Gravagne *et al*. (2008) report on the use of TRNSYS in a graduate elective course on solar energy in the department of mechanical engineering at Baylor University. The authors mention the use of TRNSYS for LEED certifications of buildings and for SRCC certifications of solar thermal systems as key aspects in support of selecting the program, as well as a series of features introduced in version 16 that made the software more relevant to classroom use. TRNSYS was only used midway through the class, and it was used to revisit problems that had been solved by hand or with generic software such as Excel or Matlab. One benefit of this approach is that students had a deeper understanding of the software assumptions and results. They could identify spurious results more easily after developing intuition by obtaining results the "hard way". TRNSYS was then used as a design tool in the final project. This allowed students to perform activities (design) for complex systems that they would not have been capable of analyzing without the program. The "mixed quality" of the documentation required a careful preparation by the instructor, so that students are not frustrated by hard-to-find information. Cryptic error messages, and non-standard units, such as the use of kJ/h for energy rates, are also pointed out as weaknesses. But overall, TRNSYS improved the learning experience and most students expressed their wish to start using TRNSYS earlier in the course.

These examples show that TRNSYS can be used successfully for teaching solar energy engineering and other topics. But there is a need for a larger body of shared knowledge about how the tool can be used efficiently for teaching and learning, and there is also a need for publicly available material to support that objective. This paper and the accompanying website is the author's attempt to contribute to that material.

Why was TRNSYS selected?

Ideally, an engineering course should be tool-independent. However, the pursuit of this noble objective quickly faces practical problems: can the instructor master all the tools involved? is the time invested in software installation and basic learning justified? can all the licenses be obtained without investing too much time and money? As discussed below, the students taking this course sometimes felt that using different programs would have been beneficial, while attempts to be tool-independent (and therefore using several different tools) can lead to students being frustrated at the time and energy involved to install and master these software tools (Beausoleil-Morrison and Hopfe, 2016). In many cases – as well as in this course – students also express the need for more software training material adapted to the course (Gravagne and Van Treuren, 2008; Beausoleil-Morrison and Hopfe, 2016). Over the years, a course instructor can reasonably build specific training material adapted to a particular course for a software program, but creating and maintaining that material for several different tools seems impractical.

As indicated in the introduction, the choice of TRNSYS came naturally to the course instructor, as he was very familiar with the program and confident that he could not only use the program to obtain simulation results but also investigate its assumptions and algorithms. When teaching an engineering discipline, being able to examine the actual source code of the software is a great advantage that few commercial programs offer, and open-source alternatives are not always available. Numerous validation studies including TRNSYS have been published, such as the BESTEST inter-model comparison (ASHRAE, 2014). TRNSYS is also used as a reference tool in international standards (ISO, 2013) and certification programs (Burch *et al.*, 2012; SRCC, 2015), which is a testimony to the software relevance for solar energy systems.

TRNSYS' main advantage is probably its flexibility, which comes from its modular structure and from the well-developed libraries of component models. Components can be connected together to form a system, and then configured by modifying the relevant parameters. Assessing different system configurations only requires to add/remove components from the libraries and modify the connections, without modifying the equations and algorithms used in the model. The program flexibility is also expressed by the fact that many different *domains* (Clarke, 2001) can be analyzed together: thermal processes and electrical flows within buildings, HVAC systems and renewable energy systems can form one coupled system. This is a great advantage over some easier-to-use tools which are generally restricted to a single domain or technology (e.g. solar thermal systems for hot water production, or solar photovoltaic systems).

Flexibility has a cost: students can be overwhelmed by the numerous components and libraries, and they can define wrong connections that will result in meaningless results without being flagged as errors. If students do not know how a system operates, i.e. if they do not understand the physical processes involved and the

control strategies, they will not be able to create a TRNSYS model of that system. In that respect, it is the author's point of view that TRNSYS is fully aligned with the learning objectives of a graduate course on solar energy systems engineering.

How TRNSYS and other tools are used

During the first part of the course, students are encouraged to use generic software tools such as spreadsheets and EES (Klein, 2014) to solve sun-earth geometry and solar radiation calculation problems (e.g. anisotropic tilted radiation calculation) and radiative heat transfer problems (e.g. spectral transmittance and absorptance).

TRNSYS (Klein *et al.*, 2014) is used from the beginning for homework assignments, in parallel with hand calculations or generic tools. This is intended to familiarize students with the program and to provide practical examples of the notions defined during the lectures. Examples of assignments include assessing the incident radiation incident for different slope and azimuth angles in TRNSYS using different tilted radiation models (isotropic vs. Perez), comparing the sun position, extraterrestrial, terrestrial and tilted radiation values calculated by TRNSYS to hand-calculated values. Other authors use this two-step approach to help the students develop an understanding of underlying assumptions and algorithms, and intuition (or skepticism) when analyzing simulation results (Gravagne and Van Treuren, 2008; Bernier *et al.*, 2016). Simple solar thermal systems are also introduced (without requiring students to actually build them in TRNSYS) so that students can study the "instantaneous" (i.e. time-step) efficiency of solar collectors, and compare these values to the efficiency curve provided by manufacturers or certified performance tests. Later homework assignments include simple design exercises, mostly involving changing component sizes and control parameters. During the final project, the design exercise can be related to the "create" level in Bloom's taxonomy, as the students start with a clean sheet and a realistic set of constraints and objectives (e.g. reach a given solar fraction, attain the net-zero objective, or design a stand-alone system). In most cases the load (thermal and/or electrical) that the system must meet is provided to the students in data files or calculated using simple methods, so that the students can focus on the solar system itself.

Over the years, specific assignments were introduced which relied on other tools dedicated to PV systems and solar thermal systems, but this led to mixed feedback by students (it is good to experience different tools, but students need more time to learn how to use each of them), and to some uncomfortable situations for the instructors involving crippling software bugs and licensing problems. These problems can happen with any program, including TRNSYS, but it is obviously less demanding to deal with the peculiarities and limitations of one program than to do it for several tools, especially when the instructor and his/her team are using that one program for research on a regular basis.

Teaching how to use a program vs. using a program to teach

As shown in section 3, the course learning objectives are related to understanding and applying solar engineering principles, as well as simulating, analyzing and designing solar systems. "Mastering TRNSYS" (or any other tool) is not one of the learning objectives. Other university-level courses using simulation generally share that approach (Gravagne and Van Treuren, 2008; Megri, 2014; Beausoleil-Morrison and Hopfe, 2016; Bernier *et al.*, 2016). The emphasis should be on underlying assumptions and algorithms, and results analysis, rather than expertise with a particular tool. The key to applying simulation effectively for design and analysis is to develop confidence in the simulation while keeping a critical mind.

One approach to avoid the difficulties of using the software is to employ "simulation specialists" who do the modelling work while students focus on proposing design alternatives. Successful applications of this approach for teaching to engineering and architecture undergraduate students have been reported by Charles and Thomas (2009), who compare cases where the simulation specialist is an external expert, the instructor, or a subset of volunteer students. Reinhart *et al.* (2012) also relied on a pool of "simulation experts" to perform the simulation in a design exercise that they transformed into a game where students compete to obtain the lowest energy use intensity within predefined cost limits. The game was useful in teaching how to interpret simulation results and use them in an iterative design process, and also served as a teaser.

In a later paper, Reinhart *et al*. (2015) describe how the same "learning by playing" approach was applied to a group of 18 undergraduate and graduate students who performed the simulations themselves. The course

included a series of simulation exercises culminating in a game where the students competed to design the building with the lowest greenhouse gas emissions. The authors report overwhelmingly positive student feedback, but insist on the need to keep the complexity of input files provided to the students at a reasonable level. They insist that instructors must be intimately familiar with the strengths and weaknesses of the programs used, so that they can detect and explain wrong results caused by user errors or software limitations. They mention that for larger classes, the teaching staff (one instructor and a teaching assistant) will need to increase and the use of online tutorials may be required to complement lectures and lab sessions.

The approach taken by the author in the course described in this paper is to have students use TRNSYS themselves, individually (for homework assignments) and in groups of 2 or 3 (for the final project). The software is introduced right from the first assignment, and the emphasis is placed on obtaining and analysing results during the first weeks. Later assignments and the final project are actual design exercises of increasing complexity.

6. Course structure

An example of course schedule is provided on the accompanying website (see first page).

Part 1: fundamentals

After the introduction lecture, the first part of the teaching term (approximately six 3-hour lectures over 6 weeks) follows the topics presented in (Duffie and Beckman, 2013). Table 1 shows the topics and examples of assignments.

Table 1: Topics and example of assignments for course part 1 (Fundamentals)

Topics	Examples of homework assignments
Course objectives, context, introduction to TRNSYS Example of successful solar energy systems Worldwide context : energy and environment, solar (thermal and photovoltaic) resource and markets	**First contact with TRNSYS** Run existing solar thermal project Configure an output component (printer) Examine the impact of collector slope and azimuth Obtain and analyze results
Extraterrestrial solar radiation Solar geometry, sun position angles, equation of time	
Available solar radiation Measurement of solar radiation, clear sky radiation, beam and diffuse radiation, isotropic and anisotropic models for incident radiation on tilted surfaces	**Tilted radiation, SDHW system balance** Calculate incident radiation on a tilted surface Compare results with TRNSYS for different anisotropic models Perform an energy balance of a Solar Domestic Hot Water (SDHW) system using TRNSYS
Radiation characteristics of opaque materials Kirchhoff's law, spectral distribution of solar and long-wave radiation, absorptance, reflectance and emittance	**Collector absorptance and emittance, collector shading** Calculate α and ε from spectral properties and solar spectrum In TRNSYS, optimize collector rows (azimuth, slope, spacing).
Radiation transmission through transparent surfaces Reflection, absorption, and transmission, spectral and angular dependence of properties, transmittance-absorptance product ($\tau\alpha$)	**Collector stagnation temperature and efficiency** Calculate (by hand) the stagnation temperature of a collector In TRNSYS, examine the dynamic collector efficiency and compare to the performance curve. Students must use certified performance (ISO or SRCC) to configure the TRNSYS components.
Flat-plate solar collectors Collector energy balance, overall heat loss coefficient, collector heat removal factor and flow factor, Hottel-Willier equation, collector testing and performance data.	

Example of collaborative learning through individual assignments

In some of the assignments, students are given different conditions, which are then combined by the instructor during the feedback session to provide a complete picture. One simple example is the slope and azimuth of solar thermal collectors in an SDHW system. Students are provided the TRNSYS project shown in Figure 2 and are asked to assess its performance for a given slope and azimuth angle. All student answers are then combined and used to draw plots of the collector useful energy (Figure 2, top right) and collector efficiency (Figure 2, bottom right) for all slopes and azimuth angles. This is used to discuss the fact that the collector output is not necessarily maximum at the maximum of incident radiation (not shown in the figure) and that the collector efficiency does not really show where the system output will be maximum.

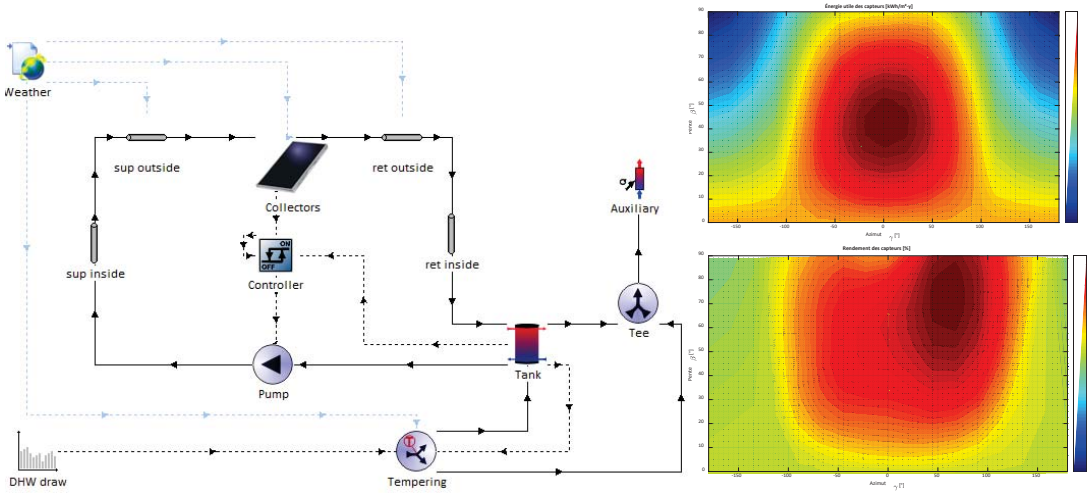

Figure 2: TRNSYS model of an SDHW system and example of results for different orientations and slopes

Part 2: applications

The second part of the teaching term (approximatively six 3-hour sessions) combines short lectures with practical design exercises. The course focuses on solar thermal applications for domestic hot water and space heating, but concentrating solar power generation and solar cooling are also covered. Photovoltaic systems are considered from a design perspective in combination with solar thermal systems, e.g. to design net-zero buildings. Occasionally wind energy is also introduced in the design of stand-alone systems. The subjects covered are sometimes adapted to make room for a graduate student who presents his/her work. Past examples include solar thermal/photovoltaic collectors, and control / fault detection of solar thermal systems.

This part of the course strongly relies on a series of homework assignments and on the final project, which all use TRNSYS. Examples of assignments and projects are again available on the accompanying website (see first page). The following paragraph briefly describe a few examples.

Design of solar thermal systems: thermal load, collectors, thermal storage

Generally, the load is provided for assignments and for the project, but for one assignment students are asked to use 2 weeks of measurements from a real site to extrapolate the design load used in a simulation. The importance of sizing the thermal storage in a solar system is shown by various examples. One assignment asks the students to compare the system performance for various collector areas and thermal storage capacities. This is also used to introduced parametric studies in TRNSYS, and student are developing the classical solar fraction vs. collector area and storage volume curves.

Photovoltaic and PV-T systems

The theory of photovoltaic system is covered briefly, the focus being on system-level design and on the interaction with other renewable energy technologies.

Examples of assignments are to design a stand-alone PV-powered system for a bike-sharing company (inspired by the actual systems in Montréal), and to design an off-grid house powered by wind and PV (optimization between the two renewable energy sources and the battery capacity).

Economic Analysis for renewable energy systems

Basics of engineering economic analysis (cash-flow, discounted payback time, internal return rate, etc.) are briefly covered. The concept of levelized life cycle cost is introduced to compare different renewable and non-renewable energy technologies. Economic analysis is typically integrated into the last two homework assignments, while the first ones focus on energy performance only. This is generally combined with exercises asking the students to perform and present energy balances, e.g. through Sankey diagrams.

Concentrating Solar Power and solar cooling

Due to time constraints, these applications, which are less relevant for the Montréal context, are typically covered in a descriptive manner through a lecture presenting the principles and successful applications. These topics generate a significant interest among the students so the possibility of offering optional final project topics is being investigated.

Putting it all together: the final project

The final project is intended to be a comprehensive design exercise where students must optimize the performance of their proposed configuration through an economic analysis. The energy performance is defined by the levelized life cycle cost of energy, or specified through targets such reaching a given solar fraction, net-zero energy, or stand-alone operation. Examples of final projects are:

- Design of an SDHW system for a building serving food to homeless people (this project used data from a real project including on-site DHW draw measurements, mechanical room and roof space constraints and local shading). Students were using different weather data, transposing the real site into different contexts.
- Design of a solar combisystem with a 75 % solar fraction for a residential building (students were allowed to select any city and exact location, including local shading).
- Design of a stand-alone polar research station (latitude higher than 75°) powered by solar thermal, PV and wind with a 90 % renewable energy fraction.

One difficulty of the final project is providing detailed feedback to the students, as it is typically due at the end of the exam session. Oral presentations were used during some years but the number of students make it difficult to organize during the last weeks of the term. The project start has been moved earlier in the term (typically before the mid-term exam), and intermediate deliverables are used to provide some feedback.

7. Student feedback and lessons learned

Formal independent surveys (2011 – 2016)

Polytechnique Montréal has a formal assessment program where students fill out anonymous evaluation forms which are collected by an independent school department (“bureau d’appui pédagogique”, teaching support group). Professors then receive the compiled evaluation results in the form of percentages of agreement to some 20 questions. Two questions are related to the use of TRNSYS: one on the clarity of homework instructions (it was noticed that complaints were mostly related to difficulties with the TRNSYS files), and one on “equipment, materials, and software”. Table 2 shows responses to both questions.

Table 2: Answers to independent student surveys (in % over the 6 years, total number of respondents = 150 over 180 students)

Question	Strongly disagree	Disagree	Agree	Strongly agree
Instructions for homework assignments are clear	0.5 %	4.5 %	45 %	55 %
Equipment, materials, and software used are useful	0 %	0 %	14 %	86 %

In addition to these questions, students are asked to comment on the course in a dedicated space. All answers are again collected by the independent department and then communicated to the instructor. The question is formulated to ask students if they have suggestions to improve the course, but some students use the space to identify the parts that they especially like. The most frequent or relevant comments are summarized below:

- An overwhelming number of students write positive statements on the course as a whole and the fact that it mixes theoretical aspects (the “fundamentals” part) with practical design applications. The fact that these

practical applications are simulation-based design exercises is very often mentioned as a positive point.

- The use of TRNSYS is appreciated, and a few students have suggested also using other programs that would be more likely to be used by consultants.
- Some students have complained that the gap between homework (where "ready-made" TRNSYS projects are provided most often) and the final project (for which students start from a clean sheet) was too large.
- Some students have suggested to spend more time on how to use TRNSYS, or to organize a specific course on the program at the beginning of the term. They have also mentioned that it would help to have more online tutorials available.
- A few students have also suggested increasing the time spent in class using the software (i.e. reducing the lectures). In one extreme case, a student complained about the "fundamentals" part with "equations that we will probably never use in our engineering career", and he/she suggested replacing it with more simulation-based case studies with economic analysis.
- During the years when other programs were used, some students appreciated the mix of programs but many complained that there was not enough time to learn how to use the different programs.
- Over the years, a few students also complained specifically about the place of TRNSYS in the course, and that the course was on simulation rather than on solar energy (2 students over 6 years). One specific comment was that TRNSYS was "irrelevant in the real world", being "much too complicated".

In-class specific survey in 2016

In addition to the formal surveys, the instructor asked some specific questions at the end of the course in 2016. The written survey was anonymous, but answers were collected and processed directly by the instructor. 30 students (over 35) responded to the survey, which had 3 closed questions and was also asking for any other suggestion to improve the course. Table 3 presents the results of the closed questions.

Table 3: Answers to specific student survey in 2016 (in %, total number of respondents = 30 over 35 students)

Question	Strongly disagree	Disagree	Agree	Strongly agree
Simulation-based applications are an important part of the course	0 %	0 %	3 %	97 %
It is a good idea to use TRNSYS, which is flexible and forces users to understand how systems operate, instead of other programs that would be easier to use	0 %	0 %	37 %	63 %
Even if the course is mostly about solar thermal systems, it is a good idea to also cover solar photovoltaic systems and wind energy conversion, even briefly, and to use PV and/or wind in the final project.	0 %	0 %	4 %	96 %

The suggestions to improve the course were wide-ranging, and the most significant ones are summarized below (the numbers in bracket indicate the number of students who made the suggestion (there were 24 comments in total for 30 respondents, and 4 of these comments repeated that TRNSYS was a good tool to understand how systems operate, which was already covered by the second question):

- (5) There should be a separate course (or some periods in the solar class) dedicated to TRNSYS.
- (3) The instructor should provide more explanations on specific TRNSYS components before they are used for the first time in homework or in the project.
- (3) More practical sessions should be devoted to TRNSYS during the course.
- (3) Other easier-to-use programs should be presented as well.
- (3) TRNSYS homework should insist more on creating systems (not just using "pre-canned" systems).
- (2) More TRNSYS tutorials and exercises should be available online.
- (1) TRNSYS documentation should be available in French

Lessons learned

Student feedback has been overwhelmingly positive on the use of TRNSYS, and most student seem satisfied that the course combines theoretical notions (through hand-written exercises and exam) with practical, simulation-based design exercises. The choice of TRNSYS is approved by the vast majority of students, even though they realize that other programs exist which would be easier to use. The second question of the 2016 survey was especially formulated to validate that hypothesis. Some students would like to be exposed to other programs, but they do see value in using a more flexible program even if it is more complicated.

The students generally suggest to spend more time teaching how to use TRNSYS, either in the solar course or in a dedicated training course. They also point at the lack of suitable online examples and tutorials. This illustrates the challenge of teaching solar energy engineering with TRNSYS rather than teaching how to use TRNSYS – it does not seem possible to avoid "software training courses" completely, whether they happen during the class or they are provided elsewhere. The students also indicated a need to evolve more progressively from the first homework assignments, which are very simple and rely on using ready-made projects, to the final project where students must create their system model from scratch. In particular, the difficulty of knowing which components to use and how each component should be used is insufficiently addressed in the present course structure. Again, training material specifically adapted to the course should be developed and provided, either as part of the course material or as online tutorials.

Although not directly indicated by survey answers, anecdotal evidence gained during the attempts to use other programs suggests that the level of comfort and expertise of the instructor with the software is critical to its successful use in teaching. It the instructor uses the program on a regular basis for teaching and research, he/she will know the software limitations and quirks. Even if the problems cannot be fixed, students can be warned about misleading indications, bugs and other problems before they get frustrated with them, which will completely change the dynamics of the exercise. In the author's experience, just quickly trying a few examples before an assignment using a program that is only used once a year for teaching is asking for trouble, even with commercial programs.

8. Conclusions

This paper presents a graduate solar energy engineering course which relies on the TRNSYS simulation tool to engage the students in the learning process through design and analysis activities. The learning objectives, course structure, and teaching and assessment methods are discussed. TRNSYS is used for assignments during the entire teaching term, in order to help students gain confidence in the program and in their skills using it. Some assignments compare hand-calculated values to simulation results to encourage the developments of intuition and skepticism toward simulation results. Student feedback has been overwhelmingly positive on the use of TRNSYS, and on the fact that the course combines theoretical notions (through hand-written exercises and exam) with practical, simulation-based design exercises. Students appreciate the fact that TRNSYS encourages them to think about the design and operation of solar systems before being able to model them, even if they realize that other tools might be easier to use and deliver results faster. The main criticism against the use of the simulation tool is the lack of training material specific to the subject, which leads to difficulties in selecting and configuring the appropriate TRNSYS components. An accompanying website provides examples of course schedule, assignments and projects.

9. Acknowledgement

I wish to thank Sandy Klein and Bill Beckman from the University of Wisconsin-Madison Solar Energy Lab, who provided material that was very helpful when I started teaching this course – and more importantly inspired me with their passion for teaching and research in solar energy.

End-Users Decision Making Factors for Heating and Cooling Systems

Stefano Lambertucci

European Solar Thermal Industry Federation

Brussels (Belgium)

Abstract

This paper aims at showing the results of a survey carried across users of heating and cooling systems, done in order to identify what key decision factors are influencing consumers' behavior when it comes to buying a heating and cooling system. The results are analyzed and presented with a particular focus on the respondents having installed a solar thermal system in the residential sector.

Keywords: *renewable heating and cooling; solar thermal; consumers; decision making factors.*

1. Introduction

The objective of the survey carried out under the European FROnT project (Fair Renewable Heating and Cooling Options and Trade) was to identify end-users' decision making factors for heating and cooling systems in five European countries (NL, PL, PT, ES, UK), in order to understand consumer behavior and to facilitate stakeholders at European and national level to provide better and transparent information to consumers.

Although the survey has been carried out in three different sectors – residential, non-residential, industrial – this paper focuses its analysis on the residential sector, as it is the one in which more data analysis has been carried out.

The paper is structured as follows: it first gives a background on the FROnT project, describing the relation between the survey and the rest of the project areas. It outlines the survey objectives, and then goes into the details of the methodology underpinning the whole exercise, and describes the characteristics of the sample. Then, the paper will present the structure of the survey itself, describing the different steps and their specific aims. Finally, the paper will present the general results of the survey, and then the specific results for solar thermal residential owners, drawing some conclusions at the end.

2. Background of the survey – the FROnT Project

The FROnT project, co-funded by the European Union through the Intelligent Energy Europe programme, aims to develop strategies for a greater deployment and to advance the penetration of renewable energy sources for heating and cooling (RES-HC) technologies by providing a better understanding of how to deploy renewable heating and cooling technologies in the market and of the costs of such technologies[1].

In pursuit of this goal, the project aims at understanding the main barriers that are hampering the deployment of RES-HC installations and analyzes how to possibly overcome them. The project is proposing a set of short and long-term policy recommendations to address these barriers. It analyses both existing support schemes and end user decision factors, in order to help establishing strategic policy priorities for RES-HC.

Specific objectives of the project are:

- To support a better insight of the value of the energy supplied by RES-HC systems, promoting transparency and clarity towards end-users and other stakeholders

[1] More information at www.front-rhc.eu.

doi:10.18086/eurosun.2016.04.07 Available at http://proceedings.ises.org

- To improve the understanding of the end-users decision making process with regard to heating and cooling systems in order to develop tailored approaches and facilitate adequate measures enhancing the uptake of RES-HC
- To facilitate the setting-up of improved and sustainable RES-HC integrated support schemes
- To promote the implementation at national and European level of strategic policy priorities that can contribute to efficiently and cost-effectively implement the NREAPs

In order to improve the understanding of how end-users decide which heating and cooling system to use/acquire, and to map this decision making process across different countries and sectors (residential, non-residential, industrial), a survey has been foreseen, as part of an information and data collection exercise which involved all project countries[2].

The project is led by a consortium gathering European industry associations representing the solar thermal, geothermal, aerothermal and biomass technologies, and national energy agencies from Spain, Portugal, The Netherlands, Poland, and UK, assisted by the Austrian Institute of Technology, CREARA (consulting and energy management company), and Quercus (a non-profit environmental organisation based in Portugal).

3. Objectives of the Survey

The main objective of this report is to identify end-users' decision making factors when making choices about heating and cooling systems in the five participating European countries covered by the FROnT project. These countries are: The Netherlands, Poland, Portugal, Spain and the United Kingdom.

Specific objectives of the survey are:

- Identify end-user decision making factors for H/C systems (Renewable and fossil fuels)
- Understanding the decision process when deciding on a H/C system
- Obtain the Key Purchasing Criteria (KPC) which will provide information on "Willingness to Pay"
- Comparison among countries – a list of KPC weighting the criteria will be obtained in each country. Results must be comparable

To achieve these objectives a national survey has been carried out in each country under the coordination of the respective national energy agency and project partner.

The surveys, conducted in three different sub-sectors: residential, non-residential and industrial, allows the project to identify key purchasing criteria (KPC) across the whole sector. These surveys have addressed the heating and cooling sector as whole, not only renewable energy solutions.

4. Methodology and sample characterization

Questionnaires for each analyzed sector (residential, non-residential and industrial) were developed by all the partners, under the supervision of Quercus, in order to use a homogenous tool and get comparable results. The execution time for this activity, excluding subcontracting launch period, was around 2 months.

The number of interviews conducted at European level was: 4,195 in the residential sector, 896 in the non-residential sector and 585 in the industrial sector.

The details per country, and related representativeness of each group is described in the Figure 1 below. The overall confidence level on the representativeness of the sample is 95%.

[2] The full results of the survey, as well as detailed analyses per country, are available in the project portal http://www.front-rhc.eu/library/.

SECTOR	COUNTRY	NUMBER OF QUERIES	CONFIDENCE LEVEL	SAMPLE ERROR
RESIDENTIAL	NETHERLANDS (NL)	560	95%	4.14%
	POLAND (PL)	960	95%	3.16%
	PORTUGAL (PT)	900	95%	3.27%
	SPAIN (ES)	1,250	95%	2.77%
	UNITED KINGDOM (UK)	525	95%	4.28%
NON-RESIDENTIAL	NETHERLANDS (NL)	15	95%	25.29%
	POLAND (PL)	150	95%	7.97%
	PORTUGAL (PT)	250	95%	6.16%
	SPAIN (ES)	300	95%	5.62%
	UNITED KINGDOM (UK)	181	95%	7.25%
INDUSTRY	NETHERLANDS (NL)	35	95%	16.55%
	POLAND (PL)	100	95%	9.78%
	PORTUGAL (PT)	100	95%	9.78%
	SPAIN (ES)	250	95%	5.62%
	UNITED KINGDOM (UK)	100	95%	9.78%

Figure 1 Sample confidence level per country, per sector

A common methodology among partners has been agreed, concerning sample definition and size: error, confidence level, balance of the sample, timing of the application, form of application: by phone, on line, etc. Questions have been based on studies on consumer behavior, external influences, energy labelling, Building Performance Certificates, etc.

The main features of the sample interviewed in the residential sector are shown in Figure 2. This sample is balanced compared with the relative figures of the participating countries (in terms of age, gender, level of education, etc.). Additionally, the sample is balanced in each Member State.

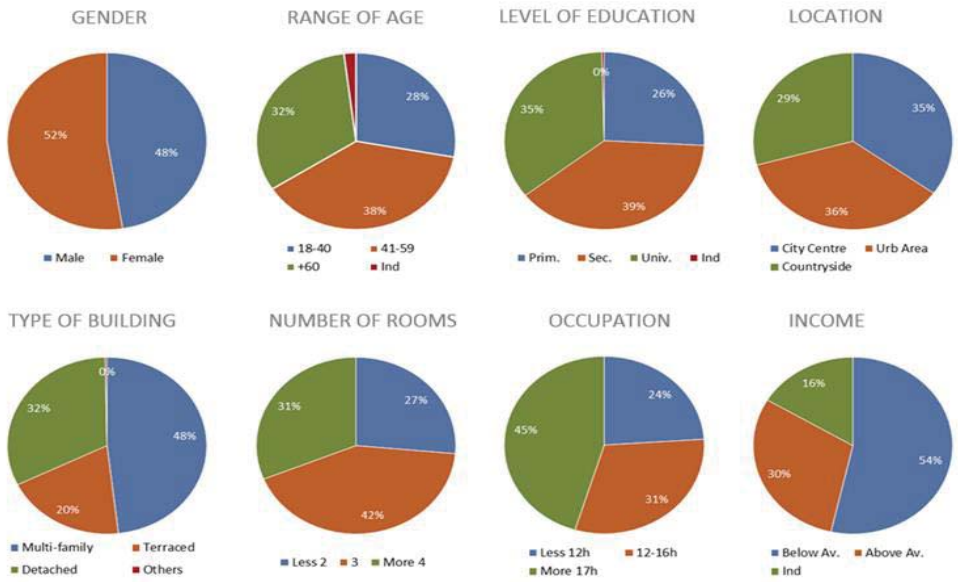

Figure 2 Sample characterisation

5. Structure of the Survey

The survey on the residential sector has addressed consumers on the heating and cooling sector, not only renewable energy solutions. The survey foresees a filter question on ownership of the house. Negative responses lead to the termination of the survey. Results are thus only including residential owners, in order to

simplify analysis.

The survey includes a first part on general information in order to characterize the sample (age, gender, education level, occupation, household income), a second part on the description of the building (location, type of building, number of bedrooms), a third part on heating and cooling system description and, the level of satisfaction with the systems, the main information source, awareness about renewable heating and cooling, adequacy of RES-HC and identification key purchasing criteria and provided information about "willingness to pay", including environmental and social parameters.

The flow diagram in Figure 3 below summarizes the structure of the survey.

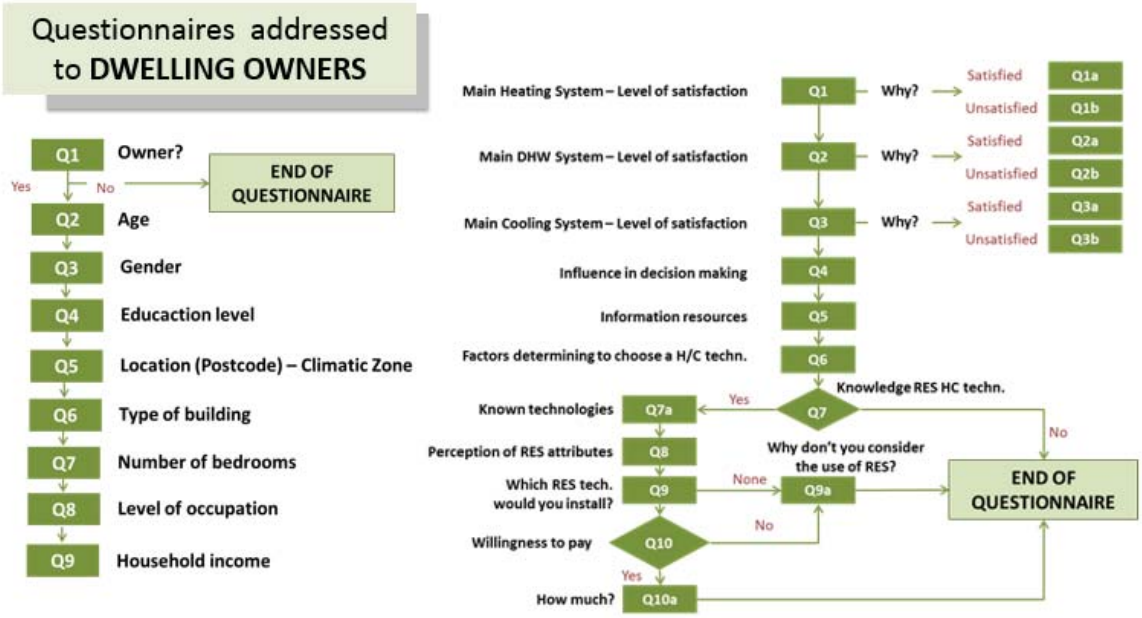

Figure 3 Flow Diagram of the questionnaire in the residential sector

6. General results of the survey

According to the results of the surveys[2], the main energy source employed in all sectors is natural gas followed by electricity. There is also a considerable variability in the industrial sector.

In general, the main information source is professionals' opinions. However, its influence is more relevant in the non-residential and industrial sectors than in the residential sector, where there are other important information sources such as the Internet or relatives.

Regarding key purchasing criteria, total economic savings is the most important criterion for the residential sector while for the non-residential sector it is reliability, followed by total economic savings. The industrial sector presents the same pattern as the non-residential sector.

In particular, in the residential sector, total economic savings is the most important criterion to choose H&C systems (84% of respondents) followed by comfort level (78%). Initial investment is also important (75% of respondents). Total economic savings is the most important criterion in Poland. Comfort level is the most important factor in Spain, the Netherlands and Portugal (followed in these three countries by total economic savings). Reliability and safety is the major factor in the United Kingdom. In general, architectural integration and environmental reasons are more relevant for women than for men. Economic savings, investment and maintenance are more important for people between 41 and 59 years-old than for young people. The importance of savings and recommendations from relatives for those who have primary education (higher than the average) is remarkable.

[2] To access the full results of the survey and the dataset, as well as detailed analyses per country, see http://www.front-rhc.eu/library/.

The non-residential sector presents the greatest level of RES technology awareness followed by the industrial sector, making the residential sector the least aware. In the residential sector, 65% of respondents declared being aware of RES-HC options, of those 96% quoted solar thermal as a familiar technology (against 49% for biomass, 40% for heat pumps, 42% for geothermal)[3]. Women, people over 60 years-old, those with primary education, people from countryside and income below the average know less about RES than the rest. The perception of RES-HC technologies is very similar in all sectors: it is considered to require high investment costs and to deliver high economic savings.

The main rejection reason for RES technologies in the residential sector is the high investment required, followed by structural changes involved and the need of approval by neighbors or superiors. In the non-residential sector, the latter has less weight than the two former. The main rejection factor in the industrial sector is, by far, the high investment required.

Considering the total sample of the respondents in the residential sector who are familiarised with RES-HC (65%), 50% of them would be willing to make a higher initial investment, 39% would not, and 11% did not answer this question. According to the results, 12% of respondents would pay up to 5% more for an RES-HC system, 15% would pay between 5 and 10%, 12% would pay between 10-25%, 6% would pay between 25-40% and 5% did not answer this question.

In general, men, young people and those with university a university level education are more willing to pay more for a RES-HC system than the rest. This is also the case for people who live in the countryside. The willingness to pay is lower in Portugal than in the rest of countries (28%).

The industrial sector is most willing to pay for RES-HC, compared to residential and non-residential sectors.

7. Specific results of the survey – Solar Thermal

By analysing the dataset of the survey results, it is possible to isolate the answers originating from people using solar thermal systems, and assess their answering patterns, as opposed to the general ones. A specific analysis of the solar thermal results per country is more difficult, as the difference in available data across countries is quite considerable (see paragraph 7.1). As for the non-residential and industrial sectors, further data analysis is required in order to process the dataset and draw some specific solar thermal conclusions there too.

For this reason, this section focuses on the residential sector, analyzing the sum of solar thermal users across the five project countries.

7.1. Solar Thermal sample

Out of the 4195 people surveyed in the residential sector, a total of 94 people declared using solar thermal as their heating and cooling system, that is 2.25% of the total sample. In particular solar thermal users are distributed as follows across countries: 16 in Spain, 48 in Portugal, 20 in the UK, 1 in Poland, 9 in the Netherlands.

Out of the 94 solar thermal users, 16 declared using it for space heating, 69 for domestic hot water (DHW), 9 for both. None was using solar thermal for cooling application. Auxiliary system for users of solar thermal for space heating is as follows: 5 electric heater, 2 gas boilers, 1 biomass, 1 heat pump, 1 geothermal, 6 ‘other’. Auxiliary system for users of solar thermal for domestic hot water is as follows: 21 gas boiler, 12 electric heaters, 5 biomass, 5 heat pumps, 5 oil boilers, 2 coal, 1 LPG, 18 none.

In terms of general sample characterization, solar thermal users are depicted in the Figure 4 below. Overall, if

[3] Data should be interpreted as the 96% of the respondents familiarised with RHC (65%) would be familiarised with solar thermal energy for heating uses. It means that 62% (0.65 x 0.96) of the total sample would be familiarised with solar thermal energy. Behavioral biases and confusion with solar photovoltaic might need to be taken into account in explaining this result vis-á-vis the other technologies.

compared with the general sample (4195 respondents), they result distributed in more rural areas (+6% countryside, -14% city centre), mostly on detached buildings (+35% detached buildings), and with a slightly higher level of income (-7% below average) and education (+5% university) than the overall average.

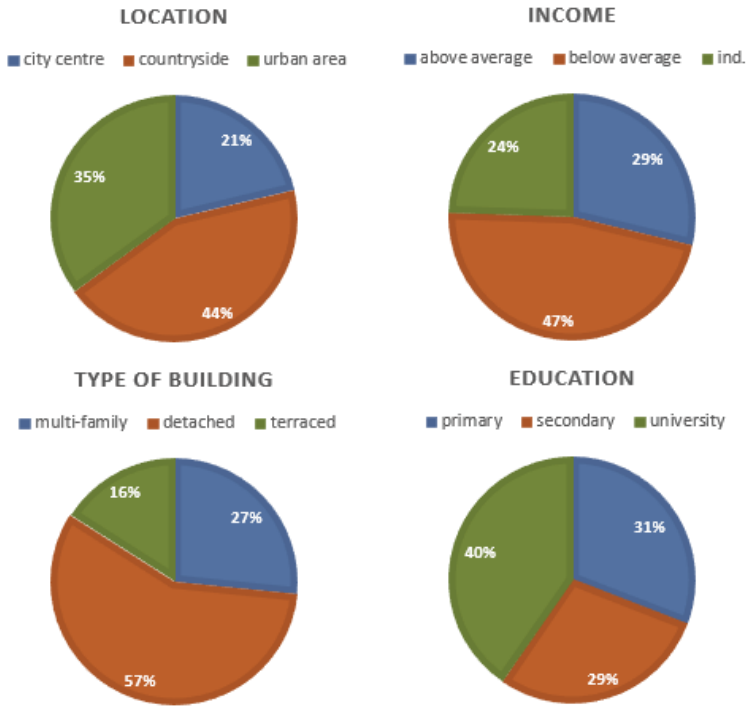

Figure 4 Sample characterisation for solar thermal users

7.2. Satisfaction with Solar Thermal

Satisfaction levels related to the use of solar thermal are relatively high, with 15 out if 16 solar thermal space heating users being satisfied of their systems, 61 out of 69 for domestic hot water users, and 7 out of 9 combi-systems users.

When asked about the reasons of their satisfaction with the solar thermal system, top four respondents answers were comfort, environmental friendliness, fuel price and reliability and safety for both space heating and DHW users (though the order slightly varies). The detailed answers to this open question (multiple choices possible) are depicted in the Figure 5 below.

Satisfaction of solar thermal users is consistent with the general answers of the full sample, as the general satisfaction level is high (satisfied – 90%; no answer – 9%; dissatisfied: 1%) and the main satisfaction reasons are: comfort levels (54%) and easy use, reliability and safety (39%). The different features of the sample (age, gender, etc.) are not really influential.

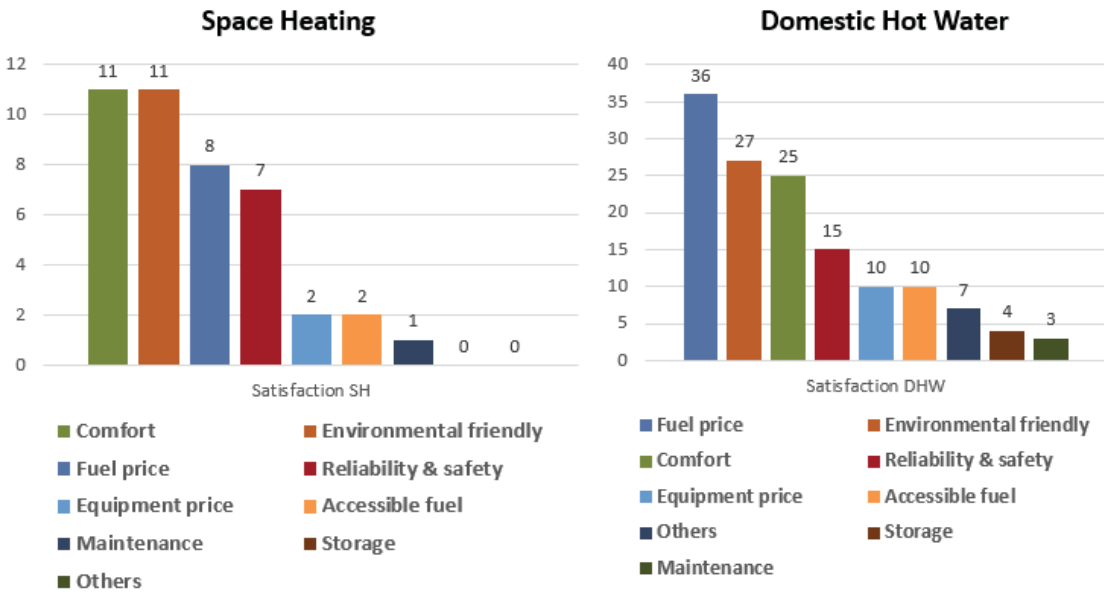

Figure 5 Satisfacion reasons for solar thermal users

7.3. Influence in decision making and information resources

Solar thermal owners did opt for those solutions for space heating or DHW because the system was already existing, because of incentives, because of the cheap cost of the system or of the fuel. Detailed answers are shown in Figure 6 below.

This is again more or less in line with the average response of the full sample, where the main reason to use current heating and DHW systems in dwellings is because they already exist there (52% and 50%, respectively). Other reasons given by respondents are: access and fuel costs (18% – 15% in the case of DHW systems) and equipment price (11% in both cases). Legal obligation is not a predominant reason to support the installation of heating and DHW systems.

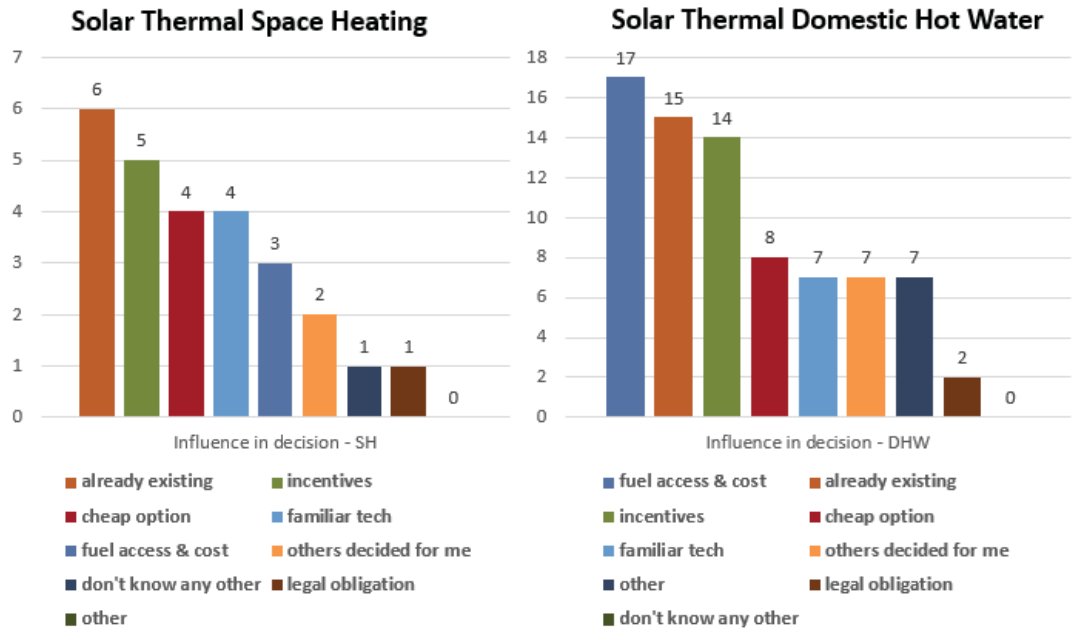

Figure 6 Influence in decision making for solar thermal users

In order to decide which system to opt for, solar thermal users used predominantly professionals as source of information, distanced by sales agents, internet, and family or friends' advices. The predominant role of installers in channeling information to consumers seems therefore confirmed.

Comparing those results with the general sample, it is to be observed an increased relevance of sales agents (+12%), and of consumers/ environmental NGOs (+9%). The detailed preferences in terms of sources of information are displayed in Figure 7 below.

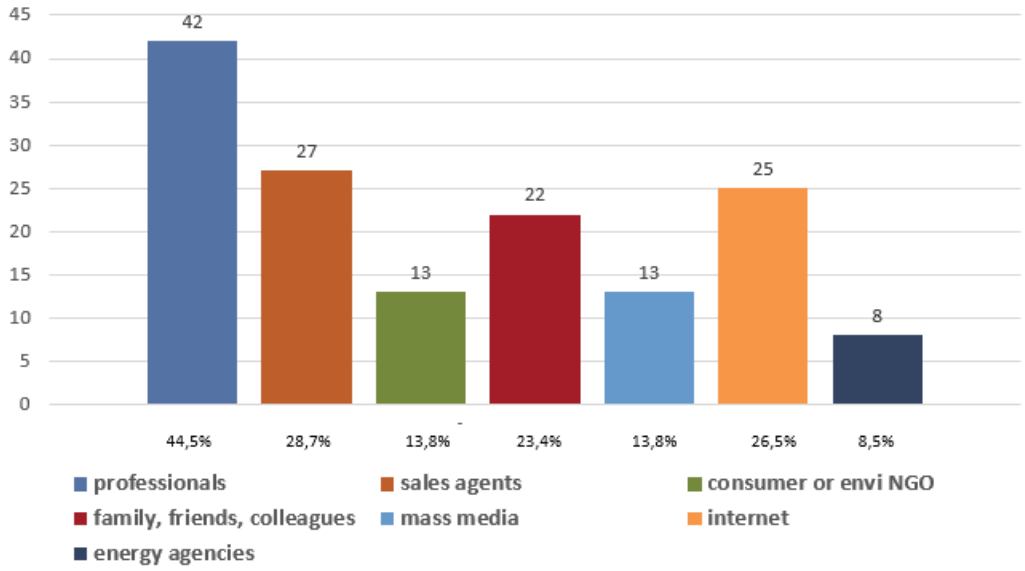

Figure 7 Information sources for solar thermal users

7.4. Key decision factors for Solar Thermal

When asked 'Which factors do you take into account when you buy new heating/cooling/DHW equipment?', solar thermal users did mention savings and comfort as their top two decision factors, with initial investment, reliability and safety, environmental reasons and reliable brand following afterwards.

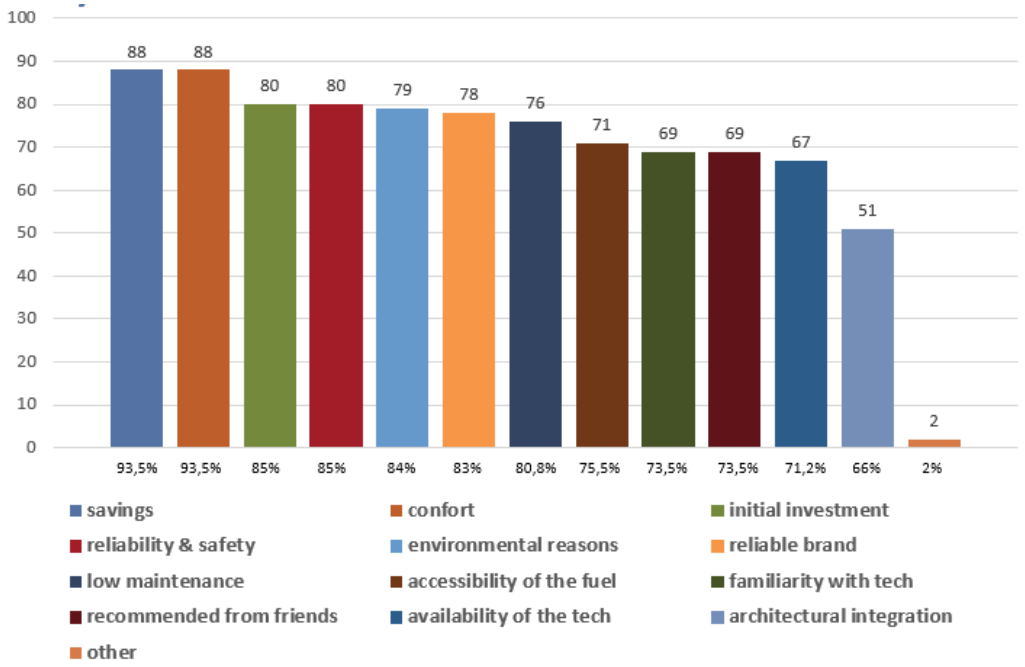

Figure 8 Key Decision Factors for solar thermal users

The detailed preferences in terms of key decision factors are displayed in Figure 8 above. In this case it is interesting to notice the differences between those results, and the overall results from the full sample. Several decision factors seem to be more relevant for solar thermal users, than the average respondents. Most notably, environmental reasons are quoted +23% than the average of the full sample, and reliable brand +26%.

8. Conclusions

The survey shows very interesting results when it comes to identify the end-users' decision making factors. Several key observations can be made both analyzing the general results of the survey, and the specific results from solar thermal users.

For the general results:

- ✓ There is an overall positive satisfaction with current heating systems in Europe;
- ✓ Professionals, sale agents and the Internet are the preferred sources of information;
- ✓ Guarantee of comfort and savings are the main key decision factors in all the participating countries;
- ✓ The awareness about RES-HC is high in Europe (63-79%). RES technologies are more familiar for heating than cooling uses. Solar Thermal the most known technology;
- ✓ Surveyed consider that RES-HC technologies are more expensive, but they provide more savings;
- ✓ Around 60% of the surveyed in Europe considered RES suitable for their heating systems.

For the solar thermal results:

- ✓ Solar thermal is less deployed in city centers and in non-detached houses;
- ✓ Solar thermal is bought by slightly higher income and higher education people;
- ✓ Solar thermal is bought mostly for domestic hot water, with gas as auxiliary space heater;
- ✓ Professionals and sales agents are the main information sources;
- ✓ Vast majority of solar thermal owners unaware of solar thermal cooling;
- ✓ Solar thermal is perceived as reliable, safe technology, providing high level of comfort and with a reasonable initial investment;
- ✓ Comfort, fuel price, environmental friendliness and reliability & safety top reasons for consumers' satisfaction with their solar thermal systems; savings and comfort also being the top two key decision factors for buying solar thermal;
- ✓ Environmental matters are very important for solar thermal buyers. Incentives do also play an important role;
- ✓ Brand reliability does matter for solar thermal buyers!

More interesting results could be extracted from the dataset, as time and resources limited the scope of the FROnT project in this area. However, the dataset will be made publicly available, and more research can be carried on by interested stakeholders. Most important areas of further analysis would be to compare results across different countries, and to cross results according to sample characteristics (gender, age, income...). Such analysis could provide additional information on consumers' behaviour on heating and cooling appliances choices, as well as important marketing and social considerations.

Linear tube solar receiver as stratified flow vapor generator/separator for absorption machines using $NH_3/LiNO_3$

Antonio Lecuona-Neumann[1], Rubén Ventas-Garzón[1] Ciro Vereda-Ortiz[1] Mathieu Legrand[1]

[1] Dep. Ingeniería Térmica y de Fluidos, Grupo ITEA, Universidad Carlos III de Madrid, Leganés, Madrid (Spain)

Abstract

Straight receiver tubes of either parabolic trough or Fresnel solar collectors can substitute the vapor generator and the solution separator of an absorption machine for producing cold/heat/power, so that no intermediate thermal fluid is required for transporting heat from the collector field to the machine. This way more compact and simpler layouts are possible. Medium temperature solar collectors are attractive for activating innovative cycle absorption machines for producing cold, pumping heat or producing electricity either single or combined.

Solar heat is absorbed directly by the solution that internally slides in the lower segment of an inclined tube by the effect of gravity yielding refrigerant vapor and concentrated solution in a stratified two-phase flow configuration.

The paper in his first part offers an introduction to this innovative technology and I its second part presents a numerical model for the performance evaluation of the concept, highlighting heat transfer issues. Integral 1D steady-state balances are used to establish equations in a simplified form to accelerate pre-design duties and capture main influencing parameters.

Results indicate that this concept is attractive and offers the potential for reducing the cost and burden of nowadays solar facilities in the small and intermediate size range.

Keywords: *Solar cooling, Two-phase flow, receiver tube, parabolic trough, Fresnel, Medium temperature solar collector, stratified flow, direct vapor production.*

1. Introduction

Solar heating and cooling (SHC) concept has been established as a current technology and is well supported by basic studies, such as (Duffie & Beckman, 1980) among others. Recent reviews confirm its interest, e. g. (Mauthner & Weiss, 2013), (The European Technology Platform on Renewable Heating and Cooling, 2014), as well as its potential in different countries has been analyzed, e. g. (CTAER. Solar Concentra., 2015). Nowadays medium temperature (150 – 250 ºC) solar collectors (MTC) e.g. (Jradi & Riffat, 2012) attract much attention because they enable new solar applications for small and medium scale applications. They offer higher flexibility than fixed geometry low-temperature collectors and enjoy the advances in the technology of high-temperature parabolic troughs collectors (HTC) used in large solar power plants.

Solar cooling by a heat pump consumes the solar heat in a thermal machine, generally following an absorption cycle, (Herold, et al., 1996). Some recent studies confirm its interest for industry and for buildings, e. g. (Henning, 2007) (Baniyounes et al., 2013). Typical application is for air conditioning, such as presented in (Henning, 2007), showing a good efficiency of the cycle owing to the mixture Water/Lithium Bromide used as working fluid. Water freezing limits extracting heat below 0 ºC, as water is used as a refrigerant. Ammonia as refrigerant offer the possibility of refrigerating even below -20 ºC and much experience has been accumulated on its use. Ammonia is a natural refrigerant, widely accepted in industry for its reduction capability of greenhouse and ozone depletion gasses (Danfoss, 2015). The absorption cycles using this refrigerant need higher temperatures on the driving source of energy, making medium temperature solar collectors ideal for that.

Currently, ammonia based absorption machines use the mixture Ammonia/Water (Wu et al., 2014). Several studies have performed on-the-field performance evaluation driving the machine with heated fluid through MT solar collectors (Wang, et al., 2015).

doi:10.18086/eurosun.2016.04.11 Available at http://proceedings.ises.org

Ammonia is good for solar energy storage in combination with absorbents, either solid or liquid, e. g. (Yu, et al., 2013), enhancing its interest in SHC.

Machines using Ammonia/Water need a rectification tower to purify the ammonia vapor reducing minute proportions of water. The solution of Ammonia into Lithium Nitrate salt ($NH_3/LiNO_3$) offers to eliminate this bulky and expensive component, but salt crystallization at the inlet of the absorber must be avoided. This solution offers a lower risk of corrosion than Ammonia/Water. Several studies confirm the potential of this working fluid (Ventas et al., 2010). Some operating test results are available (Hernández-Magallanes, et al., 2014). Even pre-industrial prototypes are now operative (Zamora et al., 2014).

The current layout of a solar cooling facility includes an outdoor primary circuit of a heat transfer fluid (HTF) including anti-freeze capability, a secondary indoor circuit, typically of water, including a heat storage tank and a tertiary circuit of cold water, (Kalogirou S. , 2004) (Lecuona et al., 2009). A heat rejection circuit is also needed when the machine is not air cooled. This leads to a high complexity and high procurement, high maintenance costs and the need of professionals for this. The end result is an increase in the Levelized Cost of Energy (LCOE). In addition, there appears some reluctance to invest, reinforced by the tailored character of every facility. Some studies confirm this appreciation, e. g. "*The lack of an optimized solution is the most critical barrier for rural or off-grid application of CSP*", in (The Carbon Thrust, 2013). Meaning "CSP" Concentrated Solar Power.

Direct steam production is an objective in large solar power plants, e.g. (Eck, et al., 2003) and (Kalogirou et al., 1997) always underpinning the objective of simplification, cost reduction, and higher energy efficiency. In solar cooling facilities, this can also be explored. The working fluid of the absorption machine has to flow partially filling the solar collector receiver tube, this way simplifying the facility and drastically eliminating the cost of heat exchangers, piping, and HTFs. In absorption machines, the liquid phase evaporates only some % of mass. This precludes the dangerous dry-out and rewetting processes. Refrigerant vapor separation is not needed at the outlet as it happens spontaneously thanks to the density difference. Stratified flow favors this, as the liquid phase flows falling under gravity effect in the lower part of an inclined tube, while the vapor phase flows upwards in the opposite direction, already separated, see Fig. 1 as it is progressively heated by the wall. This layout allows reducing the tube peripheral temperature gradients in Fresnel collectors and in parabolic trough ones near midday (Lecuona-Neumann et al., 2016).

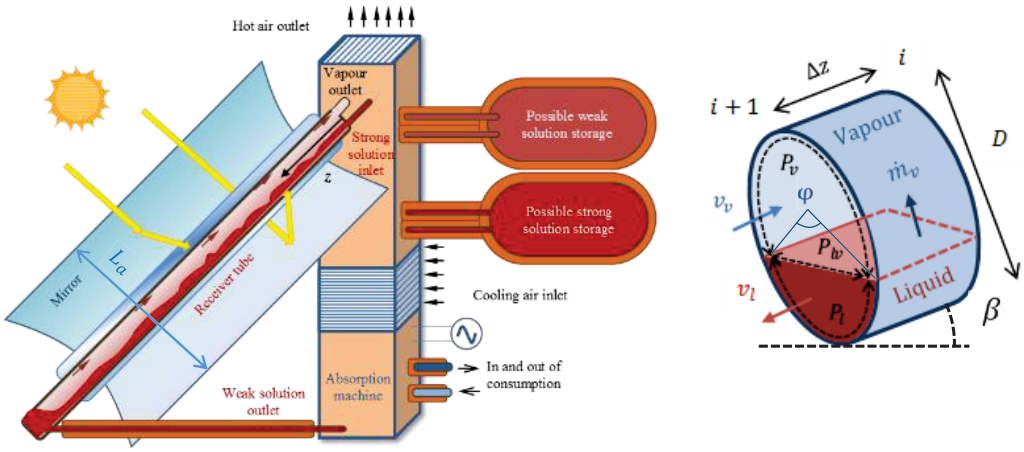

Fig. 1: Left: Scheme of an elementary solar cooling layout with gravity stratified flow in the receiver tube and attached air cooled absorption machine, eventually incorporating energy storage. Right: 1D flow discrete element.

The proposed layout is shown in Fig. 1. It includes an air-cooled absorption machine attached to the solar collector ensemble. This way no indoor building space is consumed for the machine room. Freezing/crystallization of the $NH_3/LiNO_3$ solution is no problem down to around -15 ºC ambient temperature with no specific measures.

The higher driving temperature with MTCs allows the application of advanced cycles (Ventas et al., 2016). This way several opportunities appear to reduce the Levelized Cost of Energy (LCOE) and increase coverage of the user demand: i) cooling capacity boost consuming electricity with the same machine (Vereda et al., 2014),

ii) directly produced or pumped heat production in winter, iii) increased COP using double stage/double effect (Ventas et al., 2016) and iv) even allowing electricity production in periods when neither heat nor cold is needed. NH_3 is suitable for this purpose as it generates high-pressure differentials between condenser and evaporator, allowing expanders to produce work. Small scale MT solar collectors can be built with stationary receiver tubes, thus eliminating the extra cost to avoid NH_3 leaks that are typical in large format high-temperature parabolic trough solar collectors that use articulated tubing.

This paper addresses the basic analysis of the vertically stratified flow using a simplified 1D modeling of the solar collector receiver tube of a circular cross-section, following a sequential calculation process. Stratified flow is assumed. The low velocities involved precludes either annular flow or appreciable effect of waves on the free surface of the liquid, excepting an effective roughness increase, as the inclination of the receiver tube ranges from several degrees up to the local latitude plus solar declination (Wallis, 1969). Application of the model to the promising mixture $NH_3/LiNO_3$ is performed and consequences are obtained aiming at pre-design and optimization duties.

2. Numerical model assumptions

The stratified or wavy-stratified nature of the flow is supported by the moderate mass flux and the relatively high void fraction in the flow, according to (Turgut et al., 2016) among others. Here the liquid phase is gravity driven, such as in (Faccini et al., 2015). Even this, here both flows are counter-current, differently to the most analyzed layout of co-current pressure driven two-phase flow inside typically small diameter tubes, e. g. (Issa R. I., 1988).

The slenderness of the receiver tube(s) of a parabolic trough or Fresnel type solar collector facilitates 1D modeling as a separated stratified flow with no liquid holdup, allowing separate equations and flow variables for both flows (Wallis, 1969). There the full set of governing equations applicable to the opposite direction flows is described in a generic way, as well as the single interphase jump conditions. One difficulty in the proposed layout is that the single outlet of the vapor flow is the accumulation of the opposite liquid flow vapor production and heat transfer, both with the tube wall and the interphase. In addition to that, there is mutual friction at the interphase free surface with the added complication of evaporation. This coupling makes necessary solving a large number of simultaneous equations for balances, fluid properties, and momentum plus heat transfer, when applied to a discrete number of finite elements of the tube along z, Fig.1. This would mean around 10 to 15 equations per element. Momentum and heat balances are not a closed issue when establishing 1D equations across a surface where there is evaporation because the 1D flow is represented by a single average velocity, density, temperature and NH_3 mass fraction. Some issues can be found in (Wallis, 1969) and a complete treatment is presented in (Issa, 1988) for co-current laminar (Ullmann et al., 2004) and turbulent flow with wavy interphase (Ullmann & Brauner, 2006). Fortunately, heat and momentum transfer to the liquid from the vapor flow can be considered negligible without much loss in accuracy for our case, as is supported below.

1D governing equations are coherent with heat and mass transfer correlations for respectively Sherwood and Nusselt numbers, especially when both concentrations and temperatures can safely be averaged in a cross section.

Nusselt number Nu for the liquid and vapour flow are of the same order of magnitude, as well as hydraulic diameters and wall contact areas, but for extreme cases. Thermal conductivity of NH_3 vapour is one to two orders of magnitude less than that of the liquid solution, yielding the heat transfer coefficients in the same proportion. Thus heat transfer from vapour to liquid $\dot{q}_{vl}$ can be considered negligible in front of wall-to-liquid heat transfer rate $\dot{q}_{wl}$. In addition to that the smaller heat capacity of NH_3 makes this flow approaching the wall average temperature $T_w\langle z\rangle$ faster than the liquid, so that $\dot{q}_{wl} \gg \dot{q}_{wv}$. From now on $\langle\ \ \rangle$ means functional dependence. As a consequence the net absorbed, solar heat will be applied only to the liquid as a first approximation.

Friction stress across the interphase is continuous. At the indicated pressure ~ 15 bar one finds $\rho_l \sim 10^2 \rho_v$, the vapor production is about Δx =3-8% in mass. The chosen void fraction $\alpha = A_v/A_l$ is large to minimize ammonia inventory for safety reasons. This makes $v_v \sim v_l$ by mass conservation; actually at the liquid outlet $v_v = 0$ and at the vapor outlet $v_v = \frac{\Delta x}{1-x}\frac{\rho_l}{\rho_v}\frac{v_l}{\alpha}$, see Fig. 2 to 5. This is in contrast with the much studied two-phase co-current flow in evaporators and boilers, whose mission is oriented toward either the full or a substantial phase change, implying significant acceleration near the shared outlet, with the frequent result of

liquid hold up. Friction factors $f_l \sim f_v$ as Reynolds numbers are of the same order of magnitude, mainly owing to the much larger hydraulic diameter of the vapor flow on which they are based, $Re_l \sim Re_v \rightarrow \frac{1}{2}\rho_l(v_l - v_{lv})^2 f_l = \frac{1}{2}\rho_v(v_l + v_{lv})^2 f_v$, the velocity of the interphase v_{lv} is near the liquid velocity v_l. For the case indicated in Fig. 2, at $z = 0$ $Re_l = 3{,}8 \times 10^3$ and $Re_v = 4{,}6 \times 10^3$. In This means that the liquid surface can be considered free of viscous stress with not much loss in accuracy. According to this, the pressure loss of the vapour flow is negligible in front of the tube pressure, which is determined by the saturation pressure of pure ammonia in the condenser of the absorption machine $p_s\langle T_c\rangle$, in the order of 5-20 bar when T_c is atmospheric temperature plus 5 to 10 K. Only needing standard commercial information of the collector is another advantage of this approach.

Similar reasoning will lead to considering limiting the heat transfer coefficient α_v in the mutual heat transfer at the interphase.

According to (Cussler, 2009) p. 504, mass diffusion relaxation time τ in turbulent flows is controlled by the summation of two mutually independent relaxation times, the first one is for the formation of packets of size l and the second one is for molecular diffusion into these packets with coefficient D_{diff}; this datum is obtained from (Infante-Ferreira, 1985). This leads to total a relaxation length L_τ:

$$\left.\begin{array}{r} \tau = \frac{D^2}{4E} + \frac{l^2}{4D_{diff}};\ L_\tau = v_l\tau \\ Pe = \frac{Dv_l}{E} = 2 \\ v_l \approx 2\frac{\mathrm{m}}{\mathrm{s}};\ D \approx 5\ \mathrm{cm} \\ l \sim 30\ \mu\mathrm{m};\ D_{diff} \sim 10^{-5}\frac{\mathrm{cm}^2}{\mathrm{s}} \end{array}\right\} \rightarrow E \approx 500\frac{\mathrm{cm}^2}{\mathrm{s}} \left.\right\} \rightarrow L_\tau = \left(\frac{D^2}{4E} + \frac{l^2}{4D_{diff}}\right) = (0{,}013\ \mathrm{s} + 0{,}2\ \mathrm{s})2\frac{\mathrm{m}}{\mathrm{s}} = 0{,}4\ \mathrm{m} \qquad \text{(eq.1)}$$

With collector length of 4-20 m this indicates that assuming negligible transversal concentration gradients in the liquid bulk is assumable, thus saturation can be accepted at the vapor pressure as a first approximation. Pure NH_3 forms the vapor flow, thus the mass diffusion resistance is null for this vapor flow. For temperature through the interphase, a jump is accepted between both well-mixed vapor and liquid flows as a reasonable assumption, in the turbulent regime for the resultant Reynolds numbers Re. No hydraulic pressure is considered in the liquid.

As a consequence, and in order to develop a comprehensive model, the simplifying assumptions are steady state and well mixed fully developed flows, flat free interphase with a rough surface owing to low amplitude waves, saturation equilibrium at the adiabatic interphase for liquid flow, but diabatic for vapor flow at constant pressure. Radiation and buoyancy are negligible effects inside the tube. Friction of the gas phase is negligible for the liquid flow. Constant liquid central angle φ ($\varphi = \pi$ for diameter) derives into constant falling velocity v_l $\forall z \in [0, L]$. Constant wall temperature T_w is assumed around the tube periphery, but variable along z. Solar radiance is constant along z.

Comprehensive models have been developed for the local efficiency of the parabolic trough solar collector and the subsidiary calculation of the tube wall temperature, e. g. (Forristal, 2003). For the lower optical concentration that MTCs have in comparison with HTCs and for liquid flow, the temperature average difference between wall $\bar{T}_w$ and fluid $\bar{T}$ is small, in the order of 20 ºC. This allows using the local average wall temperature instead of the fluid temperature averaged from inlet to outlet, not hindering the accuracy of the model. On the other hand this reduces the computing load substantially and allows to use available commercial information in solar collector performance. For simplicity it is acceptable using the reduced characteristic efficiency equation (no wind, no axial incidence, steady-state) determined according to standards such a (ISO/DIS 9806, 2016). As the characteristic curve is quite horizontal at the usual values of T not compromising error is expected. This curve is reduced to:

$$\eta\langle T_w\rangle = a_0 - \frac{a_1(T_w - T_{amb}) - a_2(T_w - T_{amb})^2}{G_{Tb}} \qquad \text{(eq.2)}$$

G_{Tb} is the tilted beam irradiance.

3. Numerical model setup

Terminal liquid velocity is assumed to happen just at the inlet. As a consequence average falling velocity

derives from the balance between gravity and wall friction, resumed into a Darcy friction factor $f_{D_{h,l}}$, function of the liquid hydraulic diameter through the liquid flow Reynolds number Re_l and the relative roughness of the wall $\varepsilon_r = \varepsilon/D_h$, where ε is the absolute equivalent roughness.

$$v_l^2 = \frac{2g\sin(\beta)D_{hl}\langle\varphi\rangle}{f_{D_{hl}}\langle Re_l,\epsilon_r\rangle};\ D_{hl}\langle\varphi\rangle = \frac{4A_l\langle\varphi\rangle}{P_l\langle\varphi\rangle};\ A_l\langle\varphi\rangle = \frac{D^2}{8}(\varphi - \sin\varphi);\ P_l\langle\varphi\rangle = \frac{D}{2}\varphi\ ; Re_l = \frac{4\dot{m}_l}{\mu_l\langle x,T\rangle D_{hl}} \quad \text{(eq.3)}$$

This expression neglects the momentum transfer by evaporation (Wallis, 1969), negligible in our case. This is an approximation that fits well into other analytical approximations, such as (Hetsroni, 1982) p. 2-84, originally by (Taitel & Dukler, 1976), although that considers the coflowing configuration. An implicit continuity equation allows solving for liquid central angle $\varphi\ \forall z\ \epsilon\ [0, L]$ for a given liquid mass flow $\dot{m}_l$, applied to the inlet ($_{in}$):

$$\rho_l\langle x_{in}, T_{in}\rangle v_l A_l\langle\varphi\rangle = \dot{m}_l \quad \text{(eq.4)}$$

The liquid density ρ_l is function of the local NH_3 mass fraction x and liquid temperature T. At the liquid inlet $z = 0$ ($_{in}$) pressure p is equal to the saturation of pure ammonia at the machine condenser $p_{s,NH_3}\langle T_c\rangle$. At the same point we consider, saturated inlet of the liquid solution. Subcooled or superheated solution is not considered here. Constancy of pressure both across the interphase and along z in addition to the saturation condition allow determining the NH_3 mass fraction x at any axial location z, including the outlet $z = L$ ($_{ou}$), $i = n$ when T were determined for any z:

$$p_l\langle x_{in}, T_{in}\rangle = p_l\langle x_{ou}, T_{ou}\rangle = p_l\langle x, T\rangle = p_{s,NH_3}\langle T_c\rangle \doteq p \quad \text{(eq.5)}$$

The machine condensation temperature T_c is the ambient temperature T_{amb} plus 5º to 10 ºC, depending on the heat rejection parameters. This assumption neglects the pressure decrease towards $z = 0$ because of friction and gravity and also because of the accelerating vapour flow that appears as a consequence of the accumulation of evaporation from $z = L$ down to $z = 0$. Its order of magnitude is $\rho_v v_v \frac{\partial v_v}{\partial z} L \sim \rho_v \left[\frac{(x_{in}-x_{ou})\dot{m}_l}{\rho_v A_v}\right]^2$, negligible in front of p.

As a consequence of constant pressure and saturation both x and T for the liquid are related this way:

$$\mathrm{d}p\langle x, T\rangle = 0 = \frac{\partial p}{\partial x}\mathrm{d}x + \frac{\partial p}{\partial T}\mathrm{d}T \rightarrow \frac{\mathrm{d}x}{\mathrm{d}T} \doteq x_T\langle x, T\rangle = -\frac{\partial p}{\partial T}\Big/\frac{\partial p}{\partial x} \quad \text{(eq.6)}$$

Only transversal heat transfer is considered, neglecting it in the z direction. Wall temperature tangential and radial gradients are considered negligible. Wall temperature T_w can be determined along z assuming that all the absorbed heat is transferred to the liquid, through a heat balance, where the heat transfer coefficient is α_{wl} and the aperture width of the mirror is L_{ap} (Fig. 1) on which a beam irradiance G_{Tb} is normal:

$$T_w = T_{amb} + \frac{\left(b^2+4a\right)^{0.5}-b}{2}\ ;\ a = (T - T_{amb})c + \frac{G_{Tb}a_o}{a_2};\ b = \frac{a_1}{a_2} + c\ ;\ c = \frac{P_{tl}\alpha_{wl}}{a_2 L_{ap}}\ ;\ P_{tl} = P_l \quad \text{(eq.7)}$$

For the local heat transfer coefficient α, either for liquid or vapour flow, a Gnielinski correlation (Gnielinski, 1976) has been chosen for the Nusselt number Nu in the turbulent regime ($2{,}300 < Re_{D_h}$) including the Prandtl number $Pr = c_p\mu/k$ and the friction factor from (Haaland, 1983) ($4{,}000 < Re_{D_h}$). Correction for the entrance region has been chosen from (Al-Arabi, 1982), referred in (Sigalés, 2003) p. 645. Correction for vapor transpiration at the interphase is neglected.

$$\alpha = Nu\frac{k}{D_h};\ Nu = \frac{\frac{f}{8}\left(Re_{D_h}-1000\right)Pr}{1+12.7\left(\frac{f}{8}\right)^{\frac{1}{2}}\left(Pr^{\ 2/3}-1\right)}\underbrace{\left(1 + 2.8(1-0.8)\left(\frac{D}{z}\right)^{0.8}\right)}_{C_{en}}\ ;\ f = -1.8\log\left(\left(\frac{\epsilon_r}{3}\right)^{1.11} + \frac{6.9}{Re_{D_h}}\right) \quad \text{(eq.8)}$$

The entry length correction C_{en} is for local Nu, here considered on the high side of the several formulae found in the literature, but not the highest. No correction has been implemented in α_{lv} because of vapour blowing out of the liquid free surface ($\dot{m}_v$) as it is of low magnitude (Sigalés, 2003).

The explicit (eq.4) allows calculating T progressively from inlet to outlet through the net solar heat received by a finite element Δz, between control surfaces i and $i + 1$. Using an Euler explicit advancing scheme this leads to:

$$T_{i+1} = T_i + \frac{L_{ap} G_{Tb} \eta \langle T_w \rangle}{\dot{m}_{l,i}(c_l - c_x)_i} \Delta z \; ; c_x = x_T \frac{\partial h}{\partial x} ; T_0 = T_{in} \quad \text{(eq.9)}$$

$c_x < 0$ takes into account the evaporation, acting as an increased effective specific heat c_l for the liquid. The increase in temperature leads to a decrease in x and the corresponding production of vapour at each element $\dot{m}_v$:

$$x_{i+1} = x_i + x_T(T_{i+1} - T_i) \; ; z = L \; \rightarrow x_{ou} = x_n \quad \text{(eq.10)}$$

In order to check the validity of assuming constant φ and v_l, local liquid mass flow can be corrected by:

$$\dot{m}_{l,i+1} = \dot{m}_{l,i} - \dot{m}_{v,i+1} \quad \text{(eq.11)}$$

And verify that the loss in mass can be just up to around 3%-8% along L. The accumulated vapour at point i can be calculated afterwards. The vapour velocity could be calculated when its temperature T_v is previously calculated:

$$\dot{m}_{av,i} = \sum_{j=n}^{j=i} \dot{m}_{v,j} \; ; \; n = \frac{L}{\Delta z} \; ; v_v = \frac{\dot{m}_{av,i}}{\rho_v \langle p, T_v \rangle} \quad \text{(eq.12)}$$

T_v at station i, is the result of mixing from $j = n$ down to $j = i$ and the cumulative heating from the walls and free surface of the liquid. Both of them must result in a negligible figure in front of the heat transferred from walls to the liquid for the simplifying assumptions to be valid. Assuming an average $c_{p,v}$ in the mixing process:

$$T_{v,i-1} = \frac{\dot{m}_{v,i} T_{v,i} + \frac{\left[\alpha_{wv,i}\left(T_{w,i} - T_{v,i}\right) P_v + \alpha_{v,i}\left(T_i - T_{v,i}\right) P_{lv}\right]}{c_{pv,i}}}{\dot{m}_{av,i} + \dot{m}_{v,i}} \; ; T_{v,n} = T_n \quad \text{(eq.13)}$$

4. Fluid properties

Ammonia properties are evaluated using the FluidMAT® software (Kretzschmar, Stoecker, Kunick, & Blaeser, 2015), mainly based on Tillner-Roth formulation (Tillner–Roth et al., 1993).

Ammonia/Lithium Nitrate solution properties are not so well documented. The properties of (Libotean et al., 2007) and (Libotean, et al., 2008) were used, extended for lower ammonia mass fraction and higher temperatures from data of the same source, still to be published. These results were checked against (Farshi et al., 2014) for enthalpy, correcting the reference datum. Thermal conductivity was obtained from (Cuenca et al., 2014). Crystallization boundary data, originally from (Infante Ferreira, 1984) were reported in (Wu et al., 2013). The adaptation was performed to formulate the boundary line in a more convenient form for the model.

5. Results

First, some characteristic data are presented and then a parametric study shows the results. Maximum representative irradiance has been taken into account $G_{Tb} = 800$ W m^{-2}, no wind and steady-state operation with an ambient temperature $T_{amb} = 30$ ºC.

The model can be applied to a representative MTC, in this case, the Abengoa PT-1 small scale MTC, shown in Tab. 1 (Solar Rating & Certification Corp., 2014).

Tab. 1: Basic data for the representative concentrating MTC Abengoa-IST PT-1. Effects of wind, sky infrared radiation and incidence are ignored. * for reported net aperture surface.

L_{ap} * [m]	L * [m]	$a_0 \equiv F'(\tau\alpha)_{en}$ [-]	a_1 [W m^{-2}K^{-1}]	a_2 [W m^{-2} K^{-2}]	Original fluid	T_{max} allowed [ºC]
2.2	6.0	0.71	0.3581	0.0019	water	250

For the inlet conditions, the condenser temperature chosen is $T_c = T_{amb} + 10$ K. This corresponds to $p = 15.5$ bar. Choosing an inlet temperature $T_{in} = 100$ ºC this corresponds to $x_{in} = 0.428$, thus no subcooling is considered in this case, neither the presence of bubbles at the inlet. A large inclination angle $\beta = 40$ º will be near optimum for capturing sun rays at mid-latitudes, for a collector oriented toward the equator, e. g. Madrid (Spain). $G_b = 800$ W m^{-2}, this is a compromise between the highest expected with the adequate collector inclination β around noon during a clear day and tracking the sun with a single axis, around 1.000 W m^{-2}, and an average figure because of some longitudinal incidence and cloudiness.

The flow evolution for this case is shown in Fig. 2 with some extra data indicated in the caption. It is worth to highlight:

- The evolution of the flow variables is linear, excepting wall and to a lower extent vapor temperatures. This is a consequence of the increase of α_l; α_v and α_{lv} in the entry region, around 0.5 to 1.0 m. Eliminating this correction in α (eq.8) eliminates these non-linearities. This would occur in a second additional collector located downstream the first one, Fig. 3.
- The downstream increase of T_w, does not substantially affect the local efficiency of the collector η, owing to its high stagnation temperature. This supports using the characteristic efficiency curve with T_w (eq. 2) instead of calculating the collector heat losses. The resulting average efficiency is $\eta_{av} = 0.64$.
- T_l increases up to 136 ºC in this case. This implies: a) a lower rate of the decrease downstream (decrease along z) of the vapor temperature T_v, as it is the result of mixing of vapor produced upstream b) wall heating near the exit and cooling near the inlet c) liquid cooling all along. In order to indicate the proportion of cooling by the liquid, $T_{v,a}$ indicates exclusion of any heat transfer. $T_{v,ou} = 117$ º; $T_{va,ou} = 115$ ºC. These temperatures are higher than the liquid inlet wall temperature at the same station, $T_{w,in} = 109$ ºC.
- There is a fairly constant difference between wall and liquid temperatures downstream the entrance region, 9 ºC at the inlet and around 15 ºC downstream the entrance length.
- $x_{ou} = 0.344$, meaning an 8.41% decrease from the inlet. This means a crystallization temperature of 15 ºC.

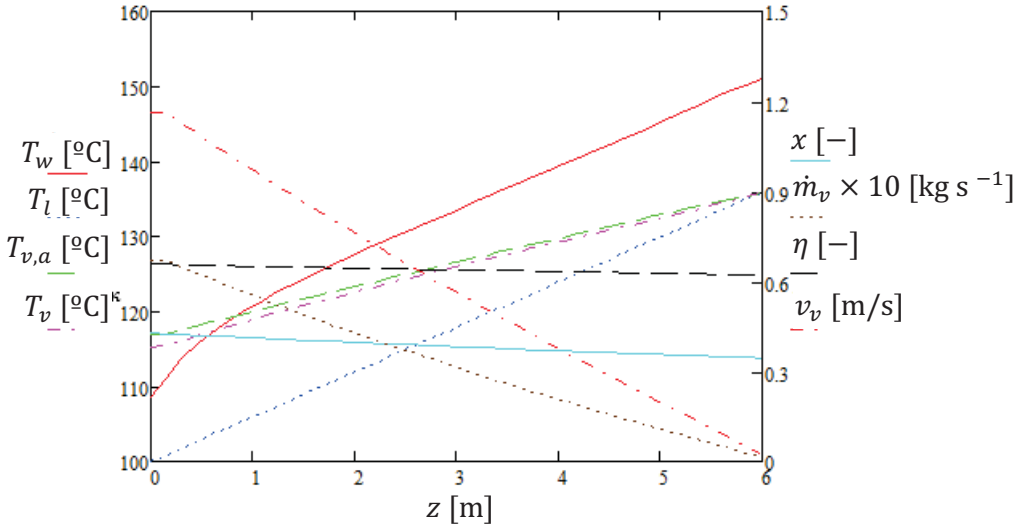

Fig. 2: Evolution along z of flow variables with $L = 6$ m; $D = 3$ cm; $m_l = 0.0833$ kg s^{-1}; $\beta = 40$ º; $\varepsilon = 0.1$ mm; $\varphi = 90$ º; $v_l = 1.32 \frac{\text{m}}{\text{s}}$.

One interesting question is how the length of the collector L affects the performance for constant mass flow. Fig. 3 uses the same input condition than Fig. 2 (ceteris paribus) but doubles the length of the collector, $L = 12$ m. The cooling of the vapour now is, $T_{v,a} - T_v = 6$ ºC. $x_{ou} = 0.28$, resulting in a crystallization temperature of 47 ºC, thus impeding operation of the absorption machine unless mass flow rate is increased. This is the logical choice as the solar power will be around twice. Fig. 4 shows the results of doubling the mass flow ceteris paribus; $x_{ou} = 0.343$.

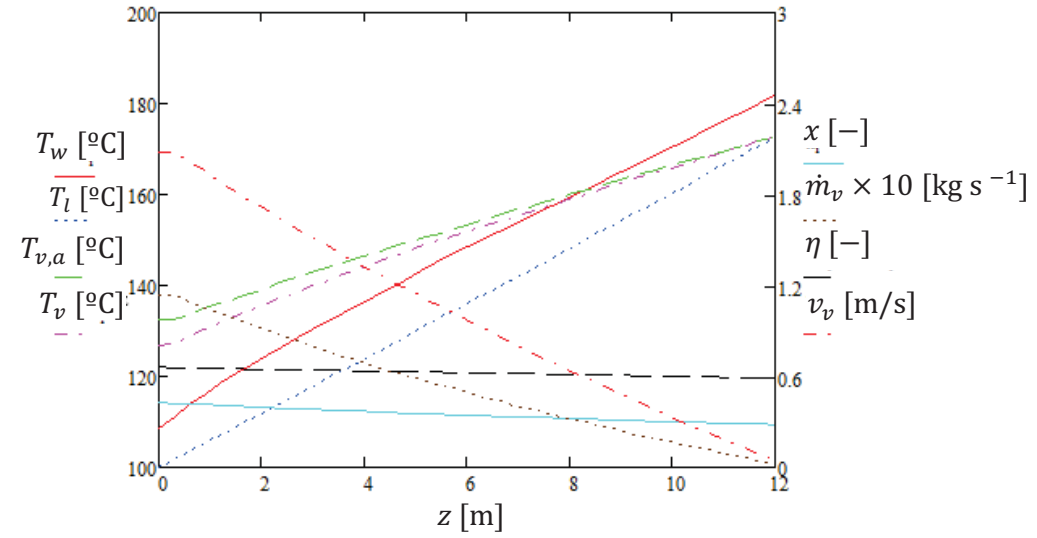

Fig. 3: Evolution along z of flow variables with $L = 12$ m $D = 3$ cm; $m_l = 0.0833$ kg s^{-1}; $\beta = 40$ º; $\varepsilon = 0.1$ mm; $\varphi = 90$ º; $v_l = 1.32 \frac{\text{m}}{\text{s}}$.

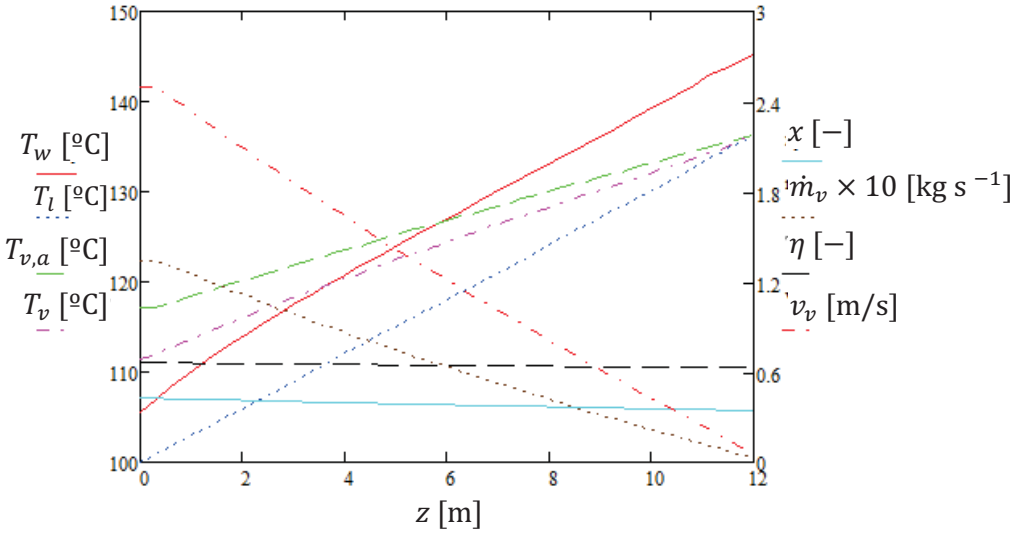

Fig. 4: Evolution along z of flow variables with $L = 12$ m $D = 3$ cm; $m_l = 0.167$ kg s^{-1}; $\beta = 40$ º; $\varepsilon = 0.1$ mm; $\varphi = 108$ º; $v_l = 1.61 \frac{\text{m}}{\text{s}}$.

The possibility of selecting different inclination facilitates the installation in different ceiling surfaces of buildings. Thus the effect of changing inclination angle β is interesting. Fig. 5 shows decreasing down to 5 º. This is valid for equatorial locations with the same G_b, but lower values should be expected at higher latitudes. The result is partially similar to the ones presented in Fig. 2, $x_{ou} = 0.344$; this means the same vapour production with the 40 º inclination, ceteris paribus, but the wall temperature is higher, although not affecting η. This is an interesting results as it indicates that the inclination angle can be widely changed. Now vapor suffers a small net heating.

Simplifying hypothesis now do not hold so well owing to the increased φ implying an increase in depth of the liquid vein that would limit reaching near NH_3 equilibrium in the bulk liquid flow. The lowest Reynolds number is for this case, $Re_l = 3{,}780$.

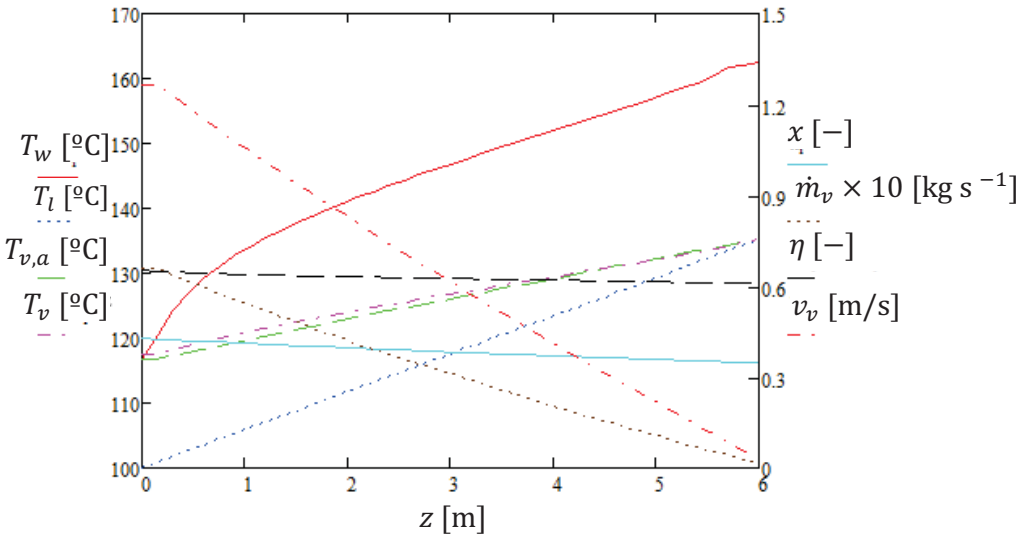

Fig. 5: Evolution along z of flow variables with $L = 6$ m; $D = 3$ cm; $m_l = 0.0833$ kg s^{-1}; $\beta = 5$ º; $\varepsilon = 0.1$ mm; $\varphi = 116$ º; $v_l = 0.67 \frac{\mathrm{m}}{s}$.

6. Conclusions and further work

Reasonable simplifications lead to the development a comprehensive 1D model of the flow evolution along the receiver tube of a parabolic trough solar collector under separated stratified two-phase flow. This model allows a sequential calculation that almost avoids iterations, excepting the liquid angle φ single equation calculation. The results support the simplifying assumptions. The model emphasizes the heat transfer process under evaporation in a MT solar collector.

The moderate heat flux from wall to liquid, always below 10 kW/m^2, the large interphase surface and temperature differences between the wall and liquid smaller than 5 K allow to be confident on the absence of significant bubble formation, thus nucleate boiling does not have to be taken into account excepting the lowest inclination angle, such as $\beta = 5$ º, Fig. 4 (Ghoshhdastidar, 2004). This large temperature difference, in spite of the low heat flux, is due to the small heat conductivity of the solution $k_l \approx 0.3$ W m^{-1}K^{-1} in comparison to water.

The innovative operation of a solar collector here described is meant for its application as a vapor generator and separator of an integral absorption machine using the promising solution $NH_3/LiNO_3$. This allows cold production at subzero temperatures using medium temperatures of the driving heat in the range of 100-200 ºC. This working fluid allows other possibilities, such as COP larger than 1.0 if double effect is used, electric backup if a hybrid cycle (Vereda, et al., 2014) is used and presumably electricity production using an expander in the refrigerant branch of the cycle.

The counter-flow layout allows minimizing heating of the vapor, owing to the cooling effect by the liquid and also by the wall near the liquid inlet. This is favorable for the operation of the absorption machine as a chiller, reducing the load of the condenser and increasing the collector efficiency. For producing power an alternative coflowing layout would be favorable because the higher is the vapor temperature the higher is the enthalpy at the inlet of the expander. Thus the enthalpy jump is higher.

Further work will likely include the effects of the mass transfer resistance in the liquid and the non-uniform transversal temperature in the tube wall, using newly developed simplified calculus (Lecuona-Neumann et al., 2016). Another line of work would be to study the evolution when the solution enters the tube subcooled or superheated. The inclusion of some correction for the interphase heat transfer in eq. 9 will increase the accuracy of the model. Experimental validation is under work.

7. Acknowledgements

The partial funding of the research project “Tecnologías energéticas térmico-solares y de aprovechamiento de calores residuales a baja y media temperatura integradas en la red eléctrica”, ENE2013-45015-R from the

Spanish Ministerio de Economía y Competitividad is greatly appreciated.

Abstract

A steady-state analytical-numerical heat conduction model has been developed for the peripheral temperature profile in the wall of a straight receiver tube applicable to either parabolic trough or Fresnel solar collectors using innovative counterflow two-phase flow. It uses the slender 1D fin model of heat conduction along the tube wall periphery, which gives an analytical solution to be coordinated with boundary conditions. Constant heat transfer and solar incident irradiance are assumed on finite angle sectors of the tube periphery. This allows consideration for irradiance inhomogeneities and/or two-phase internal flows.

The model has been applied using parameters representative of medium temperature collectors of innovative design. Inside them, a sliding liquid film is established under the effect of gravity vertically stratifying a liquid/vapor two-phase flow. This flow configuration is considered for direct vapor generators/separators for advanced solar driven absorption machines and power plants.

The results show that for a circular tube with wall thicknesses large enough for withstanding typical pressures the peripheral temperature inhomogeneity is reduced. The inhomogeneity increases in the non-central hours of the day above the inhomogeneity found in the central hours of the day. This is so especially if the liquid film is shallow and for parabolic trough solar collectors.

Keywords: *Solar cooling, receiver tube wall, parabolic trough, Fresnel, Medium temperature solar collector,*

1. Introduction

1.1 Solar thermal

Solar heating and cooling (SHC) concept has been established as a current technology but still developing. It is well supported by basic studies, such as (Duffie & Beckman, 1980) among others. Nowadays medium temperature (150 – 250 ºC) solar collectors (MTC) e.g. (Jradi & Riffat, 2012) attract much attention because they enable new solar applications for small to medium scale applications. They offer higher flexibility than fixed geometry low-temperature collectors and enjoy the advances in the technology of high-temperature collectors (HTC) of either parabolic trough or Fresnel type collectors used in large solar power plants.

1.2 Absorption and working fluids

Producing cold with the solar heat is an attractive technology, especially for the synchronicity of sun and cold demand.

Absorption machines consume the heat collected from the sun and work as a thermochemical heat pump, following a thermodynamic cycle. They can work either as chillers or as heaters when respectively the useful effect is evaporating or condensing a refrigerant vapour, the same as in mechanical compression cycles (Herold, et al., 1996).

doi:10.18086/eurosun.2016.04.17 Available at http://proceedings.ises.org

Ammonia as refrigerant offer the possibility of refrigerating even below -20 ºC and much experience has been accumulated on its use. Ammonia is a natural refrigerant, widely accepted in industry for its capability of reducing greenhouse and ozone depletion gasses (Danfoss, 2015). The absorption cycles using this refrigerant need higher temperatures on the driving source than with water as a refrigerant when the working fluid is the solution Water/LiBr. This makes medium temperature solar collectors ideal for application to ammonia absorption cycles.

Currently, ammonia based absorption machines use the mixture Ammonia/Water as working fluid (Wu et al., 2014). Several studies have performed on-the-field performance evaluation driving the machine with heated fluid through MT solar collectors (Wang, et al., 2015).

Machines using Ammonia/Water need a rectification tower to purify the ammonia vapor for reducing minute proportions of water. The mixture Ammonia/Lithium Nitrate ($NH_3/LiNO_3$) does not need this bulky and expensive component, but salt crystallization at the inlet of the absorber is a risk. The absence of water reduces corrosion. Several studies confirm the potential of this working fluid (Ventas et al., 2010). Some operating test results are available (Hernández-Magallanes, et al., 2014). Even pre-industrial prototypes are now operative (Zamora et al., 2014). Ammonia as refrigerant implies pressures in the order of 15 bar in the vapour generator.

The current layout of a solar cooling facility includes: a) an outdoor primary circuit of a heat transfer fluid (HTF) including anti-freeze capability, b) a secondary indoor circuit, typically using water, including a heat storage tank and c) a tertiary circuit of chilled water for cold delivery, (Kalogirou S. , 2004) (Lecuona et al., 2009). A heat rejection circuit is also needed when the machine is not air cooled. This leads to a complex facility and the corresponding high procurement and maintenance costs, frequently requiring professionals for maintenance. Efforts toward improving competitivity seem of value for the dissemination of solar polygeneration technology.

1.3 Direct steam production

Direct steam production has been explored and continues to be explored in large solar power plants, e.g. (Eck, et al., 2003) and (Kalogirou et al., 1997). In solar cooling facilities, this can also be of interest, although there is not much work available on that in the open literature. For direct refrigerant vapour production in an absorption machine one proposal would be that the working fluid slides freely inside an inclined receiver tube along its length, partially filling it, see Fig. 1. Stratified two-phase flow favors vapour separation, as the liquid phase flows falling under gravity effect in the lower part of an inclined tube (angle β in Fig. 1) progressively evaporating the refrigerant in a fairly homogeneous way. As a consequence the vapour phase flows upwards in the opposite direction, already separated. In (Lecuona et al., 2016) the details and advantages of this layout are described.

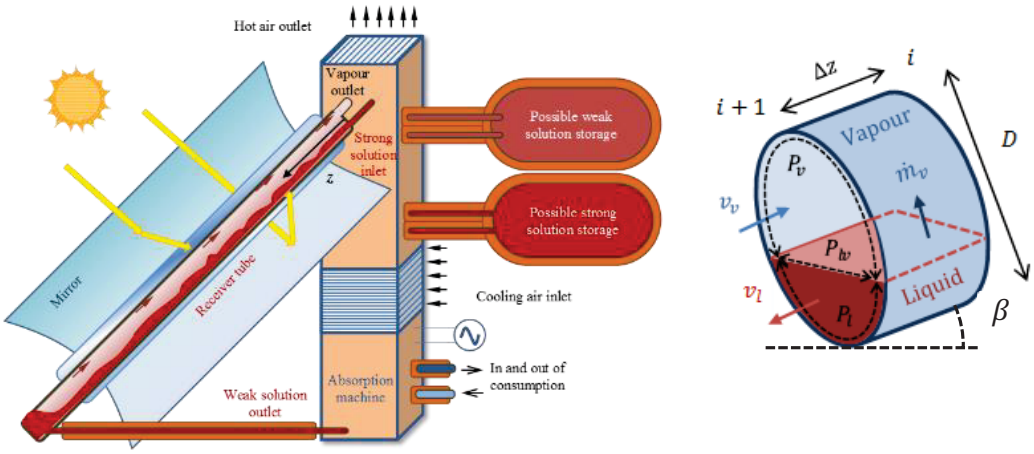

Fig. 1: Left: Scheme of an elementary solar cooling layout with stratified flow in the receiver tube and attached air cooled absorption machine, eventually incorporating two external storage tanks for energy storage. Right: 1D flow discrete element.

The higher driving temperature attainable with MTCs allows reaching innovative solar systems using advanced cycles (Ventas et al., 2016). This way, several opportunities appear to reduce the payback period of the solar system and increase coverage of the user demand. As a result cooling capacity can be boosted consuming electricity with the same machine (Vereda et al., 2014). In winter solar direct and/or pumped heat can be produced. Increased *COP* can be attained using double stage/double effect (Ventas et al., 2016). In addition to that production of electricity is possible in periods when neither heat nor cold is needed. The vapors of NH_3 are suitable for this purpose as it generates high-pressure differentials between condenser and evaporator of the absorption machine, allowing to easily produce work using expanders or turbines. Small scale MT solar collectors can be built using stationary receiver tubes, thus eliminating the extra cost to avoid NH_3 leaks. This is one risk in large format high-temperature parabolic trough solar collectors as they use articulated tubing.

1.4 Objectives of the paper

The receiver tube in linear solar thermal concentrators, such as parabolic trough or Fresnel types, is subjected to bending because of the differential heating between the concentrated sun-irradiated part and the non-irradiated part, typically the upper sector along the tube. This framework can be complicated if a two-phase flow develops inside the tube. Boiling regime is sometimes established when direct steam production is searched for, in conventional solar/electric power plants. This will imply a non-constant peripheral heat transfer to the flow. A higher inhomogeneity develops for a stratified two-phase internal flow. This unconventional flow distribution appears in a novel research area, above described.

There is not much information on the transversal temperature distribution on the wall with this particular flow and irradiation configuration, excepting for other applications, such as (Logie et al., 2015), (Eck et al., 2004), among others. One can expect that when the concentrated solar rays impact on the lower sector of the tube the liquid will evacuate heat at a higher pace that the vapor does in the upper non-irradiated sector of the tube (excepting secondary optics effect). This way there is a compensating effect. In a parabolic trough collector during the morning and afternoon, the sun impacts on the tube laterally so that there is the possibility of overheating as a high irradiance can impact on a vapor flow region. As described in (Lecuona et al., 2016) for the layout described above and schematized in Fig. 1, the vapor can have a lower temperature than the tube wall, but also a higher temperature; thus a practical procedure for calculating the temperature profile around the tube geometry seems useful.

The simulation of the whole solar cooling installation is generally pursued, becoming a complex but accurate model, as complex CFD codes and large computers are required, e. g. (Lobón et al., 2014). Some efforts on simplification are evident (Ahmed, 2014). In order to reduce modeling cost, there is an interest on low order models that keep the relevant physics, thus valid for preliminary studies.

The calculation of the temperature distribution on the wall of the receiver tube is well addressed decomposing the tube wall perimeter in a numerous ensemble of finite elements and applying the combined tangential-radial 2D heat conduction equation, including heat application and/or heat transfer in the radial direction. Axial heat conduction is frequently neglected owing to the much lower temperature gradient in this direction, excepting near brackets. The resolution of a large set of algebraic linear governing equations is performed in a standard way, delivering precise enough temperatures. Reducing the problem to 1D allows considering tangential conduction on top of the radial conduction, thanks to the linearity of the governing equations.

This paper addresses the simplified calculation of the temperature distribution on the periphery of the tube. In order to avoid the excessive computer load of a finite elements calculation, at each axial stage of the tube, the exact 1D analytical solution of the heat conduction equation is invoked. This is typically called the fin approximation (Incropera, De-Witt, 1990). A single explicit algebraic equation is needed for each peripheral segment with constant heat transfer, either toward the ambient or towards the inner fluid and constant irradiance. The fins are each other connected to complete the periphery of the tube. Solving a set of

simultaneous linear equations gives the temperature distribution. This can be done analytically in order to get an explicit overall solution, but excepting the simplest cases, the expression gets too large. Consequently, numerically solving the linear system yields a fast and numerically stable solution.

This paper describes a simplified calculation scheme for the steady-state peripheral distribution of the thickness-wise average temperature in the wall of a receiver tube of a linear solar collector with especial emphasis on MT collectors. The external net irradiance is assumed known as well as the heat transfer coefficients in different perimeters of the internal flow.

