three different flow rates: 550 l/h, 1650 l/h and 2750 l/h. Fig. 8a shows the HTF and average temperature of RT58 charge and discharge temperature profiles for the different HTF flow rates. Notice that the higher the flow rates, the faster the PCM was charged or discharged. Taking into account the properties of Sylthem 800, only laminar flow regime could be achieved. Hence, the heat transfer coefficient was constant for the different flow rates evaluated, and therefore the temperature difference between HTF and PCM determined the value of heat transfer rate. With a higher flow rate, the temperature difference was higher and, as a consequence, the heat transfer was higher, which caused the PCM to heat up or cool down faster. The energy accumulated and delivered by the HTF and RT58 was also analysed. For instance, during the charging process with an HTF flow rate of 1650 l/h, the energy stored by the PCM was 5.74 kWh and the energy released by the HTF was 6.33 kWh, giving an efficiency of 90.68%. During the discharging process, the energy recovered by the HTF was 5.03 kWh, which was obtained from the PCM and the metallic parts of the TES system, which gives an efficiency of 89.15 %.

Regarding the evaluation of bischofite, Gasia et al. (2015) studied the suitability of bischofite as TES material in both sensible storage and latent storage. This material was selected for IWH and CHP purposes taking into account its melting range of temperatures (100-110 ºC). Several charging and discharging processes with a flow rate of 1650 l/h were performed, going from from 50 ºC to 80 ºC to evaluate the TEs material under the sensible form, and from 80 ºC to 120 ºC to test the latent form (Fig. 8b). Notice that the first two hours corresponded to the charge in sensible form, and from the 3rd hour until 7.64 h corresponded to the latent form. Discharging took place between 9.69 h and 14.12 h. During the experimentation, the subcooling effect at pilot plant scale was observed to be lower than the results obtained at laboratory scale. Regarding in energy stored/released during the first charging process, it was observed that the energy released by the HTF was 4.02 kWh and the energy stored by the bischofite was 3.07 kWh, giving an efficiency of 76.4%. During the second charging process, the energy given by the HTF was 13.5 kWh and the energy stored by the bischofite was 11.97 kWh, giving an efficiency of 88.7%. The reason for this difference between the two charging processes lies on the fact that while in the first charging process the bischofite increased 30 ºC in the sensible form, in the second charging process the bischofite increased 40 ºC in both the sensible and latent form. Moreover, results showed a good behavior of the 204 kg of bischofite evaluated at pilot plant but further research is needed because of the bischofite nature and the impurities embedded in it.

As shown in Table 6 two more PCMs have been studied, tested and compared at the pilot plant of University of Lleida in order to find the best PCM candidate for a real solar cooling plant available at University of Seville (Spain)(Gil et al. (2013a)). Several charging and discharging processes were performed with two different temperature ranges, 130-200 ºC and 145-187 ºC, and with three different flow rates: 1400 l/h, 2200 l/h and 3000 l/h (Fig. 8 c and Fig. 8d). As for the results obtained with RT58, the higher the flow rates, the faster the PCMs were charged or discharged. However, due to the thermophysical properties of the Therminol VP-1, the three representative flow regimes could be obtained for the three studied flow rates: laminar, transition and turbulent. The subcooling effect at pilot plant scale of hydroquinone was also lower than the results obtained at laboratory scale. However, d-mannitol showed high subcooling and polymorphism at pilot plant scale. Furthermore, for the same boundary conditions, the energy stored and released by d-mannitol was higher than hydroquinone. For instance, during the charging process with d-mannitol as PCM, with a temperature range of 145-187 ºC and an HTF flow rate of 1400 l/h, the energy released by the HTF was 22.35 kWh and the energy stored by the d-mannitol was 19.89 kWh, giving an efficiency of 88.9%. On the other hand, with hydroquinone, the energy released by HTF was 17.55 kWh and the energy stored by hydroquinone was 14.82 kWh, giving an efficiency of 84.4%. During the discharging process with d-mannitol, the energy recovered by the HTF was 18.11 kWh and energy released by d-mannitol was 18.46 kWh, giving an efficiency of 88.6 %. With hydroquinone, the energy recovered by the HTF was 13.30 kWh and the energy released by hydroquinone was 14 kWh, giving an efficiency of 92%. Results showed that d-mannitol and hydroquinone were good candidates as PCM for solar cooling applications. However, the subcooling effect is a parameter which should be addressed if these materials are selected.

In all the PCMs evaluated, it was found that that one of the most important drawbacks were their low values of thermal conductivity in both solid and liquid, which causes a limitation in the heat transfer ratios between the HTF and the PCM. In order to overcome such drawback, different heat transfer enhancement techniques were tested at the pilot plant facility. Two studies were carried out with the aim of evaluating the influence of adding fins: hydroquinone (Gil et al. 2013b) and RT58 (Gasia et al 2016). Another project was carried out with the objective of testing the multiple PCM concept, or cascaded, with hydroquinone and d-mannitol (Peiró et al 2015). Results showed that the addition of fins increased up to 28% the time of the charging/discharging process under the same working conditions. Moreover, results also showed that the multiple PCM configuration introduced a higher uniformity on the HTF temperature, and introduced an effectiveness enhancement of around 20%.

7. Conclusions

In the literature, most of the TES materials thermal behaviour analyses are performed at laboratory scale. Taking into account that some thermophysical properties are present size-dependant behaviour, analyses at higher scales are needed.

In the present paper, some results of all the experimentation performed at the pilot plant facility designed and built at University of Lleida with different TES materials (in both sensible and latent forms) are presented. In the experimentation carried out to test STES materials, a TES tank based on shell-and-tube heat exchanger concept and a two-tank molten salts system were used. In the experimentation performed to test LTES materials, a different storage tank based on shell-and-tube heat exchanger concept. The effects of the TES materials thermophysical properties, HTF flow rates, the addition of fins, and the multiple PCM concept was tested and analysed. Moreover, six different materials were used in the experimentation: NaCl and molten salts as STES materials, and RT-58, Bischofite, d-mannitol and hydroquinone as PCM.

The experimentation carried out at the pilot plant facility of the University of Lleida, has shown the relevance of testing at a relevant scale in order to face important progress in the roadmap to reach commercial development. A proper design of a pilot plant has allowed the evaluation of various materials, different designs of TES tanks, instrumentation, auxiliary equipment, and different operational strategies such as the effect of adding fins or the flow arrangement, using the same installation. Moreover, this experimentation has shown that the thermophysical behaviour of the TES materials is different at different scales such as subcooling effect.

Abstract

In the present paper different heat exchangers designed to be installed into an ice storage for solar and heat pump heating applications are experimentally investigated. Analyzed heat exchangers are capillary mats and flat plate types. For each heat exchanger, different designs, materials and number of heat exchanger units are evaluated using two different mass flows. This paper aims at i) characterizing different heat exchanger designs by means of measurements in a laboratory-size ice storage of 2 m^3, ii) determine specific advantages and disadvantages of different heat exchanger concepts for ice storages used in combination with solar collectors and a heat pump and iii) provide a source of experimental data for model validation.

Keywords: ice storage, heat exchangers, solar-ice.

Nomenclature

A_{ext}	external area of one hx [m^2]	Q	energy delivered to the storage [kWh]
A_{hx}	total hx area in the storage [m^2]	$T_{w,avg}$	averaged storage temperature [^oC]
d_i	inside diameter of CM tubes [m]	$T_{f,in}$	heat transfer fluid temperature at the inlet of the hx [^oC]
d_o	outside diameter of CM tubes [m]	$T_{f,out}$	heat transfer fluid temperature at the outlet of the hx [^oC]
H_{hx}	height of FP hx [m]	U	heat transfer coefficient of the hx [$W/(m^2K)$]
L_{tube}	length of U-shape tubes [m]	$\dot{V}_n$	nominal volume flow of the experiments [l/h]
L_{hx}	length of FP hx [m]	V_r	ice fraction [kg_{ice}/kg_{water}]
$\dot{m}$	mass flow rate of the brine [kg/s]	V_r^*	ice fraction calculated from energy exchanged [kg_{ice}/kg_{water}]
n_{hx}	number of hx in the storage	x_{tubes}	distance between tubes in one CM [mm]
n_{tubes}	number of tubes in one CM	x_{hx}	distance between hxs [mm]

1. Introduction

Ice storages are a well proven technology for cooling applications where their main role consists in peak shaving of cooling loads at noon or in providing high cooling power for industrial processes (ASHRAE, 2007). On the other hand, ice storages can also be used for solar heating applications where less extraction power is needed because they serve as heat source for a heat pump and not to cover peak demands. Therefore, ice storages used in solar heating applications, in so-called solar-ice systems, can be designed with less heat exchanger area per storage unit volume compared to cooling applications (Carbonell et al., 2016b). However, this is not often the case when companies that have been traditionally working for the cooling sector are trying to enter the solar heating market designing the ice storage with the experience gained from cooling applications only.

In solar-ice applications, it is important to provide ice storages at low cost in order to be competitive with respect to alternative solutions such as boreholes for ground source heat pump systems. Furthermore, ice storages have to be reliable to keep maintenance costs as low as possible. In order to reduce installation costs, a de-icing concept can be used to avoid installing heat exchangers in the whole ice storage volume (Philippen et al. (2012),Carbonell et al. (2015)). However, for small ice storages, e.g. below 10 m^3, the ice fraction that can be achieved using a de-icing concept is significantly smaller than using a non de-icing concept. For single family houses, a solar-ice system with a large ice storage, e.g. higher than 10 m^3, will most likely not be cost competitive compared to a ground source heat pump system. Therefore, for single-family houses, ice storages based on a non de-icing concept seem to be a more attractive solution. Moreover, market available ice storages are based on a non de-icing concept, not only for small, but also for large ice storages. Most of ice storages installed in Europe are based on ice-on-coil heat exchangers, and although other heat exchanger concepts exist on the market, their specific advantages and disadvantages remain unclear.

This paper is focused on the experimental analyses of several heat exchangers for ice storage concepts that do not use a de-icing concept. The aim is to compare different heat exchanger concepts in terms of efficiency and cost with the final goal to define the cost effective heat exchanger area needed for solar heating applications. In order to achieve the final goal, it is necessary to simulate the complete solar-ice system with a well validated ice storage model that is able to consider all heat exchanger designs. Therefore, the experimental data presented in this paper will be used to validate an ice storage model in a second step. Examples of complete solar-ice system simulations can be found in recent publications, e.g. Trinkl et al. (2009), Tamasauskas et al. (2012), Winteler et al. (2014) and Carbonell et al. (2016a). Moreover, the experiments presented in the paper are also helpful to understand the physics behind the solidification and melting of ice on the different heat exchangers.

2. Experiments

2.1. Experimental set-up

The scheme of the experimental set-up is shown in Fig. 1. The inner dimensions of the ice storage are 2 m x 1 m x 1.3 m and it is insulated with 5 cm of Armaflex® (λ = 0.041 $W/(m \cdot K)$). The storage is filled with 2 m^3 of water. The heating and cooling is provided by a chiller with approximately 6 kW heating and cooling power. Five Pt100 sensors are installed inside the storage for measuring the temperature at different heights. Three Pt100 sensors are installed at the inlet/outlet of the heat exchangers, considering two possibilities for loading/unloading. An ultrasonic sensor is used to measure the height of the water level and to derive the total fraction of ice inside the storage. A volume flow sensor is installed and the volume flow is regulated by a PID control. A LabVIEW interface has been developed to run all testing sequences automatically.

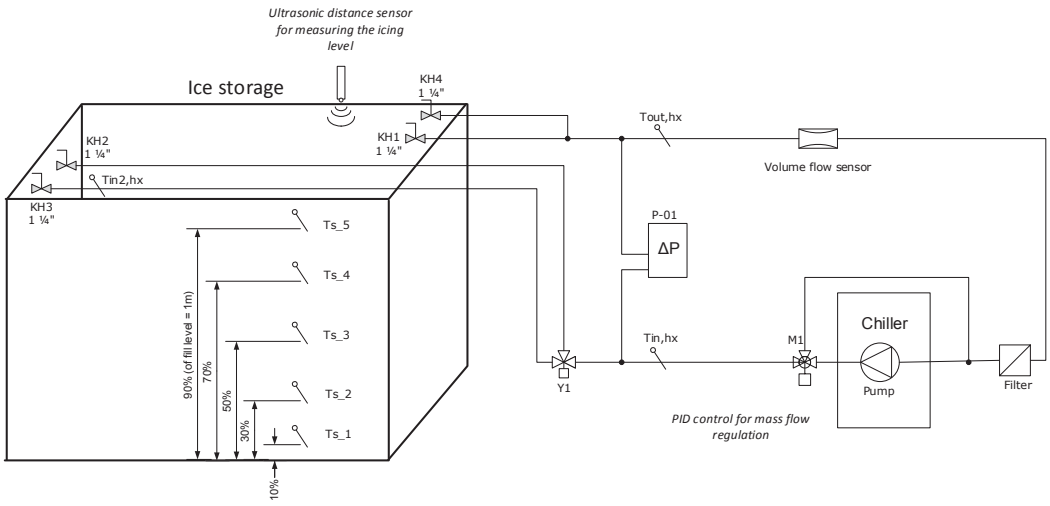

Fig. 1: Hydraulic scheme of the experimental set-up with sensor locations.

2.2. Measurement uncertainties

The temperature sensors have been calibrated in a Fluke Dry-Block Calibrator for the temperature range of the test cycles ($(-10)-40°C$). Based on the calibration, the output values of each temperature sensor were corrected according to a 1^{st} order polynomial. The remaining uncertainty of the Pt100 sensors after calibration was in the order of 0.03-0.04 K. The mass flow rate measurement was done using a magnetic flow meter, that has been calibrated for flows between 500 and 1400 l/h. The relative uncertainty of the volume flow rate measurement after the calibration of the flow sensor was determined to be 0.6% . For the glycol concentration, an acceptable range of 31.92%-34.66% has been defined. The maximal relative uncertainty of the mixture density is then estimated to be 1.0%. The relative uncertainty of the specific heat capacity is smaller than 1.3%. All these uncertainty values are used to calculate the total uncertainty of the derived values such as power or heat transfer coefficient. The relative uncertainty of the extracted power is in the order of 2%. The calculated heat transfer coefficient is affected by an uncertainty that ranges from 2.5% up to 14%. High uncertainty values are caused by small temperature differences when the ice storage temperature approaches the chiller set point temperature. Thus, system operating points with significant energy transfer are not affected by this large uncertainty values. The ice fraction calculation was done based on the changing water level in the storage tank when ice is formed or melted. The ultrasonic sensor has a precision of 0.5 mm which results in an uncertainty of the icing fraction in the order of 0.5%-1%.

2.3. Heat exchangers tested

Two capillary mats (CM) from the manufacturer Clina have been experimentally evaluated: G and S-type. All CM are made with the same kind of tubes and materials but have a slightly different design (see Fig. 2). In the S-type, the U-shape of the tube observed in the G-type is modified and the down-flow and up-flow on each tube are on the same plane. Therefore, S-types are plane and G-types are U-shaped. The G-type has 22% more heat exchanger area than S-type, but the S-type can be installed with half the time approximately.

In both designs, the mats have been connected in parallel to the distribution pipes and are tested with two different number of heat exchangers, 16 and 8. In total, four capillary mats combinations have been tested as shown in Table 1.

Two different flat plate heat exchangers have been tested, one made of stainless steel (SS) from the manufacturer Energie Solaire and the other made of polypropylene (PP) from the manufacturer MEFA. The physical

3. Methodology

In order to test the heat exchangers an experimental sequence has been defined and programmed in LabView. The testing sequence is summarized in Table 3. The nominal mass flow rate defined as $\dot{V}_n$ has been set to 2000 l/h. The parameter n is a factor used to reduce the mass flow when desired. All heat exchangers have been tested with n = 1 and with n = 0.5 where the volume flow is regulated with a PID control. Each test lasted around one week for each mass flow and a total of 9 heat exchanger set-ups have been evaluated. This means a total of 18 weeks of testing time are shown in this paper.

3.1. Performance indicators

For each test sequence several indicators are calculated. The heat exchanger power $\dot{Q}$ is calculated as:

$$\dot{Q} = \dot{m} c_p (T_{f,out} - T_{f,in}) \tag{1}$$

Tab. 3: Testing sequences considered for each heat exchanger.

Test phase	Name	Mass Flow	T_{set} of the chiller	Begin of sequence	End of sequence
Sensible heating	T1	$n \cdot \dot{V}_n = 1000$ l/h	20 °C	Storage at 10 °C or end of T8	steady state
	T2	$n \cdot \dot{V}_n = 2000$ l/h	40 °C	End of T1	steady state
Sensible cooling	T3	$n \cdot \dot{V}_n = 1000$ l/h	-10 °C	End of T1	$T_{s,av} \approx 0$ °C
	T4	$n \cdot \dot{V}_n = 2000$ l/h	-10 °C	End of T2	$T_{s,av} \approx 0$ °C
Solidification	T6	$n \cdot \dot{V}_n$ [a]	-10 °C	End of T3 or T4	$V_r \approx 95\%$ (or 3 days)
Cycling : Ice/melt	T8	$n \cdot \dot{V}_n$ [a]	-10 °C (40 min)		
			10 °C (20 min)	End of T6	10 cycles
Melting	T9	$n \cdot \dot{V}_n$ [a]	10 °C	End of T8	steady state

[a] with n=0.5 and n=1

where $\dot{m}$ is the mass flow, c_p the specific heat capacity and T_f the heat transfer fluid temperature. The cumulated energy for the whole test sequence until the time t is calculated as:

$$Q = \int_{t=0}^{t} \dot{Q} \cdot dt \tag{2}$$

where the time step dt is set to 10 seconds. The ice fraction is calculated as the ratio between the mass of ice and the total amount of water of the storage.

$$V_r = \frac{M_{ice}}{M_{water}} \tag{3}$$

The ice fraction is experimentally evaluated measuring the change of height of water due to the volume change between water and ice. For some processes, e.g. melting cases where the initial ice fraction is very large and the ice is above water level, the mass of ice can not be accurately obtained from experiments and therefore it is calculated from the energy exchanged with the storage, neglecting heat gains from ambient trough the storage walls. Ice fraction results that are calculated from the exchanged energy are labeled as V_r^*.

The global heat transfer rate of the heat exchanger UA is obtained from:

$$UA = \frac{\dot{Q}}{LMTD} \tag{4}$$

where the logarithmic mean temperature difference LMTD is calculated as:

$$LMTD = \frac{(T_{f,out} - T_{w,av}) - (T_{f,in} - T_{w,av})}{ln\left(\frac{T_{f,out} - T_{w,av}}{T_{f,in} - T_{w,av}}\right)} \tag{5}$$

where $T_{w,av}$ is the averaged water temperature in the storage.

The heat transfer coefficient of the heat exchanger is calculated as:

$$U = \frac{UA}{A_{ext}} \tag{6}$$

where A_{ext} is the external surface area of each heat exchanger

4. Results

The experimental results are split into sensible heating , sensible cooling, icing, melting and cycling of icing/deicing. Results for flat plates made of polypropylene with a volume flow of 1000 l/h are not shown in the following sections because we have detected problems in the flow distribution.

4.1. Sensible heating (T1 and T2)

Measured overall heat transfer coefficients for sensible heating process with capillary mats and flat plates are shown in Fig. 3 . Circle marks are for 2000 l/h and for T2, i.e. the storage is heated from 20 °C to 40 °C. Filled triangles are for 1000 l/h and for T1, i.e the storage is heated from 10 °C to 20 °C.

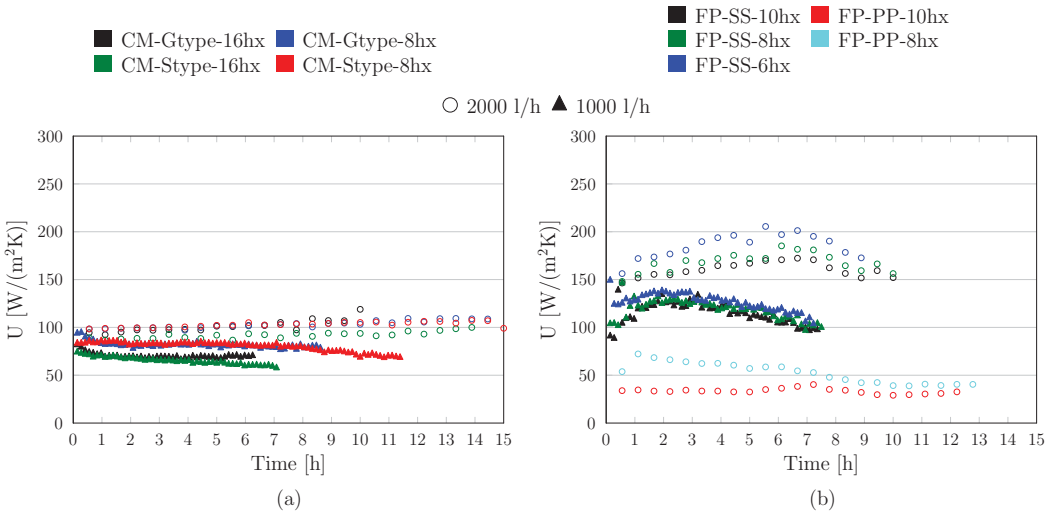

Fig. 3: Overall heat transfer coefficient results for sensible heating sequences T1 and T2 for (a) CM and (b) FP. Circle marks are for 2000 l/h and T2 (heating from 20 °C to 40 °C) and filled triangles are for 1000 l/h and T1 (heating from 10 °C to 20 °C)

The overall heat transfer coefficient U is shown in Fig.3. FP-SS show higher capacities for providing energy to the storage by means of sensible heat. For a flow rate of 2000 l/h, U is in the range of 90-110 W/(m^{2}K) for CM and between 150-200 W/(m^{2}K) for FP with SS. For 1000 l/h U values are decreased to values between 70 and 90 W/(m^{2}K) for CM and to 100-140 W/(m^{2}K) for FP-SS approximately. The main difference between the two different designs of capillary mats, G and S types, is the heat exchanger area as U values are very similar. FP-PP show a much lower performance compared to FP-SS and the performance of CM is better than the one of FP-PP but worse than the one of FF-SS. The performance of CM and FP-PP remains relatively constant for all the sequence even that the Reynolds number (Re) increases due to the lower viscosity of the fluid when it is heated. During the whole test sequence the Re number remains below 400 for 2000 l/h and below 150 for 1000 l/h and therefore is always in a theoretical laminar regime. In a laminar flow regime the Nussel number is relatively constant and therefore the performance of the capillary mats are not affected by the increase of Re during the heating process and only slightly due the change of mass flow. However, FP-SS are significantly affected by the mass flow because they have a special design that enhances turbulence. For these type of heat exchangers the Re number where the flow is turbulent is much lower than that for smooth pipes. The flow regime found in these experiments for FP-SS are most of the time in the transition regime between laminar and turbulent and therefore, the Nu numbers, and thus the U values, are affected by the Re number.

4.2. Sensible cooling (T3 and T4)

Overall heat transfer coefficients U for capillary mats and flat plates for sensible cooling process are shown in Fig. 4 . Circle marks represent $\dot{V}_n$ of 2000 l/h and a test sequence in which the storage temperature is cooled from 40 °C to 0 °C. Triangle marks represent $\dot{V}_n$ of 1000 l/h and a test sequence in which the storage temperature is cooled from 20 °C to 0 °C.

The overall heat transfer coefficient shows a very different behavior for CM and FP-SS. For FP-SS, the U values decrease significantly with time. For CM the U values remain approximately constant for a large time period. The reason for that is the same given in section 4.1, i.e. capillary mats are always in a laminar regime while

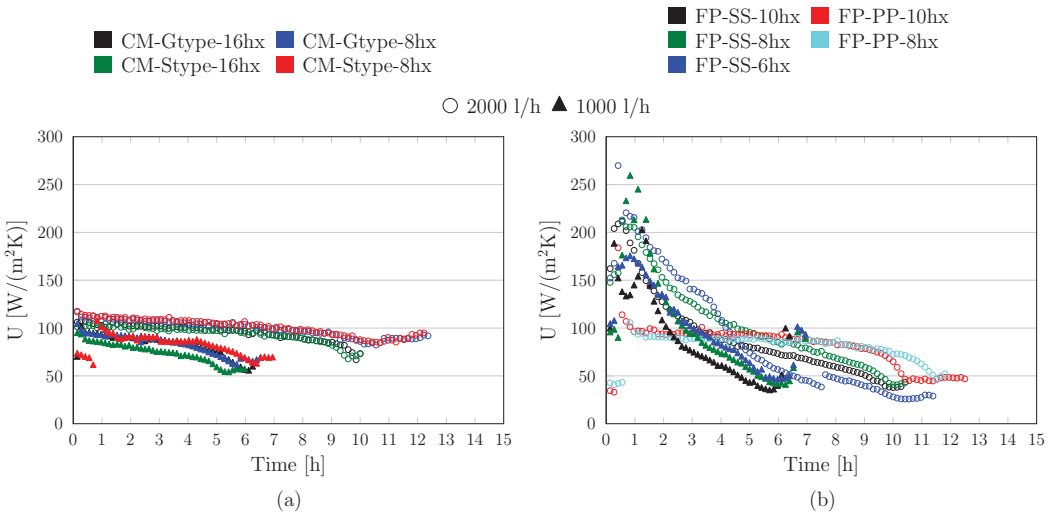

Fig. 4: Overall heat transfer coefficient results for sensible cooling sequences T4 for (a) CM and (b) FP. Solid lines are for 2000 l/h and the cycle starts at T_s of 40 °C; dashed lines are for 1000 l/h and the cycle starts at T_s 20 °C

FP-SS are in the turbulent and transition regime. In this case, the Re number decreases along the sequence because the fluid's viscosity is increased when cooled down to 0 °C. At the beginning of the test sequence, FPs perform significantly better than the CMs, and the opposite is true at the end of the test sequence. The U values range from 120 to 75 W/(m^{2}K) for 2000 l/h and from 100 to 60 W/(m^{2}K) for 1000 l/h when CMs are used; and they range from 220 W/(m^{2}K) to 40 W/(m^{2}K) using 2000 l/h and from 175 W/(m^{2}K) to 40 using 1000 l/h when FP-SS are used. The evolution of U along time for FP-PP is similar to the one observed with CM when 2000 l/h are used. The U values are relatively constant and in the range of 100 W/(m^{2}K) for a large period. The efficiency of the heat exchangers is reduced when the storage water temperature is close to 0 °C, when ice starts to grow, the U value increases.

4.3. Solidification (T5)

The amount of ice produced for capillary mats and for flat plates are shown in Fig. 5. From these results it seems clear that capillary mats are faster compared to flat plates in the process of water solidification. Ice fractions above 95 % were achieved with CM without damaging the casing. Due to the specific height of the

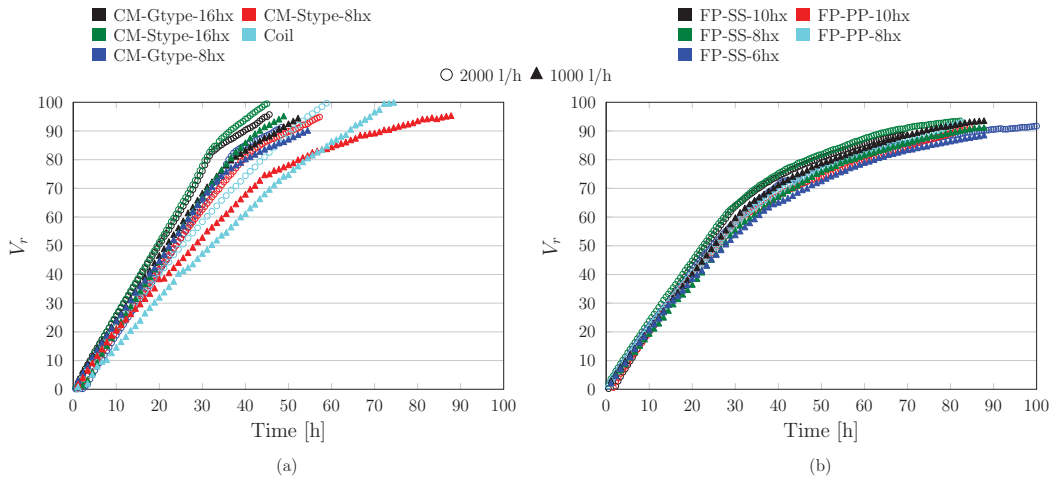

Fig. 5: Evolution of the ice fraction over time for the icing sequence T5 for (a) CM and (b) FP.

FP, only 85% of the storage height was covered by the heat exchangers, limiting its capacity to ice the whole storage. Mass ice fractions higher than 85% with FP are possible but with very low power since ice has to grow on the surface of a compact ice cube that includes all plates with a long path between the heat transfer fluid in the heat exchanger and liquid storage water. For FP, ice fractions above 90% where achieved and the casing of the storage did not show any problem.

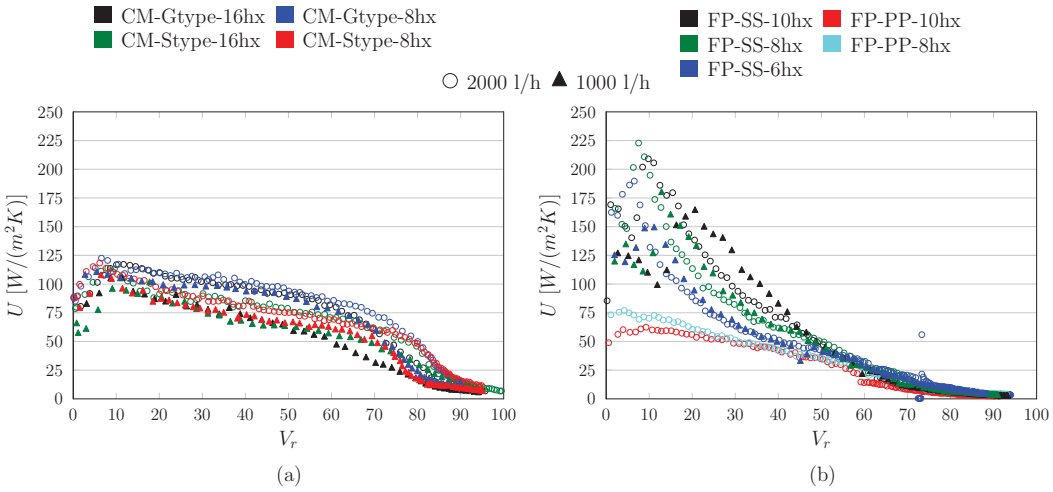

Fig. 6: Overall heat transfer coefficient as a function of the ice fraction for the icing sequence T5 for (a) CM and (b) FP.

The overall heat transfer coefficient is shown in Fig. 6 as a function of the ice fraction. From this graph it can be observed that the decrease of U for CM is much smaller compared to FP. Considering the ideal case of ice growing on a single tube, the higher thermal resistivity of the ice layer when ice grows is partially compensated by the higher contact area on the outside of the tube. Therefore, the heat transfer rate UA value remains relatively constant when ice grows on a cylinder (Carbonell et al., 2015). However, CM, are composed of many tubes very close to each other and the ideal unidimensional ice growing on a single tube is only valid until ice growing from neighboring tubes contact with each other. For example, for the S-type, the distance between tubes in one heat exchanger is 20 mm. Assuming that ice grows homogeneously on all pipes and along the whole pipe length, ice layers start to touch to each other within one heat exchanger when V_r is approximately 27% and 14% for 16 hx and 8 hx respectively. For G-type, the distance between pipes is 30 mm, this means that ice layers between pipes touch when the ice fraction is approximately 80% and 40% for 16 hx and 8 hx, respectively. The phenomenon of physical contact between ice layers is usually called constrained ice growing (Jekel et al., 1993). For all CM, the heat exchangers suffer of a two step constrained ice growing, the first one when the ice is constrained within one heat exchanger (ice between adjacent tubes touch each other) and the second when ice is constrained between neighboring heat exchangers. When ice growing is constrained the overall heat transfer coefficient decreases compared to the unconstrained case because the contact area between the growing ice and storage water decreases. However, in the experimental results it is not possible to observe a sharp decrease of the U value when ice constrainment occurs because ice grows unequally along the length of each tube and thus the ice growing is constrained slowly over a long period. For FP ice starts to be constrained when the ice thickness is half the distance between heat exchangers. This corresponds always to an ice fraction of approximately 83%. At these conditions all water between heat exchangers is frozen and ice can only grown on the surface of a solid cube of ice with very low U values. Comparing CM with FP one can observe that for low ice fractions the U values of FP-SS are higher. However, the decrease of the U value when ice grows is much more pronounced for FP-SS compared to CM. As said before, the contact area between ice and water increases when ice grows in CMs. Instead, for FPs the ice surface area remains approximately constant and the U value decreases rapidly. For FP with PP, the decrease of efficiency is much less pronounced in comparison to SS because the heat transfer resistance of the polypropylene is the limiting factor, in comparison to the FP-SS

where the ice thickness is the limiting factor.

4.4. Melting (T9)

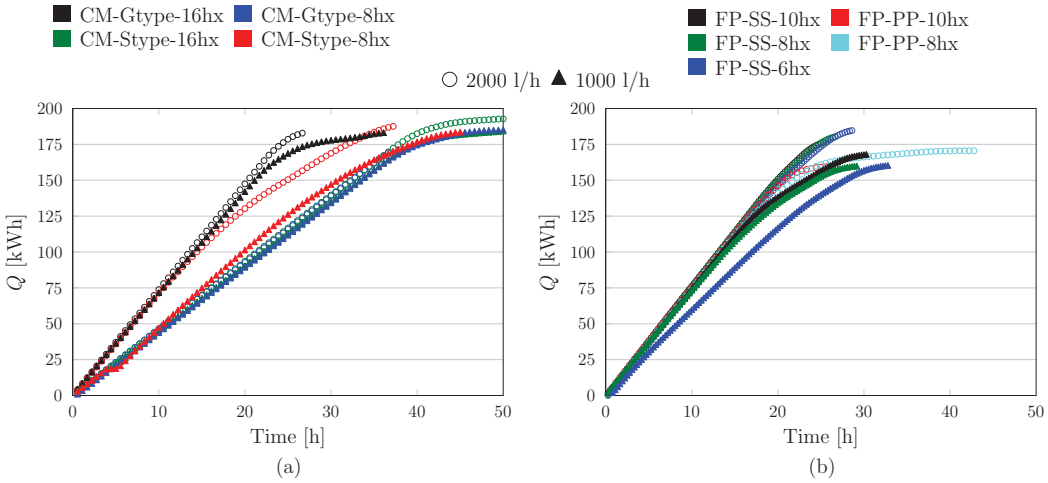

Fig. 7: Energy delivered to the storage by the heat exchangers for the melting sequence T9 for (a) CM and (b) FP.

The energy delivered for melting the ice is shown in Fig. 7. Melting 2 m^3 of water needs about 185 kWh. On top of that, the energy needed to heat the subcooled ice to 0 ^oC and the sensible heat to raise the temperature from 0 ^oC to 10 ^oC needs to be considered. Comparing CM with FP one can observe that FP-SS are usually able to melt completely the ice in less time. The measure for the ice fraction for capillary mats was not accurate with the method used in these experiments. A water layer above the ice block was not always present at high ice fraction (> 95%) and the measure of solid ice was disturbing the accuracy. Because the flat plates had a layer of 17 cm of water above them, the measurement of the melted ice were much more accurate. However, even in this case, with the method used, it is not possible to measure the ice fraction until the melted ice connects to the water of the storage. Before this cavity of ice is melted, the change of density when the ice is melted creates an underpressure around the hx that would either expand the heat exchanger or evaporate part of the water until the change of volume is filled.

Overall heat transfer coefficients are shown in Fig. 8. FP-SS have the highest melting capacity at high ice fractions with values above 250 W/(m^2K). For ice fractions below 60% the U values reduce to 50-60 W/(m^2K) for FP with SS. For CM, the U values are more stable over the whole melting process with values between 50-80 W/(m^2K).

4.5. Cycling (T8)

The cycling experiment consist of 10 sequences of heating and cooling which are used for melting and icing. This test sequence is performed at a very high ice fraction after the icing sequence T5. Each cycle is performed with a constant time of 20 min for heating and 40 min for cooling. All experiments with CM were tested with cycles always on the subcooled zone and therefore melting was not achieved. For this reason the test control was changed such that it heats up the storage until the outlet of the heat exchanger is close to zero before cycling starts. In this way it is ensured that ice is melted and solidified during each cycle. As an example, results for cycling sequence are presented in Fig. 9 for FP with 10 hx. For all the cycles the inlet temperature of the heat exchangers increases above 0 ^oC, which means that it is always possible to melt ice, at least the entrance of the heat exchangers. For the first four cycles, the outlet temperature remains at 0 ^oC, which means

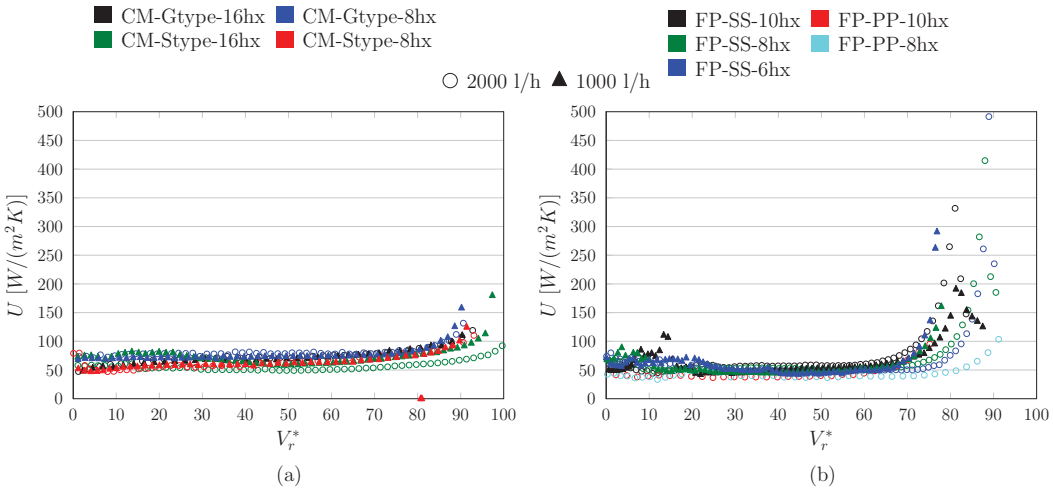

Fig. 8: Overall heat transfer coefficient for melting sequence T9 for (left) CM and (right) FPs.

that ice is never subcooled at the end of the heat exchanger. After the first cycles, the outlet temperature starts to drop below 0 °C which means that ice is subcooled, and the UA values are reduced because the heat of fusion is not released along the whole length of the hx.

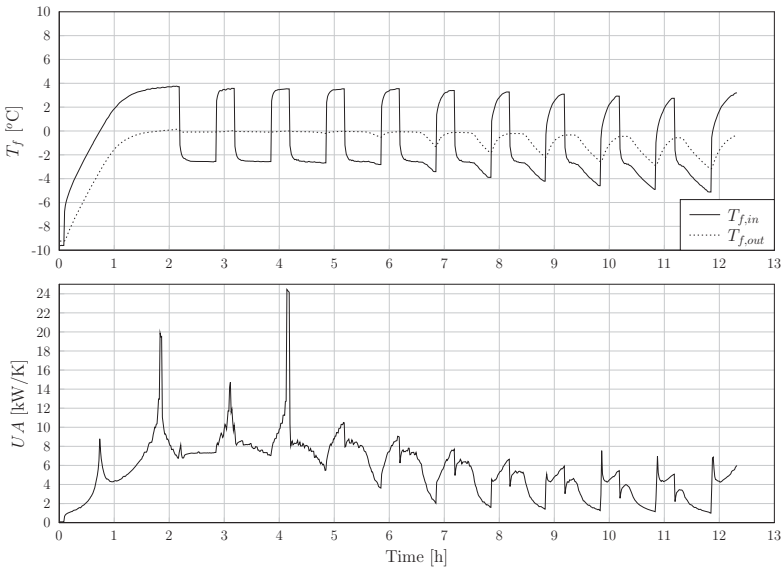

Fig. 9: (a) Heat exchanger temperatures and (b) overall heat transfer coefficient for cycling sequence T8 and FP.

The danger of breaking the casing of the storage is potentially higher when cycles of melting and icing exist at high ice fractions. In normal icing conditions without any cycles, the solid ice will always push the liquid water to the surface. Therefore, as long as there is an escape way for the water, there is no risk for the casing. The problem may occur when a volume of water in contact with the casing is trapped within an ice block. If then this water is iced, the volume expansion will produce a strong force to the wall of the casing with the danger of breaking it. This situation may occur when the dynamics of the system are on a specific state, which was never the case in the lab.

In this test several cycles of melting and icing have been performed at very high ice fractions in order to test the robustness of the heat exchangers under these dynamic conditions. The mechanical stress that was caused

by the dynamics of icing and melting was neither found to be a problem for the heat exchangers nor for the storage casing. However, long term tests should be performed to investigate the robustness and stability.

The cycling sequence will also be very useful for the validation of the ice storage model (not provided in this paper), since in each cycle different physical phenomena take place. Fig. 10 shows one cycle of melting and icing for FP-SS with 10 hx (zoom into Fig. 9). The sequence has been split into five zones, from I to V as shown in Fig. 10. Zones I to II correspond to heating/melting and zones III to V correspond to cooling/icing.

- Zone I : switch from cooling to heating.
- Zone II: the ice is heated from the subcooled state to 0 ^{o}C and melted starting from the entrance of the heat exchangers. Most likely, melting does not occur over the whole length since the outlet temperature remains below 0 ^{o}C.
- Zone III: cooling of the water until freezing conditions.
- Zone IV: icing of the water.
- Zone V: subcooling of ice.

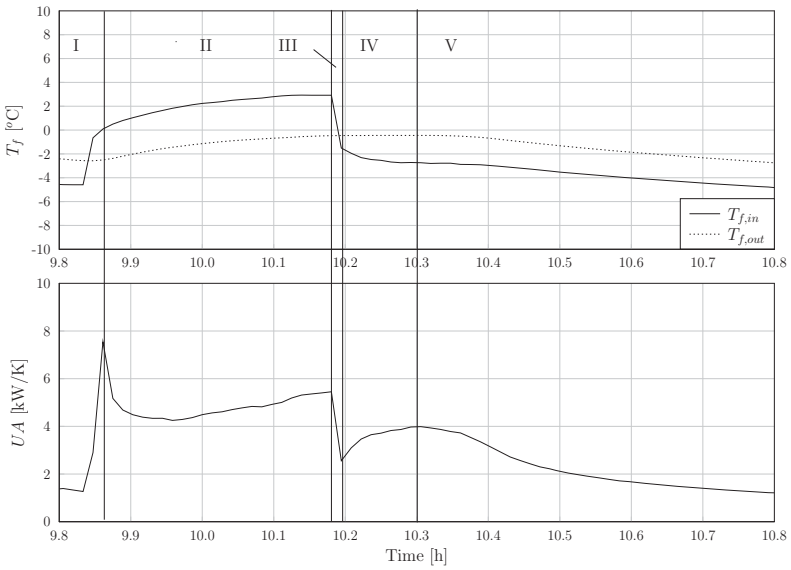

Fig. 10: (a) Heat exchanger temperatures and (b) heat transfer rate for cycling sequence T8 and FP.

5. Conclusions and future actions

In the present work several heat exchangers have been analyzed, including capillary mats with different designs made of polypropylene and flat plates made of stainless steel and polypropylene. The area analyzed has been modified for each heat exchanger and all test have been performed using two different mass flow rates. In total, nine possibilities have been experimentally evaluated for several test sequences including sensible heating and cooling, icing, melting and cycling. The main conclusions of the study can be summarized as:

- Very high ice fraction can be reached with all heat exchangers and mass flows.
- The casing did not show any damage under high ice fraction conditions. This means that designing an ice storages able to reach 95% ice fraction or higher should be safe.

- All heat exchangers showed to be reliable and robust under the test conditions. Long term tests were not carried out.
- Flat plates made of stainless steel are better suited compared to capillary mats for sensible heating and cooling and for melting processes.
- Capillary mats are better suited compared to flat plates for the icing process due to the strong decrease of performance that flat plates suffer when ice grows.
- Flat plates made of polypropylene have shown the worst thermal performance of all tested hxs.
- The poor flow distribution for 1000 l/h in the case of flat plates made of polypropylene needs to be further investigated.

An ice storage model able to consider all these heat exchanger designs has been developed and it is being validated with the experiments presented here. As a next step, system simulations with TRNSYS will be carried out with the validated ice storage model. With these simulations, it will be possible to find an optimum between the energetic system efficiency and the cost of the ice storage as a function of the heat exchanger area.

Abstract

In our labs and pilot sites, a novel heat battery for dwellings and offices is being developed. Based on a thermochemical sorption reaction, space heating, cooling and generation of domestic hot water will eventually be demonstrated in an existing dwelling by using solar or waste heat in the CREATE project. Developments of the active materials, of the reactor and components, and of the system were mainly performed in the MERITS project, and results are briefly described. Upon wide-spread use, the technology of compact thermal storage can be the game changer in the transformation of our existing building stock towards near-zero energy buildings.

Keywords: *thermal storage, energy storage, sorption storage, thermochemical storage, seasonal storage*

1. Introduction

For the transition to a 100% renewable energy economy, the application of solar energy (including electricity and thermal energy) is essential. As solar energy strongly fluctuates not only during the day but also during a year, it will be necessary to store large amounts of energy during at least half a year. Diurnal thermal storage can be arranged by mature boiler technology (sensible storage), but seasonal storage requires considerably lower heat losses. Besides, seasonal heat storage for domestic applications requires compact systems. Thermochemical storage provides a favorable solution, theoretically being loss-free during storage, and very compact. In this paper, we show (Fig. 1) that for the first time thermochemical energy storage has been demonstrated on a large and relevant scale.

Fig. 1: MERITS Field Test Demonstrator 3D systems model (left) and Field Test Demonstration container during pre-testing in Lleida, Spain (right)

doi:10.18086/eurosun.2016.03.08 Available at http://proceedings.ises.org

In practice, energy storage densities can be reached that are in the order of boiler technology storage densities, but with much reduced thermal energy losses during storage periods. The current paper describes results obtained from the MERITS project (www.merits.eu), which was aimed at designing, building and evaluating prototypes of a compact seasonal solar-thermal energy storage system based on thermochemical storage materials, i.e. a thermal battery. The team worked with a novel thermochemical material reaction having high energy density that can supply required heating, cooling and domestic hot water (DHW) for a dwelling with up to 100% renewable energy sources throughout the year. Furthermore, an outlook of future improvements to be performed in the CREATE project (www.createproject.eu) will be given. The CREATE project has as main aim to develop and demonstrate a heat battery, i.e. an advanced thermal storage system based on Thermo-Chemical Materials, that enables economically affordable, compact and almost loss-free storage of heat in existing buildings. To this end, demonstration will eventually take place in a dwelling.

2. Improvement over available thermal energy storage techniques

Loss-free compact affordable thermal energy storage would greatly enhance the use of sustainable heat from solar or waste sources. Different forms of thermal energy storage exist today: sensible storage, latent storage (through phase-change materials) and thermochemical storage.

Sensible storage makes use of the thermal capacity of a liquid or solid. Through heating, a certain quantity of heat can be sensibly stored in said materials, e.g. in hot water systems. Roughly 50 m^3 of water would be needed for storing 10 GJ (2778 kWh) of heat in a temperature range between 40 and 90 °C. Even when this volume would indeed be available in domestic applications, it will have insufficient storage capacity because of the thermal losses.

Latent thermal energy storage makes clever use of melting/solidification of certain classes of materials (phase change materials, PCMs). Examples are ice/water, different kinds of salts, or paraffins, having storage densities roughly between 0.2 – 0.4 GJ/m^3 (roughly 56 – 111 kWh/m^3) on a materials level and for temperature ranges for domestic applications. Although slightly more compact than sensible energy storage, losses play a large role here as well.

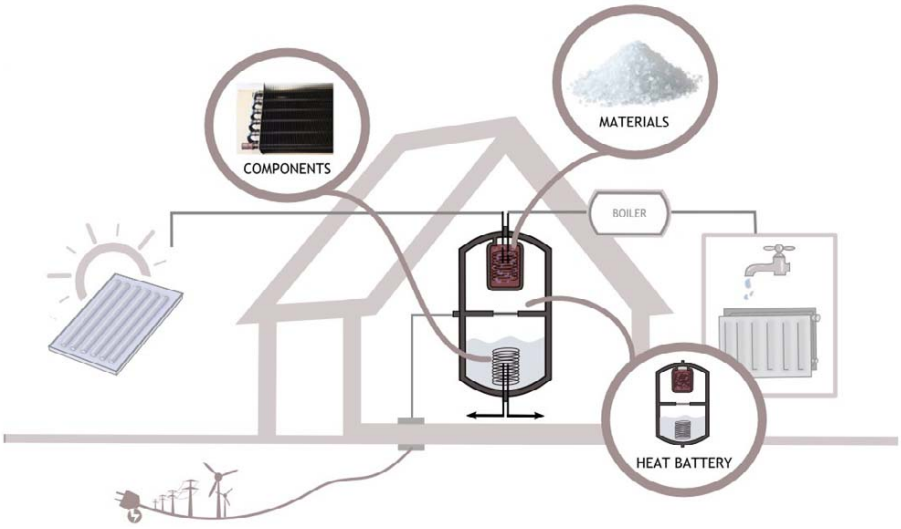

Fig. 2: Schematic of the project concept for heat battery development for dwellings application (Low-temperature heat source not shown)

Thermochemical storage is the process of using heat of reaction (enthalpy) of reversible chemical reactions for thermal storage applications. In theory, very high thermal storage densities can be reached (as high as 1-3 GJ/m^3 or 278 – 833 kWh/m^3 at the level of storage material for typical sorption reactions of salt hydrates around temperatures of 60-140°C). In addition, no thermal losses occur during storage. For this reason, the MERITS project ultimately targeted demonstration of thermochemical storage solutions for dwelling applications. Further key development issues are delivery of heat on different dedicated temperature levels

for heating, cooling and DHW, design and development of a dedicated solar collector, integrated design for the components and enhanced thermochemical materials, including the control system, and development of business models and market strategies to foster swift market take-up. Many of these developments have been described already elsewhere (see e.g. de Jong et al., 2014; Solé et al., 2015; Volmer et al., 2015)). The follow-up project CREATE aims to deal with 3 key aspects:

- Economical affordability: For the existing building stock our project will target at least a reduction of 15% of the net energy consumption on building level with a potential simple payback time shorter than 10 years;
- Compactness: Novel high-density materials will be used in order to limit the use of the available space to a maximum of 2.5 m^3 thermochemical material;
- No heat losses during storage: This is an intrinsic material/system property of thermochemical storage technology, thereby enabling long-term storage.

As sub-objectives of these aspects, stable and efficient materials for thermochemical storage, a long life-time, affordable technology, efficient and high power discharge, and safe and reliable operation are specifically addressed. In addition, the future value-chain is mobilized, having all the required key players in the supply and value chain from the material level up to the system level and the energy grid in the current consortium. The project concept is based on advanced compact thermal storage for existing dwellings using thermochemical storage materials (Fig. 2). The heart of the system is a modular setup consisting of vessels that contain the salt. In the time between dehydration and hydration the energy is stored in the salt. We envision two applications for the heat battery:

- Decentral thermal energy storage bridging supply and demand of renewable thermal energy;
- Decentral grid-connected storage for increasing energy efficiency and introducing flexibility in the electricity grid, e.g. using a heat pump.

A more efficient system design will enable demonstration of the concept in the real conditions: the system will be installed into a single family house in Warsaw, Poland, where a continental climate delivers both cold winters and warm summers.

3. Thermochemical storage – principle

Several possible examples of reversible thermochemical reactions taking place in the relevant temperature range are given below:

$K_2CO_3 + 1½H_2O \rightarrow K_2CO_3.1½H_2O$ (eq. 1)

$Na_2S.½H_2O + 4½H_2O \rightarrow Na_2S.5H_2O$ (eq. 2)

$MgCl_2.2H_2O + 4\ H_2O \rightarrow MgCl_2.6H_2O$ (eq. 3)

$CaCl_2 + 2H_2O \rightarrow CaCl_2.2H_2O$ (eq. 4)

The same hydration states occur in the reverse reactions.

When heating the hydrated salt to 80°C and condensing the water at a temperature below 20°C, both dehydration steps can theoretically be used and a very high theoretical storage density (up to 2.9 GJ/m^3 hydrate or 806 kWh/m^3 hydrate, at the level of the storage material) can be achieved forming the dried salt and water. On hydrating the salt by evaporating the water again at a temperature of >10°C, heat is released at temperature levels that can be used for heating and DHW purposes (>60°C). Keeping the compounds separate ensures storage of the reaction enthalpy, i.e. the heat. Typically, a low-temperature heat resource, e.g. a nearby lake, canal, or ground-source, takes care of the heat necessary for evaporation and of

condensation upon drying. Unlike in the sensible and latent thermal storage techniques, thermochemical storage takes place at ambient rather than at elevated temperatures because technically chemical potential is stored. In turn, it makes efficient thermal storage independent of storage times. Only when the products are brought together the enthalpy of reaction is released again, thereby generating heat. Uniquely, this ultimately enables long-term low-loss heat storage with very high thermal energy storage densities. The MERITS technology has been previously shown to enable theoretical storage densities around 1000 MJ/m^3 (278 kWh/m^3; de Jong et al., 2016). Further requirements playing a role are of course cycleability, safety, and toxicity, alongside cost.

4. Field test demonstration

The current system, the demonstration system of the MERITS project containing various subsystems such as solar collectors, short term storage vessel, long term thermochemical storage modules, underfloor heating, ceiling cooling, and a DHW system, was designed in July 2014. All compartments, i.e. the heating & cooling systems, the technical space and the single family dwelling compartment complete with windows, ventilation and door, are integrated in a 45 ft. sea container and fully equipped with measuring and control equipment (Fig. 1).

The performance of the MERITS Field Test Demonstrator (FTD) (Fig. 3) has been tested successfully at different levels: subsystem testing, where each component (i.e. Short Term Storage Vessel (STSV), High Temperature Solar Collectors (HCS), Space Heating Distribution System (HDS), Adsorption Cooling Distribution System (CDS), Domestic Hot Water Distribution System (WDS), Long Term Storage System with Thermochemical Storage Modules (LTS), Power supply, and data acquisition and control system) is tested under specific initial and boundary conditions; scenario testing, where each component is tested according to its standard operation; and 'MERITS mode' testing, where all subsystems are tested altogether according to the standard operation of the whole field test demonstrator.

The long term storage system, the main innovation in the FTD, is connected to the short term storage vessel and in periods with surplus of solar heat, used to sequentially charge the long term storage modules. During periods wherein the solar collectors do not provide sufficient heat, the modules are discharged into the short term storage vessel to provide sufficient temperature in the storage vessel, to provide DHW and heating of the dwelling at all times. All relevant volume flows and temperatures and additionally also the pressures inside the TCM modules are measured and recorded using the data acquisition and control software.

Until now, the actual application of thermochemical storage in the built environment has not been demonstrated. The main reason for this is that the thermochemical storage system is currently still complex, and as yet still too large and costly. Laboratory tests have been performed with thermochemical storage modules in an emulated environment, using the parameters below for loading and unloading the thermochemical material.

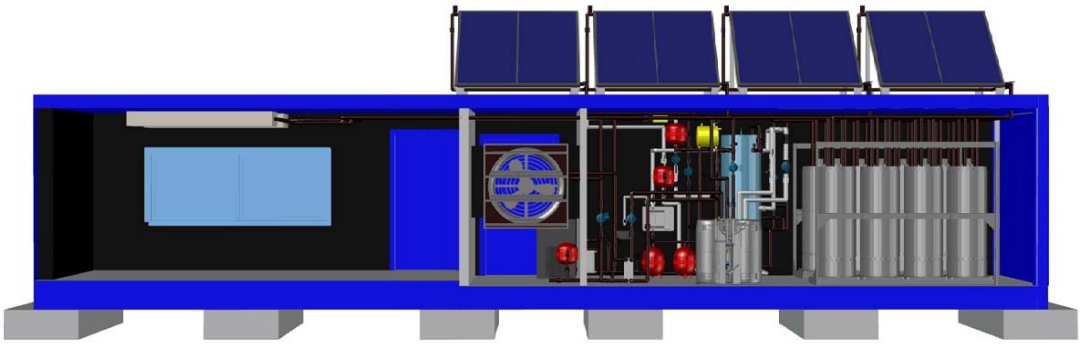

Fig. 3: 3D Visualization of the FTD

The goal of field test demonstration of a heating system with thermochemical storage modules is to enable scientists and application engineers to assess characteristics of the full system including all interactions

outside of laboratory circumstances. Not only is the tested system more complex and more voluminous than any tested laboratory setup, variations in conditions deliver 'real' and ever changing use-case conditions. Whereas in the laboratory the external conditions can be fully specified and controlled, in a real environment these conditions vary widely with time (day/night, seasons) and this will have a great impact on the system performance; especially the influence of condenser heat sink and evaporator heat source temperature fluctuations on system performance should be properly assessed. The system behavior with these varying circumstances offers a wealth of data for analysis and improvement. Moreover, the field test container is mobile, and therefore enables testing in different climate zones.

The long term thermochemical storage system (heat battery) in the MERITS project consists of 8 modules providing a low-loss design thermal energy storage capacity of 482MJ delivered from the water and salt working-pair. The 8 modules are placed into two racks (Fig. 4). Each rack is equipped with header piping, actuator valves and electronics to control the water flow through the TCS module and control the internal valve of TCS module. In order to limit the thermal energy losses during the start-up processes before the actual charge or discharge of a module can be executed, the choice has been made to build 4 smaller modules per rack rather than one big one. In addition, modularity helps to tune the system to the local needs without the need to make dedicated designs for every particular case.

Fig. 4: Rack with 4 thermochemical storage modules inside the Field Test Demonstrator

5. Active materials cycling – results

For the FTD's, 7 batches of ~90kg salt hydrate powder have been produced after which the modules were filled. After finishing of the modules, they have been tested in the lab before integration into the FTD container. Constant and well-defined testing conditions have been applied to evaluate both the potential storage density as well as the dynamics of charging and discharging. Additional tests with closed internal valve have been performed to evaluate the thermal losses. In addition, after integration of the modules into the FTD container, more charging and discharging tests have been performed before the system was actually run with the automated system control.

Fig. 5 shows a typical example of the measured powers on evaporator/condenser side and on absorber/desorber side for a discharge/charge/discharge cycle with a desorber inlet temperature of 80°C during charging reaching 52°C during discharge at a constant evaporator/condenser inlet temperature of 10°C both for charge and discharge. During discharge a power >500W with a plateau between 600 and 700W is delivered for about 12h (Fig. 5 red line, first half cycle). In sum, more than 30 MJ of energy is released in this module under these conditions. After recharging for 30 hours (Fig. 5, second half cycle),

another discharge took place with similar characteristics (Fig. 5 red line, third half cycle). Taking into account the losses (especially internal losses between reactor and evaporator) and the thermal mass of the reactor (heat exchanger, active material), an amount of about 9 kg of water is cycled under these conditions. This is roughly half of what would theoretically be possible from material equilibrium data.

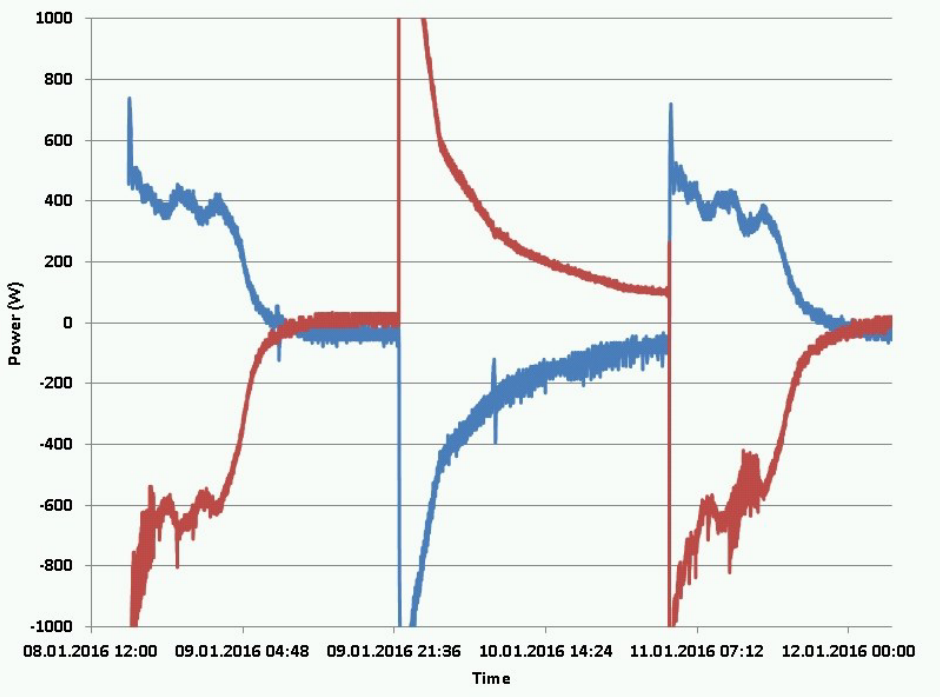

Fig. 5: Power of a typical module during 3 consecutive half-cycles (discharge/charge/discharge) of 30 hours each, showing reversible behavior during loading and unloading of the thermochemical material under relevant operating conditions, with power exerted in the absorber/desorber in red, and power exerted in the evaporator/condenser in blue; + is heat delivered to heat exchanger; - is heat delivered by heat exchanger.

During operation of the FTD, it became clear that several operational issues still have to be resolved. For example, the low amount of water cycling inside the field test demonstrator might be due to the fact that the charging power drops to very low values due to an additionally observed gas pressure in the charging phase that reversibly disappears during discharge. Furthermore, additional losses in the external hydraulic circuit and specific behavior of the discharge control are thought to be to blame for this.

6. Conclusions & outlook

For the first time, a thermochemical storage system has been demonstrated on a relevant scale for domestic application (heating & DHW), with thermochemical energy storage densities in the order of sensible storage density on a module level, but without thermal energy losses during storage periods. Initial results demonstrate the applicability of the compact long-term storage system for seasonal solar energy storage. In the present studies, our initial results show a storage density of around 100 MJ/m^3 (28 kWh/m^3) on a module level, i.e. in the same order of magnitude of some existing sensible thermal storages but with the benefit of unlimited storage times. In the CREATE project, salt selection is still under investigation. In future application in the CREATE project, a theoretical thermal energy storage density of up to 600 MJ/m^3 (168 kWh/m^3) should be achievable on a module level, i.e. well beyond existing thermal storages on the market today.

The system heat storage density depends on much more than just the active material reaction storage density, because additional components such as vapor and heat conducting structures (e.g. tubing, vessel, heat exchangers, etc.) are present. The main challenge of designing the FTD was to dimension all components

properly. Another challenge was the scale-up of the material production from lab-scale to full size prototype-scale.

Future research is directed towards further clarifying the cyclic behavior of the thermochemical storage modules, amongst others by clarifying cycling behavior of the active materials alone or as composites. In addition, the major points of attention are to increase thermal storage density in the modules significantly, and to increase the storage capacity on a system level. Also an in-depth life-cycle analysis will be performed after the first major improvements have been made.

In short, during operation of the FTD, it became clear that several operational issues still have to be resolved. Implementation of the CREATE project concept taking into account many of these issues is foreseen in typical European dwellings. To demonstrate applicability of the thermochemical storage solution and its operation in real life conditions and to receive early user feedback, a full scale solar TCS system will be installed in a single-family house in Warsaw, Poland, where a continental climate delivers both cold winters and warm summers. Optimizing the current compact storage technology to its full extent will lead to reduction of CO_2 emission and energy savings due to better use of available renewable energy sources instead of fossil energy.

7. Acknowledgements

The research leading to these results has received funding from the European Commission Seventh Framework Program (FP/2007-2013) under grant agreement No ENER/FP7/295983 (MERITS) and from the H2020 research programme under grant agreement No 680450 (CREATE). Experimental Investigation of Water Evaporation for Closed Adsorption Storage Systems

Bao Nam Dang[1], Wim van Helden[1], Michael Olbricht[2] and Andrea Luke[2]

[1] AEE - Institute for Sustainable Technologies, Gleisdorf (Austria)

[2] University of Kassel, Kassel (Germany)

Abstract

Closed adsorption for thermal energy storage is a promising technology, which was recently proven on real scale. Nevertheless further improvements of its material and components are necessary to enhance the system performance and to make it economically viable. One of the issues is the evaporation of water at low pressure during discharging ("adsorption") of the storage. The current lack of accurate experimental data and correlations for the heat transfer coefficient makes the design of the evaporator difficult. Therefore the goal of the work is to gather deeper knowledge in order to design the evaporator more properly and thus improve the sorption storage efficiency. In this work a test rig was designed and constructed for the experimental investigations of water evaporation at sub-atmospheric pressure. For the commissioning, first experiments with falling film evaporation were conducted on a copper tube bundle (3 x 8 tubes) to determine the relation of the outer heat transfer coefficient to different parameters. In all experiments the observed flow patterns between the tubes consist of columns. Varying the saturation pressure from 20 to 23 mbar or the range of the $Re_{\dot{I}}$ 29 to 109 shows no effects. Apart from that, the measured results were compared to values from two correlations. It is concluded that the Nu numbers from the measurements were in good agreement with those from the Lorenz and Yung model.

Keywords: closed adsorption thermal storage, falling film evaporation, water

1. Introduction

Efficient seasonal thermal energy storages are necessary to cover all the domestic heat demand with solar thermal energy over the whole year. An innovative and proven concept in real scale - the solid sorption heat storage - uses the reversible adsorption/desorption process of water vapor in zeolite 13XBF. This material pair provides a significantly higher energy density S (theoretically: 250 kWh/m³) compared to water. In general a sorption storage system consists of one or more vessels with the sorption material, a condenser/evaporator and a water reservoir. For loading the storage ("desorption") the moist zeolite is dried by the heat from solar collector and the emerging vapor is condensed and stored separately in a water tank (Fig. 1a).

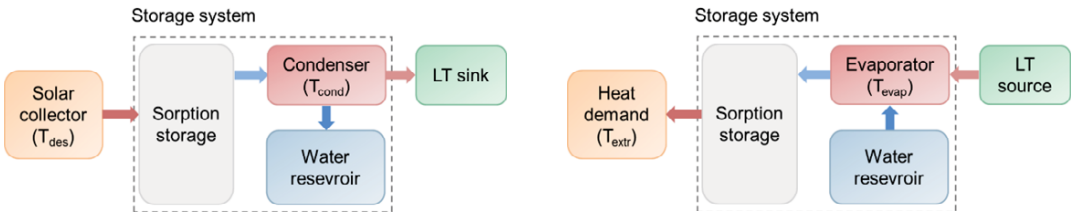

Fig. 1: Scheme of the sorption storage system during desorption (a) and adsorption (b)

doi:10.18086/eurosun.2016.03.09 Available at http://proceedings.ises.org

Regardless of the sensible heat, the thermal sorption energy can be stored over months virtually without losses. To discharge the sorption storage, the distilled water is evaporated at low temperature using the heat of the low temperature source. The vapor will be adsorbed by the zeolite and the resulting heat from the adsorption can be used for domestic hot water, space heating or other purposes (Fig. 1b). In reality the storage is limited by the operation conditions and cannot be fully charged or discharged. Because the storage system is evacuated, the pressure difference drives the vapor transport between the sorption storage and the heat exchanger for evaporation/condensation, and depends on the temperature in the single components. In order to achieve a high material energy density, a maximal desorption (T_{des}) and a minimal condensation temperature (T_{cond}) is required during the desorption as well as a maximal evaporation (T_{evap}) and a minimal extraction temperature (T_{extr}) during the adsorption process. This means an efficient evaporator with high heat transfer leads to smaller temperature overheating and thus a higher evaporation temperature, which as a result enhances the energy density and the storage efficiency (Tab. 1). This coherence was also verified by our closed adsorption storage system for a single-family house from the "COMTES"-project, which was operated successfully during the last heating period from October 2015 to January 2016. Further improvement of the evaporator is only possible with a thorough knowledge of the evaporation process of water at low pressures. (Engel, 2016) (Köll, 2016)

Tab. 1: Material energy density (*S*) of zeolite 13XBF. (In all cases: T_{des} = 180 °C and T_{extr} = 25 °C) (Köll, 2016)

T_{evap}	*S* (T_{cond} = 17°C)	*S* (T_{cond} = 25 °C)	*S* (T_{cond} = 35 °C)
10 °C	126 kWh/m³	115 kWh/m³	106 kWh/m³
15 °C	146 kWh/m³	135 kWh/m³	126 kWh/m³
20 °C	150 kWh/m³	139 kWh/m³	130 kWh/m³

In recent years the experimental studies on water evaporation with different concepts and at temperatures from 5 to 20 °C has been intensified. Still, there is a lack of accurate experimental data. Furthermore there are many known and unknown factors, which influence each other and have a different impact depending on the prevailing conditions. These are the heat flux density, the fluid properties, the saturation pressure, the roughness and the material of the heating surface, the dimension of the apparatus and operation-specific parameters. In sum, the proper design and the improvement of the evaporation of water at low temperatures is currently imprecise and troublesome. One of the main issues for water as refrigerant is the local saturation pressure with p_{evap} = 8.7 to 23.4 mbar, which also depends on the liquid level above the heating surface. Due to the hydrostatic pressure of the water, the pressure increases around 0.98 mbar per cm ($\Delta p = \rho \cdot g \cdot \Delta h$). For example, a flooded evaporator operates at 10 °C with a corresponding pressure of 12.3 mbar. Its heating surface lays 3 cm deep under the water level, which causes a hydrostatic pressure of 2.9 mbar. Hence the local saturation pressure is 15.2 mbar and the temperature 13 °C. This temperature increase can immensely diminish the evaporation power. Because of this concepts with evaporating thin liquid films are preferred to minimize the hydrostatic pressure effect, like the falling film and the capillary assisted evaporation.

Recently the capillary assisted evaporation is increasingly investigated. Its working principle is using capillary structured or coated heating surfaces, which are partly immersed into the refrigerant pool. Due to the capillary forces a thin liquid film covers the surface passively, so no further active components like pumps are necessary. However, the heat transfer coefficient still depends heavily on the liquid level. In addition the long-term functionality is not clear, because fouling can easily accumulate in the capillaries and limit the capillary forces. Overall these evaporators are less complex and have lower weight. But they are probably more suitable for systems with low volume of the refrigerant capacity. (Bahrami, 2016) (Xia, 2007) Falling film-type evaporators with horizontal tubes have been used in different applications like desalination, refrigeration and air conditioning. Furthermore their functionality is also proven for absorption cooling systems. In contrast to the large falling film evaporators like in the food or pharmaceutical industry, the evaporating liquid film will be sprayed or dropped on to the top of a horizontal tube bundle. So the film falls gravitational from tube to tube redistributing itself on each tube again. Therefore a good alignment of the tubes and the proper liquid distribution are required in order to maintain the wetting of the heating surfaces area and thus an efficient evaporation. Especially for deep bundles it is difficult to have a consistent flow and prevent local dry outs. Although it is more complex, this type of evaporator works with much less refrigerant and has higher performances than flooded evaporators. Due to the thin liquid layer with inner turbulences,

the evaporation occurs by natural convection with low surface overheating. Therefore the falling film evaporation seems to be suitable for the application of the seasonal sorption storage and will be experimentally investigated in this work. (Ribatski and Jacobi, 2005) (Thome, 2009)

2. Experimental design and procedure

The goal of this work is to experimentally determine the heat performance $\dot{Q}_{evap}$ and the heat transfer coefficient h_o of a falling film evaporator at certain conditions. Therefore a test rig was designed and built that is similar to the apparatus of Li (2010a, 2010b) or Olbricht (2013, 2016). As shown in Fig. 2, it consists of a cylindrical evacuated vessel, containing the test tube bundle. The vessel contains also temperature sensors and a pressure sensor for measuring the conditions inside. On top of the bundle is the feeding system, which is fed from a water reservoir (in Fig. 2: Reservoir 1). This reservoir collects all the surplus water that is not evaporated at the bundle. To minimize the liquid pool at the bottom of the vessel, tilted plates below the tube bundle channel the water to the drain. Meanwhile the vapor from the evaporator will be drawn off into a plate heat exchanger, where it condenses and falls into a second reservoir. Both reservoirs are hydraulically connected to each other, so shifting the amount of water between the both reservoirs is possible. As seen in the Fig. 2, each of them consists of two differently sized tanks, where the smaller contains a liquid level sensor. Depending on the valve control between the two tanks, the liquid level in the smaller tank and in the vertical tube, which parallel to the tank, is measured with or without the level in the bigger tank. Overall there are three liquid circuits in the test rig: the water used for the evaporation (refrigerant), the water circuit for heating the tube bundle from the inside and the cooling water circuit for the condensation. The last two of these are connected via heat exchangers to our laboratory's hot water and cold water circuit. They are also equipped with sensors for measuring the inner flow's inlet and outlet temperature and the volumetric flow rate.

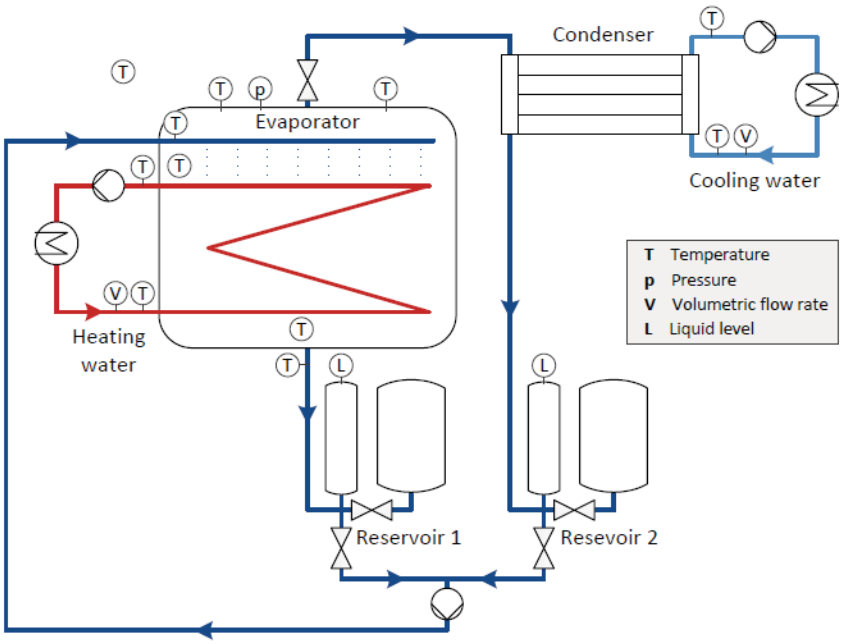

Fig. 2: Scheme of the test rig

The tested tube bundle is similar to the bundle of Olbricht (2013, 2016). It consists of three parallel tube rows, whose outer and inner diameters are 12.70 mm and 12.04 mm (Fig. 3). Both sides of the tube surfaces are plain and not processed. Each single tube row is eight columns high with a center to center tube spacing of 31.75 mm and the inlet and outlet are all connected to the bigger header tube. The liquid feeder is shown in Fig. 4. It consists of three parallel tubes, perforated at the bottom, where the sub cooled refrigerant drops out into a closed box. The box's floor consists of 3 x 39 small pipes, which are all vertically positioned and arranged directly over each tube row of the bundle. The pipe diameter is 1 mm and the spacing is 10 mm. In

addition, all the pipes jut out around 3 mm at both floor's side, so water drains out gravitationally of the box, when there is a small liquid pool in it.

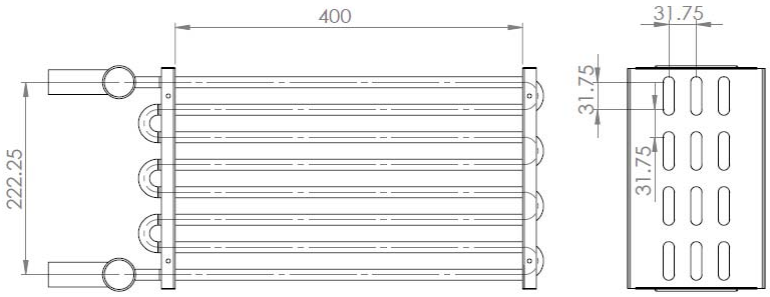

Fig. 3: Sketch of the tube bundle

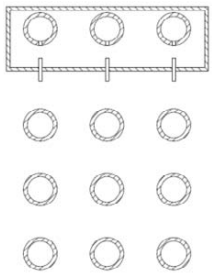

Fig. 4:Sectional view of the liquid feeder

Before the experiment starts, the refrigerant will be conditioned below the saturation pressure, such that when it leaves the feeder it will not evaporate directly until it gets heated by the tube bundle. This will be checked with one temperature sensor inside the feeding tubes and two sensors at the drain of the vessel. During the experiments the inlet temperature of the heating ($T_{hw,in}$) and cooling water ($T_{cw,in}$) are maintained constant. The volumetric flow rate for the refrigerant and the heating water is also set. For controlling the pressure inside the vessel, a PD controller changes the flow rate of the cooling water in the condenser. Tab. 2 shows the setting temperatures, which were set at the examined saturation pressures.

Tab. 2: Setting temperature for each pressure condition

p_{evap}	$T_{\mathrm{H_2O,liq}}$	$T_{hw,in}$	$T_{cw,in}$
20 mbar	17 °C	23 °C	9 °C
23 mbar	19 °C	25 °C	9 °C

Furthermore in each pressure condition, the irrigation density for the refrigerant has been also varied over a range of 0.007 to 0029 kg/(ms), which correspond to a $Re_{\dot{\Gamma}}$ from 29 to 107.

3. Measurement evaluation

There are two different options to measure the performance of the evaporator at stationary conditions. The first option is by measuring the temperatures and the volumetric flow rate of the heating and cooling water. With these values the heat flow at each component can be calculated.

$$\dot{Q}_{hw} = \dot{m}_{hw} \cdot c_{p_{hw}} \cdot \left(T_{hw,in} - T_{hw,out}\right) \quad \text{(eq. 1)}$$

$$\dot{Q}_{cw} = \dot{m}_{cw} \cdot c_{p_{cw}} \cdot \left(T_{cw,in} - T_{cw,out}\right) \quad \text{(eq. 2)}$$

Another method is using the liquid level of the reservoirs. During the measurements, all the valves at Reservoir 2 are closed. So the liquid levels in the vertical tube from the condenser and in the smaller tank rise. The heat flow can then be determined with the change of the liquid volume per time, the liquid density and the vapor enthalpy of water.

$$\dot{Q}_{rv2} = \Delta \mathrm{H}_{\mathrm{H_2O},vap} \cdot \rho_{\mathrm{H_2O,liq}} \cdot \dot{\mathrm{V}}_{\mathrm{H_2O,liq}} \quad \text{(eq. 3)}$$

Ideally, the three measured heat flows should be equal. But because the ambient of the test rig cannot be conditioned, heat gains or losses need to be considered when calculating the evaporation performance. For this, the thermal heat transfer coefficient of the vessel and the condenser was identified. Overall the experiments show that the results of all three measurement methods for the evaporation performance $\dot{Q}_{evap}$. With the temperature difference between the mean temperature of heating water flow and the saturation

temperature of the refrigerant, the overall heat transfer coefficient UA can be calculated. Taking it into account, the results of all three measurement methods for the evaporation power $\dot{Q}_{evap}$were in good agreement.

$$UA = \frac{\dot{Q}}{\Delta T} \qquad \text{(eq. 4)}$$

In all measurement the Reynolds number of heating water inside the tubes was in the range of 5600 to 5900. So for calculating the convection heat transfer coefficient h_i, the relations of Gnielinski (2010) for the transition region between laminar and turbulent flow are used:

$$Nu_i = (1-\gamma)\cdot Nu_{lam,2300} + \gamma \cdot Nu_{tur,10^4} \qquad with \qquad \gamma = \frac{Re - 2300}{7700} \qquad \text{(eq. 5)}$$

The mean outer heat transfer coefficient h_o, which is the heat transfer coefficient of the falling film evaporation, can be calculated by using the tube's thermal resistance formula.

$$h_o = \frac{1}{d_o \cdot \left(\frac{\pi \cdot l_{tube}}{UA} - \frac{1}{h_i \cdot d_i} - \frac{1}{2 \cdot k_{tube}} \cdot \ln\left(\frac{d_o}{d_i}\right)\right)} \qquad \text{(eq. 6)}$$

For the complete measurement evaluation, the irrigation density $\dot{\Gamma}$and the associated Reynolds number $Re_{\dot{\Gamma}}$ are also calculated with the following equations. In this case $\dot{m}_{H_2O,liq}$ is the total mass flow which is used for wetting the total tube length of the bundle l_{tube}.

$$\dot{\Gamma} = \frac{\dot{m}_{H_2O,liq}}{2 \cdot l_{tube}} \qquad \text{(eq. 7)}$$

$$Re_{\dot{\Gamma}} = \frac{4 \cdot \dot{\Gamma}}{\mu_l} \qquad \text{(eq. 8)}$$

4. Experimental results

At constant saturation pressure condition and with a fixed flow rate for the heating water inside the tubes, the irrigation density or the Reynolds number for the falling film was gradually reduced. As seen in Fig. 5a, the flow pattern between the tubes with low irrigation density consists of droplets and very thin columns. These columns remain only for a few seconds, then they shortly break up and subsequently form again mostly at the same place. With increasing irrigation density more columns occur, which are also thicker (Fig. 5b). However, they exist only for a few seconds, too. Apart from that, few liquid droplets or jets do not fall vertically on the next below tubes. Because of the high flow velocity at the radial edge of the tubes, they will be deflected and fall diagonally. This happens at every experimental setting and mainly at the first three top tube rows, when the liquid falls with too high momentum. Furthermore, very few local dried out spots can be identified at every condition. Mostly they are at the lowest tube rows or at the longitudinal ends of the tubes. A change of number and size of the dried out spots was not visible with different parameter settings.

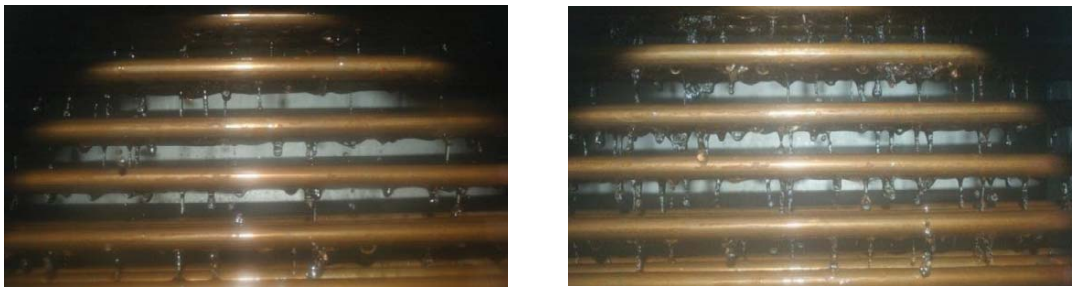

Fig. 5: Flow pattern during measurements with low (a) and high irrigation (b)

Fig. 6 depicts the measured outer heat coefficient in dependency of the saturation pressure and the Reynolds Film number. In our investigated range for $Re_{\dot{\Gamma}}$, the outer heat coefficient at the tubes maintains nearly constant. Similar measurement results can be also found from Li (2010a, 2010b). Furthermore reducing the saturation pressure does not have any effect on the heat coefficient in our experiments, because all deviations are within the accuracy of the measurements. This can be expected as a small difference in pressure, which is equivalent to small temperature changes, leads to very small alteration of the water's properties.

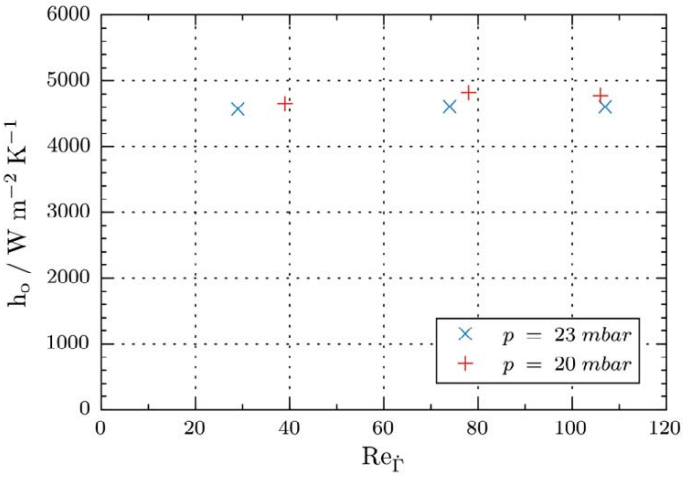

Fig. 6: Results of the measurements at 23 mbar and 20 mbar.

For comparing the measurement results, two correlations were used. The first one is from Hu and Jacobi (1996), where the different types of flow patterns are considered and can be identify by $Re_{\dot{\Gamma}}$. In our case with a Re_{Γ} between 29 and 107, the droplet flow model can be used. The Nusselt Number for this flow pattern can be calculated with the following formulas. Here, D is the outer diameter of the tubes and S is the center to center spacing between two of them.

$$Ar = \frac{D^3 \cdot g}{\nu^2} \qquad \text{(eq. 9)}$$

$$Nu_{\dot{\Gamma},droplet} = 0{,}113 \cdot Re_{\dot{\Gamma}}{}^{0{,}85} \cdot Pr^{0{,}85} \cdot Ar^{-0{,}27} \cdot \left(\frac{S-D}{D}\right)^{0{,}04} \qquad \text{(eq. 10)}$$

The other empirical model is from Lorenz and Yung and is described by Thome (2009). Instead of using several empirical equations for each flow pattern, the heat transfer coefficient is described by a combined model for the evaporation of a subcooled $h_{\dot{\Gamma},dev}$ and of a saturated film $h_{\dot{\Gamma}}$ and the nucleate boiling h_{nb}:

$$h_o = h_{\dot{\Gamma},dev} \cdot \frac{L_{dev}}{L} + h_{\dot{\Gamma}} \cdot \left(1 - \frac{L_{dev}}{L}\right) + h_{nb} \qquad \text{(eq. 11)}$$

where L is the circumference of a single horizontal plain tube and L_{dev} is the developing length of the film, which is calculated by the Nusselt theory for liquid films. The ratio of both lengths is calculated by this equation:

$$\frac{L_{dev}}{L} = \frac{\frac{\dot{\Gamma}^{\frac{4}{3}}}{4 \cdot \pi \cdot \rho \cdot a} \cdot \sqrt{\frac{3 \cdot \mu}{g \cdot \rho^2}}}{\pi \cdot D} \quad . \qquad \text{(eq. 12)}$$

The falling saturated film is calculated by the model of Chun and Seban, which consists of two empirical equations for determining the laminar and the turbulent heat transfer in the evaporating film. For predicting the type of the film flow the Weber Number (We) can be used. In all measurements We was lesser than 1, so the liquid film is laminar and will be calculated with the following equation:

$$h_{\dot{\Gamma},lam} = 0{,}821 \cdot \left(\frac{\mu_l^2}{g \cdot \rho_l^2 \cdot k_l^3}\right)^{-0{,}33} \cdot Re_{\dot{\Gamma}}{}^{-0{,}22} \quad . \qquad \text{(eq. 13)}$$

The heat transfer coefficient of the film's developing region $h_{\dot{\Gamma},dev}$ can be determined with this equation.

$$h_{\dot{\Gamma},dev} = 0{,}375 \cdot c_p \cdot \frac{\dot{\Gamma}}{L_{dev}}. \qquad \text{(eq. 14)}$$

In our experiments, nucleate boiling did not appear and its heat transfer coefficient h_{nb} can be ignored. Therefore only the heat coefficients of the film evaporation are used for calculating with (eq. 12). With the resulting overall heat transfer coefficient of the evaporation film, the associated Nu will be determined.

$$Nu = \frac{h_O}{k} \cdot \left(\frac{\nu^2}{g}\right)^{\left(\frac{1}{3}\right)} \quad . \qquad \text{(eq. 15)}$$

As shown in the diagram of Fig. 6a, there are huge discrepancies between the measurements results and the correlation of Hu and Jacobi, especially at low irrigation density. However at $Re_{\Gamma} > 100$ the values match well. Another point to note is the deviation with the flow pattern. As already mention we observed a column flow patterns between the tubes, which did not change with varying the irrigation density. But according to this model and with a $Re_{\dot{\Gamma}}$ ranging from 29 to 107 it should be droplet flow. A possible reason for this is the different liquid feeder, which was used in Hu and Jacobi's experiments. They used a feeder tube, which has a row of small holes along the bottom, and placed a second tube directly underneath it to help distribute the flow. It has to be assumed that with this configuration the water falls with lower momentum on to the tubes than with the feeding system in this work. However, the empirical results from Lorenz and Yung's correlation are in good agreement with our measurements (see Fig. 6b). Still further detailed investigations are needed to justify the results.