1.5 Preliminary considerations

From now on $\langle \quad \rangle$ indicates functional dependence. The longitudinal distribution of temperature $T\langle x\rangle$ by conduction along the length L in extended surface bodies that are geometrically slender $\frac{L}{A^{0.5}} \gg 1$ and thermally slender $\frac{\alpha t}{k} \ll 1$ accepts a 1D analytical approximation for some cross sectional area $A\langle x\rangle$ distributions. Such are pins and fins, not having to be straight, but with central line curvature radius $r_{av} \gg t$, being t the material thickness. Additional requirements are constant: a) heat conductivity k, b) lateral heat transfer coefficient α and c) heat added/generated per unit of lateral area g. Although the wall in our case exhibits varying temperature along its periphery it is usual to use a constant average heat transfer coefficient from experimental correlations for a single-phase flow, even in the case of adiabatic portions of the wall. Although under different operational conditions (Yang et al., 2012) indicates low inhomogeneities in the Nusselt number of a collector tube. With this generalized practice, only care must be taken to register the adequate hydraulic and thermal diameters of the cross section and eventually to correct if they are different (Sigalés, 2003) and (Lecuona et al., 2016) among others.

This extended surface theory is much used in basic texts, such as (Incropera & DeWitt, 1990) and with more detail in (Sigalés, 2003), among others. A single ordinary linear differential equation results for the temperature T distribution along the large coordinate x:

$$\frac{\mathrm{d}^2 T\langle x\rangle}{\mathrm{d}x^2} - \frac{\alpha P}{kA}\left(T\langle x\rangle - T_\infty\right) + \frac{g}{k} = 0 \qquad \text{(eq.1)}$$

P is the wetted perimeter and T_∞ the unperturbed fluid temperature used for α.

This model is used for determining the peripheral wall temperature of the receiver tube, assuming $x = r\phi$, where ϕ is the circumpherential central angle, thus neglecting curvature effects besides considering that the inner radius is smaller than the outer radius. A fin is used for every segment of periphery where the conditions are fulfilled, actually constant α, T_∞ and g. These segments will fulfill the boundary conditions with the neighbor ones in order to complete the full periphery. These boundary conditions fully determine the problem and require the simultaneous resolution of a small number of linear algebraic equations. The peculiarities of our case are:

- There are two temperatures T_∞, for heat transfer: internal T_i for either liquid ($_l$) or vapor ($_v$) and external for losses to ambient T_e. Each one has its own heat transfer coefficient, respectively α_i and α_e.
- On the external side, there is a concentrated incident solar irradiance, affected by optical losses, determining an equivalent per unit volume heat generation g.

This simplification is relevant for larger models, such as of an entire solar collector. In these models ease of use, simplification and speed of calculation are important, not neglecting the stability of the numerical algorithm. In our case of stratified two-phase flow, it serves as a tool for preliminary optimization.

2. Numerical model development

The one-dimensional heat transfer for the wall temperature T along the periphery central angle ϕ , Fig. 2, is given by reformulating eq. 1 using the internal and external heat transfer coefficients α_i and α_e. Wall thickness is t and average receiver tube radius, assumed circular, $r_{av} = r_i + \frac{t}{2}$; $w = \frac{t}{r_i}$:

$$\frac{\mathrm{d}^2T}{\mathrm{d}\phi^2} - m^2T = -T_\mathrm{I};\ m^2 = \frac{r_{av}[\alpha_i+\alpha_e(1+w)]}{kw};\ T_\mathrm{I} = \frac{T_i\alpha_i+(T_e\alpha_e+G_{bT}S)(1+w)}{kw} \quad \text{(eq. 2)}$$

Tilted incident solar irradiance on the aperture of the collector is G_{bT} and $S = Ca_0$ is the number of incident suns on the receiver tube; it is the product of the purposely defined geometric concentration $C = L_{ap}/P_s$ times the total optical efficiency of the solar collector a_0. L_{ap} is the mirror(s) aperture width, perpendicular to the axial coordinate z. P_s is the total perimeter of the receiver tube radiated; thus in a first approximation the irradiance on the tube is considered constant either concentrated, direct ($C = 1$) or null, see Tab. 1. Extension to more elaborate layouts is straightforward.

There are widely used codes for the calculation of the external heat transfer coefficient α_e, e. g. (Forristal, 2003), among others as it the series and parallel composition of radiation, conduction, and combined convection heat transfers. Here a practical way is adopted, needing only commercial information, widely available, without needing to know details of the construction and materials of the collectors.

For a three-term efficiency standard curve of the solar collector, according to (ISO/DIS 9806, 2016), with an estimated overall averaged wall temperature T_{est} and an ambient temperature T_e it follows that under nominal steady-state operating conditions with no wind and no axial incidence, α_e can be estimated as:

$$\alpha_e = \frac{[a_1+a_2(T_{est}-T_e)]L_{ap}}{2\pi r_e} \quad \text{(eq.3)}$$

Further corrections are possible, according to the standard prescriptions.

We assume all parameters in eq. 2 constant, excepting dependent variable T and angle independent variable ϕ. This makes the differential equation linear non-homogeneous, admitting a well-known analytical solution as the addition of a general exponential solution plus a particular solution T_{pj}, Tab. 1. For a generic segment j can be expressed as:

$$T_j\langle\phi\rangle = T_{C1j}e^{m\phi} + T_{C2j}e^{-m\phi} + \underbrace{\frac{(T_e\alpha_e+G_{bT}S)(1+w)}{\alpha_i+\alpha_e(1+w)}}_{T_{pj}} \quad \text{(eq. 4)}$$

The peripheral temperature distribution $T\langle\phi\rangle$ is determined by imposing temperature continuity and energy balance by peripheral conduction at both ends of each peripheral sector using this analytical solution that linearly depends on two boundary constants, actually characteristic temperatures, T_{C1j} and T_{C2j}. They are free boundary conditions for segment j, Fig. 2. Namely:

$$T_{j-1} = T_j;\ \left.\frac{\mathrm{d}T}{\mathrm{d}\phi}\right|_{j-1} = \left.\frac{\mathrm{d}T}{\mathrm{d}\phi}\right|_{j} \quad \text{(eq. 5)}$$

Fig. 2 represents the application case of a single parabolic trough solar collector in a generic non-symmetrical case, corresponding to an out-of-noon solar position and vertically stratified flow of liquid and vapor, a most challenging stratified regime. The circular periphery is divided into 5 sectors, j = Ia, II, III, IV, Ib, as Fig. 2 depicts. The temperature distribution follows the five equations in Tab. 1.

Unknowns are ten inter-boundary temperatures T_{cjk}. The five boundary conditions necessary for determining these unknowns and thus the temperature distribution are indicated in Tab. 2.

3. Results and discussion

As the parabolic trough solar collectors incorporate a rotatable mirror for sun tracking, the irradiance can impact on the side of the receiver, suggesting the larger temperature inhomogeneities than with Fresnel type collectors of similar receiver tube layout.

Tab. 3 indicates the chosen common parameters as a base case for the application of the model to some representative cases of a parabolic trough collector, varying remaining parameters. This corresponds to a clear day of the year #100 in Madrid (Spain) corresponding to 10th March of a non-leap year, as some kind of overall year representation. No changes in α_i have been considered for changes in wall temperature T as the bulk and wall temperatures are not dissimilar enough for the low concentrated irradiance on the wall of a MT

solar collector, in the order of 10^4 W m^{-2}.

The first study performed analyzes the effect of variations in the tracking angle γ_M along the day around the base case $\gamma_M = 0$ corresponding to solar noon. This implies *ceteris paribus*; meaning this "all other parameter unchanged". This implies the same G_{bT} along the day, what is really extreme. Fig. 3 shows the results. The data corresponds to a really shallow liquid depth $h_l = 5$ mm and a void fraction near to one. Low liquid heights are recommended to minimize the ammonia inventory for safety reasons. For the afternoon parabola orientation, $\gamma_M = 35$ deg, the solar irradiance affects laterally the receiver wall in contact with vapor flow, inducing a local moderate overheating of 35 K and increasing the difference of maximum to minimum temperature from 14 K to 53 K. One has to note the displacement of the high temperature peak down the liquid flow angles owing to heat conduction. These temperature increases will not happen so intensively with a Fresnel collector neither with a higher liquid height h_l.

Fig. 4 shows the effect of varying the mirror aperture angle α_M around the base case $\alpha_M = 120$ deg and sun tracking angle measured from zenith (asymmetry) $\gamma_M = 35$ deg in order to show the effect of sun radiance concentration on one side on the temperature side peak. Decreasing the aperture angle α_M reduces wall temperatures below 420 K as a result of a concentration reduction, so that thermal stresses and tube deformations diminish. Increasing the aperture angle causes a higher displacement of the high temperature arch toward either the liquid or the vapor arches, and vice versa, with respect to Fig. 3(B). Geometrical sun concentration increases up to 43 as G_{bT} is considered constant irrespective of the changes in these angles.

Fig. 5 shows the effect of increasing the liquid level h_l above the base case, by an increase of the liquid central angle ϕ_l, indicated in Fig. 2(B) in order to show the effect of liquid convection on the side temperature peak. Velocity of both fluids change as the liquid is falling freely under the sole action of gravity against friction with the wall (Lecuona et al., 2016). The vapor velocity results from the variation in vapor production and the reduction of the cross section. These effects mean a mass flow increase for both phases and a reduction of the void fraction. The results indicate the beneficial effect of a larger liquid angle ϕ_l from the point of view of limiting temperature differences in the wall, so that with $h_l = 20$ mm the wall temperature approaches the corresponding phase temperature, irrespective to γ_M, owing to α_l is much larger and α_v. This case is extreme as more than half the tube cross section is filled with liquid and the high counter-flowing vapor velocity will deform the interphase free surface forming waves. Other effects are considered in (Lecuona et al., 2016).

4. Conclusions

A simplified method has been developed to estimate the wall temperature peripheral distribution on the circular section of the receiver tube of linear solar collectors, typically of the parabolic trough and Fresnel types. The more complex layout of a vertically gravity stratified counter-current two-phase flow has been studied.

This method relies on an exact solution of the 1D conduction heat transfer, thus more precise than its discretization on finite 1D elements.

The application has been performed to data from a representative medium temperature (MT) parabolic trough collector as it can present the most noticeable temperature inhomogeneities. Results indicate that the

temperature differences can be of concern when either/both the liquid phase central angle ϕ_l is small compared with the mirror aperture angle α_M. This is more pronounced when a parabolic trough type collector points to the sun when it is out of zenith, $\gamma_M \neq 0$. This caveat is of much lower importance for Fresnel collectors, even lower with secondary optics.

Matching the angle of the liquid sector ϕ_l to the mirror aperture angle α_M and even setting it with a larger angle benefits the temperature homogeneity of the receiver tube wall. But having a lower liquid angle is of not much concern during the morning and afternoon, as the irradiance G_{bT} decreases going away from midday, just when wall temperature inhomogeneity tends to increase in parabolic trough collectors.

The data obtained allow developing mass and heat transfer simulations of the innovative layout of direct vapor production using stratified two-phase flows with liquid film driven by gravity. This is of relevance for advanced absorption cycles for polygeneration. They allow also to ascertain the bending of the tube to avoid overstressing and touching the glass envelope.

Simulated Evaluation of Combined Use of Building Thermal Mass and Thermal Storage in Solar Hybrid Heat Pump System for Demand Response

Kyoung-ho Lee[1], Jae-hyeok Heo[1], Soon-myoung Lee[1], Moon-chang Joo[1]

[1] Solar Thermal Laboratory, New and Renewable Energy Research Division, Korea Institute of Energy Research

Abstract

In this study, TRNSYS simulations were employed to evaluate simple strategies for controlling energy demand response by utilizing building thermal mass and daily and weekly solar thermal storage. All control setpoints (i.e., for the building indoor space temperature, for heat pump on/off controls, and for pump and valve control for the weekly storage tank) were adjusted before and during the demand response period. Simulation results showed that a significant reduction in electric energy consumption could be achieved through combined use of thermal storage.

Keywords: *Demand response, Thermal storage, Solar heating, Heat pump, Weekly thermal storage, Setpoint adjustment*

1. Introduction

Demand response (DR) is an effective tool to reduce peak electric consumption of a national power grid when power supply is lower than demand. Energy storage systems can be utilized effectively to mitigate peak electric consumption during on-peak periods. In the case of electric heating systems combined with thermal energy storage, thermal energy storage systems are directly coupled with electric energy systems. Effective and intelligent use of thermal storage can therefore contribute to mitigating the electricity burden on the power grid. There has been significant research into DR technologies to reduce electric energy consumption during on-peak periods using thermal storage (Arteconi et al., 2016). However, most studies have focused on the summer period, when electric consumption due to space cooling is significant. Peak electric demand could also occur during winter time if electric heating systems (such as electric heaters or electric heat pumps) are widely used. During the heating season, solar thermal energy (through thermal storage) could be used for DR (Lee et al, 2015). In this study, we consider a solar hybrid electric heat pump system in an office building, with additional weekly thermal storage to use stored solar thermal energy, in order to reduce electric consumption related to heat pump operation for space heating. We consider combined use of thermal storage (such as building thermal mass, thermal storage connected to heat pumps, and weekly solar storage) for various control strategies.

2. Description of system and control strategy

Thermal storage systems could potentially contribute to managing response to electric load demand. They are activated by a control signal from electric utilities. The purpose of this control is to reduce peak demand on the power grid system. In this study, electric load shifting was evaluated by using a solar heating system with a ground-source heat pump and additional weekly thermal storage (ST_W); this is shown in Fig. 1.

doi:10.18086/eurosun.2016.04.16 Available at http://proceedings.ises.org

Weekly solar thermal storage can be feasible in office buildings because, during there is generally nearly no heating demand during weekends and surplus solar heat energy can be stored in the weekly storage tank on Sundays. A daily thermal storage tank(ST_D), used for heating domestic water and supplying energy for space heating, was connected with solar collectors and the heat pump. During weekends, the surplus solar yield was stored in the weekly storage tank. This stored thermal energy, together with building thermal mass control, could then be utilized for DR control during the following week. In this study, TRNSYS system simulation was used to evaluate the control strategy for load shifting to meet DR control. For DR with the weekly solar storage tank, the hot water in the ST_W tank was set to flow through the ST_D, so that the fluid temperature at the location controlled by the heat pump in the tank was maintained as high as possible during the DR period. In addition, the setpoint of the heat pump was set higher and lower than normal prior to and during the DR period, respectively. In this study, this control strategy was termed Solar DR (Demand Response). Simultaneously, the building indoor setpoint temperature can be set higher than conventionally the case before the DR period, to an upper limit temperature within the thermal comfort range; afterwards, the setpoint is reduced to a lower temperature within the thermal comfort range during the DR period. In this way, the building thermal mass and daily and weekly solar storage tanks could be utilized in combination to reduce the duration of heat pump operation as much as possible during the DR period. In this study, this control strategy was termed BC (Building Control). In addition, prior to the DR period, the storage setpoint temperature monitored by the heat pump can be set to an upper temperature higher than conventionally the case; subsequently, the setpoint is lowered to an allowable lower temperature suitable for space heating. This control strategy was termed HPC (Heat Pump Control). The three different control strategies can be employed either separately or simultaneously for combined use of thermal energy storage to maximize reduction of peak electric consumption.

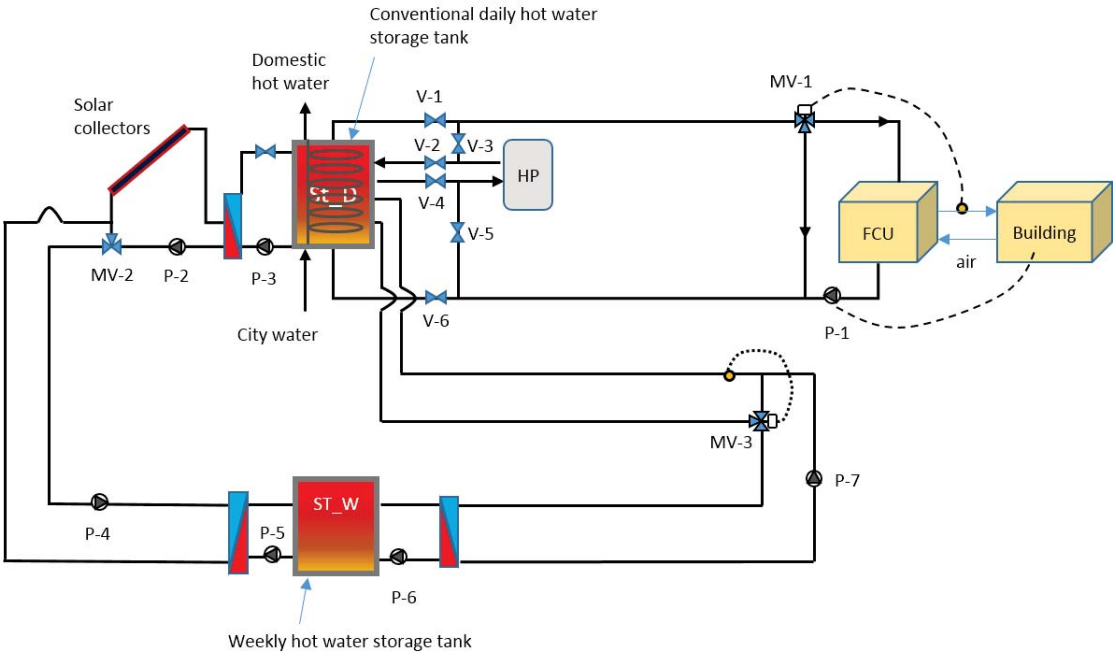

Fig. 1: Schematic diagram of solar hybrid heat pump system with daily and weekly storage tanks.

3. Simulation method and results

3.1. Simulation method

TRNSYS (SEL, 2013) simulation software was used to model the heating system. A simple capacitance and

resistance model was employed for the building thermal load. A small office building was modeled for this study with total floor area of 150 ㎡. Type 88 module in TRNSYS was used for the building model with 150,000kJ/K of thermal capacitance and thermal loss coefficient of 2.2kJ/hr-㎡-K. The building model parameters were calibrated using measured load data from an actual office building. Fig. 2 compares simulated TRNSYS model and actual measured data for space heating load and domestic hot water on a monthly basis. In this study, demand response was requested from 10 am to 12 pm and from 5 pm to 7 pm, for four hours. For simulation convenience, the Thursday of every week from December to February was selected for employment of the control strategy. The ratio of the solar collector area to the total building area was 0.04 ㎡/㎥, the ratio of the volume of the daily solar storage tank to the area of the solar collector area was 83 L/㎡, and the ratio of the volume of the weekly solar storage tank to the solar collector area was 25 L/㎡. The weekly storage tank is designed to be smaller than the daily storage tank, taking into consideration the fact that the weekly storage tank is used for one day (Sunday) per week, while the daily storage tank is used on Saturdays.

3.2. Simulation results

The annual solar fraction was estimated at approximately 10%. Figs. 3 and 4 show simulation results resulting from the application of diverse control strategies. For the purpose of the simulated evaluation, it was assumed that a DR signal is called on Thursday each week from December to February. The resultant values are averaged on a monthly basis for comparison. 'Nonsolar' indicates use of only the heat pump heating system, without solar collectors and weekly storage. 'CC' refers to conventional control. The control strategy using the weekly solar storage tank is termed DR_Solar, while HPC and BC indicate heat pump setpoint control and building thermal mass control, respectively. It was found that electric energy consumption of the solar heating system, with DR control, was reduced on average by 45.3%, 84.2%, 82.7%, and 99.4% for Solar DR control, DR_Solar+HPC, DR_Solar+BC, and DR_Solar+BC+HPC, respectively, over the three-month period. In addition, it was found that solar irradiation conditions over weekends contributed significantly to performance of solar DR control. Figs. 5 and 6 represent the performance over a day with the highest electric energy consumption due to space heating over the year. The results are similar to yearly average performance, with significant reduction of electric energy consumption during DR periods through combined use of thermal storage. However, it should be also noted that electric energy consumption over whole days could be increased by employing thermal storage control, due to the efficiency of thermal storage between thermal charge and discharge periods. This increase in energy consumption on a whole daily basis could be compensated by different hourly electric rate structures. In general, the electric charge rate during the DR period is much higher than during other periods. Fig. 7 compares the variation of heat pump electric consumption for 'Nonsolar', 'Solar(CC)', and 'DR_Solar+BC+HPC' according to time of day with highest electric consumption. It should be noted that heat pump almost does not operate during on-peak periods for the control strategy using combined thermal storage, including weekly solar thermal storage, daily thermal storage, and building thermal mass.

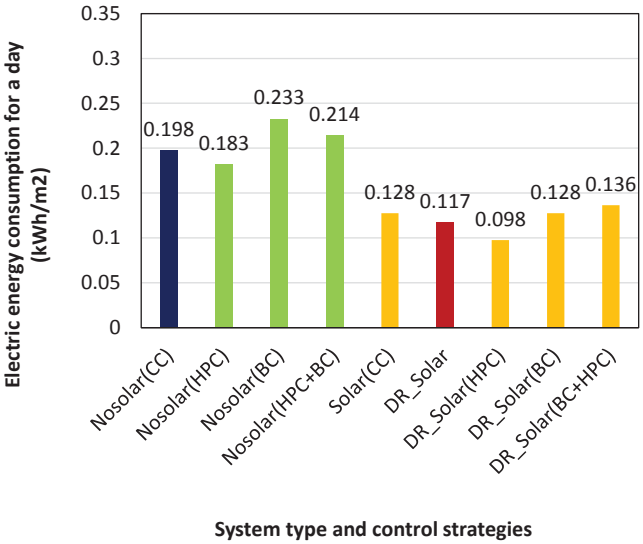

Fig. 4: Average electric energy consumption of solar hybrid heat pump system for whole day of demand response control implementation

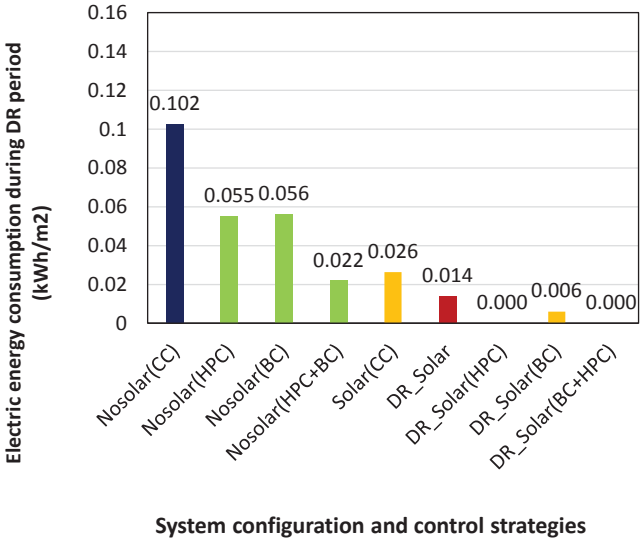

Fig. 5: Electric energy consumption of solar hybrid heat pump system during the demand response period on the day with highest electric energy consumption throughout the year

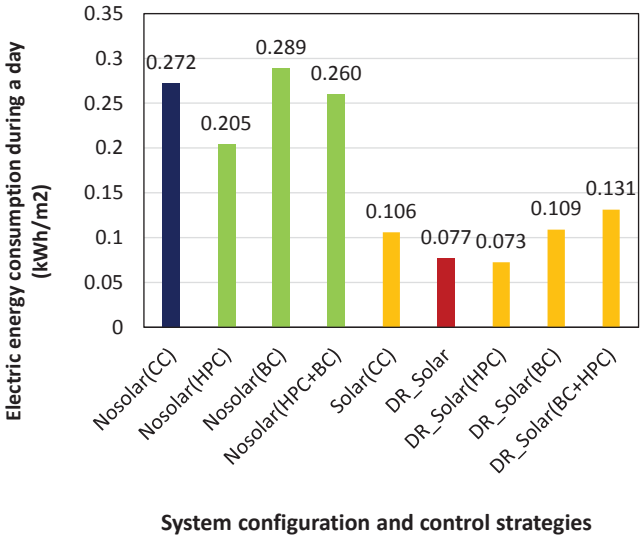

Fig. 6: Whole-day electric energy consumption of solar hybrid heat pump system on the day with highest electric energy consumption throughout the year

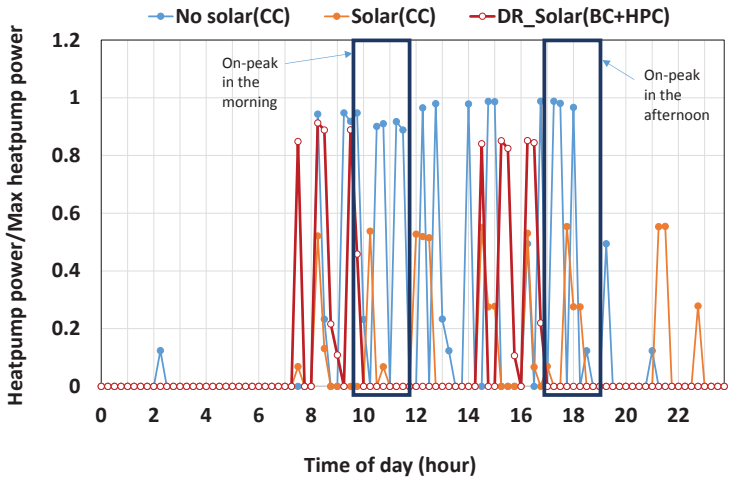

Fig. 7: Comparison of heat pump power according to time for control strategies during the day with highest electric energy consumption

4. Conclusion

The study evaluates the performance of a simple control strategy using a combination of building thermal mass and daily and weekly solar thermal storage. The TRNSYS simulations for the system indicated significant reduction in electric energy consumption of the heating system during the DR period. It was assumed that the control was called every Thursday from December to February from 10 am to 12 pm and 5 pm to 7 pm. On average, when using combined thermal storage, 99.4% of electric energy consumption during the DR control period could be shifted to the period before DR control. Based on simulation results, it can be concluded that weekly solar thermal energy storage can be used for electric demand management during space heating periods for electric heating systems installed in office buildings. The effect of demand management in solar hybrid heat pump systems can be enhanced by combined use of building thermal mass, conventional daily thermal storage, and weekly solar thermal storage.

Abstract

The combination of solar thermal, photovoltaic, and heat pump technologies is a welcome advancement in countries with large solar resources such as Turkey. These systems could have similar efficiencies throughout the year for different locations in Turkey if we adjust the solar storage according to the weather conditions. In this paper, solar heating with a heat pump system for buildings have been designed to achieve different values of the fraction of primary energy saved using Flat Plate Collectors (FPC) and solar photovoltaic (PV) technology, and having a high system efficiency resulting in net zero energy for thermal production.

Keywords: *Solar thermal; heat pump; photovoltaic; geothermal; combisystems.*

1. Introduction

Turkey has large solar resources as shown in Figure 1 and a relatively large population. This country has the second largest newly installed solar thermal capacity worldwide in 2014, and this has made Turkey the largest European solar thermal market [1]. The solar combisystems are becoming popular for villas [1], where for arrive to a high comfort and efficiency we need a system with heating and Domestic Hot Water during all the year with a large solar systems.

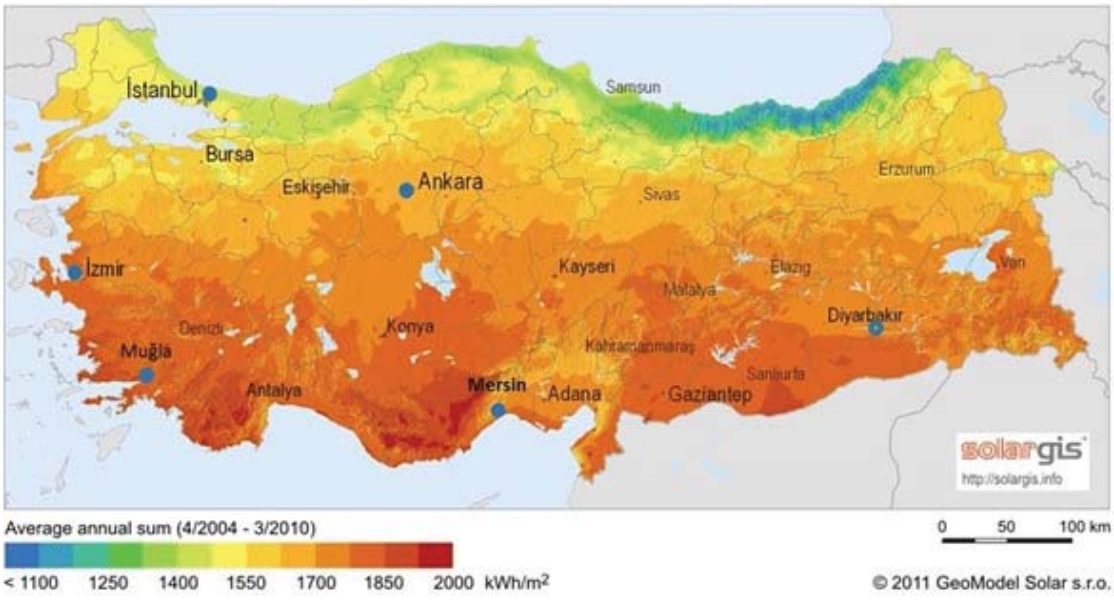

Fig. 1 Solar Radiation in Turkey and location of the studied cities. SolarGis [2]

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/eurosun.2016.04.22 Available at http://proceedings.ises.org

The actual prices of PV systems and mature technology of Flat Plate Collectors (FPCs) and water-to-water heat pump for ground-coupled applications have provided a new model: solar-electric heat pump assisted with solar-thermal collectors. These systems have been integrated in some software programs as Polysun. This article shows that these systems will be cheaper and easier to install than the shallow geothermal systems.

2. Description and results

Six different locations in Turkey (see Figure 1) have been simulated with FPC, PV and heat pumps (Water-water) as presented in Table 1. The used software Polysun [3] includes solar thermal, photovoltaics, heat pumps and geothermal systems. The PV system has been simulated as well with PVsyst[4] for adjust the power. The proposed system can operate with outside temperatures lower than 0ºC with a high solar fraction and with a high efficiency of the solar collector [5]. The storage is changing during the year according to the external temperature, in order to obtain higher efficiency from the thermal collector, PV and work with the maximum efficiency of the heat pump.

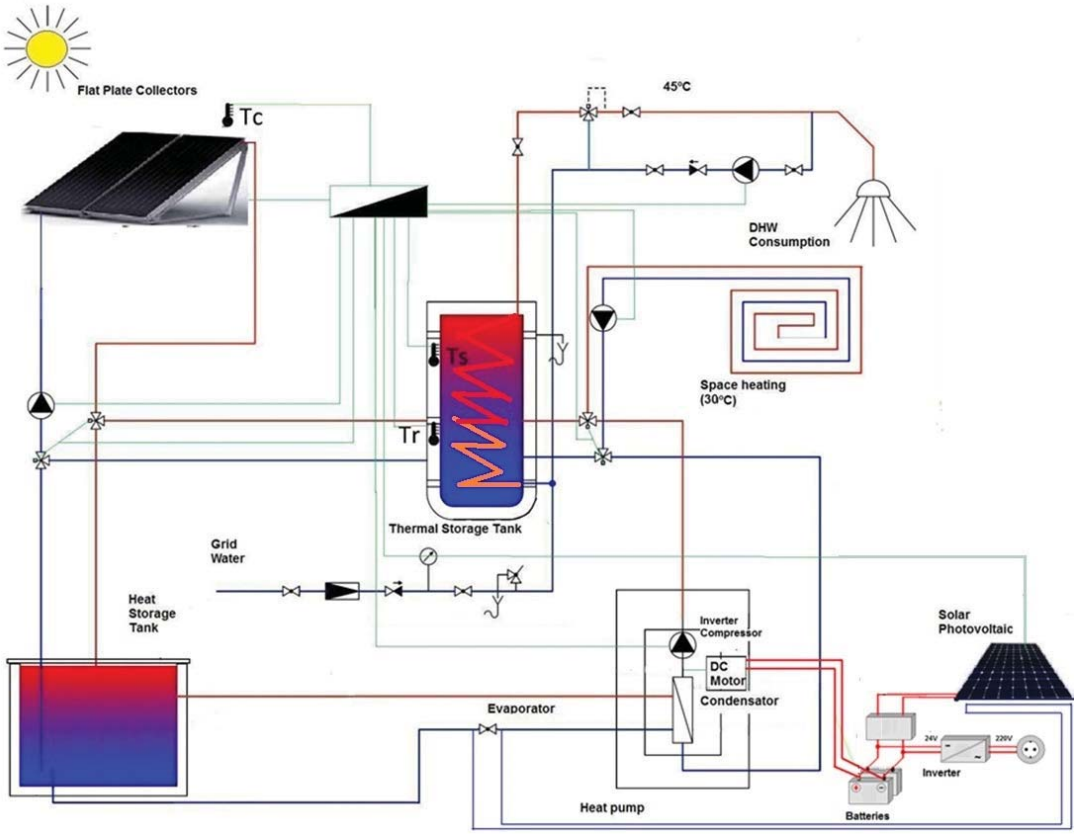

Fig. 2 : Simulation of the thermal system.

One interesting combination is for houses with swimming pool or with rain storage tank, where we can save the investment of the buffer storage tank using an isolated pool with thermal cover. In Mediterranean areas many Villas with pool or rain water storage tank have solar collectors to use the pool in autumn months. The heat can be dumped into a swimming pool in the autumn months, and the swimming pool used like a big buffer tank in the cooler days, being more efficient than the geothermal systems [9].

ST Collector Efficiency $\eta = 0{,}807 - 3{,}075(Tm\text{-}Ta)/G - 0{,}022((Tm\text{-}Ta)/G)^2$ (eq. 1)
Coefficient of Performance Heat Pump = 4.2423+0.087 T (eq. 2) ($T_{max\ evap}$=15ºC)

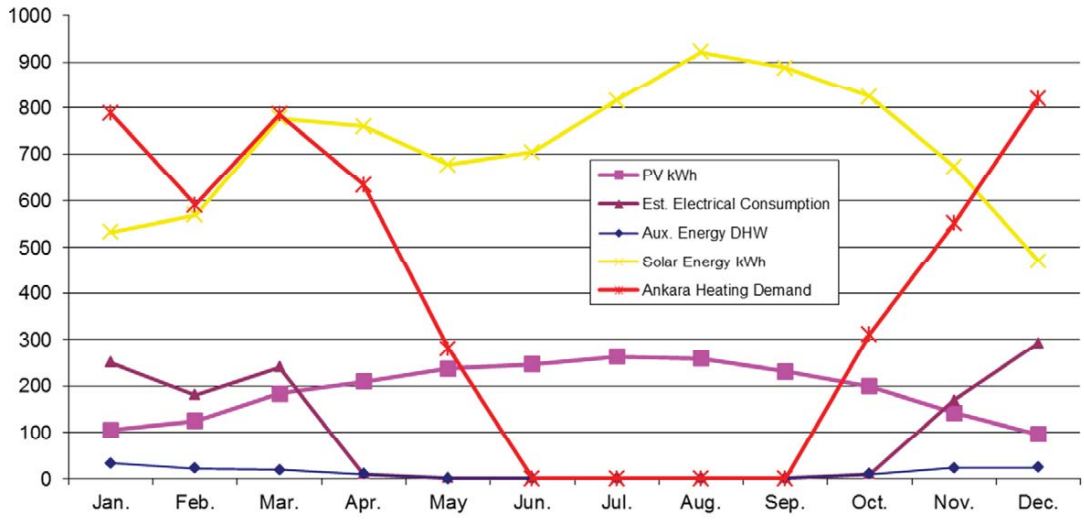

Fig. 3 : Annual Thermal demand (in kWh) with ST and PV production for Ankara

Simulating the whole year system we reach different solar fractions for the different locations, due to the efficiency of the system, the working temperature of the storage system, and the different COP of the heat pump. This system can have a very high Coefficient of Performance and adapt its efficiency to a variety of conditions. It is ideal for both cold and mild climates, and therefore for a country like Turkey with different weather conditions in the biggest cities.

Tab. 1: Results of one year simulation in three locations for DHW and Space Heating.

Location , Latitude	Thermal Energy Demand (kWh)	Solar Energy kWh/m^2	Electric Energy kWh	Solar Thermal Fraction	Average FPC Efficiency	PV installed power (Wp)	FPC (m^2)
Ankara, 39.9º	6370	1702	2284	88%	72%	1400	8
Mersin, 36.7º	3385	1486	524	93%	72%	360	6
Mugla,37.2º	4132	1798	1239	96%	74%	750	6
Izmir, 38.4º	3340	1697	1051	95%	74%	750	5
Diyarbakir, 37.9º	3993	1865	1423	96%	74%	750	5
Istanbul, 41º	2269	1486	529	94%	71%	520	4

There are some heat pump manufacturers that sell a hybrid air +PV system, and geothermal and air system for heating applications, in order to reduce the initial cost of the borehole and piping system, they have been analyzed, only shallow geothermal with PV. The size of the system is not very large for Turkey, and the maximum surface needed is less than 20m^2 if we take in account than these houses have a roof of 80 m^2 , these system fit perfectly. If there is any case without sufficient roof space, PVT technologies can be used, when it used for low temperatures with limited space is a good option, these collectors are good for low temperature heating systems, like fan coils or floor heating.

Recently, hybrid photovoltaic solar thermal collectors (PVT) became a topic of many research projects because of the possibility to gain heat and electricity simultaneously. PVT represents the alternative to separate PV panels and solar thermal collectors by integrating the two into one device [7]. Other studies have evaluated different possibilities to integrate PVT collectors in an air to water heat pump system and to compare the results with the combination of an air to water heat pump system together with a PV-system. The system P/S (PVT + heat pump in parallel and serial connection) in combination with a High Thermal Conductivity collector type turned out to be the most efficient and promising way to integrate uncovered PVT [8] collectors in a system at different locations. As the PVT collector serves essentially as a heat source for the heat pump (and is thus independent of solar radiation), the useful heat gains of the collectors occurs at the same time as heat is needed in winter. The rear insulation of the PVT collector is

in terms of best possible heat absorption from ambient air rather obstructive for such a system configuration.

FPC and PV with heat pump systems are a good solution for familiar households, both technologies are necessary in order to arrive to the future scenarios of zero emissions for net-zero energy building for Turkey.

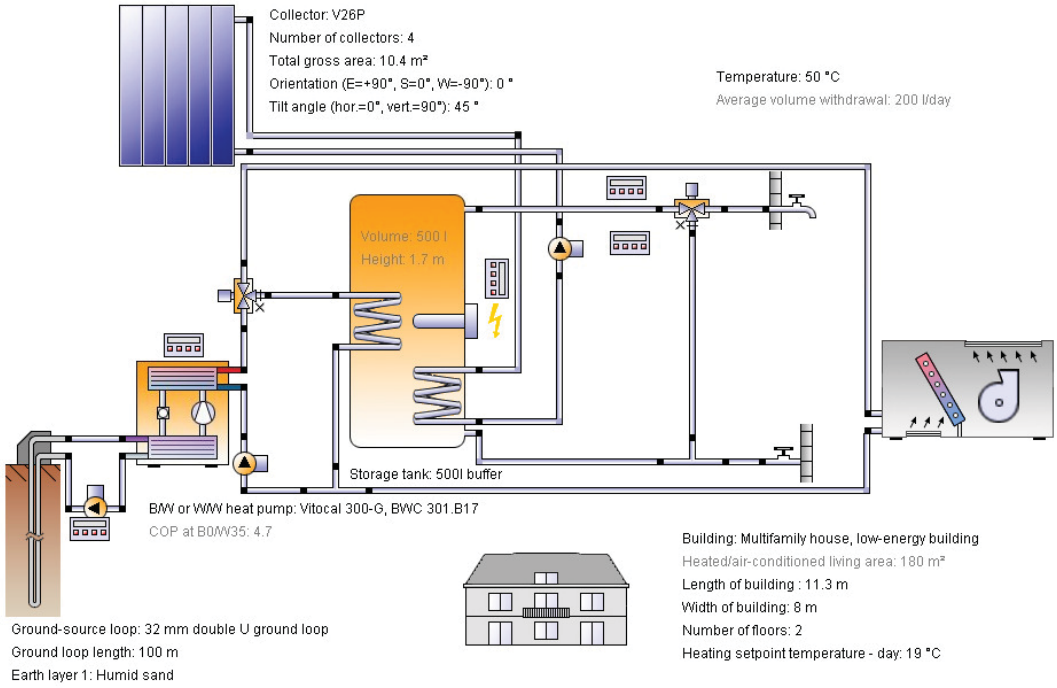

Fig. 4 : Diagram with Ground source+ Solar Thermal [3] for Istanbul.

The main problem of the geothermal is in some places the composition of the soil very uncertain, and the environmental barriers. They need a detailed geological analysis and sometimes they need some borehole, making the initial investment very high. In the analyzed case two boreholes of 120 meters were assumed. The results are presented in Table 2, standard commercial list prices of the different elements, the operational cost and maintenance hasn't been studied, supposing that is similar in both cases.

Tab. 2: Comparing cost of the system vs. Geothermal in Turkey

	Estimated cost		**Estimated cost**
Heat Pump + PV system	7 050 €	Heat Pump + PV system	7 050 €
Solar Thermal + Pipes	2 100 €	Borehole + Pipes	13 300 €
Thermal Storage Tanks	4 500 €	Thermal Tank	1 815 €
Total	**13 650 €**		**22 165 €**

The analyzed solar thermal-PV system is cheaper and has a similar efficiency than the Geothermal system, which gives an advantage. The only disadvantage will be for cooling, the geothermal will be easy to change in contrast with the Solar Heat Pump which will be needed a dry cooler or some auxiliary system in the heat pump in order to cool the house.

3. Conclusions

The analyzed solar thermal-PV system is cheaper and has a similar efficiency to the geothermal system, which gives an advantage. The only disadvantage will be for cooling, the geothermal will be easy to change in contrast with the Solar Heat Pump which will be needed a dry cooler or some auxiliary system in the heat pump in order to cool the house.

Abstract

The application of solar heating and cooling systems for building air-conditioning actually shows a significant potential of exploitation, particularly in sunny regions. The choice whether or not to apply such technologies in different climates should be based on the assessment of their energy/environmental, economic and social sustainability, as well as their technical characteristics as reliability, durability and energy efficiency. To support researchers and decision-makers in the selection of the best solar air-conditioning solution in a specific geographic and energy context, the paper proposes a set of technical, economic, energy/environmental and social key performance indicators. The research activity was developed within the Task 53 "New generation solar cooling & heating systems (PV or solar thermally driven systems)" of the International Energy Agency.

Keywords: *Solar heating and cooling, sustainability, key performance indicators, energy*

1. Introduction

The selection of the best performing solar heating and cooling (SHC) system for satisfying the cooling and heating demand of buildings in a specific location is a complex task (Beccali et al., 2012; 2014; 2016), which has to include different assessment criteria (costs, environmental impacts, etc.). This is particularly relevant for the assessment of new generation technologies, which need to be carefully evaluated for their subsequent inclusion in the market.

This topic was investigated within the International Energy Agency SHC Programme - Task 53 "New generation solar cooling & heating systems (PV or solar thermally driven systems)" aiming to the definition of a set of key performance indicators (KPIs) (Mugnier, 2013), which can be useful for helping researchers and decision-makers to have a complete overview of the performance of different SHC technologies.

2. A set of key performance indicators for solar heating and cooling systems

The set of KPIs is based on a multi-disciplinary approach that takes into account the three pillars of sustainability: environmental (including energy), economic and social sustainability (Ardente et al., 2016; Sala et al., 2015). Furthermore, a fourth element is added, describing the technical performance of the SHC technology.

In all, the set includes 19 KPIs, each of which is synthesized by using an "ad hoc" format, including the following sections:

- KPI name: it indicates the name of the KPI and its acronym.
- Typology: it specifies if the KPI is an economic, energy, environmental, social or technical indicator.
- Type of assessment: it clarifies the qualitative or quantitative nature of the indicator.
- Unit of measure: only for quantitative KPIs.
- Description: it includes a brief description of the indicator.
- Performance target: it defines the target to be achieved for improving the performance of the system under investigation for the selected KPI.

doi:10.18086/eurosun.2016.04.14 Available at http://proceedings.ises.org

- Measurement process: it describes the process or the methodology used for measuring the value of the indicator.

In detail, the following KPIs where identified for describing the SHC systems:

- Energy KPIs: global energy requirement (Table 1), energy payback time (Table 2), energy return ratio (Table 3).
- Environmental KPIs: global warming potential (Table 4), acidification potential (Table 5), eutrophication potential (Table 6), ozone depletion potential (Table 7), photochemical ozone creation potential (Table 8), GWP payback time (Table 9).
- Economic indicators: money savings during the operation (Table 10), initial cost ratio (Table 11), operation/maintenance costs ratio (Table 12), payback period (Table 13).
- Social indicators: customer satisfaction (Table 14), ease of use of the system (Table 15).
- Technical indicators: useful life of the system (Table 16), thermal performance coefficient of the ab/adsorption machine (Table 17), electrical COP (Table 18), reliability of the system (Table 19)..

Tab. 1: Energy KPI: Global Energy Requirement

KPI name	Global Energy Requirement (GER)
Typology	Energy indicator
Type of assessment	Quantitative
Unit of measure	MJ
Description	GER represents the entire (renewable and non-renewable) energy demand, valued as primary energy, which arises in connection with the production, use and disposal of an economic good (product or service).
Performance target	Percentage reduction of GER during the life cycle of the system (to be fixed case by case).
Measurement process	The KPI can be calculated following a life cycle approach with the formula: $GER = GER_M + GER_U + GER_{RD}$ (eq.1). GER_M is the primary energy consumed during the manufacture (including energy and raw materials supply) of a product or a service; GER_U is the primary energy consumed during the use of a product or a service; GER_{RD} is the primary energy consumed during the end-of-life of a product or a service (recycling or disposal).

Tab. 2: Energy KPI: Energy Payback Time

KPI name	Energy Payback Time (EPT)
Typology	Energy indicator
Type of assessment	Quantitative
Unit of measure	Years
Description	EPT is defined as the time during which the SHC system must work to harvest the additional primary energy required for its manufacturing and end-of-life, if compared with a conventional system. The harvested energy is considered as net of the energy expenditure for the system operation.
Performance target	EPT lower than the useful life of the system
Measurement process	The KPI can be calculated with the formula: $EPT = \left(GER_{SHC-system} - GER_{Conventional-system}\right) / E_{year}$ (eq.2). $GER_{SHC\text{-}system}$ is the GER related to the life cycle of the SHC system except for the operation phase; $GER_{Conventional\text{-}system}$ is the GER related to the life cycle of the conventional system except for the operation phase; E_{year} is the net yearly primary energy saving due to the use of the SHC system in replacement of a conventional one.

Tab. 3: Energy KPI: Energy Return Ratio

KPI name	Energy Return Ratio (ERR)
Typology	Energy indicator
Type of assessment	Quantitative
Unit of measure	-
Description	ERR represents how many times the energy saving overcomes the primary energy consumed during the manufacturing and the end-of-life of the SHC system.
Performance target	N.A.
Measurement process	The KPI can be calculated with the formula: $ERR = E_{overall} / GER_{SHC-system}$ (eq.3). $GER_{SHC\text{-}system}$ is the GER related to the life cycle of the SHC system except for the operation phase; $E_{overall}$ is the net primary energy saving during the overall lifetime of the SHC system.

Tab. 4: Environmental KPI: Global Warming Potential

KPI name	Global Warming Potential (GWP)
Typology	Environmental indicator
Type of assessment	Quantitative
Unit of measure	kg CO_{2eq}
Description	GWP is a measure of the relative, globally averaged, warming effect arising from the emissions of a particular greenhouse-gas. The GWP represents the time-integrated commitment to climate forcing from the instantaneous release of 1 kg of a trace gas expressed relative to that from 1 kg of carbon dioxide.
Performance target	Percentage reduction of GWP during the life cycle of the system (to be fixed case by case).
Measurement process	The KPI can be calculated following a life cycle approach with the formula: $GWP = \sum_1^n (m_i * CF_i)$ (eq.4). m_i is the mass of the substance *i* emitted; CF_i is the characterization factor that reflects the relative contribution of the substance *i* to the impact on GWP.

Tab. 5: Environmental KPI: Acidification Potential

KPI name	Acidification Potential (AP)
Typology	Environmental indicator
Type of assessment	Quantitative
Unit of measure	kg SO_{2eq}
Description	AP measures the impact generated by the emission of airborne acidifying substances (as nitrogen oxides and sulphur dioxide). Acidification refers literally to processes that increase the acidity of water and soil systems by hydrogen ion concentration.
Performance target	Percentage reduction of AP during the life cycle of the system (to be fixed case by case).
Measurement process	The KPI can be calculated following a life cycle approach with the formula: $AP = \sum_1^n (m_i * CF_i)$ (eq.5). m_i is the mass of the substance *i* emitted; CF_i is the characterization factor that reflects the relative contribution of the substance *i* to the impact on AP.

Tab. 6: Environmental KPI: Eutrophication Potential

KPI name	Eutrophication Potential (EP)
Typology	Environmental indicator
Type of assessment	Quantitative
Unit of measure	kg $PO_4^{3-}{}_{eq}$
Description	EP is defined as the potential of nutrients to cause over-fertilization of water and soil which in turn can result in increased growth of biomass. For example, it causes excessive plant growth like algae in rivers which causes severe reductions in water quality and animal populations.
Performance target	Percentage reduction of EP during the life cycle of the system (to be fixed case by case).
Measurement process	The KPI can be calculated following a life cycle approach with the formula: $EP = \sum_1^n (m_i * CF_i)$ (eq.8). m_i is the mass of the substance *i* emitted; CF_i is the characterization factor that reflects the relative contribution of the substance *i* to the impact on EP.

Tab. 7: Environmental KPI: Ozone Depletion Potential

KPI name	Ozone Depletion Potential (ODP)
Typology	Environmental indicator
Type of assessment	Quantitative
Unit of measure	kg $CFC\text{-}11_{eq}$
Description	ODP indicates the potential for emissions of chlorofluorocarbon compounds and other halogenated hydrocarbons to deplete the ozone layer in the stratosphere, where it shields the earth from harmful ultraviolet radiation.
Performance target	Percentage reduction of ODP during the life cycle of the system (to be fixed case by case).
Measurement process	The KPI can be calculated following a life cycle approach with the formula: $ODP = \sum_1^n (m_i * CF_i)$ (eq.7). m_i is the mass of the substance *i* emitted; CF_i is the characterization factor that reflects the relative contribution of the substance *i* to the impact on ODP.

Tab. 8: Environmental KPI: Photochemical Ozone Creation Potential

KPI name	Photochemical Ozone Creation Potential (POCP)
Typology	Environmental indicator
Type of assessment	Quantitative
Unit of measure	kg C_2H_{4eq}
Description	POCP is related to the potential for volatile organic compounds and oxides of nitrogen to generate photochemical or summer smog in the presence of heat and sunlight.
Performance target	Percentage reduction of POCP during the life cycle of the system (to be fixed case by case).
Measurement process	The KPI can be calculated following a life cycle approach with the formula: $POCP = \sum_1^n (m_i * CF_i)$ (eq.8). m_i is the mass of the substance *i* emitted; CF_i is the characterization factor that reflects the relative contribution of the substance *i* to the impact on POCP.

Tab. 9: Environmental KPI: GWP Payback Time

KPI name	GWP Payback Time (GWP-PT)
Typology	Environmental indicator
Type of assessment	Quantitative
Unit of measure	Years
Description	GWP-PT is defined as the time during which the avoided GWP impact due to the use of the SHC system in replacement of a conventional system is equal to GWP impact caused during its manufacturing and end-of-life.
Performance target	GWP-PT lower than the useful life of the system.
Measurement process	The KPI can be calculated with the formula: $GWP-PT=\left(GWP_{SHC-system}-GWP_{Conventional-system}\right)/GWP_{year}$ (eq.9). $GWP_{SHC\text{-}system}$ is the GWP related to the life cycle of the SHC system except for the operation phase; $GWP_{Conventional\text{-}system}$ is the GWP related to the life cycle of the conventional system except for the operation phase; GWP_{year} is the net yearly avoided GWP due to the use of the SHC system in replacement of a conventional system.

Tab. 10: Economic KPI: Money savings during the operation

KPI name	Money savings during the operation (MSDO)
Typology	Economic indicator
Type of assessment	Quantitative
Unit of measure	€
Description	MSDO represents the money saving during the useful life of the SHC system due to its lower energy (electricity and natural gas) consumption if compared with a conventional system.
Performance target	Lower than the cost of energy (electricity and natural gas) consumed by the SHC system during its useful life.
Measurement process	The KPI can be calculated with the formula: $MSDO=\sum_1^n\left(\begin{array}{l}\left(NG_{Conventional-system-i}-NG_{SHC-system-i}\right)*NG_{price-i}+\\+\left(EL_{Conventional-system-i}-EL_{SHC-system-i}\right)*EL_{price-i}\end{array}\right)$ (eq.10). $NG_{Conventional\text{-}system\text{-}i}$ is the natural gas consumption of the conventional system in the year *i*, expressed in MJ or in kWh; $NG_{SHC\text{-}system\text{-}i}$ is the natural gas consumption of the SHC system in the year *i*, expressed in MJ or in kWh; $NG_{price\text{-}i}$ is the price of natural gas in the year *i*, expressed in €/MJ or in €/kWh; $EL_{Conventional\text{-}system\text{-}i}$ is the electricity consumption of the conventional system in the year *i*, expressed in MJ or in kWh; $EL_{SHC\text{-}system\text{-}i}$ is the electricity consumption of the SHC system in the year *i*, expressed in MJ or in kWh; $EL_{price\text{-}i}$ is the price of electricity in the year *i*, expressed in €/MJ or in €/kWh.

Tab. 11: Economic KPI: Initial cost ratio

KPI name	Initial cost ratio (ICR)
Typology	Economic indicator
Type of assessment	Quantitative
Unit of measure	-
Description	ICR is the ratio between the price set by supplier/vendor in their price list when the customer purchases the SHC system from them and the corresponding price of the conventional system.
Performance target	Lower than 1
Measurement process	The KPI can be calculated with the formula: $ICR = P_{SHC-system} / P_{Conventional-system}$ (eq.11). $P_{SHC-system}$ is the price of the SHC system defined by the supplier/vendor; $P_{Conventional-system}$ is the price of the conventional system defined by the supplier/vendor. Both $P_{SHC-system}$ and $P_{Conventional-system}$ can be found by the customer in the price list given by the supplier/vendor.

Tab. 12: Economic KPI: Operation/maintenance cost ratio

KPI name	Operation-maintenance cost ratio (OMC)
Typology	Economic indicator
Type of assessment	Quantitative
Unit of measure	-
Description	OMC is the ratio between the cost to the customer during the useful life of the SHC system for its operation and maintenance (regular maintenance and repair) and the corresponding cost of the conventional system.
Performance target	Lower than 1
Measurement process	The KPI can be calculated with the formula: $OMC = \frac{\left(NG_{SHC-system-i} * NG_{price-i} + EL_{SHC-system-i} * EL_{price-i} + M_{Cost-SHC-system-i}\right)}{\left(NG_{Conv.-system-i} * NG_{price-i} + EL_{Conv.-system-i} * EL_{price-i} + M_{Cost-Conv.-system-i}\right)}$ (eq.12). $NG_{SHC-system-i}$ is the natural gas consumption of the SHC system in the year *i*, expressed in MJ or in kWh; $NG_{Conv.-system-i}$ is the natural gas consumption of the conventional system in the year *i*, expressed in MJ or in kWh; $NG_{price-i}$ is the price of natural gas in the year *i*, expressed in €/MJ or in €/kWh; $EL_{SHC-system-i}$ is the electricity consumption of the SHC system in the year *i*, expressed in MJ or in kWh; $EL_{Conv.-system-i}$ is the electricity consumption of the conventional system in the year *i*, expressed in MJ or in kWh; $EL_{price-i}$ is the price of electricity in the year *i*, expressed in €/MJ or in €/kWh; $M_{Cost-SHC-system-i}$ is the cost for the maintenance of the SHC system in the year *i*; $M_{Cost-Conv.-system-i}$ is the cost for the maintenance of the conventional system in the year *i*.

Tab. 13: Economic KPI: Payback period

KPI name	Payback period (PP)
Typology	Economic indicator
Type of assessment	Quantitative
Unit of measure	Years
Description	PP is the time in which the initial cash outflow of an investment for the SHC

	system is expected to be recovered from the economic benefit (positive cash flow) generated by the investment.
Performance target	PP lower than the useful life of the system
Measurement process	The formula to calculate the KPI depends on whether the economic benefit (positive cash flow) per period is even or uneven. In case it is even, the formula to calculate the KPI period is: $PP = P_{SHC-system} / B_{annual}$ (eq.13). $P_{SHC-system}$ is the price of the SHC system defined by the supplier/vendor; B_{annual} is the net annual benefit (positive cash flow) due to the use of the SHC system in replacement of a conventional one in terms of decrement in expenditure for electricity and natural gas. When the economic benefit is uneven, it is needed to calculate the cumulative net cash flow for each period and then use the following formula for the KPI: $PP = A + B/C$ (eq.14). A is the last period with a negative cumulative cash flow; B is the absolute value of cumulative cash flow at the end of the period A; C is the total cash flow during the period after A.

Tab. 14: Social KPI: Customer satisfaction

KPI name	Customer satisfaction (CS)
Typology	Social indicator
Type of assessment	Qualitative
Unit of measure	N.A.
Description	CS indicates how satisfied the client is with the SHC system
Performance target	Positive value of CS
Measurement process	The KPI can be estimated by using the following qualitative judgments: • Totally satisfied (positive value); • Mostly satisfied (positive value); • Neither satisfied nor dissatisfied (neither positive nor negative value); • Mostly dissatisfied (negative value); • Totally dissatisfied (negative value).

Tab. 15: Social KPI: Ease of use of the system

KPI name	Ease of use of the system (EUS)
Typology	Social indicator
Type of assessment	Qualitative
Unit of measure	N.A.
Description	EUS indicates the ease of use of the SHC system
Performance target	Positive value of EUS
Measurement process	The KPI can be estimated by using the following qualitative judgments: • Very easy to use (positive value); • Easy enough to use (positive value); • Neither easy nor difficult to use (neither positive nor negative value); • Not very easy to use (negative value); • Not easy to use (negative value).

Tab. 16: Technical KPI: Useful life of the system

KPI name	Useful life of the system (ULS)
Typology	Technical indicator
Type of assessment	Quantitative
Unit of measure	Years
Description	ULS indicates the period during which the system is expected to be usable for the purpose it was acquired.
Performance target	N.A.
Measurement process	The KPI can be estimated based on the indications given by the supplier/vendor.

Tab. 17: Technical KPI: Thermal Performance Coefficient of the ab/adsorption machine (Boudéhenn et al., 2013)

KPI name	Thermal Performance Coefficient (COP_{th}) of the ab/adsorption machine
Typology	Technical indicator
Type of assessment	Quantitative
Unit of measure	-
Description	COP_{th} is the ratio between the thermal cooling energy supplied by the evaporator and the thermal heat energy supplied to the generator of the sorption machine.
Performance target	To be fixed case by case
Measurement process	The KPI can be calculated with the formula: $COP_{th} = Q_{Cool-Ev} / Q_{Heat-generator}$ (eq.15). $Q_{Cool-Ev}$ is the thermal cooling energy supplied by the evaporator; $Q_{Heat-generator}$ is the thermal heat energy supplied to the generator of the sorption machine.

Tab. 18: Technical KPI: Solar Electric Performance Coefficient of the system (Boudéhenn et al., 2013)

KPI name	Solar Electric Performance Coefficient ($COP_{Elec-sol}$) of the system
Typology	Technical indicator
Type of assessment	Quantitative
Unit of measure	-
Description	$COP_{Elec-sol}$ corresponds to the ratio of the system's useful solar energy to auxiliary consumption.
Performance target	To be fixed case by case
Measurement process	The KPI can be calculated with the formula: $COP_{Elec-sol} = ESU / E_{Aux-sol}$ (eq.16). ESU refers to the thermal solar energy exploited by the system integrating thermal losses from hot and cold storage; $E_{Aux-sol}$ Electricity consumption of the solar system auxiliaries.

Tab. 19: Technical KPI: Reliability of the system

KPI name	Reliability of the system (RS)
Typology	Technical indicator
Type of assessment	Quantitative
Unit of measure	%
Description	RS at time *t* is the probability that the system will perform its function without failure under stated conditions in the interval [0, *t*).
Performance target	RS higher than 90%
Measurement process	The KPI can be calculated with the formula: $RS(t) = P(X > t)$ (eq.17). X is a random variable that represents the time to occurrence of system failure.

3. Conclusions

A complete evaluation of SHC systems should be based on the assessment of their economic, energy/environmental and social sustainability, as well as their technical characteristics.

The proposed set of KPIs gives a complete picture of the SHC system, aimed at measuring different aspects of its sustainability and technical performance. It can be useful for enabling researchers and decision-makers to take sustainably-based decisions in the field of SHC technologies, starting from a comprehensive investigation of the technical, economic, energy/environmental and social performance of the systems along their life cycle.

Abstract

Assessing the performance of Solar Heating and Cooling (SHC) systems, especially cooling systems using solar thermal or PV driving energy, in a common comparable format, is complicated by the numerous, alternative energy sources and design possibilities. A generalized technical and economic assessment methodology was developed and tested in the course of IEA SHC Task 53.

At a glance seven best practice plants were analyzed and compared in a comprehensive format. All systems can achieve non-renewable primary energy savings greater than 50%, but none is reaching a cost ratio lower than 1 compared to a reference system. The results might not be representative but show interesting trends. There is almost no difference between solar thermal and PV driven systems. Both technologies can succeed the same magnitude of savings with similar cost ratios. Plants that are achieving or aiming higher primary energy savings turn out to be more expensive.

Finally the assessment shows that solar heating and cooling can achieve cost competitiveness with an appropriate design and solar fraction if investment costs can be decreased simultaneously.

Keywords: *assessment and benchmarking, new generation solar heating and cooling, IEA SHC Task 53*

1. Introduction

A tremendous increase in the global market for air-conditioning can be observed, especially in developing countries. The results of the past IEA SHC Tasks and the ongoing activities on solar cooling show the enormous potential of this technology for building air-conditioning, particularly in sunny regions. However, solar thermal cooling faces barriers to emerge as an economically competitive solution. Thus, there is a strong need to stimulate the solar cooling sector for efficient and cost effective small and medium sized systems.

IEA SHC Task 53, which builds up on earlier IEA SHC work in this field, is working to find solutions to make solar driven heating and cooling systems cost competitive and helps to build a strong and sustainable market for solar, photovoltaic and new innovative thermal cooling systems. These objectives are tackled through five activities:

1. Investigation of new small to medium size PV & solar thermal driven cooling and heating systems, as well as development of best suited cooling and heating systems technology with a focus on reliability, adaptability and quality.
2. Demonstration of cost effectiveness of the above mentioned solar cooling and heating systems.
3. Investigation on life cycle performances on energy and environmental terms (LCA) of different options.
4. Assistance with the market deployment of new SHC systems for buildings worldwide.

doi:10.18086/eurosun.2016.04.04 Available at http://proceedings.ises.org

5. Increasing energy supply safety and influencing the virtuous demand side management behaviors.

The Task's scope is technologies for the production of cold/hot water or conditioned air by means of solar heat or solar electricity. Therefore, the Task starts with the solar radiation reaching the collectors or the PV modules and ends with the chilled/hot water and/or conditioned air transferring to the application. It is focused on solar driven systems for both cooling (ambient and food conservation) and heating (ambient and domestic hot water).

The following work deals with the economic and technical (energetic) evaluation of different configurations and technologies of New Generation Solar Heating and Cooling.

Tab. 1: Nomenclature and Subscripts

Subscripts			
C	Cooling	out	Output
DHW	Domestic hot water	NRE	Non-renewable
EC	Energy Carrier	ref	reference system
el	Electrical	SH	Space heating
equ	equivalent	sys	Overall system (C & DHW & SH)
Nomenclature			
ACM SE	Absorption chiller, single effect	PER_{NRE}	Primary Energy Ratio (-)
CR	Cost ratio (-)	SEER	Seasonal Energy Efficiency Ratio (-)
ε	Primary Energy Factor (kWh/kWh_{PE})	SPF_{equ}	Seasonal Performance Factor (-)
$fsav_{\_NRE}$	Fractional savings (-)	VCC	Vapour compression chiller

Several studies in the past years show the competitiveness of solar thermal and PV driven systems. Depending on the boundary condition each system configuration shows appropriate advantages. Existing simplifying studies (e.g. Streicher (2010), but also more detailed studies (e.g. Henning (2010), Eicker (2012), Wiemken et al. (2013)) are evaluating both technologies under different boundary conditions.

The results of these studies depend on climatic conditions (ambient temperature, irradiation) as well as on the type of application (DHW, C, etc.), size and operation hours of the system, etc. Furthermore they show that reasonable system configurations (base or peak load design) and different control strategies have a crucial impact on reachable non-renewable primary energy savings. Even under various economic considerations the results can differ significantly. But in general in common controversy PV driven systems get more positive remarks than solar thermal driven systems. Often quoted arguments are regarding efficiency, costs and handling of surplus energy.

Selected performance indicators for evaluating technical and economic quality and cost effectiveness are fully discussed and defined in Neyer et al. (2015) during the course of IEA SHC Task 48 (http://task48.iea-shc.org/). The procedure is valid for thermal driven plants with vapor compression chillers (VCC) as cold backup. If a compression chiller is the main component and is supported by PV or other renewable electricity, the methodology has to be adapted.

This adaptation was performed under the course of IEA SHC Task 53 and is described in this paper. Furthermore numerous realized systems with in-situ monitoring or rather simulation studies of solar thermal (ST) driven and photovoltaic (PV) driven systems with different capacities and applications are shown. The plants are evaluated with the tool developed in Task 53 and are benchmarked among each other with technical and economic key figures. Sensitivity analysis of four plants show the impact of specific boundary conditions (primary energy factor, costs, etc.) on the performance and the difference between ST and PV driven systems.

2. Methodology

The assessment and evaluation tool of Task 48 was generalized and extended, with the focus on new generation of solar heating and cooling with either solar thermal or photovoltaic driven systems. It enables the assessment for a wide range of systems available on the global market. Systems can contain bivalent heating and/or cooling devices (boiler or chiller respectively). The component base information includes technical as well as economic data to evaluate and benchmark the systems. Multiple usage of each component in the entire system (energy flows) can be added and analyzed.

In Figure 1 the overview of all components and main energy flows is presented in an energy flow chart, invented in IEA SHC Task 44 based on work of Frank et al. (2010). Traded energies include electricity and other energy carriers and are arranged on the left (displayed in grey); free energy sources including solar and other ambient source/sinks on the top (in green); the application and its heating (in red), cooling (in blue) and electricity demand (in grey) on the right.

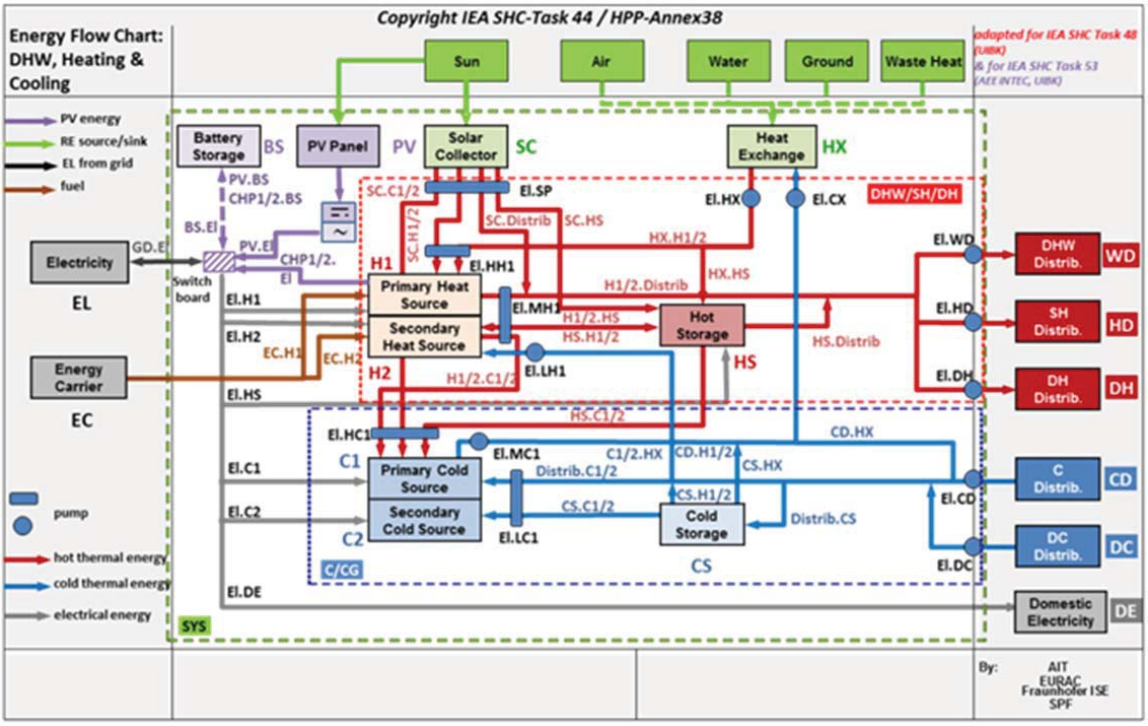

Fig. 1: Energy flow chart including all possible components for the technical and economic assessment of IEA SHC Task 53

Due to the dependency of the results on the system boundaries, it is obvious to display them in the energy flow chart. All components and auxiliary pumps can be identified easily. Within the Tool for each demand (DHW, SH, etc.) a separated assessment can be performed for the entire solar fraction and the overall performance; resulting in a maximum of five subsystems including further five solar sub boundaries and one overall system assessment.

The component selection includes reversible heat pumps (electric or thermal driven), chillers (air/water cooled VCC, SE/DE absorption, etc.), several boiler types (natural gas, CHP, oil, pellets, etc.) and storages (thermal, electrical). The database for the single components include either cut off or standardized (minimum) performance and cost indicators. For eight countries (Austria, Australia, France, Germany, Italy, P.R. China, Spain and Singapore) all input values, if applicable, were collected (primary energy factor, energy costs, etc.) and can be used for country specific assessments.

Nevertheless, these values are subjects of permanent changes, either driven by political decisions or technical issues. Furthermore the values depend on the choice of energy trading company or even on the territory. Therefore the tool enables the implementation/creation of self-calculated or investigated values, valid for a specific region or configuration / analysis. The assessment tool calculates and indicates regularly one set of

Task 53 (T53) standard Key Performance Indicators (KPI) and one set of specific (standard country or own choice) KPI's. The T53 Standard KPI's are based on a pre-defined reference system (natural gas boiler and air cooled vapor compression chiller) and the appropriate cost and primary energy factors. It allows the comparison of different plants under the same boundary conditions. In this study all KPI's are related to the T53 standard.

2.1. Technical assessment

The Seasonal Performance Factor (SPF), for a given system boundary, is generally defined as the ratio of useful energy (supplied to satisfy the needs of the application) to energy effort from any source. The SPF can include several auxiliary components within the defined boundary and is calculated over a defined period of time (e.g. annual or monthly). Well known SPFs are based upon thermal or electric energy inputs.

However, the electrical SPF_{el} can be misleading when a system with different energy inputs (thermal and electrical) is analysed. The SPF_{el} might show high results even when large amounts of fossil fuel (e.g. gas) back up is consumed with overall poor environmental performance. Therefore the Primary Energy Ratio (PER) and derivative key figures like the electrical equivalent SPF_{equ} and fsav are calculated and provide a better base for assessing different SHC systems.

- Non-renewable Primary Energy Ratio (PER_{NRE})

The non-renewable Primary Energy Ratio converts all non-renewable energy flows into primary energy equivalents. This provides appropriately comparable quality ratings for energy derived from alternative electricity, solar and fossil fuel heat energy sources. It is defined in eq. 1 as the ratio of useful energy (ΣQ_{out} supplied to satisfy the needs of the building) to non-renewable primary energy (electricity and other energy carriers). Certain primary energy conversion factors (ε) for each type of energy source have to be provided to calculate the PER_{NRE}. The primary energy factors depend on local conditions (e.g. the source from which local electricity is derived).

$$PER_{NRE} = \frac{\sum Q_{out}}{\sum\left(\frac{Q_{el}}{\varepsilon_{el}} + \frac{Q_{EC}}{\varepsilon_{EC}}\right)} \quad \text{(eq. 1)}$$

A high value for PER indicates that the heating and cooling services can be obtained with a relatively small amount of fossil derived energy and is therefore an environmentally friendly system. However, values for PER_{NRE} (in a magnitude of ca. 1 to 2.5) are not directly comparable with any widely available industry figures of merit such as the EER or SEER of a vapor compression chiller.

- Fractional saving (f_{sav})

A further key performance indicator is the so called fractional saving (f_{sav}). This represents the percentage reduction in non-renewable primary energy for the application compared with a reference (business as usual) system. Thereby the reference system can also be another renewable system. The PER_{ref} uses the same calculation as PER but takes the standardized component information to calculate its non-renewable Primary Energy demand. The non-renewable primary energy savings ($f_{sav\text{-}NRE}$) in comparison to a reference system can be calculated as follows (eq. 2).

$$f_{sav-NRE} = 1 - \frac{PER_{ref}}{PER_{sys}} \quad \text{(eq. 2)}$$

The f_{sav} cannot exceed a value of 1 but can be negative, depending on the choice of reference system (standard or renewable) and the performance of the SHC system (auxiliary electricity demand and fossil backup). A high f_{sav} indicates that a high solar fraction is given in the entire SHC system. The application's primary energy consumption has been eliminated by substitution with solar energies (solar thermal or photovoltaic).

These savings are used to generate a labeling to express the quality of the SHC systems. The labelling is based on the European energy labelling guideline 2010/30/EU (2010). The rating levels start from A+++ (best rating) to G (worst rating). If the considered SHC system has a lower primary energy demand than the reference system, the f_{sav} is greater than zero. The energy label is calculated for all subsystem (SH, DHW, C etc.) and the total system. The rating levels are kept in ten percent steps.

- Electrical Equivalent Seasonal Performance Factor (SPFequ)

Another technical key figure that is used to compare the systems is an "Electrical Equivalent SPF" (SPF_{equ}), which combines all non-renewable final energy sources (both electrical and energy carrier), by converting them into primary energy flows expressed in electrical equivalent units. This is achieved by using the relevant non-renewable primary energy factors for electricity (ε_{el}) and energy carrier (any kind of fuel) input (ε_{EC}). The SPF_{equ} is calculated following the unit conversion and ending up in eq. 3.

$$SPF_{equ} = \frac{PER_{NRE}}{\varepsilon_{el}} = \frac{\sum Q_{out}}{\sum\left(Q_{el} + \frac{Q_{EC}}{\varepsilon_{EC}} * \varepsilon_{el}\right)} \quad \text{(eq. 3)}$$

The electrical equivalent Seasonal Performance Factor for a subsystem (e.g. cooling $SPF_{equ\text{-}C}$) can thus be used to compare the application performance with a commonly used SEER value, even when hot backup is used as part of the heat supplied to a thermal chiller. The SEER declares the efficiency of a component under standardized testing conditions. The actual system performance is often much lower than these SEER values (cf. Wiemken et al. (2013), Nocke et al. (2014) and many more). Same SPF_{equ}'s indicates finally an equal primary energy demand, although the systems are supplied by different energy quantities.

However, when the building has a small solar cooling system relative to the size of a backup VCC system, the good performance of the solar cooling system may be undermined by the large fraction of cooling done by the conventional backup chiller. In this case, the SPF_{equ} of the solar subsystem can be used to represent the quality of SHC systems.

2.2. Economic assessment

Under the consideration of specific investment, replacement, operation and consumption based costs, the annualized costs for the entire system can be calculated by using the annuity method. Therefore derivative key figures (e.g. PE avoidance costs, etc.) are calculated easily.

All economically influencing parameters are pre-defined for the T53 Standard and country specific. Some of the values influencing the economical calculation are challenging and details could be discussed extensively. The aim of these calculations and definitions is to generate cut off values indicating a reasonable magnitude of economic effects. The results present best known averages and may differ from specific values.

If desired, own, project specific values can be implemented in the calculation. E.g. this is necessary if the application is serving domestic, commercial or industrial usage. Domestic prices are higher, but are mainly based on energy consumption. Commercial and industrial prices have low energy based costs, but can include capacity prices.

The economics that are defined prior for T53 and the eight countries are reaching from period under consideration, credit period, inflation rate, market discount rate, credit interest rate, inflation rate for energy prices electricity, inflation rate for energy prices, fraction of initial investment without financing up to the public funding's rate. Their main influence is visible when the different cost assets are discounted.

The consumption based costs are electricity and energy carrier prices for both energy and capacity or yearly costs. Water consumption costs are also defined as well as feed-in tariff for PV and for CHP with and without subsidies. The economic analysis is performed under the T53 standards. Main energy costs and economics are listed below. The prices are rather valid for commerce and industry and thus challenging for solar heating and cooling systems.

- Period under consideration (25 a), credit period rate (10 a)
- Inflation rate, market discount rate and inflation for energy prices (3%)
- Electricity energy prize (0.1 €/kWh) and electricity peak prize (80 €/kW)
- No subsidies, feed-in tariff for PV (0.03€/kWh)
- Natural gas energy prize (0.05€/kWh) and annual allowance (80 €/a)
- Water consumption (2.50 €/m²)

Not included are water treatment, distribution and heat / cold supply system costs.

Specific costs for each component include economy of scale prices. The greater the capacity of a certain component is the cheaper are the specific investment costs. Examples for different types of chillers are included in Figure 2. The investment curves indicate typical average and cut off values mainly valid for Central Europe. For each component the estimated lifetime, costs for maintenance, service and inspection is defined under consideration of VDI 2067. It has to be noted, that significant deviations to specific projects may occur. Therefore all values may be changed and user defined values can be implemented in the Excel Tool.

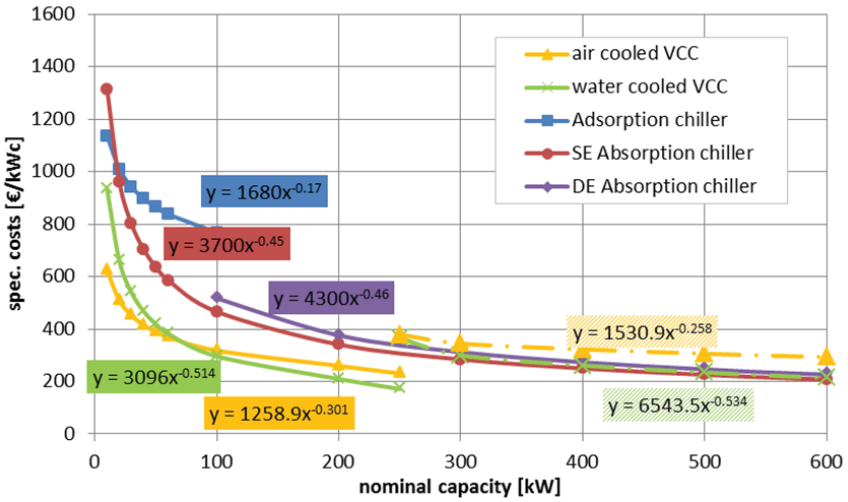

Fig. 2: Example of specific investment costs used for T53 standard calculation of investments for thermal and electrical driven chillers

The costs for each category are summed up and discounted to an annualized value according to the defined economics. The total annualized cost is the sum of yearly annualized investment, replacement and residual values, maintenance, electricity (auxiliary and if applicable domestic), energy carrier and water costs using the set of standard costs in the assessment tool. The Levelized costs of the SHC and also the one of the reference system are the ratio of annualized costs to the overall useful energy provided to the application.

Nevertheless, to avoid the discussion of absolute costs (e.g. when only taking sub systems into assessment) a cost ratio is calculated by comparing the Levelized costs of energy of the renewable systems with the Levelized costs of the reference systems.

$$CR = \frac{C_{tot.SHC}}{C_{tot.REF}} \qquad \text{(eq. 3)}$$

3. Analyzed best practice examples

The requirement for an annual cost analysis is the availability of annually measured or simulated data. There are many plants as demo- or research project in operation, but only a few were able to contribute with data. Therefore, the analyzed plants are a small selected group of photovoltaic driven and solar thermal driven systems.

Three PV and four ST systems, including some calculated derivatives, are presented and analyzed here. The most important facts are summarized in Table 2. The summary contains information of the status (monitored or simulated), the application (SH, DHW, C) and corresponding demand, solar technology used with capacity/size (ST in m², PV in kW_{peak}) and achieved solar fraction, the boiler and chiller type and its nominal capacity. The sizes vary from small scale (2 kW) up to large scale (1.5 MW). Main applications are domestic hot water combined with cooling

Regarding the design a differentiation between "full load" and "base load" is reasonable. In this sense the definition and explanation is as following.

- Base load: the solar heating and cooling system is design for assisting a larger auxiliary heating or cooling system, typically solar fraction appear between 20 to 60% appear in these bivalent systems.
- Full load: there is no backup for the solar heating and cooling system. Solar satisfies 100% of the energy demand of the according application.

None of the plants is intended for pure full load design. 6 of the example feature more than one application. The design often aims to satisfy one application by solar 100% whereas the second one runs in base load.

If there is no information available for the entire auxiliary heating / cooling system (no overall demands measured), the plants economic analysis appears to be a full load design. Two examples (#2, #3) are used to show the effect of full/base load design. A solar fraction is assumed for both and the key figures are recalculated. The derivations of these plants are marked with subscripts (3a, 5a).

Tab. 2: Fact sheet of examples

Plant	Status	demand		Solar technology			Boiler		Chiller		Source
	Monitored (MON) Simulated (SIM)	DHW/SH/C	Energy (MWh)	ST/PV	ST: Area (m^2) PV: peak capcaity (kWp)	Base or full load / magnitude SF [%]	Type	Capacity (kW)	Type	Capacity (kW)

7a				PV	2.5	base / 10					
7b				PV	2.5	base / 40					

4. Results

The assessment follows the above mentioned method of Task 53 and uses the standardized costs resulting in the following figures.

Figure 3 shows the breakdown of the total annualized cost of all plants and derivative calculations. Main cost driver are the investment cost; they aggregate between 40-60% of the overall costs. The ratio of investment cost is higher when the plants are smaller (#6, #7) or the information of the entire total system is missing (#2,#3). Second largest cost fraction are the energy cost (energy carrier or electricity). If PV surplus is feed in, the total costs reduce only slightly in #7a and #7b and up to 10% in #5. In the majority maintenance and replacement and residual value sums up to 20%.

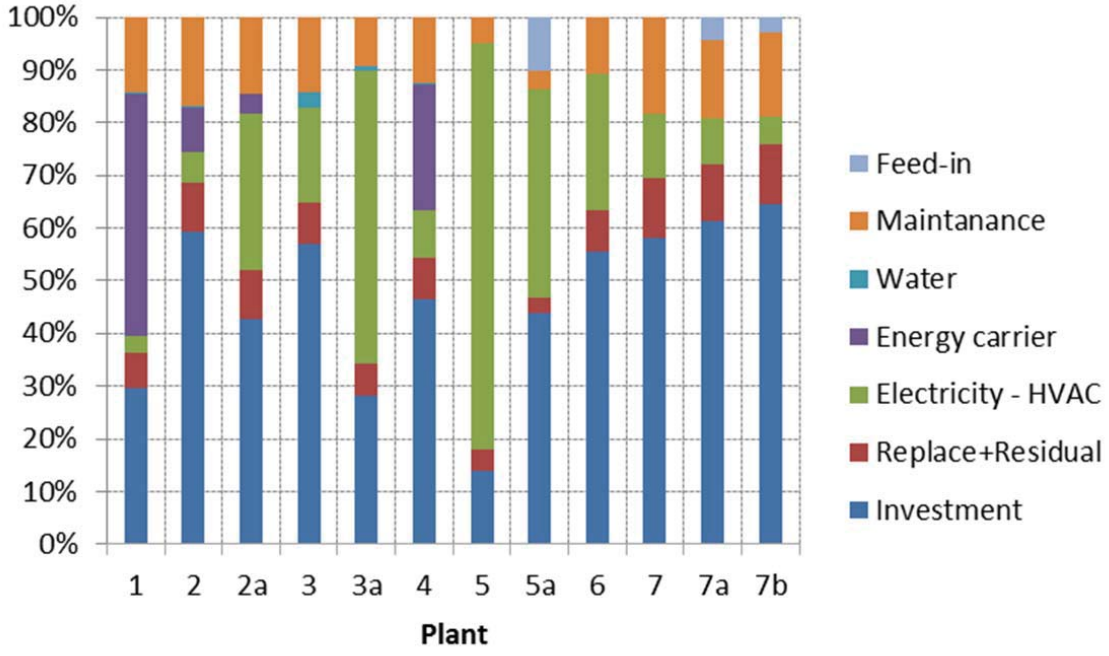

Fig. 3: break down of total annualized cost for al plants calculated with the T53 standard values.

The combined influence of non-renewable savings (f_{sav}) and the Cost Ratio (CR) is shown in Figure 4. The CR is displayed in reversed order on the y-axis in Fig. 4. A cost ratio of one is highlighted as bold line and is the value to be beaten by the solar driven heating and cooling systems. Values lower than 1 indicate that the entire SHC system is economical viable and thus cheaper than the T53 standard reference system (natural gas boiler, vapor compression chiller).

Each marker represents one plant. The target is a high non-renewable primary energy saving at affordable costs. The area in the upper right side represents that target. None of the analyzed plants can reach that area nor beat the CR of one. The trend shows, that more savings result in higher cost ratios and thus more expensive plants. Vice versa, the higher the investments are the more savings can be achieved – at least for these best practice examples.

All plants can achieve savings greater than 50% against the standard reference system. If another reference system would be chosen (e.g a heat pump system like #5a), the base is shifted accordingly (dashed lines). The average linear trend of PV and ST is displayed with a bold dotted line (PV) and a bold chain dotted line (ST).

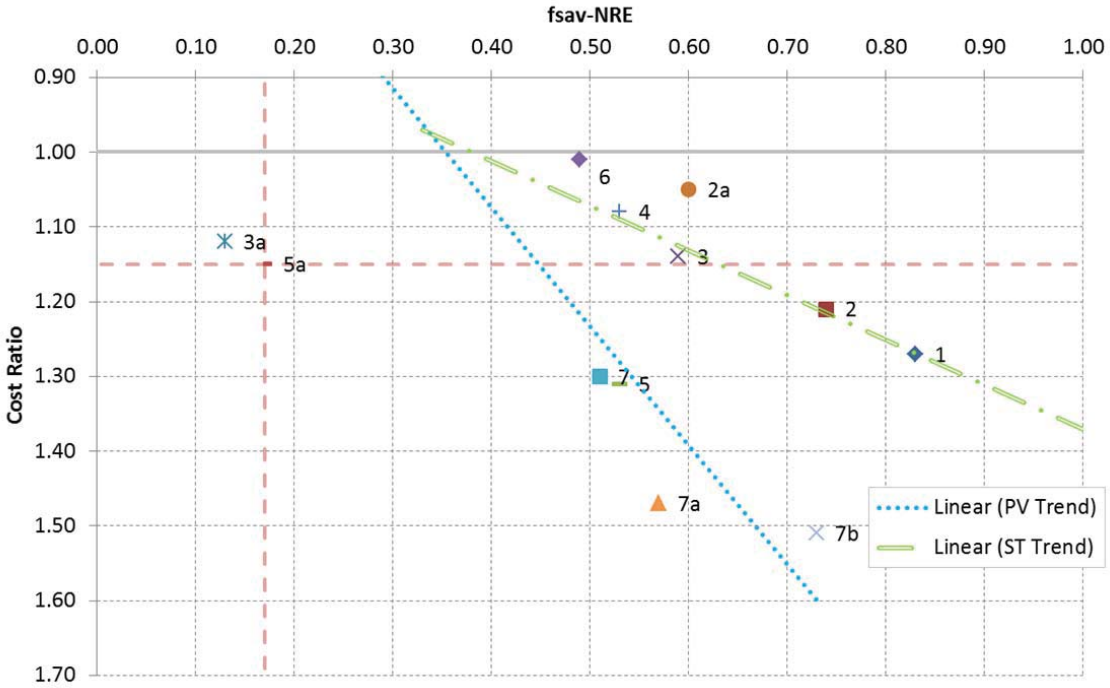

Fig. 4: Cost Ratio vs. non-renewable primary energy savings of the analyzed plants (1-7) and trends observed by PV and ST driven systems

Some findings of this line up are listed below. Including only 7 plants in the compilations, this is not representative, notwithstanding the trends are from interest and give a general view of solar heating and cooling.

- If 5a would be the reference (bold dashed lines), some examples would achieve cost competitiveness; one derivative example would decrease to negative savings.
- The plants with space heating (#1, #7a, 7b) are more expensive and can achieve higher savings.
- Heat pump systems (#5, #7) are more expensive than others.
- There is hardly any effect of the system size visible (cf. #6 – 2 kW & #3 1.5 MW).
- Type of heat pump system is shown clearly (#5 - DHW vs. #7 - SH)
- Climatic conditions are negligible.
- If gas back up is used, the f_{sav} is slightly smaller than the solar fraction (#3, #4)
- Against the common arguments the trend of PV and ST express that the sum of all solar thermal driven systems shows a smaller cost ratio with higher reachable savings than the PV driven systems.
- In this summary the economic parity of PV and ST can be reached below 40% savings.

After analyzing Figure 3 questions, especially regarding the boundary conditions of the comparison, are arising: What are the driving parameters for this constellation and how do they affect the results?

The sensitivity analysis was carried with four plants (ST: #1, #2 & PV: #5, #6). Following parameters were varied in the mentioned range.

- Primary energy factor (ε_{el}) 70 – 160% of ε_{el} = 0.4 kWh_{el}/kWh_{prim}
- Investment costs (invest) 50 – 130% for solar components
- Electricity costs (C_{el}) 50 – 150% of C_{el}=0.10 €/kWh
- Electrical efficiency ($Q_{el.sys}$) 70 – 130% of auxiliary electricity demand

The results are presented in Figure 5. The primary energy conversion factor for electricity is only affecting the non-renewable primary savings and results in horizontal lines. The investment cost and the electricity cost are only affecting the cost ratio, consequently resulting in vertical lines. An effect on both key figures is achieved by the change of the electricity demand of the entire system. This can be interpreted either as an improvement of the electrical efficiency of the heat pump or the reduction of the auxiliary electricity demand.

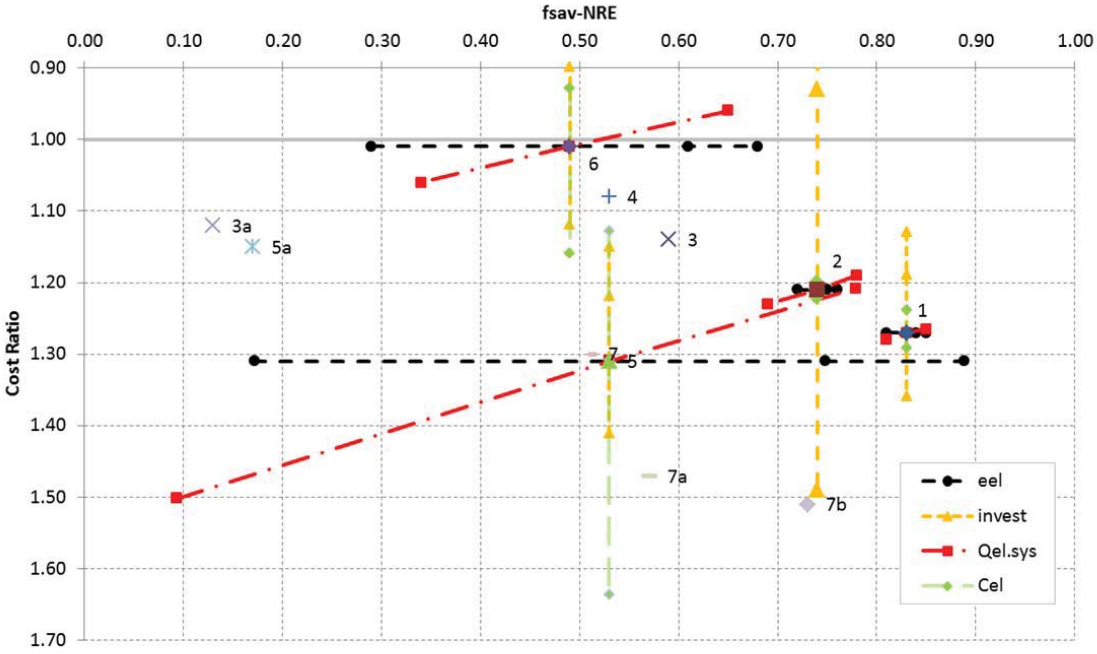

Fig. 5: Sensitivity analysis of two PV and two solar thermal driven plants

The two solar thermal plants (#1, #2) are less sensitive on the electric parameters (ε and SPF_{el}). Both thermal systems were designed and optimized regarding the auxiliary electricity demand. Thus the influence of changing input values is lower than for electrical driven systems.

The variation of ε_{el} results in a change of ±0.05 in the f_{sav} for the solar thermal plants but ±0.3 for the PV driven plants. The influence is less for ST because they are optimized towards low auxiliary electricity consumption. Thus electricity driven system are more sensitive the less the solar fraction.

Electrical efficiency is an important issue for PV supported systems. Only if the heat pump systems are optimized the systems get economical viable. Increasing the PV area increases the savings but also the cost ratio although the surplus energy rises and the revenues due to feed-in are increasing. If a system is optimized to a high standard, the less it can be influenced by varying input parameters.

Investment costs have a higher influence on the results of the solar thermal plant, due to the fact that the ratio of investment cost to all other costs is higher. Plant #6 and #2 could reach a cost ratio of 1 with lower investment costs. Plants #5 and #1 would reach affordable economics.

The sensitivity analysis shows that PV and ST are cutting across with the same trends (e.g. #2 and #5 if electricity demand is optimized). To reach cost competiveness lower investment costs have to be derived first, followed by the efficiency of the system. The chosen (or rather standardized) primary energy conversion factors have a great influence on the results and need to be stated clearly to interpreter correctly.

5. Conclusions

A comprehensive tool was developed in the course of IEA SHC Task 53 and is available for the analysis and assessment of new generation of solar heating and cooling systems. The key figures that are calculated allow a benchmarking and simplify the comparison of different system configurations. The Tool can be used to benchmark against a standardized reference systems or against other renewable heating and cooling technologies. Still, the comparability is challenging if applications and configurations are mixed. Nevertheless, a trend wise comparison of magnitudes can definitely be achieved. The tool can be downloaded at http://task53.iea-shc.org/.

One figure, that can be used to compare the application performance with a commonly used SEER value based on electricity, is the electrical equivalent Seasonal Performance Factor (SPF_{equ}). This key figure summarizes the performance even when both, electricity and heat is used to supply the entire system.

The presented plants show good performances resulting in non-renewable primary energy savings of more than 50%. None of the plants can reach a cost ratio below 1. The trend shows, that more savings result in higher cost ratios and thus more expensive plants. The four solar thermal plants show a lower gradient in the comparison than the three PV driven systems resulting in higher costs per saving.

The sensitivity analysis displays that PV and ST are cutting across with the same trends. Lower costs have to be derived first, followed by the efficiency of the system. Cost competiveness is achievable for both technologies! Change of conversion factors equals PV and ST driven systems even more, independently of the total system. Both technologies have their advantages and are desirable.

More comprehensive collection of annual data will be carried out in the ongoing Task 53 and will be presented within those activities.

Abstract

The variety of designs for solar assisted heating systems (also called solar combisystems) in multi-family houses is wide and has not been evaluated systematically. Functional insufficiencies, resulting from unfavorable device combinations as well as improper control design place significant market barriers for the application of this technology. Using hardware-in-the-loop tests, functional aspects of the most common system designs are investigated and evaluated. Further dynamic system simulations on an annual basis allow an energetic evaluation and later a comparison of the different design options. In this contribution we present the results for the first tested solar assisted heating system. Furthermore, the study suggests the introduction of a novel evaluation parameter referred to as the *performance factor of the central heating facility,* and a novel reference parameter referred to as the *demand-specific collector area*. A newly developed benchmark procedure is comparing the central heat demand of the building to the maximum solar thermal gain of the solar circuit in order to calculate the maximum performance factor possible for an idealized central heating facility. Using this benchmark procedure, optimization potentials are exemplarily disclosed for the tested solar combisystem. The results highlight a high optimization potential of the system control and the process layout of central heating facilities, achievable with low cost at the same time.

Keywords: *solar combisystem, hardware-in-the-loop, whole system testing, system simulation, benchmark*

1. Introduction

The high theoretical potential for the reduction of final energy demand through the use of solar assisted heating systems was pointed out in earlier studies (e.g. Papillon, 2010). But there is a difference between theoretical potential and real final energy savings. One reason for the divergence are significant insufficiencies of the yield and the efficiency of solar assisted heating systems as result of inadequate hydraulic installation (Letz et al., 2010). Moreover, there is a wide and largely un-evaluated variety of available hydraulic designs for solar combisystems, especially for multi-family houses (MFH). Such systems combine the components solar thermal collectors, thermal storage tank(s), heat source(s) and distribution circuits. The research project "solar assisted heating systems for multi-family houses" (SUW-MFH) intends to identify the most efficient system design based on a functional, energetic and economic evaluation of these systems.

Selected common designs of large central solar combisystems are tested as integrated systems by hardware-in-the-loop (HIL) measurements to identify insufficient controller, valves, hydraulic connections and interaction between components. Besides functional evaluation of the investigated systems, the results of HIL measurements serve as data base for the validation of dynamic simulation models. Based on simulation results an energetic evaluation is performed by comparing the results to a newly developed benchmark procedure. An economic evaluation and comparison of the diverse system designs will be performed at a later stage of the project and respective results will be reported in future communications.

$Q_{sol,pot}$	potential solar thermal gain	[kWh]
T_m	mean temperature	[°C]

2. Methodology of performance testing and evaluation

2.1. Hardware-in-the-loop measurements and dynamic system simulation

In order to standardize boundary conditions for performance tests of solar combisystems, only the central components of these systems (in the following referred to as *central heating facility*) are integrated into HIL tests. These central components may be thermal storage tank(s), a solar heat transfer station, an auxiliary heater, central fresh water station(s) and respective hydraulic connections. The components are implemented factory-set and connected to several emulators which serve as solar heat source and building heat sink (space heating, domestic hot water draw and circulation). The behavior of the emulators and their interaction with the central heating facility is calculated by real-time simulations in TRNSYS. Employing a time discretization of one minute, measured data of the HIL test is given as an input to the simulation environment which then adjusts the present set-values of the emulators. Therefore, the emulators are allowed to react to the instant behavior of the central heating facility rather than just follow a predetermined load profile. Weather conditions and solar thermal collectors as well as the building are part of the dynamic simulation model to ensure equal conditions for all solar combisystems under consideration in this work (see Table 1).

Tab.1: Boundary conditions for hardware-in-the-loop measurements and dynamic system simulation

	Description	**Values**
weather data	Meteonorm, location: Zurich, Switzerland	• days for HIL measurements: 38, 71, 99, 112, 175, 230, 250, 356
solar thermal circuit	solar thermal collectors as well as pipes between roof and central heating facility	• collector area: variable between 0 m² and 32 m² • inclination: 45°, orientation: south • total pipe length: 53.5 m
space heating and distribution	multi-family house in Germany with a construction year between 1958 and 1968 and an energy-focused refurbishment according to the standards of EnEV 2009	• multi-zone simulation model (52 thermal zones) • number of flats: 8 or 16 (depends on the size of the tested system) • detailed distribution network with more than 100 pipe sections (for a house with 8 flats) • size of a flat: 65 m² • heating system: radiators
domestic hot water draw	draw profile generated with DHWcalc (Jordan, Vajen, 2014)	• 55 litre per flat and day (assumption of 1.8 inhabitants per flat)
domestic hot water circulation	constant circulation 24 hours a day	• 19 litre per hour and flat (according to a maximum temperature difference in the flow line of 5 K)

HIL measurements are performed for eight individual days capable of representing typical meteorological patterns during the course of a year. The days are selected in order to cover all possible load situations of the systems which can occur over a year. Related approaches exist on the literature, e.g. a good prediction of the annual thermal performance (Haller et al., 2013), but have turned out to be inadequate for the HIL method employed in this work. The chosen day sequences include sunny and cloudy days in all seasons as well as extreme climate settings for winter and summer. The respective HIL tests are measured separately, always regarding both pre- and post-conditioning of the system and the related simulation model to ensure defined start conditions for devices and model and to allow the calculation of thermal capacity changes.

A new HIL test facility has been developed and implemented at the ISFH, capable of emulating up to 20 flats in a MFH. Figure 1 provides an overview of this test facility. It shows the first tested solar combisystem during operation.

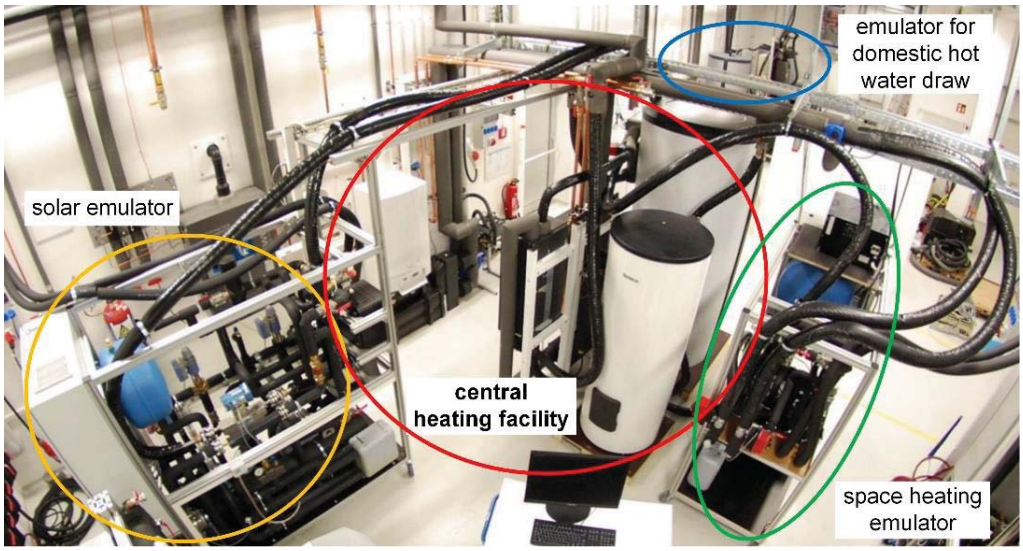

Fig. 1: Hardware-in-the-loop test facility developed for the emulation of up to 20 flats in a MFH and 60 kW solar thermal collector power, equipped with a central heating facility (red encircled), space heating emulator (green), solar emulator (yellow) and emulator for domestic hot water draw (blue)

For simulations of the complete solar assisted heating systems, the dynamic simulation model is extended by the components of the central heating facility. The added components of the model are parametrized and validated by using datasets from the HIL tests. Firstly, by qualitative comparison of measured and simulated temperature and mass flow curves, respectively, to ensure adequate implementation of control strategies and control hysteresis. Secondly, by quantitative comparisons of the energy balances of both individual components and the overall system, to guarantee the eligibility of the simulation model for further energetic evaluations of the solar assisted heating system. Therefore, the validation procedure can ensure high quality of simulated values on the one hand while allowing fast variations and optimizations of the control system, hydraulic connections or components on the other hand. The performed system simulations are covering a complete annual period, discretized by minutes, thus allowing to assess the specific system dynamics.

2.2. Energetic evaluation of solar assisted heating systems

Figure 2 shows the system boundaries employed for balancing a solar assisted heat supply for MFH. Of particular interest are the boundaries of the central heating facility comprising the solar thermal and final energy inputs and the heat loss and central heat demand as output. The final energy input covers fossil fuel and electricity whereas the central heat demand of the building ($Q_{central}$, see Equation 1) considers the heat demand for space heating (Q_{SH}) and distribution heat losses (Q_{dist}) as well as the heat demand for domestic hot water draw (Q_{DHW}) and circulation (Q_{circ}). Distribution heat losses as well as heat losses caused by domestic hot water circulation address heat demands to the central heating facility such that, the central heat demand of the building must not be equalized with useful energy.

$$Q_{central} = Q_{SH} + Q_{DHW} + Q_{dist} + Q_{circ} \quad \text{(eq. 1)}$$

A part of distribution and circulation heat losses can be credited as heat gains if they are localized inside the boundary of useful energy in Figure 2. By occurring outside of the boundary of a central heating facility it is not of further interest for an energetic evaluation of a central heating facility. For an overall evaluation of the heat supply of a MFH, which is not part of this paper, heat gains have to be taken into account.