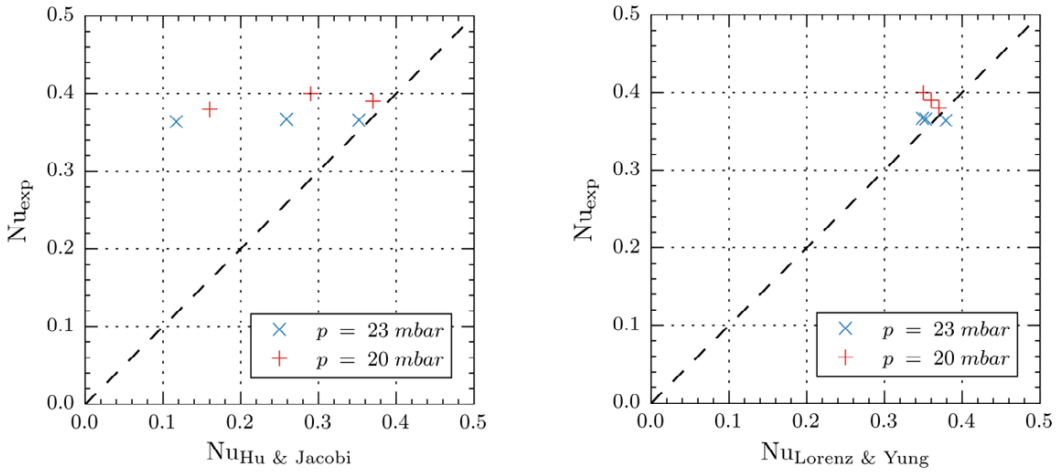

Fig. 7: Comparing measurements results with the correlation of Hu and Jacobi (a) and of Lorenz and Yung (b)

Apart from that, it has to be point out that the determination of the outer heat coefficient depends heavily of the identification of the heating water's inner heat coefficient h_i and of the corresponding temperature difference for calculating the overall heat transfer coefficients UA. Because every other experimental work use different correlations or assumptions, so it can be troublesome to compare with other results and correlations. So for future precise measurements, it will be of interest to heat the irrigated tubes electrically and to measure simultaneous their temperatures.

5. Conclusion

A test rig for experimental investigation of the falling film evaporation was designed and built. For the commissioning, first measurements on a plain copper tube bundle were conducted and evaluated at saturation pressure of 20 and 23 mbar. Varying the falling film Reynolds number in a range from 29 to 109 changes the flow pattern from droplets-columns to columns. However, the heat transfer coefficient for the film evaporation remains nearly constant. This was also observed, when the saturation pressure was differed with unchanged other settings. The experimental data were also compared with values from two empirical models. The comparison shows discrepancies with the correlation of Hu and Jacobi, especially at smaller irrigation density. However, the measurement results were in good agreement with the correlation of Lorenz and Yung. Still, further precise measurements are necessary to justify the results.

In future, further experiments need to be carried out with larger parameter density and range, like the irrigation density. Moreover, experiments at lower saturation pressure can be conducted. Another point is to test with a similar feeder system like from Hu and Jacobi, to check the reason of the discrepancy in this work. Finally, a critical point is the heating water flow, which has large influence on the determination of the evaporation film heat coefficient. Theoretically the flow mode is in the transition region, but it could be also more turbulent due to the elbows in the bundle. So for precise measurement results, experiments with electrical heating tubes and temperature sensors at the tubes should be considered. To sum up, this and all upcoming works are necessary for designing and operating efficient evaporators, which then will be beneficial for sorption storage systems and also other sorption applications, like cooling and heat pumps.

6. Acknowledgements

This research was funded by the project “Solar Heat Integration Network” (SHINE), which is part of the Marie Curie program of the European Union. We thank all our colleagues from AEE - Institute for Sustainable Technologies and the Institute of Technical Thermodynamics at the University of Kassel. Furthermore we want to thank the company Luvata UK Ltd. for manufacturing the tube bundle.

Advantages using inlet stratification devices in solar domestic hot water storage tanks

Janne Dragsted, Simon Furbo, Federico Bava

DTU Civil Engineering, Technical University of Denmark, Kgs. Lyngby (Denmark)

Abstract

The thermal performance of a domestic hot water system is strongly affected by whether the storage tank is stratified or not. Thermal stratification can be built up in a solar storage tank if the heated water from the solar collectors enters the tank through an inlet stratifier.

Measured thermal performances of two solar domestic hot water systems are presented. One system is a traditional high flow system with a heat exchanger spiral in the tank. The other system is a low flow system with an external heat exchanger and a newly developed inlet stratifier from EyeCular Technologies ApS installed in the tank. The two systems are otherwise identical which makes it possible to compare the thermal performance and the thermal stratification built up in each tank.

Based on a measuring period of 140 days in the period from April 26, 2016 to September 25, 2016, the investigation shows, that the system with the stratification device has a higher thermal performance compared to the system with the heat exchanger spiral inside the tank.

The relative performance (defined as the ratio between the net utilized solar energy of the low flow system and the net utilized solar energy of the high flow system), is a function of the solar fraction. The lower the solar fraction is, the higher the relative performance will be. Weekly relative performances up to about 1.10 are measured. That is, weekly extra thermal performances of up to 10% are measured for the system with the inlet stratifier.

Keywords: Solar domestic hot water system, thermal performance, thermal stratification, measurements.

1. Introduction

1.1. Background

The heat from solar collectors is, in most marketed solar domestic hot water (SDHW) systems, transferred to the hot water tank in such a way, that the entire tank is heated to a uniform temperature since hot water tanks with built in heat exchanger spirals are typically used as solar tanks. The lack of thermal stratification in the hot water tank can result in up to a 25 % reduction in the thermal performance of a solar domestic hot water system. Thermal stratification in hot water tanks is therefore important in order to obtain a high thermal performance of the solar domestic hot water systems (Furbo et al 2004, Furbo et al 2005, Andersen et al 2006).

Thermal stratification in a storage tank can be established with a stratification device used to transfer solar heat to the hot water tank (Andersen et al, 2007). Stratification devices can be designed in different ways, for instance rigid pipes with holes, with or without flaps preventing back flow and flexible stratifiers made of fabric or polymer films, with one or more layers (Andersen et al, 2007).

doi:10.18086/eurosun.2016.03.11 Available at http://proceedings.ises.org

In this paper investigations of an inlet stratifier from Eyecular Technologies ApS are presented. In 2013 EyeCular Technologies ApS invented a new flexible stratifier with good results both in terms of performance and durability in accelerated long term tests. The stratifier makes use of the pressure difference between the water in the storage tank and the incoming water in the stratifier.

1.2. Side-by-side laboratory tests of small SDHW systems

Two small solar domestic hot water systems are installed side by side in the solar heating test facilities at the Technical University of Denmark (DTU), Lyngby, Denmark. The systems are identical, with the exceptions of the stratification device and the heat exchanger methods, see Fig. 1.

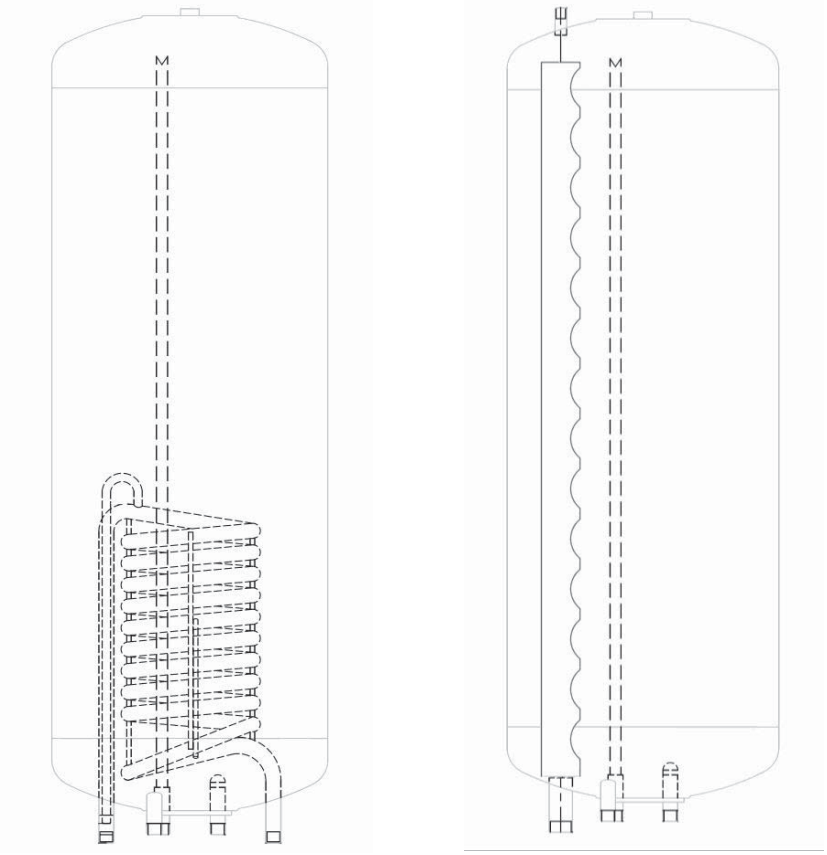

Fig. 1: Sketches of the two tanks in the SDHW systems.

The solar collectors for each system have an aperture area of 2.36 m², see Fig. 2. The solar collectors are facing south with a tilt of 45°. The data of the collectors are given in table 1.

Tab. 1: Data for solar collectors used in the two SDHW systems

Collector type	TLP ACR 2600, Hewalex, Poland
Maximum efficiency	0.827
First order heat loss coefficient	3.247 W/m²K
Second order heat loss coefficient	0.020 W/m²K²
Incidence angle modifier for an incidence angle of 50°	0.94

The daily hot water consumptions for each system is 135 liter heated from 20 °C to 50°C, corresponding to approximately 4.5 kWh. The daily hot water consumption is tapped at 7 am, at noon and at 7 pm in three

equal volumes. The tanks, which are produced by METRO THERM A/S, Denmark, have volumes of 255 l, see figure 2.

One of the systems is a typical marketed small solar domestic hot water system with a built in heat exchanger spiral in the hot water tank.

The other system has an identical tank but without the spiral heat exchanger. This tank is equipped with a polymer film inlet stratifier developed by EyeCular Technologies ApS.

The specific stratifier model applied in the present test is developed for low flow solar combi systems with flows rates from 2 - 4 l/min. If operated at lower flow rates than 2 l/min, the efficiency of this specific stratifier model will, according to the company, decrease due to heat loss from the stratifier. Unfortunately, the company has not yet developed a stratifier for flow rates below 2 l/min, let alone a flow rate of 0.5 l/min.

An optimized low flow system operates at a flow rate of 0.15 – 0.20 l/min/m² solar collector. In the present test, the low flow system should therefore ideally be operating at a flow rate of approx. 0.5 l/min. Higher flow rates than 0.5 l/min will reduce the thermal performance of the system somewhat. Together with the company, a compromising flow rate of 1.0 l/min was decided upon, still knowing, that this flow rate is not ideal for the stratifier nor the system.

The solar heat is transferred from the solar collector fluid to the DHW water through an external flat plate heat exchanger. The heat exchanger has a heat exchange capacity rate of about 150 W/K. The propylene glycol/water mixture used as solar collector fluid in the solar collector loops is a 40% mixture.

Fig. 2 Pictures of the storage tanks and solar collectors in the two SDHW systems.

The high flow system with the heat exchanger spiral has a volume flow rate of 2.5 – 3.0 l/min in the solar collector loop. The low flow system with the stratifier has a volume flow rate of 1.0 l/min, both in the solar collector loop and in the DHW water loop transferring the solar heat to the tank. The upper 95 l of the tanks have the option of being heated to 50.5 °C by means of 3 kW heating elements.

Copper pipes with a total length of 34 m for each system are used in the solar collector loops.

The solar collector loop in the high flow system with the heat exchanger spiral is equipped with a circulation pump having a power consumption of 50 W in order to ensure a flow of about 2.5 – 3.0 l/min throughout the entire test duration. The two circulation pumps on either side of the external heat exchanger in the low flow system with the stratification device, has a power of 36 W and 50 W to ensure a flow rate of 1.0 l/min in both loops.

In both systems the circulation pumps are controlled by differential thermostats based on temperature sensors measuring temperature differences between the outlet from the solar collectors and the bottom of the tanks.

2. Measurements and calculation of performance

The data collected from both systems consist of temperature levels, flow rates and energy readings. Temperatures are measured at the in- and outlet of the solar collectors along with the in- and outlet

temperatures from the heat exchanger and from the tank. Also temperatures are measured inside the tank in different levels in order to evaluate the level of thermal stratification build up in each tank.

The thermal performances of the two systems are compared by the net utilized solar energies and the solar fractions. The net utilized solar energy is determined as the energy drawn from the system subtracted the auxiliary energy supply to the tank. The solar fraction is the ratio between the net utilized solar energy and the energy drawn from the system. By subtracting the net utilized solar energy from the solar heat transferred to the hot water tank the heat losses from the tank are given.

Tab. 2: Measured energy quantities for the two SDHW systems in the period 18/4-2016 – 26/9.2016 (Excluding the period 27/6 2016 - 17/7 2016 due to malfunction of measurement system).

Energy quantity	SDHW system with stratification device	SDHW system with heat exchanger spiral
Hot water consumption (kWh)	596	598
Auxiliary energy supply (kWh)	95	109
Net utilized solar energy (kWh)	501	490
Solar fraction (-)	0.84	0.82

The measured quantities for both systems are shown in Tab. 2 for the period from 18/4-2016 to 27/6-2016 and from 17/7-2016 to 25/9-2016. The period from 27/6-2016 to 17/7-2016 is excluded due to measurement malfunction. Measurements are available for 140 days during the summer 2016. In Tab. 2 it is seen that the total hot water consumption from each system is 596-598 kWh, which is approximately 4.3 kWh a day. Also as expected the consumption of auxiliary energy is higher for the high flow system with the heat exchanger spiral compared to the low flow system with the stratification device. This results in a higher net utilized solar energy for the low flow system with the stratification device.

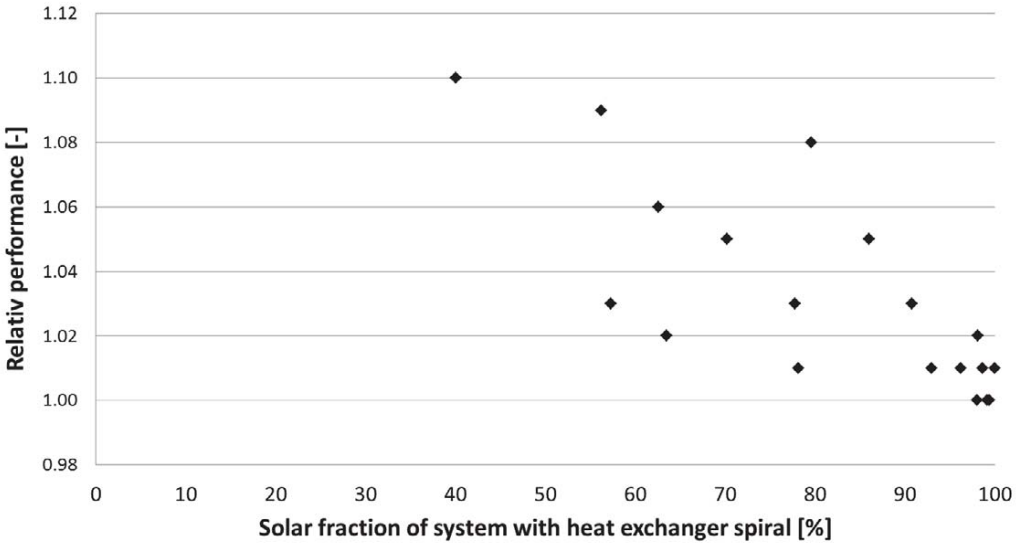

Fig. 3: Weekly relative performance of system with stratification device as function of the weekly solar fraction of the spiral tank system

The 140 days of measurements are divided into 20 periods of 7 days. Weekly relative performances as a function of the solar fraction of the system with the heat exchanger spiral tank are shown in Fig. 3. The relative performance is defined as the ratio between the net utilized solar energy of the system with the stratification device and the net utilized solar energy of the system with the heat exchanger spiral.

Fig. 3 shows as expected that the relative performance increases with a decreasing solar fraction. The measurements show that the thermal performance of the system with the stratification device is up to 10 % higher than the thermal performance of the spiral tank system at solar fractions between 40-50 %.

3. Conclusions

Measurements of thermal performances of two small SDHW systems tested side-by-side under realistic conditions in a laboratory test facility are carried out. One system is a traditional high flow system with a heat exchanger spiral in the tank. The other system is a low flow system with an external heat exchanger and a newly developed inlet stratifier from EyeCular Technologies ApS installed in the tank. The two systems are otherwise identical.

The relative performance defined as the ratio between the net utilized solar energy of the low flow system with the inlet stratifier and the net utilized solar energy of the high flow system with the spiral tank is a function of the solar fraction. The lower the solar fraction is, the higher the relative performance will be. Weekly relative performances up to about 1.10 are measured for solar fractions around 50%. That is, the extra thermal performance is about 10% if the solar fraction is about 50%.

The measurements will be continued during the autumn and winter 2016-2017. It is expected that the extra thermal performance of the system with the stratification device will increase in the winter period with low solar fractions, and that the extra yearly thermal performance will be about 12% if the yearly solar fraction is about 30%.

Seasonal Thermal Energy Storage with Aqueous Sodium Hydroxide – Experimental Methods for Increasing the Heat and Mass Transfer by Improving Surface Wetting

Mihaela Dudita[1], Xavier Daguenet-Frick[1] and Gantenbein Paul[1]

[1]Institute for Solar Technology SPF, HSR University of Applied Sciences, Rapperswil (Switzerland)

Abstract

Using thermochemical storage based on water absorption/desorption in a fluid with high volumetric energy density like sodium hydroxide solution (NaOH-H_2O) is an effective method for developing seasonal thermal energy storage. For the desorption process step which takes place in summer, a high renewable energy fraction can be reached by using solar thermal collectors. The system efficiency is influenced by the residence time of concentrated NaOH in the water vapor and the surface wetting behavior of the heat and mass transfer unit. This strongly depends on the solid surface characteristics and on the thermo-physical properties of sodium hydroxide, especially the high surface tension of the concentrated NaOH solution from the absorption process. An improved wetting of the concentrated NaOH was achieved by modifying liquid's properties (e.g. surface tension) or by changing the solid surface structure and chemistry.

Keywords: *seasonal thermal energy storage, sodium hydroxide, surface wetting, surfactant, surface texturing*

1. Introduction

Almost half of the final energy demand in Europe is needed for heating and cooling applications. An important percentage can be supplied from sustainable heat sources like waste heat or renewables. However, the energy production is most of the times not synchronized with the energy demand. Seasonal heat storage/long-term storage of heat makes the energy available when it is needed. Moreover, these "heat batteries" are very advantageous when stand-alone systems are involved and when the security of supply is required.

Current research is focused on compact thermal energy storage (TES) technologies with high energy density like phase change materials (PCM) and thermochemical materials (TCM) or sorption processes. These concepts were investigated by researchers in different projects like the IEA joint Task/Annex 42/29 or the European financed COMTES project (Cabeza, 2015; Daguenet-Frick et al., 2015a; Navarro et al., 2016). Although considerable efforts were made to find and improve thermal energy storage materials, the seasonal/long term heat storage systems are still at lower technology readiness levels.

Water absorption/desorption in a high volumetric energy density sorbent as aqueous solutions like LiCl, LiBr, KOH or NaOH were successfully reported (Cabeza, 2015; Daguenet-Frick et al., 2015b; Navarro et al., 2016). Sodium hydroxide has the advantage of having high-energy density as well as low cost. Nevertheless, the challenges are related to process engineering and transferring the materials thermo-physical properties to a running system with the expected performance (Daguenet-Frick et al., 2015a; Fumey et al., 2014; Olsson et al., 1997).

Previous experiments made in the EU funded COMTES project have indicated a lower power compared with the theoretical value during the absorption (storage discharging) phase. This can be explained by the poor wetting of the concentrated sodium hydroxide over the tube bundle from the absorber/desorber unit

doi:10.18086/eurosun.2016.03.13 Available at http://proceedings.ises.org

(Daguenet-Frick et al., 2014; Fumey et al., 2014). The tube bundle made from stainless steel (AISI 316L) was not efficiently wetted with the sorbent fluid. The sorption process of water in sodium hydroxide is influenced by the residence time, while the heat transfer is strongly influenced by the fluid surface wetting.

The focus of our work is to develop a 1 kW absorption/desorption demonstrator unit using the falling film working principle. One of the first steps is to optimize the heat and mass transfer at the tube bundle surface by improving wetting of the NaOH-H_2O (sorbent-sorbate) pair (see Fig. 1). In this paper, we present several experimental methods used for increasing the surface wetting of the stainless steel tubes with the concentrated sorbent. As wettability is depending on the surface roughness, surface oxygen content and the polar components, different surface modifications (structuring, annealing) and fluid properties tuning (use of surfactants) were investigated.

2. Working principle of a thermochemical storage using sodium hydroxide

The aim of the work is to develop a seasonal heat storage based on water absorption/desorption in sodium hydroxide solution. The main objective of our lab-scale system (1kW, Fig. 1) is to develop and improve the power unit. There are two main processes in such a system: charging and discharging. The charging process occurs in the desorber unit under reduced pressure. The thermal energy produced by the solar collectors in summer is used to partially vaporize the water contained in a diluted sodium hydroxide solution. The water vapors are condensed in the condenser unit, which is connected to a heat sink, e.g. a borehole. Water and sodium hydroxide are stored at room temperature in separate tank. The storing tank is giving the storage capacity, while the heat and mass exchangers are the power unit. This closed sorption heat storage system has the advantage of power and storage capacity separation.

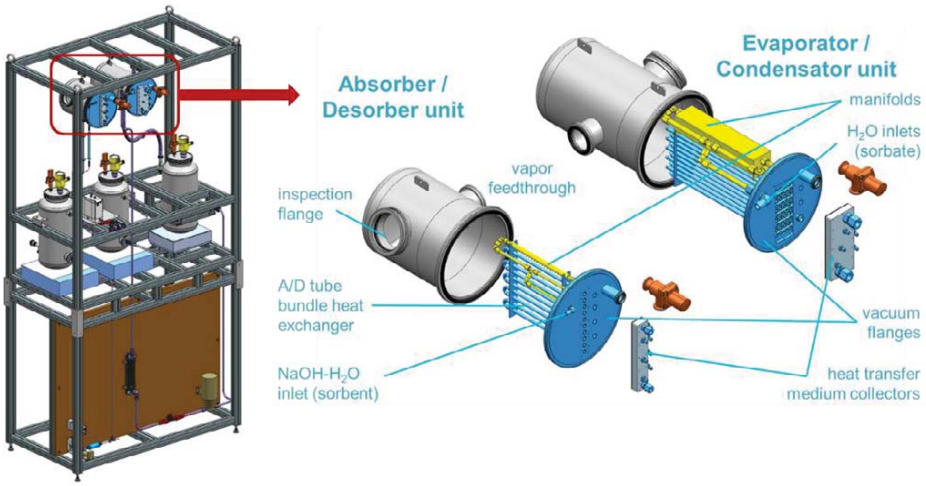

Fig. 1: Experimental 1kW thermochemical storage using sodium hydroxide - experimental facility (left) and construction details of the heat and mass exchangers: absorber/desorber unit (A/D) and evaporator/condenser unit(E/C), right

During the discharging process, the ground heat is used as a heat source to evaporate the stored water under reduced (sub-atmospheric) pressure in the evaporator. In the other chamber, the sorbent, concentrated NaOH solution (50 wt.%) is flowing as a falling film over the tube bundle of the A/D unit. Heat is gained from the water vapor absorption. Dissolution of the sodium hydroxide in water is a highly exothermic process (heat of solution at infinite dilution of NaOH is -44.51 kJ/mol at 25°C) (Parker, 1965). The heat is transferred to a working fluid (floor heating). Sodium hydroxide has a high water affinity; nevertheless, the fluid wetting on the tube bundle influences the efficiency when a fixed transfer area is involved.

3. Theoretical methods to improve the wetting

Wetting (Fig. 2) can be improved by modifying the liquid's properties (e.g. surface tension) or by changing the solid surface structure and chemistry.

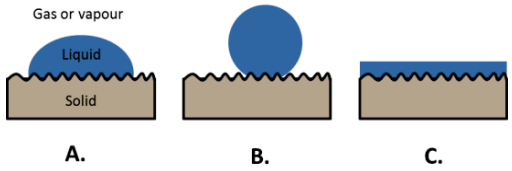

Fig. 2: Surface wetting : A - partial wetting, B - complete non-wetting, C - complete wetting

Surface tension of liquids at constant temperature and pressure and in equilibrium is physically equivalent to the specific surface free energy. The surface tension for liquids is depending on the London dispersion forces and hydrogen or metallic bonds, if they are present. According to Zisman (Tadros, 2006), total wetting is dictated by a single parameter called the critical surface tension, which is independent of the liquid. This model applies when only dispersion forces are considered. In other cases, the value obtained is not equal to the free energy of the surface, but it is a good practical measure of its liquid repellency. Stainless steel AISI 316L, the typical material used for tube bundle construction when NaOH is involved, has the critical surface tension between 20 to 33 mN/m. The value depends on the surface treatment: mechanically, electropolished or plasma treatment (Trigwell and Selvaduray, 2006). The surface tension is decreasing with temperature increasing, thus the highest value is expected to be at the minimum temperature from the system (room temperature in the 1kW system). In addition, the surface tension is decreasing for lower concentration, thus the worst case is for the concentrated solutions at low temperatures.

Sodium hydroxide has a surface tension of 116.72 mN/m for a 50 wt.% aqueous solution at 20°C (Feldkamp, 1969). To decrease it, surface active agents (or surfactants) in very low concentration can be used. The surfactant ability to reduce the surface tension is due to both hydrophilic and hydrophobic components (Tracton, 2006). The surfactant efficiency depends on the chemical structure and concentration, pH-value, temperature, and solid surface properties (e.g. composition, pore structure, surface roughness). Surfactants have a point of critical concentration called CMC – critical micelle concentration (Fig. 3). For higher solution concentrations than CMC, the surface tension does not decrease any more (reaches a rather constant value at constant temperature).

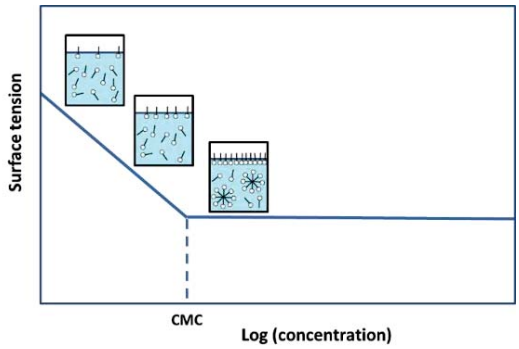

Fig. 3: Evolution of the surface tension depending on the critical micelle concentration

Based on their stability in hot alkaline solutions, two surface active agents (surfactants) were chosen for our study: 1,4-bis(1,3-dimethylbutyl) sulphonatosuccinate sodium salt (S1) and Triton™ QS-15 (S2). Sulfosuccinate surfactants are used in a wide range of industries from paints, adhesives, agrochemicals, plastics to cosmetics. Previous studies were performed on the wetting properties and stability of di-alkyl sulfosuccinate salts under alkaline solutions at different temperatures. It was shown that these anionic surfactants are stable in solutions with high pH and high temperature up to 80°C (Majmudar, 2014), which is at the desorption temperature level in a sodium hydroxide sorption heat storage. Triton™ QS-15 is also an anionic surfactant based on polyether sulfate (C12–14-tert-alkyl-ethoxylated sodium sulfate). It is soluble and stable in hot alkaline solutions, biodegradable and it will not persist in the environment. It is used for highly alkaline metal cleaners, bottle washing, zinc plating brightener, gas well cleaning, steam cleaners, etc.

The second category of methods for wetting improving is related to solid surfaces modifications. There are

three mechanisms: mechanical, physical and chemical. Better wetting is promoted when a large surface area is in contact with the liquid. Higher surface area is obtained by varying the surface roughness and mechanical texturing. According to Wenzel's equation, increased roughness will decrease the contact angle on hydrophilic surfaces, but it will increase the contact angle on hydrophobic surfaces. Thus, roughness amplifies both hydrophilicity and hydrophobicity, but not necessarily linearly (Brutin, 2015). In order to modify the surface chemistry, more techniques can be applied, e.g. changing the surface functional groups (Trigwell and Selvaduray, 2006). Studies have shown that a heat treatment is increasing the chromium oxide content in the surface (Williams, 2011). This would promote a better wetting due to the formation of physical bonding with the polar groups from the aqueous sodium hydroxide solution. It is favorable to have chromium and nickel oxide on the surface due to corrosion issues. However, different surface treatments have different effects. For example, the Cr concentration decreases, while the Fe concentration increases in the case of mechanically polishing process. In addition, the surface nickel content is reduced to about 3%. After mechanically polishing, Cr is mainly bounded in the oxide form (Cr_2O_3). The oxygen bonding in the oxide form is reduced by electropolishing, simultaneous to a considerably increase in oxygen bonding as hydroxide. This is because the process is done in an aqueous environment. An enrichment of chromium on the surface oxide layer normally occurs when stainless steel is electropolished. After plasma treatment, the proportion of Cr as Cr_2O_3 and Fe as Fe_2O_3 is increasing, to the detriment of metallic Cr and Fe and their hydroxides. In addition, the divalent Fe is oxidized. A chromium depleting effect takes place in the case of plasma treatment (Trigwell and Selvaduray, 2006).

Surface modifications by texturing or annealing and fluid properties tuning by using surfactants were experimentally investigated.

4. Experimental part for surface wetting improvement

Different tubes with a flat surface or structured (with horizontal, perpendicular or cross grooves) made from stainless steel AISI 316L were used. Moreover, a heat treatment in air at 300°C was applied for the optimum surface textured tube and for a plane tube.

Prior to the surface wetting experiments the samples were first washed with demineralized water and then with ethanol. To avoid carbonization of the sodium hydroxide with CO_2 from the air, experiments were performed into a glove bag (ca. 94x94x64 cm) filled with N_2. The N_2 4.5 (purity ≥99.995%) functions as the inert gas.

The following chemicals were used for performing the wetting experiments: sorbent to be used in the heat and mass exchanger - sodium hydroxide, 50 wt.% in H_2O (Sigma Aldrich), wetting agents: 1,4-bis(1,3-dimethylbutyl) sulphonatosuccinate sodium salt (S1, Sigma Aldrich) and Triton™ QS-1 (S2, DOW), demineralized water and ethanol (technical).

A computer-controlled multipurpose tension-meter (Sigma 700, Biolin Scientific, with OneAttension v. 1.6) from Transilvania University of Brasov was used to determine the surface tension of the sodium hydroxide solution with surfactant.

In order to avoid the influence of gravity, small volumes (100 μL) were used for the wetting experiments. When the radius of the droplet is much smaller than the capillary length, the effects due to gravity are negligible and the drop deposited on the solid substrate maintains a spherical shape.

5. The influence of surfactants and mechanical texturing on the surface wetting

5.1 The surfactant influence on the surface tension of the aqueous sodium hydroxide solution

Wetting and spreading of sodium hydroxide is mainly depending on the following physical properties of fluid: the dynamic viscosity of the liquid and the surface tension (Fig. 4 and Fig. 5, Feldkamp, 1969; Olsson et al., 1997). The values corresponding to aqueous sodium hydroxide solution are considerably higher compared with water, which is the low cost fluid for the classical sensible storage method. In order to have a good heat and mass exchange, the fluid properties must be tailored together with the surface properties of the

solid surface.

Thus, the influence of surfactants (e.g. S1) on the surface tension of concentrated sodium hydroxide solution was assessed. Previous research studies recommend the use of di-alkyl sulfosuccinate salts under alkaline solutions in concentration from 0.1 to 0.5 wt.%, under the critical micelle concentration (Majmudar, 2014).

The surface tension of different surfactant solutions (0.1 wt.%, 0.3 wt.%, 0.5 wt.%) was determined (at room temperature) and compared with the one corresponding to aqueous NaOH solutions and to NaOH-surfactant system (Fig. 6). The addition of small amounts of surfactant solution reduces the surface tension of the sodium hydroxide with approx. 39% in the case of concentrated sodium hydroxide (30 wt.%). Therefore, the wetting of the NaOH-H_2O over the tube bundle surface from the absorption unit can be improved. Further tests are under development for assessing the stability of the sodium hydroxide solution with surfactant in different system configuration.

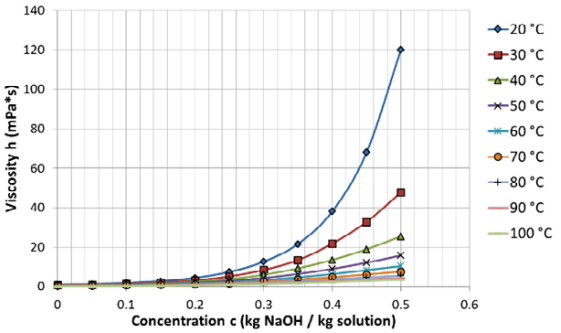

Fig. 4: Viscosity in function of temperature and concentration for aqueous solutions of sodium hydroxide

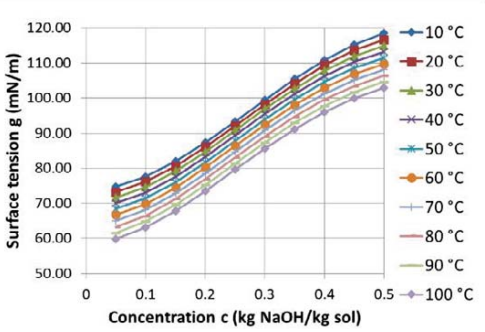

Fig. 5: Surface tension in function of temperature and concentration for aqueous solutions of sodium hydroxide

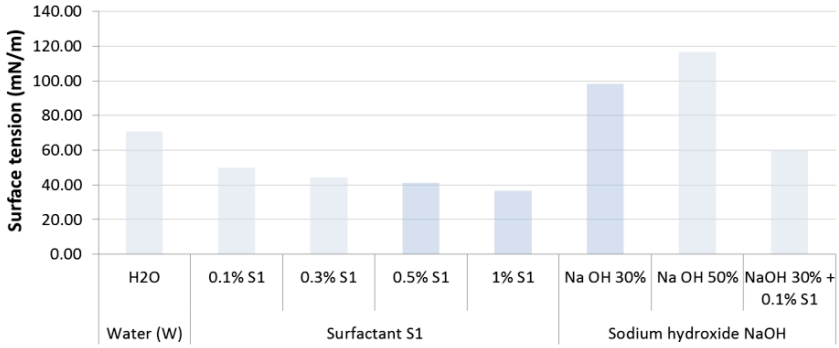

Fig. 6: Influence of the surfactant 1,4-bis(1,3-dimethylbutyl) sulphonatosuccinate sodium salt (S1) on the surface tension values

5.2 Surfactant impact on wetting stainless steel plane tubes

The influence of the two selected surfactants and concentration NaOH solutions on wetting the as received plane tubes was performed. The reference was a solution of NaOH 45 wt.%. The surfactants had the same concentration (1000 ppm). In order to quantify the wetting of the fluid over the tube, wetting time was used (Stache, 1995). This is defined as the shortest time until the drop (100 µL) wets and falls over the tube. Both surfactants lead to good wetting, compared to only sodium lye case (Fig. 7). In the reference case, the droplet was stable for minutes.

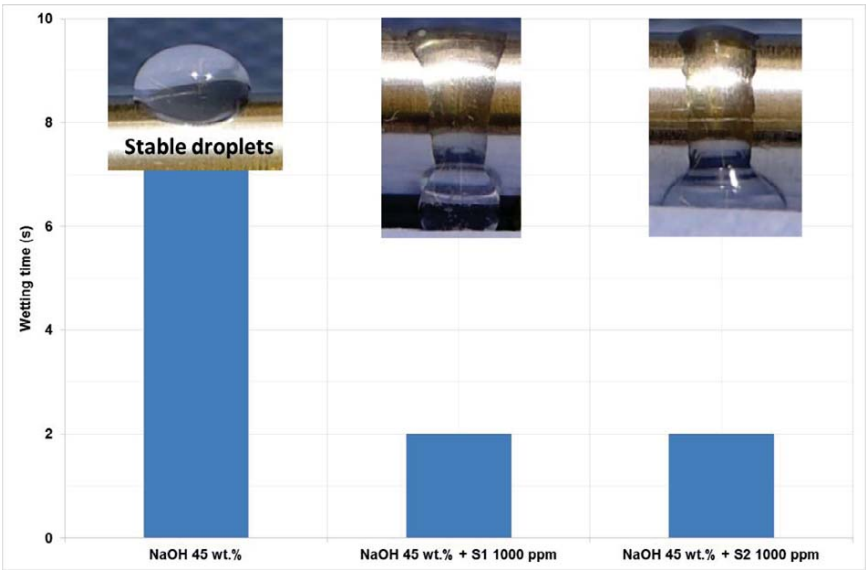

Fig. 7: Influence of the surfactants: 1,4-bis(1,3-dimethylbutyl) sulphonatosuccinate sodium salt (S1, 1000 ppm) and Triton™ QS-15 (S2, 1000 ppm) (S2, 1000 ppm) on the wetting time

5.3 Surface texturing and surfactant influence on the tubes wetting with concentrated sodium hydroxide solutions

The influence of different surface texturing on the wetting with concentrated sodium hydroxide, without/or with surfactant addition (S1 100 ppm) was assessed. Compared to the reference case (T0), where the aqueous concentrated sodium hydroxide solution forms stable droplets, all the textured tubes present better wetting. The surfactant addition leads to a better wetting, decreasing the wetting time. The best results were obtained in the case of sample T4. This pattern is also used in sodium heat pipes to improve the wetting (Bacanu, 1991). It was proven to have good stability in time in highly corrosion environments. Sample T1, with very small fines in the axial direction is a promising solution that can have good residence time. Sample T3 has lower wetting compared to the others due to the hill like structures. In the case of T5 and T6, good wetting can be achieved, but the vertical fins limit the fluid spreading.

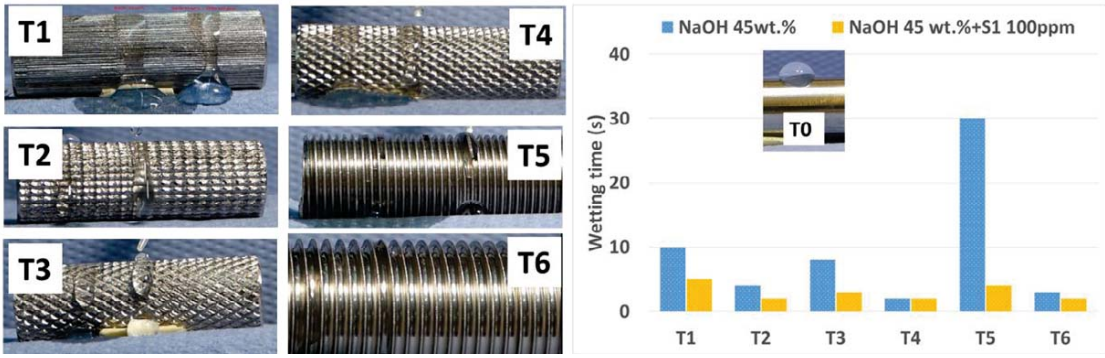

Fig. 8: Influence of surface texturing and surfactant addition (S1 100 ppm) on the surface wetting

5.4 The influence of thermal treatment on the wetting time

Annealing in air increases the surface metal oxide content. A plane tube (as received) and the optimum textured tube were thermally treated in air for 1h, 2h and 3h at 300°C. Wetting experiments were performed by placing a 100µL droplet of concentrated sodium hydroxide solution (45 wt.%), without surfactant or with the addition of Triton™ QS-15 (S2, 1000 ppm). A better wetting was obtained for all the annealed samples (see Fig. 9). The good wetting time values can be explained by physical bonding formation between active

groups from the testing fluid and from the metal surface. In the case of sample A1, very small droplets were added. This has led to a rather stable droplet, with higher wetting time.

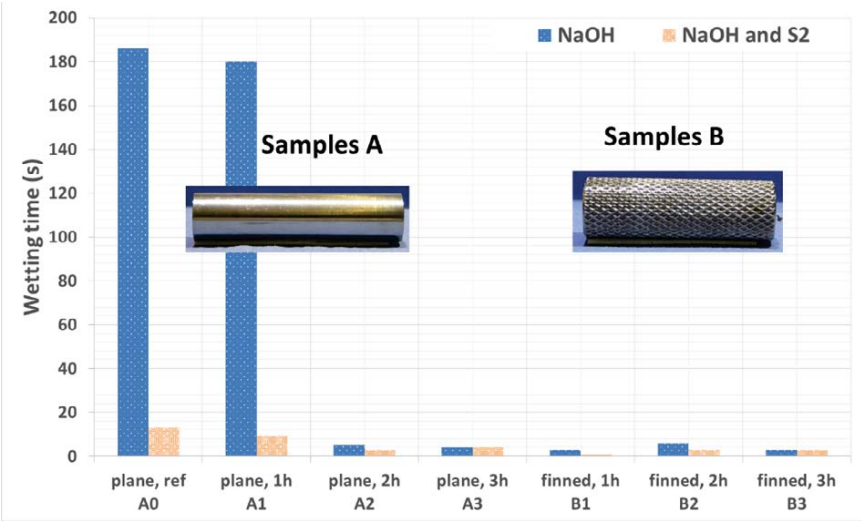

Fig. 9: Influence of thermal treatment on the wetting time for two types of surfaces and for sodium hydroxide with and without the surfactant S2 (Triton™ QS-15)

Moreover, in the heat and mass exchanger from the 1kW prototype, a manifold nozzle will be used. This was simulated by placing three large droplets (1000 µl of testing fluid, see inset image from Fig. 10) compared to the standard experiments where small droplets were used (100 µL). The pipet diameter was similar with the nozzle diameter from the prototype system (Fig. 1). A better spreading was observed in the case of the textured tube compared to the plane tube (see Fig. 10, bottom).

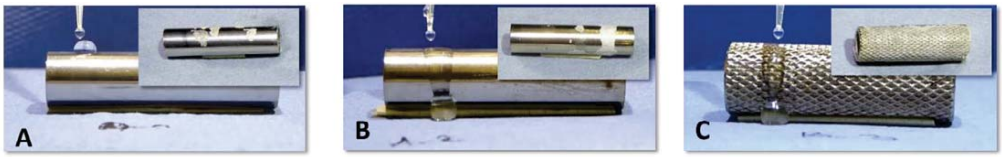

Fig. 10: Comparison between wetting of sodium hydroxide 45 wt.% and different tube surfaces – plane tube as received (A), plane tube, thermally treated for 2 hours at 300°C (B) and optimized textured tube, thermally treated for 3 hours at 300°C (C). The photos are taken 5s after adding 100 µL of sodium lye, while in the inset, a higher volume was used (3x1000 µL) and the photos were taken after the tubes were completely dried.

6. Conclusions

Water absorption/desorption in a high volumetric energy density fluid, as aqueous sodium hydroxide solution, is an efficient method to develop compact seasonal thermal energy storage. Previous experiments made in the EU funded COMTES project have indicated a lower power during the absorption (storage discharging) phase. This can be explained by the poor wetting of the concentrated sodium hydroxide over the tube bundle from the absorber/desorber unit.

The focus of our work is to develop a 1 kW absorption/desorption demonstrator unit using the falling film working principle with improved wetting of the NaOH-H_2O as sorbent-sorbate pair. One of the first steps is to optimize the heat and mass transfer at the tube bundle surface from the absorption process. This can be done by tailoring the surface wetting.

Different experimental methods were investigated for increasing the surface wetting of stainless steel tubes: surface modifications (structuring, annealing) and fluid properties tuning (use of surfactants). Higher surface area was obtained by mechanical texturing. The development of the structured surfaces not only enhances the heat transfer, but it also reduces the size of absorber unit. Annealing in air increases the surface metal oxide

content. A better wetting in terms of low wetting times was obtained for all the annealed samples. This can be explained by physical bonding between polar groups from the testing fluid and the surface metal oxide. The influence of different surface texturing on the wetting with concentrated sodium hydroxide, without/or with surfactant addition was assessed. Compared to the reference case, the surfactant addition leads to a better wetting, decreasing the wetting time.

Further work is related to the investigation of the fluid residence time in the water vapor. This can be improved by the number of tubes on each other or by a concept of inclined surface (from the vertical) over which the fluid is flowing. In addition, the use of ceramic foams is currently investigated. The improved tube bundles will be tested by integrating them in the 1 kW prototype.

7. Acknowledgments

This research was supported by the Swiss Federal Office of Energy in the frame of the Abstorex project and by Commission of Technology and Innovation CTI in the frame of SCCER Heat and Electricity Storage as well as by the University of Applied Sciences of Rapperswil.

Abstract

In the present study, new molten-salts are being proposed for Thermal Energy Storage (TES) materials at high temperature, but their corrosion characteristics are not available in the literature. The corrosion issues have to be resolved completely before commercial application of the molten-salts as the HTF in CSP plants.

To mitigate corrosion, different alumina forming alloys have been exposed to the most promising molten salts to be proposed for the new storage trends in CSP plants. This paper includes an extended corrosion study for these new developments, including nitrate, carbonate and chloride molten salts.

Ni base steels showed a better behavior in the corrosive environments and electrochemical impedance tests showed the formation of a protective layer in the first 24 hours.

The gravimetric results and SEM analyses that were performed, confirm the excellent behavior of the steels tested in nitrates and carbonates salts reducing the corrosion ability in these promising novel molten salts compared with the solar salt currently used in solar technology.

On the other hand chloride molten salt presents a very aggressive environment and the steels proposed are not recommended for its use as container materials in CSP plants.

Keywords: *Thermal Energy Storage, Molten Salt, Corrosion, Electrochemical Impedance Spectroscopy*

1. Introduction

High temperature corrosion is one of the most important issues for materials selection, structure design and service life prediction of engineering parts which are exposed to high-temperature enviroments. The prevention of high temperature corrosive attacks on materials play a critical role in aspects such as reliability, quality, safety and profitability of any industrial sector associated with high temperature process and in the study case, solar energy storage market, using inorganic molten salt (Vignarooban, Xu et al.).

Solar power tower technology is the current and future trend for CSP installation, because of its potential to achieve very high temperatures which leads to enhanced efficiency of converting heat into electricity.

The operating temperature range in the currently available solar power tower plants is between 300 and 565 C. In the future, even higher operating temperature up to 800^0C are anticipated (Kruizenga 2012). In this context, only molten-salts with extremely high boiling points can be used in the forthcoming solar power tower plants. Other possibility is reduce melting point in current molten nitrate salts in order to increase the work temperature range (Wang, Mantha et al.; Fernandez, Ushak et al. 2014). In this direction, LiNO3 is the most promising candidate and it´s eutectic formulation will be study in this paper.

doi:10.18086/eurosun.2016.03.16 Available at http://proceedings.ises.org

It is known that Electrochemical Impedance Spectroscopy (EIS) is a powerful technique that has been used to determine corrosion mechanisms in aqueous corrosion of alloys and metals for decades. The method has gained popularity since it can be performed in-situ, and also because it usually doesn't require any artificial acceleration of the corrosion process (Vidal 2014). The greatest advantage of this technique is the low intensity of excitation signal used which causes minimal disruption in the electrochemical system state, constituting a non-destructive technique and reducing the error associated with the measurement process. Impedance spectra obtained by this method are adjusted to an electrical circuit of a combination of resistors and capacitors (equivalent circuits), in order to interpret the corrosion processes.

This research is focus on corrosion ability of different thermal storage materials due to is one of the critical components for transferring thermal energy in concentrating solar power systems. Various types of thermal storage materials including nitrates, carbonates and chlorides have been selected in order to discuss the better materials for avoid corrosion issues in future developments.

The selected salts were the most promising candidates to be use in the new generation of CSP plants:

- 30wt% $LiNO_3$ + 57wt% KNO_3 + 13wt% $NaNO_3$
- 32wt% Li_2CO_3 + 33wt% Na_2CO_3 + 35wt% K_2CO_3
- 45wt% LiCl + 55wt% KCl

The corrosion tests were carried out at 550°C (nitrates), 650°C (carbonates) and 750°C (chlorides) during 1000 hours.

Regarding the materials selected, in the last years Oak Ridge National Laboratories (ORNL) have explored the effects of alloying additions on oxidation and creep behavior with an emphasis on the variation of Nb content as a function of Ni and Al levels. Niobium additions is an important factor in oxidation resistance because increase niobium and nickel levels may reduce alloy oxygen solubility, which favors external protective Al_2O_3 scale formation (Brady, Yamamoto et al. 2007) with a superior degree of protection that Cr_2O_3.

The AFA alloys show a promising combination of oxidation resistance, creep resistance, tensile properties and potential for good welding behavior. The optimal alloy composition appears in the range of (20-25%)Ni-(12-15%)Cr-(3-4%)Al-(1-3%)Nb wt% base, with a temperature limit from an oxidation standpoint approaching 9000C for alloy compositions at the higher aluminum, niobium and nickel contents of the range. The steels selected for this research are shown in table 1.

Tab. 1: Chemical composition of the steels tested in molten salts

Steels	Weight (%)							
	Al	Mn	Ni	Cr	Mo	Ti	Nb	Fe
AISI 304	-	1.7	8.04	18,28	0.27	0.01	0.008	Balance
OC-4	3.5	2	25	14	2	0.1	2.5	Balance
OC-T	3	-	35	14	-	2	3	Balance
In 702	2.7-3.7	-	75	14-17	-	-	-	2
HR224	3.2	-	47	21	-	-	-	27.5

2. Procedures

The saline nitrates that were used in the research were $NaNO_3$, KNO_3 and $LiNO_3$ (Merck 98%).
The dimensions of the analyzed samples in the gravimetric corrosion tests are 20 mm × 10 mm × 2 mm; the dimensions of each sample were measured using an electronic caliber, and each sample was weighed using an analytical balance with a 0.00001 g responsiveness. Subsequently, the samples were placed in alumina crucibles with the saline mixture and then were heated in a resistance oven at 550°C-650°C-

750°C. Gravimetric measurements were performed at 170, 335, 500, 675, 850, 1000h of the analysis for the isothermal immersion test. After the samples were removed from the oven, they were slowly cooled in warm distilled water to eliminate the salt in which they were immersed. Next, they were dried and weighed, with the average value of the weight obtained from five weight values. The formula (Eq. [1]) to calculate the mass gain over time is:

$$\frac{\Delta m}{S_0} = \frac{m_f - m_i}{S_0} \qquad \text{(Eq 1)}$$

where m_i is the initial mass of the specimen, m_f is the mass of the same at time t and S_0 is the initial area of the specimen.

The same procedure was following for carbonate salts Li_2CO_3, Na_2CO_3 and K_2CO_3 (Merk 98%) but in this case the samples was cleaned after immersion using a clark solution 10% H_2SO_4 in order to remove the salt remaining. This procedure was also used in chloride molten salt: LiCl, KCl (Merk 98%).

PPS and OCP were used to determine the Tafel slopes and corrosion rates of steels tested after immersion in molten 45wt% LiCl + 55wt% KCl at 750°C. EIS was employed to determine the corrosion mechanisms. Down selection of the best conditions per alloy was performed based on corrosion rates obtained from PPS tests. Nyquist plots obtained with time were employed to determine the corrosion mechanism change.

A two-electrode arrangement was used with the working electrode (WE) as the sample, the reference electrode (RE) and the counter electrode (CE) were connected in the same sample. The electrochemical tests were performed using a potentiostat (AUTOLAB–PGSTAT302N).

For the PPS experiments, the WE' potential (E) was continuously recorded starting immediately after its salt' immersion until dE/dt ≤ 100 µV/s was obtained and thus OCP was stablished. PPS test was conducted immediately after by applying cathodic (–) and anodic (+) external potentials from –0.35 V to +0.6 V around the OCP or corrosion potential at 0.001 V steps and 0.001 V/s. More than five coupons per test were performed under the same conditions to evaluate the reproducibility of the results. Some results were discarded based on PPS curve behavior. The corrosion current density, jcorr, was calculated from the intersection of the extrapolated straight sections of the cathodic and anodic Tafel slopes within an interval of 120 mV with respect to Ecorr.

3. Results

The steels tested in lithium nitrate salt at 550ºC were stainless steels, Inconel and AFA alloys (OC-4 and OC-T) with compositions presented in table 1; the steels were immersed in the molten salt for 1000 hours. The gravimetric gain that occurred in these steels is shown in figure 1.

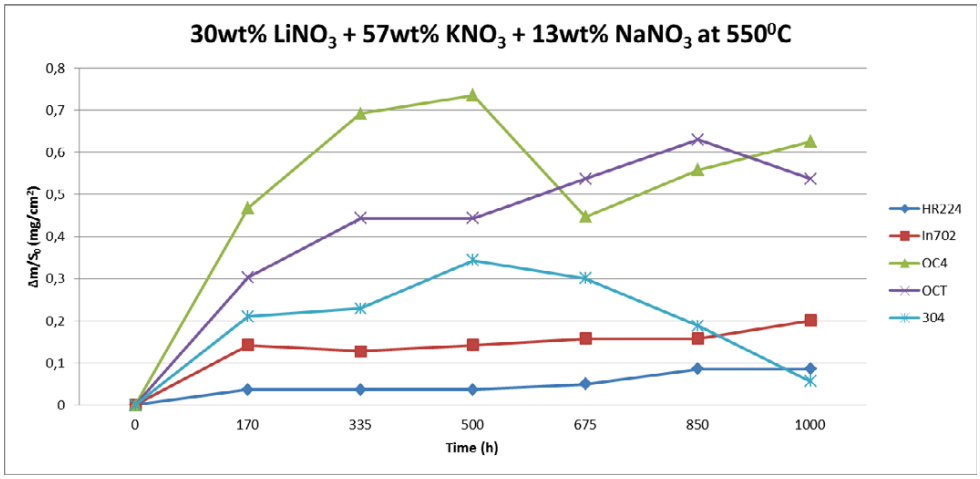

Figure 1: Gravimetric corrosion curve in saline 30%$LiNO_3$ +57%KNO_3 + 13%$NaNO_3$ at 550C for 1000 hours of test

The OC steels (with Al content) show higher mass gain after 1000 hours of saline exposition, resulting in an irregular growth of mass, with different weight gains and losses. In contrast, In702 and HR224 show the best behavior in this environment with a reduced mass gain.
It is important to point out the weight gain in 304SS with a linear corrosion rate until 500h of exposure and a change on this trend at the end of the experiment.
To explain this behavior, a micro-structural (superficial) study of the 304 stainless steel was performed using Scanning Electron Microscopy (SEM). Figure 2 shows the superficial appearance of the sample after 500 and 1000 hours of exposure as well as the EDX analysis performed.

Spectrum	O	Mg	Cr	Mn	Fe
Spectrum 1	32.46	4.08	3.02	2.04	58.39
Spectrum 2	22.39	7.99	2.55	2.63	64.44

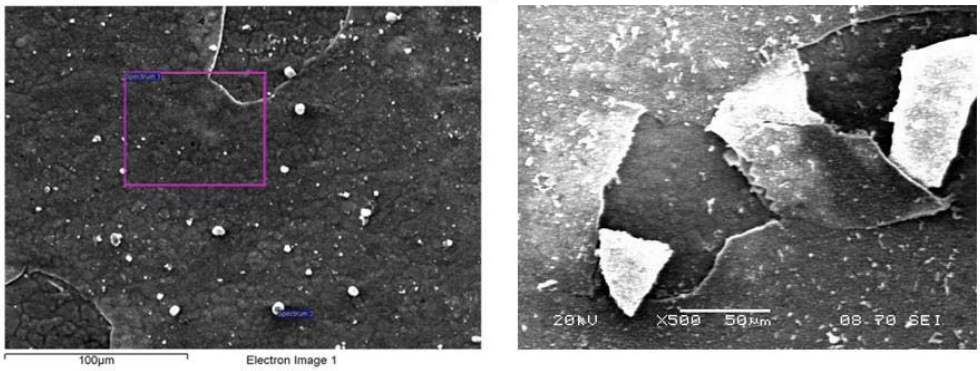

Figure 2: Superficial image of 304SS at left) 500 h and right) 1000h of test

The formed oxidation layer is very fragile, with several releasing zones, which explains the continuous fluctuations in the mass gain and the weight reduction at the end of the test.
HR224 (figure 3 left) and In702 (figure 3 right) showed the best behavior against corrosion due to the formation of a protective alumina scale.

Spectrum	O	Mg	Al	Cr	Fe	Ni
Spectrum 1	29.93	4.63	4.92	12.12	28.91	18.69
Spectrum 2	31.37	5.92	2.60	7.06	41.29	11.52
Spectrum 3	40.29	46.60	0.74	0.82	9.00	2.43

Spectrum	C	O	Mg	Al	Cr	Ni
Spectrum 1	9.00	28.64	8.89	2.13	5.80	45.53

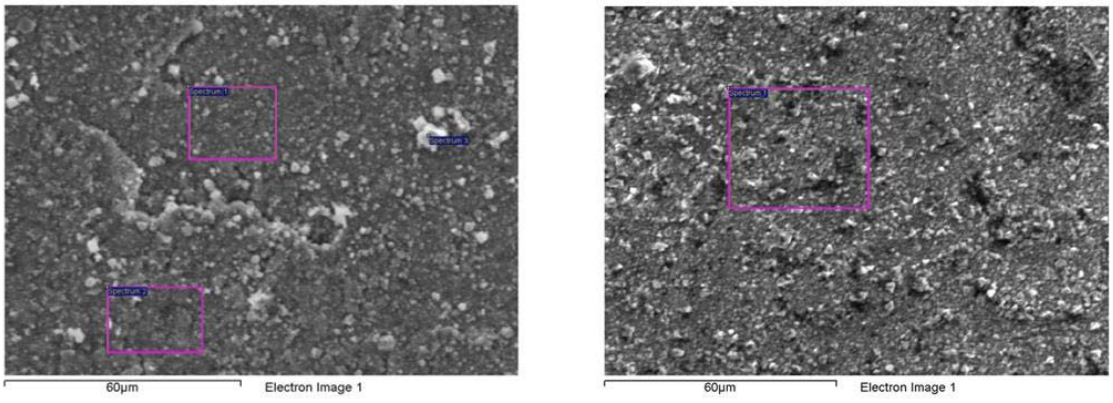

Figure 3: Superficial image of left) HR224 and right) In702 at 1000h of test

HR224 showed a higher Al and Cr content compared with In702 explaining the best behavior in the corrosive environment.
The steels tested in lithium carbonate salt at 650ºC were, the same alloys, 304SS, Inconels and AFA alloys (OC-4 and OC-T) with compositions presented in table 1; the steels were also immersed in the molten salt for 1000 hours. The gravimetric gain that occurred in these steels is shown in figure 4.

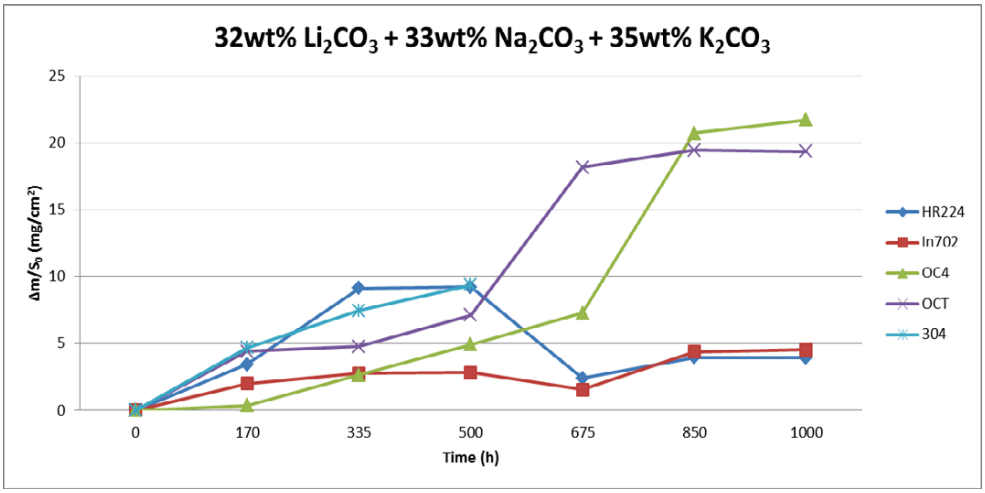

Figure 4: Gravimetric corrosion curve in saline 32%Li2CO_3 +35%K2CO_3 + 33%Na2CO_3 at 650C for 1000 hours of test

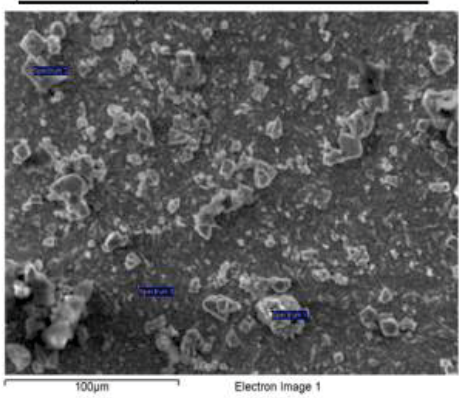
Corrosion rate showed a higher increase compared with nitrate molten salts. 304SS test only could be carried out until 500 hours of immersion, showing a severe and catastrophic corrosion spallation (fig 5).

Figure 5: Corrosion observed in 304SS immersed in saline 32%Li_2CO_3 +35%K_2CO_3 + 33%Na_2CO_3 at 650C during 500 hours of test

AFA alloys, OC4 (figure 6 left) and OCT (figure 6 right) showed the higher mass gain in contact with carbonate molten salt studied. The superficial study revealed small Al_2O_3 particles on OC4 surface that not offer a complete protection in the steel. Superficial study on OCT steel revealed an unprotective $MgFe_2O_4$ scale.

Spectrum	O	Al	Mn	Fe
Spectrum 1	56.74	37.06	3.69	
Spectrum 2	36.07			60.40
Spectrum 3	31.66			68.34



Spectrum	O	Mg	Fe
Spectrum 1	33.00	2.06	61.65
Spectrum 2	32.01	2.67	62.15

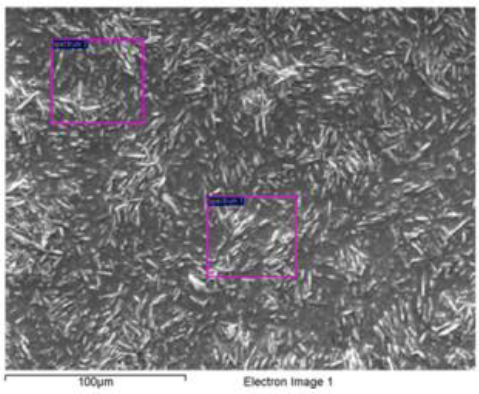


Figure 6 Superficial image of left) OC4 and right) OCT immersed in saline 32%$Li2CO_3$ +35%$K2CO_3$ + 33%$Na2CO_3$ at 650C during 1000 hours of test

HR224 and In702 shoed the best behavior against carbonate corrosion and, in this case, are forming a protective Al-O-Ni scale in the steel surface (Fig 7)

Spectrum	O	Al	Fe	Ni
Spectrum 1	23.80		2.26	73.95
Spectrum 2	21.41	1.59	2.51	72.98

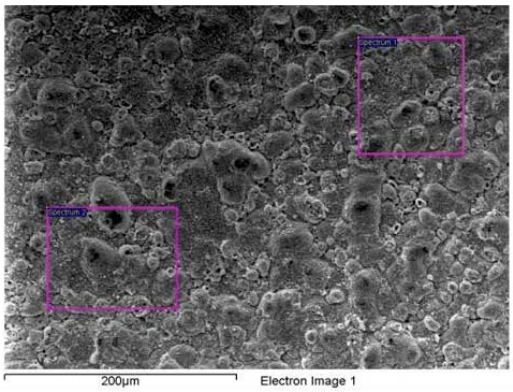

Figure 7: Superficial image of In702 immersed in saline 32%Li_2CO_3 +35%K_2CO_3 + 33%Na_2CO_3 at 650C during 1000 hours of test

According with results obtained, the corrosion study on chloride molten salt at 750^{0}C was only performed on HR224 and In702. The gravimetric results obtained are shown in figure 8.

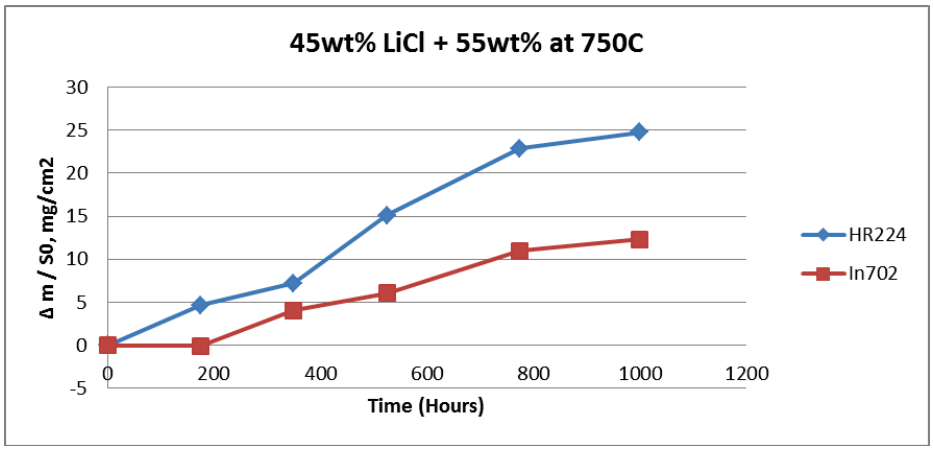

Figure 8: Gravimetric corrosion curve in saline 45%LiCl + 55%KCl at 750C for 1000 hours of test

In this case, In702 showed a lower mass gain compared with HR224 and this molten salt was the most corrosive tested in this study. Some EIS test has been developed in chloride molten salt in order to obtain corrosion rates and mechanism.
PPS and OCP were used to determine the Tafel slopes and corrosion rates of steels. Results are shown in table 2.

Tab. 2: PPS and OCP results obtained in EIS test

Alloy	Area immersed	CR, mm/y	Polarization Resistance	Test Temperature	OCP (LSV)	E corr
HR224	2,32412	0,93039	124,05	750	-0,348	-0,426
In 702	1,95158	0,61475	297,07	750	-0,414	-0,54

This technique was also used for monitorize the corrosion and Nyquist diagrams were obtained for In702 at 24 and 100h.

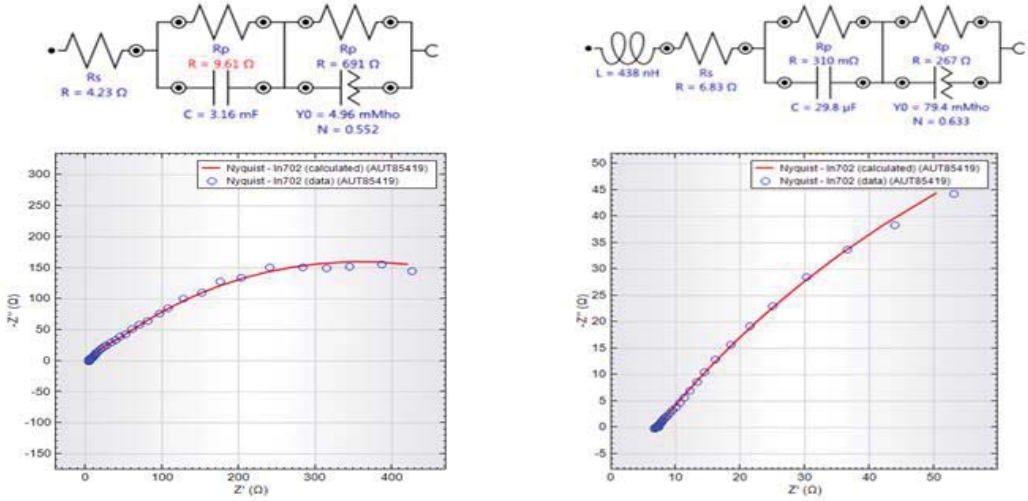

Figure 9: Nyquist diagrams for EIS study performed in saline 45%LiCl + 55%KCl at 750C for left) 24 h and right) 100 h of test

To fit the data, corrosion models in molten salts must be used. In this case, the Nyquist plots and their respective equivalent circuits are matching for a protective layer (fig 9 left) and localized corrosion model (fig 9 right).
Two semicircles are typical of protective layers and the latter type is produced by the rupture of protective layers which initiates pits creating a localized corrosion.

4. Conclusion:

Molten salts act as the electrolyte in a corrosive system that attacks the metal containers. High operating temperature is necessary to improve efficiency in the CSP system and molten-salts are the most promising TES materials at high temperatures. Different Alumina Forming Austenitic (AFA) steels have been proposed as container and pipping materials, HR224 and In702 showed the best corrosion resistance in the molten salt tested. On the other hand, their use it is not recommended for container material in storage tanks involving chloride molten salt.

Abstract

The present paper reports the design, realization and testing of a lab-scale latent heat storage, specifically realized for solar cooling applications. The latent heat storage is based on a fin-and-tubes heat exchanger configuration employing a commercial paraffin as PCM. The paper mainly focuses on the experimental characterization, carried out by means of a test rig, available at the laboratory of the CNR ITAE, able to simulate working boundaries of a solar cooling plant. The experimental outcomes confirmed the increased heat storage density obtained by such a new component, compared to standard sensible heat storage. Nevertheless, still some limitations in the achievable heat transfer rate is highlighted, due to improper realization of the component.

Keywords: *heat storage, solar cooling, PCM*

1. Introduction

During last years, an innovative technology, known as solar cooling, has gained more and more interest (Henning, 2007). Such a technology exploits the fact that cooling demand of buildings is in phase with the highest availability of solar irradiation during the year. Accordingly, it is possible to couple solar thermal collectors to thermally driven chillers for air conditioning applications (Henning et al., 2013). Usually, a closed cycle solar cooling plant is based on three main components, namely, the solar collectors field, the high temperature thermal energy storage and the thermally driven chiller (Henning et al., 2013). In the past, a lot of efforts have been paid to the identification of the optimal plant layout, in terms of surface of solar collectors, high temperature thermal energy storage size, backup system and thermally driven heat pump nominal power (Iranmanesh and Mehrabian, 2014; Hang et al., 2013). For solar cooling systems employing non-concentrating solar collector technologies (i.e. flat plane and evacuated tubes solar collectors), the high temperature heat storage relies on the sensible heat storage technique, mostly employing water as heat storage medium. Nevertheless, it is quite known that there are other opportunities to efficiently store heat. Among them, latent heat storage, based on the employment of phase change materials (PCMs) could be an interesting alternative (Mehling and Cabeza, 2008). Indeed, since they store and release heat in a narrow temperature range, they allow to feed the thermally driven chillers with an almost-constant temperature for long time, which can be beneficial for the performance of the chiller itself, increasing, at the same time, the heat storage density. Since in a solar cooling plant, the temperature difference between inlet and outlet on the heat storage side is limited to the temperature difference across the regenerator of the thermally driven chiller, which, from experimental outcomes, is usually around 10°C (Monnè et al., 2011), the employment of PCMs as heat storage medium seems quite reasonable.

Accordingly, in the present paper, the design, realization and testing of a lab-scale compact latent heat storage based on a fin-and-tube heat exchanger and a commercial paraffin is presented. Particularly, thanks

doi:10.18086/eurosun.2016.03.10 Available at http://proceedings.ises.org

to a properly designed test rig, it was possible to verify the achievable performance under working conditions typical of a heat storage for solar cooling applications, both during charging and discharging phase.

2. Thermal storage system

2.1. Employed PCM

In the present paper, the studied PCM is the organic Plus-Ice A82 manufactured by PCM Products®, whose nominal melting temperature, 82°C, perfectly suits the typical working range of solar cooling plants driven by non-concentrating solar thermal collectors. It consists in blend of linear and branched hydrocarbons. Its calorimetric features have been evaluated by means of a DSC-1 Mettler – Toledo. Ten milligrams of the material were tested cycling five times between 30°C and 110°C, with rate of 5°C/min, in static air and in a closed stainless steel pan sealed by means of a Viton® O-ring. The results reveal that the Plus-Ice A82 present good stability, with replicable latent heat and limited supercooling phenomenon. The measured melting enthalpy was 140 J/g, peak temperature during melting process was 85.7°C and peak temperature during solidification process was 80.8°C, thus showing slight supercooling. In order to take into account both sensible and latent heat, the integral heat curve between 40°C and 100°C was drawn, as reported in Figure 1. It is a useful tool to evaluate achievable heat storage density under different working boundary conditions. In the same figure, the mathematical fitting for the integral heat curve is represented, through which the theoretical energy for charge/discharge has been calculated.

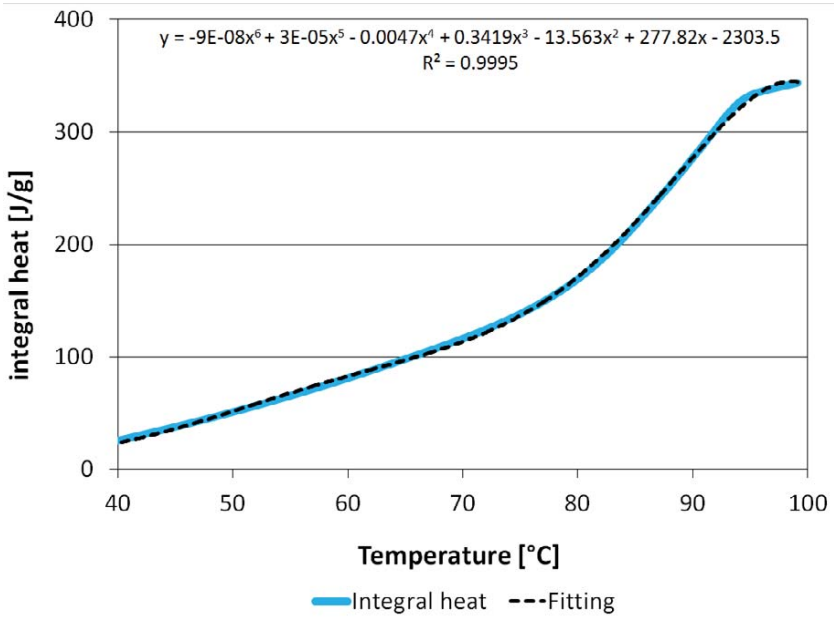

Figure 1: Integral curve of PCM PlusIce A82 and the numerical fitting.

2.2. Designed and realized prototype

In order to overcome the well-known limitations of low thermal conductivity of PCMs, in the present work, a fin-and-tube heat storage configuration has been designed through the aid of a detailed mathematical model.

In Figure 2, a 3D rendering of the storage and two picture of the realised system are presented, before and after the thermal insulation. The insulation has been realized with a 3 cm thick polymeric foam and by applying a layer of reflective aluminum foil.

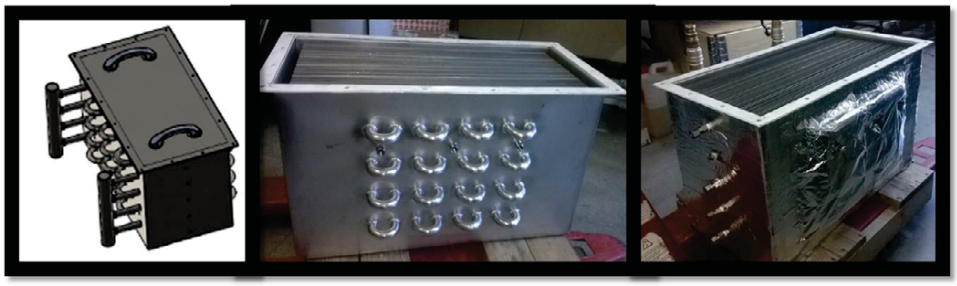

Figure 2: the fin-and-tube heat exchanger for the latent storage, 3D rendering and pictures of the system before and after thermal insulation.

The main features of the storage are summarized in Table 1. It consists of 48 fins and 4 parallel hydraulic circuits, each one made up of 8 pipes, connected to the external sources via a manifold. Fin distance chosen is 5 mm, which allows to partially compensate for the low thermal conductivity of the chosen material. All the components are realized in AISI 416L.

Table 1: Main features of the fin-and-tube heat storage.

Material	AISI 416
Technology	Fin-and-tube heat exchanger with welded fins
Number of pipes	32
Diameter pipes	½ ”
Ranks	4
Number fins	48
Fin dimensions	400 x 650 x 2 mm
Fin space	5 mm
Overall dimensions	400 x 650 x 350 mm
Overall weight	240 kg

8 thermocouples have been inserted inside the storage, their position chosen to highlight possible transversal and longitudinal temperature gradients, by distributing them along two different ranks and at different distances from the sides of the exchanger. The arrangement of the temperature sensors inside the storage is reported in Figure 3.

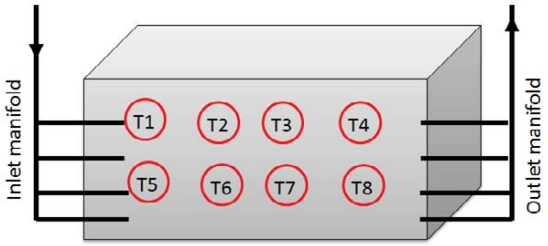

Figure 3: Schematic of the thermocouples position inside the compact heat storage.

3. Experimental testing

3.1. The testing rig

The tests of the prototype have been carried in a testing rig in the laboratory of CNR-ITAE, specifically designed for the characterization of latent heat thermal storages. The layout of the rig is shown in Figure 4, while Figure 5 shows a detail of the hydraulic circuit of the testing bench and the storage connected to it.

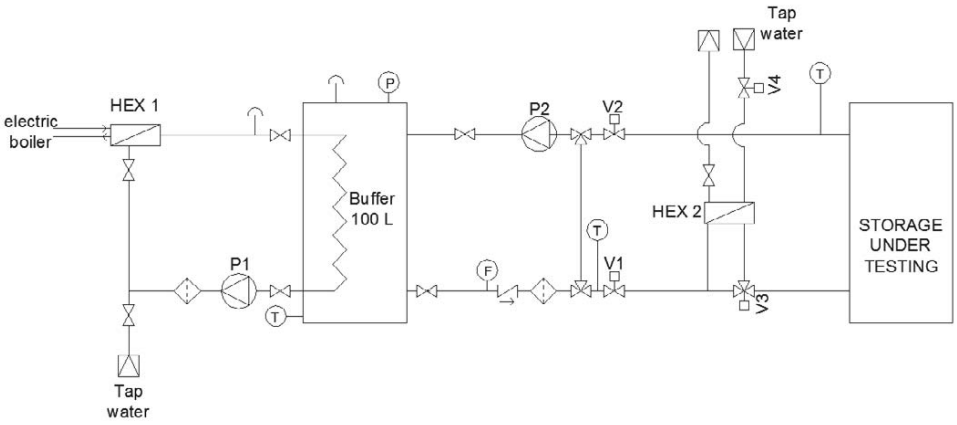

Figure 4: Layout of the test rig for latent heat storage.

Figure 5: detail of the storage during tests.

The main heat source of the testing bench is a 24 kW electric boiler that has been connected to a service buffer, with the aim of providing a constant temperature inlet. A plate heat exchanger is connected, through a mixing valve, to tap water and to the service buffer, thus allowing setting any desired temperature in the range 20°C-85°C for discharge. The management of the testing bench and the acquisition of all the main parameters are made through a software specifically compiled in LabVIEW® environment. For the measure of temperatures, class A thermocouples are used, while a magnetic flow meter with ±1% FS is used for the determination of mass flow rate of the heat transfer fluid (i.e. water). Uncertainty analysis has been carried out for the performed tests, the output showing that uncertainties of 5-8% for all the measured quantities are achieved.

3.2. Methodology

Following Figure 6 schematically represents the steps followed to perform both charging and discharging phase.

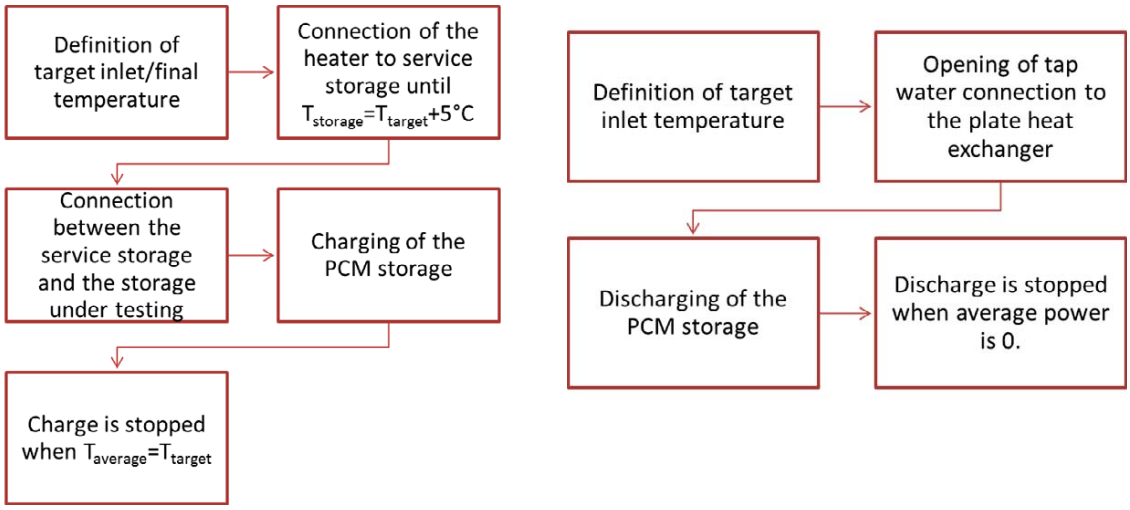

Figure 6: methodology followed for charge and discharge of the storage.

3.3. Calculated figures

The following figures have been calculated for characterization and comparison purposes:

- Charge/discharge energy, calculated as the integral of the instantaneous power for the whole duration of the charge/discharge process.

$$E = \int_0^{\tau_{fin}} \dot{m} c_p (T_{in} - T_{out}) \cdot d\tau \qquad \text{(eq.1)}$$

- Average power, calculated as the average of the instantaneous powers for the whole duration of the process.

$$P_{ave} = \frac{\sum_{i=0}^{t_{fin}} \dot{m}_i c_p (T_{in,i} - T_{out,i})}{t_{fin}} \qquad \text{(eq. 2)}$$

- Charge efficiency, calculated as the theoretical energy given to the system for the phase change over the total one.

$$\varepsilon_{ch} = \frac{E_{th,ch}}{E} \qquad \text{(eq. 3)}$$

- Discharge efficiency, calculated as the total amount of energy recovered from the system over the theoretical one.

$$\varepsilon_{disch} = \frac{E}{E_{th,disch}} \qquad \text{(eq. 4)}$$

4. Experimental results

4.1. Charging phase

Figure 7 shows the temperature evolutions of different thermocouples for various tests, differing for the applied flow rate. The same behaviour is shown by all of the sensor: there is an initial rapid increase up to about 75°C, representing the onset temperature of melting, followed by a slower increase, with an almost constant rate until the target temperature is reached and the test is stopped. The curves for T2 and T6 that are placed at two different heights (corresponding to 2 different ranks) show no significant temperature gradients along the height of the system. Instead, marked differences are visible by comparing, for example, the trend for T2 and T4, the

former one in the central part of the heat exchanger while the latter one is near the side wall. Along all the duration of the test a temperature difference of almost 15°C exists between them, mainly due to the poor heat transfer inside the material, which has a low thermal conductivity. It is clear that the material in the central part of the exchanger, which is closer to the fins and especially the tubes, exhibits the highest melting rate, whereas the material on the side of the exchanger even after 5 hours has not completed the phase change. It is interesting to notice that, as already reported in (Cho and Choi, 2000; Torregrosa-Jaime et al., 2013), the melting range is not easily identifiable, since the phase change occurs in a wide range of temperatures. The effect of flow rate is also recognisable: higher flow rates correspond to faster melting dynamics.

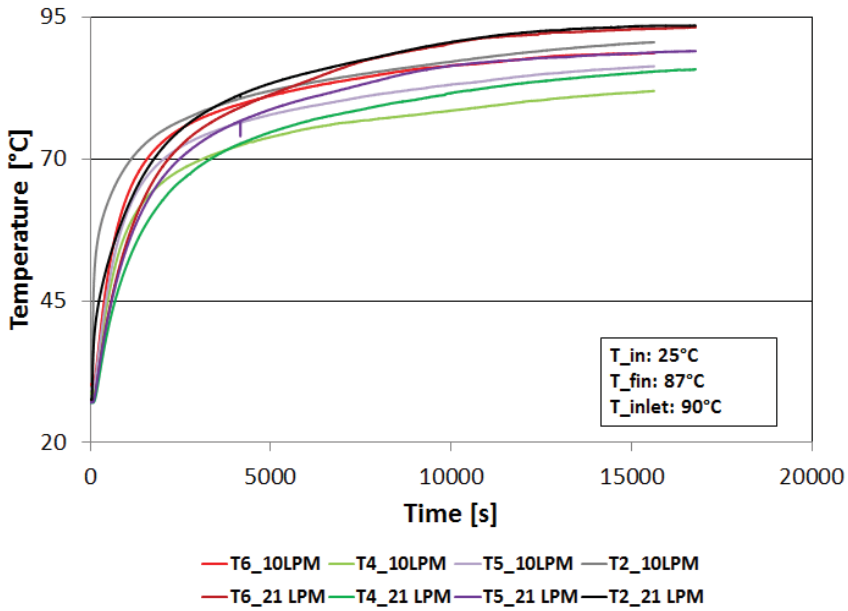

Figure 7: Temperature evolutions of four thermocouples for charging tests at different flow rates.

In Figure 8, efficiency of the storage for charging phase, defined according to eq. 3, is plotted against the temperature difference between the initial and final average temperatures in the storage. Temperature differences from 32°C to 63°C are considered, for two cases, differing in the final temperature reached. From the picture, it is clear that efficiency increases with the temperature difference inside the material, even though in a non-linear manner. The gap in the efficiency for the two series of test, in each condition, lies in the range of 2-4% and therefore is negligible in most conditions. Such a behaviour could be explained considering that, for higher temperature differences, the energy stored includes both the latent heat and a relevant amount of sensible heat, whereas, for lower temperature differences, the highest share in the energy stored is that of latent heat. Indeed, considering that the phase change is a slower process than the sensible heating up, the effect of thermal losses is more relevant when the temperature interval is smaller.