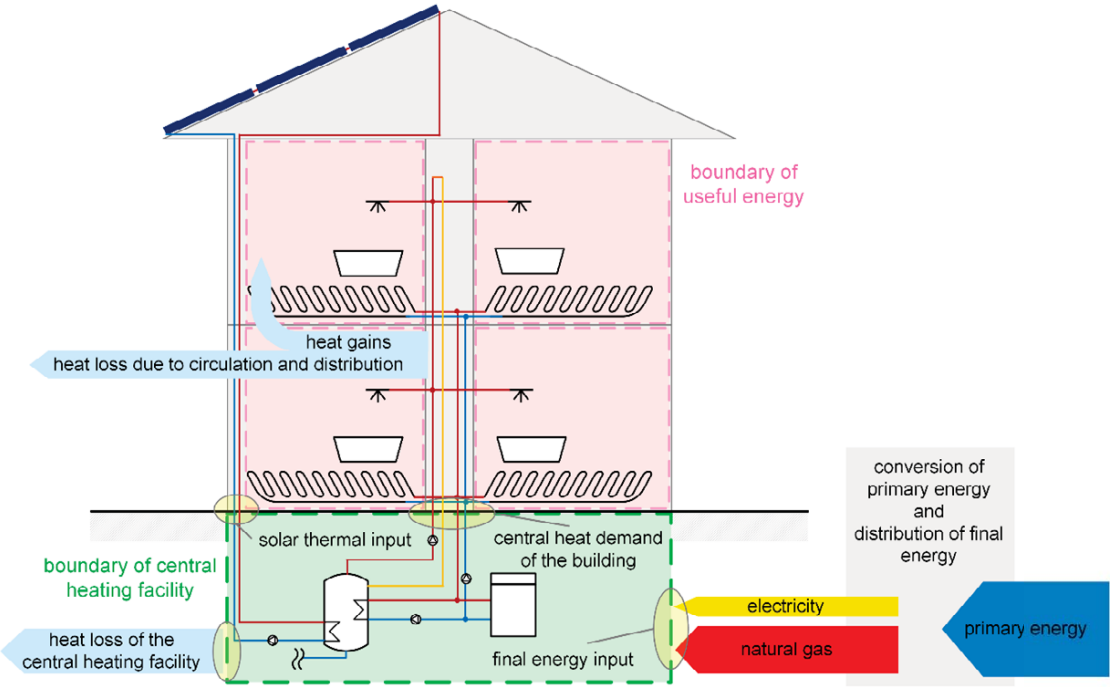

Fig. 2: Definition of system boundaries for the energetic evaluation of central heating facilities as part of solar combisystems in multi-family houses

To evaluate and compare different designs of solar assisted heating systems a novel evaluation parameter is introduced, referred to as the *performance factor of the central heating facility* (CPF, see equation 2). It is defined by the ratio between the central heat demand of the building as energetic benefit and the final energy input (E_{final}) as energetic effort.

$$CPF = \frac{Q_{central}}{E_{final}} \qquad \text{(eq. 2)}$$

The interpretation of the CPF is comparable to the seasonal performance factor (SPF) of solar heat pump systems as of IEA SHC TASK 44 (Malenković et al., 2013). In extension to this, the CPF is applicable to all central heating facilities of solar assisted heating systems owing to proper definition of system boundaries. Note that in the specific case of a solar combisystem without a central heating facility, or 100 % solar fraction, it is not advisable to use the CPF as evaluation parameter.

The CPF if highly dependent on the defined boundary conditions of performance testing (solar thermal circuit, weather and building properties). In consideration of this, and to ensure a wide comparability of systems, we also suggest a novel reference parameter, referred to as *demand-specific collector area* (a_{dsc}). It is defined as the ratio between collector area and central heat demand of the building:

$$a_{dsc} = \frac{A_{col}}{Q_{central}} \qquad \text{(eq. 3)}$$

2.3 Benchmark procedure

A benchmark procedure has been developed to estimate the effective solar thermal gain ($Q_{sol,eff}$) which can be utilized by an idealized central heating facility. The procedure extends an approach by Steinweg et al. (Steinweg et al., 2016) and employs the calculation of a maximum possible CPF. The method is comparable to the FSC procedure of IEA SHC TASK 26 (Letz, 2002). In contrast to the FSC method the benchmark procedure used here matches the central heat demand of the building with the maximum solar thermal gain of

the solar circuit ($Q_{sol,max}$) rather than the solar thermal potential. Both approaches rely on monthly energy data. However, it turned out that taking into account the efficiency of the solar thermal collectors and heat losses between collectors and central heating facility yields to a more realistic estimation of the CPF. Central assumptions and boundary conditions of the benchmark procedure are:

- monthly correlation of maximum solar thermal gain and central heat demand of the building (idealized thermal storage tank)
- no heat losses and no parasitic energy (electricity) consumption of the central heating facility
- conversion of final energy without losses
- characteristics of solar thermal collector, weather conditions and central heat demand of the building are boundary conditions

Main part of the benchmark calculation is the determination of the effective solar thermal gain which represents the solar thermal input to the central heating facility. Basis of this is on the one hand the calculation of the maximum solar thermal gain for different mean temperatures (T_m) of the collector fluid with the chosen collector specification (see Figure 3). On the other hand the central heat demand of the building needs to be separated into different heat sinks with their mean temperatures (see Figure 4).

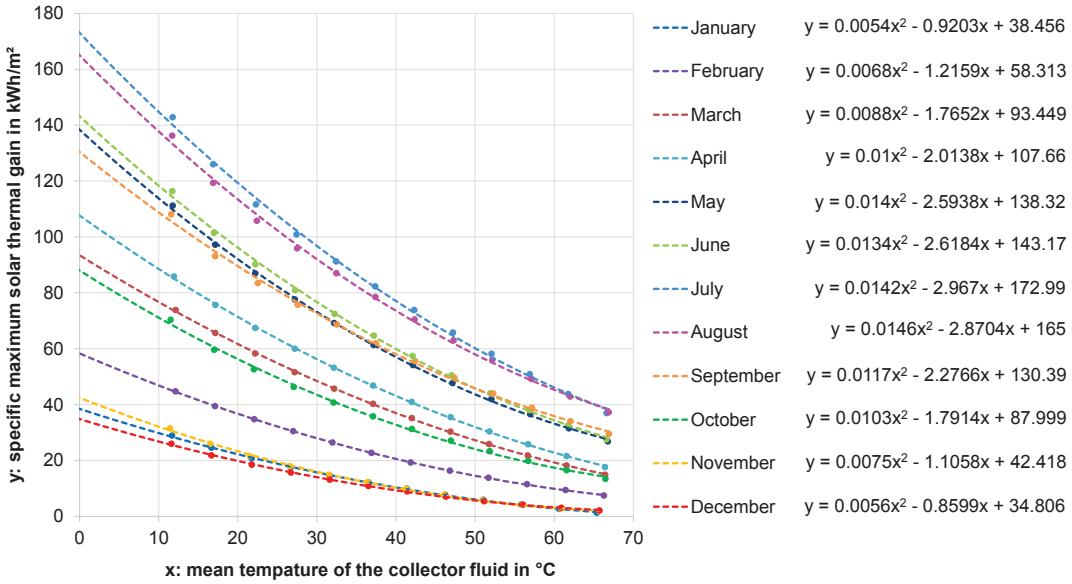

Fig. 3: Specific maximum thermal gain of the solar circuit over the mean temperature of the collector fluid on a monthly base accompanied by formulas of the trend lines (weather: Zurich)

Figure 3 shows the area specific maximum gain of the solar thermal circuit as function of the mean temperature of the collector fluid. The functions are correlated for every month in the year based on dynamic system simulations performed with TRNSYS, regarding an area specific mass flow rate of 50 kg/(h·m²) and Meteonorm climate data for the city of Zurich. The correlated functions (second degree polynomial) are provided in the figure. The functions allow the direct calculation of the maximum solar thermal gain for each month, once the collector area and the mean temperature of the individual heat sinks are set.

Figure 4 exemplifies for a selected month (March), how the central heat demand of the building may be split up into different heat sinks. The same procedure is used for the other months of a year. The figure regards three heat sinks: space heating (SH: red), domestic hot water draw (DHW: green) and domestic hot water circulation (circ: blue). For these heat sinks the specific heat demand and the temperature interval at which the demand occurs are indicated. Inspection shows that the respective temperature intervals for space heating and DHW circulation are quite small (7 K and 4 K, respectively), but the one for DHW draw is much higher (56 K: from 10°C to 66°C), than a standard solar thermal collector could possibly provide. Standard solar devices are typically capable of temperature shifts of about 15 K (with some degree of type- and operation-strategy-

specific variety). To adjust a system to this interval, heat sinks comprising larger temperature intervals may be subdivided accordingly. For example in Figure 4, the domestic hot water demand is subdivided into four separate heat sinks which sum up to the same total demand, while the temperature intervals of the individual sink is adjusted to a level of about 14 K, maintaining the following temperature level order:

- $T_{m,i} < T_{m,(i+1)}$: $T_{m,DHW,1} < T_{m,SH} < T_{m,DHW,2} < T_{m,DHW,3} < T_{m,DHW,4} < T_{m,circ}$

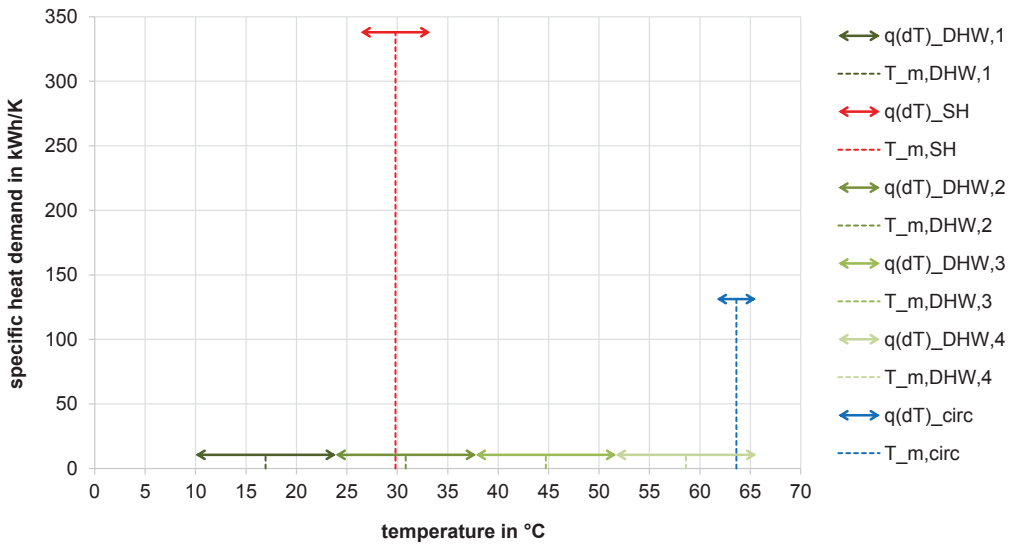

Fig. 4: Specific heat demand (q) over the corresponding temperature intervals (dT) and the resulting mean temperature (T_m), exemplified for the month March and for different heat sinks considered: hot water circulation (circ), space heating (SH) and domestic hot water draw (DHW,1-4: divided into four heat sinks)

The effective solar thermal gain is calculated on monthly basis ($Q_{sol,eff,k}$) by the following procedure: Firstly, the heat demand of the heat sink ($Q_{hs,i}$), which appears at the lowest temperature level is matched with the maximum solar thermal gain at this temperature ($Q_{sol,max}(T_{m,i})$). If the heat demand of the first heat sink is lower than the maximum solar thermal gain, the remaining solar gain is offered to the next heat sink in the temperature range. This procedure may be repeated until the maximum number of heat sinks (n_{hs}) is reached, or the maximum solar thermal gain is exploited. The potential solar thermal gain ($Q_{sol,pot}$) is an auxiliary quantity and not subject of further reflection:

$$Q_{sol,eff,k} = \sum_{i=1}^{n_{hs}} Q_{sol,eff,k,i} \qquad \text{(eq. 4)}$$

with: $Q_{sol,eff,k,i} = min\left(Q_{sol,pot,k,i}, Q_{hs,k,i}\right)$

$i = 1$: $Q_{sol,pot,k,i} = Q_{sol,max,k}\left(T_{m,i}\right)$

$i > 1$: $Q_{sol,pot,k,i} = Q_{sol,max,k}\left(T_{m,i}\right) \cdot \left(1 - \frac{Q_{sol,eff,k,(i-1)}}{Q_{sol,pot,k(i-1)}}\right)$

month: $1 \leq k \leq 12$

heat sinks: $1 \leq i \leq n_{hs}$ with $T_{m,i} < T_{m,(i+1)}$

The maximum possible CPF (benchmark) can be derived from the sums of the monthly central heat demand and effective solar thermal gain under consideration of the assumptions mentioned above:

$$CPF_{benchmark} = \frac{\sum_{k=1}^{12} Q_{central,k}}{\sum_{k=1}^{12}(Q_{central,k} - Q_{sol,eff,k})} \qquad \text{(eq. 5)}$$

3. Evaluation and optimization potential of the first tested solar assisted heating system

3.1. Description of the system and validation of the simulation model

The tested solar combisystem represents a conventional central heating facility upgraded by a solar thermal unit. A simplified hydraulic layout is sketched in Figure 5. Solar complemented parts (besides the solar thermal circuit) are a solar thermal storage tank, a solar station and a fresh water economizer. Solar thermal heat is fed into the system only through the solar thermal storage tank, from where the heat is distributed for preheating of cold freshwater and for shifting the temperature of the return flow to the boiler. The boiler is providing heat either for space heating or for the domestic hot water tank with priority for the latter. Both thermal storage tanks are equipped with internal heat exchangers without stratified charging devices. The emulated hydraulic circuits of the system are indicated by yellow background color in Figure 5. Beside the hydraulic circuits two temperature sensors are emulated by electrical resistor cascades. These are the ambient temperature sensor, used by the boiler for calculating the heating curve and the collector temperature sensor which is important for the operation of the solar station.

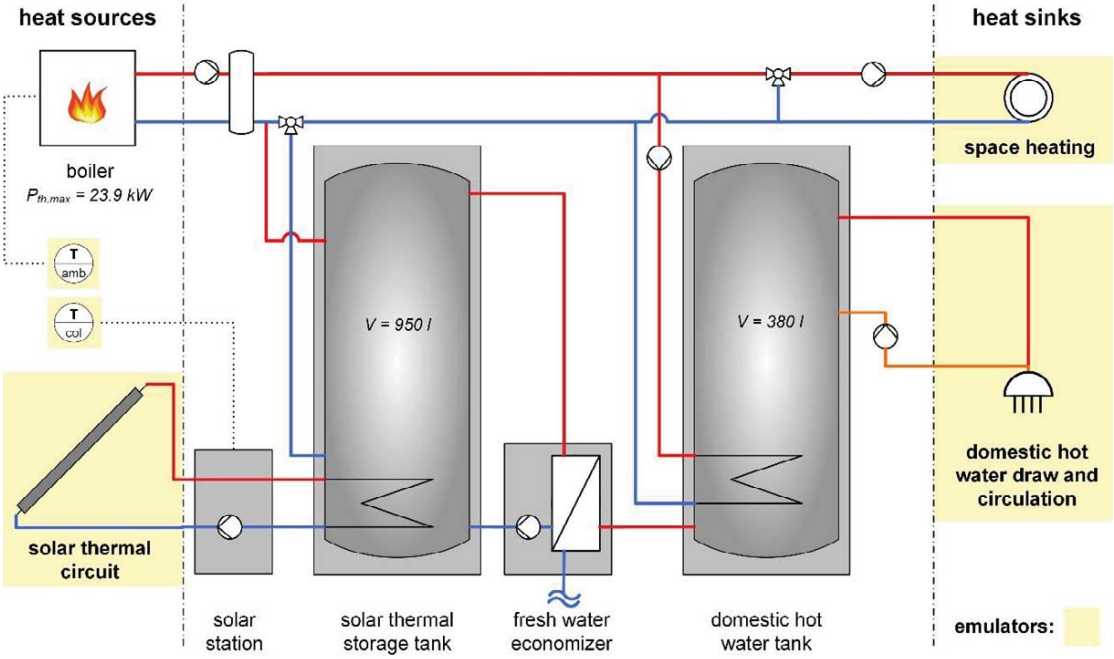

Fig. 5: Simplified hydraulic layout of the tested central heating facility with attached emulators (yellow)

The tested solar assisted heating system is dynamically simulated in TRNSYS. The validation of the model shows good results in the qualitative as well as in the quantitative comparison, see Table 2. These results have been calculated using the system boundary of the central heating facility indicated in Figure 2. The calculation considers the sequence of eight representative days during the course of the year, as explained earlier. As it turned out, for the day which represents an extreme, hot summer day, the allowed operation temperature of the solar thermal emulator was exceeded and therefore, this specific day had to be excluded from the results. Electricity as parasitic energy for the operation of electric devices like pumps and system control has not been measured and is therefore not part of the comparison in Table 2. But being a simulation result, the electricity consumption will be considered for the energetic evaluation based on the annual simulation results.

Tab. 2: Comparison of energy balances between HIL measurement and simulation of the first tested central heating facility as cumulated values of seven analyzed days (without extreme summer day)

			HIL measurement [kWh]	**simulation** [kWh]	**difference** [%]
input	final energy input	natural gas	2893	2894	0
	solar thermal input		173	169	-3
output	central heat demand of the building	SH + dist	-2408	-2428	1
		DHW	-95	-97	2
		circ	-113	-115	1
	heat losses		-65	-45	-30

The differences between simulated and measured cumulated energy amounts are lower than 4 % (relative value). There is one exception of this: the heat losses of the central heating facility exhibit a deviation of -30 %, which, however, results from the heat loss measurement and not from the simulation. The heat losses represent not a directly measured quantity but is calculated from the energy balance of the individual components of the central heating facility. In this situation, related measurement errors are superimposed as heat loss which leads to overestimation of the true value. Despite of this, the absolute divergence between simulated and measured heat losses amounts to 20 kWh. Compared to the total central heat demand of the building of 2617 kWh (measured), the heat loss deviation between HIL measurement and simulation can be tolerated.

3.2. Functional analysis

HIL measurements of the tested solar assisted heating system disclose two functional insufficiencies of the control system:

- The boiler controller is not working properly.
- A restricted interaction between the boiler controller and the controller of the solar thermal storage tank leads to a limited usage of solar thermal heat.

The boiler comprises a modulating burner with a nominal heat output between 4.8 kW and 23.9 kW (in condensing mode). As long as heat is solely produced for space heating, the burner is modulating perfectly within this power range. However, when supplying heat for the domestic hot water tank, the boiler is operating like having a single stage burner at maximum heat output. Due to a limited heat transfer capacity of the internal heat exchanger in the domestic hot water tank, the burner displays a high number of start-stop-cycles. Although this behavior does not entail efficiency loss, reduced durability of the burner device must be expected.

Another insufficiency of the tested system is the limited usage of solar thermal energy. As it is shown in Figure 5, there is a hydraulic connection (via the hydraulic separator) for using solar heat from the solar thermal storage tank to heat up the domestic hot water tank (under consideration of temperature levels). But the control system is not allowing an exclusive usage of solar thermal energy for charging the domestic hot water tank. Instead, the boiler is running the whole year, providing heat which could also be taken partly from the solar thermal storage tank without using any fossil fuel.

3.3. Identification of optimization potential by means of the benchmark procedure

The energetic analysis is based on dynamic system simulations covering a complete annual period. Among other possible parameters the evaluation is focused on the performance factor of the central heating facility as a function of the demand-specific collector area (see Figure 6). Therefore, several simulations with a variable collector area (between 0 m² and 32 m²) and a constant central heat demand of the building were performed. A comparison between the tested system installed factory-set and the benchmark allows to assess the optimization potential. A detailed analysis with a simulative approach identifies thereby single limitation sources.

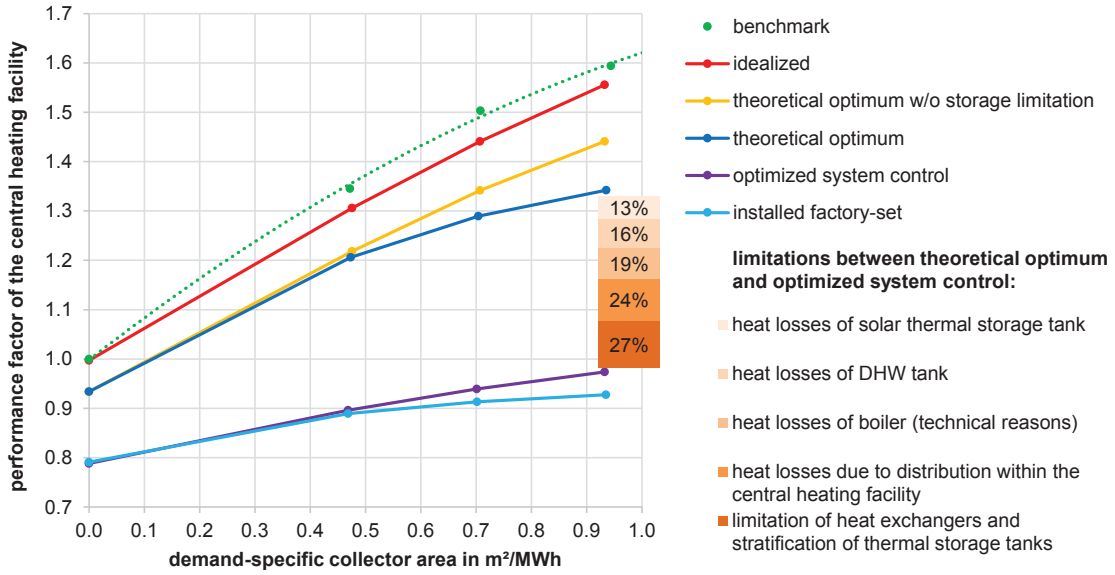

Fig. 6: Comparison between the benchmark and the CPF of the tested central heating facility (installed factory-set) by analyzing the different limitation sources

In the first place, the control system is optimized by eliminating the functional insufficiencies of the system which have been described earlier. This optimization can be done without any financial or material effort. The larger the demand specific area, the higher the optimization potential of the CPF by an improved usage of solar thermal energy. A second optimization series has been simulated, called "theoretical optimum". Therefore, different technical and chemical possible optimizations have been done, without changing any system components. The single limitation sources between "optimized system control" and "theoretical optimum" and their percentage influence for the improvement of the CPF are shown in Figure 6. The limitation of heat exchangers and a limited stratification of the thermal storage tanks have the largest influence on the CPF. Whereas the heat losses of the thermal storage tanks show the lowest limitation, the heat losses due to distribution within the central heating facility comes up to be the second highest deficit. Heat losses of the boiler only consider technical limitations caused by radiation losses and combustion inefficiency. Another limitation of the analyzed system, compared to the benchmark, is the limited storage capacity of the solar thermal storage tank. The impact of an increased solar thermal storage tank from ca. 1 m³ to 10 m³ is shown with the yellow curve. Thereby the improvement of the CPF is getting bigger, as the demand specific collector area increases. It has to be considered that all optimizations done before are maintained, like no heat losses of the storage tanks and an idealized stratification.

After optimizing the system it is idealized in a final step. For this purpose the parasitic energy demand of electric devices (e.g. pumps) is neglected and a complete utilization of the higher calorific value of fossil fuel is assumed. Both approaches are neither technical nor chemical possible. The simulation results of the idealized version of the tested solar heating system are almost approaching the benchmark. The remaining difference between these two curves can be explained with the fundamental limitation of the hydraulic connection of the analyzed system. Heat from the solar thermal circuit can only be fed into one heat sink: the solar thermal storage tank. In contrast, in the benchmark procedure the single heat sources are supplied with solar heat in sequence of their temperature level.

4. Conclusion and prospect

HIL measurements offer the possibility of functional evaluations of solar assisted central heating systems under standardized test conditions. The HIL results of the first tested central heating facility showed major insufficiencies concerning the control system causing a restricted usage of solar thermal energy. First results of the second evaluated system disclose also functional deficits in the control system. Managing the interaction of the different system components is one of the most important tasks and offers a lot of possibilities for the

improvement of system performance with low financial or material effort. Functional evaluations of further systems will show, if this result can be confirmed and therefore be generalized.

The results of the HIL measurements provide also the basis for further investigations concerning the energetic efficiency of systems. With validated dynamic simulation models a high quality of simulation results can be assured. For the analysis of annual simulation results a new parameter - *performance factor of the central heating facility* - is introduced. The parameter is applicable to all central heating facilities due to the clear definition of system boundaries. Together with the new reference parameter - *demand specific collector area* - they allow an objective comparison of different analyzed solar combisystems, which will be done in the course of the project in order to identify the most efficient system design under consideration of functional, energetic and financial aspects.

A newly developed benchmark procedure is matching the central heat demand of the building with the maximum solar thermal gain of the solar circuit to determine the maximum performance factor possible of an idealized central heating facility. For a detailed analysis of the single systems a comparison to the benchmark and an itemization of single limitation sources showed to be a good procedure for the identification of optimization potential. This approach disclosed the limitation of heat exchanger and a limited stratification of thermal storage tanks to be the largest limitation factor besides the heat loss due to distribution within the central heating facility. Furthermore the restriction of efficiency due to insufficiencies in the control system is numbered and compared to the impact of the remaining limitation sources.

5. Acknowledgement

The project SUW-MFH presented in this paper is funded by the German Federal Ministry for Economic Affairs and Energy based on a decision of the German Federal Parliament (reference number: 03ET1212B). The project is carried out in cooperation with the University of Applied Sciences Düsseldorf. The authors are grateful for the financial support and responsible for the content.

Annual Performance of a Solar Active House Prototype – Comparing Measurement and Simulation

Jan Steinweg[1] and Gunter Rockendorf[1]

[1] Institut für Solarenergieforschung Hameln, Am Ohrberg 1, 31860 Emmerthal

Abstract

A new concept for solar active houses is being tested under practical conditions. While conventional solar house concepts combine large collector areas with large storage volumes (up to 10 m³ in a single family house) in order to achieve solar fractions above 50 %, our new concept only needs small storage volumes (1 m³). To substitute the lack of storage capacity, the new system design uses thermally activated concrete elements directly fed by the solar collector. After having been dimensioned and tested by several simulation studies, a prototype building, equipped with the new heating system, has been constructed and extensively monitored.

The first year of operation already revealed the concept´s functionality. During a first monitoring period from April 2015 to March 2016 the recorded data exhibit good agreement with the simulations (based on historical weather data) while storage heat losses are identified as too high. Nonetheless, the annual overall end energy demand for domestic hot water and space heating is 8 kWh/m². This contribution analyses the first year of operation, also covering a peak load test.

Keywords: *solar active house, energy storage, thermally activated concrete elements, TABS, ground heat exchanger, heat pump, experimental study, prototype measurement*

1. Introduction

Previous solar active house concepts combine large collector areas (30…40 m²) and storage tanks (up to 10 m³) with wood stoves as auxiliary heater in order to achieve a combination of high solar thermal fraction (> 50 %) and low primary energy consumption. The new concept presented in this work is aiming at the same high energy efficiency at largely reduced buffer storage volume towards common sizes of about 1 m³, thus allowing buffer installations in the utility rooms, which is particularly favorable in case of energetic retrofit of buildings. As a matter of fact, this approach saves expensive building space, and any maintenance is now possible since all system components fit into standard utility rooms.

The resulting lack of storage capacity is substituted by direct solar thermal activation of already existing masses in the building's concrete slabs. This approach of direct solar thermal room heating has already been evaluated in the 1990´s by Papillon (1993) and generates significant advantages. Due to the characteristically low operation temperature of thermally activated building slabs (TABS), a high collector efficiency even at low irradiance levels can be achieved, which is important during the winter months.

The backup heat is provided by a heat pump (HP) coupled to a slender ground heat exchanger (GHX) which receives regeneration by solar thermal heat. Moreover, the GHX is used for the prevention of stagnation during the summer months, thus permanently obtaining the collector's energy delivery readiness. The concept is covering an innovative control strategy for temperature optimized solar heat distribution which has been

doi:10.18086/eurosun.2016.04.12 Available at http://proceedings.ises.org

designed regarding component and system simulations by Glembin (2012, 2013, and 2014) who has theoretically proven the concept's functionality. For practical testing of this concept, a test building has been planned, built and equipped with the system hydraulics developed according to the outcomes of the simulation studies. The present paper reports results of the first measurement period from April 2015 to March 2016 considering function and performance at monthly and annually scales.

2. System concept and prototype building

Fig. 1 displays the designed energy flows of the solar thermal collector, the heat pump and the different sinks for solar and backup heat. In contrast to simple solar thermal systems, the collector supplies heat to three different heat sinks. A new control strategy developed within the project is applied to utilize the heat fluxes with respect to an optimal effect on the system´s end energy savings, see Glembin (2014). According to this strategy both TABS and storage tank may experience positive demand signals, for example during the transitional periods of spring and autumn. The controller then determines the appropriate sink for which the collector is able to gain maximum efficiency. In this case, this may be either a sink provided with a higher priority or a lower demand temperature. As a result of this, the collector can be conducted with very low temperatures starting at 20 °C in cases where the TABS are supplied, and even lower temperatures down to 5 °C in cases of GHX regeneration.

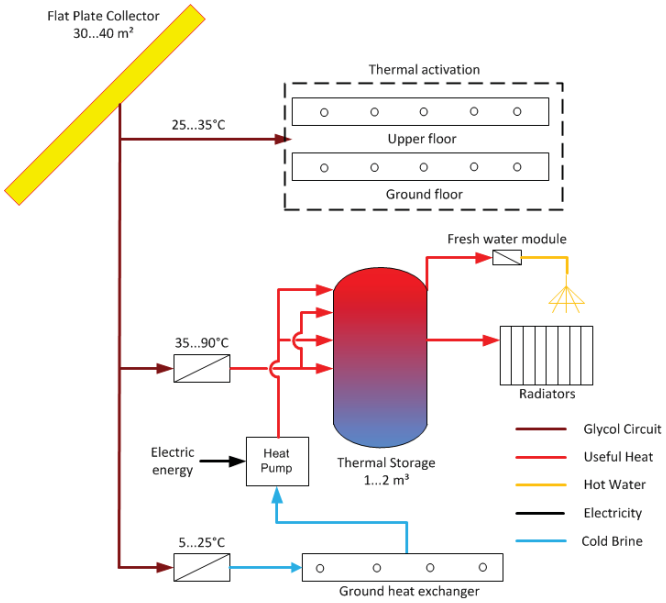

Fig. 1: Scheme of the solar thermal heating system (the lines indicate energy flows)

The test building is located in the urban area of Hanover, Germany, comprising a heated area of 270 m² on three floors; basement (BA) ground (GF) and first floor (FF), and with a nominal annual space heat demand of 39 kWh/m². The building is equipped with a solar collector area of 30 m², facing south with an inclination of 45°. TABS layers, which have been designed for maximum performance with minimum effort using component simulations according to Glembin (2012), are placed in GF and FF. To keep them highly efficient and cost effective, only one distribution loop with central temperature control is used for each floor. The utility room houses a simple buffer storage of 1 m³ from which the domestic hot water preparation (DHW) as well as the space heating demand (SH) are supplied, the letter via conventional radiators. The buffer storage is fed by the solar collector as well as an auxiliary heater, which is a ground coupled compression heat pump. A small horizontal ground heat exchanger with an area of 170 m² serves both as the heat source for the HP and the heat sink for the solar collector´s overcapacities during summer. Accordingly, the solar collector can remain in standby for further heat production throughout the summer and experiences almost absent stagnation. Correspondingly, the ground heat exchanger experiences intense regeneration. Therefore, it can be dimensioned significantly smaller than compared to standard design, e.g. due to the German guideline VDI 4640 (2010). A sketch of the concept and a picture of the realized building is displayed in Fig. 2.

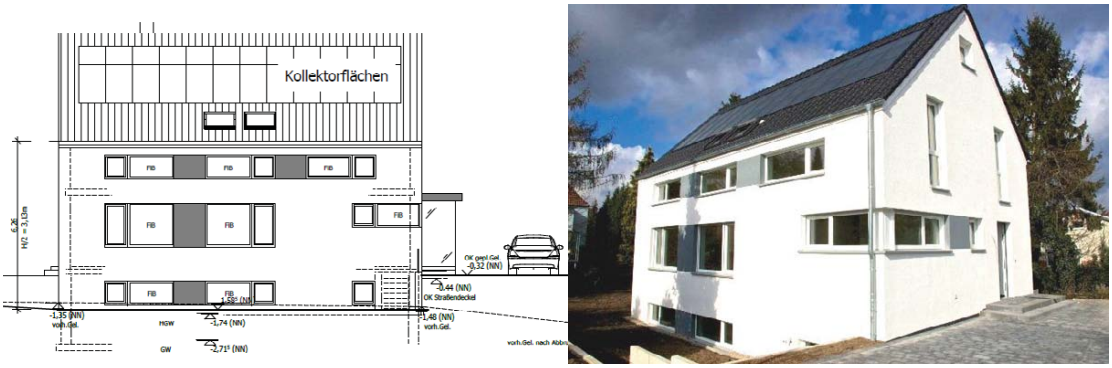

Fig. 2: Sketch of the experimental building during conception (left) and photo of the competed building after the commissioning in January 2015

A central ventilation unit has not been installed so it is up to the inhabitants to set the air change rate by window ventilation. The windows of the GF are equipped with non-automatic external mounted shading elements on the south, east and west façade, as well as the bath and sleeping room windows at the eastern and western façades of the FF. The other windows are (partially) equipped with self-mounted internal shadings. Throughout the phase of measurement, the experimental building has been inhabited by two persons. Further facts of the most important components are given in Tab. 1

Tab. 1: Generic parameters of the main system components of the experimental house

Solar thermal collector	Roof integrated, south, 45° inclination, aperture area 30 m²
Heat pump (HP)	Brine water compression HP, 8 kW nominal power at 2 kW compressor power
Ground heat exchanger (GHX)	170 m² area with four distribution circuits (excluding supply pipes), polyethylene pipes with 0.5 m distance
Thermally activated building slabs (TABS)	Approx. 160 m crosslinked polyethylene pipe per slab (ground and upper floor) with 0.5 m distance, bifilar installation, direct connection to glycol circuit of solar collector

3. Measurement and analysis

Measurement concept

The monitoring concept is regarding 65 sensors placed inside and outside the test building and its hydraulic system to gain information about the building´s boundary conditions as well as the heating system´s performance. The recorded data is evaluated firstly to prove the technical integrity of the concept, including the system controller, the component´s interaction and the identification of system and installation issues. Secondly, the system performance will be analyzed by means of indicators such as solar yield Q_{sol} and solar fraction f_{sol}, end energy demand Q_{EE} and the seasonal performance factor SPF of the HP. These quantities are defined by:

$$Q_{sol} = Q_{St} + Q_{TABS,GF} + Q_{TABS,FF} + Q_{GHX} \quad \text{(eq. 1)}$$

$$f_{sol} = \frac{Q_{St} + Q_{TABS,\mathrm{GF}} + Q_{TABS,FF}}{Q_{St} + Q_{BTA,EG} + Q_{BTA,OG} + Q_{HP,St}} \quad \text{(eq. 2)}$$

$$Q_{EE} = W_{el,HP,con} + W_{el,HP,aux} + W_{el,Pump} + W_{el,c} \quad \text{(eq. 3)}$$

$$SPF = \frac{Q_{HP,St}}{W_{el,HP,con} + W_{el,HP,aux}} \quad \text{(eq. 4)}$$

Q_{sol}	Solar energy gain from collector in kWh
Q_{St}	Solar energy to storage tank in kWh
$Q_{TABS,GF/FF}$	Solar energy to TABS in GF and FF in kWh
Q_{GHX}	Solar energy to GHX in kWh
$Q_{HP,St}$	Energy of HP to storage tank in kWh
$W_{el,HP,con}$	Electrical energy consumption of HP compressor in kWh
$W_{el,HP,aux}$	Electrical energy consumption of HP auxiliary heater in kWh
$W_{el,Pump}$	Electrical energy consumption of the hydraulic pumps in kWh
$W_{el,c}$	Electrical energy consumption of the controller, including energy for all valves in kWh

The system components, the overall hydraulic scheme and the system boundaries regarded by the energy balances are provided in Fig. 3. Technically, the energy flux is balanced through combined mass flux and temperature measurements, calibrated as pairs. The heat sinks (space heating and hot water preparation, blue areas in Fig. 3) are measured by heat meters and the electricity demand of the heat pump, all hydraulic pumps, valves and controllers is measured by electric meters. The thermal comfort of the building is rated through temperature sensors in representative rooms as well as CO_2 and moisture sensors on each floor as indicators for the level of air change due to window ventilation. The data scan interval for all sensors is set to 30 seconds.

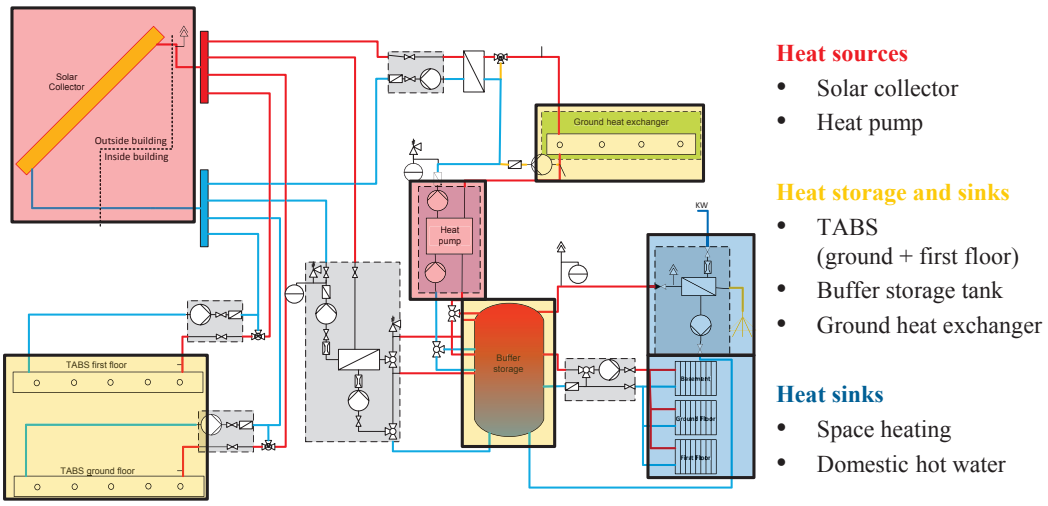

Fig. 3: Scheme of the hydraulic concept of the experimental building including the main components energy balance rooms.

Data analysis concept

We present the system indicators measured during the time period between April 2015 and March 2016 at annual and monthly scales. For further analysis, measurements will be compared to the results of system simulations based on a set of equivalent, historical weather data which had been identified from measurements in the same region during 1989 - 2001. This approach was mandatory for the following reasons:

- Some meteorological data required for the simulation were not measured with the test building, e.g. the ratio of diffuse and direct irradiation, sky temperature, wind speed and ground temperatures.
- Over the course of a year, partially shading of the solar collector and the irradiation sensor occurs, effecting localized signals to sensors and the collector.
- Missing reliable data for the inhabitant's behavior. Room temperatures are not measured building-wide, air change or shading cannot be registered directly at all.

- Some sensor values are considered to be representative for a large area or a component with a wide spread. Examples are again room temperatures but also the core temperatures of the buildings slabs, which are measured with a single sensor and assumed to be equal for the whole room or component.

Hence, to provide consistent simulation parameters, suitable historical weather data are used. As similarity indicators the annual irradiation (on the 45° south inclined surface), the mean ambient temperature and the degree-day numbers are employed and the similarity of the historical and in-situ data are judged by means of least square fit. As result, the best fit was assigned to the weather data of year 1994 which also shows good comparability at monthly scale; hence the 1994 weather data is used as climate environment for the simulations in the sequel. The respective similarity indicators are given in Tab. 2. The remaining differences between the two periods is small indeed, but has to be kept in mind when concluding the results.

Tab. 2: Comparison of the indicator values of the measured year 2015/16 and the historical weather data of Hanover 1994

	Measurement 2015/16	Hanover 1994
Irradiation (45°)	1146 kWh/m²	1185 kWh/m²
Degree-day number	3382 Kd	3312 Kd
Mean temperature	10,3 °C	10,7 °C

The useful energy demand, i.e. the energy emitted via the radiators and the domestic hot water, applied to the simulations is adjusted to the measured useful energy of the test building. The simulated space heating energy demand is adapted based on a mean room temperature. To compensate for the situation of partially heating of the building during the monitoring period, the simulations regard a slightly reduced indoor temperature of 19.1 °C. The resulting useful energy demand for space heating (via the radiators) is 5360 kWh/a. The amount of tapped hot water has not been measured. Instead the existing standard domestic hot water demand profile according to IEA Task 44 in Weiss (2003) and Dott (2012) has been adapted to match the respective energy demands of measurement and simulation. Again to adjust to the situation of reduced building usage, the demand profile was scaled by a factor of 0.46 (original data refer to four inhabitants). The resulting energy demand for domestic hot water preparation is 995 kWh.

4. Measurement and simulation results

The following analysis considers measurement and simulation outcomes of the new solar house concept. The comparison is conducted following the method described above. In the first step, annual calculations of the main indicators are compared. In the second part further details are outlined at monthly scale. The following section also concludes the experiences of the peak load tests, which were conducted during February and March 2016.

Annual results

Tab. 3 compares some of the main indicators of both the measured and the simulated building concept which characterize the system performance.

While the overall annual collector yield of ca. 275 kWh/m²a differs slightly only (by 1 %) between measurement and simulation, the spatial supply distribution of the produced solar heat exhibits some differences. The measured energy delivered to TABS contributes by 48 % to the overall solar heat produced, while in the simulation the same share is 64 % (a difference of about 1300 kWh). Analysis of the test building´s runtimes shows that TABS are fed by the collector about 25 % shorter than in the simulation. The reasons might be a lower collector performance, larger dead band temperatures or more frequent lock waits due to room temperatures exiting the controller´s high limit cut out during the measurement phase.

The lower energy input in TABS in the test building is then compensated by a higher energy input to the storage tank. Consequently, a respective difference of 1300 kWh occurs between measured and simulated storage input, too, such that in sum, the overall energy transfer between TABS and storage input are compensated. The remaining difference of the overall annual data of 1% is leveled by a slightly higher amount

of energy transferred to the GHX while runtimes are almost equal. The stagnation time of the solar collector is 48 h for the simulated system. This only occurs in rare events of GHX outlet temperatures exceeding 25 °C (which is the maximum evaporator inlet temperature of the HP). Since the collector temperature has not been measured, stagnation hours could not be detected directly during the monitoring period.

Tab. 3: Annual results of measurement from April 2015 to March 2016 and simulation based on Hanover weather data of 1994 for the new solar house concept

	Measurement 2015/16	Simulation 1994	Difference
Total solar collector yield	8525 kWh (274 kWh/m²)	8610 kWh (276 kWh/m²)	+1 %
To TABS ground floor	1949 kWh (23 %)	2893 kWh (34 %)	+48 %
To TABS first floor	2150 kWh (25 %)	2593 kWh (30 %)	+21 %
To storage	2844 kWh (33 %)	1573 kWh (18 %)	-45 %
To GHX	1295 kWh (15 %)	1094 kWh (13 %)	-16 %
Solar fraction	52 %	54 %	+4 %
Energy HP → Storage	6438 kWh	6006 kWh	-7 %
Total electricity demand	2173 kWh	1875 kWh	-14 %
SPF	3,45	3,69	+7 %

Little deviations exists for the solar gains. The difference between solar fraction of measured and simulated test house is 4%. Slight difference occurs for the energy delivered to the storage by the HP (-7%). Accordingly, the SPF of the HP is 7 % higher in reality than simulated and for the same reason, the total electricity demands differ by 14 %. The difference of the SPF can be explained by the following reasons:

- During October and November 2015, the system controller caused a problem which lead to unnecessary HP running on high temperature level. A major part of that energy got lost via the solar collector to ambient which may explain the 400 kWh higher storage input.
- As of Tab. 2 there are some residual differences in the weather data used for simulation. The mean annual ambient temperatures differ by 0.4 K only, however, between October and March the differences are slightly higher (about 0.7 K). This influences the demand of SH energy and also affects the GHX temperatures.
- The space heating zone inside the storage tank exhibits a mean temperature which is 3.8 K higher during the monitoring 2015/16 as compared to the simulations. This is most likely caused by a lower stratification efficiency of the real storage tank compared to its model. Additionally, the slightly lower ambient temperature mentioned above also has a little impact on the demand supply temperature level of the SH which is calculated with regard to the ambient temperature.

All despite this, the remaining energy demand is very low, especially when considering the sometimes imperfect performance of the system during the first year due to its commissioning. The overall electricity demand (including all electric loads necessary for the annual heat supply) is 2173 kWh or 8 kWh per m² of heated area. Considering primary energy demand, this is passive house level although the measurement period includes commissioning tests and dysfunctions during the first months in 2015 as well as peak load tests during February and March 2016.

Monthly results

To rationalize why a significantly higher share of solar energy is delivered to the storage and how this affects the system performance, Fig. 4 displays diagrams of the monthly solar energy yield distributed to the storage tank and the TABS.

The diagram on the left refers to simulation results which have been concluded in Tab. 3. These are based on a specific parameterization of the storage tank through the design heat loss rate of 5.2 W/K and also taking into account heat losses by thermal bridges and internal recirculation flows according to Wilhelms (2008). The diagram of Fig. 4 (left) shows a pronounced deviation of storage energy inputs between measurement and

simulation during the summer months: here, the measured energy input is 45 % higher between May and August than simulated. Since in this time period the only heat demand results from DHW tapping, which is the same amount at measurement and simulation, the difference must be the consequence of significantly deviating heat losses of the storage tank.

As consequence of this, the test house´s storage heat loss rate has been calculated to 7.8 W/K. Some physical reasoning for this could be identified: Considerably circulating flows between the storage tank and its adjacent components (HP and fresh water unit) were located. These flows have been detected with help of the analysis of detailed measurement data and occurred despite the installation of heat traps at the related storage connections. Although further evaluation of thermal bridges supported by thermography did not show any additional indications, other heat loss paths cannot be excluded completely, either. Given by the adverse position of the temperature and mass flow sensors, heat losses of the solar heat transfer unit and the piping are also included in the measured energy delivered to the storage. In consequence to that, the simulation model has been adapted considering these additional heat losses.

The measured overall energy delivered to TABS according to Tab. 3 is almost 1400 kWh lower than in the simulation. As Fig. 4 displays, this difference essentially occurs during the spring and autumn months. This deviation may be rationalized by taking into account passive solar gains and air change rates. The simulated building has an automatic external shading of all east, south and west oriented windows with a threshold total irradiation of 300 W. The air change rate is 0.4 h^{-1} with an optional night ventilation of 2 h^{-1} once the room temperature exceed 26 °C. The monitored test building, in contrast, has to be shaded manually and additional, not all of the windows are equipped with effective external shadings. On the other hand, the real air change is low as a consequence of the reduced building usage. As consequence, the simulated passive solar gains are underestimated while the heat losses due to ventilation are overestimated. Though, the TABS threshold room temperature in both cases is 24 °C. If the temperature hysteresis between room and threshold room temperature is lowered by higher solar gains and lower air change the potential for energy delivery by TABS is lowered as well. In sum, this explains the higher active solar energy input to the simulated building.

Taking into account adjusted storage heat losses, improved simulation results are displayed in the right diagram of Fig. 4. We see that the mean deviation between measured and simulated solar energy inputs to the storage tank from May to August has now decreased to 10 %. The measured system performance indicators used in Tab. 3 are again given in Tab. 4 and compared to the new simulation results of the model with matched storage heat losses including the losses of the solar heat transfer station.

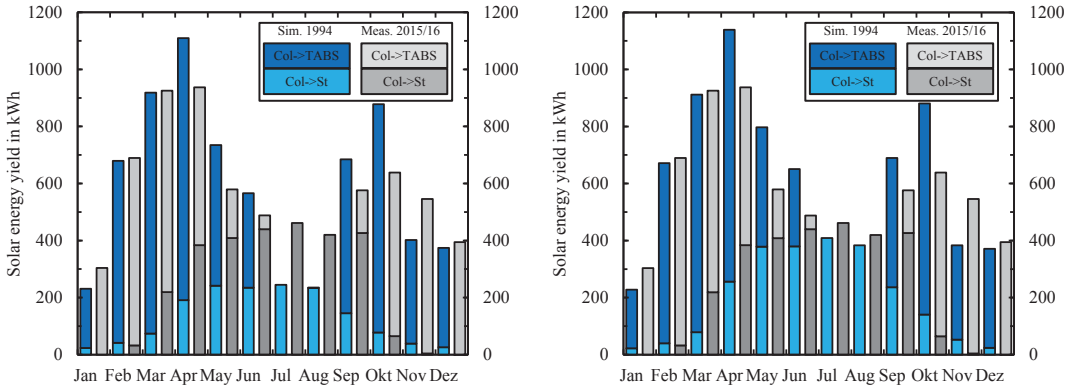

Fig. 4: Comparison of monthly solar energy distribution to storage (St) and TABS for simulation (blue bars) and measurement (grey bars), simulated with design storage heat loss rate (5.2 W/K, left diagram) and heat loss rate of the measured storage (7.8 W/K, right diagram) including heat losses of the solar heat transfer unit

When comparing Tab. 3 and Tab. 4 a slight increase of the solar collector yield is visible. Also the distribution of the solar heat to TABS and storage has changed. The improved results indicate TABS get a 6 % lesser share while the storage supply rises by 9 %. Due to elevated heat losses regarded by the new parameters, the heat transferred to the storage by heat pump also increases by more than 250 kWh. Together with a slight decrease of HP efficiency, the total electricity demand rises by 100 kWh. The solar fraction of eq. 2, in this case it yet

rises to 55 % since the solar yield rises stronger than the heat supplied by HP.

Compared to the measurements, it can be concluded that the difference in solar collector yield increases while the distribution of the solar energy to the different sinks now fits much better. With a solar yield now being a little higher than measured, the performance of the HP, its heat delivered to the storage tank and the total annual electricity demand moves closer to the measured results. Although the shares of the solar heat sinks do not fit perfectly, the order of the heat distribution can be approximated quiet well by the simulation. The remaining difference is most likely caused by the different shading and air change parameters.

Tab. 4: Annual results of measurement 2015/16 and simulation (Hanover, 1994) for the new solar house concept with matched storage heat losses

	Measurement 2015/16	Simulation 1994 (matched storage losses)	Difference
Total solar collector yield	8525 kWh (274 kWh/m²)	8891kWh (285 kWh/m²)	+4 %
To TABS ground floor	1949 kWh (23 %)	2610 kWh (29 %)	+34 %
To TABS first floor	2150 kWh (25 %)	2503 kWh (28 %)	+16 %
To storage	2844 kWh (33 %)	2402 kWh (27 %)	-16 %
To GHX	1295 kWh (15 %)	920 kWh (10 %)	-29 %
Solar fraction	52 %	55 %	+6 %
Energy HP → Storage	6438 kWh	6260 kWh	-3 %
Total electricity demand	2173 kWh	1974 kWh	-9 %
SPF	3,45	3,66	+6 %

Peak load tests

From February 23rd to March 29th, the new solar active house system of the test building has been stressed by a peak load test. It was aiming at the evaluation of the remaining thermal backup of the system, especially of the HP and its GHX source as auxiliary heat supply, under practical conditions. A higher load shall be obtained by increasing the room set temperature on the one hand while reducing the available GHX area by 50 % to about 85 m² on the other. This leads to a more frequent HP operation while the heat pump´s energy source is significantly smaller.

For the realization of a higher room set temperature the inhabitants have been instructed to adjust the radiator´s thermostats by a certain amount. The remaining heating circuit parameters have not been changed, so the threshold room temperature of the TABS remains 24 °C. The resulting mean daily room temperatures of BA, GF and FF during the peak load test are displayed in the right diagram of Fig. 5.

The distribution of the room temperatures remains the same as before the peak load tests. Due to the higher temperature of the utility room situated in the basement, this floor shows the highest temperatures, followed by the GF. As only few rooms of the FF are heated, it has the lowest temperature level. The mean overall temperature ($T_{r,m}$) increases by almost 2.5 K to 22 °C. A related simulation study reveals that this higher room temperature means an increase of the energy demand for SH of 36 %.

The diagram on the right of Fig. 5 displays the soil temperatures ($T_{soil,m}$) measured between the GHX pipes, the daily minimum of the GHX in- and outlet temperatures ($T_{GHX,in,min}$ and $T_{GHX,out,min}$) and the ambient temperature (T_{amb}) during the peak load test. The beginning of the test is clearly remarkable since the daily minimum temperatures of GHX in- and outlet decrease by almost 2 K. Both minimum temperatures remain below zero for the whole test period. While the mean runtime of the HP remains around 20 minutes, the number of cycles of HP operation increases. The reduced GHX area has been achieved by a reduced number of parallel circuits has also been reduced from four to two. This leads to a higher mass flow through the remaining circuits which, in combination with the lower heat exchanger area, also leads to a decrease of fluid temperatures. It is remarkable that the mean soil temperature measured right between the GHX pipes which are arranged with a distance of 0.5 m shows hardly no affection by this temperature decrease. Its temperature runs in closer

accordance to the ambient temperature.

However, the soil temperature at the beginning of the peak load test is almost exactly the same as at the end of the test which most reasonably is caused by the further increasing ambient temperature at the beginning of March. The grey area of the right diagram shows the slowly decreasing amount of energy which is withdrawn from the GHX while the blue area of the left diagram indicates that a significant share of SH energy is already delivered by TABS. In effect, the system withstands the higher thermal loads despite the significantly smaller GHX area very well. Nonetheless, it has to be concluded that the test has been performed quite late in the heating season and with insufficient load demand for a significant stress of the auxiliary heater to its limit. Anyway, the test clarified that the system concept provides considerably heating reserves, which corresponds to recent outcomes of system.

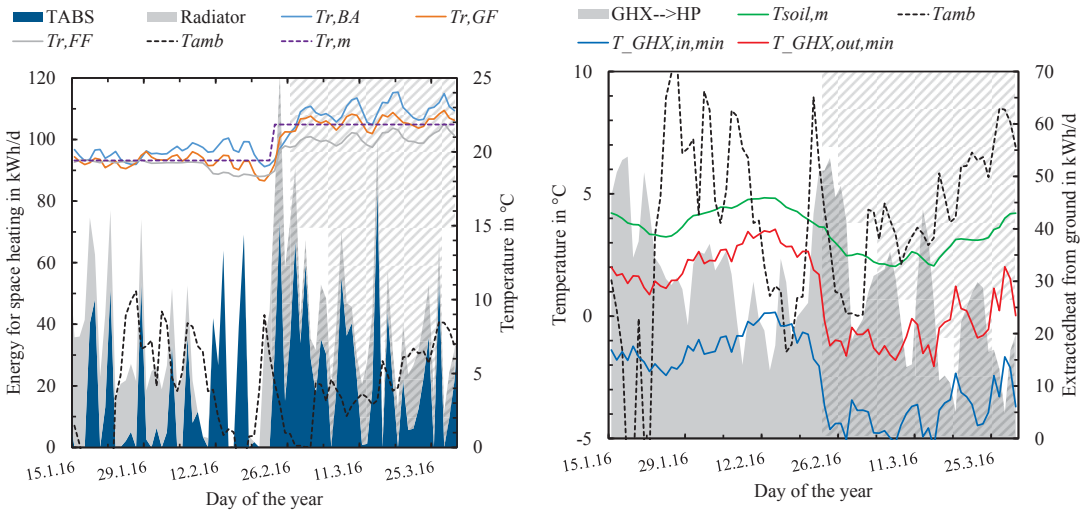

Fig. 5: Room and GHX temperatures during the peak load test, test period in both diagrams marked with hatching Room temperatures during peak load tests (left): Energy transferred to space heating from TABS and radiators, room temperatures in basement (*Tr,BA*), ground floor (*Tr,GF*), first floor (*Tr,FF*) and mean temperature (*Tr,m*), Ground temperatures during peak load tests (right): Energy transferred from GHX to HP (GHX→HP), mean soil temperature (*Tsoil,m*), ambient temperature (*Tamb*), minimum in- (*T_GHX,in,min*) and outlet temperature (*T_GHX,out,min*)

Conclusion and outlook

The measurement results of the first year show that the new solar active house concept is already working very satisfying although several initial malfunctions and issues which had to be solved lowered the systems performance. The measured solar fraction of 52 % is already within the expectations. With a remaining overall electricity demand of 8 kWh/m² the primary energy demand is very low. The comparison to system simulations shows a good correspondence but also reveals higher storage heat losses than expected. The losses can mainly be affiliated to unwanted circulating flows through heat pump and fresh water unit. Though heat traps have been provided by the installer as well as a good pipe and component insulation, backflow preventers in the prefabricated components hydraulics were missing almost completely.

The peak load test which has been performed at the end of the heating season was not intensive enough to show the backup heaters limit. Anyway, the current system configuration appears to be well prepared for seasons with higher energy demands. The GHX area might prospectively be further reduced which should be object of further simulation studies.

The missing backflow preventers have now been added, the improvements of controller algorithms, parameters, hydraulics and different performance tests are finished. The GHX temperature has been fully recovered after the end of the peak load test within two months. Since June 2016 a second measurement period is running. The aim is to get results of a full year´s period with optimized system performance and no further interference to identify the concepts full potential under practical conditions.

Review of Solar Thermal Systems and Their Potential in Lithuania

Rokas Valančius, Andrius Jurelionis and Juozas Vaičiūnas

Kaunas University of Technology, Faculty of Civil Engineering and Architecture, Kaunas (Lithuania)

Abstract

Solar thermal systems with a total solar panel area varying from 2 to 204 m^2 have been installed in Lithuania for over 20 years. The market of such systems is slowly growing and the trend continues towards larger domestic hot water systems in multifamily buildings, hospitals, hotels and other large complexes. Nevertheless, there's still lack of performance reviews and analysis of these systems. The aim of this paper was to analyze medium size solar thermal systems from the perspective of energy production and economic benefit as well as to outline the differences of their actual performance compared to the numerical simulation results. A number of different solar thermal systems in Lithuania were selected for the study, and both financial analysis and performance analysis by means of simulation software were performed. Solar thermal domestic hot water (DHW) systems in question produce up to 528 kWh per year per one square meter of solar collector absorber area. However, the performance of these systems depends on the type of energy users, design solutions, equipment used and maintenance of these systems. Calculation of internal rate of return showed that a grant is required in most cases for solar thermal project to be fully profitable.

Keywords: *solar thermal systems, domestic hot water, energy prices*

1. Introduction

Renewable energy share continued to grow worldwide in recent years alongside with the increasing global energy consumption, particularly in developing countries, and a dramatic decline in global fossil fuel prices in last two years. Renewable energy provided an estimated 19.2% of global final energy consumption in 2014, and growth in capacity and generation continued in 2015.

Global capacity of glazed and unglazed solar thermal collectors rose by more than 6% in 2015, despite a market slowdown due primarily to the continued contraction of markets in China and Europe. China accounted for about 77% of newly installed solar water heater capacity, followed by Turkey, Brazil, India and the United States. Cumulative capacity of water collectors reached an estimated 435 GWth by year's end (with air collectors adding another 1.6 GWth), enough capacity to provide approximately 357 TWh of heat annually. Market development varied widely from country to country. Denmark, Israel, Mexico, Poland and Turkey reported significant growth. By contrast, low oil and gas prices in Europe and the ongoing slowdown in housing construction in China dampened these markets (REN21, 2016).

In 2014, the European market underwent a reduction in the newly installed capacity. In 2014, the market amounted to 2 GWth (approximately 2.9 million m²). This represents a decrease of 7.1 % in comparison with the previous year. The total installed capacity registered a net increase of 1.6 GWth, now reaching 31.8 GWth (45.4 million m²). This represents an increase of 5.3 % compared with the total installed capacity at the end of 2013. Only about 10400 m² (7280 kWth) of glazed solar collectors were installed by the end of 2014 in Lithuania, and the applications were mostly limited to single-family buildings (ESTIF, 2015). Only in recent years the trend continued towards larger DHW systems in multifamily buildings, hospitals, hotels and other large complexes, due to support from the government, EU and other funds. In 2016 more than 1500 m² solar collectors in over 15 hospitals will be installed for DHW and other needs.

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/eurosun.2016.04.15 Available at http://proceedings.ises.org

The major part of thermal energy used in public and multi-family buildings in Lithuania is supplied via the district heating network. 72.4% from all district heating produced energy was used for household purposes in 2012 (LSTA, 2012) and the price in different Lithuanian cities varies in the range from 0.044 Eur/kWh to 0.095 Eur/kWh (01.06.2016). In the last two years, district heating energy price dropped by 9.2% (LSTA, 2016). Quite frequently, natural gas, bio fuel or electricity are used for building heating systems. Switching from natural gas to bio fuel reduced the district heating energy price significantly within last two years. Due to a dramatic decline in oil and natural gas prices, conventional fuel prices decreased up to 35% in last five years as well.

The aim of this study was to review the existing medium-scale solar thermal (ST) systems and their potential in Lithuania in relation to traditional energy prices and government policies.

2. Review of Solar Energy Potential and Market in Lithuania

Average global solar irradiation in Lithuania is similar to the irradiation levels in such countries as Germany, Austria, Denmark, Poland, Latvia and Estonia with the annual potential of solar energy yield of approx. 1000 kWh/m². The daily potential in the country varies from 0.55 kWh in January to 5.8 kWh from one square meter in June; therefore, almost the whole irradiated solar energy can be collected during the warm period of the year (from April till end of October). Due to this fact, solar hot water (SHW) systems are most efficient in DHW applications in Lithuania (Kytra, 2006). Nevertheless, technical-economic potential of solar heat energy production in the country reaches up to 1.5 TWh/year (129 ktoe). The values of expected solar energy yield are increasing during the last decade as solar irradiation increased by 7% during the years of 2005 to 2014 compared to the long-term statistical data (Valancius et al., 2015b).

According to ESTIF 2014 statistics about 64 % of installed solar thermal systems in Lithuania were equipped with evacuated tube collectors. In fact the evacuated tube collectors are mostly used in small projects. Several studies showed that despite the fact that both evacuated tube and flat plate collectors are considered suitable for solar heating in Central European Climates, the evacuated tube collectors do not reach the additional expected energy yield (Trinkl et al., 2005). Flat plate collectors and evacuated tube collectors produce the same amount of energy from effective area during the summer season in Lithuania, but flat plate collector installations require much lower investment costs in most cases (Ambrulevicius, 2005; Jonynas et al., 2011; Sarka and Streckiene 2014). In recent years, the price of good quality evacuated tube collectors is slowly decreasing followed by the increase of the usage of this technology, yet there is still a lack of real efficiency and life span data at the moment. According to the European standard EN 15459:2006 the life span of solar collectors are from 15 to 25 years, but the actual life span of the vacuum varies from collector to collector, anywhere from 5 years to 15 years (Bhatia, 2014).

Some studies in Lithuania and in other countries of similar climate showed that small and medium-scale solar DHW systems with flat plate or evacuated tube collectors can produce from 335 to 523 kWh/m² of thermal energy per year, and the payback time of these systems is over eight years without the subsidies. The potential of ST systems is quite high; however, the support from government and EU funds is still necessary in most cases to achieve reasonable payback (Adomavicius, 2010; Ayompe and Duffy, 2013; Hugo and Zmeureanu, 2012; Jonynas and Valancius, 2010; Perednis et al., 2007; Valancius et al., 2015a; Valancius et al., 2015b). In Lithuania, some limited subsidy systems and funds for renewable energy installations exist since 2005. Depending on a project, it is possible to apply for a subsidy covering from 30 to 100% of initial costs. For example it is possible to get a subsidy up to 30 % for single family building, up to 40% for multifamily building and up to 100 % for hospitals. Such subsidies can be applied for solar thermal systems as well as other renewable energy installations. Evidence that the most important factor for users is the payback time and only two systems (Table 1) analyzed in this report were installed without any subsidies.

Some studies showed that relation between installation costs and area of the flat plate solar collectors (including heat storage tanks and auxiliary equipment) can vary in the range from 600 to 150 Eur/m² in SHW from 10 m² to 10000 m². The installation costs, annual maintenance and repair costs vary in wide range depending on the type of solar collectors and other components, but in general, larger SHW installations are relatively cheaper to maintain than small-scale SHW systems (Andrews et al., 2012; Leutgöb and

Rammerstorfer, 2013). Additional costs for design of the systems in Lithuania add up to 8% from the installation costs. In some cases, the costs of SHW installations in existing buildings can be up to 20% higher compared to new buildings (Valancius et al., 2015b).

The number of medium-scale SHW systems in Lithuania is still relatively low and represent the potential direction for development of these systems. There is a number of medium-scale SHW systems installed in the country varying from 60 to 204 m² of total solar panel area. Most of these systems are installed within the past few years in public buildings, hospitals and industrial facilities. The oldest still operational SHW system 77 m² was installed in 2002 in children sanatorium "Žibutė" (Kačerginė). However, it took 10 ten years for the first SHW system to be installed in multi-family building, as the first such system was launched only in 2012 (Katinas et al., 2013; Karbauskaite and Perednis, 2011; Valancius et al., 2015a; Valancius et al., 2015b).

Fig. 1: The first solar thermal system 60 m² in multi-family building in Panevėžys city and the biggest solar thermal system 204 m² in Plungė town hospital (till the end of 2015).

Some studies in Lithuania showed that public and multi-family buildings represent one of the major potential for SHW installation, as it is one of the best renewable energy alternatives for these buildings (Adomavicius, 2010; Diliunaite, 2013; Perednis et al., 2007; Valancius et al., 2015b;). More uniform DHW usage during the day is common for public or multi-family buildings, compared to the single-family houses. It is related to variability of occupants and their hot water consumption habits, and this aspect brings out a higher solar energy share without adding additional volume to the accumulation tank. Moreover, DHW consumption throughout the day presents the possibility to keep lower temperatures in solar collectors even during periods of high solar radiation. Public or multi-family buildings provide a possibility to connect several users to the same combined SHW system; therefore, the heat losses due to transformation and transportation of hot water will be incurred to a lesser extent during the system operation (Zandeckis et al., 2011).

3. Review and Analysis of Medium-Scale Solar Thermal Systems in Lithuania

Ten different ST systems in different Lithuanian cities were evaluated in this review. Most of these systems were designed for DHW applications. Flat plate or evacuated tube collectors and other equipment produced by different manufacturers were used for these projects. All of these systems are in operation for up to 5 years. Only some of the systems are equipped with heat meters or monitoring systems. Technical and economical characteristics of the analyzed systems are presented in Table 1.

Three different ST systems 4F, 5F and 3E (Fig. 3) were evaluated. All these systems are in operation from 2011 and are equipped with heat meters and monitoring systems. All of the analyzed systems have individual operational features that impacts their produced energy amounts. System 4F performs continuously from the start of the exploitation. System 5F was stopped for three weeks in August during pool renovation works. Performance of system 3E was interrupted for a few times due to system upgrades.

The measured performance of the existing ST systems was compared to the theoretical values obtained by means of simulation software "Polysun 8.1" (Velasolaris, 2015). All technical parameters of the existing systems such as inclination angle, orientation, energy demands and characteristics of the installed equipment were used as boundary conditions for the simulations.

Tab. 1: Technical and economical characteristics of the analyzed ST systems.

Description of ST systems			Total gross / absorber area, m^2	Investment per 1 m^2 gross area, Eur	Annual energy production per 1 m^2 gross area, kWh
Flat plate solar collectors	1F	SHW, main energy source – natural gas	25 / 23	519	512 (2015)
	2F	SHW, main energy source – district heating	40 / 37	516	382 (2015)
	3F	SHW, main energy source – district heating	72 / 67	418	n/a
	4F	SHW, main energy source – electricity*	114 / 106	479	488 (2013)
	5F	Indoor swimming pool heating and SHW. Main energy source – natural gas**	166 / 155	701	411 (2013)
Evacuated tube solar collectors	1E	SHW, main energy source – electricity	27 / 15	571	528 (2014)
	2E	SHW, main energy source – district heating	36 / 33	692	414 (2015)
	3E	Preheating the return water in the district heating network***	82 / 72	1079	343 (2013)
	4E	SHW, main energy source – district heating*	90 / 63	621	n/a
	5E	SHW, main energy source – district heating	145 / 77	320	n/a

* Approximate investment costs per 1 m² gross area.
** System was not in operation for three weeks during August 2013.
*** System was upgraded few times due to improper operation, therefore approximate value of the total investment is presented.

Financial analysis was performed for ten different ST systems. In this study, the assumption was made that the entire cost of the ST systems is covered during the installation and the systems were installed without any subsidies. The life span of the ST systems is considered to be 20 years. Parameters used for financial assessment of the ST systems are presented in Table 2.

Tab. 2: Parameters used for the simulations of ST systems.

Life span of ST systems, years	20
Specific district heating energy price (average), Eur/kWh	0.041
Specific energy from natural gas price (average), Eur/kWh	0,076
Specific electricity costs (standard), Eur/kWh	0.129
Index for energy prices, % per year	3.0
Interest capital, %	2.5
Running costs, %	1.5

4. Results of analysis

Analysis showed that the relation between installation costs and area of the flat plate and evacuated tube solar collectors (including heat storage tanks and auxiliary equipment) varies in the range of 320 – 1079 Eur/m² in ST systems from 25 m² to 166 m² gross area. Average price of flat plate solar collector systems is 527 Eur/m², but the investment for evacuated tube solar collector systems per 1 m² gross area varies in a wide range of 320 – 1079 Eur/m², with the average price of 657 Eur/m². Compared to the analysis made ten years ago (Perednis et al., 2007), prices of ST systems have not changed significantly.

The results of the analysis showed that ST systems with solar flat plate and evacuated tube collectors can produce from 343 to 528 kWh/m², and almost the whole irradiated solar energy – approximately 80% – can be collected during the warm period of the year (Fig. 3).

Simulations showed that analyzed ST systems in Lithuania can reduce greenhouse gas emissions from 49 to 232 kg $CO_2/m^2_{absorber}$ per year. However, CO_2 reduction per absorber area can vary in the wide range depending on the type of the system and an alternative source of energy production.

Price composition of the analyzed ST systems is presented in Figure 2. The price of solar collectors and mounting systems comprises 51 % of the total system price in cases when evacuated tube collectors are used, for example ST system 3E (Table 1).

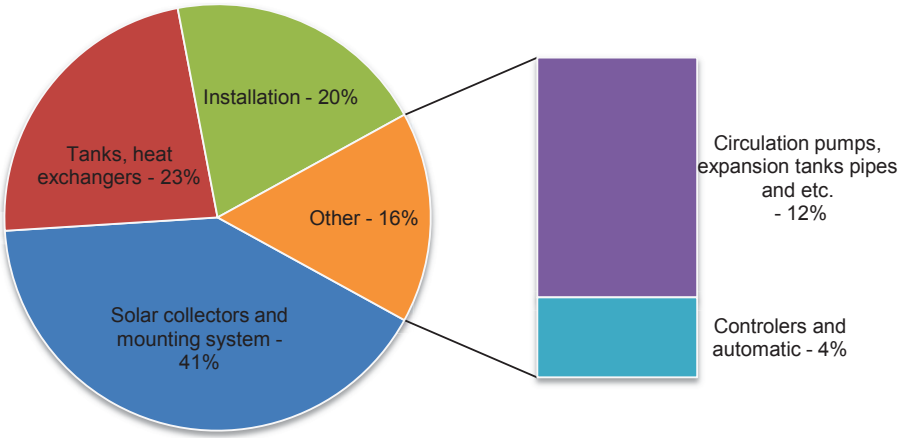

Fig. 2. Price composition of equipment in analyzed ST systems.

The financial analysis showed that heat energy generated by analyzed ST systems is not competitive in most cases in comparison with district heating (payback period from 11 to 40 years) and natural gas applications (payback period from 24 to 27 years). However, the projects were fully profitable (payback period from 6 to 10 years) in cases when electrical energy was used as an alternative to energy produced by SHW systems (Table 1). Average solar energy cost (life span is 20 years) in the analyzed cases was – 0.073 Eur/kWh.

Measured annual efficiency of the analyzed systems reached up to 44 % (4F) 39 % (5F) and 24 % (3E). The measured values of global irradiation in Kaunas city and the amount of energy produced in the analyzed systems per month are presented in Figure 3.

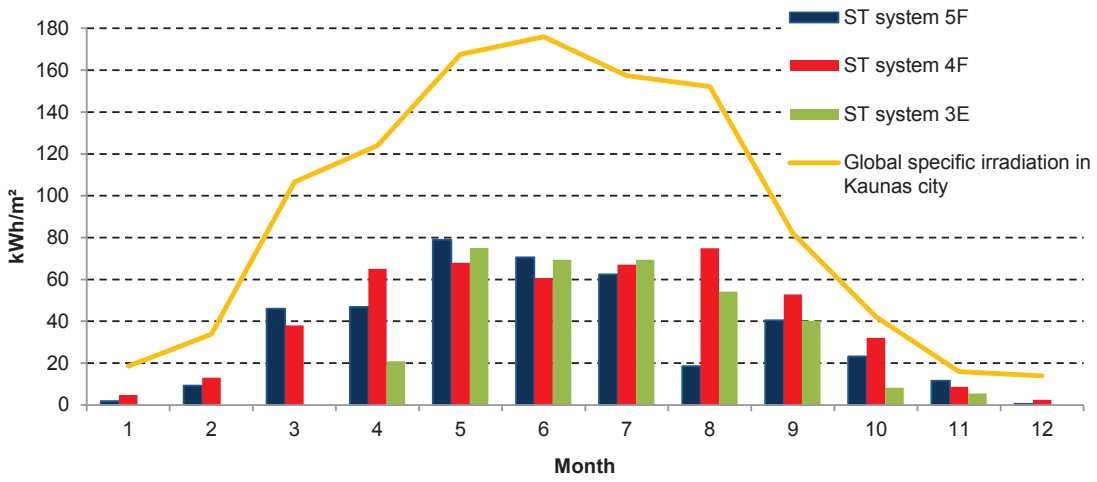

Fig. 3. Produced energy in the analyzed ST systems (kWh/m² $_{absorber}$) per month and measured global irradiation in Kaunas city (2013).

The gap between measured and modelled data of heat energy produced by SHW systems was approx. 11 % in the analyzed cases. It can either be caused by differences in actual solar irradiation compared to the standard average data, or some peculiarities of the design and maintenance of the SHW systems.

5. Discussions and conclusions

Average price of flat plate solar collector systems was 527 Eur/m² in the analyzed cases, but the investment for evacuated tube solar collector systems per 1 m² gross area varied in a wide range of 320 – 1079 Eur/m², with the average price of 657 Eur/m².

ST systems with evacuated tube collectors do not reach significant additional expected energy yield. ST systems with solar flat plate and evacuated tube collectors can produce from 343 to 528 kWh/m² of thermal energy and reduce greenhouse gas emissions from 49 to 232 kg $CO_2/m^2_{absorber}$ per year.

The results of the analysis showed that in the analyzed cases the gap between measured and modeled data of heat energy produced by ST systems was approx. 11%. From the economic perspective, the system with flat type solar collectors used for DHW production is profitable if compared with the electrical energy as an alternative.

The most expensive equipment in ST systems are solar thermal collectors. In the analyzed cases, from 28% (flat plate collectors) to 51% (evacuated tube collectors) of initial investment is required to cover the costs of solar collectors itself.

The market growth of ST systems in Lithuania and other countries depends on the policy of the governments. The payback period of ST systems in most cases is too long (from 6 to 40 years) to ensure the stable growth of ST applications without the governmental grants. Despite the long payback period the market of ST systems is slowly growing and the trend continues towards larger DHW in multifamily buildings, hospitals, hotels and other large complexes due to support from EU and other funds.

Heating, cooling and ventilation with the solar-assisted heat pump based on the air solar collector

Andrii Zakovorotnyi

Lucerne University of Applied Sciences and Arts

Abstract

A new concept for solar-assisted heat pumps based on an air solar collector is discussed in this paper. The main objectives of the system have been set on a partial covering of the cooling demand of a building during summer season and simultaneous charging of the thermal storage for domestic hot water usage. Beside this, the proposed system fully covers the ventilation need of the building. The current paper presents the performance results of proposed concept for different weather conditions. The results demonstrate that such system is competitive with the existed solar-assisted heat pumps in terms of technical simplicity to cover broad range of tasks simultaneously.

Keywords: *air solar collector, heat pump, air conditioning, air cooling, thermal storage*

1. Introduction

Past decades brought various technologies based on renewable energy sources, which are promising alternatives to the dominant use of fossil fuels, including wind power, hydropower, waste energy, geothermal energy, bio energy and solar energy. Herein, solar energy has proven itself as a clean source for electricity and heat generation in the building sector. However, its performance strongly depends on time and local weather conditions which are not completely predictable. This time shift leads further to the issue of the decreased self-consumption of the solar power, especially, of the PV-plants. Use of energy storage (electrical batteries and thermal storage such as hot water boiler or others) can increase the fraction of harvested solar energy and shift gained energy to demand time zone (Tanguy et al., 2014). Another common way of increasing of the self-consumption of the electricity produced by solar PV-cells is to use a heat pump (HP) for storing the electrical energy in thermal storage for further electricity and heat production (Dumont et al., 2015).

On the other hand, the consequences of global climate change more and more shift the focus from covering of heat demand during the winter to providing the necessary cooling power to buildings during the summer season. Jurt et al. (2016) showed that the number of overheating hours will increase by 50 % to 100 % in the next 30 years, depending on building type.

In addition, there are compulsory requirements for the mechanical ventilation systems (Swiss Norms, 2006) in office and industrial buildings.

Summarizing the requirements, it is clear that in order to get high efficiency of all systems in building all the above mentioned tasks should be considered together. Typical combination of the water solar thermal collector and water-based HP which use the water tank as a daily or weekly thermal storage is presented by a number of research papers (Bucker and Riffat, 2016, Poppi et. al., 2016). Although the combination of system components varies greatly and generally increases the COP of a HP up to 6, however, these cases can be considered only for the solution of two tasks such as covering the heat load and increasing the consumption of the installed PV cells (Fischer et al., 2016).

Combination of ventilation system and HP for covering the cooling and heat load is presented by widely spread air-to-air and air-to-water HPs, which also increase self-consumption of the electricity produced by PV-cells. However, their application for covering the heating demand during winter has lower efficiency due to the lower temperature of the air. Use of thermo-chemical (Tanguy et al., 2014), sensible or latent (Kapsalis and Karamanis, 2016) seasonal heat storage provides an opportunity to increase efficiency during winter, but such systems suffer of a high technical complexity (Tanguy et al., 2014).

doi:10.18086/eurosun.2016.04.09 Available at http://proceedings.ises.org

Ventilation system based on solar air collector (SAC) also partially covers the building's heat demand and is not sophisticated. Sicre et al. (2015) measured and analyzed the efficiency of a 24 m^2 SAC as a system which simultaneously fulfills the ventilation requirements and heats up the indoor air. With an average energy conversion efficiency of 60 % this system covers only 28 % of the heat demand of typical factory building in Luzern, Switzerland, due to the obvious lower solar gains during winter. Air collector was also used as a cooling device during night using the sky radiation effect; the resulting cooling capacity was restrained to as little as 1 kWh per night. Another way to actively cool down incoming air using air solar collector is achieved by using a desiccant cooling wheel (Eicker et al., 2010). COP of such system is up to 3.2, but hygienic aspects may rise concerns.

Summarizing different concepts of system, combination of solar thermal plant such as SAC for assistance, of the standard air-to-water HP powered by PV-plant and coupled to a thermal storage is promising. The focus of the present paper is set on the design of such system that will cover simultaneously ventilation, domestic hot water (DHW) production and partially cooling. The goal of current research is to estimate the efficiency and working ability of a solar-assisted HP based on the SAC with an evaporator, which cools down the inlet air provided into the room during summer season, and a condenser, which simultaneously charges domestic hot water tank or other heat storage that is discharged later by consumer.

2. System concept

The proposed solar-assisted HP based on SAC can be well explained using the scheme of principle in fig. 1.

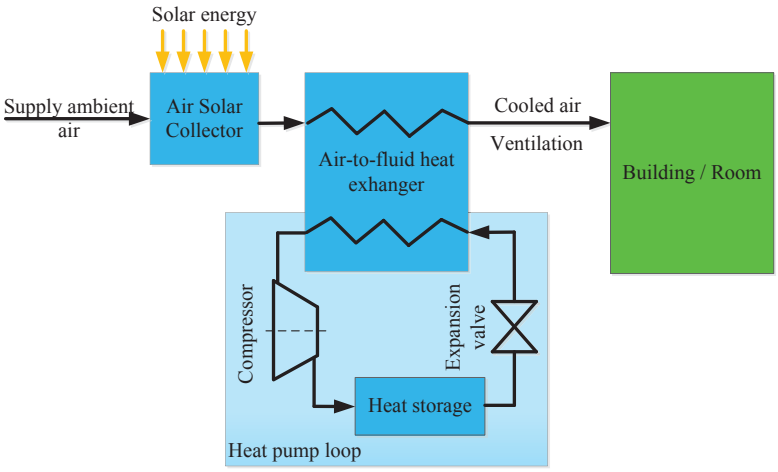

Fig. 1: Scheme of the system operation during summer season

Basically such system represents a solar-assisted air-to-water HP. Besides provision of cooling and heating, it also fulfils the function of building ventilation. During the summer season SAC sucks and heats the outside air, which is further passed through the heat exchanger, where the refrigerant of the HP evaporates. The resulting, relatively cold outlet air is sent to the rooms. On the other side, evaporated refrigerant from the heat exchanger is compressed by the compressor and supplied to the thermal storage, that may be a DHW tank or another thermal storage, which will be discharged later by consumer.

During the winter season HP can be used in combination with the SAC in a way described in Karagiorgas et al. (2010), where SAC serves during winter as an energy collector for the air-to-water HP. This solution allowed increasing the COP of the air-to-water HP by 30-50 % depending on the ambient temperature and available solar radiation.

SAC can be used alone without HP during autumn and spring to cover low heat demand (Sicre et al., 2015). Other way to cover the heat demand during winter is to use accumulated energy during summer; however seasonal thermal storage with high energy capacity is required.

Thermodynamic cycle of a HP in T-S diagram is presented in fig. 3. As a working refrigerant of the HP cycle tetrafluorethan (R134a) was chosen, due to its widespread application in cooling technologies and its critical temperature of 101,06 °C is acceptable for the investigated cycle (Lemmon et. al, 2013).

For the pressure raise simple one-stage piston compressor is used with the efficiency of 60 % (Bitzer Ecoline, 2016). Expansion of the mixture through the expansion valve assumed to occur with a constant enthalpy. In order to increase efficiency of the system the compression ratio of the compressor is changeable from 1.8 to 4.6 and depends on water temperature in storage, however, the evaporation temperature of the tetrafluorethan maintains constant and equals to 10 °C (fig. 3). But for the comparison purpose with existed systems, constant compression ratio of 4.6 is used in present paper (fig. 3 - cycle with highest compression ratio). The volume flow rate of the working fluid in a HP loop is regulated in a way that provides outlet air temperature equals to 21 °C. Technically it is fulfilled using variable speed compressor and adjustable expansion valve. Since the COP is proportional to the source temperature, the SAC HP will perform better in the summer when temperature of incoming air is increased by solar radiation in the SAC.

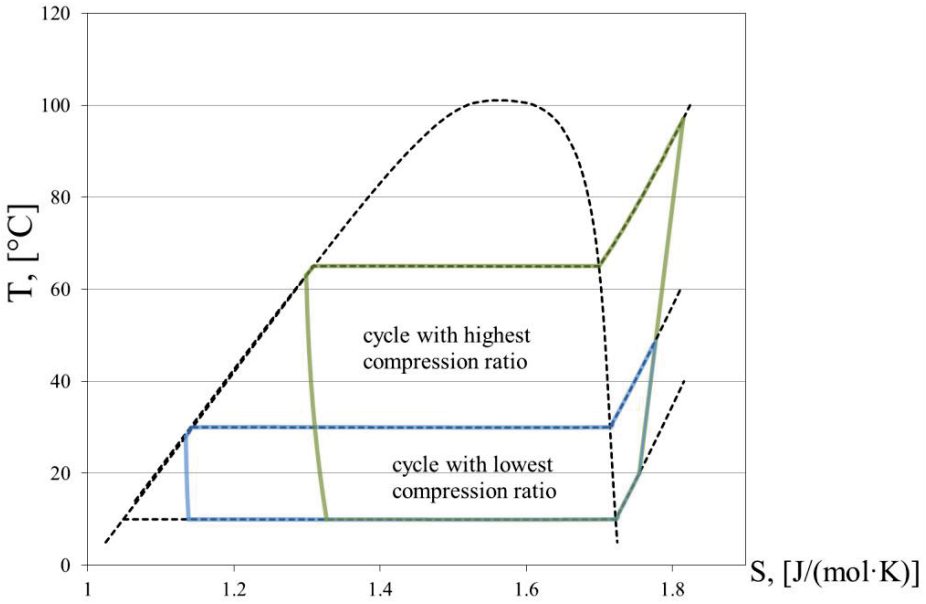

Fig. 3: T-S diagram of a HP loop

It is important to mention two running boundaries for the described system. On one hand, HP is not allowed to cool down the incoming air from the SAC below the set point temperature for the room (in present paper, 21 °C). If the ambient temperature is higher than a high room temperature limit (in present paper 26.5 °C according to Swiss Norms, 2014), use of SAC for further cooling purpose has less efficiency than direct cooling of the ambient air with the HP. Therefore, during summer operation of investigated system has lower limit of 21 °C of its outlet temperature and upper limit of 26.5 °C of the ambient temperature.

The standard characteristic of the HP cycle such as COP will be described in this case as follows:

$$COP_{cycle} = \frac{P_{heating}}{P_{compressor}+P_{ventilator}}, \qquad \text{(eq. 1)}$$

where $P_{heating}$ is energy absorbed by thermal storage, $P_{compressor}$ – electrical energy provided for the compression the working fluid in the cycle, $P_{ventilator}$ – electrical energy provided to the ventilator for the maintenance of the required volume flow rate through the ventilation channel.

3. Performance calculation

Since proposed system can be applied for the residential, office or industrial building (Sicre et al., 2015, Peci et al., 2016); and ventilation systems and requirements vary greatly, building thermal simulation will not help to achieve the goal of covering all possible options. Instead one may try to estimate the heat production of 1 m^2 area of the surface of the SAC in dependency of the geographical location.

Area of SAC is dimensioned according to the required air exchange rate in the building. According to Sicre et al. (2015) 1 m^2 of the air collector surface provides 50 m^3/h with acceptable pressure losses in ventilation channel.

For the description of the air collector performance, following equation was used:

$$\frac{Q_{SAC}}{A} = G_{90} - 9.1 \cdot (T_{SAC} - T_{air}) - 1.87 \cdot 10^{-8} \cdot \left(T_{SAC}^4 - T_{sky}^4\right) - 537 \cdot \frac{d(T_{SAC})}{d\tau}, \quad \text{(eq. 2)}$$

where Q_{SAC} – useful energy produced by the SAC, A – surface area of the SAC, T_{SAC} – mean calculated temperature of the SAC, T_{sky} – sky temperature, T_{air} – ambient temperature.

Obtained temperature of the SAC and outlet temperature of tetrafluorethan from the condenser is used for the calculation of the volume flow rate of the working fluid needed to cool down the inlet air to 21 °C. Volume flow rate is further used for the calculation of the charging power of the water boiler.

System was simulated for 8 geographical locations, which represent Mediterranean, Atlantic and Continental climates of Europe. The annual weather data for the mentioned locations was generated using software package Meteonorm 7.

In order to evaluate system's profitability, it is compared with the reference case, in which HP cycle is not changed, but inlet air in the evaporator zone is provided directly from the environment and not from the SAC. In order, to make equal $P_{heating}$ for both cases without changing the cycle, the volume flow rate of the air for reference case is increased properly due to the lower inlet air temperature. It will lead to the higher power consumption of the ventilator and lower COP of the reference system.

4. Results

Both investigated and reference systems were simulated for summer season (92 days) with the time step of 6 seconds with the mentioned boundary conditions. Comparison of the average seasonal performance factor (SPF) of the investigated and reference systems during working days with low cloudiness are shown in figure 4. For such days the SPF of the reference system is higher in southern regions due to the higher ambient temperatures – which leads to the lower air volume flow rate through the evaporator of HP.

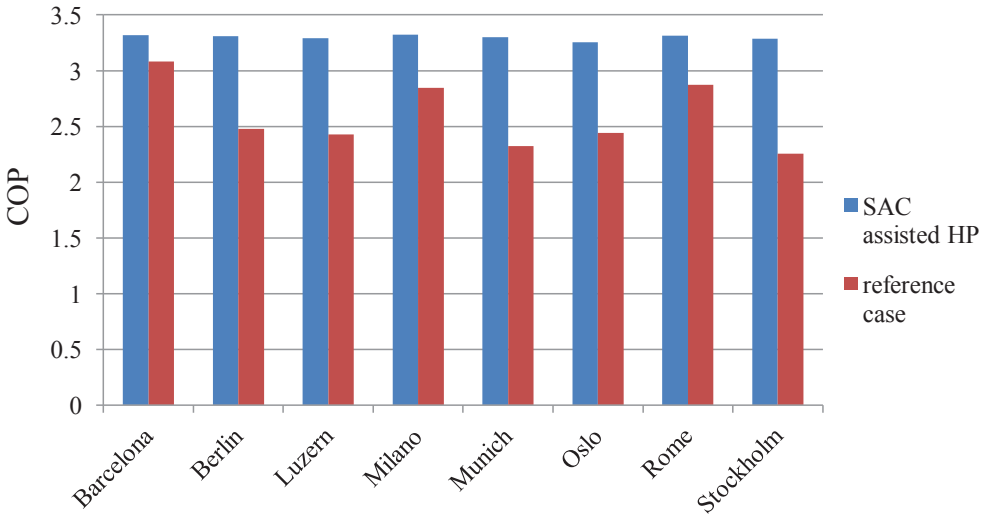

Fig. 4: Comparison of the average COP of the investigated and reference system for different geographical locations

The SPF of the investigated system is approximately the same for all geographical locations and equals 3.3. It occurs due to the application of the same governing equation (eq. 2) for the SAC in all cases with the same air volume flow rate. However, heat production of the systems in absolute values varies on geographical locations (fig. 5). The difference between average daily production per summer season and average production per cloudless day depends on the amount of the sunshine hours of each geographical location.

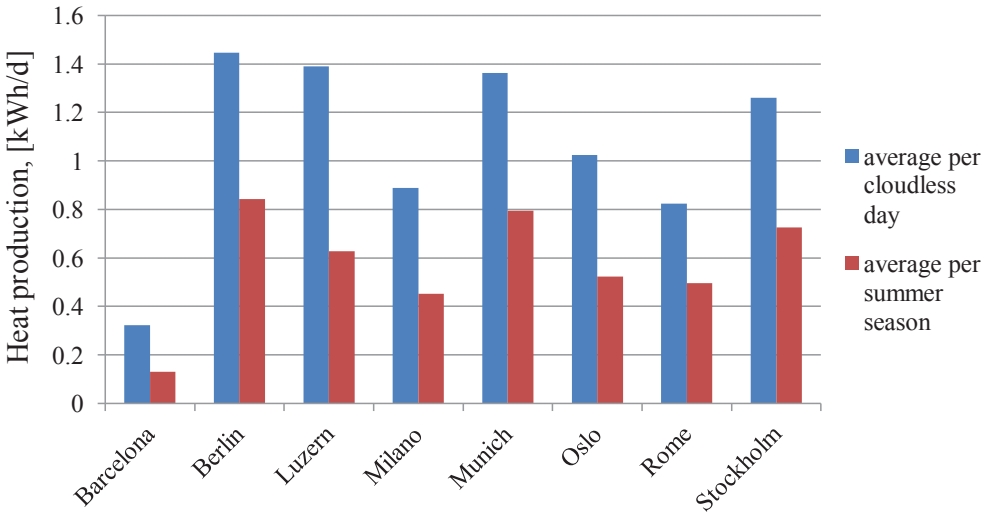

Fig. 5: Comparison of the average heat production of the investigated system with SAC area of 1 m^2 on cloudless day

From the figure 5 it can be seen that application of the SAC system has the highest production in central Europe. In the southern locations like Barcelona, Milano, Roma, ambient temperature is higher than the higher temperature set point (26.5 °C) and conventional cooling is needed. Due to this reason amount of hours during which investigated system can work is limited. On the other hand, solar radiation is lower in northern locations (Oslo and Stockholm). Useful fraction of the harvested solar energy in summer is shown in figure 6 and varies from 17 % to 26 % for office buildings, which use investigated system 5 days per week, and from 24 % to 36 % for residential buildings, which use investigated system each day.

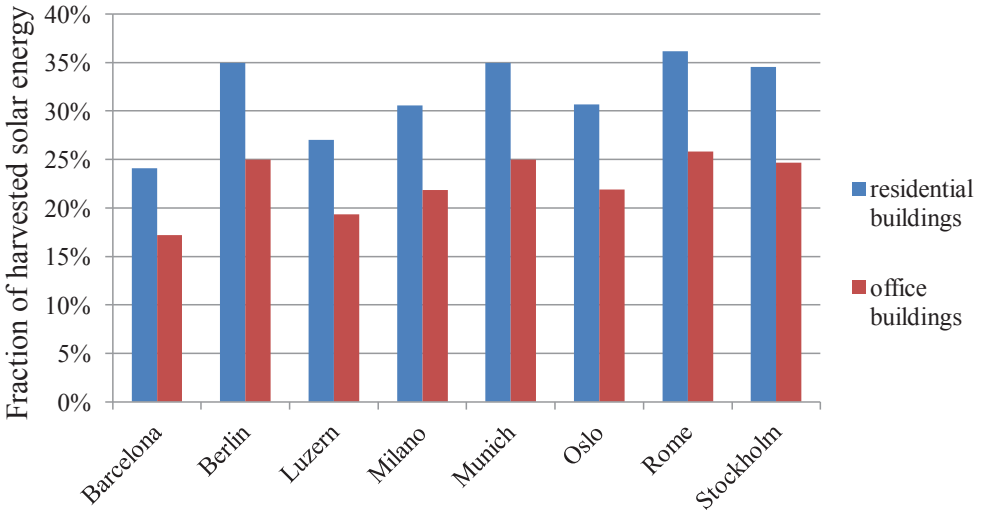

Fig. 6: Comparison of the fraction of harvested solar energy by the investigated system for different geographical locations

5. Conclusions and Discussion

This paper proposes an air-to-water heat pump cycle, which is assisted by solar air collector. Such system is handling several tasks simultaneously during summer season: ventilation and partial cooling of the rooms with internal gains, charging a thermal storage such as water tank and increasing the self-consumption of available PV-plants. It was shown that the $SPF_{heating}$ (which does not consider useful cooling energy produced by the system but only the heating up of the storage) of such system during summer season for cloudless days equals to 3.3. In comparison, the $SPF_{heating}$ of a HP-reference system would be 2.5 for central Europe.

The highest heat production can be achieved in central Europe and equals in average to 1.4 kWh/d for 1 m^2 of the solar air collector for cloudless days, which corresponds to 30 liters of water heated from 20 °C to 60 °C. The useful fraction of the harvested solar energy by the investigated system varies from 17 % to 36 % depending on the type of energy consumer (residential or office buildings). During the heating season system can run into two different modes. SAC can run standalone to cover low heating demand during autumn and spring or SAC can be used as a low temperature source for the existed heat pump which will further heat the rooms. Since the amount of energy produced by solar collector is relatively high, and the area of SAC is dimensioned according to the ventilation requirements, the amount of the heat production can be excessive and not be consumed at the same time. Therefore, accumulating of such energy also for the space heating can be promising. However, calculations should be made separately for specific building.

Compulsory Policies of Installing Solar Water Heating Systems and Normative Construction Procedure in China

Ruicheng Zheng[1], Bojia Li[1], Min Wang[1], Xinyu Zhang[2] and Tao He[2]

[1] China Academy of Building Research, Beijing (China)

[2] National Center for Quality Supervision and Testing of Solar Heating Systems, Beijing (China)

Abstract

In recent years many local governments in China have implemented compulsory policies of installing solar water heating systems integrated in new buildings. So system quality and capacity becomes a very important problem. Therefore a complete supervision system for quality control to solar water heating systems integrated in buildings during whole construction procedure has been formed gradually in China. This system includes technical code for design and acceptance, performance requirement to products of solar collectors and a normative construction procedure etc.

In this paper it is given the background of compulsory policies of installing solar water heating systems integrated in new buildings and introduced a normative construction procedure for solar water heating system. The procedure runs through design, product selecting, construction, acceptance and evaluation. As most of buildings are tall buildings in China's cities some installation types for solar collector integrated in buildings and better operation measures for central solar water heating systems to suitable special condition of China are also given in the paper.

Key-words: *compulsory policies; technical code for design and acceptance; construction procedure for solar water heating system*

1. Background

In recent years many local governments in China have implemented compulsory policies of installing solar water heating systems integrated in new buildings, and some cities publish different preferential policies, such as give financial subsidy to star green residencies which should take certain technical measures including installation of solar water heating systems etc. But some problems occur when practice, such as substandard product quality and completion inspection of projects etc. As it has influenced the health developing of these polices, for quality control and capacity promotion of the solar water heating systems, a completed supervision system has been formed gradually in China.

The system includes three important aspects. The first is national standards for products, such as "Evacuated tube solar collectors" and "Flat plate solar collectors" etc. The second is technical code for design and acceptance, such as "Technical code for solar water heating systems of civil buildings" and "Evaluation standard for solar water heating system of civil buildings" etc. The third is a normative construction procedure. Only following this construction procedure a solar water heating system integrated in building with higher quality and better effect can be completed. The procedure has 4 main steps: design, installation, acceptance and evaluation.

2. Design, examining and approving for design drawing

Engineering design in China must follow a stipulate procedure and the design for solar water heating systems

doi:10.18086/eurosun.2016.04.20 Available at http://proceedings.ises.org

integrated in buildings should also follow it. The most important step for the procedure is examining and approving to design drawing by another qualified authority after design is finished by original design authority.

2.1. Design

Design for solar water heating system integrated in building shall be done by an authority which has a certain design qualification. Design must follow the all stipulation in China's national standard "Technical code for solar water heating systems of civil buildings" GB 50364. This code has finished revision during 2014-2015 and many terms in revision version of the standard can give stronger supporting to guarantee the design quality.

For example, the term for calculating solar collector areas used in system stipulates strictly that yearly average efficiency of the solar collector shall be calculated according to the instantaneous thermal efficiency equation of a solar collector which is tested by a qualified testing authority and computation method is given in this term. The computation method of this term gives the detail selecting principle for computation parameters, such as how to select solar irradiance, ambient temperature and inlet water temperature of collector in reduced temperature difference of the thermal efficiency equation.

The revision version of the standard gives a lot of basic data used for design, such as yearly total solar irradiation and average daily total solar irradiation on horizontal and slope plane in 31 cities of China etc. In appendixes of the standard some computation methods are given, such as computation for wind load to a solar water heating system which installs on the roof of a tall building. So the revision version of the standard is a more useful design tool and can raise future design level of solar water heating system in China.

2.2. Examining and approving for design drawing

After the design for solar water heating system be finished all design materials including design drawings, calculation documents etc must be examined and approved by another authority which has a certain level of drawing check qualification.

The focus of design examining by the drawing check authority are following:

• If the design meets all stipulations in national standard " Technical code for solar water heating systems of civil buildings" GB 50364, such as various safety requirements, calculation for solar collector areas and volume of water tank etc, type selection for equipments of pump and heat exchanger etc.

• If the performance of the solar collector used in the system meets the technical requirement in concerned national standard, such as exposure and pressure-resisting etc safety performance, zero-loss collector efficiency and collector overall heat loss coefficient etc thermal performance.

• If having the reliable and flexible automatic control measure and it can prevent effectively occurring of safe faults, such as overheating and freeze of the system etc. And the control measure can give precedence to use solar energy heating water etc, so to guarantee energy saving effect of the system.

• To check the analysis for energy saving effect and economical efficiency of the system design and if it meets the original requirement.

Only an approved design scheme can be used for construction of a solar water heating system integrated in building.

3. Requirement for installation and acceptance of system construction

Requirement for installation and acceptance of a solar water heating system is stipulated in "Technical code for solar water heating systems of civil buildings" GB 50364 and acceptance is a key factor. In the revision version of the standard GB 50364, more contents are added in the chapter of acceptance for solar water heating systems, so the operability to an engineering acceptance for a solar water heating system is stronger and clearer than before, therefore the engineering quality and the effect of the solar water heating system will also has a better guarantee than before.

The standard stipulates that acceptance shall be divided into acceptance for itemized project and completion acceptance and system commissioning must be finished before completion acceptance. Acceptance for concealed work, such as embedded parts for collector installation foundation etc, must be certificated by supervision personnel of the project before concealing. After each acceptance for itemized project finished, linkage debugging to the system shall be carried out and then system commissioning must be done as practical working condition in continuous 3 days which shall be one clear day at least. When linkage debugging, temperature, flow rate and working pressure of the system shall meet the design requirement at the rated condition in which flow rate and temperature of hot water supplying equals design value.

When completion acceptance, some necessary documents, such as completion drawings, qualified certificate or performance testing reports of the main materials and equipments, records for system debugging and commissioning, testing record for thermal performance of the system etc must be given. Testing for thermal performance of the system shall be done in 4 days when having different solar daily irradiation at least, the distribution range of solar daily irradiation (shown in Table 1) and testing method shall meet the requirement in China's national standard "Evaluation standard for application of renewable energy in buildings" GB / T 50801. Only passed the completion acceptance, the engineering of a solar water heating system can transfer to users.

Tab. 1: Distribution of solar daily irradiation for thermal performance testing of a solar water heating system

days	the first day	the second day	the third day	the fourth day
daily irradiation (H)	H＜8 MJ/m^{2}d	8 MJ/m^{2}d≤H＜12 MJ/m^{2}d	12 MJ/m^{2}d≤H＜16 MJ/m^{2}d	H＞16 MJ/m^{2}d

The defects liability period for engineering quality of a solar water heating system is two years. In this period if some quality problems occur, the construction authority shall take maintenance and the responsible party shall undertake concerned economical duty.

4. Some better technical measures for solar water heating systems

As most of buildings are tall buildings in China's cities, so installation types for solar collector integrated in buildings and operation measures shall be suitable to this special condition.

4.1. Installation types for solar collector integrated in buildings

As roof area is not enough to install solar collectors which can meet demand of solar water heating system for a tall building, two main installation types are used generally in China, collectors close putting on a support structure of the roof (Fig.1 left) and collector instead of board of balcony (Fig.1 right).

Fig. 1: Two main installation types for solar collectors integrated in buildings

For installation type of collectors close putting on a support structure of the roof, in general the system can provides enough solar hot water supply to whole building which has 24 floors. As collector frame can shelter incidence sunlight, the another advantage of this installation type is to decrease the roof temperature

in summer, according to testing to a real project in Shenzhen City the roof temperature is 2℃ lower than common building, so it is favor to decrease energy consumption for air conditioning in summer.

Fig. 2: View of real projects using these two installation types for solar collectors

For installation type of solar collector instead of board of balcony the tilt angles of the collector installation are different in north part with higher latitude and in south part with lower latitude of China. In north part with higher latitude, such as Heilongjia Province etc, the tilt angles of the collector can be 90^0 (Fig.1 right), but in south part with lower latitude, such as Jiangsu Province etc, the tilt angles of the collector shall be smaller than 90^0 (Fig.2 right), so can get more incidence sunlight.

4.2. Operation measures for a central solar water heating system

For increasing energy saving effect of a central solar water heating system, it is necessary to decrease heat loss in circulation pipes of hot water supplying. So a common operation measure for hot water circulation in pipes used in China is to start circulation only when temperature of hot water is lower than a set value in the past. But now a better operation measure for hot water circulation is used in some residential buildings, circulation starting only when a user wants to use hot water. If a user in the building wants to use hot water, he/she can put a push-button on the wall of an apartment to start circulation (push-button flashing) and then use hot water till the push-button no flashing, as it (push-button no flashing) means that the temperature of hot water has reached the set value and can be used for bath etc, not only energy saving but also water saving.

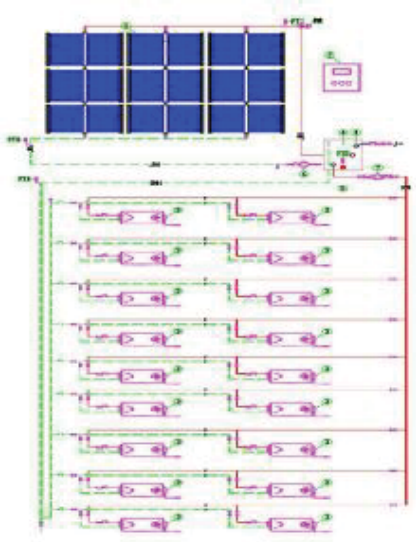

Fig.3 shows a popular central solar water heating system which is named collective-individual hot water supply system. Solar collector array of this system is installed on the roof of a tall building, and the hot water storage tanks are installed in each apartment of the building, but a small solar hot water tank is on the roof. Solar hot water is supplied into heat exchanger of water storage tank in the apartment and water in the tank is heated. The main advantage of this system is to make easier for payment of hot water using. The increasing cost for solar water heating system can be included in sale price of the apartment, the resident family need only take cold water payment when using solar hot water, so heat metering of the system can be canceled. As a possible problem of the system is unbalances heat exchange between various water storage tanks, so developed an auto-control measure to solve it. Every time heat exchange is only taken between users of selecting numbers (adjustable as real condition), not all users.

Fig. 3: Collective-individual hot water supply system

At the first round when water temperature of these tanks raise 5℃ (adjustable as real condition, in general it is 5-10℃), the hot water input valve of heat exchangers close automatically and heat exchange turn to next sets of same number's tanks for heat exchange, repeating till finishing heat exchange of all tanks, then to the

second round, so guarantee to get same solar energy for all users basically.

5. Effectiveness

Since following this normative construction procedure for solar water heating systems, many projects of solar water heating system get better effects than before in China. For spreading successful experience of better projects, China Academy of Building Research undertook a task for compiling drawing volume of excellent cases of solar water heating systems which is given by the Ministry of Housing and Urban-Rural Development of PRC in 2015. China Academy of Building Research investigated a lot of projects and National Center for Quality Supervision and Testing of Solar Heating System (Beijing) tested some projects for volume compiling and 18 engineering cases of solar water heating system are selected to put into the drawing volume.

These 18 engineering cases are located in 9 Provinces including Beijing Anhui Hebei Shandong Jiangsu Zhejiang Hainan Xinjiang Ningxia and cover 4 different weather areas of severe cold zone, cold zone, hot summer and cold winter zone, hot summer and warm winter zone in China. The system types of the cases are 7 collective hot water supply systems, 6 collective-individual hot water supply systems and 5 individual hot water supply systems. So the cases have a wide-ranging representativeness. The average solar cost of the cases is 0.11Yuan/kWh and the payback period of steady state is all smaller than 5 years, economical efficiency is very nice.

Tab.2 and Tab.3 shows a fine effect of an understanding case in the drawing volume. It is a central solar collective and hot water supply system in a living building for staff of Yimin Company, located in Nanpi County, Cangzhou City, Hebei Province, designed and installed by Jiangsu Sunrain Solar Energy Co.,Ltd which is exclusive quoted company in solar thermal field of China. Total solar collector areas of the system are 620m^2, except solar hot water supply to the building, surplus solar hot water will be transported to ground heat exchanger of a ground-souse heat pump system which is for space-heating of this building. As soil temperature will be raised through heat exchange with solar hot water, unit COP of ground-souse heat pump can be raised, so system efficiency will be also increased.

Tab. 2: Testing data for thermal performance of the project in Yimin Company Ltd

Day	Outdoor temperature ℃	Daily solar irradiation MJ/m^2	Daily solar heat gain MJ	Common energy consumption MJ	System efficiency %	Solar fraction %
1	-3.2	16.52	4241.5	0	47.7	100
2	-2.8	14.83	3983.4	0	49.9	100
3	-1.1	11.54	2545.1	804.5	41.0	76.0
4	-0.3	6.38	1234.8	2114.8	36.0	36.9

Tab. 3: Analysis results for energy saving and environment effects of this project in Yimin Company Ltd

Items	Unit	Value
Solar fraction in one year	%	81.6
Average system efficiency in one year	%	44.2
Quantity instead of common energy	tce/year	127.5
Decreasing quantity of CO_2 discharge	t/year	314.9
Solar cost	Yuan/kWh	0.04
Saving cost in one year	Yuan	498,978.00
Payback period of steady state	Year	1.4

From Tab.2 we can know that this system can get fine thermal performance even in winter. When sunny day solar fraction of the system is still attain 100%. From Tab.3 the energy saving effect and economical efficiency of the system is also very nice. Solar fraction of the system in one year is over 80%, solar cost is only 0.04 Yuan/kWh and payback period of steady state is 1.5 year, very short. The drawing volume of excellent cases of solar water heating systems will be published and as a teaching material for training. So we can believe that solar water heating systems integrated in buildings will be developed better and more healthy in China.

Abstract

An innovative small solar district heating system with one central heating plant and four solar substations has been built in Vallda Heberg, Sweden, to supply a new housing area with passive houses. The target solar fraction was 40% and the total system design, including heat distribution in the buildings, was based on previous experience and aimed to be simple and cost-effective. The main aim of this study was to determine whether the system can be designed in a more effective manner by change of distribution system and load density. TRNSYS models were calibrated against measured data and then used to predict the energy performance. Results indicate that lower distribution heat losses can be obtained by change to a distribution concept with lower operating temperatures, while potentially reducing cost. Changes in heat density cause reduced distribution losses and boiler supplied heat demand, with only minor effects on solar system yield.

Keywords: solar thermal, district heat, hot water circulation, simulation

1. Introduction

EKSTA Bostads AB (municipal housing company) has built and operates a number of solar assisted heating plants in small residential building areas, the first ones from the 1980's. The heat supply is managed via small district heating systems based on wood chips and/or wood pellet boilers and roof-integrated solar collectors of different generations, i.e. 100% heating by renewables. The buildings, commonly small multifamily buildings, have always had a bit lower heat demand than required by the Swedish building code.

The new residential area in Vallda Heberg comprises multifamily buildings, as well as single family buildings. All buildings are designed as passive houses according to the Swedish standards, i.e. well insulated buildings with air tight envelopes, and supply and exhaust ventilation with heat recovery is applied in all buildings. The whole area is supplied with heat from a small district heating system with pellet boiler and solar thermal, with a targeted solar fraction of 40% (Nielsen et al., 2014). This system (see Figure 2) comprises one central heating plant (HP) with a wood pellet boiler (and an oil boiler for back-up) and four sub-stations (SS1-4). Buffer storage tanks are installed in the central heating plant and in each sub-station. There are 108 m^2 evacuated tube solar collectors (ETC) on the heating plant and 570 m^2 flat plate roof-integrated solar collectors in connection to the sub stations. Heat is supplied from the sub-stations to the buildings with a so called GRUDIS 2-pipe system (Zinko, 2004) where hot water is circulated in plastic (PEX) pipes, similar to a standard DHW circulation system (Figure 1). This allows a very simple and inexpensive solution for transfer of heat in each building, reducing costs for the total heating system (Gudmundson, 2003): district heat and heat distribution within the buildings. However, as all buildings are passive houses, a large share of the supplied heat is lost in culverts and sub-stations, which adds to the running costs.

The main aim of this study is to determine whether it is possible to make the design of the whole heating system more efficient. In future work, costs will also be taken into account to determine the most cost-effective solution.

Figure 1 shows a schematic overview of the heating system at Vallda Heberg, with the boiler central to the right, substation in the middle and a passive single-family house to the left.

doi:10.18086/eurosun.2016.05.12 Available at http://proceedings.ises.org

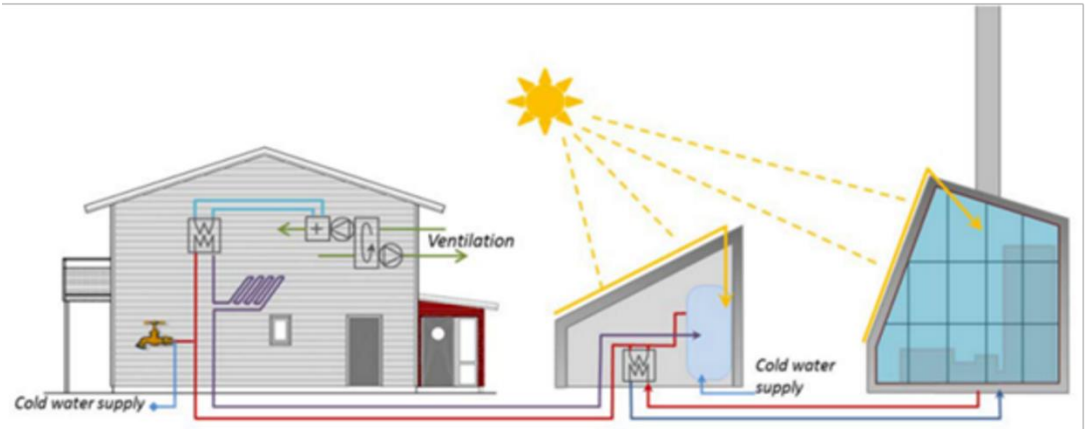

Figure 1: Simple schematic of the technical system in Vallda Heberg. (Based on figures from Markgren Arkitektur AB and Mats Abrahamssons Arkitektkontor AB).

2. Method

The main parts of the Vallda Heberg system, including buildings, have been modelled in TRNSYS and calibrated with measured data from the system. These include the single and multi-family houses, substation, primary and secondary distributions systems as well as the solar fields and central boiler plant. In order to simplify the overall system model, common "blocks" such as buildings and substations have been multiplied to give a heat load similar to that of the real Vallda Heberg system. Distribution pipes have also been lumped together to give the same heat losses as the real system. This system is then the benchmark for other system configurations where choice of culvert system and load density are varied.

3. System description

Figure 2 shows an overview of the Vallda Heberg residential area, including heat supply units and color-coded distribution pipelines. Flat-plate collectors (FPC) supply heat to storage tank through the solar heat culvert (SHC). This heat is used to pre-heat domestic hot-water (DHW) and its circulation (DHWC) flow.

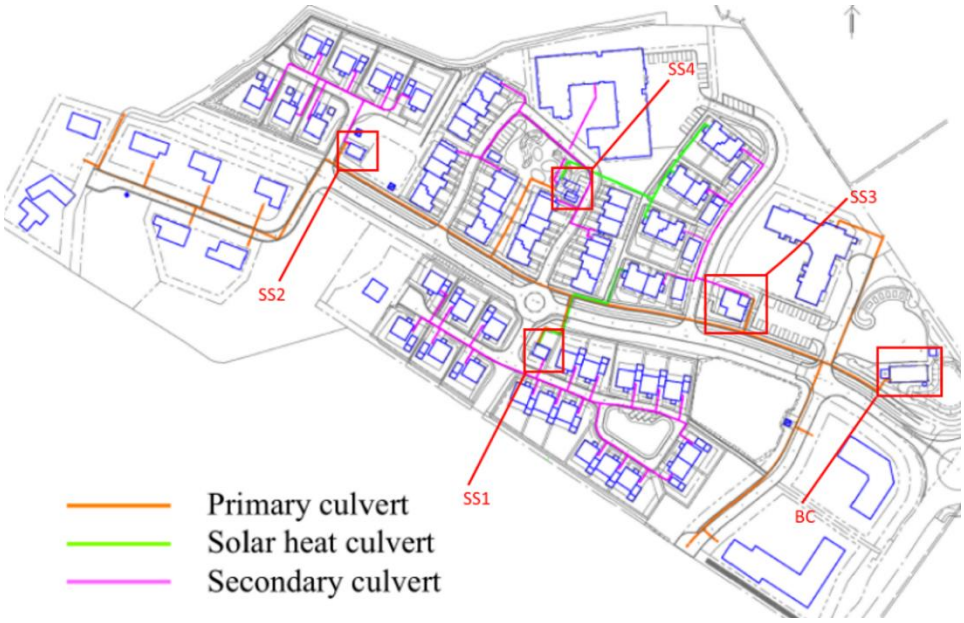

Figure 2: Residential area of Vallda Heberg with denoted substations (SS) and central heating plant (denoted BC) in red, together with color coded distribution pipelines.

Heat generated in the main heating plant (HP) by the wood pellet boiler (WPB) and evacuated-tube solar collectors (ETC) is distributed through the primary culvert (PC) to the substations. Here it acts as auxiliary heating for the DHW and/or DHWC to reach the target supply temperature to the building stock. The DHW and/or DHWC is then delivered to the residents through the secondary culvert (SC). More details on the heating system is given in the following sections.

3.1 Heat demand and distribution system

The system at Vallda Heberg supplies 128 living units, of which 16 are apartments in multi-family houses (MFH) and 64 are apartments in a senior (SEN) living facility. The remaining 48 living units are single-family houses (SFH) and row houses (RH). The heat demand of the different living units differ according to the building characteristics (Table 1), but all buildings are designed according to the Swedish passive house standard.

Table 1 shows the characteristic specific energy consumption of the buildings at Vallda Heberg, based on calculations and prognosis values as stated in a performance assessment made in 2014 (Fahlén et al., 2014).

Table 1: The characteristic specific energy consumption of the buildings at Vallda Heberg for the year April 2013 – 2014 March. The percentage value given refers to the share of total energy use in the building (including electricity).

Load	SH		DHW		Total	DHW/SH
Unit	[kWh m^{-2}]	[%]	[kWh m^{-2}]	[%]	[kWh m^{-2}]	[-]
SFH	30	58	17	32	47	0.55
RH	65	79	12	15	77	0.18
MFH	50	63	22	28	72	0.44
SEN	37	64	9	16	46	0.24

The table values have been read out of graphs for the most part and thus are somewhat uncertain. Specific demand for SH based on measurements varies significantly, as does that for DHW and the ratio of DHW to SH energy. An overview of the system characteristic demand based on measured heat consumption for 2015 and the ratio of specific energy demand presented above (Table 1), is presented below (Table 2), together with the respective collector area (CA) and storage volume (SV) for each substation:

Table 2: Characteristic demand, collector area and storage volume of the Vallda Heberg system for the year 2015

Quantity	SS1	SS2	SS3	SS4		System tot.
Load served	19 SFH	7 SFH	4 MFH (16 APT)	64 SEN APT	6 RH (22 APT)	128
Demand [kWh]	107647	44864	84599	204416	117623	559149
DHW [kWh]	38197	15919	25850	39994	18331	138292
SH [kWh]	69450	28945	58749	164422	99292	420857
CA [m^2]	142	48	64	316		570
Specific CA [m^2/MWh]	1.32	1.07	0.76	0.98		1.02
SV [m^3]	15	5	6	28		54
Specific SV [m^3/MWh]	0.139	0.111	0.071	0.087		0.10

The heat demand is supplied from the main HP to the substations through the primary culvert (PC) in regular district heating twin-pipes, but with an additional DC200 casing insulation made from expanded polystyrene (EPS) of density 30 kg/m^3 and thickness 100 mm. Pipe dimensions vary according to the load served in the different parts of the system, but the majority (~90%) of primary network pipe length is of dimension DN65, DN80 and DN100. The secondary distribution of heat from the substations to the living units is done in an EPSPEX-culvert, which consists of PEX-piping placed in an EPS-casing. These PEX-pipes are of dimensions DN32 – DN65, although the vast majority (~90%) are of dimension DN50 and DN65.

For the year April 2013 – March 2014, the losses attributed to secondary distribution were 25% and 30%, for SS1 and SS2, respectively. For the whole system, total losses were 28% for one single month (March 2014), of which about one third (10%-points) were attributed to the secondary distribution, including substations. The rest was attributed to the primary distribution and losses in HP (Nielsen et al., 2014). Two other studies estimate the heat losses during March 2014 to be around 10% each for the BC and PC (Fahlén et al., 2014; Olsson and Rosander, 2014). However, these values are highly uncertain, as the temperature difference at the heat meters used to calculate the quantities in the energy balance were small (occasionally very small, <3 °C).

3.2 Heating plant

The heat supply consists of a boiler central for which the details are listed below (Table 3). Further down, a schematic of the HP is shown in Figure 3, depicting the PC heat exchanger (HX), storage tanks, solar heat exchanger (HX), wood-pellet boiler (WPB) and oil boiler (OB). The installed solar system utilizes an ETC from Ritter XL Solar, with constant volume flow in both solar loop and charge loop. The anti-freeze system from Paradigma utilizes pure water and heat from the accumulator tanks to heat collectors and outside piping when water in loop gets near to freezing point, although the exact temperature control is unknown. The measured annual solar yield for the year April 2013 – March 2014, as well as for year 2015, was about 57 MWh/a, corresponding to about 8% and 10% of total heat demand, respectively.

Table 3: Details of the heating plant at Vallda Heberg

Boiler Central	
Installed storage volume	15 m^3
Installed collector area	108 m^2 (ETC)
Collector Slope (β)/Azimuth (γ)	70°/30°
PC design operating temperatures (S/R)	75°C/50°C
PC pipe diameter $Ø_{PC}$	100 mm
Load capacity biomass boiler	300 kW
Load capacity oil boiler (back-up)	500 kW

The installed storage volume consists of three buffer tanks of 5 m^3 each. These are connected top-to-bottom, to act as one large tank (Figure 3). The solar loop pump starts/stops when the temperature in the collector is >30°C/<25°C. When the temperature difference between the solar loop (S13) and the temperature in the bottom of the "cold" tank (S8) is >5K/<2K, the charge pump starts/stops.

Solar heat is delivered to the storage tanks according to temperature level, either through valve 1 to the "hot" tank (>75°C) or through valve 2 to the "warm" tank (<75°C).

There are two operating modes - one for winter and one for summer (boiler control sensors in parenthesis):

- Summer mode - valve 3 is open and 4 closed. The "warm" and "cold" tanks are mostly by-passed. The solar system is the preferred heat supply, with the boiler augmenting according to demand (S3, S4).
- Winter mode - valve 4 is open and 3 closed. All tanks are used, as the heat demand is larger and solar resource is less than in summer. The solar system acts as a pre-heater for the boiler (S4, S6).

The summer mode is chosen according to the availability of solar energy and the size of heat demand, and hence may commence/terminate in different months from year to year.

Figure 3 shows a schematic of the heating plant at Vallda Heberg, including all relevant temperature sensors (denoted S1 – S17) and control valves (denoted 1 – 4).

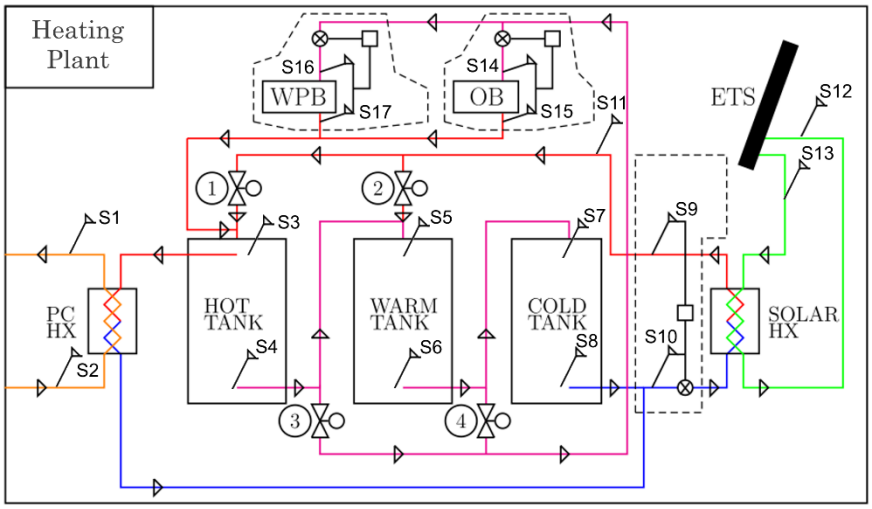

Figure 3: Schematic of the boiler central at Vallda Heberg (Olsson and Rosander, 2014)

A modulating WPB of 300 kW from Osby Parca (turndown ratio 13) supplies heat to the "hot" tank (Figure 3) when the temperature in the tank(s) falls below the target value. The flow rate of the boiler supply pump is adjusted to give an outlet temperature of maximum 95°C. There is an additional 500 kW boiler (OB) which works as reserve. Hot water supply from the tank to the PC HX is controlled to ensure a constant supply set-temperature of 70°C, increasing the flow rate if the outlet temperature to the PC (S1) is <70°C and vice versa. Note that this temperature differs from the design supply temperature (Table 3), and that the stated value is assumed based on the measured inlet temperature of SS3 and SS1). The control system is configured to start the boiler according to the temperature in the "top" and "bottom" of the tank(s), which refers to the placement of the temperature sensors in the storage. The placement of the sensors varies with operating mode, which will be explained further in the next section describing the monitoring system.

3.3 Sub-stations

The majority of sub-stations (SS1 – SS3) at Vallda Heberg have the same design, the differences being the connected load, collector area and storage volume (see Table 2). SS4 has a different design, as it supplies the senior living quarters, where SH is supplied by a radiator system, and thus is separated from DHWC.

A schematic of one of the sub-stations (SS1) used to supply a collection of 19 SFH is shown in Figure 4:

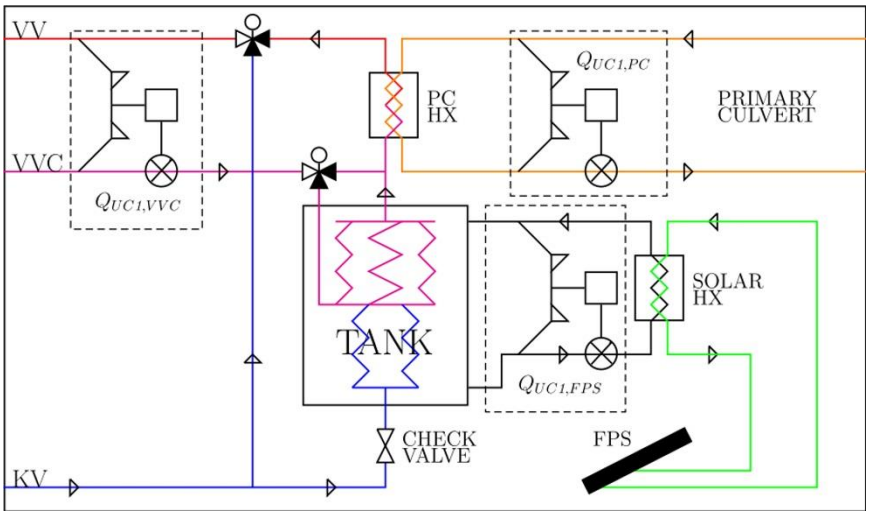

Figure 4: Schematic of SS1 at Vallda Heberg (Olsson and Rosander, 2014)

The sub-stations work as distribution units for the heat delivered by the PC and the FPC's, but also act as hydraulic separation between the higher pressure/-temperature primary distribution and the lower pressure/-temperature secondary distribution. This is important, as the pressure of the secondary distribution GRUDIS loop, must be low enough to allow for tapping of DHW.

Warm water is circulated between the buildings (the load) and the SS in the DHWC loop (denoted VVC). If storage is sufficiently warm (dT +5/+2 K), the flow is routed through the upper half of the storage through an internal HX, but only when the exiting temperature remains below a limit of 62°C. When DHW is tapped in the houses, make-up cold water (CW) enters the bottom half of the storage in an internal HX, where it is pre-heated. In the event of DHWC heating through storage, the pre-heated DHW is mixed with the DHWC flow, before entering the second internal HX. Auxiliary heat is supplied by PC HX when necessary to achieve a target supply temperature of 57°C.

3.4 Monitoring system

The monitoring system at Vallda Heberg uses flow meters from manufacturers Landis+Gyr and Kamstrup (Christensson, n.d.), with the majority coming from the former. In the HP, meters are installed at the boilers (S14 – S17) and in the charge loop (S9, S10) by the solar HX (see Figure 3). No measurements are made of the energy leaving the HP – the additional sensors (S1, S2) installed are used for system control purposes only. In SS1, they are installed in the PC loop, in the charge loop and in the circulation loop (Figure 4). SS4 monitors delivered heat to the radiator circuit in the SEN and heat from PC, whereas the remaining sub-stations (SS2, SS3) only monitor heat from PC. According to previous studies of the system, the flow meters installed in the system have large errors associated with the measured energy when the temperature differential (dT) is small between in- and outgoing flow (Fahlén et al., 2014; Olsson and Rosander, 2014).

The accuracy of heat meters is governed by European Standard EN1434, which states the methods for calculation of accuracy and their boundaries. According to EN1434, the calculated uncertainty of the heat meter is the arithmetic sum of part uncertainties - one part for the calculator, one part for the temperature sensors and one part for the flow meter. For the heat meter installed in conjunction with the WPB, about 25% of the logged temperature measurements for 2015 are below that of the operation threshold of the meter (3K < dT < 120K) (Landis+Gyr, 2015). The measurement uncertainty of the temperature component alone for these measurements is >3.5%. The average total error calculated for all measurements in the WPB is 7.5% for 2015, based on the logged temperature and flow values. This does not take into account any measurement errors in the charge loop.

For the substations, dT over the flow meter is relatively large for the majority of the values, compared to that of the lower threshold value, which means that the uncertainty is not as high as for the boiler. Nonetheless, calculations show that for SS1, about 15% of all measurements in 2015 had an uncertainty above 10%, which is still significant.

4. Model description

4.1 Overall system

Two models have been made in TRNSYS: one modelling SS1 supplying 19 SFH and one modelling the HP supplying SS1 – SS4. In order to simplify the system model when modelling the whole system, the total load was modelled as consisting of SFH only and that this load was supplied by sub-stations identical to SS1. This was done by connecting the model of SS1 (putting it in a macro) with the model of the HP in TRNSYS. By using a set of equations, the load on the SS1 model was scaled (multiplied) up by a factor giving the total system heat demand. This demand was then used to calculate the necessary mass flow in PC, depending on the inlet supply temperature and assuming a return temperature equal to that of the inlet flow in the PC HX of the SS (100% efficiency of HX).

In order to assess the differences between the demands in the different sub-stations, the demand of each sub-station was normalized to that of SS1, as shown below (Table 4):

Table 4: Overview of the heating demand of the different sub-stations at Vallda Heberg normalized to the demand of SS1. The given factor values represent the ratio between SH and DHW demand.

	SS1	SS2	SS3	SS4	Total
Load served [SFH]	19	7.9	14.9	56.8	98.7
Load factor	1.0	0.4	0.8	3.0	5.2
DHW factor	0.355	0.355	0.306	0.181	0.247
SH factor	0.645	0.645	0.694	0.819	0.753
DHW [l/day]	2630	1096	2067	7868	13676

The total heat demand of the whole heating system equals about 98.7 SFH or about 5.2 times that of SS1. In modelling the system, the number of houses modelled (24.6) were chosen so that the scale factor was exactly 4.0 with a specific collector area for the sub-station equal to the average specific collector area of 1.02 for the whole system (see Table 2).

4.2 Buildings

The SFH are modelled using a two-zone building model (type 56). One zone is heated, if necessary, by a water-air HX (with glycol anti-freeze) in the air supply duct of the mechanical ventilation system with heat recovery – the other by floor heating. Floor heating has a fixed flow rate, resulting in heating year round due to the supply temperature of around 57°C, whereas the air heating is controlled by a room sensor. The target inside temperature is 19.5°C.

The house is modelled to have low heat losses and infiltration, based on design information. Inputs for outer area of walls in different directions, air volume of different nodes etc. have been modelled based on drawings of the house. Windows and shading (provided by roof overhang and balcony) are accounted for. Internal gains are added to the main area (i.e. not bathroom) based on known electricity consumption (70 % is expected to be gained as heat) and the average number of inhabitants.

The floor heating in one zone of the building is modelled with a pipe heat load (type 682, TESS) with a 100W

constant demand based on static calculation at design conditions, which are the conditions that are dominant throughout the year. The return temperature from this model is calculated and given as input to the SC.

Active SH is supplied by pre-heating of supply air by means of heat recovery (type 667, TESS) from exhaust air, in addition to auxiliary heating by an air-fluid HX (type 670, TESS) utilizing glycol as the heat transfer fluid. The glycol circuit is supplied with heat from the SC by a fluid-fluid HX (type 5b).

4.3 DHW

The DHW consumption profile is calculated with DHWcalc (Jordan and Vajen, 2003), using a 3 minute random distribution based on the annual monitored volume for the year April 2013 – March 2014 for SS1. The base of the profile is the statistical distribution profile of a SFH, the input being the total amount of water used in one day (11676 l/day) for the whole system and the day of maximum (monitored) water load (347). The cold water supplied to the residential area of Vallda Heberg is supplied from a nearby lake. The temperature of the inlet water thus is expected to follow an annual temperature curve corresponding to a sinus function, with an average temperature of 12°C and an amplitude of 4°C (January being the coldest).

The DHW consumption profile is used as input for a data reader (type 9). Two equations are dedicated to dividing the total flow in the SC into one SH component and one DHW component, directing the correct flow to the SH and subtracting the consumed DHW from the total flow before returning to the SC return pipe.

4.4 Sub-station

The substation is modelled using the following non-standard components:

- Storage (type 340, multiport model (Drück, 2006))
- Solar collectors (type 832 QDT multi-node model (Haller et al., 2012))

The parameters for the custom made storage have been supplied by technical drawings of the sub-substation and through communication with the engineering company in charge of its design (Andersson & Hultmark – A&H). The storage has been modelled with two internal HX, one in the top of the tank and one in the bottom, which is a simplification over the real system that has six in the top of the tank and three in the bottom. This has been taken into account by sizing the top heat HX volume to be double that of the bottom HX. The solar collector parameters were taken from the supplier of the custom made collectors in this system.

The DHWC pump, storage charge pump and solar loop pump are modelled using standard components (type 3b). Pump manufacturer brand and model name has been supplied by the engineering company in charge of design (A&H), allowing to derive pump operation curve parameters from the pump datasheet. Nominal volume flow rates originated from technical drawings of the substations, but were chosen to achieve harmony between measured and simulated values during calibration. Internal piping is modelled with standard components (type 31) and heat losses from these represent the whole substation, avoiding the need of a separate building model. The UA values have thus also been chosen to allow for harmony between simulated and measured values for the SS loss in the calibration phase. All pipes with negligible flows (i.e. < 0.02 l/s) and by-pass valves have been ignored as these are irrelevant for normal operation. The PC HX and the solar HX were modelled using standard components (type 5b), with parameters supplied from technical drawings. The UA value of these was assumed to be the nominal power of the HX divided by the design temperature difference over the HX (from "hot" side inlet to "cold" side outlet).

4.5 Heating Plant

The heating plant is modelled using the following non-standard components:

- Storage (type 340, multiport model, non-standard (Drück, 2006))
- Solar collectors (type 538, evacuated tube solar collector with modulating flow, TESS)
- Boiler (type 659, auxiliary heating, TESS)
- Boiler feeding pump (type 741, variable speed pump, TESS)
- PC HX- and PC supply pump (type 742, user specified flowrate, TESS)
- PC HX (type 805, domestic hot water HX, hot side flow is output, non-standard (Haller, 2006))

Storage is modelled as one large tank instead of three small, without internal HX. Charging is done through assigned double ports according to the principle explained earlier (see section *3.2 Heating plant*). The surface-

to-volume ratio of the original storage has been maintained in scale-up of storage. The double-port feature is also used to distinguish between ports used for boiler return according to operating mode, leaving a set of ports unused for parts of the year. The switching between summer and winter mode is done with a forcing function (type 14h) in combination with a flow diverter, flow being directed to ports according to the season.

Solar collectors parameters are taken from the summary of EN12975 test results by TÜV Rheinland, annex to the Solar KEYMARK Certificate. The listed incidence angle modifiers (IAM) are compiled in a file and used as input to the model.

Boiler parameters are derived from the datasheet from the boiler manufacturer, values utilized mainly being the rated power, set-point temperature and max temperature of the boiler. The minimum flow rate is ignored, as it is considered irrelevant for modelling purposes. The boiler control is ON/OFF, as opposed to in reality where it is modulating. The modulating behaviour is imitated by implementing differential boiler control with short on/off cycles, resulting from small temperature dead-bands, much in the same way as pulse-width-modulation (PWM). Boiler control target temperature is 82°C, one differential controller checking the tank bottom and one checking the tank bottom – if both are below dead-band (1.5°C and 2°C) the boiler is ON.

The boiler feeding pump is modelled as variable speed, making modulating operation possible at a later time by implementation of a PID-controller. At present it is modelled as running when boiler is on, with the flow rate being the nominal flow rate. The PC HX pump flow rate is given as an input from the PC HX, which calculates the necessary "hot side" inlet flowrate to achieve the target "cold side" outlet temperature of 70°C. For the PC supply pump, the flow rate is given as the return flow rate from the PC, equal to the "cold side" outlet of PC HX. All pumps are modelled with a maximum flow rate taken as the nominal flow rate found in technical drawings.

Heat losses in the HP are modelled by single pipe ducts using standard components (type 31), for which the DN has been derived from the technical drawings and the dimensions have been derived from EN1057 (European Comitee of Standardization, 2006). There is one pipe for the supply from boiler to storage and one from storage to PC HX. For the solar loop, there are four pipes: two pipes for collector supply and two pipes for collector return. There is one "inside" pipe and one "outside" pipe for each of the two-pipe segments, intended to model the solar pipe heat loss to ambient. Ambient outside temperature is given by the weather data, whereas the ambient inside temperature is assumed to be a constant 25°C, as this is the target temperature for the ventilation system in the HP according to control system description.

4.6 Distribution

According to previous studies, the PC route length is 1007 m, divided into the different pipe diameters. The route length of SC connected to SS1 is 469 m, and consisted of a mix between pipes of DN32 - 63 (Olsson & Rosander 2014). To estimate the remaining length of the secondary culvert, measurements were conducted using satellite images (i.e. Google Maps). Assuming that half of the SC connected to SS1 was DN63 pipes and assigning one fourth to DN50, with the remaining being DN40 (20%) and DN32 (5%) pipes, modeling the whole load at Vallda Heberg as consisting of SFH only, the length of distribution pipes will be divided as shown below (Table 5):

Table 5: Overview of measured and estimated culvert dimensions at Vallda Heberg

Culvert dimensions							
DN [mm]	32	40	50	65 (*63)	80	100	Total
PC Length [m]	15	20	44	602	187	139	1007
SC Length [m]	56	223	278	557*	0	0	1114

The modelled PC length is divided into four pipe sections (PC1 – PC4), serving the four different sub-stations (SS1 – SS4) in the original system (see Figure 2). As can be seen, the amount of PC culvert length of DN32 – 50 is small compared to the total PC length (~8%), so that it was chosen to model the PC as consisting of DN65 – 100 pipe sections only in order to simplify the model. The section serving SS2 is also serving an area of larger SFH not currently connected to the network, and thus the length of this element was dimensioned to account for heat losses in the section. It is further assumed that the pipe diameter decreases with distance from the HP, so that SS4 and SS2 are served by DN65 pipes (600 m in total), whereas SS1 and SS3 are served by DN80 (200 m) and DN100 (150 m) piping, respectively. For the simulations, however, the four pipe elements are modelled as one pipe connected to the load (SS) at the far end.

The consequence of this simplification is that the temperature of the flow delivered to the SS is a little lower than it would be in reality. This is made up for in the model by increasing the flow through the SS, to be able to deliver the required heat. Such a simplification is considered appropriate, as the focus of this study is on accumulated energy and does not consider energy flux specifically.

Distribution pipes are modelled by use of type 951 (buried horizontal pipe, twin-pipe system). For the PC, the pipe parameters were taken from the manufacturer datasheet (Powerpipe AB, 2016), including the insulation (rigid polyurethane - PUR) parameters. For the secondary culvert, the pipe dimensions were derived as explained earlier (Table 5). Following the assumption made for the mix of pipe dimensions for the SC, the average weighted DN would be 54 mm. The insulation parameters were taken from the manufacturer datasheet for the EPS casing (Elgocell AB, 2013). Because the original EPS casing has a square/rectangular cross-section and the pipe model takes cylindrical dimensions only, the casing diameter had to be calculated assuming that the cross-sectional area of the casing was circular.

4.7 Model calibration

The two models used in this study were developed separately and then calibrated towards measured data. The SS1-model was developed using meteorological- and monitored data for the sub-station and connected houses for the year April 2013 – March 2014. Optimally, the system heat losses would be modelled separately, but due to bad quality of measurements, the total losses from SS1 and SC1 were matched to difference between delivered energy to SS (PC HX and FPC) and end-use consumption. SH demand was calibrated by changing house UA value and house set-temperature. The PC delivered heat was calibrated mainly by adjusting losses in storage heat loss. The resulting deviation between measured and simulated values after calibration was in the range 0.4 – 1.2% (absolute values), for the energy consumption of SH, DHW, distribution losses, storage charged energy and PC delivered heat.

The HP model was developed using meteorological- and monitored for the calendar year 2015. Heat delivered from PC to the sub-stations (SS1 – SS4) was used as input to a pipe heat load (type 682, TESS), calculating the return temperature to the PC HX. Calibration was done mainly by adjusting the insulation parameters and UA values of pipes, to get the appropriate heat losses. The resulting energy balance showed negligible deviations, and most of the simulated values (solar heat, heat losses) deviated only slightly (<3%) from the measured. However, there were significant deviations in the simulated boiler energy (~9% lower than measured on annual basis). Attempts to calibrate the model by assuming tenfold thermal conductivity of the EPS and threefold thermal conductivity of the PUR could not reduce the discrepancy to an acceptable level (i.e. below 5%). Studies showed that the losses of the HP and PC appeared to be underestimated for the winter months, though no explanation for this could be found. Reducing the measured boiler energy by 10% gave good correspondence between simulated and measure values, implying that the discrepancy was a consequence of the large uncertainties in measurements by the installed flow meters in the HP (7.5%) and partly in the sub-stations (up to 8%), as the monitored values from these were used as input.

4.8 Model variations – parametric studies

The parametric studies made in this study are related to the type of distribution system and the load/linear heat density (LD). There has been two types of distribution system modelled:

- Original Vallda Heberg: PC distribution, substations, and SC distribution GRUDIS
- Modified Vallda Heberg: All GRUDIS system, DHW-circulation from the HP and to the load

In the modified Vallda Heberg, the sub-station is kept and the PC HX in the HP is removed, connecting the boiler directly to the PC HX in sub-station. This allows for a more direct comparison of the distribution pipe influence on the heat losses. This in turn influences the harvested solar energy and supplied boiler energy. The model has been altered by reducing the PC length from 950 m to 0 m, and increasing the SC by the same length. The length of the pipes supplying solar heat have been assumed to be one third of the original PC length (950 m), meaning that the solar collectors are modelled as placed on the house roofs as close to the HP as possible to minimize pipe heat losses. However, one major simplification is that the pipes are modelled as being above ground, and not buried as would often be the case.

By variation of the distribution pipe length, a parametric study was made for 0.5LD, 1LD and 2LD, to show how the parameter influences the system heat losses, supplied boiler energy and the harvested solar energy.

5. Results

5.1 Distribution concept

Figure 5 depicts the simulated annual energy balance for the system at Vallda Heberg according to choice of distribution concept, showing a significant reduction in heat demand for the two simulated cases. By choosing an all GRUDIS distribution system, the supplied boiler energy was reduced by 99.5MWh (13%) mainly due to a reduction in the total pipe distribution losses by 112MWh (43%). The heating plant (HP) loss also decrease by about 5 MWh (6%) which is mainly due to reduced storage heat loss, particularly during spring and autumn months. The change in stored solar energy from FPC (HP solar) was lower by about 27MWh (17%), assumed to be due to increased solar-pipe length and -losses. Heat from ETC on the HP is about the same in both cases. The sub-station (SS) loss is similar in both cases, with minor differences. It should be noted that the house heat demand is about 1.6% lower in the all GRUDIS case, which affects the results, but not by much.

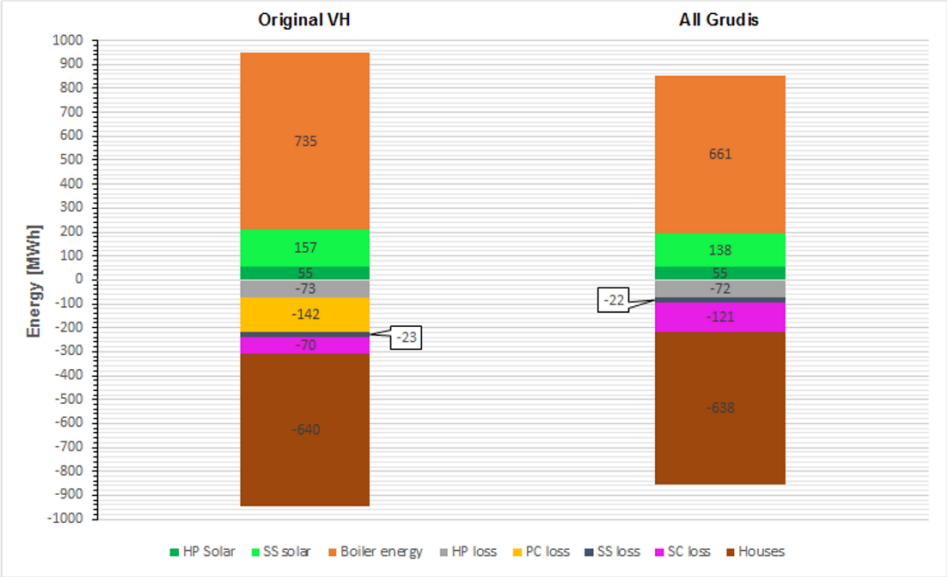

Figure 5: Simulated annual energy balance for the system at Vallda Heberg (VH) for two different choices of distribution concept. Abbreviations used: heating plant (HP), sub-station (SS), primary culvert (PC) and secondary culvert (SC).

5.2 Parametric study

Below (Figure 6) is an overview of the result from the parametric studies for the simulations conducted with the original distribution concept at Vallda Heberg, utilizing a combination of conventional DH twin pipes, sub-stations and GRUDIS.

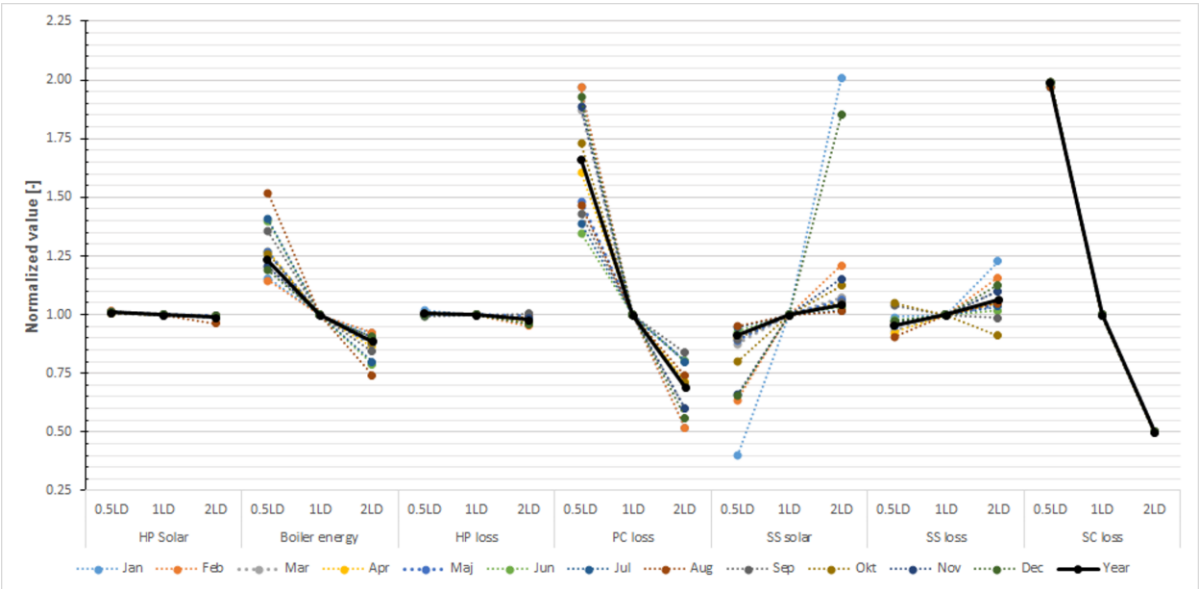

Figure 6: Influence of linear heat density on different parameters in simulation of the original distribution concept at Vallda Heberg. The values have been normalized to the simulated values for 1LD. Abbreviations used: heating plant (HP), sub-station (SS), primary culvert (PC) and secondary culvert (SC).

As can be seen, the boiler energy and distribution losses are the parameters most affected by the change in culvert length, and hence linear heat density. The SS solar energy (from FPC) varies moderately. This is expected as these parameters are directly dependent on the pipe length. The HP solar energy (from ETC) and HP loss is relatively unaffected, whereas SS loss varies moderately - mostly during winter due to higher loads and operating temperatures. For the All GRUDIS case, the influence of linear density is almost the same as that for the original system.

5.3 Discussion

In simulating the all GRUDIS system, some major simplifications were made in the model. For one, the substation was kept in the model, assuming that the available storage is divided between the HP and SS, instead of having larger stores in the HP. Doing this, the loss coefficients and stores are assumed the same for both simulated cases, instead of modelling the all GRUDIS system with a new design for a complete HP including all stores and DHWC connections. It is likely that the total losses would be lower if the HP was modelled as one unit. Secondly, the solar pipes from the FPC to the SS are not buried insulated twin pipes, but assumed to be above-ground, which overestimates the losses. Taking these two simplifications into account, the differences observed in choice of distribution concept would most likely be even greater.

Another simplification is modelling only one SS and assuming that the load is only made up of SFH. This means that the heat distribution in all buildings is the same and split between uncontrolled, year round floor heating and the heat to air supply is the same for the whole area. In the real system, there are different loads installed, many of which have a different characteristic heat demand (Table 1, Table 2 and Table 4). In contrast to the other dwellings in the system, the elderly home (SEN) has an installed radiator system with design operating temperatures of 60/40 which leads to a little lower return temperature from SS4 than for the other SS and this has not been taken into account. Furthermore, the lower ratio of DHW to SH in the RH and MFH means that the circulation flow to these buildings will be higher than in the case for SFH, which would influence the heat losses in SS3 and SS4 with associated distribution lines.

The observed pipe distribution losses in the simulations of an all GRUDIS distribution system are significantly lower than those in the original configuration. This may partly be attributed to the lower operating temperatures of the GRUDIS network and partly to the model of the SC. The modelled average ground temperature is 9°, which means that by assuming an average supply temperature of 56°C in SC and 70°C in PC, the difference in dT (47K/61K for SC/PC, respectively) is about 30%. In the twin-pipe model, the thermal conductivity of the *fill insulation* (PUR in PC and EPS in SC) surrounding the pipes is the most influential parameter for the heat losses, whereas the *gap material* (EPS for PC and clay for SC) is less influential. The PC model was calibrated to a fill insulation value 3-4% higher than that of the SC. Because the temperatures are higher in the PC, this might have a large influence on the heat losses.

The cost of distribution pipes is significantly different for PEX and conventional PUR coated steel pipes. As can be seen below (Table 6), the specific cost of SC is close to half that of the PC, whereas the trench cost is the same for both.

Table 6: Overview of the approximate costs for distribution pipes and trench work for the system at Vallda Heberg. All pipe costs are total costs including connections, welding and EPS insulation. (Andersson-Jessen, 2016; Magnus Klingheim, 2016)

		Length [m]	Price culvert [SEK/m]	Price trench [SEK/m]	Total price [10^6 SEK]
Original VH	PC	1007	1150	1600	2.8
	SC	1114	650	1600	2.5
	SUM				5.3
All GRUDIS	EPSPEX	2121	650	1600	4.8
	Solar culvert	336	1150	0	0.386
	SUM				5.2

In the all GRUDIS case, the solar culvert (SCU) length is assumed to be a third of that for PC and to be of same cost as the PC (i.e. same pipe type). It is furthermore assumed that the trench cost only applies once, with no additional trench costs for SCU going to the HP (i.e. EPSPEX and SCU in same trench). Thus, the total price of an all GRUDIS system would be about the same (-2%) as the original system cost, but with lower heat losses.

The cost of having an all-in-one HP is not calculated, but would be substantially lower than having a smaller HP and 4SS as is the present case.

The parametric study reveals it is mostly beneficial with a high linear heat density (LD), which is expected as it cuts distribution loss and consequently boiler energy. Changing the distribution pipe length has the effect of changing the LD, which is sufficient for simulation purposes, but has some practical issues in reality. Assuming that the total distribution pipe length (PC + SC) and total land area is kept the same, the implication of assuming that all living units (LU) are SFH means that more houses would need to fit in the same space. The LD would thus still be the same, but the built area would increase (i.e. higher building density). Now, if the LD is to increase, in order to get space enough for the same population living in SFH, a larger area would be needed. If the area is to be kept the same as in the original VH, increasing LD is equivalent of replacing SFH with MFH (although with the same demand characteristics as SFH). Conversely, decreasing the LD would imply having the houses further apart which, again, would require a larger area. If the space is to remain the same, then in effect, decreasing the LD implies having MFH (with the same demand characteristics as SFH) spaced further apart. Alternatively, the increase/decrease in LD can be seen as building SFH denser/sparser without limits on the area size.

5.4 Conclusions

The whole block-heating system of Vallda Heberg has been modelled in TRNSYS with some simplifications, utilizing one building model to simulate all buildings and one sub-station to simulate all sub-stations. Two distribution systems were modelled: the original system with primary culvert, substations and secondary culvert – and one all GRUDIS system using DHW-circulation piping for distribution. Results indicated a significant reduction in heat losses can be obtained by employing an all GRUDIS distribution system, while at the same time potentially reducing cost. Changes in heat density show that the distribution losses and supplied boiler energy decrease with increased heat density, and vice versa. This is as expected, as these parameters are directly related to the distribution network length. Future work should concentrate on investigating the influence of different load heat demand characteristics, as well as placement of solar collectors and type of solar collector technology.

A numerical model to evaluate the flow distribution in large solar collector fields in different operating conditions

Federico Bava, Janne Dragsted and Simon Furbo

DTU Civil Engineering, Technical University of Denmark, Kgs. Lyngby (Denmark)

Abstract

A numerical model to evaluate the flow distribution in a large solar collector field was developed in Matlab and is presented in this study. Model and measurements from a solar collector field were compared and a good agreement was found. The model was then used to study the flow distribution in different array layouts. Balancing valves proved to be an effective way to achieve uniform flow distribution also in conditions different from those for which the valves were regulated, as well as in case of irregular layouts with different compositions of the collector rows. A Tichelmann connection gave a uniform flow distribution, especially if the distribution pipe diameter is reduced so to give a constant pressure drop gradient. The reduction in power output from the collector field was approximately proportional to the square of the root-mean-square deviation of the flow distribution, but was generally small, at least under the considered assumptions.

Keywords: *solar collector, solar collector field, flow balancing, flow distribution, parallel connection.*

1. Introduction

1.1. Background

An increasing number of large scale solar collector fields have been built in Europe in the last years. Of the total collector area installed at the end of 2014, 77% was located in Denmark (Mauthner et al., 2016). The development in this country has been driven by specific factors, such as high taxation on fossil fuels and widespread use of district heating (DH), to which large collector areas can be connected (Furbo et al., 2015). More than 800,000 m^2 of collector fields were installed in Denmark at the end of 2015 and this number is expected to grow in the next future (Mauthner et al., 2016). Also the size of the collector fields has been increasing. The current largest field in Vojens has a collector area of 70,000 m^2 (Mauthner et al., 2016), but by the end of 2016 a 150,000 m^2 collector field should be completed in Silkeborg (EnergySupply, 2016).

The larger the collector fields and the higher the number of collector rows, the larger the risk of non-uniform flow distribution. Non-uniform flow distribution cause non-uniform temperature distribution across the collector field, so decreasing the thermal performance. The negative effect of flow maldistribution on the thermal performance was investigated by Chiou (1982), who treated this effect in a single collector with parallel channels. He presents a method to determine how much the collector efficiency is penalized by the flow maldistribution. Defined a *flow nonuniformity parameter* as the root mean square deviation of the channels flow rates, he concludes that the deterioration of the collector efficiency is proportional to the 1.8^{th}-1.9^{th} power of such parameter. Wang and Wu (1990) presented a model to calculate the flow distribution in collector arrays with vertical pipes, both in U- and Z-configuration. The U-configuration presents a higher maldistribution than the Z-configuration. Fan et al. (2007) investigated through CFD calculations the flow and temperature distribution in a large collector for solar assisted DH plants. Model results and measurements are compared. The authors conclude that the flow distribution is driven by friction (and so buoyancy can be neglected), if the velocity in the collector pipes is high compared to the temperature rise across the collector. Bava and Furbo (2015) propose a numerical model to calculate the pressure drop and flow distribution in a U-type harp collector. Based on the conclusions of Fan et al. (2007), the authors argue

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/eurosun.2016.05.05 Available at http://proceedings.ises.org

that in large collector fields for DH applications the relation between the fluid velocity in the absorber pipes and the temperature rise in the collector is such that buoyancy can be neglected. The model was compared against measurements carried out on a collector for solar assisted DH plants and good agreement was found.

Ideally, the layout of a collector array should be with short pipe lengths and uniform flow distribution. Though, it is not possible to optimize both these aspects simultaneously, so a compromise must be found. Rohde and Knoll (1976) analyzed different options to minimize the flow maldistribution in a collector field of 12 rows connected in parallel. The options included various size manifolds, manifold area changes, different locations of the inlets and exits to the manifolds, orifices and balancing valves. The last two are presented as the best solutions, both in terms of performance and cost. It is observed that a specific configuration of valve settings maintains the desired flow distribution only at a specific total flow rate. The topic of flow distribution in collector fields is also treated by Knabl et al. (2014). Maintaining a constant and large diameter in the distribution pipes or adopting a Tichelmann configuration (Fig. 6.b) improves the flow distribution. However, both options have higher costs due to the longer/larger pipes. Balancing valves are another possibility, but these increase the cost, installation time and maintenance (in case of defective valves). A cheaper solution is to install differently sized pipes in the collector rows, but the hydraulic design must be calculated in advance and very precisely, as a later adjustment would be very expensive.

In Danish solar collector fields, the pipe diameter of the distribution pipes is progressively reduced, as fluid is diverted to the collector rows. Balancing valves are then installed in each row to obtain a uniform flow distribution. These are regulated to achieve the desired flow distribution in full-load conditions (high flow rate, high solar radiation, nominal inlet/outlet temperatures), so that the outlet temperature from all rows is the same. This is done by supplying the different rows with flow rates proportional to the collector row area.

1.2. Sizing distribution pipes and balancing valves in solar collector fields: HySelect software

The design of the hydraulic network of a solar collector array can be a time-consuming and cumbersome procedure to be carried out manually. Hence, software able to carry out the same task can be extremely useful, making the job of planners and designers much easier. A program which can be used for this purpose is the commercial software *HySelect* from IMI Hydronic Engineering (IMI Hydronic, 2014). The software can be used to design and balance generic hydraulic networks, and so solar collector fields as well, in terms of pipe size, pump head, types and settings of balancing valves. The software returns the valve type and valve settings which should be applied to achieve a user-defined flow distribution. Additionally, it makes easy to optimize the pipe diameters (based on several pipe dimension standards) to fulfill fluid velocity or pressure gradient constraints. The software also contains built-in libraries of the thermophysical properties of a variety of fluids, including those most commonly used in solar heating systems, such as water and ethylene/propylene glycol-water mixtures. When designing a branched system, the program automatically adds and considers the pressure drop caused by the resulting tee junctions and bends. HySelect is intuitive to use and extremely fast in returning the results.

Despite these strengths, the software has some limitations. First of all, its reduced flexibility. As mentioned above, the program returns the valve setting configuration which guarantees a certain flow distribution. It does not calculate the flow distribution itself. Consequently, once a system has been balanced for specific boundary conditions (e.g. total flow rate and fluid temperature), it is not possible to analyze how the flow distribution varies, if the boundary conditions are changed. Secondly, the fluid temperature is assumed constant throughout the system. This approximation does not seem very accurate when designing solar collector fields for DH application, where the temperature rise across the collector field can be 40-50 K. Furthermore, the thermophysical properties (especially viscosity) of glycol-water mixtures are known to be strongly dependent on the temperature (see Section 2.1.2). Thirdly, complex layouts, having for example a common return pipe such as in Fig. 3, cannot be designed. Finally, the correlations used for evaluating the pressure drop in tee junctions are not in agreement with the literature (Idelchik, 1994). No reference to a literature source is provided and the used correlations are not stated in the software manual (IMI Hydronic, 2014). The difference between HySelect and Idelchik's correlations for pressure drops in tee junctions is shown in Fig. 1. The diagram was obtained assuming a distribution pipe from which 10 parallel circuits parted. The distribution pipe and the circuit pipes had diameter of 81 mm and 36 mm respectively. The system was supplied with a total flow rate of 20 $m^3 h^{-1}$, uniformly distributed in the 10 parallel circuits.

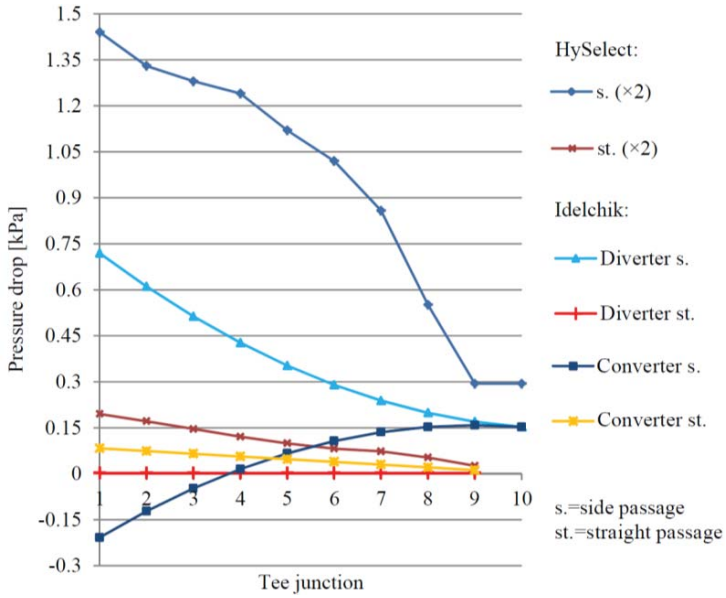

Fig. 1: Comparison between HySelect and Idelchik's correlations for pressure drop in tee junctions.

The fluid was water at 75 °C. Looking at Fig. 1, it is first of all noted that HySelect does not show the different contributions of the diverging and converging tee junctions, but only the overall pressure drop. Secondly, comparing the pressure drops in the diagram, it can be seen that for the straight passage the combined pressure drops from HySelect are approximately twice as large as the pressure drops that Idelchik's correlations give for the straight passage of the converging tee. On the other hand, the pressure drop in straight passage of the diverging tee junction predicted by Idelchik is negligible compared to that in the converging tee junction. Consequently, it could be neglected in the calculations without introducing a significant error. Regarding the side passages, the combined pressure drop from HySelect is between two and four times higher than Idelchik's pressure drop for the side passage of the diverging tee junction.

2. Material and method

2.1. Numerical model

2.1.1. Pressure drop correlations

To calculate how a fluid flow distributes in a branched system, it is necessary to know the relation between flow rate and pressure drop across each component. In fact, the fluid flow distributes in such a way that the pressure difference between two points is the same, regardless of the hydraulic path which connects one to the other. Because the relation between pressure drop and fluid velocity depends on factors such as Reynolds number, flow regime, etc., the flow distribution in a branched system may vary in different conditions.

In a collector field three main categories of hydraulic components can be identified: solar collectors, pipes and fittings (bends, tee junctions, valves, etc.).

The pressure drop characteristic of a solar collector is not always given in the technical datasheets and - even when provided - it usually refers to a specific fluid type and temperature. Different fluids and/or temperatures can affect the pressure drop. In this study the model proposed by Bava and Furbo (2016) was used to evaluate the pressure drop across each solar collectors, more specifically a HTHEATStore 35/08 from Arcon-Sunmark A/S (SP, 2016a). The HTHEATStore 35/08 is a flat plate harp collector with 18 U-connected absorber pipes. The pipes are 5.80 m long and have an inner diameter of 7.3 mm. The two manifolds are 2.24 m long and have an inner diameter of 32.9 mm. The collector gross area is 13.57 m^2 and its efficiency coefficients are η_0=0.757, a_1=2.2 W m^{-2} K^{-1} and a_2=0.007 W m^{-2} K^{-2} with respect to the collector gross area. Fig. 2 shows the modeled pressure drop for a 35% propylene glycol/water mixture, whose physical properties were evaluated through (Eq. 5) and (Eq. 7).

The friction loss along the distribution pipes was calculated by the Darcy-Weisbach equation (Eq. 1):

$$\Delta p = \lambda \frac{l}{D_h} \frac{\rho w^2}{2} \qquad \text{(Eq. 1)}$$

In (Eq. 1) Δp [Pa] denotes the pressure drop; λ [-] the Darcy friction factor; l [m] the pipe length; D_h [m] the pipe hydraulic diameter, which equals the inner diameter for a full flow circular pipe; ρ [kg m^{-3}] the fluid density and w [m s^{-1}] is the mean fluid velocity.

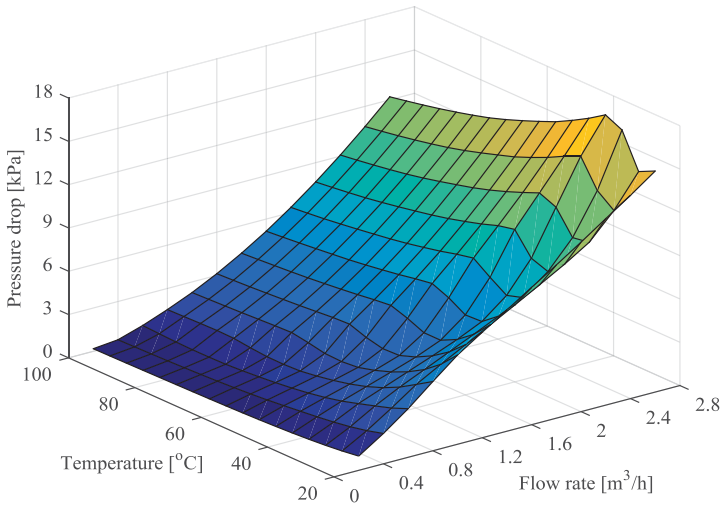

Fig. 2: Pressure drop in a HTHEATstore 35/08 collector as function of temperature and flow rate for 35% propylene glycol/water mixture.

Laminar regime was assumed for Reynolds numbers Re<2300, while turbulent regime was assumed for Re>4000 (Holman, 2002). According to the flow regime, the friction factor was calculated through the Hagen-Poiseuille law (Eq. 2) and the Haaland (1983) correlation (Eq. 3) respectively. The roughness of steel pipes was assumed to be ε=10^{-4} m. In the transition region (2300<Re<4000) the friction factor was evaluated by linearly interpolating the value obtained from (Eq. 2) at Re=2300 and that from (Eq. 3) at Re=4000.

$$\lambda = 64/Re \qquad \text{(Eq. 2)}$$

$$\lambda^{-1/2} = -1.8 \log_{10}\{[\varepsilon/(3.7\, D_h)^{1.11} + 6.9/Re]\} \qquad \text{(Eq. 3)}$$

Correlations from Idelchik (1994) were used to estimate the local losses in fittings, such as bends, tee junctions, changes of flow section area, etc. Regarding the balancing valves, the manufacturers usually provide the pressure drop characteristic as flow factor K_v (Eq. 4):

$$K_v = V \cdot [SG/(\Delta p \cdot 10^{-5})]^{1/2} \qquad \text{(Eq. 4)}$$

In (Eq. 4), V [m^3 h^{-1}] represents the volume flow rate and SG [-] the fluid specific gravity.

The flow factor is mainly function of the valve setting. However, deviations from the nominal K_v value can be expected with fluids different from water and flow rates significantly smaller than the valve nominal flow rate (IMI Hydronic, 2015). In these cases, the nominal K_v value should be corrected. In this study, valves from IMI-Hydronic were used and their corrected flow factors were evaluated through HySelect software.

2.1.2 Fluid properties

Propylene glycol/water mixtures with glycol concentration of 30-40% (Windeleff and Nielsen, 2014) are normally used as heat transfer fluid in solar assisted DH plants. In this study, the thermophysical properties of these mixtures were evaluated using the correlations proposed by Conde (2011).

$$\rho = 508.4 - 0.1824x + 965.8T^* + 0.2803xT^* - 472.2 \cdot (T^*)^2 \qquad \text{(Eq. 5)}$$

$$c_p = 4476 + 608.6 - 715.0T^* - 1939xT^* + 478.7 \cdot (T^*)^2 \qquad \text{(Eq. 6)}$$

$$\ln \mu = -1.028 - 0.1003x - 19.94T^* + 0.1464xT^* + 14.6205 \cdot (T^*)^2 \qquad \text{(Eq. 7)}$$

When comparing the thermophysical properties of propylene glycol reported in literature (Conde, 2011; DOW, 2008; George and Sastry, 2003; Melinder, 2007), a large variability was found. So, for the model validation, a sample of propylene glycol/water mixture was taken from the collector field and its properties were determined with an Anton Paar DMA4100 densimeter and an Anton Paar AMV200 viscometer. The sample (35% glycol) was tested every 10 °C in the range 20-80 °C. The following correlations were found:

$$\rho = 1038.3 - 0.4419T - 1.940 \cdot 10^{-3} T^2 \quad \text{(Eq. 8)}$$

$$\mu = \begin{cases} -1.449 \cdot 10^{-8} T^3 + 3.066 \cdot 10^{-6} T^2 - 2.337 \cdot 10^{-4}\, T + 7.289 \cdot 10^{-3} & if\ T < 38\,°C \\ 0.1803 T^{-1.232} & if\ T > 38\,°C \end{cases} \quad \text{(Eq. 9)}$$

In (Eq. 5)-(Eq. 9), ρ [kg m^{-3}] denotes the density, c_p [J kg^{-1} K^{-1}] the specific heat, μ [Pa s] the dynamic viscosity, x [%] the mass concentration of propylene glycol in the mixture, while T* is a factor defined as T*=273.15/(T+273.15), where T [°C] is the fluid temperature.

2.1.3 Matlab implementation

Based on the above mentioned correlations, a numerical model was developed in Matlab, to calculate the flow distribution in a solar collector field. The layout of the collector field, the collector pressure drop, valves types and settings, dimensions of distribution pipes, fittings and the operating conditions (fluid type, field flow rate and fluid inlet temperature) need to be specified in the model. The temperature profile along the collector rows can be evaluated in two ways. The first is that a unique outlet temperature, equal for all collector rows, is defined in input and a linear temperature profile is assumed along the collector row. The second option requires the collector efficiency parameters, solar irradiance and ambient temperature. The temperature profile in each row is given by the solution of (Eq. 10), which assumes steady state conditions.

$$\dot{m}\, c_p \frac{dT}{dA} = G\, \eta_0\, K_\theta - a_1 \cdot (T - T_{amb}) - a_2 \cdot (T - T_{amb})^2 \quad \text{(Eq. 10)}$$

In (Eq. 10), $\dot{m}$ [kg s^{-1}] is the mass flow rate, A [m^2] is the gross/aperture collector area, G [W m^{-2}] is the hemispherical solar irradiance on the collector plane, η_0 [-] is the peak efficiency of the solar collector coherent with the definition of A, K_θ [-] is the incident angle modifier, a_1 [W m^{-2} K^{-1}] and a_2 [W m^{-2} K^{-2}] are the first and second order heat loss coefficients coherent with the definition of A, T [°C] is the fluid temperature and while T_{amb} [°C] is the ambient temperature.

To determine the actual distribution, the set of equations (Eq. 11) is solved iteratively. (Eq. 11) imposes both the mass conservation across the collector field (first line in (Eq. 11)) and the uniformity of pressure drop along the different hydraulic paths (from second line downward):

$$\begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 \\ k_{1,j} \cdot \dot{m}_{1,j} & -k_{2,j} \cdot \dot{m}_{2,j} & 0 & 0 & 0 & 0 \\ 0 & k_{2,j} \cdot \dot{m}_{2,j} & -k_{3,j} \cdot \dot{m}_{3,j} & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & k_{N-1,j} \cdot \dot{m}_{N-1,j} & -k_{N,j} \cdot \dot{m}_{N,j} \end{pmatrix} \begin{pmatrix} \dot{m}_{1,j+1} \\ \dot{m}_{2,j+1} \\ \dot{m}_{3,j+1} \\ \vdots \\ \dot{m}_{N,j+1} \end{pmatrix} = \begin{pmatrix} \dot{m}_{tot} \\ 0 \\ 0 \\ \vdots \\ 0 \end{pmatrix} \quad \text{(Eq. 11)}$$

In (Eq. 11), k [kg^{-1} m^{-1}] is a hydraulic resistance coefficient; the subscripts 1, 2, ..., N denote the collector row and N is the total number collector rows; the subscript *tot* refers to the total flow rate supplied to the solar collector field and the subscript j denotes the iteration number. The factor k_i is defined so that the product $\left(k_i \cdot \dot{m}_i{}^2\right)$ represents the pressure drop along the entire i-th hydraulic path. The value of k_i takes into account both the pressure drop along the i-th collector row, proportional to the square of the row flow rate $\dot{m}_i$, and the pressure drop along the portion of distribution pipes and tees included in the i-th hydraulic path, properly normalized to the flow rate $\dot{m}_i$.

The system (Eq. 11) is iteratively solved until the maximum difference in the collector row flow rates between two consecutive iterations is lower than 0.1%.

2.2. Description of the solar collector field and experimental setup

The developed model was based on the layout of the solar collector field installed near Høje Taastrup (Denmark). The layout is shown in Fig. 3. The collector field (gross collector area of 3257 m^2) consisted of

two subfields of 12 collector rows each. The rows consisted of 10 HTHEATStore 35/08 collectors each and were 5.5 m apart from each other. Because near the collector field there was no auxiliary heating plant, the control strategy aimed at reaching an outlet temperature from the collector field which was approximately the DH supply temperature. Nominal inlet and outlet temperatures of the field were 50-55 °C and 90-95 °C respectively, and the flow rate ranged between 8 and 50 $m^3 h^{-1}$, depending on the solar irradiance.

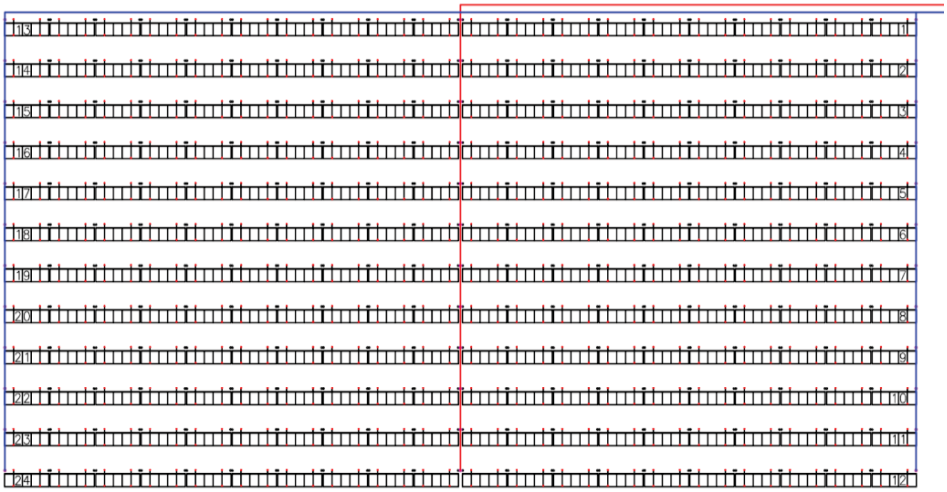

Fig. 3: Layout of Høje Taastrup solar collector field: blue and red lines represent supply and return pipes respectively (adapted from Arcon-Sunmark A/S).

The distribution pipes were made of preinsulated steel pipes. The largest inner diameter was 10.7 cm and it progressively became smaller as more fluid was diverted to the collector rows. At the inlet of each row a balancing valve was installed. In the middle of the field, the flows from each couple of row outlets were merged and then directed into the return pipe. The heat transfer fluid was a 35% propylene glycol/water mixture (Section 2.1.2).

To measure the flow distribution in the collector field, a differential pressure sensor TA-SCOPE from IMI Hydronic was used. The balancing valves have two measuring points, one before and one after the valve member. By measuring the pressure drop across the valve, the flow rate can be calculated through (Eq. 4). Specifying the type of fluid in the device, this calculates the fluid density and viscosity thanks to the built-in temperature sensor and corrects the valve flow factor. The maximum relative error when measuring the flow rate with this method is shown in Fig. 4. The error increases rapidly for low valve settings, so it is recommended to use settings higher than two. In Høje Taastrup collector field the lowest setting was 2.2.

The volume flow rate to the field was measured by an electromagnetic flow meter with accuracy of 0.5%.

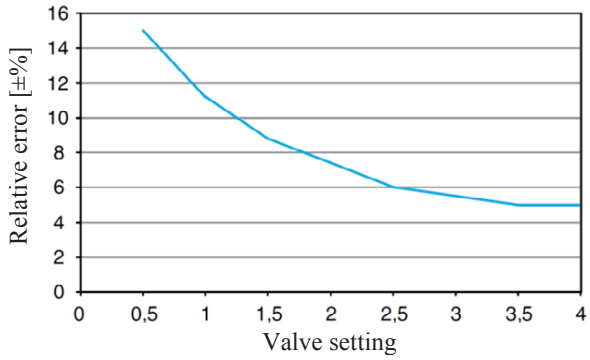

Fig. 4: Relative error on the measured flow rate across a STAD valve as function of the valve setting (IMI Hydronic, 2015).

At first, the flow distribution was measured keeping the same valve settings as in normal operation. However, the difference in the row flow rates was lower than the measurement error. Hence, the measurements were repeated after changing the setting of the first 10 valves in the eastern subfield, so to

introduce a higher maldistribution, which could be more easily detected. The flow distribution across the collector field was measured for a total flow rate of 50.3±0.3% $m^3\ h^{-1}$. The test was carried out in a cloudy day, so that the temperature across the field was constant (45.0±1.3 °C) during the entire duration of the test.

3. Results and discussion

3.1. Validation of the model

To compare the flow distributions at different field flow rate, the dimensionless row flow rate was introduced. The dimensionless flow rate V_i' in the *i*-th collector row is defined by (Eq. 12) as:

$$V'_i = \frac{V_i}{(\sum_{i=1}^{N} V_i)\cdot A_{row,i}/A_{field}} \qquad \text{(Eq. 12)}$$

In (Eq. 12), V [$m^3\ h^{-1}$] is the row flow rate, A [m^2] is the collector area, subscript *i* denotes the collector row number and N is the total number of collector rows. So, the dimensionless flow rate V'_i represents the ratio between the actual flow rate in the *i*-th collector row and the ideal flow rate in case of uniform distribution.

The measured and modeled flow distributions in terms of dimensionless flow rate are shown in Fig. 5. It is easy to recognize the effect that the change in first 10 valve settings had on flow distribution in the eastern subfield (rows 1-12) compared to the western subfield (rows 13-24). In the eastern subfield the row flow rates decreased progressively in the first 10 rows, only to return to their nominal value in the last two rows, whose valves were not changed. In the western subfield, where the valve settings were not modified, the row flow rates were much more similar to each other.

The agreement between model and measurements was evaluated through the root-mean-square deviation (*RMSD*) (Eq. 13).

$$RMSD = \sqrt{\frac{\sum_{i=1}^{N}(\hat{V}_i' - V_i')^2 \cdot b_i}{N}} \qquad \text{(Eq. 13)}$$

In (Eq. 13), V_i' [-] is the dimensionless form (Eq. 12) of measured flow rate in the *i*-th collector row in case of the model validation, while V_i'=1 in case of the investigated scenarios (Section 3.2); $\hat{V}_i'$ is the dimensionless form (Eq. 12) of modelled flow rate in the *i*-th collector row. The parameter b_i is a weight defined by (Eq. 14). If all rows are identical, *b*=1.

$$b_i = A_{row,i}/(A_{field}/N) \qquad \text{(Eq. 14)}$$

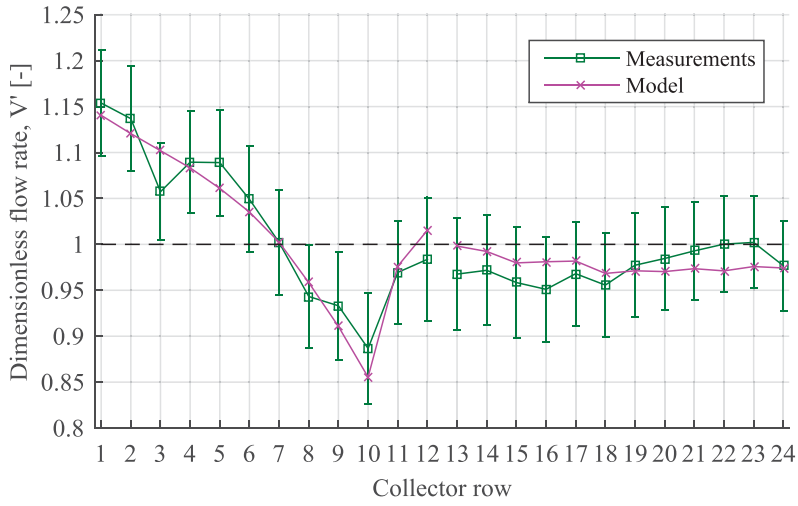

Fig. 5: Comparison between measured and modeled flow distribution for a field flow rate of 50.3 $m^3\ h^{-1}$.

Measurements and model showed an overall good agreement, with a RMSD of 0.022. In the eastern subfield the measured and modeled flow distribution profiles had the same trend, except for the third row, characterized by the highest deviation between measurement and model. In fact, the measured flow rate was

significantly lower compared to the neighboring rows. This deviation was most likely caused by additional flow resistance in this collector row, maybe due to some obstruction or dirt clog. Also the original setting of its balancing valve was larger (and hence the valve more open) than the valve settings of neighboring rows. So, already when balancing the flow at the start-up phase of the collector field, it was noted that, in order for the third row to receive the design flow rate, its valve had to be opened more than expected.

3.2. Investigated scenarios

Using the developed model, the flow distribution across a solar collector field was evaluated in different scenarios. A 35% propylene glycol/water mixture was assumed as collector fluid and its fluid properties were evaluated through (Eq. 5-Eq. 7). The following scenarios were investigated:

- Case 1. The operating conditions used for the simulation were similar to those actually used in Høje Taastrup collector field. The inlet temperature was 55 °C and the solar irradiance on the collector plane was varied with the flow rate so that the outlet temperature was about 95 °C (Eq. 10). The same balancing valves settings as those used in Høje Taastrup collector field in normal operation were used in the model.
- Case 2. As shown by the experience of the first solar collector fields built in Sweden in 80'-90', good flow distribution can be achieved without balancing valves in case of collector array with regular geometry and constant diameter of the distribution pipes. To see the effect that a more complex geometry would have on the flow distribution in case of no balancing valves, the layout of the collector field was modified as shown in Fig. 6.a. The 24 rows were now connected all in parallel and they had a different number of collectors. Because in this case the collectors were 204 instead of 240 (case 1), the highest field flow rate was proportionally decreased from 50 m^3 h^{-1} to 42.5 m^3 h^{-1}. Two different subcases were considered. In case 2.2 the diameter of the supply and return pipes decreased as fluid was diverted to the collector rows. In case 2.1 the pipe diameter of the distribution pipes was kept constant and equal to 10.7 cm, i.e. the largest diameter in subcases 2.2. Pipes commercially available for this kind of application (Logstor, 2005) were used. The field inlet and outlet temperature was 50 °C and about 85 °C respectively.

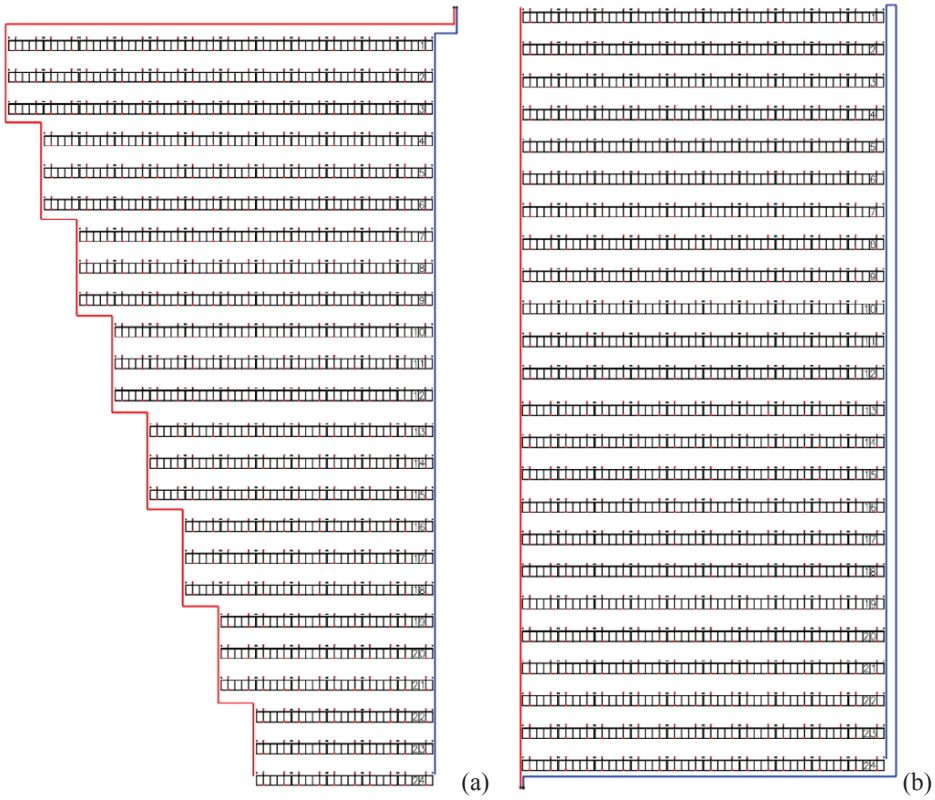

Fig. 6: Layout of the collector field assumed in case 2 (a) and in case 3 (b) (adapted from Arcon-Sunmark A/S).

- Case 3. This scenario used a Tichelmann connection (Fig. 6.b), which is expected to give a fairly uniform configuration due to the identical length for each hydraulic path. Hence, no valves were installed. As in case 2, two subcases were considered: case 3.1, having a constant pipe diameter of the distribution

pipe, and case 3.2, with decreasing pipe diameter according to the flow rate in each pipe segment. As in case 1, the inlet temperature was 55 °C and field outlet temperature was about 95 °C.

3.2.1. Case 1: normal operating conditions

The flow distribution in this case is shown in Fig. 7 for different field flow rates.

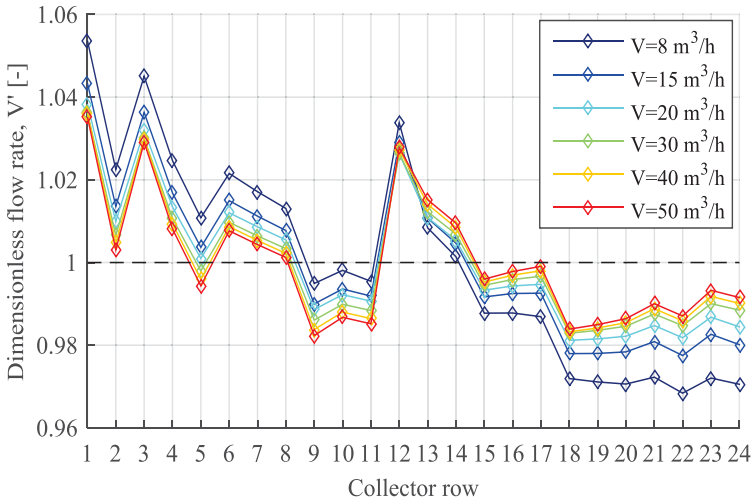

Fig. 7: Modeled flow distributions in Høje Taastrup solar collector field for different field flow rates, assuming normal operating conditions (case 1).

Also in the simulated scenarios the RMSD was used as the main parameter to quantify the level of maldistribution. Though, as no measurements were carried out for the simulated scenarios, the uniform distribution profile was now taken as term of comparison and hence z=1 in (Eq. 13) for any value of i.

Fig. 7 shows that the higher the flow rate, the more uniform the flow distribution. For $V \geq 30$ m^3 h^{-1}, the RMSD was approximately constant and equal to 0.015. At lower flow rates this value increased up to 0.025 for a flow rate of 8 m^3 h^{-1}. This was expected, as the balancing valves were set to give a uniform distribution at the nominal field flow rate, i.e. the highest flow rate the collector field operates at. The highest deviation between row flow rates and perfectly uniform flow distribution was lower than 6%, and the maximum difference between highest and lowest row flow rates was within 8%. Hence, the flow distribution can be considered acceptable for all the considered flow rates, as it differs from the ideal case less than 10%, which is considered the maximum acceptable deviation according to the German standard (VDI, 2004).

3.2.2. Case 2: Collector rows with different number of collectors

This scenario considered only cases where no balancing valves were installed, as these would give uniform flow distribution when properly regulated. The flow distribution in the two investigated subcases is shown in Fig. 8, with the subcase 2.1 characterized by much stronger maldistribution than subcase 2.2.

Given the field layout (Fig. 6.a), the collector rows became shorter while getting farther away from the pumping station. As the collector row represented the main contribution in terms of pressure drop along a hydraulic path, rows with fewer collectors had a much lower hydraulic resistance. So, in absence of balancing valves, these rows diverted flow rates higher than their design value. In case of constant pipe diameter in the distribution pipes (case 2.1) the flow maldistribution was higher with the RMSD ranging between 0.40-0.43 depending on the flow rate. The maximum deviation occurred in the last three rows, with flow rates about twice as high as the nominal value. The distribution was not very uniform, but still considerably better, in case 2.2, where the diameter was progressively decreased. In this case, the maximum deviation was only 40% and the RMSD was in the range 0.18-0.20. In fact, in case of constant diameter the fluid velocity progressively decreased in the pipe segments, making their contribution to the pressure drop of the entire hydraulic path very small. In order for all hydraulic paths to give the same pressure drop, the flow rate in the rows with fewer collectors had to increase significantly. Conversely, decreasing the pipe diameter gave similar pressure gradient in the different pipe segments. This increased the resistance of the hydraulic

paths of the collector rows which lay farther away, resulting in a more uniform flow distribution.

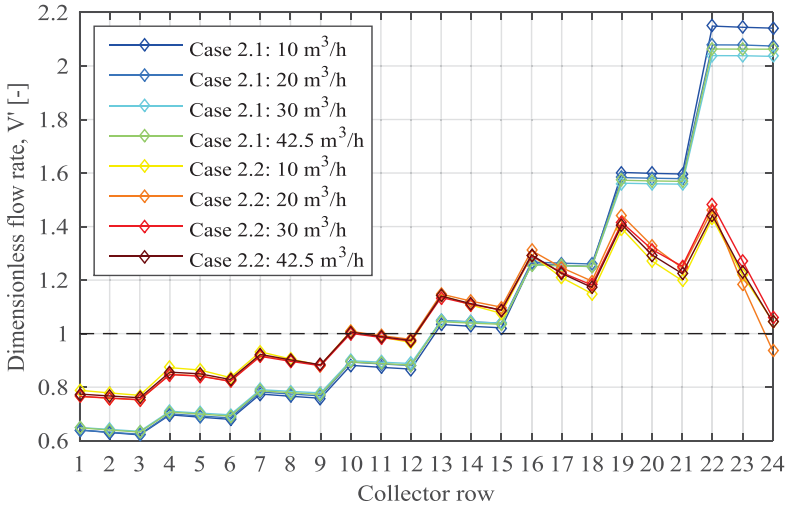

Fig. 8: Modeled flow distributions for different field flow rates in case 2.

3.2.3. Case 3: Tichelmann connection

Fig. 9 shows the flow distribution in the subcases 3.1 and 3.2. For sake of clarity, for each subcase only two flow rates, which gave the most and least uniform distribution, are shown. In both scenarios the Tichelmann connection assured a good flow distribution with deviations from the perfectly uniform case no larger than 4%. Subcase 3.2 achieved a slightly better distribution (RMSD=0.008-0.010) compared to subcase 3.1 (RMSD=0.014-0.016). In the latter, the choice of keeping a constant pipe diameter resulted into a U-shape flow distribution profile. In fact, although the pipe length was the same for each hydraulic path, the paths in more central position (rows 9-13) were supplied with lower flow rates. This was due to the fact that these paths included distribution pipes segments with higher flow rates (and hence higher pressure drop) compared to the more peripheral paths. In subcase 3.2 the distribution pipe diameter was progressively varied, so that the fluid velocity was similar in all pipe segments. This resulted in similar pressure drops and hence a more uniform flow distribution. Varying the pipe diameter also saved pipe material (steel and insulation), reducing cost and thermal losses. The main drawback of a Tichelmann connection is the longer pipe length.

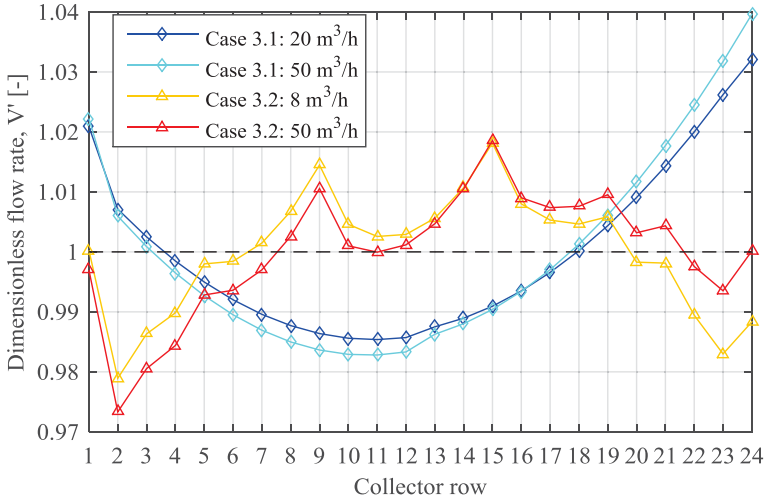

Fig. 9: Modeled flow distributions for different field flow rates in case 3.

3.3. Effect of the flow maldistribution on the thermal performance of the collector field

Modifying the row composition of the collector field shown in Fig. 6.a, different degrees of flow maldistribution were caused. The effect on the power output of the collector field is shown in Fig. 10 for two collector types, a HTHEATStore 35/08 (SP, 2016a) (Section 2.1.1) and a HTHEATBoost 35/08 (SP, 2016b)

(η_0=0.786, a_1=2.97 W m^{-2} K^{-1} and a_2=0.009 W m^{-2} K^{-2}). The collectors differed only for the presence of a polymer foil, working as convection barrier, between glass cover and absorber in the HTHEATBoost model. The loss in power output was calculated with respect to the case where the collector row flow rates were exactly proportional to the collector row area. The power output, P_{out} [W], was calculated through (Eq. 15):

$$P_{out} = \sum_{i=1}^{N} \left(\dot{m}_i \cdot c_{p,i}(\bar{T}_i) \cdot \left(T_{out,i} - T_{in} \right) \right) \qquad \text{(Eq. 15)}$$

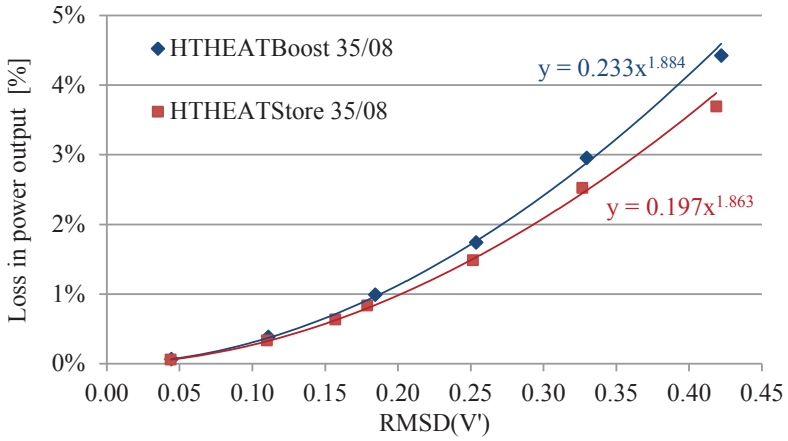

Fig. 10: Maximum reduction in power output of a solar collector field as function of the flow maldistribution.

It can be seen that the reduction in power output is proportional to the RMSD of the flow distribution to the 1.9th power, very similar to the result of Chiou (1982) for a single collector (Section 1.1). The loss in power output is relatively small, within 5% for RMSDs up to 0.4. However, it should be noted that in the current study pipe losses were neglected and the collector efficiency was assumed independent of the collector flow rate. In reality, lower efficiency is expected at low flow rates, especially if these cause laminar regime in the absorber pipes (Bava and Furbo, 2014). Slightly stronger effect on the power output would result, if these aspects were taken into account too. As expected, the performance of the collector field made of HTHEATBoost modules was more affected by the flow maldistribution. In fact, given the higher heat loss coefficients of this collector, its efficiency was more penalized in those rows which were supplied with lower flow rates and hence reached unnecessarily higher temperatures.

4. Conclusions

A model for calculating the flow distribution in a solar collector field was developed. The model results were compared against measurements and a good agreement was found.

The model was used to study different scenarios. Balancing valves in each collector row guaranteed good flow distribution in all the operating conditions. Although the valves were set in full load conditions, the deviations occurring at different operating conditions were still within the range of ±10%.

A Tichelmann connection gave a good flow distribution also without balancing valves. Reducing the pipe diameter of the distribution pipes was a good measure to improve the distribution and decrease the pipe cost.

In case of irregular field layout with collector rows having a different number of modules, balancing valves seemed to be the only way to reach uniform flow distribution.

5. Acknowledgements

The authors are thankful to the Marie-Curie Actions - Initial Training Network research programme of the European Union which supported the first author through the SolNet-SHINE project. The authors are also grateful to the company Arcon-Sunmark A/S and the DH company Høje Taastrup Fjernvarme for providing useful information necessary to develop the model and for granting access to the solar collector field.

Abstract

All technical processes are subject to dysfunctions during their lifespan, and large solar thermal systems (LSTS) are no exception to this rule. In order to deal with them and minimize their impact, a good knowledge of dysfunctions affecting LSTS is a major issue. In this way, the return on investment can be increased and the competitiveness of solar thermal energy could be also improved.

This paper presents a study of the dysfunctions which can affect LSTS. We first conducted a literature review and found out that more studies are necessary to obtain some up-to-date reliability data on the dysfunctions. To complete the available information, our methodology combines a top-down approach based on a Failure Modes, Effects and Criticality Analysis (FMECA) with a bottom-up approach based on a survey for domain experts. Thanks to the merging of various sources, we propose a ranking of sub-systems reliability, showing in particular that the less reliable solar sub-systems are the controller (control and sensors) and the primary transport (hydraulic components of the primary loop). Other sub-systems are less prone to failure, but the status of solar collection is particularly interesting. While previous studies often point it out as a critical sub-system, our results tend to show that it is more reliable in recent LSTS.

Keywords: *Failure Modes Effects and Criticality Analysis, large solar thermal system.*

1. Introduction

Large solar thermal systems (LSTS) can provide renewable and low cost energy to district heating networks and industrial processes. Over the last 25 years, many of them have been developed mostly in Northern European countries. At the end of 2015, the total area of LSTS installations in operation in Europe reached 1 million m^2 (Mauthner et al., 2016). In France, the first two installations (about 800m^2) started operating in 2014 (Renaude, 2016), and more installations are planned.

All technical processes are subject to dysfunctions during their lifespan, and large solar thermal systems (LSTS) are no exception to this rule. A dysfunction refers to the interruption of the system's ability to perform a required function under specific operating conditions. This interruption can be permanent or intermittent, abrupt or progressive. In any case, dysfunctions can entail a degradation of the production yields and/or additional maintenance costs. This can significantly hinder the return on investment and the competitiveness of solar thermal energy. Fortunately, the scaling increase of large systems enables more monitoring, which should be used to detect early and diagnose precisely many dysfunctions. However, few works have already been proposed to build fault detection and diagnosis (FDD) methods especially suited for LSTS (Ohnewein et al., 2006; Shahbazfar et al., 2012).

In order to develop a FDD method, a good overview of the type of dysfunctions that can affect the plant is a major prerequisite. In particular, FDD approaches can be developed with various aims, from short term detection of severe faults to long term detection of specific components wearing or fouling. Moreover, there is often a trade-off between detection of all possible faults (completeness) and precise diagnosis of the fault sources (resolution) (Venkatasubramanian et al., 2003). As a consequence, classifying the types of dysfunctions, their occurrence rate and their criticality provides useful information about which FDD method can give the most interesting results for LSTS systems.

In this paper, we present a study of dysfunctions of large-scale solar thermal systems (LSTS). Our methodology combines a top-down approach based on a Failure Modes, Effects and Criticality Analysis with a bottom-up approach based on a survey for domain experts, and provided us qualitative data about the main dysfunctions in LSTS. In section 2, we will first describe the state-of-the art of studies on dysfunctions in LSTS. In section 3, we introduce the methodology we adopted for this study. In section 4, we detail and discuss our results, from a

doi:10.18086/eurosun.2016.05.01 Available at http://proceedings.ises.org

global perspective to more precise results on the most frequent and critical dysfunctions. At last, section 5 summarizes our conclusions and opens perspectives on the development of new FDD methods.

2. State of the art

In this section, we introduce the current state of the art about dysfunctions of large scale solar systems. We first briefly present the system we consider, especially by defining the main relevant sub-systems (subsection 2.1). Please note that this description intends to be the most representative of LSTS configurations. We then report on our initial literature study (subsection 2.2).

2.1. System description

In this study, we consider LSTS with a total collector area above 500m², for the production of hot water at low and medium temperatures (80-120°C) with a focus on the production up to the feed-in. Other restrictions are applied in order to decrease the number of allowed layout while keeping the most common ones:

- Auxiliary heating: not studied ;
- System: pressurized, filled with water-glycol mixture ;
- Solar collector: no active tracking ;
- Storage: systems without storage are included. Only daily water, with passive stratification storages are taken account. Bi-energy storages are not considered in this study.

The remaining system is divided in five sub-systems to simplify the analysis as presented in Fig. 1:

- *Solar collection*: solar collectors, connections between collectors, fastening system.
- *Primary transport*: hydraulic components between solar field and first heat exchanger or storage (if no external heat exchanger).
- *Storage*: storage tank and internal heat exchangers if there are any.
- *External heat exchanger(s)*: if any.
- *Secondary transport*: hydraulic components between first heat exchanger or storage (if no external heat exchanger) and the feed-up.
- *Controller*: control-command components and sensors.

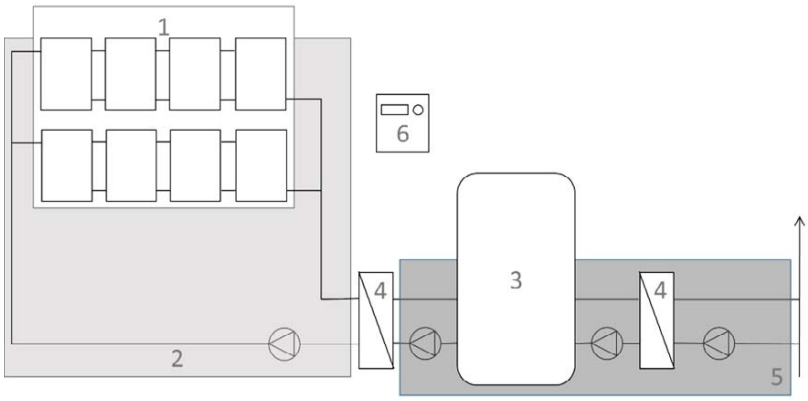

Fig. 1: Example of division of a LSTS plant in five sub-systems: solar collection (1), primary transport (2), storage (3), external heat exchanger(s) (4), secondary transport (5) and controller (6).

2.2. Literature review

Keeping in mind the characteristics of the system we have described in the previous section, we conducted a review of the literature dealing with the reliability of LSTS, with a specific focus on studies that provided data on the type and frequency of dysfunctions for each sub-system.

We can first notice that the most complete research studies on reliability of solar thermal systems date back from several decades ago (Chopra, 1980; Jorgensen, 1984). Some recent examples are the Solarthermie2000 and Solarthermie2000plus studies (Peuser et al., 2005), which are also based on solar systems in operation since the early 80's. Although these studies provide interesting inputs in terms of methodology, their results are difficult to exploit nowadays, since many of the considered technologies have been improved or are not in use anymore.

More recent studies are rather focused on small scale systems and solar domestic hot water (SDHW) system. They have especially been conducted in relation with governmental programs fostering the installation of solar

thermal systems, and sometimes provide data based on monitoring results (ADEME, 2008; Cholin, 2011). Although some findings of these studies can be applied to LSTS, there are many differences in terms of size, kinds of sub-systems and overall installation and maintenance policies, which strongly affect the type and occurrence of potential dysfunctions. As an example, problems with the solar panels' fastening system are often reported in SDHW, but will likely be not as significant in LSTS due to the standardization of the components.

A main drawback of available studies is also the lack of feedback data about the actual occurrence rate of dysfunctions. Although one older study provides occurrence data for some defaults (Jorgensen, 1984), a similar study conducted 25 years later concluded in the lack of precision and reliability of available data (Menicucci, 2009). One important issue is the lack of consistency between databases, which often yields biases and contradictory results depending on the information source.

Despite the lack of recent and reliable data on dysfunctions in LSTS, we can highlight several important conclusions from this literature review:

- **Primary transport** consistently appears to be the most impacted sub-system. In particular, insulation is often lacking or not adequate, especially to resists UV rays and bird attacks. Leaks are a usual source of dysfunction, as well as pressure loss and air bubbles, which can also result from leaks. Finally, especially in large-scale installations, a bad hydraulic balancing between the solar subfields is sometimes reported.
- **Regulation and controllers** can have a high number of dysfunctions, often related to poor installation and parameter tuning, as well as wrong placement of sensors. Especially temperature sensors yielding wrong measurement strongly impact the performance of the system.
- **Solar collection** may have some dysfunction, but is less frequently cited. Moreover, some of the problems appearing in earlier studies have been fixed in more recent products.
- **Secondary transport and heat exchanger** appear to have much less dysfunctions, primarily because these are well-known, classical systems.
- **Storage** also appears to have few dysfunctions, for the same reasons. However, this could differ in large-scale systems with unusual storage sizing and technologies.

Based on this literature review, we decided to conduct a new study in order to better assess the type, occurrence rate and criticality of dysfunctions in LSTS.

3. Methodology

This part describes the methodology used to study the dysfunctions that can affect a LSTS. Subsection 3.1 gives a description of the chosen method: the Failure Modes, Effects and Criticality Analysis. In order to apply the procedure, we collected more data thanks to a survey (subsection 3.2). The last section presents the determination of an important figure, the Failure Risk Priority Number, based on the collected data. This number is a way to emphasize dysfunctions that are critical for the system.

3.1. Failure Modes, Effects and Criticality Analysis (FMECA)

In order to study the dysfunctions that can affect LSTS, we applied a standard methodology: the Failure Modes, Effects and Criticality Analysis (Isermann, 2006; Laronde, 2011; Villemeur, 1988). FMECA is a formalized method, developed in the 60's and commonly used in industry nowadays to evaluate the dysfunctions that can occur on a system. It consists of doing the inventory of the components, their functions and the ways they cannot perform these functions (failure modes). The analysis can be extended by adding possible causes of the failures and their effects on the whole system. Finally a Failure Risk Priority Number (FRPN) can be estimated to show the criticality of different failures. The results of this work is a large table as illustrated in Tab. 1.