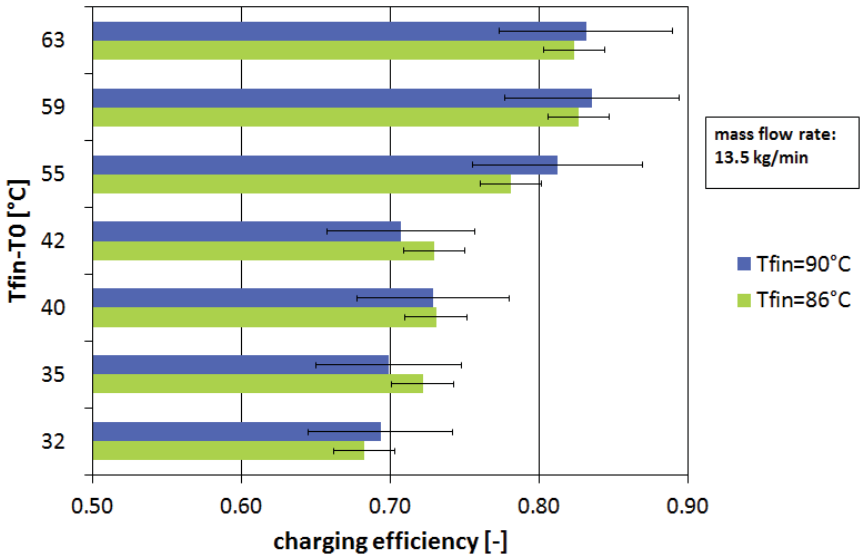

Figure 8: Efficiency vs temperature difference at the beginning and ending of charging tests.

Finally, Figure 9 shows the effect of the mass flow rate of the heat transfer fluid on both the efficiency and the average power supplied. As expected, increasing the average flow rate increases the power input to the storage. At the same time, this has a beneficial effect on the efficiency of the system: since the fluid is in laminar regime, increasing the average flow rate allows enhancing heat transfer from the heat transfer fluid to the material.

4.2. Discharging phase

The melting range of the chosen paraffin is suitable for the collection and storage of low-grade waste heat or solar energy, that are typical heat sources of thermally driven chillers. Considering the typical temperatures for the driving circuit of such chillers, discharging tests with temperatures of 65°C and 70°C were considered.

In Figure 10, the temperature evolutions of two thermocouples at variable flow rates are shown. In particular, the presented sensors are placed in the central part (T3) and in the side of the exchanger (T2). As for the charging phase, a typical behaviour can be identified for T3: at first, the temperature decreases rapidly, until a value of about 85°C is reached. At this temperature, as shown from DSC experiments, solidification starts, and is highlighted in the picture by a decrease of the temperature with a constant slope. Instead, the thermocouple indicated as T4, at the beginning of the examined tests, is around the onset value for solidification and therefore it undergoes a slow constant reduction in temperature for the whole duration of the test. Flow rate has a clear effect on the discharging process of the system, since higher flow rates lead to higher heat transfer dynamics, and therefore a more rapid completion of the phase change process.

In Figure 11, the efficiency of the storage is presented as a function of the initial temperature of the storage. The melting range is highlighted as well, in order to better clarify the results obtained. Indeed, a peculiar trend has been observed: when the initial temperatures are in the range 81°C to 86°C, the efficiency decreases with an increasing of initial temperature, while the efficiency tends to increase when the initial temperature falls below 81°C and when the initial temperature is above than 86°C. This indicates that the efficiency is lower when only the latent heat is released during the tests and increases when part of the sensible heat can be recovered.

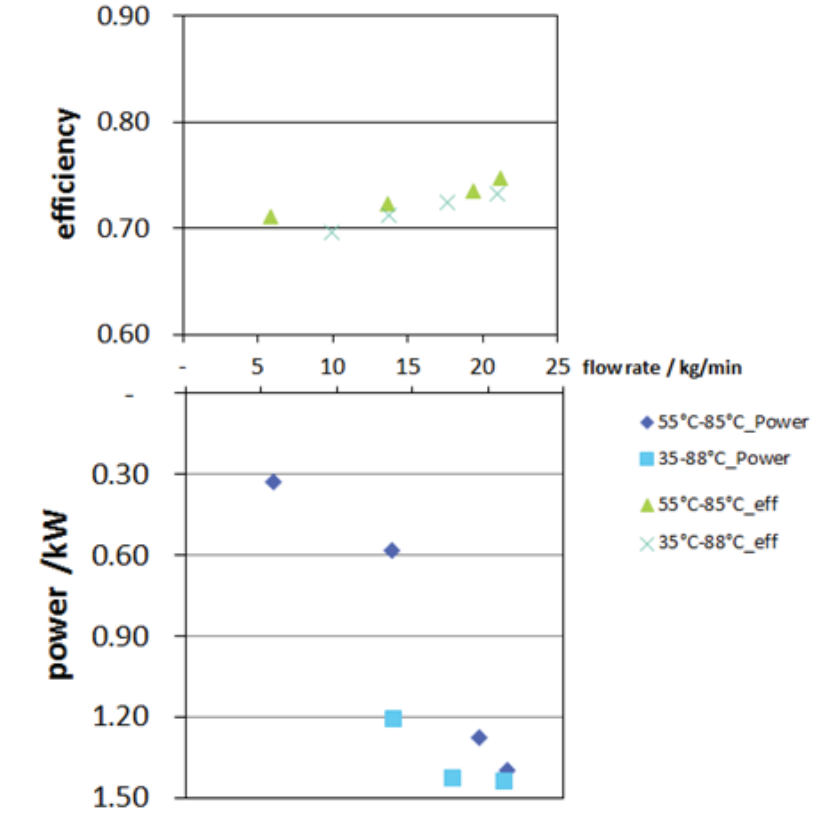

Figure 9: Effect of the flow rate of the heat transfer fluid on the charge of the storage.

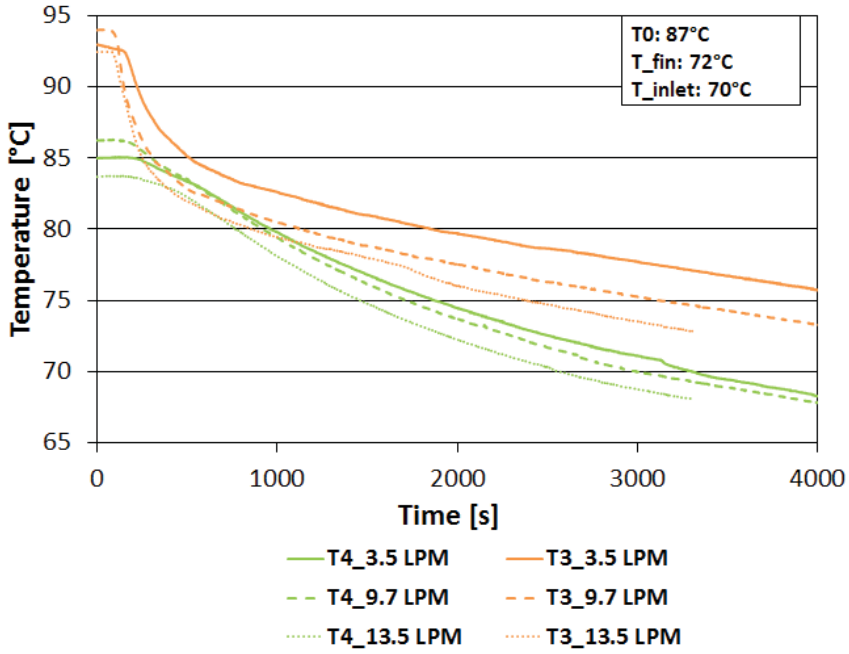

Figure 10: Temperature evolutions inside the storage for three discharging tests at different flow rates.

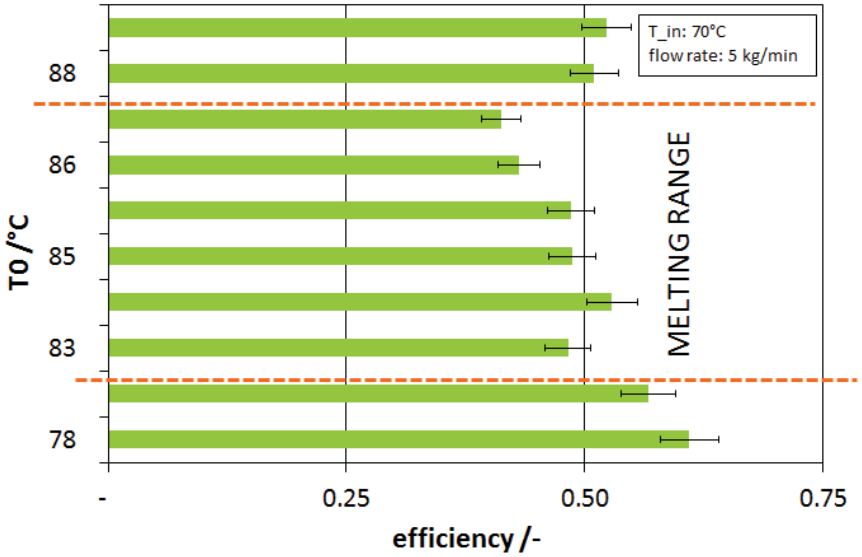

Figure 11: efficiency of the storage for different initial temperature of the storage.

Finally, average discharging power is shown in Figure 12 as a function of flow rate of the heat transfer fluid and average inlet temperature for discharging. The results obtained can be explained by considering that, for the phase change process, the main driving forces are the temperature difference between the storage and the heat transfer fluid, and its flow rate, which affects the rate at which heat is transferred from the fluid to the material on the external side of the pipes. Consequently, the tests with higher temperature of the storage and the lower inlet temperature of the heat transfer fluid correspond to higher power, up to 1.20 kW. The lowest measured powers, for discharging temperature interval of 85°C-70°C and flow rates of 3.5 kg/min or 5 kg/min are of 0.7 kW.

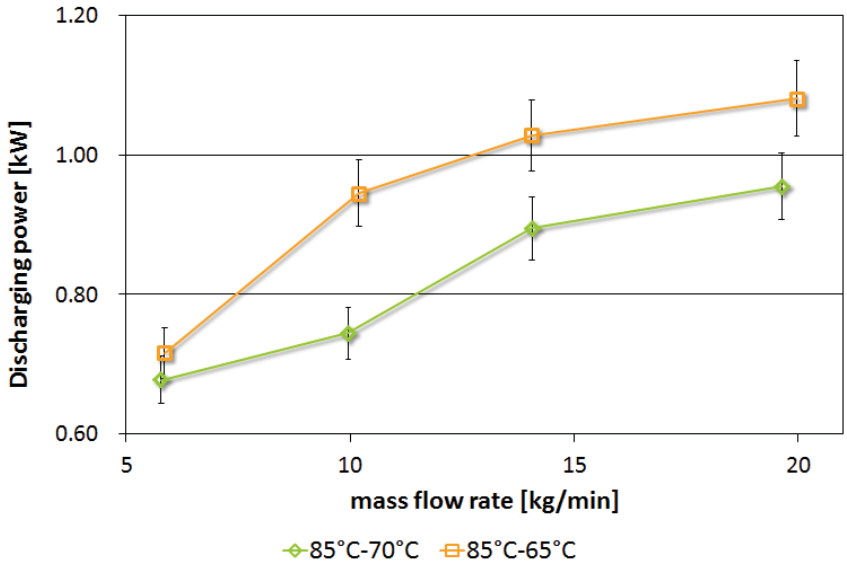

Figure 12: Average discharging power under different boundary conditions.

5. Conclusions

In the present paper, the experimental characterization of a lab-scale latent heat storage for solar cooling application is presented. It is based on the fin-and-tube configuration, employing an organic commercial PCM, PlusIce A82. The experimental outcomes confirmed that the system is characterized by good performance, both in terms of charging/discharging efficiency as well as achievable heat storage density. Indeed, efficiencies ranging between 0.7 and 0.9 during charging and between 0.45 and 0.6 during discharging have been measured.

Furthermore, the energy discharged under typical working conditions corresponds to an energy storage density of about 135 MJ/m^3, which is about 30% higher than a typical sensible heat storage working under the same conditions.

On the contrary, looking at the dynamic performance, in terms of charging and discharging power, it is evident that still the heat transfer efficiency of the system is not optimized. This is due to the intrinsic low thermal conductivity of the PCM as well as to the improper manufacturing of the heat exchangers. Indeed, the fins were not perfectly welded to the tubes, thus adding a high heat transfer resistance, which strongly limits the achievable dynamic performance.

Further investigations are still ongoing to simulate other working boundary conditions typical of a solar cooling plant.

Abstract

A Salt Gradient Solar Pond (SGSP) is a basin of water where solar energy is trapped due to an artificially imposed salinity gradient. Three main zones can be identified: the surface and bottom zones that are both convective and an intermediate zone in between intended to be non-convective. This zone acts as a transparent insulation allowing the storage of thermal energy at the bottom, where it is available for later use.
A numerical model where the SGSP dynamics is described in terms of velocity, pressure, temperature and salt concentration is presented. This model is based on the Navier-Stokes equations for an incompressible fluid, coupled to two advection-diffusion equations: one for temperature and another one for salt concentration. The fluid density ρ depends on temperature and salinity and the Boussinesq hypothesis is adopted. The variation of the daily solar radiation and its attenuation along the depth of the pond are also considered.
The objective of this work is to reproduce existing experimental data with a model robust enough to describe the physical phenomena involved for a long period of time. A transient computation with the finite element *deal.II* library and a finite volume model in *ANSYS Fluent* account for the dynamic behavior of the pond. This way it will be possible to contribute to the correct design and operation of these long thermal storage energy devices.

A Salt Gradient Solar Pond (SGSP) is a basin of water that collects and stores solar thermal energy. A temperature gradient is established in a natural way induced by solar radiation absorption at the pond surface. Three distinct zones are present in the SGSP: A upper convective zone (UCZ), a lower convective zone (LCZ) and an intermediate zone intended to be non-convective (NCZ). A salt concentration gradient (denser at the bottom and lighter at the top) is established to prevent convective motions. These motions would promote the return of the stored energy to the outside ambient destroying the SGSP very purpose. Thus a double advection-diffusion process occurs in the SGPS with the temperature and salinity fields making opposite contributions to the fluid density.

Studies of Solar Ponds have been performed since 1902, Kalecsinsky (1902). The experimental, analytical and numerical studies of SGSP pursued with Stommel et al. (1956), Weinberger (1964), Turner (1974), Tabor (1969) and Veronis (1968). A significant number of Solar Ponds were constructed with different characteristics: coupled to desalination units; as low cost seasonal thermal energy storage reservoirs for solar thermal energy production agricultural applications as greenhouse heating Joyce et al (2001) or heating aquaculture ponds especially if constructed near coastal zones.

Concerning modeling, Weinberger (1964) was the first to give a mathematical formulation of a SGSP behavior. The numerical solution of the governing equations that describes a SGSP was firstly reported by Hull (1980), and Hawlader and Brinkworth (1981). Rubin et al. (1988) applied a finite difference method to discretize the governing equations, while Jayadev and Henderson (1979) used a finite element method (FEM). Meyer et al. (1982) developed a numerical model to predict the time dependent behavior of the interface between the convective and the non-convective regions. Panahi et al. (1983) used a one-dimensional model. A SGSP year control operation was successful obtained with a one-dimensional model by Ouni et al (2003).

One of the critical factors in SGPS performance is the stability of the non-convective zone. Stability has been studied by researchers like Da Costa et al. (1981), Schechter et al. (1981), Dake et al. (1969), Akbarzadeh et al. (1980), Cha al. (1982), Meyer et al. (1982) and Giestas et al. (1996, 1997). They resorted in most cases to a linear perturbation theory. The results obtained provided important information regarding the onset of the instabilities, as well as the existence of several possible stable or unstable states that may arise (see Jin et al. (1996) and Mambole et al. (2004)). In Pina et al. (2005), a 2D numerical model that considers the viscosity dependent on both temperature and salt concentration was presented.

Mansour et al. (2006) solved numerically the problem of transient heat and mass transfer through a two-dimensional finite volume method. Angeli and Leonardi (2004, 2005) analyzed the evolution of salt concentration profiles in a SGSP.

Ould Dah et al. (2010) studied experimentally the transient evolution of profiles in a small Solar Pond in Tunisia. Boudhiaf and Baccar (2014) payed special attention to the hydrodynamic behavior of a two dimensional SGSP model in transient regime. Results have shown that the buoyancy ratio and the aspect ratio have an important effect in the thermal performance of the SGSP. Boudhiaf (2015) analyzed those effects using a finite volume technique in transient regime with a fixed salt concentration profile. Those authors used *ANSYS Fluent* to better understand ponds performance. With the development of this kind of finite volume analysis, a new way of visualization of SP behavior was possible.

This work presents a 2D CFD model for the described mathematical problem. Density is assumed to vary acording to the Boussinesq hypothesis, heat conduction is treated according to Fourier´s law and salt diffusion obeys Fick´s law. Initial and boundary condition are given in Section 2.2 and Section 2.4. To validate this model, comparisons with available experimental data, namely with the results of Ould Dah et al. (2010) are presented. These authors studied experimentally the time evolution of profiles in a small Solar Pond in Tunisia and presented results for temperature profiles. The cylindrical tank considered was insulated, the area of the surface is 0.64 m^2 and the depth is 0.90 m. In that small tank the temperature and salinity profiles were measured through a set of 27 thermocouples each of 6mm diameter. The obtained results give a special contribution to the validation of the model proposed here.

The solution of the time-dependent coupled system of equations of a SGSP is a difficult numerical task. To perform equally well the solution with respect to the several physical phenomena, a sequence of simpler sub-problems in correspondence with the underlying physics was performed. The study involves the splitting of the temperature, salinity and Navier-Stokes equations the later employing a pressure correction approach leading itself also to a decoupling of velocity and pressure. A general introduction to operator splitting techniques can be seen in Farago and Havasiy (2009). A computer code was developed using the finite element (FE) library *deal.II* (Bangerth et al. 2007) with some parallelization achieved in the assembling of element matrices and vectors and the solver of the linear system.

A 2D pressure based ANSYS Fluent simulation was also performed based on the same model hypothesis.

2. Physical and Mathematical Formulation

2.1 Physical model and simplifying assumptions

A numerical model for the SGSP dynamics of the fluid flow and heat and mass transfer was developed. The SGSP prototype is modeled as a rectangular cavity of height

We present below the governing partial differential equations as well as the boundary conditions adopted for the studied case. These governing equations are the standard conservation laws for continuum media.

Heat equation:

Therefore the domain in study is

Where

A bounded second order implicit scheme was chosen for the time marching solution. The time step was constant and equal to 0.8 seconds.

We present the results for computations in a transient regime in order to better describe and understand the inherent dynamics of a SGSP. A particular interest of this work is the long term simulation of the physical SGSP phenomena with heating of the fluid due to the absorption of solar radiation.

An important issue one should answer at this time is whether the model simplifications and the numerical methods for solving this problem are robust enough for a long term simulation (in order of days or even months) or not. The comparison of the numerical data with the available experimental data should provide some insight on this question and verify the respective limitations. Prior to this, it could in theory, be refined to model larger times and larger or different geometries.

The incident solar radiation

Fig. 4 also shows a good accordance with ED. Although, comparing Fig 3 with Fig.4, it can be observed that the F-ND differs mainly in the UCZ and NCZ. On the F-ND it can be observed a larger temperature gradient on the NCZ and a less sharp transition from the NCZ to the UCZ.

One important feature that is implemented in the present model is the time evolution of the LCZ, NCN and UCZ's. The dynamics of these zones are very important to the stability of the SGSP, thus it should not be neglected. Fig. 5 represents the salt concentration profiles, where the three zones can be identified. As expected, both UCZ, LCZ and salt concentration gradient increase with time.

Fig. 6 shows a visual representation of temperature and velocity taken for day 5 with *Ansys Fluent* post processing software. It is patent in this figure the two convective zones that separate the NCZ. Fig. 7 is a Schlieren representation, taken from *deal.II* data for the same day as the case of Fig. 6. Comparing Figs. 6 and 7, becomes clear that the UCZ is greater in Fig. 6 which corresponds to the F-ND.

6. Conclusions

The results presented here comprise a subset which is considered representative of the results available. Although, the validation of the results are for a small scale prototype, it is believed that the information gathered can be useful for the full scale SGPS dynamics.

The developed model seems to be able to predict the main features of the physics involved in a SGSP. Particularly, it was possible to get a good prediction for temperature in the three main zones of the SGSP with either the *deal.II FEM* code or with the *Ansys Fluent* software.

It is intended in future work to include the wall shading effect, heat extraction and long term SGSP simulation.

Corrosion Behavior of Stainless Steel Alloys in Molten Solar Salt

A. Gomes[1], T. Paiva Luís[1], I. Figueira[1] and T.C. Diamantino[1]

[1] Laboratório Nacional de Energia e Geologia, Lisboa (Portugal)

Abstract

Molten nitrate salts ($NaNO_3$–KNO_3) have been widely used as heat transfer fluids (HTF) and energy storage media in concentrated solar power (CSP) plants. In the present work, the corrosion resistance of two austenitic stainless steels 316SS and 321SS was assessed during long term isothermal immersion in binary nitrate salt mixture, Solar Salt. The experiments were carried out at 550 °C under static conditions. The corrosion rates were determined by weight loss methodology, recording the weight changes of the coupons at different time intervals up to 3000 h. The corrosion scale products were characterized by scanning electron microscopy (SEM), energy-dispersive X-ray spectroscopy (EDS) and X-ray diffraction (XRD). The formation of multiple oxides was verified, being Fe_2O_3 and Fe_3O_4 the main products as confirmed by XRD. A stable $FeCr_2O_4$ inner layer was formed on the 316SS surface. At t>1000 h, a partial spallation occurred in the corrosion layers at 321SS. The corrosion rates were found to be 7.3 and 9.0 μm per year for 316SS and 321SS, respectively.

Keywords: *Molten nitrate salt, Heat transfer fluid, Thermal energy storage, Metallic corrosion*

1. Introduction

Thermal energy storage is a key performance parameter for improving the viability of the CSP plants. The accomplishment of this target allows the solar heat storage from solar radiation, to generate electricity at night or on overcast days with significant economic advantages of the solar plants. (Kuravi et al., 2013; Liu et al., 2016).

Nowadays, molten nitrate salts (MS) have been extensively used in CSP to transfer and store heat given their unique thermal properties (Vignarooban et al., 2015; Weinsten et al., 2015). In two-tank systems, based on MS as storage solution, the cold tank operates at 290 °C and the hot tank at temperatures greater than 550 °C. Due to the high operating temperature, the construction of the hot tank requires the use of stainless steel materials, being the austenitic stainless steels considered as prime candidates (Dorcheh et al., 2016).

At elevated temperatures, it was demonstrated that nitrate ions decompose giving rise to nitrite ions and oxygen (Nissen and Meeker, 1983). These strong oxidizing species combined with operating temperatures plus salt impurities generate propitious conditions for corrosion acceleration of stainless steels. In this context, it is crucial to evaluate the corrosion resistance and lifetime of stainless steels to optimize the material selection since their failure could lead to severe damage of the CSP plants operation.

In the present work, a comparative study of the corrosion resistance of two austenitic stainless steels, 316SS and 321SS, was assessed. The main objective was to evaluate the aging impact of the MS contact on the stability and corrosion properties of these container and piping materials, generally used in CSP, at the high-temperature at which the binary nitrate mixture (Solar Salt) is handled. To achieve this, static immersion tests have been performed, simulating the operative conditions in hot storage tanks at CSP plants.

The corrosion rates were determined by weight loss methodology, recording the weight changes of the coupons for long term isothermal immersion in Solar Salt (60% $NaNO_3$ and 40% KNO_3), for up to 3000 h at

doi:10.18086/eurosun.2016.03.12 Available at http://proceedings.ises.org

550 °C. The corrosion scale products were characterized by scanning electron microscopy, energy-dispersive X-ray spectroscopy and X-ray diffraction.

2. Experimental

Rectangular coupons measuring approximately 50 mm × 60 mm × 4 mm in thickness were cut from 316SS and 321SS stainless steel from Acerinox Europa and ACCIAITERNI (Italy), respectively. Table 1 shows the elemental composition of the studied stainless steels. Before corrosion tests, the coupons were ground with 320-grit SiC abrasive paper and then degreased by ethanol followed by rinsed with distillated water. After that the coupons were measured and weighted. Initial mass average values of (97.45±0.48) g for 316SS and (89.27±0.65) g for 321SS were recorded.

Tab. 1: Elemental composition of the studied stainless steels (wt.%)

Stainless steel	C	Mn	Si	P	Cr	Ni	Mo	Ti	Cu	Fe
316SS	0.020	1.346	0.361	0.036	16.635	10.025	2.011	–	–	Balanced
321SS	0.030	0.960	0.640	0.027	17.260	9.100	0.490	0.280	0.320	Balanced

The stainless steel coupons were mounted on sample hangers and fully immersed in binary nitrate molten salt mixture (60% $NaNO_3$ and 40% KNO_3). The nitrate salts were provided by SQM and COBRA and were used without further purification. The corrosion tests were performed at 550 °C with long-term duration up to 3000 h in presence of atmospheric air under static conditions. A vertical tubular furnace was used during this process. Four metallic samples were collected at different immersion intervals, namely 120, 1440 and 3000 h. After cooling at room temperature, the coupons were rinsed with distillated water and weighed after having been dried. Besides mass gain, descaling method was applied according to International Standard ISO 17245:2015 to evaluate the weight loss. From the descaled data, the corrosion rate (CR) was evaluated using equation 1 (Kruizenga and Gill, 2014)

$$CR\ (\mu m/yr) = \frac{87600\ \Delta m}{\rho\ t} \qquad \text{(eq. 1)}$$

where Δm is descaled mass loss per unit area (mg/cm^2), ρ is stainless steel density (g/cm^3) and t immersion time (hours).

To complement the stainless steel samples characterization, morphological and structural analysis were done before and after the corrosion process.

X-ray diffraction analysis of stainless steel coupons were carried out using a Rigaku Geigerflex D/MAX-III C diffractometer operating with a monochromatic Cu Kα radiation. XRD patterns were recorded in the 2θ range from 10 to 90°, using a 1.2º/min acquisition rate.

The elemental composition, surface and cross-sectional morphologies of the corrosion scale were investigated using a Phillips Scanning Electron Microscope, Model XL 30 FEG, coupled to an Energy Dispersive Spectrometer.

3. Results and discussion

The long-term corrosion process was evaluated through weight loss measurements as shown in Fig 1. Relatively low values of average weight loss were obtained. They increase with time, varying between 0.7 and 2.5 mg cm^{-2}. These results are acceptable for austenitic stainless steels under these experimental conditions and are similar to others reported by Kruizenga et al. (2013). After 3000 h of immersion, the corrosion rates were found to be 7.3 and 9.0 μm per year, at 550 °C, for 316SS and 321SS, respectively. The values obtained point to corrosion rate of 316SS is lower by 20% in comparison to 321SS. This suggests that

the corrosion scales formed in 316SS are slightly more protective than the ones formed in 321SS.

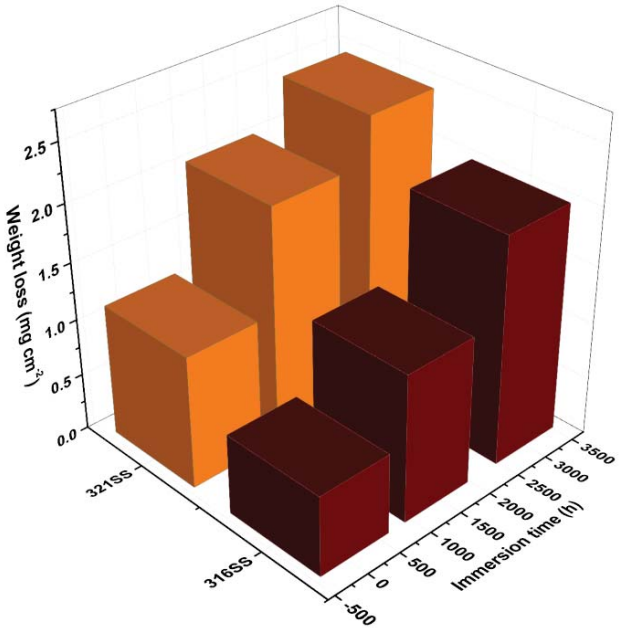

Fig. 1: Descaled weight loss data for 316SS and 321SS exposed to Solar Salt at 550 °C

After exposure to Solar Salt at 550 °C, corrosion products have been formed and the visual inspection of steel coupons shows that they lost their silver shiny aspect, acquiring a black colour for shorter times and a mixed black and rust-red coloration for longer times of immersion. By XRD analysis, it was depicted that the corrosion scale is composed of multiple crystalline oxide (Fe_2O_3, $FeCr_2O_4$, Fe_3O_4) compounds for both steel substrates, Fig 2. According to published studies, it could be assumed that Fe_2O_3 forms the external layer in contact with the molten salt, whereas Fe_3O_4 is located more internally near the metallic substrate (Fernández et al., 2012). Comparing the data recorded after 3000 h of exposure, it can be observed that the intensity ratio $I_{oxide\ scale}/I_{substrate}$ is higher for 316SS than for 321SS. This suggests that spallation phenomenon has occurred at the surface of 321SS for the longest immersion time. In addition, the XRD results pointed out that the relative abundance of iron oxides is different for the two stainless steels studied. Based on relative intensity of the diffraction peaks, it seems that the amount of spinel phases ($FeCr_2O_4$, Fe_3O_4) is more elevated at the 316SS surface. This may indicate that for 321SS, the surface protective Cr_2O_3 phase necessary to the formation of $FeCr_2O_4$ (see eq. 2) may be destroyed, promoting and accelerating the Fe corrosion due to the permeation of corrosion agents to the chromium depleted surface.

$$2\,Fe + 2\,Cr_2O_3 + O_2 \rightarrow 2\,FeCr_2O_4 \qquad \text{(eq. 2)}$$

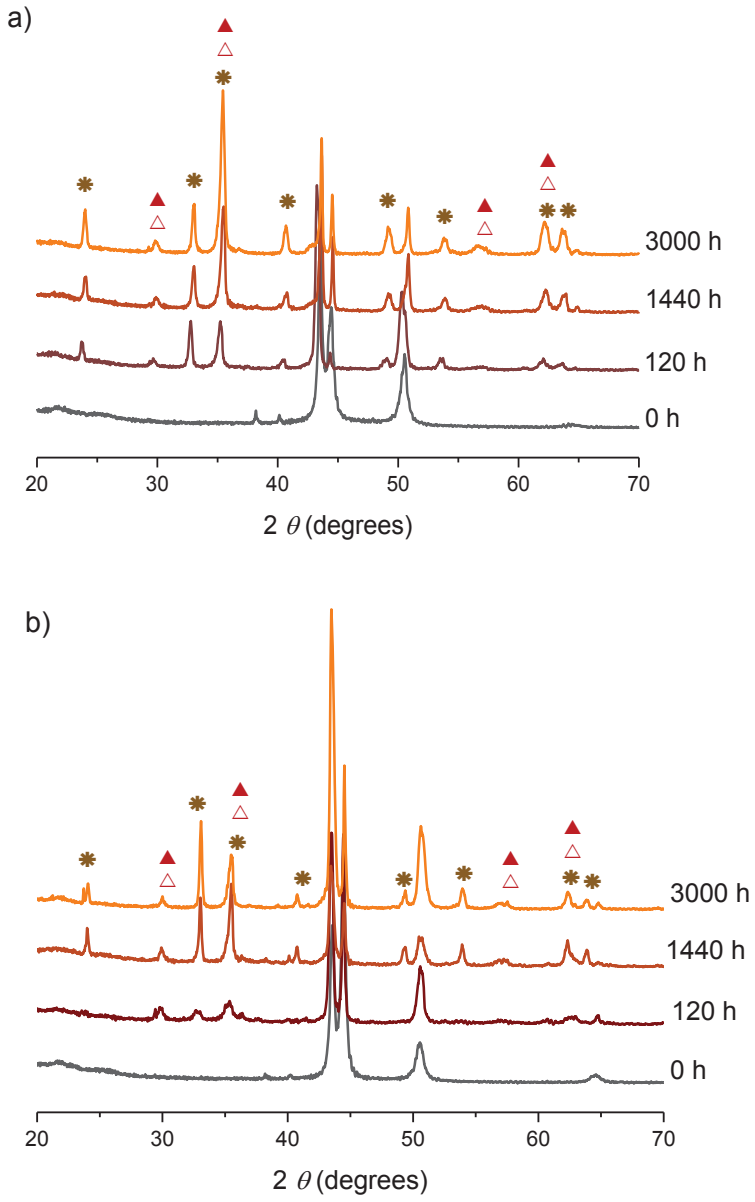

Fig. 2: XRD patterns of 316SS (a) and 321SS (b) immersed in Solar Salt for different time intervals (✱ - Fe_2O_3, △ - $FeCr_2O_4$, ▲ - Fe_3O_4)

Figures 3 and 4 show the morphological images of the surface of the oxide layers formed over time at the 316SS and 321SS, respectively. For comparison purposes, it is also shown the SEM image of the bare substrates where the abrasion marks can be easily observed. As it can be seen, after the oxidation process the surface of both steels became rougher and homogenously covered by an oxide layer. This is formed by polyhedral grains whose size increases with immersion time. At lower times, no cracks are observed at the oxide surface layer. However, partial surface spallation is observed on 321SS for exposure times equal or greater than 1440 h. This trend is not verified for the oxide scale formed at the 316SS, indicating that the scale corrosion is more adherent in this case. Spallation of oxide scales on stainless steel surfaces was previously reported (Trent et al., 2016), and explained due to stresses arising from the coefficient of thermal

expansion mismatch of the steel substrate and corrosion scale during cooling. In addition, the detachment of the oxide scales may also occur in –situ, leading to iron oxides re-growth (Scott and Wei, 1989).

From the cross-sectional images recorded after 3000 h of immersion, it is shown that the corrosion scales were multi-layered. For 316SS, a uniform and continuous inner layer was observed, and a less continuous and more irregular outer layer. According to this result, it seems plausible to assume that oxidation layers have been formed through uniform corrosion mode. For 321SS, it is evident that the oxide scale is detached from the substrate which is in agreement to other observations aforementioned. Furthermore, in this case it is more difficult to observe the irregular outer layer which could be related to mechanical failure during sample handling or metallographic preparation. Besides, in this sample, oxide features can also be seen just below the oxide-metal interface suggesting that oxide scale growth proceed via intergranular corrosion mode. More research is undertaken to better clarify the corrosion mechanism on both stainless steels.

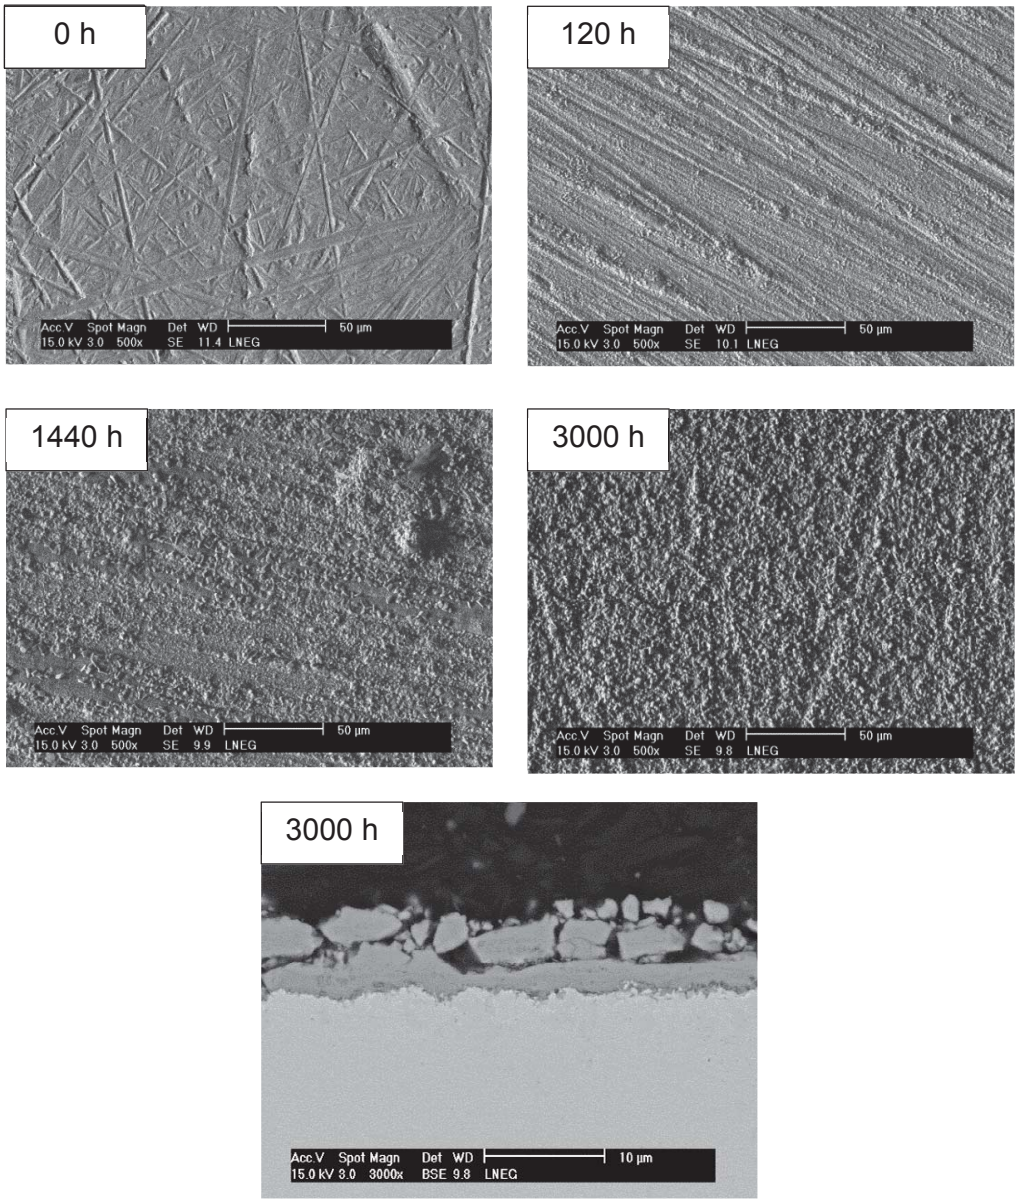

Fig. 3: Top view and cross-section SEM images of the oxide scales formed on 316SS after different immersion times in Solar Salt

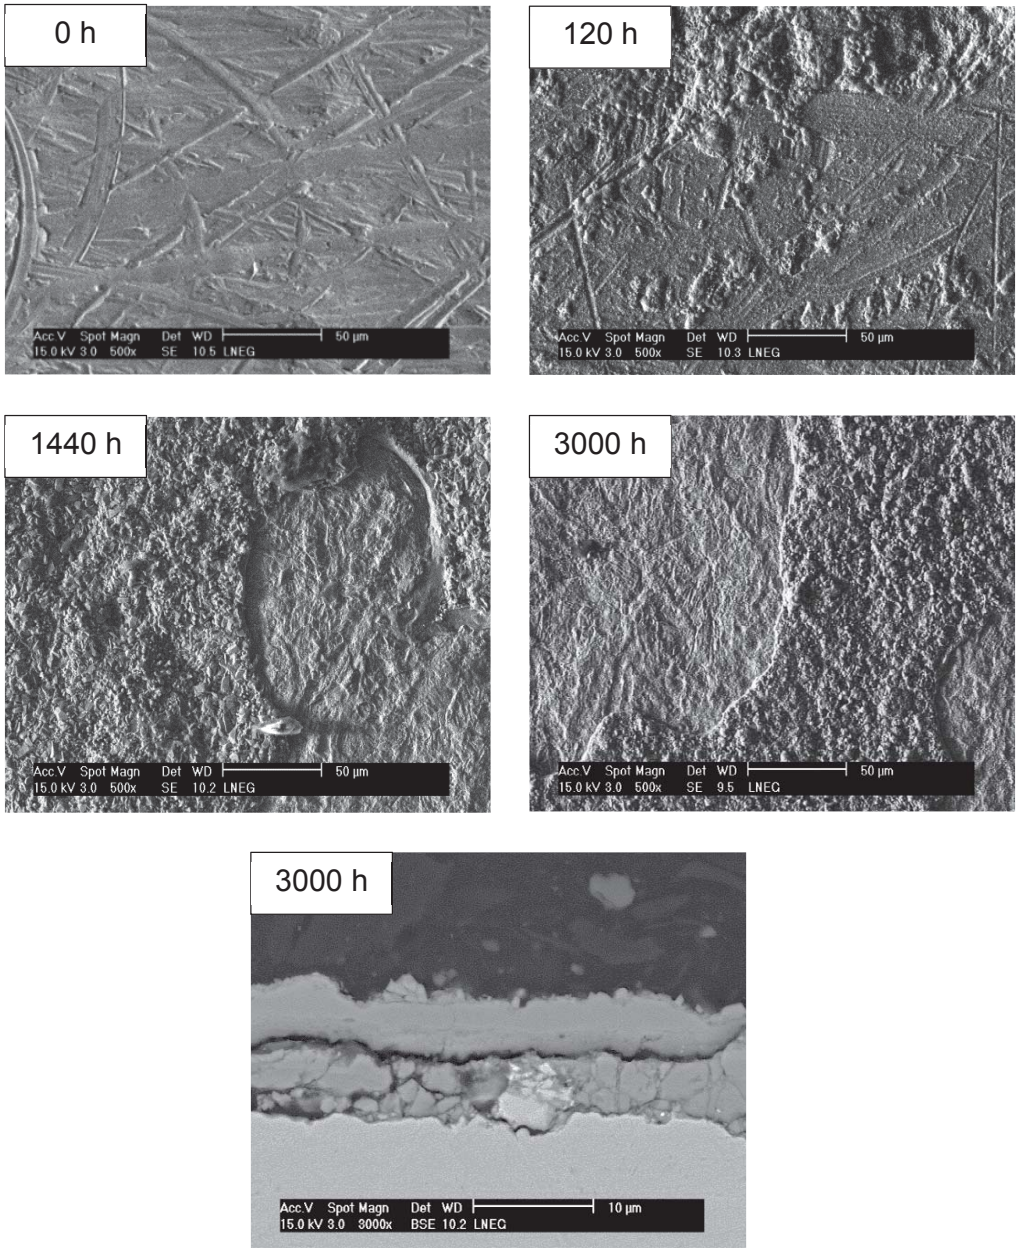

Fig. 4: Top view and cross-section SEM images of the oxide scales formed on 321SS after different immersion times in Solar Salt

Figure 5 show the elemental mapping of Cr, Ni, Fe and O for the corrosion scale developed after 3000 h of exposure for 316SS and 321SS, respectively. According to this figure, for both stainless steels, the outer layer of the corrosion scale is mainly composed by iron oxides. In the inner layer, an enrichment of chromium is verified. These results are in agreement with the XRD results. At the interface corrosion scale|steel substrate, nickel enrichment occurs, that is assumed to be the result of the depletion of chromium from the bulk (Kruizenga and Gill, 2014).

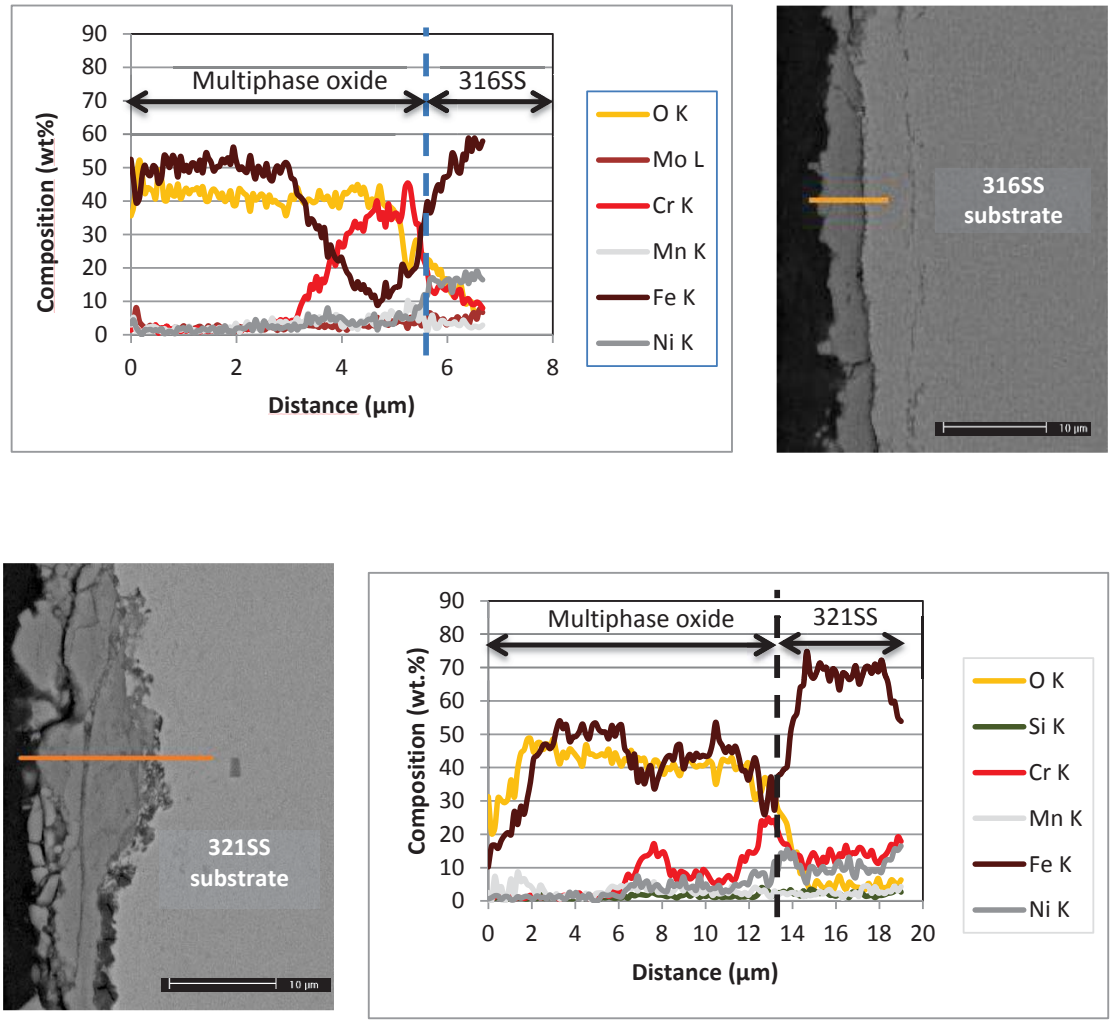

Fig. 5: Quantitative line scans and corresponding back scattered image of 316SS (a) and 321SS (b) after 3000 h immersed in MS

4. Conclusions

This study allows the following conclusions to be drawn:

- The formation of multiple oxides was verified, where Fe_2O_3 and Fe_3O_4 are the main corrosion products in both austenitic stainless steels.
- The scale morphology was similar for the two tested steel alloys.
- A stable $FeCr_2O_4$ inner layer was formed on 316SS surface.
- At t>1000 h, a partial spallation of the corrosion layers was observed at 321SS.
- After 3000 h of immersion, the corrosion rates were found to be 7.3 and 9.0 µm per year, at 550 °C, for 316SS and 321SS, respectively.

Further studies are underway to accurately determine the key factor that justifies the differences found on the corrosion behavior of these two austenitic materials.

Abstract

Solar Thermal Electricity (STE) is an important alternative to PV electricity production, due to the cost competitiveness in locations with high DNI as well as for the intrinsic value of having thermal storage which can give an important contribution to the energy mix in countries like Spain where STE has more than 2500MW installed capacity. In recent years, research has been performed, on alternative storage systems, to which features like modularity and validation of new thermal storage materials are important with the goal of achieving lower investment cost. Concrete storage has been studied in the past up to an operating temperature of 500ºC [1] [2], and several prototypes were built and tested without reaching commercial plants. Nowadays, new design and new concrete mixes are under research in order to validate its usage up to 550ºC [3]. Simulation results leading to this new design are presented.

Keywords: *Energy Storage, High Temperature, Concrete mix, Solid material*

1. Introduction

Decreasing the cost of an overall CSP plant is a fundamental goal in order to make this technology more cost competitive. Current commercial solutions include, a 2-tank molten salt indirect system (e.g. Andasol plant in Spain, 7.5h of storage capacity), a 2-tank molten salt direct system (e.g. Gemasolar plant in Spain, 15h of storage capacity) or steam accumulators (e.g. Khi plant in South Africa, 2h storage capacity). Alternative storage systems with concrete have been analyzed in the projects WANDA, ITES and WESPE (Fig.1), with thermal cycles performed between 315ºC and 390ºC and a thermal capacity of 350kWh. A specific heat capacity of 916 J/kgK [2] was measured for temperatures in the range 300-390°C. However, the concrete module design was optimized for a full scale 1010MWh storage for Andasol type CSP plants.

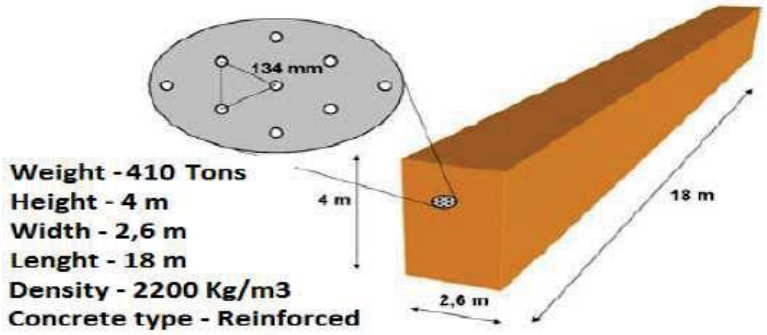

Fig. 1: Concrete Module designed in Project WANDA

doi:10.18086/eurosun.2016.03.14 Available at http://proceedings.ises.org

2. Methodology

In order to obtain a model that could be evaluated against previous work, a module with similar outer dimensions was used as a starting point, a cross section of the storage module is shown in Fig. 2. The tube register consists of 609 stainless steel tubes with an outer diameter of 18 mm. The tubes embedded in the storage module were arranged in a triangular pitch to obtain a better temperature distribution in the solid storage module. The entire storage consists in several storage units with regular hexagonal cross sections.

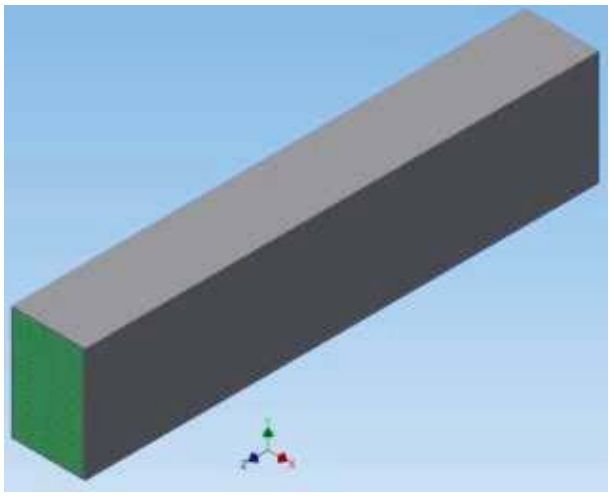

Fig. 2: Concrete Module with dimensions 2,6*18*4m [W*L*H]

The analysis of the storage unit was then simplified by substituting cylindrical storage unit geometry for the regular hexagonal shapes (Fig.3) with the same cross sectional area. The geometries were related by:

(eq. 1)

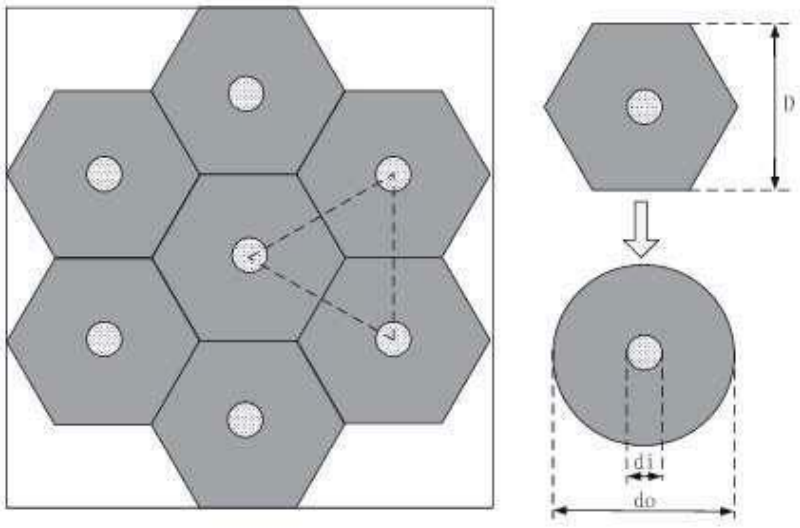

Fig. 3: Cross section of the solid storage module

The model is based on the following assumptions:

- the storage module has the same thermal behavior as the cylindrical storage unit shown in Fig. 4;
- thermal conduction in the axial direction in the fluid is negligible;
- the HTF directly contacts the solid;
- tube thickness can be assumed to be zero;
- there are no heat losses from the storage unit to the surroundings;

The finite element method is applicable to the thermal conduction in the solid media in the radial direction; thus:

(eq. 2)

The 3D model can be simplified to a 2D mesh of nodes.

Assuming that the mass flow rate, , is constant over the length of the tube, the thermal energy balance for the fluid in the differential control volume, *dz*, in Fig. 4 is:

— (eq. 3)

Where:

is the effective heat transfer coefficient in the tube;

P is the heat transfer surface perimeter

is the cross section of the tube

Substituting the average fluid velocity in the cylindrical heat storage unit , and rearranging Eq.(3), the fluid energy balance equation becomes:

— — —— (eq. 4)

For the solid storage material, a mesh of nodes was used in the same control volume *dz* as shown in Figs. 4 and 5. The same *dz* was used for the spacing in the nodes in the radial direction.

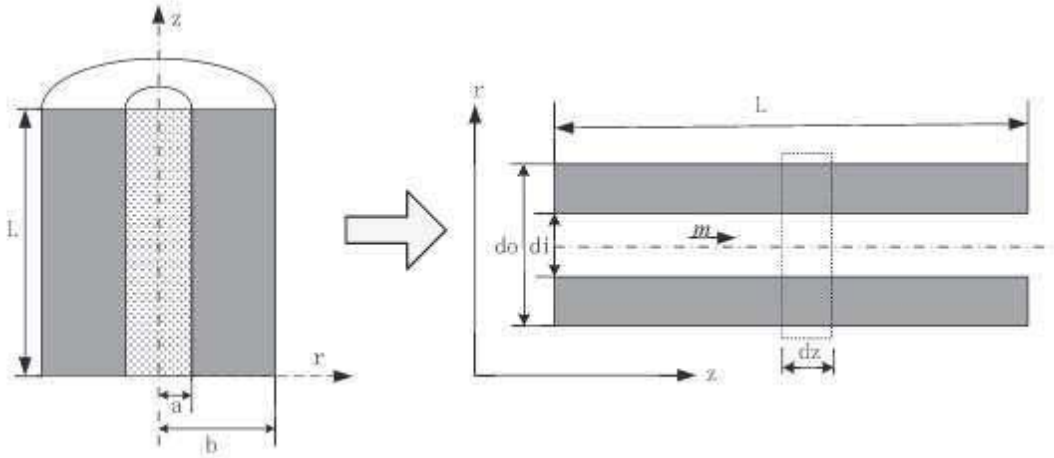

Fig. 4: Cylindrical heat storage unit model

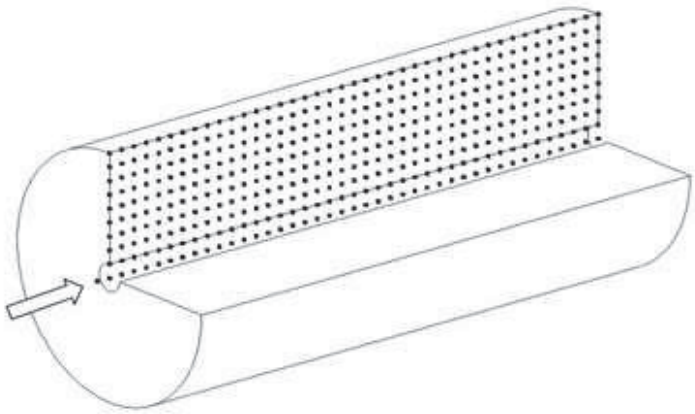

Fig. 5: Grid scheme of nodes in the cylindrical heat storage unit model

For the two-dimensional system of fig. 5, under transient conditions with constant properties and no internal heat generation, the appropriate form for the heat equation is:

— — — (eq. 5)

Concrete was used as the storage material and *Solar Salt* (a mixture of sodium and potassium nitrates) the Heat Transfer Fluid (HTF). The thermos-physical properties of the concrete mix considered are listed in table 1:

Tab. 1 - Thermal physical properties of concrete

Material	Density (kg/m^3)	Specific heat (J/kg K)	Thermal conductivity (W/m K)	Viscosity (Pa s)
Concrete (400 °C)	2250	1050	1.20	–

The temperature dependent equations used to obtain the thermo-physical properties of the fluid are listed below. Since the changes in the overall heat transfer coefficient are so low when we change the thermo-physical properties with temperature, a fixed temperature of 823 K was assumed in the calculation of the properties. The conductivity is not temperature dependent and it is assumed to be 0.45.

- For density: (eq. 6)
- For viscosity:

(eq. 7)

- For heat capacity: (eq. 8)

3. Results and Discussion

A Matlab simulation was performed using the methodology and equations described. To simulate real conditions of a solar power plant, an 8 hour charging cycle was assumed. Constant concrete properties during the cycle were considered. It is assumed that the fluid leaves the collector field at 550 ºC and enters the solid storage at that same temperature.

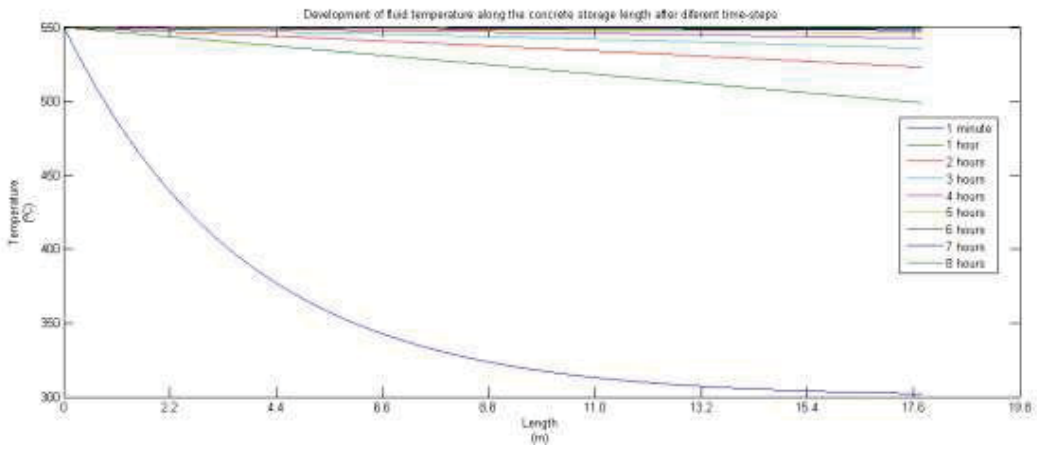

Fig. 6 - Development of fluid temperature along the concrete length with 1 hour intervals

In fig.6 it is represented the development of fluid temperature (solar salt) over the length of the module after different time steps varying from 1min up to 8hours.

In fig.7 it is represented the development of concrete temperature for radial nodes in an 8 hour charging cycle in the entrance and exit region of the module.

In fig.8 it is represented the development of temperature for different radial layers in the concrete over the module length. In these cases the considered was 250 ºC (initial temperature of 300ºC and final temperature of 550ºC for the concrete), the concrete thermal conductivity and the flow rate corresponding to the velocity of in the cross section of a single tube.

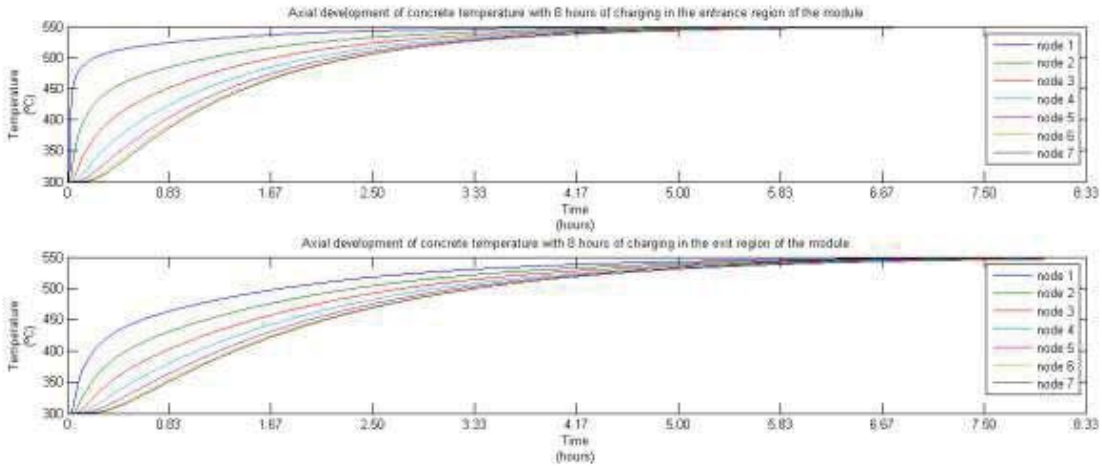

Fig. 7 – Development of concrete temperature in a 8 hour cycle in the entrance and exit region of the cylindrical module from node 1 (after fluid) to node 8 (concrete border)

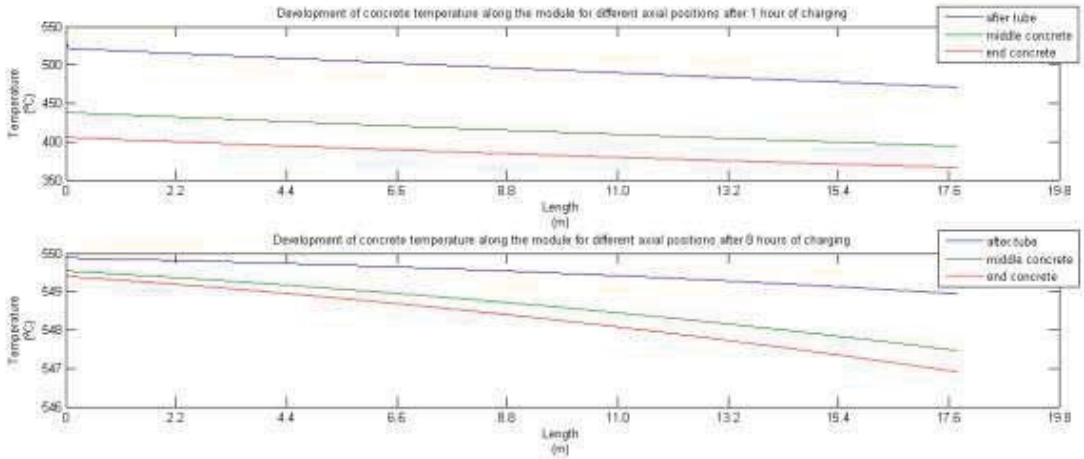

Fig. 8 - Development of concrete temperature along the length for different radial positions after 1h, 8h time steps

As it's shown in Fig. 6 the initial fluid temperature drop is very high, due to the high between the fluid inlet temperature and the concrete. This tends to change over time as the module reaches thermal balance.

In Fig. 7 is visible the radial development of temperature over time. In the entrance region the rise in temperature is faster than in the exit region as it is expected, especially the node nearest to the tube. After 5 hours one can observe that the module is fully charged, as the temperature in all the nodes reaches steady-state.

Finally in Fig. 8 it is visibly that temperature slightly drops along the concrete module length in every case as it is expected, with the nodes after the tube being always the ones with higher temperatures.

Knowing that concrete mix development is one of the current research topics, where interesting results have been obtained by several researchers, it was simulated an increase in the concrete thermal conductivity in order to evaluate changes in heat transfer and temperature development in the concrete storage unit.

The parameter thermal conductivity was simulated to have an enhancement to , behavior along the time, up to 8h is shown in the following figures.

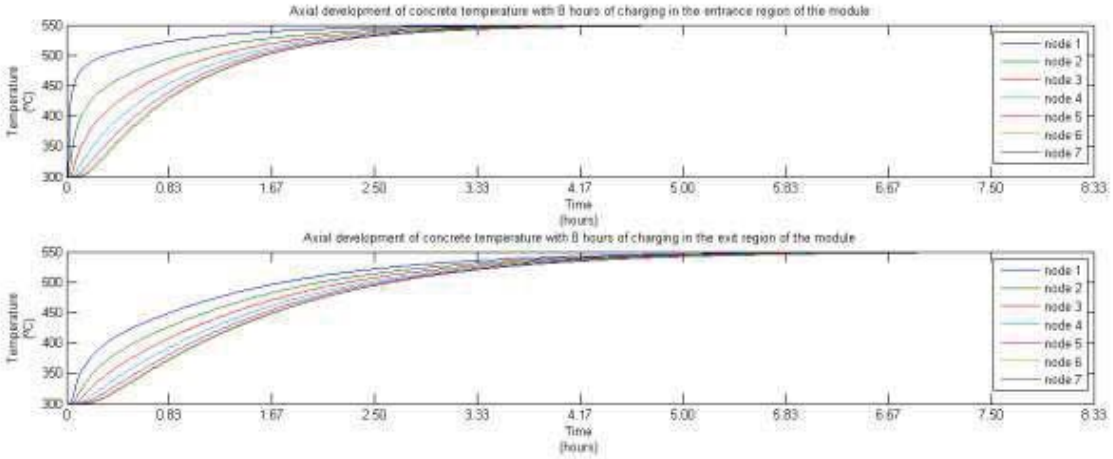

Fig. 9 - Development of concrete temperature in a 8 hour cycle in the entrance and exit region of the cylindrical module from node 1 (after fluid) to node 8 (concrete border), for radial development.

The main difference is observed in the radial development, where the development of temperature in different radial nodes is much more similar, seen in the less spaced curves of the different nodes.

In Fig.9 an increase in charging behavior can be observed when compared with Fig.7, that is, instead of 5h for full charge it takes less than 4h. However, in order to achieve further improvement in overall heat transfer, not only the material properties are important, but also the design needs to be optimized. For that reason, following the results obtained, a new design is proposed as shown in Fig.10 and Fig.11.

This new design section considers a new concrete mix developed with a thermal conductivity of about 2 W/m*K. The number of pipping is reduced significantly (when compared with steam as a HTF) since the heat transfer fluid are molten salts and not steam, meaning that the thickness of the pipes can be reduced, and heat exchange between fluid and concrete improved by means of fins welded to the pipping.

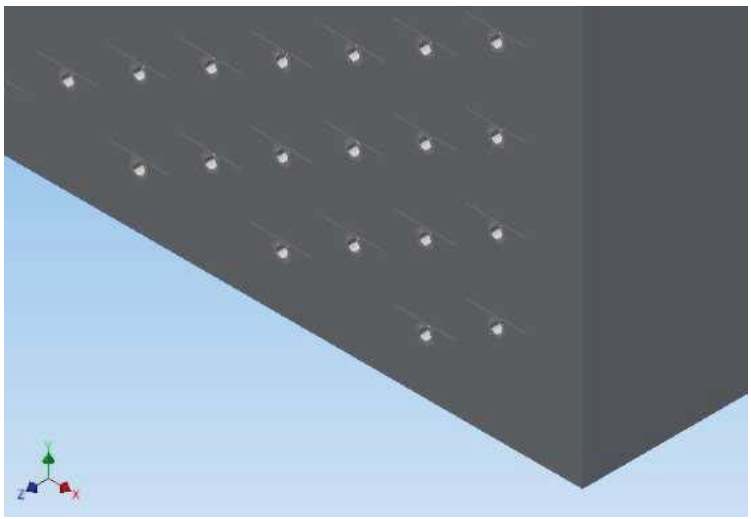

Fig. 10: Concrete Module new section design, isometric perspective

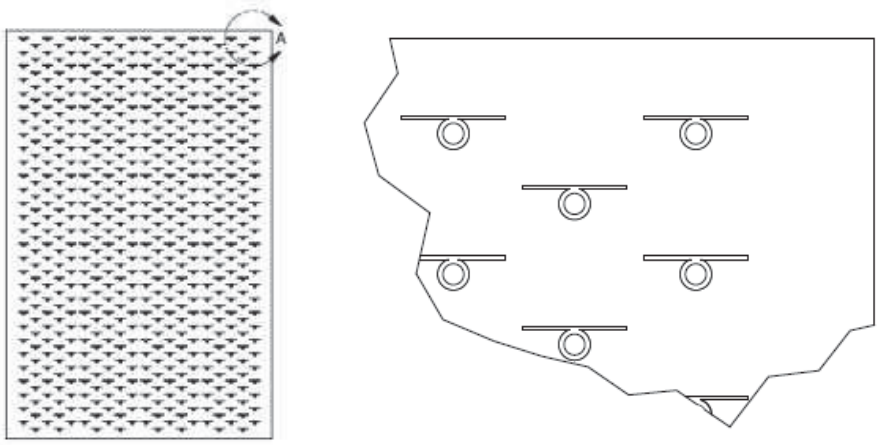

Fig. 11: Concrete Module new section design, (left side: section, right side: detail)

4. Conclusions

Simulation using Matlab is an appropriate tool for simulating thermal behavior of a concrete heat storage unit. Different cases have been simulated to demonstrate the methodology and the impact of improving some of its features. Enhancing properties like thermal conductivity is possible to be evaluated through the method applied. The improvement in the thermal conductivity of concrete allows a faster increase in temperature in the concrete as well as less difference in the temperature along the radial nodes, showing that the heat transfer inside the concrete is faster between the nodes.

Using the same method other parameters (like the flow rate) can be varied in order to simulate its behavior. Nevertheless, in order to increase significantly the charging and discharging performance, new section designs need to be fully evaluated and simulated. A new design has been proposed to improve the overall concrete storage unit behavior.

A concrete module is a concept that has several advantages: can be planned with a certain number of units, easily scalable, can be built in phases, the investment can be diluted for a longer period of time, can operate partly depending on the radiation among other advantages. If all technological aspects are taken into consideration, a significate improvement can be achieved, making concrete storage an interesting alternative to mainstream molten salts tank storage.

Abstract

A constrained multi-objective optimization approach is used to optimize the exergy efficiency and material costs of thermocline packed-bed thermal energy storage systems. The storage height, top and bottom radii, insulation-layer thickness, and particle diameter were chosen as design variables. The competing objectives of maximizing the exergy efficiency and minimizing the material costs are dealt with by forming a Pareto front. The Pareto front allows the identification of the most efficient design for a given cost and is an important tool in the design of thermal energy storage systems. Constraints are imposed to obtain storage systems with a specified capacity. The optimization approach is applied to identify the influence of various design variables on the exergy efficiency and the material costs. The results show that a storage shaped like a truncated cone with the smallest cross-section on top has a higher exergy efficiency than common designs with a cylindrical shape or a truncated cone with the largest cross-section on top. The basic thermodynamic mechanisms leading to this superior performance are identified with detailed information about the axial temperature distribution in the packed bed and thermal losses through the structure and insulation materials.

1. Introduction

Thermal energy storage (TES) systems are required when there is a time difference between the availability and demand of thermal energy. Examples are concentrated solar power (CSP) [1] and advanced adiabatic compressed air energy storage (AA-CAES) plants [2]. CSP plants have an irregular power input due to the time-dependent nature of solar radiation and require TES to control the electricity output by partially decoupling electricity production from solar radiation. AA-CAES plants store the thermal energy produced during compression in a TES and use the stored energy later to reheat the air before expansion in a gas turbine. For both CSP and AA-CAES plants, the integration of a TES improves the system efficiency and the competitiveness on the electricity market [2, 3]. Especially thermocline TES systems using a packed bed of rocks as sensible storage material are suitable because they require only low-cost storage materials and have been shown to have high thermal efficiencies [4, 5].

The design of TES systems requires an accurate and efficient numerical model. A TES system is characterized by a large number of design variables and may need to satisfy several constraints and objectives. Tab. 1 lists the operational, geometrical, thermophysical, and performance parameters of a general TES system. The operational parameters are in general defined by the application in CSP or AA-CAES plants, the values of the geometrical parameters are usually arbitrary but need to satisfy structural constraints, the thermophysical parameters depend usually on the temperature and pressure (and therefore the operational parameters), and the performance parameters are used to compare and characterize TES systems. The large number of geometric parameters can lead to very large number of design combinations. For example, considering ten values each of the storage height, the top and bottom radii, the two insulation layers, and the particle diameter would lead to 10^6 designs, each of which would need to be simulated long enough to reach quasi-steady-state conditions. If, in addition, a combination of three storage materials is

doi:10.18086/eurosun.2016.03.03 Available at http://proceedings.ises.org

considered, the number of simulations would increase to 10^8. Even with efficient one-dimensional numerical models, the computational cost of evaluating this many designs is prohibitive. To reduce the computational cost of finding the optimal design, a numerical optimization procedure is essential. By *optimal design*, we mean a TES design that combines high efficiency with low costs. It is important to note that it is in general not possible to identify any single design as optimal because high efficiency and low cost are usually contradictory requirements. Instead, the optimization procedure should provide a series of designs depending on the relative importance of high efficiency compared to low costs.

Tab. 1: Operational, geometrical, thermophysical, and performance parameters of general TES systems. The subscript *i* indicates that several instances of a particular parameter exist, such as multiple structural and insulation layers.

Operational parameters	Geometrical parameters	Thermophysical parameters	Performance parameters
Mass flow: $\dot{m}_c$, $\dot{m}_d$ Charge/discharge time: t_c, t_d Inflow temp.: $T_{f,\mathrm{in},c}$, $T_{f,\mathrm{in},d}$ Charge/discharge pressure: p_c, p_d	TES (packed-bed) height: H_{PB} Top/bottom radius: $r_{\mathrm{PB},t}$, $r_{\mathrm{PB},b}$ Structural thickness: $l_{\mathrm{struc},i}$ Insulation thicknesses: $l_{\mathrm{ins},i}$ Particle diameter: d_p Packed-bed porosity: ε	Thermal cond.: k_f, k_s, $k_{\mathrm{ins},i}$ Density: ρ_f, ρ_s, $\rho_{\mathrm{ins},i}$ Heat capacity: $c_{p,f}$, c_s, $c_{\mathrm{ins},i}$ Viscosity: μ_f	Charged capacity: E_c Net discharged energy: $E_{d,\mathrm{net}}$ Supplied energy: $E_{c,\mathrm{in}}$ Efficiency: η_{en}, η_{ex} Cost: C_{TES}

Several TES optimization studies were published that optimize only the thermal performance of TES systems without considering the TES costs [6, 7] or consider a multi-objective optimization approach where the TES efficiency and the costs are optimized simultaneously [8-10]. The above-mentioned publications use models with strong simplifications to predict the TES performance, such as algebraic equations to calculate the one-dimensional temperature distribution in packed-bed TES systems, together with basic optimization methods such as the direct search method to find optimal operating and design parameters. The restrictive model simplifications and basic optimization methods can be used for a rough evaluation of packed-bed TES systems. To advance the scope and improve the accuracy of TES optimization, the model must be more sophisticated to simulate realistic charging and discharging cycles. Therefore, the TES model in this work is capable of handling variable charging, discharging, and idle periods, multiple structural and insulation layers with different thicknesses, non-cylindrical TES geometries, and temperature-dependent thermophysical properties. In addition, an efficient optimization method is required to reduce the computational costs. In this work, the objective function is formed from the exergy efficiency at the quasi-steady state and the material costs. We expect the objective function to be continuous and to have a single maximum. Because reaching the quasi-steady state often requires a large number of charge-discharge cycles to be simulated, the objective function can be relatively expensive to compute. To decrease the computational cost, the number of evaluations of the objective function should be small. Therefore, the gradient-based sequential quadratic programming (SQP) algorithm is used for the optimization in this work.

The objective of the present study is to use multi-objective optimization to design packed-bed TES systems with rocks as heat-storage medium and air as heat-transfer fluid (HTF). The objective function is formed from the exergy efficiency and the material costs. The design variables include the packed-bed height, top and bottom radii, insulation-layer thicknesses, and particle diameter while the net discharged energy and the packed-bed volume are used as nonlinear constraints. The trade-off between increasing the exergy efficiency and reducing the TES material costs is demonstrated through the concept of Pareto optimality to identify optimal designs that combine a high efficiency with low costs.

2. Model and numerical method

The optimization tool is a combination of a previously developed heat-transfer model [4] and the optimization package NPSOL [11, 12]. The coupling of the heat-transfer model with the optimization package is described in [13].

2.1. TES model

The heat-transfer model can accurately predict the one-dimensional temperature distribution of packed-bed thermocline TES systems and is described in [4]. The model was verified with the exact solutions for the simplified cases of no axial conduction and wall losses during the first charging of the TES [14] and during the steady charging-discharging behavior in the limit of fast switching times [15]. Several experimental

studies were used to validate the model, including storages with rocks [5] and ceramic particles [16] using air as HTF and a storage with a combination of quartzite and sand using molten salt as HTF [17].

2.2. Optimization package

The optimization package NPSOL uses the SQP method to minimize an objective function that depends on design variables and linear and non-linear constraints [18]. The optimization problem can be formulated as

$$\text{minimize} \quad f(\vec{x}) \quad \text{subject to} \quad \vec{l} \leq r(\vec{x}) \leq \vec{u} \quad \text{with} \quad r(\vec{x}) = \begin{cases} \vec{x} \\ \bar{\bar{A}}\vec{x} \\ \vec{c}(\vec{x}) \end{cases} \tag{1}$$

where $\vec{x}$ is a vector of n design variables, $f(\vec{x})$ is the objective function, $\vec{l}$ and $\vec{u}$ are vectors with the lower and upper bounds of each design variable, $\bar{\bar{A}}$ is a $m_L \times n$ matrix describing the m_L linear constraints, and $\vec{c}(\vec{x})$ is a vector with m_N nonlinear constraint functions. The values of $\vec{l}$, $\vec{u}$, $\bar{\bar{A}}$, and the initial values of $\vec{x}$ are required as input parameters to NPSOL. The functions $f(\vec{x})$ and $\vec{c}(\vec{x})$ are calculated by the TES code described above and provided to NPSOL. Besides the function values of $f(\vec{x})$ and $\vec{c}(\vec{x})$, the SQP method requires also the gradients of $f(\vec{x})$ and $\vec{c}(\vec{x})$ with respect to each design variable.

2.2.1. Complex-step derivative approximation

To avoid the "step-size dilemma" of finite-difference methods, the complex-step derivative approximation is used [19-21]. This method uses complex calculus to calculate the derivative without subtraction and hence is unaffected by cancellation errors. This allows a very small step size to be used to reduce the truncation error and therefore the accuracy of the complex-step derivative approximation can exceed the accuracy of finite difference by several orders of magnitudes [19, 21].

To apply the complex-step derivative approximation, the floating-point variables and constants used in the TES code are converted into complex variables and constants and the intrinsic Fortran functions and operators are overloaded to handle complex arguments. The conversion process is automated by a code that adjusts all Fortran files and the overloaded intrinsic functions and operators are defined in an additional Fortran module similar to [21]. By introducing a complex step size to a specific design variable, e.g. x_1, while setting the complex part of the other design variables to zero, the complex part of the objective function $f(\vec{x})$ can be used to approximate the derivative of the objective function with respect to this particular design variable using

$$\frac{\partial f}{\partial x_1} \approx \frac{\mathrm{Im}[f(x_1 + ih, x_2, \ldots, x_n)]}{h} \tag{2}$$

where $x_{1,2,\ldots,n}$ are the design variables and h is the complex step size (typically chosen to be 10^{-12}). The same procedure can be applied to any function calculated by the converted TES code.

2.2.2. Multi-objective optimization

The objectives in multi-objective optimization are in general competing, so one objective can only be improved when at least another objective is worsened [22]. This trade-off can be visualized with the Pareto front that describes the best possible combinations of the competing objectives within the objective function space [23]. Several approaches exist to combine the competing objectives to calculate the Pareto front [24]. One of the simplest methods is the weighted-sum method in which a single objective function is calculated by combining the competing objectives according to

$$f(\vec{x}) = \sum_{i=1}^{N_o} w_i \hat{f}_i(\vec{x}) \tag{3}$$

where N_o is the total number of objectives and w_i is the relative weight of objective $\hat{f}_i(\vec{x})$. The sum of all weights is equal to unity. For competing objectives, the Pareto front can be computed by varying the weights gradually and computing for each set of weights the optimum of the weighted sum [25].

Two objective functions are considered in the present study: the exergy efficiency of one charge-discharge cycle at the quasi-steady state and the material costs of the TES. The weighted sum of these two

objective functions is given by

$$f(\vec{x}) = w(1-\eta_{\mathrm{ex}}) + (1-w)\frac{C_{\mathrm{TES}}}{C_{\mathrm{TES,ref}}} \quad (4)$$

where η_{ex} is the exergy efficiency, C_{TES} is the total material cost of the TES, and $C_{\mathrm{TES,ref}}$ is an estimation of the material cost. The normalization is used to avoid one objective function dominating the other. The exergy efficiency is defined in [4] and the material cost of the TES is computed from

$$C_{\mathrm{TES}} = \sum_{i=1}^{N_m} c_i V_i \quad (5)$$

where N_m is the total number of materials, c_i is the volumetric cost of material i, and V_i is the volume of material i. The material cost includes the storage material, the structural materials, and the insulation materials. The volumetric costs of the various materials are given in [4].

2.2.3. Non-linear optimization constraints

In the present study, two non-linear constraints are considered: the net discharged energy $E_{d,\mathrm{net}}$ and the packed-bed volume V_{PB}. The net discharged energy describes the net thermal energy extracted from the TES during discharging and is given by

$$E_{d,\mathrm{net}} = E_{d,\mathrm{out}} - E_{d,\mathrm{in}} = \int_0^{\Delta t_d} \dot{m}\left\{h_f\left(T_{d,\mathrm{out}}\right) - h_f\left(T_{d,\mathrm{in}}\right)\right\} dt \quad (6)$$

where $\dot{m}$ is the mass flow rate and h_f is the temperature-dependent enthalpy of the HTF. The volume of the packed bed is calculated with the well-known expression for a conical frustum.

3. Results

The results will be presented in two parts. In the first part, the optimization procedure is illustrated by using a simple TES configuration characterized by two design variables. This allows the objective and constraint functions to be visualized. In the second part, a pilot-scale TES, similar to that shown in [5], is optimized for several combinations of design variables. For the second part, each multi-objective optimization considers the exergy efficiency and the material costs as objective functions and uses the weighted-sum method as shown in Eq. (4) to find Pareto-optimal solutions. Each multi-objective optimization uses 9 values of the weight ($w = \{1.0, 0.99, 0.95, 0.8, 0.5, 0.2, 0.05, 0.01, 0.0\}$) to form the Pareto front. For all configurations, the TES geometry is a truncated cone with variable top and bottom radii. The structure of the TES is given by two concrete layers consisting of ultra-high performance concrete (UHPC) and low-density concrete (LDC) together with two layers of insulation material consisting of Microtherm® (MT) and Foamglas® (FG) as explained in [5]. To calculate the thermal losses through the structure and insulation layers, the outer wall of the TES is assumed to be at ambient temperature. The thermophysical properties of all structure, insulation, and thermal storage materials and the HTF are temperature-dependent as specified in [26]. Each TES simulation is run until a quasi-steady state is reached.

3.1. Visualization of optimization procedure

A simple method to visualize and examine the optimization procedure is to use one or two design variables and plot the objective and constraint functions as a function of the design variables. The visualization of the optimization procedure is done for the pilot-scale TES with a fixed packed-bed height of $H_{\mathrm{PB}} = 8$ m and the top and bottom packed-bed radii of the TES as design variables. The used model parameters are listed in Tab. 2. Fig. 1 shows contour lines of the exergy efficiency, the material costs, the net discharged energy, and the packed-bed volume, as a function of the top and bottom packed-bed radii. The visualization depicted in Fig. 1 is based on 400 quasi-steady-state TES simulations for discrete values of the design variables together with a linear interpolation routine to smooth the contour lines.

Fig. 2 shows on the left-hand side the exergy efficiency as a function of the top and bottom packed-bed radii together with the optimization iterations for different initial conditions and on the right-hand side a close-up of the computed optima together with the predicted optimum. Depending on the initial condition,

the optimizer requires between 12 and 35 iterations to reach the optimum. The computed optima differ by less than 0.01% from the optimum predicted from the interpolated results of the 400 quasi-steady-state simulations. Compared to a systematic approach with twenty discrete values for both design variables and the simulation of all design combinations, the gradient-based optimization reduces the computational cost by about 91 and 97%. This reduction will be even more significant when the number of design variables is increased.

Tab. 2: Operational and geometrical parameters of the pilot-scale TES model.

Operational parameters	charging duration, t_c	8.0 h	Geometrical parameters	void fraction, ε	0.342
	discharging duration, t_d	8.0 h		particle diameter, d_p	0.03 m
	mass flow rate, $\dot{m}_{\mathrm{air}}$	0.75 kg/s		1st concrete layer, l_{UHPC}	0.05 m
	charging temperature, T_c	823.15 K		2nd concrete layer, l_{LDC}	0.3 m

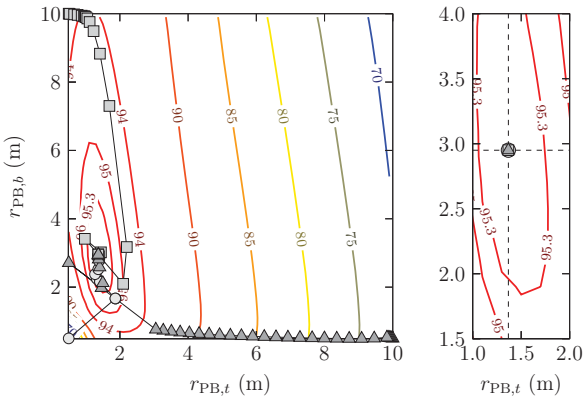

Fig. 2: Left-hand side: exergy efficiency as a function of the top and bottom packed-bed radii of the TES together with optimization iterations for different initial conditions. Right-hand side: close-up of the computed optima for all initial conditions (symbols) and the predicted optimum (dashed lines).

3.2. Pilot-scale TES

To simplify the interpretation of the multi-objective optimization results, the TES configurations have the same operating conditions but different numbers of design variables and constraints. With this approach, the influence of individual design variables on the optimization results can be pointed out. The optimization uses two nonlinear constraints and five design variables as shown in Tab. 3. The nonlinear constraints are the net discharged energy and the packed-bed volume and the design variables are the height, top and bottom radii of the packed bed, the outer insulation-layer thickness, and the particle diameter. For simplicity, the considered structure and insulation materials have on the top, bottom, and side walls of the TES the same thicknesses. Depending on the optimization configuration, the packed-bed volume and some of the design variables are fixed or variable as indicated in Tab. 3. To have a benchmark for the designs, the net discharged energy is used as constraint and must be $\mathrm{E}_{d,\mathrm{net}} \geq 3$ MWh. (For all configurations, $\mathrm{E}_{d,\mathrm{net}}$ does not exceed 3.3 MWh.)