Tab. 1: Extract of the resulting FMECA table.

Component	Function	Failure mode	Effects	Possible causes	Properties of the causes	Detection method	FRPN
Primary pump	Set the heat transfer fluid in motion	Never start	No energy production	Pump not connected	Installation error	No flow when sunshine and demand	25
			Overheating of the primary loop	Electricity grid failure	Environment		

In practice, we made a first analysis based on prior knowledge, discussions with local experts and the literature review presented in the previous section. However, the amount of collected information was insufficient to

estimate the FRPN. In particular, no specific data about the failure occurrence rate was available. We then decided to conduct a survey with a larger panel of experts, as described in the following subsection.

3.2. Survey of domain experts

The survey was emailed to 23 experts in the field of LSTS. It was deliberately based on open-ended questions and consisted in:

- listing, for each sub-system, the dysfunctions that can affect it;
- giving a rough estimation of the occurrence rate for each listed dysfunction by choosing between "low", "medium" and "high";
- adding any significant information (cause, effect, detection…).

A sample of the survey form is given in Fig. 2. 90% of the surveyed experts returned an answer, and we collected results from a total of 21 experts from 7 countries and 20 different organizations (research institutes, consulting engineers, solar manufacturers, LSTS managers, training organizations). These additional information helped completing the FMECA and computing the FRPN as described in the next section.

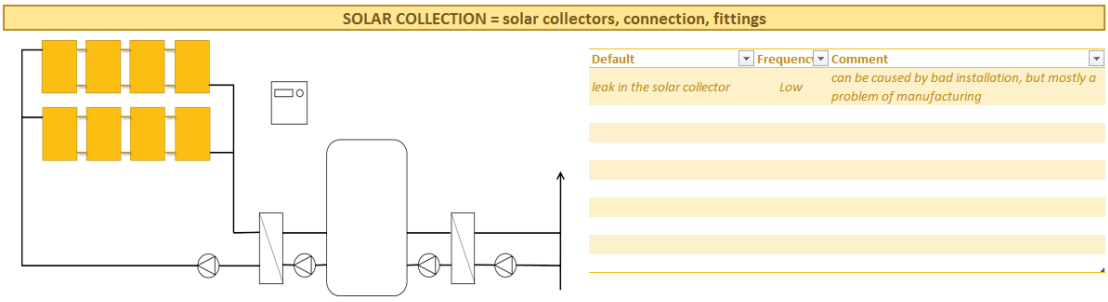

Fig. 2: Part of the survey concerning the solar collector sub-system. The same presentation is used for the other sub-systems.

3.3. Determination of the Failure Risk Priority Number (FRPN)

The Failure Risk Priority Number gives an indication of the criticality of a given failure mode for the system. It is computed for each failure i using equation *(eq. 1)*:

$$FRPN_i = ON_i \times EN_i \qquad \textit{(eq. 1)}$$

where ON_i (Occurence Number) is a number representing the occurrence rate of failure i, EN_i (Effect Number) is a number describing the effects of failure i on the system. ON_i and EN_i are ranking values with a scale from 1 to 5. FRPN is itself a ranking number with a scale from 1 to 25, 1 standing for the less critical failure modes.

To compute ON_i we first derive a raw "occurrence rate" value O_i from the results of the survey and the state of the art using *(eq. 2)*:

$$O_i = 0{,}45 * N_i + 0{,}45 * \frac{3 * Nhigh_i + 2 * Nmed_i + Nlow_i}{6} + 0{,}1 * b_i \qquad \textit{(eq. 2)}$$

N_i is the total number of citations of a failure i in the survey. $Nhigh_i$, $Nmed_i$ and $Nlow_i$ are respectively the number of "high", "medium" or "low" frequency qualifications for this failure. b_i is a value ranked between 0 and 2 describing if the failure is often reported in the literature. We obtain ON_i by scaling O_i to an integer between 1 and 5 (the higher the number, the more probable the failure occurrence).

To compute EN_i, we estimated the effect of each failure based on its description and experts comments. Possible effect numbers are given in Tab. 1, and range from 1 ("No effect") to 5 ("No more solar production").

Tab. 1 : Criteria to estimate EN_i, the rank of a failure according to its effects on the system.

EN_i	Effect on the system
1	No effect - client does not notice anything
2	Slight and stable drop in yield
3	Progressing drop in yield
4	Significant drop in yield with immediate risk of substantial degradation of the system
5	No more solar production

The resulting FRPNs allow classifying the reported failure modes from the less critical ones, which have a low occurrence rate and no effect, to the most critical ones, which have both high occurrence rates and severe consequences on the system integrity. It has to be noticed that although the computation of the ONs and the FRPNs depend on the coefficients used in *(eq. 2)*, a sensitivity analysis showed that their value have a low impact on the results of the study. More specifically, using different sets of coefficients in *(eq. 2)* does not affect the ranking of failure modes along their FRPNs.

4. Results and discussion

We identified 130 possible failure modes or dysfunctions. One failure mode is the result of one or more causes, and leads to 392 independent causes or basic events. The main characteristics of these causes are presented in subsection 4.1. We also worked at the failure modes level, first by observing the distribution of the computed ranking values (subsection 4.2), then by focusing on the more critical failure modes (subsection 4.3).

4.1. Types of causes

This first subsection is dedicated to the study of the main causes of the failure modes. The causes that leads to failure modes with a very low occurrence rate are not taken into account. After this selection, 326 independent events remain. The literature concerning faults (Isermann, 2006; Villemeur, 1988) proposes different ways to describe and classify the failure modes and their causes:

(a). The sub-system affected by the cause.

(b). The origin of the cause, which can be a design fault, an installation error, a wrong operation (missing maintenance, wrong manipulation…) or the ageing of the components. Causes resulting from environment (weather conditions, power cut…) are also distinguished.

(c). The appearance's time, showing whether this cause is already existing during the commissioning stage or whether it appears during the operation.

(d). The time's dependency, distinguishing between abrupt (stepwise), progressive (drift-like, incipient) and intermittent causes, as defined by Isermann.

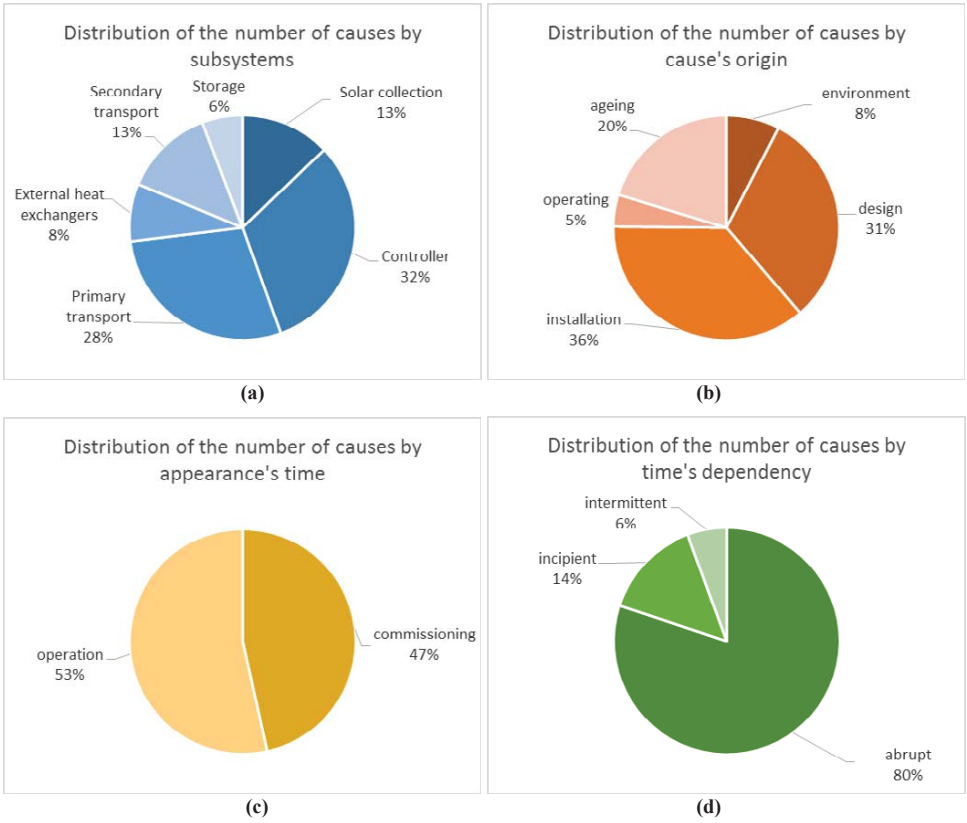

Fig. 3: Distribution of the number of found causes along some criteria: (a) sub-system, (b) cause's origin, (c) appearance's time, (d) time's dependency.

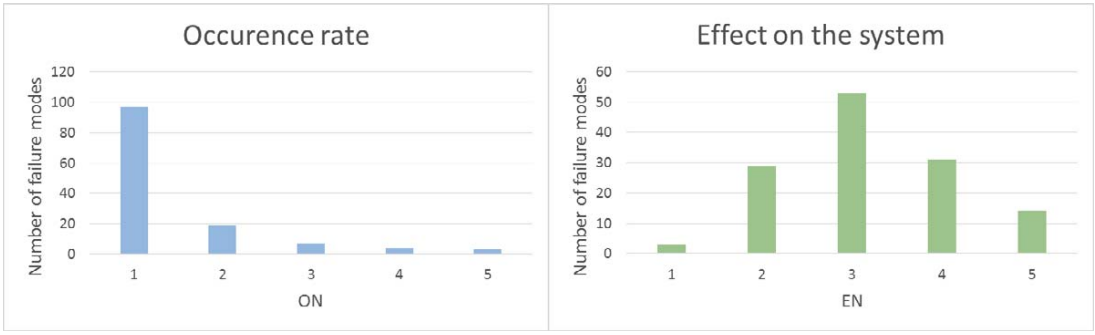
Fig. 3 presents the classification of the causes along these criteria. According to pie chart Fig. 3.a, controller and primary transport concentrate the largest number of causes of failure (60% together). Solar collection and secondary transport concerns both 13% of the inventoried causes. Storage and heat exchanger are less subject to failure. The results are in good agreement with the literature review of subsection 2.2. The pie chart Fig. 3.b shows that the main causes are design and installation problems (67%). Ageing is also a significant factor of failure. Operating and environment are less critical, in one hand because the system's environment is not extreme, and in other hand because the system is fully automatized and is designed to require few maintenance. Due to the high rate of design and installation dysfunctions, 47% of the causes are already present at the commissioning (Fig. 3.c). The pie chart Fig. 3.d teaches us that if mainly dysfunctions appears suddenly (80% of the causes), 14% are progressive, which is not negligible. The part of intermittent causes is quite low.

This first part does not take into account the criticality of the failure mode and the causes associated. It speaks about "what can happen". In the next parts, the criticality of the failure mode will be studied in order to work about "what is likely to happen".

4.2. Distribution of the failures along the key ranking numbers

Fig. 4 shows the distribution of the ranking number representing the occurrence rate (ON_i), the effect on the system (EN_i) and criticality ($FRPN_i$) of the failure modes or dysfunctions. The histogram plotted on Fig. 4.a reveals that there are few frequent failure modes. This is in accordance with some general commentaries made by experts when then reply to the survey: "defaults are rather occasional.", "a large scale solar thermal plant does not need much effort to secure an operation without failure", "we identified few defaults on solar plants". On the contrary, the impact of the failures on the global system is significant: histogram Fig. 4.b shows that more than 75% of the dysfunctions implies at least a progressing drop in solar yield ($EN_i \geq 3$), with a high risk of material degradation for almost 35% of them ($EN_i \geq 4$). Due to the low frequency of most of failure modes, the criticality is generally low (histogram Fig. 4.c). We can however show off one dysfunction with the maximal criticality ($FRPN_i = 25$). It will be detailed in the next sub-section.



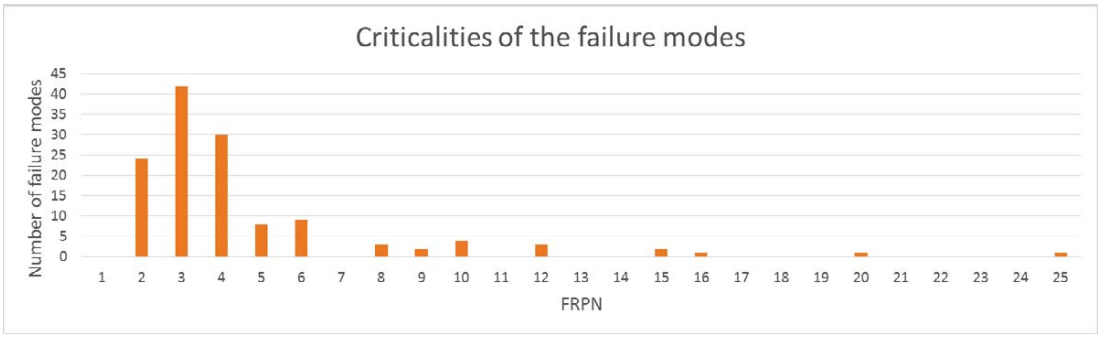


Fig. 4: Distribution of the failure modes along (a) their probability of occurrence, (b) their effect on the system, (c) their criticality.

Tab. 2 confirms that the distribution of the couples (ON_i, EN_i) follow the tendencies previously discussed: on the one hand, failure modes have in general a low probability of occurrence apart from their effect on the whole system; on the other hand the effect is mostly medium independently of their frequency.

Tab. 2: Distribution of the pairs (ON_i, EN_i).
The area delimited by a bold border includes the most critical failure modes which are studied afterwards.

		EN_i					
		1	**2**	**3**	**4**	**5**	**Total**
ON_i	**1**		22	42	25	8	97
	2	2	4	7	3	3	19
	3		2	2	1	2	7
	4	1		2	1		4
	5		1		1	1	3
	Total	3	29	53	31	14	130

4.3. Critical dysfunctions

Tab. 3 shows the most critical failure modes: those which have a Failure Risk Priority Number ($FRPN_i$) equal or above 8. This threshold represents the area delimited by a bold border in Tab. 2. This area is the lower-right corner of the table corresponding to the highest $FRPN_i$ without the pairs (1,5) which are less representative of a high criticality event, since an EN_i of 1 is "No effect - client does not notice anything" (see Tab. 1) and an ON_i of 1 can be achieved with only one citation. The failure modes are sorted along sub-systems, then along their $FRPN_i$. The most affected sub-systems are at the beginning of the table.

Tab. 3: Failure modes with a Failure Risk Priority Number equal or above 8.

Sub-system	Component	Failure mode	ON_i	EN_i	$FRPN_i$
Controller	Solar collector temperature sensor	Wrong measure	5	4	**20**
	Heat exchanger input/output temperature sensor	Wrong measure	4	4	**16**
	Solar collector temperature sensor	No more measure	3	5	**15**
	Heat exchanger input/output temperature sensor	No more measure	2	5	**10**
	Pyranometer	No more measure	2	5	**10**
	Controller	Breakdown	2	5	**10**
	Controller	Non-optimal control	3	3	**9**
Primary transport	Solar pump	Never starts	5	5	**25**
	Hydraulic connectors	Leak	4	3	**12**
	Heat transfer fluid (mixture of water and propylene- or ethylene-glycol)	Bubbles in the heat transfer fluid	3	4	**12**
	Pipes	Leak	3	3	**9**
	Pipes	Bad hydraulic balancing	2	4	**8**
	Expansion vessel	Too low pressure	2	4	**8**
	Solar pump	Too low flow	2	4	**8**
Secondary transport	Pumps	Never starts	3	5	**15**
Storage	Storage tank	Heats less than expected	4	3	**12**
Solar collection	Solar collector	Produces less energy than expected	5	2	**10**

These results have to be analyzed qualitatively more than quantitatively. Indeed, they are the results of a bibliography and a survey, which are far less accurate than an experimental test or the assembly of a large amount of representative data. For example, we can pick up on some bias on the reported occurrence rate (ON_i) for the failure mode "solar collector produces less energy than expected". ON_i is maximum for this dysfunction and seems overestimated, given the literature review (see subsection 2.2). Since the solar collector is the main component of a solar system, and one of the most complex, we can assume responders had a tendency to focus on reporting dysfunctions on this component first. Actually, additional interviews showed that the first quoted dysfunctions concerned the solar panels, even if the experts added later that these dysfunctions are uncommon. Moreover, solar collection appeared as the first item in the survey form, which could be an additional source of bias.

Generally, Tab. 3 is in line with the bibliography (subsection 2.2). Two sub-systems are more likely to fail: controller and primary transport with both 7 critical failure modes. Secondary transport, storage and solar collection have one critical failure mode each. External heat exchangers are not present in the results.

5. Conclusion and perspectives

In this paper, we report on a study concerning the dysfunctions that can affect large solar thermal systems (LSTS). We began with a review of the state of the art and noticed that there are few up-to-date information about large solar installations. Therefore, we performed a Failure Mode Effects and Criticality Analysis and completed it with an expert survey in order to obtain more elements. We finally presented the results of this analysis with a focus on the typology of the causes of failure and on the more critical dysfunctions. An important result is the fact at the commissioning almost half of the causes of the dysfunctions can already occurred. As a consequence, if a fault detection method is applied to a solar system, it cannot suppose that the plant works well at the beginning of the monitoring. As far as the risk of failure is concerned, although the majority of the dysfunctions is quite occasional, their impact on the efficiency and the degradation of the system is high. An automatic detection and a diagnosis of these problems are then of interest. In particular we demonstrated that two sub-systems are particularly subject to dysfunctions: the controller and the primary transport. Other sub-systems are less prone to failure, but the status of solar collection is particularly interesting. While previous studies often point it out as a critical sub-system, our results tend to show that it is more reliable in recent LSTS.

Based on the results of this study, our future work will focus on the development of FDD methods for specific sub-systems, starting with controllers, primary transport and solar collection. We can note that many available FDD methods work well for the controller part, but the two other sub-systems are less well covered. In particular, the detection, diagnosis and localization of dysfunctions on the primary transport sub-system and on solar collector are more complicated to perform, but are of prime importance due to the size of the solar field.

Additionally, we can mention that the study presented here could be a preliminary step for a complete reliability analysis of LSTS. A study like the one done by (Laronde, 2011) for the solar photovoltaic systems or the ANL Solar Reliability and Materials Program conducted by the Argonne laboratory in the late 70s (Chopra et al., 1978; Waite et al., 1979) could provide reliability data such as lifespan and failure rate of the main components of a LSTS. These data would be useful not only for the development of fault detection and diagnosis (FDD) algorithms but also for the design of the products and the optimization of the preventive maintenance.

IMPACT OF FORM AND DENSITY ON THE URBAN OUTDOOR SPACE COMFORT IN HOT AND DRY CLIMATE

Zahra Ferhat[1], Noureddine Zemmouri[1], Houda Saddok[1] and Mohamed El-Hadi Matallah [1]

[1] **Laboratory of architecture and environmental design (Lacomofa)**
University of Biskra, Algeria.

Abstract

In recent years, rapid urbanization and a tremendous increase in population have exerted pressure on urban developments in developing countries. The strategy adopted by most governments in the past twenty years in Algeria was that of densification. New and different urban forms have evolved from this strategy, but resulting in a loss of public green spaces and creating new problems in terms of environmental issues.
The present paper examines the relationships between forms and resulting environmental parameters such as temperature, ventilation, relative humidity.
The investigation is carried out by using the three dimensional numerical model « Envi-met 4.0 » which simulates the microclimatic parameters within urban environment and neighborhood. Models calculations are run for typical summer day 'Design Day July 21st ' in Biskra, south East of Algeria (34,48° N, 5,4° E), a region characterized by a hot and dry climate.
The aim of this study is to develop guidelines for architects and urban designers in order to develop new strategies and urban forms for a better and sustainable urban space.

Keywords: *hot and dry climate, outdoor space comfort, urban density, urban form, urban microclimate*

Introduction

Cities' planning and design has been conditioned throughout history by many and diverse factors including political, environmental, cultural, social, etc.
There are two main challenges related to the design of modern cities; the first is linked to global climate change, urban morphology (shape, density, vegetable and mineral volume, atmospheric air pollution, energy consumption ... etc.) is achieved in a context of rapid climate change (Vinet, 2000).
The second issue concerns the specific microclimate of cities. The phenomenon of urban heat island "UHI" is known for decades as a direct consequence of urbanization (Claverie, 2011). A sharp warming in air temperature of city centers, caused mainly by pollution from industries and transport. It has been defined (Oke, 1987) as the temperature difference between the city center and the surrounding countryside.
The urban heat island is the most dramatic manifestation of the global climate change consequences. It can be very drastic and leads to a temperature difference of the order of 10°C to 15°C between urban and surroundings areas (Musy, 2014).
Urban heat island is responsible for an increased mortality during heat waves periods. The elderly are mostly among the worst affected (Campbell, 2009).
It can also cause discomfort, weakness, and disorders of consciousness, cramps, syncope and heat stroke or exacerbate pre-existing chronic diseases such as diabetes, respiratory failure, and cardiovascular disease, cerebrovascular, neurological or renal, to the point of death (Filiatreault, 2015).

1-City configuration and heat island risk

The structural and morphological characteristic of the city allows storing and trapping heat from solar radiation. Different parameters can increase or decrease the storage capacity or heat dispersion; several factors contribute to the increase in the appearance of the urban heat island as given in table 1:

Factors	Parameters
Climate	Sky state, wind speed and direction
Geographic	City location
Energy	Heat rejection from energy consumption
Morphology	Building density, mineral and vegetal surfaces
Policies	Land management practices
Structural	City size, plot ratio

Table 1: factors favoring the urban heat island.

According to Bozonnet (Bozonnet, 2005) the heat island phenomenon is linked to cities expansive increase of energy consumption see figure 1.

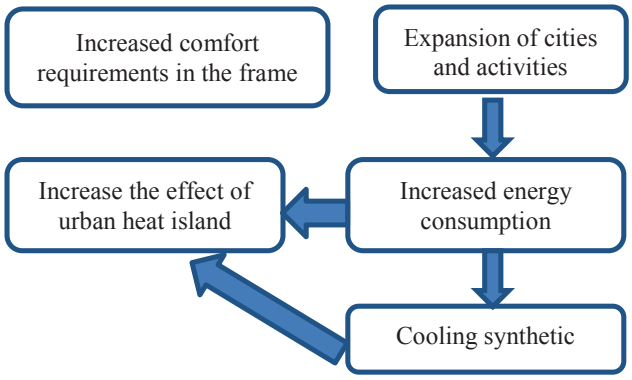

Figure 1: The relationship between the urban heat island and energy consumption (Bozonnet, 2005).

The present research examines the relationships between cities' forms and resulting environmental parameters such as temperature, air speed, and relative humidity.

2- Case study description

The city of Biskra, located in Algeria, is chosen for its hot and arid climate of the country. It has a rigorous climate characterized by very hot, dry summer and mild winter.

Meteorological data of Biskra show that the average temperature ranges from maximum of +44, 9°C and a minimum value of−2.1°C with high insolation exceeding 3500h/year and intense direct sunlight which can reach 900 to 1100 W/m² on a horizontal plane, relative humidity values vary between 25% to 40% with rare and irregular rainfall. This city is characterized by violent seasonal sandstorms (Khelil, 2015).

3-Methodology and approach

In order to assess the effect of urban configuration on the heat island risk in Biskra, a series of simulations has been performed using the Envi-met "*Environment- Meteorology*" version 4.0 code.

ENVI-MET is multidisciplinary simulation consultancy with a core services portfolio including architecture, building physics and microclimate; landscape architecture and garden design; it also includes urban planning and climate change adaption and human comfort and health.(Envi-met, 2014)
A simulation has been performed specially for the 21st July 2011 as it represents the hottest day of the year 2011. At 4 p.m, the air temperature reached almost 53°C.

4 -Urban typologies modelization

Biskra is an urban configuration with a variety of typologies: traditional, colonial and post-colonial. Creating a very diverse urban landscape, see figure 2.

(1)

(2)

(3)

Figure 2: Different typologies of Biskra: (1 traditional, (2) colonial and (3) post-colonial.

In order to assess the risk of heat island in this specific town, we have selected typical typologies (4 cases) representing a general trend form and typology of new urban developments, described in table 2.

Case	Total surface (m²)	Sb (m²)	Nb	Plot ratio	D (m)	Total plant area (m²)
1	12800	400	12	3.75	10	300
2	12800	400	10	3.125	10	300
3	12800	400	8	2.5	10	300
4	12800	400	6	1.875	10	300

kTable 2: Biskra urban typologies characteristics.

In order to assess the natural environment, a specific species of trees has been selected in order to be incorporated in the modelization process. The tree species is widely planted in the region and known as *Abies Alba* see figure 3.

Figure 3: The species of the tree *Abies Alba.* Source (http://www.lesarbres.fr/sapin.html)

This tree is characterized by:

- Height: 30m to 50 m
- Width: 10m to 15 m
- The leaves are needle-like, flattened, 1.8–3 centimetres (0.71–1.18 in) long and 2 millimetres (0.079 in) wide by 0.5 millimetres (0.020 in) thick

4- Simulation process

The four cases selected urban configuration representing Biskra urban landscape as described in table 2, have been used as models for the simulations.

- Case 1 consisting of 12 detached blocs aligned in result grid.
- Case 2 is 10 blocs configuration with a central courtyard.
- Case 3 consisting of 8 blocs aligned in U form.
- The last case, case 4 is 6 blocs urban composition evenly distributed over the surface area.
- Two green belts of *Albies Alba* tree have been added on the models on the East and West orientation as given in figure 4, 5 and 6.Wich a total vegetal density 0.1875 given by: vegetal density **(Vd)** = total plant area / total area
  Vd = [30 x 10 x 8] / 12800 =
  0, 1875

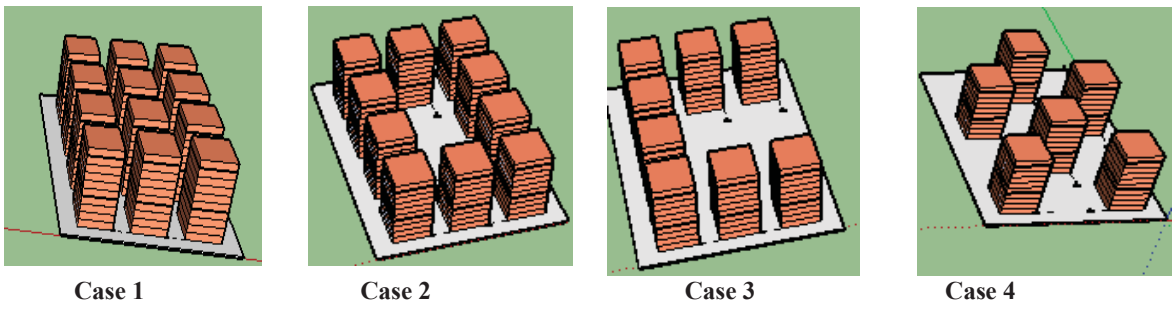

Figure 4: Generics models via Skeutchup.

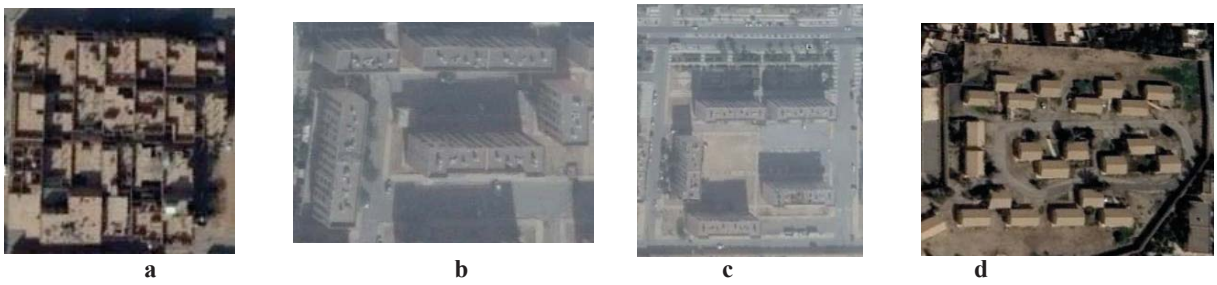

Figure 5: Different urban configuration in Biskra. a: city 1000 lodgements, b: city 500 lodgements, c: city 300 lodgements, d: city Bab Al Dherb.

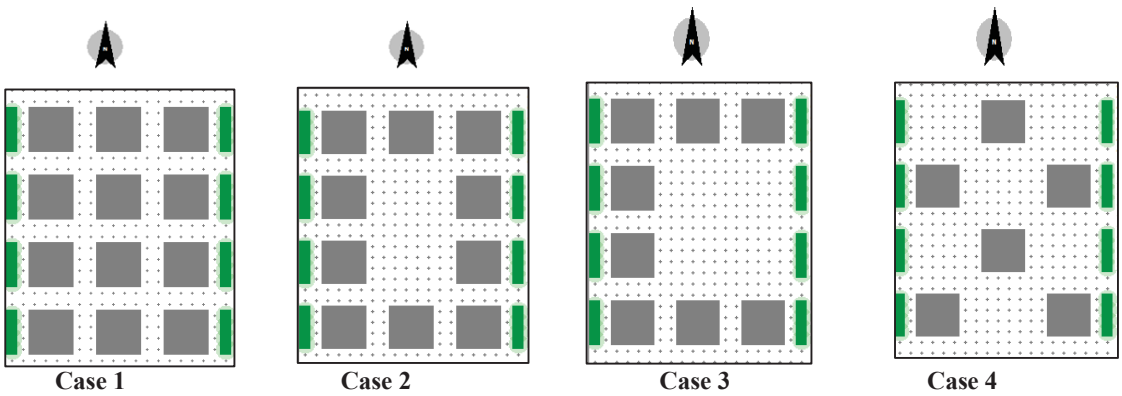

Figure 6: Generics models via Envi-met 4.

5- Results and discussion

From the results shown in figures 7 to 9 and tables 3 to 5 it is clear that, air temperature, air speed and relative humidity varies differently from one urban configuration to another.

3-1- Air temperature

Air temperature inside the models decreases with increasing plot ratio and vice versa.

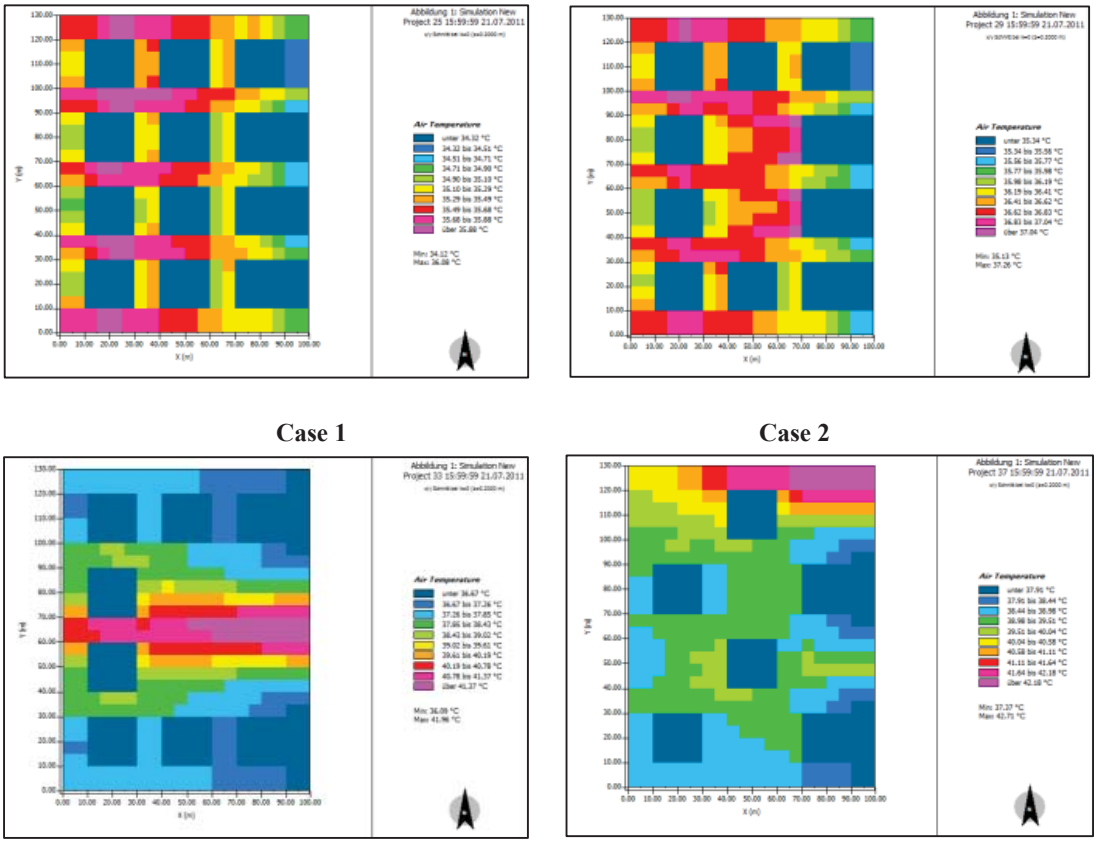

Figure 7: Air temperature variety results for each configuration

T°c	Case 1	Case2	Case3	Case4
Tmin	34.12	35.13	36.09	37.37
Tmax	36.08	37.26	41.96	42.71

Table 3: Max and Min values of air temperature inside each configuration.

The increase in the number of blocs on the same surface area helps to decrease the outside air temperature.
The effects of shadowing bloc to bloc reduce the blocs surfaces exposed to direct sun heat. The same effect can be seen on case 2 and 3.
The outside air temperature rises as the number of blocs decreases.
However, the orientation and the green belt have different subsequent results as seen in case 2, 3 and 4, see figure 5.

3-2- Air speed

It has been reported that during anticyclonic periods and during the months of July and August reduced wind speed 2 m/s to 3 m/s (APUR, Bigorgne, 2012), combined to a clear sky increases the risk of creation of urban heat island.

Figure 8 and table 4 shows the results of the simulations for the wind speed factor for the four typical urban configurations.

The air speed is quite uniform for all the four configurations with slight differences between the reference case (case 1) and case 4. The risk of heat island is more probable for case 4.

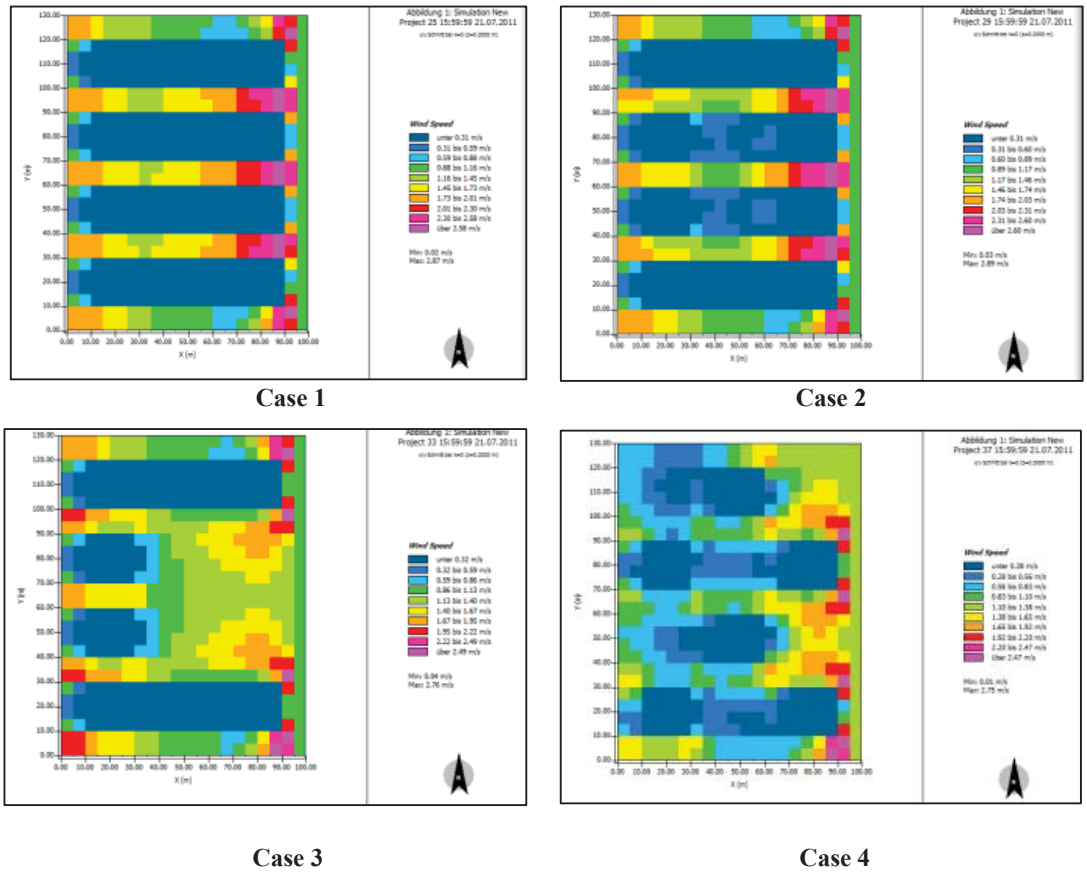

Figure 8: Air speed variety results for each configuration.

V (m/s)	Case1	Case2	Case3	Case 4
V min	0.02	0.03	0.04	0.01
V max	2.87	2.89	2.76	2.75

Table 4: Max and Min values of air speed inside each configuration.

3-3- Relative humidity

Relative humidity values could influence the risk of the urban heat island.

When humidity is low, climate becomes too dry promoting water and energy consumption. The evapo-transpiration phenomenon “green and water spaces” helps to reduce outside air temperature.

However, it could be pointed out that excessive increases in relative humidity reduce comfort temperature.

From figure 9 and table 5, we can deduce that relative humidity values are at their highest in cases 3 and 4. On the East orientation in case 4 and evenly distributed all over the urban configuration in case 3.

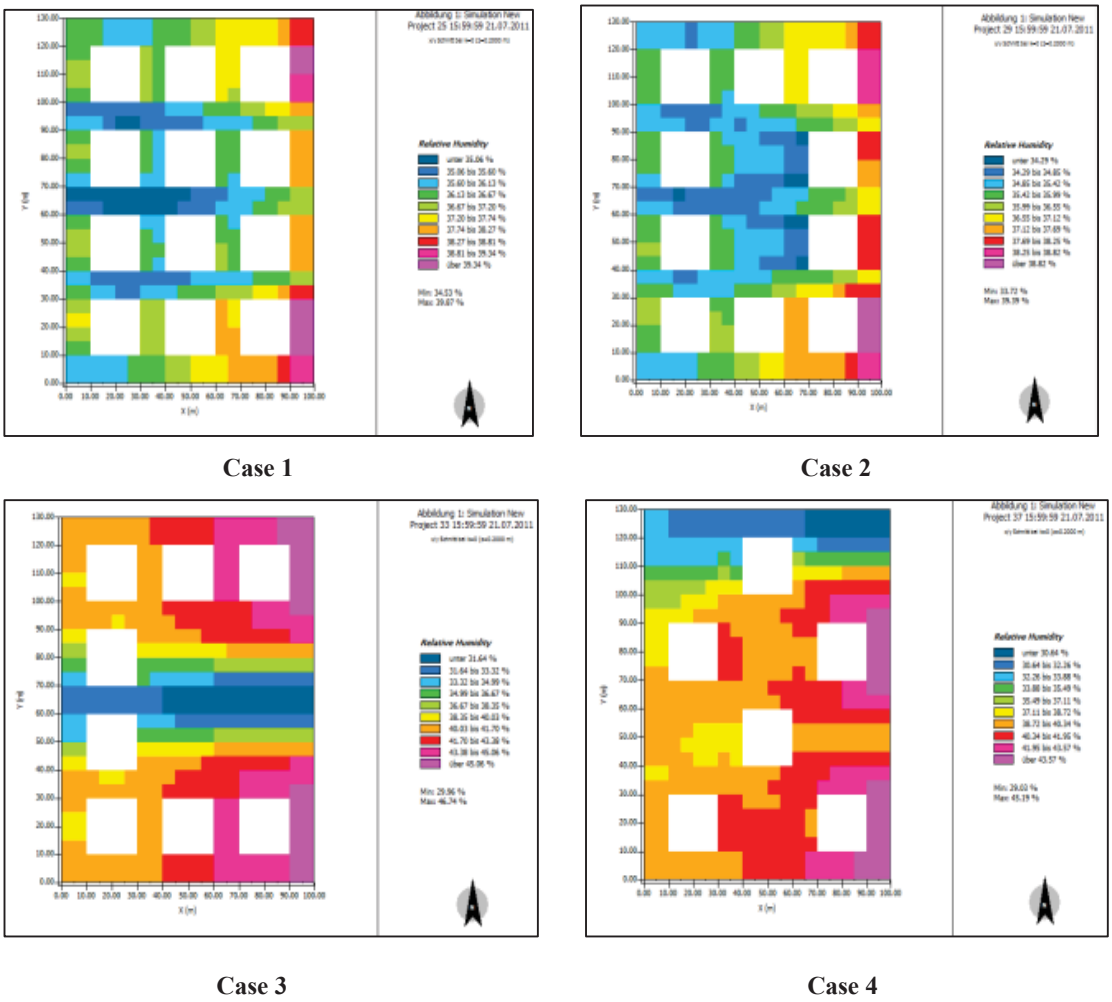

Figure 9: Relative humidity variety results for each configuration

RH%	Case1	Case2	Case3	Case4
RH min	34.53	33.72	29.96	29.03
RH max	39.87	39.39	46.74	45.19

Table 5: Max and Min values of relative humidity inside each configuration.

Conclusion

The results show that in hot and dry climate; the urban density creates a microclimate on the urban outdoor spaces by the diminution of air temperature and the urban heat island risk.
Urban typology has a great effect on the urban heat island risk. Designers of new urban development should take into account all the factors influencing urban morphology such as: form, geometry, density and orientation in the design of new towns and districts.
A sustainable architecture or urban design, should take into account all the variables which could influence positively the resulting urban climate.
A holistic approach could constitute a fundamental strategy for resolving nowadays urban issues and problem.

Flexibility of Large-Scale Solar Heating Plant with Heat Pump and Thermal Energy Storage

Katarzyna M. Luc[1], Alfred Heller[1] and Carsten Rode[1]

[1] Department of Civil Engineering, Technical University of Denmark, Kongens Lyngby (Denmark)

Abstract

In the future energy system, based wholly on renewable energy sources, biomass is likely to become a scarce resource because of high demand especially by the transport sector. The current paper investigates, what is the possibility of utilizing excess electrical energy from renewable generation to decrease biomass use in a district heating system. The paper focuses on the renewable energy-based district heating system in Marstal, Denmark, with heat produced in central solar heating plant, wood pellet boiler, heat pump and bio-oil boiler. The plant has been the object of research and developments since its construction in 1996 and its operation is well documented. In the first part of the paper, the background of the current study is explained and the system in question is presented. Subsequently, the methodology of the study is explained and the model used in the study is described. Due to lack of widely accepted definition of a metrics for comparing system flexibility the paper proposes such an indicator. It was concluded, that cheap electricity can partially replace scarce biomass for heat production for district heating system.

Keywords: *Central Solar Heating Plant, District Heating, Heat Pump, Integrated Energy System*

1. Introduction

1.1. Background

The goal of the Danish energy system, including electricity, heating, industry and transport, is to wholly transition to renewable energy resources by 2050. In contrast to fluctuating renewable energy sources such as solar and wind energy, biomass offers generation flexibility on similar level as traditionally used fossil fuels. However, there is a number of considerations that need to be taken into account in case of evaluating environmental impact of biomass use for energy purposes. Removal of biomass can impact soil, hydrology and water quality, and habitat resources (Abbas et al., 2011). Reijnders (2006) lists a number of conditions that are required for sustainable biomass-for-energy production: levels of soil, organic matter and nutrients should not decrease over time, erosion and water usage should not exceed additions to soil and water stocks and the use of virtually non-renewable phosphate ores and fossil fuels should be significantly reduced. The author states also, that meeting such conditions requires major effort and most likely leads to relatively low productivity per hectare (estimated for around 3 metric tons per hectare per year of woody biomass, both in the temperate and tropical areas (Pimentel et al., 2008)). In Denmark, realistic biomass potential for energy purposes was estimated supply by Danish Energy Agency to be 20-25% of current total energy supply (Lund, 2007). Additionally, in the future energy system based wholly on renewable energy sources, in some development scenarios biomass is expected to be in high demand by the transport sector (Lund, 2007). Thus, its availability for heat production is going to decrease. It is also expected, that with increasing share of wind in electricity sector, periods when electricity generation exceeds the demand will occur more and more often. Thus, utilizing this excess electrical energy can provide an opportunity to simultaneously decrease biomass use for heating purposes and provide cost-effective heat generation.

1.2. Aim of the study

The aim of the study was to investigate, to what degree the biomass use in the a large-scale solar heating plant with seasonal storage could be reduced through the use of heat pump during the periods with excess electrical energy generation from the fluctuating renewable sources. It was expected, that the central solar heating plant remains the main heat source for the system.

2. Methodology

2.1. Investigated system

The system investigated in the study is the district heating system in Marstal, Denmark. The system supplies heat to around 1,600 consumers. 50-55% of heat production comes from solar energy, 40% from a wood pellet boiler, 2-3% from a heat pump and the rest from a bio-oil boiler (Marstal Fjernvarme). Three solar collector fields sizing respectively, 9,000 m^2, 9,300 m^2 and 15,000 m^2. The plant has the thermal capacity of 23,300 kW_{th} and is equipped with water thermal energy storages of the size of 2,100 m^3 (steel tank), 10,000 m^3 and 75,000 m^3 (pit heat storages). The storage can act both as diurnal storage and seasonal storage. The plant runs with an adjustable flow both on the primary and secondary side. Thanks to this, it is possible to ensure requested outlet temperature through regulating the flow, using the efficiency curve for the solar collectors and taking into account sun radiation and return temperature to the collectors (PlanEnergi, 2013a). The first heat pump uses R290 as refrigerant and has the power use of 100 kW. The second heat pump uses CO_2 as a refrigerant and has the power use of 475 kW and thermal output of 1.5 MW_{th}. The 4 MW wood chip boiler includes thermal oil boiler for ORC and has a heat output of 3.25 MW (PlanEnergi, 2013a). The diagram of the existing system is shown in Figure 1.

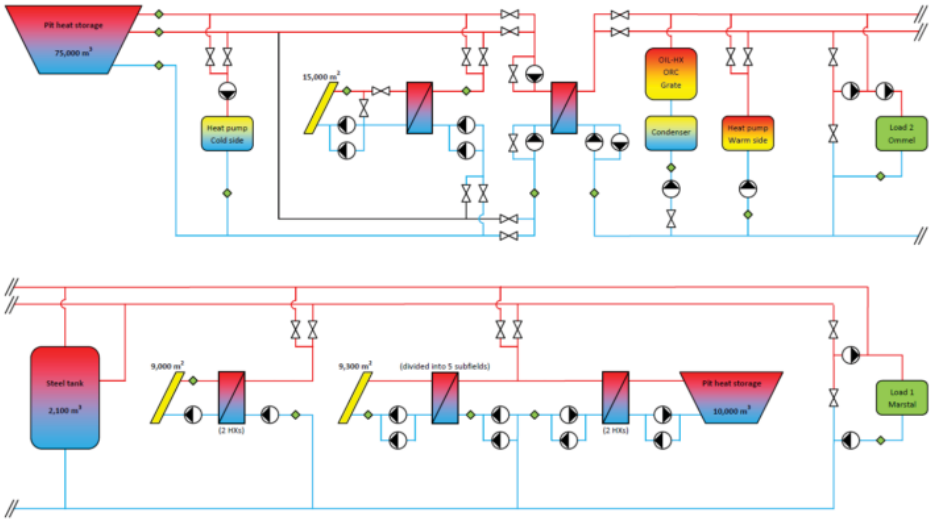

Figure 1. System diagram of the Solar District Heating plant in Marstal (PlanEnergi, 2013b)

The system was chosen as the subject of investigation, as has been the object of research and developments since its construction in 1996 and its operation is well documented (Fan et al., 2009; Heller, 2000; Heller and Dahm, 1999; Sørensen et al., 2012). Moreover, it is entirely based on renewable energy sources and therefore it is interesting in the context of developing such systems in the future.

2.2. Model

2.2.1. Model with simple electric heater

The model of the energy system in question was created by the Danish consultant company PlanEnergi in the TRNSYS software (Solar Energy Laboratory, 2014). The system was modelled in a simplified way, with the demand side represented in an aggregated way and certain simplifications on the supply side. The collector fields were modelled by using three separate 2nd-Order Incidence Angle Modifier (Type 1b) components representing the three collector fields. The largest pit heat storage was modelled in TRNSYS using the non-

standard XST- Seasonal Ground Heat Storage component (Type 342) (Mazzarella and Holst, 1992). Two smaller storages were modelled as non-standard Type 340 (Multi-port water storage) (Drück, 2006). The heat pumps were modelled by a set of equation, not with the use of an existing TRNSYS heat pump component. The annual heat load was set at 32,000 MWh/year, the number of degree-days at 81834.3936 and the GAF ratio at 0.709. GAF is the part of heat demand dependent on the weather conditions (degree days) and the ratio expresses the share of heat demand dependent on the number of degree days in the total heat demand. The electricity prices used in the simulation were Elspot prices for DK-Vest for year 2009 ("Nord Pool Spot," 2016). Elspot is the day-ahead market for electrical energy operated by Nord Pool Spot. Nord Pool Spot is the market for electrical energy that operates in Denmark, Finland, Norway, Sweden, Estonia, Latvia, Lithuania, Germany and the UK ("Nord Pool Spot," 2016). Supply and return temperatures were set based on the measurements in the system. The supply temperatures are between 72 and 77 °C and the return temperatures between 33 and 41 °C. Bio oil boiler was modelled in a simplified way as an Auxiliary heater (Type 6) with the maximum heating rate of 10 MW. The ORC was set to operate from October 7th (280th day of the year) to June 6th (160th day of the year), to avoid using it in the summer period. Both heat pumps already existing in the system were set to operate from September 30th to April 1st (91st day of the year).

The reference model, was then validated by PlanEnergi (PlanEnergi, 2013a) by comparing the results from the model with the measurements taken in the year 2009. The new parts of the installation were disabled in the simulation (thus, no heat pumps or wood chip boiler were taken into account), as it was done before the expansion of the heating plant. The system in its current form and resulting mix of heat production technologies were taken as the reference.

The heat pumps or a potential electric boiler were identified as the elements of the systems that can be used to connect electrical and thermal energy systems. To investigate the possibility of decreasing the biomass use in favour of heat pumps during the low electricity price periods, the above model of the existing system was then modified to simulate the future application.

In an initial phase of the investigation, the system was expanded by a simple electrical heater placed before the wood chip boiler. This was done just to investigate how an additional heating source influences operation of the plant without introducing additional "disturbances" to the simulations. The efficiency of the heater was set to 1 and heat losses in this component were not accounted for. The electrical heater was set to operate during the periods, when the electricity price was below a certain set point. The same way as the ORC, additional electric heater was set to operate from October, 7th to June, 6th, to avoid using it in the summer.

A parameter variation on a) the size of the electric heater b) limit electricity price for the heater operation was carried out by simulation with the above TRNSYS model. The initial investigation for the data from 2009 was performed for electric heater sizes between 0.01 MW and 10 MW and for the price limit for electric heater operation between 0 and 300 DKK/MWh. Then, the range of analyzed electric heater sizes was limited to the range between 0.1 MW and 7.5 MW. This was done, as the smallest of the investigated heat sources did not have any significant influence on the system's operation. On the upper end of the parameter scale, the largest value is chosen to be able to supply the max demand of the whole district heating system. Results showed that values the 10 MW additional heater had power overshooting the largest observed load. Moreover, no significant increase in energy delivered by electrical heater was observed after increasing the heater size from 7.5 MW to 10 MW.

Then, influence of different price levels on the energy delivered by electrical heater (and subsequent reduction in biomass use by ORC unit) was investigated by running the simulations with the Nordic Elspot electricity prices from four different years (Energinet.dk, 2015). This was done to investigate sensitivity of the results concerning the amounts of biomass saved to the electricity prices, with respect to the variation in prices during the last years. Data from 2009 were used for the reference case. For the other three cases, data from 2006 (to represent a year with very high electricity prices), 2013 (a year with high electricity prices) and 2015 (a year with relatively low electricity prices) were used. Price curves for the years between 2000 and 2015 are shown below in Figure 2. The highest prices were not shown in the graph, as they occur for a very short period and do not influence the results of the investigation. It was assumed, that the heat demand was independent from the electricity prices and was the same in all analyzed cases.

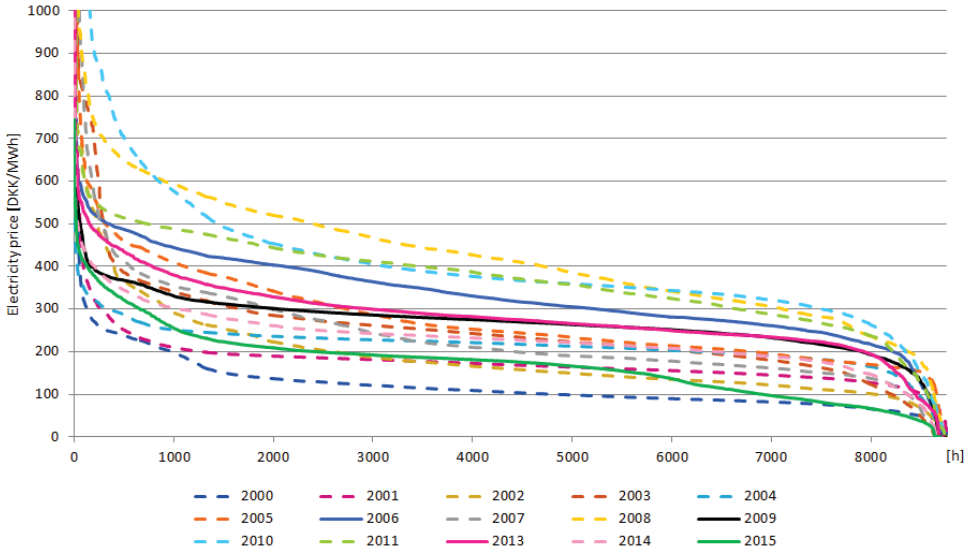

Figure 2. Elspot price curves for the period from 2000 to 2015 (Energinet.dk, 2015)

2.2.1. Model with heat pump

In the above simulation a simplified model with idealizes electrical heater was applied to find the overall potential for substituting part of the biomass use by the excess electricity. In the second model the heat pump was placed in the same spot in the system as the heater. Two sizes of the heat pump were investigated – the first one was chosen to correspond to the 1.25 MW electric heater, the second one to 3.25 MW electric heater. The absorbed power rating for the first heat pump was set at 350 kW and for the second one at 1050 kW.

The general control system in the modified model was not changed compared to the original model applied by PlanEnergy in 2013. The same way as the electric heater before, the heat pump was set to operate from October 7th to June 6th, to avoid using it in the summer period and so its operation substitutes the operation of ORC unit. As the data used is in 1-hour resolution, the concerns about the heat pump compressor turning on and off frequently for very short periods was not considered to be relevant. It was assumed the heat pump is a ground source heat pump. However, as the TRNSYS heat pump component (Type 927) requires more detailed input than the one that could be provided based on the model used, the heat pump was modelled using a set of equations, as two other heat pumps in the system. The equations used were based on the ones used for the propane heat pump. The investigation, due to its general character, was not aimed at optimizing the heat pump operation. It was assumed, that the mass flow through the warm side of the heat pump stays the same as the mass flow directed to boiler. To prevent circular reference, caused by making COP depend on the outlet temperature that at the same time can depend on the COP, the outlet temperature from the previous step was used, the same way it was done for CO_2 heat pump. The resulting COP levels correspond to the ones indicated in "Technology Data for Energy Plants" from Energinet.dk (Energinet.dk, 2012).

$$Q_{warm} = P_{HP} \cdot 3600 \cdot COP_{AHP\ warm} \cdot HP_{ON?} \quad \text{(eq. 1)}$$

$$T_{WS\ out} = min(T_{setpoint} + 5, T_{WS\ in} + \frac{Q_{warm}}{c_{p\ water} \cdot m_{WS\ out}}) \quad \text{(eq. 2)}$$

$$COP_{AHP\ warm} = 0.6 \frac{T_{WS\ out} + 273.15}{T_{WS\ out} - T_{CS\ in}} \quad \text{(eq. 3)}$$

where: Q_{warm} – heat output of a heat pump [kWh], P_{HP} – electrical power used [kW], $COP_{AHP\ warm}$ - Coefficient of Performance of the heat pump operating as a heat source, $HP_{ON?}$ - is the heat pump on (1 if yes, 0 if no), $T_{WS\ out}$ – output temperature on the warm side [°C], $T_{setpoint}$ – setpoint temperature [°C], $T_{WS\ in}$ – input temperature on the warm side [°C], $m_{WS\ out}$ – mass flow on the warm side of the heat pump [kg/h], $T_{CS\ in}$ – input temperature on the cold side [°C].

The TRNSYS model of the modified system with a heat pump can be seen in Figure 3. The figure shows only the water loops of the model – layers with control systems, weather files and outputs were switched off to make the schematics clearer.

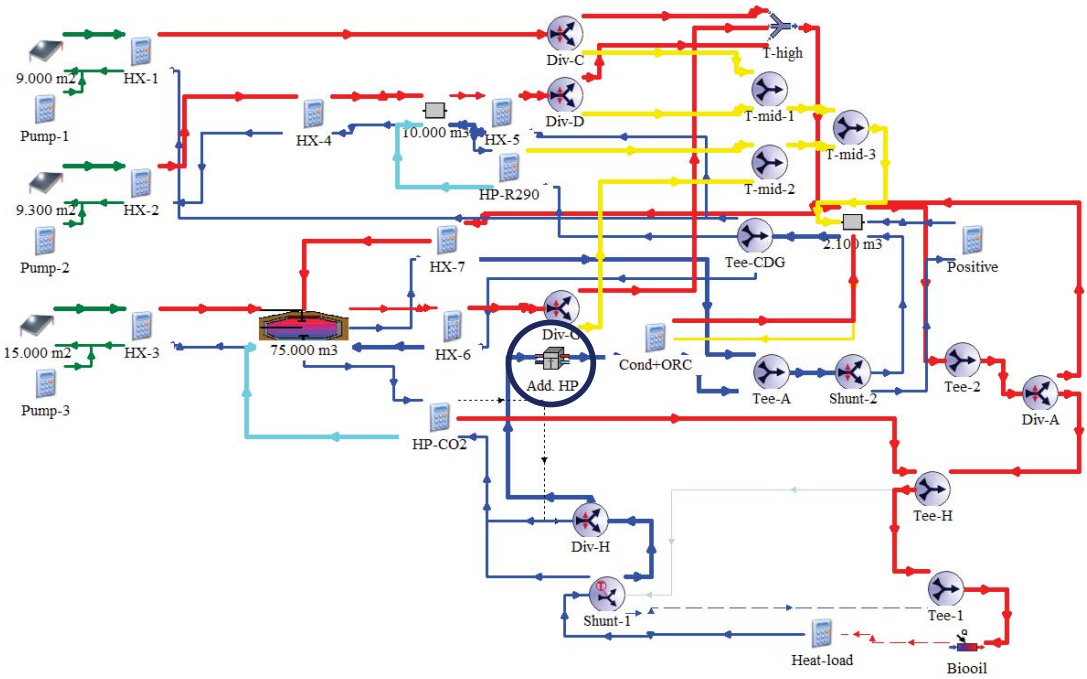

Figure 3. Model of the water loops in TRNSYS after modification. Left side of the model represents solar collector fields, connected to the rest of the system with the use of heat exchangers; followed by the storages (labeled "75..000 m3" and "2.100 m3" and "10.000 m3"); the black circle indicates additional heat source in the system added in the current investigation, "Cond+ORC" represents the woodchip boiler and ORC unit

2.3. Biomass use

The biomass savings were calculated in a simplified way, to estimate the amount of biomass saved thanks to substitution of ORC unit by the heat pump. First, the biomass burned to generate 1 MWh of heat was calculated. The fuel efficiency of the wood chip boiler in the ORC unit depends on the temperature of the cooling water, which is the return temperature from the district heating system. The return temperatures in the district heating system are between 33 and 41 °C, with the average return temperature of 36 °C. So, based on the information from the report by PlanEnergi (2013a), it was assumed the efficiency of the boiler is $\eta = 108\%$. The heating value of the wood chips at 45% of moisture content was estimated as LHV = 2.63 kWh/kg, using the information from (WoodEnergy.ie, 2015). The amount of biomass saved, $m_{biomass\ saved}$, was calculated using eq. 4.

$$m_{biomass\ saved} = \frac{Q_{boiler\ ref} - Q_{boiler}}{\eta \cdot LHV} \qquad \text{(eq. 4)}$$

where: $m_{biomass\ saved}$ – mass of biomass saved [kg], $Q_{boiler\ ref}$ – heat output of the boiler in the reference scenario [kWh], Q_{boiler} – heat output of the boiler [kWh], η – efficiency of the boiler, LHV - lower heating value of the wood chips [kWh/kg]

2.4. Flexibility indicator

There is no one single, universal way of defining flexibility in literature (Alizadeh et al., 2016; Lund et al., 2015). Cochran et al. (2014) used the definition of flexibility as "the ability of a power system to respond to change in demand and supply". While flexibility is often defined as the ability of the system to shift the use of certain amount of energy in time (Nuytten et al., 2013; Six et al., 2011), it can relate to its ability to utilize different energy sources.

Based on the definitions from literature, in the context of this study, the energy flexibility of the system in question was defined as its ability to utilize different energy sources, also called fuel shifting. So, the energy

in MWh that can be shifted over a year in an analysed scenario was used as an indicator of system's flexibility.

3. Results

3.1. Results for the model with electric heater

3.1.1. Change in production distribution and in biomass use

Results of the initial simulations done with the data for 2009 can be seen in Figure 4. The graph shows annual energy production by the biomass boiler in the Organic Rankine Cycle (ORC) unit and electric heater (added to the existing system) in MWh for different electric heater sizes and limit price set-points. It can be seen, that there is a significant increase in energy generation from the electric heater between the limit price of 200 DKK/MWh and 250 DKK/MWh. This is related to the shape of the electricity price curve and elaborated on in the further in the Discussion chapter. It should be noted, that for the heaters greater than 1.5 MW for limit price higher than 225 DKK/MWh temperature in one of the storages exceeded 100 °C. Heat delivered by the ORC and electric heater for these cases was not shown in the graph.

Additionally, the ratios between annual energy generation and heater size were compared for heaters of different sizes at different price limit levels. The results of this comparison indicated, that for the heaters up to 1.25 MW, this ratio remained constant and above that size gradually decreases. However, the smaller heaters were not able to replace significant part of the heat generation from the ORC unit – for the limit price of 225 DKK/MWh, electric heater of the size of 1.25 MW delivered 5.6% of energy generation of ORC unit (1,018 compared to 1,8087 MWh). Hence these sizes are excluded from further analysis.

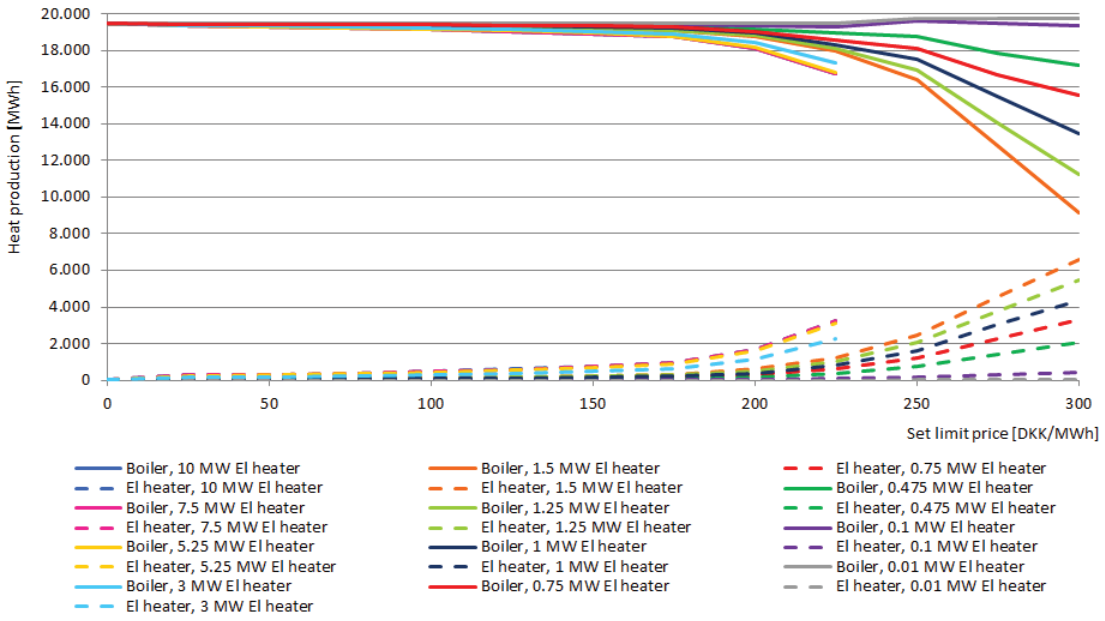

Figure 4. Heat generation by ORC unit and electric heater for different sizes of the heater and different levels of limit price for electricity prices from 2009

Subsequently, the following simulations were run for identical range of limit prices as above, but for the reduced range of heat source sizes 0.1 - 7.5 MW, using the electricity prices for year 2006, 2013 and 2015. Figure 5 shows how much heat can be delivered to the system by 1.25 MW electric heater for different limit price levels for electricity prices from different years. It can be seen that for 2015, a year with relatively low prices (Figure 2), energy delivered increases significantly at much lower limit price than in case of three other years. It can be seen that, as expected, electricity prices during the year have significant impact on the level of substituting biomass by electricity. For example, for the prices from 2006, for the limit price of 225 DKK/MWh, 1.25 MW electric heater delivered 948 MWh, and for the prices from 2013 - 928 MWh.

However, for the price levels from 2015, a heater of the same size delivered 5,981 MWh, so significantly more than both in 2006 and 2013. Additionally, small changes in the limit price may have significant influence on the substitution level, also due to the shape of the price curve. This can be seen for example for the data from 2015, where the energy delivered to the system by electrical heater at the limit price of 200 DKK/MWh is 201% of the energy delivered at the limit price of 175 DKK/MWh for the heaters between 0.1 MW and 1.5 MW.

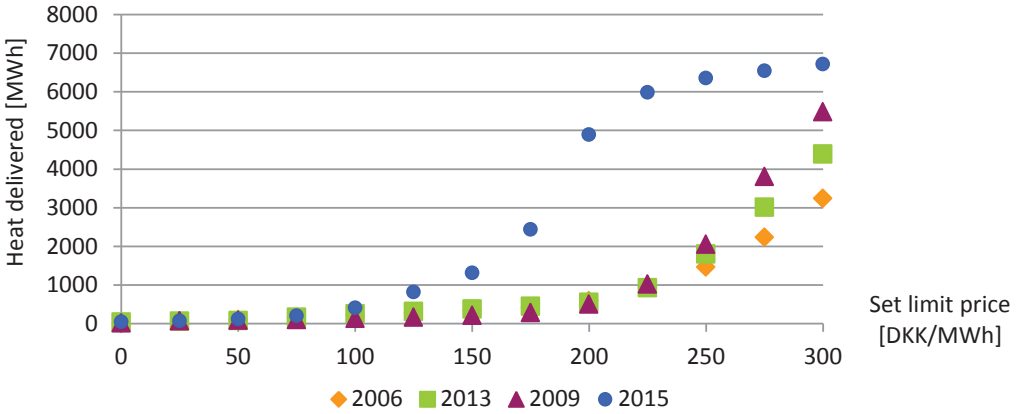

Figure 5. Heat delivered to the system by 1.25 MW electric heater for different limit price levels for electricity prices from different years

Figure 6 shows duration curves for the load, the ORC unit, the oil boiler and electrical heater (in case of the modified systems). All curves are based on results of simulations run with the electricity prices from 2009. Three cases of the systems with additional heater installed were shown: 1.25 MW heater with limit price of 225 DKK/MWh, 1.25 MW heater with limit price of 250 DKK/MWh and 3 MW heater with limit price of 225 DKK/MWh. It can be seen again that the slight increase in limit price resulted in significantly greater number of operation hours for the electric heater. Reduction in ORC unit operation occurred for all three shown cases, the greatest for the case with 1.25 MW heater and limit price of 250 DKK/MWh. The differences between cases with 1.25 MW heater and different limit prices is greater than between the case with 3 MW and 1.25 MW at the same limit price. However, it should also be noticed that the use of bio oil boiler is greatest for the case with highest degree of ORC unit substitution. This is caused by the fact that the operation of the electric heater prevents ORC unit from turning on, but the heat supplied is not sufficient to cover the system demand.

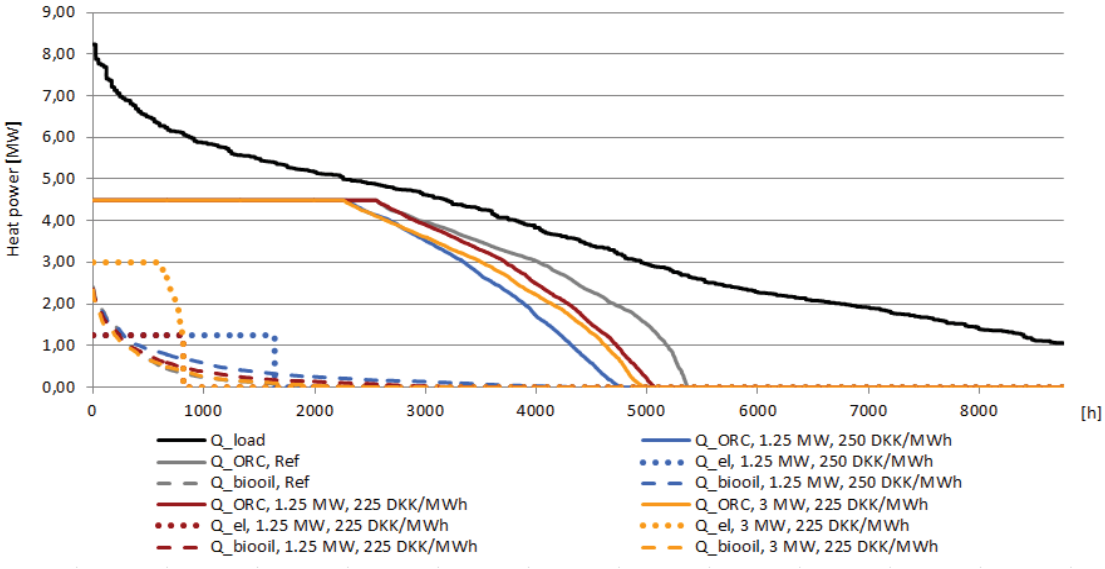

Figure 6. Duration curves for the load, the ORC unit and the oil boiler for the reference system

It was observed, that heater size at which the heat delivered by bio oil boiler changes the least between 2.70 - 3.25 MW. Thermal output of the ORC unit is 3.25 MW. This is caused by the fact that the operation of the electric heater prevents ORC unit from turning on, but the heat supplied is not sufficient to cover the system demand. Another problem at the investigated system configuration is the injection of the heated up water to the cold part of the 2,100 m^3 storage tank. This is also the reason of the overheating in 10,000 m^3 tank that occurs in systems with large supplementary electric heater at high limit prices, so if the heater operates for many hours during a year (exact level of the limit price depends on the price levels in a given year). Table 1 shows more detailed information about heat delivered by different technologies in the system and about calculated heat losses from heat storages. All the results presented in the table were calculated using electricity prices from 2009.

Total	31.997	32.000	31.998	31.999

After this initial observation, additional simulations were run with the electric heaters at sizes between 1.5 and 5.25 MW. It was observed, that heater size at which the heat delivered by bio oil boiler changes the least between 2.70 - 3.25 MW. Thermal output of the ORC unit is 3.25 MW. This is caused by the fact that the operation of the electric heater prevents ORC unit from turning on, but the heat supplied is not sufficient to cover the system demand. Another problem at the investigated system configuration is the injection of the heated up water to the cold part of the 2,100 m^3 storage tank. This is also the reason of the overheating in 10,000 m^3 tank that occurs in systems with large supplementary electric heater at high limit prices, so if the heater operates for many hours during a year (exact level of the limit price depends on the price levels in a given year).

It was decided that for the needs of this study, the configuration of the system will not be modified. However, if the additional heat source is to be installed in the suggested place in the system, modification of the system and adjustment of the control scheme is necessary. This is further elaborated on the in the Discussion section.

3.1.3. Sizing of the supplementary heat source

Based on the initial investigation, two sizes of the heat pump were proposed 1.25 MW and 3.25 MW. The 1.25 MW heat pump was chosen, as it was the largest electric heater size for which the ratio between annual energy generation and heater size remained the same as for all smaller heaters. The 3.25 MW heat pump was chosen to investigate the situation where the supplementary heat pump has the same thermal output as the ORC unit.

3.2. Results of the simplified heat pump investigation

Schematic of the system with heat pump in question is shown in Figure 3. Results of the performed simulations can be seen in Figure 7. Heat generation by ORC unit and additional heat pump for different sizes of the heat pump and different levels of limit price for electricity prices from 2009 The graph shows annual energy production by the biomass boiler in the Organic Rankine Cycle (ORC) unit and heat pump in MWh for two heat pump sizes and different limit price set-points. It can be seen, that there is a significant increase in energy generation from the heat pump between the limit price of 200 DKK/MWh and 250 DKK/MWh, similarly as it was for the simplified electric heaters. It should be noted, that for the larger heat pump 250 DKK/MWh temperature in one of the storages exceeded 100 °C, similarly as it was in case of the electric heater. Energy delivered by the ORC and electric heater for these cases was not shown in the graph.

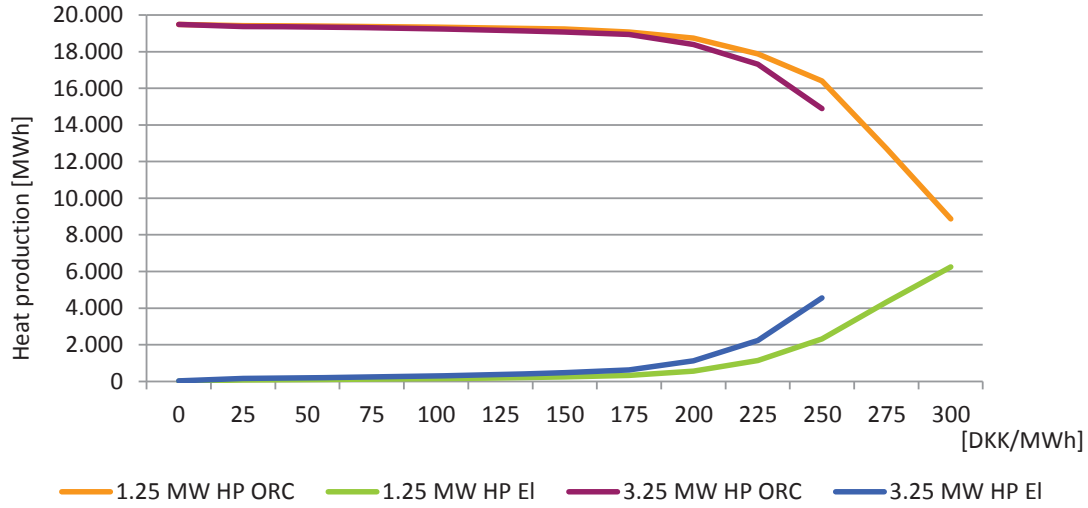

Figure 7. Heat generation by ORC unit and additional heat pump for different sizes of the heat pump and different levels of limit price for electricity prices from 2009

3.2.1. Change in production distribution and in biomass use

Figure 8 shows the energy production in each month both for the reference case and for two heat pump cases, with the share coming from bio oil use and delivered by heat pump highlighted (yellow parts). It can be seen, that they do not constitute significant part of the production. However, introducing the heat pump to the system leads to the decrease in heat production from biomass boiler in the ORC unit that is directly substituted by the heat pump. This shows the potential for biomass savings due to a combination of low electricity prizes and the potential of the heat pump installed. It can be seen, that this potential in the proposed setup is not significant compared to the energy output of the whole system.

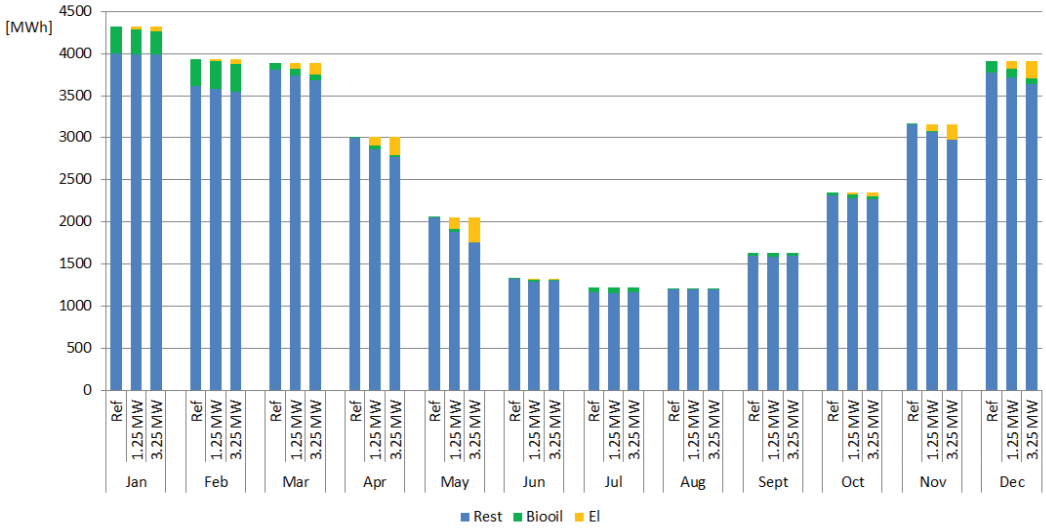

Figure 8. Monthly heat production for the reference case and two heat pump cases with the production from bio oil boiler and additional heat pump highlighted

Amount of biomass saved annually thanks to the use of heat pump for two investigated heat pump sizes at different limit prices is presented in

Table 2.

Table 2. Biomass saved for two investigated heat pump sizes at different limit price levels

Limit price [DKK/MWh]		25	50	75	100	125	150	175	200	225	250	275	300
Biomass replaced by electricity [tonne]	1.25 MW HP	18	26	35	47	64	84	145	260	563	1080	2381	3734
	3.25 MW HP	36	46	62	82	110	143	189	381	759	1613		

3.3. Flexibility of the system

Finally, the flexibility of different systems was compared. We decided to use the energy in MWh that can be shifted over a year as an indicator of system's flexibility under chosen control conditions. System's flexibility understood that way increases with the increase in the size of additional heat source. For the system with 1.25 MW heat pump was calculated to be 153 MWh annually for the set limit price of 100 DKK/MWh, 320 MWh for 175 DKK/MWh and 2324 MWh for 250 DKK/MWh. For the system with 3.25 MW heat pump it was calculated to be 301 MWh annually for the set limit price of 100 DKK/MWh, 630 MWh for 175 DKK/MWh and 4552 MWh for 250 DKK/MWh. After adjusting the system control to cope with additional large heat source, the flexibility indicators independent of the control scheme and set limit price should be established. This is further elaborated on in the Discussion.

4. Discussion

One of the assumptions made in the analysis is related to the use of electricity prices as an input for control system. In the study, electricity prices from Nordic Elspot market were used as a control signal for the additional electricity-based heat source, with a constant price limit indicating whether the electric heater / heat pump should turn on or not. Low electricity prices occur in periods when expected demand is relatively low compared to the expected supply. Very low electricity prices in Denmark are frequently associated with periods of high electricity production by wind turbines. However, middle-sized district heating utilities are not participating in trade at Nord Pool. So, in the current conditions, proposed solution brings no economic benefit for the district heating plant and is beneficial only from the perspective of energy system as a whole.

It was assumed, that the heat demand was identical for all analyzed cases for different electricity prices and thus, indirectly, that heat demand and electricity prices are fully independent. This is a simplification. However, it was decided that electricity market prices are influenced by numerous factors not connected to the local heat demand and that such an assumption provides a good way of investigating the influence of electricity prices during a year on the analysis' results.

Another factor that significantly influences the results is the set limit price and market electricity prices. As it was discussed in section 3.1, the exact energy delivered to the system by additional electricity-based heat source during a year is very sensitive to the set limit price and price levels on the electricity market. This causes trouble in case of a potential economic analysis, when estimating e.g. Net Present Value of the system's modification. Additionally, results of such analysis would be also heavily influenced by assumptions on future energy market and taxation.

In the proposed system setup, operation of the additional heat source competes with the operation of ORC unit. So, if the district heating utility benefits from selling electricity generated by the ORC unit, adding additional heat source in proposed configuration decreases this profit. However, it can be argued, that generating electricity during the low-price periods does not benefit energy system as a whole and should be avoided.

As it was mentioned in section 3.1.1, it was decided that for the needs of this study, the configuration of the system will not be modified. However, if the additional heat source is going to be installed in the system, adjustment of the setup and control strategy would be necessary. Such an adjustment would have to include connections between the electric heater / heat pump, boiler and ORC unit and heat storages. Moreover, it should be assured that the operation of the additional heat source does not result in increase in energy delivered by the bio oil boiler – both for economic and for environmental reasons. After this adjustment, also the flexibility indicator for a given system configuration should be estimated, by calculating theoretically possible heat production by the additional electrical heat source when the set limit price is higher than highest electricity price during a year.

5. Conclusions

We showed in the paper that cheap electrical energy can replace scarce biomass in a large-scale solar heating plant with large storage capacities. However, location of the additional heat source in the system and control scheme for the new setup need to be carefully considered, as there is a risk the new heat source will destabilize system's operation, as it was shown. Increasing the size of additional heat source increases also system's flexibility, understood as the ability to utilize different energy sources, but makes incorporating in the existing system more difficult and results in high investment costs. Results of the performed study indicate, that for the system in question the potential for such a replacement is not significant. Additionally, results are characterized by large uncertainties due to the significant influence of the level of electricity prices on the results in the proposed control strategy. While the investigation was made based on the solar district heating plant and renewable-based district heating system in Marstal, Denmark, we believe that such solution can also be applicable for other similar systems, where biomass is used as supplementary heat source.

In further work, we will investigate the possibility of replacing biomass that may become a scarce resource, by cheap electricity from renewable sources for a district heating system with seasonal storage based on different energy sources than solar energy. This will be done for a generic model also with that will be

applied on concrete city districts.

6. Acknowledgement

The authors thank Danish EUDP EnergyLab Nordhavn for funding. Additionally, the authors would like to thank Niels From and Per Alex Sørensen from PlanEnergi for their input, provided model of the system and information about the solar district heating plant.

[3] ENEA Casaccia Research Center, Rome (Italy)

Abstract

A solar multi-generation approach has been implemented through four demonstrative plants in Italy, Cyprus, Jordan and Egypt based upon solar concentrating collectors. Different design options have been developed, including technologies that have been adapted and downsized from the utility scale of CSP plants, with the aim to be integrated at building, settlement and community scale. Demo plants have been conceived as living labs in order to support the further development of the technologies in a real-life environment, supporting the local smart specialization strategies in collaboration with SMEs, local stakeholders and citizens.

Keywords: *multi-generation, solar thermal, CSP, storage, concentrating solar collectors, solar cooling, building integration, smart specialization, living labs*

1. Introduction

Global space cooling energy consumption increased by 60% between 2000 and 2010, reaching 4% of global consumption (OECD/IEA Report 2013), meanwhile the production of heat accounts for more than 50% of global final energy consumption (OECD/IEA Report 2014). The seasonal switch among the winter demand of heat and the summer demand of cold is already a characteristic of the solar belt regions, including the Mediterranean area. Therefore, specific efforts are needed in piloting innovative approaches to cover the complex mix of heat, electricity, cold and other energy driven services by an optimized harvest, storage and conversion of the solar radiation. As a matter of fact, seasonal demand can be holistically managed at a settlement level by multi-generative solar concentration systems; the collection of high quality solar radiation, mostly available in summer periods, can feed a solar cooling system in the hot days, while the same collectors can cover the moderate heat demand in winter-time. Electricity can be generated from small turbines or integrated PV panels. Residual heat can be used to drive other services, as the purification of brackish, waste water or sea water desalination. Since November 2012, such a challenge is undertaken through the Small scale Thermal Solar district units for Mediterranean communities (STS-Med) project, supported by the ENPI- CBCMED program, with the construction of 4 pilot plants:

- in Palermo, Italy, led by Consorzio ARCA - coordinator of STS-Med - in the campus of the University of Palermo, in partnership with the Italian National Agency for New Technologies, Energy and Sustainable Economic Development (ENEA) for the Thermal Energy Storage (TES) system,
- in Aglantzia, Cyprus, led by the Cyprus Institute (CyI), in the campus of the institute,
- in Markaz Belbes, Egypt, at Sekem Hospital, led by Academy of Scientific Research and Technology (ASRT) and built by Elsewedy Electric,
- in Irbid, Jordan, led by Al Balqa Applied University (ALBUN) and built by Millennium Energy Industries.

The 4 plants demonstrate that a smart integration and optimization of both commercially available and innovative solar technologies can open a way towards the goal of "zero energy" communities in the Mediterranean region (Rashad et al. 2015 and Kiwan et al. 2016).

doi:10.18086/eurosun.2016.05.06 Available at http://proceedings.ises.org

Figure 1. Novel Technologies Laboratory (left), rooftop of the University College in Irbid (right)

The buildings concerned self-produce the energy they need through sustainable systems, integrated at a settlement level, with a significant reduction of CO_2 emissions and consumption especially in seasonal peak. The design of each demo site has been adapted accordingly with the result of specific energy audits and the availability of either ground or roof space for the collectors. Local communities have been involved in awareness activities and local SMEs have been invited to take part into educational activities during the preparatory and erection phases.

In Italy, the collectors are installed in a field nearby the building and the plant is generating electricity by an existing ORC (Organic Rankine Cycle) and heat/cold with the help of an absorption chiller integrated on the HVAC system. The case-study in Cyprus is located in the premises of the Cyprus Institute in Aglanzia (district of Nicosia), Cyprus. The objective of the plant is to support the heating, cooling and hot water system of the Novel Technologies Laboratory (NTL, Figure 1, left) by reducing the use of the existing electric heat-pumps. NTL was designed to be a "near to zero energy" building (Papanicolas 2015 et al.) by a specific selection of the materials and orientation of the windows and walls, which minimize the energy demand for air-conditioning. A 14.5 kW peak power photovoltaic generator covers a part of its electricity consumption. In Jordan the collector is installed on the roof of one of the buildings at University College in Irbid (Figure 1, right). As for the Cypriot plant, the system is installed on the roof a public building (Figure 2, right). The objective of the plant is to provide heating and cooling to classrooms of the university and hot water in case of over-production. A small steam turbine can be activated to generate electricity. The pilot plant in Egypt is located in Belbes to support Sekem medical center HVAC, at 60 km from Cairo city center as the crow flies. The collector is installed on plain field next to the hospital. A small ORC turbine is generating electricity balancing the seasonal demand of cold.

2. Solar collectors

As shown in Figure 2 and Figure 3, solar fields in Cyprus, Egypt and Italy are based on North-South aligned Linear Fresnel Collectors (LFC) or Linear Fresnel Reflectors (LFR). The installed LFRs, specifically designed for integration in built environments, have been developed by Idea (Vasta 2013 et al.), an Italian company affiliated to Consorzio ARCA. In Jordan the plant relies on a Parabolic Tough Collector (PTC, Figure 3) manufactured by the Italian company Soltigua. The characteristics of the collectors are detailed in Table 1. Platforms are located at different latitudes, from 30°25'05.5"N in Egypt to 38°06'01.0"N in Italy.

Figure 2. LFR at Palermo, Italy (left) and Nicosia, Cyprus (right)

Figure 3. PTC at Irbid, Jordan (left) and LFR at Egypt Markaz Belbes (right)

Table 1. Characteristics of the solar fields

	Cyprus	Egypt	Italy	Jordan
Location	Aglantzia, on the roof of a school, next to the NTL	Markaz Belbes, nearby the Sekem medical center	University of Palermo, on the ground at ARCA premises	Irbid, roof a building of the Balqa University College

Average DNI per year (Source: SolarGis)	2142 $kWh.m^{-2}$	1958 $kWh.m^{-2}$	1703 $kWh.m^{-2}$	2377 $kWh.m^{-2}$
Type of collector	LFR - Idea	LFR - Idea	PTC - Soltigua	LFR
Global aperture area	184.32 m^2	299.50 m^2	483.84 m^2	163.2 m^2
Thermal oil, Heat Transfer Fluid (HTF)	Duratherm 450	Therminol 66	Paratherm NF	Seriola eta 32 - Total Lubmarine
Peak thermal power	70 kW	115 kW	190 kW	85 kW
Total receiver length	32 m	52 m	84 m (3 x 28 m receivers rows)	38.56 m
Working temperatures (outlet)	170°C	140°C	280°C	240°C

All the collectors are working with thermal oil as heat transfer fluid (HTF) at different temperature: from 140°C to 280°C. The total thermal peak power of the plants is 460kW. The platform in Palermo is the main contributor with 190kW with 3 identical LFC parallel loops. Figure 4 shows a simplified layout of the solar plant installed in Sicily.

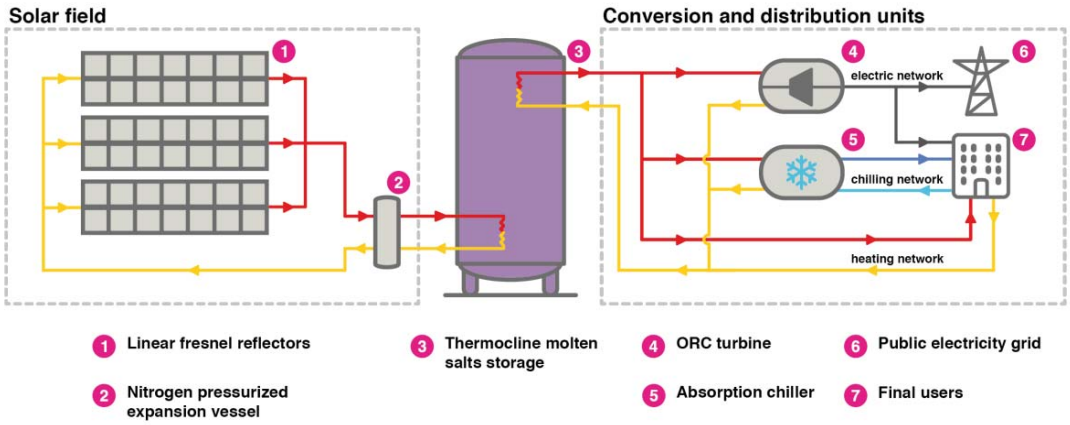

Figure 4. Layout of the field at ARCA (Sicily)

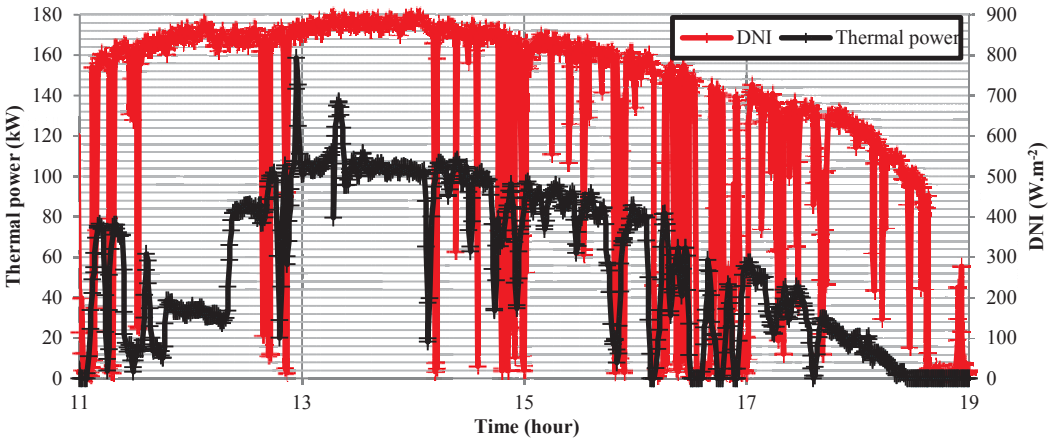

Figure 5. DNI and thermal power on the 6th of September 2016 (Italy)

The thermal power and DNI on the 6th of September 2016 are shown in Figure 5. A peak of 160kW was achieved at 12.30PM. In Cyprus 70kW peak power is installed. On the 26th of July 2016, the Fresnel collector was commissioned. Thermal power and DNI are show in Figure 6. The output power reached 68.7 kW with a DNI of 800 $W.m^{-2}$ at 12.52PM.

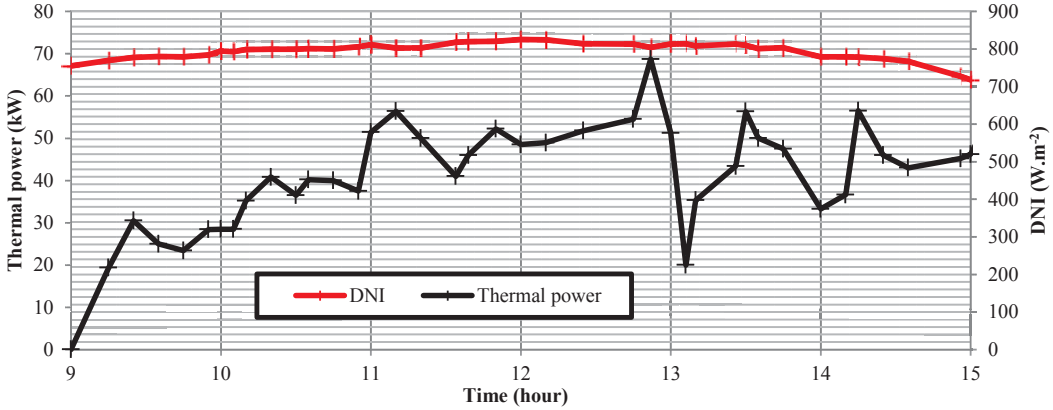

Figure 6. DNI and thermal power on the 26th of July 2016 (Cyprus)

The peak power installed in Egypt is 115kW and 85kW in Jordan. All the 4 for plants are equipped with a vacuum receiver and with the association of a secondary reflector for the LFRs in Cyprus, Egypt and Italy with estimated 90% optical efficiency. DNI is the highest in Jordan with 2377$kWh.m^{-2}$ per year. DNI in Cyprus is 2142$kWh.m^{-2}$ per year and in Egypt 1958$kWh.m^{-2}$ (Source: SolarGis Imaps, Beták et al. 2012). DNI in Palermo is the lowest with 1703 $kWh.m^{-2}$ per year. The solar fields were all completed in September 2016. Dimension of the mirrors of the 3 LFRs are identical: 0.32m x 2.000m. Cypriot LFR was the first to be installed on the island (Montenon and Fylaktos 2016). It is composed of 288 mirrors with a reflective area of 184.32 m^2, driven by 72 DC motors (4 mirrors per motor). In Egypt, the system is composed of 468 mirrors and the reflective area is 299.52 m^2, but driven by 13 DC motors (36 mirrors per motor). The Italian field is hybrid: 2 LFC modules are configured as in Egypt and the third collector is configured according to the Cypriot model. In this way it is possible to lead comparisons between the two strategies. On the one hand in Cyprus the flexibility of the field is higher but requires more maintenance due to larger number of motors: if one motor fails, the system will be only slightly impacted and can continuously operate with the rest of the 71 motors. On the other hand, the Egyptian collector relies on fewer motors, so requiring less maintenance, but if one motor has to be changed a larger area of the solar field will be impacted; furthermore, tracking angles of the motors is not independent and the whole field cannot be placed in flat position for cleaning purpose for instance. In Cyprus and Italy, HTF loops are separated from the thermal storage medium. Nonetheless, small buffers are installed in the HTF loops in order to stabilize the temperatures.

Figure 7. HTF Loop at CyI (Cyprus) : oil loop (left) and pressurized vessel (right)

As shown on the main layout (Figure 4), in Sicily, on the field installed at ARCA a buffer tank is also integrated in the HTF loop with a total volume of 800L containing 500L of thermal oil (Paratherm NF) pressurized with nitrogen at 3bar (for a thermal storage capacity of 22kWh). In Cyprus the thermal oil (Duratherm 450) is stored temporarily in an 800L tank (containing 425L of oil), pressurized with nitrogen at 3bar (Figure 7). A 3kW electric heater is wrapped around the tank to pre-heat the oil in case of cold start-up. The role of these tanks is also to stabilize the outlet temperature of the piping. Pre-heating the oil decreases the viscosity of the HTF and increases the Reynolds number to maintain it above 10,000 (turbulent flow). Based on experience, the solar absorber pipe bends at low ranges of the Reynolds number, due to thermal gradients, and it may get in contact and break the external glazing pipe. As soon as the oil inside the buffering tanks is heated to a satisfactory value, the inverter pump of the HTF loop starts. The control of the platforms in Cyprus and Italy aims to correlate the output with the real time value of the DNI. To that end, two pyrheliometers are installed on the respective sites (Figure 8).

Figure 8. Pyrheliometers at ARCA (left) and the Cyprus Institute (right)

3. Thermal storage

Thermal storage is a key element of the four platforms. It permits to buffer the production for some minutes to several hours. Details of the thermal storage in use in the 4 platforms are exposed in Table 2. In the plants built in Jordan and Egypt, the HTF is directly stored respectively at 240°C and 140°C. In both Cyprus and Italy, a heat-exchanger transfers the heat from the oil to TES system. In Cyprus thermal storage is based on water pressurized with nitrogen up to 146°C ensuring 2 hours of autonomy for cooling in summer or 4 hours for heating in winter. The same nitrogen tank is used to pressurize the thermal oil (Figure 9). Storage with water is a low cost technology and vessels are available on Cypriot market.

Table 2. Thermal storages

	Cyprus	Egypt	Italy	Jordan
Medium	Pressurized water	Thermal oil (Therminol 66)	Ternary molten salts mixture	Thermal oil (Seriola eta 32 - Total Lubmarine)
Storage Volume	2.0 m^3	2.8 m^3	8 m^3	1.3 m^3
Storage capacity	100 kWh	21 kWh	400 kWh	30 kWh
Average temperature	146°C	140°C	260°C	240°C

Figure 9. Buffer of oil, expansion vessel, thermal storage tank (left to right) at CyI (left) and molten salts storage, oil storage and expansion tank (left to right) at ARCA (right)

Safety relief-valves are installed on the tank in case of over-pressure. The developed TES integrated in the pilot plant built in Sicily includes innovative features. Different options have been reviewed. TES systems commonly applied in conventional CSP plants operate with "solar salts" (molten nitrates mixture $NaNO_3/KNO_3$ 60%/40% of weight distribution), in two-tanks heat storage system operating from 290°C (cold tank) to 385°C (hot tank) when oils are used as HTF in the solar field (Lovegrove and Stein 2012). In small CSP plants (lower than 1MW range) it is rather difficult to replicate such a complex scheme due to the lower operative temperatures (280°C maximum in Sicily) and principally due to the need of expert personnel to manage molten salts loops too. Therefore, an innovative TES system has been specifically developed in STS-Med project. It is also based on molten salts, but the management of the TES is eased. This is lower than the melting point "solar salts", which is around 220°C (Serrano et al. 2013). Hence, the temperature range is much more compatible with the above-mentioned small-medium CSP temperatures (up to 300°C). Also the "two-tanks" configuration is replaced by a single-tank system avoiding any external pumping of the molten salts and the critical management of pipelines against freezing. In the developed TES at ARCA, all the typical operations of a CSP plant of charging and discharging are achieved inside the single buffer tank where given temperature gradients and molten salts circulation are easily determined. Therefore, besides lower equipment volume and cost reduction potentials, the plant operator does not have to manage molten salts flows. Thus, the developed TES is tailored for residential users and fits into the STS-Med requirements. The developed TES system is represented in Figure 10. The operation concept is based on the properties of unmixed molten salts in the tank to thermally stratify along the vertical axis, as an effect of their low thermal conductivity and the density variability with temperature. Two heat exchangers are immersed in the zones where the temperature is lower (bottom) and higher (top) to be operated during the charging and discharging phases. In a conventional two-tanks TES systems with the high temperature tank at $T_{S\text{-}high}$ = 385°C (and the low temperature tank at $T_{S\text{-}low}$ = 290°C) about 280 m^3 of "solar salts" shall be loaded to store 20 MWh thermal energy, to drive a steam Rankine cycle.

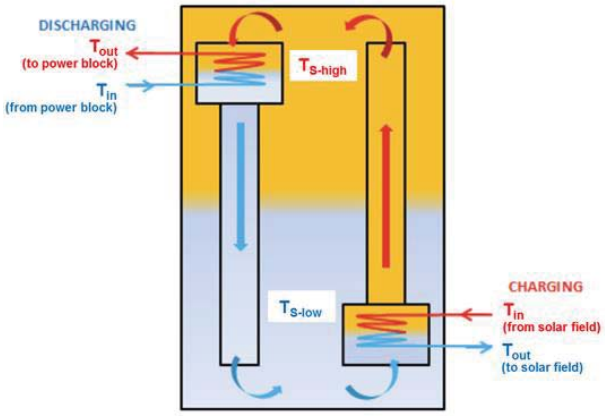

Figure 10. Optimized TES system developed for STS-Med: general scheme with explanatory working conditions (left) and prototype drawings (right)

The same principle can be applied to a smaller TES system with maximum temperature of 300°C, combined with an Organic Rankine Cycle. In the pilot plant in Sicily, TES is filled up with about 7 m^3 of eutectic ternary salt mixture (42%/15%/43% of weight distribution). Considering the reduction of the overall amount of salt, the use of a single tank instead of two tanks and the avoidance of external molten salt pumps and pipelines, the cost (€/kWh thermal) of this optimized heat storage system developed can compete with the large scale CSP benchmark.

In the framework of the STS-Med project a small TES prototype of 0.96 m^3 has been designed, built, installed and successfully tested at ENEA-Casaccia research center (Rome) in order to validate the concept before the installation in the pilot plant in Sicily. Loading, mixing, and melting procedures of the salts in the TES have been studied. The experimental results and concept validation with the prototype enhanced the design of an up-scaled TES for the demonstration plant in Palermo. Specifically, further optimizations and improvements have been performed in a "new" version of the TES installed in the STS-Med pilot plant in Sicily. This upgraded prototype is designed to work in a thermal range of 160-280°C. It is characterized by an inner volume around 8.0m^3 (1.8m diameter, 4m height) corresponding to effective heat capacity of about 400kWh (thermal). The charging/discharging thermal power averages 250/125 kW (thermal). The tank has been insulated with a 20cm coating of rock wool.

4. Cooling, heating and hot water

4.1. Cooling

Cooling is the central task of all the STS-Med platforms, due to climate considerations in the Mediterranean areas concerned by the project. The 4 plants rely on absorption chillers (Figure 11) to provide chilled water at 7°C. The global cooling capacity of the platforms averages 110.1kW. Chillers in Cyprus, Egypt and Italy are LiBr (Lithium Bromide) based, while in Jordan it is ammonia based. In Cyprus, the model used is YAZAKI WFC-SC10. It is water-fired at low temperature (88°C inlet, 83°C outlet). Its cooling capacity is 35kW with a COP (Coefficient of Performance) of 0.7.

Table 3. List of absorption chillers

	Cyprus	Egypt	Italy	Jordan
Model	YAZAKI WFC-SC10	YAZAKI SH10	Broad BCT 23	Robur ACF 60-00 HT
Type	LiBr – Single effect	LiBr – Single effect	LiBr – Double effect	Ammonia – Single effect
Firing medium	Water	Thermal oil	Thermal oil	Thermal oil
Cooling capacity	35 kW	35 kW	23 kW	17.1 kW
Inlet temperature	88°C	88°C	200°C	240°C
COP cooling	0.7	0.7	1	0.6
Heating capacity		48.3 kW	23 kW	

Figure 11. Absorption chiller and cooling tower at CyI (left) and at ARCA (right)

The heat is transferred to the absorption chiller from the thermal storage medium through a heat-exchanger (pressurized-water and water). Then the heat is stored in a 500L tank of water. This stabilizes the inlet temperature for the chiller. A cooling tower dissipates the heat from the absorber and condenser chambers (Figure 11). In Egypt the same capacity chiller is used but the heat medium is thermal oil instead of water. In Italy, the double effect absorption chiller is the most performant with a COP of 1 and it includes its own cooling tower (Figure 12). The cooling capacity is 23kW. The Jordanian chiller is a Robur HT model with a cooling capacity of 17.1kW at COP 0.6. Its working temperature is 240°C.

4.2. *Heating and hot water*

The absorption chillers in Egypt and Italy are also heating in winter with better COP than cooling. Heating capacity is 48.3 kW in Sekem and 23 kW in Palermo (Figure 11). In Cyprus the absorption chiller is simply by-passed to heat directly two water stratified tanks (2000L each). The heat is supplied to the Air Handling Units (AHU) and the Fan Coil Units (FCU) for the offices of the NTL. In Jordan, the absorption chiller is also by-passed in winter. If the available solar energy exceeds the cooling and electricity generation demands, the excess heat is released to hot water network through shell and tubular heat-exchanger. The heated water is then stored in a tank. If the excess heat exceeds the storage capacity, it is dissipated by dry cooling.

5. Electric power units

Platforms in Egypt and Italy (Figure 12) cogenerate with ORCs (Organic Rankine Cycles) fired with thermal oil. They both have an electric capacity of 10 kW and gross efficiency of 10% (Table 4) and need a cooling tower to dissipate the heat rejection. They produce electricity in parallel with heating or cooling. The ORC in Egypt works with inlet temperatures of 125°C to 150°C. In Jordan the oil exchanges its heat with a steam loop to operate a demonstrative steam turbine of 1.2kW of electric power (Figure 12).

Table 4. Power units in Egypt, Italy and Jordan

	Egypt	Italy	Jordan
Element	ORC	ORC	Steam turbine
Electric power	10 kW	10 kW	1.2 kW
Medium	Thermal oil	Thermal oil	Steam

Figure 12. Steam turbine during the installation in Irbid (left) and ORC Rank turbine in Palermo with cooling tower (right)

6. Conclusions

Nowadays solar concentration platforms are designed to produce several thermal MW and generally for electricity generation in desert places. STS-Med project demonstrated the possible application of solar concentrating technologies within integrated multi-generative plants at small/middle scale in built environment either on the ground (Egypt and Italy) either on roofs (Jordan and Cyprus). Production of heat to directly drive absorption chillers through thermal energy storage permits to avoid the stage of transformation to electricity. The residual heat can be used for electricity production with the help of ORCs. Thus, the co-generation of heat and electricity reduces the global balance of the energy consumption of

buildings and not only the electric part. The thermal storage permits to shift the production at peak load with good flexibility. In the plant built in Sicily an innovative thermal energy storage system based on the use of molten salts and specifically tailored for small scale concentrating solar applications has been integrated. The main limitation to downscale solar cooling is the lack of commercial small scale absorption chillers and ORCs. At the same time COP of absorption chiller, even with double-effect, is still poor if compared to electric heat-pumps. Efficiency of small ORC turbine is also poor and their application at the project scale (5-10 kW) can be considered as demonstrative of larger (50-100kW) applications. In this scope, the 4 plants have been conceived as living labs, introducing the technology mix into different real-life environments acting as showcases for the respective local communities. Comparative studies of design options and subsystems will permit to identify the best strategies for the overall optimization of both efficiency and cost; at the same time the local academic and technical communities will have a joint and open access to the demo facilities as platforms for future collaborations and developments.

7. Acknowledgments

The Small Scale Thermal Solar District Units for Mediterranean Communities (STS-MED) project was financed by CrossBorder Cooperation initiative funded by the European Neighbourhood and Partnership Instrument (ENPI). In its scope, the project aimed to raise 4 pilot solar plants for air-conditioning and electricity generation in four different locations: Cyprus, Jordan, Egypt and Sicily. We would like to thank the European Neighbourhood and Partnership Instrument, as well as the 14 partners in the project (Consorzio ARCA, ENEA, Sicilian Region, CEEI, CEA, IASA, Egyptian new and Renewable energy ministry, ASRT, Elsewedy Electric, Jordanian Ministry of Energy and Mineral Resources, ALBUN, Millenium Energy Industries, Cyprus Chamber of Commerce and Industry and CyI).

Abstract

A new CSP plant combined with biomass CHP, using ORC technology, will be built and taken into operation in Brønderslev, Denmark during spring 2017. The price for Biomass is expected to increase with more and more use of this very limited energy source and then CSP will be cost effective in the long run, also in the Danish climate. Oil is used as heat transfer fluid instead of steam giving several advantages in this application for district heating at high latitudes. Total efficiencies and costs, competitive to PV plants, are expected.

Keywords: *CSP, ORC, CHP, Biomass.*

1. Introduction

In the report "ORC og dampmotor til små flisfyrede varmeværker" [1] the potential for installing ORC-units in Danish district heating plants with wood chip boilers, is calculated to approximately 30 utilities with more than 20,000 MWh in yearly heat production. The first Danish plant (4 MW heat and 0.75 MW electricity) was implemented in December 2011 in Marstal. Aalborg CSP has developed a concentrating solar collector that has been demonstrated in pilot plants. 800m^2/0.6MW in Thisted, 1350m^2/0.8MW in Brønderslev and 4000m^2 / 2.8MW in a Combi plant in Tårs.

The Technical University of Denmark (DTU) has evaluated the performance of the parabolic trough array design in these plants at temperatures up to 350°C [2, 4]. The result was an array efficiency curve with a maximum efficiency of 0.75 and a total heat loss coefficient of only 0.04-0.06 W/m^2/K, in the temperature range 100-350 °C.

The Brønderslev district heating company expects lack of biomass in the future, resulting in higher prices. They therefore want to implement a CSP-plant, to supply the ORC with hot oil from a CSP collector array in periods with enough DNI (Direct Normal Irradiance).

doi:10.18086/eurosun.2016.05.02 Available at http://proceedings.ises.org

2. The Plant Technology

The Italian Company Turboden will deliver the ORC-units for the CSP plant. In the last 15 years Turboden has implemented ORC-units in approximately 300 places. Of these, around 250 plants are heated up with oil from biomass boilers and of these 250 plants, 170 are placed in Germany, Italy and Austria. One plant using solar energy as heat source (parabolic trough) was implemented in Morocco in 2010 and 3 new plants using hot oil from parabolic troughs (PTC) are under implementation or planning in Italy. The technical efficiency when using solar as heat source is higher than 15%. Solar power with ORC is thus as efficient as photovoltaic systems.

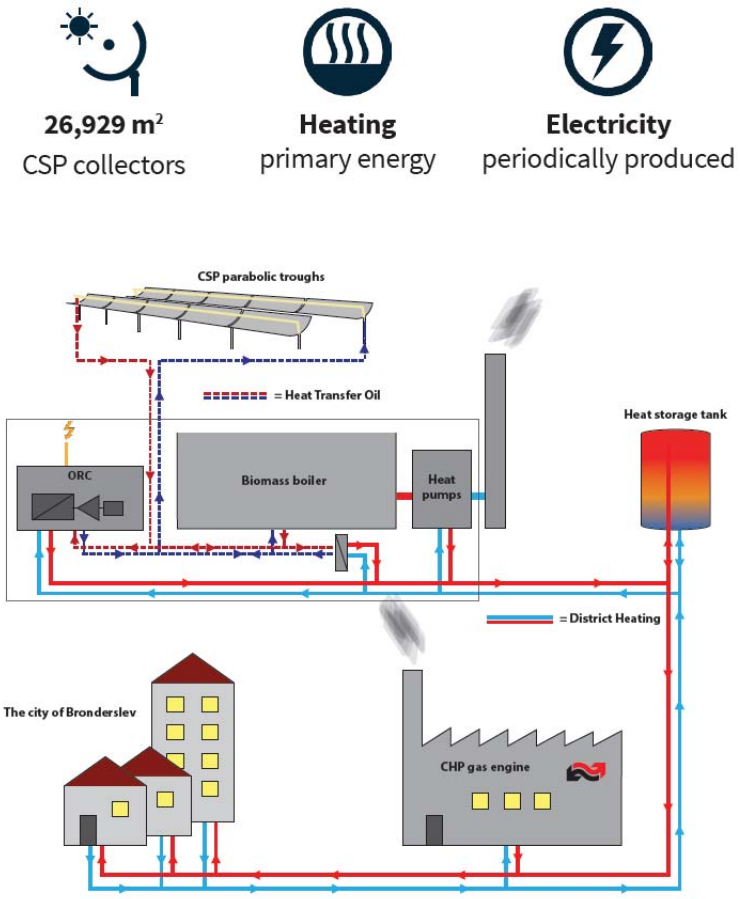

Fig.1. Flow duagram of the biomass CHP-plant with ORC-power unit and feed-in of solar thermal energy both to the ORC and District heating network. Drawing from http://www.aalborgcsp.com/

.

Compared to steam systems, ORC has the following advantages:

1) Low mechanical stress (lower pressure and temperatures in the turbine).
2) No corrosion of turbine blades. Simple start procedure.
3) No demand from continuous supervision.
4) Easy maintenance.
5) Long lifetime (more than 20 years).
6) No use of demineralized water.
7) Possible with maintenance guarantee (95 % of running hours guaranteed).

Disadvantages are the low electrical efficiency (19 – 20 %) compared to a high pressure steam turbine. Thus ORC is a proven technology and when the heat production from the cold side of the ORC unit is utilized – as it is from most biomass fueled plants – also an efficient technology.

CSP (Concentrated Solar Power) plants operating by temperatures higher than 300°C and producing power are already installed in Southern Europe. Aalborg CSP has installed several of these plants already and knows the technology.

The pilot CSP-plant in Thisted, in northern Denmark, was monitored and evaluated for high end district heating temperatures up to 120°C during July 2013 [2] see figure 2. The result was a maximum zero loss collector array efficiency of 75 % and an array heat loss coefficient as low as 0.04 W/m^2/K. Later higher temperature operation was investigated in the pilot test in Brønderslev 2015 [4] at up to 350°C giving the collector parameters 0.75 respectively 0.06 W/m^2/K.

Thus at a temperature difference of 300 K above ambient, assuming a heat loss coefficient of 0.06 W/m^2/K will mean a total heat loss as low as 18 W/m^2. Even if the direct radiation level is as low as 100 W/m^2 the net production will still be 100 W/m^2 *0.75 – 0.06 W/m^2/K *300K = 57 W/m^2. Therefore the plant will be able to deliver 300°C also with low DNI levels. Normal clear sky irradiation levels are in the range of 600-900 W/m^2. The main reason is the selective vacuum tube absorber, a very precise tracking mechanism, and stiff enough mirror- plus absorber support to keep the focal line on the absorber all the time.

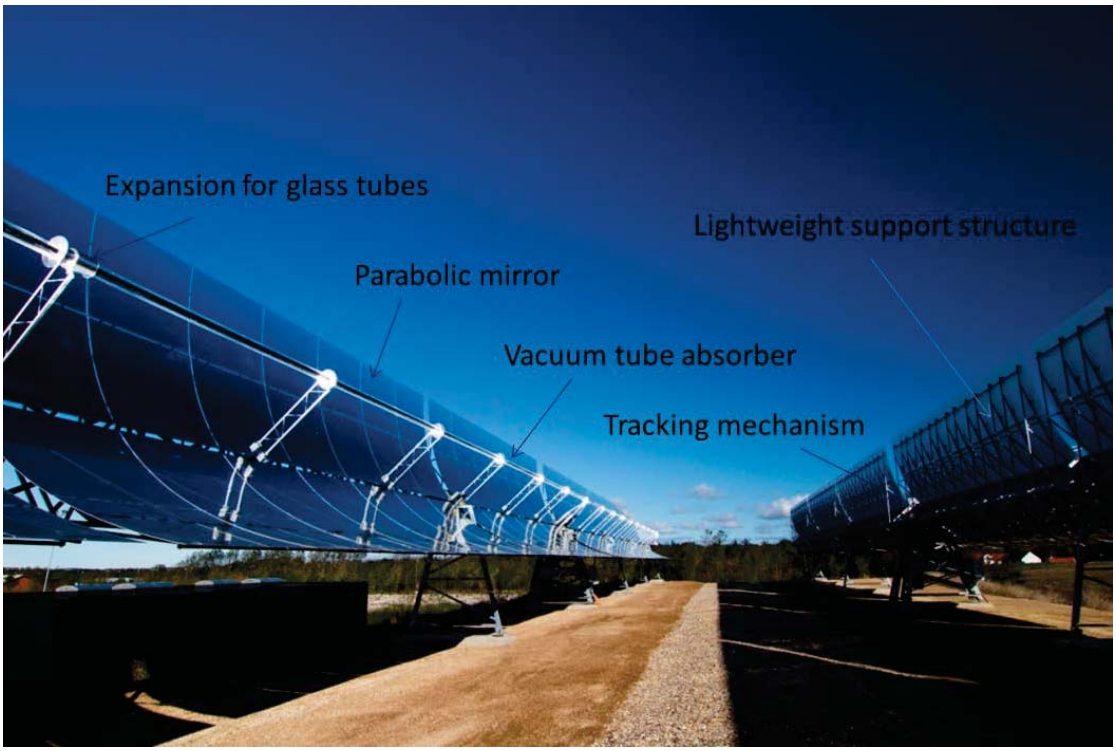

Fig.2. Close up of the Aalborg CSP concentrating collector array in Thisted (Ref. 2).

The Bøndereslev plant is now under intensive construction. See figure 3 and 4. Small improvements of the collectors have been done during the final design and construction phase of the plant that will improve the performance.

Fig 3. Photo of the CSP collector field, under construction. The collector rows are 240 m long and a total length of 480m of collectors are series connected in each series loop. (No absorbers or connecting pipes are installed in this photo).

Fig 4. Close up of one mirror element of the CSP collectors. The width is almost 6 m. Glass mirrors are used. The metal structure is optimized for low material use, but till enough stiffness in windy conditions.

3. Collector field modelling

A detailed TRNSYS model has been developed for the full size collector field, so that control and performance can be investigated in detail. The TRNSYS model is based on the modelling experiences for the 0.8 MW pilot plant in Brønderslev.

Later when the plant is in operation the model will be precisely validated and then used to check and optimize the whole plant operational performance. Then effects of for example weather and operating conditions like deviations in operating temperature from design, can be exactly taken into account and a true performance check of the collector field can be made. Also the 30 degree offset of the tracking axis from south can be accurately taken into account.

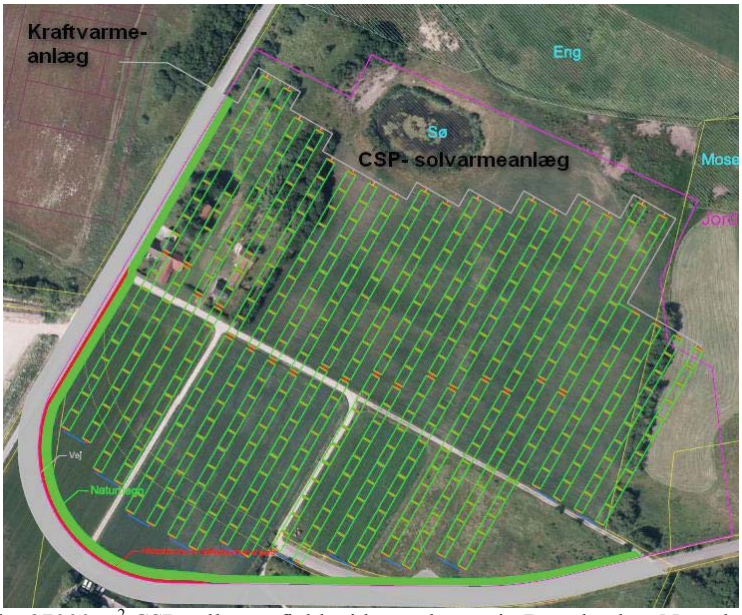

Fig 5. Photo of the 27000 m^2 CSP collector field with row layout in Brønderslev. Note that the troughs are turned approximately 30 degrees from south to match the available land area. This has been found to reduce the annual performance relatively little and was a finding in [2] giving a large flexibility in installation of such plants.

The simulation tool in TRNSYS see fig 6 and 7, is now up and running, but we await further final design information, after the construction of the plant is finished. The aim of the TRNSYS tool is also to be able to use the TRNSYS setup for continuous plant performance check and optimization of control and operation.

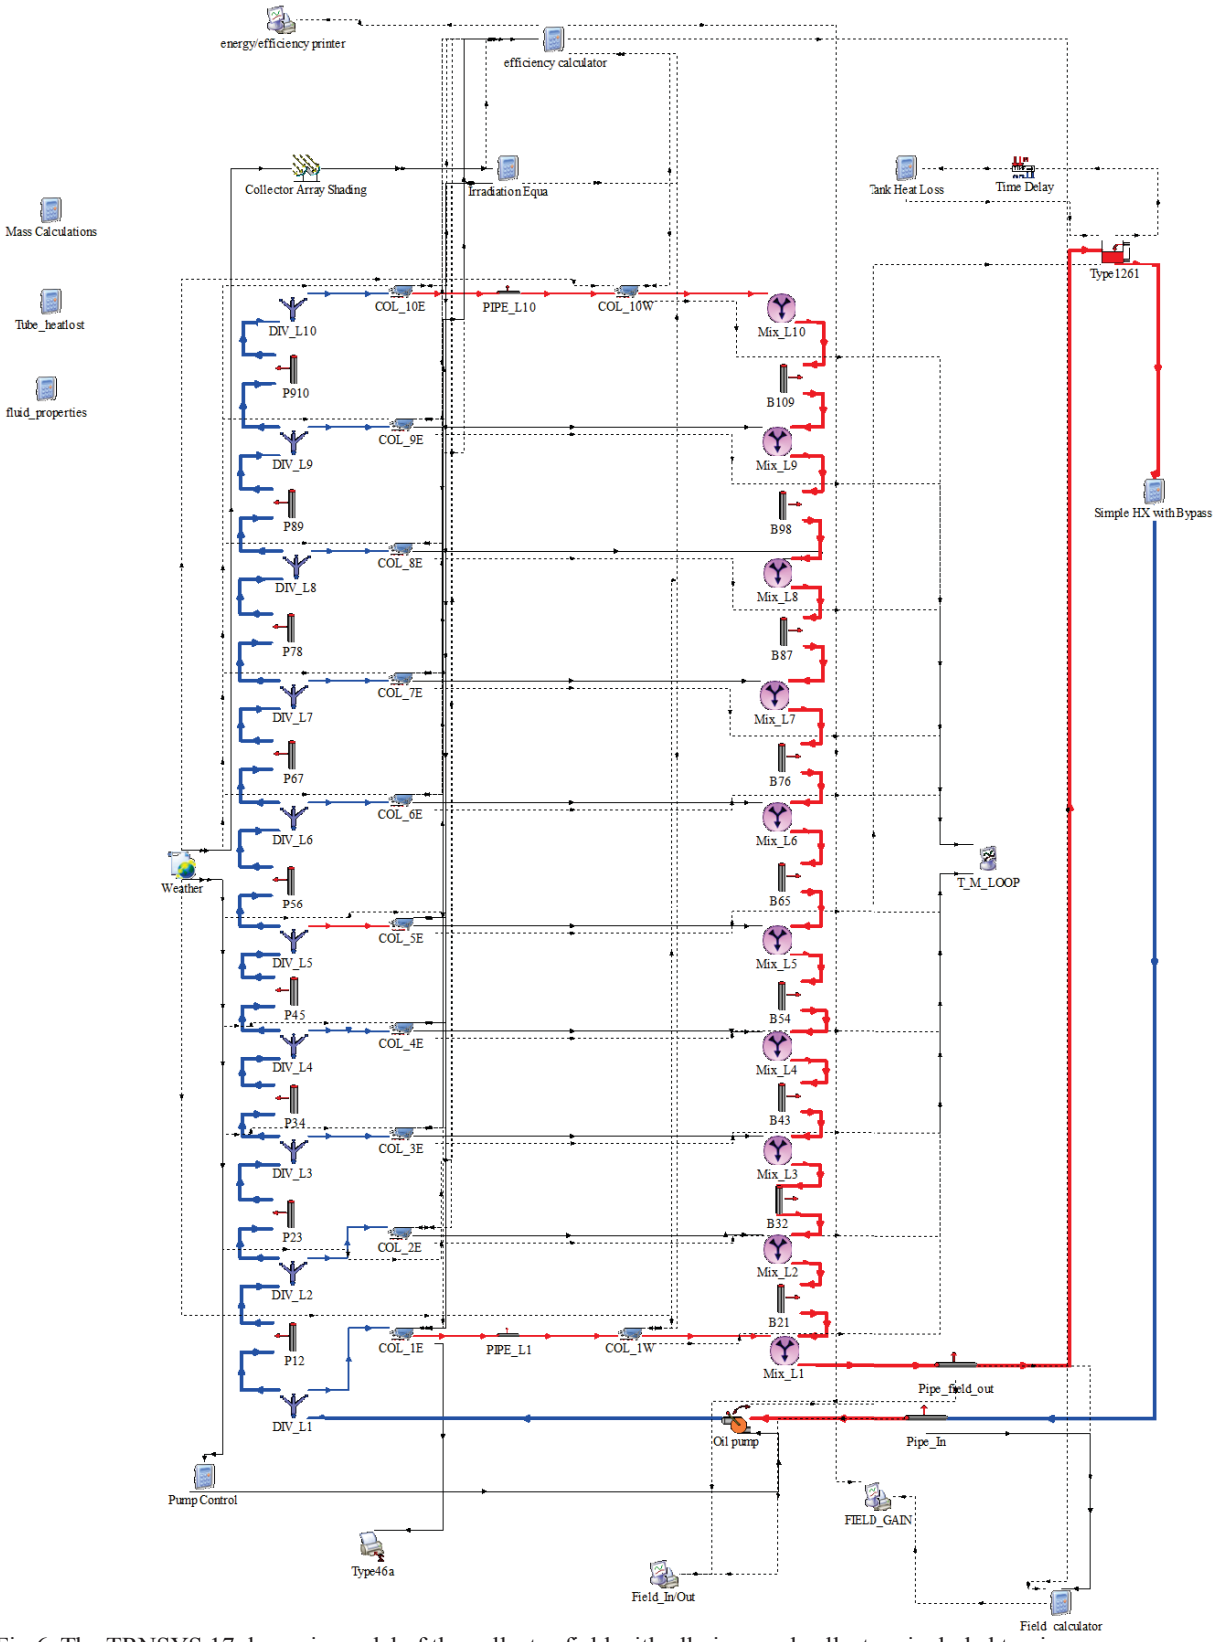

Fig 6. The TRNSYS 17 dynamic model of the collector field with all pipes and collectors included to give a very realistic simulation including transient behavior under variable weather conditions.

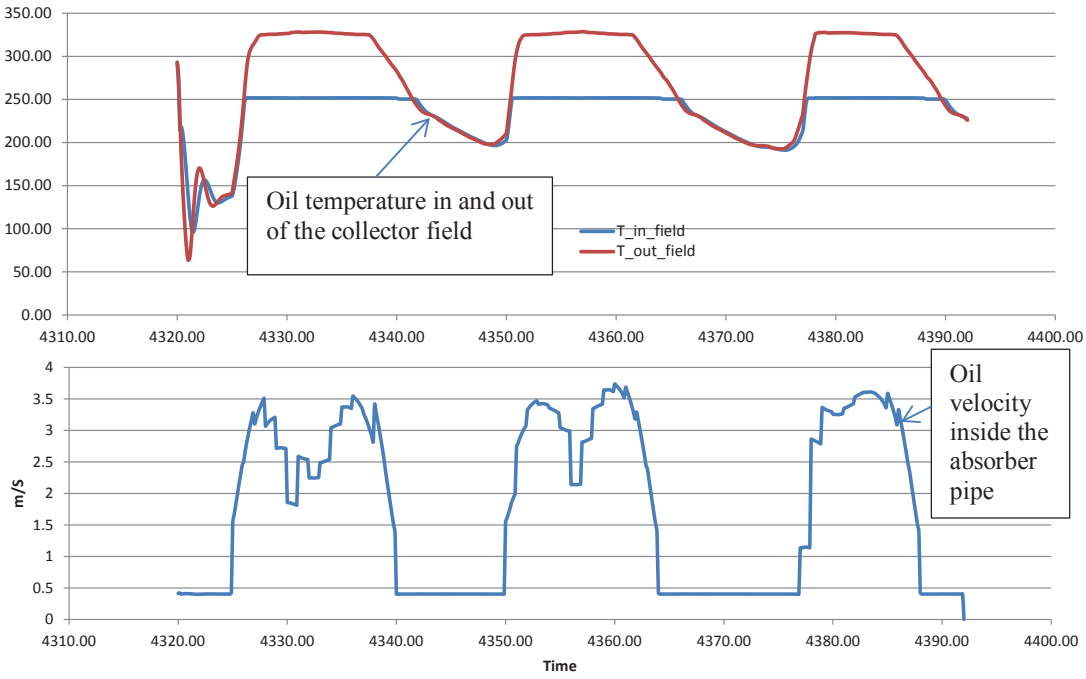

Figure 7: Simulation results for a few days in summer with variable solar radiation during the days. The flow control (lower curve) gives a constant output temperature of 330 °C (upper curve) by varying the flow according to the available radiation level and collector design parameters.

4. Conclusions

The CSP, ORC and CHP technology will be evaluated together in the Brønderslev plant in Denmark. The previous demonstration plants built in other climates indicates favorable long term performance and economy.

Pilot testing of a 0.8 MW sub array of the plant [4], show very good performance, even at these very high operating temperatures, above 300°C, in the Danish climate.

The construction work is ongoing and can be seen online [6].

Abstract

In the Southern European countries solar thermal energy is harvested few moths per year as heating, thus, solar cooling is a suitable option to increase the yield of solar fields that supports tri-generation power plants. In this kind of facilities solar cooling integration is achieved with the use of absorption chillers and appropriated energy generation management strategies. These strategies depend on the resource availability, primary energy price and energy storage facilities.

Sizing these generation systems or planning modifications on existing ones, requires detailed studies and deep knowledge on the particular boundary conditions of the site and the possible scenarios that the power plant can be subjected at. In this work a comparison between solar system and CHP system is carried out for different repowering scenarios of an existing power plant. Different tilt angles are tried out in order to obtain the most cost-effective solution over useful life for a solar system which is size to harvest solar for cooling purposes.

Keywords: *Solar thermal, CHP, Cooling, District heating and cooling, Absorption, Optimization*

1. Introduction

Worldwide the energy panorama is rapidly changing; the appearance of renewable energies is gaining relevance in despite of conventional technologies based on fossil fuels. Nevertheless energy consumption is increasing in amount and in forms such as heating, cooling and electricity. This three forms of energy are considered the threefold of energy consumption in residential, public and commercial buildings (Sivak, 2009). Furthermore, in warm environments, the demand of cooling as form of energy is exponentially increasing, especially in developed countries where as the life standards improve the demand increases. In such places it is common to find heating demand for domestic hot water (DHW) coexisting with cooling demand for space cooling.

In warm environments solar thermal energy can be harvested few moths per year as heating, therefore solar cooling is a suitable option to increase the yield of solar fields as heating and cooling demands are complementary along the year. Such fields are usually connected to a hybrid generation plant to soften its generation variability and uncertainty.

In hybrid power plants, solar cooling integration is achieved with the use of absorption chillers, thus, enduring the power plant with poly generation. These hybrid poly generation power plants require an appropriated energy generation management strategies to maximize energy generation.

doi:10.18086/eurosun.2016.05.07 Available at http://proceedings.ises.org

Given a complex generation system, the plant manager bases management strategies on appropriated tools to support optimal decisions. Such tool shall include information regarding non-dispatchable thermal energy forecast, prices for primary energy and power plant efficiency on the different performance points.

Once the generation is sorted out, the demands can be aggregated and centralized by means of a distribution network, in those cases a District Heating and Cooling (DHC) network fulfils the transportation requirements of a centralized generation point supplying energy consumers located in various locations.

This paper present two repowering options and their possible working scenarios and it is organized as follows: next section provides an overview of the problem description. Section 3 describes the methodology used to approach the problem. Section 4 presents the result obtained and the conclusions from those are given in Section 5.

2. Problem description

The hybrid poly generation plant under study in this work is located in Majorca, Spain and constructed in 2000. The generated energy is provided to the Balearic Islands University and the Innovation centre of Balearic Islands "Parc Bit" through a DHC. The customers are the university facilities, including the student house and the sports centre and office buildings from the innovation park; in total the system provides heating and/or cooling to 25 different customers with different load profiles. The DHC network is detailed explained in (Perez-Mora et al., 2016b).

The actual cooling generation system comprises two absorption chillers of almost 2.0MW_c, two electric chillers summing 2.5MW_c, plus cooling towers and dry coolers for condensing purposes.

In the other hand, the heating generation system comprises an existing solar thermal installation with 864m^2 of solar collectors, two Combined Heat and Power (CHP) engines of 1360kW_e, biomass burner and a diesel burner as auxiliary summing 3.0MW_t. The system includes, as well, energy storages for heating and cooling; there are four tanks of 100m^3, two for cooling and two for heating. The system schematic can be seen in Fig. 1 and the generators figures and technologies can be seen in Tab. 1.

Currently the solar collector field generation is quite decreased due strong deterioration and the proper ageing of a 16 years old solar collector (Fan et al., 2009).

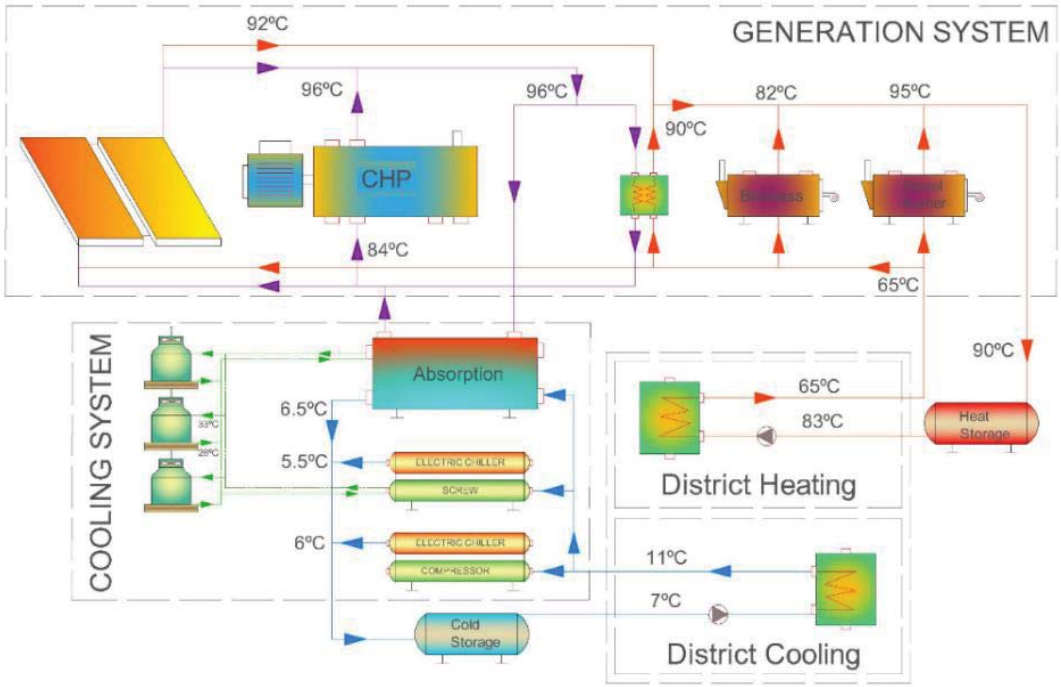

Fig. 1: Current energy generation system schematic.

Tab. 1: Current figures of installed generators at Parc Bit.

	Element	Technology	Installed Figure	Design parameters
Generation	IC Motor (2)	Diesel	2 x 1.36 MW_e	η_e=0.415; η_t=0.43
	Solar Collectors	Flat Plate	864m^2	η_0=0.76; a_1=3.5; a_2=0.002
	Biomass	Wood chip	1 MW_h	η_t=0.95
	Burner (2)	Diesel	1.2+0.8 MW_h	η_t=0.9
Cooling	Absorption (2)	Single. Li-Br	1.32 + 0.64 MW_c	η_c=0.6
	Electric Chiller	Compressor	1.2 MW_c	η_c=3.5

Storage	Heat Storage	Water	2 x 100 m^3	η_t=0.998
	Cold Storage	Water	2 x 100 m^3	η_t=0.999

2.1. Repowering scenarios

As mentioned before the hybrid poly generation power plant providing energy to the DHC was built more than 16 years ago and therefore its lifetime is coming to an end. This work studies possible scenarios that could be carried out in order to repower the existing power plant. In those scenarios only the main heating generator change is proposed, keeping the use of the auxiliary, cooling, storage and distribution systems.
In the repowering scenarios the following assumptions are taken:

- Heating system is backed up by the existing auxiliary diesel boiler,
- Biomass burner, solar collector field and CHP engines are decommissioned,
- The existing installation can be used and only the generator has to be replaced,
- Only one technology is considered at once, either CHP or solar thermal system,
- Absorption and electric chillers are able to work at any load with a fixed COP,
- The cooling towers are sufficient to fulfil the condensing requirements at any time,
- Energy storages have a fixed heat loss expressed in stored energy by hour,
- The inertia of the DHC is not taken into consideration at simulation time step,
- The heating generation temperatures matches the absorption chiller requirements,
- Heating and cooling demands must be matched by all means,
- Energy demands are measured at generation point and not at customer location, therefore delay or inertia is not taken into consideration,
- Selling electricity price from CHP is equal to the market at the feed in hour,
- Purchasing electricity price for the power plant is equal to the market plus fees and taxes,
- There is not governmental incentive for green energy generation, neither electric nor thermal,
- Requested land area is considered as part of the existing power plant and there is not extra rent cost.

The proposed repowering thermal generation system is designed to harvest the required amount of energy requested by the absorption chillers during the summer simulation. Therefore it is dimensioned so its peck generation fulfils the requirements from the existing absorption chillers. This design aims to boost solar cooling as main supplier of the District Cooling (DC) and its power calculation explained in equation 1.

$$P_{sys} = \frac{P_{abs}}{COP} = \frac{2.0MW}{0.6} \approx 3.33MW \rightarrow 3.4MW \qquad \text{(eq. 1)}$$

2.2. Solar thermal system

The proposed solar thermal system is designed to harvest the required amount of energy during the summer simulation at the first year of installation, without taking into consideration any performance loss due ageing. Therefore the collector area and tilt are dimensioned so its peck generation fulfils the requirements set form the existing absorption chillers. To do so, the collector field present the following features and design data summarized as:

- Range of tilt angle used: 20º - 65º,
- Azimuth angle used: 0º South.
- Collector performance figures are η_0=0.816; a_1=2.418; a_2=0.085,
- Collector area installed depends on the tilt angle; installation land free of charge and available,
- IAM = 1, albedo = 0.2,
- Mean temperature inside collector is 75ºC, as return from the DH or absorption can be considered 60ºC and flow to either of the options is fixed in 90ºC,
- Peak generation in summer week = 3400 kW,
- Operation and Maintenance (O&M) cost is fixed in 1€/MWh generated,
- Approximated cost of installation = 248€/m^2,(Bava et al., 2015)
- Useful life: 25 years.

Accordingly, solar generation can be used either directly for heating along the year for the customers in the District Heating (DH) or for cooling being converted with absorption chillers for the users in DC. In addition to the solar generation field, the existing heating and cooling storages are kept to improve solar performance. The heating storage being used as buffer, is able to provide a constant output temperature to the DH or the absorption chiller, meanwhile, the cooling storage helps increasing system reliability and improving cooling generation performance. Moreover, the solar generation is backed up by the diesel auxiliary boiler which provides the energy shortages that may occur during operation. In the same way, electric chillers back up cooling generation in case of shortage. In figure 2 the location for new solar collector field is shown, the total area of the addressed land is about 20.000m^2.

Solar generation forecast is required during the power plant daily optimization, to acquire such information generation forecast can be made by using historical data related with climatic information. The most relevant information can be extracted from irradiation and temperature at the power plant site and it is used to improve forecasting accuracy (Inman et al., 2013; Perez-Mora et al., 2015)(Perez-Mora et al., 2015).

Fig. 2: New solar system location.

2.3. CHP system

The proposed diesel CHP system is, as well, designed to harvest the absorption chiller requested heating energy during the summer simulation. Therefore the heat to be recovered fulfils the requirements set form the existing absorption chillers. The CHP system is designed with generation flexibility by adding two

engines of half of the required power instead of a single unit. The CHP system present the following features and design data summarized as:

- 2 CHP diesel engines of 1700kW$_t$,
- CHP performance figures are η_e=0.45; η_t=0.45,
- Installation site and pipework already existing and free of charge,
- Flue smokes recovered at a heat exchanger which output temperature is 90ºC,
- High temperature circuit heat recuperation output temperature is 90ºC,
- Nominal heating generation = 3400 kW$_t$,
- Nominal electricity generation = 3400 kW$_e$,
- O&M cost is fixed in 20€/MWh$_e$ generated, overall maintenance included,
- CHP electricity price equal to the wholesale market,
- Approximated cost of installation = 265€/kW$_t$,
- O&M stops not included on the simulation. Motor availability = 100%,
- Useful life: 25 years, including overall,
- Capital cost of installation turnkey = 900.000€.

In the same way as in solar, the heating generation can be used in both DH directly or in DC once is converted by the absorption chillers. In addition to the CHP system, the existing heating and cooling storages are kept to improve power plant performance. Moreover, the diesel boiler and electric chillers as kept as auxiliary systems in case of power shortage.

In this case the fuel price uncertainty impacts harder than in the previous case since is the only and main energy source for heating generation at the power plant. This system is tied, as well, to the wholesale energy price which variations affect in two ways to the generation; positively when selling electricity from the CHP and negatively when generating cooling with the electric chillers.

2.4. Proposed scenarios

In order to study several cases where the two proposed systems can be compared and evaluated the scenarios are created by the variation of selected figures. The following ranges and variables are modified:

- Tilt angle and collector area. The tilt is ranged from 20º to 65º in 5º step. The area is calculated so the peak power in the summer week is equal to 3400kW$_t$.
- Fuel price, the variability of the Brent crude oil price impacts strongly on CHP generation, moreover when the auxiliary system is fed with diesel as well.
  The purchase diesel prices used range from 0.3€/l to 1.0€/l with a 0.1€/l step; such values depend on Brent crude oil price and national taxes. As an example, for a given Brent price of 50$ the price per litre is 0.4€/l and 150$ correspond to 1.0€/l. These variations bring a huge uncertainty for the power plant manager and energy consumers.
- Wholesale price, OMIE, hourly values of electric energy price. The average price of OMIE has been increasing rapidly in the past decade. The values vary hourly and there are great price differences among seasons, even though the daily trend is similar. The values for the selected weeks are shown in figure 3. To create new scenarios the shape of curve and trend are kept the same and the hourly figures are increased by a percentage. The value of increasing percentages range from 0% to 50% increase with a 5% step.

To compare the different scenarios four weeks, considered standard demand wise, are selected. Such weeks are considered representative for the whole year, and thus, its demand is used as annual demand once is multiplied by an annual conversion factor. Figure 3 shows wholesale energy price, heating and cooling demand on the selected weeks. In table 2 the energy loads for the different weeks are shown.

Tab. 2: Heating and cooling demands in the DHC

Week	Dates	Heating	Cooling
Winter	19/1/15 – 25/1/15	219.68MWh	3.50 MWh
Spring	20/4/15 – 26/4/15	76.70 MWh	10.66 MWh
Summer	20/7/15 – 26/4/15	8.15 MWh	142.53 MWh
Autumn	19/10/15 – 25/10/15	39.23 MWh	33.76 MWh
TOTAL	Annual	4481 MWh	2483 MWh

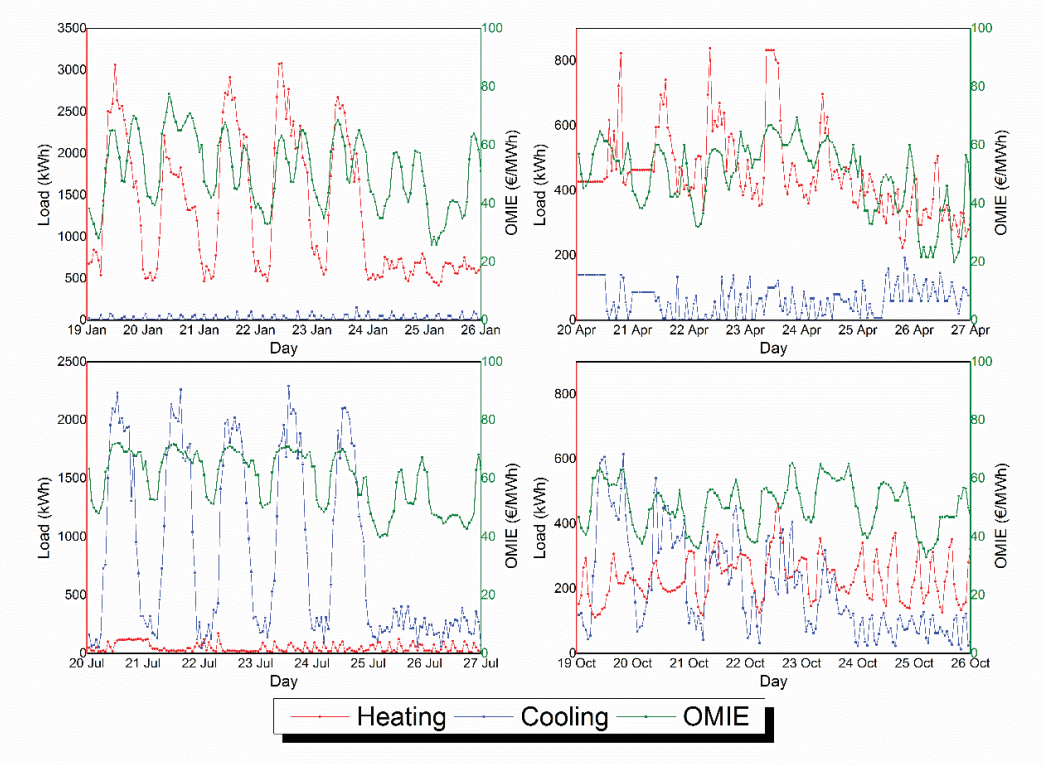

Fig. 3: Typical week loads and OMIE price.

3. Methodology

The methodology followed to compare the different scenarios and systems is explained in this section. To study the proposed scenarios it is necessary to develop an optimization tool to find the best fitting between generation and demand. Besides the detailed generation knowledge of the power plant, to achieve a proper energy curve fitting, an accurate estimation of the solar thermal generation, cooling energy demand and wholesale price of electricity is required; in this work, to run simulations of scenarios, historical values are used from the year 2015.

Creating a plant simulator to include such information into the model attempts to improve the generation strategies by reducing expenses and maximizing revenues. Once this model is operational and includes the requested information, a decision maker tool, based on Mixed Integer Linear Programming (MILP) (Carpaneto et al., 2015), is used. This tool supports the plant manager decision process while aiming to optimize heating and cooling energy generation.

In this work a tool is proposed to optimize the generation of a hybrid poly generation plant. The tool, XEMS13, has been developed in the Energy Department of Politecnico di Torino (Italy) and some parts have been developed in collaboration with the company Sampol Ingenieria y Obras (Spain). The tool is extensively explained on (Perez-Mora et al., 2016a).

The optimization tool is used to set new scenarios and configurations for heating and cooling generation and to seek optimal demand matching. The savings coming from primary energy consumptions are compared with the investment cost of such system modification during its lifetime to determine the suitability of the investment. In particular, four relevant weeks are selected, one for each season of the year. These four weeks represent the whole year in terms of demand diversity, and therefore, the economic results calculated in the simulations can be extrapolated to a whole year.

In a first instance, different tilt angles are used to create different solar generation scenarios. The tilt angle ranges from 20º to 65º, covering from summer to winter solar generation optimization. Once those scenarios are set with different angles and a range of fuel and wholesale energy prices, the best tilt angle is selected for the purpose by looking to the economic expenses along the year.

Accordingly, to calculate the generation during the useful life of the solar system the annual generation is multiplied times the useful life, without taking into account the effects of ageing.

The better optimized solar system is then compared with the CHP system to calculate savings on O&M. Those savings are, afterwards, compared with the capital cost of both systems in order to find the scenarios where each system is more interesting. Such comparison brings then the conclusions for the different systems and its influences from scenarios.

To compare the results, Interest Rate of Return (IRR) of the system cost, fuel or primary energy price increases are not considered during the systems useful life. Energy price and fuel are modified to generate different scenarios, but they fixed along the useful life of the system.

4. Results

In this section the results obtained by the optimization tool, XEMS 13, are shown.
At first the solar generation calculated using the different tilt angles presented along with the calculated collector area for each scenario. Using the solar generation and DHC demand profiles, the power plant optimization is carried out to compare the influence of a field optimized for summer, winter or annual generation. From the studied options the one serving better the purpose of this work is selected.
The final economic results from the solar collector field is then compared with the results given by the CHP system and their investment costs.

4.1. Solar generation

The first obtained results are the solar generation depending on the tilt angle used. As mentioned before, the solar collector area is dimension so its peak generation on the summer week is equal to 3400kW$_t$. This procedure brings along a calculation of the required solar collector area for each tilt angle. Obviously, the collector area increases with the increase of tilt angle since the lower angles provide its maximum generation during summer. In figure 4 it is show as well the weekly generation of the proposed solar system for each tilt in MWh. The generation shown is by means of total collector installed area. This fact is the reason why the summer week generation is more or less steady comparing with the winter generation which increases rapidly with the increase of tilt.

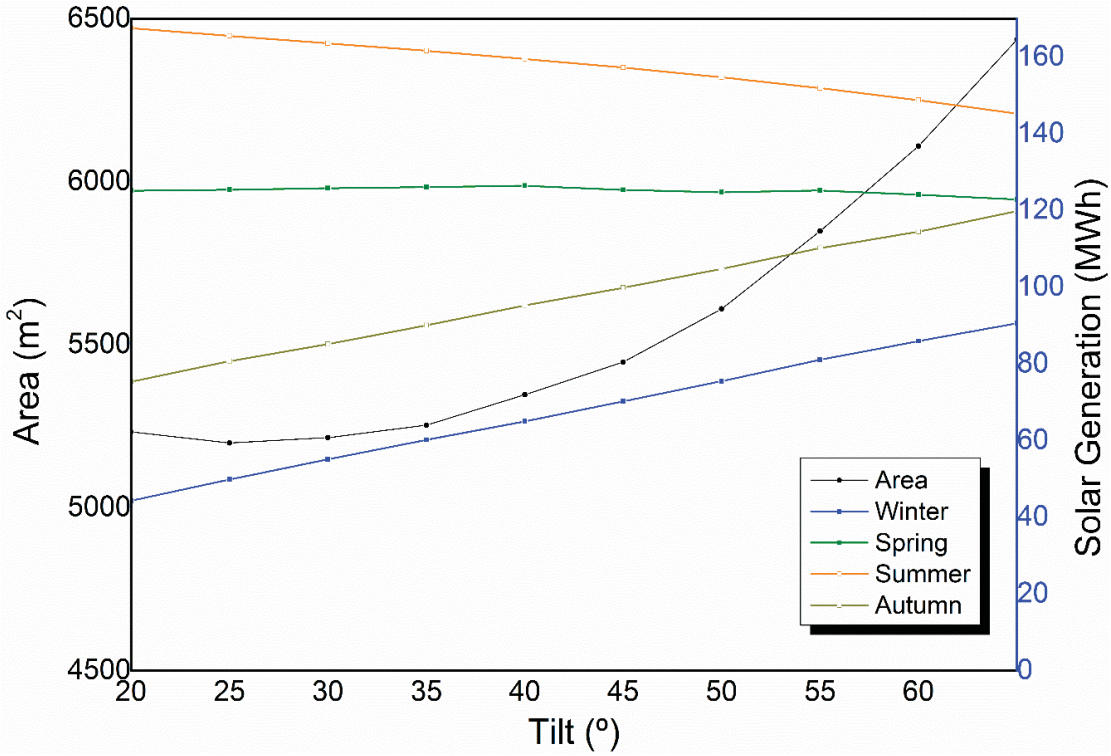

Fig. 4: Solar generation and collector area depending on tilt angle.

The largest solar collector area calculated for any tilt is 6436m^2, being the lower solar collector area equal to 5198m^2, both collector field sizes are able to fit in the proposed land. A larger solar collector area increases linearly the initial investment on the system.

4.2. Solar optimization

Once the solar generation is calculated for the different tilts, the system optimization is carried out. In this optimization the whole system is simulated, including cooling, auxiliary systems and storages. As result, the economic cost of running the plant is given, this result is influenced by the different scenarios proposed in which wholesale energy market and fuel prices are modified.

From those simulations the results show the generation cost for the selected four weeks as a 3D map, as could be obvious, the higher the fuel and energy price is the higher the operation of the power plant becomes. In figure 5 the O&M cost for the selected four weeks on the ten proposed cases are shown and it is possible see how the O&M cost varies in the different scenarios. The figure shows as well how the variation of fuel and wholesale price affects in the same way to all the scenarios, and thus, the result maps are parallel surfaces. The result surfaces of the different scenarios decrease their generation cost with the increase of solar tilt angle, being the most expensive O&M for a 20º tilt angle and the cheapest for 65º tilt angle. It is possible notice than the fuel price increase has a stronger impact in the final power plant operation cost than the wholesale energy price increase.

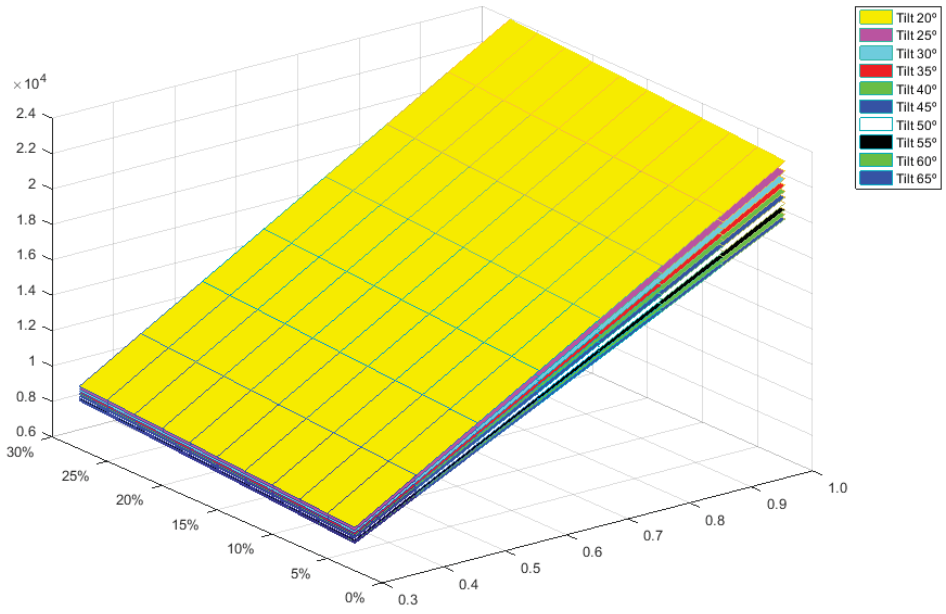

Fig. 5: Solar system tilts generation cost.

The cost for power plant operation is calculated as the sum of solar O&M cost plus the O&M cost of auxiliary systems at the power plant and is shown in figure 6. Solar O&M is fixed in 1€/MWh$_t$ generated at the collector field. The scenario selected to show the power plant generation cost in figure 6 is the one corresponding with the situation nowadays, the figures for the wholesale market correspond to the 0% price increase and the cost per litre of fuel is 0.4€/l. Nevertheless, this value does not influence how the final result looks like, as has been shown the generation cost are parallel surfaces for the different tilt angles, therefore, the only significant variable is the tilt angle. In the figure 6 is shown how the increase of annual solar generation increases, and thus, the solar O&M cost with the increasing tilt angle; this is due the increase of solar collector area. In the other hand, the operation cost decreases with increasing tilt angle, this is due the increase of annual solar yield. Figure 6 also shows the final cost of the solar collector field repowering plus the O&M cost of the whole power plant, including solar field, calculated for a useful life of 25 years and

excluding ageing impact. The cheapest solution taking into consideration generation cost and initial investment is given for a tilt angle of 45º. In this scenario the solar annual yield is 5449MWh which represents a solar fraction of 63.22% of the total heating and cooling demand. The total installed area of solar collectors is equal to 5446m^2 which corresponds to a investment cost of 1.352.000€.

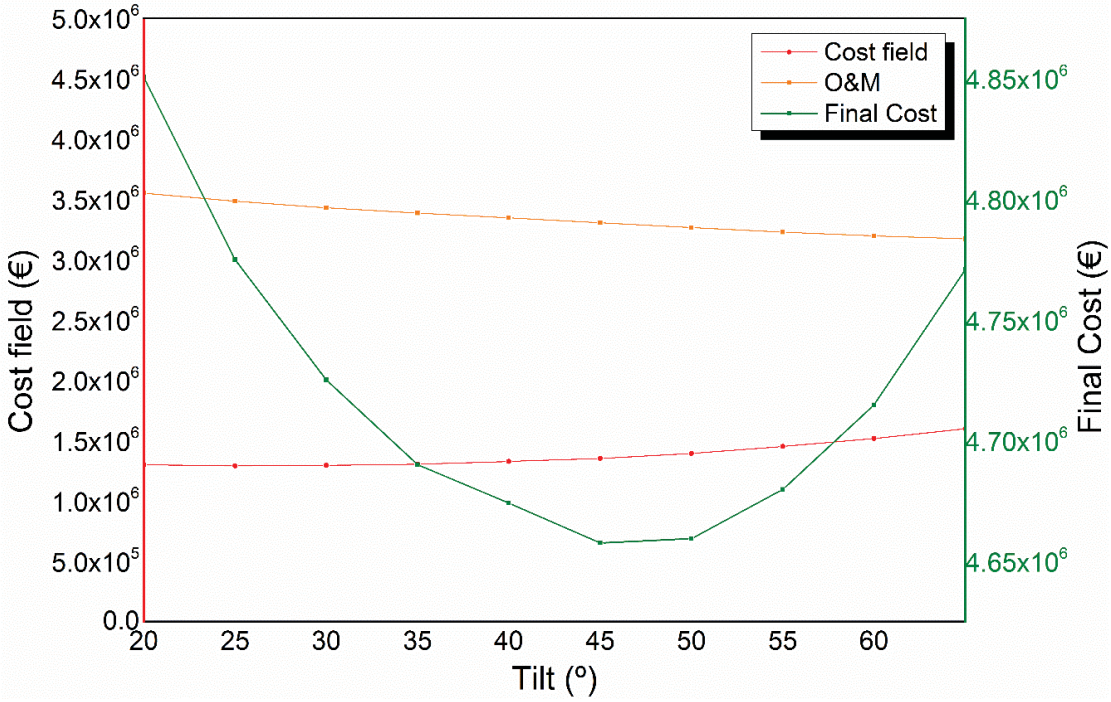

Fig. 6: Solar system total cost over useful life.

4.3. Repowering scenarios comparison

At last, the two proposed system are compared in this section. As shown in the previous section the tilt angle case which provides the most cost effective solution is 45º, therefore, this scenario is compared against the CHP scenario. To do so, systems operation costs through their useful life plus the capital cost of purchasing the systems are compared. For both systems the assumed useful life is 25 years.

In figure 7A, is shown the O&M cost over a year of the CHP system ($O\&M_{CHP}$), in the proposed scenarios and in figure 7B, the O&M cost over a year for the solar system are shown ($O\&M_{sol}$). In figure 7A it is possible notice that for some scenarios the cost of O&M in the CHP is negative, this means that it is profitable to run the CHP even when the thermal energy is not used. Those scenarios occur when the fuel is very cheap and the wholesale energy market price, OMIE, is very high, as happens for instance when the CHP generation is subsidized by electric generation.

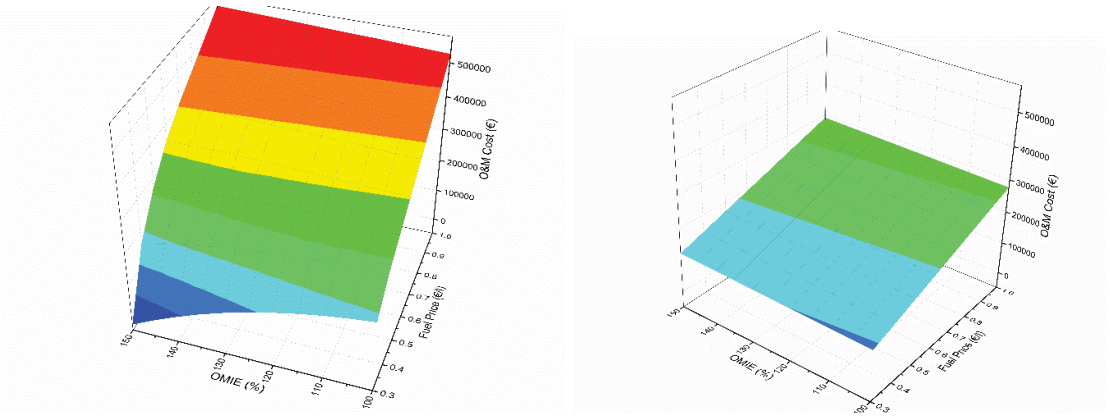

Fig. 7: O&M cost over a year for different scenarios for A) CHP system and B) Solar system.

In figure 8 the final cost of the systems over their useful life are compared, the calculation is done according to equation 2. The result given by equation 2 is positive for any scenario where it is more profitable to install a CHP system instead of a solar system. The useful life for both systems is fixed in 25 years. Figure 8 shows how most of the scenarios give negative values, this means that the solar generation system is more profitable than the CHP scenarios. The purple line is used as break-even point to separate scenarios where it is better to install a CHP system or solar system. The scenarios when is better to install a CHP system have, at least, a minimum increase of electricity price of 20% and the maximum fuel cost of 0.4€/l.

$$Result_{sys} = \left(C_{sol} + \sum_{n=1}^{25} O\&M_{sol_n}\right) - \left(C_{CHP} + \sum_{n=1}^{25} O\&M_{CHP_n}\right) \qquad \text{(eq. 2)}$$

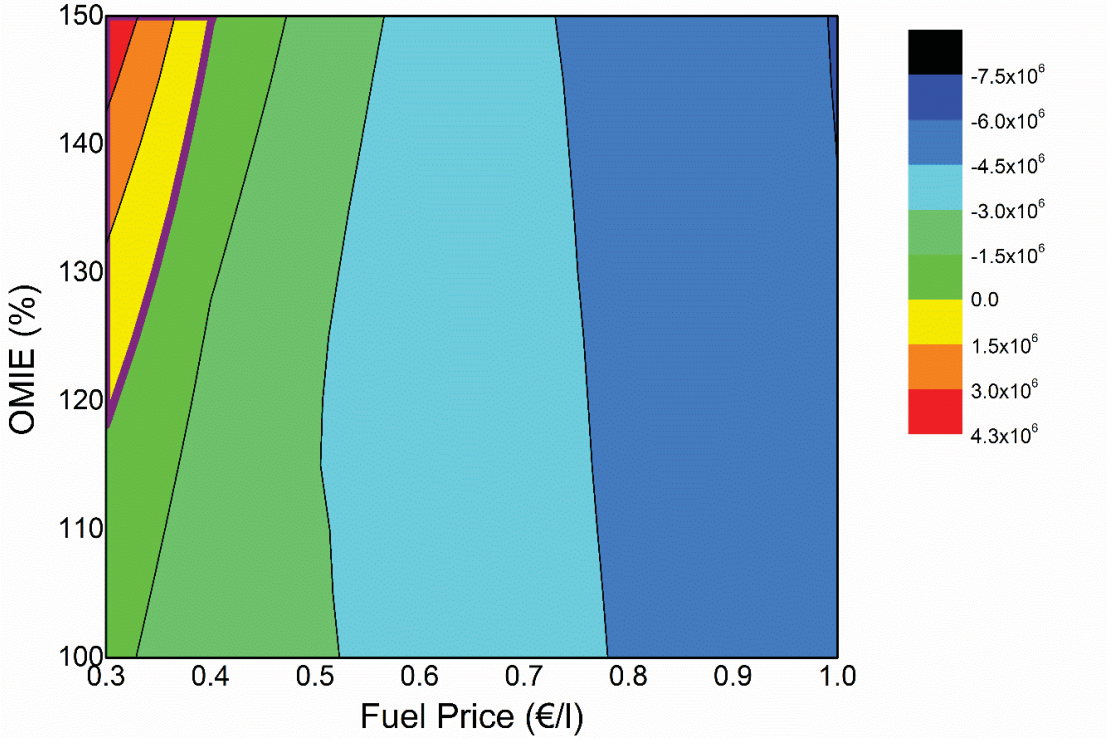

Fig. 8: Total cost comparison over useful life.

5. Conclusions

In the present work a comparison between different repowering scenarios for an existing power plant has been carried out. The different scenarios include solar system configurations and a CHP system. The comparison is made with help of an energy optimizer, XEMS13, by means of generation cost of the whole system.

The first step taken is to select the optimum tilt angle of the solar collector field, to do so, the system is optimized using four typical weeks. The best performing tilt angle, in annual minimum generation cost, is 45º, followed closely by 50º, therefore, it can be concluded than, for the given demands in this case, the system is more economic when it is annually optimized. Even if the power is dimensioned to fulfil cooling requirements in summer, the presence of storage motivates the annual optimization over the summer optimization. The large collector area required to fulfil cooling requirement when the system is winter optimized makes it very expensive comparing with the other optimization cases.

In solar system calculation over its useful life, ageing is not taken into consideration as it is very difficult to estimate the real efficiency drop on the collectors and how it will affect the system performance. In the same way, the cost of land renting for the new solar collector field is not accounted in the calculations as it is considered part of the existing power plant land. If those two factors are taken into consideration the

comparison with CHP system shown in figure 8 would present more scenarios where the CHP system overrules the installation of a solar collector field.
Nevertheless, figure 8 shows how most of the scenarios suggest the installation of a solar collector field against a CHP system. This is mainly due a high O&M cost for the CHP system which represent almost twice the cost of the solar system O&M, the relation can be seen in figure 7, and the fact that the solar system cost, 1.352.000€ is greater than the CHP system, 900.000€, but the difference pays of along its useful life. The cost of energy, regardless if heating or cooling in a mix like the given on this DHC, on a scenario as the current one where the cost of the fuel can be considered 0.4€/l and the wholesale price is taken from year 2015, is for the solar system 19.52€/MWh and for CHP system 32.19€/MWh. These values evidence that currently and with no subsidies were taken into account, it is better to repower the power plant with the installation of a solar system over a CHP system.

Renewable District Heating and Cooling in a Technology Park in Catalonia

Saad Saleem, Alaia Sola, Laura Sisó and Jaume Salom

Thermal Energy and Building Performance Area, IREC, Sant Adrià del Besòs (Spain)

Abstract

As part of the SmartReflex project, supported by the Intelligent Energy Europe Programme, the region of Catalonia is performing a study to increase the number of smart and flexible district heating and cooling (DHC) systems with a high percentage of renewable energy sources (RES). This regional strategy includes analysis of case studies for development of new DHC and the integration of renewable energy in existing DHC.

One case study is of a Commercial Technology Park. A detailed study to design a new DHC plant, including DHC demand characterization, shall be carried out using energyPRO, incorporating combinations of several renewable energy technologies comprising biomass, geothermal heat exchanger and solar cooling.

The objective is to evaluate the environmental, technical and economic feasibility of the RES DHC and which combination of renewable energies is best suited for this new DHC.

Keywords: *Solar cooling, district heating and cooling, smart cities, energy infrastructure*

1. Introduction

The region of Catalonia is located in north east Spain, next to the Mediterranean Sea and bordering France at the Pyrenees. Having various climatic zones, Catalonia has different characteristics that justify the demand of establishing district heating and cooling (DHC) networks over its territory. As of 2015, Catalonia had 84 district heating and cooling networks, according to the Spanish association of district heating and cooling (ADHAC). Majority of the networks are small heating networks and four of them provide heating and cooling simultaneously. Biomass is the main renewable energy source used in the small networks.

As part of the SmartReflex project (Smart and Flexible 100 % Renewable District Heating and Cooling Systems for European Cities, 2016), supported by the Intelligent Energy Europe Programme, the region of Catalonia (along with five other European regions) is pursuing different activities to increase the number of smart and flexible district heating and cooling systems with a high percentage of renewable energy sources including solar, biomass, biogas and geothermal energy. One of the activities is the performance of studies to promote the construction of new networks by proving their technical and economic feasibility.

This paper presents the results of the case study named “Parc de l´Alba”, which is a Technology Park in Cerdanyola del Vallès (near Barcelona) in Catalonia, Spain. Currently, the Park comprises of a Particle Accelerator (Synchrotron), a data center and some office buildings. In the coming years, there is a forecast of construction of several non-residential buildings, implying an increase in the cooling, heating and electricity demands. The new consumers shall be mainly office buildings and data centers. An existing Combined Heat and Power plant (ST-4) satisfies the present day demand of the existing DHC network. The components of ST-4 plant are shown in Fig. 1. A new plant (ST-5) shall be built in the future along with an extension of the DHC network in order to accommodate the increased demand. By 2020, there will be a total of 9 buildings with total floor area being 112,230 m^2 . The large area indicates a high demand of cooling and heating and thus is an encouragement to integrate renewable energy in the district heating and cooling plant.

doi:10.18086/eurosun.2016.05.11 Available at http://proceedings.ises.org

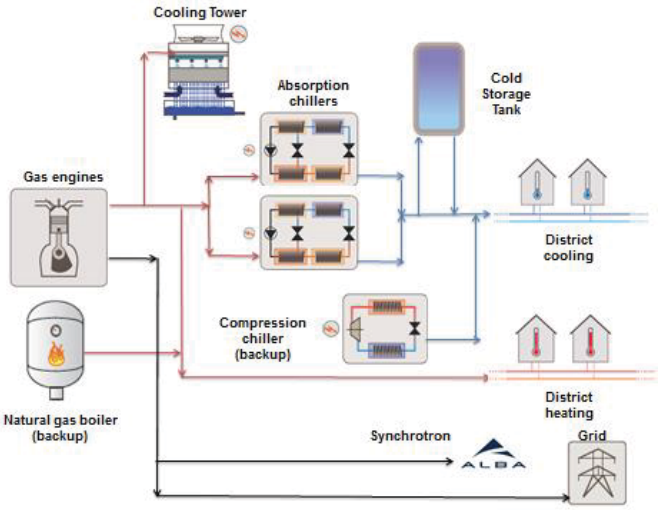

Fig. 1 Scheme of operation of the existing ST-4 plant at Parc de l'Alba

A detailed study to design the new DHC plant is carried out using the EnergyPRO (EMD International A/S, 2016) software, by performing simulations from present day (2016) till 2020. The plant will incorporate several combinations of renewable energy technologies.

2. Objectives and Methodology

The main objective is to determine if the construction of a new RES DHC is an environmental, technical and economically feasible option and which combination of renewable energies is best suited for this new DHC. The most feasible options(s) shall be decided by several Key Performance Indicators (KPIs), namely the Net Present Value (NPV), primary energy consumption and carbon dioxide (CO_2) emissions obtained in each scenario.

Two key goals must be fulfilled to reach this objective:

- To model the energy demand growth until 2020, including demand characterizations of space heating, space cooling and Domestic Hot Water (DHW) of the new consumers
- To create 5-years scenarios incorporating several renewable energy sources (RES) in the DHC plants comprising biogas, biomass, geothermal heat pumps and solar thermal cooling.

3. Base model validation

As an initial step, a base model was created in 2015 by obtaining real data from the plant (from 2014); validation was done by comparing simulation results with the real plant operation. This was done to ensure that analysis of future scenarios will be accurate.

EnergyPRO (version 4.4) is a powerful and flexible computing tool to model district heating and cooling systems. On the basis of several inputs such as the demand profile, meteorological conditions, efficiencies and capacities of various energy conversion units and tariffs, energyPRO calculates annual productions in steps of typically one hour, giving a comprehensive output on economics, emissions and operational strategy. Instead of the traditional approach of chronological hour-by-hour calculations of energy production, energyPRO is able to place productions in the most favorable time periods of the year, i.e., in the cheapest production unit /tariff combination, and so on, until the complete demand is met or there is no more production capacity left of the energy conversion units in the model.

Time Series, which are data sets of typically 8,760 time steps, are an integral part of the energyPRO software. Hourly temperature and solar irradiation data for Barcelona were input to the software as Time Series, along with some other time series to generate the Spanish electricity markets (to consider the changes

in electricity pool price). For the base model, Tab. 1 shows the details of the energy conversion units which were provided as input to the software.

Tab. 1 Details of energy conversion units and cold storage unit at Parc de l' Alba presently (2015)

Unit type	Quantity	Specifications (each unit)	Comments
Cogeneration Engines	3	3.28 MW_{th}; 3.35 MW_e; η_{el} = 44.9%	Turned on simultaneously whenever electricity spot markets are high
Single Effect Absorption Chiller	1	3 MW_c; COP = 0.7	Driven by hot water from the engines at 90 ºC
Double Effect Absorption Chiller	1	5 MW_c; COP = 1.3	Driven by exhaust gases of the engines at 398 ºC
Natural gas boiler	1	5 MW_{th}; η_{th} = 60%	Back-up
Compression Chiller	1	5 MW_c; COP = 5	Back-up
Cold water storage tank	1	4000 m^3; 21 MWh_c	
Total plant capacity: 8.0 MW_c , 9.8MW_{th} and 10.1 MW_e			

Tab. 2 shows the various revenues generated by the ST-4 plant in 2015, while Tab. 3 and Tab. 4 show the expenses incurred. Details of the two consumers served by the plant, i.e. Synchrotron facilities and an office building (referred to as "Plot 1") are shown in Tab. 5.

Tab. 2 Prices for heating, cooling and electricity sales at Parc de l'Alba for base model (2015)

Payment	Value for heating	Value for cooling	Value for electricity (Synchrotron)	Value for electricity (grid)
Connection payment	48.21 €/kW_{th} connected	145.77 €/kW_c connected	-	-
Capacity payment	13.98 €/kW_{th}/ year	23.01 €/kW_c /year	617,132 €/year	529,193 €/year
Variable price	34.84 €/MWh_{th} sold	34.84 €/MWh_c sold	114.24 €/MWh_e sold	113.20 €/MWh_e sold

Tab. 3 Fuel expenditure at Parc de l' Alba for base model (2015)

Fuel	Value
Natural gas	0.402 €/m^3
	37.78 €/MWh
Electricity imported	40.73 €/MWh_e

Tab. 4 Maintenance expenditure at Parc de l'Alba for base model (2015)

Maintenance type	Value
Fixed maintenance	245,064 €/year
Variable maintenance	13.27 €/MWh_e from gas engines
Overhaul of engines	6.83 €/hour operation

Tab. 5 Energy demands at Parc de l' Alba for base model (2015)

Type of demand	Consumer	Value
Cooling demand	Synchrotron	21,710 MWh_c
	Plot 1	651 MWh_c
Heating demand	Synchrotron	895 MWh_{th}
	Plot 1	532 MWh_{th}
Electricity demand	Synchrotron	20,419 MWh_e
	In-house consumption and losses	5,314 MWh_e

4. Key Performance Indicators

After the base model validation, simulation models were created for the years 2016, 2017, 2018 and 2020 (2019 is assumed to have identical performance as 2018) incorporating new demands. Different combinations of RES were used to satisfy this demand. The best combination was evaluated on the basis of CO_2 emissions, Primary Energy consumption and Net Present Value (NPV)

The CO_2 emissions were calculated by the software simulation once the user had entered specific emission factors of each fuel, while primary energy consumption was calculated by multiplying the fuel consumption with their respective primary energy factors (PEFs). Specific emission factors and PEFs were taken from a Joint Resolution of the Ministries of Industry, Energy and Tourism and Ministry of Development (Resolución conjunta de los Ministerios de Industria, Energía y Turismo, y Ministerio de Fomento, 2016) of Spain. They are shown in Tab. 6.

Tab. 6 Specific emission factors and Primary Energy Factors for fuels used in Parc de l' Alba

Fuel	Specific emission factor (kg CO_2/unit fuel)	Primary Energy Factor
Imported Electricity	0.357 kg/kWh	2.368
Natural gas	2.681 kg/m^3	1.195
Biogas	0.62 kg/m^3	0.500
Biomass	0.0621 kg/kg	0.034

The NPV is basically the difference in the between present value of cash inflows and present value of cash outflows. A positive NPV indicates that the projected earnings exceed the expected costs, while it is the other way around for a negative NPV. To calculate NPV for each scenario, an extensive economic calculation is done by construction of Profit and Loss (P & L) sheets from the present year (2016) up to the end of concession period (2037) for each scenario, as explained by Ross et al. (2014) in Fundamentals of Corporate Finance. The NPV is calculated by eq. 1.

$$NPV = -C_0 + \sum_{t=1}^{T} \frac{C_t}{(1+i)^t} \quad \text{(eq. 1)}$$

Where

C_0 (€) = Free Cash Flow in year zero, i.e., in 2016

T (years) = Lifetime of technology (21 years)

i (%) = Interest rate (assumed as 10%)

C_t (€) = Free Cash flow in year‘t’

The Free Cash Flow in each year is calculated by eq. 2.

$$Free\ cash\ flow = Operating\ Cash\ Flow - Increase\ in\ Working\ capital - CAPEX \quad \text{(eq. 2)}$$

CAPEX refers to the capital expenditure. The inflation applied to natural gas prices, variable and fixed prices of heating and cooling was 7.48%, which is the increase in gas prices in Spain in the past 13 years according to International Energy Agency (IEA, Energy Policies of IEA countries – Spain 2015 Review). Similarly, an inflation of 9.72% was applied to variable price of electricity, as per IEA. For all other revenues and expenses, the inflation was assumed as 2%, according to the European Central Bank. Information of taxes for 2016 was received from Parc de l'Alba; they are the IAE (city council tax for business activity), IBI (city council tax for property), IS (national corporation tax), tax on electricity export (7% of total export earnings) and tax on natural gas consumption (0.00234 €/kWh gas consumed).

5. Demand characterization

The demands of Parc de l'Alba from 2016 till 2020 are shown in Tab. 7.

Tab. 7 Present and future energy demands of Parc de l' Alba

	2016	2017	2018	2020
Cooling demand (MWh_c/year)	23,600	25,368	26,048	31,848
Heating demand (MWh_{th}/year)	1,426	2,386	2,738	3,398
Electricity demand (MWh_e/year)	22,847	22,768	23,921	48,429

The main consumers are the Synchrotron facilities (cooling and electricity), office buildings (cooling and heating) and data centers (cooling and electricity). The Synchrotron has a cyclic operation throughout the year and hence its cooling and electricity demand was modelled accordingly (shown in Fig. 2), as per information received from Parc de l' Alba. For offices, the cooling demand was modelled according to the Barcelona Energy Improvement Plan (Pla de Millora Energètica de Barcelona, 2002), while the heating demand was based on a study by Pedersen and Ulseth (2006), as shown in Fig. 3. Finally, the cooling and electricity profiles of data centers (Fig. 4) were modelled on the basis of real data (operation of IT loads throughout the day) simulated in the Renew IT project (European Union, 2013).

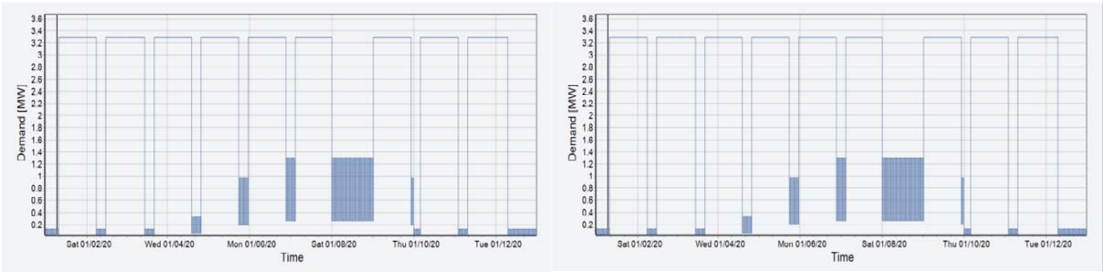

Fig. 2 Annual cooling (left) and annual electricity (right) demand profiles of Synchrotron facilities

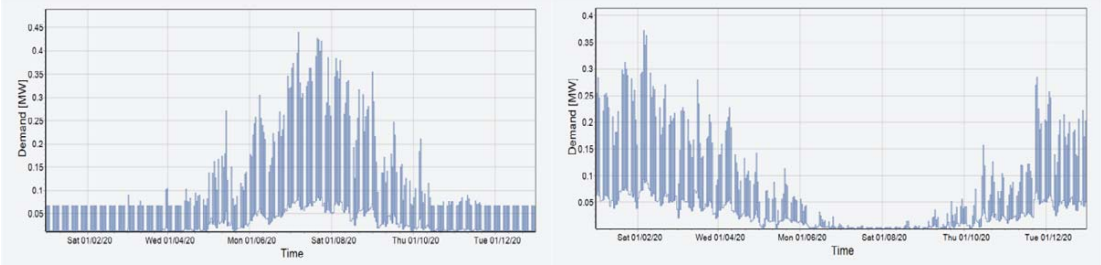

Fig. 3 Annual cooling (left) and annual heating (right) demand profile of office buildings

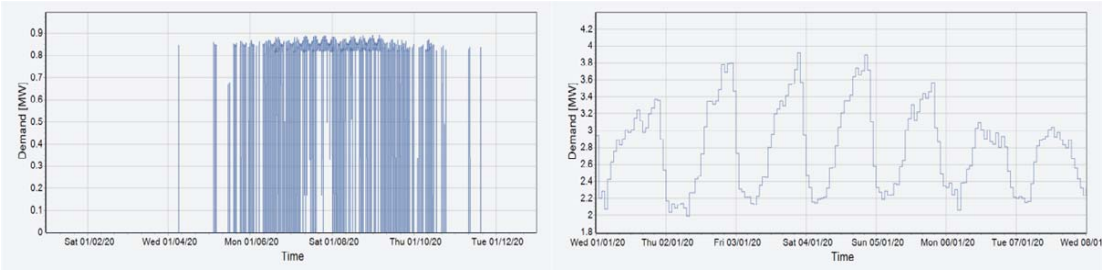

Fig. 4 Annual cooling (left) and weekly electricity (right) demand profile of data centers

6. Supply modeling

In order to supply the growing energy demand of Parc de l' Alba, three different scenarios have been considered, namely:

- Scenario 1: Solar cooling and Biomass cooling (SCBC)
- Scenario 2: Ground Source Heat Pumps (GSHPs)
- Scenario 3: Business As Usual (BAU)

All three scenarios involve the incorporation of a biogas boiler in the ST-4 plant from 2017 till 2019, while for 2020 each of the scenarios incorporates different energy conversion technologies in the new ST-5 plant. Each scenario shall be described in detail, including specifications of the energy conversion units and CAPEX (capital expenditures). Common to all scenarios are some miscellaneous investment costs (engineering, monitoring, permits, legalization etc.) which are taken as 25 % of the total physical investment of the equipment, as recommended in the guide published by the Catalan Energy Institute (Institut Català d'Energia, 2010). In the SCBC and GSHPs scenarios, it is assumed that electricity for new data centers is purchased from the grid and sold to the data centers. For the BAU scenario, the new gas engines installed at the ST-5 plant are used to directly sell electricity to the new data centers while any excess is exported to the grid. The costs of fuels in 2020 for all scenarios are shown in Tab. 8. The prices of energy sales after transformation are according the ones in Tab. 2 updated by inflation.

Tab. 8 Fuel costs in 2020 (all scenarios)

Fuel	Cost (€/MWh)
Imported electricity	60-68
Natural gas	50
Biomass	33

For the biogas boiler, all information is received from the Parc de l' Alba management. The fuel used is landfill gas, with a current price of 8 €/MWh and a calorific value of 6.2 kWh/m^3. The percentage of methane in this gas is 60 %, the specific emission factor of CO_2 is 0.62 kg/m3 and the PEF is 0.5. The biogas boiler has a capacity of 1.5 MW_{th} and currently costs € 147,500. The aim is to use this boiler to substitute the existing 5 MW_{th} natural gas (backup) boiler since it is oversized for heating demands till 2020.

6.1. Scenario 1: Solar cooling and biomass cooling (SCBC)

For the SCBC scenario, a part of the rooftop of the ST-5 plant was used for installing Parabolic Trough Collectors (PTCs) that would be connected to a double effect absorption chiller. For the remainder (major) cooling demand, a biomass boiler connected to another absorption chiller was used.

Currently, EnergyPRO can only model flat plate or evacuated tube solar collectors. Because of this, TRNSYS software was used to model the PTCs, with TRNSYS Type 536 (Linear Parabolic Concentrating Solar Collector with Capacitance and Flow Modulation). Data for the simulations was acquired from the Swedish manufacturer "Absolicon Solar Collector AB". The chosen collector model for simulations was

T160 by Absolicon. Data on the solar collectors' field simulated on TRNSYS are shown in Tab. 9

The output of the TRNSYS simulation was an hourly time series of the heating energy produced by the solar field, with 8,760 time steps. This time series was then provided to EnergyPRO as the heat input to the double effect absorption chiller.

Tab. 9 Parameters for modeling parabolic trough collectors for solar thermal cooling in Parc de l' Alba

Parameter	Value
Aperture area of each collector	10.37 m^2
Total number of collectors	105
Total aperture area	1088 m^2
Outlet temperature from collectors	180°C
Return temperature to collectors	160°C

According to the manufacturer, the present day cost of the PTCs is approximately 300 €/m^2 while the cost of the absorption chiller was assumed as 640 USD/kW_c (570 €/kW_c), as quoted by Shirazi et al. (2016). The total investment for the solar thermal cooling system was calculated by doubling the sum of the cost of the collectors and chiller, assuming that roughly 50% of the total system cost is of the buffer storage tank, piping connections, cooling tower, control system, etc. For the biomass boiler, the investment cost was taken from a study conducted by IREC for a project, while costs of the large absorption chillers were provided by the Parc de l' Alba management.

Tab. 10 Details of energy conversion units and storage units modelled for SCBC scenario

Unit type	Quantity	Specifications (each unit)	Cost
Parabolic trough collectors	1	1,088 m^2 ; 298 kW_{th} (417 kW_c)	€ 353,468
Absorption chiller (connected to solar collectors)	1	450 kW_c; COP = 1.4	€ 277,449
Biomass boiler	1	2,500 kW_{th}; η_{th} = 90%	€ 1,171,659
Absorption chiller (connected to biomass boiler)	1	3,300 kW_c; COP:1.4	€ 658,616
Cold water storage tank	1	6,400 m^3; 29.8 MW_c	€ 1,394,574
Hot water storage tank	1	200 m^3; 5.8MW_{th}	€ 97,419
Total plant capacity: 3,717 kW_c and 2,500 kW_{th} **Total CAPEX: € 5,730,128**			

6.2. Scenario 2: Ground Source Heat Pumps (GSHPs)

For the GSHPs scenario, the cooling and heating demands are served by ground source heat pumps that simultaneously produce cooling and heating. For every unit of electricity input, 3.2 units of cooling are produced (Energy Efficiency Ratio: 3.2) while 4.2 units of heating are produced (Coefficient of Performance: 4.2). The COP and EER are similar to the ones calculated for ground source heat pumps in Mollet hospital near Barcelona, as part of the Green Hospital project (European Commission, 2015). For Parc de l'Alba, the GSHPs are oversized in terms of heating capacity since cooling demand is higher than heating demand but the units have a heating output higher than the cooling output (for the same electricity input). The investment cost of the GSHPs for Parc de l'Alba was assumed as 1,583 €/kW_{th}, in accordance with a study done in France by Boissavy (2015). Additionally, the rooftop of the plant was used to install mono crystalline solar photovoltaic (PV) panels, manufactured by Suntech Power. Costs of this PV system were taken from IEA.

Tab. 11 Details of energy conversion units and storage units modelled for GSHPs scenario

Unit type	Quantity	Specifications (each unit)	Cost
Solar PV system	1	1800 m^2; 275 kW_e; η_{el} = 15.4%;	€ 389,675
Ground Source Heat Pumps	1	Input: 1,214 kW_e ; Output: 3,900 kW_c and 5,113 kW_{th}	€ 8,761,075
Cold water storage tank	1	6400 m^3; 29.8 MW_c	€ 1,394,574
Hot water storage tank	1	200 m^3; 5.8MW_{th}	€ 97,419
Total plant capacity: 3,900 kW_c and 5,113 kW_{th} **Total CAPEX: € 13,303,429**			

6.3. Scenario 3: Business As Usual (BAU)

In this scenario, cogeneration engines are installed at the new plant so as to directly sell electricity to the data centers connected in 2020. The exhaust heat of the engines would be used to serve the heat demand and to power an absorption chiller to serve the cooling demand. A backup boiler is also installed.

Tab. 12 Details of energy conversion units and storage units modelled for BAU scenario

Unit type	Quantity	Specifications (each unit)	Cost
Cogeneration engine	3	3.28 MW_{th}; 3.35 MW_e; η_{el} = 44.9%	€ 4,931,299
Double effect absorption chillers	1	5 MW_c; COP = 1.3	€ 997,902
Natural gas boiler (backup)	1	5 MW_{th}; η_{th} = 60%	€ 123,214
Cooling tower	1	-	€ 493,812
Cold water storage tank	1	6,400 m^3; 29.8 MW_c	€ 1,394,574
Hot water storage tank	1	200 m^3; 5.8MW_{th}	€ 97,419
Total plant capacity: 5,000 kW_c, 9,840 kW_{th} and 10,050 kW_e **Total CAPEX: € 10,047,775**			

7. Results

The important results obtained from the energyPRO simulations and economic analyses are presented in this section. The results from 2016 till 2018 are shown first, and then results for 2020 are shown for all scenarios.

7.1. Energy Performance of the three scenarios

From 2016-2018, the simulation models of each year are the same for all three scenarios. Tab. 13 shows the energy balance of all scenarios from 2016 till 2018. Energy demand can be checked in Tab. 7.

Tab. 13 Energy balance at Parc de l'Alba from 2016 to 2018 (MWh/year)

	2016	2017	2018
Energy Consumption			
Imported Electricity	16,842	16,957	17,525
Natural gas	92,890	94,854	92,378
Biogas	-	9,176	9,107
Primary Energy Consumption			
Imported electricity	39,881	40,154	41,499
Natural gas	111,004	113,348	110,391
Biogas	-	4,588	4,554
Total	150,885	158,090	156,444

In 2020, increase in demand is enough to implement the new plants according to the different scenarios (SCBC, GSHPs and BAU). The energy distribution depending on the scenarios is shown in Tab. 14.

Tab. 14 Energy balance at Parc de l'Alba in 2020 (MWh/year)

	SCBC	GSHPs	BAU
Energy Consumption			
Imported Electricity	41,383	44,964	10,067
Natural gas	93,528	98,304	288,712
Biomass	13,756	-	-
Primary Energy Consumption			
Imported electricity	97,995	106,475	23,838
Natural gas	111,765	117,473	345,010
Biomass	468	-	-
Total	210,228	223,948	368,848

From Tab. 14, it can be noticed that biomass contributes with primary energy nearly zero and heat pumps have slightly higher electricity consumption in comparison to SCBC scenario. The BAU scenario consumes a large amount of natural gas in comparison to the two RES based scenarios. This higher consumption is due to the fact that cogeneration engines at the ST-4 plant are running more hours than they were in the SCBC and GSHPs scenarios, since there are no RES-based energy conversion units (in BAU scenario). Also, in the BAU scenario, the backup boiler at the ST-4 plant is now allowed to operate throughout the whole year and not only in winter months like SCBC and GSHPs scenarios, where RES are prioritized. Finally, the ST-5 plant now has three cogeneration engines and another backup boiler, implying further use of natural gas.

7.2. Environmental assessment of the three scenarios

Tab. 15 shows the CO_2 emissions of all scenarios from 2016 till 2018, while emissions produced in 2020 for each scenario are shown in Tab. 16

Tab. 15 CO_2 emissions in Parc de l' Alba from 2016 till 2018

	2016	2017	2018
CO_2 emissions (tons/year)	29,418	30,872	30,443

Tab. 16 CO_2 emissions in Parc de l' Alba for 2020 (all scenarios)

	SCBC	GSHPs	BAU
CO_2 emissions (tons/year)	38,588	40,822	76,342

Tab. 16 clearly shows that the BAU scenario produces almost three times the amount of CO_2 when compared to the RES based scenarios, only because it is burning much more natural gas because of the new cogeneration engines, new backup boiler and the longer running hours of the old engines and old boiler.

7.3 Economic assessment of the three scenarios

Tab. 17 shows the main economic indicators of all scenarios from 2016 till 2018.

Tab. 17 Economic indicators of Parc de l' Alba from 2016 till 2018

	2016	2017	2018
Revenues	€ 7,651,061	€ 8,819,717	€ 10,155,051
Operating Costs	€ 5,079,909	€ 5,603,887	€ 5,887,325
EBITDA	€ 2,571,152	€ 3,215,829	€ 4,267,726
Free Cash Flow	€ 629,143	€ 1,962,362	€ 2,722,148

EBITDA refers to the earnings before interest, taxes, depreciation, and amortization. The main economic indicators of 2020 for each scenario are shown graphically in Fig. 5 and in tabular form (with NPV and CAPEX) in Tab. 18.

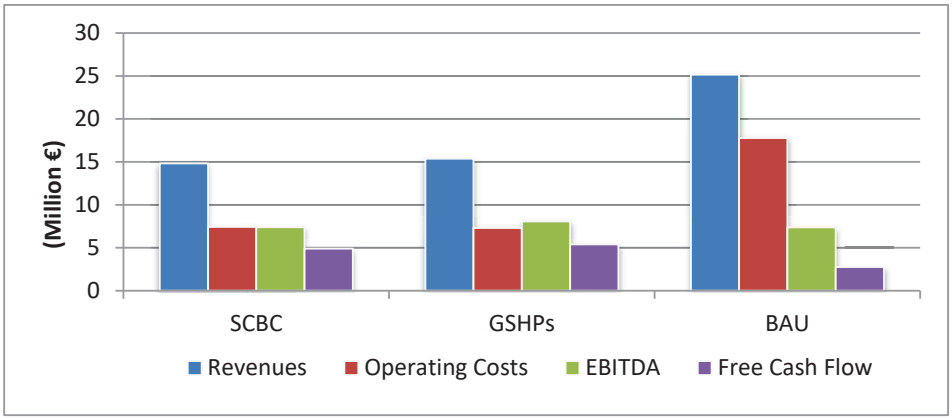

Fig. 5 Economic indicators of Parc de l' Alba for 2020 (all scenarios)

Tab. 18 Economic indicators of Parc de l' Alba for 2020 (all scenarios)

	SCBC	GSHPs	BAU
Revenues	€ 14,824,125	€ 15,371,743	€ 25,153,832
Operating Costs	€ 7,433,577	€ 7,299,363	€ 17,779,229
EBITDA	€ 7,390,549	€ 8,072,380	€ 7,374,604
Free Cash Flow	€ 4,894,266	€ 5,403,243	€ 2,765,192
NPV	€ 62,629,325	€ 61,226,405	€ 60,680,186
CAPEX	€ 5,730,128	€ 13,303,429	€ 10,047,775

Tab. 18 shows that the most profitable scenario is the SCBC scenario with the highest NPV and lowest CAPEX, followed by the GSHPs scenario and finally the least profitable being the BAU scenario. As mentioned in section 6 (page 7), the GSHPs were oversized in terms of the heating capacity since there is not a balanced demand between heating and cooling. The main consumers of Parc de l'Alba, located in a Mediterranean climate, are offices and data centers and hence cooling demand is significantly higher than heating. Hence, the option of using GSHPs is perhaps more profitable when there is a large demand of heating; the heat that is being 'wasted' to the soil could then have been sold to bring additional revenues. GSHPs have average energy efficiency roughly four times better than boilers burning biomass and using heat in absorption chillers of SCBC scenario. However, price of electricity is double the price of biomass and CAPEX of GSHPs is nearly three times higher than CAPEX of SCBC. Another important conclusion that can be drawn, in the case of Parc de l'Alba, is that it is apparently more profitable to import electricity from the grid and then sell it to the data centers at a profit, rather than self-production by cogeneration engines. Basically, the BAU scenario has higher taxes because of higher electricity export to the grid and higher natural gas consumption and hence it has a lower free cash flow.

Conclusions can be summarized in Fig. 6, which shows the environmental benefits and economic cost-effectiveness together. It is clear that the solution with the best results is the system with solar thermal cooling and biomass with absorption chillers (SCBC scenario).

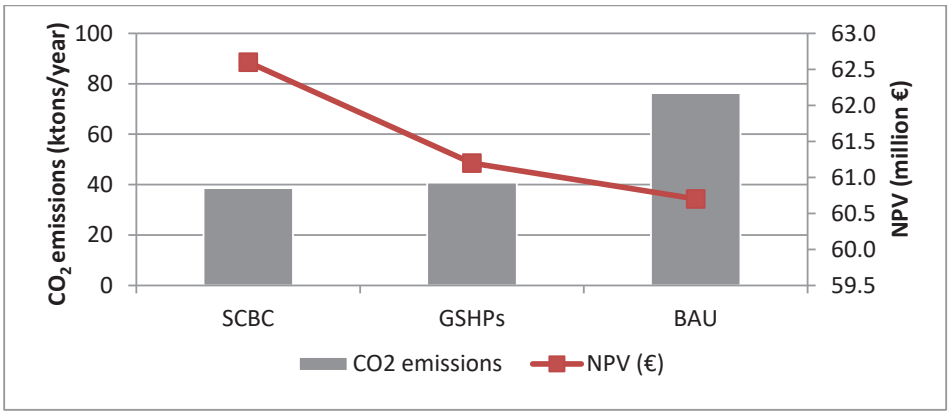

Fig. 6 Relation of environmental and economic key indicators for different scenarios in 2020

8. Conclusion

In this study, a comprehensive feasibility study has been performed to integrate renewable energy systems in the district heating and cooling network at Parc de l' Alba, a technology park in the region of Catalonia in Spain. Three 5-year projection scenarios were created on the energyPRO software, after validating a base model, in order to simulate the energy demand and supply of Parc de l'Alba from 2016 till 2020.

The projected cooling, heating and electricity demand of Parc de l'Alba were modelled on the software in accordance with the nature of the consumers, which were mainly offices, data centers and a particle accelerator. For all scenarios, data for the KPIs, namely primary energy consumption, CO_2 emissions and NPV, was collected by literature review and personal communications with relative authorities. All three scenarios incorporated a biogas boiler in the existing plant from 2016 till 2019. In 2020, different technologies were used to model the energy supply by the new plant. In scenario 1 (SCBC), a biomass boiler connected to an absorption chiller was mainly used to supply the cooling and heating demands. A small part of the cooling demand was provided by the solar thermal collectors installed on the roof of the plant connected to a small absorption chiller. Scenario 2 (GSHPs) mainly utilized ground source heat pumps that simultaneously provided heating and cooling, and the plant rooftop was used for installing solar photovoltaic panels to cater for some in-house electricity consumption of the plant. Scenario 3 (BAU) relied on cogeneration engines, an absorption chiller and a natural gas (backup) boiler to serve not only the cooling and heating demands of Parc de l'Alba, but also the electricity demands of the new data centers.

The results of the simulations and economic evaluation showed that the SCBC scenario is the most feasible option in comparison to the GSHPs scenario, due to its lower primary energy consumption (210,228 MWh/year vs. 223,949 MWh/year), lower CO_2 emissions (38,588 tons/year vs. 40,822 tons/year) and higher NPV (€ 62,629,325 vs. € 61,226,405) with lower CAPEX.

When talking about the SCBC scenario, solar thermal cooling has a great potential for primary energy savings and savings in CO_2 emissions (no combustion of any kind), but in the case of Parc de l'Alba, the limited roof area availability was the reason that solar thermal cooling could only contribute very little in the large cooling demand. Only 2% of the cooling demand of 2020 came from solar thermal cooling. This was expected because the maximum output of the system was 417 kW of cooling, while the total cooling capacity of ST-5 plant was 3,717 kW.

In the GSHPs scenario, the units are producing heating and cooling simultaneously, the former being larger in quantity than the latter, i.e. each kW of electricity (input to compressor) produces 4.2 kW of heating and 3.2 kW of cooling. For Parc de l'Alba, this excess heat has to be rejected to the soil and cannot be taken profit of. Hence, implementation of this technology is not so feasible for offices and data centers located in

the Mediterranean climate (Catalonia) where cooling is the major requirement and not heating. Moreover, digging of boreholes to install GSHPs requires large areas of land, which is an additional investment.

In contrast to the solar thermal cooling system and the ground source heat pumps, biomass boilers (burning woodchips) connected to double effect absorption chillers appear to be the most favorable solution in this study. Not only is cost of the fuel low compared to importing electricity for GSHPs (for example in 2020, woodchips cost 33 €/MWh while electricity was imported at an average price of 60 €/MWh), but also there are large savings in primary energy consumption (wood chips have a PEF of 0.034 while for electricity it is 2.368). Additionally, for the same cooling capacities, biomass boilers and absorption chillers require less land space for installation compared to GSHPs and solar thermal cooling systems.

To conclude, in the frame of this study, biomass boilers connected to absorption chillers with support from solar thermal cooling are the most feasible renewable energy systems technology for the large district heating and cooling network of Parc de l'Alba.

Thermoeconomic Analysis of Cogeneration Systems Assisted with Solar Thermal Heat and Photovoltaics

Eduardo A. Pina[1], Miguel A. Lozano[1], Luis M. Serra[1]

[1] GITSE I3A, Universidad de Zaragoza, Maria de Luna 3, 50018, Zaragoza, Spain

Abstract

This work aims to perform a thermoeconomic analysis of a cogeneration system assisted with solar thermal heat and photovoltaic power, and determine the daily optimal operation taking into consideration the effects of thermal energy storage (TES) and hourly variations of solar radiation, energy prices and energy demands. The system is considered to be interconnected to the national electric grid, thus purchase and selling of electricity are possible. A linear programming model was developed to represent the hourly operation of the system. The results presented herein correspond to the optimal operation for a representative day in April. It was shown that the cogeneration module operates at full load throughout the day and the system sells electricity to the grid for a total of 8 hours. The marginal cost analysis showed the different situations in which heat is charged/discharged to/from the TES and how it affects the unit cost of the heat produced. It has been proposed a thermoeconomic model that incorporates a new set of equations to contribute towards a better understanding of the charge and discharge in different time periods in the TES. The obtained unit costs for internal flows and products showed that the electricity and heat produced by the cogeneration system are always cheaper than the separate conventional production (43-53% cheaper for the electricity and 19-67% cheaper for the heat).

Keywords: *cogeneration, thermal storage, solar thermal energy, photovoltaics, thermoeconomics*

1. Introduction

The increasing world energy demand as a consequence of society development, along with a growing concern about environmental issues and fossil fuel depletion have motivated the development of more efficient energy systems and that consume a greater share of renewable energy. Conventionally, the electricity consumed by buildings is purchased from the national electric grid and the heat demand is covered by onsite production, e.g. in a natural gas boiler. The building sector accounts for 40% of total energy use in the European Union. The Directive 2010/31/EU on energy performance of buildings set the framework for energy efficiency in buildings and nearly zero-energy buildings and states that new buildings must assess the technical, environmental and economic feasibility of incorporating high-efficiency alternative systems such as cogeneration (Combined Heat and Power, CHP) and of producing energy from renewable energy sources (e.g. solar thermal heat and photovoltaic power).

In CHP systems, electric (and/or mechanical) and thermal energy are produced from the same primary energy source. This combined production allows for primary energy savings and a reduction of pollutant emissions relative to the conventional separate production. By incorporating CHP systems in buildings, a shift from centralised to distributed generation takes place, which is accompanied by benefits such as reduction in transmission and distribution costs, reduction in energy dissipation, increase in energy efficiency of the system (Serra et al., 2009; Mancarella, 2014). In order to achieve the benefits described, two fundamental issues must be addressed (Lozano et al., 2010; Yokoyama et al., 2015): (i) the synthesis of the plant configuration (equipment number and capacity for each type of technology employed) and (ii) the operational planning (equipment operational strategy, energy flow rates, purchase or selling of electricity, etc.). However, the variability of energy demands in buildings as opposed to the simultaneous and often constant production in

doi:10.18086/eurosun.2016.05.03 Available at http://proceedings.ises.org

industry impose some issues to the optimal operation of the system. Moreover, the same reasoning applies to the incorporation of renewable energy sources (RES), such as photovoltaic panels and solar thermal collectors, which are characterised by low predictability and non-simultaneity between production and consumption. Therefore, it becomes convenient to incorporate thermal energy storage units, allowing a decoupling of production and consumption, reducing heat wasting to the environment and enhancing the overall performance of the system (Ashouri et al., 2013; Buoro et al., 2014).

The objective of the present work is to perform a thermoeconomic analysis of a cogeneration system assisted with solar thermal heat and photovoltaic power. A linear programming model was formulated, taking into consideration only the operational planning of the system. The daily optimal operation for a representative day in April was determined, considering the effects of thermal energy storage and hourly fluctuations of solar radiation, energy services prices and energy demands. The cost of internal flows and products of the system were assessed by analysis of marginal costs and thermoeconomic unit costs calculation.

2. System description and data elaboration

The cogeneration system analysed in the present work (Fig. 1) consists of the following productive units: (i) a cogeneration module CM, which includes a natural gas reciprocating engine and a hot water heat recovery system, producing electricity W_c and heat Q_c; (ii) an oil-fired auxiliary boiler AB, producing heat Q_a; (iii) a thermal energy storage TES that can be either charging Q_{in} or discharging Q_{out}; (iv) photovoltaic panels PV for electricity production W_{pv}; and (v) solar thermal collectors ST for heat production Q_{st}. All energy flows (in bold) are given in kW, except for the energy stored in the TES Sq, which is given in kWh.

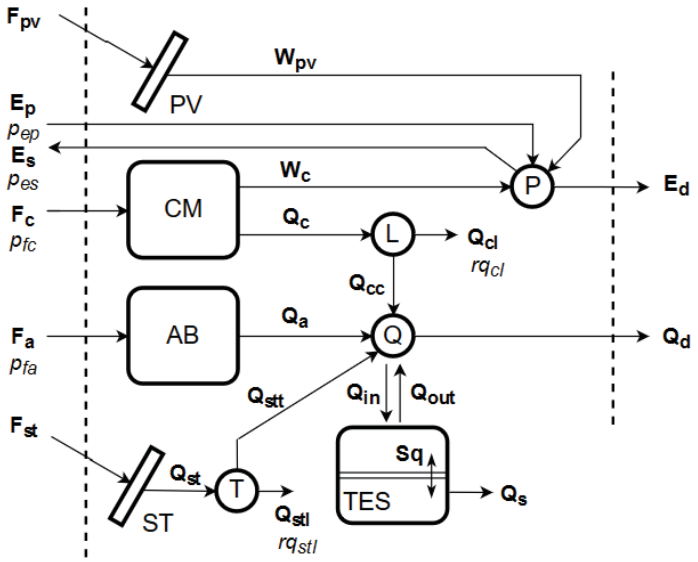

Fig. 1: Diagram of the cogeneration system

Tab. 1: Technical parameters and capacity limits of the cogeneration system's equipment

Equipment	Technical parameters	Capacity limits
Cogeneration Module (CM)	$\alpha_w = W_c/F_c = 0.35$ $\alpha_q = Q_c/F_c = 0.40$	$W_{max} = 400$ kW
Auxiliary Boiler (AB)	$\eta_q = Q_a/F_a = 0.80$	$Q_{max} = 600$ kW
Photovoltaic Panel (PV)	$P_{pv} = 0.300$ kW, $A_{pv,m} = 1.93$ m² $\eta_{pv} = 0.1538$, $\mu_T = -0.0035$ K^{-1}	$A_{pv} = 700$ m²
Solar Thermal Collector (ST)	$k_0 = 0.8170$, $k_1 = 2.2350$ W/(m²·K) $k_2 = 0.0135$ W/(m²·K²)	$A_{st} = 700$ m²
Thermal Energy Storage (TES)	$\eta_{TES} = 0.99$	$V_{max} = 1200$ kWh

Tab. 1 presents the technical parameters and capacity limits of each of the system's components. The cogeneration system was designed to attend all the electric E_d and thermal Q_d demands of a consumer centre (e.g. multifamily building). For the present work, the energy demands of a representative day in April were considered, being the total daily electric and thermal values 10,100 kWh and 19,200 kWh, respectively. As can be seen in Tab. 2, the demands and the daily operation of the system are described by 24 consecutive periods of 1-hour duration.