Tab. 3: Nonlinear constraints and design variables of the pilot-scale TES optimization configurations.

Configuration		1	2	3
Nonlinear constraints	net discharged energy, $E_{d,\mathrm{net}}$	≥ 3 MWh	≥ 3 MWh	≥ 3 MWh
	packed-bed volume, V_{PB}	300 m^3	–	–
Design variables	packed-bed height, H_{PB}	8.0 m	0.5–10.0 m	0.5–10.0 m
	top radius, $r_{\mathrm{PB},t}$	0.5–10.0 m	0.5–10.0 m	0.5–10.0 m
	bottom radius, $r_{\mathrm{PB},b}$	0.5–10.0 m	0.5–10.0 m	0.5–10.0 m
	outer insulation, $t_{\mathrm{ins,out}}$	0.1 m	0.1 m	0.01–1.0 m
	particle diameter, d_p	0.03 m	0.03 m	0.001–0.1 m

3.2.1. Configuration 1

The first configuration uses $E_{d,\mathrm{net}} \geq 3$ MWh and $\mathrm{V_{PB}} = 300$ m^3 as nonlinear constraints and the top and bottom packed-bed radii as design variables. With a fixed packed-bed volume, all Pareto-optimal solutions must lie on the contour indicating a packed-bed volume of 300 m^3 in Fig. 1.

Fig. 3 depicts the TES geometries for the two extreme cases $w = 1.0$ and $w = 0.0$ together with the intermediate case $w = 0.5$ according to Eq. (4). (During charging, the HTF enters the TES from the top and exits from the bottom; during discharging, the flow direction is reversed.) The inflow and outflow ports are not indicated in Fig. 3 because they are not considered in the simulations.

For the Pareto optimal designs, a comparison of the TES material costs are presented in Fig. 4. Since the packed-bed volume is constant, the cost of the storage material is constant and the cost reduction is caused by the reduction of the required structure and insulation material. The cost of the storage material is negligible compared to the structure and insulation material. The cheapest design has a cylindrical shape because this minimizes the surface area per volume and accordingly requires the smallest amount of structure and insulation materials.

The Pareto front of the two objective functions is presented on the left-hand side of Fig. 5. The exergy efficiency can only be increased when the TES material costs is increased, which reflects the trade-off between maximizing the exergy efficiency and minimizing the material costs of a TES system. From the Pareto front, it is possible to identify the most efficient TES for a given cost and vice versa. The right-hand side of Fig. 5 shows the exergy efficiency as a function of the top and bottom radii of the packed bed. The difference between the top and bottom radii decreases with decreasing exergy efficiency while the top radius is smaller than the bottom radius until a cylindrical shape is reached. Next to the exergy efficiency, the left-hand side of Fig. 5 also presents the exergy-loss breakdown that indicates how the pumping work, thermal loss, and internal heat transfer decrease the exergy efficiency. The main decrease of the exergy efficiency results from an increase of the thermal loss while the exergy loss due to internal heat transfer stays for all designs almost constant and the required pumping power is negligible.

Fig. 6 shows on the left-hand side the net charged and net discharged exergy for each design. The net charged exergy stays constant and with a negligible exergy loss due to the required pumping power, the exergy efficiency depends mainly on the net discharged exergy. The net discharged exergy increases when the air outflow temperature during discharging increases. The comparison of the HTF outflow temperature during discharging for designs 1 and 9 is shown on the right-hand side of Fig. 6. As expected, for both designs the outflow temperature decreases during discharging while for design 1 the mean outflow

temperature is about 11 K higher than for design 9.

The mean outflow temperature during discharging is strongly influenced by the energy losses through the TES walls, particularly the top wall. Fig. 7 compares for all designs of Configuration 1 and for one charge-discharge cycle the energy losses from the storage material to the structure and insulation material through the top and side walls. When comparing the cheapest with the most efficient design, the losses increase by about 800 and 140%, respectively. This increase depends mainly on the increase of the top radius and accordingly an increase of the surface areas on the top wall and the upper part of the side wall where the temperatures and the temperature gradients to the outside are higher than in the lower section of the TES. The loss through the bottom wall is negligible compared to the top and side wall losses because the bottom wall temperature is close to the ambient temperature.

Fig. 8 shows the thermocline of the fully charged and fully discharged states for designs 1 and 9. The thermoclines of the two designs differ mainly in the upper section where the hot air enters the TES during charging. Compared to design 9, design 1 has a smaller cross-section in the upper part that leads to a higher flow velocity of the HTF and accordingly the temperature front moves further down during charging. An additional effect of the higher flow velocity is a higher Nusselt number that leads to a better interphase heat transfer.

The efficient designs in this study have, as depicted in Fig. 3, a shape like a truncated cone with the smaller cross-section on top and accordingly a negative cone angle. This shape is in contrast to existing designs that are either cylindrical [17] or have a positive cone angle [27, 28]. The trend of negative cone angles having smaller losses is consistent with the results shown in Fig. 13 of [27]. In prior works, negative cone angles appear to have not been considered because of possible drawbacks related to thermal ratcheting. Thermal ratcheting is a well-known problem of packed-bed TES systems caused by different thermal-expansion rates of the storage and structural materials. The different expansion rates can cause the storage material to settle and pack with cycling and eventually cause the storage structure to fail [29, 30]. To prevent material failure, positive cone angles have been suggested as a way to guide the expanding storage material upwards along the inclined wall and hence reduce the stresses on the storage and structural materials [27, 28]. This study does not consider mechanical stresses for simplicity. The practical implementation of a packed-bed thermocline storage with negative cone angle may require structured storage materials [31, 32] or additional material layers between the storage material and the structure to absorb the mechanical stresses [33].

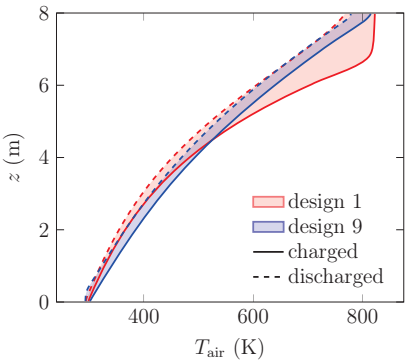

Fig. 8: Air temperature along the axial direction at fully charged and fully discharged state for two designs of Configuration 1.

3.2.2. Configuration 2

The second configuration of the multi-objective TES optimization uses $E_{d,\mathrm{net}} \geq 3$ MWh as a nonlinear constraint and the height and the top and bottom radii of the packed bed as design variables. Compared to Configuration 1, the packed-bed volume is variable. The storage geometries are depicted in Fig. 9 for the two extreme cases $w = 1.0$ and $w = 0.0$ and the intermediate case $w = 0.5$.

Fig. 10 shows the exergy efficiency as a function of the packed-bed height (left), the packed-bed volume (middle), and the material costs (right). When increasing the height, the volume and therefore the material costs increase considerably. An increased height has a favorable influence on the exergy efficiency by expanding the thermocline and reducing thereby the possibility of overcharging and overdischarging the

TES, which leads to an undesirable increase and decrease of the outflow temperatures during charging and discharging, respectively. This trend can be seen in Fig. 11 where the fully charged and discharged thermoclines of the most efficient and cheapest designs are presented. The most efficient design has temperature difference between the fully charged and discharged states of about 10 K at the top and bottom of the storage whereas the temperature differences of the cheapest design are about 200 K. Depending on the application of the TES, the minimum and maximum outflow temperatures during the charge-discharge cycle are important operational parameters that need to be considered during the design phase of the TES. For brevity, the breakdown of the TES material costs is not shown.

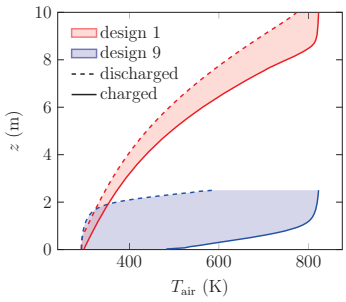

Fig. 11: Air temperature along the axial direction of the fully charged and fully discharged TES for two designs of Configuration 2.

3.2.3. Configuration 3

The third configuration of the multi-objective TES optimization uses $E_{d,\mathrm{net}} \geq 3$ MWh as a nonlinear constraint and the height, the top and bottom radii of the packed bed, the thickness of the outer insulation layer, and the particle diameter as design variables. The TES geometries for the two extreme cases $w = 1.0$ and $w = 0.0$ and the intermediate case $w = 0.5$ are depicted in Fig. 12. Compared to Configuration 2, the main difference of the TES geometries is the increased outer insulation-layer thickness of design 1.

Fig. 13 shows on the left-hand side the exergy efficiency as a function of the outer insulation-layer thickness consisting of Foamglas®. As expected, the more efficient designs have a larger insulation-layer thickness, which reaches the upper limit of 1.0 m and the lower limit of 0.01 m for the most efficient and for the cheapest designs, respectively. Increasing the insulation-layer thickness reduces the thermal losses through the top, bottom, and lateral walls but also increases the material costs as indicated on the right-hand side of Fig. 12. A breakdown of the material costs is shown in Fig. 14. For all designs, the cost for the insulation materials is the major contributor to the total TES material costs while the cost for the storage material is negligible. The four most efficient designs have an outer insulation-layer thickness between 0.66 and 1.0 m that contributes to about half of the total costs. Reducing the required amount of the insulation material is therefore essential to reduce the material costs.

Fig. 15 presents the exergy efficiency and the exergy-loss breakdown as a function of the particle

diameter. The exergy efficiency increases with increasing particle diameter. The least efficient design has a particle diameter that is equal to the lower limit of 1.0 mm while the most efficient design has a particle diameter that is 21.5 mm and therefore below the upper limit of 100.0 mm. A decreasing particle diameter influences the TES performance in two ways: it increases the heat transfer between the solid and fluid phase and it increases the pressure drop over the packed bed. An increasing heat transfer reduces thermal irreversibility and therefore increases the exergy efficiency while an increasing pressure drop increases the exergy loss due to the required pumping power and therefore decreases the exergy efficiency. The strong increase of the required pumping power for very small particles can be seen from the exergy-loss breakdown in Fig. 15. For design 9, the required pumping power is about 140 times bigger than for design 1. The increase of the heat transfer between the solid and fluid phase for a decreasing particle diameter results mainly from an increase of the specific surface area. The optimal particle diameter is therefore a trade-off between increasing the pressure drop and increasing the interphase heat transfer.

4. Summary and Conclusions

A gradient-based multi-objective optimization method was used to optimize the exergy efficiency and the material costs of packed-bed TES systems based on their height, top and bottom radii, insulation-layer thickness, and particle diameter. Competing objectives like maximizing exergy efficiency and minimizing material costs are treated using Pareto fronts. The Pareto front shows the best possible TES designs and enables the most efficient TES for a given cost to be determined.

A systematic optimization of three pilot-scale TES configurations was used to point out the

influence of individual design variables on the exergy efficiency and material costs. In general, increasing the TES height increases the exergy efficiency but also increases the material costs. The optimization of the top and bottom radii showed that a TES design with a negative cone angle has a higher exergy efficiency than commonly used cylindrical shaped TES or designs with a positive cone angle. This results mainly from a reduced surface area in the hot upper section of the TES and therefore decreased thermal losses to the environment. The basic thermodynamic mechanisms leading to the superior performance of a TES with a negative cone angle were identified with detailed information about the axial temperature distribution in the packed bed and thermal losses through the structure and insulation materials. The potential mechanical drawbacks of a negative cone angle related to thermal ratcheting are not considered in this work but could perhaps be solved by using structured storage materials without loose particles or material layers that absorb the thermomechanical stress during charge-discharge cycles. Detailed material-cost breakdowns showed that for low-cost storage materials like rocks, a reduction of the required insulation material is essential to further reduce the TES material costs. In addition, the optimization revealed the trade-off between reducing the pressure drop and improving the interphase heat transfer when optimizing the particle diameter.

EXPERIMENTAL AND SIMULATIVE CHARACTERIZATION OF A FIN AND TUBES HEAT EXCHANGER WITH PCM FOR PROCESS HEAT APPLICATIONS

Hannah Neumann[1], Dominik Seiler[1], Peter Schossig[1] and Stefan Gschwander[1]

[1] Fraunhofer Institute for Solar Energy Systems ISE, Freiburg (Germany)

Abstract

Thermal storage is one option to make solar or conventional process heat applications more efficient. Phase change material (PCM) storages offer the potential to keep constant temperatures for different time periods. In this paper a fin and tubes heat exchanger filled with the sugar alcohol D-mannitol was characterized regarding its usability as PCM storage in the temperature range between 100 and 250 °C. D-mannitol melts at ca. 166 °C. Different heating and cooling experiments were carried out. The specific heat capacity of the PCM as well as the latent heat was determined. The heat flow into the storage was determined at different mass flow rates for heating and cooling processes. During the measurements thermal losses to the ambient were very high leading to high uncertainties. Due to the viscosity of D-mannitol natural convection between the fins seems to have no significant influence on heat transfer during melting of the PCM. Some results led to the assumption that the heat distribution in the heat exchanger was not even. A simulation model was created and a first validation was carried out. Geometry improvement with the aim of more even heat distribution and higher charge and discharge power will be carried out by using the simulation model and further measurements.

Keywords: *Phase Change Material, D-mannitol, fin and tubes heat exchanger*

1. Introduction

Thermal storage offers the potential to increase energy efficiency of solar or conventional process heat applications. Thermal storage based on phase change materials (PCM) is advantageous for applications having to ensure small temperature differences during several hours. PCM can store high energy densities in small temperature ranges due to the phase change from solid to liquid. When storing above 100 °C PCM storages can be run unpressurised compared to water storages. In the temperature range between 100 and 250 °C sugar alcohols are potential candidates. They have higher storage densities than other materials in this temperature range.

In order to charge and discharge a PCM storage with sufficient power a suitable heat exchanger type has to be chosen. In a recent project a heat exchanger concept based on plates will be developed. As a reference for comparison an optimized fin and tubes heat exchanger with PCM will be used.

In this paper the characterization of the fin and tubes heat exchanger in combination with a sugar alcohol will be described. It was experimentally characterized in a testing facility. From the results first information about the behavior of the heat exchanger as well as about the PCM in application scale could be derived.

2. Experimental setup

Fig. 1, top left, shows a picture of the empty fin and tubes heat exchanger. Its inner dimensions are 270 x 259 x 81 mm. The distance between the fins is 4.5 mm with a fin thickness of 0.3 mm. The heat exchanger is made of stainless steel. Fig. 1, bottom left, shows the dimensions in cross section. The height of the fins is 28 mm. Under the fins is a gap of 26.5 mm. Thus when filling the heat exchanger with PCM, a 26.5 mm PCM layer will be under the fins. The temperature of the PCM is measured at the same height as the tubes, at three different locations in the heat exchanger (indicated in Fig.1, right). Additionally the temperature at the inner and outer surfaces of the insulation surrounding the heat exchanger is measured (the insulation is not visible in Fig. 1).

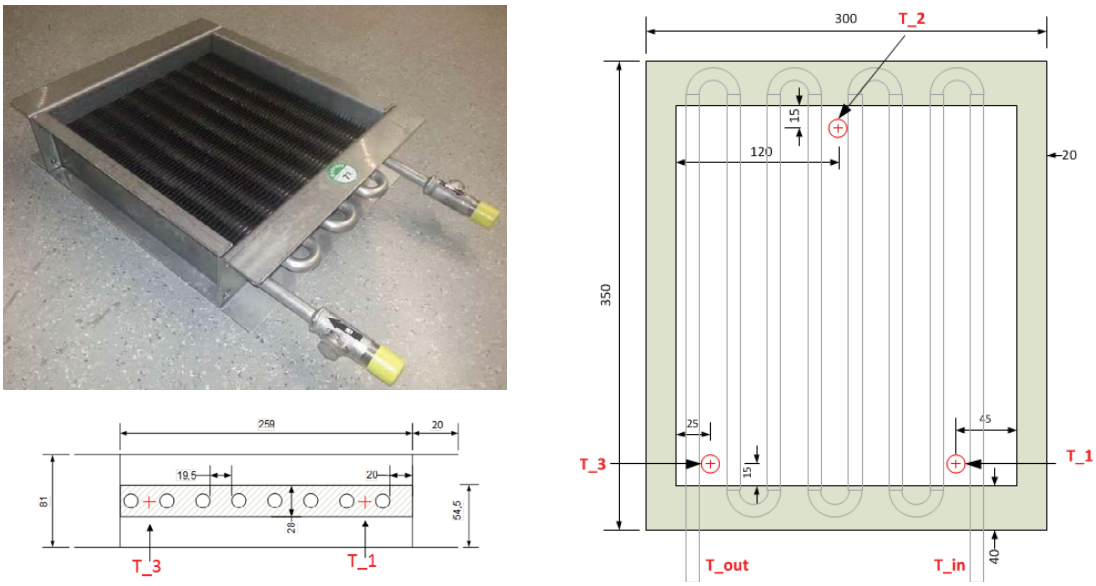

Fig. 1: Top left: fin and tubes heat exchanger used as PCM storage, bottom left: cross section of the heat exchanger with position of temperature sensors, right: position of temperature sensors from top view

In the testing facility thermal oil is used as heat transfer fluid (THERMINOL® 66 from FRAGOL GmbH+Co. KG). Mass flow is measured using a Coriolis mass flow meter. At the inlet and outlet of the heat exchanger the temperature of the oil is measured (Fig. 1, right).

The heat exchanger was filled with the sugar alcohol D-mannitol having a melting temperature of ca. 166 °C. Thermal properties of D-mannitol are presented in Tab. 1. The measurements not given a source were measured at Fraunhofer ISE.

Tab. 1: Thermal properties of D-mannitol

Property	Value solid	Value liquid	Material	Source
c_p (kJ kg^{-1} K^{-1})	1.79 (at 120 °C)	2.75 (at 180 °C)	Batch 1	
ρ (kg m^{-3})	1390 (at 150 °C)	1267 (at 170 °C)		(Godin, 2015)
k (W m^{-1} K^{-1})	0.88 (at 130 °C)	0.43 (at 190 °C)	Batch 2	
η (Pa s)	-	0.046 (at 170 °C)	Batch 2	
β (1 K^{-1})		1.3 * 10^{-3}		Based on (Godin, 2015)
Δh_m (kJ kg^{-1})	258.3 / 233.8		Batch 1 / Batch 2	
T_{onset} (°C)	160.9 / 150.4		Batch 1 / Batch 2	

3. Theory

To characterize the heat exchanger several properties were calculated.

The packing factor of the storage was calculated according to (Castell et al., 2011):

$$PF = \frac{V_{PCM}}{V_{storage}} \quad \text{(eq. 1)}$$

Heat flow of the heat transfer fluid was calculated as:

$$\dot{Q}_{HTF} = \dot{m}_{HTF} * c_{p\_HTF} * (T_{in} - T_{out}) \quad \text{(eq. 2)}$$

The energy balance equation is written as:

$$\int_0^t \dot{Q}_{HTF}\, dt = \int_0^t \dot{Q}_{loss}\, dt + Q_{HX} + Q_{PCM} \quad \text{(eq. 3)}$$

The energy of the insulation material was neglected.

With

$$Q_{HX} = m_{HX} * c_{p_{HX}} * dT \quad \text{(eq. 4)}$$

$$Q_{PCM} = m_{PCM} * c_{p_s} * \left(T_{pc} - T_{start}\right) + m_{PCM} * \Delta h_{PCM} + m_{PCM} * c_{p_l} * \left(T_{end} - T_{pc}\right) \quad \text{(eq. 5)}$$

The UA-value was calculated as:

$$U * A = \frac{\dot{Q}_{HTF}}{\Delta T_{lm}} \quad \text{(eq. 6)}$$

with the logarithmic mean temperature difference for a PCM storage according to (Mehling and Cabeza, 2008):

$$\Delta T_{lm} = \frac{\left(T_{pc} - T_{in}\right) - \left(T_{pc} - T_{out}\right)}{ln\frac{T_{pc} - T_{in}}{T_{pc} - T_{out}}} \quad \text{(eq. 7)}$$

The effectiveness was calculated according to (Castell et al., 2011) as follows:

$$\varepsilon = \frac{T_{in} - T_{out}}{T_{in} - T_{pc}} \quad \text{(eq. 8)}$$

The PCM temperature was assumed to be a mean value of the three measured temperatures in the PCM:

$$T_{pc} = \frac{(T_1 + T_2 + T_3)}{3} \quad \text{(eq. 9)}$$

4. Experiments

In the beginning measurements with the empty heat exchanger were carried out. Thermal losses to the ambient were determined at different temperatures and mass flow rates. Before starting the measurements the temperature was kept constant until steady state was reached. During the measurements a constant inlet temperature T_{in} was supplied for half an hour. $\dot{Q}_{loss}$ was calculated using (eq. 2). Afterwards the specific heat capacity of the empty heat exchanger was determined. Therefor a step function was implemented to the inlet temperature T_{in}. Calculation was done with (eq. 3) and (eq. 4). In (eq. 3) Q_{loss} was calculated from the determined losses in the measurement before and $Q_{PCM}$was zero. The results of these experiments were needed to calculate further values of the heat exchanger filled with PCM.

Afterwards the heat exchanger was filled with D-mannitol. The material was filled until the upper end of the fins. Thus a gap of air was left to tolerate the volume change of the PCM. D-mannitol was filled into the heat exchanger in fresh form, thus as a powder. Once the powder was filled until the upper end of the fins, it was heated over the phase change and cooled down again. Thus it melted and crystallized once. After crystallizing, the D-mannitol was a solid mass. Since the density of D-mannitol in this state is much higher than the one of the powder, five of these filling, melting and crystallization processes were necessary. During these processes coloration to brown started which is a hint for degradation (Solé et al., 2014).

After finishing most experiments a second filling process was done, because some experiments (heating and cooling through the phase change) were repeated using fresh material. For this filling process the D-mannitol was melted in an oven and afterwards poured into the heat exchanger in liquid state. Thus only one melting cycle was necessary leading to less degradation during the filling process.

In all experiments with D-mannitol a step function was implemented to the fluid inlet temperature T_{in} at constant mass flow. Before starting an experiment the oil inlet temperature was kept constant for several hours to reach steady state. First, experiments in sensible state of the PCM were carried out (in solid and in liquid state) in order to determine the specific heat capacity of the PCM in solid and liquid state. The calculation of the specific heat capacity was done using (eq. 3) and (eq. 4). Afterwards measurements including the phase change were carried out. Several step functions for heating and cooling at different mass flow rates were performed and analyzed. The latent heat, the UA-value, the effectiveness and the heat flow were calculated for this case using (eq. 2) to (eq. 9).

5. Results and discussion of experiments

5.1 Packing factor

In total 4.29 kg of D-mannitol were implemented into the heat exchanger during the first filling. As described, some experiments were repeated using fresh material and a different filling procedure. Using this procedure the heat exchanger was filled with 5.1 kg of D-mannitol. The filling level after the second procedure was a bit higher than after the first one. The PCM contents lead to packing factors according to (eq. 1) of 0.55 after the first filling and 0.61 after the second filling taking into account the inner dimensions of the heat exchanger (and thus the air gap). The packing factor of this heat exchanger mainly depends on the dimensioning of the air gap on top of the fins and the PCM layer under the fins.

5.2 Thermal losses

Fig. 2 shows the results of the thermal losses to the ambient measured in empty state of the heat exchanger. They increase with increasing oil inlet temperature T_{in}. The relative standard uncertainty of the thermal losses is quite high (up to 25 %). The reason for that is the small temperature difference between oil inlet and outlet temperature.

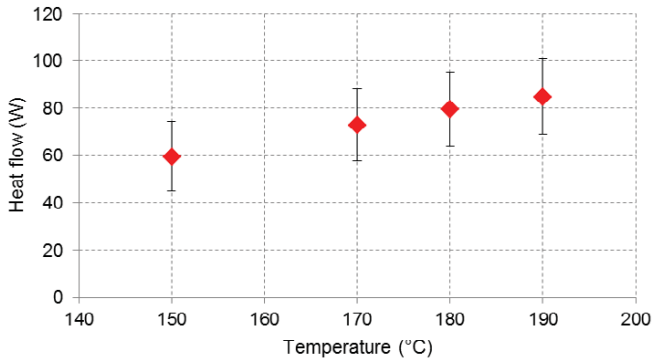

Fig. 2: Thermal losses of the heat exchanger through the insulation material at a mass flow rate of 5.5 kg/min and different oil inlet temperatures T_{in}

5.3 Natural convection

In liquid state of the PCM natural convection can occur. This heat exchanger has two different regions of PCM: the region between the fins and the PCM layer under the fins (see Fig. 1). The Rayleigh number for the region between the fins was calculated according to (Deborah A. Kaminski, Michael K. Jensen, 2011) (natural convection in vertical enclosures). The exact value of the Rayleigh number depends on the material property data. The expansion coefficient β was calculated based on density literature data and its uncertainty is not clear until now. A lower expansion coefficient would lead to a lower Rayleigh number. According to (Deborah A. Kaminski, Michael K. Jensen, 2011) viscous forces are much larger than buoyancy forces and no fluid motion occurs if the Rayleigh number is lower than 2000. Fig. 3 shows the calculated Rayleigh numbers depending on the fin distance and for three temperature differences between liquid PCM and wall. Assuming a temperature difference of 5 K, the Rayleigh number reaches 2000 at a fin distance higher than 5 mm. For a temperature difference of 10 K the value is reached slightly above 4 mm. Taking into account a temperature difference of 15 K, it is reached at approximately 3.6 mm.

It is assumed that natural convection will start developing slowly at Rayleigh numbers higher than 2000. In completely liquid state natural convection between the fins might occur very weakly in the present heat exchanger at temperature differences between PCM and fin higher than 10 K. During the melting process it is assumed that natural convection between the fins has no significant influence on the heat transfer of the heat exchanger. During melting the gap between the melted and the still solid PCM will grow. Until a liquid layer of 3.6 to 4 mm is reached, no natural convection will occur. After that, it might occur very weakly, but as the gap is only 4.5 mm width, most of the melting process has already happened without natural convection.

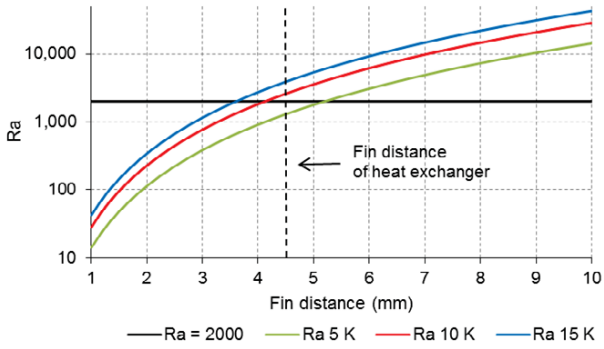

Fig. 3: Raleigh number of D-mannitol in a vertical enclosure according to (Deborah A. Kaminski, Michael K. Jensen, 2011)

In the PCM layer under the fins natural convection should occur when the PCM is completely in liquid state. Heating and cooling of the PCM layer takes place from the top. So during cooling convection in this region should be developed more intense than during heating.

5.4 Temperature profiles and temperature distribution in the PCM

Fig. 4 shows two examples of the step functions carried out in the sensible state of the PCM, the left one in solid and the right one in liquid state. Oil inlet and outlet temperature as well as the three PCM temperatures are shown. At the time the measurements were stopped the PCM had not reached the oil temperature. In solid state the PCM temperatures come closer to the oil temperature after 60 min than in liquid state. This is due to the higher heat conductivity of the solid PCM compared to the liquid PCM. As the PCM temperatures are measured between the fins and the temperature difference between the oil and the PCM is lower than 5 K after 60 min no natural convection occurs. Thus heat conductivity is the dominant factor for heat transfer in this case.

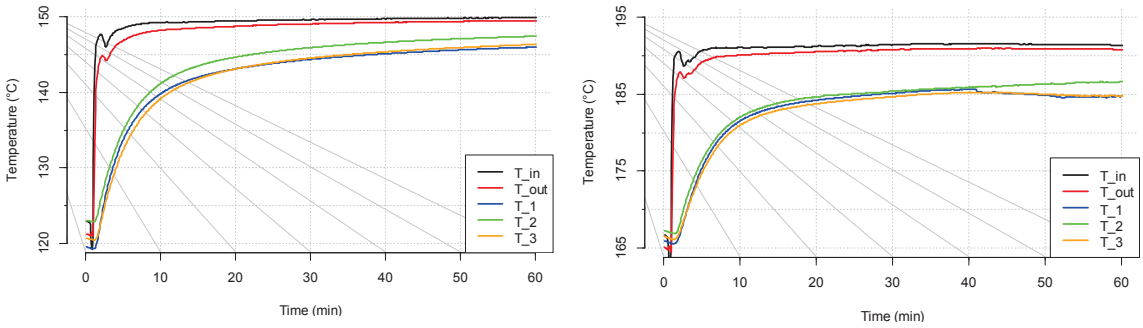

Fig. 4: Left: step function in solid state of the PCM (mass flow = 5.8 kg min^{-1})
right: step function in liquid state of the PCM (mass flow = 6 kg min^{-1})

Fig. 5 shows one melting (left) and one crystallization cycle (right) of the PCM in the heat exchanger. The inlet and outlet temperature of the oil as well as the PCM temperature is shown. Melting takes place at ca. 165 °C whereas the crystallization plateau is visible at 162.5 °C, thus a hysteresis of 2.5 K is visible. Additionally supercooling takes place during crystallization. DSC-measurements of D-mannitol showed hysteresis of up to 40 K (Solé et al., 2014). The much lower hysteresis in the heat exchanger can have several reasons: I) it could be due to the higher sample mass. II) If not all the PCM was melted in the heating cycle before, the still solid PCM could have acted as nucleus. III) The surface of the heat exchanger could also have acted as nucleus. This will be examined in future work.

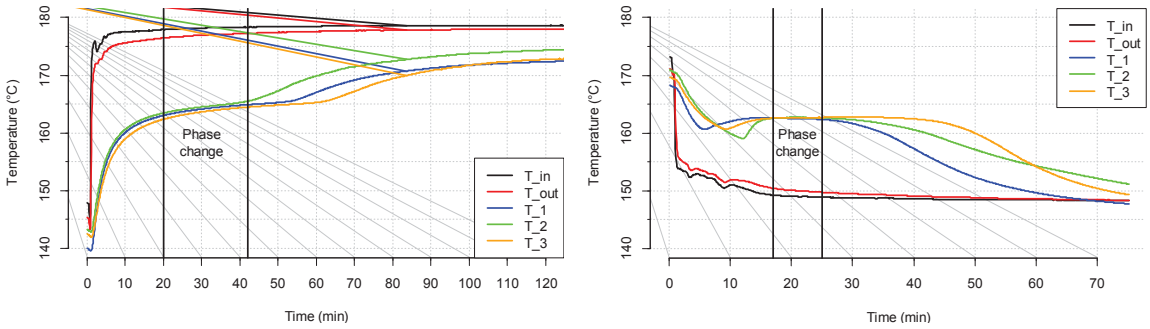

Fig. 5: Left: melting of the PCM; right: crystallization of the PCM both at a mass flow rate of 5.5 kg min^{-1}

Fig. 6 shows one measurement during the phase change. In this case the temperature sensors in the PCM were put deeper into the PCM close to the bottom plate of the heat exchanger. At the end of the measurement the PCM temperatures reach 170 °C, which is slightly above the melting temperature or could still be at the upper end of the melting range. Nevertheless the PCM temperature does not show a visible melting plateau.So it cannot be assured that the PCM at all locations of the heat exchanger was melted completely. The other measurements during the phase change were stopped after 180 min. Thus in these measurements it cannot be assured that all the PCM in the heat exchanger was melted, especially in the ones with lower temperature differences between oil inlet temperature and PCM temperature.

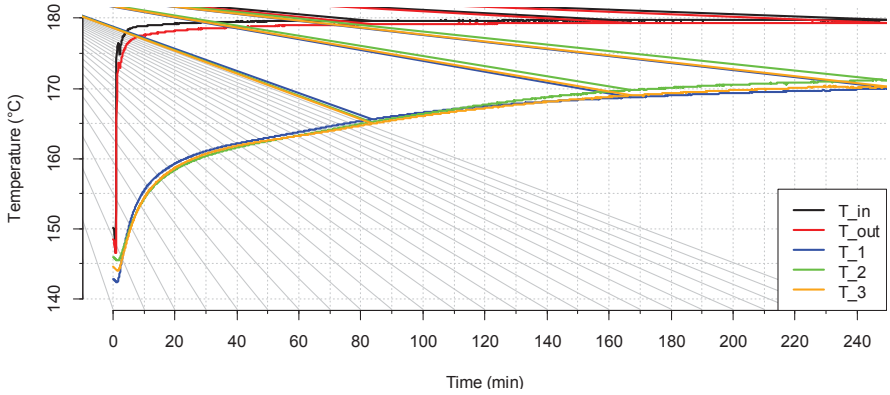

Fig. 6: Melting of the PCM with temperature sensors close to the bottom plate at 8 kg min^{-1}

At the right margin of the heat exchanger the distance between tube and margin is higher than the distance between the tubes in the other parts of the heat exchanger (see Fig. 1, right). After having finished all measurements and opened the heat exchanger, it was visible that the PCM in this part was less brown than the rest of the PCM surface, which might be an indication for less degradation. This effect might have been caused by lower temperatures occurring in this part or by melting this PCM less often than the PCM in the other locations. The darkest brown parts visible in Fig. 7 are on top of the tubes. It could be an indication that the PCM above the tubes was exposed to the highest temperatures.

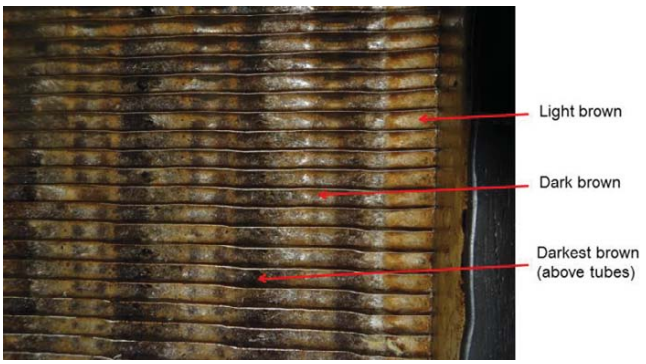

Fig. 7: Surface of the D-mannitol in the heat exchanger after having finished the experiments. The surface close to the right margin is lighter brown than the rest of the surface. The material above to the tubes shows the darkest brown coloration.

5.5 Determination of specific heat capacity and latent heat

Tab. 2 shows a summary of the calculated specific heat capacity and latent heat. Given values are mean values of several measurements. A comparison of the obtained cp-value for the empty heat exchanger with literature data shows good accuracy.

Tab. 2: Summary of determination of specific heat capacity and latent heat

Measurement	Result (mean value)	Comparative DSC-measurement respectively literature value
c_p HX (empty) (kJ kg^{-1} K^{-1})	0.55 +/- 11.3 % (at 152.6 °C)	0.518 (at 150°C) (Richter)
c_p D-mannitol solid (kJ kg^{-1} K^{-1})	1.65 +/- 33.3 % (at 134.2 °C)	1.79 +/- 5 % (at 120 °C)
c_p D-mannitol liquid (kJ kg^{-1} K^{-1})	2.86 +/- 28.5 % (at 175.9 °C)	2.75 +/- 5 % (at 180 °C)
Δh_m (kJ kg^{-1})		
1st filling	142.8	Fresh material: 258.3 After measurements in HX: 200.0
2nd filling	179.5	Fresh material: 233.8 After measurements in HX: 219.3

Comparing the specific heat capacity of D-mannitol in solid and liquid state to DSC-measurements, it is visible that the value of the solid state is lower than DSC and the one of liquid state is higher than the DSC measurement. Both heat exchanger measurements were stopped after 1 h (see Fig. 5). It is assumed that no homogeneous temperature distribution in the PCM was reached as the lower PCM layer is not well thermally coupled to the rest of the heat exchanger. This leads to an underestimation of the specific heat capacity. In liquid state heat transfer in the PCM layer under the fins might take place faster due to convection in this part. The high standard uncertainty of the thermal losses (see Fig. 2), that are taken into account in the calculation of the specific heat capacity, additionally lead to a deviation between the measurements in the heat exchanger and in the DSC.

The standard uncertainty of the specific heat capacity of the empty heat exchanger is lower than the one of the specific heat capacity of the PCM in solid and liquid state. The reason is the shorter measurements time of ten minutes in case of the measurement of the empty heat exchanger compared to 1 h in the other two cases. When considering energy balances, the uncertainty increases with increasing measurement time due to the uncertainty of the losses to the ambient (see Fig. 2).

The comparison of the latent heat with DSC-measurements shows differences. DSC-measurements of the PCM were carried out before filling the heat exchanger and after finishing all measurements. A decrease from 258.3 to 200.0 kJ kg^{-1} takes place. This is due to the degradation of D-mannitol under oxygen atmosphere (Solé et al., 2014). The calculation of the latent heat based on the heat exchanger measurements gives a value of 142.8 kJ kg^{-1} and thus almost 60 kJ kg^{-1} lower than the DSC-measurement after the treatment in the heat exchanger. Due to the geometry of the heat exchanger it could not be ensured that the PCM below the fins was melted completely (see Fig. 6). In the calculations the mass of the whole PCM is taken into account instead of only the molten part, which leads to an underestimation of the latent heat. A further reason for the difference between the measurements in the DSC and in the heat exchanger is the standard uncertainty of the heat losses to the ambient of the heat exchanger of up to +/- 16 W (see Fig. 2). Due to the long measurement time to determine latent heat of up to 3 h, the high standard uncertainty of the heat losses lead to an even higher standard uncertainty of latent heat. When calculating the latent heat with heat losses that are 16 W lower, a latent heat of approximately 180 kJ kg^{-1} is calculated. After the second filling the difference is a bit lower. In this case the temperature difference between inlet temperature and melting temperature was higher. So it might be possible that more PCM was melted.

5.6 Characterization of the phase change period

To be able to compare the performance of the investigated heat exchanger to the performance of other heat exchangers, some characteristic parameters were calculated. As the heat exchanger is used to melt or crystallize the PCM inside the storage, the parameters were calculated for these phase transitions (marked in Fig. 5). Afterwards a mean value over the phase change period was calculated to compare different measurements to each other.

Fig. 8 (left) shows the mean value of the heat flow of the heat transfer fluid during the phase change (absolute value). The logarithmic mean temperature difference between PCM and heat transfer fluid (see Fig. 8, right) was almost the same in all measurements, but in the case of crystallization with the mass flow of 1.8 kg min^{-1} it was lower than during melting.

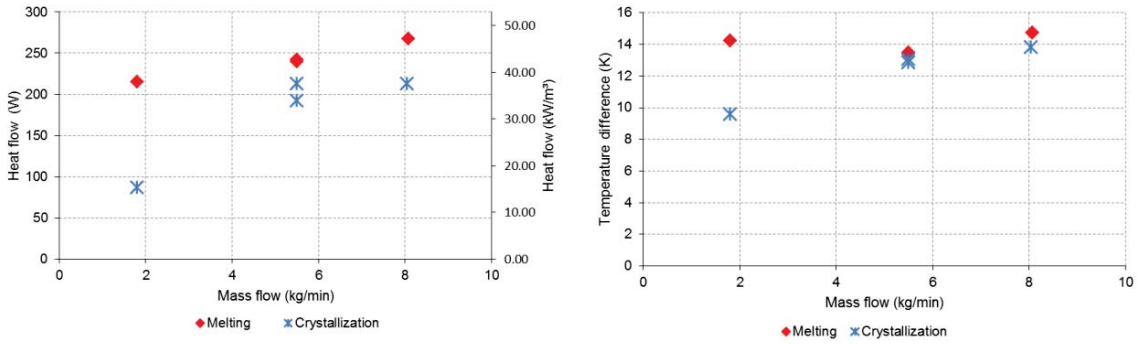

Fig. 8: Left: mean value of the heat flow ($\dot{Q}_{HTF}$) during the phase change (absolute value), right: mean value of the logarithmic mean temperature difference between PCM and heat transfer fluid during the phase change

To make the obtained heat flows comparable to each other, the UA-value of the heat exchanger was calculated taking the heat flow and the logarithmic mean temperature difference of Fig. 8 into account. Fig. 9 shows the results.

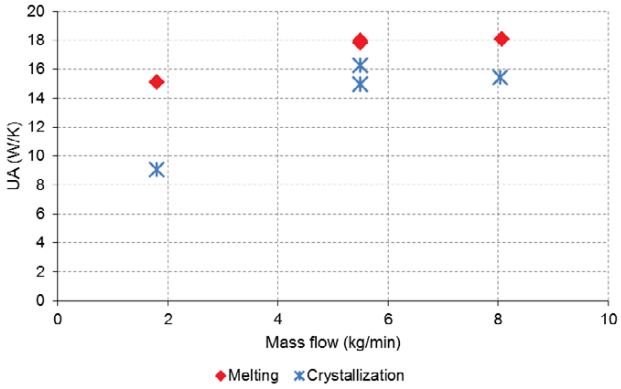

Fig. 9: UA-value at different mass flow rates

According to the results the UA-value is higher during melting than during crystallization. This result has to be interpreted carefully, because many uncertainties due to the way of calculating the UA-value appear. For calculating the UA-value of the heat exchanger properly, it would be necessary to consider only the heat flow between the heat transfer fluid and the PCM. The calculation for Fig. 9 was done using the heat flow of the heat transfer fluid ($\dot{Q}_{HTF}$) according to (eq. 2). This heat is not completely transferred to the PCM. During charging part of it goes to the storage enclosure and from there to the ambient and to the colder PCM. Thus the UA-value is overestimated. During discharging, not only the heat of the PCM is transferred to the heat transfer fluid, but also heat from the storage envelope. Part of the heat from the envelope and most likely from the PCM also goes to the ambient. Thus for discharging it cannot be judged if the UA-value is under- or overestimated without further investigation. In order to evaluate the UA-value properly further measurements and calculations have to be carried out to determine only the heat transfer between the heat transfer fluid and the PCM.

A further uncertainty is the calculation of the logarithmic mean temperature difference. The phase change temperature T_{pc} was calculated as a mean value of the three temperature sensors inside the PCM. As all of them are installed between the fins, the temperature regarded as PCM temperature might not be representative for the whole PCM. The phase change might take place at different times in different parts of the PCM.

Fig. 10 shows the effectiveness of the heat exchanger. It increases with decreasing mass flow. In case of the mass flow rate of 1.8 kg min^{-1} the effectiveness during crystallization is lower than during melting. The reason is the smaller logarithmic mean temperature difference during crystallization compared to melting (see Fig. 8, right). The effectiveness of this heat exchanger is low compared to other PCM-storages. (Castell et al., 2011) reach more than 50 % in a tube in PCM tank. One reason could be that the PCM layer under the fins is not

activated properly. Additionally the mass flow could be further reduced to increase the effectiveness.

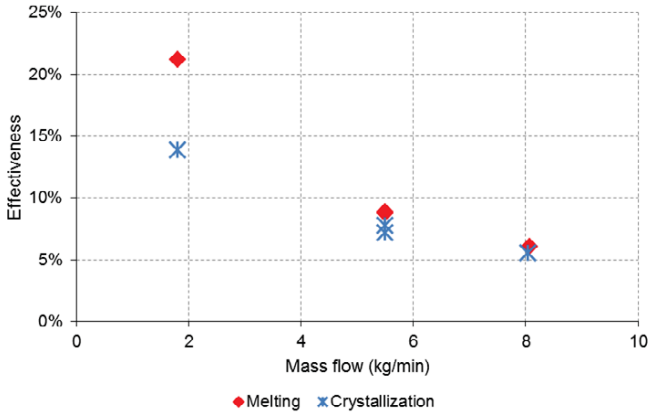

Fig. 10: Mean value of the effectiveness during the phase change

6. Model validation and simulation

A simulation model for the fin and tubes heat exchanger was created in COMSOL Multiphysics. A first model validation was carried out for one heating and one cooling cycle. Material properties of D-mannitol were chosen according to Tab. 1. Latent heat of the PCM was introduced to the model based on measured data from the DSC. Natural convection in liquid part of the PCM was not taken into account (neither between the fins nor in the PCM layer under the fins). The envelope and the insulation of the heat exchanger were not taken into account. Losses to the ambient were introduced as constant heat flow with values taken from the measurements according to Fig. 2. A comparison of the oil as well as PCM temperatures for the heating and the cooling case are shown in Fig. 11.

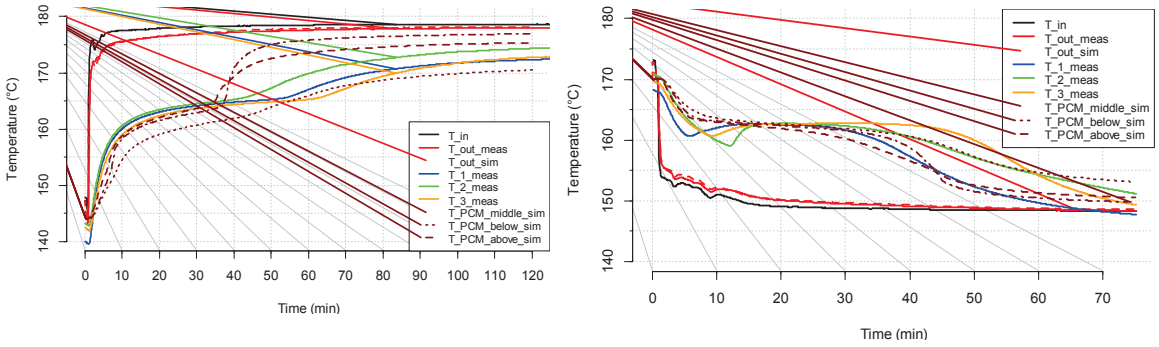

Fig. 11: Validation of the simulation model at a mass flow rate of 5.5 kg min^{-1}: comparison of simulated and measured temperatures for heating (left) and cooling (right)

The highest differences are visible in the PCM temperatures. One uncertainty is the latent heat of the D-mannitol due to its degradation. Measurements of the latent heat were carried out with the fresh material and after having finished all experiments. This experiment taking for validation was done at some time in between the two DSC measurements. Thus the value for the latent heat of the fresh material will be too high and the one of the degraded PCM will be too low. The DSC data taken is the one of the fresh material, thus latent heat in this simulation might be overestimated. The simulation shows that the height of the locations where temperature is measured is important. In the measurements it cannot be assured if the PCM temperature was measured exactly at a height in the middle of the tubes. The simulation shows that moving the temperature sensor 1 cm up or down can lead to temperature differences of up to 5 K.

In the cooling case the melting temperature of the PCM was shifted downwards 2.5 K. The nucleation is not modeled. Still the PCM temperatures seem to fit better to the measurement during cooling than during heating.

Although there are still uncertainties in model validation, the model reproduces the main characteristic of the fin and tubes heat exchanger with D-mannitol. That is why the model was already used to compare the heating and cooling process under similar circumstances to each other.

The same model used for validation was used in a simulation, but this time no losses to the ambient were introduced. Thus all the heat from the heat transfer fluid was transferred via the heat exchanger to the PCM. The envelope was not taken into account in this simulation. Fig. 12 shows the results of the UA-value. Here the result during crystallization is higher than during melting. As natural convection was not taken into account, thermal conductivity is crucial for the heat transfer. During melting it is the thermal conductivity in liquid PCM, during crystallization it is the one in solid state. Thermal conductivity in solid state is two times higher than the one in liquid state. This characteristic could not be shown in the measurements until now due to the above described reasons. Thus, the model helps to analyze the heat transfer processes in the heat exchanger in more detail and will be used for further analysis and optimization.

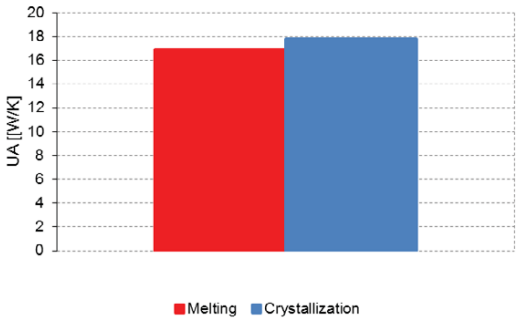

Fig. 12: Comparison of UA-value during melting and crystallization from a simulation without thermal losses to the ambient

7. Conclusion and outlook

A fin and tubes heat exchanger with D-mannitol was experimentally characterized. A simulation model was created and a first validation was carried out.

During experimental characterization the thermal losses to the ambient were very high in relation to the heat transfer of the heat exchanger itself. To reduce the losses and make the boundary conditions of different measurements more comparable a heating device will be installed around the heat exchanger in future. Thus ambient temperature will be raised and thermal losses reduced.

More temperature sensors will be installed in future experiments to determine the heat transfer more exactly. Inside the PCM more sensors are needed to determine temperature differences in the PCM as seen in the simulation. Especially differences in the height of the PCM are expected.

The strong degradation of D-mannitol in oxygen atmosphere leads to uncertainties during evaluation of the experiments and model validation. To reduce the degradation of D-mannitol the experiments should be carried out under controlled atmosphere. Alternatively a different PCM with a melting temperature between 100 and 250 °C that does not show degradation should be used.

When using D-mannitol as PCM a larger fin distance than 5 mm seems to be reasonable to increase charging power by the influence of natural convection. How much natural convection influences charging power at higher fin distance shall be examined by further tests and simulation. In general, the effect of different fin distances for charging and discharging process shall be tested by using the simulation model and further measurements.

The simulation model has to be improved. The envelope and the insulation will be taken into account to reduce deviations to the measurements. Additionally natural convection will be implemented in order to determine its effect also with the help of the simulation model. By improving the measurements with the means stated above, it will be possible to carry out the model validation with more accuracy.

To increase the thermal power of the PCM heat exchanger it might be reasonable to fabricate it out of a material with higher heat conductivity than stainless steel, e.g. aluminum. To ensure that the whole PCM will be melted or crystallized in convenient time, the layer of PCM below the fins should be reduced, thus the fins should reach the bottom plate of the heat exchanger. Further geometry parameters as fin thickness, piping and outer dimensions will be optimized by the help of the simulation model.

Abstract

Urban design and local boundary conditions have been detected to significantly affect the local microclimate and, therefore, the environmental quality of urban areas. In this view, the purpose of the present work is to investigate the local microclimate variation in historic districts with respect to the surrounding areas situated in the same temperate climate zone. To this aim, four areas around a historical city center in Italy were monitored during summer 2015 and investigated through microclimate simulation in summer and winter conditions. After the experimental monitoring, that allowed to characterize the main microclimate parameters of each case study area, a calibrated numerical analysis was performed in order to assess the Urban Heat Island (UHI) intensity of the historical district and the implementation passive mitigation techniques. Therefore, the effectiveness of thermal storage solutions as innovative UHI mitigation technique was studied by simulating the implementation of Phase Change Materials (PCMs) within (i) the buildings' walls and (ii) the outdoor pavement of the historic neighborhood. Thermal benefits due to the application of phase change materials were detected both in summer and winter. In summer, the high-capacity PCMs integrated pavement is able to reduce the outdoor air temperature by a maximum of about -0.3 K. On the other hand, in winter, the increased thermal storage potential seems to mitigate the nighttime cooling.

Keywords: *Urban Heat Island, Experimental monitoring, Numerical analysis, Microclimate simulation, Phase Change Materials*

1. Introduction and Motivation

Local microclimate can be significantly altered due to the complex interaction between microclimate parameters and the thermal-optical properties of urban and buildings' surfaces. Urban Heat Island (UHI) represents one of the main microclimate phenomenon able to generate discomfort in urban areas due to the high building density, lack of vegetation, reduced surfaces sky view factor, and convective mixing (Santamouris et al., 2015). Moreover, more than half of the world's population is living in urban settlements. Therefore, the necessity to design efficient, sustainable, and healthy built environments is becoming a crucial issue for both designer and urban planners (Nikolopoulou et al. 2001).

Many UHI mitigation strategies have been proposed over the course of the years, such as green and cool materials (Akbari et al., 2016; Galli et al., 2013; Santamouris, 2014) and tested through experimental and numerical analysis (Allegrini et al., 2015). On the contrary, the use of thermal storage technologies for such purpose (Navarro et al., 2016) as a further outdoor microclimate mitigation strategy is still not very well investigated. However, PCM doped infrared reflective coatings were proved to present lower surface temperatures than common and cool coatings of the same color (Kolokotsa et al., 2013). In particular, peak temperature differences occurred between PCM and common or cool coatings from 7:00 and 10:00 a.m. In this view, some works studied the performance of roofs with PCMs and cool materials to mitigate UHI

doi:10.18086/eurosun.2016.03.05 Available at http://proceedings.ises.org

effect. For instance, Roman et al. (2016) performed different thermal energy simulations of cool roof and PCM based roof with varying climatic zones within the United States. In general, increased albedo led to better performance in terms of UHI effect reduction. However, PCM roof showed a heat flux from roof surface to the surrounding environment of 40 % lower than the cool roof technology. By using experimental tests, Chung and Park (2016) analyzed PCM doped cool tiles for roof applications in an artificial environment and showed a decrease of surface temperature and air temperature in the chamber in summer conditions, while an increase of air temperature in winter conditions. Therefore, PCM doped roof reduced the heating penalty of the cool paint in winter. Similarly, Lu et al. (2016) measured the surface temperature and heat flux of a coupled PCM and cool roof in Tianjin of China, which showed a significant effect in decreasing temperature and heat flux peaks. Also heat-harvesting pavements were proposed to mitigate UHI phenomenon in urban environments (Qin, 2015). They seemed to be capable to stay cool and to harness renewable energy. However, such prototypes require further tests on the power output, durability, and lifetime. Moreover, the performance of cool and heat storage pavements was simulated by Qin and Hiller (2014). Increasing pavements albedo was demonstrated effective to suppress the sensible heat and mitigate the UHI effect, while raising the pavement thermal inertia decreased the sensible heat during the daytime but increased this factor at nighttime. On the other hand, no significant results have been found in the assessment of PCMs doped walls for the Urban Heat Island phenomenon mitigation.

Building upon the above mentioned considerations, in this work the local microclimate differences between four areas with different urban configuration and development located in the same climate zone were taken into account. In particular, the historical district of the city of Perugia (Italy) was found to be characterized by a non-negligible Urban Heat Island intensity. Therefore, the capability of innovative thermal storage solutions, i.e. phase change materials, to mitigate UHI phenomenon in the historic district when integrated in different buildings' elements and urban outdoor materials, i.e. external building walls and pavement, was evaluated by means of microclimate calibrated simulation.

2. Materials and Methods

The research methodology included two main steps. Firstly, the experimental monitoring campaign of four case study areas with different building density, configuration, and vegetation level, i.e. an historical urban district, a more recent urban neighborhood, and two suburban-rural areas, was carried out in the same city, i.e. Perugia (central Italy) during summer 2015. The local microclimate of each area was assessed by means of outdoor microclimate stations. Therefore, the numerical modeling of the historic district (Fig. 1a) was performed to evaluate the benefits achievable in terms of local microclimate by applying innovative passive cooling strategies in order to mitigate the UHI phenomenon.

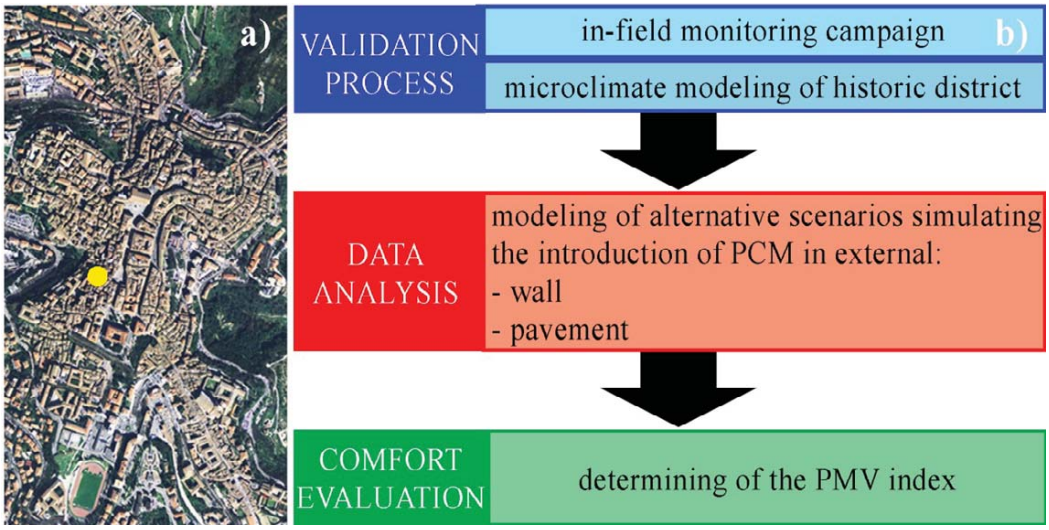

Fig. 1: (a) Position of the modeled area within the historic center of Perugia and (b) scheme of the adopted methodology

The microclimate simulation was carried out by using ENVI-met V4 in order to assess the effectiveness of thermal storage solutions for mitigating the Urban Heat Island phenomenon by preserving the environmental quality of the urban area and the thermal-visual comfort of the pedestrians. More in detail, the integration of Phase Change Materials in (i) the walls of the monitored building and (ii) in the outdoor paving was simulated in order to evaluate the impact of increased thermal capacity of the materials on the local microclimate, both in summer and winter conditions. To ensure the reliability of simulation results, a preliminary phase of validation was conducted. The daily weather profiles were selected from the typical July (July, 15th) and typical January (January, 15th) provided by IGDG TMY (Typical Meteorological Year) for the city of Perugia, built on 1951-1970 period of record (U.S. Department of Energy, 2014). Finally, the simulation results were analyzed in terms of the thermal comfort index PMV (Predicted Mean Vote) (ENVI-met 4, 2015; Fanger, 1972) to assess how the integration of PCMs could affect pedestrian perception of the local urban environment (Fig. 1).

2.1. Modeling and validation process

The simulated area in the historic district is an East-West oriented street, 40 m long with a width varying from 3 to 12 m along its length (Fig. 2). Moreover, between the eastern and western side there is a height difference of 5 m. Buildings in the street are characterized by thick stone walls and outdoor pavements are manly covered by bricks and plates made of *pietra serena* (except for the eastern side recently asphalted) (Fig. 2b), since it is located in the historical center of the city.

ENVI-met V4 was used for the numerical analysis, which is three-dimensional microclimate modeling system designed to simulate the surface-plant-air interactions with a resolution from 0.5 m to 10 m in space and from 1 s to 5 s in time (Huttner and Bruse, 2009). A realistic model of the area was developed and calibrated by using experimentally monitored data, according to the ASHRAE GUIDELINE 14-2002 (ASHRAE, 2005). In order to be representative of the real configuration, the 3D model has a square unit of 1x1 m and a geometrical rotation of 111° North out of the grid. Therefore, it is based on a 30x60x35 grid. The materials used to characterize walls, roofs, and pavements in the reference scenario were selected from the software database and their thermo-physical properties are summarized in Tables 1 and 2.

Fig. 2: (a) View of the street from the western side, (b) different kinds of pavement present in the area, and (d) localization in the plant of the monitoring probes

Tab. 1: Characteristics of the walls and roofs composing the reference scenario

Element	Albedo [-]	Emittance [-]	Specific heat [J/kg·K]	Thermal conductivity [W/m·K]	Density [kg/m^3]
Walls	0.30	0.90	840	0.86	930
Roofs	0.50	0.90	800	0.84	1900

Tab. 2: Characteristics of the different pavement profiles composing the reference scenario

Pavement profile	Albedo [-]	Emittance [-]	Volumetric Heat Capacity (upper layer) [J/m^3·K]	Heat Conductivity (upper layer) [W/m·K]
Brick Road	0.30	0.90	$2.00 \cdot 10^6$	1.00
Basalt Brick Road	0.80	0.90	$2.39 \cdot 10^6$	1.73
Asphalt Road	0.20	0.90	$2.25 \cdot 10^6$	0.90

The data for the calibration were collected through the monitoring campaign during summer 2015. A portable weather station was placed at 15 m height (Pisello et al., 2014) and two Tinytag temperature and relative humidity probes and data-loggers (Pisello et al., 2015) were installed at 2 m above the ground (Fig. 2c). As weather input for the model the following data were used:

- Initial wind speed: value collected from the weather station at 6 a.m., start time of the simulation;
- Wind direction: value prevailing during the three days of the monitoring campaign;
- 24 h air temperature and relative humidity forcing: data collected by the probe located on the South-oriented side (Fig. 2c, point B).

The simulation run for 24 h and the data compared for the calibration were those collected from the North-oriented probe (Fig. 2c, point A) and those extracted from its representative point within the model.

2.2. Modeling of alternative scenarios

Once calibrated the model, alternative scenarios to the reference one, named S0, were developed by analyzing the effectiveness of the application of PCMs at urban level for Urban Heat Island mitigation. Therefore, traditional materials were replaced with high-thermal capacity ones as follows:

- High-thermal capacity walls, i.e. scenario "wall";
- High-thermal capacity pavements, i.e. scenario "pavement".

The innovative materials, were selected to be realistically implemented in the case study area, which presents architectural constrains since it is located inside the historical center of the city. In particular, the thermal-storage capability of buildings' envelope was improved through the application of PCM wallboards. Moreover, pavement's thermal properties were implemented based on the real necessity to substitute the current asphalted area. Since PCMs dynamic characteristics and behavior cannot be modeled in ENVI-met V4, their modeling was simplified by increasing the materials heat capacity, as summarized in Table 3. Therefore, no specific PCMs' melting temperature was defined in this analysis. Nevertheless, in the investigated climate, PCMs with melting temperature from 20°C to 25°C are recommended in summer applications for this increase in heat capacity to happen.

Tab. 3: Characteristics of the components modified in each mitigation scenario

Scenario	Element	Mitigation technique	Properties
wall	Walls	Introduction of PCMs	Specific Heat: 1620 J/kg·K
pavement	Pavement	Introduction of PCMs	Volumetric heat capacity: $3.6 \cdot 10^6$ J/m^3·K

The three scenarios, i.e. S0 and the alternative scenarios, were simulated during a representative summer and winter day in the climate context of Perugia, Italy, by using as weather input the TMY weather files for the months of July and January, respectively.

2.3. Outdoor thermal comfort analysis of mitigation scenarios

In order to evaluate the effectiveness of the proposed mitigation strategies, the data obtained as output in the numerical simulation were analyzed in terms of microclimate improvements in the surrounding outdoor area.

The following parameters were considered: air temperature, relative humidity, reflected solar radiation, mean radiant temperature, and the PMV at the pedestrian level (Fanger, 1972), for the outdoor comfort of pedestrians. PMV was analyzed through the PMV Model implemented in ENVI-met (ENVI-met 4, 2015), which is the human thermal comfort model mostly used for indoor applications. In fact, it was originally developed for steady-state indoor situations, but it can also be applied, with limits, to outdoor situations by extending the energy flux related parts of the model with solar and long-wave radiation and allowing wind speeds above an indoor room situation. A comparison between data obtained in the reference and alternative scenarios was performed by analyzing the variation in time during the day of the above mentioned environmental parameters. Time series were extracted at 1.5 m from the ground in two different points selected because of their different characteristics (Fig. 3).

	Location	SVF	Time range when reached by direct solar radiation
Point 1 [x=12, y=28, z=5]	within the urban canyon, above the historical pavement	0.15	12:00-2:00 p.m. in summer, never in winter
Point 2 [x=5, y=8, z=1]	on the western part of the street, above the area originally asphalted	0.51	3:00-8:00 p.m. in summer, never in winter

originally asphalted area

Fig. 3: Positions of the points selected to extract data at pedestrian level

3. Results and Discussion

3.1. Model calibration

The statistical and graphical approach was carried out for the model calibration according to the ASHRAE GUIDELINE 14 (ASHRAE, 2005). The calibration accuracy was evaluated in terms of two statistical indexes, i.e. *Mean Bias Error* (MBE) and *Root Mean Square Error* (RMSE) (ASHRAE, 2005), as reported in Table 4. The maximum gap in terms of both air temperature and relative humidity is reached during the hottest hours of the day, when the software tends to overestimate the outdoor microclimate parameters. According to the obtained results, the model can be considered representative of the real area with good approximation. Therefore, it can be used to simulate which could be the improvements in the outdoor microclimate of the zone due to the application of the selected mitigation strategies.

Tab. 4: Calibration parameters results

Parameter	MBE	RMSE
Air Temperature	0.82 K	1.05 K
Relative Humidity	2.21 %	2.96 %

3.2. Summer analysis

Observations on the experimental monitoring carried out during summer 2015 in the different locations revealed a significant nighttime UHI phenomenon in the two monitored urban areas, with peaks of 2 K and 5 K temperature difference in the recent urban neighborhood and the historical district, respectively, compared to the suburban green area.

Therefore, the alternative scenarios were simulated to assess the possible benefits achievable from the implementation of phase change materials in the built surfaces, i.e. walls and paving, as mitigation technique. Summer results showed the major contribution of the high-thermal capacity pavement, i.e. scenario "pavement". In detail, the high-capacity PCMs integrated concrete pavement is able to reduce the outdoor air temperature by a maximum of -0.31 K in the summer day in point 2 (Fig. 4b). However, in point 1 the high thermal capacity soil effect is negligible in terms of air temperature reduction (Fig. 4a). In fact, at the point

with higher Sky View Factor (SVF) the peak air temperature is higher than in point 1 and it is detected two hours before the other one (at 1:00 p.m. instead of 3:00 p.m.). The reason is the different relation between these points and the built environment and the different time-period when they are exposed to direct solar radiation: just two hours for point 1 (from 12:00 p.m. to 3:00 p.m.) and five hours for point 2 (from 3:00 p.m. to 8:00 p.m.). Moreover, point 2 is located above the ground surface covered by asphalt in the reference configuration and, therefore, the effect of the materials' thermal properties improvement is higher. On the contrary, point 1 seems to suffer from the presence of solar radiation, both direct and diffuse, since it is subjected to higher mutual reflections of short way radiations from the surrounding structures. On the other hand, the scenario where increase of specific heat in walls is applied, i.e. scenario "wall", negligible effect is found in both point 1 and 2 during the daytime (Fig. 4). However, slightly better values are reached during the night in both points and in both scenarios, leading to differences up to -0.13 K and -0.26 K (6.00 p.m.), compared to S0, for "wall" scenario in point 1 and 2, respectively. These night-time lower temperature values are due to the less contribution of the built surfaces in the thermal balance determined by lower surfaces' temperatures. As regards the relative humidity trend, it is strictly connected to the one of the air temperature and no significant differences.

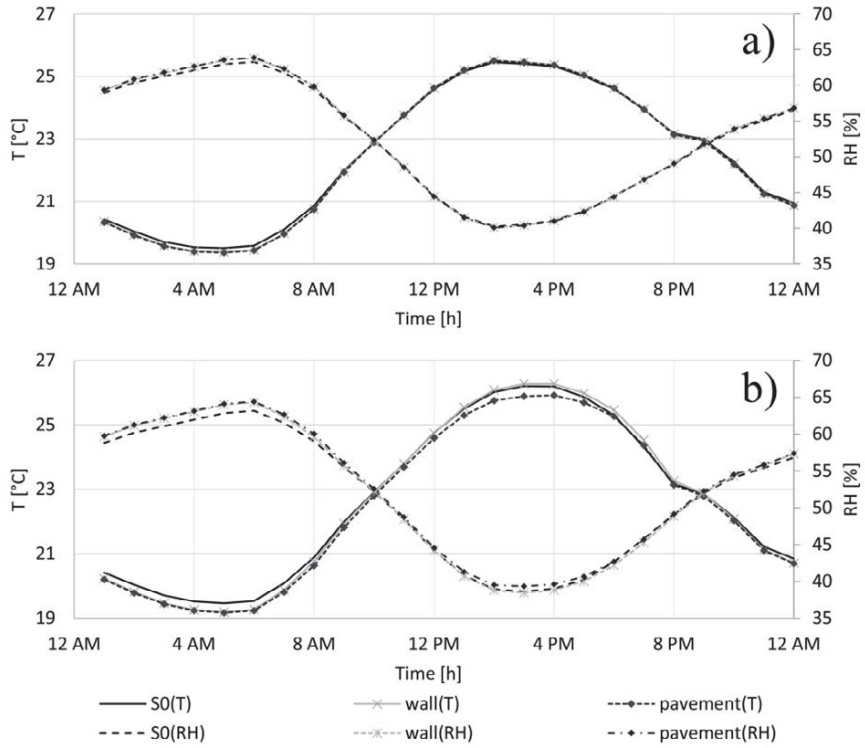

Fig. 4: Simulated air temperature and relative humidity hourly profiles in (a) point 1 and (b) point 2 in the different scenarios during the summer day

The reflected solar radiation and the mean radiant temperature were also analyzed (Fig. 5). It is interesting to notice that the trend of the MRT assumed in point 2 shows two peaks (Fig. 5b), differently from point 1 showing just one peak (Fig. 5a). This is due to the presence of direct solar radiation that occurs at different times in the two selected locations. In point 1, the peak coincides with the maximum values of reflected solar radiation (around 1:00 p.m.), while in point 2, a first relative peak is detected due to the maximum value of the reflected radiation and an additional one is achieved at 3:00 p.m., when the point is reached for the first time from the direct radiation. Conversely from the previous results, negligible differences between the mitigation scenarios and S0 are found in terms reflected solar radiation in point 2, while a significant increase is found in "pavement". Moreover, an increase of MRT is found in "pavement" with a maximum of +2.18 K at 3:00 p.m. and +2.28 K at 2:00 p.m. in point 1 and 2, respectively.

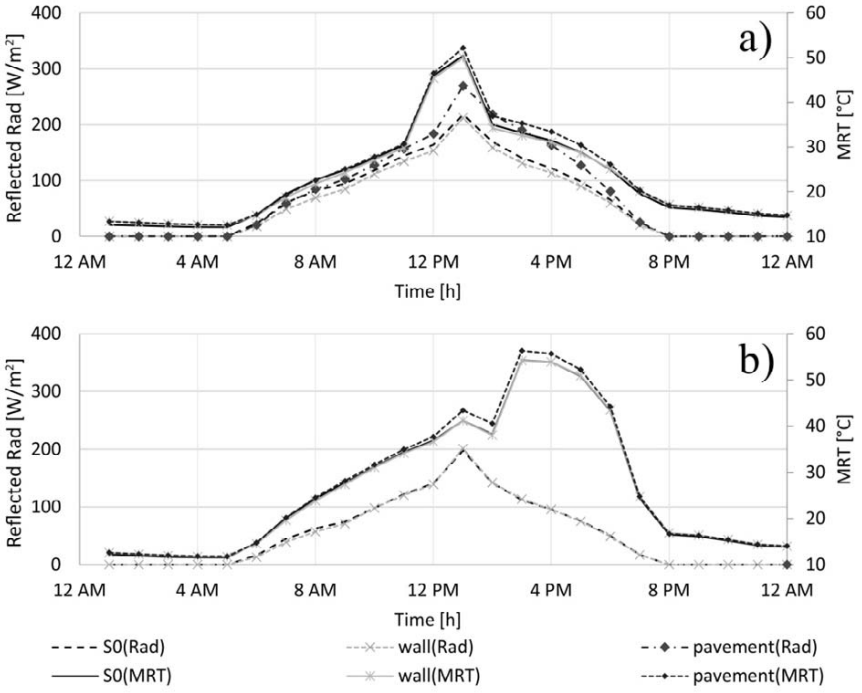

Fig. 5: Simulated mean radiant temperature and reflected solar radiation hourly profiles in (a) point 1 and (b) point 2 in the different scenarios during the summer day

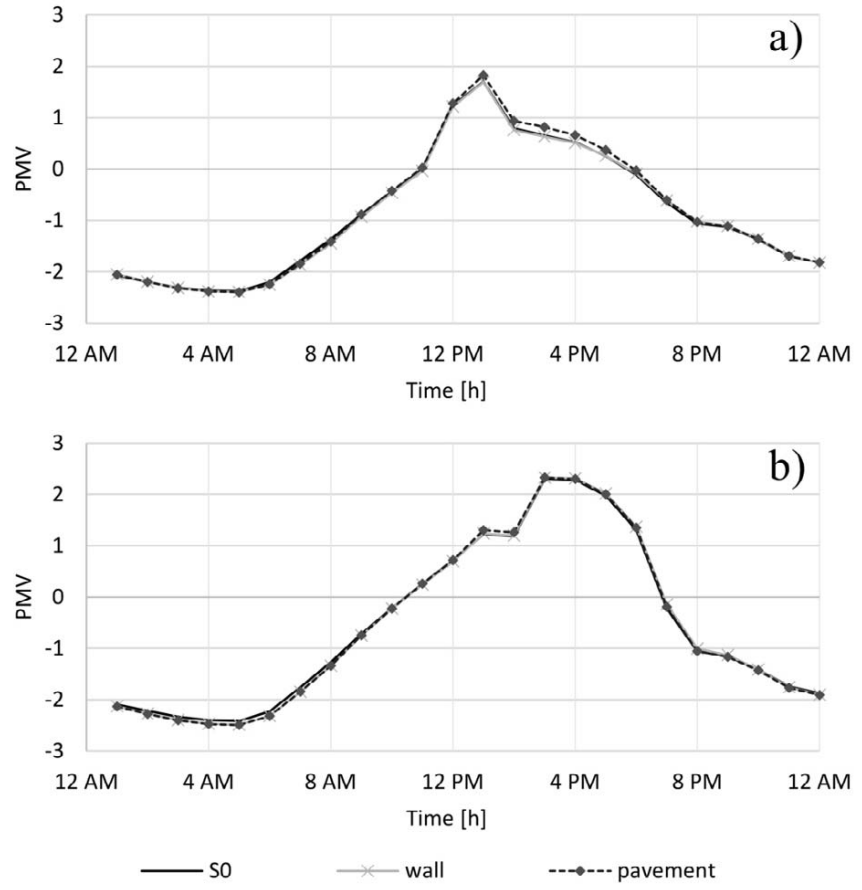

Fig. 6: Comparison between all the simulated scenarios in terms of PMV daily trend at pedestrian level in (a) point 1 and (b) point 2 during the summer day

As regards the pedestrians' comfort analysis (Fig. 6), the PMV was evaluated by imposing a clo (static clothing insulation) equal to 0.5. The resulting PMV values vary from a minimum of about –2.4, achieved before the sunrise, and a maximum of +1.8 and +2.3 (scenario "pavement") for point 1 and point 2, respectively. However, negligible variations in terms of PMV are found between the different scenarios, due to the small temperature difference.

3.3. Winter analysis

Although the proposed mitigation techniques were proposed to improve the outdoor microclimate conditions of the selected area during the hottest season (in order to mitigate the Urban Heat Island phenomenon), their effect during winter was also analyzed. The aim is to evaluate if the thermal comfort could be enhanced also in the cold season.

During the winter day, the increased thermal storage potential of the built surfaces leads to the mitigation of the night cooling (Fig. 7). Air temperature data extracted in point 2 (i.e. SVF = 0.51) are subjected to greater variations compared to the ones in point 1 (i.e. SVF = 0.15). In fact, the outdoor air temperature in point 2 increases up to +0.23 K and +0.32 K in scenario "wall" and "pavement", respectively, compared to S0 (Fig. 7b). On the other hand, lower improvements are detected in terms of air temperature from 11.00 a.m. to 4.00 p.m. All in all, scenario "pavement" seems to be the most effective strategy in winter conditions, when increasing the outdoor air temperature and, therefore, reducing the relative humidity.

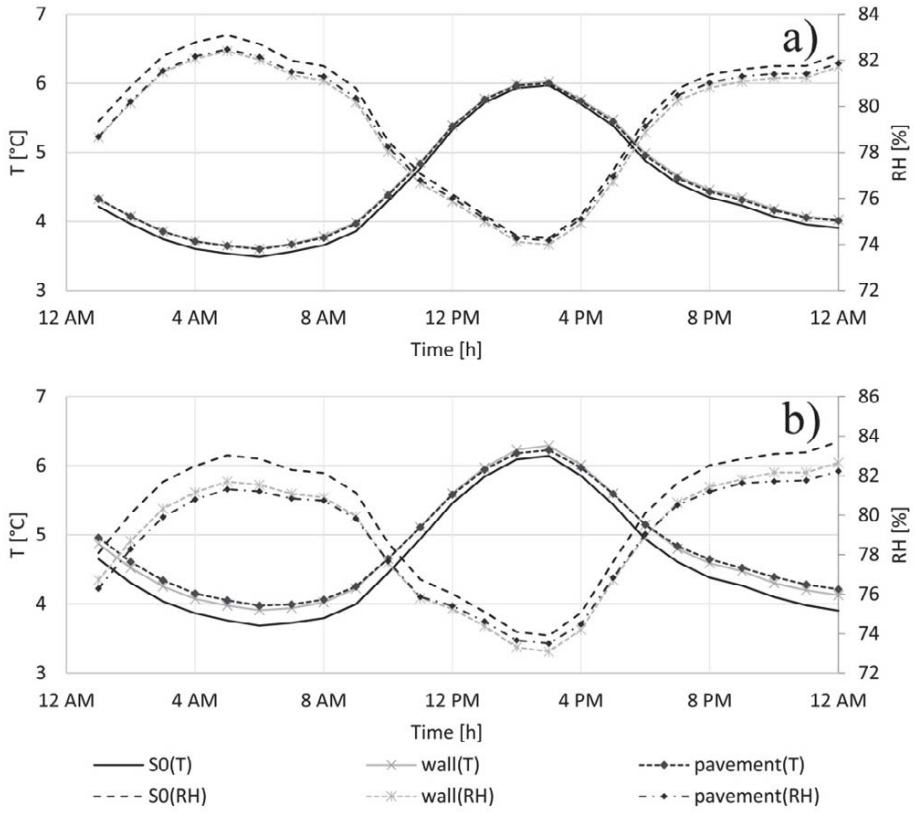

Fig. 7: Simulated air temperature and relative humidity hourly profiles in (a) point 1 and (b) point 2 in the different scenarios during the winter day

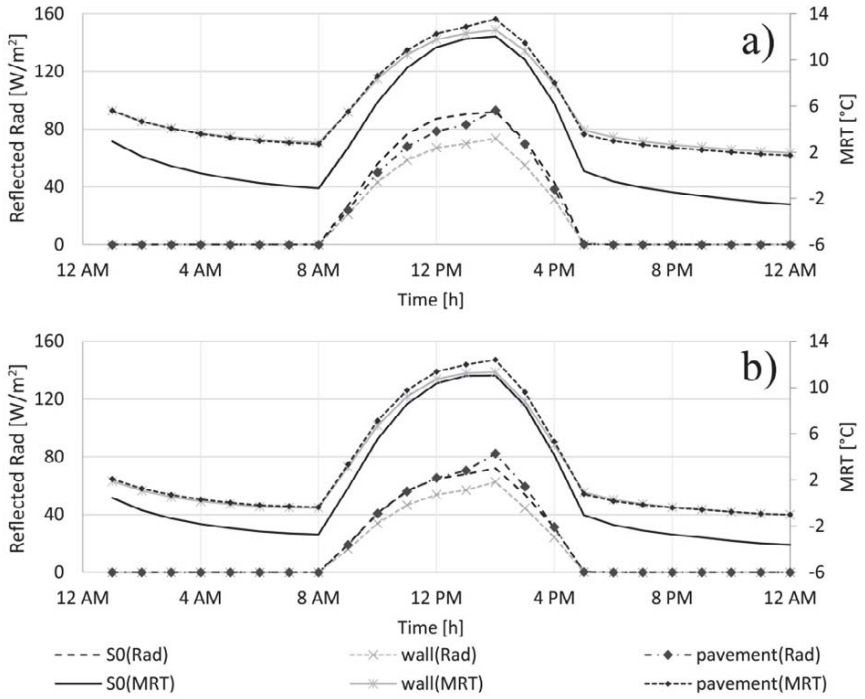

Fig. 8: Simulated mean radiant temperature and reflected solar radiation hourly profiles in (a) point 1 and (b) point 2 in the different scenarios during the winter day

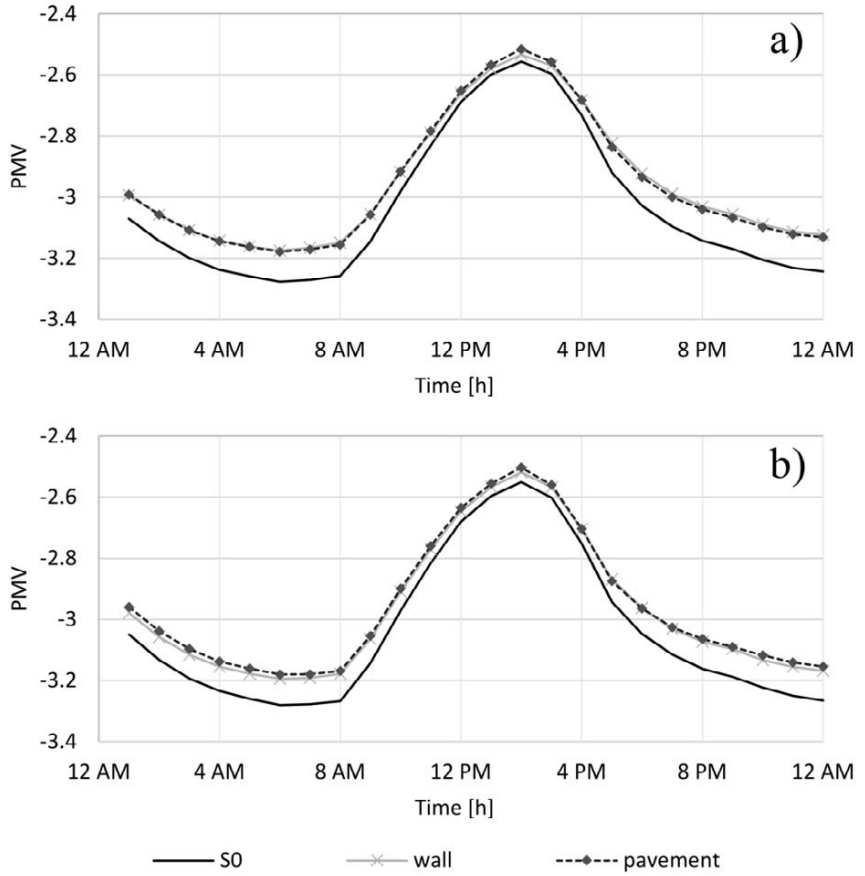

Fig. 9: Comparison between all the simulated scenarios in terms of PMV daily trend at pedestrian level in (a) point 1 and (b) point 2 during the winter day

Opposite behavior was detected in terms of mean radiant temperature, since greater modifications were obtained in point 1, the one presenting the lower value of SVF (Fig. 8). In fact, during the day both the points are not reached by direct solar radiation, due to the lower height of the winter sun, and, therefore, the effect of mutual reflectance between built surfaces has a stronger impact on the MRT. In general, the increased surfaces' heat capacity is able to significantly increase the MRT in the two analyzed points, with a slightly greater performance of pavement's included PMCs. In particular, after the sunset (i.e. from 5:00 p.m.) the effect of the applied mitigation actions provides a MRT increase up to +4.47 K and +2.60 K for "wall" and +4.25 K and +2.56 K for "pavement" at midnight, in point 1 and 2, respectively.

The PMV was evaluated also for winter conditions, by imposing a cloth resistance of 1.2 clo (Fig. 9). In general, improvements in terms of PMV are detected to be very low. However, it is interesting to notice that the PMV in the two mitigation scenarios is higher during the coldest hours of the day with respect to the reference scenario, showing a mitigation effect of the proposed strategies.

4. Conclusions

Microclimate variations due to local phenomena such as Urban Heat Island are nowadays very well acknowledged. This paper investigated the UHI in different areas belonging to the same climate zone with particular attention to the its intensity in a historic district. Therefore, the analysis of the impact of different boundary conditions on the local microclimate at neighborhood level was performed through coupled experimental and numerical analysis. The numerical analysis of the historical urban scenario, presenting the worst microclimate conditions, was performed in order to assess the effectiveness of thermal storage solutions, i.e. PCMs integration within building walls and outdoor pavements, as UHI mitigation measures in improving the thermal quality of the environment at neighborhood-urban scale.

The experimental campaign showed a significant nightly Urban Heat Island in the dense urban historic area compared to the other suburban areas. Therefore, the numerical analysis showed the non-negligible role of thermal storage strategies in mitigating outdoor air temperature both in summer and winter at local scale. In summer, the high-capacity PCMs integrated pavement appears to reduce the peak outdoor air temperature, while in winter PCMs are able to mitigate the nighttime cooling. Moreover, the MRT is improved under winter conditions when high thermal capacity materials are used.

The work demonstrated the importance of the relation between the built environment's characteristics and its microclimate. It was proved that the accurate analysis of the local boundaries conditions produces non-negligible findings supporting the realistic simulation of the urban environments.

Testing a new design of latent storage

Margarita M. Rodríguez-García[1] and Esther Rojas Bravo[2]

[1] Ciemat-Plataforma Solar de Almería, Almería (Spain)

[2] Ciemat-Plataforma Solar de Almería, Madrid (Spain)

Abstract

A modified spiral plate heat exchanger used as latent storage module for direct steam generation was proposed in the REELCOOP project. Under the failure of eight other phase change materials claimed in the literature as potential latent storage media, the phase change material used to meet the temperature range needed is the Hitec® salt. This paper presents the melting/ freezing tests performed with the Hitec® salt previous to its use in the storage module, the general scheme of the experimental facility constructed at the Plataforma Solar de Almeria, as well as the acquired know-how during the filling of the TES module and the commissioning of the facility.

Keywords: *Latent storage, phase change material, Hitec® salt.*

1. Introduction

One of the objectives in Prototype #3 of the REELCOOP project (7th Framework program of the European Union Ref N. 608466, www.reelcoop.com) is to drive an organic ranking cycle (ORC) using parabolic trough solar collectors with direct steam generation combined with a biogas boiler. In order to cover the gap between the full operation of the biogas boiler and the absence of solar radiation, a latent thermal energy storage was planned.

At Ciemat-Plataforma Solar de Almería, a modified spiral plate heat exchanger for its use as thermal energy storage (TES) has been selected for its test using Hitec® salt as storage medium. This salt has been tested both in nitrogen and argon atmospheres in order to demonstrate the feasibility of this material as phase change material (PCM).

The TES has been installed at the Plataforma Solar de Almería where some issues had to be solved previous to performing the tests. During the commissioning some problems had to be addressed: mainly the filling of the spiral thermal energy storage module and the presence of water remaining from a previous pressure test.

The present paper is organized as follows. The phase change material selected is presented in the next section and the tests performed with Hitec® salt are presented; section 3 presents the concept of the storage module. Section 4 describes the facility operation modes, while section 5 outlines the main issues solved during the commissioning. Finally, section 6 summarizes the main conclusions.

2. Phase change material selection

The working temperatures of the ORC machine in the REELCOOP Prototype#3 are in the range of 130 °C – 170 °C, and hence the material storing the thermal energy has to change phase in the same range of temperature.

From the several compounds suggested in the literature (Sharma and Sagara, 2005; Waschull et al., 2009) as good candidates for latent storage, D-mannitol, hydroquinone and salicylic acid were previously tested by Bayón (2015). Hydroquinone and salicylic acid presented a strong vapor emission upon melting, and D-

doi:10.18086/eurosun.2016.03.15 Available at http://proceedings.ises.org

mannitol displays supercooling during freezing, a decrease of the melting temperature and enthalpy together with a strong degradation under just few freezing/melting cycles. This degradation process of the D-mannitol can also be observed after melting/freezing cycling in both nitrogen and argon atmospheres (Rodríguez-García, 2016). Another four materials were also considered (X165, Galactitol, $CaCl_2 \cdot 2H_2O$, KNO_3-$Ca(NO_3)_2$ and $LiNO_3$-KCl) and all disregarded, either for being available at only specific shapes, or changing phase at a temperature a bit higher –around 190 ºC-, or having a thermochemical reaction more than a phase change, or becoming hydrated or for promoting pit corrosion)

The finally selected PCM was the Hitec® salt ($NaNO_3$-KNO_3-$NaNO_2$; 7/53/40 % w). The freezing point of this salt is 142 °C, presenting stability up to 535 °C. Other properties reported by Serrano-López et al. (2013) and Vignarooban et al. (2015) are stated in Tab. 1. This salt has been selected despite the relatively low enthalpy of fusion because its melting temperature fits in the selected temperature range, and because of its chemical stability when melting/freezing cycled.

Tab. 1: Thermal and physical properties of Hitec® salt.

Density, ρ, [kg/m^3] (T expressed in Kelvin)	Thermal conductivity λ, [W/mK]	Heat capacity Cp, [J/kgK]	Enthalpy of fusion ΔH, [kJ/kg]	Cost [$/kg]
ρ=2279.799- 0.7324·T	0.48	1560	83.6	0.93

Sohar, M.S. et al. (2013) describes that Hitec® salt is somewhat hygroscopic, containing absorbed moisture. Nitrite salt present in the Hitec® mixture can change to nitrate in O_2 presence, as shown in eq.1, increasing the fusion temperature of the mixture.

$$2NaNO_2 + O_2 \rightarrow 2NaNO_3 \qquad \text{(eq. 1)}$$

At the same time, the presence of water sustains the electrochemical corrosion mechanisms usually associated with aqueous systems, including galvanic corrosion. In order to avoid this, nitrogen has to be circulated through the TES module in the Hitec® channel.

The thermal behavior of Hitec® as phase change material, and its degradation after 50 melting/freezing cycling between 120 °C and 165 °C under inert atmosphere has been tested. Although nitrogen is cheaper than argon, it could somehow react with the molten salt, changing its chemical composition. According to this, both argon and nitrogen atmospheres have been considered for the tests.

The testing device is the one described by Rodríguez-García, M.M. et al. (2016). The melting/freezing cycles reproduce the "standard" daily operation conditions in a commercial plant. Understanding "standard" as a sunny day where the salt is melted sometime during the day (charging process), storing the energy for some hours and then giving up its latent energy to the water, i.e. the salt freezes, at a certain point of the day, e.g., the sunset (discharging process). In the tests, the salt is melted, keeping it liquid for 12 hours. After this period the salt provides its latent energy while it freezes, remaining frozen until the 24 hours are completed and a new cycle starts.

The fig. 2 (left) displays temperature/time curves of a 20 g Hitec® sample for the 1st and the 50th melting/freezing cycles under N_2 atmosphere. As can be seen the melting temperature interval for the first cycle has a well-defined plateau at 142 °C – 144 °C corresponding to the Hitec® salt melting that lasts around 10 minutes. The curve corresponding to the 50 cycles overlaps with the first cycle curve, and the melting temperature interval fits very well to the first cycle. The same can be said for the melting/freezing cycles under Ar atmosphere, as can be seen fig. 2 (right). As a result of these tests we can say that no degradation after melting/freezing cycling has been observed.

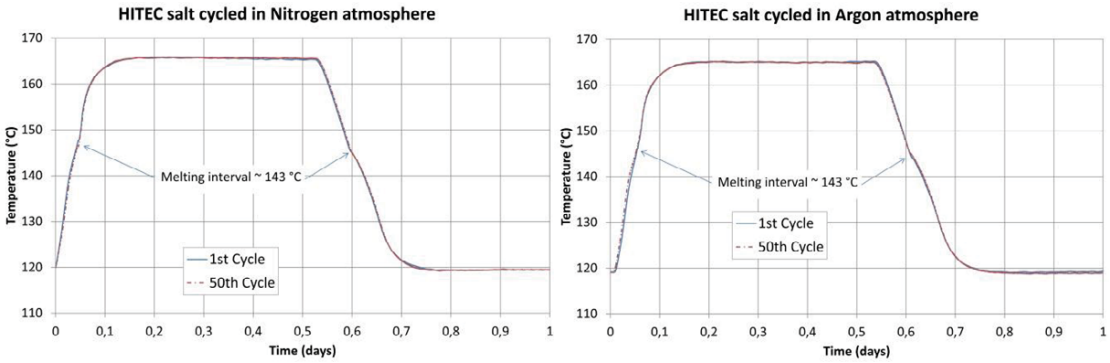

Fig. 1: Melting/freezing cycles of Hitec® in N_2 (left) and Ar (right) atmosphere.

3. Storage module

The proposed thermal energy storage design concept has a double spiral plate geometry, where one of the channels is filled up with the phase change material, remaining still along the time. Through the other channel runs the water in vapor or liquid state depending on the operation mode (charge of discharge). As stated by Rivas et al. (2012), this geometry presents a large energy exchange surface by unit volume providing an effective heat transfer, in spite of using storage medium with low thermal conductivity as most inorganic PCM have and that follows solid to liquid transitions to store the energy.

Patented by Rivas et al. (2011), the module tested in the REELCOOP project is an adaptation of a commercial spiral plate heat exchanger, due to limitations in budget and project time frame.

With 825 mm diameter and 1000 mm height, the spiral heat exchanger used as TES module has volume at the water/steam channel of 205 liters, and 230 liters at the molten salt channel. The effective heat transfer area is 29.3 m^2. The expected thermal capacity is 6 kWh, assuming a latent enthalpy of 50 kJ/kg, which is the figure we have obtained in the DSC tests we have previously performed (in previous literature a figure of around 84 kJ/kg can be found).

The TES module has been provided with thermocouples to follow the temperature evolution during the charging and discharging processes. Thermocouples were inserted through the four connecting flanges as represented in fig. 2a. Due to the internal structure of the TES module, with double spiral plates separated by separators, no additional thermocouples could be inserted at intermediate plates. Nitrogen injection lines were installed at the connecting flanges of the PCM channel (B1 and B2 in fig. 2a).

Once the instrumentation was settled at the TES module, this latter was installed adapting an already existing thermal storage testing facility, initially connected to the PSA Direct Steam Generation facility (DISS) but that was adapted, becoming independent of such a solar dependent facility. See Fig. 2b.

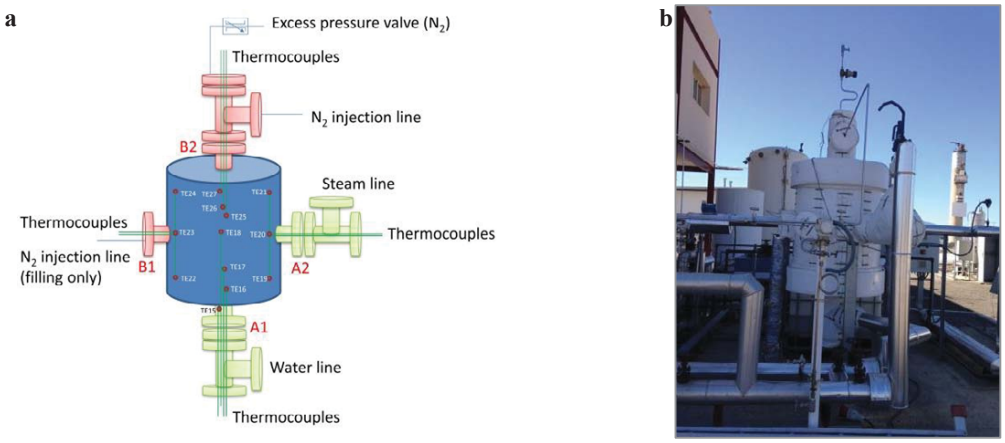

Fig. 2: a.- TES Temperature sensors and N_2 line. b.- Installation of the TES module at the PSA facilities.

4. Facility operation description

The used testing facility is designed to operate in both charging and discharging modes. Fig. 3a displays the charge mode, while the discharge mode is represented in fig. 3b. For the charging (discharging) mode a steam generator (water heater) provides saturated steam (warm water) to the storage module where energy is transferred to (from) the PCM. The storage module provides a mixture of steam and liquid water in an undetermined ratio or steam quality. This water-steam flow is later mixed with liquid water at known temperature and flow. The resulted water-liquid flow and its temperature is measured and the cycle is closed.

During the charge operation saturated steam at 150 °C enters the TES through the A2 conduction (see fig. 2a.) and, once the heat is transferred to the molten salt, saturated water at 140 °C exits the TES module through the A1 pipeline. During the discharge, the operation takes place in the contrary flow direction: saturated water at 130 °C enters the TES through the A1 conduction and, after evaporating in the TES, saturated steam at 130 °C. Tab. 2 summarizes the nominal operation conditions. Here it has been assumed that the pressure drop at the TES is 0.01 MPa.

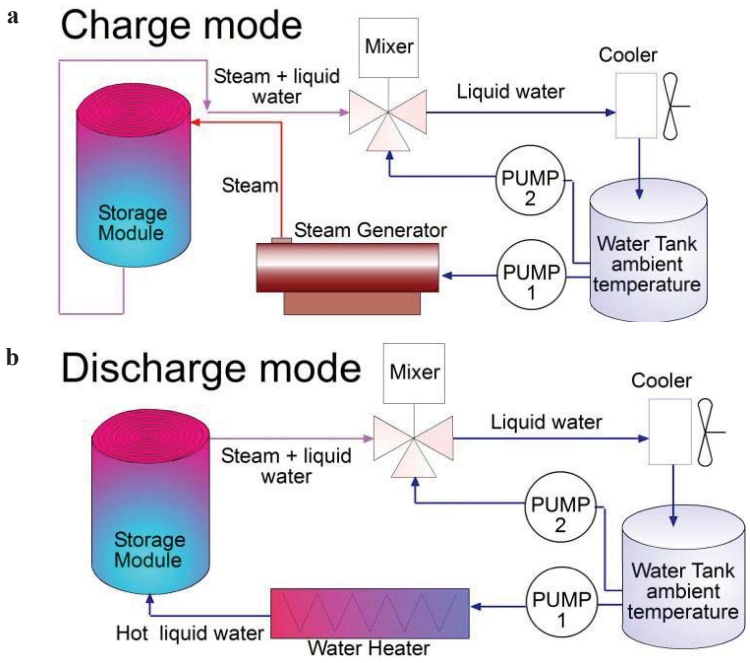

Fig. 3: Charge (a) and discharge (b) operation mode schemas of the test facility at Plataforma Solar de Almería

Tab. 2: Nominal operation conditions for the charge and discharge modes at TES module.

Charge mode				
	Temperature [°C]	Pressure [MPa]	Flow [kg/s]	Water phase
Inlet (A2)	150	0.47	0.04	Saturated steam
Outlet (A1)	140	0.36	0.04	Saturated water
Discharge mode				
	Temperature [°C]	Pressure [MPa]	Flow [kg/s]	Water phase
Inlet (A1)	130	0.27	0.05	Saturated water
Outlet (A2)	130	0.26	0.05	Saturated steam

5. Commissioning of the facility

During the filling of the TES module and the commissioning of the facility significant know-how has been acquired. The most remarkable aspects regarding commissioning of this experimental facility are explained in this section.

5.1. Water from the pressure test.

As stated in section 2, the presence of water and oxygen when using Hitec® as PCM should be avoided by blanketing the storage module with nitrogen. Blanketing should occur previous to the filling of the storage module with molten salt.

Nitrogen is injected on the top of the module (B2 in fig. 2a), exhausting it through the exit at the B1 connection. Since nitrogen is denser than air, the TES module will remain full of nitrogen when the B1 connection is closed by a screw cap and the upper flange in B2 is removed for the filling of the system.

The TES module should be preheated with steam at 150 °C in order to avoid any plug formation when the molten salt enters the system. During the preheating of the TES module unexpected water steam exhausted through the nitrogen venting system. This water was the remaining of the pressure test performed by the commercial company which sells the module previous to the delivery of the module to PSA and in accordance with the safety procedures any standard equipment that may work under certain pressure should follow. Nitrogen was injected via the B2 inlet (see fig. 2) passing through the complete spiral channel, and forcing the steam to move to the central upper exit B1 (see fig. 4a).

5.2. Filling the TES module with molten salt.

The spiral plate internal structure of the TES module makes necessary an external melting of the Hitec® salt previous to the filling of the module. Hitec® was melted in a separate furnace, provided with electrical resistances and a control that allows a safe melting of any salt and its release in the TES module. For this purpose, the flange at the top of the TES module was dismounted once the TES module had been innerted with nitrogen, allowing the molten salt charge

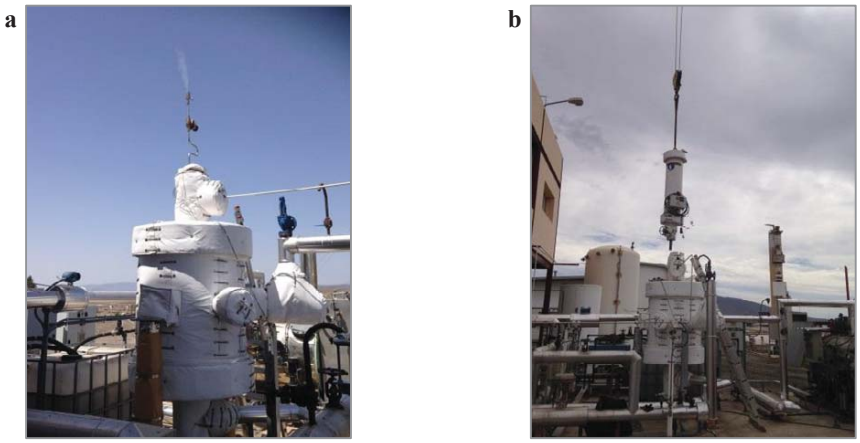

Fig. 4: a. Water steam exhausted through the nitrogen venting system. b. Filling of the TES with the external salt furnace.

6. Conclusions and future works

Candidate PCMs in the range of 130 °C to 170 °C have been studied. From the most promising ones proposed in the literature, hydroquinone and salicylic acid presented a strong vapor emission upon melting; and D-mannitol displays not only supercooling during freezing, but also a strong degradation after just 50 melting/freezing cycles. The commercial Hitec® salt has been selected because of its chemical stability and despite its relatively low enthalpy of fusion.

This salt is very hygroscopic, which can produce a change in the melting temperature, and forces to a previous drying of the TES module and a N_2 blanketing.

Due to the delay caused by the unexpected problems occurred during the commissioning, the expected testing procedure refinement and the evaluation of the thermal behavior are close future activities. The testing procedure to be followed is the one proposed at the SFERA project and named SFERA15T2#1 ('*HTF power curve in discharge/charge*'), case III (Rojas et al., 2011). This procedure allows establishing both discharging and charging curves working at different temperature/pressure pairs. From these curves it is possible to find out experimentally the real Biot number of the storage module, which may be important to validate the simulated behavior of the new design here implemented.

7. Acknowledgements

The authors would like to acknowledge the E. U. through the 7th Framework Program for the financial support of this work under the REELCOOP (Renewable Electricity cooperation) project with contract number: 608466, the DETECSOL project (Ref. ENE2014-56079-R) with ERDF funds, and the operation, instrumentation and maintenance departments at the PSA for their collaboration during the development of this work.

Energy efficient building cooling by combining a regenerative cooling system, a large TES and a phase change material cooling ceiling

Stephan Weismann[1], Felix Klinker[1], Helmut Weinläder[1], Dietrich Büttner[1]

[1] Bavarian Center for Applied Energy Research (ZAE Bayern), Würzburg (Germany)

Abstract

The Würzburg division of the Bavarian Center for Applied Energy Research (ZAE Bayern) moved into its newly-built research building, the Energy Efficiency Center, upon its completion in 2013. It is a highly innovative building and was designed as a living lab. The cooling system is highly efficient, incorporating a combination of Passive Infrared Night Cooling (PINC), thermal energy storage (TES) and newly-developed ceiling cooling elements with integrated phase change materials (PCM). The PINC system can achieve high energy efficiency ratios (EER) of approx. 10-20. The PCM in the cooling ceiling provides passive cooling during the daytime in the transition period. Active cooling is only required in summer. In practice, the large-scale thermal energy storage tank has provided cooling for periods even up to ten weeks. This paper presents the first results of the combined system (PINC, TES, and cooling ceiling) as well as some of the measures undertaken to optimize it, and ideas for further improvement.

Keywords: *passive infrared night cooling (PINC), phase change material (PCM), cooling ceiling, High-Level-Controller, thermal energy storage, energy efficiency ratio, monitoring*

1. Introduction

In 2010, a project was launched by the Energy Efficiency division of ZAE Bayern in Würzburg to design, finance and build a new headquarters for the expanding institute. This new building, the "Energy Efficiency Center" (EEC), incorporates the cutting-edge and energy-efficient building technologies, mainly developed by ZAE Bayern itself, and present information about their relevance and impact in an information center open to the public. This is described in details in Weismann et al. (2014). Not only are the current new technologies and systems used in the building monitored and improved, but the modular design of the structure enables experimental components and systems to be integrated into the building for testing and further development.

ZAE Bayern moved into the building in June 2013. The building automation system was gradually put into operation, initial improvements being made in the areas of heating, ventilation, cooling and, according to Reim (2016) in lighting as well.. The Energy Efficiency Center is being extensively monitoring within the framework of a project (MoniResearch).

2. Cooling Concept

2.1 Passive Infrared Night Cooling

Building directives stipulated that the EEC needed two underground fire protection water tanks with a volume of 100 m^3 each. It was decided to additionally utilize them for cold water thermal energy storage. They are both connected to the building's water cooling circuits by means of heat exchangers.

Fig. 2: Underground fire protection water tank.

One tank is cooled by a conventional compression cooler (and used as a backup for PINC), the other is connected to the passive infrared night cooling system developed by ZAE Bayern. A schematic diagram of this system can be found in Fig. 3, more details are described in Rampp et al. (2013).

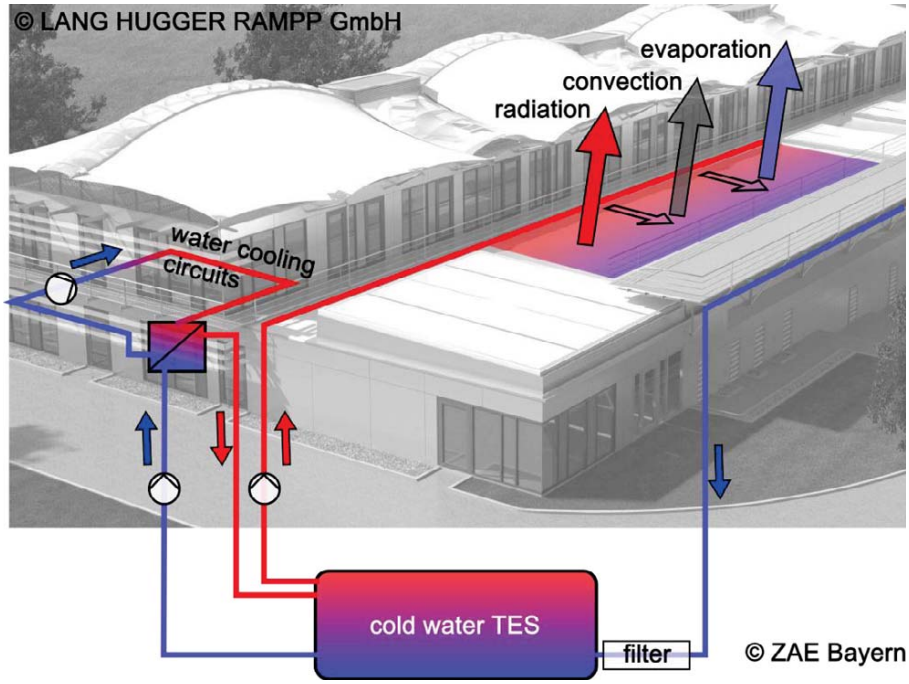

Fig. 3: The cooling load is connected to the TES by means of a heat exchanger. The water in the open circuit is re-cooled via infrared radiation, convection and evaporation when distributed over the surface of the roof when the temperature is sufficiently low (mainly at night).

Heat from cooling appliances in the laboratories and the PCM cooling ceilings in the offices is transferred into the TES by means of a heat exchanger. In order to re-cool the TES, the water is pumped onto the metal-sheeted area of the roof. Since it is a hydraulically open system, the water runs freely over the slightly sloped rooftop surface and ideally cools down to just under dew-point temperature. Heat is released via radiation exchange with the cold night sky, convection, as well as evaporation. The cooling power density is:

$$\dot{q} = \dot{q}_{rad} + \dot{q}_{conv} + \dot{q}_{ev}, \qquad \text{(eq. 1)}$$

The main part of the cooling power density is apportioned to the radiation exchange with the night sky which is given by

$$\dot{q}_{rad} = \varepsilon_w \cdot (\sigma \cdot T_w^4 - G), \qquad \text{(eq. 2)}$$

where ε_w is the emissivity of water, σ the Boltzmann constant, T_w the water temperature and G the radiation density of the long-wave radiation from the sky given by

$$G = \sigma \cdot T_{sky}^4, \qquad \text{(eq. 3)}$$

with the effective sky temperature T_{sky}.

It is recognizable in eq. 2 that there is a strong dependence between the cooling power density and the water temperature. Thus higher water temperatures lead to a higher cooling power density. Assuming typical water temperatures of about 18°C and the climate conditions in Würzburg, a cooling power density of around 60 to 120 W/m^2 roof area can be achieved at night even in summer.

The cooled water flows through rain pipes, a filter, and collects back in the cold water TES. Electricity is only needed to pump the water, so a high energy efficiency ratio (EER) can be achieved. As PINC is an open system, water evaporates and the loss is balanced out by rain water.

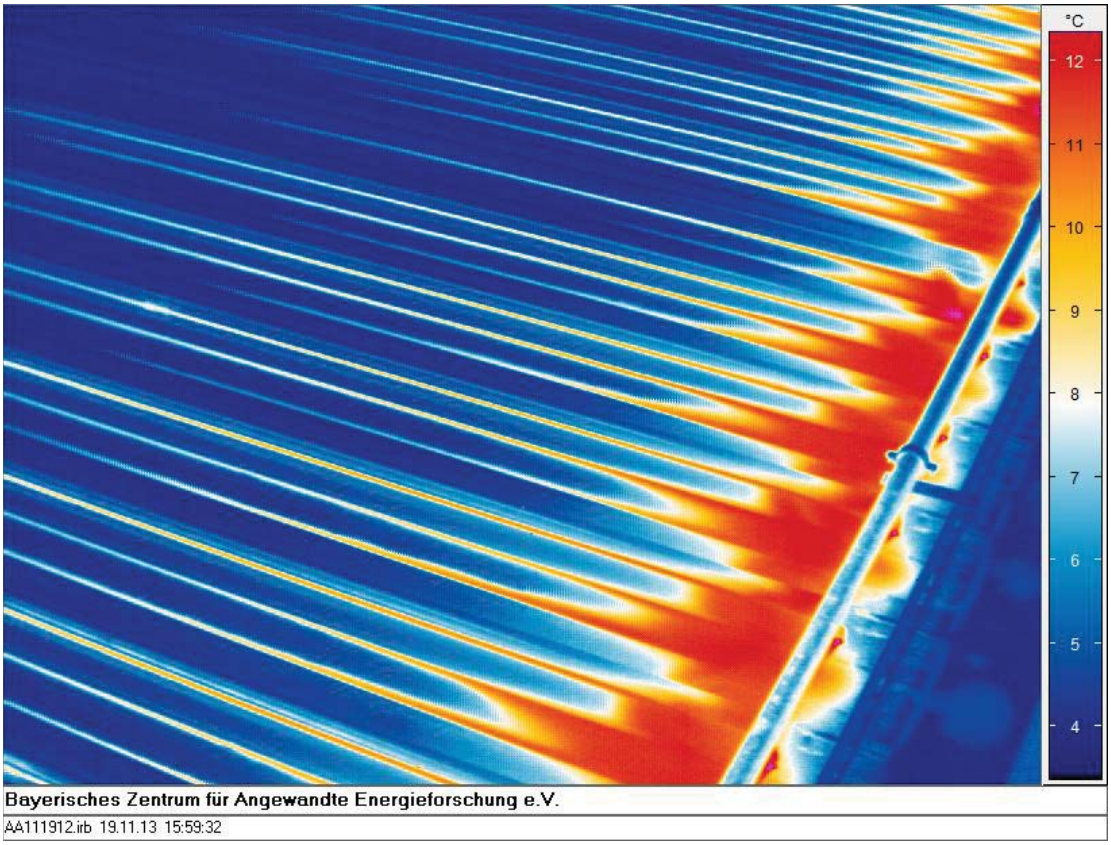

Fig. 3: Infrared image of the roof area used in the PINC system. On the right is the pipe which distributes the approx. 12 °C warm water over the roof surface. The water cools down over the roof to approx. 4 °C.

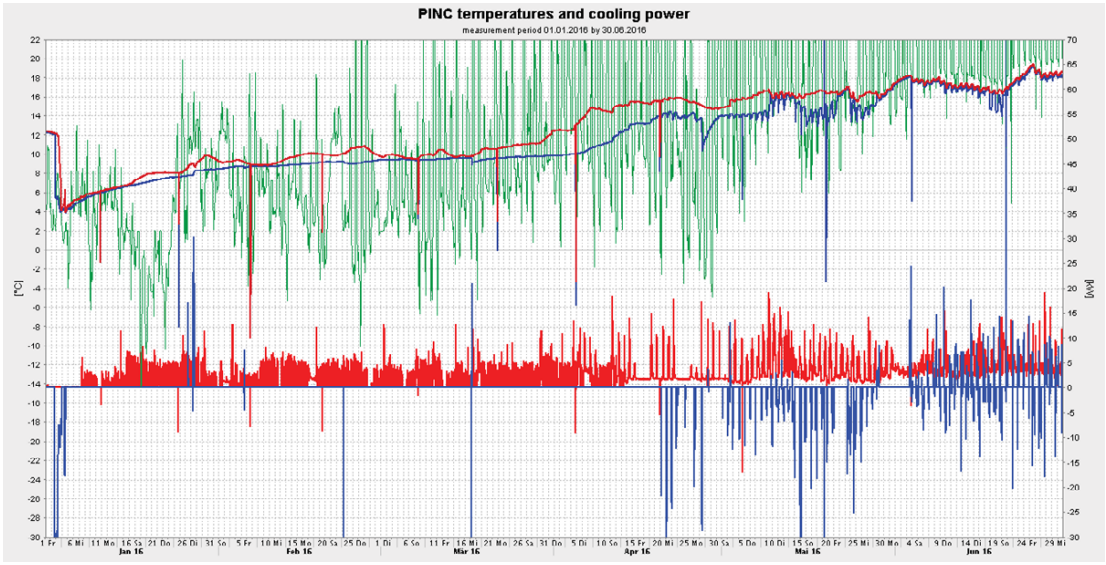

Fig. 4: PINC data from the first half of 2016. The red and blue plot lines in the top half show the temperatures in the TES, and the green represents the temperature on the metal roof. The bottom plot lines represent the cooling power (red = cooling required, blue = TES being cooled, right y-axis).

Fig. 4 shows the PINC data from the first half of 2016. Of particular note is the fact that right at the beginning of the year, on 03.01.2016, the PINC control system malfunctioned, causing the water in the TES

to be cooled down from approx. 12°C to approx. 4°C within a couple of days. The frost failsafe mechanism then kicked in and turned the PINC off. The temperature unintentionally reached in the TES was so low that the PINC system was not needed to provide cooling until the middle of April 2016. When the TES is used to provide cooling, the temperature of the water in the tank increases. When it reaches 14°C, the PINC system is activated. The PINC's cooling power is typically between 8 kW and 16 kW for the 300 m² roof area, on clear, cold nights even higher.

An almost complete set of data was collected for 2015. The PINC system is compared here to a conventional compression cooling system that serves as a backup in the EEC (a DYNACIAT LG/LGP 240V R410A manufactured by Ciat with a net cooling capability of 69.2 kW). Recent (2017) investigations have shown that the backup system supports the PINC system at 29 % of the measured time steps in 2015 and in approx. 30 % of the time steps in 2016, which is more support than designed and estimated. Therefore the control of the PINC and the backup system actually is redesigned.

Nonetheless, from the measured data the EER of the PINC and the backup system can be determined. Tab. 1 shows an evaluation of the collected data.

Tab. 1: Data collected for PINC in 2015 shown in comparison to a conventional cooling system, with data also given separately for winter and summer.

	Whole year conventional	Whole year PINC	Winter conventional	Winter PINC	Summer conventional	Summer PINC
Generated cool / kWh·a^{-1}	58570	21740	6080	6450	52490	15290
Electrical energy consumption / kWh·a^{-1}	16545	1102	975	157	15570	945
EER /	3,54	19,73	6,24	41,08	3,37	16,18

If the cooling generated for the whole year by the conventional system and PINC are compared (each measured directly at the cooling unit, not taking the heat exchanger and pumps into consideration), it can be seen that the conventional system produced considerably more cooling. The PINC's EER, however, is more than 5 times higher than that of the conventional system. The difference is even greater when comparing the data for winter: the PINC's EER of 41.08 is even 6 times higher than that of the conventional system. Winter is defined here as the period from November to March. During the remaining period (summer), the PINC's EER of 16.18 is still considerably higher than that of the conventional system (3.37).

If the additional energy consumption caused by pumps, valves and heat exchanger connecting the cooling systems to the TES are taken into consideration when calculating the EER, the conventional system has an EER of 1.95 and PINC has an EER of 10.66 (whole year each). The pump regulation system for the heat exchanger is, however, still a little bit faulty and requires optimization.

2.2 Cooling ceiling with integrated phase change material

Heating/cooling ceilings were installed in the upstairs offices of the EEC to utilize the cold generated by the PINC for energy-efficient building temperature control. These cooling ceilings were built by Lindner AG based on their cooling ceiling Plafotherm-E 200, and specially modified to incorporate PCM. 20 offices have cooling ceilings with macroencapsulated PCM modules on top of the water pipes (PCM on top), and 3 offices have cooling ceilings with the PCM modules attached underneath the water pipes (PCM at the bottom). Figure 5 shows the two different cooling ceilings. A graphite layer is used to improve the thermal

contact between PCM, water pipes and the cooling ceiling surface.

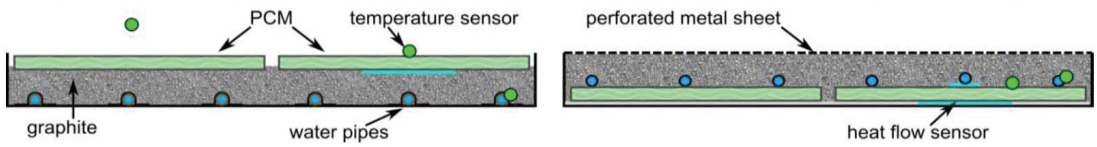

Fig. 5: Schematic diagram of the two PCM cooling ceiling systems "PCM on top" (ceiling type 1 on the left) and "PCM at the bottom" (ceiling type 2 on the right). The additional sensors are also indicated.

The PCM modules in both ceiling types are produced by Rubitherm Technologies GmbH. The metal cases contain a salt-hydrate-based PCM with a melting range between 22 °C and 24 °C. Five PCM modules are attached to one ceiling panel as shown in Figure 6.

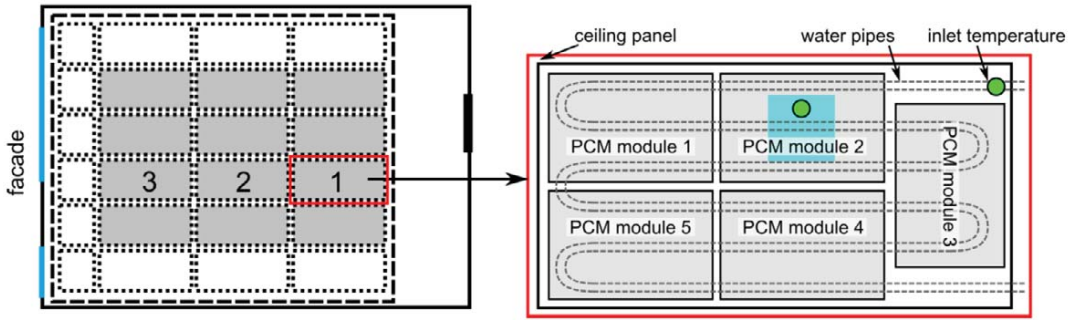

Fig. 6: Schematic diagram of the cooling ceiling panel arrangement in the offices (left) and the placement of the PCM modules on a single ceiling panel (right). The blue square indicates the position of the heat flow sensor.

The two different ceiling constructions were designed to enhance different operation modes of the ceiling. The operation modes are defined as follows:

- Passive cooling mode (PC mode):

  PC mode (no water flowing through the ceiling) occurs, if the system is not in one of the other operation modes mentioned below, and if the PCM temperature is below the operative room temperature.

- Active cooling mode (AC mode):

  AC mode occurs during the daytime, if the room temperature exceeds the set cooling temperature and the passive cooling power of the PCM is not sufficient. In AC mode, cold water flows through the ceiling.

- Active regeneration mode (AR mode):

  AR mode does the same as AC mode, but at night, thereby ensuring PCM regeneration.

The cooling circuit is connected to the PINC's TES by means of a heat exchanger. The standard room temperature is set at 24 °C, but this can be adjusted by the user by ±3 °C. Ceiling type 1 (PCM on top) was designed for balanced performance in every operation mode. This system performs well in AC mode as the water pipes have direct thermal contact to the ceiling panel, but also in AR and PC modes as the PCM has good thermal contact with the pipes and the ceiling surface via the graphite layer.

The design of ceiling type 2 (PCM at the bottom) is targeted towards PC mode. In PC mode, the system benefits from the direct contact of the PCM modules with the cooling ceiling surface. In AR mode, the system also shows decent results as the cold water in the pipes is not heated up by the room temperature while the PCM is regenerating. However, in ceiling type 2, the PCM acts as thermal resistance, meaning the

room temperature cannot be regulated as well in AC mode.

Data on the cooling ceilings' performance was collected at the weekend when the building was not occupied. To minimize the influence of factors which are hard to quantify (such as solar gains), the outside blinds were closed during the whole measurements. The internal heat gains in the rooms were replicated using electrical heating devices designed to emit the heat equally via radiation and convection. The heating devices could produce heating powers between 350 W and 1000 W which correspond to specific heat loads between 16 and 46 W/m² floor area. During typical measurement days the heating devices were turned on between 7 am and 8 pm. Weinläder et al. (2016) has found that the passive cooling power $P_{t,PCM}$ of the two PCM ceiling types was a function of the specific heat load as well as the room globe temperature . For a globe temperature of 26 °C typical passive cooling powers range from 10 to 15 W/m² (Figure 7). For these measurements the cooling set point of the room temperature was increased from 24 °C to 26 °C. This allowed globe temperatures of up to 27 °C before the active cooling mode started.

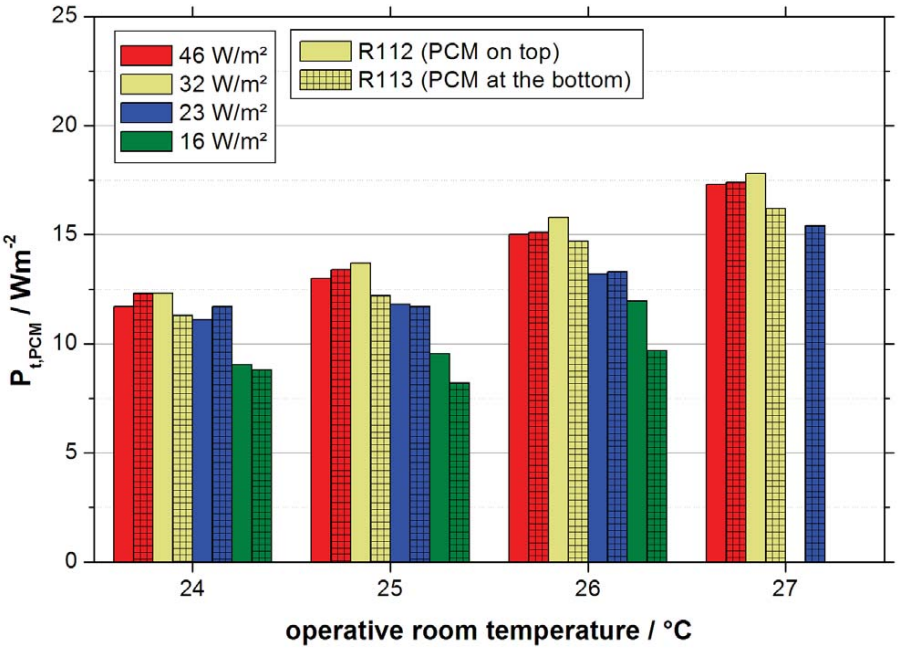

Fig. 7: Mean total passive cooling power $P_{t,PCM}$ of the PCM cooling ceilings as a function of operative room temperature for the different specific heat loads. No data are available in some cases for operative room temperatures of 27°C and for low specific heat loads.

The energy needed for active cooling was also measured during these weekends. The measurements took place in four office rooms with different systems as shown in Table 1. In addition to the PCM cooling ceilings all of the rooms except the reference room are equipped with PCM wallboards. For the sake of completeness further research results of passive PCM systems can be found at Kalnaes and Jelle (2015), Pomianowski (2012) and at Zhou et al. (2016).

Tab. 1: Overview of the different setups in the four measurement rooms.

room number and description	setup
R110: reference room	conventional cooling ceiling + conventional wallboards
R111: PCM on top + Energainboard	PCM cooling ceiling (PCM on top) + DuPont PCM wallboards (Energain)
R112: PCM on top + Comfortboard	PCM cooling ceiling (PCM on top) + Knauf PCM wallboards

	(Comfortboard)
R113: PCM at the bottom + Comfortboard	PCM cooling ceiling (PCM at the bottom) + Knauf PCM wallboards (Comfortboard)

The control during the day was the same for all four rooms, which means that the cooling set point for active cooling was 26 °C. During the night between 10 pm and 6 am the active regeneration mode was on in all the PCM rooms (R111-R113) but not the reference room. The cooling energy for active cooling was measured with a cold flow meter that detects the volume flow as well as the inlet and outlet temperature. The cooling energy is depicted in Figure 8 for the two periods during working hours (between 8 am and 6 pm) and outside working hours (from 0 to 8 am and 6 to 12 pm). The PCM passive cooling power was measured with heat flux sensors. The signal of the heat flux sensors was taken only during the working hours and only when the active cooling was turned off. The results for two measurement weekends (four days) during the summer with specific heat loads of 46 W/m² are depicted in Figure 8.

While the reference room has high cooling energy consumption during the daily working hours, the PCM systems reduce the active cooling energy during the day by 40 % to 80 %. This is achieved by their passive cooling potential (green bars in Figure 8). During the night, the rooms with the PCM systems require more cooling energy due to the regeneration process of the PCM (blue bars in Figure 8). This yields to a higher total amount of active cooling energy (sum of red and blue bars in Figure 8) in R111 and R112 compared to the reference room R110 while the total active cooling energy in R113 is slightly lower than that of R110.

It must be noted, that the PCM systems in R111 and R112 which had a higher total energy consumption could achieve mean globe temperatures during the working hours of about 1 °C lower than the reference room (temperature values in white areas in Figure 8). Even the PCM system in R113 which needed less cooling energy than the reference room achieved mean globe temperatures that were about 0.5 °C lower than that in R110.

The measurement results can be summarized as follows:

- PCM systems can shift a big portion of the daily cooling loads to the night
- PCM systems need a lot of energy for cooling down due to the nightly PCM-regeneration; this could lead to higher total cooling energy consumption than for a conventional cooling ceiling, depending on PCM system
- the PCM system in room R113 (PCM cooling ceiling with PCM at the bottom + Knauf PCM wallboards) is slightly advantageous compared to a conventional cooling ceiling with respect to the total energy consumption
- the efficiency of the cold production during the night is highly important for the investigated PCM systems
- since cold usually can be produced more efficiently during the night due to lower ambient temperatures, even the PCM systems in R111 and R112 with a higher total cooling energy consumption might be advantageous compared to a conventional cooling ceiling
- the PCM systems improve thermal comfort (lower mean globe temperatures) compared to the reference room at the same control parameters. Due to the time shift to the night, even with a much smaller TES the cooling energy in this case can be produced more efficient.

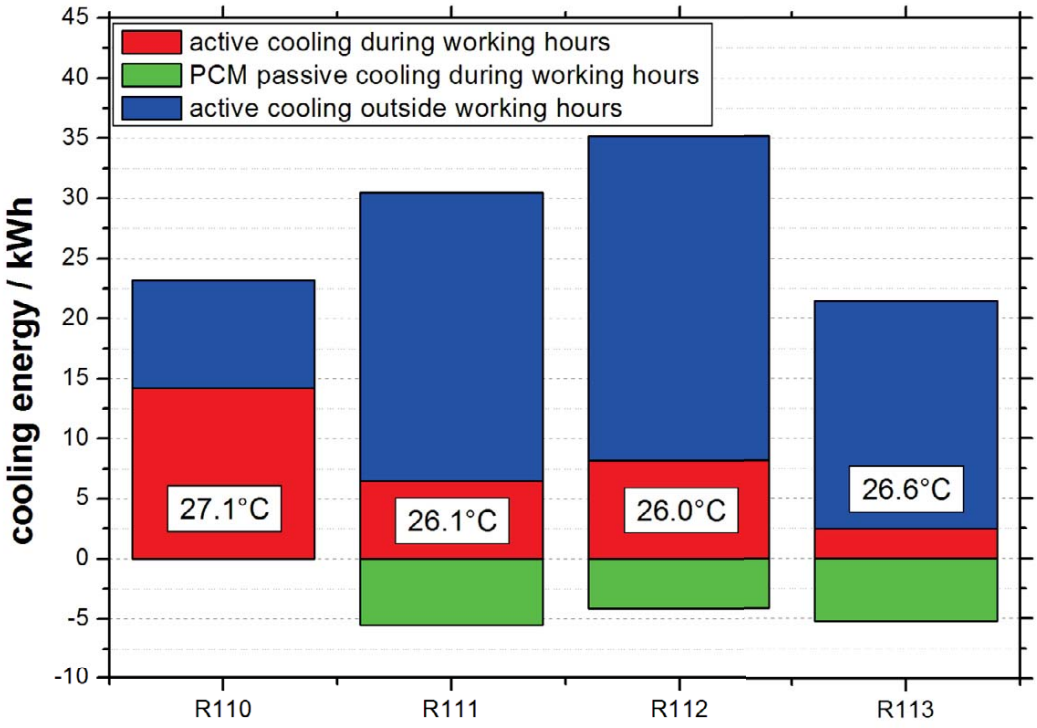

Fig. 8: Active and passive cooling energy of the cooling ceilings in four office rooms with specific heat loads of 46 W/m² between 7 am and 8 pm. The values in the white areas depict the mean globe temperature during the working hours.

3. Improvements and Outlook

A new water distribution method was introduced to increase the efficiency of the PINC system. The water is now distributed over the roof through a pipe with slits instead of nozzles, with hardly any loss in pressure.

The cooling circuits in the EEC are going to be restructured so that the PINC system can also be used in winter.

Furthermore, work is being carried out on developing the PINC's control system. Instead of using fixed trigger criteria, a high-level controller which factors in the weather forecast as well as cooling load prognoses calculated by means of building simulation enabling optimum control could improve the performance of the PINC. Simulations of the improved control system have shown an increase in efficiency of approx. 30% of the EER.

The conventional compression cooling unit (for backup purpose) is connected to ab big TES as well. For higher efficiency it is planned, to operate this cooling unit only at night time. At daytime, the TES should have sufficient cold stored for the cooling load of the EEC as shown at Gwerder and Illi (2016).

The PCM systems as well as two cold production systems (PINC + conventional compression chiller) will be implemented into a TRNSYS model that will be validated with the monitoring data. The models then will be used to investigate the performance of the PCM systems including cold production.

Abstract

The proposed paper explains in detail the sizing process and dynamic simulation of a solar powered system designed to satisfy the energy demand of a school in the rural area of Haridwar district, India. The system is able to satisfy heterogeneous power demands for typical rural applications: hay pasteurization process, refrigerated storage for vegetables (explained in a second publication) and steam cooking. The considered layout is first described and evaluated under steady state assumption to identify the rough size of the main components. The specific configuration is then implemented and simulated using a Modelica-based layout, specifically developed for the case study. The dynamic behaviour of the system for different power requirements is simulated and analyzed over a typical day of usage. The goal to properly size and study the solar field, Phase Change Material (PCM) thermal storage and overall Balance Of Plant (BOP) is achieved.
Simulations results show that an optimal sizing can be achieved despite the large area of solar collectors required to ensure the power requirements of the facility. A better trade off between economic investment and system effectiveness can be accomplished slightly shifting the daily cooking activities.
The final designed system is going be implemented and commissioned in the proposed rural area. Future work will consist in comparing experimental data with the dynamic model predictions.

$\mathbf{r}_{\mathbf{p,P}}^{*}$	Pressure ration
Δp	Pressure loss
k	Friction factor
ρ	Fluid density
A	Cross sectional area
$\dot{V}$	Volumetric flow rate

1. Introduction

India is the second most populated country in the world, almost 1.3 billion of people (Worldmeter, 2016) with more than 50% below the age of 25 and more than 65% below the age of 35 (BBC report, 2007). The astonishing population growth over the past 20 years can be mainly attributed to a remarkable economic growth, which placed the country among the 10 largest economies in the world by nominal Gross Domestic Product (GDP) (IMF, 2014). Economic progress made significant changes all around this vast nation, both in cities and minor villages, with a remarkable effect on the life style and habits of millions of people.

This rapid change eventually created strong disparities between rural and metropolitan areas. The signs of this important gap can be easily found in many aspects of people's daily life.

While most part of the Indian cities and central villages can base their daily activities on a reliable and stable electric power distribution grid, this is not liable for smaller communities. Rural areas are in fact non-uniformly electrified, depending on the financial resources of each single state. Due to this aspect, 400 million Indians are without electricity in rural India, 40% of the whole world's population without access to electricity (University of Washington, 2013). Lack of internal resources, economic poverty, and poor planning are some of the most relevant causes which has contributed to leave rural villages in India without electricity, while urban areas have experienced in the last few decades' growth in electricity capacity and consumption. In these circumstances, diesel generators fulfill the basic electric demand, which is normally used to guarantee food preservation (through refrigerators) or essential illumination. Cooking and heating necessities need also to be taken into account. In rural communities most part of the cooking activities are still accomplished through the use of traditional wood fired stoves or fossil fuels such petrol and kerosene. The dependence of rural households on traditional fuel is mainly due to the poor purchasing capacity of the people to buy commercial fuel and the easy accessibility to traditional sources like cow-dung and agricultural wastes (Kumar et al., 2010). As it is easy to expect, the thermal efficiency of these traditional sources is very low, approximately 15% (energy efficiency). The use of these traditional fuels is estimated to cause around 400,000 premature annual deaths due to various respiratory problems (NISTADS, 2008). Furthermore, the vast availability of unemployed and cheap manpower for fuel collection worsens this situation.

The government is increasingly trying to improve these harsh conditions by funding projects and initiatives related to biogas, solar and wind energy applications. Since the slow process of total electrification will perhaps take many years to provide an extended and reliable grid, alternatives, based on clean and abundant renewable energies, need to be evaluated as viable solution for small and middle size rural applications for India villages. Among the bigger programs, the Jawaharlal Nehru National (JNN) Solar Mission has the ambitious goal of implementing 20,000 MW of solar power by 2022 reducing the cost of solar power generation in the country (Ministry of new and renewable energy, 2013). The Indian government is also tying to sensitize people to clean energies. In a five-year plan, 30,000 million INR (approx. $500 million USD) are budgeted for clean cooking education in more than 500,000 schools (Wikia, 2016).

In this context, the India Trento Program for Advanced Research (ITPAR) is running the "Sustainable Technologies for distributed level Applications and energy support to Rural development" (STAR) project. ITPAR is bilateral collaboration supported by the Department of Science and Technology of the Indian Government (DST) and by the Province of Trento with the supervision of the Italian Ministry for Foreign Affairs. It involves some of the main university teams and research institutes of the Province of Trento and India. The STAR project is participated by the research institute Fondazione Bruno Kessler (FBK) from Trento, the Indian Institute of Technology (IIT) Roorkee, IIT Delhi and University South Campus Delhi. The project aims at the integration of a novel energy system in the district of Hardwar, composed of a combined solar thermal plant able to satisfy part of the daily thermal requirements of the Chudiyala Mohanpur village's high school. At the same time, the system is able to store thermal energy and run a hay processer prototype used by the village's farmers to improve the nutritional properties and quality of hay for animal feedstock.

The thermal system integrates two different technologies of solar collectors and a high capacity PCM thermal storage to decouple solar energy and thermal necessities. It is designed as demo system but it will be able to satisfy part of the energy-related necessities of the school.

The hay-processing device will be also implemented at a demonstrative size to prove the concept. In parallel, the school will be also supplied with an innovative solar cooler machine to store vegetables for short to mid

term periods. Since the analysis of this second system is beyond the scope of the paper, the description will not be included.

A preliminary system evaluation identifies energy requirements and components considering the steam requirements for the community's daily activities. After this first stage of design, the main components of the system are selected and a dynamic simulation in Modelica environment is chased with the objective of meeting collector's area and the thermal storage dimension. Figure 1 conceptually summarizes the paper structures and how the different chapters are structured and linked each other.

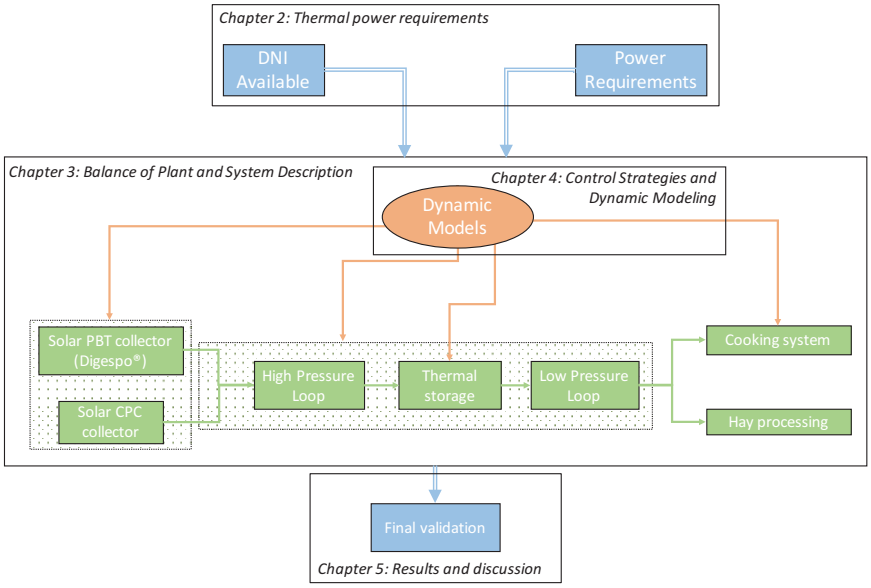

Fig. 1: Flow chart of the design development process. Inputs and outputs are highlighted in light blue. Dynamic model and P&I blocks are highlighted in orange and light greens, respectively.

2. Thermal power requirements

Within the framework of renewable energy system integrations for medium and small-size rural villages, a multi-purpose concentrated solar power (CSP) application is designed and presented. The proposed layout implements a thermal solution able to supply a reliable and clean source of thermal power. The system will be employed in a high school of an Indian rural village with a total number of about 600 people, including students and teachers.

The solar system has the initial target to demonstrate the application of the concept and further increase the size of the prototype. The researchers of the Indian Institute of Technology of Roorkee have assumed reference values for the quantity of food the system has to guarantee daily.

Assuming rice as the most common food prepared for the students, comprehensive analyses on the energy for cooking consumptions are available in literature. The studies help to estimate the energy required to cook rice, under specific assumptions such as type of cooking process, time needed and pre-treatment of the rice (Tribeni et al., 2006). Controlled energy input, cooking under pressure and soaking of rice before cooking are the three approaches that can be directly traduced into energy saving. (Dilip Kumar De et al., 2014) also chased a detail study related to the energy required for rice cooking process. According to this study, the energy consumption for fired open cooking of 1 kg of non-soaked rice requires 1.6 kg of water. Furthermore, the majority of the households in rural countries use firewood to prepare their daily meals. This process approximately needs 1.64 MJ of heat delivered to the pot. Energy cooking consumption easily varies depending on the process but values for fired open pots are reasonably similar to the ones for the discussed system (steam injected kettle). Hypotheses therefore are necessary to quantify the steam consumption on the working fluid side. Assuming that only the latent heat of vaporization/condensation of steam is transferred to the product, the delta enthalpy of vaporization for steam Δh_{EVAP} is 2326 kJ/kg. The specific heat of water is

assumed constant and equal to 4.186 kJ/kgK. Assuming a reference efficiency of the cooking system of η_{POT}: 75%, the amount of steam required to cook 10kg of rice can be estimated. Table 1 lists the constants introduced for this evaluation.

Tab. 1: Summary of the ingredients properties and total energy required for the cooking process.

Primary sources	Quantities (kg)	Heat capacities (kJ/kgK)	Total energy required (kJ)	Efficiency of the cooking pot	Total steam required for cooking (kg)
Rice	10	2.5	16400	75%	9.4
Water	1.6	4.186			

Once the energy demand of the main cooking process is identified, the power system is designed in order to fulfill the demand. The system will be opportunely oversized due to the uncertainty of some variables and assumptions such thermal losses due to poor insulation. Furthermore, the system has also to be able to provide the right amount of energy required to process the hay for the village's farmers.

3. Balance of Plant and System Description

Scheme of Figure 2 shows how the designed layout can be divided into two different main blocks. The plant has two separated loops: high pressure loop, circled within the blue line segment, and low pressure loop, highlighted in green. In the first circuit, high-pressure water is heated up close to the saturation temperature through a combination of Compound Parabolic Collectors (CPC) and an innovative Parabolic Through Collectors (PTC) technology. The proposed solution includes high efficiency CPC coupled with novel coaxial PTC, developed in the framework of the EU funded DIGESPO project (FP7-DIGESPO, grant agreement n° *241267*). Due to the high working temperature of the system, these two different technologies linked together ensure respectable values of nominal efficiency even with temperatures close to the upper limit set point. Because of this specific solution, high temperatures can be reached at the solar field outlet, ensuring good efficiency with acceptable investment costs. At the same time, high temperature energy can be stored inside the thermal storage, reducing for instance the risk of sub-cooled vapor at the low-pressure side. High-pressure loop works at nominal pressure of 10 bar (with possible maximum pressure of 12 bar). At this stage, water changes phase at approximately 179 °C, guaranteeing high temperature in the storage. The control of the solar system is implemented in order to work with a safe sub-cooling temperature of 10 °C. If outlet temperature T4 of Figure 1 overpasses the maximum temperature, a safety control defocuses the DIGESPO solar field, before emergency relief valves empty the system.
Temperature and pressure and mass flow sensors (according to the legend) are located in the most significant parts of the system.
The choice of using pressurized water instead of thermal oil is an advantage in terms of BOP simplicity and reliability. Avoiding oil allows the use of inexpensive working fluid and components, such pumps or expansion vessels. Solar collectors do not require any changes to work with pressurized water and both typologies of collectors can handle the nominal design pressure. Additionally, the maintenance cost is considerably reduced and spare components are expected to be easier to find for water or steam rather than for oil, especially in rural areas. This choice globally helps to decrease the initial investment cost as well as the maintenance of the storage system.
The final system, designed to exploit the solar thermal power for different rural applications widespread in most part of the Indian rural communities (Kuldeep Ojha, 2010), is expected to be flexible and easily scalable to increase its potential.

3.1 High-pressure loop

The high-pressure loop is composed by CPC solar collectors connected in series with PTC DIGESPO collectors. CPC field pre-heats the fluid before entering the DIGESPO collectors. In this part the fluid will reach the maximum target temperature with relatively low thermal losses. The fluid flow is regulated through variable speed pump of Figure 1, which can be tuned in order to reduce and eventually stop the flow. The pressurized loop discharges the liquid water directly inside the thermal storage. For this reason, the tank does

not have internal coil but is itself working at the same nominal pressure of the collectors. Two parallel loops are added in case the thermal storage requires maintenance or direct steam generation tests want to be carried out (see Figure 2).

3.2 Low-pressure loop

The low-pressure loop is in charge of delivering high temperature thermal energy using water at steam phase as thermal vector. In order to provide a low-pressure steam circuit, the thermal storage is built up with a finned internal coil to allow improved heat exchange between the hot pressurized water and the non-pressurized water. The expected temperature difference between the two loops (pressurized water inlet and non-pressurized water inlet) is around 100 °C. The thermal storage is filled with PCM balls in order to keep the temperature controlled inside the tank and to reduce its total dimensions.

The low-pressure distribution system, highlighted in green in Figure 2, connects this first part of circuit with all the final devices. A three-way valve allows to manually choosing whether to divert the steam flow to the hay processer or to the cooking kettle. If the steam produced is exploited through the hay processor, a reintegration of fresh water is necessary. In case the steam is used for the cooking system, no reintegration is needed since the loop is close. Despite this, a small condenser with steam trap is built-in directly in the kettle's loop to guarantee liquid phase before the feeding pump.

The feeding pump is chosen as variable speed, driving the mass flow rate in this loop. This choice is because a variable flow is able to guarantee a constant inlet temperature at the exchanger, guaranteeing the right amount and quality of steam.

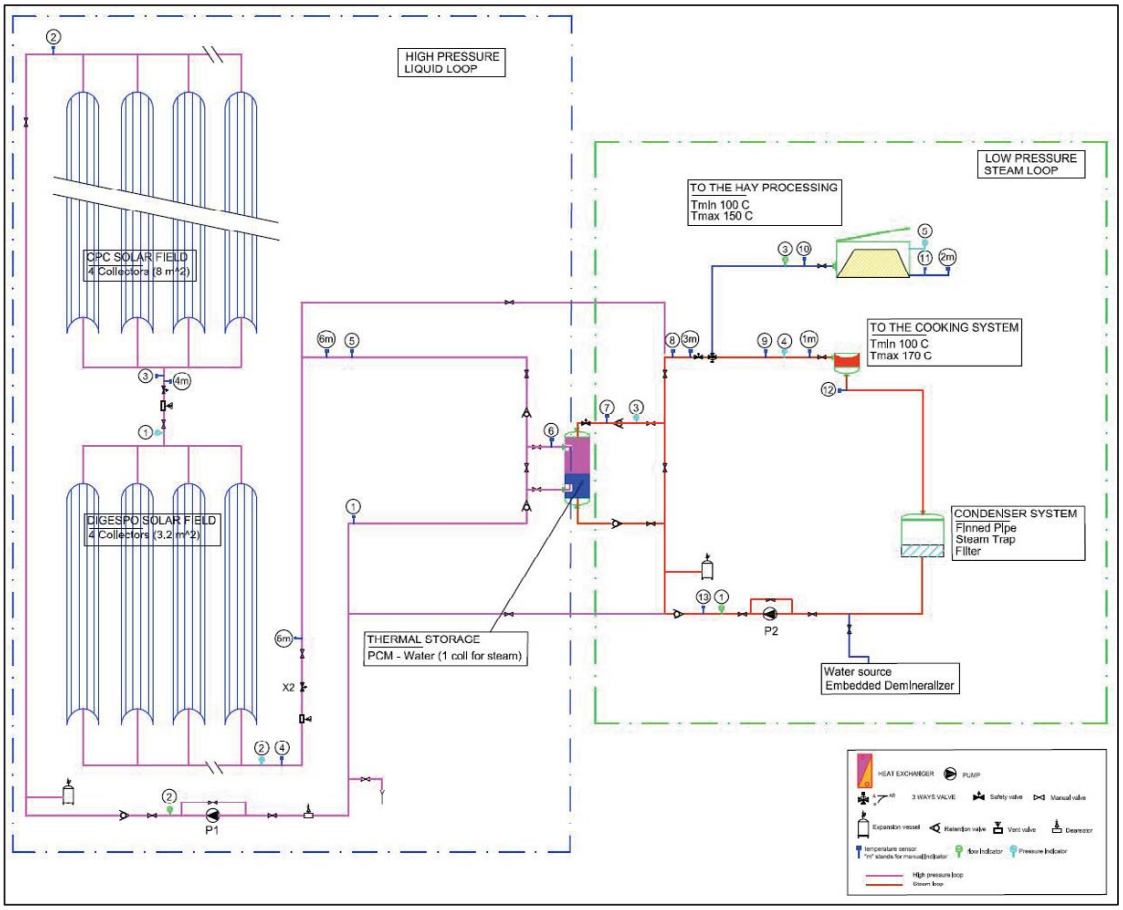

Fig. 2: BoP for the system proposed. High and Low pressure loops are highlighted in blue and green, respectively.

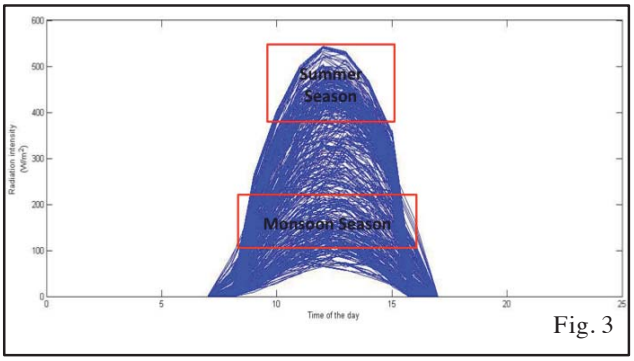
3.3 Thermal storage

The chart of figure 3 shows the typical DNI trend along the different seasons in the Uttarakhand sate. During the sunniest period of the year (summer season), the maximum value of DNI available in the demo site area hardly reaches 520 W/m^2. This is mainly due to the though typical weather of the region. Despite the high temperatures reached during summer season, clouds often cover sky, directly affecting the power available. Furthermore, the chart shows the irradiation distribution all along the day. The peak of power is expected around midday, when the sun is higher in the sky. This is a considerable issue for cooking applications, since they are expected to work at full load during this period of the day. The cooking system will be mainly used between 11AM and 1PM to prepare the daily meals for the school. Less problematic is the use of the hay process because it doesn't require activation during specific periods of the day. For these reasons, a thermal storage is necessary to partially decouple solar power and thermal demand. The thermal storage requires being capable to storage at least the amount of energy necessary to cook the preselected amount of food.
Since the power required for the cooking process is much higher than the power delivered through the sun, the storage will be rapidly discharged when the cooking process is active. Because of that, the dimension of the storage has to be enough large to avoid this problem. On the other hand a bigger storage could affect the maximum temperature reached.



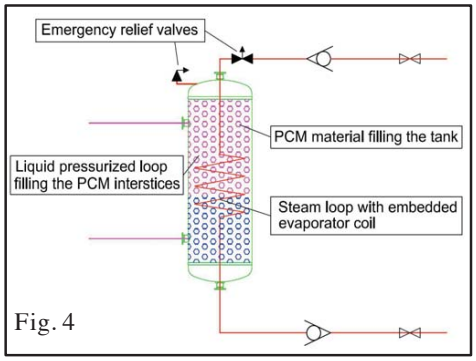


Fig. 3: Distribution of Direct Normal Irradiation (DNI) along the days of a typical year.
Fig. 4: Schematic of the pressurized thermal storage with PCM balls.

If the power available is not sufficient to charge the storage, the temperature reached could be too low to produce steam when necessary. This concern could be even more amplified with the use of PCM material inside the tank. If is true that PCM materials help reducing the total volume occupied by the storage, on the other hand the material has to reach the saturation temperature in order to change phase and to store sensible heat. If this doesn't occur, the PCM material is un-useful since only latent heat without a controlled temperature is stored. For these reasons the storage requires a careful sizing and a simplified approach to implement and study the dynamic behavior of the whole system is pursued. Figure 4 briefly describes how the storage is designed. The phase change material fill the pressurized vessel and the water coming from the solar field will fill the interstices among each ball. In this way the heat power will be directly exchanged between fluid and metal balls containing the PCM. The pressurized tank has a built-in coil connected to the low-pressure steam loop to provide the power only when necessary through the use of a variable speed pump.

3.4 Solar collectors

The designed system is characterized by two different kinds of collectors: CPC and PTC DIGESPO tubes. Parabolic through collectors with evacuated tubular absorber are renown as the most reliable technology in the Concentrated Solar Power (CSP) field (Cabello et al., 2011). In the proposed system, the CPC solar field works as a pre-heater for the CSP collectors, reducing the global investment cost of the solar field. CPC collectors have high reliability ensuring a good compromise between efficiency and capital cost.
CPC collector field is connected in series to the higher temperature DIGESPO technology collectors. This

second stage has the fundamental role to increase the temperature up to the maximum temperature before going directly to the thermal storage to heat up the PCM material. An external glass tube and an internal metallic support compose the evacuated solar tube developed within the DIGESPO project. The metallic support is tubular while an absorber pipe made from stainless steel had been specifically realized with a molybdenum protection layer and coated with CerMet. The potential problem arising from thermal stress dilation and glass cracks has been solved with the use of a coaxial tube. A spiral wire is present between the two coaxial pipes solving the thermal gradient problems and reducing thermal deformations. The full-evacuated solar tube has an inner diameter of 12 mm and a total length of 2 meters for an active surface of 0.8 m^2. The solar technology has been fully proven on a demonstration site. The solar plant prototype was installed in Malta, supplying thermal energy for industrial heat processes. The solar collector's efficiency reached 55% with DNI of 900 W/m^2 and working temperature of 300°C. Due to the noticeable efficiency that the collectors are able to show at high temperature, is reasonable to expect that the thermal losses related to the last stage of the solar field will be considerably low compare to a solution made by CPC collectors only.

3.5 Cooking system and hay processing

The low-pressure system delivers the steam directly to the steam-cooking kettle, a device specifically designed to use steam as thermal vector. The typical steam kettles are large container with a round or spherical bottom. Kettles have a double wall or "jacket" covering the bottom and at least half of the height of the sides, to provide space for steam to circulate thereby heating the cooking surface. In principle, the steam kettle operates like the classic kitchen double boiler. The kettle operates within a specific pressure range at which the steam can be injected into the kettle. This range is typically between 0,07 Bar and 3,5 Bar with nominal temperature up to 150°C. The kettle used for this application is 100-liter capacity SS304 kettle. The outlet part of the kettle is provided with steam safety valve and condenser system, including air vent, Y type strainer and steam trap.

Through a three-way valve, the steam coming from the PCM tank can be diverted to the hay processer when cooking demand is absent. The process for which the steam is involved is to pasteurize wheat straw without complete sterilize the cereal. Unlike sterilization, pasteurization is simply the process by which amounts of microscopic competitors in a substrate are reduced (IDFA, 2016). Sterilization in fact, would remove all living organisms, leaving the straw without beneficial bacteria and therefore susceptible to contaminants. As consequence, having beneficial microorganisms allows inoculating the straw without using special sterile procedures. Pasteurization generally occurs between 70-75° C but it is strongly dependent by the thermal death point of fungus or spores. Due to the scientific aspect of the system will be implemented, a maximum temperature up to 150°C is required for the hay processer. Steam temperature and exposure time are crucial components of this process.

4. Control Strategies and Dynamic Modeling

The control strategies for the system is developed and simulated using thermal daily requirements of the elementary school coupled with yearly weather data of the specific geographical area. Weather data are available at (Weather Data Reference, 2012).

The typical trend of thermal requirements for food cooking and hay processing is represented in the chart of Figure 5. Here, the simulated power requirements used for the dynamic simulation are depicted with time dependency.

At the very beginning of a typical day, thermal demand is absent since neither cooking stoves or hay system is activated. This is considered as small advantage for the system, which is therefore able to cumulate the solar energy available the early hours of the morning before cooking activities begin. At 11AM the school kitchen starts to warm up the circuits with high temperature steam. At this stage the power requirement is much higher then what instantly available from the solar field. For this reason, the lack of power is fulfilled through the thermal storage system.

The cooking energy requirement of 7 kWh can be reasonably approximated constant for one hour, between 11.30AM and 12.30AM when the school activities are still on going. This is approximately happening the

whole year, with exception for the monsoon season, which lasts from June to early September. During this period in fact, thermal cooking requirements are absent and the system will be completely dedicated to produce steam for hay processing or different sporadic activities requiring steam, such sterilization or cleaning. Outside the monsoon season, the hay process thermal requirements are satisfied during the afternoon period. Since this action does not need to respect strict schedule as the school lunchtime, hay processing activities are simulated as two sessions requiring 2, 5 kWh energy (including extra energy due to thermal inertia) for one hour each. This choice allows the system having enough time to store energy inside the thermal tank after the cooking period. This strategy has been developed and selected among different proposals and it will be implemented at the first stage of the on-field tests.

In order to forecast and study the transient behavior of the whole layout during the proposed typical day, a Modelica based system has been simulated with Dymola environment using the thermodynamic library ThermoCycle. ThermoCycle is an open-source Modelica Library (Modelica Website, 2016). This is a powerful tool able to describe in details the dynamic behavior of complex thermodynamic systems thanks to a user-friendly and widely tunable interface. (Desideri et al., 2015).

The model is first used to complete the design of the layout and to properly size the embedded thermal storage indispensable to decouple solar energy from power demand.

In Figure 6, the Dymola layout describing the implemented system is presented.

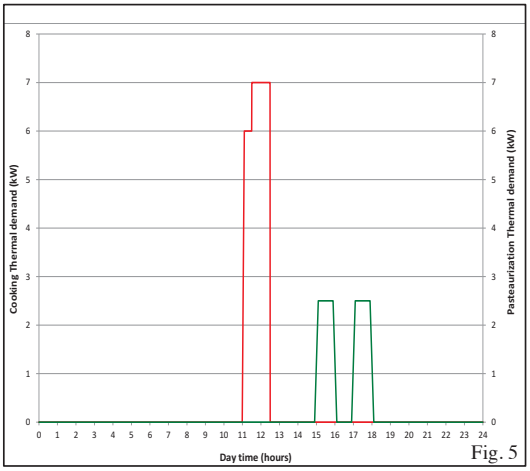

Fig. 5

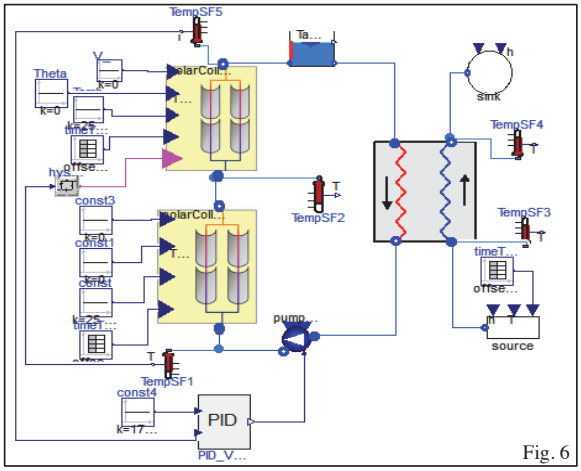

Fig. 6

Fig. 5: Scheduled thermal requirements of the system for both hay processing and cooking.
Fig. 6: Overview of the system layout implemented with Dymola.

High-pressure, liquid phase water is simulated inside the solar system while the evaporation process is modeled on the heat distribution part, right side of Figure 6. The water going to the storage tank warms up the phase change material to produce superheated steam through a dedicated boiling system. The steam loop is designed as open loop that delivers the power provided by the solar plant directly to the final users.

The dynamic modelling is necessary to define the size of the main components of the system as well as the reactiveness of the layout to rapid changes of working conditions. In addition, the dynamic model tests if safe working conditions in terms of maximum pressure and temperatures are guaranteed.

4.1. Dymola modeling: Solar collectors

Assuming homogeneous pressure drop and equal ambient input data, the solar field can be modeled as a single CPC collector in series with four PTC DIGESPO type collectors arranged in parallel. For this particular connection, the mass flow inside each single PTC collector is one fourth of the total mass flow. Parabolic through collector model of *ThermoCycle* library is used. Given the ratio between the diameter and the length of the parabolic through unit, the modeling approach is based on a finite volume one-dimensional discretization along the collector axial axis. The model is the result of two subcomponents. *Flow1Dim* component models the fluid flow through the Heat Collector Element (HCE) accounting for energy and mass transfer. At the same time, thermal inertia in the HCE is accounted by the *MetalWall* and *SolAbs* models as

depicted in Figure 7. Moreover, the model implements the relations between the environmental parameters (DNI, θ_{incid} , T_{amb} , V_{wind}) and the axial temperature distribution along the absorber. The equations defining the thermal energy transfer from the sun energy concentrated on the heat collector element to the heat transfer fluid are listed below. The first equation describes the thermal energy transfer from the sun to the metal wall of the absorber (refer to nomenclature table):

$$\dot{q}_{tot,t} = \frac{DNI \cdot \eta_{opt,t} \cdot A_{ref}}{A_{ext,t}} \quad \text{(eq. 1)}$$

Thermal energy transfer from the sun to the glass envelope:

$$\dot{q}_{tot,g} = \frac{DNI \cdot \eta_{opt,g} \cdot A_{ref}}{A_{ext,g}} \quad \text{(eq. 2)}$$

Radiation to the ambient air:

$$\dot{q}_{rad,air} = \epsilon_g \cdot \sigma \cdot (T^4_{ext,g} - T^4_{sky}) \quad \text{(eq. 3)}$$

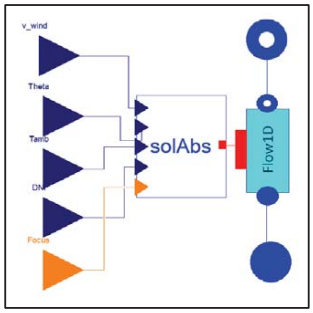

Fig. 7: Solar collector model available on ThermoCycle library.

4.2 Dymola modeling: PCM storage

A PCM tank is a major component for most part of the solar power plants due to its capacity to storage thermal energy for short and medium periods of time (Casati et al., 2013). The PCM storage of this study is modeled using three discretized one-dimensional subcomponents of the *ThermoCycle* library. Two *Flow1Dim* components accounting for mass and energy exchange in the two separated coils are merged with the PCM*Wall* component, which accounts for the overall energy accumulated in metal coils, metal balls containing the PCM and in the water filling tank. *PCMWall* component derives from the basic *MetalWall* component available on Modelica. *MetalWall* generally accounts for thermal energy accumulation in the metal wall. In this study this component has been modified in order to describe the typical thermodynamic behavior of PCM materials. The models are discretized based on the finite volume approach as depicted in Figure 8. No pressure losses are considered in the two *Flow1Dim* models and the temperature in the storage is supposed to be homogenous for each layer. Thermal energy accumulation is expressed as:

$$\frac{M_w}{N \cdot c_w} \cdot \frac{dT_w}{dt} = \Lambda_{ext} \cdot \dot{q}_{ext} + \Lambda_{int} \cdot \dot{q}_{int} \quad \text{(eq. 4)}$$

where M_w is the total mass of the wall, N is the number of cells and c_W is the heat capacity. The secondary fluid is modelled as an incompressible fluid whose density and specific heat capacity are assumed constant throughout the exchanger length. The component has been modified in order to consider the latent heat during the transition phase of the PCM at the specific temperature of 150°C. The computation of the heat transfer coefficient for the PCM storage and more generally for all the heat exchangers of the dynamic system, is based on a structure taking advantage of the object-oriented Modelica language. The basic interface, define an ideal heat transfer element with no thermal resistance. The object takes as an input the

bulk state of the fluid and computes the thermal energy flow per area.

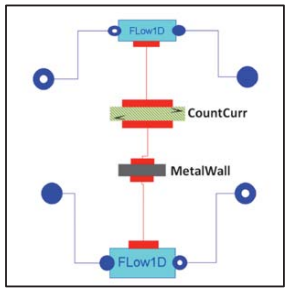

Fig. 8: Representation of the finite volume heat transfer basic block.

Based on these considerations, equation 4 is used to model convective heat transfer coefficient accounting for mass flow variation (refer to nomenclature table):

$$U = \frac{(U_l + U_{tp} + U_v)}{3} \left(\frac{\dot{m}}{\dot{m}_{nom}}\right)^n \quad \text{(eq. 5)}$$

where the exponent n varies depending on the flow regime between 0.65 and 0.8.

4.3 Dymola modeling: Cooking system

Three different models from ThermoCycle library compose the cooking pot model. *Flow1Dim* describes the steam flow through the cooking pot while *MetalWall* model is used to consider the thermal inertia of the device's metal wall. The last component takes into account the heat transfer between the steam and the food. Inputs for the final component are the food quantity and the cooking time to assess the power extraction considering constant convective and radiative ambient losses.

4.4 Dymola modeling: Pump, pressure drop, bypass valve and PID

The *Pump* model of *ThermoCycle* library is used to simulate the pump units installed on the system. It is a lumped fictitious model simulating the compression of a fluid in a turbo or volumetric machine, where given the flow fraction or the pump frequency, a constant volumetric and isentropic efficiency, the mass flow and the consumed power are computed (Desideri et al., 2015). The isentropic efficiency is simulated in Eq. 6 with a second order polynomial with cross terms as a function of the non-dimensional pressure ratio ($r^*_{p,P}$), and the non-dimensional pump frequency (f^*_P).

$$\varepsilon_{is,P} = c_0 + c_1 \cdot f_P^* + c_2 \cdot (f_P^*)^2 + c_3 \cdot r_{p,P}^* + c_4 \cdot (r_{p,P}^*)^2 + c_5 \cdot f_P^* \cdot r_{p,P}^* \quad \text{(eq. 6)}$$

$$\Delta p = \Delta p_{linear} + \Delta p_{quadratic}; \quad \Delta p_{linear} = k \cdot \dot{V}; \quad \Delta p_{quadratic} = \frac{1}{A^2} \cdot \frac{\dot{m}^2}{2 \cdot \rho} \quad \text{(eq. 7)}$$

A linear and quadratic pressure drop terms are used to compute the total pressure drop, as depicted in equation 7. *Valve* model from the *ThermoCycle* library is also a lumped model where no dynamic and thermal energy losses to the ambient are considered.

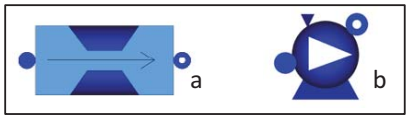

Fig. 9: (a) Pressure losses modelica block. (b) Ideal pump modelica block.

5. Results and Discussion

Four different configurations are simulated over the period of 24 hours and presented with the intention of properly address the solar field and energy storage sizing. A typical averaged day of the summer season has been identified to exploit the simulations. Phase change transitions directly affect the complexity of the simulations. For this reason only daily simulations can be performed at this stage of the study. During the worse season of the year, which is identified in as the monsoon season, the system will be totally deactivated; therefore there is no real necessity to perform simulations with the lowest irradiation values.
Each of the following charts presented includes the selected DNI used for the Dymola simulations. The solar system is composed of two different parts. Four DIGESPO parabolic through collectors for a total constant area of 3.2 m^2 and a CPC assembly, with a variable total collector area. An extensive study can become interesting if considering a future potential cost reduction of the DIGESPO collectors involving local manufacturing or large-scale production.
To summarize, the four scenarios describe the behaviour of the system changing the PCM total mass and the CPC collector area. The PCM change phase temperature equal to 150°C allows choosing among a wide range of phase change materials available on the market (Haillot et al., 2010).
Each simulation is described through two charts. Charts a) of each figure describes the trend of energy storage in the PCM tank as function of time and power demand (blue trend line). The systems starts in the morning at the storage tank lowest temperature set point of 140°C. In order to correctly estimate the actual size of the energy reserve, the reference value of the energy stored is set at 0 kWh for the simulation starting point. Charts b) of the four tests show the trends of the working steam temperature available at the thermal storage outlet and the average storage temperature.

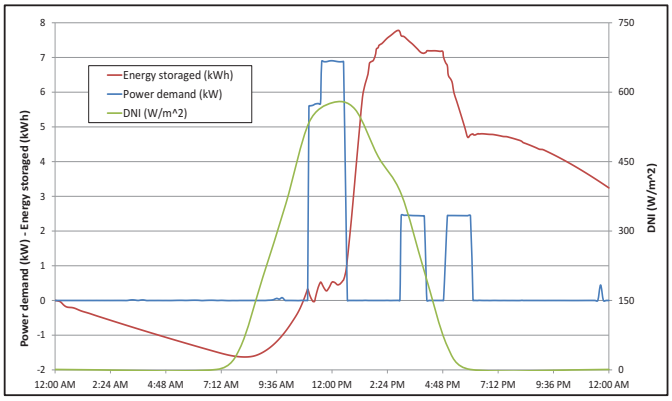

Fig. 10: Scenario 1_Power demand and energy available in the PCM storage

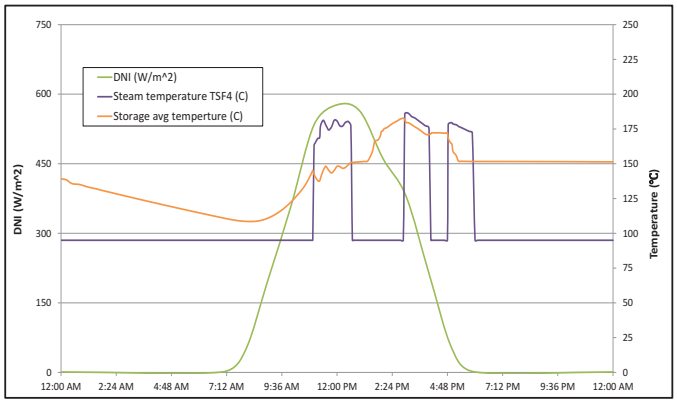

Fig. 11: Scenario 1_ Temperatures of supplied steam and tank average temperature over daily time.

Figure 10 describes the first scenario modelled shows interesting results regarding the potentiality of the thermal storage. This test is characterized by collector areas of 12 m^2 and 3.2 m^2 for CPC and PTC DIGESPO collectors, respectively.
The system depicts a natural drop in terms of energy at the beginning of the day. This is due to the thermal losses when sun is not shining (negative value is due to the reference starting point at 0 kWh). The storage temperature starts to increase when irradiation occurs (around 7.10 AM) together with the storage energy value. A small change of the energy storage slope is shows around 12.00AM when the cooking power requirements is at his top. Here, the power required can be higher than the power instantly available from the collector and the thermal storage working as backup is therefore strictly necessary. The large collector area allows a fast increase of the energy loaded through the PCM after lunch time, with a peak in energy available around 3 PM. At this stage the energy stored exceed the energy requirements of a typical day and Figure 11 shows a possible overheating of the PCM material. This suggests that a possible decrease of the thermal storage and collector area can be followed without affecting the thermal behaviour of the system.

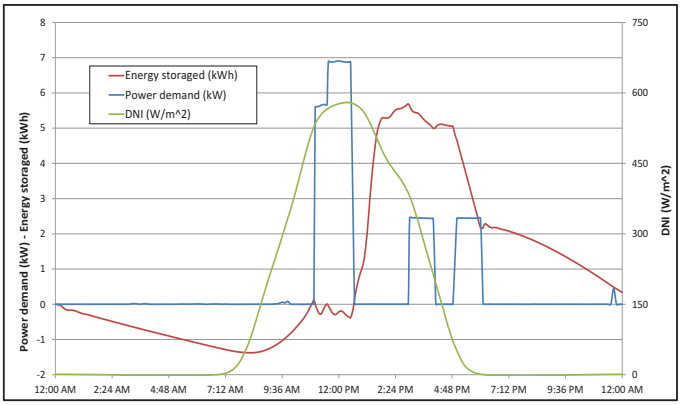

Fig. 12: Scenario 2_Power demand and energy available in the PCM storage

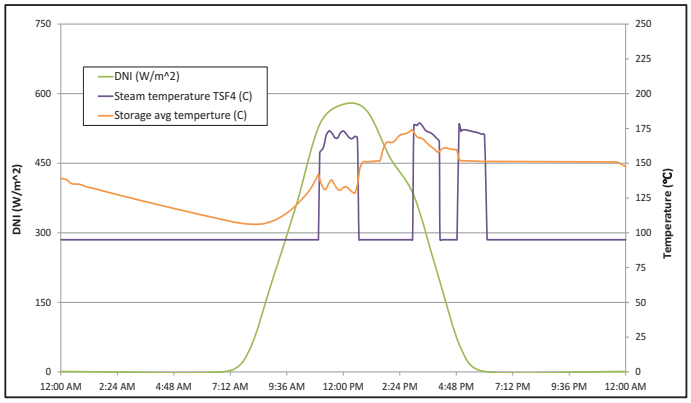

Fig. 13: Scenario 2_ Temperatures of supplied steam and tank average temperature over daily time.

Figure 12 describes the scenario modelled reducing the dimension of the CPC area to 10 m^2 and the storage tank total mass to 70 kg. This configuration seems to satisfy the power demand along a typical day. The maximum peak of energy saved is sufficient to cover the thermal power demand of the hay processing at the end of the day, but an overheating of the phase change material is still depicted in Figure 13.
Outlet steam temperature is strongly dependent by the instant solar irradiation (and therefore by the pressurized water) especially if the storage has not reached the target temperature yet. This behaviour is always true for the cooking power demand, and the highest influence is visible in Figure 13 observing the steam temperature trend. The power demand of the cooking process in fact is required along the morning when the solar radiation has not already refilled the PCM tank. On the other hand, the cooking demand

occurs when the sun is shining and for this reason the power collected is directly exploited by the cooking system and high temperature can be delivered to the cooking pot.
Test showed in chart Figure 13shows a total deployment of the energy stored despite an overheating is still visible in the simulation. Now the possible superheating of the thermal storage simulated does not overpass 190°C as in the previous case but still reaches almost 175°C, over a temperature transition phase of 150°C. This could be reasonably limited reducing the collector area of the power system.

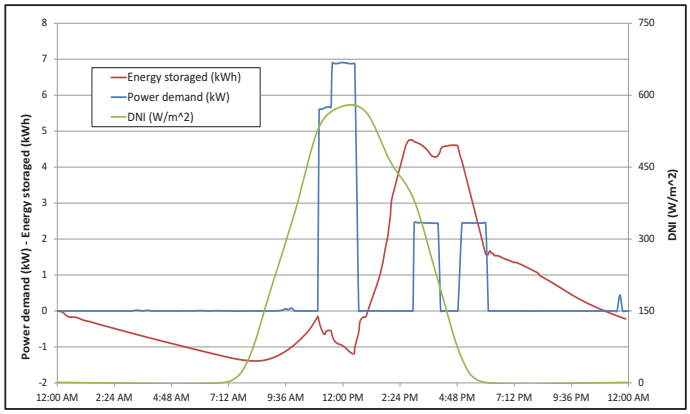

Fig. 14: Scenario 3_Power demand and energy available in the PCM storage

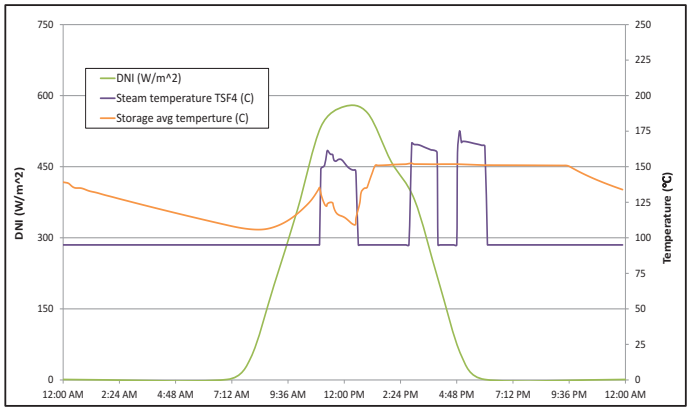

Fig. 15: Scenario 3_ Temperatures of supplied steam and tank average temperature over daily time.