The system is considered to be interconnected to the national electric grid, therefore electricity can be purchased, E_p, at a price p_{ep} = 0.100 €/kWh, and sold, E_s, at a price p_{es} = 0.080 €/kWh. Natural gas and fuel oil are purchased from the market at prices p_{fc} = 0.025 €/kWh and p_{fa} = 0.020 €/kWh, respectively. There is the possibility of wasting cogenerated heat Q_{cl} and solar thermal energy Q_{stl} without cost ($rq_{cl} = rq_{stl} = 0$).

The PV and the ST are characterised by their surface areas (A_{pv} and A_{st}, respectively) and hourly specific productions (x_{pv} and x_{st}, respectively). The photovoltaic electricity W_{pv} and solar thermal Q_{st} productions can be obtained by multiplying the respective equipment area by its specific production. In order to evaluate x for each hourly period, the hourly ambient temperature T_a and the hourly radiation over tilted surface Q_r must be determined. The Erbs' correlation for ambient temperature (Erbs et al., 1983) was used to calculate the hourly T_a, using the monthly mean temperatures for the month of April from the *Guía Resumida del Clima en España 1981-2010* (AEMET, 2010). The hourly radiation Q_r over tilted surface (beam, diffuse and total) is calculated using the isotropic sky model (Duffie and Beckman, 2013). The sky clearness index can be obtained from the average daily horizontal radiation and the extraterrestrial radiation, which depends on the city latitude and the date. This index is used to calculate the daily diffuse radiation with Erbs' correlation (Erbs et al., 1982). The total horizontal radiation is hourly distributed with the Collares-Pereira and Rabl (1979) correlation, and the diffuse horizontal radiation is hourly distributed with Liu and Jordan (1960) correlation. The difference between total radiation and diffuse radiation is the direct (beam) horizontal radiation. Specific data required are: the monthly average of daily solar radiation on a horizontal surface (AENOR, 2007), latitude (41.6º for Zaragoza), surface azimuth angle (0º), reflectance of the ground (0.2) and tilt (35º for both PV and ST).

For each hourly period, x_{st} was determined by Eq. 1 using the performance coefficients from the manufacture's catalog (Tab. 1), the hourly data of the solar radiation over tilted surface Q_r, and the hourly temperature difference ΔT between the collector $T_{c,st}$ and the ambient T_a. Only the positive values of collected heat are considered. Further, $T_{c,st}$ is considered constant throughout the day and equal to 60 ºC.

$$x_{st}(h) = Max(k_0 \cdot Q_r(h) - k_1 \cdot \Delta T(h) - k_2 \cdot \Delta T(h)^2; 0) \quad \text{(Eq. 1)}$$

For each hourly period, x_{pv} was determined by Eq. 2 according to the methodology described in Duffie and Beckman (2013). The maximum power P_{pv}, the surface area $A_{pv,m}$, the module efficiency η_{pv}, and the temperature coefficient of power μ_T, were obtained from the manufacture's catalog (Tab. 1). Irradiation and cell temperature at SRC conditions are $Q_{r,SRC}$ = 1 kW/m² and $T_{c,SRC}$ = 25 ºC, respectively. Irradiation, cell temperature and ambient temperature at NOCT conditions are $Q_{r,NOCT}$ = 0.8 kW/m², $T_{c,NOCT}$ = 47 ºC and $T_{a,NOCT}$ = 20 ºC, respectively. The efficiency of power-conditioning equipment, η_e, is 0.9. The hourly cell temperature $T_{c,pv}$ and the hourly temperature correction factor F_{top} were obtained by solving Eqs. 3 and 4.

$$x_{pv}(h) = \left(P_{pv}/A_{pv,m}\right) \cdot \left(Q_r(h)/Q_{r,SRC}\right) \cdot F_{top}(h) \cdot \eta_e \quad \text{(Eq. 2)}$$

$$F_{top}(h) = 1 + \mu_T \cdot \left(T_{c,pv}(h) - T_{c,SRC}\right) \quad \text{(Eq. 3)}$$

$$T_{c,pv}(h) = T_a(h) + \left(T_{c,NOCT} - T_{a,NOCT}\right) \cdot \left(Q_r(h)/Q_{r,NOCT}\right) \cdot \left[1 - \left(\eta_{pv} \cdot F_{top}\right)/0.9\right] \quad \text{(Eq. 4)}$$

3. Optimal operation model

In order to determine the hourly operation modes that minimise the daily cost of meeting the energy demands, a linear programming model was developed and solved, as described in the following sub-sections. The LINGO modelling language and optimiser was used (LINGO, 2011).

3.1. Objective function and restrictions

The objective function is set to minimise the daily operation cost *DC* (€/day) of meeting the energy demands,

$$DC = \sum_{h=1}^{NP} HC(h) \quad \text{(Eq. 5)}$$

which is the sum of the hourly operation costs *HC(h)* of the 24 periods (*NP*) of 1-hour duration (*NHP*) that comprise the day,

$$HC(h) = \left(p_{ep}(h) \cdot E_p(h) + p_{fc}(h) \cdot F_c(h) + p_{fa}(h) \cdot F_a(h) - p_{es}(h) \cdot E_s(h)\right) \cdot NHP(h) \quad \text{(Eq. 6)}$$

subject to

Capacity limits:

CM_Wmax: $W_c(h) \leq W_{max}$ (Eq. 7)

AB_Qmax: $Q_a(h) \leq Q_{max}$ (Eq. 8)

Sqi_Vmax: $Sq_i(h) \leq V_{max}$ (Eq. 9)

Equipment efficiency:

CM_W: $\alpha_w \cdot F_c(h) - W_c(h) = 0$ (Eq. 10)

CM_Q: $\alpha_q \cdot F_c(h) - Q_c(h) = 0$ (Eq. 11)

AB_Q: $\eta_q \cdot F_a(h) - Q_a(h) = 0$ (Eq. 12)

PV_W: $A_{pv} \cdot x_{pv}(h) - W_{pv}(h) = 0$ (Eq. 13)

ST_Q: $A_{st} \cdot x_{st}(h) - Q_{st}(h) = 0$ (Eq. 14)

Balance equations:

P: $W_c(h) + W_{pv}(h) + E_p(h) - E_s(h) - E_d(h) = 0$ (Eq. 15)

L: $Q_c(h) - Q_{cc}(h) - Q_{cl}(h) = 0$ (Eq. 16)

Q: $Q_a(h) + Q_{cc}(h) + Q_{stt}(h) + Q_{out}(h) - Q_{in}(h) - Q_d(h) = 0$ (Eq. 17)

T: $Q_{st}(h) - Q_{stt}(h) - Q_{stl}(h) = 0$ (Eq. 18)

TES: $Q_{in}(h) - Q_{out}(h) - Q_s(h) + (Sq_i(h) - Sq_f(h))/NHP(h) = 0$ (Eq. 19)

The cyclical characteristic of the TES operation means that the energy stored at the beginning of an hourly period equals the energy stored at the end of the previous period (Eq. 20). Likewise, the energy stored at the beginning of the day (h = 1) must be equal to the energy stored at the end of the previous day (h = 24) (Eq. 21). The heat losses Q_s in each hourly period is a function of the TES efficiency η_{TES} and the stored energy at the beginning of the hourly period Sq_i (Eq. 22).

$$Sq_i(h) = Sq_f(h-1) \quad \text{(Eq. 20)}$$

$$Sq_i(1) = Sq_f(24) \quad \text{(Eq. 21)}$$

$$Q_s(h) = (1 - \eta_{TES}) \cdot Sq_i(h) \quad \text{(Eq. 22)}$$

3.2. Optimal operation and marginal costs

Tab. 2 presents the main flows of the system's optimal operation, for each hourly period, that brings the minimum total daily cost of 848.50 €. Positive Q_{TES} values correspond to the charged energy flow Q_{in} whereas negative values correspond to the discharged flow Q_{out}. The CM operates at full load throughout the day, while the AB modulates as needed. The daily photovoltaic production reaches 483.90 kWh, about 5% in relation to the total CM electricity production (9600 kWh). From hours 6 to 13 the system is able to sell 110.42 kWh/day of electricity to the grid, resulting in an income of 8.83 €/day; in all other hours the system purchases electricity from the grid, except for hour 5, in which the CM power production matches the electric energy demand.

Concerning the heat production, it can be seen that the solar thermal energy production peaks at hour 13, 308.42 kWh, adding up to a total daily production of 1894.70 kWh, about 17% in relation to the total cogenerated heat produced (10,971.40 kWh). Such production displaces the operation in the AB, avoiding 47.37 €/day of fuel consumption. Regarding the TES operation, for this representative day in April, it is most charged by the end of hour 4, with 416 kWh, about a third of its storage capacity. Attention should be paid to the different scenarios in which charging takes place:

given in: [1] kW, [2] ºC, [3] W/m^2, [4] kWh.

- Excess heat production: in hours 1 to 4, 13 and 14 the heat production from solar thermal collector and cogeneration module surpasses the thermal energy demand. The surplus heat stored for later consumption allows a reduction in the conventional heat production;
- Conventional heat required: in hours 7 and 17 to 19 the system must store energy in order to guarantee supply in hours of peak thermal demand (1200 kWh), e.g. hours 8, 9 and 20. Therefore, the AB is put into operation at the closest feasible period to the discharge, as to reduce heat losses to a minimum.

Dual prices obtained from the linear programming model help to unravel the marginal costs of internal flows and products, and to evaluate the economic impact of changes in demand or operational condition of the equipment (Lozano et al., 2009b).

Regarding the optimal operation, from hours 6 to 13, when the system is selling electricity to the grid, supplying an additional unit of electricity to the consumer centre means reducing selling by the same amount, therefore its marginal cost equals the selling price ($\lambda E_d = p_{es} = 0.080$ €/kWh); on the other hand, when the system matches the electric demand (hour 5) or purchases electricity from the grid (the rest of the time), the marginal cost of the electricity corresponds to the purchasing price ($\lambda E_d = p_{ep} = 0.100$ €/kWh).

Supplying an additional unit of heat to the consumer centre will always result in an increase in the production of the AB because solar thermal energy is a non-dispatchable resource and the CM already operates at full load throughout the day. Therefore, the important thing to notice is when this production takes place. Fig. 2 presents the 24 hourly periods and their respective marginal costs in €/kWh. The grey circles represent periods in which the AB is modulating. In such periods, the additional unit of heat is produced and consumed at the same hourly period, thus its marginal cost is the cost of producing 1 kW in the AB ($\lambda Q_d = p_{fa}/\eta_{AB} = 0.025$ €/kWh). The red circles indicate periods in which the dispatchable equipment (CM and AB) are not able to increase their productions (CM and AB operate at full load) and thus the deficit of heat must be produced in an earlier period and stored. In these cases, the AB will have to produce more than 1 kW as to compensate for the storage heat losses, resulting in a marginal cost that equals the cost of producing 1 kW plus heat losses in the AB. The blue circles correspond to periods of excess heat. Consuming an additional unit of heat in such periods means that one less unit is stored in the TES, so, in a later period, the AB will have to increase its production in not 1 kW, but less. Thus, the marginal cost will be the cost of producing 1 kW minus heat losses in the AB. The marginal costs of interconnected periods (red and blue circles) can be calculated by Eq. 23, which relates the cost of producing 1 kW in the AB, the TES efficiency and the storage time between the period k of AB production and the period h of additional unit of heat consumption.

$$\lambda Q_d(h) = \left(p_{fa}/\eta_{AB}\right) \cdot \eta_{TES}^{(k-h)} \qquad \text{(Eq. 23)}$$

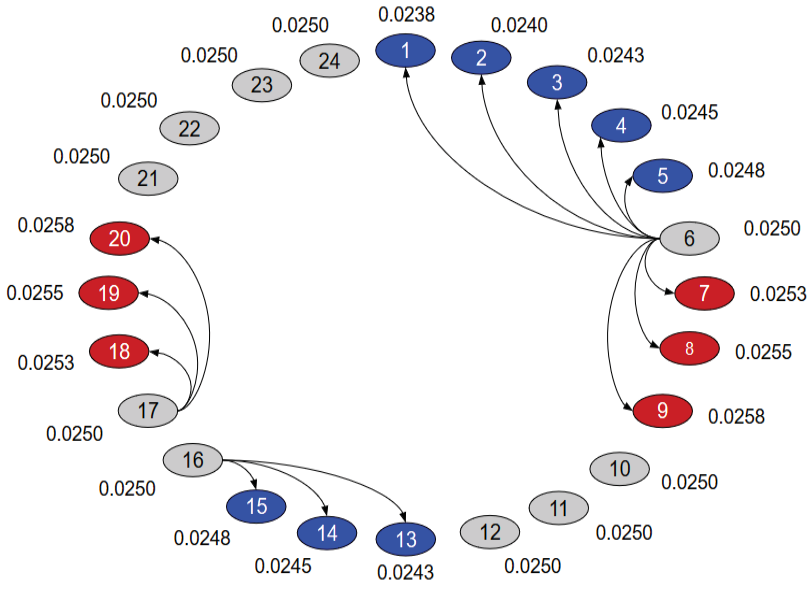

Fig. 2: Hourly marginal costs of the heat supplied to the consumer centre in €/kWh

4. Interconnection Between Hourly Periods

As stated by Chicco and Mancarella (2009), the effective combination of the different alternatives of production can bring forward enhanced benefits in terms of economic profitability, among others. In the analysed system, the thermal energy demand can be met by heat production in the CM, AB and/or ST at different productions costs. Because of the TES, heat can be produced and consumed at the same hourly period or produced and stored for later consumption. Therefore, as important as evaluating how much energy must be charged and discharged from the TES at each period, is knowing its source period. Only then the cost of the discharged flow can be traced back up to its production.

The optimal operation model described in section 3.1 gives the amount of heat that must be charged or discharged into the TES in each hourly period. In order to broaden this view and allow for a better understanding of how charge and discharge periods are interconnected through the TES, it was proposed to include a new set of equations in the model. It should be noted that such considerations do not change the results obtained; only more detailed information about the optimal processes of heat charge and discharge is revealed.

The diagram presented in Fig. 3 can be taken as example to clarify the interconnection between charging and discharging periods: the heat discharged in period z, $Q_{out}(z)$, is composed of virtual energy flows originated in three different earlier periods: OUT(i,z), OUT(j,z) and OUT(k,z) (Eq. 24); the pair (i,z) meaning i as the source period and z the destination period. Therefore, the heat stored in period i, $Q_{in}(i)$, may be divided into several virtual flows IN(i,x) that are going to be discharged in later periods, OUT(i,x) (Eq. 25). On account of heat losses, the discharge flow is always lower than the charge one (Eq. 26). The heat losses LOSS are assessed at the end of each period for each pair, and are proportional to the stored volume and duration (Eq. 27); the notation (i,z,j) means i as the source period, z as the destination period, and j the period in which the heat losses are being assessed. Thus, the longer the storage duration, the greater the heat losses along the pair, as can be seen by comparing pairs (i,z) and (k,z), the former with three LOSS flows and the latter with only one. The total heat losses of each period Q_s can be calculated as the sum of all LOSS flows in that period (Eq. 28), thus replacing Eq. 22.

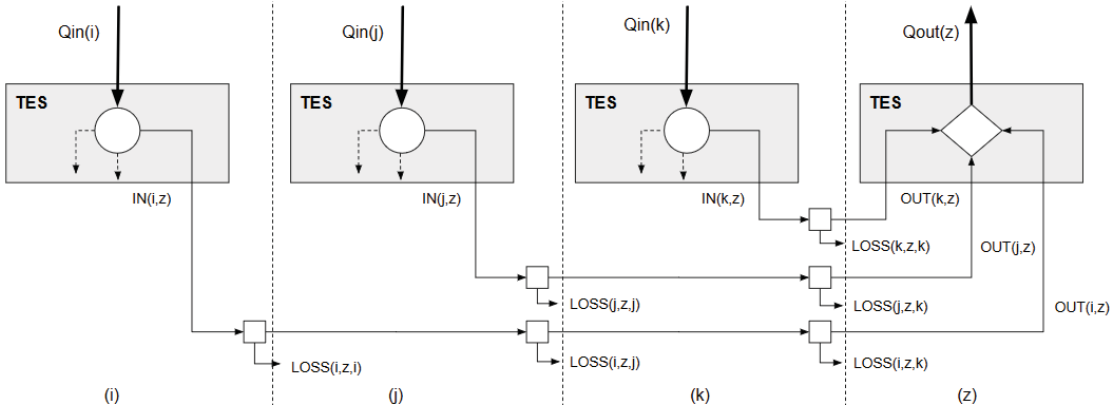

Fig. 3: Diagram for the charging and discharging of the TES

$$Q_{out}(h) = \sum_{i \neq h} OUT(i,h) \quad \text{(Eq. 24)}$$

$$Q_{in}(h) = \sum_{z \neq h} IN(h,z) \quad \text{(Eq. 25)}$$

$$IN(i,z) = OUT(i,z) + \sum_{h=i}^{z-1} LOSS(i,z,h) \quad \text{(Eq. 26)}$$

$$\sum_{h=i}^{j} LOSS(i,z,h) = IN(i,z) \cdot \left(1 - \eta_{TES}{}^{(j-i+1)}\right) \text{ for all } j = i, \ldots\ldots, z-1 \quad \text{(Eq. 27)}$$

$$Q_s(h) = \sum_{i,z} LOSS(i,z,h) \quad \text{(Eq. 28)}$$

The chart in Fig. 4 presents, for each relevant pair of periods (j,k), the charged energy IN, the discharged energy OUT and the heat losses LOSS between them. Because heat losses increase with storage time, as explained earlier, the model seeks to keep energy stored for the minimum time necessary in order to guarantee supply, meaning that the first unit of energy to be charged must be the first unit of energy to be discharged. Even though the model may infringe this rule once in a while, e.g. pairs (1,9) and (2,6), the optimal operation still stands, as both pairs form a loop in a way that shortening a pair and extending the other, e.g. (1,6) and (2,9), would provide equivalent heat losses.

5. Thermoeconomic Analysis and Cost Allocation

In energy systems, resources are consumed in order to produce certain qualities to the internal flows until the desired final products are obtained. Thermoeconomics allows the cost formation process to be transparent throughout the system, from energy resources to final products (Lozano and Valero, 1993).

In the cogeneration system analysed herein (Fig. 1) the possibility of selling electricity to the grid provides an income ($p_{es} \cdot E_s$) that reduces the operation cost. As the CM and the PV are the two productive units that can produce electricity, it was proposed to proportionally distribute E_s between both equipment according to their power productions. By doing so, the benefit of selling electricity to the grid could be incorporated to the internal flow costs of cogenerated W_{cc} and photovoltaic W_{pvv} electricity produced by the system. For each hourly period, the parameter γ, defined by Eq. 29, was used to determine the cogenerated E_{cs} and photovoltaic E_{pvs} electricity sold to the grid.

$$\gamma(h) = W_{pv}(h)/\left(W_{pv}(h) + W_c(h)\right) \quad \text{(Eq. 29)}$$

$$E_{pvs}(h) = \gamma(h) \cdot E_s(h) \quad \text{(Eq. 30)}$$

$$E_{cs}(h) = (1 - \gamma(h)) \cdot E_s(h) \quad \text{(Eq. 31)}$$

In order to properly carry out a thermoeconomic analysis, it is essential to identify the correct productive structure of the system (Lozano et al., 2011). Fig. 5 presents the productive structure devised for the thermoeconomic analysis, showing the energy flows in bold, the market prices of the resources in italic and the unit costs of internal flows and final products.

For each hourly period, all energy flows of the system and the prices of the commercial energy sources consumed are known (p_{ep} = 0.100 €/kWh, p_{es} = 0.080 €/kWh, p_{fc} = 0.025 €/kWh, p_{fa} = 0.020 €/kWh). There is no cost related to the dissipation of heat to the ambient (rq_{cl} = 0 and rq_{stl} = 0) and to the heat losses in the TES

(c_{Qs} = 0). The solar resource is obtained at zero cost (c_{Fst} = 0 and c_{Fpv} = 0). Thus, there remain 9 unit costs to be determined (c_{Wpvv}, c_{Wcc}, c_{Qcc}, c_{Qa}, c_{Qstt}, c_{Qin}, c_{Qout}, c_{Ed}, c_{Qd}).

Applying the cost conservation principle as described in Lozano et al. (2009a) to PV+V, ST+T, AB and P brings c_{Wpvv}, c_{Qstt}, c_{Qa} and c_{Ed}, respectively. There remain 5 unit costs to be determined (c_{Wcc}, c_{Qcc}, c_{Qin}, c_{Qout}, c_{Qd}). To complete the calculation of unit costs the following auxiliary equations are proposed.

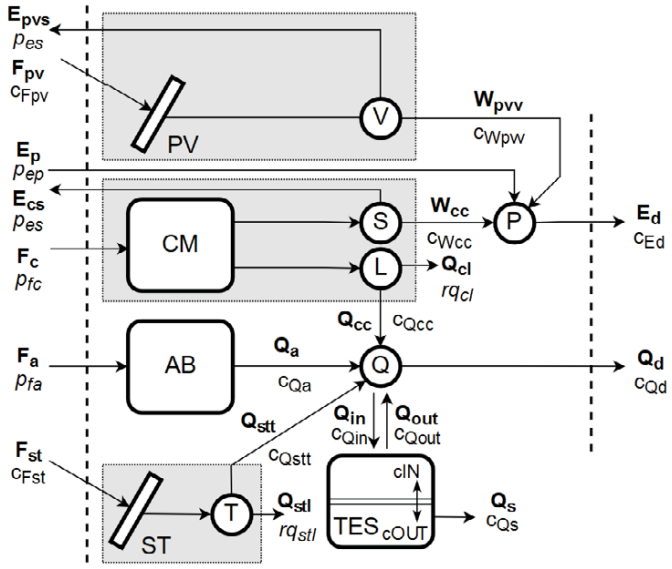

Fig. 5: Productive structure of the cogeneration system for the thermoeconomic analysis

Apart from the cost balance in CM+S+L, another equation is needed in order to determine the unit costs of the cogenerated products (c_{Wcc} and c_{Qcc}). The cogeneration subsystem is characterised by concurrent production of energy services, which is achieved through the energy integration of the process occurring in the equipment. Such a high level of integration hinders the determination of a unique distribution of the resource consumed F_c towards the obtained products W_{cc} and Q_{cc}. Considering an equal share of benefits, it was proposed (Lozano et al., 2011) to apply the same discount d to both products of the cogeneration subsystem (see Fig. 5) with respect to the cost of their conventional separate production: the purchasing price of electricity, $(c_w)_{ref} = p_{ep}$ = 0.100 €/kWh, for W_{cc}, and the cost of producing heat in the AB, $(c_q)_{ref} = p_{fa}/\eta_{AB}$ = 0.025 €/kWh, for Q_{cc}.

$$d(h) = 1 - c_{Wcc}(h)/(c_W)_{ref} = 1 - c_{Qcc}(h)/(c_Q)_{ref} \quad \text{(Eq. 32)}$$

$$c_{Wcc}(h)/p_{ep} = c_{Qcc}(h)/(p_{fa}/\eta_{AB}) \quad \text{(Eq. 33)}$$

The cost balance in junction Q will change according to the operation of the TES. When the TES is charging, an accepted rule can be applied, which establishes that the unit cost of several flows obtained from a homogeneous flow is the same (Lozano and Valero, 1993). This same rule can be applied to distribute c_{Qin} between the virtual IN flows (see section 4). Hence, Eq. 34 follows:

$$c_{Qin}(h) = c_{Qd}(h), \text{ when } Q_{in}(h) > 0 \quad \text{(Eq. 34)}$$

When the TES is discharging, the cost balance in Q gives c_{Qd}. In this case, the unit cost of the discharged flow c_{Qout} must be known. It can be determined by applying the cost conservation principle to Eq. 24.

$$c_{Qout}(h) = (\sum_{i \neq h} c_{OUT}(i,h) \cdot OUT(i,h))/Q_{out}(h), \text{ when } Q_{out}(h) > 0 \quad \text{(Eq. 35)}$$

The unit cost of the discharged energy c_{OUT} in a pair (h,j) (see section 4) can be determined by considering the increase in the unit cost of the charged energy c_{IN} in the same pair due to heat losses:

$$c_{IN}(h,j) = c_{Qin}(h) \quad \text{(Eq. 36)}$$

$$c_{OUT}(h,j) = c_{IN}(h,j) \cdot IN(h,j)/OUT(h,j), \text{ when } OUT(h,j) > 0 \quad \text{(Eq. 37)}$$

Tab. 3 presents the unit costs obtained for internal flows and products of the system. It was verified that the

unit costs of the final products c_{Ed} and c_{Qd} are always lower than the cost of their separate production.

Tab. 3: Unit costs of the main internal flows and products of the system, in €/kWh

[1] Discount applied to the cogenerated products, nondimensional.

Photovoltaic production and/or selling of electricity contribute to reducing c_{Ed}. In fact, at hour 12, when the system is selling electricity to the grid and the PV production is highest, c_{Ed} reaches its lowest value, 53% cheaper than p_{ep}. On the other hand, c_{Ed} peaks at hour 23, when there is no PV production and the system is purchasing electricity from the grid. Then, c_{Ed} is only 43% cheaper than p_{ep}. Considering the unit cost of the heat supplied to the consumer centre, it plunges at hour 13, when solar thermal production is highest, attaining a 67% reduction relative to the cost of producing heat in the AB. The highest c_{Qd} takes place at hour 20, when there is no solar thermal production, the AB works at full load and the TES is in discharging mode. At this hour, the reduction in c_{Qd} is of about 19%.

Regarding the products of the cogeneration subsystem, c_{Wcc} and c_{Qcc}, their unit costs are aprox. 45% cheaper than the cost of their conventional separate productions. This is due to the discount d applied, as explained earlier. The discount values increase between hours 6 and 13 because of the selling of cogenerated electricity to the grid. The income associated with the selling of E_{cs} is incorporated into the cogenerated products, reducing their unit costs and increasing the discount in those hours, as can be seen from Tab. 3.

By considering free of charge the solar resource, the income due to the selling of photovoltaic electricity to the grid results in negative unit costs of the photovoltaic electricity supplied to the system c_{Wpvv}, which contributes to lowering even further c_{Ed}.

Similar to Fig. 4, Fig. 6 presents the internal costs of the charged and discharged heat from the TES, for each pair (j,k) and for each hourly period z.

Fig. 6: Internal costs of charged and discharged heat from the TES

As can be seen from Fig. 6, the unit cost of the heat discharged from the TES c_{Qout} is always lower than the cost of its separate production (p_{fa}/η_{AB} = 0.025 €/kWh). Looking into each section (j,k), it can be noted the considerable variation of c_{Qout} throughout the day, which reaches a 133% difference between its highest and lowest values. Such variations are due to the nature of the charged heat. Different system equipment produce heat at different unit costs, e.g. c_{Qa} = 0.025 €/kWh, c_{Qcc} = 0.0139 €/kWh and c_{Qstt} = 0 €/kWh. Because the CM operates at full load at all hourly periods, the unit cost of the charged heat will be closer or farther from c_{Qcc} depending on its share in the total heat produced. For example, for hours 1 to 4, $c_{Qin} = c_{Qcc}$ because all the thermal energy produced by the system comes from the CM. In hours 7 and 17 to 19, there is a higher share of conventional than cogenerated heat (e.g. 57% Q_a and 43% Q_{cc}, for hour 7), resulting in a c_{Qin} closer to c_{Qa}. On the other hand, in hours 13 and 14 the free solar resource allows the c_{Qin} to be lower than c_{Qcc} (e.g. 62% Q_{cc} and 38% Q_{stt}, for hour 14).

6. Closure

Cogenerated Heat and Power systems have been progressively used in commercial and residential buildings in order to reduce primary energy consumption and costs of the energy services relative to the separate conventional production. The present work proposed to analyse a cogeneration system assisted with solar thermal heat and photovoltaics, located in Zaragoza (Spain). The daily optimal operation for a representative day in April was obtained by a linear programming model developed in LINGO.

The marginal cost analysis evinced the fundamental difference between (i) storing excess heat for later consumption because it is a better option than wasting it into the environment, and (ii) producing heat to be stored in order to guarantee supply in a later period.

Thermoeconomic analysis was used to determine the cost of internal flows and final products of the system. It has been shown that the electricity and heat produced by the cogeneration system were always cheaper than the separate conventional production, e.g. electricity purchase from the national electric grid and onsite heat production in an auxiliary boiler. However, it must be noted that the way in which costs are allocated to products will influence the consumer's behaviour. The incorporation of a TES adds a new dimension to the cost allocation problem: not only it requires to know from which equipment the heat produced comes from, but also in which time period it was produced.

7. Acknowledgments

This work was developed in the frame of the research project ENE2014-57262-R, partially funded by the Spanish Government (Energy Program), the Government of Aragon (Spain) and the European Union (FEDER Program). The authors also want to acknowledge the program "Ciência sem Fronteiras" offered by CNPq (Brazil).

Solar Driven Organic Rankine cycle (ORC) – A Simulation Model

Florian Theede, Andrea Luke

Institute of Technical Thermodynamics, University of Kassel, Kassel (Germany)

Abstract

In this work, an ORC-process driven by solar heat is simulated, analyzed and dimensioned for reliable electricity generation in remote areas, especially for refugee camps. The most common fluid for ORC-systems is R245fa. In 2022 this fluid will not be available because of the f-gas decree from 2015. Butane, pentane, R1233zd(e), R1234ze(z) are fluids with low global warming potential and are simulated in the ORC-process to analyze the performance and potential to replace R245fa. From the performance results, R1233zd(E), R1234ze(z) and n-butane have the potential to replace R245fa in organic Rankine cycles with low temperatures. Evacuated tube collector with the heat pipe system in low flow is found to be the best collector type for this application. 60 m² ETC collector area is needed for the generation of 2 kW electrical power. The increasing thermal efficiency of the ORC with higher source temperatures has more influence than the decreasing collector efficiency. In conclusion, the solar driven organic Rankine cycle is a potential alternative off-grid power technology to generate reliable electricity in remote areas in the sunbelt area. The whole system as a container concept is simple, robust, low-maintenance, mobile and can power, for example, a medicate centrum and public light with 2kW.

Keywords: *Organic Rankine cycle, low temperature waste heat, working fluid, solar thermal energy*

1. Introduction

In many remote areas exist no electricity grid or it is very unreliable. The international energy agency reported 1.2 billion people without access to electricity in the world (WEO, 2015). According to the general secretary Ban Ki Moon, all people should have universal access to modern energy sources. People in developing countries should have access to renewable and environmentally friendly energy sources (se4all, 2016). Electricity is necessary to develop the economy and to improve the health and education situation. Many people without electricity live in the rising refugee camps. In the end of 2015, 63.5 million people refuge from war, poverty and religious or political persecution, increasing tendency (UNHCR, 2015). A big part of the refugees live in camps, with until 400000 people in one camp. The greatest camps are located in countries like Kenya, Ethiopia, Jordan, Gaza Strip, Mauritania, South Sudan, Uganda, Tanzania and India. In refugee camps 90 % of people have no access to electricity. (Leach, 2015) Big problems in these camps are the medical care without a reliable electricity supply and the dark nights without light and high criminal violation.

The most less-developed countries are located equatorial respectively in the sunbelt of the earth, therefore solar energy represents a big potential for these countries. A big problem by using the sun for electricity generation with photovoltaic is the unreliability in times without sun and high priced power stores. An alternative is to heat up water by solar collectors and store it in a boiler, to save energy for the few hours without sun. An organic Rankine cycle (ORC) generates reliable electricity with the heated water out of the storage. ORC-processes in connection with solar heating and a heat reservoir have the potential for safe and environmental friendly electricity-generation in these camps and remote villages. With the right dimensioning of collector field and heat reservoir it is possible to generate enough electricity for medical equipment and light supply. Also a thinkable task is the stability of isolated electricity grids (rotated masses and black start) and energy supply in public buildings, server rooms and hospitals. Many new projects exist at the moment in modernization and new building of hospitals in less-developing countries in Africa.

A study on a 3kW solar driven ORC with concentrated collectors and temperatures around 150°C is published by Orosz et al. (2009). Organic Rankine cycles have usually small thermal efficiencies, because of the usage of

doi:10.18086/eurosun.2016.05.08 Available at http://proceedings.ises.org

low temperature heat sources with a small exergetic part of energy like solar thermal systems. The design of the components and the choice of a suitable working fluid are important to ensure a proper working process without any losses in the efficiency. Studies on the fluid selections for ORC-processes especially driven by a solar heat source are made from researchers like Tchanche et al. (2008), Rayegan and Tao (2011), Delgado-Torres and Garcia-Rodrigez (2010). They all did not analyzed new environmental friendly refrigerants like R1233zd(e) and R1234ze(z).

The biggest challenge to design an ORC-process is the selection of the working fluid and the design of the heat exchanger for the application in dependence of specified temperature levels. In this work, the heat source is solar energy and usually bounded in temperatures between 20°C and 180°C, depending on collector type, without considering concentrated systems.

In this paper, an ORC driven by solar heat is simulated, analyzed and dimensioned for reliable electricity generation in remote areas especially for refugee camps. The whole system should be simple, robust, with a low-maintenance and mobile with 2kW electric power for a medicate centrum and public light. The most common fluid for ORC-systems is R245fa. In 2022 this fluid will not available because of the f-gas decree from 2015 (EG-VO 517, 2014). Different working fluids in the ORC-process for the temperatures of a designed solar system are simulated to analyze the performance of low GWP working fluids for the potential replacement of R245fa.

2. System description and dimensioning

The whole system is dependent from the climate and weather conditions. Refugee camps located in the sunbelt and offer a high potential in the usage of solar energy. As reference in this paper, Aleppo is chosen from meteonorm software. The ambient temperature and the radiation in hour values are relevant. The system schematic is shown in figure 1. On the right side, the ORC is illustrated; on the left side the solar system. The systems are connected by the evaporator as heat exchanger and a storage tank for the compensation of hours without sun. It is also possible to operate directly without storage in hours with maximum turbine power output and high sun radiation to raise the efficiency.

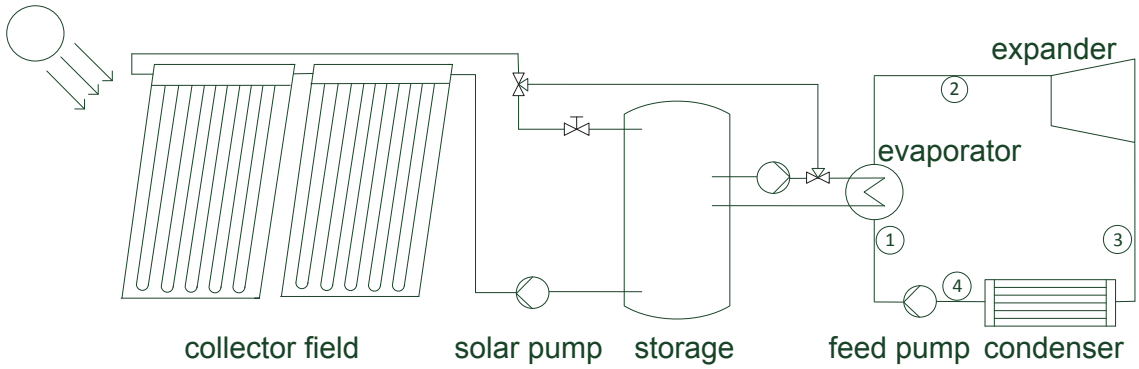

Fig. 1: Overview of the electricity-generation-system with solar heat and ORC

Solar collector:

Because of the limitation in Carnot efficiency and the dependence of exergetic and thermal efficiency on temperature [Theede and Luke, 2016], higher temperatures are preferable for the ORC. To avoid complex collectors with concentrated systems and to use water for a simple system, an evacuated tube collector (ETC) with the heat pipe system is chosen. This collector type has a high operation safety because of the easy replaceable tubes, need less space than flat collectors, has a freezing protection and has a higher performance at high temperatures, because of the better isolation. Collector outlet temperatures are in the rage of 80°C and 140°C. The usage of water at temperatures of 140°C results in a pressure level of maximum 4 bar to avoid evaporation with low heat transfer coefficients. The low flow operation is chosen to generate high temperatures in a big solar system. In this work, the mass flow is calculated to 0.28kg/s in the simulation with an assumed flow rate of 20 l/m²h and a first evaluated collector area of 55m². The fluid velocity is fixed at 1 m/s to avoid high pressure losses in the pipes. The commercial solar collector named Vitosol-T SPA is chosen for the dimensioning and simulation. It is an ETC working on the heat pipe principle. Other collector data with the optical efficiency and heat loss coefficients for the calculation of the collector efficiency are listed in table 1.

The collector efficiency is calculated in

$$\eta_{Coll} = \eta_{op} - \frac{a_1 \cdot (T_m - T_a)}{G} - \frac{a_2 \cdot (T_m - T_a)^2}{G} \qquad \text{(eq. 1)}$$

and depends on the collector a_1, a_2 and η_0 data on the mean average fluid temperature in collector T_m, the ambient temperature T_a and the sun radiation G.

In Figure 2, the characteristic of the ETC is shown. The efficiencies are calculated with radiations between 200 W/m² and 1200 W/m² and an average ambient temperature of 18°C in Aleppo. The collector efficiency decreases with higher collector temperatures and lower sun radiation. The less strong decreasing efficiency of the ETC in comparison to the decreasing efficiency with higher collector temperature in common flat collectors is conspicuous. Because of the good insulation with the vacuum, this is a big advantage of this collector type.

The product of the hour values of sun radiation from meteonorm and calculated collector efficiencies are taken and summarized to the solar thermal heat energy per square meter. In Aleppo, this value was 1875 kWh/m²a in 2003. This value shows the big potential in the usage of solar thermal energy in this region.

Organic Rankine Cycle:

The ORC-process consists of four components similar to the conventional Rankine cycle, but uses a refrigerant as working fluid to enable the generation of electricity from heat with low temperatures. The feed pump raises the pressure for the evaporation. The fluid is heated up, evaporated completely and superheated in the evaporator. The turbine expands the vapor and generates work, which is transferred in the generator in electricity. Finally, the vapor is condensed at the lower pressure.

The ORC-process should have 2kW of electrical power and generate electricity with a source temperature between 80°C and 130°C. The temperature spread in heat exchangers are 10 K and the evaporator is designed with superheat of 5 Kelvin. The evaporator uses a coaxial heat exchanger because of the simple construction. A tube bundle heat exchanger is not worth because of the slow fluid velocity in the solar process.

Tab. 1: collector data (VITOSOL 200-T SPA)[Q]

gross surface	4.62 m²
absorber surface	3.03 m²
aperture surface	3.13 m²
width	2.061 m
height	2.241 m
optical efficiency η_0	0.81
heat loss coefficient a_1	1.103 W/m²K
heat loss coefficient a_2	0.007 W/m²K
permissible pressure	6 bar

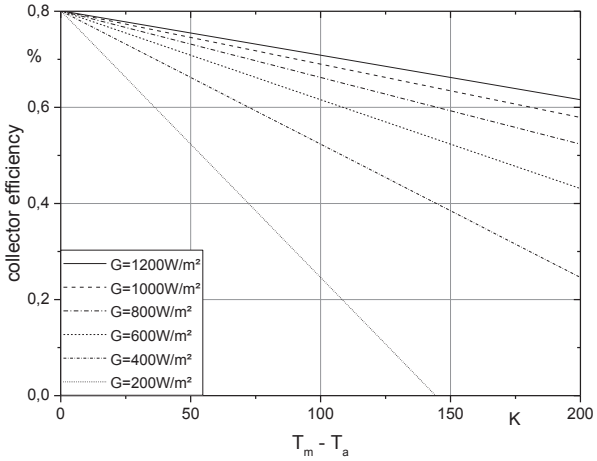

Fig. 2: collector efficiency characteristic of ETC

turbine inlet temp.: 130°C power output: 2 kW isentropic efficiency: 80%	evaporator type: coaxial heat exchanger	condenser type: tube bundle with cross streamed air
feed pump isentropic efficiency: 70%		heat source (solar) fluid: water inlet temp.: 140°C pressure: 4 bar velocity: 1 m/s mass flow: 0.28 kg/s	super-heat: 5K velocity: 2 m/s ambient conditions temp.: 18°C pressure: 1 bar	number of tubes: 100 (shifted) inner diameter: 0.5 cm distance between tubes: 1 cm Condensation temp.: T_a+10K air velocity: 20 m/s

A tube bundle heat exchanger with cross streamed air is chosen for the condenser, because of the lack of water as a coolant in remote areas. So the re-cooling temperature is the average ambient air temperature (18°C in Aleppo) plus the temperature spread in the heat exchanger. Many fluids are reviewed in the temperature range until 90°C [Theede]. The best fluids are found to be R245fa and n-butane. This fluids, n-pentane and two new environmental friendly fluids R1233zd(e) and R1234ze(z) with a low global warming potential are analyzed in this paper. The design conditions are summarized in table 2.

3. Simulation tool

The simulation, realized with the engineering equation solver (EES), is based on change of state in the thermodynamic cycle and is calculated with energy balances, equations of states and the definitions of the isentropic performance of expander and feed pump in equation (3) until (8).

turbine: $P_T = \dot{m} \cdot (h_3 - h_2)$ (eq. 3) $\eta_{s,T} = \frac{h_3 - h_2}{h_{3s} - h_2}$ (eq. 4)

feed pump: $P_P = \dot{m} \cdot (h_1 - h_4)$ (eq. 5) $\eta_{s,P} = \frac{h_{1s} - h_4}{h_1 - h_4}$ (eq. 6)

condenser: $\dot{Q}_C = \dot{m} \cdot (h_3 - h_4)$ (eq. 7)

evaporator: $\dot{Q}_E = \dot{m} \cdot (h_2 - h_1)$ (eq. 8)

where P is power of turbine or feed pump, $\dot{Q}$ is heat transfer rate, $\dot{m}$ is the mass flow of the working fluid, h is the enthalpy in the points of the process, calculated with the equation of states of the fluids. The pressure losses are neglected and evaporation and condensation are assumed to be isobaric. The heat exchangers are simulated according to the kinetic. The simplified simulation structure for the main process is shown in figure 3. The code calculates all working conditions and the parameters of the components.

The results of the thermodynamic process in equation (3-8) are used to calculate the thermal and exergetic efficiency:

$$\eta_{th} = \frac{P_T}{\dot{Q}_E + P_P} \quad \text{(eq. 9)}$$

$$\eta_{ex} = \frac{P_T}{\frac{T_3 - T_a}{T_3}\dot{Q}_E + P_P} \quad \text{(eq. 10)}$$

T_3 is the turbine inlet temperature and T_a is the ambient temperature. The other simulation parameters are reported in table 2. The operating conditions of the heat source are taken from the solar collector calculations.

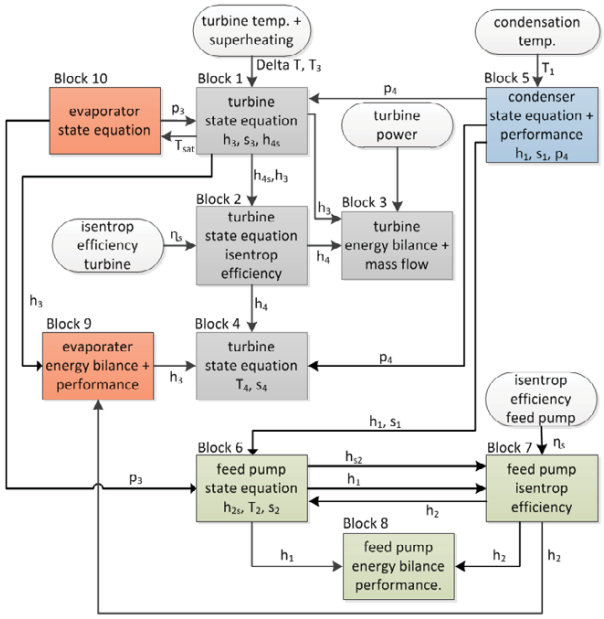

Fig. 3: simplified simulation structure of the ORC

A coaxial heat exchanger is set for pre-heating, evaporation and super-heating and a tube bundle condenser with cross streamed air for desuperheating and condensation. The thermodynamic parameters of the heat exchangers are numerically calculated with a segment-method. The different heat transfer coefficients are calculated and generate the overall heat transfer coefficient for the cell with

$$\frac{1}{k} = \frac{d_o}{d_i \cdot \alpha_{prim}} + \frac{d_o}{2 \cdot \lambda_{Co}} \cdot ln\frac{d_o}{d_i} + \frac{1}{\alpha_{sec}} \qquad \text{(eq. 11)}$$

for each cell with a default length, where k is the overall heat transfer coefficient, d_o outer diameter, d_i inner diameter, α_{prim} heat transfer coefficient inside the pipe, α_{sec} heat transfer coefficient on the outside of the pipe and λ_{Co} the thermal conductivity of copper. At the same time, conditions for the next segment like the new temperatures, vapor quality and the heat flux are calculated. The heat flux in the first segment is simulated with a loop of the first cell that compares the heat fluxes of two consecutive loop cycles until the error is negligible.

In this work, correlation of Steiner (Kind and Saito, 2013) are chosen to calculate the heat transfer coefficients for flow boiling inside the evaporator and the correlation of Gnielinski (2013) for pre- and super-heating plus the heat transfer in the gap (solar fluid) in the coaxial heat exchanger are chosen. The condensation correlation from Thome et al. (2003) is used in the inner tube flow condensation and Gnielinski (2013) for the circulated flow of the air around the tubes. The desuperheater is calculated by Gnielinski (2013) for flow in tubes.

4. Results and discussion

Some primary results of the simulation and conditions of the fluids are reported in table 3. The critical point of the fluids is between 150.1°C and 196.5°C. The differences in the critical temperature of R245fa, n-butane, R1233zd(e) and R1234ze(z) lie in a small range of 15.5 K. R245fa is in many reviews the best and common refrigerant for ORC-process with low temperature heat sources. The F-gas decree from the January 1st, 2015 [EG-VO 517, 2014] prohibits the use of refrigerants with a GWP higher than 150 at 2022. So R245fa will not available for ORC projects in future. The GWP from n-butane, n-pentane, R1233zd(e) and R1234ze(z) are 5 or lower and could be an alternative to replace R245fa.

The pressure levels in evaporation and condensation in the design point are presented in table 3. Pressure levels in evaporation in dependence of the turbine inlet temperature are shown in figure 4. The evaporation and condensation pressure level of the fluids are similar. Only n-pentane has a significant lower vapor pressure curve. The mass flow of process and of different fluids in design point are between 25 g/s (pentane) and 89 g/s (R1234ze(z)). The differences in mass flow are due to the enthalpy difference in the turbine between the given condensation and evaporation pressure level in equation 3. The enthalpy range of the hydrocarbons is higher than the other fluids. R1234ze(z) with the highest mass flow has a significant small enthalpy difference in the turbine. A high mass flow requires bigger components and more use of material, but in this case all mass flows are very low. The feed pump depends on the pressure difference between low and high pressure and the mass flow.

The heat exchanger are the biggest elements of the ORC. Depending on the working fluid, the evaporator and condenser have different heat transfer areas. In figure 5 the evaporator heat transfer surface in dependence of the turbine inlet temperature is shown. The differences in the volume of the evaporator depend mainly in the heat transfer coefficient. In evaporation, the pressure level has the biggest effect in the value of heat transfer coefficient. The increasing evaporation pressure with higher turbine inlet temperatures (see fig. 4) results in a decreasing heat transfer surface in the evaporator with increasing temperatures (see fig. 5). Butane and R1234ze(z) with the highest evaporation pressures have the smallest evaporator. The fluid properties, in particular the thermal conductivity, have the biggest influence on heat transfer coefficient in condensation.

Tab. 3: ORC results of the simulation and fluid conditions on the design point

Fluid	critical temp.	pressure evap.	pressure cond.	massflow	pump power	HX(evap.) surface	HX(cond.) surface	GWP
[-]	[°C]	[bar]	[bar]	[kg/s]	[W]	[m^2]	[m^2]	[-]
R245fa	154	21.25	1.65	0.052	53.1	0.181	3.723	1030
n-butane	152	24.13	2.68	0.027	70.1	0.175	3.695	4
n-pentane	196.5	9.98	0.77	0.025	26.2	0.199	3.274	5
R1233zd(e)	165.6	17.33	1.44	0.051	45.2	0.194	3.662	1
R1234ze(z)	150.1	22.32	1.98	0.089	60.3	0.175	3.603	< 1

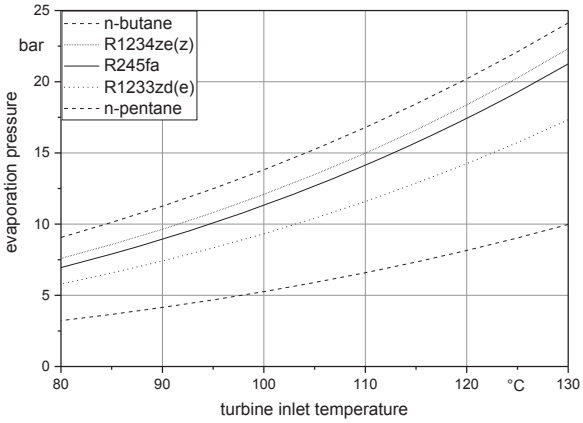

Fig. 4: evaporation pressure in dependence of turbine inlet temperature

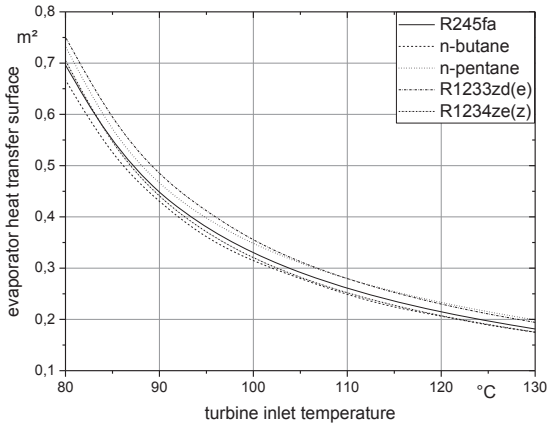

Fig. 5: evaporator heat transfer surface in dependence of the turbine inlet temperature

The design point of the evaporator can be fixed at medium collector temperatures. In ORC-operation driven by the heat of the boiler with lower temperatures, the extra pump can produce (see fig. 1) a higher heat transfer coefficient on the secondary side of the heat exchanger by raising the mass flow.

In table 4 the efficiency results of the ORC, the needed thermal power and energy for 2kW turbine power plus the efficiency of the whole system and the resulting collector area in the design point at 140 degrees source temperature is shown. The thermodynamic efficiency of the ORC-process in dependence of the turbine inlet temperature is shown in figure 6. The thermal efficiency depends on the turbine power, feed pump power and the transferred heat in the evaporator and increases with a slight digressive trend. The difference between the thermal efficiency of the best fluid (R1234ze(z)) and the worst fluid (n-pentane, R245fa) in design point is about 3.85%. These small differences are due to the similar physical characteristics of the fluid. R1234ze(z) has the best thermal efficiency (15.6%) because of the smallest difference of the evaporation temperature to the critical point. So the relation between specific heat capacity and the evaporation enthalpy is the smallest.

Tab. 4: The results of the simulation on the design point

Fluid	thermal efficiency (ORC)	exergetic Efficiency (ORC)	heat flux evaporator	thermal energy	system efficiency* (ORC+solar)	collector area
[-]	[%]	[%]	[kW]	[MWh/a]	[%]	[m²]
R245fa	15.0	53.5	13.27	116.25	9.59	61.99
n-butane	15.2	53.9	13.10	114.76	9.71	61.19
n-pentane	15.0	53.8	13.28	116.32	9.61	62.02
R1233zd(e)	15.4	54.8	12.98	113.68	9.82	60.62

* sun radiation 800 W/m²

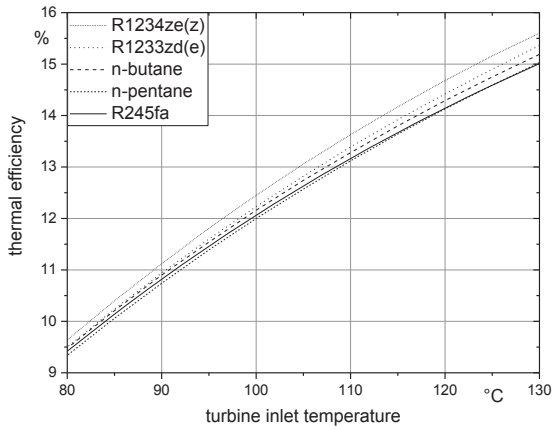

Fig. 6: thermal efficiency of the ORC-process in dependence of the turbine inlet temperature

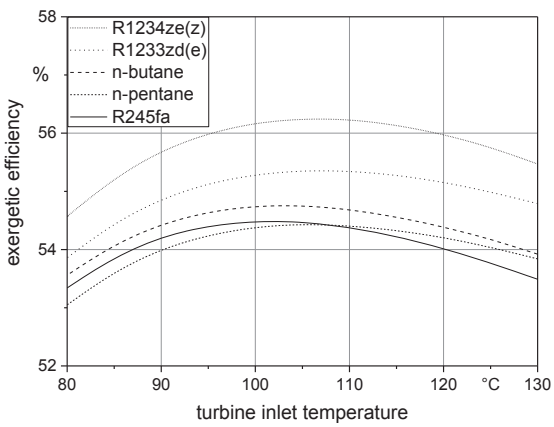

Fig. 7: exergetic efficiency of the ORC-process in dependence of the turbine inlet temperature

The exergetic efficiency of the fluid in dependence of the turbine inlet temperature is shown in figure 7. The exergetic efficiency in equation 10 includes the quality of the heat source (solar) in relation of the ambient temperature. With increasing temperature, the exergetic efficiency increases first, because the increasing exergetic part of the transferred heat is higher than the efficiency loss than the increasing pump power. After the point with the maximal exergetic efficiency at ca. 105°C, the increasing pump power has more influence in the exergetic efficiency and the value decreases. All differences in exergetic efficiency of the fluids with fixed turbine power and fixed ambient temperature depend on the feed pump power and the transferred heat in the evaporator (preheating, evaporation, superheating). The difference between the exergetic efficiency of the best fluid (R1234ze(z)) and the worst fluid (R245fa) in design point is about 3.60%. R245fa has the worst exergetic efficiency because of a combination of a higher relation of specific heat capacity and evaporation enthalpy, a higher feed pump power and a high enthalpy difference between high and low pressure combined with more preheating. The performance data of R1233zd(E) and R1234ze(z) in the respective temperature range are comparable to or better than the performance data of R245fa. R1233zd(E) and R1234ze(z) shows well performance results in figure 6 and 7 to have the potential to replace R245fa in ORC future.

The solar thermal energy of the chosen collector in Aleppo (2003) calculated with hour values in the design point equals 1875.35 kWh/m²a. Other thermal energy values for different collector outlet temperatures are listed in table 5. The thermal energy increases with lower temperatures, because of the rising collector efficiency (see in equation 1).This quantity of thermal energy is in good agreement with other works [Kalogirou, 2002]. The required heat to generate 2kW electricity over the whole year is reported in table 4. The quotient of the thermal energy and the solar thermal energy per m² equals the needed collector area. The collector area in dependence of the source temperature is plotted in figure 8. The collector area decreases with higher temperatures because of the rising thermal efficiency of the ORC. The trend is digressive because of the decreasing collector efficiency with higher collector temperatures.

Tab. 5: solar thermal energy

temperature	solar thermal energy
[°C]	[kWh/m²a]
140	1875.35
130	1899.33
120	1921.90
110	1942.97
100	1962.54
90	1980.61

Tab. 6: collector and system efficiency in design point for R1234ze(z)

sun radiation	collector efficiency	system efficiency
[W/m²]	[%]	[%]
600	59.61	9.13
800	63.92	9.97
1000	67.15	10.48

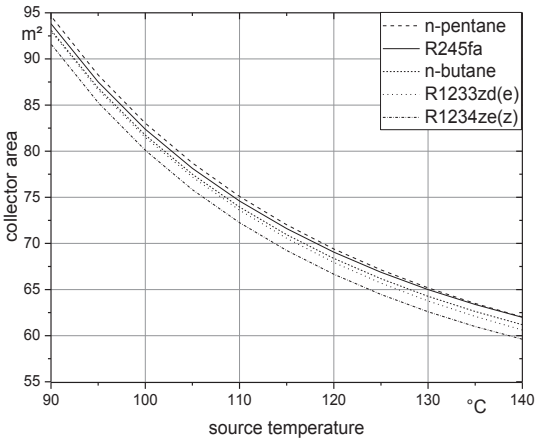

Fig. 8: collector area in dependence of the source temperature

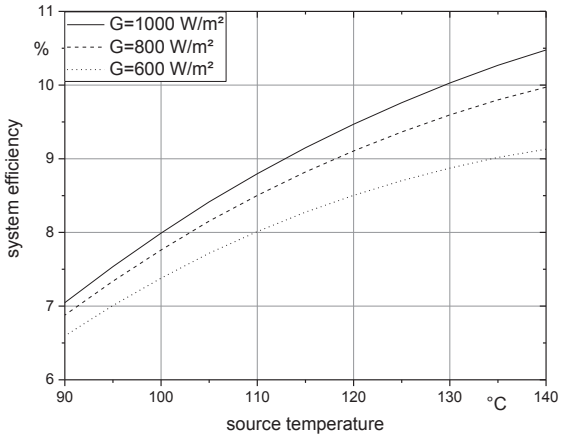

Fig. 9: system efficiency in dependence of the source temperature

In table 6 the collector efficiencies and the system efficiencies in three cases of sun radiation are listed. The values are generated in the design point and for the fluid R1234ze(z). Values for other fluids are listed in table 4 with a fix sun radiation of 800 W/m². The product of the collector efficiency and the thermal efficiency of the ORC equals the system efficiency. The system efficiency increases with higher sun radiations because of increasing collector efficiency. The dependence of the system efficiency with varying source temperature is plotted in figure 9. The system efficiency increases with the source temperature.

The trend is digressive because the collector efficiency is the product of the collector efficiency and the thermal efficiency of the ORC equals the system efficiency. The system efficiency increases with higher sun radiations because of increasing collector efficiency. The dependence of the system efficiency with varying source temperature is plotted in figure 9. The system efficiency increases with the source temperature. The trend is digressive because the collector efficiency is decreasing with higher temperatures. So the influence of the increasing thermal efficiency of the ORC in figure 6 is higher than the decreasing collector efficiency in figure 2. The trend of the system efficiency is more digressive with lower radiations because of the relation of the strong degreasing collector efficiency with lower sun radiation (figure 1). The trend of the system efficiency with 600 W/m² radiation is more decreasing and reaches nearly the maximum point.

In the design point with the selected ETC the system needs 59.6 m² collector absorber area with the fluid R1234ze(z). The absorber area of a ETC has 3.03 m² with 24 heat pipes (see table 1). So the whole system needed 20 ETCs, respectively 480 heat pipes to generate 2 kW electricity over the year. That's a value of 29.8 m²/kWe.

The whole system should be designed simple, robust, low-maintenance and mobile for refugee camps in remote areas. Solar thermal energy and the orc system are much tested and both systems need, with a good control engineering system, no supervision personnel. To make the system simple and mobile an ISO-container is most suitable (see in figure 10). The solar system is installed on the roof of the container and the ORC-process and water boiler are installed in the container. The transport goes by ship and truck. An ISO-container has a volume of 67.4 m² and a roof area of 28.3 m² (12.032 m length, 2.352 m width, 2.382 m high).

An optimal collector slope is the geographic latitude minus ca. 10 degree (Eicker, U., 2011). Aleppo with geographic latitude of 36.2 degree has an optimal collector slope of 26.2 degree. With a space factor of 2.2, four collectors take place on one container in the operation. With an installed rail system 10 collectors take place on one container. Two containers get enough space for a collector field of a 2 kW solar-ORC-power-system. The boiler can be free scaled, because there is enough space in the container. The ORC and boiler take place in one container and the other container can use for service quantities and other technical systems to compensate the hours were no electricity is needed. A potential technology is a water treatment system.

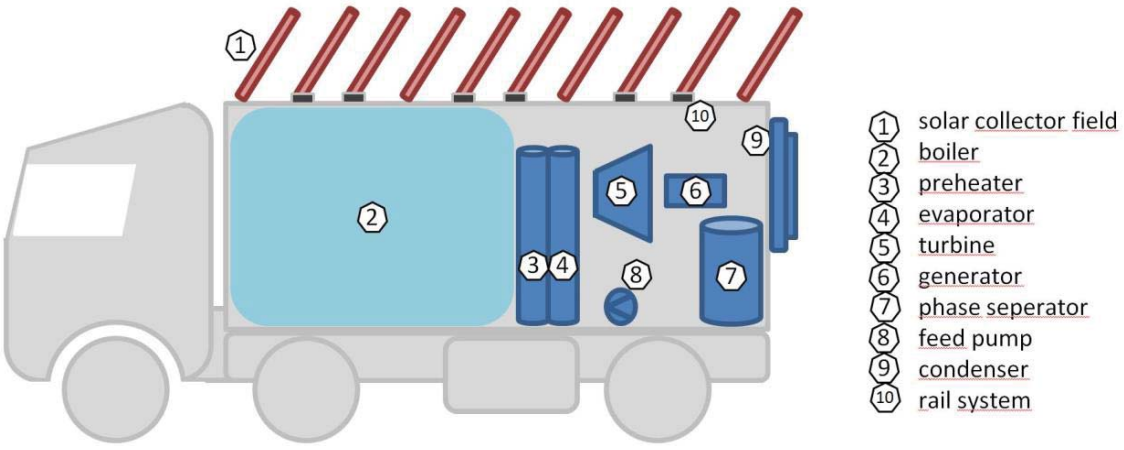

Fig. 10: schematic drawing of the solar driven ORC as container system

5. Conclusions

An ORC-process driven by solar heat is simulated, analyzed and dimensioned in this work for reliable electricity generation in remote areas, especially for refugee camps. ORC-processes in connection with solar heating and a heat reservoir plus a high value of sun radiation in remote areas in the sunbelt have the potential for safe and environmental friendly electricity-generation. The whole system as a container concept is simple, robust, low-maintenance, mobile and can power for example a medicate centrum and public light with 2kW. Evacuated tube collectors with the heat pipe system in low flow are chosen as the best collector type for theses application because of the easy replaceable tubes, higher performance at high temperatures (better isolation). 60 m² ETC collector area is needed for the generation of 2 kW electrical power. This value increases with lower temperatures. The system efficiency is increasing with higher source temperatures. Therefore the increasing thermal efficiency of the ORC with higher source temperatures has more influence than the decreasing collector efficiency. The most common fluid for ORC-systems is R245fa. In 2022 this fluid will not be available because of the f-gas decree from 2015. Four different fluids (n-butane, n-pentane, R1233zd(e), R1234ze(z)) with low GWP for the temperatures of a designed solar system are simulated in the ORC-process to analyze the performance and potential to replace R245fa. All fluids produce similar results in terms of evaporation pressure and thermal respectively exergetic efficiency. Only n-pentane has lower efficiencies and evaporation pressures in comparison to the other fluids. A local maximum point for the exergetic efficiency is found. After this point, the increasing pump power with higher temperatures has more influence as the raising exergetic part of solar heat. R1234ze(z) offer a high mass flow because of the low enthalpy difference between high and low pressure in the turbine. From the in performance results R1233zd(E), R1234ze(z) and n-butane have the potential to replace R245fa in organic Rankine cycles with low temperatures. Other analysis concerning thermal stability, security and economical aspect should be made in future. Also, the pressure losses should be analyzed. In conclusion, the solar driven organic Rankine cycle is a potential alternative off-grid power technology to generate reliable electricity in remote areas in the sunbelt.

Integration of solar thermal systems in existing district heating systems

Carlo Winterscheid[1], Jan-Olof Dalenbäck[1] and Stefan Holler[2]

[1] Chalmers University of Technology, Gothenburg (Sweden)

[2] HAWK University of Applied Science and Arts, Göttingen (Germany)

Abstract

The integration of large solar heating systems in district heating (DH) networks with large combined heat and power (CHP) plants is rarely considered. This is often due to low costs for heat but also due to subsidies for the electricity by CHP plants. Possible changes in subsidies and requirements in the reduction of fossil fuel based CO_2 emissions raise an awareness of improving the operational flexibility of fossil fuelled CHP plants. This paper provides a rather simple but detailed methodology of including large solar heating systems in an existing district heating system, where heat is supplied by a large CHP plant. It uses hourly data of load and temperature patterns as well as radiation data and collector efficiency data to determine collector field size and storage size. The possibility of largely independent operation of sub-networks is analysed, which allows different system temperatures. A feasibility study indicates specific heat generating costs for different collector types. It is demonstrated that a sub-network can operate without a back-up boiler and that both network parts benefit from the interaction.

Keywords: *district heating, solar district heating, solar thermal systems*

1. Introduction

The integration of solar thermal systems in DH systems is a more and more common practice in some countries; however, few studies have been performed on methodologies and benefits of integrating solar thermal systems in DH systems that are mainly supplied by large scale CHP plants with low heat generation costs.

The general idea behind including solar collector fields in DH networks is to lower or even completely supply the low heat demand of a DH network during the summer months. Since the 1980s Denmark and Sweden have built many solar heating plants (Fisch et al. 1998). In some of these cases a seasonal storage is used to provide a solar share even above 50 % of the total system demand. The high taxation of primary energy sources supported the ambitions in Denmark that lead to seasonal storages which are only feasible in a very large scale (Meißner et al. 2012). In comparison to the Danish and Swedish developments solar DH systems in Germany started to be built later, at the beginning of the 1990s.

The large DH systems in Germany are generally supplied by large CHP plants. These plants are often operating as base load power producers and can supply heat and electricity at a cost-efficient level during summer and winter due to funding through the CHP production law (KWKG) (Berberich et al. 2015). In addition to the availability of low-cost heat, high and very high system temperatures in the DH systems also prevented solar heat generating systems (Urbaneck et al. 2015). In the case of the DH system Chemnitz, only a large change in the system structure in one district made a change feasible. Possibilities of including solar collector systems in existing DH networks that are not about to change radically and are using large scale CHP plants as a main heat source were rarely analysed. Despite of the higher specific generation costs a solar collector field can also bring several advantages to systems of the mentioned kind.

doi:10.18086/eurosun.2016.05.09 Available at http://proceedings.ises.org

This paper presents aspects where a solar collector field can be beneficial for a DH system based on a large scale CHP plant and how such a collector field can be included. The work was carried out by evaluating the load pattern of a part of an existing DH system in Germany. In the given case the system analyse was based on the following conditions:

- A fixed supply temperature in a connected sub-network that is not needed in the whole system
- A long connection pipeline between the main network plant and the connected sub-network
- A reduction of the primary energy factor (PEF)
- A reduction in CO_2 emissions

Taking into account the interests of the network owner different methodologies of including a solar collector field were developed. In the given case a solution without a local backup boiler is preferred; instead a daily reheat of a storage from the large CHP plant was suggested.

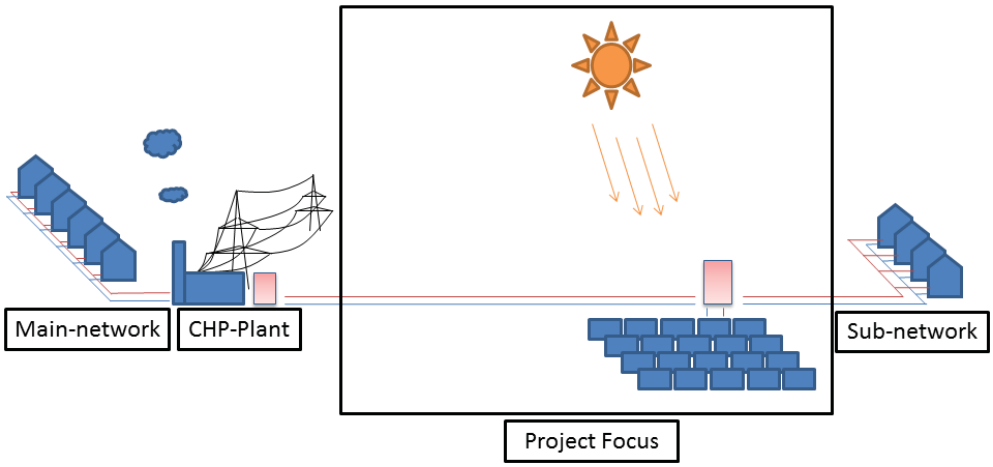

Figure 1. Project focus: The solar thermal field and the thermal storage are located between main-network and sub-network

2. Methodology

The calculations for this project have been performed in MATLAB and are based on four years of measurements of heat consumption, volume flow and flow temperatures. Values in 15 min time steps for the solar radiation of an average day of each month were imported from PVGIS (European_Commission) for the specific location. Additional weather evaluation has been performed using outdoor temperature data from 1974 to 2014 from Germany's National Meteorological Service (DWD) (Deutscher Wetterdienst).

Figure 2 below visualizes the methodology in a flow-chart starting with the input over a decision in solar share, resulting in collector areas, storage sizes and finally an energy flow overview and a storage operation visualization.

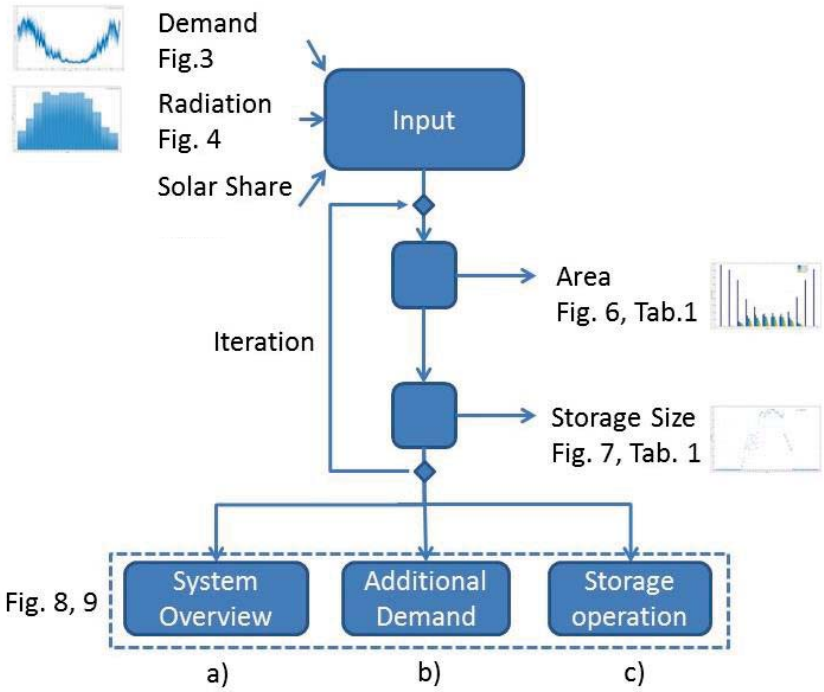

Figure 2. Methodology for the integration of solar heat into existing DH systems

Figure 3 shows the average heat load $Q_{dem,av}$ of the given consumer, the sub-network of the years 2013-2015. The following figure 4 shows the solar radiation during a year on a surface tilted south with an angle of 35°.

Based on the smoothened outdoor temperature line of the average outdoor temperature from 1974 to 2014 given by DWD (Deutscher Wetterdienst) and a graph displaying the required supply temperature to the sub-network, the time span from hour 3241 to hour 6337 of a year was calculated when the supply temperature is at its allowed minimum (Figure 5). In this time span the DH main-network could further decrease the supply temperature, if it could operate independently of the sub-network. The focus of this project was how the sub-network can be supplied by a solar heating system during this period.

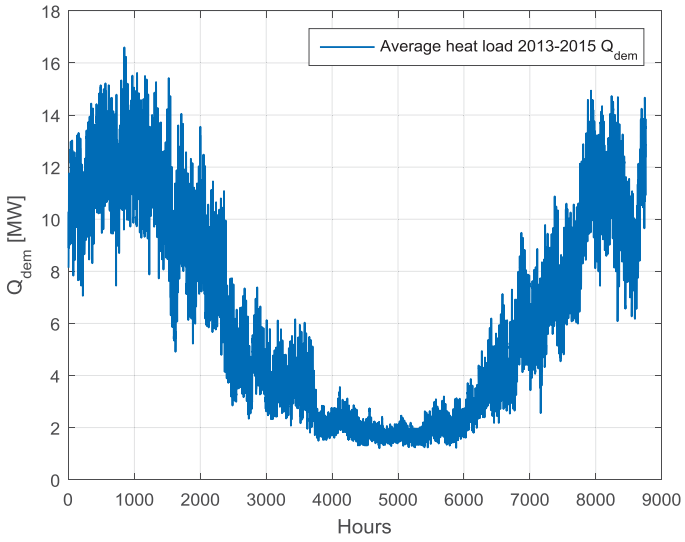

Figure 3. Example of annual the heat load curve in a sub-network

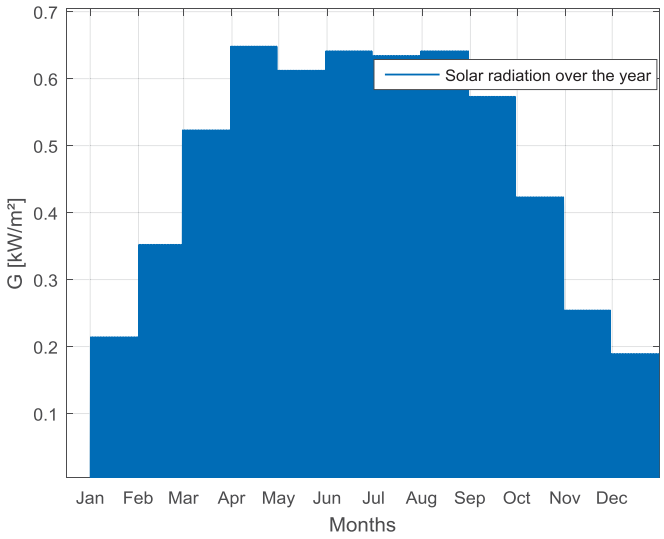

Figure 4. Example of maximum solar radiation on an average day on a south oriented 35° tilted surface in southern Germany

The efficiency of solar collectors η_c was calculated according to the European Standard EN 12975 (Kovacs 2012) as follows:

$$\eta_c(t) = \eta_0 - a_1 \frac{(T_m(t) - T_a(t))}{G(t)} - a_2 \frac{(T_m(t) - T_a(t))^2}{G(t)} \quad \text{(Eq. 1)}$$

$$T_m(t) = \frac{(T_{out}(t) + T_{in}(t))}{2} \quad \text{(Eq. 2)}$$

η_0 Collector zero-loss efficiency (-)

a_1 First degree coefficients of the collector heat losses (W/Km²)

a_2 Second degree coefficients of the collector heat losses (W/Km²)

G Global radiation (W/m²)

T_m Hourly medium temperature (K)

T_a Hourly ambient temperature (°C)

T_{out} Hourly collector outlet temperature (°C)

T_{in} Hourly collector inlet temperature (°C)

Accordingly, the net solar gain $Q_{sol}(t)$ is:

$$Q_{sol}(t) = \eta_c(t) * G(t) \quad \text{(Eq. 3)}$$

As the average global irradiance ins given in 15 minute steps the resolution was reduced to hourly steps in order to use the actual DH return temperature as collector inlet temperature T_{in} and the DH supply temperature as the collector outlet temperature T_{out} if it was above 80 °C, otherwise T_{out} was set to 80°C. The ambient temperature T_a was taken from PVGIS as well. The collector dependent values η_0, a_1 and a_2 were taken from collector datasheets of a Arcon HT-HEATboost 35/10- flat plate collector (FPC) and a RitterXL XL 19/49P evacuated tube collector (ETC).

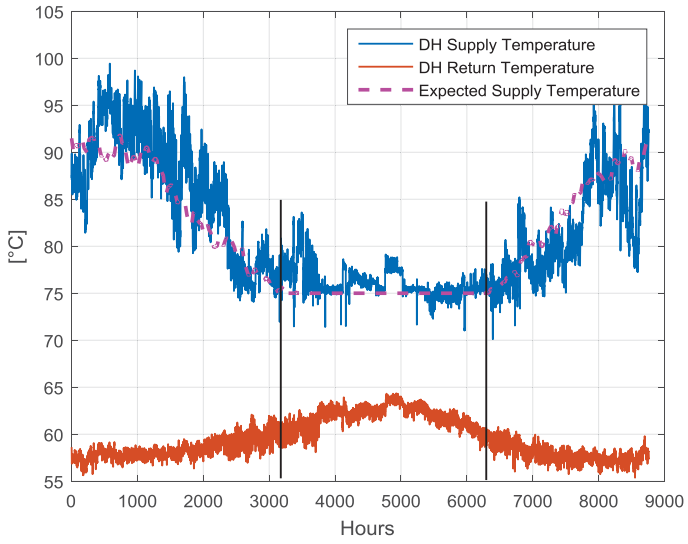

Figure 5. Average supply and return temperature and expected supply temperature of the sub-network

2.1 Area selection

Field sizes were calculated depending on different annual solar shares of 5 %, 10 %, 15 % and 20 % of the total annual heat consumption. Additionally, one approach aims to supply the heat consumption of July completely, which corresponds to 14 % solar share, because this is the month with the lowest consumption throughout the year. The following calculation steps are used to receive the actual collector aperture area in m²:

$$Rel(t) = \frac{Q_{dem,m}(t)}{Q_{dem,tot}} \quad \text{(Eq. 4)}$$

$$Q_{sol,m}(t) = Q_{sel} * Rel(t) \quad \text{(Eq. 5)}$$

$$A = \max\left(\frac{Q_{sol,m}(t)}{q_{sol,m}(t)}\right) \quad \text{(Eq. 6)}$$

Rel Relative monthly energy demand (-)

$Q_{dem,m}$ Monthly energy demand by the sub-network (kWh)

$Q_{dem,tot}$ Annual energy demand by the sub-network (kWh)

$Q_{sol,m}$ Monthly energy to be supplied by solar (kWh)

Q_{sel} Annual energy chosen to be supplied by solar (kWh)

$q_{sol,m}$ Specific net solar gain per month (kWh/m²)

A Aperture area needed (m²)

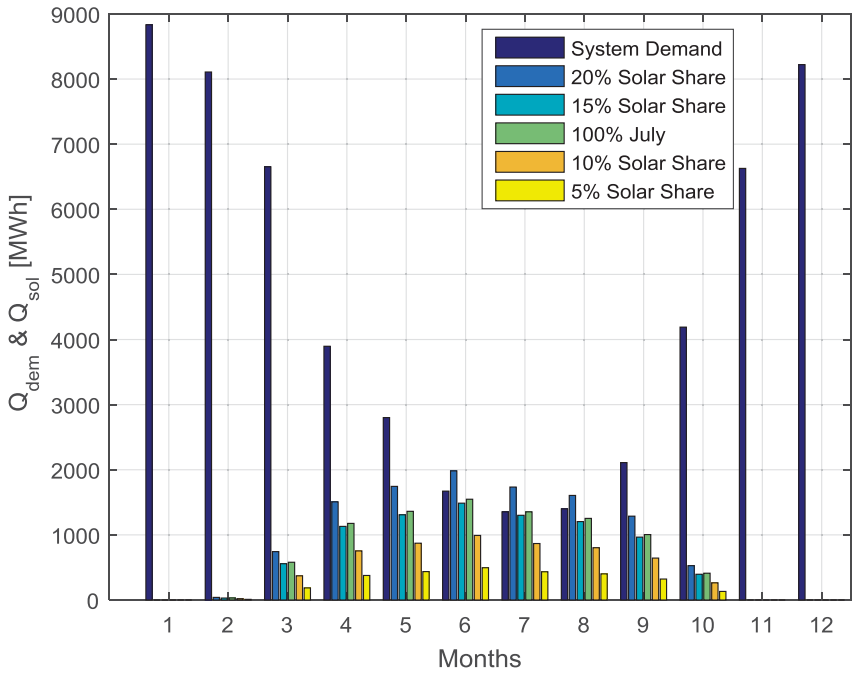

Figure 6. Net solar gain compared to demand for different solar share variations

Figure 6 shows an overview of the different solar shares compared to the monthly energy demand. At an annual solar share of 14 % the solar heat energy fully covers the heat demand in the month of lowest demand (July). A higher annual solar share provides a surplus of solar heat during the summer that cannot be used.

Table 1 shows an overview of the calculated variations with the collector area, the relative storage dimension and the achieved CO_2 savings.

Table 1. Calculation results for different annual solar share

Solar share	Collector area (m²)	Specific storage volume (l/m²)	Storage volume (m³)	CO_2 savings (t/a)
5 %	6507	7.3	50	480
10 %	13029	30.3	403	961
14 %	18319	39.5	728	1348
15 %	19536	40.5	802	1424
20 %	26044	46.2	1220	1725

2.2 Storage dimensioning

For this project it was required to store only the surplus solar heat that can be received within a single day and dimension the storage size accordingly. Figure 7 shows the solar surplus of each day that can be received when having an average load and a solar collector field size corresponding to the July demand (annual solar share of 14 %).

The conversion from MWh storage capacity to m³ water in storage capacity was performed according to the following formula:

$$V = \frac{Q_{st}}{\varrho * c * (T_{max} - T_{min})} \qquad \text{(Eq. 7)}$$

V Storage volume (m³)

Q_{st} Storage energy capacity (MWh)

ϱ Density of water (kg/m³)

c Heat capacity of water (Wh/(kg*K))

T_{max} Maximum storage temperature (°C)

T_{min} Minimum storage temperature (°C)

T_{min} is the maximum return temperature measured, 63 °C and T_{max} is the maximum allowed temperature in the storage 95 °C.

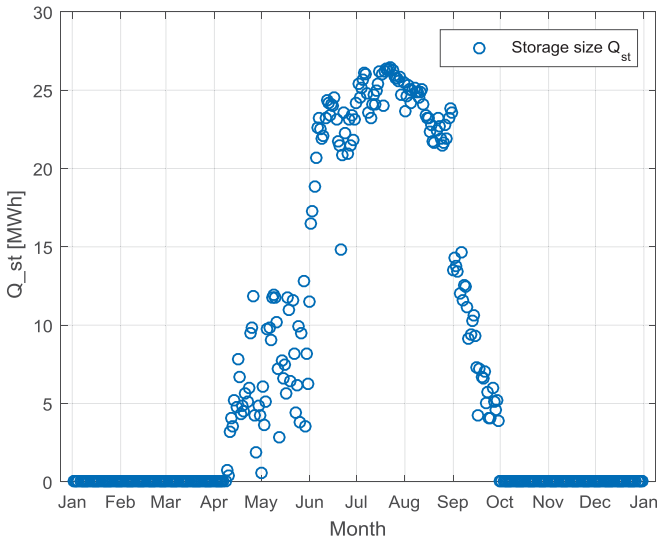

Figure 7. Needed storage capacity to store the solar surplus energy

2.3 Storage operation

To enable the sub-network to operate as independently as possible without having a backup boiler it is considered that the storage is reheated once per day. In this scenario the recharge from the main-network is set to be done every evening at 21.00 h with a supply temperature of 80 °C. This means that during summer time 3 different temperature zones will develop in the storage; one with the DH return temperature, one with 80 °C from the CHP plant and one with a maximum of 95 °C from the collector field.

2.4 Iteration

At this point an iteration is needed because the collector efficiency calculation depends on the DH supply and return temperatures that influence the collector inlet and outlet temperatures. To utilize the thermal storage to its maximum the storage temperature was set to a maximum of 95 °C. For the days that the storage is charged to its maximum the collector outlet temperature needs to be at least 95 °C. With the adjusted temperatures and thereby changed efficiencies the area and storage calculation was repeated.

3. Results

The first thing to realize throughout the calculation was that the needed storage size to store a solar surplus was below 50 l/m² collector area. A relatively small dimensioned storage is also recommended by Meißner et al.. Meißner et al. also points out that a solar storage is normally not used for the largest part of the year. This statement is also visually confirmed in Figure 7.

Figure 8a shows the supply and demand curves for the summer season if a recharge every evening is done for a solar collector area of 18,319 m² which corresponds to 14 % solar share. Figure 8 b) shows the additional demand of the system, meaning the heat power that is needed at some hours to cover the demand of the sub-network if the storage is empty and not enough direct solar energy is available. Equation (8) below shows the relation between the different heat power terms:

$$\dot{Q}_{dem} = \dot{Q}_{sol,dir} + \dot{Q}_{dis} + \dot{Q}_{add} \quad \text{(Eq. 8)}$$

$\dot{Q}_{dem}$	Heat load of the sub-network	(MW)
$\dot{Q}_{sol,dir}$	Directly used solar heat rate	(MW)
$\dot{Q}_{sol,stor}$	Stored solar heat rate	(MW)
$\dot{Q}_{dis}$	Storage heat discharge rate	(MW)
$\dot{Q}_{add}$	Additional heat supply rate	(MW)
Q_{re}	Daily storage heat energy recharge	(MWh)
Q_{ch}	Level of storage charge	(MWh)

Figure 8c and 9c display the storage charge and the energy the storage is charged with during the reheating process. In Figure 9a it can also be seen that when the storage is recharged, $\dot{Q}_{dem}$ of the sub-network at that moment is covered by the main-network, too.

While Figure 8 presents the complete summer season of a system with 14 % solar share, Figure 9 shows the supply and demand for the same system but this time only for 4 days. In Figure 9c, the excerpt of Figure 8c, it becomes visible that a regular evening recharge enables a projectable operation of main- and subnetwork. When analysing the red state of charge line in Figure 8c one can see that a daily recharge is not even needed every day.

The optimal system choice is therefore an offset between a system that needs as little additional energy during the summer season as possible, with the aim to let the main-network operate as independent as possible and a system that has a collector area as little as possible to reduce the system costs as well as to reduce the losses during the summer due to storage limitations.

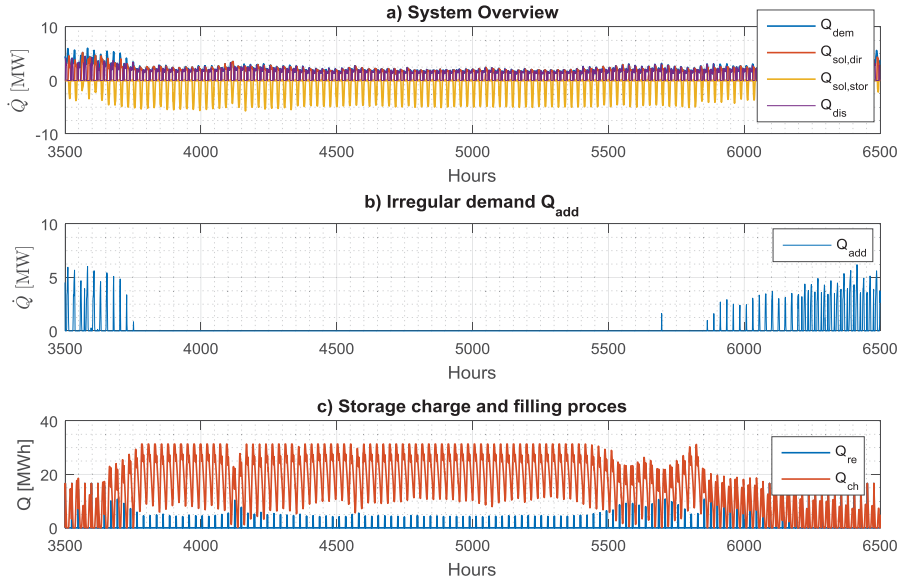

Figure 8. Supply and demand curves (a), additional heat power demand (b) and storage charging (c) during the summer season with 14 % solar share

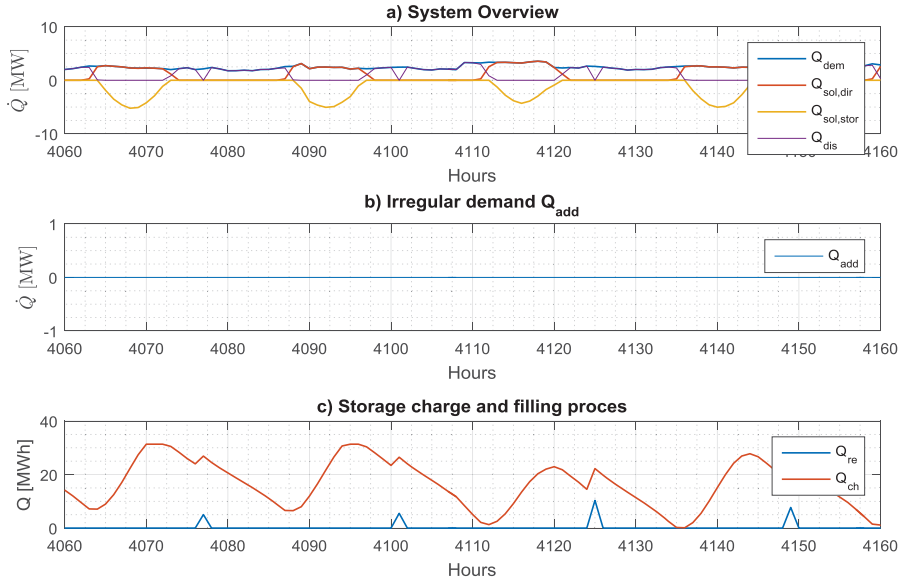

Figure 9. Zoomed in 4 days of supply and demand for the scenario with 14 % annual solar share

$\dot{Q}_{dem}$	Heat load of the sub-network	(MW)
$\dot{Q}_{sol,dir}$	Directly used solar heat rate	(MW)
$\dot{Q}_{sol,stor}$	Stored solar heat rate	(MW)
$\dot{Q}_{dis}$	Storage heat discharge rate	(MW)
$\dot{Q}_{add}$	Additional heat supply rate	(MW)
Q_{re}	Daily storage heat energy recharge	(MWh)
Q_{ch}	Level of storage charge	(MWh)

Figure 8 shows that a system of the given specification can supply the sub-network's demand during the summer season to a large extent independently of the main-network if an overnight charging of the storage to 80 °C is given. An increase from 14 % solar share to 20 % solar share will reduce the need for additional energy supply from the main network during the summer season but will also increase the losses of solar energy as the storage is not emptied for the largest part of the summer season. Furthermore, the difference in the collector area between 14 % and 20 % solar share is 7725 m² and will also have a large economic impact.

Additionally, a decrease in CO_2 emissions, as visible in Table 1, is possible by up to 1725 t CO_2 per year in the case of 20 %.

4. Feasibility study

The economic analysis of the calculated system is based on the main components as collectors, storage and the cost of land. Additional costs as control technology, system technology, construction works, planning and costs for system integration were added in percentage on the sum of the costs of the main components according to Schmidt & Deschaintre. The discounting of the investment costs is performed over 25 years and an interest rate of 4 % is applied. The collector costs used are 200 €/m² (Trier 2015) for flat plate collectors and 340 €/m² (AGFW 2013) for evacuated tube collectors. Cost of land were in this calculation set to 9 €/m² and the specific costs for the thermal storage were set to 140 €/m³(Maripuu & Dalenbäck 2011).

Additional subsidies based on German legislation were taken into account for this example system. According to (Pauschinger) 40 % of the collector costs and 30 % of the storage cost can be subsidized in Germany.

The following figure 10 shows the specific heat generating costs depending on the collector costs. The turn in both collector type lines at about 15 % solar share can be explained with the maximal capacity of the short-term thermal storage. If the collector area is too large the solar gains per day exceed the demand of the DH network per day.

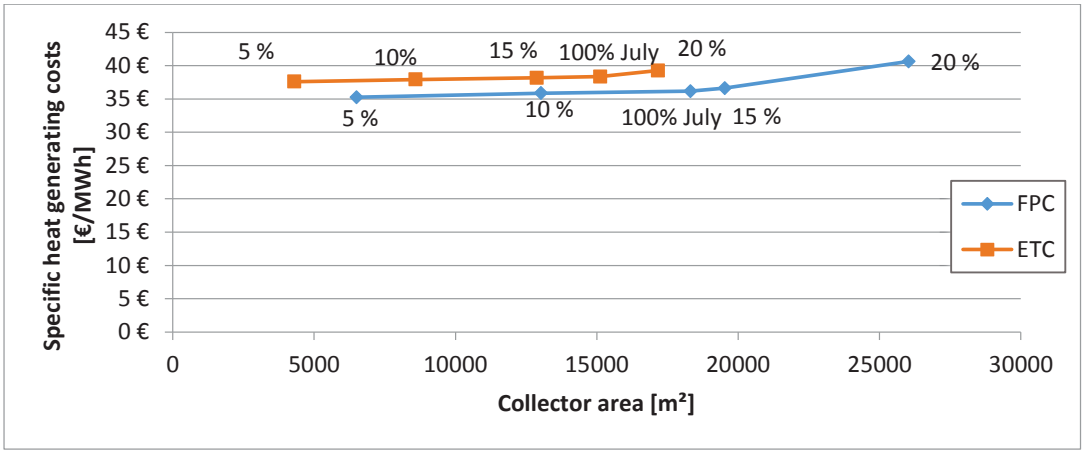

Figure 10. Specific heat generating costs dependent on the collector area for both collector types.

Figure 11 shows that the annual cost per amount of CO_2 reduced develop rather linear for both collector types until about 15 % when the issue of the storage limitation and too low network demand change the balance.

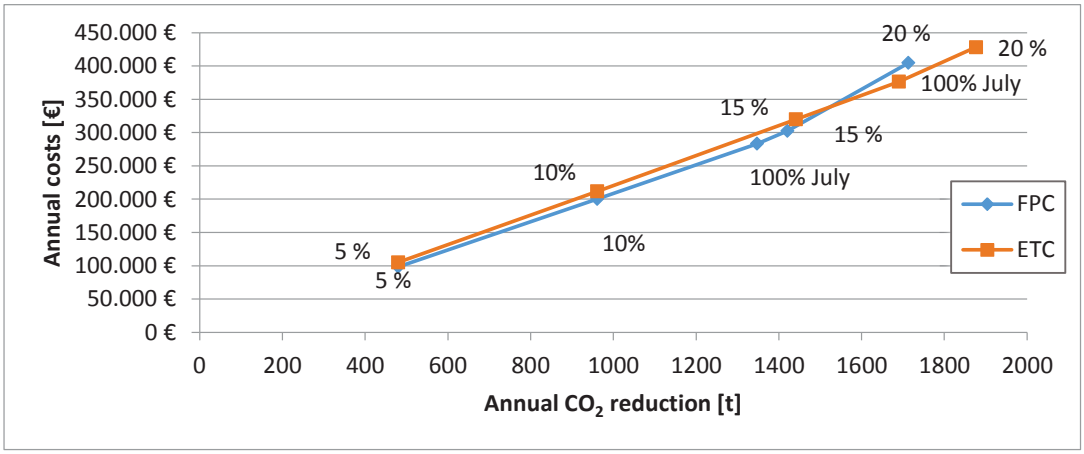

Figure 11. Annual system costs depending on the annual achievable CO2 emission reduction

5. Discussion

The comparison of the presented results against results of a freeware calculation tool (SDH Online-Calculator (Solites & AGFW)) with similar input data shows a generally good validity of the method. However, due to different methodological approaches the results cannot be compared to each other directly.

Firstly, the irradiation on the collector field was about 16 % higher in this project. This is due to a different location that was chosen but most of all due to the different meteorological data source of both calculations.

Secondly, it has to be mentioned that losses in the piping system and the storage of about 5 to 10 % have to be added.

Thirdly, results in the CO_2 savings differ in this project compared to the SDH-Online tool as the CO_2-emission factor of 172 g/kWh for the given example DH system was used.

The reader also has to be aware that small variations on the specific collector price [€/m²] have huge influence on the overall costs as the collector costs account for 70% of the whole system costs. The collector prices are changing depending on the system size, the location and are also expected to change over time.

6. Conclusion

The integration of solar heat into existing DH systems brings benefits to a fossil CHP plant based system such as CO_2 reduction, primary energy factor improvement and a larger operational flexibility. The possibility to supply a sub-network for certain periods of the year mainly by solar heat, allows an increasing efficiency of the CHP plant in the main network for the time that the temperatures can be lowered.

Furthermore, a solar thermal system enables the whole DH network to react better on future changes in the German electricity price market when it may be economically beneficial to decrease the energy production of the plant from an electricity production point of view.

The study shows that the accuracy of dimensioning a solar district heating system highly depends on the quality of the input data used. Calculations on the basis of annual data provide a rough idea on the necessary collector area and storage volume for a given heat demand. However, an exact dimensioning can only be done by using hourly-data of solar radiation and heat load for a whole year period.

The methodology for the integration of solar heat into DH systems that is presented in this paper leads to more detailed results and avoids over-dimensioning of solar fields and storage volume.

The example calculation shows that a solar thermal DH sub-network with a thermal storage and an annual solar share of 14 % can be realized without auxiliary gas or biomass boiler, if the main-network can adapt to a lack of heat power in the sub-network. The option of a regular recharge of the storage makes the operation of the centralized CHP plant more predictable. During the summer months the solar heat gains cover the total heat demand of the sub-network for long periods, whereas in other times of the year the main-network provides the additional heat. A short-term storage with a specific volume below 40 l/m² is sufficient under the here give load pattern.

7. Outlook

The results of the presented calculations can be improved by optimizing the storage recharging time and level as well as by adding the piping system as a temporary storage. In the example of a DN300 pipe without extractions an additional specific volume of 78 m³/km can be taken into account to store water at 80 °C for a short time once a day. In this case a focus will also have to be put on the losses over the pipeline.

Finally, the methodology needs to be applied on an operating SDH system.

Abstract

The main R&D challenges in the development of Solar Thermal Collectors are focused on increasing reliability and long-term performance stability. Absorber coatings have a major role in conversion of solar radiation into thermal energy. For this reason, testing procedures for qualification were developed and are described in ISO 22975-3:2014. Full application of the test methodologies proposed in ISO 22975-3:2014 is seldom referred for commercial absorber coatings commercially available. This work reports the results of the full tests to five absorber coatings (commercially available), two obtained by physical vapor deposition (PVD) and three by air spray with selective paints. Additional results, obtained with different accelerated aging tests including salt spray and/or sulfur dioxide and nitrogen dioxide as contaminants, are presented. The advantages and limitations of the methodologies proposed in ISO 22975-3:2014 will be discussed, as will be analyzed and proposed new methods of accelerated aging tests.

Keywords: *Solar thermal collectors, Absorber coatings, Qualification tests*

1. Introduction

Countries with high solar resource and a significant amount of coastal regions are the places with the highest population density, constituting a large and prospective market for solar thermal technology and a challenge in terms of reliability and durability for solar thermal technology. Solar thermal collectors (STC) have to withstand stress conditions like high temperatures, high humidity, ultraviolet irradiance or wind and snow loads depending on the geographic location. Literature points out to dependence on other influences like prevailing wind conditions, contaminants like chlorides, SO_2 and NO_x, global solar irradiation, wetness time and precipitation (Köhl, M., et al, 2004; Slamova, K et al, 2016).

Most of the absorbers materials are metallic, copper or aluminium, with different types of coatings obtained by different application methods (Mihelčič M.et al, 2015). Metallic materials are particularly susceptible to corrosion due to combined effect of the different atmospheric parameters namely chloride ions, sulphur dioxide, temperature and relative humidity.

For absorber coatings, due to its major role in conversion of solar radiation into thermal energy, testing procedures for qualification were developed (ISO 22975-3:2014). This international standard specifies a scheme of accelerated ageing tests for qualification of absorber surfaces. Three types of degradation processes are considered: high temperature degradation, degradation by the action of condensed water and degradation caused by high humidity in air containing a small concentration of sulphur dioxide (SO_2). Although SO_2 is one of the dominating airborne pollutants for atmospheric corrosion, the consideration of SO_2 as main corrosion factor for absorber surfaces may be disputable for collectors placed in marine environments as chloride ion from sodium chloride is considered to be major corrosion agent in these regions (Slamova, K et al, 2016; Diamantino, T et al, 2017). Additionally, nitrogen oxides levels have remained constant or even increased with urban NO_x levels higher than SO_2 levels in most cities (Castãno et al, 2007).

In this work, commercially available absorbers with different substrate materials and coatings, PVD - Physical Vapor Deposition and PC – Paint Coatings, were submitted to the full set of tests of ISO 22975-3:2014 and to additional accelerated aging tests with different atmospheric contaminants. The objective of this study allowed the test laboratories involved to gain experience in the application of the tests, but also to identify the advantages and limitations of the methodologies proposed in ISO 22975-3:2014.

doi:10.18086/eurosun.2016.06.01 Available at http://proceedings.ises.org

2. Experimental

2.1. Selective solar absorber coatings

In this study five selective absorber coatings applied on aluminum were considered, 2 coatings obtained by PVD are commercially available and were acquired from STC manufacturers (PVD 1 - commercial name *mirotherm*® and PVD 2 - commercial name *eta plus*®); 3 selective paint coatings (two PCs thickness sensitive spectrally selective (TSSS) with silicone binders (PC1 and PC2) which commercial names are SUNCOLOR TS S Black and SOLKOTE HI/SORB-II ™, respectivelly; 1 PC thickness insensitive spectrally selective (TISS) with a poly(urethane) binder (PC3) which commercial name is SUNCOLOR PUR Black. All the paints used were aquired from the selective paints commercially available. The paints were applied according with the technical instructions of the products on aluminum substrates. Before the application of the paints, all the aluminum samples were subjected to a pre-treatment without chromium. Firstly the panels were acid degreased/deoxidized with Gardacid P 4307 and Gardoclean 450B for 10 min at ambient temperature. Then the specimens followed to a passivation stage with Gardobond X 4707 for 45-60s at ambient temperature. For application by air spray it was used a gravity fed spray gun with a 1.5 mm nozzle and air compressor settled to 2 bar pressure.

The samples evaluated have a dimension of 50 X 50 mm for tests under ISO 22975-3:2014 (section 2.2) and 65 x 140 mm for tests describe in 2.3 and 2.4..

2.2. Methodologies for Solar Absorber Surfaces Qualification (ISO 22975:2014)

2.2.1. Optical properties

All the selective solar absorber samples used specifically in this study were optically characterized by measurement of solar absorption (α_s) and thermal emittance (ε_t). The solar absorption (α_s) was determined based on the solar absorption hemispherical solar spectral irradiance (incident on a 37° tilted plane, equator-facing) and the reflectance measurements were done on Perkin Elmer's Spectrophotometer Lambda 950 UV/VIS/NIR with a 150 mm integrating sphere. The thermal emittance (ε_t) was determined with a portable emissometer, Devices & Service Company model AE-AD3, which measure a surface emittance at 80 °C of temperature and compared later with measurements using a Spectrophotometer Frontier IR/NIR of Perkin Elmer, with integrating sphere For measurement of the spectral reflectance between 2,5 and 20 μm a diffuse gold coating reference calibrated by Avian Technologies LLC was used.

Evaluation of absorber coatings according to ISO 22975-3:2014 is based on a performance criterion (Pc) dependent directly on the optical properties of the collector and which is defined according to equation (1).

$$Pc = -\Delta\alpha_s + 0{,}5\,\Delta\varepsilon_t \quad (1)$$

Where $\Delta\alpha_s$ is the change of solar absorptance during an aging test and $\Delta\varepsilon_t$ the change in thermal emittance in the same test. In order to an absorber coating be qualified the value of Pc shall be lower or equal to 0.05.