Based on the previous considerations a third scenario is pursued and presented in Figure 14. Here, the total CPC collector area is further reduced. Thermal storage average temperature depicted in graph of Figure 15 does not overpass the PCM transition temperature of 150°C. Obviously, after the sunset a faster temperature drop is now visible. In this scenario the PCM storage works below the design temperature for almost all the typical morning, and a lower steam temperature is expected when lunchtime occurs. This is a second effect related to the CPC area reduction. The average temperature in the storage at 11AM is slightly above 125 °C and dramatically drops below 115°C at the end of the cooking process. This behaviour could affect the cooking effectiveness and reliability of the system, especially if thermal transmission losses on the real installation would be higher than what expected due to poor insulation during the commissioning phase. Moreover, an expected reduction of the optical performances of the solar collectors are normally expected during the lifetime and when used in dusty environments. This, would cause a dramatic decrease of the nominal power available from the collectors with an ulterior effect on the steam production. For these reasons, if the reduction of the collector area certainly reduces the overall economic impact of the system and eliminates PCM's overheating, criticalities regarding the maximum cooking temperature and minimum temperature of the storage are expected.

The last scenario described in Figure 16 further reduces the quantity of PCM material within the storage, keeping the same total collector area of Scenario 3. This reduction deeply affects the economic impact of the thermal storage. The direct consequence is showed in Figure 17. Here, a small peak of overheating is visible in the storage average temperature. Beside this, very low temperature is visible at the end of the day in the thermal tank, suggesting that the new match is not able to satisfy the power requirements. The minimum temperature of the storage tank reached at the end of the day here is much lower than in any other previous case. If this last scenario could show an expected reduction in terms of economic impact the thermal storage cannot be completely exploited, resulting in very low average temperature along the day.

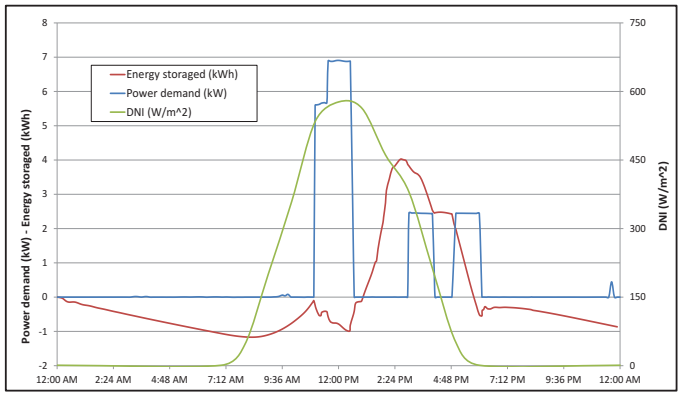

Fig. 16: Scenario 4_Power demand and energy available in the PCM storage

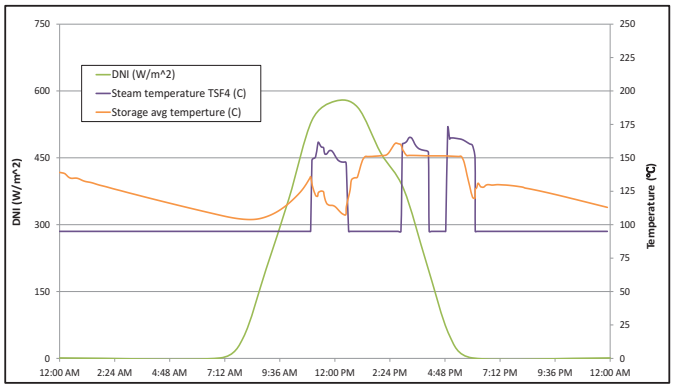

Fig. 17: Scenario 4_ Temperatures of supplied steam and tank average temperature over daily time.

5. Conclusions and Future Works

Dynamic simulations of four different scenarios have been studied in order to properly address the size of solar collectors and PCM thermal storage for a multifunctional rural energy system. The engineering of the system is looking to develop several forms of thermal energy supplied to the school. One of the priorities is a reliable and fossil fuel-free cooking system. Furthermore, the thermal energy accumulated is used during the afternoon to provide high temperature steam to a dedicated hay processing digester. Several technology scenarios have been modelled on a multi objective optimization. Results of the simulations are summarized in Table 2. Scenario 1 shows the best cooking temperature, with an average storage temperature close and stable at 150°C for the most part of the working daily time (a small overheating up to 180°C is visible in the simulation). Due to the large collector area this temperature is rapidly reached at the beginning of the day ensuring reliable temperatures even during the daily cooking activities. Scenario 3 also achieves interesting results. First, a reduction of collectors and PCM material definitely affects the total capital investment. In addition, no overheating is visible in the storage tank and the temperature is constant at 150°C. Despite this, the reduction of collectors' number deeply affects the temperature reached in the storage at the beginning of the cooking time, with dangerous effects on the cooking effectiveness. Scenarios 2 and 4 have been

discharged due to mismatching values between the storage availability and the steam generation temperatures.

Based on these considerations, Scenario 1 is identified and selected as the most reliable solution despite the initial investment cost. At the same time, Scenario 3 could be deeper investigated especially considering the possibility of shifting the cooking habits of the school by 30-45 minutes later in the morning. If agreed with the local community, solar power instantly available could be directly used to satisfy the thermal necessities of the school at lunchtime reducing the necessity of thermal backup. The system could be potentially resized in order to achieve a reduction of costs (reducing the PCM storage) without affecting the performances. This hypothesis may also help to reduce the required dimension of solar collectors, directly affecting the economic investment but maintaining the efficiency and reliability of the system.

Tab. 2: Technical specification of the simulations performed and summary results.

	CPC Area (m^2)	PTC Area (m^2)	PCM total mass (kg)	Max. Energy stored (kWh)	Max Storage avg. temp. (°C)	Min Storage avg. temp. (°C)	Max Steam temp. TSF4 (°C)
Scenario 1 (Fig. 4)	12	3.2	90	7,7	179	108	182
Scenario 2 (Fig. 5)	10	3.2	70	5,6	171	106	177
Scenario 3 (Fig. 6)	7	3.2	70	4,6	150	105	170

Efficiency Analysis of Solar Assisted Heat Supply Systems in Multi-Family Houses

Oliver Arnold[1], Oliver Mercker[1], Jan Steinweg[1] and Gunter Rockendorf[1]

[1] Institut für Solarenergieforschung Hameln (ISFH), Am Ohrberg 1, 31860 Emmerthal (Germany)

Abstract

There are two major approaches to mitigate energy-related emissions of dwellings: Insulating the building's envelope on the one hand and modernizing its heat supply system on the other hand. Often the insulation of dwellings leads to lower energy savings than expected (Greller et al., 2010), which is assumed to be related to the heat losses of the heat distribution system itself. So attention needs to be drawn to the modernization of the heat supply system, which can lead to a significant reduction of the building's final energy demand (Jahnke et al., 2015). This paper is following this approach and focuses on the heat supply and distribution system of multi-family houses (MFH), representing a significant share of Germany's residential market. The present work compares different systems for multi-family houses by means of its primary energy demand, energy efficiency and economic aspects. Heat distribution losses are analyzed and their relevance for efficient systems is discussed. Based on this analysis, the work highlights effective integration routes of solar thermal supply systems which may lead to increased efficiency of the overall heat supply system.

Keywords: *Multi-family houses, heat supply, heat distribution, heat distribution losses, energy efficiency*

1. Introduction

Measured energy demands of insulated dwellings are often higher than theoretically expected, as shown by Majcen et al. (2013). One reason for this are so called 'rebound effects' caused by the dwelling's inhabitants, such as higher room temperatures or higher air exchange rates, which are difficult to model. Another, technical reason for the observed model/measurement divergences are commonly related to heat losses of the heat distribution system. A part of the distribution losses replaces normal operation of the room heating elements and thus may be credited to the energy demand. However, if there is no heat demand at a certain time and in an individual room, occurring distribution losses lead to overheating and as a result to increased transmission and ventilation losses of the building. In this case, the usability of the heat losses is very low. This effect is pronounced in well insulated buildings. In the present paper, this situation is analyzed by means of simulation studies.

A detailed model of a multi-family house has been established, using the TRNSYS software as appropriate modelling environment. The underlying building model refers to typical construction types and equipment which is representative for multi-family houses in Germany. The model allows the dynamic investigation of temperatures, mass flow rates and energy balances as well as the impact of heat distribution losses of individual rooms as well as the entire building. This allows a detailed investigation of the heat losses and their potential contribution to the space heating demand. As a matter of fact, such analysis must be based on simulations, because reproducible and highly analyzable field data are impossible to determine because of the enormous number of parameters, the inhabitant's behavior, the building and weather dynamics and distributed energy flows.

The modelling of the building's heat demand is based on an investigation of different systems that will be compared and rated in this paper. This investigation is initiated concerning the most common heating system in Germany. Based on this, different approaches are rationalized to reduce respective heat distribution losses, in order to improve their usability and – thereby – to decrease the system's energy demand.

doi:10.18086/eurosun.2016.04.21 Available at http://proceedings.ises.org

Eventually, a solar thermal system is suggested as effective approach to increase the energy efficiency of the building. The appropriate design of such solar thermal system is explained related to the analysis of building and energy system and economical aspects are reflected.

2. Simulation environment, building and meteorological model

The simulations are carried out employing the TRNSYS 17 modelling suite, a dynamic system simulation program. The temporal resolution is adjusted by a simulation time-step of one minute and the timescale of a typical simulation spans a one-year period. The building's heat distribution system is modelled quite detailed to correctly simulate the dynamic behavior of the heat distribution and especially the heat losses. It regards over 100 duct sections (using Type 604) for proper spatial resolution of the heat distribution system in the building, which are capable of dynamically calculating heat losses under local thermal and flux conditions.

The model of the considered multi-family house (MFH) was built employing the module TRNBUILD. The model is based on statistical data of MFH designs in Germany. The model comprises four floors, unheated basement and staircases and eight identical flats. Each flat contains five rooms and a corridor. The model assumes an occupation by two dwellers per flat. Every room of the building represents an individual thermal zone which is thermally interacting with adjacent rooms (zones) through walls, floors/ceilings and pipe ducts. In total, the model building consists of 52 thermal zones. The outer shell of the building is assumed to be insulated according to the corresponding German regulation EnEV (2014), always using the minimum values defined by here. For the internal room temperatures a set point of 20 °C is used. The climate model is based on Meteonorm data for the city of Zurich (Swiss), which is proven to be appropriate for central-European moderate climate situations, see Streicher et al. (2003). The resulting specific overall space heating demand of the model building is 35 kWh/(m² a) and a total heat demand is 56 kWh/(m² a). This includes load profiles for domestic hot water as described in Mercker et al. (2016a).

3. Investigated Systems

Four-line pipe network (4L)

A four-line heat distribution network with central heat generation, as shown in Figure 1, is a very common heat supply system for MFH in Germany, see Wolff et al. (2012). Heat for space heating (SH) and domestic hot water (DHW) is distributed via two separate pairs of pipes. The DHW is stored in a central storage at a minimal temperature of 60 °C for hygienic reasons. The heat generation system studied here represents a condensing gas boiler. The design temperatures of the space heating system are 50 °C (flow-line) / 35 °C (return-line) at an ambient temperature of -10 °C.

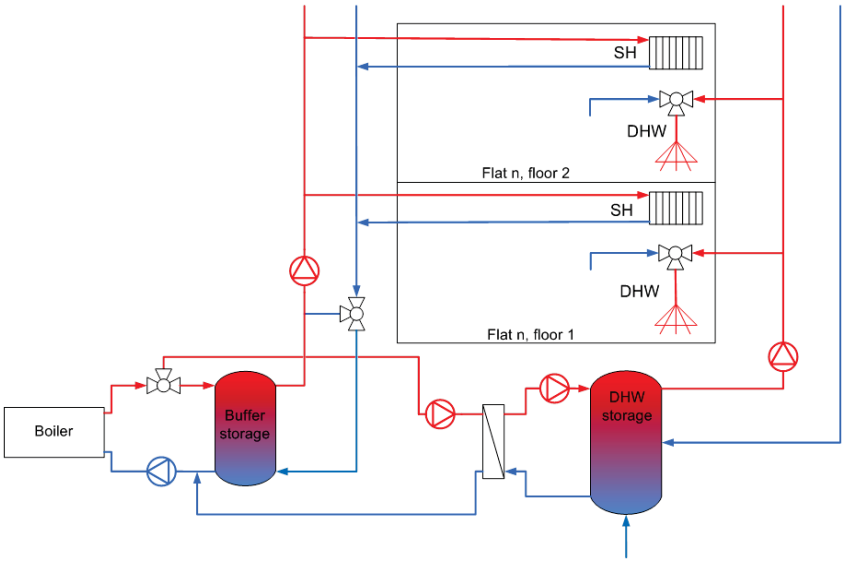

Fig. 1: Four-line pipe network with central heat generation

Dual-line pipe network (2L)

The second set-up considers a dual-line pipe network as shown in Figure 2. It comprises only one pair of pipes for both DHW and SH supply, which contains heating water. The DHW is then heated up on demand in decentralized heat transfer units, which are installed in every individual flat. Accordingly, the overall fluid temperature in the distribution pipes may be allowed to drop below 60 °C. The heat distribution network must meet a DHW comfort criterion of 45 °C draw temperature. To achieve this securely, the supply temperature is set to 50 °C in the simulation. The advantage of 2L over the 4L pipe network results from the lower forward line temperature, the absence of a central DHW-storage as well as the reduction of overall pipe length. Simplified integration of solar thermal heating technology is another advantage of 2L pipe networks in general. An optimized 2L system variant (2L-opt) allows a further reducing of the pipe network's temperature level by electric backup heaters in the local heat transfer modules of the individual flats. The backup heaters ensure the desired tap water temperature (of 45 °C - in this case). They are arranged after the DHW heat exchanger (compare Figure 2).

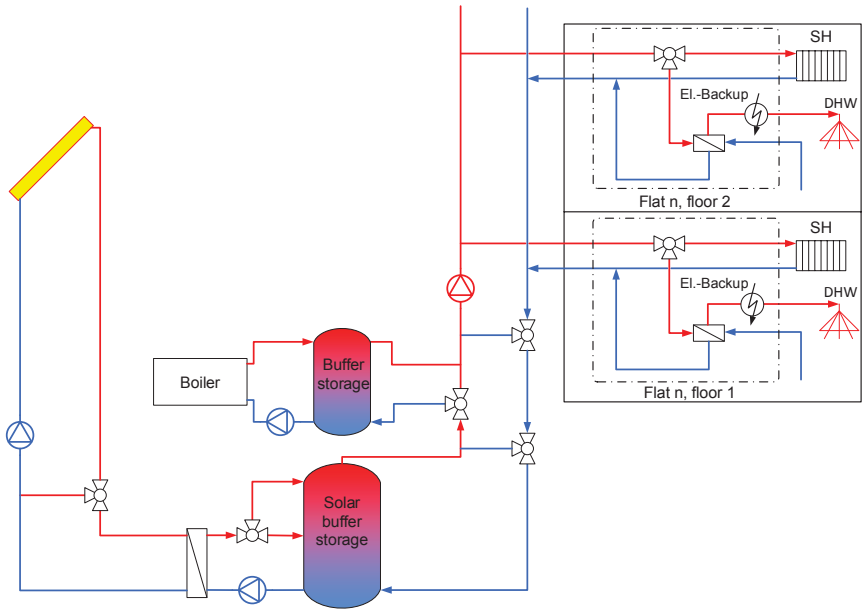

Fig. 2: Dual-line pipe network with central heat generation and integrated solar thermal system

Dual-line pipe network with decentralized storages

The design of this system is the same as standard 2L systems, but with decentralized buffer storages for DHW preparation. These buffers are assumed in each individual flat. The DHW is prepared on demand (when tapped) by near-by domestic hot water modules, which draw heat from the buffers for this purpose (compare Figure 3).

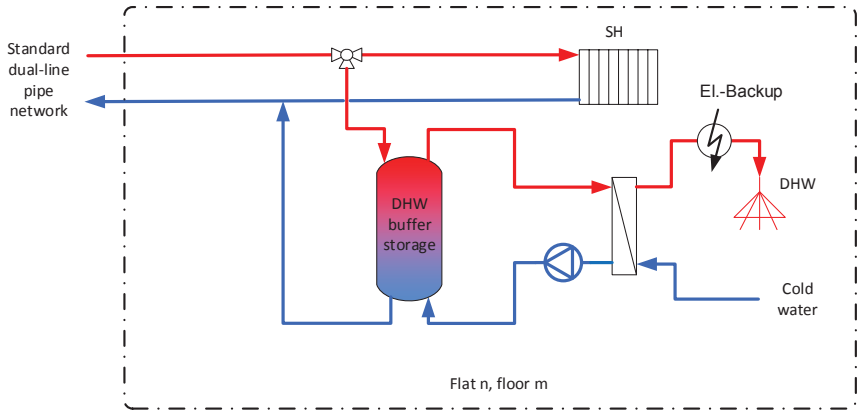

Fig. 3: Dual-line pipe network with decentralized storages in each individual flat

Dual-line pipe network with decentralized boilers

Another design approach to reduce distribution-related heat losses is the de-centralization of the heat generation using fossil fuels. In the present model this can be achieved by decentralized gas boilers installed in the individual flats (compare Figure 4). Because of the low-power level of the boilers, decentralized DHW storages (identical with those in the previous system) are necessary to grant for DHW-comfort. For this concept, the only heat distributed from the heat central to the flats is solar heat.

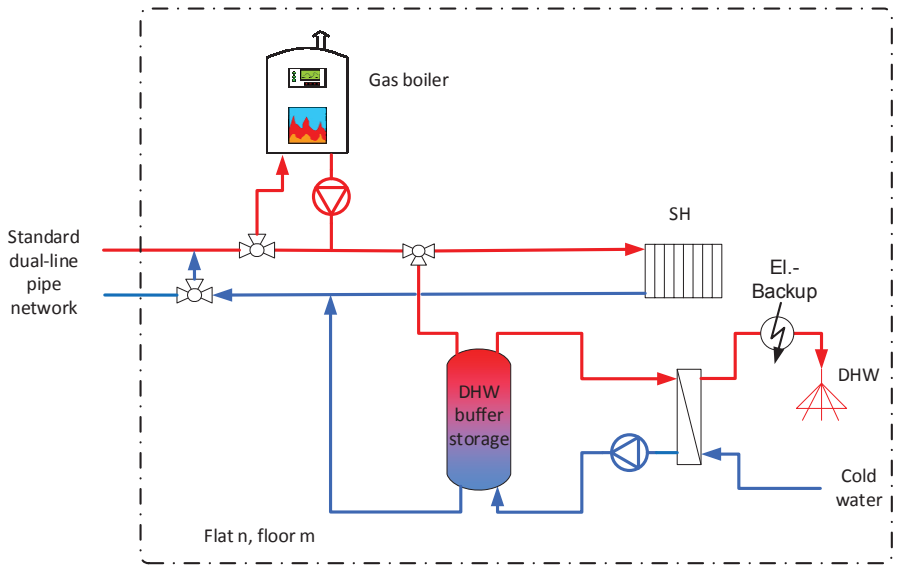

Fig. 4: Dual-line pipe network with decentralized boilers in each individual flat

Dual-line pipe network with decentralized heat pumps

Another design approach regards decentralized heat pumps for heat generation in the individual flats. The heat pumps are assumed to supply small, localized buffer storages. In contrast to the two previous model designs, the local storages, which contain heating circuit water, do supply heat for both SH and DHW, the latter via DHW modules (compare Figure 5). The model design assumes that the common heat source supplying the heat pumps is produced from geothermal resources through borehole heat exchangers. For this purpose, low-temperature geothermal heat is buffered in a central heat storage from which it is distributed to the individual heat pumps in the flats. In an alternative setting, the central heat supply may also be supported by a solar thermal system. In this case, the central storage keeps also the solar heat.

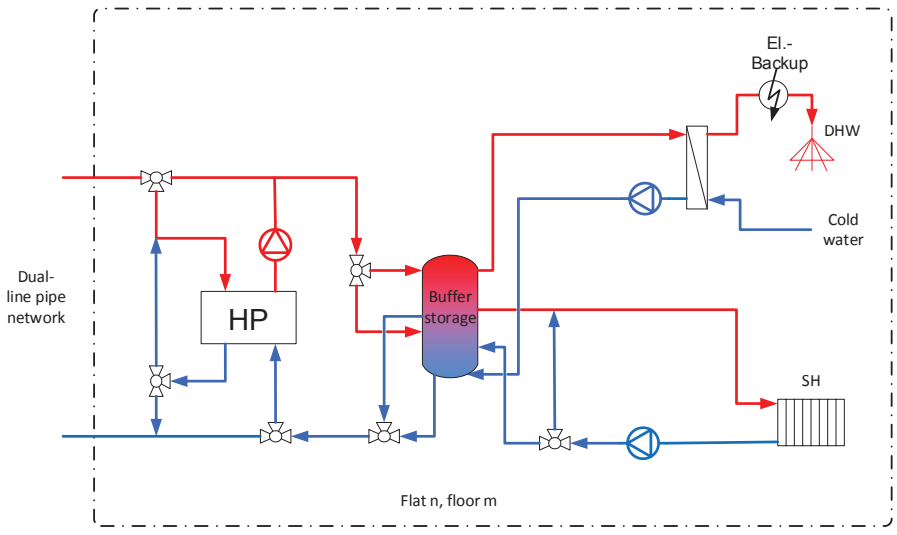

Fig. 5: Dual-line pipe network with decentralized heat pumps in each individual flat

4. Results

The results are presented in three separate sections: Firstly, regarding the optimization of the heat distribution network, secondly, regarding the utilization of solar heat and thirdly, regarding the alternative supply routes.

Optimization of the heat distribution network (2L-opt)

The optimization of the heat distribution network regards the transformation from the common four-line pipe network to the dual-line pipe network, keeping the conventional central gas boiler for heat generation in place. Figure 6 shows the impact of this configuration change on the building's overall heat demand, comparing four situations: (1) an idealized reference system without any heat distribution losses; (2) the four-line and (3) the dual-line systems as described above; (4) a further optimized dual-line pipe network, referred to "2L-opt" in Figure 6. The latter assumes electric backup heaters in the local heat transfer stations of the individual flats, which allows reducing the temperature level in the flow line pipe from 50 °C to 40 °C to further reduce the distribution losses without suffering in DHW comfort.

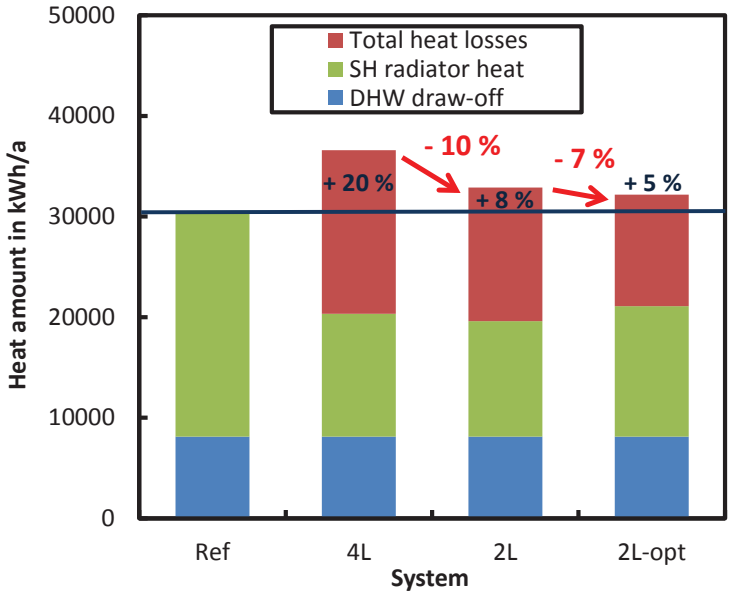

Fig. 6: Impact of distribution pipe network optimization on the buildings heat demand

The conventional 4L system exhibits 20% higher heat demand, than the idealized, loss-less reference system, thus indicating the total optimization potential of the supply design at given room comfort level. The configuration change from 4L to a basic 2L setting reduces the total energy demand by 10 % with respect to the conventional design, but the demand is still 8 % above the idealized reference system. The optimized 2L system allows further reduction by 7 %, resulting into an offset of 5 % above the ideal system. In other words, the reduction potential of the model building is already met to an extent of 75 % by a configuration change of the heat distribution network, without regarding advanced de-centralizing of the entire heat generation system (except for the electric DHW backup heaters). This reduction is the result of minimizing the heat exchanging surface area (from 4L to 2L) and the decreased pipe network temperatures (from 4L via 2L to 2L-opt). Figure 4 provides the details: Unusable heat distribution losses are reduced significantly by the described configuration change such that the distribution efficiency is increased. This efficiency may be judged from the usability of the heat losses, which is defined as the ratio of the usable heat losses of the system and the overall heat losses,

$$Usage\ factor\ of\ losses = \frac{Q_{loss,use}}{Q_{loss,total}} \qquad \text{(eq. 1)}$$

"Usable" are heat losses from the piping systems, if the heat leaks into the building so as to support the space heating. "Unusable" heat losses lead to higher room temperatures as designed and thus are finally dissipated

to the environment. As of Figure 7, the usability of the heat losses can be increased from 63 to 86 % by the design change from 4L to the 2L-opt setting.

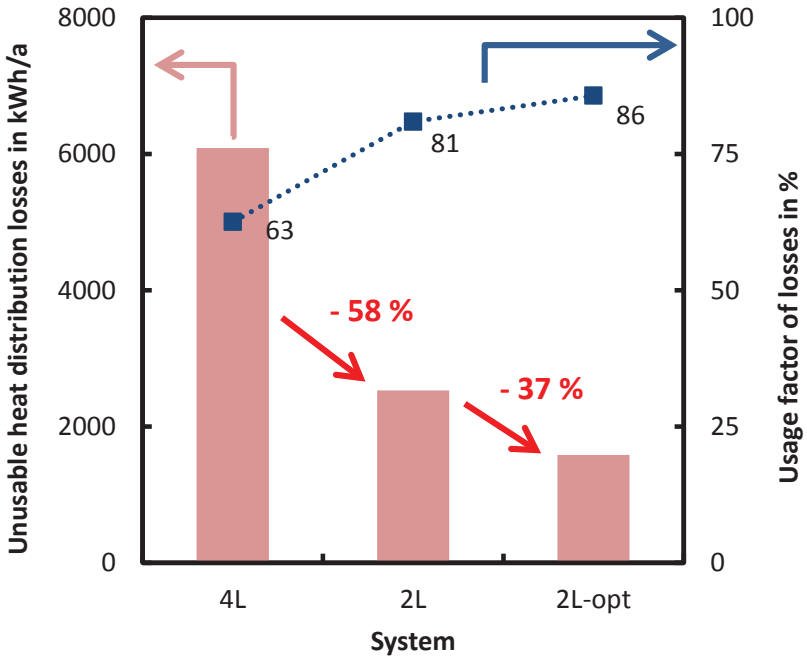

Fig. 7: Impact of the heat distribution network optimization on the usability of heat losses

The remaining unusable heat distribution losses, which mark the heat demand's reduction potential, amount to 1582 kWh or 5 % of the total energy demand according to Figure 6. These results are based on the strong assumption that all inhabitants share the same heating habits (single-zone temperature: 20 °C in all rooms). It may be noted that simulations performed with localized (multi-zone) room set temperatures exhibit even more reduced usability ratios, see Mercker et al. (2016b & 2016c). In non-homogeneously heated buildings the heat distribution losses are expected to be higher (doubling is possible) and their usability lower (even less than 50 %) – All despite this, the present study keeps the assumption of homogenous set temperatures of the rooms for the sake of simplicity (individual living behavior is difficult to predict) as well as comparability. Therefore, the discussed results mark the lower end of the expected spectrum.

Utilization of solar heat

The integration of a solar thermal system leads to both decreased fossil energy demand and significant reduction of heat distribution losses covered by fossil energy. Figure 8 indicates how solar radiation and unusable heat distribution losses coincide during the summer months. The coincidence can be used to increase the energy efficiency of heat supply systems.

The reason for the peak of unusable heat losses during summer lies in the fact of missing space heating demand during this period, which might profit from heat losses in a situation of still necessary DHW heat distribution demands. Therefore, 54 % of the total unusable heat losses occur during May to September. Because the solar thermal system has its production maximum during the same period, it is suitable to cover the summer heat demand from solar resources. The model predicts 54 % reduction of fossil energy consumption related to unusable heat distribution losses.

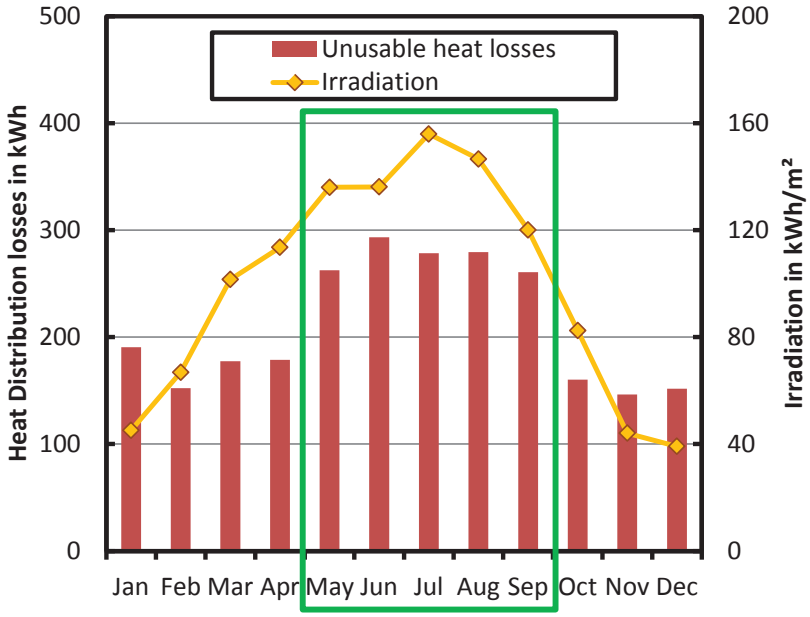

Fig. 8: Comparison of monthly solar irradiation and unusable heat distribution losses of a four-line pipe network

The collector aperture area is calculated with reference to the German guideline VDI 6002-1 (2004). The resulting field size is in the range from 5 to 8 m² or 0.3 to 0.5 m² per person. Additionally, collector areas of 16, 24 and 32 m² have been simulated to investigate the effect of larger solar thermal systems. The solar storage size is set to 50 l/m²coll. Table 1 shows the relation of different field sizes to the solar yield (as energy output of the solar storage) and the gained solar coverage of the total heat demand.

Tab. 1: Size comparison of the solar heat systems

Collector area in m²	Collector area in m²/person	Solar yield in kWh/m²	Solar coverage of total heat demand in %
8	0.5	474	12
16	1.0	411	20
24	1.5	350	26
32	2.0	306	30

We see that with a collector field size of 32 m², a solar coverage of the total heat demand of 30 % can be reached, comprising a collector yield of 306 kWh/m². Note that this field size is at least four times larger than the area recommended by the considered guideline VDI 6002-1 (2004).

Figure 9 shows both, the monthly heat demand, distinguished between SH, DHW and distribution losses, and the monthly solar yield for the four examined collector field sizes in one diagram. Both y-axis are limited to 2000 kWh, although the monthly heat demand (which is the sum of total heat losses, DHW-draw-off and radiator heat) exceeds 2000 kWh from November to March.

We conclude from this figure, that the total heat demand of the model building during May to September may be covered by a solar thermal system with a minimal collector area of 32 m². A 16 m² system still allows a (nearly) 100% solar fraction within July and August. The 8 m² system, designed according to the VDI 6002-1 (2004), however, only just covers the DHW demand, but nothing of the heat distribution losses.

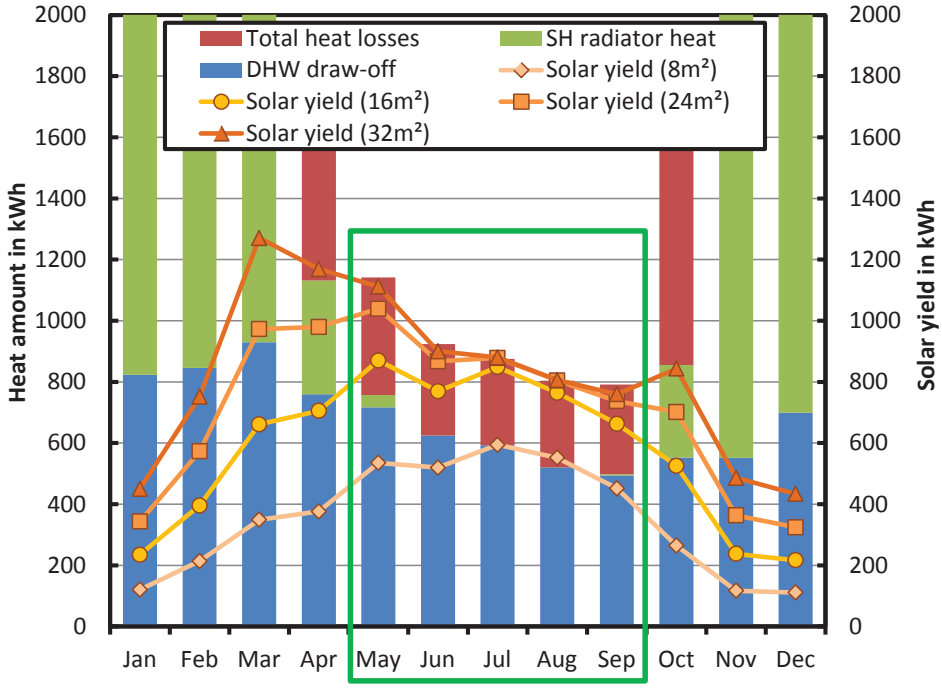

Fig. 9: Comparison of the monthly heat demand of an optimized dual-line pipe network and collector yield reached by different field sizes

Using a suitably scaled solar thermal system, the total heat demand – including distribution losses – may be completely supplied during May to September and the boiler may be turned off during this period. This saves ca. 54 % of the formerly fossil-fuel covered unusable heat losses, as well as the standby losses of the boiler and related inefficient part load operation during the summer season. In sum, this means that the remaining pipe network induced optimization potential for the building's heat demand of 5 % (or 1582 kWh/a according to concept 2L-opt) is reduced further to 2 % (or 728 kWh/a).

The alternative approach with the integration of electric backup heaters for DHW supply into the 2L system, installed in the local heat transfer stations of individual flats, allows the boiler to be turned off during the summer months without suffering a loss in DHW comfort (as with the design before), but the solar thermal systems may be designed smaller. The model predicts that in this case the solar thermal system may be down-sized to 8 m² collector area. Because a down-size of the solar thermal system also reduces the solar yield during spring, autumn and winter, this design approach incorporates less fossil-fuel savings, than the design without electricity supply, but larger solar yields than discussed before. Table 2 shows that with an enlarged solar collector from 8 to 16 m², the electric energy will be reduced by two thirds. With 32 m², electric heating is nearly negligible. Note, that the lower pipe network's temperature in summer leads to significantly higher collector yields at smaller collector areas.

Tab. 2: Heat generation and energy demands for different collector field sizes in the 2L-opt system

Collector area in m²	Solar yield in kWh/a	Electricity consumption in kWh/a	Gas consumption in kWh/a
8	4210	1156	31174
16	6891	399	29671
24	8586	147	28276
32	9869	65	27066

Alternative systems

The last studied design approach to minimize the unusable part of the heat distribution losses regards fully-decentralized heat generation. This situation is modelled concerning decentralized boilers or heat pumps in

individual flats with and without DHW storage tanks, see Section 3. Integration of local storages allows partial downtimes of the building-wide heat distribution network while still maintaining DHW comfort. The model regards nightly (11.00 pm to 5.30 am) downtimes of the central heat supply for this purpose. The results show that the respective distribution losses are avoided indeed. However, the decentralized storages incorporate increased heat leakage rates, thus counteracting the overall heat loss balance. In sum, losses of the storages exceed the savings of heat losses of the heat distribution network.

Figure 7 shows the total heat distribution losses of the examined systems and the respective usage factors. The diagram confirms the high loss-reduction potential of a 4L to 2L configuration change and the subsequent system optimization of Figure 6. Among the studied decentralized designs, the system with decentralized boilers exhibits lowest overall heat losses. The overall reduction potential of this design is comparable to the optimized 2L system, but the usage factors of the 2L-opt design is significantly higher: Heat leakage from commonly insulated DHW storages in the decentralized boiler system are significant but can be utilized for SH of the flats only during the heating season. The simulations show that the losses during summer are large enough to even counterbalance the annual usage factor below the level of the competing 2L-opt design.

The system design comprising decentralized heat pumps exhibits higher losses because the decentralized storage volumes for combined DHW and SH storage are two times larger than DHW-only storages. Larger storage volumes are necessary for the operation of the small heat pumps (2.5 kW condenser power in the present study).

To summarize, the simulation study suggests that decentralized storages should be avoided because of their significant heat loss rates, which may be utilized for space heating only partly during the course of the year. In specific design cases which allow avoiding decentralized storages, however, such de-centralized solutions are expected to be more efficient than centralized ones from the perspective of heat-loss reduction.

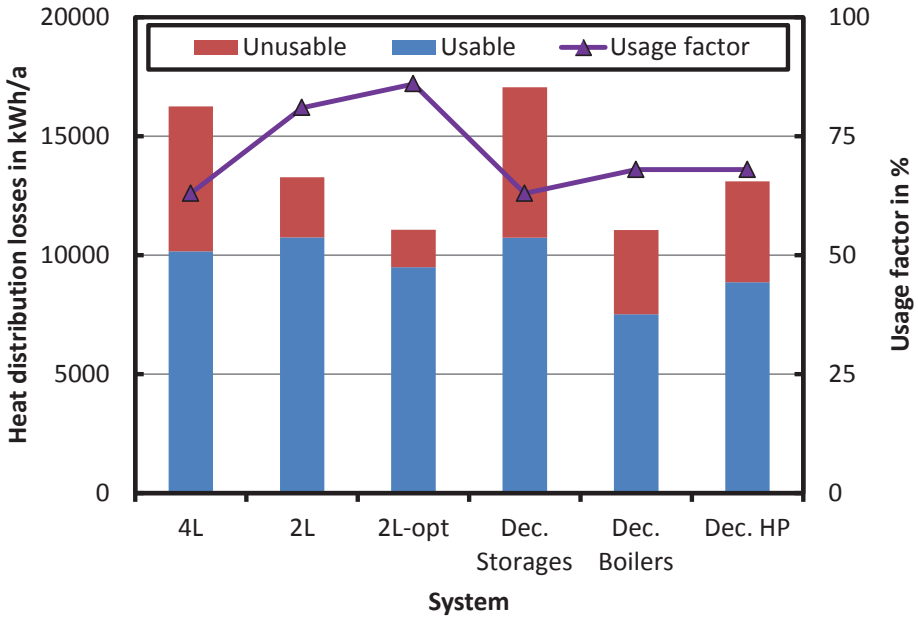

Fig. 10: Comparison of heat distribution losses and the respective usage factor for the studied systems.

The perspective of energy demand of the studied solar designs is provided in Figure 11, specifying both the final energy demand including losses (by columns) and the primary energy demand (by plot lines). The latter takes into account three different primary energy factors for the electricity part: 3.0 for fossil-based electric energy (EnEV 2002), 2.4 for the electric energy mix of Germany in 2015 (EnEV 2014) and 1.8 for the same mix as predicted for 2016 (EnEV 2016). All design cases regard a solar thermal system with 32 m² collector area.

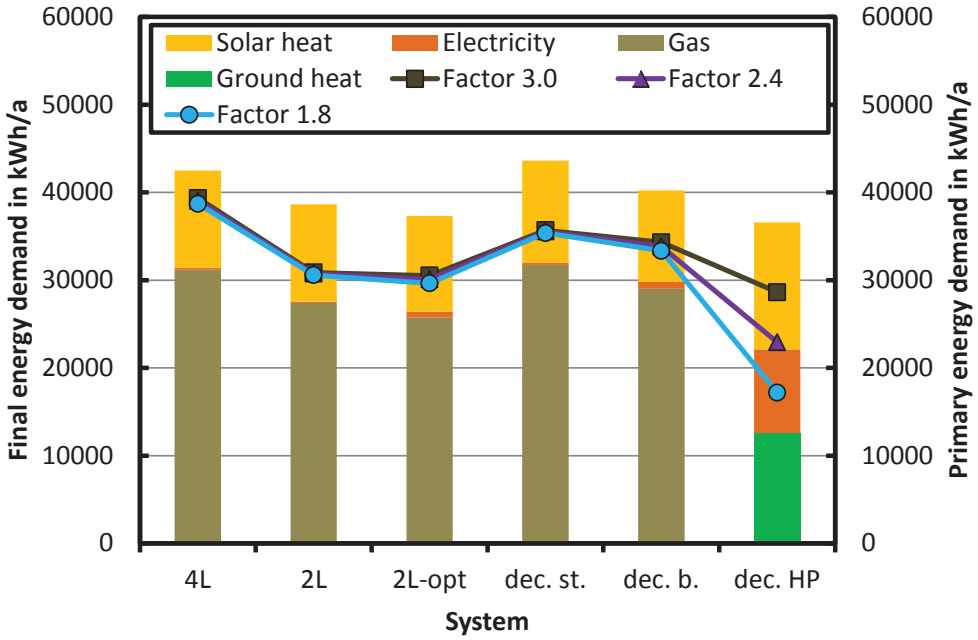

Fig. 11: Comparison of the final and primary energy demand of different systems

The solar thermal supply share is almost the same for all of studied model designs, except for the system with decentralized heat pumps. Here the solar share is significantly higher (ca. + 31 %), than for the other systems. The reason for this observation is that the solar heat can additionally be used indirectly – as a heat source for the heat pump (both, ground heat exchangers and solar collectors are supplying the same central heat storage). In fact, the direct use of the solar energy for DHW or SH is even lower than in other designs. The indirect integration route also incorporates the advantage of low-temperature solar energy production, which also allows using cheaper collector types (e.g. uncovered collectors).

Regarding the final energy demand of the studied systems the optimized dual-line pipe network shows the smallest demand among the fossil supplied designs. The system with decentralized storages has the highest demand owing to the heat losses of the storages. Designs with decentralized boilers have slightly higher final energy demands than the 2L system. The decentralized heat pump system has a lower final energy demand than the optimized dual-line pipe network. The reason for that is the further reduction of distribution heat losses, due to partial operation of the pipe network below indoor temperature even heat gains occur, because the ground heat exchangers deliver heat at an average temperature of 7 °C.

A comparison of the primary energy demands of the studied designs leads to the result that the design comprising decentralized heat pumps has the lowest demand, because it can benefit from the primary factor Germany's electric energy mix. Next to it is the design comprising the optimized 2L configuration.

5. Conclusion

Heat distribution losses have a significant impact on the heat demand of well insulated multi-family houses and must be regarded in situations of both, new constructions and system retrofits. Essential for decreasing the heat distribution losses is to minimize the length of pipe ducts and to lower the distribution net's temperature. Both can be realized by choosing a dual-line pipe network instead of a common four-line pipe network. When electric backup heaters are installed, the system's efficiency can be further increased by an additional reduction of the flow line temperatures.

A well-designed dual-line pipe network is even more effective regarding distribution heat losses as well as final and primary energy demand than systems with decentralized boilers, at least when they also have decentralized storages.

Solar thermal systems are of great advantage both to increase the system's effectiveness and to lower the system's final and primary energy demand. But it is of high importance to scale the system to the appropriate size. Common guidelines in Germany recommend field sizes that are quite small. This modelling study shows that such design is not able to cover the building's heat demand including distribution losses even in July and August. Thus, under energetic aspects, scaling the collector field to a bigger size is reasonable. This is because most of the system's unusable heat losses are occurring during the summer months because of their low usability in this period. With a large scaled solar thermal system of 2 m^2_{coll} per person, the heat demand can be covered completely by solar thermal energy from May to September and the boiler can be switched off during this time. By that, a total of 54 % of the overall unusable losses can be covered by solar heat. The same effect can be reached with smaller scales of the solar thermal system if electric backup heaters are installed in the heat transfer stations to compensate the lack of solar heat in case of a boiler that is switched off in summer.

Compared to a common four-line pipe network, an optimized dual-line pipe network with a sufficiently scaled solar thermal system (2 m^2_{coll} per person) reduces the unusable heat distribution losses by 87 %, which leaves a potential for further optimizations of only 2 % of the total heat demand. Doing that, the building´s heat demand is reduced by 12 %. The gas consumption is reduced by 39 % and the primary energy demand (factor 2.4 for electricity) by 36 %.

Using a heat pump for heat generation grants better use of solar energy and the lowest energy demand (regarding final and primary energy) of all investigated systems. Though not examined in this study, it can be assumed that an optimized dual-line pipe network in combination with a central heat pump and a suitable solar thermal system would be the most effective system in every aspect. Further research work is necessary to validate this.

Abstract

In order to monitor the energy yield of solar thermal systems, a thermal energy counter with connectivity must be installed. Multiple thermal energy counters and connectivity criteria are available. However, implementation and communication costs differ drastically from one to another. Taking into account market restrictions, in order to widely implement monitoring of energy yield of solar thermal systems these costs should be reduced as much as possible.

The paper presents an experimental comparison of the energy yield of a solar thermal system measured with different energy counters at communication time steps of one hour in order to reduce communication costs. These data are compared to those obtained from detailed measuring of the energy yield with time steps of 1 minute. The evaluated energy counters combine different technologies for the measuring of the flows and temperatures (ultrasound flow sensor, constant flow, single-jet flow meter, vortex flow sensors and RTDs).

Keywords: *solar thermal systems, energy counter, monitoring*

1. Introduction

Recently, there is an increased market demand of low cost monitoring equipment for solar thermal systems in order to evaluate their performance. Energy yield of the solar thermal system is the most basic parameter to be monitored. In the market there are multiple thermal energy counter solutions with different communication procedures.

The authors have recently been working on the measuring of solar thermal energy yield at the primary circuit using low cost commercial energy counters with energy integration time steps of one hour in order to minimize volume of data, and therefore, costs.

A number of three low-cost energy counters have been analysed. They have been installed in the primary circuit of a solar thermal system. The energy counters use different sensors technologies. Temperatures at the thermal fluid are measured by RTD sensors directly immersed in the flow or assembled in a sheath or using multivariable vortex flow meter. Volumetric flow is measured by a single jet meter, a vortex-flow meter, or set at a constant pre-calibrated value. Additionally, detailed measuring of the energy yield of the system primary loops is also performed in time steps of one minute with a none-intrusive meter based on ultrasound technology for the volumetric flow measurement and RTDs for the temperature measurements.

Main technical parameters of the analyzed energy counters are described in section 2 and 3. Results obtained are presented in section 4 comparing the instantaneous and daily energy yield measured with the different energy counters. Some conclusions are finally also presented.

2. Conceptual description of a thermal energy monitoring system

A thermal energy monitoring system is an instrument that reads the thermal energy produced in a plant and transfers the energy value through any kind of communication channel (Ethernet, sim…) to a computer that

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/eurosun.2016.04.01 Available at http://proceedings.ises.org

collects the data and publishes it according to final user needs, where the user is any person that may be interested in the metered data.

Main components of the energy monitoring are the sensors, in-site device, communication and IT infrastructure. A conceptual scheme of the different parts of an energy monitoring system is shown in Figure 1.

The sensors are used to measure the temperature of the thermal fluid between the two points in which the thermal energy is to be measured, they will be here referred as Th (hot temperature) and Tc (cold temperature). Additionally, a sensor to measure the volumetric flow of the thermal fluid, V_{flow}, is also necessary. The in-site device reads the data from the sensors and calculates the thermal energy. The communication infrastructure reads the thermal energy in certain communication time steps, and transfers the data to the IT infrastructure. Finally, the IT infrastructure collects, processes and publishes the thermal energy data according to the user needs.

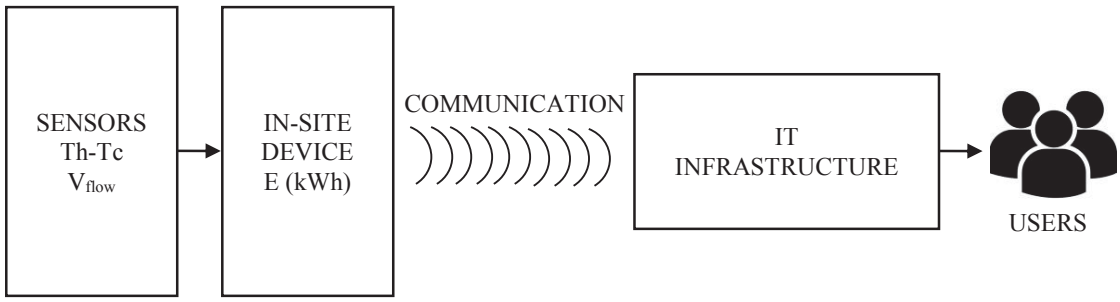

Fig. 1: Main parts of a thermal energy monitoring system. Conceptual scheme.

In order to develop a low-cost thermal energy monitoring system, attention has to be paid in the four components previously described. Commercial thermal energy counters, normally offers a compact solution of sensors and in-site device with internet connection interface. Additionally, a communication and IT Infrastructure is also needed.

The authors have developed an IT Infrastructure based on the free, simple and fast platform www.omnilus.com (2016). OmniluS reads the hourly thermal energy produced with a resolution of 1kWh. This drastically reduces the volume of data to be transferred from the in-site device to the cloud resulting into very low communication costs. More detailed explanation on how OmniluS works as intelligent energy meter can be found in González Valero et al. (2016).

3. Analysed energy counters

Three energy counters making use of the OmniluS platform have been analysed. Additionally, energy measurements have also been obtained with a none intrusive energy counter installed in-site with metering time step of one minute and finer communication energy counting resolution

Main technical parameters of the four energy counters are presented in Table 1.

The energy counters A, B and C, are connected the cloud platform OmniluS, and provide thermal energy data in intervals of Δt=1h with a resolution of 1kWh. The in-site devices use finer resolution to count the energy, however communicated energy resolution is set at 1kWh. This means that if during the previous communication interval (last hour), the energy produced was for example 14.6 kWh, a value of 14 is communicated, and the difference, 0.6 kWh, will be added to the energy to be communicated in the following time step.

The retail price of the components of the energy metering systems A, B, C ranges from 250 to 500 Euro, while the communication to cloud costs are below 4 Euro per month including data communication and cloud services.

Tab. 1: Main technical parameters of the analysed thermal energy metering systems

Name	Sensors			Communication		IT Infrastructure
	Th	Tc	Vflow	Resolution	Δt	
A	PT1000 immersed	PT1000 immersed	single jet	1kWh	1h	OmniluS
B	PT1000 sheath	PT1000 sheath	constant pre-calibration	1kWh	1h	OmniluS
C	PT1000 sheath	vortex flowmeter	vortex flowmeter	1kWh	1h	OmniluS
R	PT100	PT100	ultrasound	0.01kWh	1min	In-Site

4. Results and conclusions

The analysed metering systems A, B and C have been installed together with the reference system R at a solar thermal plant placed at the premises of the authors. The plant consists of a solar field of flat plat solar thermal collectors that collect energy from the sun which is accumulated in a storage tank with an internal serpentine by means of a single loop, so called primary loop.

The volumetric and temperature sensors have been placed at the inlet and outlet of the serpentine in order to measure the solar thermal energy yield of the primary loop. All of them have been carefully insulated. Additionally, silicone thermal cream has been used whenever necessary to assure thermal contact between the thermal fluid and the thermal RTD sensors.

The sensors have then been connected to the corresponding devices that calculate the instantaneous thermal power, count the energy yield and communicate the thermal energy yield. The devices of the metering systems A, B and C, transfer the thermal energy yield in intervals of one hour to the cloud were the OmniluS platform lives. On the other side, the thermal energy yield and the instantaneous power measured by the reference metering system R are recorded in-site (no connection to the cloud) in intervals of one minute.

No specific calibration of the sensors and devices has been performed, therefore data has directly been obtained with the instruments and sensors as delivered by the manufacturers with no additional post processing.

Data for seven different days is here presented in Figures 2 and 3 and Table 2. For each day, daily evolution of the energy yield and power measured with the four analysed metering systems A, B, C and R are shown in Figures 2 and 3.

Measured daily values of the energy yield are presented in Table 2. Additionally, absolute and relative differences of the daily energy yield are also shown by using the data measured by the system R as reference value.

As observed, although communication time steps and resolution in the systems A, B, C are large, the evolution of the cumulative daily energy yield measured with these systems pretty well reproduces the evolution of the cumulative daily energy yield measured with the detailed metering system R.

Of course the systems A, B and C cannot measure small time scale (minutes) phenomena and are therefore not appropriate for a detailed audit of the thermal system. However, they are able to predict the daily energy yield reasonably. As shown in Table 2, absolute differences of the daily energy yield measured with the systems A, B and C with respect with the data obtained with system R are below 2.5 kWh per day, which results into relative differences of the measured daily energy yield of 5%.

Abstract

In the near future, with the introduction of the Smart City concept, all systems and elements placed in a city will publish their performance data through open platforms. This paper presents an open data solar thermal meter component for the Smart City platform Sentilo. The solar meter includes four different sensors with instantaneous values of the solar energy yield, equivalent CO_2 emissions savings, economical savings and system status.

The paper describes the solar meter and how it is implemented within Sentilo, gives directions on how to create a solar meter using the data of any on-line connected solar thermal system, and gives examples on the data obtained from several solar thermal meters installed in different cities nearby Barcelona.

Keywords: *open data, solar thermal meter, Sentilo, smart cities*

1. Introduction

Solar thermal technology for domestic water heating (SDHW) is already a mature technology competitive to other conventional energy based systems. This has motivated some countries, regions or local authorities worldwide (Spain, Portugal, Italy, Chile...) to implement solar ordinances or regulations to obligate the use of solar thermal or other renewables in new and refurbished buildings. As a result, the number of residential apartment buildings (RA buildings) with SDHW systems has increased considerably during the last years. Only in Spain a total number of about 50.000 RA buildings with SDHW with a minimum collector area of about 15 m^2 are estimated, while more than 1 Million are estimated worldwide.

Practical experience, however, has shown as an important part of the SDHW in RA buildings are not performing appropriately resulting into reduced solar energy savings and bad reputation for the solar thermal technology.

Based on market experience, the authors have developed a low-cost smart solar thermal meter to support maintenance and operation of the SDHW systems. Research has been undergone in order to focus on costs (including devices and communications), standardization and best practices, effective and continuous metering and continuous communication with all involved bodies: users, O&M companies and public organizations as municipalities. Main technical results have already been patented, see González Valero et al. (2016).

With the increasing introduction of the Smart City concept, there is a need of further development of open data transversal platforms including standardized procedures to manage specific components data.

Cities in the area of Barcelona have been leading the implementation of Smart City solutions by making use of the horizontal, global and open platform called Sentilo, see www.sentilo.io (2016). Among others, the platforms sites for Barcelona and Terrassa are already available at http://connecta.bcn.cat and http://sentilo.terrassa.cat respectively.

doi:10.18086/eurosun.2016.04.06 Available at http://proceedings.ises.org

The number of instantaneous city data type uploaded to Sentilo is increasing constantly, ranging from sound sensors, trash-containers tracking, lighting, to electrical consumption.

Among the different systems in a city, solar thermal energy systems also play their role. There are many questions still to answer around the installed solar thermal systems related to their maintenance and real performance. The upload of instantaneous performance parameters of the solar thermal systems in an open Smart City platform will provide data that can be post-processed by anyone connected to the platform in order to obtain a response of these questions, and that will definitively contribute to improve the solar thermal technology reputation and dissemination.

The paper gives an overlook on the smart low-cost solar thermal meter developed by the authors, and how it is implemented as a component of the platform Sentilo. More than 30 SDHW plants in the area of Catalonia have already been equipped with this technology. Some examples on data obtained from these plants are also here presented.

2. The smart solar thermal meter

With the sensor technology available nowadays is of course possible and easy to monitor any data in a solar thermal system in small temporal intervals (in the range of seconds or even smaller) and send them to the cloud where the Sentilo platform lives through any kind of internet connection. However, the larger the number of sensors are installed and the smaller the temporal communication intervals the total implementation and communication costs increase.

In order to develop a solar thermal meter that would be accepted by the market, the costs of communication and devices (including sensors) to be installed must be reduced as much as possible.

The meter here described has been specifically designed for solar thermal plants with a maximum pick power of 70 kW. A scheme of the meter is shown in Figure 1. Metering is performed in two steps. The first step takes place in-site and the second step is done at the cloud by an instantaneous post processing of the data obtained in the first step.

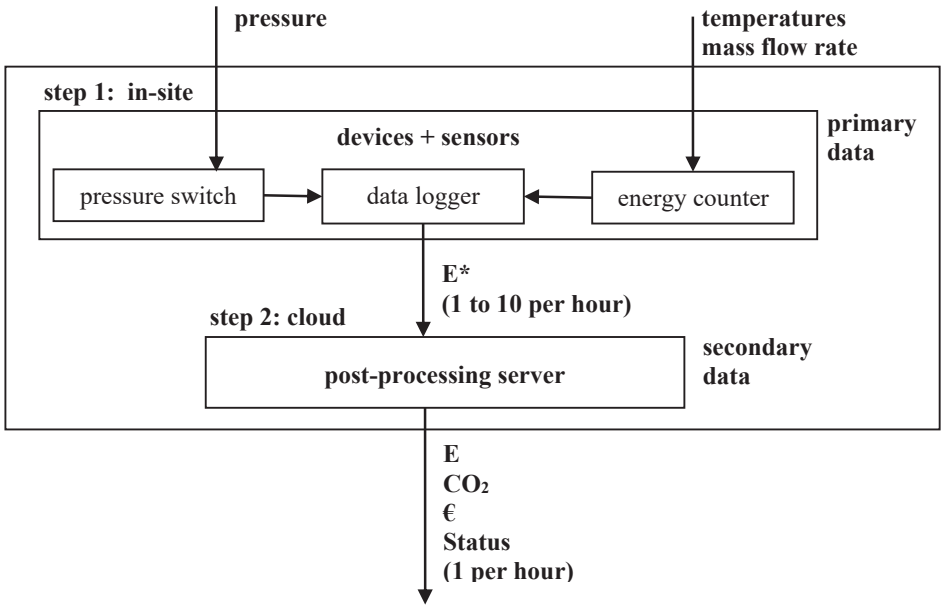

Fig. 1: Scheme of the smart solar thermal meter.

A data logger, a thermal energy counter and a pressure switch are installed in-site. The data logger must be connected to the internet. The value of the energy produced within the communication intervals is transmitted to the cloud. A frequency of communication of 2 to 10 transmissions per hour is suggested. This drastically reduces the communication data (and therefore costs) while, according to authors experience, having enough practical instantaneous data to monitor the plant status.

The pressure switch is installed at the primary loop (solar loop of the plant) and electrically connected to the electrical power input of the data logger. Therefore, in case the pressure at the loop decreases, which is one of the major failures in these plants, the data logger stops communication and no data is transmitted to the cloud.

Therefore, the only communication data used by the smart solar thermal meter is the energy produced in intervals of 1 to 10 transmissions per hour, whenever the pressure in the solar loop is enough to guarantee proper operations conditions. Otherwise, no value is sent. This energy production is called as smart energy yield, and is represented by the symbol E*.

At the cloud, a server instantaneously receives the value of the smart energy yield and calculates the instantaneous equivalent reduction of the CO_2 emissions, the economical savings and the Status de of plant. These three values, together with the value of the smart energy yield are then sent to Sentilo.

An important point to highlight is that the cost of the communication data from the step two (server at the could) and Sentilo is 0 because they both live in the cloud and are already connected to internet. However, the transmission data from the in-site infrastructure to the server at the cloud has a cost that may depend on type of communication used (e.g. Ethernet or SIM card).

The instantaneous value of the plant Status is to be calculated by software and in accordance to what is expected to be the theoretical production of the plant. Four status of the plant are considered:

- OK: the plant is working properly
- Overproduction
- Underproduction
- No reading: in case the instantaneous value of E* has not been transmitted to the cloud

A simple algorithm to determine the status when a value of E* is available, is to set the status at Overproduction in case E* is larger than the maximum energy production capacity of the plant during the communication interval, to underproduction in case E* is below 0 (this would mean a failure in the energy counting) and set the status to OK otherwise. This algorithm can of course be improved by providing intelligence to the server like statistical analysis of the instantaneous production of other equivalent solar plants.

The two steps could also take place in-site. However, this introduces two major additional difficulties. From one side, the amount of data to be transmitted from the in-site infrastructure to the cloud increases significantly resulting in larger communication costs. From another side, the data to be calculated in step two (CO_2 equivalent emissions, economical savings and plant status), require specific information of the plant that needs updating during all the meter life time. This introduces additional communication costs while when the second step takes place at the cloud this can be done automatically with no costs.

3. Coupling of the smart solar thermal meter with Sentilo

3.1. Sentilo configuration

All devices that send data to Sentilo have to be defined in an internal Sentilo data base. The smart solar thermal meter is defined as a new Sentilo component with four sensors as described in Table 1. The first sensor is the energy yield from the last communication step to the current communication step. As it is directly measured from in-site sensors it is labelled as a primary sensor. The other three sensors are secondary sensors calculated from the instantaneous value of the smart energy yield, and are the instantaneous plant status, and the economical savings and equivalent CO_2 emissions reduction corresponding the energy yield.

Extensive information on how to set-up a Sentilo server, define the data bases, sign up new sensors and download and upload data can be found in http://www.sentilo.io (2016).

Tab. 1: Sensors of the solar thermal meter component

Sensor	Type	Description
Energy Yield	Primary	Energy counter
Installation status	Secondary	Alerts generated from the energy yield
CO_2 equivalent emissions	Secondary	Post-processed value derived from the energy yield
Economical savings	Secondary	Post-processed value derived from the energy yield

3.1. Data flow

The smart solar thermal meter is designed to send cost-effective data of the solar thermal plants to those persons that may be interested. These persons will be identified as the data target. They can be classified in different groups depending of their role and connection to the solar thermal plants. Table 2 shows a simple classification in four groups, the plants owners, the O&M companies, public organizations and general public.

Tab. 2: Data target: classification in groups

Group Name	Description/role
Owner	Plant owner/s
O&M companies	Maintenance and operation performers
General public	Third parties
Public organization	City councils, energy agencies and policy makers

The data flow from the domestic hot water system to the target making use of the smart solar thermal meter and the platform Sentilo is represented in Figure 2. Sensors of temperature, mass flow and pressure (pressure switch) placed at the domestic hot water system, provide instantaneous data to the smart solar thermal meter. The meter, according to the procedure described in section 2, processes the input data and provides hourly values of the energy yield, the equivalent CO_2 emissions, economical savings and plant status to Sentilo. Finally, Sentilo publishes the data through its front-end platform and through its back-end.

The Sentilo front-end shows a map in which all monitored components are geolocated. With a simple click on a component it is possible to view real-time and some historical data of its sensors.

From another side, all data in Sentilo can be downloaded by external applications through its back-end using an API. For example, the authors have developed an application available through the free cloud platform www.omnilus.com (2016), called SeYe. This app is designed to automatize and simplify as much as possible the communication between the target groups and the monitored solar plant and provides three major functionalities: configuration of the solar system plant, edition of historical data and, automatic generation of emails to the different target groups informing about installation status and production.

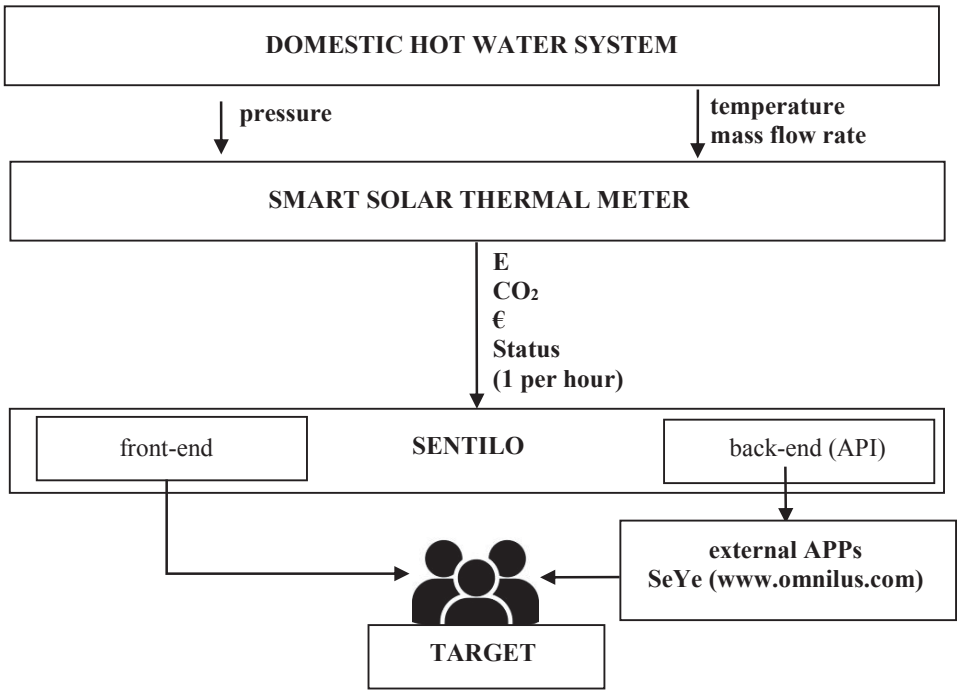

Fig. 2: Scheme of the data communication flow from the DHWS to the TARGET through the smart solar thermal meter and Sentilo.

4. Results

The open data solar thermal meter for smart cities presented in this paper has already been installed in more than 30 different plants located in the area of Barcelona.

As an example, results of plants located in the city of Terrassa will be here presented by making use of the front-end platform provided by Sentilo. The geolocation and some basic data of the solar thermal meter are shown in Fig 3. The solar thermal meter is located in a map among other meters in the area using a symbol made of a green circle with a white sun in it. By clicking on the solar meter symbol, basic data of the sensors are shown.

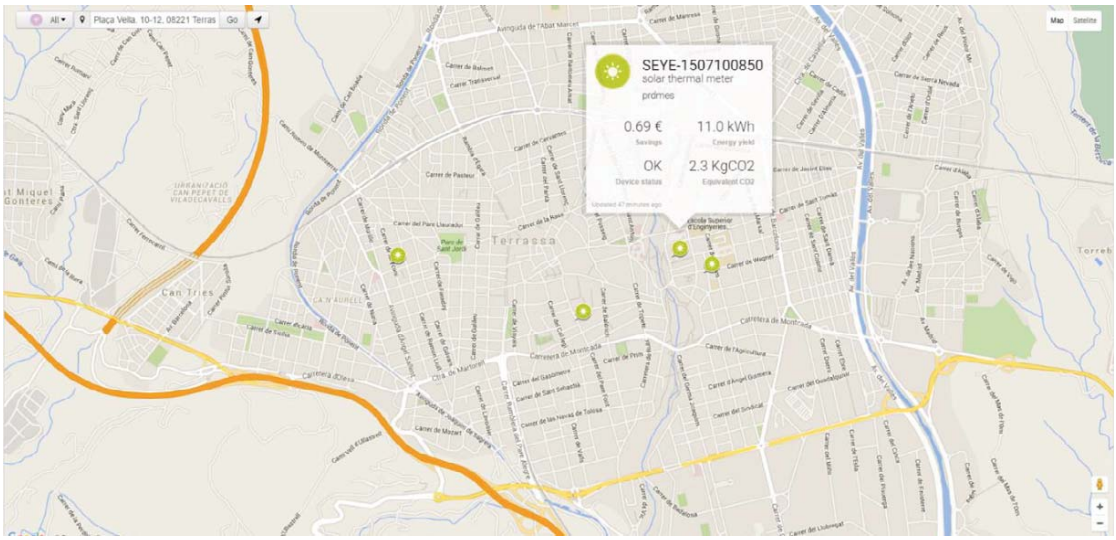

Fig. 3: Geolocation and basic data of the smart solar themal meter as shown on the front-end Sentilo platform.

Some historical data is also stored in the Sentilo platform. Real time value and historical data of the energy yield and the installation status as presented by the Sentilo front-end platform are shown in Figure 4 and 5 respectively.

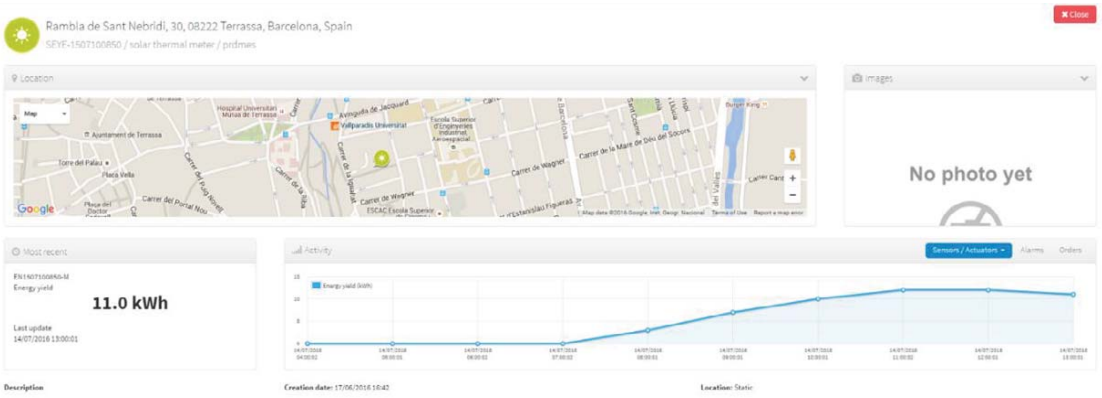

Fig. 4: Geolocation and some historical data of the energy yield as shown on the front-end Sentilo platform.

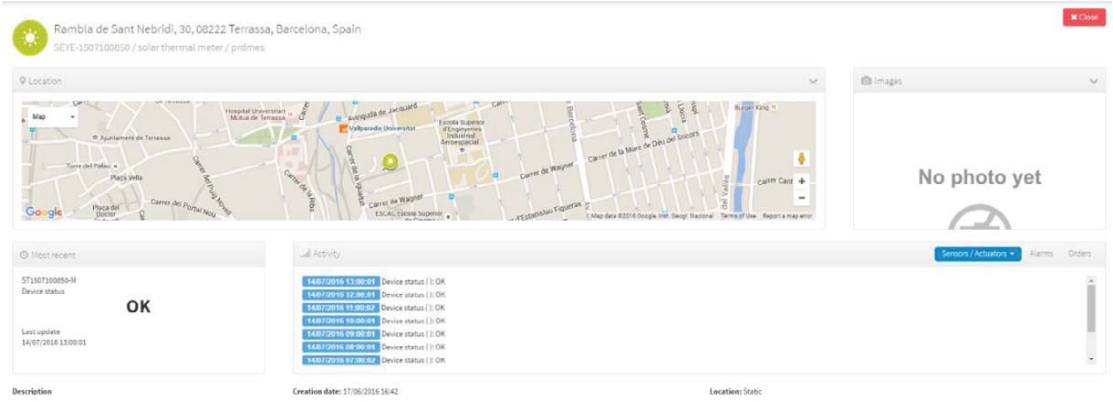

Fig. 5: Geolocation and some historical data of the installation status as shown on the front-end Sentilo platform.

5. Conclusions

With the introduction of the solar city concept, the market is now demanding for meters and sensors of relevant city activities connected to open data platforms. Solar thermal sector must be aware of that, and must provide solutions to publish the data of the domestic hot water systems installed in cities in the open data platforms.

The authors have designed a smart solar thermal meter connected to the open data platform Sentilo where the volume of transferred data is minimized in order to reduce communication and devices costs. The paper describes in some detail the smart solar thermal meter and the procedure adopted to send real time values of the energy yield, CO_2 equivalent emissions reductions, economical savings and plant status to Sentilo.

Energetic and economic comparison of different energy concepts based on solar energy for residential buildings

Thomas Duschner[1], Michael Klärner[1] and Wilfried Zörner[1]

[1] Institute of new Energy Systems, Technische Hochschule Ingolstadt (Germany)

Abstract

This paper investigates the benefit of the combination of solar thermal systems and photovoltaic systems for residential buildings. In this study, different solar energy supply concepts were modelled in the Matlab/Simulink toolbox CARNOT. The simulations were conducted with changing ratios of installed solar thermal and photovoltaic surface. Each concept was equipped with an optional battery storage. The results indicate an advantage of a combination of both solar systems with respect to the percentage of self-consumption. Economically, solar thermal plants affect the investment costs adversely because of higher unit prices compared to PV modules. Nonetheless, a combination of both systems is useful for some concepts.

Keywords: *solar thermal, photovoltaic, residential building, energy concept;*

1. Introduction

The EU guideline EPBD (Energy Performance of Building Directive), which came into effect in 2010, requires stricter building standards for new construction. To comply with this directive, all new buildings from 01.01.2021 onwards must fulfill at least the "nearly zero-energy building"-standard (European Union, 2010). For this purpose, the majority of the energy demand must be provided by renewable energies. The resulting significantly lower heat demand, however, means that the current demand ratio for thermal and electrical energy in residential buildings will change. Until now, electricity has only represented 16 % of the energy consumption in German households while 84 % was used for thermal purposes, in which room heating required 69 % and domestic hot water 15 % (Deutsche Energie-Agentur, 2015). As a result of this lower heating demand, the ratio between requirements for room heating and domestic hot water will also converge until they are almost balanced. Accordingly, greater priority must also be given to the domestic hot water demand.

In new buildings photovoltaic systems are primarily used as a solar renewable energy. This is reinforced also by the fact that in recent years the investment costs for photovoltaic systems have declined (Wirth and Schneider, 2016). Solar thermal systems have not experienced such a steep learning curve and as a result the investment cost has remained constant. In addition, the economy of PV systems is easier to identify. The energy production depends only on the irradiation and, in contrast to solar thermal systems, is not user related. The generated and fed energy is remunerated with a fixed sum. The federal government implemented a "flexible ceiling" for these feed-in tariffs which makes it more difficult to operate grid-connected PV systems economically. One key to more economical operation is self-consumption. In 2012, grid parity was reached as a consequence of the steady reduction of the feed-in remuneration and the increase of electricity prices for households (Quaschning et al., 2012). This was the turning point where the use of generated PV power became more cost-effective then the consumption of grid electricity. This development leads to new options for the use of photovoltaic energy in single-family homes. Covering the heat demand with electric energy becomes an interesting opportunity for increasing self-consumption. One possibility is to combine photovoltaic systems

doi:10.18086/eurosun.2016.04.02 Available at http://proceedings.ises.org

with heat pumps in order to cover the heat demand of single-family houses. As a result, heat generation with PV competes with other heat generation systems, in particular with solar thermal systems. The objective of this paper is to analyze this competition between and evaluate the combination of solar electric and solar thermal systems in residential buildings.

2. Methodology

The presented studies were performed in Matlab/Simulink (The MathWorks Inc., 2016). In addition, the expansion Blockset CARNOT (Conventional And Renewable Energy System Optimization Blockset) was used (Hafner et al., 1999). CARNOT contains predefined Simulink blocks from the fields of building and supply technology and has been conceived to perform detailed simulations and analyses in building energy supply.

2.1. Concepts

Four different concepts are implemented in Matlab/Simulink with different backup-heating systems. First, with a fossil fuel-boiler and a biomass-boiler, two systems are applied which operate independently from the electrical grid. Furthermore, two concepts based on power-to-heat (p2h) are part of the investigation: an electrical heating rod and a heat pump.

Due to the focus on solar energy supply, both photovoltaic and solar thermal systems were considered in each model. Based on the simulation model, a 50 m² roof was analyzed for the use of either solar thermal collectors, PV modules, or a combination of both. The ratio of installed PV modules and solar thermal collectors is varied in steps of 10 m². The results were then compared to the pure use of each solar technology, i.e. only solar thermal collectors or PV modules. In addition, the influence of energy storage for each concept was investigated. The capacity of the electrical as well as thermal storage was adjusted according to system sizes. For each kW_{peak} of installed photovoltaic power, a battery capacity of 1 kWh is used. The thermal storage has a defined basic volume of 250 l, which increases by 500 l per 10 m^2 solar thermal collector.

2.2 Database and control parameters

Meteorological data are an important aspect for solar energy simulations. Especially for photovoltaic and solar thermal systems, a temporally high resolution of the weather data is desired. For this investigation the climate data of Ingolstadt, Germany are used. The data were generated with the software Meteonorm (Meteonorm, 2016). The weather data set has to be adapted and extended for use in CARNOT. After this modification, the data now includes relevant parameters such as the direct and diffuse radiation on a horizontal surface and also location-based parameters such as hour angle, zenith angle and declination angle of the sun.

The analysis is exclusively carried out for detached single-family houses. Within the IEA-SHC Task 44, reference buildings were defined for the simulation setting which ensure the same conditions for all simulations to allow for comparison between investigated concepts (Dott et al., 2013). These buildings do not differ in geometry but solely in their U-values for the walls and therefore building types with different energy standards arise. Three building types are further defined: SFH15, SFH45 and SFH100. SFH stands for Single Family House and the additives 15, 45 and 100 indicate the specific heating demand in kWh/(m²*a). SFH15 represents a building envelope with very high energy efficiency, SFH45 represents current legal requirements or a renovated building with a building envelope of good thermal quality, and SFH100 represents a non-renovated existing building (Dott et al., 2013). Because of the higher heat demand, the SH100 building type requires radiator heating. All other boundary conditions (weather data, building orientation, roof slope and orientation) of the simulation remain the same. The building is oriented south and the roof pitch is 45°.

The thermal load of the building arises from the building parameters in the model and the weather conditions. The domestic hot water tapping profile is generated according the VDI-guideline 4655 (reference load profiles of single-family and multi-family houses for the use of CHP systems). The guideline includes standardized load profiles for 10 typical days for 15 different climate regions. These typical days differ depending on the day of the week, the temperature and the cloudiness. The average daily temperature determines whether it is a summer, winter, or a transition day. Regarding the cloudiness, a fine and a cloudy day can be distinguished. A

combination of all possibilities would yield 12 typical days, but no distinction is made according to the cloudiness of the summer typical days. Public holidays are treated like Sundays. To determine the public holidays, 2015 is chosen as the reference year. Using the meteorological data, profiles for the annual simulation are generated. Based on the guideline, which provides a domestic hot water demand of 500 kWh/person/a, results for the assumed 4-person household indicate an annual hot water demand of 2,000 kWh/a. The electrical load profile can be generated in a similar fashion. Contrary to the assumption of 1,750 kWh/person/a, a value of 1,000 kWh/person/a is assumed here. Especially in newer buildings, much more efficient components are installed. This leads to annual electricity consumption of 4,000 kWh/a for a 4-person household.

For the reference building in the IEA Task 44, a room temperature of 20°C is set, wherein a hysteresis of ± 0.5°C is set for activation of the heating circuit. The inlet temperature is regulated depending on the outside temperature. The maximum value for floor heating is 35°C and for radiator heating 55°C. The domestic hot water is mixed to a temperature of 45°C. The inflowing cold water, used for mixing, has a constant temperature of 10°C. The combined thermal storage tank is divided into two areas. The upper part is kept in a temperature range between 48°C and 52°C (SFH15 and SFH45). For the SFH100 this area is heated up 62°C. During the winter months, the lower part of the thermal storage is kept at a minimum temperature of 35°C in the case of floor heating. In case of radiator heating, this part is reserved for the solar thermal system. The loading of the upper part has thereby priority within the control. The biomass-powered boiler differs from fossil-fueled boiler with regard to start-up and switch-off times. Due to the somewhat sluggish overall system, the system is booted up slowly when reaching the lower threshold value and accordingly the power is lowered already slowly just before the maximum permissible temperature.

3. Energetic evaluation

The simulation results are evaluated in terms of energy coverage. The electrical coverage for the PV-system is the PV generation E_{PV} less the feed-in energy $E_{\mathrm{PV,feed\text{-}in}}$ relative to the total energy consumption $E_{\mathrm{el,total}}$.

$$C_{\mathrm{el}} = \frac{E_{\mathrm{PV}} - E_{\mathrm{PV,feed\_in}}}{E_{\mathrm{el,total}}} \qquad \text{(eq. 1)}$$

The total energy demand results from the household electricity demand $E_{\mathrm{el,HH}}$ and the electrical demand for heating $E_{\mathrm{el,heat}}$.

$$E_{\mathrm{el,total}} = E_{\mathrm{el,HH}} + E_{\mathrm{el,heat}} \qquad \text{(eq. 2)}$$

For the solar thermal system the thermal coverage can be determined in a similar manner by setting the thermal energy generated by the solar thermal system E_{ST} in a relation to the total thermal energy demand $E_{\mathrm{therm,total}}$.

$$C_{\mathrm{therm}} = \frac{E_{ST}}{E_{\mathrm{therm,total}}} \qquad \text{(eq. 3)}$$

The total energy demand is calculated from the sum of energy for domestic hot water $E_{\mathrm{therm,dhw}}$, the demand for space heating $E_{\mathrm{therm,heat}}$ and the thermal losses $E_{\mathrm{therm,loss}}$.

$$E_{\mathrm{therm,total}} = E_{\mathrm{therm,dhw}} + E_{\mathrm{therm,heat}} + E_{\mathrm{therm,loss}} \qquad \text{(eq. 4)}$$

In addition, the electric self-consumption of the photovoltaic system is assessed. These are calculated similarly to coverage only that in this case, the used photovoltaic energy is set in a relation to the total generated power of the PV system.

$$SC_{\mathrm{el}} = \frac{E_{\mathrm{PV}} - E_{\mathrm{PV,feed\_in}}}{E_{\mathrm{PV,total}}} \qquad \text{(eq. 5)}$$

Tab. 1 shows the annual thermal electrical energy amounts results from the simulated systems and the predetermined load profiles. All other annual amounts vary with the collector area, because the run-times of the backup-systems depends on the energy generated from the solar thermal system.

Tab. 1: Annual energy amounts of the reference buildings SFH15, SFH45 and SFH100

	SFH15 Values in kWh/a	**SFH45** Values in kWh/a	**SFH100** Values in kWh/a
Annual electricity consumption			
household	4.090	4.090	4.090
Annual heating demand			
domestic hot water	2.100	2.100	2.100
space heating	3.100	8.010	21.200

If one calculates the specific heat demand for the simulated annual space heating demand and an assumed floor area of 140 m^2, one obtains the values 22 kWh/m2/a, 57 kWh/m2/a, and 152 kWh/m2/a. These values differ from the defined values 15 kWh/m2/a, 45 kWh/m2/a and 100 kWh/m2/a. This is mainly due to the different weather dataset for Ingolstadt. To determine the defined values the weather data set for Strasbourg was used. The annual average outdoor temperature is in Ingolstadt with 8.8°C below the temperature in Strasbourg with 11°C. The radiated energy on the 45° inclined surface is with 971 kWh/m2/a 20 % smaller than that of the referenced weather data set (1,227 kWh/m2/a). The designations are retained hereinafter.

3.1. Concepts without electrical energy storage

As already described in the methodology, different ratios of the installed photovoltaic modules to solar thermal panels are compared and evaluated. This examination is carried out for various concepts and building standards. Fig. 1 shows the result for the SFH15 building type. The electrical coverage is lower in systems with p2h combined with PV systems, because the total electrical consumption is higher. Due to the even higher electrical demand when using a heating rod, the electrical coverage is about 20 %, slightly below the heat pump (23 %). The electrical self-consumption percentage changes accordingly (34 % compared to 26 %). Due to the higher electrical energy demand, a higher self-consumption can be achieved with these two systems in comparison to the boiler systems.

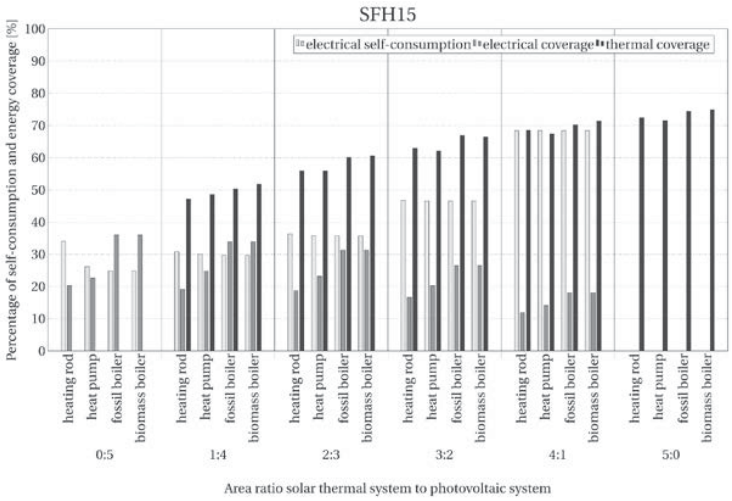

Fig. 1: Percentage coverage and self-consumption at different area ratio and backup systems for the building standard SFH15

Through the addition of a solar thermal system, lower operation time for the backup-systems is required. Moreover, the solar thermal system is now simultaneously active with the photovoltaic system and the produced photovoltaic power is used to cover the domestic electrical demand primarily. Thus, the electrical self-consumption of all concepts increases and the electrical coverage decreases. However, this is also due to the now-smaller photovoltaic surface. With this decrease, it is possible to consume a higher percentage of the generated energy. For the fossil fuel boiler and for the biomass boiler, the electrical characteristic values are the same, as they both operate independently of the power and only the domestic electricity demand is covered.

For the thermal coverage, a maximum value of 75 % can be achieved. If one increases the solar thermal surface from 30 m^2 to 50 m^2, the thermal coverage hardly changes. The heat demand of the SFH15 building is too low as the possible heat, generated by a 40 m^2 or 50 m^2 solar thermal system, can be used. The system is oversized and is therefore often in stagnation.

For the SFH45 building type, the results are similar to SFH15 (cf. Fig. 2). The electrical characteristic values for the fossil system and the biomass system remain unchanged by the independence of their power production. The heating demand of the SFH45 is higher, which results in a higher utilization of the heating system. With a heating rod or a heat-pump can thus be increased the self-consumption of the photovoltaic power. But this also means that the total power consumption of the building is higher and hence the electrical coverage decreases. Also the thermal coverage is lower than for the SFH15 because of this higher heat demand.

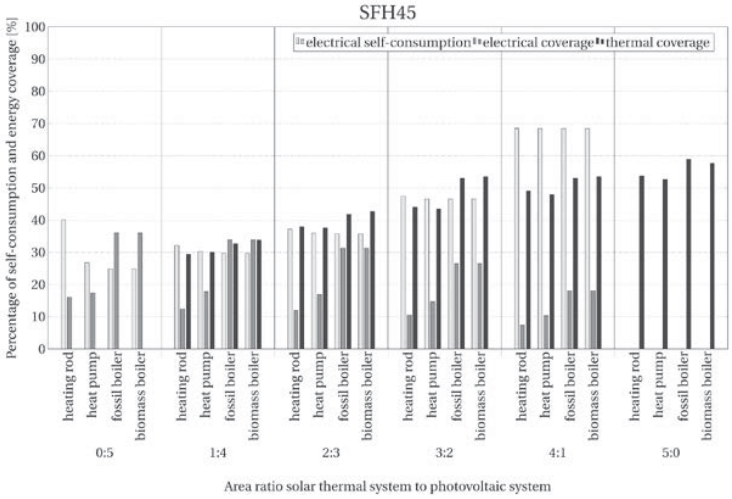

Fig. 2: Percentage coverage and self-consumption at different area ratio and backup systems for the building standard SFH45

When a vastly poorer building standard is considered (cf. Fig. 3), the results change once more. Here, the percentage of self-consumption with a photovoltaic-only system in combination with a heat pump is as high as with a heating rod. This is because heat pump operation and photovoltaic production occurs simultaneously more often due to the higher heat demand. The heat pump's higher electrical coverage of 15 %, compared to the heating rod with 8 %, is a result of the total energy demand as well as the electric energy demand of the heat pump, which is lower due to its coefficient of performance.

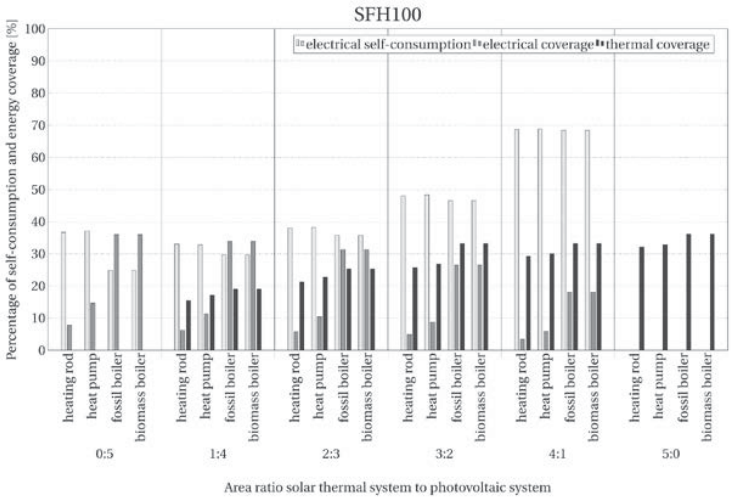

Fig. 3: Percentage coverage and self-consumption at different area ratio and backup systems for the building standard SFH100

This examination also shows that the electrical coverage of p2h-systems reacts similarly sensitive to the building standard as the solar thermal system. When the heat pump at a ratio of 3:2 is used as an example, the percentage of thermal coverage falls from 70 % (SFH15) to 53 % (SFH45) to 33 % (SFH100). In contrast, the percentage of electrical coverage drops from 20 % (SFH15) to 15 % (SFH45) to 9 % (SFH100). This corresponds to a deterioration of 55 % from building standard SFH15 to SFH100 for the electrical coverage and a decrease of 53 % for the thermal coverage. It is also seen that even for the SFH100, despite the increased heating demands little improvement of the thermal coverage can be achieved by increasing the solar thermal plant of 30 m² to 50 m².

3.2. Concepts with electrical energy storage

For the electrical characteristic values other results are obtained when an energy accumulator is integrated as a buffer for the electrical energy. Fig. 4 shows the simulation outcome for the SFH15. By the electrical storage, it is possible to achieve a balance between production and demand, thus a higher electrical self-consumption as well as a higher electrical coverage can be reached.

An electrical storage is beneficial for systems with heat pump technology and a photovoltaic system. It can be used a similar energy quantity with a heating rod as well as with a heat pump but due to the lower overall electrical energy demand of the heat pump the electrical coverage is higher. The influence of the electrical storage deceases with a reduction of the photovoltaic area. In combination with a 50 m^2 photovoltaic system a doubling of the self-consumption to the system without an electrical storage can be attained. Even the electrical coverage can be doubled with a battery storage and a large photovoltaic system. By contrast, increases in self-consumption for smaller photovoltaic systems are lower, for example about ten percentage points (20 m^2 photovoltaic system) or about four percentage points (10 m^2 photovoltaic system) with a heating rod, as this represents an increase of about 37 % and 25 %. The rise in electrical self-consumption is less, too. An electrical storage results not in a change of the thermal characteristic values.

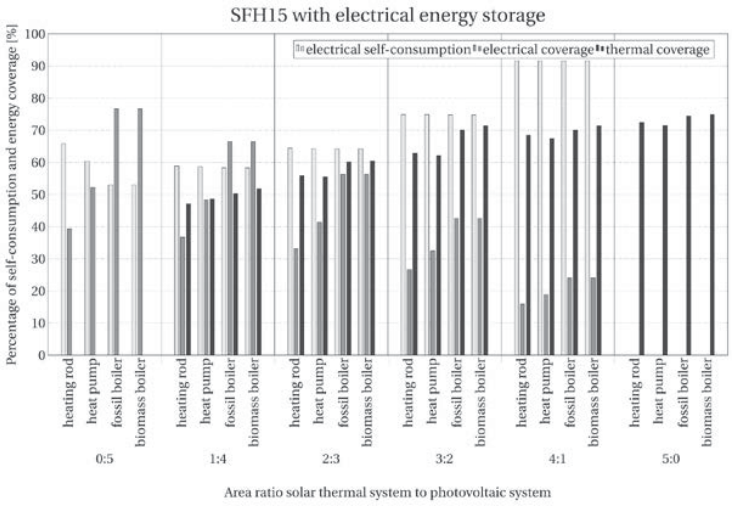

Fig. 4: Percentage coverage and self-consumption at different area ratio and backup systems for the building standard SFH15 and a battery storage

Owing to the higher thermal energy demand of the SFH45 the situation is somewhat different here (cf. Fig. 5). Although the battery storage maximum leads to a doubling of the electrical self-consumption, only lower electrical coverage can be accomplished here by the use of a heating rod or a heat pump, even though the electrical self-consumption remains almost the same. Again, the reason is the higher total energy demand of the building with poorer energy standard, which also has the consequence that a lower thermal coverage by solar thermal system is possible. The values for boiler systems, however, are again independent of the building standard.

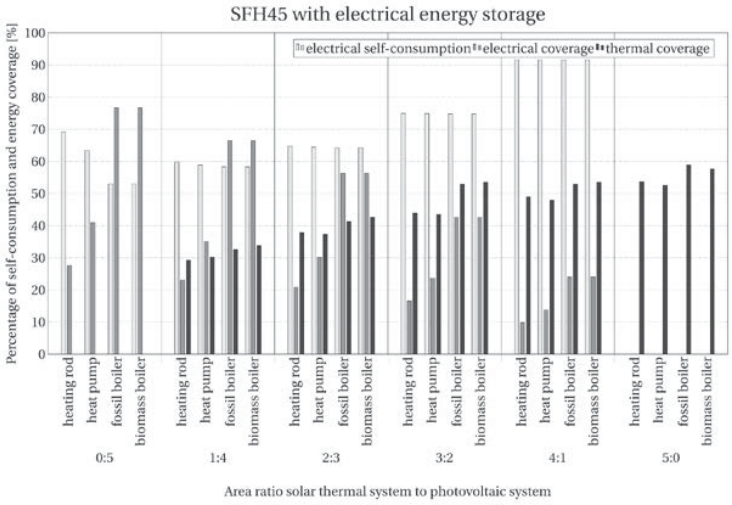

Fig. 5: Percentage coverage and self-consumption at different area ratio and backup systems for the building standard SFH45 and a battery storage

The same can be observed for the SFH100, whose results are shown in Fig. 6. Again approximately similar electrical self-consumption rates are achieved. However, the coverage ratio of the electrical energy at the total energy demand for electrical backup systems decreases.

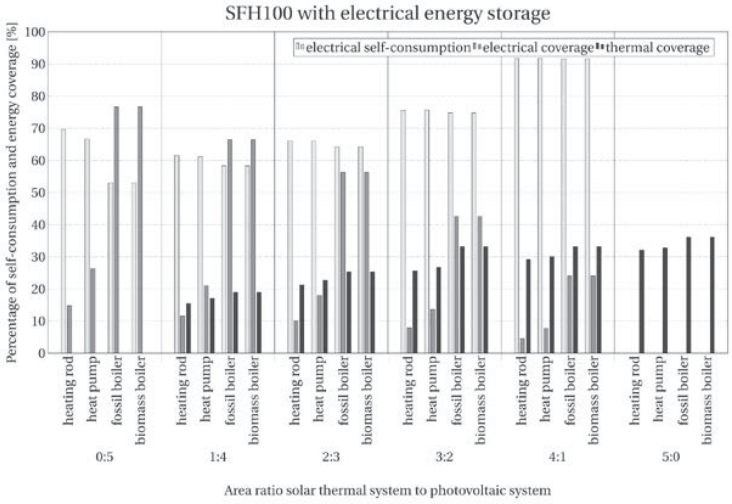

Fig. 6: Percentage coverage and self-consumption at different area ratio and backup systems for the building standard SFH100 and a battery storage

4. Economic evaluation

For the economic evaluation of the different concepts, the VDI-guideline 2067 is used. The method suggests summarizing the one-time investment costs and the ongoing payment during the period under consideration in equal annual payments, the so-called annuities. This approach allows a comparison of different system concepts. The annuity A_N of a system is calculated from the sum of the annuity of capital related costs, the annuity of needs related costs and operational related costs minus the annuity of the revenues (Lopez et al., 2011):

$$A_N = (A_{N,K} + A_{N,V} + A_{N,B}) - A_{N,E} \quad \text{(eq. 6)}$$

with: $A_{N,K}$ = annuity of capital related costs
$A_{N,V}$ = annuity of needs related costs
$A_{N,B}$ = annuity of operational related costs
$A_{N,E}$ = annuity of the revenues (e.g. grid feed-in)

To calculate the annuities some assumptions regarding the observation period, the costing interest as well as rates of price change must be taken. The adopted actuarial mathematical parameters and assumptions about the energy are summarized in Tab. 2.

Tab. 2: Boundary conditions for the calculation of the profitability

Parameter	Value	Explanation/Reference
Observation period	20 years	VDI 2067
Interest rate	3 %	-
Price change	2 %	-
Electricity price	29.16 ct/kWh	BMWi, 2016
Gas price	7.06 ct/kWh	BMWi, 2016
Firewood price	4.46 ct/kWh	DEPV, 2016
Feed-in remuneration	12.31 ct/kWh	Bundesnetzagentur, 2016

The investment costs of the different components are shown in Tab. 3. The costs for the thermal components are based on the Viessmann pricelist 2016. For the components which are variable in size (e.g. solar thermal system, photovoltaic system and battery storage) cost functions are used.

Tab. 3: Investment costs for different area ratio

	0/50	10/40	20/30	30/20	40/10	50/0
Heating rod				400 €		
Heat pump				6,000 €		
Gas-boiler				5,000 €		
Pellet boiler				12,000 €		
Thermal Storage	1,000 €	1.400 €	2,000	2,500 €	3,000 €	3,600 €
Solar thermal system	--	3,000 €	6,000 €	9,000 €	12,000 €	15,000 €
Photovoltaic system	7,500 €	6,000 €	4,500 €	3,000 €	1,500 €	--
Battery storage (lead)	9,240 €	7,280 €	5,600 €	3,640 €	1,680 €	--

Tab. 4 shows the total investment cost of each considered energy concept. The heating rod with its low investment costs shows in particular an economical advantage while concepts with a solar thermal system and without a battery storage have the higher investment costs. The high price of the pellet boiler increases the investment costs for these concepts. A battery storage compensates the higher cost of solar thermal collectors compared to photovoltaic modules and there is, with regard to various area ratios, only a small difference in the investment costs.

Tab. 4: Investment costs of the considered energy systems with and without battery storage

	0/50	10/40	20/30	30/20	40/10	50/0
Systems without battery storage						
Heating rod	8,900 €	10,800 €	12,900 €	14,900 €	16,900 €	19,000 €
Heat pump	14,500 €	16,400 €	18,500 €	20,500 €	22,500 €	24,600 €
Gas-boiler	13,500 €	15,400 €	17,500 €	19,500 €	21,500 €	23,600 €
Pellet boiler	20,500 €	22,400 €	24,500 €	26,500 €	28,500 €	30,600 €
Systems with battery storage						
Heating rod	18,140 €	18,080 €	18,500 €	18,540 €	18,580 €	19,000 €

Pellet boiler	29,740 €	29,680 €	30,100 €	30,140 €	30,180 €	30,600 €

4.1. Concepts without electrical energy storage

Contrary to the investment costs the system with gas-boiler has the lowest degree of annuities (c.f. Tab. 5). One the one hand, this is due to the relatively low investment cost of the gas boiler and on the other hand it is mainly up to the currently low gas price. The high cost of a pellet-boiler means that this system has the highest annuities for buildings with low heating demand (SFH15). For SFH45 and SFH100 standard are the mains supply costs for the heating rod however so high, that this concept has the highest annuities. For concepts based on power-to-heat the area ratio of 10/40 has the lowest annuity for the building standard SFH15 and SFH45. Here, the higher investment costs of the solar thermal system is compensated by the less electricity purchases form the grid. That the annuities of these systems greatly depend on the power consumption can be seen for example at SFH100 standard. There, the ratio of 20/30 has the lowest annuity because of the higher heating demand and therefore higher power consumption for thermal purposes.

Systems without thermal use of electricity have the lowest annuities by the ratio of 0/50 and increases with the enhancement of solar thermal collector area. These systems are also significantly more independent from the building standard. While here the annuities only rises between 10 %-20 %, these can double in power-to-heat-systems.

Tab. 5: Comparison of the total annuities of different concepts and building standards for various area ratios

4.2. Concepts with electrical energy storage

When a battery storage is taken into consideration, the overall result of the different concepts does not change (c.f. Tab. 6). The concept with a gas-boiler has still the lowest annuity and the concepts with the pellet-boiler (SFH15) and with the heating rod (SFH45 and SSFH100) correspondingly the highest. For large-scale photovoltaic-systems, the annuity raises significantly and decreases depending on the size, what is owed to high investment costs of the battery storage. Therefore, the annuity for the area ratio 50/0 remains unchanged. However, this means that the economically optimum ratio shifts to larger solar thermal systems when higher heating demand exists. Is the optimum ratio for SFH15 standard still at 10/40, so it is at 30/20 for SFH45 standard and even at 40/10 for SFH100 standard. The advantage of an increased self-consumption is equalized by the high costs of the battery storage. In addition, the self-consumption cannot be increased as high that the savings in grid-consumption recoup the investment costs of the electrical storage. Especially for buildings with lower energetic standard, the mains supply can only be reduced about approximately 10 %.

Accordingly, a battery storage in combination with a conventional regulation is from an economical perspective not worthwhile. Only when the investment costs continue to fall, or the service life will be improved, changes may arise. Another improvement could cause an intelligent control strategy which considers forecasts of production and demand.

Tab. 6: Comparison of the total annuities of different concepts with battery storage and building standards for various area ratios

Pellet boiler	4,839 €/a	4,861 €/a	4,423 €/a	5,167 €/a	5,374 €/a	5,658 €/a

5. Conclusion

The simulation-based study reveals that in terms of energy consumption it is possible to increase the electrical self-consumption with electric heating systems. The higher total electric energy demand is decreasing the electrical coverage and it must be obtained more energy from the grid. When using a heat pump the electrical coverage is slightly higher due to the better efficiency. With the addition of solar thermal systems for these systems the electrical self-consumption declines because then simultaneously with the solar electric energy also solar thermal energy is available and thus the photovoltaic power can often be used only to cover the household´s electricity demand. The use of a battery storage has only impact on the photovoltaic system and therefore only on the characteristic values of the electrical components. These values can be improved by the electrical storage. It turns out, however, that simultaneity is a crucial factor which is not always made possible by the battery storage.

From an economic view the conventional concept with a gas-boiler is the best system. In addition to the lowest investment costs are the running costs very low due to current gas prices. The economic viability of power-to-heat systems depends on the photovoltaic plant. Only if a large proportion of the electrical demand is generated by the photovoltaic system, the purchase of a heat pump is worthwhile. Otherwise, the improved efficiency of the heat pump cannot offset the high electricity costs. An electrical storage is no advantage because the invest costs are too high and savings in power supply costs are also too low. The acquisition pays off only if the costs of the battery storage decline, the costs of electricity increase or the feed-in tariff decreases.

The presented results are based on a simple system control and occurring simultaneity. Therefore, the impact of an energy management system on the self-consumption, thermal and electrical coverage will be examined in a next step. For this purpose a prediction of the expected production and load are included in the regulation in order to optimize the runtimes of the backup system.

Abstract

Nowadays, solar drying is becoming more important than ever before around the world. If more people use solar energy to dry agriculture and others products, our environment would be cleaner and the drying process will be more efficient. This paper discusses the performance and energy analysis of natural convection indirect solar drying system. The study rig that used consists from three main parts; flat plate air solar collector, dryer cabin and chimney. This system has been instilled in the laboratory of Szent IstvánUniversity in Gödöllő city in Hungary with collector tilt angle is 45° to the south according Budapest region, to get on the maximum amount of solar radiation. MATLAB software program has been developed to model the parts of this system, according the basic heat energy balance equations. The equations have been validated with many experimental results for different agricultural products. The experimental results showed the temperature and *RH* during drying period and the losses of water and moisture of the products.

Keywords: *solar collector, dryer, energy balance, performance*

1. Introduction

The use of the solar energy is getting a greater importance especially in the agriculture products drying. At the same time, the quality control and quality preservation technology becomes also very important technologies for processing of agricultural products than before. The Traditional application and very widely used product preservation is the drying process. Solar drying technology has many features upon the traditional dry technologies, it is low cost process and clean. In the past, the Agricultural and other products have been dried by the direct sun and wind in the open air for thousands of years. A typical solar dryer improves upon the simple open-air sun system, many main features:

- Products can be dried in a shorter period of time than the simple systems. Solar dryers improve drying process time by two methods. The first, by enhancing the translucent cover (the glass cover over the heat collection area inside the solar collector to raising the temperature of the air) and enhancing absorber plate area by increasing heat transfer area. Secondly, the flexibility of improving the solar collection area allows for greater amount of the solar radiation energy.
- Solar dryers more efficient than open-air sun system. The products can be dried faster, less possibility will be lost to spoilage immediately after harvest. This is especially for products that require immediate drying such as fresh grain with high moisture content.
- Control features, the control on the drying process parameters such as air temperatures, product and air moisture content, air velocity, etc. are better than the open-air sun dryers.

According to the brief review for many literatures the performance of drying process depend mainly on the performance of solar collector. So, the improvement of solar collector will improve the dryer work also (Mahendra et al., 1987). At the same time, some products do not need for high air temperature because it will damage such as fish, meats, etc. So, the control on the process parameters, air temperature, moisture content for air and product and air speed are very important.

Othieno (1986) explained solar cabinet dryer, it was very simple structure, and consists basically from small box has been made from wood. A transparent glass sheet was used as cover at upper edges surface. The box sides and bottom surfaces can be constructed from metal sheet (Aluminium) or wood. To circulate air through

doi:10.18086/eurosun.2016.04.19 Available at http://proceedings.ises.org

the system, holes has been made on the sides of the drier for this purpose. Indirect solar dryers also made of wood and plywood as presented by Amouzou et al. (1986). 10–15 kg of product can dried by drying chamber in 3 days. The absorber plate for solar collector is made galvanized sheet metal painted black to get selective surface.

Madhlopa et al. (2002) studied a solar dryer system had composite absorber plate systems on the principles of psychometric. The dryer consists of a flat plate solar collector, absorber plate approved with wire mesh, glass cover, chimney and insulated drying chamber. The drying chamber and solar collector box were made from wood sheets. The solar collector was connected to a drying chamber for product dehumidification.

Simate (2003) presented a comparison of optimized mixed-mode dryer and indirect-mode with natural convection solar dryers for maize. The two solar drying simulation models were validated against results from a laboratory solar dryer with experiments carried out under a solar simulator at the University of Newcastle, UK. They reported that, in both types, the collector and dryer width are the same. Airflow in the system is driven by buoyancy force. The drying cost with the mixed-mode dryer system using was 12.76 $/ton which was about 26% less than the indirect-mode system using; the quantity of dry grain obtained from the mixed-mode dryer for the one year was approximately 2.81 tones and was less than that from the indirect mode dryer by 15%.

Halewadimath et al. (2015) studied and fabricated an indirect forced- natural convection solar air dryer to estimate its performance under dry and hot weather conditions of Hubli, Karnataka, India. The system has been tested experimentally for both natural and forced convection. The performances of natural and forced convection systems are compared. The system consists of solar flat plate collector, drying chamber and a chimney. There are six baffles (fins) attached to the absorber plate to increases the turbulence of flow and increase heat transfer area for heated air in the collector which. Also, a mathematical model was developed by Ramos et al. (2015) to simulate solar drying of grapes, the heat and mass transfer models are solved by an explicit finite differences method, by considering changing boundary conditions. Many experiments were performed on a mixed mode solar dryer located in the North of Portugal, with amount pre-blanched grapes. Simulations showed with the developed model can be good to estimate accurate drying times and then to design, control and optimize the production of foods.

Then, according to the above brief review for many literatures, the performance of drying process depend mainly on the performance of solar collector. And the improvement of solar collector will improve the dryer work also. But, some products do not need for high air temperature because it will damage such as fish, meats, etc. So, the control on the process parameters, air temperature, moister content for air and product and air speed very important. In the recent paper, mathematical analysis of passive indirect solar drying system, consists from main parts: flat plate air solar collector, dryer chamber and chimney.

2. Description of the dryer

The study represented the performance of simple convective solar dryer (distributed solar dryer with natural convection), shown in Fig. 1. The test rig is constituted of two main parts; a flat plate air solar collector. It is composed of the flat aluminium plate used as an absorber surface, covered from the above by a glass sheet was fixed on the upper edges of collector box, and collector box that insulated from all sides to decrease heat losses. There is a space between the absorber surface and the glass sheet cover. This narrow space used as an air flow duct through the solar collector and integrated with the second part.

The second part is the drying chamber made with support many trays where the product is placed. Drying chamber has been insulated and painted with black paint to decrease the losses by radiation to the surrounding. As mentioned, the study was by free convection, the movement of air was by bouncy force with using a long chimney, which permits to have a good air speed by free convection and homogeneous distribution of the heated air inside the drying chamber, it allows also having better control of the drying process.

Fig. 1: Solar dryer test unit

The drying system is energized by the sun's rays (solar radiation energy) passing through the collector glazing cover. The trapping of the solar radiation (short waves) is enhanced by the inside surfaces of the solar collector that were painted black to change it to heat energy (long waves). Then, the heat energy will transfer from the black absorber plate to the air which passing inside the collector by convection. The last energy collection method is called the greenhouse. The air current will flow through the drying chamber by the effect of green house in the solar collector. Energy exchange (heat and mass transfer) between products items and hot air inside the dryer chamber. Then, the moist and hot air rises and escapes from the upper vent in the drying chamber (chimney) while cooler air at ambient temperature enters through the lower vent in the solar collector. Therefore, an air current movement is maintained, as cooler air at a temperature ($T_{collector,in}$) enters through the lower suction vent and hot air at a temperature ($T_{chimney,out}$) leaves through the upper chimney vent.

When the dryer is empty (no products in it), the entering air at a temperature T_{in} with relative humidity X_{air} and the discharged air at a temperature T_{exit}, has a relative humidity X_{exit}. With the dryer contains no item, the inlet relative humidity X_{in} higher than exit X_{exit} because T_{exit} higher than T_{in}. As referred before, there is tendency for the hot exit air to get more moisture within the dryer, as a result of the moisture difference occurs between X_{air} and X_{exit}.

For flat-plate solar collector, it is always tilted in such a way that it receives maximum solar radiation during the day and to be perpendicular with solar radiation rays at noon. Based on Duffie and Beckman (2013), the best stationary orientation is due south in the northern hemisphere and due north in southern hemisphere. Therefore, solar collector in this work is oriented facing south and tilted at 45° to the horizontal according to the solar chart for Budapest region (Budapest 47.5° N, 19.05° E).

3. Modelling assumptions

According to the classical way to modelling, the physical base with many assumptions are used the performance for every thermal system generally and drying systems especially. To simplify physical model, there are many assumptions have been taken before modelling, as following:

1. Drying system performance works with steady state condition.
2. Air flow distribution through system components is assumed homogeneous.
3. Mass and heat transfer are one-dimensional inside system components (always with air flow direction).
4. There is one-dimensional heat flow through back insulation for solar collector.
5. Dust and dirt effects on the flat plate solar collector are negligible.
6. Wind speed is approximately constant.
7. Connecting air channels is assumed to be with no leakages and without heat losses.
8. Products items initial moisture is uniform throughout the mass of the product.

9. Product size and distribution of product items assumed uniform inside the drying chamber.
10. Product surface moisture content of the sample items instantaneously reaches to the equilibrium state with the surrounding air.
11. Surface resistance to the mass transfer at the product surface is negligible compared to internal resistance of the sample.

4. Energy balance calculations

In this section, the energy balance relations are described for the main components of drying unit as solar collector and drying chamber.

4.1. Solar collector

The solar collector has the size of 2 m x 0.5 m x 0.2 m. The solar collector with about 1 m^2 absorber plate area integrated to the dryer chamber to heat air flow that will enter the chamber. It has a transparent glass cover fixed on the top edges of the collector box and thermal insulation at the bottom base side of the metal box. For the better energy collection a black absorber plate was put on the half height of the collector body box. As mentioned, the solar collector in this work is oriented facing south line and tilted at 45° to the horizontal according to the solar chart for Budapest region. To get more absorption of solar radiation and radiation reflection reduction, absorber plate painted with matt black colour.

The energy balance on the absorber plate is obtained by equating the total radiation gained from the sun rays through the glass cover with transmittance (τ) to the total heat loosed from the absorber plate of the solar collector. Therefore:

Solar radiation per unit area = useful heat +heat losses+ reflected losses.

If τ is the transmittance of the top glazing cover sheet, I is the total solar radiation incident on the top surface of the solar collector and A_c is the area of absorber plate, then mathematically the solar radiation per unit area will be:

$$Solar\ radiation\ per\ unit\ area = \tau\ I\ A_c.$$

The solar radiation represented the total solar radiation, beam, diffuse and ground reflected radiation. Experimentally, it can be measuring by simple calibrated solar measurement device. Theoretically, according the position (Gödöllő) and the time, MATLAB software program has been developed to estimate it. For beam (direct) radiation component on the collector surface, calculated according ASHREA 2005 standard. For the diffuse (indirect) and ground reflected solar radiations, depending on Al-Joboory (2012) has been estimated.

The same for the reflected radiation from the collector, the mathematical expression reflected energy from the absorber surface is given by the following expression:

$$Reflected\ losses = \rho\ \tau\ I\ A_c,$$

where ρ is the reflection coefficient of the absorber surface plate. By the Substitution of solar radiation and reflected losses expressions in the general energy balance equation for the absorber plate, will get:

$$\tau\ I\ A_c = useful\ heat + heat\ losses + \rho\ \tau\ I\ A_c.$$

By rewriting the above relation:

$$Useful\ heat = \tau\ I\ A_c.\ (1-\rho) - heat\ losses.$$

For an absorber plate, according to Duffie and Beckman $(1-\rho) = \alpha$ and then:

$$Useful\ heat = (\alpha\tau)\ I\ A_c - heat\ losses.$$

The above expression represents the energy balance equation for the absorber plate surface. For this study, it is very important to estimate air temperature rise thorough the collector. The change of air temperature through it depend on how much energy that absorbed (collected) by the absorber plate. So the above energy balance is not enough useful to show the behaviour of air temperature.

In the direction of air stream, the inlet ambient air to the collector carried sensible heat energy also depend on its mass m^o and temperature $T_{c,i}$. The same for the outlet air, it will catch the heat from stored absorber plate energy by convection, then it will leave the solar collector with the same mass flow rate and new temperature equal to $T_{c,o}$. Then by considering the heat energy content for inlet and outlet air, the final energy balance for the air solar collector system will be:

Useful heat = $(\alpha\tau)\ I\ A_c$ – heat losses+ inlet air heat content – outlet air heat content.

Mathematically:

$$M\ C_p \frac{dT_{c,o}}{dt} = (\alpha\tau)\ I\ A_c - U\ A_c\ (T_c - T_a) + m^o\ C_p\ T_{c,i} - m^o\ C_p\ T_{c,o}. \quad \text{(Eq. 1)}$$

Then by rewriting Eq. (1), get:

$$\frac{dT_{c,o}}{dt} = \frac{1}{M.C_p}\left[(\alpha\tau)\ I\ A_c - U\ A_c\ (T_c - T_a) + m^o\ C_p\ T_{c,i} - m^o\ C_p\ T_{c,o}\right], \quad \text{(Eq. 2)}$$

where M is the mass of air inside collector duct in (kg), T_a is the temperature of ambient air in (K), T_c is the average temperature of the absorber plate in (K), C_p is an air specific heat at constant pressure in (J/kgK), $\tau\alpha$ is called transmittance-absorptance product for glazed collector, and it was for black colour absorber plate about 0.87 (considered for this study) according to Anderson et al. (2009) and U represents to the total energy losses from the flat plate solar collector: top U_t, back (bottom) U_b and side edges U_s heat losses. It means:

$$U = U_b + U_s + U_t. \quad \text{(Eq. 3)}$$

The bottom heat loss coefficient and by the basic of conduction heat transfer resistance for the wall or material layer with thickness equal X_b and material thermal conductivity equal K_b, the back heat loss coefficient U_b will be as follow in Eq. (4):

$$U_b = \frac{K_b}{X_b}. \quad \text{(Eq. 4)}$$

The same for collector edges heat loss coefficient U_s, but with multiplying by the area ratio between collector side edges area to the solar collector area as shown in Fig. 2. Then, U_s for collector length L, width W and depth X will when the side edges have K_s as a thermal conductivity and side thickness equal X_s, will be:

$$U_s = \frac{K_s}{X_s}\left[\frac{X.(L+W)}{L.W}\right]. \quad \text{(Eq. 5)}$$

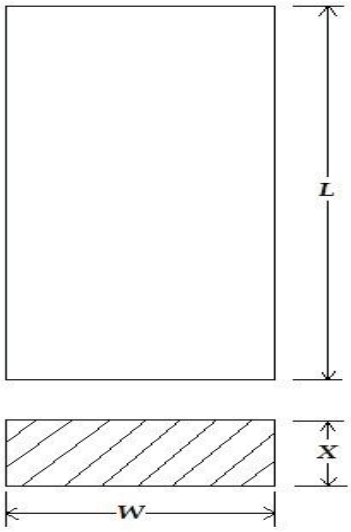

Fig. 2: Solar collector dimensions

The estimation of top energy loss coefficient for most solar collectors is complicated with using basic heat transfer relations. However, with good designed system, the collector loss should be low so that it is not necessary to predict it with great accuracy. To estimate the value of tope loss coefficient, as Kalogirou mentioned in his book an empirical useful formula is used by depending on number of covers, absorber plate temperature, and ambient temperature, etc. as follow:

$$U_t = \left[\frac{N}{\frac{C}{T_c}\left[\frac{T_c - T_a}{N+f}\right]^e} + \frac{1}{h_w}\right]^{-1} + \frac{\sigma(T_c+T_a)(T_c^2+T_a^2)}{\frac{1}{\varepsilon_p+0.0059N.h_w} + \frac{2N+f-1+0.133\varepsilon_p}{\varepsilon_g} - N}. \quad \text{(Eq. 6)}$$

where N represents to the covers number, h_w is an wind heat transfer coefficient, σ is Stefan-Boltzmann constant, ε_p and ε_g are the absorber plate and glass cover emissivity, and each of C, f and e are constants and calculated from Eq. (7) as follow:

$$C = 520\ (1-0.000051\ \beta^2).$$
$$f = (1+0.089\ h_w - 0.1166\ h_w \varepsilon_p)\ (1+0.07866\ N). \quad \text{(Eq. 7)}$$
$$e = 0.43\ (1-100/T_c).$$
$$h_w = 2.8+3V.$$

where β is a bulk coefficient of expansion of air in K^{-1} and V represents to the ambient wind velocity in m/s.

4.2. Dryer

The drying chamber (the dryer) with 7 trays for the different products items. The drying cabin dimensions are 0.8 m x 1 m x 0.65 m. The drying chamber is integrated with the solar collector by a small duct (indirect drying). The heated air exit from the collector will enter the chamber with high temperature and low moisture content. The total energy required for drying process for given quantity of any type of products items can be determined by using the basic energy balance equation for the evaporation of water. According to the schematic diagram for the dryer, the basic energy balance equation (mass + heat), as written below:

$$Q_{air,inlet} + Q_{product,inlet} = Q_{air,outlet} + Q_{product,outlet} + energy\ losses\ .$$

For perfect system insulated, the value of energy losses from the dryer will be very small, so it can be neglected. Then, the latent energy of the evaporated water from the product with mass W_v and latent heat of vaporization equal L_v will equal the heat lost from the air which flowed through the dryer. Mathematically:

$$W_v\ L_v = m^o\ C_p\ (T_{d,i} - T_{d,o}), \quad \text{(Eq. 8)}$$

where $T_{d,i}$ and $T_{d,o}$ are inlet and outlet temperatures through the dryer. The inlet dryer temperature $T_{d,i}$ equal to the outlet temperature of the solar collector $T_{c,o}$ by assuming that is no heat losses through connection small duct between the solar collector and dryer. Where the mass of water evaporated from the product W_v calculated from Eq. (9):

$$W_v = m_i \frac{w_i - w_f}{100 - w_f}, \quad \text{(Eq. 9)}$$

where m_i is the initial mass of product in (kg), w_i is the initial moisture content and w_f is the final moisture content. During drying process, water at the surface layer of the product evaporates and water in the inner part transfer gradually to the surface to get evaporated. The ability of this water movement depends on the porosity of the product item material and the surface area available.

The basic theory of drying process was described by Lewis (1921) based on the partial similarity with Newton's law of cooling and is often used to mass transfer in thin-layer drying as follow in Mahedra et al. (1987):

$$\frac{dw}{dt} = -k\ (w - w_e), \quad \text{(Eq. 10)}$$

where k represents drying process constant, w_e is an equilibrium mass, by solving the above differential Eq. (10) for these conditions, (at $t = 0$, $w = w_o$) and (at $t = \infty$, $w = w_e$), get:

$$\frac{w_t - w_e}{w_o - w_e} = -e^{-kt}. \quad \text{(Eq. 11)}$$

The above term in Eq. (11) called moisture ratio (MR), then:

$$\frac{w_t - w_e}{w_o - w_e} = MR\ . \quad \text{(Eq. 12)}$$

A product material stills for a long time at a fixed temperature and relative humidity then will eventually gradually reach a moisture content that is in equilibrium with the moist air. The equilibrium state does not mean that the product item and the air have the same moisture content. It simply means that an equilibrium condition exists such that there is no net exchange of moisture (latent heat) between the product material and the heated air. This equilibrium moisture content (w_e) is a function of the temperature, the relative humidity, and the type of the product.

Finally, to estimate the efficiency for all the system (solar collector and dryer chamber), the following relation represent the ratio between input energy and output energy to the totally system has been calculated. The system efficiency indicates the overall thermal performance of a drying system including the efficiency of a solar collector, the drying chamber and any other supplement add to the system:

$$Totalefficiency = \frac{W_v \, L_v}{I \, A_c}. \quad \text{(Eq. 13)}$$

As known to increase heat transfer by convection, turbulence of air should increase. So, the effects of free convection will be enhanced by adding a long chimney in which exiting air is heated even more by friction and enhance the buoyant flow of air. Some studies showed that the installation of three small fans and a photovoltaic cell is equivalent to the effect of chimney with 12 m length.

5. Results for validation

In this section a validation of the energy relation are performed based on the measured results for different products drying and environmental variables. The solar drying experiments were carried out between April and May 2006 at Gödöllő, Hungary (Farkas et al., 2006).

5.1. Environmental variables during the experiments results

This section shows the conditions of temperature and relative humidity during the drying period for different products as carrot, apple and potato (Tables 1-3 and Figs 3-4).

Table 1: Relative humidity (RH) and average inlet and outlet temperatures for carrot

Day	RH ext, %	Temp, ºC ext	RH int, %	Temp, ºC, int
1				
2	16,89	22,71	15,13	23,07
3	11,49	20,5	11,04	21,65
4	7,59	22,64	7,15	22,59
5	8,84	21,14	12,74	21,74
6	13,88	14,7	14,56	21,39
7	29,92	19,78	28,52	23,22
8	74,87	13,22	77,37	16,43
9	61,16	11,33	57,11	16,8

5.2. Loss of water

In Figs 5-7 the changes in mass of the carrots, placed in different trays, are represented through the drying period. In Fig. 5 it can be seen that after 4 days the carrots lost 87% of the initial weight. In Fig. 6 it can be seen that after 24 hours the apples lost 84% of the initial weight. In Fig. 7 it can be seen that after 24 hours the apples lost 83,5% of the initial weight.

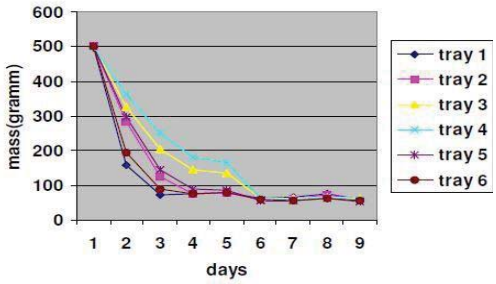

Fig. 5: Loss of water during the drying period for the carrot

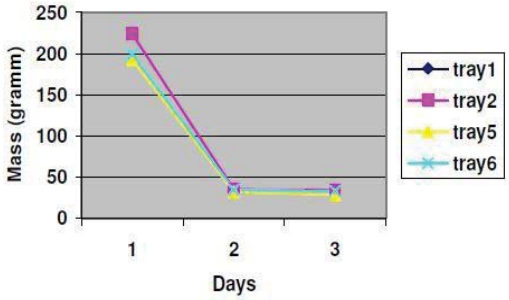

Fig. 6: Loss of water during the drying period for the potatoes

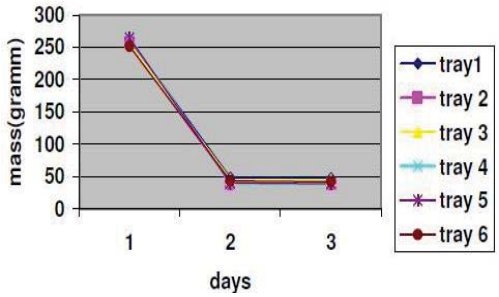

Fig. 7: Loss of water during the drying period for the apple

5.3. Temperature distribution

Figs 8-10 show for the products the distribution of the temperature outside and inside the dryer between 8 a.m. and 4 p.m. Fig. 8 shows that for the carrots there is no difference in temperature among the trays and inside the chamber is higher than outside in the second part of the day (12-16) hours. For the apples the temperature inside the chamber is always higher than that outside. This difference is more evident between 11-16 hours. The Fig. 10 shows, that for the case of potatoes there is difference in temperature among the trays in particular in the first tray where the temperature is higher than that other trays and the temperature inside the chamber is always higher than that outside.

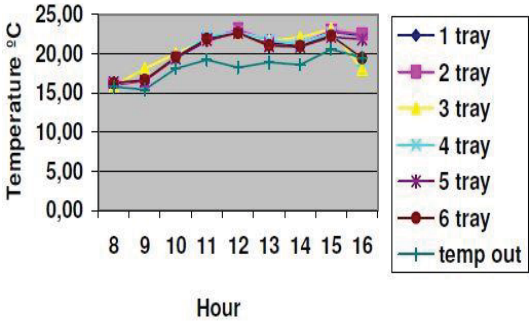

Fig. 8: Temperature distribution outside and inside the dryer for the carrots

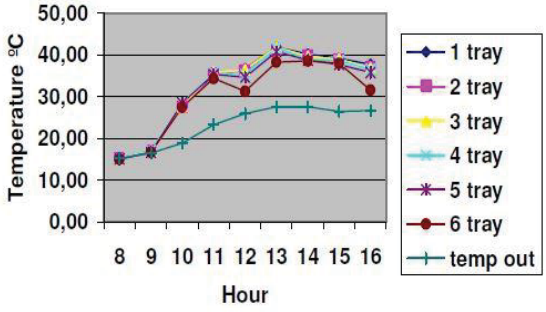

Fig. 9: Temperature distribution outside and inside the dryer for the apples

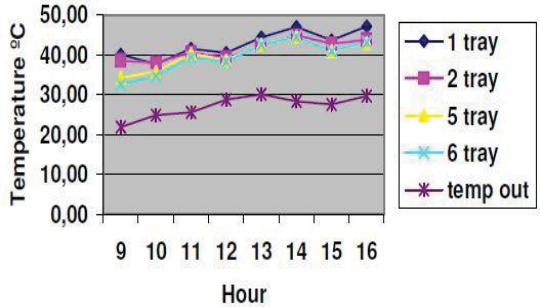

Fig. 10: Temperature distribution outside and inside the dryer for the potatoes

6. Conclusions

The temperature of air inside the system (drying chamber and solar collector) is much higher than the surrounding temperature during most times of day. That means, these systems better performance than open-air sun drying systems. The control on the drying parameters such as air velocity, temperatures, moisture contents, etc. are not complicated and not expensive.

Drying process with using solar heater, depends on the temperature and moisture content difference between an air stream and product items inside the insulated chamber. It is very important to know the type of product item, to estimate the temperature rang that is suitable to save it from damaging during drying process. With some drying products like fish, meat, yam chips, etc., over heating must be avoided to save the quality of the product.

Also that is many methods to enhance these types of dryers, such as heat transfer area is increasing, air turbulence increasing, and improvement the insulating of the system, etc. for this study, a long chimney is integrated with the drying chamber to increase air velocity during drying process. The increasing of air velocity will improve the rate of water evaporated from the product item. Also, the very important point in this dryer, it is very economic process (low costs of constructions), simple design and efficient control.

Abstract

The paper deals with the lifetime estimation of black-pigmented, glass-fiber reinforced polyamide (PA-GF) absorber grades for absorber/storage tanks of pressurized, non-pumped hot water systems at different sites (Athens, Fortaleza, Pretoria). The annual absorber time/temperature distributions were simulated. Global aging data were gathered by exposure of specimens in hot water at elevated temperatures (115 and 135°C) and analytical and mechanical characterization after aging. Lifetime assessment for the absorber/storage-tank material was done by combining the time/temperature loading profiles, extrapolated endurance times from aging tests and assuming cumulative damages. Depending on the chosen aging indicator, glass fiber content and climate zone, the lifetimes varied between 35 and 47 years with lowest values for the hot-and-humid climate zone. The grade with 30 m% glass-fibers exhibited a slightly better long-term performance than the grade with 35 m%.

Keywords: *Polypropylene; Solar thermal collector; Absorber; Lifetime*

1. Introduction

Fiber-reinforced polymer composites represent an important material class for solar thermal systems (Wallner and Lang, 2005). Material properties like low weight, high mechanical strength, thermal, dimensional and chemical stability as well as mass production capability are of paramount importance for cost-efficient pressurized non-pumped systems based on integrated storage collectors (Celina et al., 2005; Kahlen et al., 2010). Today for solar thermal collectors a lifetime of up to 20 years or even more is mandatory (Köhl et al., 2005). In previous research the opportunities and limitations of injection moulding technologies for the production of absorbers of integrated storage collectors were evaluated (Brunold et al., 2012). It was shown that glass-fiber reinforced polyamides exhibit a high potential for such applications.

A main task of current research work is the lifetime assessment of these novel absorber materials for more cost-efficient and reliable collector systems. Hence, the main objective of the paper is to investigate the aging behavior and to assess the lifetime of various glass-fiber reinforced polyamide 66 grades for pressurized, non-pumped integrated storage collector systems. Therefore, temperature loading profiles were estimated for three different climate locations (Mediterranean (Athens, Greece), hot-and-humid (Fortaleza, Brazil) and hot-and-dry (Pretoria, South Africa)) with maximum temperatures up to 95°C. The technological parameter stress-at-break and the analytical parameter area crack density were determined for standardized specimens after exposure to hot water at elevated temperatures (115 and 135°C). Using an Arrhenius approach endurance times at service-relevant temperatures ranging from 5 to 95°C were calculated. For lifetime

doi:10.18086/eurosun.2016.04.03 Available at http://proceedings.ises.org

assessment a recently published approach based on calculated temperature loading profiles, extrapolated endurance times and cumulated damages was used (Wallner et al., 2016).

2. Methodological approach

2.1 Collector design and modelling of service relevant conditions

The investigated solar thermal integrated collector storage (ICS) (s. Fig. 1) combines the thermal absorber and the storage tank in one component. The system consists of cylindrical tubes with a diameter of about 150 mm and a thickness of 3 mm. These tubes are friction welded out of injection molded half shells and subsequently connected in series. Reinforced ribs and insulation are applied to fulfill mechanical and thermal properties. Under service conditions the tubes are permanently filled with drinking water under a given pressure, while the outside of the tubes remain dry. Consequential the tubes are loaded under permanent stress while recurring temperature changes lead to complex and superimposed conditions (Geretschläger, 2015).

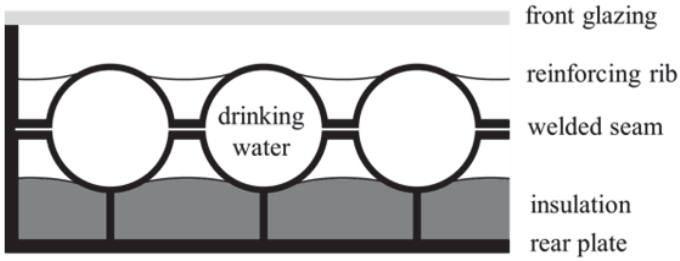

Fig. 1: Cross section of the ICS collector with injection molded absorber/storage tank made from half-shells [Geretschläger, 2015].

Based on the study by Kaiser et al. (2013) and prevalent market potentials, three different climatic conditions (Mediterranean (Athens, Greece), hot-and-humid (Fortaleza, Brazil) and hot-and-dry (Pretoria, South Africa)) are taken into account for this work. Based on Meteonorm-data, relevant climatic parameters (e.g. air temperature, relative humidity, global radiation) are established on an annual basis. In a further step for all three climate zones market-based polymeric collectors for hot water preparation in single family houses are defined and evaluated. By theoretical modeling using the software tool SHW (Streicher et al., 2004), annual time/temperature distributions for the absorber are obtained.

2.2 Materials, aging conditions and characterization

Based on established property requirements for materials of pressurized absorbers/storage-tanks aliphatic polyamide 66 grades with glass-fiber contents of 30 and 35 m% and carbon black pigmentation were selected for the investigations. The long term hydrolytic stability was characterized at elevated temperatures of 115 and 135°C. Therefore standardized dumbbell specimens were exposed in water filled pressure cooker autoclaves and withdrawn at defined intervals.

As global aging indicators, the technological parameter stress-at-break and the analytical parameter area crack density were monitored. Limit values of these aging parameters were defined on basis of maximum mechanical loads and material key-properties of an ICS. Tensile tests were carried out at 23°C using a screw-driven universal testing machine with a test speed of 50 mm/min. The lower limit as aging indicator for stress-at-break values was defined at 25 MPa. Microscopic investigations on surface defects were achieved by using a conventional microscope with a 5x-objective (2.0x2.8 mm²). Area crack density was calculated by the ratio of single cracks on the surface relative to the size of the picture. The limit value for failure was the first appearance of cracks on the surface of the specimen. A similar methodological approach dealing with the aging characterization of glass-fiber reinforced polyamides in hot water and air was carried out successfully by Geretschläger and Wallner (2016).

2.3 Lifetime assessment

For lifetime estimation a cumulative damage approach was used established by Wallner et al. (2016) for

black-pigmented PP solar absorber materials. The main elements of the approach are the simulation of temperature loading profiles, the extrapolation of aging data and the cumulation of damages of different temperature levels (Fatemi and Yang, 1998). The experimental global aging data gathered at elevated temperatures were extrapolated to service-relevant temperatures. Therefore, the log(t)/(1/T)-linear Arrhenius approach was applied assuming a specific degradation mechanism in the temperature range. Additionally, a constant endurance time of 50 years was assumed according to Leijström and Ifwarson (1998) to ensure not to overrate lower temperatures. The lifetime was deduced by weighting the temperature dependent endurance times with the loading profiles according to ISO 13760. This lifetime modelling approach neglects superimposed static and cyclic mechanical loads induced by temperature changes that are to be expected during operation of the ICS collector.

3. Results and discussion

3.1 Service relevant loading conditions

Fig. 2 illustrates the simulated absorber surface temperatures profiles for mediterranean (Athens), hot-and-humid (Fortaleza) and hot-and-dry (Pretoria) climate conditions. Two different situations (with hot water consumption and stagnation) are considered. The solid curve represents the stagnant condition whereby no water is used from the integrated storage collector. For the consumption condition, an assumed daily use of 110 litres at 45°C is taken into account. A maximum of hot water draw is assumed mainly in the morning (6am to 8am) and in the evening (7pm to 9pm) while a reduced water abstraction is given during day. Regarding the temperature loading profiles maximum temperatures of about 90°C are obtained for the collector system in Fortaleza. Slightly lower values are calculated for Pretoria and Athens. Also the maximum of the time/temperature distribution is significantly dependent on the installation site. The high temperature loads between 70 and 90°C are more pronounced for Fortaleza while minimum temperatures of about 30°C are obtained. Athens reveals lowest collector temperatures of about 5°C. In all locations the stagnant conditions lead to a slight shift of the profile curve towards higher temperatures. Hence, stagnant condition is selected to calculate a worst case scenario for lifetime modelling.

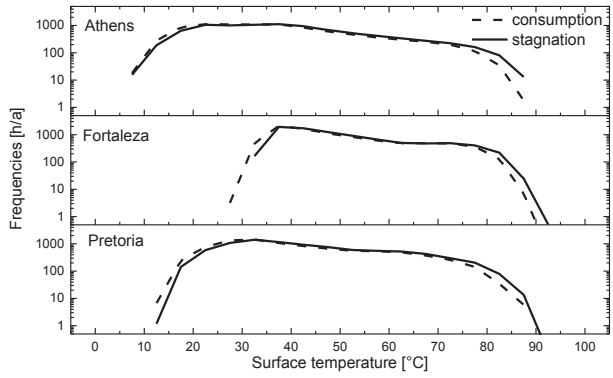

Fig. 2: Annual ICS absorber surface temperature profiles for three different climate zones with and without hot water consumption.

3.2 Aging behavior at elevated temperatures

Fig. 3 shows the stress-at-break values and the area crack density of the investigated GF-reinforced PA66 grades as a function of aging time in hot water at 115 and 135°C. Ultimate failure with stress-at-break values below 25 MPa are indicated with open symbols in the chart. The limit value for area crack density is the first visible appearance of cracks. Aging in hot water led to a steady decrease of stress-at-break values. Limit values of 25 MPa were obtained after about 750 h and 5000 h at 135 and 115°C, respectively. The aging behavior of the investigated grades was slightly differing. First cracks on the surface were detected within 350 h and about 2500 h at 135 and 115°C. Hence, this aging indicator was more sensitive and critical. The amount of cracks per area increased significantly for ongoing exposure. A higher tendency of crack formation was observed for PA66-GF35 and therefore a worse hydrolytic stability. Both materials exhibited

a regular crack pattern primarily oriented perpendicular to the fiber direction i.e. line of injection (s. Fig. 4).

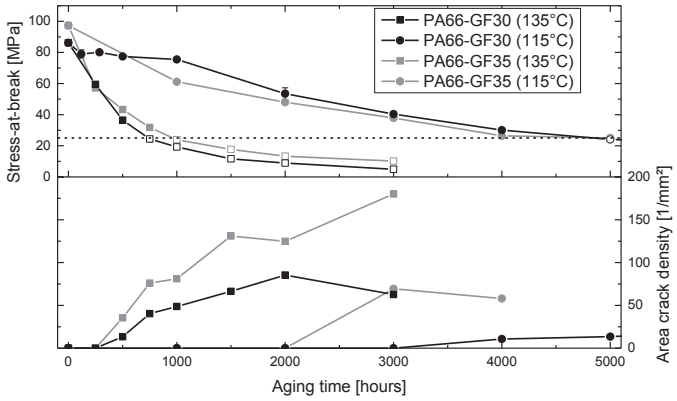

Fig. 3: Stress-at-break values (top layer) and area crack density (bottom layer) for glass-fiber reinforced PA66 specimens as a function of aging time exposed to hot water at 115 and 135°C.

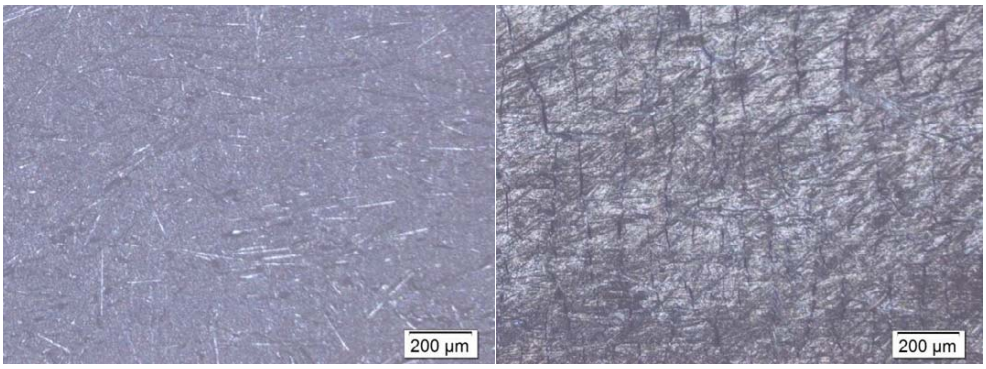

Fig. 4: Unaged (left) and degraded/cracked (right) surface of PA66-GF30 after exposure to hot water at 135°C for 750 h.

3.3 Extrapolated endurance times and estimated lifetimes for glass-fiber reinforced PA66 specimen

The derived Arrhenius plots for material endurance time estimation is presented in Fig. 5. The filled symbols represent the stress-at-break limit values while the open symbols depict crack formations on the surface of the samples for 115 and 135°C in hot water. The experimental data were fitted using an Arrhenius approach and extrapolated to service-relevant temperatures ranging from 5 to 95°C. A similar methodological approach dealing with the assessment of long-term mechanical performance of glass fibre reinforced polyester composites in aqueous environments was carried out by Carra and Carvelli (2015).

Due to the fact, that PA66-GF35 exhibited a slightly less drop of the strength at 135°C and a comparable aging behavior at 115°C, the extrapolated curves of both investigated grades intersect resulting in a worse aging behavior for PA66-GF35 below 115°C. To examine this phenomenon, additional exposure tests are ongoing at 125 and 105°C.

The shorter failure times for the aging indicator area crack density results in left shifted extrapolated curves with lower endurance times. The material with the higher glass-fiber content exhibited a more pronounced formation of cracks and therefore a worse aging behavior. For the assumed 50 years cut-off a temperature threshold of 74 and 68°C was deduced for PA66-GF30 and PA66-GF35, respectively.

Table 1 depicts the deduced lifetimes which are ranging from 35 years in the hot and humid climate of Fortaleza up to 47 years for the less critical mediterranean climate of Athens. Comparable maximal lifetimes of 47 years were deduced for the hot-and-dry climate condition of Pretoria. However, all results were significantly affected by the 50 years cut-off. Lower lifetime values were obtained for the grade with 35 m% glass fibers. This can be attributed to differences in the stabilization packages. For both materials the aging

indicator area crack density exhibited slightly lower lifetimes (less than 10% deviation).

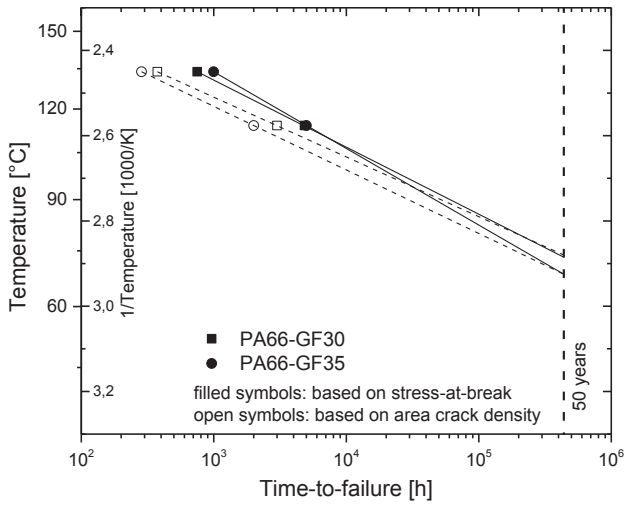

Fig. 5: Experimental failure times for glass-fiber reinforced PA66 based on stress-at-break and area crack density as limit values with extrapolated endurance times in the service relevant temperature range.

Tab. 1: Estimated lifetimes for the investigated glass-fiber reinforced PA66 grades for integrated storage collectors at the installation sites Athens, Fortaleza and Pretoria.

Aging indicator	Material	Predicted lifetimes in years		
		Athens mediterranean	**Fortaleza** hot and humid	**Pretoria** hot and dry
Stress-at-break	PA66-GF30	47	44	47
	PA66-GF35	44	38	43
Area crack density	PA66-GF30	47	43	47
	PA66-GF35	42	35	41

4. Summary and conclusion

Lifetime estimation was established for two black-pigmented glass-fiber reinforced PA66 grades used for integrated storage collectors for hot water preparation. Therefore, temperature loading profiles for three different climate zones were determined based on climatic input data. As experimental failure limits, the drop of stress-at-break below 25 MPa and the appearance of cracks on the surface of the specimen was defined. These aging indicators were observed for exposition in hot water at 115 and 135°C. Furthermore, endurance times at service relevant temperatures (5 to 95°C) were extrapolated using an Arrhenius approach. A model of cumulative damages (Miner's rule) was applied to assess lifetimes for the investigated materials.

Absorber temperature loading profiles ranging from 5 to 95°C were obtained. The profile was dependent on the installation site with longer exposure times at higher temperatures for Fortaleza. The stagnant condition led to a shift of the loading profile towards higher temperatures for all three locations. Thus, these temperature loading profiles were used for lifetime assessment.

Hot water exposure of the investigated grades at elevated temperatures resulted in a decrease of stress-at-break values with ultimate failure times of 750 and 5000 h at 135 and 115°C, respectively. Crack formation started after 350 h at 135°C and 2500 h at 115°C. Both materials showed a regular crack pattern primarily oriented perpendicular to the fiber direction with a higher tendency for crack formation for the PA66-GF35 grade.

The obtained lifetime values were ranging from 35 to 47 years. The Mediterranean climate in Athens and

hot-and-dry climate in Pretoria exhibited highest calculated lifetimes, while the hot and humid climate in Fortaleza led to shorter lifetimes (4 to 7 years lower). PA66-GF35 exhibited lower lifetimes, which was attributed to differences in the stabilization package. To assure the extrapolated endurance times and the deduced lifetime values exposure tests at 125 and 105°C are carried out additionally.

Abstract

Solar electrical and thermal driven systems are promising for a sustainable supply of heat and cold demand. The target of the Austrian research project SolarHybrid is the optimization of both. Thermal and electrical systems are combined in solar hybrid systems to utilize advantages of each (sub-) system. The evaluation of the steps toward the hybrid solution including system design and control strategies, are performed with detailed component models. The dynamic simulation studies are supplemented with Hardware-in-the-Loop laboratory measurements.

Initial design optimization for photovoltaic and solar thermal driven system include dimensioning, control strategies and energy cascade usage. Cost savings will be achieved by common used components e.g. for the electrical and thermal driven chillers. A demonstration of such arrangements is realized with specifically designed and adapted chillers in the laboratory and investigated under dynamic tests. The controllers get further enhanced by mathematical methods and the implementation of predictive control.

The so far optimized solar thermal driven systems can achieve up to 60% non-renewable primary energy savings with a cost ratio of 1.1 compared to a simple reference system with natural gas boiler and vapor compression chiller. If an electrical driven system with a reversible heat pump is applied as benchmark, savings remain at 50%, but the cost ratio drops to 0.9. Further improvements and comparisons of the photovoltaic and solar thermal driven systems as well as the hybrid solutions will be performed in detail within the course of the project.

Keywords: *solar hybrid, solar heating and cooling, simulations, DHW preheating, Hardware-in-the-Loop*

1. Introduction

Solar technologies are promising for a sustainable heat and cold supply. An increase of solar cooling systems is observed by Mauthner et al (2016). Solar includes both technologies solar thermal and photovoltaic driven systems. Several IEA Tasks are related to this topic, one of them is IEA SHC Task 53. The objective is to assist PV and solar thermal driven systems to a sustainable market development (http://task53.iea-shc.org/).

Several studies of the previous year's show the competitiveness of solar thermal and solar electrical driven systems. The advantage of each system configuration depends on the boundary conditions. Different boundary conditions try to carve out these advantages. Magnitudes of efficiency or rather primary energy savings and costs can be equal for both technologies.

These controversial statements are taken up by the Austrian project SolarHybrid. The major target of SolarHybrid is to develop and evaluate economic, efficient and reliable solar hybrid systems. Hybrid includes solar electric (PV) and solar thermal supported heating and cooling systems in different combinations. Effective solar hybrid systems can be realized if the underlying base technologies are

doi:10.18086/eurosun.2016.04.23 Available at http://proceedings.ises.org

optimized and when they are adapted for a certain kind of applications.

In a first step both technologies were enhanced regarding the economical and energetic efficiency. The potentials have to be utilized before solar hybrid systems are examined. Only when optimized single technologies are used, solar hybrid systems lead to success. Both technologies are optimized by the mean of optimization tools. The optimization of the single systems is a basis for the hybrid ones. An automatic optimization of the control strategy supports the improvement of different parameters.

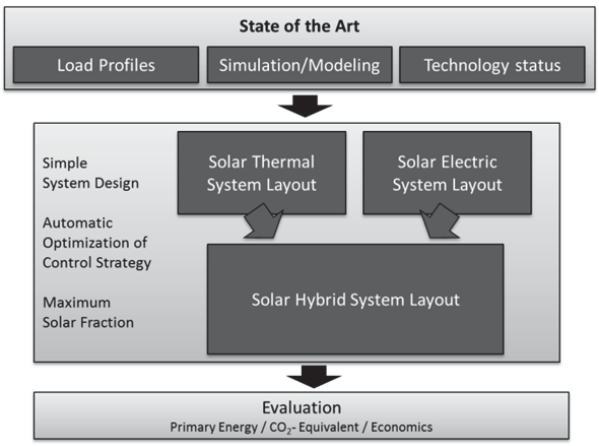

Fig. 1: Methodological approach and workflow of SolarHybrid

Optimization and development of the solar hybrid system is based upon the same methodology. Dynamic simulations are built up, taking a minimized number of components and enhanced schemes into account. The systems and their control strategies are designed using automated algorithms. The complex minimization problems lead to ideal efficiency. Applying these minimized schemes with combined used components, the solar hybrid systems allow interesting economic alternatives. The performance of this development will be proven in hardware-in-the-loop laboratory measurements.

2. Steps towards a solar hybrid solution

In this section all main steps carried out in the course of SolarHybrid are described including ideas, methodologies, highlights and results.

2.1. Assessment

The assessment follows the method of IEA SHC Task 48 and Task 53 (Neyer et al. 2015b). The main figures are non-renewable Primary Energy Ratio for the entire system (PER_{NRE}) and a pre-defined reference system (PER_{ref}). Derived from the comparison of these PER's, non-renewable Primary Energy Savings ($f_{sav\text{-}NRE}$) are calculated. The two main primary energy conversion factors used in this assessment are electricity (ε = 0.4 kWh_{el}/kWh_{prim}) and backup fuel (natural gas with ε=0.9 kWh_{end}/kWh_{prim}).

For the economic evaluation the annualized costs for investment, replacement & residual value, maintenance, energy and water costs are calculated with pre-defined values, representing cut off values derived in the Tasks. Levelized costs of energy (space heating-SH, domestic hot water-DHW, cooling-C and domestic electricity) are derived for both, the entire system and the reference system. The ratio of these levelized costs of energy (CostRatio) is used for assessing and presenting the effect of the simulation studies.

The standard reference system consists of a natural gas boiler as heat source and a vapor compression chiller as cold source. For further comparison a specific reference system was defined. The system boundary for technical and economic analysis includes all energy demands of the entire study: space heating, domestic hot water, pool heating, cooling and domestic electricity.

- Seasonal Performance Factor (SPF)

The SPF is the ratio of useful energy (out: energy supplied to the application) to energy effort from external sources. It is distinguished between thermal and electrical performance.

$$SPF_{th} = \frac{\sum Q_{out}}{\sum Q_{in}}, \; SPF_{el} = \frac{\sum Q_{out}}{\sum Q_{el,in}} \qquad \text{(eq. 1)}$$

- Non-renewable Primary Energy Ratio (PER_{NRE})

The PER converts all energy inputs of the system into primary energy equivalents. This provides appropriately comparable quality ratings for energy derived from alternative electricity, solar and fossil fuel heat energy sources. The PER_{NRE} is also calculated for the entire reference system.

$$PER_{NRE} = \frac{\sum Q_{out}}{\sum\left(\frac{Q_{el}}{\varepsilon_{el}} + \frac{Q_{EC}}{\varepsilon_{EC}}\right)} \qquad \text{(eq. 2)}$$

- Fractional Saving (f_{sav})

f_{sav} represents the non-renewable primary energy saving due to the entire SHC system compared with a reference system.

$$f_{sav-NRE} = 1 - \frac{PER_{ref}}{PER_{sys}} \qquad \text{(eq. 3)}$$

- Cost Ratio (CR)

The cost ratio is determined with the levelized costs of energy for the SHC system ($C_{tot.SHC}$) and the levelized costs of the reference system ($C_{tot.REF}$). The levelized costs ($EUR/kWh_{useful\ energy}$) are calculated including the sum of the annualized costs (invest, replacement, maintenance, energy, etc.) and the delivered energy flows of the application.

$$CR = \frac{C_{tot.SHC}}{C_{tot.REF}} \qquad \text{(eq. 4)}$$

2.2. Simulation model adaption

Crucial models in the system analysis are the component models for the vapor compression- and the absorption chiller. An ordinary effort was prosecuted to reach reliable and realistic results especially in part load conditions. Beside the chillers, other component models (e.g. cooling tower) were analyzed and adapted.

- Vapor compression chiller

Three types of compression chillers ((1) on/off screw, (2) on/off double scroll, (3) part load controlled turbo compression) are taken into account. For each compressor type a suitable simulation model was set up. Operating conditions, which remain uncovered by manufacturer data, were extrapolated using the Thin-Plate-Spline method. Fig. 2 shows this limitation due to the operation range and the limitation due to the available data.

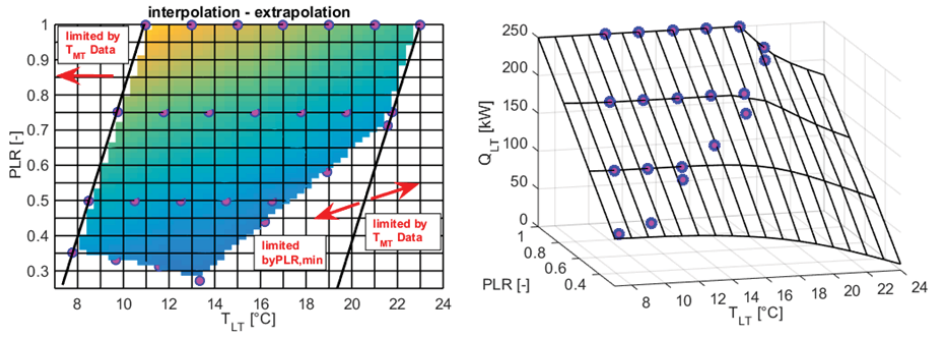

Fig. 2: Interpolation and extrapolation of boundaries for the vapor compression chiller for the turbo compressor (PLR…part load ratio, LT…chilled water, MT…cold water)

Several publications (e.g. Fillard 2009, Bettanini 2003) suggest modeling the part load energy efficiency ratio (EER) of compression chillers as function of the part load factor (PLF). While this approach correlates with the performance map for the chiller #1, major deviations from the part load behavior of the other models (especially the turbo-chiller) could be observed.

For the double compressor chiller (chiller #2) the PLF-model is valid at constant heat rejection temperature within an error interval of 1%. Thus the chillers have been modelled by a normalized lookup-table containing the performance data.

Dynamic effects were modeled by adding a thermal capacity to the output and taking the start-up time of the chillers into account. For the model of the turbo compression chiller (chiller #3), the minimum part load due to the operating range of the compressor have to be considered. Lower cooling capacities have to be provided by on/off switching.

- Absorption chiller

In case of hybrid systems, solar thermal cooling can represent a good alternative to electrical driven chillers. Therefore the influence of the usage of ammonia/water absorption chillers is investigated by simulations and assisted by real measurements of an appropriate chiller prototype. For simulations the physical models were developed for a single- and half-effect chiller (SE- and HE-chiller) and were used to create the data base for a simplified lookup-table model (Hannl 2012). Both lookup-tables are used by a newly developed TRNSYS Type (Type 1005). The data provided by the lookup-tables are interpolated accordingly. The model reflects the SE-chiller's performance curves as a function of 6 input variables (3 temperatures and 3 mass flow rates). The HE-chiller is currently implemented with 3 independent temperature input variables, volume flows are constant (Tab. 1). The mode (HE or SE) can be switched manually. Either single mode can be used in the simulations or a proper control strategy can be implemented according to the actual requirements of the entire heating and cooling system.

Tab. 1: Matrix for the characteristic curve diagrams for the SE- and HE-chiller

Parameter	Unit	SE	HE
T_{HT}	°C	75 – 80 – 85 – 90 – 95	75 – 80 – 85 – 90 – 95
T_{MT}	°C	24 – 28 – 32 – 36	25 – 28 – 31 – 34 – 37 –40
T_{LT}	°C	6 – 9 – 12 – 15	-6 – -3 – 0 – 3 – 6 – 9 – 12
$\dot{V}_{HT}$	m³/h	1 – 2 – 3 – 4 – 6	2 (GEN1 und GEN2)
$\dot{V}_{MT}$	m³/h	1 – 1,5 – 3 – 4.5 – 6 – 9	5/4/3 (ABS1, ABS2, CON)
$\dot{V}_{LT}$	m³/h	1 – 2 – 4.5 – 7	3.5

The model provides a very realistic start/stop-behavior and includes the electricity demand of the solvent pump. The chiller is scalable due to the integrated normalized data lookup-table. The Type is validated by steady state and dynamic measurements of the absorption chiller prototype at different operation modes.

2.3. System concepts

The simulations are set up in TRNSYS & MATLAB and are based on a load file concept. This concept enables the separation of building- and HVAC-simulation.

- Building profile

The building-simulation was set up in TRNSYS with a four-star Hotel (Gritzer 2016). This hotel has a capacity of 240 beds and an area of 10'080 m². Internal loads and geometry are based on different standards (e.g. SIA, etc.). The south oriented building has a high quality thermal envelope. Shading is achieved by construction and active shading elements. The hotel includes the following usage zones: accommodation, reception, lobby, bar / restaurant, kitchen and spa area with a pool. Geometry, design and control strategies determine the load profiles and energy demand for space heating, pool heating, domestic hot water and

cooling accordingly. The profiles are defined on a daily basis and change monthly. Ventilation includes heat recovery. Air change rates and specified temperatures correlate with each usage zone. Depending on the boundary condition, heat and cooling loads arise for each usage zone. These assumptions result in the following details for the Innsbruck climate profile, which is investigated in detail here.

Tab. 2: Energy demand and loads for the hotel profile in Innsbruck

Application	Demand (MWh)	Load (kW)
Space heating	271.2	190
Pool heating	766.1	208
Domestic hot water	562.5	260
Air conditioning	85.7	80
Domestic electricity	517.5	

Demand and different system configurations are evaluated separately by focusing on the profile of interest and neglecting the others.

- Thermal driven systems

The scope of the simulation study with the solar thermal driven heating and cooling systems is to survey following points as listed in Table 3.

Tab. 3: Matrix for the characteristic curve diagrams for the SE- and HE-chiller

Main Problem	Explanation / Examples
(1) System design issues	Optimization of the solar thermal heating and cooling system due to design and control strategies. Comparisons of PV driven systems simultaneously. E.g. variable collector area, hot /cold water storage tanks, ACM and VCC capacities depending on a variety of load files (pool off, SH off, cooling 100%, DHW 100% and 25%).
(2) Cascade energy use	The temperature level of re-cooling of the ACM and VCC enables possibilities of usable energy cascades. E.g. rejected heat for DHW pre-heating
(3) Common used components	Commonly used components can be forced for economic reasons, but also when refurbishing system common used components enables potential E.g. Serial or parallel use of ACM and VCC in MT- and LT-circuits
(4) Multiple use of components	Solar parts, but also the thermal driven chillers are main investment cost drivers. The multiple usage of these and other components should increase the economic competitiveness. E.g. ACM used as heat pump, combined with low temperature heating/cooling

Selected results for the (1) step are e.g. the optimization of the DHW only solar thermal systems (ST) and the comparison with PV driven heat pump (HP) systems. The solar thermal driven system is shown in Figure 3. The solar collectors feed the hot storage, back upped with a natural gas boiler. The applications for the first studies are reduced to DHW and cooling. The solar energy driven absorption chiller is running in parallel to a vapor compression chiller. Both are keeping the cold storage tank at a certain temperature to fulfill the needs of the load profile.

For the design of the ST system two different hot storage sizes are considered: 30 and 50 l/m² solar thermal collector area. The size of the solar collector is designed that 10 h of stagnation are observed. The DHW consumption is scaled from 100% down to 25% in four steps. The smaller tank volume combined with a moderate collector size (0.5-1.5 m²/person, depending on DHW demand) was chosen to be best for further applications. Solar fractions of 20-25% are reached at cost ratios of 1.25-1.1 for the standard reference system.

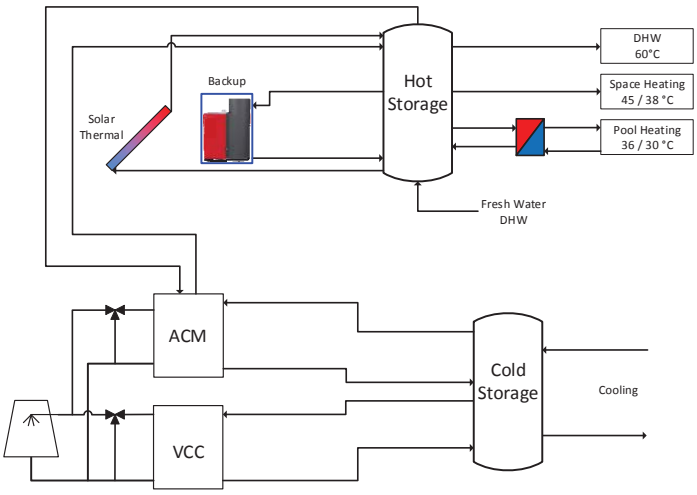

Fig. 3: Solar thermal system layout with hot and cold backups

Compared to a simple heat pump, a cost ratio of 0.82 can be reached. Because of the low solar fraction the non-renewable primary energy savings reach 17%. Hence, the solar collector area was increased to reach a cost ratio of 1. Finally, a collector field of 720 m² was determined with a f_{sav} of 0.39 compared to the heat pump. If the heat pump is equipped with a PV, 140 kW_p would be necessary to reach the same primary energy savings as the thermal driven system. Simultaneously the cost ratio drops down to 0.7. Main reason is the DHW application at its 60°C set temperature that enforces a low EER of the HP system.

With these findings a second simulation study, including the cooling demand, was started. Result of this study is an optimized control strategy and a system design. Solar fractions of 55% can be obtained with this configuration. Compared to the standard Task 53 reference primary energy savings of 49% and a cost ratio of 1.11 can be achieved. The optimization is e.g. reflected in the auxiliary electricity demand of the system.

In Figure 4 the carpet plots of the electrical efficiency SPF_{el} are shown and include the annual trend (x-axis: days of the year, y-axis: hours per day, color of each pixel: SPF_{el}). The maximum value of thermal cooling has a SPF_{el} of 21.5 and the vapor compression chiller of 5.7. The maximum for the thermal cooling efficiency appears simultaneously with small loads whereby the chiller is driven with hot water stored in the tank (mainly at night). The maximum for the vapor compression chiller appears during minimal loads. On an average, the electrical efficiency of absorption and electrical cooling results in a value of 4.

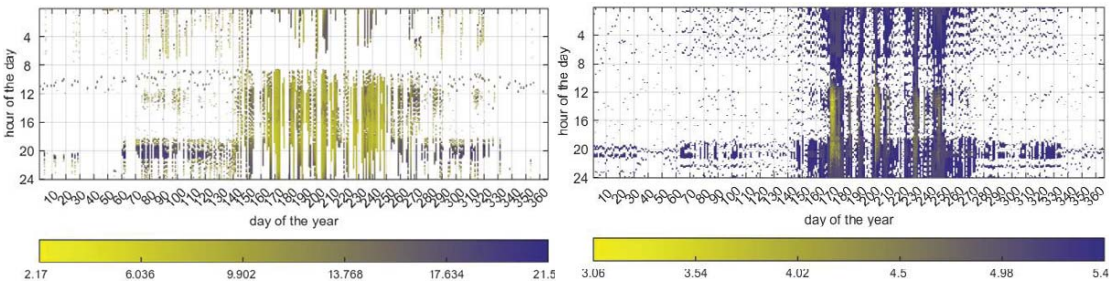

Fig. 4: Carpet plots of the electrical efficiency for the thermal cooling- (left) and vapor compression chiller (right)

The so far optimized solar heating and cooling system was used to integrate ideas of cascade energy usage (2). The heat rejection of the chillers (absorption and electrical) with temperatures around 25-40°C enables the use of this energy flux for DHW pre-heating (Fig. 5). The heat exchangers for the fresh water (DHW) pre-heating are situated in the cooling tower circuits. Thus, the hydraulic of each rejection circuit has to be extended with one mixing valves (V_{MT}) and one bypass (V_{CT}).

The first valve is used to keep a certain set point for the chiller re-cooling inlet temperature. This set point can change according to the different control strategies of the system (e.g. chilled water set temp., etc.). If the

outlet temperature of the cooling water after the heat exchanger (HX) drops below the set point, the cooling tower will be bypassed.

In Table 4 all results for DHW only and DHW&C are presented for the total DHW demand (1) and for the smallest demand (0.25). Accordingly, the ratio of C/DHW changes and affects the results.

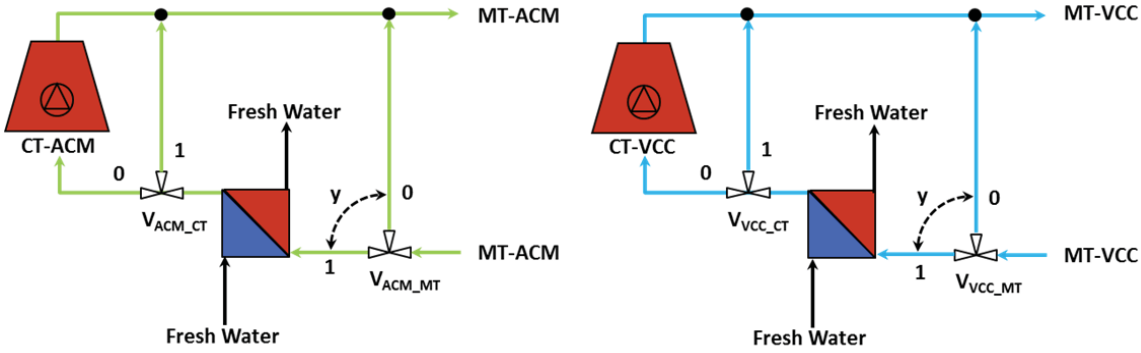

Fig. 5: DHW-pre-heating in the heat rejection circuits of the ACM (left) and VCC (right)

When DHW pre-heating is activated, the fractional savings increase from 49% to a level of 53% (DWH=1) and from 55% to 57% at low DHW demands respectively. At the same time the Cost Ratio decreases from 1.11 to 1.09 (DHW=1) and from 1.44 to 1.43 (DHW=0.25). This can be explained when the energy balance for the hot storage is disposed. All energy used for preheating, as it is arranged in continuous flow mode, reduces the affordable energy input. When the system is compared to the specific reference system (HP), the savings arise to 50% with a corresponding CR of 0.91 (65%/1.4 for DHW 0.25).

Tab. 4: Comparison of achievable cost ratio (CR) and primary energy savings (f_{sav}) for different applications of solar thermal systems

Results	Additional information	DHW only		DHW&C		DHW&C preheating	
Collector area	m²	420	131	720	431	720	431
DHW load	-	1	0.25	1	0.25	1	0.25
Solar fraction	-	0.25	0.19	0.55	0.75	0.55	0.74
f_{sav} – T53	Ref: natural gas boiler & VCC	0.25	0.19	0.49	0.55	0.53	0.57
CR – T53		1.10	1.25	1.11	1.44	1.09	1.43
f_{sav} spec.	Ref: heat pump	0.17	0.11	0.46	0.63	0.50	0.65
CR spec.		0.82	0.88	0.93	1.41	0.91	1.40

The differences in the savings and the cost ratio between highest and lowest DHW demand, derive from the specific collector area and the ratio of investment to overall costs. The 25% DHW is equipped with a greater collector area. Thus solar fraction, primary energy savings, costs and the cost ratio increase accordingly.

- Electrical driven systems

Considering the high electric loads, the integration of PV-panels or PVT-panels can lead to a decrease of primary energy consumption. Depending on the amount of low temperature thermal energy demand and on the internal heat transfer coefficient of the panel PVT or PV are used. Especially the internal heat transfer is critical for the low temperature thermal efficiency and improvement of the electric efficiency of the PVT compared to a PV panel. The PVT panels are simulated by using the model of Bertram (2012). This model takes the effective solar cell characteristic for the electrical part and the thermal model from EN 12975 (now EN ISO 9806) into account.

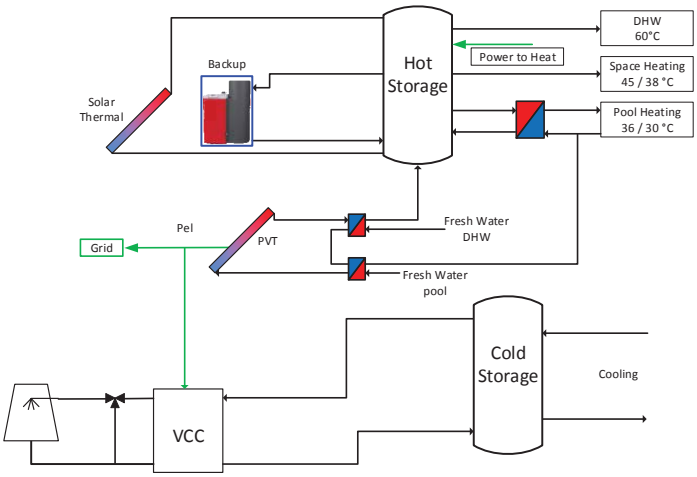

Fig. 6: Integration of PVT panels for DHW pre-heating or pool heating

The available load profile of the hotel contains a high demand of freshwater for DHW and the pool at low temperatures (around 12°C). Thus different feed in points for PVT are studied (Fig. 6). Regardless of the decision for PV or PVT, the produced electric energy is a dimensioning factor for the amortization (ecological or economical). Power to heat can only be an option if excess electric energy is produced and variable feed-in tariffs are considered. In this case it can be better from an economical point of view to store the energy in the system.

Other components, such as chillers, could also benefit from this low temperature energy demand as sink for rejection heat. This energy exchange is addressed at first in the design process. Secondly, the optimization process, which is part of the control strategy, determines the energy flow at runtime with respect to the above mentioned optimization problem amongst others (compare chapter 2.2).

The achieved results are used to show the impact of PVT collectors on the seasonal performance factor, the primary energy ratio and the Cost Ratio.

2.4 Optimization

The optimization problem described and used in the project is used to find the optimal strategy to operate the introduced systems (solar thermal and PV driven systems). Improvements of the system itself (e.g. size of the hot storage, etc.) are not considered here.

Solar hybrid systems consist of several components to fulfill specific targets. A typical configuration is a solar thermal collector and a hot backup for domestic hot water preparation, an absorption chiller and a vapor compression chiller to meet the cooling demand. To run such a system, several control loops have to be designed. The satisfaction of the energy demand is given high priority and thus complicating the above described system with three options to provide hot water, and two options for chilled water. Numerical optimization routines can help to find the operating strategy of the system, which leads to a specific minimum of a quantity. The design could e.g. aim at minimizing the primary energy demands.

The strategy of the control system is as follows: If a (course, control oriented) mathematical model of each component is given, the overall system can be described as $\dot{x} = f(x,u)$, $y = g(x,u)$ where x is the system state, u are the inputs (control signals, e.g. pump speed) and y are the control outputs. At any given time instance k, the model is used to make a *prediction* into the near future (e.g. oncoming 24 hours), which depends on u. An optimization algorithm can be used to find the optimal control signal u^* for the following 24 hours. Therefore, the primary energy usage is minimized. After implementing the first element of this optimal time series, the horizon is shifted, $k \rightarrow k+1$ and the optimization problem is formulated and solved again.

The optimization problem can be solved efficiently by using standard tools. Depending on the structure of the models, nonlinear optimization techniques are a particular solution. However, their solution takes usually a long time and the result might be only a local minima. If the system can be approximated with local linear models with reasonable accuracy, the optimization problem boils down to a linear one for which the global optimum can be found within a fraction of the time-constants of such systems.

The predictive nature of the control system requires a prediction of the energy production of the PV and solar collector, which in turn requires a prediction of the irradiation and temperature. Such values are easy to access and quite accurate over a 24 hour time window.

2.5. Chiller prototypes

According to the original idea of designing a hybrid (absorption/vapor compression) ammonia/water (NH_3/H_2O) chiller comprehensive studies were undertaken. The main difficulty in realization represents the separation and purity of the different substances (ammonia, water and oil) needed for the diverse circuits. Therefore the decision was made to combine the absorption and vapor compression chiller externally via hydraulic connections of the water circuits. Both chillers are based on ammonia and have the same capacity.

- Absorption chiller

In another research project at University of Innsbruck (DAKtris 2012) a new generation of absorption chiller was designed and adapted to the use of dry cooling tower and the resulting high re-cooling temperatures. The development is based on the existing single-effect chiller (PC19), which got improved by analyzation further investigations. This new absorption chiller concept includes a switchable half- and single-effect (HE, SE) combination, flat plate heat exchangers for the evaporator, absorber and generator, enforced throughput of the generator, a new injection nozzle and an adapted internal control strategy.

Correspondingly a prototype of this chiller was built and investigated by measurements at different modes and boundary conditions. This includes the variation of volume flows and chiller inlet temperatures at single- and half-effect, shown in Tab.5.

Tab.5: Set-point variations for measurements of the absorption chiller

Circuit	ACM-Mode	T_{in} (°C)	$\dot{v}_{min}$ (m^3/hr)	$\dot{v}_{mid}$ (m^3/hr)	$\dot{v}_{max}$ (m^3/hr)
LT / evaporator	SE	12,18	1.5	2	3
	HE				
MT / condenser & absorber	SE	20,25,30,35	4.25	5	6.5
	HE	20,25,30,35,40,45			
HT / generator	SE	80,85,90	3	3,5	4.5
	HE				

The prototype runs stable and delivers satisfactory capacities and EER's. Recording of the chiller performance map was performed by steady state measurements executed with equivalent settling time and a moving average exercised on data.

One characteristic diagram of the absorption chiller at HT temperature of 85°C, LT temperature of 18°C on the left and 12°C on the right side is shown in Fig. 7. Reached capacities are printed in the upper charts with related energy efficiency ratios, beneath corresponding to the MT inlet temperature. Especially the course of capacity shows the potential of the HE chiller mode at higher MT inlet temperatures. Regarding the costs SE has to be preferred due to the higher thermal efficiency. Depending on the overall system other operation modes can have advantages.

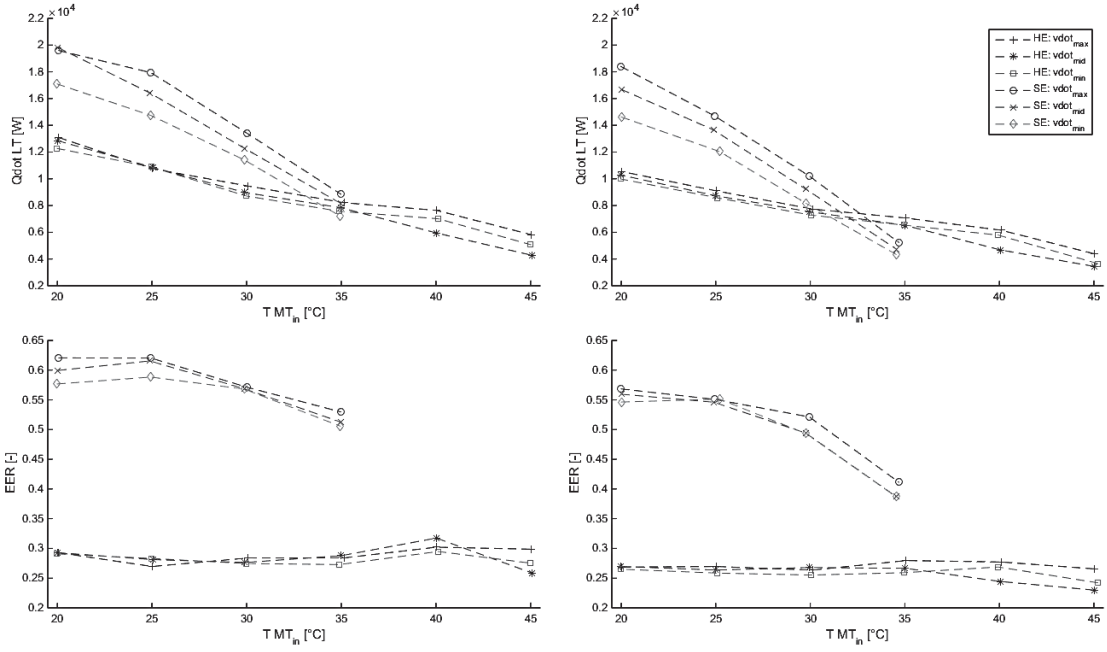

Fig. 7: Measured performance of the new SE/HE ammonia/water chiller with flat plate heat exchangers. LT temperature of 18°C (left) and 12°C (right)

Additionally to the steady state measurements, dynamic hardware-in-the-loop tests take place to evaluate the influence of fluctuating operation and different system setups especially in combination with the vapor compression chiller prototype.

- Vapor compression chiller

The vapor compression chiller L7KW 2T PP, produced by Engie Kältetechnik GmbH, is a water cooled liquid chiller and uses the natural refrigerant R717 (ammonia). The system is built up on the principle of a flooded evaporator in thermosiphon. Nominal cooling capacity is 20 kW (ϑeva = 4°C, ϑcond = 50 °C). The compressor can be continuously controlled by an inverter from 100 to 50%. The range of capacity control is enlarged by a hot-gas by-pass. The chilled water temperature at the evaporator outlet side can vary between 5 °C and 15 °C. On the condenser side the inlet temperature can diversify from 20 °C to 42 °C. These limits are mainly based on the compressor limits.

The theoretical EER varies between 14.59 at the highest evaporator outlet temperature and the minimum condensing temperature and 4.02 at the lowest evaporating and the highest condensing temperature. The chiller will be measured extensively in steady state and dynamic test in the Hardware-in-the-Loop environment of University of Innsbruck in individual operation but also in combination with the absorption chiller.

3. Conclusions

The project SolarHybrid aims to show how solar thermal and solar electrical driven heating and cooling systems can get more efficient and economical viable. This idea implies several optimization steps and comprehensive studies. It becomes obvious that a hybrid solution will benefit from single optimization of the different systems and components.

Detailed models for the adapted absorption and vapor compression chillers are used in the complex HVAC simulations. Huge effort was taken to realize models with data lookup tables, which enable realistic performance even under dynamic conditions, especially in part load. The system simulation model built up in TRNSYS & Matlab, is able to handle the multitude of the different and switchable energy cascades. Several sensitivity studies and the control strategies of the simulation variants were optimized.

The solar thermal systems show promising results for DHW but also for solar thermal cooling. The ST driven system can achieve up to 60% non-renewable primary energy savings with a cost ratio of 1.1 compared to a simple reference system with natural gas boiler and vapor compression chiller. If an electrical driven system with a reversible heat pump is applied as benchmark, savings remain at 50% but the cost ratio drops to 0.9. This magnitude of savings and costs can only be reached with domestic hot water pre-heating in the re-cooling circuit of the chillers (energy cascade).

The integration of PVT collectors benefit from the low temperature levels of the used load profile (hotel with pool). First results show an increased electrical output of roughly 10% compared to ordinary PV yield. Different hydraulic schemes with various temperature levels are under investigation. The effect on non-renewable primary energy savings and the cost ratio will be detailed in future developments.

The optimization procedure is arranged and first tests with solar thermal systems are successful. Additional solar thermal cooling will be set up and tested with integrated models for the chillers (ACM, VCC), hot and cold storage tanks as well as collectors (PV and ST). Finally, the hybrid solution will be optimized accordingly.

Two prototypes, an absorption chiller and a vapor compression chiller, were adopted to the boundary conditions due to the solar hybrid application. The absorption chiller is able to handle re-cooling temperatures up to 45°C under various generator temperatures. The new concept shows promising energy efficiency ratios under the investigated conditions. The vapor compression chiller is designed for the combined operation and especially adapted for large part loads. The laboratory measurements will show this operation mode and the advantages of the new developed chiller concept.

In the following course of the project the steps towards the hybrid solution and the final results will be discussed in detail. A high non-renewable primary energy saving and cost effective solution is expected after the successful first steps.

COMBINATION OF SOLAR THERMAL COLLECTORS AND HORIZONTAL GROUND HEAT EXCHANGERS AS OPTIMIZED SOURCE FOR HEAT PUMPS

Fabian Hüsing, Hauke Hirsch and Gunter Rockendorf

Institut für Solarenergieforschung Hameln GmbH (ISFH), Emmerthal (Germany)

Abstract

Heat pumps coupled to thermal ground sources, such as Horizontal Ground Heat Exchangers (HGHX), represent an efficient option to supply heating demands of single- and multi-family houses. However, the high land-use yet often prevents HGHXs from installation. The combination with solar thermal energy promises reduction of the HGHX area while retaining high system efficiencies. Our contribution studies the combination of HGHXs and solar thermal collectors, focusing on solar thermal regeneration of the soil. This is analyzed through both numerical modelling and experimental investigations. Modelling rests on a novel TRNSYS type for the HGHX, developed at ISFH. A test facility, installed on the premises of ISFH in Lower Saxony / Germany is used to validate the model. System simulations extrapolate the perceptions on differently configured heating systems.

Keywords: *horizontal ground heat exchanger, TRNSYS Type, system simulations, regeneration, bivalent source, HGHX area reduction*

1. Introduction

HGHX systems are integrated into the shallow subsurface at depth of 1-2 meters below surface. They represent flat, extended heat exchangers which extract naturally stored energy from the ground. To withdraw the heat from ground, heat pumps (HP) are used, which face the HGHX system as cold heat source and the buffer storage of a supplied building as heat sink. Characteristic performance quantity is the temperature shift between cold and hot ends of the heat pump. Especially, the coefficient of performance of the heat pump is related to this shift. One advantage of ground coupled heat pumps over ambient-air based systems is the fact that the temperature shift changes little during the course of the year as a result of the thermal inertia of the ground, provided that the HGHX size is properly designed. The existing technical guideline in Germany (VDI 4640-2) is presently under revision. The current draft (Verein Deutscher Ingenieure 2015) gives advice for the design of HGHX systems: The size (land-use) of an HGHX system for a given heating demand, soil type and climate zone. However, for typical heat pump systems in residential buildings the land-size recommended often exceeds the existing potential.

The combination of HGHX and solar thermal collectors provides a solution, as the land-use of the HGHX can be reduced significantly while maintaining high system efficiencies. This contribution deals with the investigation of this combination, analyzing solar regenerated HGHX heat pump systems through both numeric modelling and experimental investigations. A model of the HGHX developed at ISFH as a type for the modelling suite TRNSYS (Klein et al. 2010) and it's validation are presented. The validation is performed using a 150 m^2-sized HGHX, installed on the premises of ISFH in Lower Saxony / Germany as part of a test facility. We explain the model and evaluate different system configurations studied.

2. Horizontal ground heat exchanger model

2.1 Numerical model

To represent the dynamic behavior of a HGHX precisely, the model includes the following physical components: It is based on a two dimensional formulation of transient conductive heat transport problem. Fourier's Law is employed to model conductive heat transport from and to soil, which is in contact to a pipe axially streamed by a heat carrier fluid. The model reduces the heat transport between soil and pipeline to a plane perpendicular to the pipe, see Figure 1. The plane is discretized by a rectilinear mesh, which refines towards the pipe and the soil surface. The selected boundary conditions are adiabatic to the lateral edges of the plane (as explained below), radiative heat exchange and convective heat transport at the surface edge and a constant temperature at the lower edge of the plane. The interior boundary to the pipe domain is represented by a convective heat transfer condition which takes into account the carrier flow regime. The temperature of the fluid results from an axial energy balance of the pipeline. The transport equations for soil and pipe are numerically solved by the method of (explicit) finite difference, coupled through the thermal conditions at the interior boundary between soil and pipeline.

The TRNSYS type distinguishes two soil domains, see Figure 1. Soil domain A represents an inner segment of the HGHX, which is enclosed by adjacent pipes. Symmetry is assumed and thus left and right boundaries are adiabatic, which leads to significantly lower computational effort. Soil domain B represents a fluid pipe at the HGHX edge or a supply pipe. In contrast to soil domain A, it extends to a variable distance (parameter b) on one side, which can be considered as undisturbed soil if parameter b is chosen sufficiently large.

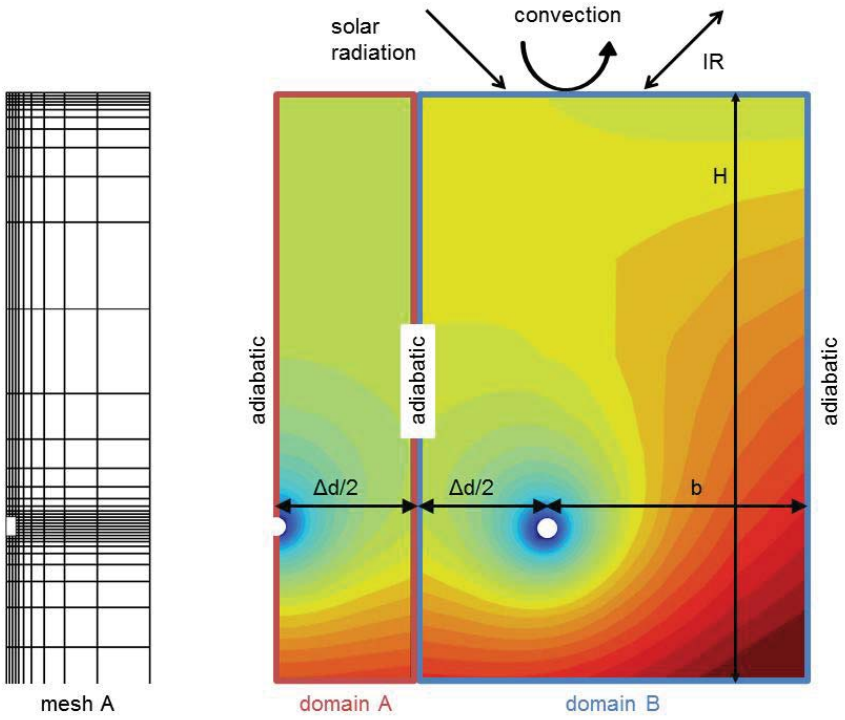

Fig. 1: Soil domain and discretization of HGHX model. Left: Discretization of soil domain A. Right: Charactersitic temperature contour plots for both soil domain A and B as well as indicated boundary conditions.

In comparison to previously published HGHX models (e.g. by Giardina 1995, Ramming 2007 or Glück 2009), the presented model has the advantage of combining all of the following properties:

- Sufficiently fine discretization of the soil domain
- Modelling of latent heat extraction and change of soil properties during freezing
- Consideration of the fluid capacity inside the HGHX, in both situations with and without massflow

- Consideration of heat gains through HGHX lateral edges
- Implementation as computation time optimized TRNSYS Type

An extended experimental validation for the presented model was conducted at ISFH for which exemplary results are presented in the following paragraph.

2.2 Model validation

For validation of the numerical model under static and dynamic operation conditions, a test facility was installed on the premises of ISFH, Figure 2 (left). It includes a shallow horizontal ground heat exchanger covering 150 m², a compressor heat pump and a resistant heater to emulate heat generation by solar thermal collectors. On the condenser side of the HP, a load module is installed, which emulates pre-defined thermal load profiles. Monitoring equipment is installed at the test facility to measure soil, brine and water temperatures, as well as meteorological data (ambient air temperature, solar irradiation, and infrared radiation (IR)) during and also between individual test runs.

Different experiments were performed to assess the quality of the model. For the simulations, measured operation data (heat transfer rate at the HPs evaporator, mass flow, and start temperature of the soil domain) and meteorological data are used as inputs to the model. The results for a selected experiment and the associated simulation are shown in Figure 2. The experiment is conducted using only a single out of four fluid circuits of the HGHX. The pipe length is 65 m. Constant mass flow of 0.278 kgs^{-1} and a heat extraction rate of 1.2 kW were the operating conditions of the experiment. The setup is chosen to validate the ability of the HGHX model to represent impacts of lateral heat gains at HGHX edges. Two model configurations are compared: A 2d model, using only soil domain A (neglecting HGHX edges) and a virtual 3d model, using a series connection of soil domain A and B and thus taking into account HGHX edges.

For both model configurations, Figure 2 confirms acceptable coincidence between measurement and simulation at the beginning of operation (see inset subfigure for first half hour). Especially for long periods of heat extraction the effects of the border segments are of significant magnitude. The virtual 3d model allows an accurate representation of this effect, as the deviation is only 0.2 K after 80 hours of operation.

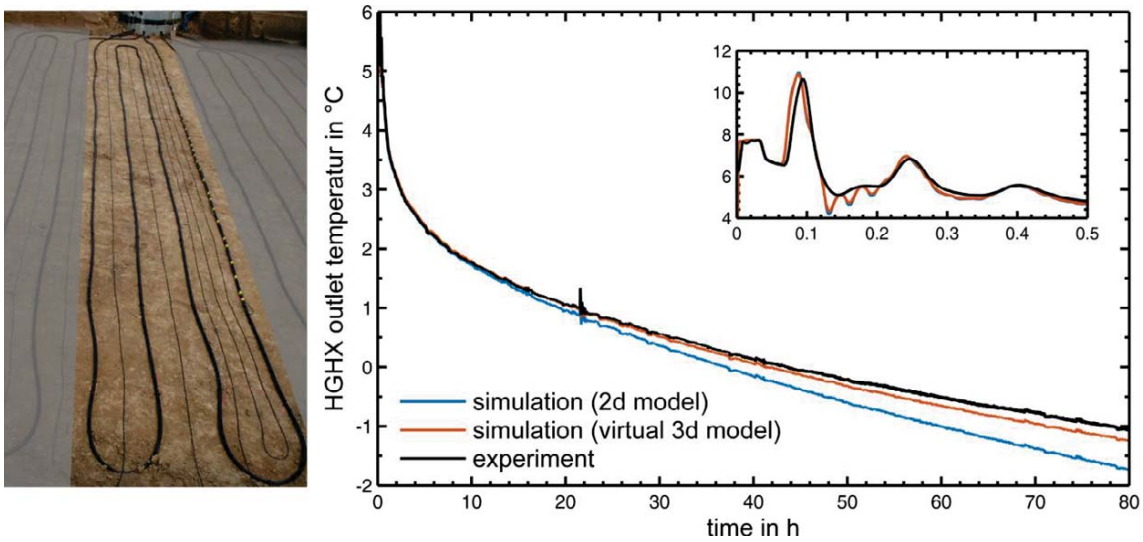

Fig. 2: Experimental setup and comparison of measured and simulated temperatures

Therefore the TRNSYS-Type can be regarded as a precise model for a HGHX for application in heat pump coupled system simulations. Further information on the HGHX model can be found in Hirsch et al. 2016.

3. System simulations

To investigate performance and efficiency of HGHX supplied heat pump systems and subsequent integration routes of solar thermal energy, TRNSYS simulations employing the presented HGHX model are evaluated.

3.1 Boundary conditions

The boundary conditions of the system simulation model are, in large part, taken from the Task 44 (Solar and Heat Pump Systems) of the Solar Heating and Cooling (SHC) program of the International Energy Agency (IEA) (Haller et al. 2012). This concerns the examined reference buildings (a newly constructed building: SFH45 and an existing building: SFH100) as well as internal load profiles for heat gains (Dott et al. 2012). The SFH45 uses a floor heating system while the SFH100 is equipped with radiators. At the chosen location of Zurich the buildings have annual heating demands of approximately 8500 kWh (SFH45) and 18000 kWh (SFH100), respectively. The domestic hot water tapping cycle adds an annual heat demand of approximately 2200 kWh. Supply configurations are equipped with two zone buffer storages for domestic hot water (DHW) and space heating (SH), each of which can be supplied with the connected heat pump.

The subsurface is characterized by three soil types according to 2015's draft of VDI guideline 4640-2 (Verein Deutscher Ingenieure 2015). Table 1 gives an overview over the properties of the three soil types used as parameters for the HGHX model. The total simulation time period is two years for each configuration, while only the data of the second year is used for evaluation.

Tab. 1: Parameters of the soil types used for the simulations

Soil nr.	1	2	3
Soil type (acc. to USDA)	Sand	loam	sandy clay
λ in $Wm^{-1}K^{-1}$ (unfrozen)	1.2	1.52	1.76
λ in $Wm^{-1}K^{-1}$ (frozen)	1.37	2.35	2.85
c_p in $Jkg^{-1}K^{-1}$ (unfrozen)	802	1218	1319
c_p in $Jkg^{-1}K^{-1}$ (frozen)	687	880	886
ρ in kgm^{-3}	1512	1815	1820
h_F (heat of fusion) in Jkg^{-1}	17648	51457	65977

3.2 System configurations

Two different HGHX-equipped supply configurations are studied, with and without solar thermal system, as shown in Figure 3. The HGHX is installed at a depth of 1.5 m in all cases. The simulations employ type 401 to model the heat pump. Parameters are taken from data determined by experimental testing of a commercially available heat pump at ISFH by Pärisch et al. 2014.

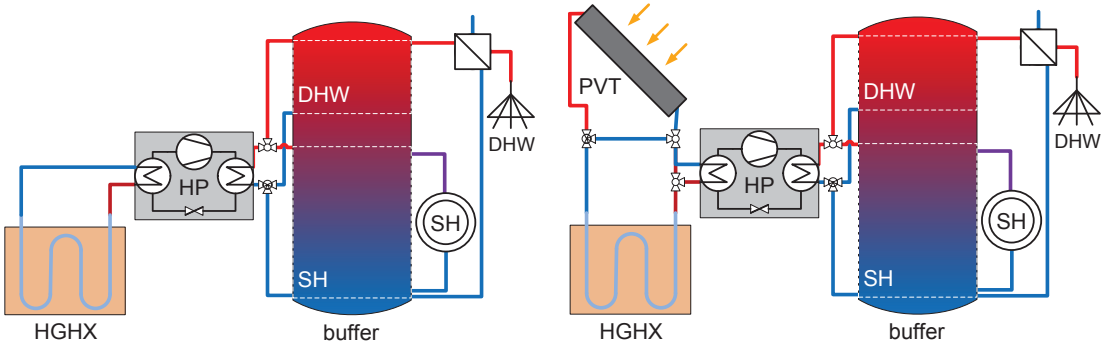

Fig. 3: System schemes for configurations without (left) and with (right) use of solar thermal energy on the source side

An unglazed photovoltaic thermal hybrid collector (PVT) is assumed as solar thermal supply system. The hydraulic layout allows different operation modes: (1) stand-alone HP/HGHX, while there are no (sufficient) solar thermal gains; (2) serial connection of the PVT and HGHX/HP, while heat demand and solar thermal gains coincide; (3) recharging of the HGHX by PVT (at lower mass flow), if solar thermal gains allow regeneration of HGHX and there is no present heat demand. The state of the system is monitored during the simulations and the specific operation mode is selected by a controller developed for this purpose. The upper limit of 25 °C for fluid entering the HGHX is observed in all operation modes to avoid overheating of the

ground.

3.2 Performance indicators

To assess the quality of the simulated system configurations a set of performance indicators is defined. For a ground coupled heat pump system there are two classes of quality to assess: efficiency and sustainability.

Sustainability of a HGHX means to avoid states of exhaust as well as securely avoiding critical frost conditions. An HGHX is exhausted if the temperature of the carrier fluid on influx to HP evaporator falls below -5 °C during operation. This is the temperature at which the HP is no longer operated and an electric auxiliary heater is used instead. Accordingly the amount of heat supplied by the auxiliary heater (Q_{aux}) is used as an indicator for HGHX exhaustion. The critical frost conditions affect the biosphere as well as important soil properties like rainfall infiltration etc. To detect states of induced frost two gauges are implemented, vertical and horizontal. The "vertical" frost indicator, referred to as vertical FI, is activated once the frost around the HGHX pipe collides with the surface frost. The horizontal frost indicator, referred to as ISFH FI, is activated once the frozen domains around adjacent HGHX pipes grow horizontally into contact, in absence of surface frost.

The efficiency of a heat pump system is assessed by the seasonal performance factor of the system (referred to as SPF_{SHP} following a definition by D'Antoni (2013)). This indicator takes into account the useful heat divided by the total electric energy spent for its generation:

$$SPF_{SHP} = \frac{\text{useful heat}}{\text{electric energy}} = \frac{\int (\dot{Q}_{DHW} + \dot{Q}_{SH})dt}{\int (P_{HP\_compressor} + P_{aux} + P_{pumps} + P_{control})dt} \qquad \text{(Eq. 1)}$$

3.3 Results

Figure 4 depicts the seasonal performance factor for different soil types as function of HGHX area. The results are based on the spacing between HGHX pipes (dx) recommended for each soil by 2015's draft of VDI guideline 4640-2 (Verein Deutscher Ingenieure 2015) for laminar flow. The size recommended for each soil type by the guideline is marked by a black diamond. Furthermore the occurrence of critical frost conditions is displayed by the frost indicators for vertical and ISFH criteria.

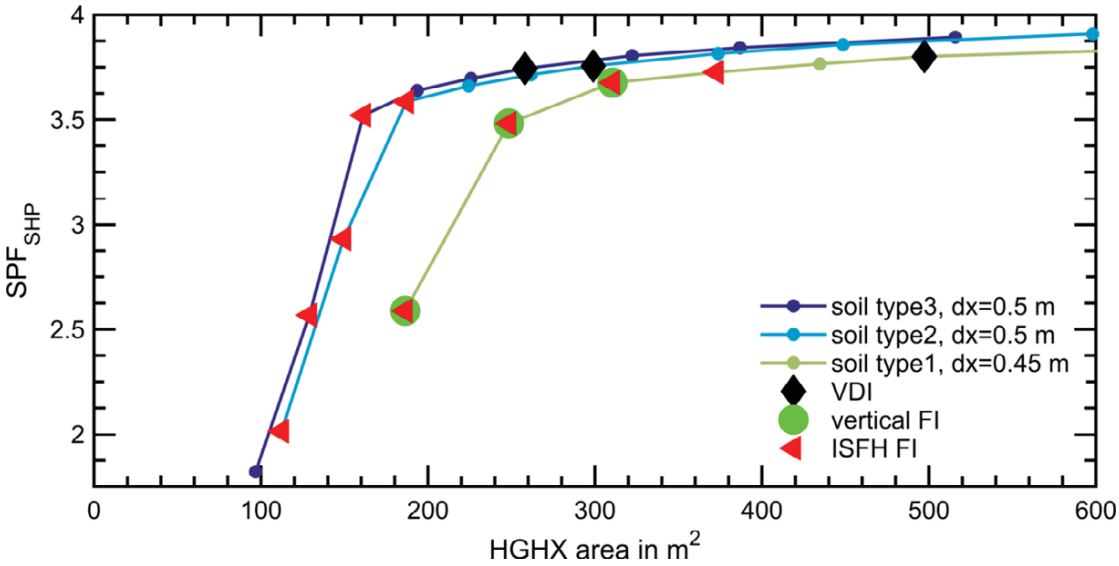

Fig. 4: Seasonal performance factor SHP for different soil types over HGHX area

The shapes of the graphs are characteristic of HGHX systems. From their curvatures follows, that the reduction of the HGHX area below a critical size causes significant degradation of the system performance, while beyond this critical value only moderate efficiency wins are possible. The designs recommended by the VDI guideline are always well beyond the critical size, securely avoiding critical frost conditions and reaching seasonal performance factors of approximately 3.75. The ISFH frost indicator is the strongest frost criteria limiting small HGHX areas. The vertical frost indicator is only activated for soil type 1 (sand), which

has the lowest enthalpy of fusion (h_F).

To analyze the underlying effects responsible for the characteristic shape of these graphs, the auxiliary power and energetically weighted evaporator inlet temperatures are plotted as function of the HGHX area in Figure 5. The occurrence of high demands for auxiliary power, Figure 5 (left), correlates with the significantly reduced seasonal performance factors below the critical systems size. Because electric auxiliary heaters have a lower thermal efficiency than heat pumps, exhausted HGHX systems cause break-in of overall system efficiency. The VDI 4640-2 avoids the necessity for auxiliary heating for all three soil types by sufficiently large design recommendations.

The energetically weighted mean evaporator inlet temperature, defined in Eq. 2, takes into account which amounts of energy are extracted at which temperature. Therefore it represents a good indication of the averaged condition of the heat source during heat pump operation throughout the year.

$$\overline{T}_{evap,\ energetically\ weighted} = \frac{\int (T_{evap}(t) \cdot \dot{Q}_{evap}(t))dt}{\int \dot{Q}_{evap}(t)dt} \qquad \text{(Eq. 2)}$$

The energetically weighted mean evaporator inlet temperature over HGHX area is shown in Figure 5 (right). For small HGHX areas, where auxiliary power demands cannot be avoided, the temperature stays in an interval from 0 to 1 °C, uncorrelated to HGHX area variations. This is explainable, as the extraction of heat from the HGHX is limited by states of exhaustion. Additionally produced heat near the state of exhaustion mainly originates from latent heat extraction at constant temperatures. Above the critical size, the increase of HGHX area increases the source temperature levels. Here, the natural soil temperature is the theoretical limit for the evaporator inlet temperature; hence the decreasing slopes of the respective curve branches. The small size-sensitivity of the source temperature for larger HGHX sizes is reflected by the HP performance. The detected performance gains are in agreement with values published earlier by Pärisch et al. 2014. The designs according to VDI recommendations reach energetically weighted mean evaporator inlet temperatures in a range from 3 to 4 °C.

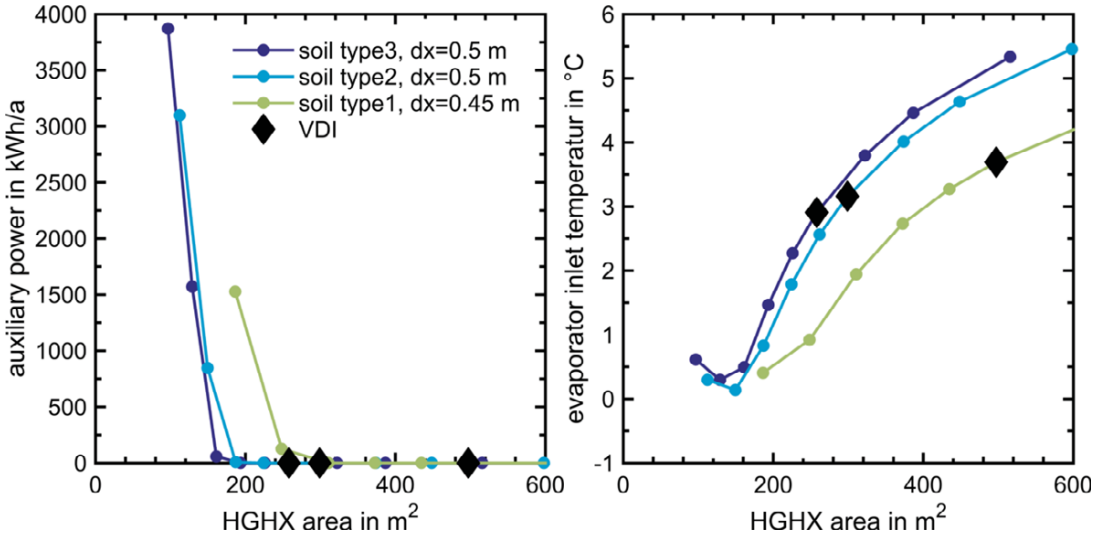

Fig. 5: Auxiliary power and energetically weighted evaporator inlet temperature for different soil types over HGHX area

Figures 6 and 7 present the seasonal performance factors for soil type 2 (loam) as function of the HGHX area, parametric in the pipeline spacing and for ascending sizes of the PVT collector. The VDI 4640 design recommends, under assumption of laminar flow, a pipeline spacing of 0.5 m. Figure 6 (left) shows the results for a system without solar thermal regeneration. The shapes of the graphs are therefore similar to the ones shown in Figure 4. All plots confirm that narrower pipeline spacing enables higher efficiencies in general. We see that a size reduction of 28 % (A_{HGHX} from 311 m² to 224 m²) of the HGHX relative to the VDI 4640 design recommendation may be tolerated at almost missing efficiency losses.

In the second diagram (Figure 6 right) results for systems equipped with 6.7 m² of PVT collector area are

depicted. To focus on the thermal/regeneration process, electrical energy yield of the PVT collector is not included in the calculation of seasonal performance factors at this time. At high HGHX areas, the seasonal performance factors are lowered, due to the added electric energy demand of the collector pumps. At lower HGHX areas the seasonal performance factors increase. The main reason therefor is that the HGHX is less frequently exhausted and thus the demand for auxiliary power is lower. Also the occurrence of critical frost conditions is slightly limited.

With increasing PVT collector areas (Figure 7), the described trends proceed, until at 26.6 m² of PVT collector area critical frost conditions are completely prevented, even for the smallest HGHX areas simulated. At this PVT collector size the HGHX area may be as much as 64 % smaller (A_{HGHX} from 311 m² to 112 m²), while achieving almost the same system efficiency as an unsupported system. Only 5 % efficiency losses (SPF_{SHP} from 3.76 to 3.60) are predicted in this case.

Similar results are obtained for soil types 1 and 3. For narrower spacing between the HGHX pipes and with solar thermal regeneration the simulations predict possible HGHX size reductions between 49 to 66 %, taking into account limited efficiency losses below 5 %. Note that Soil type 3 (sandy clay) has greater potential for area reductions (66 %) than soil type 1 (sand, 49 %) due to both higher heat conductivity and higher heat capacity.

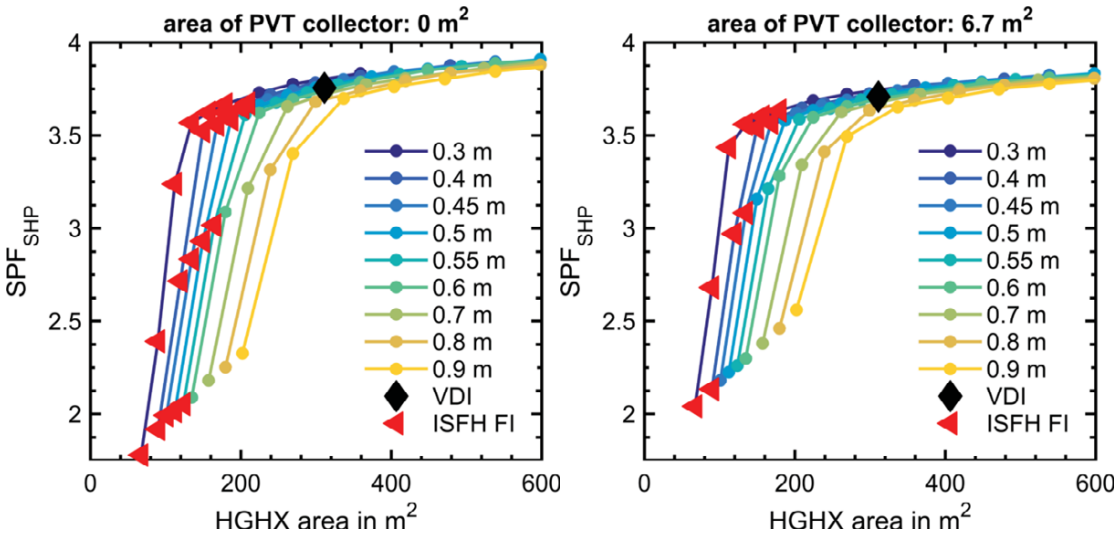

Fig. 6: Seasonal performance factor for soil type 2 over HGHX area for different spacing between HGHX pipes

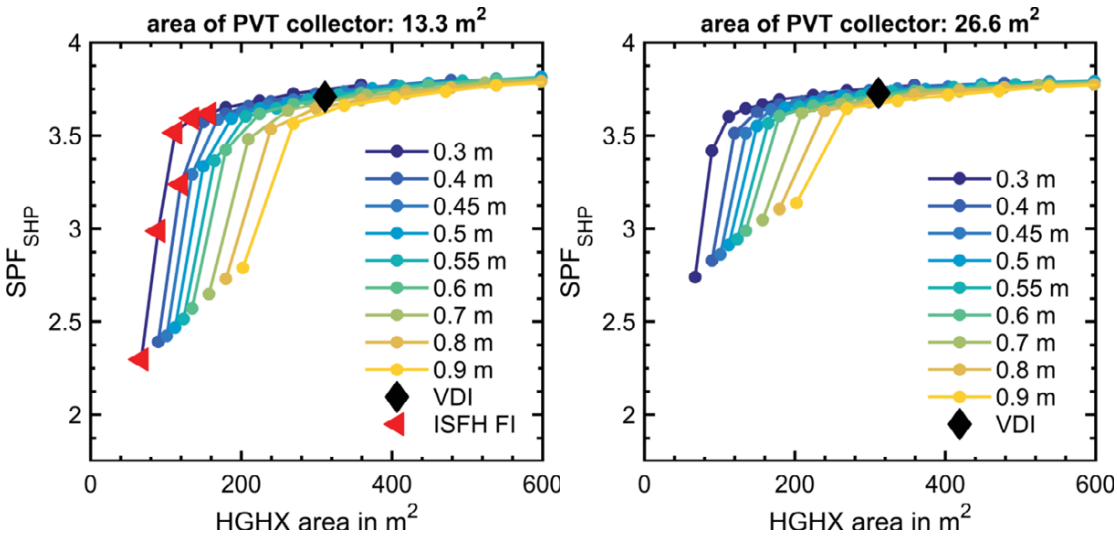

Fig. 7: Seasonal performance factor for soil type 2 over HGHX area for different spacing between HGHX pipes

In the following we analyze the operation of the HGHX fluid cycle with and without solar thermal regeneration. For this purpose the progression of energy quantities of the HGHX and the PVT collectors is considered in time on a monthly basis. The considered HGHX system has a size of 134.6 m^2 comprising a pipe separation of 0.3 m. It is supported by PVT collectors of two selected sizes (13.3 and 26.6 m^2).

Figure 8 provides the monthly net heat extraction from the HGHX with and without the PVT collectors of respective sizes. Net heat extraction is defined as heat extraction subtracted by solar thermal heat supplied to the soil. For the system without active solar regeneration (purple graph), the net heat extractions resembles a typical domestic HP heat demand progression. High heat demands in the winter oppose low demands in the summer, when domestic hot water preparation is the only demand.

Systems with solar thermal regeneration (blue and green graphs) show a slightly different progression. While the differences in net heat extraction are reduced for October (month 10) to December (month 12), i.e. the beginning of the heating season, the difference grows significantly larger towards March (month 3). Solar regenerated systems exhibit negative net heat extractions, once more heat is fed into the HGHX than extracted. The model predicts maximum regeneration heat inputs between March (month 3) and July (month 7), dependent on the size of the PVT collectors.

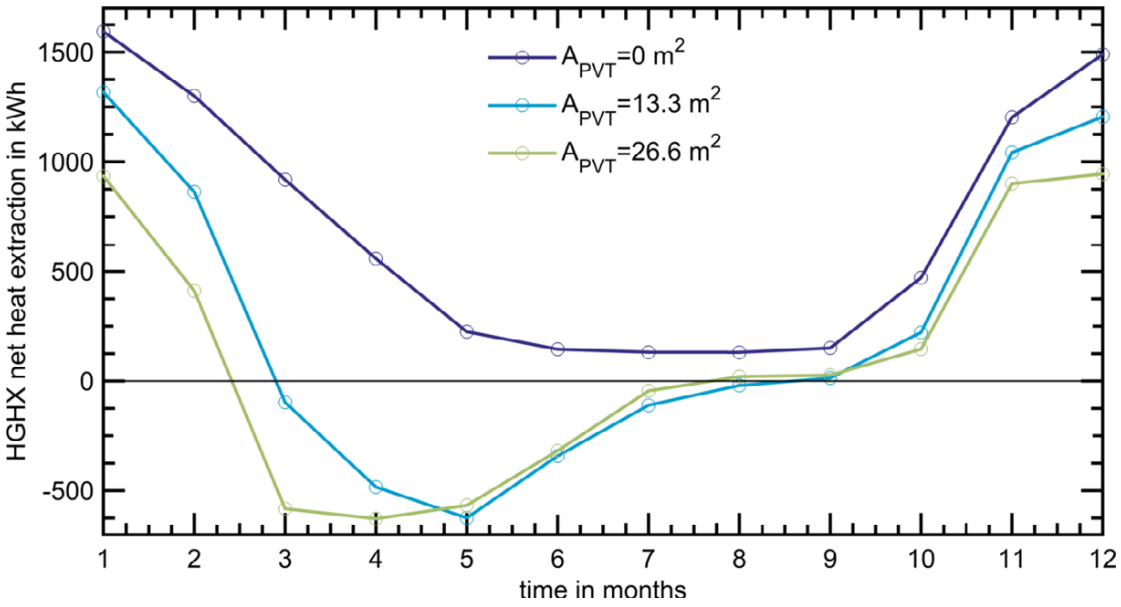

Fig. 8: Monthly distribution of HGHX net heat extraction

Figure 9 provides the monthly progression of the related solar yields, the quantity thereof fed to the soil (regeneration heat) and the solar irradiation on the collector plane. The maximum yield occurs in March (month 3, for A_{PVT} = 26.6 m^2) and April (month 4, for A_{PVT} = 13.3 m^2), respectively and coincides with the lowest net heat extractions shown in Figure 8. This shows that regeneration mainly takes place at the end of the heating season, when the HGHX tends to be exhausted.

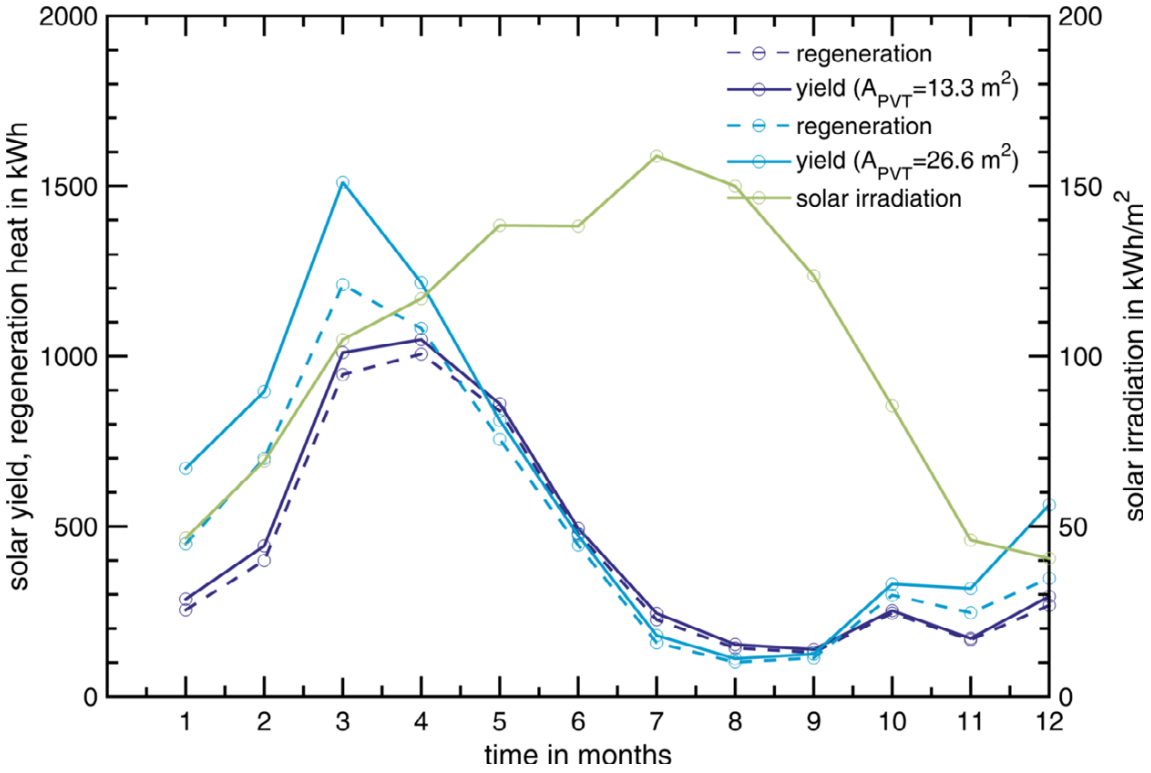

Fig. 9: Monthly distribution of solar yields, regeneration heat and insolation

For the smaller PVT collector area (A_{PVT} = 13.3 m^2) almost the entire solar yields are used for soil regeneration. Only systems with the larger PVT collector size exhibit tangible differences between solar thermal yield and regeneration heat from November (month 11) to April (month 4). In this case, the solar yield suffices to directly supply the heat pump during the heating season.

Comparing the yield and solar irradiation curves over the year, we see that significant solar irradiations (from May (month 5) to October (month 10)) remain unused in configurations connected only to the HGHX. The time period during October (month 10) to May (month 5) offers great potential for using solar thermal yields at low temperatures efficiently. Furthermore optimal synergy conditions exist for the solar/HGHX system, because of reduced competition between direct use and HGHX recovery.

Figure 10 illustrates the effects of regenerating a possibly undersized HGHX system. It shows energy quantities in the fluid carrier cycle along with auxiliary energy and energetically weighted evaporator inlet temperatures on a yearly basis. A HGHX system with a size of only 89.7 m^2 with a pipe separation of 0.3 m is considered.

The blue column represents the energy extracted from the fluid carrier cycle in the heat pumps evaporator (symbol Q_evap). This quantity scales with the PVT collector area size, because the source is less often exhausted. The auxiliary power demand (symbol E_aux, red column) shows the opposite behavior. This quantity scales inverse to the PVT collector area size. The second column shows the heat quantities delivered from the HGHX to the evaporator (symbol Q_HGHX->evap / dark green), from the PVT collectors to the evaporator (Q_PVT->evap / light green) and from the PVT collectors to the HGHX (symbol Q_PVT->HGHX / yellow). The diagram shows that while the system without PVT collector extracts the entire heat from the HGHX, the PVT supplied system may use the solar yields partially in the evaporator. Hence the heat extraction from the HGHX can be reduced, while most of the solar yields are used to actively regenerate the HGHX. The energetically weighted evaporator inlet temperature increases from -0.74 °C without PVT collectors to 2.32 °C with a PVT collector size of 26.6 m^2.

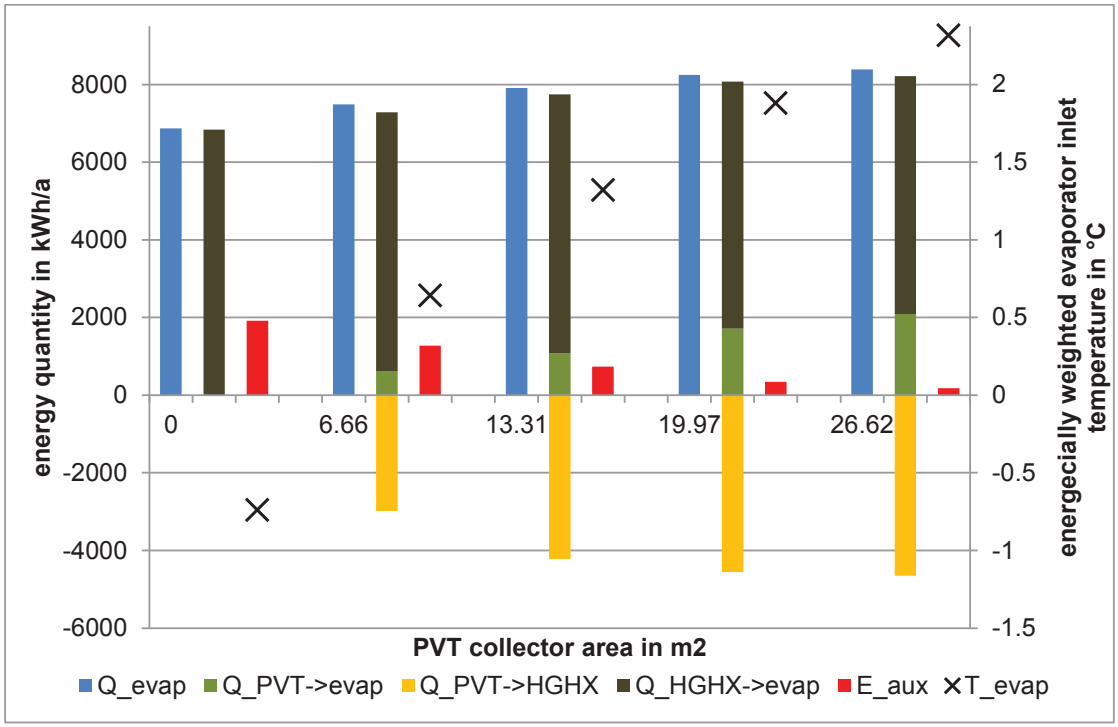

Fig. 10: Energy quantities of the source cycle, auxiliary energy and evaporator temperatures over PVT collector area

The simulations predict that the integration of 26.6 m² of PVT collectors on the source side allows the seasonal performance factor of an undersized HGHX (~29 % of VDI's recommendation) to be increased from 2.4 to 3.4. When taking into account the potential of electricity co-generation of the PVT modules (using only electricity obtained from grid for the calculation of the seasonal performance factor) the overall systems seasonal performance factor may even reach 3.7, which means the PVT-supported, undersized HGHX system is as efficient as the standard VDI design – but two thirds smaller.

4. Conclusion and prospect

A TRNSYS model for HGHX has been developed and successfully compared against measurement data. For analysis of system configurations including a heat pump and solar thermal regeneration it is successfully integrated into a system model. The ability to use the model in differently configured heat supply systems in TRNSYS allows a variety of future applications.

The presented results of system simulations show that critical frost conditions and exhaustion are the limiting factors in lowering the area of a HGHX. Solar thermal regeneration is able to avoid critical frost conditions and strongly limit exhaustion at small HGHX areas, if smaller separation between the HGHX's pipes is used.

Analysis of monthly solar yields and HGHX heat extraction reveals that a HGHX is not a seasonal storage. Still its comparatively large heat capacity allows to smoothen solar thermal heat generation and supply peak loads as a combined source for a heat pump. Unglazed and presumably even low-end collectors can be used, because of the low temperatures needed. As a result promising applications for solar thermal heat at low temperatures are enabled, while only sparsely affecting the potentials to directly use yields in the summer.

Ongoing research concerns the utilization of low-end and façade integrated collectors for regeneration of HGHXs as well as an additional connection to the buffer storage to make direct use of possible solar yields in the summer. For these configurations suited control strategies are being developed.

After demonstrating the technological potential of the combination of solar thermal collectors and HGHXs, analysis of the feasibility of differently configured solutions is the next important step towards a comprehensive assessment.

Design of Portable and Sustainable Solar Refrigerator

Joanna Juárez[1], Dolores Durán[1], Cuauhtémoc Palacios [1], Iván Martínez [1]

[1] Universidad Autónoma del Estado de México, Facultad de ingeniería, Toluca (México)

Abstract

This paper is presented as a preliminary design of a portable solar refrigerator, which uses a solar adsorption system. The aim is to achieve a sustainable design that includes not only the materials but also considerations for the useful life of the equipment and its final disposition.

This equipment has been considered as an economical solution for rural communities where there is no electricity, and whose food goods need to be preserved.

The suggested design considers a CPC as primary source of energy for the coolant fluid, which its three analyzed substances are: water, methanol and biogas, obtained from the bovine manure and organic domestic trash (wastage).

Vegetal carbon is recommended, for this project, as adsorbent material that is usually used in several researches around world as substitute of activated coal.

Keywords: *Solar cooling, adsorption cycle, CPC.*

---

1. Introduction

Cooling is one of the basic principles of food safety around the world because food slows degradation (Das Surah, 2010).However, according to the International Institute of Energy, approximately 15% of all electricity produced in the world it is used for cooling processes (Kim DS, 2008). Currently the most widely used are vapor-compression refrigeration systems, which work with synthetic materials, such as CFCs, HCFCs or HFCs. When released into the atmosphere, such refrigerants affect the ozone layer and contribute to the greenhouse effect. JA Edmunds et. al (1987), estimated that emissions from synthetic refrigerants, during operation or after life represent 33.3% of the greenhouse effect (Fernandes, 2012). As an immediate response care environment, various protocols, such as the Montreal Protocol (1987) and the Kyoto Protocol (1997), were established in order to eliminate or at least significantly reduce emissions of these gases. (Gupta, 2013 and Gutierrez, 2013).

Countries around the world have made some efforts to make the change or elimination of the use of HCFCs. According to SEMARNAT (Secretariat of environment and natural resources) in Mexico in 2010 was totally eliminated in the country consumption of chlorofluorocarbons (CFCs), substances used in refrigeration, air conditioning, aerosols and polyurethane foams and raised under the framework of the "National Plan for Elimination of hydro-chlorofluorocarbons (HCFC) ", which aims to eliminate 30% of consumption of HCFCs by 2018. Despite efforts in some countries, after 29 years of being created the Montreal Protocol, the situation continues to claim the development of alternative technologies that operate with friendly substances to the environment, mainly due to increased emissions of HFCs, although the emission of CFCs and HCFCs have been declined since 1980s. (Metivier, 2003 and Hassan, 2012).

doi:10.18086/eurosun.2016.04.10 Available at http://proceedings.ises.org

Computational fluid dynamics (CFD) modelling would be a viable choice, which can reduce experiments (Y Ge et al, 2010). Many studies have shown that CFD modelling is a promising and valuable tool to improve refrigeration efficiency in terms of energy savings and the required temperature maintenance. (Foster et al, 2005)

Based on the above, it may be noted that it is important to developed cooling systems that consume no electricity, because electricity usually comes from fossil sources; also, it is necessary that this system do not use refrigerants CFCs that affect the ozone layer and produce greenhouse effect. Therefore, the purpose of this research project is to design a refrigerator that uses solar energy for cooling and food preservation, particularly seafood, operating with a CPC collector and adsorption system, using natural refrigerants; proposing the analysis between three pairs of adsorbent-adsorbate: coal - water, coal -methanol and coal-biogas, and selecting the best option for the design of the prototype. As already it mentioned that the solar refrigerator would be used for seafood, thus is proposed that the design be portable for to be used in rural communities with no electricity for the conservation of their food.

2. Solar adsorption refrigeration system

The principles of operation of the adsorption refrigeration system are described by the ideal cycle in the Clapeyron diagram (ln *P* versus–1/*T*). See Fig. 1.

Isosteric heating. At sunrise, sunlight falls in the parabolic solar collector, which contains the activated carbon saturated with methanol at the focal line. The mixture is heated until its pressure reaches a level that enables refrigerant to be desorbed (state B).

Desorption and condensation. Between B and D addition of heat from the solar energy results in desorption of vapor refrigerant, which condenses in the condenser by the air surrounding it. In an ideal cycle, the condensation pressure remains constant. At state D, when the maximum temperature of adsorbent is reached, solar irradiance starts to decrease.

Isosteric cooling. At state D, the temperature and pressure decrease. Meanwhile, the liquid refrigerant is being collected in the evaporator.

Adsorption and evaporation. The adsorbent continues decreasing its temperature and pump the refrigerant. This evaporates and extracts heat from the evaporator generating a cold atmosphere. At sunrise the next day, the temperature of the collector is minimal and reaches the value at state A., the cycle is said to be intermittent because the cold production happens during the night.

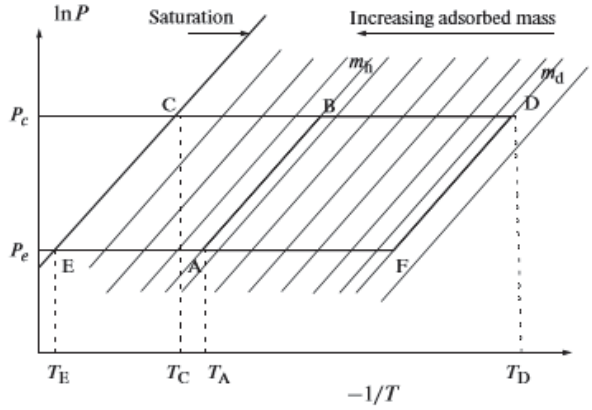

Fig. 1: Clapeyron diagram of ideal adsorption cycle. (Tashtoush et al., 2010)

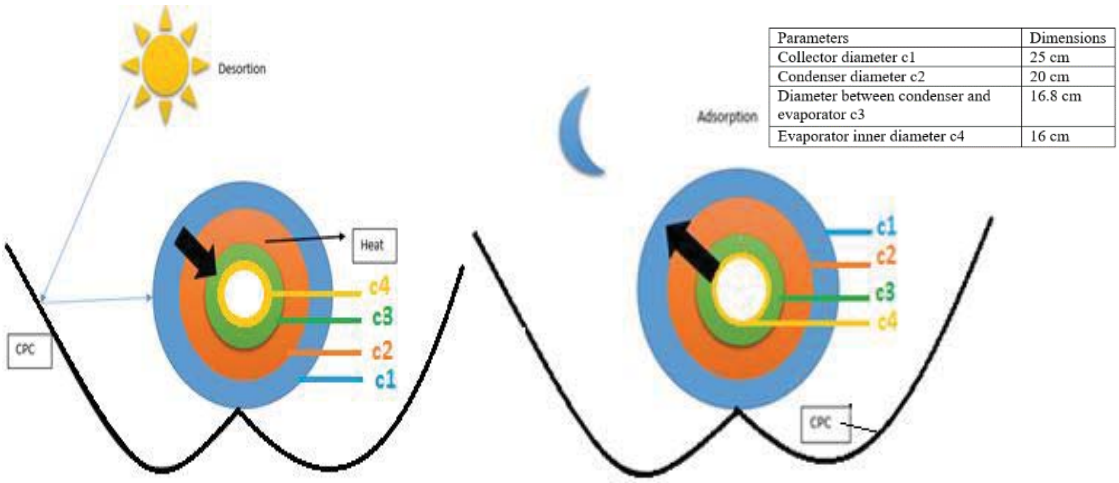
The operation and principle of the solar adsorption refrigeration system is shown in Fig. 2. The system is composed of a sorption bed, which locates at the focal line of a solar collector, a condenser, and an evaporator that acts like a refrigerator. The adsorbent and the adsorbate are in a closed and vacuumed system. The collector is supplied with carbon, which is adsorbed with natural refrigerant (methanol, water or biogas). During the daytime Fig. 2a, the adsorbent (carbon) and the natural refrigerant is heated in the collector. The natural refrigerant evaporates from the adsorbent and then is cooled by the condenser and stored in the evaporator. In the nighttime Fig. 2b, the ambient air cools the collector and the temperature of the adsorbent reaches a minimum. In this period, natural refrigerant begins to evaporate by adsorbing heat from the water to be frozen and is adsorbed by the adsorbent. As the evaporation of the natural refrigerant continues, the water temperature decreases until it reaches 273 K, where ice starts to be formed. An ideal cycle assumes the use of valves to connect the collector, condenser, and the evaporator. In real unit, this can be avoided and we may depend on the pressure difference to move the refrigerant.



Parameters	Dimensions
Collector diameter c1	25 cm
Condenser diameter c2	20 cm
Diameter between condenser and evaporator c3	16.8 cm
Evaporator inner diameter c4	16 cm

Fig. 2: Operation principle of solid adsorption refrigeration system using solar heat. A- sorption bed (solar collector); B condenser, C- evaporator and D- cold area.

3. Description of the design

The prototype consists of four concentric cylinder, called c1, c2, c3, c4; c1 is considering that larger diameter and below cylinder c4 is smaller diameter. (Fig.2). The first space formed by c1 and c2, forms the area called collector, wherein the pair adsorbate-adsorbent is placed. The second space formed by the c2 and c3 is the space where a serpentine is located and water to form the condenser; the space formed by c3 and c4 are the evaporator.

The condenser and evaporator are connected by a small serpentine, which performs the function of expansion valve.

It is important to mention that c1 should be a material with high thermal conductivity, so that the solar radiation concentrated by the CPC is absorbed; c2 must be an insulating material to completely separate the area of the collector and the condenser; c3 should also be an insulating material separates the condenser and the evaporator; however c4 must have a high conductivity to extract energy from the area to be cooled, in which food will be located; finally rejoins the evaporator with the manifold by a pipe; in Figure 3 shows the configuration proposed.

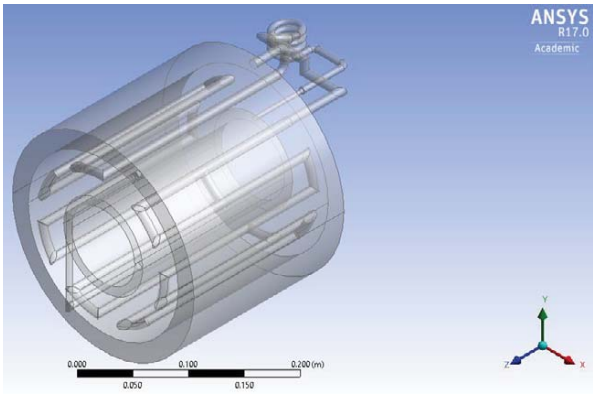

Fig. 3: Solar Refrigerator demonstration system

4. Adsorption capacity of different materials

As part of the project, we have analyzed the adsorption capacity of different materials because this is the first and fundamental part for thermal calculation and the subsequent design of the solar refrigerator. Jaraba (2012), made a comparison of adsorption capacity between orange peel and orange peel modified with chitosan for removal methyl of orange, of that investigation it was found that orange peel is best adsorbent that material orange peel modified (Metivier, 2003).

On the other hand, in 2008, E. Gonzalez, analyzed the percentage of adsorption for two particle sizes of 0.425 mm and 0.5 mm, managed to obtain maximum removal percentage of 66.8% and 62.5%, concluded that smaller particles are more adsorption capacity (Incar, 2014).

In Mexico and Malaysia, there are extensive analysis of materials with different adsorption capacities, such analysis has concluded that in order to make a sustainable adsorption system it is necessary to analyze local organic materials from the place they are used.[9], [10]. According to the analysis capacity of adsorption and desorption for proposals mixtures, tests were performed by analyzing the adsorption capacity of methylene blue, these tests were proposed by Xialong Zhang and Vargas with a stirring time of 24 hours and 48 hours respectively, which adsorption capacities were determined with efficiencies up to 60%. (Anisur, 2013 and Fernandes, 2014)

For testing, the following parameters shown in table 1 were considered. (Xialong, 2015).

Table 1: Testing parameters

Parameter	Specification
Reactive	Methylene blue
Volume of solute	10 mL
Concentrations	(2- 50 mg/L)
Temperature to generate coal	350°C
Types of organic material to generate coal	-Tangerine peel -Orange peel -Tomato peel -Shell “huaje”
Mass of adsorbent	4 mg

The results of capacity of adsorption they show in fig. 4 and it can be seen that the types of coal which has higher adsorption capacity in descending order they are: huaje, tomato and orange, but it is important to note that these three samples have higher adsorption capacity than activated coal for fishbowl, this preliminary result is very important because if we do not activate the coals we would not use substances as phenolphthalein or oxalic acid and therefore waste pollutants are reduced by the project.

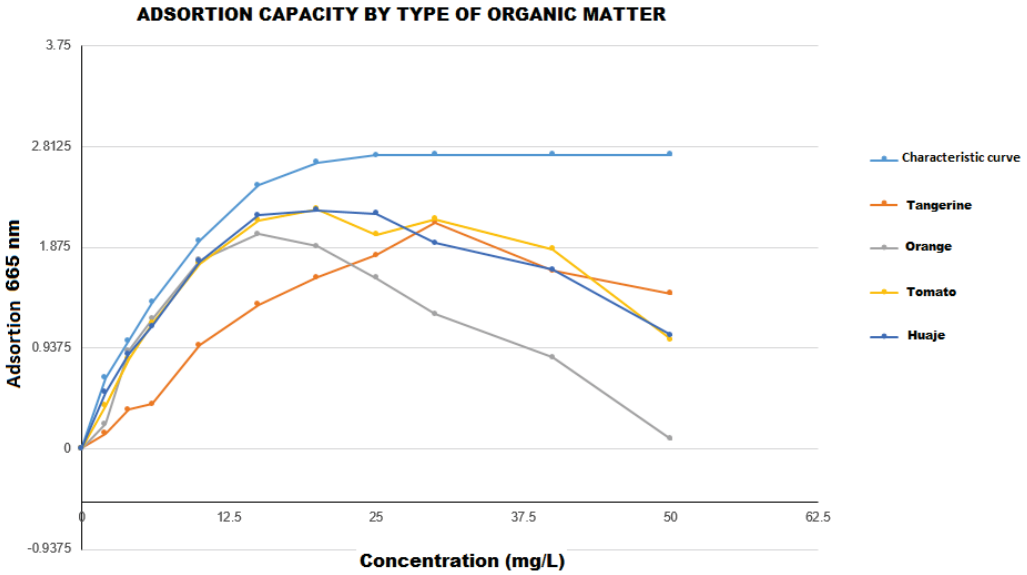

Fig. 4: Comparison of adsorptivity between organic materials

Regarding the materials used as adsorbates, it is important to point out that the biogas to be analyzed shall be deemed like methane for analysis in Ansys (CFD) and the other two adsorbates to analyze are H_2O and methanol, for the properties adsorbates are considered the values of the database of CFD.

5. Thermodynamics and transfer design procedure

The cycle begins at point A (see fig. 1) where the adsorbent bed is at law temperature T_A and at law pressure $P_e = P_s\ (T_e)$. During the daylight, AB represents the heating of the pair. The system follows the isotherm $X_A = X(T_A, P_e)$. (Tashtoush et al., (2010)

Pressure increases until it reaches the value $P_c = P_s\ (T_c)$ at point B. Thus, the energy used to raise the temperature of both the adsorbent (ac) and adsorbate (r) from point A to B is given by:

$$Q_{AB} = m_{ac} C_{pac} (T_B - T_A) + m_{ac} X_{r-A} C_{pr} (T_B - T_A). \quad \text{(eq.1)}$$

Additional heating of the adsorbent from B to D causes some adsorbate to desorbed and its vapor to be condensed at pressure P_c. When the adsorbent reaches its maximum temperature T_D, desorption stops, and the adsorbate accumulates into the evaporator. The energy used for the additional heating of the adsorbent to point D and desorption of the adsorbate is given by:

$$Q_{BD} = m_{ac} C_{pac} (T_D - T_B) + m_{ac} \left(\frac{X_{r-A} + X_{r-D}}{2}\right) C_{pr} (T_D - T_B) + m_{ac} (X_g) H. \quad \text{(eq. 2)}$$

The total energy gained by the system during the daytime will be:

$$Q_T = (Q_{AB} + Q_{BD}). \quad \text{(eq.3)}$$

During the night-time, the temperature decreases from D to F, therefore, decreasing the pressure from P_c to P_e. Then the adsorption and evaporation occur while the adsorbent is cooled from F to A. During this period, heat is withdrawn to decrease the temperature of the adsorbent and to withdraw adsorption heat. The total heat released during the cooling period will be the heat of vaporization of adsorbate, this is given by:

$$Q_{e1} = m_{ac}(X_{r-A} - X_{r-D})L_r. \quad \text{(eq. 4)}$$

From heat transfer equation, the energy necessary for cooling the liquid adsorbate from the temperature at which it is condensed to the temperature at which it evaporates is given by:

$$Q_{e2} = m_{ac}C_{pr}(X_{r-A} - X_{r-D})(T_c - T_e). \quad \text{(eq. 5)}$$

And thus the net energy actually used to produce cold area will be:

$$Q_e = Q_{e1} - Q_{e2}. \quad \text{(eq. 6)}$$

The performance of the adsorption refrigeration can be expressed in terms:

The collector efficiency $\eta_1 = Q_T/Q_I$. (eq. 7)

The evaporator efficiency $\eta_2 = Q_{ice}/Q_e$. (eq. 8)

The cycle COP = Q_{el}/Q_T. (eq. 9)

The net COP = Q_{ice}/Q_I. (eq. 10)

6. CFD simulation

The software SolidWorks is used to build up the geometry model of the constructed component. Smooth transition is introduced at the junctions. Structured tetrahedrons elements are applied for meshing. The commercial code FLUENT is employed as the equation solver to solve the governing equations. The SIMPLE algorithm is selected to compute the velocity, pressure and temperature, and the calculations are performed in single precision.

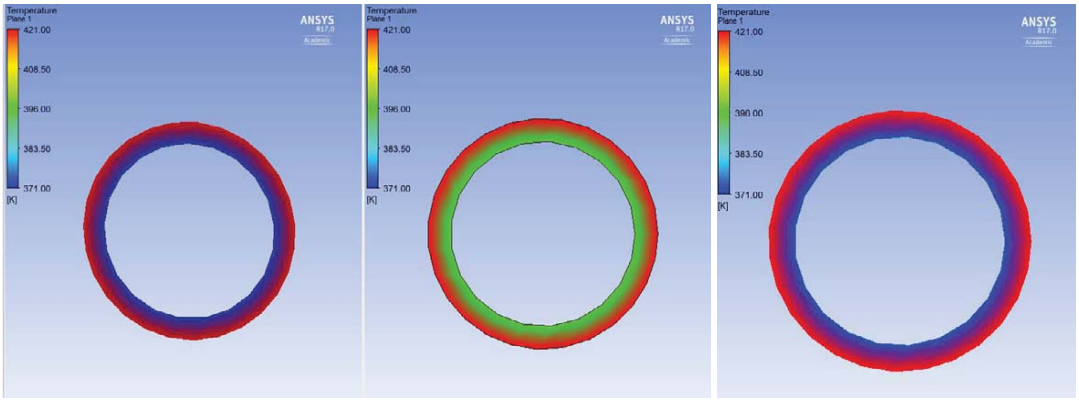
In the CFD simulation about radiation and natural convection, the model used is surface to surface (S2S) for the analysis assumes that all surface are gray and diffuse, the type is pressure- based, and consider that the radiation is constant around of diameter c1. And the method of the assembly meshing is tetrahedrons, using 836 nodes for fig. 5 and 19850 nodes for the fig. 6.

The CFD simulation is about of the heat transfer in collector, it is considered that the outlet temperature is constant with a value of 421K and a model of radiation-convection is applied. The properties of the working fluid are shown in table 2

Table 2: Fluids adsorbates properties

Fluid	Density (kg m^{-3})	Specific heat (J kg^{-1} K^{-1})	Thermal conductivity (W m^{-1} K^{-1})	Viscosity (kg m^{-1} s^{-1})
Methanol	*785*	2532	.2022	.0005495
H_2O	*998.2*	4182	.6	.001003
Biogas	*0.6679*	2222	.0332	1.087e-05

The comparison of the temperature profile for each working fluid are shown in Fig. 5. The range of temperatures is 381 K to 421 K. The dimensions are the same for the three analyses.

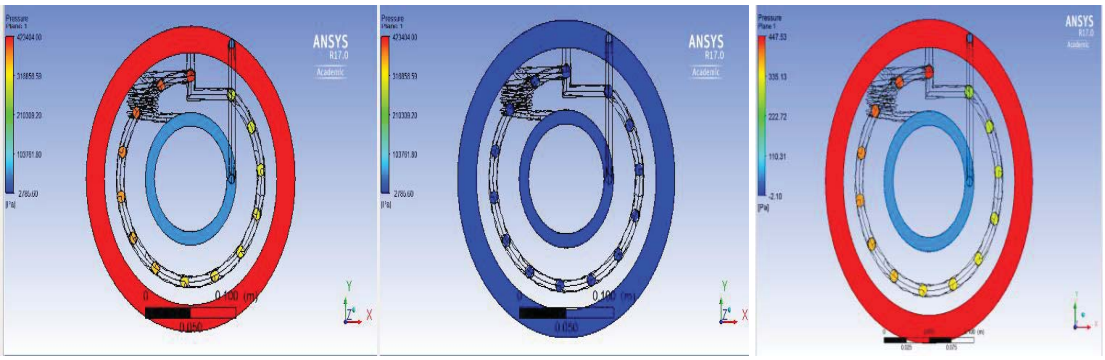


(a) Collector (Fluid methanol) **(b) Collector (Fluid H_2O)** **(c) Collector (Fluid Biogas)**

Fig. 5: Ansys radiation and natural convection with adsorbate: a) Methanol, b) H_2O and c) Biogas.

In the preliminary design, the pressure in the prototype is very important according to the Clapeyron diagram. Fig. 6 shows the pressure profile in the collector and the evaporator for each case.

Is it may be observed when the working fluid is water, the pressure decreases dramatically in the collector. Nevertheless if methanol or Biogas is used the pressure remains constant in the collector and decreases along the evaporator.



(a) Prototype (Fluid methanol) **(b) Prototype r (Fluid H_2O)** **(c) Prototype (Fluid Biogas)**

Fig. 6: Variation of pressure.

7. Results and discussion

7.1. Results of thermal analysis

In this preliminary design it was proposed assembly of four concentric cylinders, the main restriction of the design are the commercial dimensions found in the national market of alluminium tube and nylamid. The length of the cylinders are 50 cm and the dimensions in order descendent with commercial units are 6",5",3" and 1 1/2".

The function of the cylinder of 6" is be the absorber of the solar concentrator and the function of the cylinder 1 1/2" is be the wall of contact between evaporator and cold area therefore the material of the these two cylinders are alluminium cedule 40, because of termic conductivity is around of 168 W/(m K) and on these two wall is neccesary a high termic conductivity.

The function of the cylinder of 5" is be the wall of separation between the termic compressor and condenser and the function of the cylinder of de 3" is be the wall of separation between the condenser and the evaporator, the caracteristic principal of these tubes are that the material is non conductor and the material select is nylamid with a termic conductivity of 0,29 W/ mK.

The volume in the cold area is to achieve freeze approximately 0,5 liter of water. It was considered an initial ambient temperature of 15 ° C and the temperature goal of -5 °C. The initial conditions of latent and sensible heat are obtained from the total heat extracted from the cold area the which is 203,15 kJ. The mass of the refrigerant is of 0,25 kg considering that the adsorption capacity is of 0,58 kg adsorbate/kg adsorbent and the mass of adsorbent is of 0,30 kg.

The average solar radiation considered is 700 W/m2 and the captation area is 0,70 m2, through free convection was calculated superficial temperature of the absorber of 120 °C and heat transfer of 294 W.

The general equation of heat conduction is used to determine the internal temperature which is 118 °C.

Boiling inside the termic compressor has a mass flow of 0,00117 kg/s so it will take time to evaporate around of one hour, ten minutes.

The length of the tube for the condenser is at least 20 cm for evaporate all volume of refrigerant.The cooling fluid is water to condense to the refrigerant. The coefficient of convection of water is 48,99 W/m2 K

The condensation time considered was 15 minutes and the diameter between the B and C is 9.58 mm. The CPC material was considered to be aluminum with a reflectance of 0.8.

Whit the thermal analysis shown in section 5, the amounts of adsorbent- adsorbate pair were obtained. The table 2 shows the amounts obtained for the preliminary design. Also it was obtained the COP and it was observed that this value id between ranges 0.1-0.4 which is suggested for some authors (Fernandes, 2014).

Table 2: Design parameters

Parameters	Dimensions
Collector diameter c1	25 cm
Condenser diameter c2	20 cm
Diameter between condenser and evaporator	16.8 cm
Evaporator inner diameter c4	16 cm
Condenser tubes	22
Adsorbate mass	50g
Adsorbent mass	70g
CPC opening capture	0.60 m^2
COP	0.22

7.2 Discussion of CFD results

At the beginning of calculation, all the parameters took the values defined at point A. The boundary conditions used are shown in table 3.

Table 3: Boundary conditions

Parameter	Value
Condenser pressure inlet	423 kPa
Evaporator pressure inlet	103 kPa

In the Fig. 5 show the difference of the temperature are based in the specific heat of each fluid and the variation of temperature determined the change of phase of the fluids. These results are very important for the final design because is necessary the change of temperature for each element of the refrigeration cycle also the pressure change in each element propose for the prototype.

8. Conclusion

In this work it is observed that the proposed design of the portable solar adsorption refrigerator is feasible. In this design it is proposed that all the elements are together as concentric cylinders, according to the determined dimensions it was observed that this proposal is achievable.

Also in this paper adsorptivity values of charcoal obtained from different waste organic matter were analyzed. It was observed that the waste of the local product “huaje” has the major adsorption capacity, even more than the values obtained with activated charcoal.

As a result of the thermal analysis it was determined the adsorbent and adsorbate quantity required for the design proposed. The values obtained were 50g of adsorbate and 70g of adsorbent, for 1 liter of water. These values are considered suitable for a portable design. Also it was obtained the COP of the system and this value is similar to the suggested by different authors.

A CFD analysis was made in order to obtain the temperature profiles for the evaporator and condenser. It was observed that the best results are obtained with biogas and methanol. This results reinforces the proposal of using biogas as working fluid.

In future works it is proposed to compare the theoretic and experimental results with the CFD simulations and also to prove the portable solar refrigerator in rural communities.

Using TRNSYS in a graduate course on solar energy engineering

Michaël Kummert

Polytechnique Montréal, Dept. of Mechanical Engineering, Montréal (Québec), Canada

Abstract

This paper presents a graduate solar energy engineering course which relies on the TRNSYS simulation tool to engage the students in the learning process through design and analysis activities. The learning objectives, course structure, and teaching and assessment methods are discussed. Student feedback has been overwhelmingly positive on the use of TRNSYS, and on the fact that the course combines theoretical notions with practical, simulation-based design exercises. The main criticism against the use of the simulation tool is the lack of training material specific to the subject, which leads to difficulties in selecting and configuring the appropriate TRNSYS components.

Keywords: education; teaching; solar energy; simulation; modeling; TRNSYS

1. Introduction

Most university-level courses on renewable energy are taught at the graduate[1] level, either as part of a program focusing on that topic, or as elective courses in more general programs (Kandpal and Broman, 2014). Renewable energy education at Polytechnique Montréal followed the general trend in North America, where renewable energy education in universities took off in the late 20th century, in the wake of the oil crises. Solar energy was often among the first graduate courses created, with many instructors adopting the seminal "Solar Engineering of Thermal Processes" textbook currently available in its 4th edition (Duffie and Beckman, 2013). At the beginning of the 21st century, dwindling research and education funding had resulted in only about 10 US universities offering regular solar energy courses, down from around 150 in the early 1980s (Goswami, 2001). The solar energy course at Polytechnique again followed that trend; it was not taught for about 10 years before being reinstated in 2011.

The course described in this paper is known as MEC 6214 – "Énergie Solaire et Applications" (Solar energy and applications). It is taught once a year, during the winter term (January to May). The current course contents and teaching methods are the results of 6 years of trial and error by the author, although the basic structure and the learning objectives remained the same. As pointed out by Kandpal and Broman (2014), "*the scope and contents of a course essentially depend upon the expertise, interest(s) and biases of the course teacher*". The course described in this paper is no exception: both the theoretical aspects addressed in the first part of the course and the practical, simulation-based approach are a result of the author's experience and level of comfort with the selected topics and tools. As a consequence, this paper does not pretend to represent the best practice in teaching solar energy engineering. It represents the author's contribution to the sharing of teaching methods and materials, and an example of how a detailed simulation program as TRNSYS can enrich a solar energy course and help engage students in the learning process.

Note: The author has made some teaching material available on an open website accompanying this paper: https://moodle.polymtl.ca/course/view.php?name=mec6214p (most material is in French at this time)

[1] "graduate" in the paper title and in the text refers to the level of a student who has graduated from a university-level "undergraduate" program, often a Bachelor's degree (~4 years). The term is frequently used in the USA and in Canada, while "postgraduate" is often used with the same meaning in Europe and some other countries.

doi:10.18086/eurosun.2016.04.05 Available at http://proceedings.ises.org

2. Prerequisites

The general policy at Polytechnique Montréal is to have no prerequisites for graduate courses. While most students taking the course have completed or are about to complete a Bachelor's degree in mechanical engineering, students from other engineering branches and sometimes other backgrounds (architecture, economics, physics) have also taken the course. The required prior knowledge is limited to basic thermodynamics and heat transfer: energy balance of closed and open systems, conduction, convection and radiation heat transfer, heat exchangers. Reading material is provided to cover these topics, e.g. Chapter 3 in (Duffie and Beckman, 2013) or thermodynamics and heat transfer textbooks, but no special tutorial sessions are organized. No prior knowledge of the software tools (especially TRNSYS) is expected, but a small number of students have typically been exposed to them in other undergraduate or graduate courses. In particular, TRNSYS is used to some extent in many of the core courses given at the school on building physics, HVAC systems, building energy modeling, and other renewable energy systems (i.e. geothermal).

3. Learning objectives

After taking the course, the students should be able to:

- Describe the environmental and economic context relevant to solar energy engineering
- Assess the solar energy resource of a site
- Calculate the solar radiation incident on a surface (beam, diffuse and ground-reflected components)
- Explain the principles of solar collectors and solar energy systems
- Calculate the performance of solar collectors
- Analyze the economic and energy performance of solar energy systems*
- Design and simulate the performance of solar energy systems
- Justify the use of given renewable energy technologies (wind, solar thermal, solar photovoltaic) in particular applications

*It should be noted that, adopting the approach of Duffie and Beckman (2013), the course focuses on solar thermal systems but also covers more briefly solar photovoltaic (PV) systems and wind energy systems.

Using Bloom's revised taxonomy (Anderson and Krathwohl, 2001), some learning objectives listed above fall in the lowest 3 categories of educational objectives in Figure 1: remember, understand, and apply (where the "remember" objective is not mentioned explicitly but implied). These categories are more present in the first part of the course ("fundamentals" part, see below).

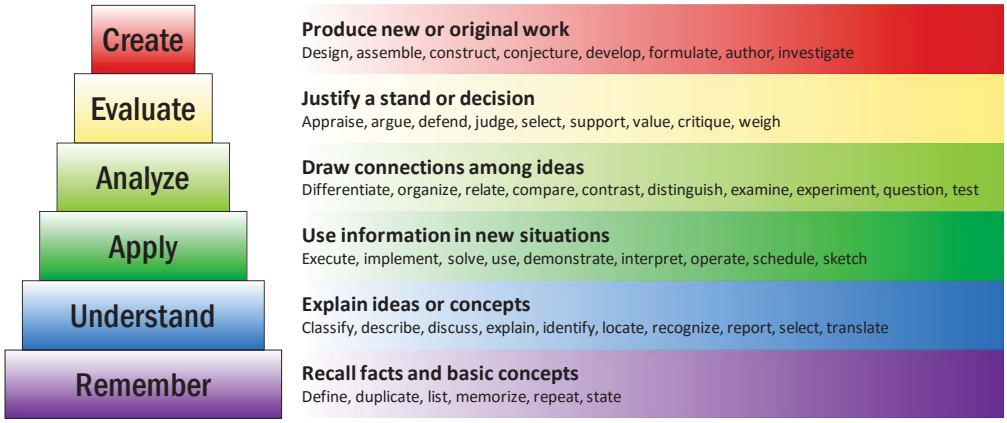

Figure 1: Bloom's revised taxonomy, adapted from (Armstrong, 2016)

The upper categories (Analyze, Evaluate and Create) rely on performance simulation with TRNSYS: students learn how to design solar energy systems first by analyzing the performance of pre-defined systems, by assessing the impact of design changes, and then by proposing and comparing different designs. In theory, it would be possible to perform these activities without relying on software tools, e.g. by using monthly

design methods such as F-Chart (Klein, Beckman and Duffie, 1976). However, using simulation programs such as TRNSYS allows to consider a much larger variety of systems combining different technologies (e.g. solar thermal, solar PV, and wind); it also allows investigating the dynamic behavior of complex systems and control strategies.

4. Teaching and assessment methods

The course follows the typical pattern for graduate courses at Polytechnique Montréal, which consists of a weekly 3-hour lecture (there are normally 13 lectures per term). There are no formal labs or tutorials, but the students are expected to dedicate time to the course at home for personal study, homework assignments and exam preparation, for a total of 96 hours. The total theoretical workload for students is 135 h over the teaching term, which corresponds to 3 credits at Polytechnique Montréal. It can be loosely translated to 5 or 6 ECTS (European Credit Transfer and Accumulation System).

The course is based on "Solar Engineering of Thermal Processes" (Duffie and Beckman, 2013), which has been one of the most popular textbooks to teach solar energy engineering since the 1970's, in North America and throughout the world. The course mainly relies on the first 6 chapters for the "fundamentals" part (see below), which is taught in conventional lectures with homework assignments.

Engaging students

There is increased evidence that traditional lectures are not the most efficient at maximizing learning and course performance in Science, Technology, Engineering and Mathematics (Freeman *et al.*, 2014). Students benefit from active learning, which is defined by the adoption of instructional practices that engage students in the learning process, such as collaborative, cooperative, and problem-based learning (Prince, 2004). While promoting student engagement is an unquestionable objective, it can be challenging to realize in a course with 39 hours of faculty-students contact and a relatively large number of students (the average course enrollment is above 30 students per term, with an upward trend).

The first approach taken to engage students in this course is to try and bring some collaborating learning in the biweekly homework assignments. Students solve the assignments and submit their results individually, but a significant part of the next lecture (roughly one hour) is taken to discuss the problem and the results. The students and instructor diagnose the errors in submitted results. In many cases, students work on different datasets, which was originally intended to prevent plagiarism, but has proven useful in transforming individual efforts into a form of teamwork, where all students contribute one part of a larger parametric analysis.

The second approach to engage students relies on simulation-based problems (assignments or intermediate steps of the final project). During the second half of the term, the time spent giving conventional lectures is considerably reduced, to approximately 1 teaching period (50 min). This leaves two periods for participative activities. Instead of the conventional classroom used for the first part of the term, the course takes place in a computer lab, which allows students to perform simulations during the class. They can analyze their results and diagnose their problems with the help of the instructor, within the constraints imposed by the number of students (i.e. each student gets relatively little time for individual assistance).

Assessment methods

The assessment relies on individual homework assignments (biweekly individual assignments, worth 1/3 of the final mark together), on a written exam (individual, 1/3 of the final mark), and the final project (groups of 2 or 3 students, 1/3 of the final mark). The weight of these different assessments have evolved over time, in response to student feedback that the initial weight for the exam (40 %) did not give a fair share to the other activities. The exam is organized as a mid-term assessment, which comes after the lecture-based "fundamentals" part of the course. It is a conventional written exam, during which students only have access to a 2-page document that they have created themselves and to a non-programmable calculator. In terms of Bloom's taxonomy, the learning objectives assessed in the exam mostly fall in the lower 3 categories (remember, understand, apply), with some attempts to reach levels 4 and 5 (analyze and justify), e.g. with questions asking to define a solar fraction that would apply to a particular system. The homework

assignments ask for numerical answers but also in many cases for a report with some analysis and critique of the results and assumptions, which can be seen as pertaining to categories 4 and 5: analyze, and evaluate. This is especially true for the assignments that use TRNSYS simulations. But to really attain the highest category of educational goals ("create", i.e. design, formulate and investigate), the course relies on simulation-based exercises, and this level is probably only reached during one or two assignments, and the final project, which is a group activity (2 or 3 students).

A practical exam using TRNSYS was introduced in 2012 and 2013. This 2-hour exam was taking place right after the conventional written exam, and was originally intended to test whether students had gained a sufficient understanding of how the program can be used to analyse solar systems, but it proved difficult to test more than basic TRNSYS skills, which was not in line with the learning objectives, so that exam was withdrawn in 2014 and for following years.

5. Use of TRNSYS and other software tools

Literature review: courses using TRNSYS

The literature on teaching solar energy with TRNSYS (or with other simulation tools) is scarce. A few papers report on successful attempts in universities across the world to use TRNSYS in teaching various subjects, from building energy systems to solar energy engineering.

TRNSYS is used in several courses at Polytechnique Montréal, from 4th year (BEng) courses in building heating and cooling mechanical systems to graduate courses on geothermal systems and solar energy (the course described in this paper). It is also used in a graduate course on building energy modeling (Bernier *et al.*, 2016). Students in graduate programs such as the recently created course-based Master in energy engineering are likely to take several of these courses (if not all), which offers synergies and reduces the student effort to learn the software.

Megri (2014) discusses the use of TRNSYS in the department of Architectural Engineering at North Carolina A&T State University. The paper presents a methodology for students to build their own model, perform numerical experiments, and analyze the results. The selected case study is a solar-assisted ground-source heat pump system coupled to a multizone building. According to the author, students prefer easier-to-use programs such as EQuest, but TRNSYS has the benefit of not restricting the type of systems which are analyzed. The instructor needs to master the TRNSYS program and the subject areas.

Charles and Thomas (2009) use TRNSYS in undergraduate courses for engineering and architecture students. The program is coupled with CONTAM for bulk airflow analysis, and other tools are used for climate analysis and Computational fluid Dynamics (CFD). The focus is on encouraging teamwork and benefitting from complementary experience, and simulation is not performed by all class students but rather by an external expert, the instructor, or a few volunteer students. The authors report that students find TRNSYS difficult and are more attracted towards the CFD software. The latter can produce visually attractive results and the authors express that using a little bit of "colorful fluid dynamics" is a necessary evil to generate interest. In spite of the difficulties, the authors conclude that simulation helps students understand the iterative nature of the design process and makes them aware of various physical phenomena. It is also a common platform to support collaboration.

Gómez-Moreno (2015) describes how TRNSYS is used in an undergraduate course on HVAC systems in Industrial Engineering at Universidad de Jaén. Transient simulations are used to help students understand the dynamic behavior of HVAC systems, enhancing the knowledge of steady-state performance that they have gained through more conventional teaching methods. The program is also used to introduce renewable energy in a course that otherwise focuses on air-conditioning systems. The authors state that a software program like TRNSYS is the ideal tool for the students to acquire new competencies and to understand the dynamic behavior of complex systems. It also has the benefits to promote student engagement and increase the motivation. They present the results of a student survey showing that 80 % or more of the students have found that the simulation tool is useful to complement the lectures, help understand the operation of HVAC and solar systems, increase their interest in the course, and improve the quality of teaching.