Optical properties, like solar absorptance and thermal emittance are also the main quantitative values for comparison of absorber coatings and its selection for use in STC. Roberts, D. E., 2013 introduces a figure of merit (FM) based on these optical properties with the purpose of making the selection of solar absorber coatings easier. This figure of merit (FM) is given by equation (2).

$$FM = \alpha_s - 0{,}44\varepsilon_t \quad (2)$$

2.2.2. Coating Adhesion

The coating adhesion of all absorber surfaces were evaluated by pull-off method according to ISO 4624:2002 for deformable substrates. A tensile tester INSTRON 4467 with a load cell of ± 5KN was used. Steel test dollies used have a nominal diameter of 20 mm. The adhesive selected was a cyanoacrylate glue.

2.2.3. Assessment of thermal stability

The assessment of thermal stability of the different solar absorber coatings was performed according ISO 22975-3:2014. The equipments used were an HERAEUS LUT 6050 until temperatures of 250ºC and a Heratherm Oven OMH100 for higher temperatures, until 330ºC. The temperature in the chambers is uniform within the range of ±1 °C.

2.2.4. Resistance to condensed water

The qualification scheme and the conditions for resistance to condensed water were according to ISO 22975-3:2014. Binder MKF 240 was used as test chamber with sample holders and cooling block as shown in Figure 1.

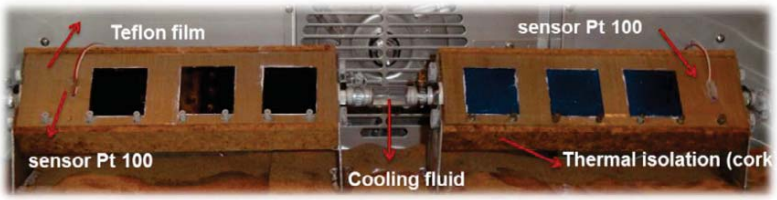

Fig. 1 - Combined sample holder and cooling block for condensation test

2.2.5. Resistance to high humidity air containing sulfur dioxide

The test procedure involves exposure in circulating air of a relative humidity of 95% RH, temperature of 20°C, a sulfur dioxide volume fraction of 10^{-6} and a linear flow rate of air in the range between 1mm/s and 5mm/s. This test is performed according to ISO 10062:2006. According to this standard, the corrosion rate of zinc is considered as a measure for severity of environmental stress on absorber surfaces. During this test, 6 samples of zinc with known initial mass were used. The mass loss was determined for specific time periods, after 90h, 180h and 360h while measuring 2 samples for each time period. Assuming that mass loss rate is linear with testing time, it is possible to calculate the zinc corrosion rate (r_{Zn}), in mg/m^2/h, by linear fitting (Least squares method). The average corrosion rate of zinc obtained (0.014g/m^2/h) is used to determine the shortest acceptable failure times in hours:

- For a type A solar collector: Shortest acceptable failure time, $t_{f,A} = 2.5/r_{Zn}$
- For a type B solar collector: Shortest acceptable failure time, $t_{f,B} = 7.5/r_{Zn}$

Since the solar absorber surfaces studied could be use in either type of solar collectors, it was decided to submit them to both failure times. According to the determined chamber corrosivity for Zinc, for a type A solar collectors, 180h, and for a type B solar collector, 540h, were respectively considered. A WEISS WK3-340/0-BSB chamber was used.

2.3. Methodologies of accelerated aging tests with continuous exposure of contaminants

2.3.1 Neutral salt spray test

A continuous neutral salt mist spray with a concentration of 50g/l ± 5g/l of sodium chloride in demineralized water, pH value of the solution between 6.5-7.2 and test chamber temperature between 35°±2°C was used (ISO 9227:2012).The inclination of test samples was 20º±5° from the vertical. The duration of the test was 120 hours with observations and evaluation of optical properties after 24, 48, 72, 96 and 120 hours. 6 replicates were used. The chamber used is an Erichsen Model 606/400L. This test was chosen because it is the oldest and most widely used method for laboratory accelerated corrosion testing.

2.3.2 Saturated atmosphere in the presence of sulfur dioxide

A test in a saturated atmosphere in the presence of sulfur dioxide according with ISO 3231:1993 during 5 cycles (24 hours each cycle) was performed. Each cycle consists of 8 h at 40ºC±3°C and 100% of RH (SO_2 – 0.2L) and 16 h at 18-28ºC and RH max 75% (test chamber vented). 6 replicates were used. The chamber used is a VLM Model CCT 400-Air CTD-A. This test was selected because is widely used to evaluate and qualify metallic and organic coatings for anticorrosive protection to industrial atmospheres with a higher concentration of sulfur dioxide than the test proposed by ISO 22975-3:2014.

2.4 Methodologies of accelerated aging tests with cyclic variation of corrosion promoting gases, higher humidity, salt spraying and drying

This study began applying a methodology of ISO 21207:2015 (Method A) that involves exposure of the test objects to the following test cycle: a) neutral salt spray testing (ISO 9227:2012 for 2 h in a mist of a salt solution containing a mass fraction of 5 % of sodium chloride at 35 °C, followed by drying for 22 h in a

standard laboratory climate; b) exposure for 120 h in a test atmosphere containing a mixture of corrosion-promoting gases, volume fraction of NO_2 equal to 1.5×10^{-6} and of SO_2 equal to 0.5×10^{-6}, at a relative humidity of 95 % and at a temperature of 25 °C, followed by drying for 24 h in a standard laboratory climate. The climatic chambers used were a WEISS WK3-340/0-BSB for mixture of corrosion-promoting gases and a Erichsen (Model 600-400L) for salt spray environment. All the tests performed with solar absorber surfaces were simultaneously monitored with reference materials to evaluate atmosphere corrosivity. The optical properties were evaluated after 2, 3 and 4 test cycles. This method was chosen because is recommended for the qualification of coatings, as well as, to predict the lifetime of electronic equipments and is also suitable for comparative testing (ISO/TR 16335:2013).

2.5 Evaluation the corrosivity of accelerated aging tests chambers

The corrosivity of the different accelerated aging test chambers were performed with Zinc standard samples (reference material 99.95%) simultaneously with absorber coatings. Two replicates (section 2.2.5) or three replicates were used for each test period (section 2.3 and 2.4). The samples are rectangular plates with dimensions 100 mm x 150 mm, and a thickness of 1 mm. After exposure, corrosion products were removed in accordance with ISO 8407:2009. The corrosion rates were obtained by weight loss per unit area during exposure periods of different accelerated aging tests.

3. Results and Discussion

3.1. Solar Absorber Surfaces Qualification (ISO 22975-3:2014)

Table 1 resumes the initial optical properties, figure of merit (FM) and adhesion of coatings. These values of optical properties are the average value of thirty samples (50 x 50 mm) and the corresponding standard deviation is also indicated (σ_α for solar absorptance and σ_ε for thermal emmitance). PVDs have similar values of solar absorptance and thermal emittance. The Paint Coatings PC1 and PC2 have also similar values of solar absorptance and thermal emittance values, but with lower solar absorptance and higher thermal emittance than PVDs. PC3 has the lower solar absorptance and the higher thermal emittance. Except for PVD1 that has a lower adhesion, all other coatings have very similar rupture resistance values.

All absorber coatings were submitted to the full tests according to ISO 22975-3:2014. In Table 2 a summary of results obtained is shown. Figure 2 shows the optical properties converted in results of performance criteria (Pc) and Figure of Merit (FM) of the different selective coatings during the different accelerated aging tests indicated in ISO 22975-3:2014 for surfaces qualification.

All the absorber coatings were qualified for the test in saturated atmosphere in the presence of sulfur dioxide, in terms of optical properties and adhesion of coatings. In terms of thermal stability PVD1 did not qualify due to the changes in optical properties (performance criteria - Pc>0,05). PC3 also did not qualify but due to low adhesion of coating (ruptures resistance < 0,15MPa).

Tab. 1 – Initial optical properties, adhesion and figure of merit (FM) of PVDs and PC coatings

Absorber reference	**Optical initial values**		**Coating Adhesion** (rupture resistance – Mpa) (σ)	**FM**
	Solar absorptance $\alpha \pm \sigma_\alpha$	**thermal emittance** $\varepsilon \pm \sigma_\varepsilon$		
PVD1	0.96±0.00(1)	0.11±0.00(2)	0.9 (0.3)	0.91
PVD2	0.96±0.00 (1)	0.11±0.00(3)	3.9 (2.1)	0.91
PC1	0.94±0.00(2)	0.46±0.04	4.0 (0.6)	0.74
PC2	0.94±0.00(1)	0.50±0.03	3.7 (1.7)	0.72
PC3	0.92±0.01	0.58±0.03	4.8 (1.4)	0.66

Tab. 2 – Overall durabilityresults of PVDs coatings and PCs according to ISO 22975-3:2014

	Thermal Stability	Condensed Water	High humidity air containing sulfur dioxide
PVD1	NQ *(optical properties)*	Q*	Q
PVD2	Q	Q*	Q
PC1	Q	Q*	Q
PC2	Q	Q*	Q
PC3	NQ *(adhesion loss)*	Q*	Q

Q – qualified; NQ – not qualified; *require confirmation with thermal conditioning

In terms of resistance to condensed water all the coatings were qualify. However, the results require confirmation because the tests were performed with samples without conditioning. This conditioning considered in ISO 22975-3:2014 consists in submiting each test the sample for at least 5 hours at maximum absorber temperature. The thermal stability tests were performed with samples without and with conditioning. The test of resistance to high humidity air containing sulfur dioxide was performed with all samples condicionated.

Table 3 shows the photographic records of selective solar absorber coatings after exposure to 180 hours and 540 hours to high humidity air with sulfur dioxide. In all coatings (PVDs and PCs) no visual degradation (Table 3) nor significant changes in the optical properties were observed (Figure 2 – e) and f)).

Tab. 3 – Photographic records of PVDs (PVD1 and PVD2) and PCs (PC1, PC2 and PC3) after 180h and 540h of exposure to high humidity air containing sulfur dioxide, according to ISO 22975-3:2014

PVD1		PVD2	
			
180 hours	540 hours	180 hours	540 hours

PC1		PC2		PC3	
					
180 hours	540 hours	180 hours	540 hours	180 hours	540 hours

3.2. *Accelerated aging tests with continuous exposure of contaminants*

Figure 3 and Table 4 show, respectively the results of the optical properties and visual degradation of the different selective solar absorber surfaces after the exposure to accelerated aging tests with continuous exposure of contaminants (salt spray and sulfur dioxide). Neutral salt spray led to a higher degradation in PVDs than in PCs. Considering only PVDs, PVD2 showed higher degradation than PVD1. For PCs, PC3 showed the best behaviour in terms of anticorrosive protection and optical properties (lower Pc and higher FM). For the sulfur dioxide resistance test opposite results are observed, i.e., the PCs showed higher degradation than PVDs. No significant changes were observed between the 2 PVDs and the 3 PCs.

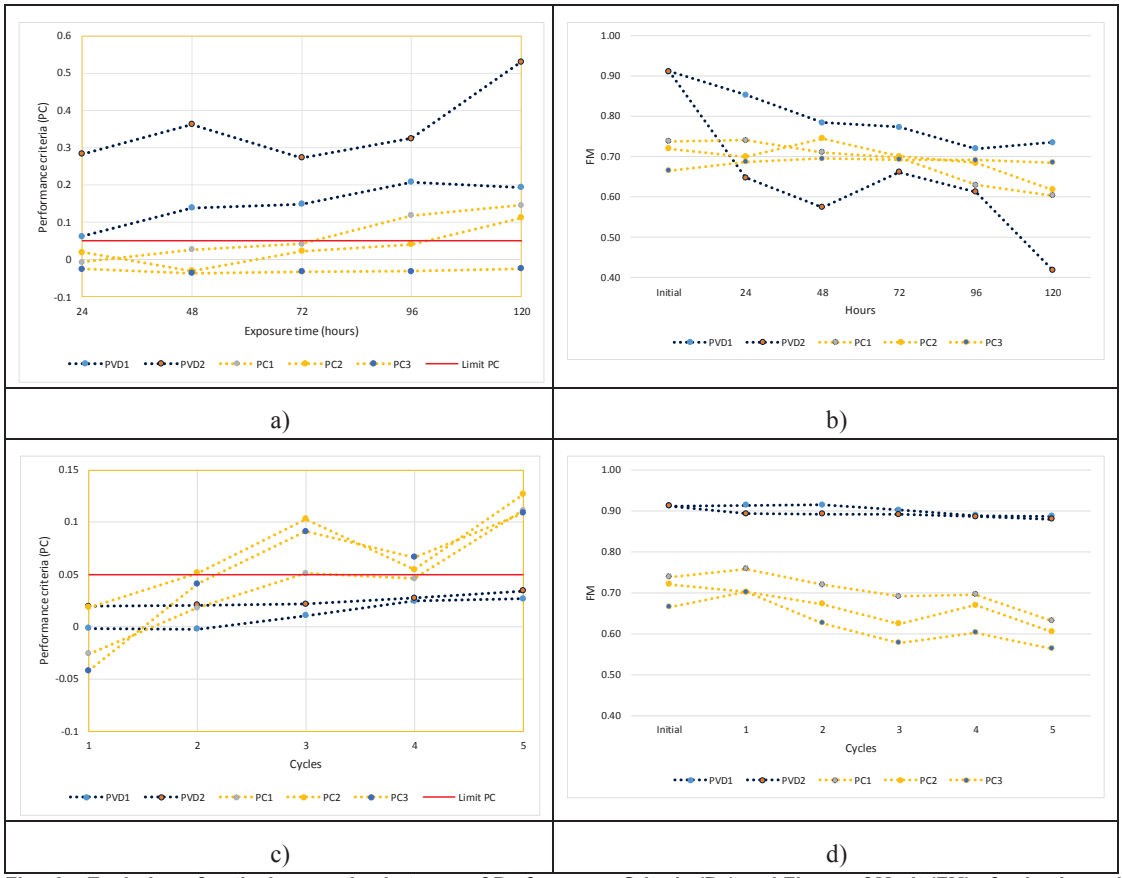

Fig. 3 – Evolution of optical properties in terms of Performance Criteria (Pc) and Figure of Merit (FM) of selective solar absorber coatings after neutral salt spray test (a) and b)) and to humid atmospheres containing sulfur dioxide (c) and d))

Tab. 4 – Photographic records of PVDs (PVD1 and PVD2) and PCs (PC1, PC2 and PC3) of exposure to neutral salt spray during 120 hours (ISO 9227:2012) and to humid atmospheres containing sulfur dioxide during 5 cycles (ISO 3231:1993)

PVD2		PC1		
PC2		PC3		

3.3. *Accelerated aging tests with cyclic variation of corrosion promoting gases, higher humidity, salt spraying and drying*

Figure 4 and Table 5 show, respectively the results of the optical properties and visual degradation of the different selective solar absorber surfaces during the 4 weeks (4 cycles – Method A) of exposure to accelerated aging tests with cyclic variation of corrosion promoting gases, higher humidity, salt spraying and drying.

PVD2 showed higher corrosion which is accompanied with the higher reduction of FM (decrease of absorptance and increase of emittance) and a Pc higher than 0.05. PCs showed also higher degradation, namely PC1 and PC2 reaching values of FM similar to PVD2.

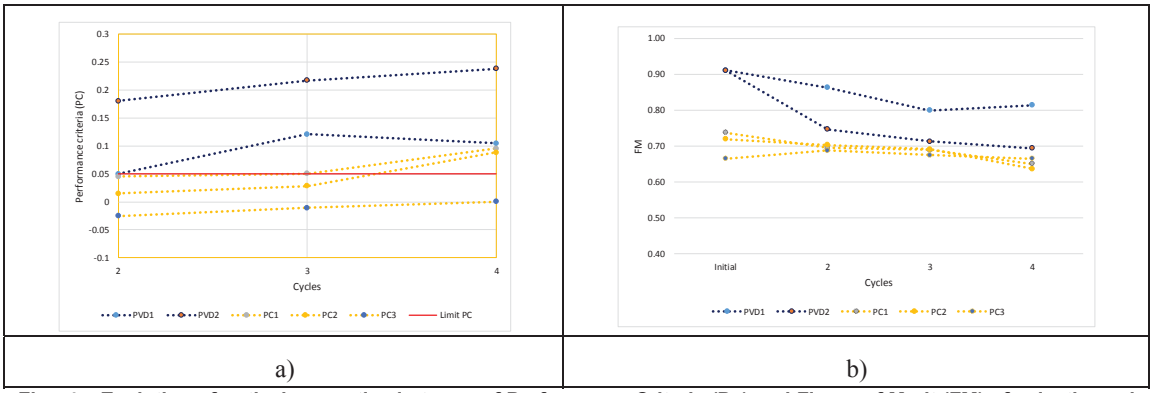

Fig. 4 – Evolution of optical properties in terms of Performance Criteria (Pc) and Figure of Merit (FM) of selective solar absorber coatings during exposure (4 cycles – 4 weeks) to accelerated aging test with cyclic variation of corrosion promoting gases, higher humidity, salt spraying and drying

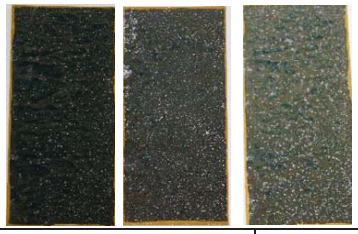
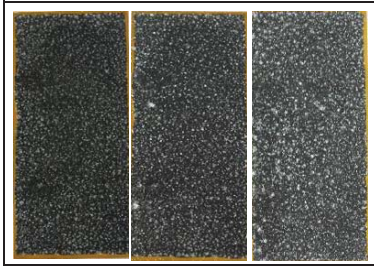
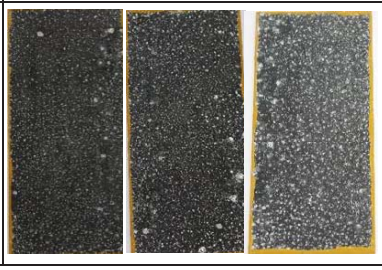
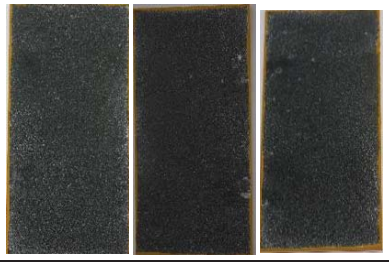
Tab. 5 – Photographic records of PVDs (PVD1 and PVD2) and PCs (PC1, PC2 and PC3) during exposure (4 cycles – 4 weeks) to accelerated aging test with cyclic variation of corrosion promoting gases, higher humidity, salt spraying and drying (ISO 21207:2015)

2, 3 and 4 cycles		
PVD1	PVD2	
		


PC1	PC2	PC3
		






The results obtained with this methodology show results similar to those presented by Diamantino et al, 2017 with the same solar absorber coatings exposed to outdoor exposure testing sites with different corrosivity (urban test site with marine influence – medium corrosivity and an industrial/marine test site with very high /extreme corrosivity) in terms of the ranking of Pc, FM and anticorrosive protection. PVD2 showed the higher Pc and PVD1 the higher FM in both OET sites as seen in this accelerated aging test. PC3 showed the best anticorrosive protection and PVD2 the lower in both OET sites, as well as, from results obtained by electrochemical impedance spectroscopy (Fernandes et al, 2017), as well as in this test method.

3.4. Zinc corrosivity in accelerated aging tests chambers

In order to compare the different corrosivity of accelerated aging tests presented, Table 6 resumes the values obtained experimentally and from literature, assuming that mass loss rate is linear with testing time. Neutral salt spray is clearly the higher corrosive test followed the SO_2 resistance test based on ISO 3231:1993.
According to ISO 22975-3:2014 the atmospheric corrosivity at the bottom part of the solar collector under service conditions may typically correspond to a corrosion rate of zinc of 0.1 or 0.3 g/m^2 per year depending of the type of collector. Other authors (Slamova et al, 2016) evaluated collectors under stagnation conditions obtaining a zinc corrosion rate of 19.72g/m^2 per year. Carvalho, M. J. et al, 2017 obtained zinc corrosion rates, in different type of collectors with different solar absorber surfaces under stagnation exposed in same atmosphere, of 4.5 g/m^2 and 99.9 g/m^2 per year. So, the corrosivity of the SO_2 resistance test proposed in ISO 22975-3:2014 seems to be insufficient to guarantee durability of 25 years for solar selective absorber surfaces.

Tab. 6 – Zinc corrosion rate (g/m^2/day) in the different accelerated aging tests

Accelerated aging tests	**Corrosion rate (g/m^2/day) (range)**
SO_2 (ISO 22975-3:2014)	0.34 (0.26-0.39)
Neutral salt spray (ISO 9227:2012)	25 (12.5-50)[(1)]
SO_2 (ISO 3231:1993)	1.25 (1.13-1.37)
Cycles (ISO 21207 - Method A:2015)	0.81 (-)[(2)]

[(1)] Value assuming that mass loss rate is linear with testing time. The value indicated in ISO 9227:2012 is 50±25g/m^2 (48 hours)

[(2)] Value assuming that mass loos rate is linear with testing time. The value indicated in ISO 21207:2015 (Method A) is 40g/m^2 (4 weeks or 4 cycles)

4. Conclusions

It was the main objective of this work the implementation of standardized test methods for qualification of different solar absorber coating surfaces. The tests according to ISO 22975-3:2014 were implemented and applied to 5 absorber coatings that were commercially available (two PVDs and three PCs).

All absorber coatings were qualified for resistance to sulfur dioxide. PVD1 was not qualified in terms of thermal resistance due to optical properties and PC3 was equally not qualified but due to loss of coating adhesion. All surfaces are qualified relatively to resistance to condensed water. However the paint and PVD coatings require confirmation because the study was performed only with samples without previous thermal conditioning. Temperature can lead to some adhesion and optical weakness in the organic and PVDs coatings respectively during the exposure to condensed water.

The methodologies of accelerated aging tests with continuous exposure to contaminants (salt spray and sulfur dioxide) revealed that PVDs are more susceptible to degradation induced by chloride rather than sulfur dioxide and PCs suffer further degradation with sulfur dioxide than chlorides. Countries with high solar resource and amount of coastal regions with high population density constitute a large and prospective market for STC and a challenge in terms of reliability and durability. The results obtained with the methodology describe in ISO 21207: 2015 considering an accelerated aging test with cyclic variation of corrosion promoting gases (SO_2 and NO_2), higher humidity, salt spraying and drying reveal similar results to those presented by Diamantino et al, 2017 with the same solar absorber coatings exposed to outdoor exposure testing sites with different corrosivity (urban test site with marine influence – *medium corrosivity* and an industrial/marine test site with *very high /extreme corrosivity*) in terms of the ranking of Pc, FM and anticorrosive protection. PVD2 obtained the higher Pc and PVD1 the higher FM in both OET sites and in accelerated aging according to ISO 21207:2015 (Method A). PC3 showed the best anticorrosive protection and PVD2 the lower in both OET sites, in accelerated aging test according to ISO 21207:2015 and from results obtained by electrochemical impedance spectroscopy (Fernandes et al, 2017).

The methodologies proposed in ISO 22975-3:2014 are an important tool for qualification of selective absorber

coatings. However these tests require many hours and don't reflect the environments where the collectors are exposed. These results showed that the accelerated aging test for qualification of selective solar absorber coatings must include at least sulfur dioxide and chloride as contaminants, beyond the resistance to temperature and humidity condensation. Additional studies are ongoing, namely to study the degradation mechanism of solar selective surfaces under the influence, separately and combined, of SO_2, NO_2 and chlorides in a defined temperature and humidity, with and without dry cycles and UV radiation under the cover. The procedures of accelerated aging tests to qualified coatings guaranteeing high durability should have gas with low concentrations together with a proper choice of temperature and relative humidity, salt spray, radiation and air flow to generate the degradation that have been observed in well characterized field environments with a specific atmospheric corrosivity.

5. Acknowledgements

This work was carried out under the Project FCOMP-01-0124-FEDER-027507 (Ref. FCT RECI/EMS-ENE/0170/2012) and the Project POCI-01-0145-FEDER-016709 FCT (PTDC/EMS-ENE/0578/2014). The authors would like to thank to industrial partners (FogãoSol, Hempel, OpenPlus and Permasolaris), by the supply of samples and the means for performing this work. Thanks are due also to Laboratory of Materials and Coatings team in particular to Ana Soares Vieira, Isabel Nascimento Alves and Soraia Páscoa.

CLASSIFICATION OF SOLAR DOMESTIC HOT WATER SYSTEMS

José Luis Duomarco

A.I.U. Montevideo (Uruguay)

Abstract

For commercial reasons it is becoming more and more necessary to have an effective way of classifying solar domestic hot water systems. Customers need a quick advice before shopping and impartial information printed on a label may help. Two indexes are defined, the energy factor and the figure of merit, that can serve this purpose. The energy factor is the rate between the volume of hot water produced in one year and the auxiliary heat needed, (L/kWh), calculated when the daily extraction is 2/3 of the storage volume, (2Vs/3), and the temperature is T_{DN} = 60°C. The figure of merit is the ratio of the energy factor to a theoretical reference yield; in turn, ratio of the total annual volume of hot water produced, at T_{DN} = 60°, to its content in sensible heat. A Transient System Simulation program (TRNSYS) model and new software, (ISO), have been developed on the guidelines of the International Standard ISO 9459-2, as simulation software on which they can be calculated. The draw-back of such procedures result from observing that the values obtained are site-dependent. An alternative classification way is presented, based on a non-dimensional number that is totally site-independent.

Keywords: *solar domestic hot water systems, international standards, solar systems classification.*

1. Introduction

For commercial reasons it is becoming more and more necessary to have an effective way of classifying solar domestic hot water (SDHW) systems. Customers need a quick advice before shopping and impartial information printed on a label may help.

The qualification test procedures are well established and are of the pass-fail type (ISO 9806-2, 1995). Instead, energy performance information adapts easily to a numeric or eventually to a color scale. At least two simulation procedures have given the raw material for such a scale. The Solar Energy Laboratory of the University of Wisconsin, UW-SEL, has developed a modular method, where each module is tested separately. The parameters obtained are then fed into especial software where annual performance is calculated. The f-chart and TRNSYS, works on these trends (Duffie & Beckman, 1991). The solar Collector and System Testing Group, CSTG, has followed a track quite different because no reference is made to components parameters. The system is characterized from the start as a black-box with input-output parameters that are determined by an all-day test (ISO 9459-2, 1995).

Until now, the main quantity used to evaluate the energetic performances of SDHW systems has been the solar fraction; defined as the percentage of the total load supplied by the sun. Solar fraction values specific to the collector area are also used (FSEC, 2002) (INMETRO, 2012). But this information should not be enough for a customer that wants to use a constant daily volume of hot water, V_D, at a specified temperature, T_D, all through the year . The auxiliary costly energy requirement is very important and should be a part of the energy performance information.

Two indexes, the energy factor (EF) and the figure of merit (FOM) are adequate. The EF is the rate of the

doi:10.18086/eurosun.2016.06.09 Available at http://proceedings.ises.org

volume of hot water produced, to the auxiliary heat used in one year (L / kWh), calculated when the only daily evening time extraction is 2/3 of the storage volume ($2V_S/3$), and the temperature is T_{DN} = 60°C. The FOM is the ratio of the EF to a theoretical reference yield (TRY); in turn ratio of the total annual volume of hot water produced, at T_{DN} = 60ºC, to its content in sensible heat or total auxiliary energy not-sun-assisted needed. The higher their values the better, as more hot water is produced with the unit of auxiliary energy.

The T_{DN} = 60ºC reference temperature, has been chosen in behalf of domestic uses.

The $V_{DN}=2V_S/3$ reference volume has been arbitrarily selected with the only restriction of being less than the storage volume V_S. It is shown in figure 3 that extractions greater or equal than V_S, tend to fade out differences between the y values of collectors, due to the cold water intrusion in the tank.

2. Method

Two different simulation procedures are used in the evaluation of the EF and the FOM:

1. ISO simulation in 2.2 (B. Bourgues, *et al*, 1991) (M. J. Carvalho & D. J. Naron, 2000) (J.L. Duomarco, 2015).
2. TRNSYS simulations in 2.3 (TRNSYS,2000)

2.1 Equations defining the EF and the FOM

- The ratio of the total annual volume of hot water produced, at T_{DN} = 60ºC, to the total sun-assisted auxiliary energy, and its inverse, are written as:

$$v_{AUX} = \frac{365\,V_D}{\sum_{i=1}^{365} Q_{AUX,i}} = \frac{1}{q_{AUX}} \qquad \text{(eq. 1)}$$

- The ratio of the total annual volume of hot water produced, at T_{DN} = 60º, to its content in sensible heat, are written as:

$$v_{DN} = \frac{365\,V_D}{\sum_{i=1}^{365} Q_{DN,i}} = \frac{365\,V_D}{\sum_{i=1}^{365} V_D c_{p\omega}\rho_{\omega}\left(T_{DN} - T_{MAIN,i}\right)} = \frac{1}{q_{DN}} = TRY \qquad \text{(eq. 2)}$$

- The ratios x and y :

$$x = \frac{V_D}{V_S} \qquad \text{(eq.3)}$$

$$y = \frac{q_{AUX}}{q_{DN}} = \frac{v_{DN}}{v_{AUX}} = \frac{\sum_{i=1}^{365} Q_{AUX,i}}{\sum_{i=1}^{365} Q_{DN,i}} \qquad \text{(eq.4)}$$

- The energy factor:

$$EF = v_{AUX} \qquad when \quad V_D = V_{DN} = \frac{2V_S}{3} \qquad \text{(eq. 5)}$$

- The figure of merit:

$$FOM = \frac{v_{AUX}}{v_{DN}} = \frac{EF}{TRY} = \frac{1}{y} \qquad when \quad V_D = V_{DN} = \frac{2V_S}{3} \qquad \text{(eq.6)}$$

2.2 The ISO simulation.

A detailed description of the test method can be found in the text of the standard ISO 9459.2. The system characterization is obtained by the fulfillment of 4 steps:

- input-output diagram,
- draw-off temperature profiles,
- store overnight heat loss coefficient,
- long term performance prediction (LTPP).

The calculation details of LTPP include two load patterns:

- Load pattern 1: determined by the volume of daily hot water consumption,
- Load pattern 2: determined by a minimum useful temperature limit for the hot water consumption. When the outlet temperature is lower than this minimum value, no water is extracted.

The new ISO software has been developed with a different load pattern:

- Load pattern 3: modeled for a nominal temperature and a nominal hot water volume production, both constant during the year, with only one daily draw-off. According to the daily climate conditions and daily hot water demand, the draw-off temperature and draw-off volume may be under or above the nominal values. If overheating is present, the excess energy over the nominal is calculated and discarded. If solar heating is under the nominal value, the auxiliary heat necessary to reach nominal settings is calculated. The calculation is extended only to 365 days assuming an annual periodicity,
- Case study systems: The performance of three different systems, System5, System8 and Baxiroca, were calculated and compared. The typical data of System 5 and System 8 were obtained from work at the Solar Collectors and Systems Laboratory from the National Research Centre Demokritos (Athens, Greece)(Belessiotis & Harambopoulos, 1993) and similar data for Baxiroca150, from a test report emitted by the "Escuela Superior de Ingenieros" (Seville, Spain) (LCS, 2009).The values are listed in Table 1, the draw-off profiles and the input-output plots are shown in Fig.1. The daily climate data for Belo Horizonte, Salto, Montevideo, Boston, Edinburgh and Punta Arenas were obtained from project "Surface Meteorology and Solar Energy" (NASA, 2010). Simultaneous daily global solar radiation on horizontal surface, maximum and minimum temperature series for year 2010, were used in the simulation.

2.3 The TRNSYS simulation .

A TRNSYS model (TRNSYS, 2000) has been built around component Type 45a and is shown in Fig.3. It requires, 39 parameters, 10 inputs and produces 12 outputs. This component models the thermo-siphon solar collector system. The system consists of a flat-plate solar collector, a stratified storage tank (either vertical or horizontal cylinder) located physically above the collector plate, a check valve to prevent reverse flow, and water as the working fluid. The tank's stratification is modeled with the plug-flow concept.
Global horizontal hourly solar radiation and simultaneous hourly ambient temperature for one year are needed. Two such databases, from Montevideo (Ewenson, 1979) and Salto (LES, 2015) are used. The daily routine consists in evaluating the storage sensible heat at 19h after a day's recollection, making the constant volume draw-off at 20h after fixing its temperature by adding auxiliary heat or discarding overheat and calculating the heat remains in the storage tank. Fig. 2a shows hourly energy variations on May 21 when auxiliary heat is necessary, Fig. 2b similarly for January 5 when overheat is present in the city of Salto and Table 2 lists some parameters, inputs and outputs present with their definitions.

3. Results

In Fig. 4, eight graphs show the index y as function of x.

The reference systems, Baxiroca in 4.1, System5 in 4.2, and System8 in 4.3, are evaluated in the six reference cities, Belo Horizonte, Salto, Montevideo, Boston, Edinburgh and Punta Arenas.

The reference systems, Baxiroca, System5, and System8, are evaluated jointly, with ISO simulation, in Boston 4.4, Salto 4.5, Montevideo 4.6, and with TRNSYS simulation, in Montevideo 4.7, and Salto 4.8

For small values of x, cold climate cities begin with high values of y, around 60%, while mild and warm climate cities begin with y values between 5% and 20%. A null y value stands for no auxiliary heat needed. When draw-off volume V_D, exceeds the storage tank volume V_S, (V_D>V_S), all y functions asymptotically get near 100%, or q_{AUX} gets near q_{DN} from below.

When systems are evaluated in the same place, for V_D less than V_S (V_D<V_S), System5 leads Baxiroca and Baxiroca leads System8, in the sense that they need less auxiliary energy to heat up one liter of water. In the trend of classifying solar collector systems with only one number, we selected arbitrarily a constant daily extraction volume $V_{DN} = 2V_S/3$. In Fig. 5, Fig.6 and Table 3, EF and FOM values, are calculated and plotted.

4. Site-independent figure of merit

From what has been said before, both EF and FOM depend on location. This hinders a universal classification of solar systems based on these indexes. It's desirable to classify SDHW systems in an intrinsic way, only dependent on their characteristics and not on their locations. Commercial confusion is likely to happen when equal indexes may address different SDHW systems measured in different places not properly recorded. An alternative classification procedure has been studied, based on a non-dimensional number γ_0 that gets together all three loss mechanisms,

$$\gamma_0 = 100^* \log_{10}\left[\frac{\delta_0^2}{2\delta_1\lambda_S}\left(\frac{G_0}{\Delta T_0}\right)^2\right] = 100^* \log_{10}\left[\frac{a_1^2 A_S}{2a_2 A_C U_S}\left(\frac{G_0}{\Delta T_0}\right)^2\right] \quad \text{(eq. 7)}$$

where

1. $\lambda_S = U_S / A_S$ with units (W/m^{2}K), characterize the heat loss of the storage tank,
2. $\delta_1 = a_2 / A_C$ with units (W/m^{2}K), characterize the heat loss of the collector,
3. $\delta_0 = a_1 / A_C$ measures the collector's optical efficiency,
4. $\delta_0^2 / (2\delta_1\lambda_S)$ gets together losses and is proportional to the surface under the input-output diagrams,
5. $(G_0/\Delta T_0)^2$ with Go= 1367 W/m^2 and ΔT = 100 K is a theory-related constant with dimensions,
6. logarithm is taken to smooth-out big variations,
7. calculation of our reference systems is shown in Table 4.

Table 4 - Site-independent non-dimensional figure of merit γ_0

System 5	System 8	Baxiroca
106	90	91

5. Conclusions

The energy factor EF (L/kWh), depends only on end points in the line; hot water production (L), and auxiliary energy to be paid-for (kWh). Free solar energy acts indirectly as a means to improve the EF. The figure of merit FOM is a non-dimensional quantity used to characterize the SDHW system relative to its basic without sun's boosting, alternative.

The simulation program must be specified. Two such simulation programs have been used. TRNSYS models require numerous modules connected with plenty of parameters, acting as input and output data, between them. Sometimes it is cumbersome to set such a simulation. On the other hand, ISO has a black-box-layout, needs fewer experimental results and is easier to use.

EF as FOM are site-dependent and so, meaningless if measuring place is not reported. From an international commerce point of view, it would be helpful to classify SDWH systems in a site-independent way. Three independent loss mechanisms may always be identified: optical efficiency, day collector-thermal-loss and night storage-thermal-loss. Improving these three characteristics, results in a increased non-dimensional γ_0 number with the additional advantage of being site-independent.

Assessment of Elastomeric Components of a Solar Thermal Collector

M.C. Ferreira, A.R. Rosado, M.J. Carvalho and T.C. Diamantino

National Laboratory of Energy and Geology, Lisbon (Portugal)

Abstract

Elastomeric components play important functions in solar thermal collectors (STC's) as sealings, fittings or absorbers, being important that they maintain their properties along STC lifetime. In what ageing is concerned, current standards for assessment of elastomeric materials put emphasis on the effect of heating.

The results presented in this paper refer to the evaluation of the effects of exposure to heating as well as to solar radiation by means of accelerated tests on two ethylene propylene diene terpolymer (EPDM) components of a commercial STC both carbon black filled compounds. At the current stage of the study, results showed that the effect of solar radiation may be relevant for the assessment of the components and, for that reason, should be considered along with temperature.

Keywords: *solar thermal collectors, elastomeric components, ageing, accelerated tests*

1. Introduction

Environmental factors cause degradation of polymers (Massey, 2007), in particular UV radiation induce photo-oxidation reactions. Even polymers with low unsaturation as is the case of EPDM, which is extensively used in outdoor applications, are prone to such reactions (Maecker and Priddy, 1991). EPDM formulations for those applications are designed to minimise photodegradation. Nevertheless changes in crosslink density, hardness, tensile properties and appearance are referred (Aimura and Wada, 2006; Zhao et al., 2007).

The work whose results are presented in this paper is part of a study aiming at evaluating the suitability of the accelerated ageing tests specified in standards ISO 9808:1990 and ISO 9553:1997 for the assessment of elastomeric components of STC's operating in high UV radiation environments and contributing to design accelerated ageing tests more capable of reproducing those environments whenever the standards are not adequate. To that end different components of STC's are characterised after the heating test described in those standards and after laboratory exposure to radiation as well as after exposure in two outdoor exposure sites. Detailed characterization of these sites can be found in Diamantino et al. (2017). The results here reported refer to the evaluation of the effects of the laboratory tests – resistance to heating and exposure to xenon-arc and to UV radiation - on two components of a commercial STC, a fitting with the function of isolating inlet and outlet connections and the glazing sealant, both carbon black filled EPDM compounds.

2. Methods

For the tests fittings were used as such while the sealing was cut in segments with a length of approximately 200 mm.

2.1 Resistance to heating test

The test was carried out at 175 ºC for 14 days according to ISO 9808:1990 and ISO 9553:1997 based on the stagnation temperature of the collector (150ºC) in an oven with forced air circulation. Complementary tests were performed at 150 ºC and 125 ºC to investigate the thermal behaviour of the components also at lower

doi:10.18086/eurosun.2016.06.03 Available at http://proceedings.ises.org

temperatures.

To evaluate the effects of the heating on the components the relative variations of total mass and dimensions were calculated, thermogravimetric analyses and mechanical tests were done.

The internal diameter of the fittings was determined with a caliper rule, three measures being taken for each sample. The length of the fractions of the sealing was determined with a scale. Relative variation of mass and dimensions was calculated for a minimum of five samples according to equation 1:

$$\text{Relative variation (\%)} = \frac{\text{Final value} - \text{Initial value}}{\text{Initial value}} \times 100 \qquad \text{(eq. 1)}$$

Thermogravimetric analyses were done according to ASTM D6370-99 in a Setaram equipment, model Setsys, with around 10 mg of sample in a platinum crucible. The first heating from room temperature to 560 ºC was carried out in argon atmosphere and the second heating from 300 ºC to 800 ºC was carried out in air atmosphere.

Mechanical tests were done with a Testing Machine Instron 4467 at 100 mm/min for fittings and 500 mm/min for sealing according to ISO 37:2011. The shape of the samples made impossible determining the cross-sectional area, so the maximum force was determined, instead of tensile strength. Elongation at break was determined according to ISO 37:2011. The initial distance between grips in the test of sealing was 10 mm. Five specimens of each component were tested.

2.2 Exposure to radiation sources

Exposure to xenon-arc radiation was done according to ISO 4892-2:2013, cycle nº 4, in an Atlas Weatherometer Ci35A with daylight (borosilicate) filters. Each cycle is composed of a dry period of 1.7 h at a spectral irradiance level of 0.51 W m^{-2} nm^{-1} at 340 nm with black panel temperature of 63±3 ºC, chamber temperature of 38±3 ºC and a relative humidity of 50±10% followed by 0.3 h of water spray at the same spectral irradiance. Samples were collected after 72, 168, 336, 668, 1030, 1436, 1922, 2234 and 3240 h of exposure.

Exposure to UV fluorescent radiation was done according to ISO 4892-3:2013, cycle nº 2, in a chamber Q-Lab, QUV spray with a UVA-340 lamp type. Each cycle is composed of a dry period of 8 h at a spectral irradiance level of 0.76 W m^{-2} nm^{-1} at 340 nm with black panel temperature of 50±3 ºC, followed by 0.25 h water spray and 3.75 h condensation without radiation and black panel temperature of 50±3 ºC during the condensation period. Samples were collected after 84, 180, 348, 732, 1080, 1404, 1752, 2076, 3240 and 4320 h of exposure.

The effect of the radiation on the components was assessed by colour difference evaluation, mechanical tests and glass transition temperature determination.

Colour difference, ΔE^*_{ab}, was determined according to ISO 11664-4:2011 with a spectrocolorimeter X-Rite 948. A minimum of five specimens were used in each determination. With the objective of showing the contribution of the variation of each of the coordinates to ΔE^*_{ab}, average values of ΔL^*, Δa^* and Δb^* were calculated.

Mechanical properties were evaluated as referred above.

Glass transition temperature, T_g, was determined in a TA Instruments DSC Q2000 equipment with a refrigeration system TA Instruments Refrigerated Cooling System 90. A mass of 5 mg was used in each test that was put in an aluminium crucible. Two cycles were carried out between -90 ºC and 100 ºC at a heating rate of 20 ºC/min, the values of the second cycle being taken.

3. Results

3.1 Resistance to heating test

Relative variations of mass and dimensions of the fitting and of the sealing after the resistance to heating test at 125 ºC, 150 ºC and 175 ºC are shown in Figure 1.

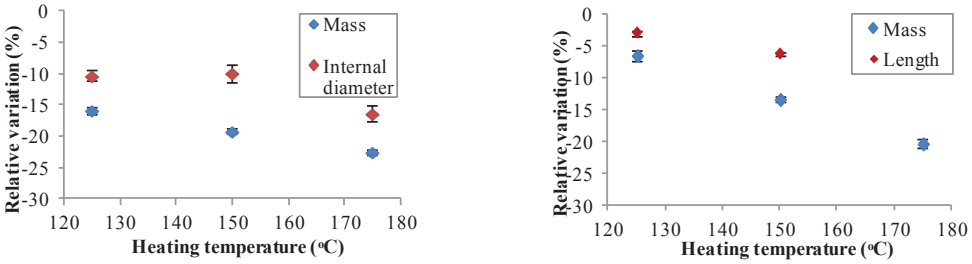

Fig. 1: Relative variations of mass and internal diameter of the fitting (left) and of mass and length of the sealing (right) after resistance to heating tests carried out at 125 ºC, 150 ºC and 175 ºC (bars representing standard deviation).

It was observed mass loss of the fitting in the three tests, variation increasing with the increase of the test temperature. The fitting lost 16% of the mass in the test at 125 ºC, 19 % of the mass at 150 ºC and 22% at 175 ºC. Internal diameter of the sealing decreased 10% after the tests at 125 ºC and 150 ºC and 16% after the test at 175 ºC. ISO 9808:1990 does not indicate an upper limit for volatiles loss.

The sealing lost 6% of the mass in the test at 125 ºC, 13% at 150 ºC and 20% at 175 ºC. The mass loss of the sealing was higher than the sum of maximum of volatiles lost (1%) and volatiles condensable (0.1%) for all the temperatures tested, which is the upper limit value admissible by ISO 9553:1997. The length of the sealing decreased 3% after the test at 125 ºC and 6% at 150 ºC. The length of this component was not determined after the test at 175 ºC as the samples were deformed and brittle.

The results of thermogravimetric analyses in the zone of heating in inert atmosphere of the fitting and of the sealing are shown in Table 1. The thermograms of the unheated components showed two zones of mass loss. The first zone begun in the region typically designated by “highly volatile matter”, referring to compounds of low boiling points (approximately 300 ºC or lower) such as oil, plasticizers, curatives, antioxidants and antiozonants, and ended already in the region designated “medium volatile matter”, referring to medium volatility material such as processing oil and processing aid (Sircar, 1992). The second zone was also included in the region of medium volatile matter where EPDM is found (Paroli et al., 1991; Sircar, 1992).

Tab. 1: Temperature range of mass loss and mass loss of the fitting and of the sealing unheated and after the heating tests at 150 ºC and 175 ºC determined in the zone of heating in argon atmosphere

Component	Heating test temperature (ºC)	Temperature range of mass loss (ºC)	Mass loss (%)
Fitting	Unheated	178 - 421	25
		421 - 500	29
	150	236 - 514	42
	175	243 - 519	36
Sealing	Unheated	171 - 418	23
		419 - 502	24
	150	276 - 501	34
	175	256 - 505	28

The thermograms of the fitting and of the sealing heated at 150 ºC and 175 ºC showed only one zone of mass loss during inert heating beginning in the region of “highly volatile matter” but at significantly higher temperatures than the observed in the first mass loss for the unheated sample indicating that compounds with lower boiling points were removed during the heating tests. In the case of the fitting while above mentioned additives and elastomer corresponded to 54 % of the mass of the unheated sample they corresponded to 42 % and 36 % of the mass of the samples heated at 150 ºC and 175 ºC, respectively. In the case of the sealing additives and elastomer corresponded to 47% of the mass of unheated sample, while they corresponded to 34% and 28% of the samples heated at 150 ºC and 175 ºC, respectively.

Figure 2 shows maximum force and elongation at break of the fitting and of the sealing unheated and after the

resistance to heating test. No appreciable variation of maximum force was observed for the fitting after the heating test at 125 ºC, but a decrease of elongation at break occurred. Maximum force clearly decreased after the tests at 150 ºC and 175 ºC. Elongation at break of this component after the heating tests at these higher temperatures was not determined due to brittleness of the samples. Maximum force of the sealing did not also change appreciably after the heating test at 125 ºC but a decrease of elongation at break occurred. Brittleness of the samples after heating at higher temperatures made impossible carrying out mechanical tests.

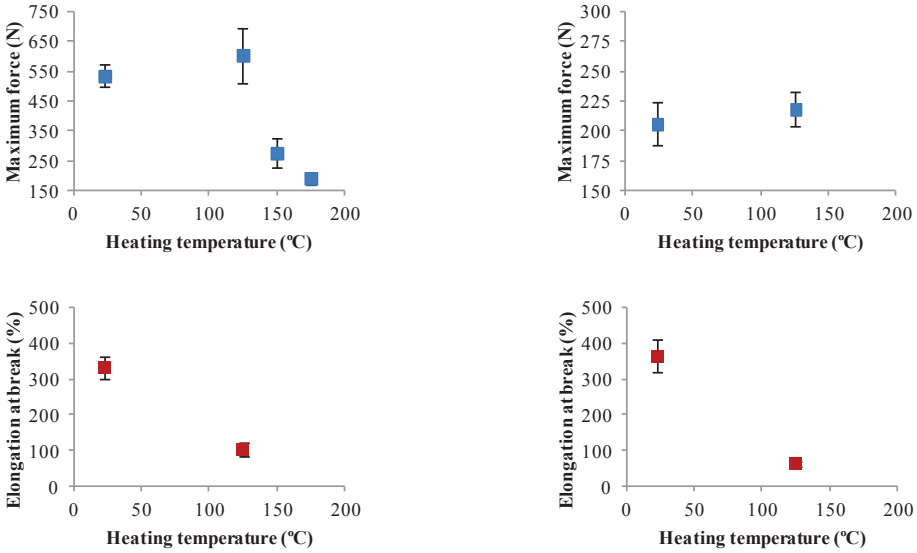

Fig. 2: Maximum force and elongation at break of the fitting (left) and of the sealing (right) unheated and after resistance to heating tests (bars representing standard deviation). Lack of data for 150 ºC and 175 ºC was due to brittleness of the samples.

3.2 Exposure to radiation sources

Colour difference, $\Delta E^*_{ab,}$ and average values of ΔL^*, Δa^* and Δb^* of the fitting and of the sealing after different exposure times to xenon-arc and to UV radiation are shown in Figures 3 and 4, respectively.

Exposure to xenon-arc radiation and water spray caused slight change of samples colour. Regarding the fitting, the final value was practically reached after 336 h of exposure. After this period, the difference in colour was mainly due to an increase of the coordinate L^* meaning the samples were lighter, with a smaller contribution of the b^* coordinate that varied towards the yellow. The colour difference of the sealing was more pronounced the most accentuated difference occurring in the first 72 h of test, after what the colour practically did not change. As observed with the fitting, the difference in colour was mainly due to the increase of coordinate L^*.

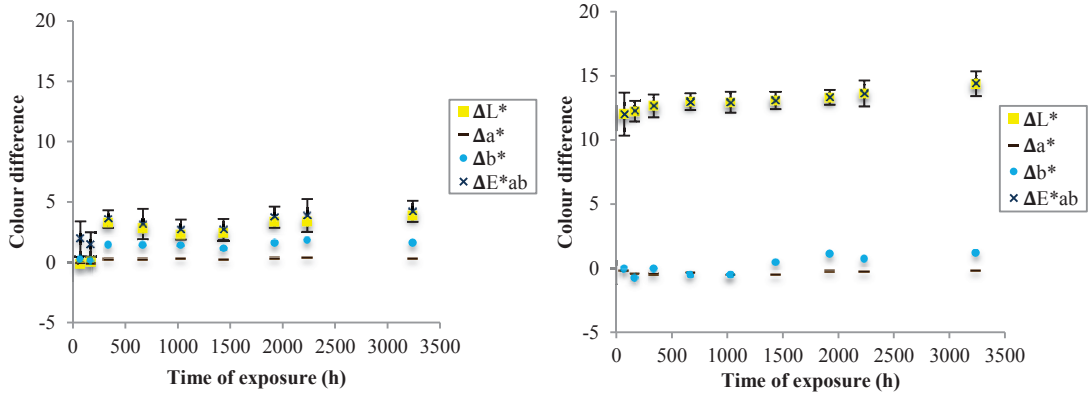

Fig. 3: Colour difference, $\Delta E^*_{ab,}$, and average values of ΔL^*, Δa^* and Δb^* of the fitting (left) and of the sealing (right) after exposure to xenon-arc radiation with water spray(bars representing standard deviation).

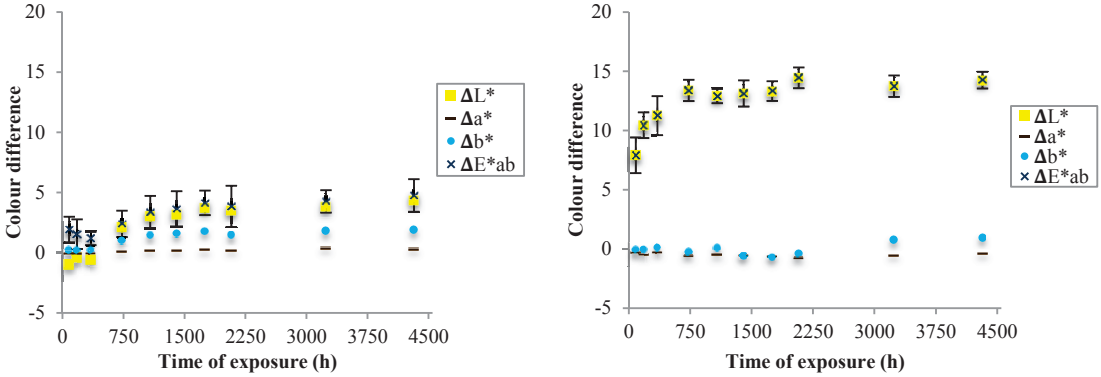

Fig. 4: Colour difference, ΔE^*_{ab}, and average values of ΔL^*, Δa^* and Δb^* of the fitting (left) and of the sealing (right) after exposure to fluorescent UV radiation with condensation and water spray (bars representing standard deviation).

Exposure to UV fluorescent radiation with condensation and water spray caused also slight change of samples colour, the variation in the final of the test being similar to the values determined at the end of the exposure to xenon-arc radiation. The main contribution to the difference of colour of the fitting was from ΔL^*, that until 348 h had negative values, meaning the samples were slightly darker, and after 732 h changed to positive values meaning the samples were lighter. There was also a small variation of the coordinate b^* after 732 h towards yellow. The most pronounced difference of colour of the sealing was observed in the first 72 h but difference of colour still increased, although less sharply until 732 h of test. The difference in colour was mainly due to the increase of L^*.

Maximum force and elongation at break of the fitting and of the sealing after exposure to xenon-arc radiation with water spray are shown in Figure 5.

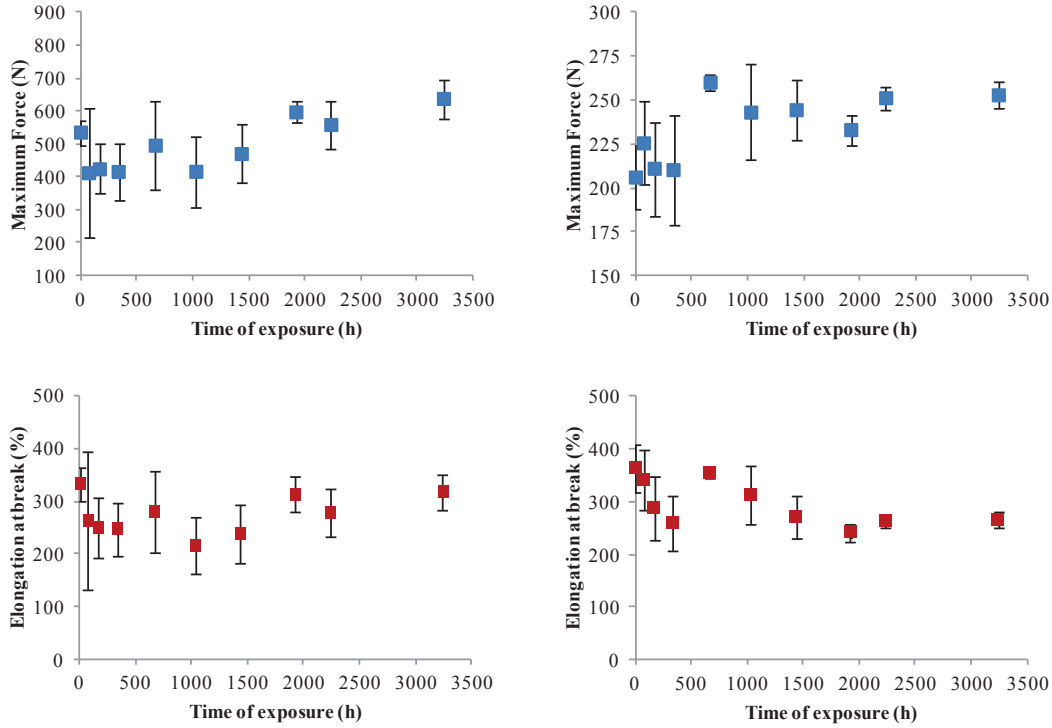

Fig. 5: Maximum force and elongation at break of the fitting (left) and of the sealing (right) after exposure to xenon-arc radiation and water spray (bars representing standard deviation).

Despite the relevant figures of standard deviation mainly due to specimen variability, changes of mechanical properties were noticed. The fitting showed a decrease of maximum force and elongation at break at early

stage of exposure followed by an increasing. The maximum force of the sealing increased after an initial period of no defined tendency while the elongation at break decreased at early stage and after a reverse in this tendency decreased again. EPDM rubber undergoes both chain scission and crosslinking upon xenon-arc weathering (Maecker and Priddy, 1991). Although the changes observed may not be straightforwardly related to those polymer changes due to the chemical complexity of compounded EPDM rubber products, the increase of maximum force of the sealing and decrease of elongation at break for longer periods of exposure relatively to the initial values is compatible with formation of crosslinks.

The patterns of maximum force and elongation at break of the fitting after exposure to UV fluorescent radiation with water spray and condensation (Figure 6) resemble in general with those observed after exposure to xenon-arc test. However the more pronounced decrease of maximum force and elongation at break at early stages of exposure seems to indicate that chemical changes were intensified in the UV test. General patterns of maximum force and elongation at break of the sealing are also similar to those observed after exposure to xenon arc radiation. However, at the early stage of exposure a decrease of maximum force was observed.

Glass transition temperatures, *Tg*, of the two components determined along the exposure to xenon-arc radiation with water spray (Figure 7) and to UV fluorescent radiation with water spray and condensation (Figure 8) showed only slight variations. The trend that was observed in the fitting to increasing at longer periods of exposure to xenon-arc radiation means that the system became stiffer. Glass transition temperature of the sealing practically did not change along exposure indicating that this parameter was not sensible to the chemical changes that occurred in the system.

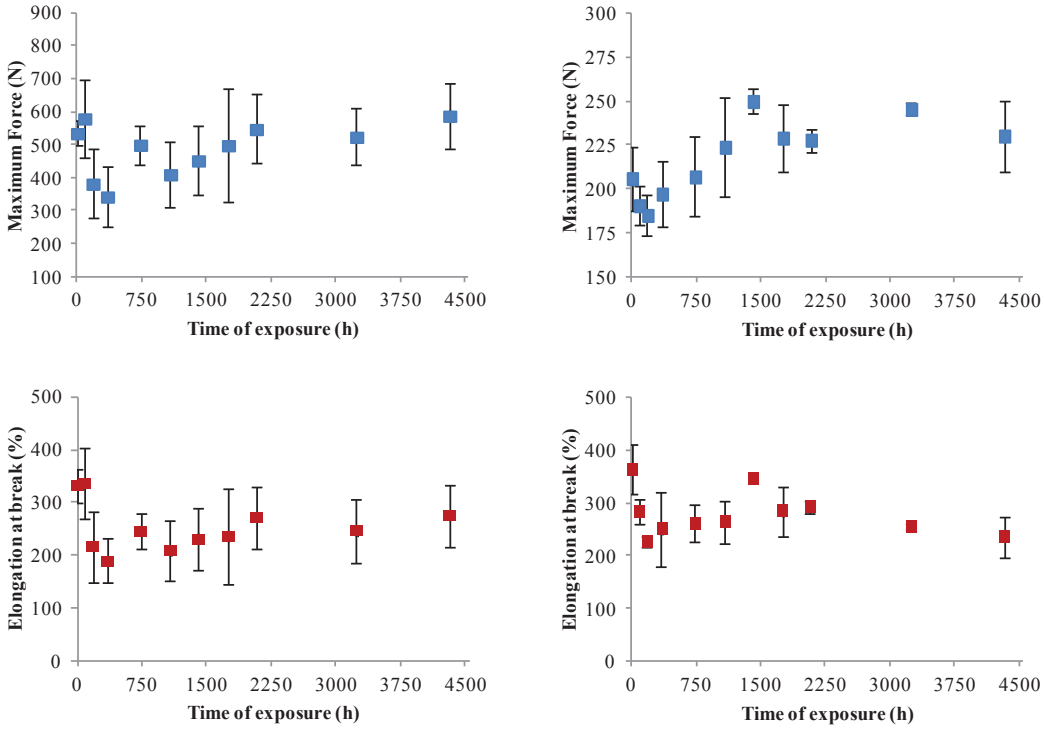

Fig. 6: Maximum force and elongation at break of the fitting (left) and of the sealing (right) after exposure to UV fluorescent radiation with water spray and condensation (bars representing standard deviation).

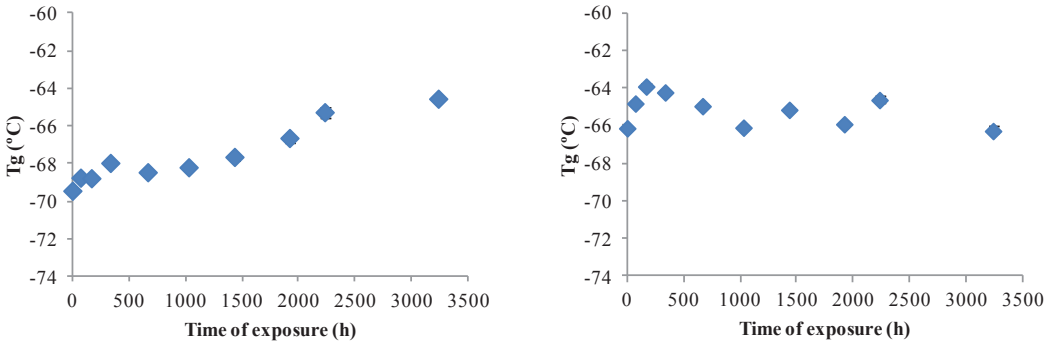

Fig. 7: Glass transition temperatures, T_g, of the fitting (left) and of the sealing (right) after exposure to xenon-arc radiation with water spray(bars representing standard deviation).

Glass transition temperatures of the fitting tended to increase at the beginning of the exposure to UV fluorescent radiation meaning that changes leading to stiffness of the system occurred. This trend was reversed after around 1050 h of test and then recovered at the end of the exposure time. Glass transition of the sealing practically did not change along exposure as observed after xenon-arc radiation.

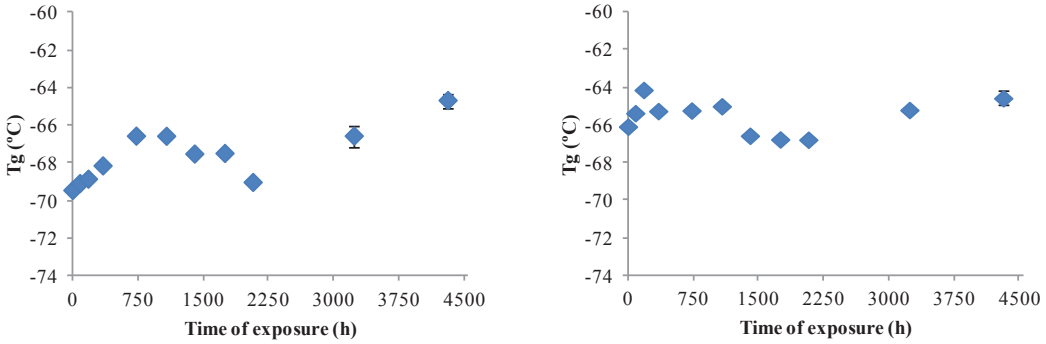

Fig. 8: Glass transition temperatures, T_g, of the fitting (left) and of the sealing (right) after exposure to UV fluorescent radiation with water spray and condensation (bars representing standard deviation).

4. Conclusions

The accelerated ageing tests - resistance to heating, exposure to xenon arc radiation and exposure to UV fluorescent radiation - performed with two elastomeric components of a solar thermal collector, a fitting and a sealing, caused chemical changes indicating that during the operation these components will be affected by high temperature and solar radiation. Resistance to heating tests performed at the temperature indicated by ISO 9808:1990 and ISO 9553:1997 and complementarily at lower temperatures led to significant mass loss and shrinkage of the fitting and the sealing, the variations being more pronounced with the increase of test temperature. Loss of mechanical performance was also clearly observed. Exposure to xenon-arc and to UV fluorescent radiation led to change of mechanical properties, the effects induced by UV fluorescent radiation being more pronounced. It is expected that those changes will be accelerated at the temperature of operation of the collector. The decrease in dimensions and mechanical performance of the fitting and of the sealing will result in poor isolation and higher permeability to atmospheric aggressions, changing the environment inside the collector. Results showed that the effect of solar radiation may be relevant for the assessment of the components and, for that reason, should be considered along with temperature.

Abstract

Part 1 of the paper series deals with the lifetime estimation of black-pigmented polypropylene (PP) absorber grades for pumped solar thermal hot water systems at different sites (Antalya, Mumbai, Phoenix). Absorber temperature loading profiles were calculated using the simulation tool SHW. Furthermore, global aging experiments in hot air or heat carrier fluid were carried out on specimen level for a commercial black-pigmented PP grade. The aging indicator strain-at-break was measured and endurance times at elevated temperatures (up to 135°C) were extrapolated to service relevant temperatures (maximum 105°C). The lifetime was assessed by weighting the temperature dependent endurance times with the loading profiles assuming cumulative damages. Depending on the extrapolation method, system specific parameters (i.e., collector size and storage tank volume) and installation site, lifetimes ranging from 20 to 45 years were obtained.

Keywords: *Polypropylene; Solar thermal collector; Absorber; Lifetime*

1. Introduction

The amount of polymers used in pumped or non-pumped solar thermal collector systems steadily increases. For polymeric solar thermal absorber materials a long-term stability in hot heat carrier fluid or hot air environment is of prime importance [Kahlen et al., 2010a, 2010b]. To meet high demands in terms of efficiency and lifetime, special attention is given to control the maximum stagnation temperature and pressure level. Based on research work in IEA SHC Task39 [Köhl et al., 2014] and collaborative projects different concepts for polymer-based collector systems have been established and successfully introduced into the market. According to Köhl et al. (2005) for solar thermal collectors a service lifetime of 20 years is required. Polymeric flat-plate collectors for pumped systems are usually operated at maximum temperatures up to 120°C and maximum pressure levels below 3 bar [Lang et al., 2013]. For overheating protection, various measures such as controlled back-cooling or venting are implemented. Novel glazed, flat-plate collector concepts allow for cost-efficient polymeric absorber materials such as black-pigmented polypropylene (PP).

At elevated temperatures some polyolefin pipe grades (e.g. polypropylene) do not exhibit the stress dependent Region II characterized by quasi-brittle failure (Ifwarson and Leijström, 1992). Hence, it is of utmost importance to investigate and characterize primarily the large scale aging and brittle failure. A main task of current research work is the lifetime assessment of these novel absorber materials for more cost-efficient and reliable collector systems. The main objective of Part 1 of the paper series is to investigate the aging behavior and to assess the lifetime of a selected PP grade for a pumped collector systems for hot water

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/eurosun.2016.06.06 Available at http://proceedings.ises.org

preparation in single family houses at selected sites. Therefore, the "One World Solar Collector" of Sunlumo Technology was used.

2. Methodological approach

2.1 Materials, aging conditions and characterization

A commercial black-pigmented polypropylene grade (PP-Bα), commonly used in swimming pool absorbers, was selected for the investigations. The amount of carbon black in the investigated grade is about 2 wt.%. The PP grade is stabilized with a stabilization package commonly used in piping applications. The specific amount and type of stabilizers are described and discussed in Povacz (2014).

Based on compression molded 2 mm thick plates, 0.1 mm thick micro-sized specimens were automatically manufactured using an adapted CNC-milling technique [Grabmayer et al., 2015]. The specimens were aged in hot air and hot heat carrier fluid in a Binder FED 53 (Tuttlingen, Germany) heating chamber with forced circulation at 95, 115 and 135°C. The hot air aged specimens were freely suspended on a grid. Hot water aging was carried out in closed stainless steel vessels with integrated sample holder to prevent contact between the samples. At least three specimens were removed and characterized per aging interval.

To assess the aging behavior, tensile tests were carried out at 23°C using a screw-driven universal testing machine with a test speed of 50 mm/min. The strain-at-break values were obtained over the aging period. Embrittlement was defined and classified when strain-at-break values dropped below strain-at-yield value ($\varepsilon_b < \varepsilon_y$). The ε_y values were 8% for PP-Bα

2.2 Modeling of service relevant loading conditions

Based on the study by Kaiser et al. (2013) and prevalent market potentials, three different climatic conditions (mediterranean (Antalya/Turkey), hot and dry (Phoenix/USA), hot and humid (Mumbai/India)) were taken into account for this work. Based on Meteonorm-data, relevant climatic parameters (e.g. air temperature, relative humidity, global radiation) were established on an annual basis. In a further step for all three climate zones market-based polymeric collector systems based on the Sunlumo "One World Solar Collector" for hot water preparation in single family houses were defined and evaluated. By theoretical modeling, annual time/temperature distributions for the absorber were obtained, which were significantly dependent on the location and the associated climatic conditions.

2.3 Lifetime assessment

For lifetime estimation a cumulative damage approach was used established by Wallner et al. (2016) for black-pigmented PP solar absorber materials. The main elements of the approach are the simulation of temperature loading profiles, the extrapolation of aging data and the cumulation of damages of different temperature levels. Endurance time extrapolation was carried out using a theoretical Arrhenius approach and an empirical extrapolation approach assuming a specific degradation mechanism in the temperature range. Various aging processes and changes of degradation mechanism of polymeric materials described by several authors [Gugumus, 1999; Kahlen et al., 2010a, 2010b] may result in an invalid use of the Arrhenius approach. Hence, an additional empirical extrapolation approach was used in this study which is based on an S-shaped degradation curve derived for polypropylene grades with comparable stabilizer packages by Gugumus (1999). Endurance times at service relevant temperatures were calculated by adapting and shifting aging data published by Gugumus (1999) to recorded failure times of the investigated materials. Additionally, a constant endurance time of 50 years at lower temperatures was assumed according to Leijström and Ifwarson (1998).

As endurance time limits the aging indicator time-to-ultimate-failure of the specimen was characterized by tensile testing. Expected endurance times in the service relevant temperature range from 5 to 105°C (in 5 K intervals) were determined using Arrhenius and Gugumus approach. A cumulative damage model according to ISO 13760 was used for lifetime assessment. It is assumed, that each effect caused by a constant service condition is proportional to the duration of the exposure and furthermore the damage from different service conditions can be added cumulatively. The lifetime is deduced by weighting the temperature dependent

endurance times with the frequency distribution of the temperature loading profiles (Miner's rule).

3. Results and discussion

3.1 Service relevant loading conditions

Table 1 presents the used technical parameters for the simulation of temperature loading profiles for three different locations. The collector areas vary between 3.6 m² in Mumbai and 5.4 m² in Phoenix per single household. The simulated absorber temperatures are strongly influenced by the environment and the storage system. Fig. 1 illustrates the simulated time/frequencies of the absorber temperatures in the polymeric collector system for hot water preparation in single family houses at three different locations. Maximum stagnation temperature values of 95°C for Mumbai or up to 105°C for Phoenix were deduced. However, differences between the collector systems can be observed by the frequencies at temperatures above 75°C, which occur more often for Phoenix and Mumbai. In the temperature range between 20 and 75°C all three locations show comparable curve shape with frequencies of about 400 h/a. While in the hot and humid location Mumbai the lower limit of the temperature profile is about 10°C, all other locations show minimum temperatures of 5°C with higher frequencies. The frequency maxima are in the temperature range between 10 and 30°C with a shift to higher temperatures of about 25°C in hot and humid sites such as Mumbai.

Tab. 1: Specific parameters of pumped collector systems for hot water preparation in single family houses at different sites.

		Antalya	Mumbai	Phoenix
Collector	Area [m²]	4.4	3.6	5.4
	Inclination [°]	36.9	19	34
	Orientation [-]	South	South	South
Storage	Volume [l]	300	150	300
	Height [m]	1.8	1.2	1.8
	Required temperature [°C]	55	45	60
	Hot water consumption [l/d]	160	120	250

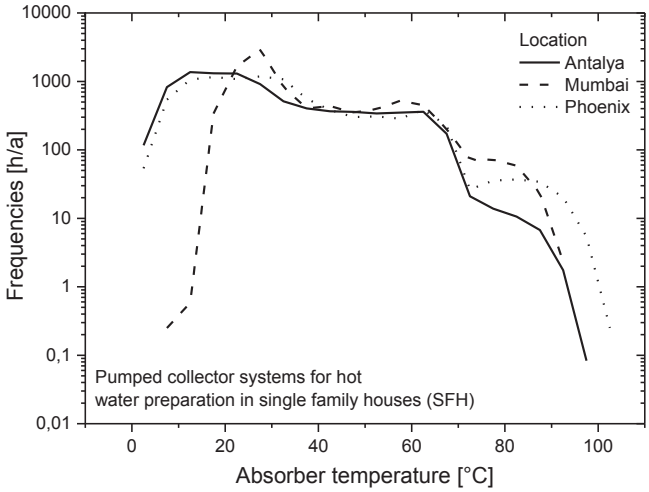

Fig. 1: Time/frequencies (h/a) of the absorber temperatures in polymeric pumped solar thermal collectors at different sites.

3.2 Aging behaviour at elevated temperatures

As reported and discussed in previous research work by Povacz (2014), for the investigated PP grade a more critical aging behavior in hot air than in hot heat carrier fluid was deduced at 95, 115 and 135°C. Based on

these results only hot air aging behavior is discussed and the aging data in hot air is used for lifetime assessment in this study. Fig. 2 shows the strain-at-break values of the black-pigmented PP-Bα as a function of aging time in hot air at 95,115 and 135°C. Ultimate failure with strain-at-break values below yield point is indicated with open symbols in the chart.

Unaged specimens reveal a highly ductile behavior with strain-at-break values of about 70. A significant decrease in strain-at-break values are obtained for PP-Bα at 135°C with ultimate failure within 2350 h. At 115 and 95°C, an initial drop appears within 150 h, presumably related to physical aging effects such as recrystallization. At longer hot air aging times the material behavior is characterized by a plateau of about 15 and 50% with ultimate failure appearing after 8400 and 26500 h for 115 and 95°C, respectively.

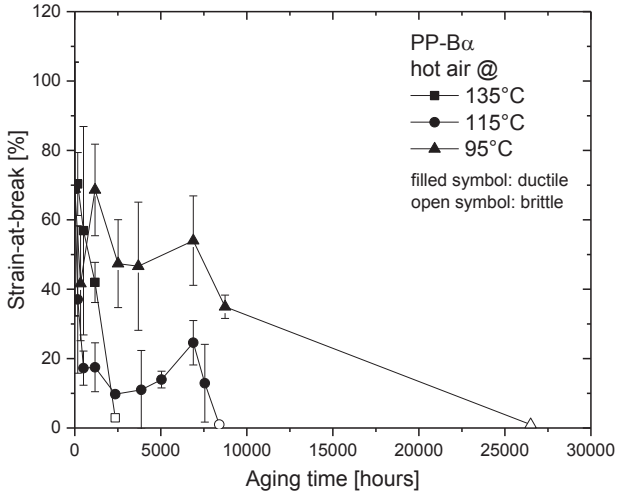

Fig. 2: Strain-at-break values for 100 µm micro-sized black-pigmented PP-Bα specimen exposed in hot air at 135, 115 and 95°C as a function of aging time.

3.3 Extrapolated endurance times and estimated lifetimes for micro-sized PP specimen

Fig. 3 illustrates the reciprocal temperature (K^{-1}) over the derived endurance limits for the investigated PP grade. The experimental embrittlement times at elevated temperatures were fitted using an Arrhenius approach (top layer) as well as the Gugumus approach (bottom layer). All extrapolated curves exhibit sufficient high coefficient of determination. The dashed vertical line depicts the assumed 50 years cut-off limit. Experimental data examined and published by Gugumus (1999) are shown in the bottom layer of Fig. 3. Two different antioxidant stabilizer packages (AO-1 and AO-7) are illustrated to show the S-shaped curve of endurance limits. In this study, average values of these curves are considered to establish endurance time limits at service relevant temperatures.

For PP-Bα the linear Arrhenius approach results in endurance limits of about 4 years (1500 days) at 90°C and of about 13 years (4650 days) at 75°C. By using the Gugumus approach, the endurance limits at 90°C are in the same range of about 4 years. The obtained endurance limits of about 5 years (1790 days) at 75°C are significantly lower compared to the Arrhenius extrapolation approach. Hence, the Gugumus approach results in more conservative behavior due to the S-shaped curve. Compared to the homopolymer grades investigated by Gugumus (1999) a much better behavior is obtained for the black copolymer grades of this study.

Lifetime estimation is deduced for the investigated black-pigmented specimens according to an optimistic upper bound scenario (Arrhenius approach) and a conservative scenario (Gugumus approach) for three different climate zones. Table 2 shows the calculated lifetimes which are ranging from 20 to 45 years for the investigated black-pigmented PP grade. Highest lifetimes are achieved for Antalya due to the mild mediterannean climate. Using the Arrhenius approach, the lifetimes are significantly affected by the constant endurance time of 50 years that is assumed for temperatures below 60°C. Due to the S-shaped curve of the Gugumus approach, this effect is even less pronounced and particularly shifted to shorter endurance times.

Hence, for all climate locations the predicted lifetimes using the Gugumus approach are much lower, ranging from 20 to 24 years. The estimated lifetime is reduced due to harsher climate conditions (hot and humid) in Mumbai to about 20 years.

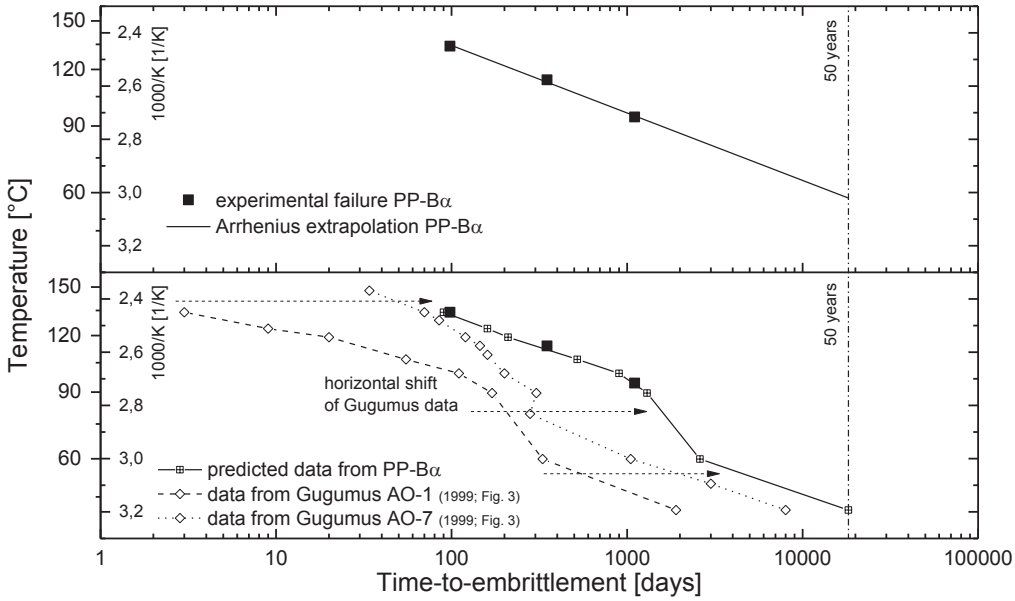

Fig. 3: Experimental failure times for micro-sized black-pigmented PP-Bα specimens and extrapolated endurance times at service relevant temperatures using an Arrhenius approach (top) and the Gugumus approach (bottom).

Tab. 2: Estimated lifetimes for PP-Bα absorber materials in pumped flat-plate collector systems at three different sites for the Arrhenius and Gugumus extrapolation approach.

Location	Climate zone	Estimated lifetimes in years	
		Arrhenius	Gugumus
Antalya	mediterranean	45	24
Mumbai	hot and humid	41	20
Phoenix	hot and dry	41	23

4. Summary and conclusion

To assess the lifetime of a black-pigmented PP absorber grade for pumped solar thermal hot water systems, temperature loading profiles for three different climate zones were established based on climatic input data. Strain-at-break values as experimental failure data were determined after exposure to hot air and hot heat carrier fluid at elevated temperatures ranging from 95 to 135°C of micro-sized specimen with a thickness of 100 µm. Due to the pronounced aging behavior in hot air, these data were used for lifetime estimation. Furthermore, endurance times at service relevant temperatures (5 to 105°C) were extrapolated using a linear Arrhenius approach (optimistic upper boundary) and a S-shaped Gugumus approach (conservative scenario). Subsequently a model of cumulative damages (Miner's rule) was applied to assess lifetimes for the investigated black-pigmented PP absorber materials.

Depending on the installation site and the system type, annual time/frequency curves over the collector temperature were simulated for polymeric hot water systems in single family houses. The absorber temperature was ranging between 5 and 105°C for the investigated climate zones with comparable curve shape between 20 and 75°C at frequencies of about 400 h/a. However, differences between the three systems were observed with pronounced frequencies at low temperatures (< 20°C) for Antalya (mediterranean) and Phoenix (hot and dry) as well as at high temperatures (> 75°C) for Mumbai (hot and humid) and Phoenix (hot and dry).

The unaged specimens exhibited ductile material behavior with strain-at-break values of about 70% for PP-Bα. Hot air aging at 135°C resulted in a steady decrease of strain-at-break values till ultimate failure appeared within 2350 h. The estimated lifetimes for the PP absorber material was ranging from 20 years (Mumbai, Gugumus approach) to 45 years (Antalya, Arrhenius approach). The calculated lifetimes were significantly depending on the used extrapolation method. As an optimistic upper boundary scenario, the linear Arrhenius approach showed estimated lifetimes higher than 41 years for all climate zones, strongly affected by the endurance cut-off limit of 50 years. Contrary, the non-linear Gugumus approach as a conservative lifetime assessment resulted in lifetimes ranging from 20 to 24 years.

5. Acknowledgment

This research work was performed in WP-03 of the cooperative research project SolPol-4/5 entitled ‘‘Solar-thermal systems based on polymeric materials” (www.solpol.at). This project is funded by the Austrian Climate and Energy Fund (KLI:EN) within the programme ‘‘Neue Energien 2020” and administrated by the FFG. The authors wish to express their acknowledgements to Susanne Kahlen, Kurt Stubenrauch and Andreas Meinecke (Borealis, Linz, A) for the cooperation, especially for making available the compounds.

Methodology for the Evaluation of Solar Thermal Energy Projects' Sustainability in Peru

Miguel Hadzich[1], Juan José Muñoz[2], Emilio Bautista[2]

[1]Sección Ingeniería Mecánica, Pontificia Universidad Católica del Perú.

[2]Escuela Técnica Superior de Ingenieros Industriales, Universidad Politécnica de Madrid

Abstract

This paper presents a new methodology to evaluate the sustainability of projects which involve any renewable energy equipment that take place in rural areas. By using the Star of Sustainability method we are able to see, visually and efficiently, the process of sustainability of technology projects.
The study includes the results of six appropriate technologies and technology transference projects with solar thermic energy done by the GRUPO PUCP during the last five years.
These validated technologies refer to the generation of heat through solar energy, such as Parabolic Cookers, Greenhouse-type dryers, Trombe Walls, Scheffler-type concentrators for coffee and cocoa and Hot Air Parabolic Concentrators for black tea drying; all of them using local materials and labor.

Keywords: *Sustainability, evaluation, qualitative methods, solar thermal energy,solar dryers*

---

1. Introduction

The Rural Sector Support Group GRUPO PUCP is an operating unit of the Department of Engineering at the Pontificia Universidad Católica del Perú (PUCP) and has made several designs and implementations of equipment in various areas of Peru. This study considers the results of six case studies conducted by GRUPO PUCP in Peruvian territory during the last five years.

The technologies evaluated are: Parabolic Cookers, Greenhouse-type dryers, Indirect Solar Dryers, Trombe Walls, Scheffler-type concentrators for coffee and cocoa and Hot Air Parabolic Concentrators for black tea drying

Star of Sustainability method that allows us to see, visual and efficiently, the technology projects process sustainability will be used.

Conclusions are analyzed by the QCA method (QUALITATIVE Comparative Analysis), using KIRQ as support free software, these methods are used due to the existence of five qualitative variables: Technology, Economics, Politics, Social and Environmental for each the cases studied.

doi:10.18086/eurosun.2016.06.08 Available at http://proceedings.ises.org

2. GRUPO PUCP

The Rural Sector Support Group GRUPO PUCP is an operating unit of Engineering Department at Pontificia Universidad Catolica del Peru (PUCP). Since 1992 we have been carrying out development projects for rural communities, related to applied scientific research, technology transfer and innovation, dissemination and promotion of appropriate technologies and conservation activities natural environment using renewable energy

Our goal is to improve the quality of life of the rural population in the areas of energy, water, agriculture and housing; through the dissemination and application of appropriate technologies to contribute to sustainable development of the rural sector of Peru.

3. Methodology used.

The proposed method, Sustainability Star, allows us to analyze the sustainability process of technology projects and provides us with a clear view to either decide the continuity of the projects or their cancelation. The Star has 5 tips that analyze the Technology (T), Economy (E), Politics (P), Social (S) and Environmental (A) factors which from now own we will refer to as TEPSA (in Spanish) or 5E`s (in English).

We believe it is a good tool to be used in all projects with a technological and political base in their development processes.
This method could also be used in other situations where projects have been completed technological base and gives us a good insight to decide the continuation or closure thereof.

SUSTAINABILITY DEVELOPMENT: TEPSA oR 5 E´s			
T	Tecnología	**E**	Engineering
E	Economía	**E**	Economics
P	Política	**E**	Ethical
S	Social	**E**	Equity
A	Ambiental	**E**	Environment

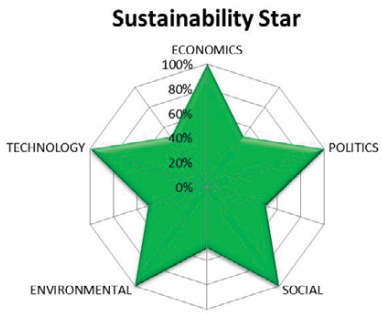

Fig 1: Factors of sustainable development in the Sustainability Star

To analyze the index that corresponds to each tip of the Star, a 25 question survey is made, defining the break percentage of the shape. These surveys refer to TECHNOLOGY (utility, sustainability, operation, reliability, maintenance), ECONOMY (income, employment, savings, affordability, innovation), POLITICS (political interest, acceptance, legal, promotion, and distribution), SOCIAL (compatibility, motivation, life improvement, participation and capacity) and ENVIRONMENTAL (friendly, climate, pollution, awareness, and health).

If all surveys questions have positive answers then the star will be perfect without any break, as shown in Fig. 1 and the project will be considered as 100% SUSTAINABLE .

In order to decide the percentage corresponding to each point of the star we use a survey of 25 questions - see Table 1 - which defines the percentage of the Star break. Negative responses from the survey will fall inside the star percentage values that indicate the failure of the project in each of TEPSA factors.

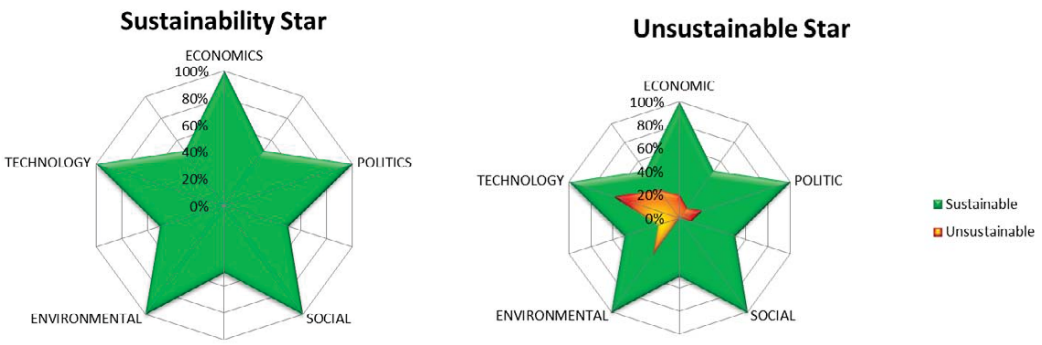

Fig 2: Example of Sustainability Stars – Perfect (left) and Broken (right).

4. Case Studied

We will analyze six case studies of technology projects related to heat generation, such as Parabolic Solar Cookers COCISOL, Indirect Solar Dryers SECASOL, Solar Greenhouse Indirect Dryers INVER, Trombe Walls TROMBEPUCP, Scheffler Concentrators for coffee and cocoa CONSOL and Hot Air Parabolic Concentrators for black tea drying CONPAR.

4.1. Hot Air Parabolic Concentrators for black tea drying – CONPAR

The project "Development and Integration of a Cogeneration System With Solar Thermal Energy for Processing of Black Tea in the Cusco region" was developed in partnership with the company AGROINKA. The company AGROINKA - Herbi brand tea producer - is located in a rural area of the department of Cusco with poor access to other possibilities of energy resources and weak technologies for various processes in the production chain. It is an area dedicated to the processing of tea to supply 80% of the market in the country and works with 750 families dedicated to tea production.

The design sought to solve the problem of shortage of fuel for drying processing in a producing factory for black tea, through the use of solar thermal concentration with the adaptation of the receiver tube of a linear parabolic concentrator for heating air. This is the design of a pilot project to develop and implement in tea enterprise AGROINKA a prototype cogeneration system with solar thermal energy consisted of 6 lines of 10 concentrators (60 linear concentrators). There is a paper describing the behavior of hot air in the receiver tube along a line of 10 concentrators in Reference 30.

Fig 3: Picture of 60 linear parabolic concentrators in AGROINKA tea factory.

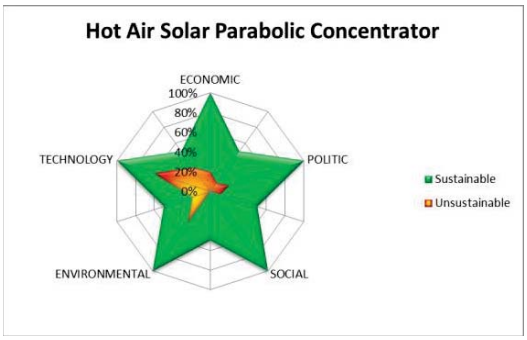

Fig 4: Sustainability Star in Hot Air Solar Parabolic Concentrator.

Sustainability Analysis: In the years 2013 and 2014, GRUPO PUCP has carried out investigations about concentrated solar thermal linear technologies, obtaining good results for toasted black tea. The mistakes observed in the star of sustainability are especially technological due to multiple failures in electronic solar trackers in the project area, especially by the highly voltage fluctuation of electricity.

4.2. Scheffler Concentrators for coffee and cocoa - CONSOL

This new technology is being investigated by the GRUPO PUCP in various applications since 2010, when Dr. Damien Puigserver of France came to Peru for an academic exchange and the first solar concentrator 2.7 m2 Scheffler cooking was built. Later PUCP funded the project to roast coffee with support from Dr. Francois Veynandt, Ing. Julien Delcol, Ing. Juan Pablo Pérez, Ing. Sandra Vergara and industrial designer Luis Miguel Hadzich.

As the results of this research were very positive, we won an announcement FINCYT in 2013 but for roasting cocoa and producing chocolate.
Currently there are two concentrators 8 m2 for this latest project and it is spreading in La Convencion Valley 300 km from Cusco city, with good results. In 2016, with the support from the university PUCP we are working on a prototype of 16 m2 for making orange and pineapple jam .

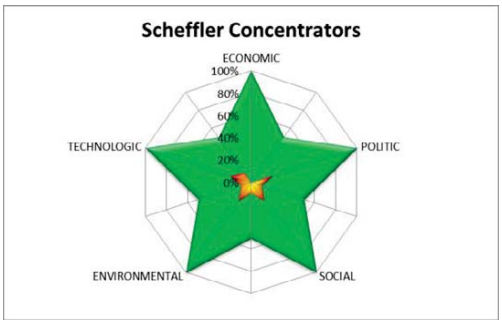

Fig 5: Sustainability Stars in Scheffler-type concentrators for coffee and cocoa

Sustainability Analysis: Since 2013, GRUPO PUCP is researching this concentrated solar thermal technology, reaching good results for roasted coffee and cocoa. We are still working on the improvements on the electronic parts, monitoring of solar concentrator design to improve efficiency. The main difficulty lies in the intermissions of climate due to the rains and the presence of clouds.

4.3. Solar Greenhouse Indirect Dryers - SECASOL

For over 20 years we have had good results with solar corn and oragano (wild marjoram) dryers in Moquegua and Tacna in southern of Peru, but one of the drawbacks is due to the low capacity of direct and indirect dryers.

A project that was relatively successful is the one on the use of solar coffee dryers promoted by the technical American institution cooperation USAID since 1990. These dryers were installed in jungle areas in the north and west of Peru in the departments of Cajamarca, Amazonas, San Martín and Piura with good results.

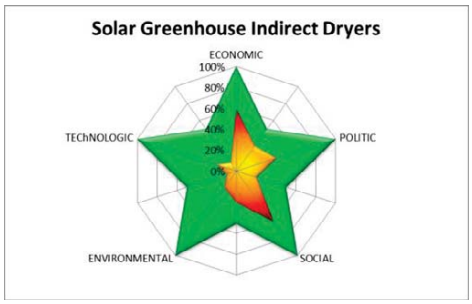

Fig 6: Sustainability Stars in Indirect Solar Dryers

Sustainability Analysis: This technology continues in an experimetal phase according to the capacity of the dryers and quantities of the product. The most used are small and medium dryers because they are cheaper for farmers. We are currently investigating the linear parabolic concentrators for drying tea and aromatic and medicinal herbs and the results will be shown in the coming years.
Research to improve higher production capacities and automatic controllers shoul be on going.

4.4. Solar Greenhouse Dryers - INVER

The glass and plastic greenhouses are having very good diffusion in highlands of Peru where the cold is very intense: its use is mainly dedicated to growing vegetables such as lettuce, tomato, pepper, chili and herbs. The lack of control of the temperature inside the greenhouses as well as the difficult control of automatic irrigation systems within them (for lack of electricity) have made this technology to be not as important as it is in other parts of the world. The material used (glass, plastic) has also been one of the obstacles for the successful dissemination and replication. In an analysis of our travels throughout Peru it can be clearly noted that greenhouse projects only last as long as the plastic degrading life timespan.

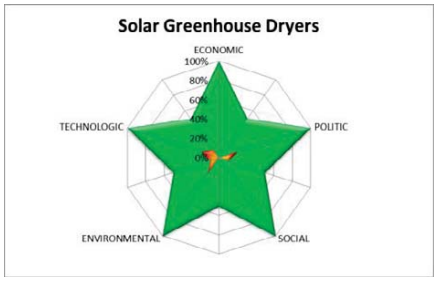

Fig 7: Pictures and Sustainability Star in Solar Greenhouse Dryers

Sustainability Analysis: The star shows us that the political component should mainly be fixed, and technological and economic aspects partially to make it perfect in its execution; It tells us that we need more presence of political authorities to replicate this project for drying coffee, cocoa, fruits in the region of the jungle of Peru. The process of the project was done with the method of participatory design or design thinking method. (Salgado, 2010).

4.5. *Trombe Walls - TROMBEPUCP*

It is a type of greenhouse that is placed on the side walls of the houses to transfer heat from the sun to the inside of the housing, there are those using plastic, polycarbonate and glass materials.
The evolution of this technology by GRUPO was very successful in its dissemination, especially due to the social adaptability of this technology as a counteract against frost and cold spell in the highlands due to climate change. Since 2008 GRUPO has installed more than 600 houses in the departments of Cusco and Puno and is expected to be a model for broadcast as a government policy in the highlands throughout Peru.

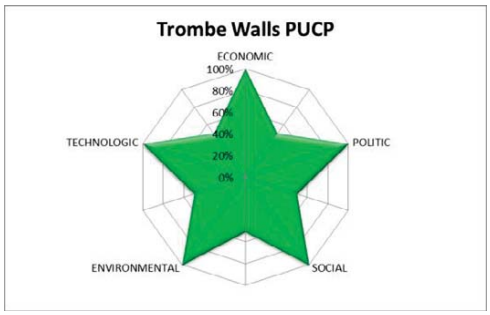

Fig 8: Example of Sustainability Stars in Trombe Walls

Sustainability Analysis: One of the ways to measure the sustainability of a product is the feedback of the beneficiaries, in this case the requests for this technology are increasing day by day due to inclement frost and cold spell in the highlands of Cusco and Puno, in southern of Peru.
The combination of four technologies: Sealing doors and windows, improved kitchen, false ceiling burlap and Trombe walls, enable us to reach a difference in average temperatures between the inside and outside of 10 ° C, which is making this technology one of the most successful projects of GRUPO PUCP and with many opportunities to be part of its replicability by the Peruvian government.

4.6. *Parabolic Solar Cookers - COCISOL*

Parabolic solar cookers have been introduced in Peru since 1982 and there have been attempts made to massify their application by several NGOs as GIZ, SOLARTEC in areas of Huancayo, Cusco, etc. The first design came to GRUPO PUCP in 1995 thanks to GIZ which funded part of the cost (50%); the cost of these kitchens was 150 US $. Later in 2004 this technology's demonstration was the starting point for a project with the NGO IAA in Yanaoca, Cusco area where 4 people were trained in the subject but none came to replicate the model.
Currently the only one that can offer this technology is the Renewable Energy& Hassan company that builds kitchens on request, but so far has not received massive orders. In 2012 several of these kitchens were installed in Pisco and Huancavelica by the PROSINERGY company as demonstration centers.

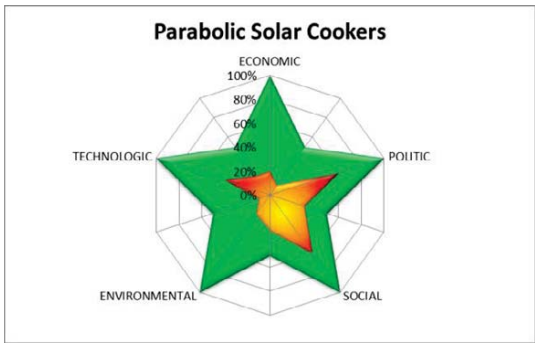

Fig 9: Pictures and Sustainability Stars of Parabolic Solar Cookers

Sustainability Analysis: These kitchens are easy to build and are easy to assemble, but do not have a good reception from women, especially by cultural reasons.
This technology will be sustainable if used in places where there is no wood or manure, when women accept it as alternative, when their costs are lowered and when they can be sold by credit.
The approximate cost of these kitchens is US $ 150, which makes it very difficult for the inhabitants of poor areas to acquire it. The introduction of gas stoves, subsidized by the state, also threaten the spread of this technology.The project is environmentally friendly, the only thing that makes interferes is the climatic variabilities that may occur when operating the kitchens, for example it can start raining or get cloudy or foggy which may result in having food left on it half cooked – this generates distrust in the population towards this technology.

5. Results Obtained

Other than using the star of sustainability that helps us to understand sustainability from 5 views TEPSA there are several versions of software for qualitative analysis to help us in numerical calculations and have been validated in social projects. These are QCA, QCA fs, KIRQ, Tosmana, etc. We decided to use the free software KIRQ due to its simplicity and effectiveness in assessing our case responses. This software is a form of QCA (Qualitative Comparative Analysis) and is suitable for cyclical factors, identifying the necessary and sufficient conditions to enable the performance of some activity by analyzing the probabilities for this to happen. It is used when the variables are dichotomous (YES / NO) as has been developed in the survey of this work.

The methodology allows us to compare the Case Studies and draw probabilities of occurrence with few variables; in this case we will rely on the KIRQ software which has been validated in similar social projects.

The results with the database of surveys give us the following table:

Table 2. Sorted Data Base of sustainability of the 6 case studies.

TECNOLOGIA	UTIL	CONT	OPER	CONF	MANT	ING	EMPL	AHOR	ASEQ	INNO	IPOL	ACEP	~LEGA	DISE	VISI	COMP	MOTI	MEJO	PART	CAPA	AMIG	EDUC	~CONTA	ECOL	~SALU	
CONPAR	1	0	1	1	0	1	1	1	0	0	1	0	1	1	1	1	1	0	0	1	1	0	1	1	1	17
CONSOL	1	0	0	1	1	1	1	1	1	0	1	0	1	1	1	1	0	0	1	0	1	0	1	1	1	17
SECASOL	1	1	1	1	1	1	0	1	0	1	1	0	1	0	0	1	0	1	1	0	0	0	1	1	1	16
INVER	1	1	1	1	0	1	1	1	1	0	1	0	1	0	1	0	0	0	1	0	1	0	1	1	1	16
TROMBEPUC	1	1	1	1	1	0	0	0	1	1	1	0	1	0	1	0	0	0	1	0	1	0	1	1	1	15
COCISOL	1	0	1	0	0	0	0	1	1	0	0	1	1	1	1	1	0	1	0	1	0	1	1	1	1	15

Table 2 gives us some interesting results, such as that the technologies that are transferred to companies are those with the highest index of sustainability and technologies that have been donated by public institutions or NGOs are the ones with worst sustainability acceptance.

From the technological point of view, the best machines turned out to be the ones massively distributed such as the Solar Dryers and Trombe walls for heating homes in highlands. Economically, politically and socially the best technologies proved to be those where local materials and communities where involved during their construction and development, respectively. From the environmental point of view every case resulted to be good for the environment but none of them passed the survey as totally clean.

6. Conclusions

The influence of the 5 factors TEPSA (Technology, Economy, Politics, Social and Environmental) in each of the cases presented has its relative importance in the final results of sustainability, since, in one way or another it influences the success of the implementation of technological projects in poor rural areas of Peru.

The proposed methodology for the evaluation of technological projects has proven to be a good tool for decision making, since it allows us to evaluate the results of a project by analyzing it's sustainability.
The evaluation of the sustainability of projects depends not only on technological and economic conditions of the equipment that works with renewable energy but also depends heavily on the social and political situations of the places where these projects are to be implemented.

Abstract

The OTSun project is a research project co-funded by the Spanish Ministry of Economy and Competitiveness, with the reference number ENE2015-68339-R, where the main goal is to develop a computational tool for high-resolution optical analysis of solar collectors. The project is runs from 2016 to 2018 and is composed of eight tasks. The main motivation of the project is to develop an open source code that serves as reference to simulate optical systems for solar energy applications where the most important optical effects are being considered. In order to achieve high-resolution results the radiation-matter interaction effects, the dependence of the incident angle on absorptive and anti-reflective surfaces, and also the dependence of the wavelength will be taken into account. The tool is based on the Monte Carlo ray-tracing method, and a useful software interface will be provided allowing the user to create, or import, the solar collector geometry. A data base of solar materials will be provided with the tool. Finally, the optical efficiency and the energy distribution on the receiver will be calculated by the program.

Keywords: *Ray-tracing, optical characterization, optical simulation, FreeCAD*

1. Introduction

Computational tools with the aim to simulate the optical performance of solar collectors are of utmost importance for optimization of a real system or during the design state of new systems. Moreover, the use of these tools produce economic savings in experimental validations, testing, and manufacturing (Osório et al., 2016); and also can be used to determine the optical behavior at different incidence angles (Hertel et al., 2016a, 2015). Nowadays there are many programs able to analyze the optical behavior of solar energy systems, such as STRAL, TieSol, ISOS, HFLCAL and HFLD. These programs are commercially available and are designed for the analysis of central tower plants with heliostats (Bode and Gauché, 2012). Programs that are available for free are SolTrace ("NREL," n.d.) and Tonatiuh (Blanco et al., 2009, 2005). Since OTSun is a project with the aim to develop an open source code with free availability, a briefly description of the specifications of the SolTrace and Tonatiuh softwares is exposed below.

SolTrace is a software tool developed at the National Renewable Energy Laboratory (NREL) to model concentrating solar power (CSP) systems and analyze their optical performance. Although ideally suited for solar applications, the code can also be used to model and characterize many general optical systems. SolTrace is free and can be downloaded from the NREL website. As for the ray-tracing methodology, the solar radiation distribution can be considered as a Gaussian, punctual or user defined models. For the optics of materials the "optical element definition" model is used to characterize any optic element of the system;

doi:10.18086/eurosun.2016.06.04 Available at http://proceedings.ises.org

this element is adjusted by parameters in order to consider mirrors or glasses, such as: the reflectivity (with incidence angle dependence), the transmissivity, the slope error, the specularity error, and the refractive index. In the case of refraction, the Fresnel equation is handling the reflection and refraction at interfaces (angular variation). SolTrace has a graphical user interface (GUI) for the visualization of the scene.

Tonatiuh is an open source code written in C++ and designed for the analysis of the optical behavior and energy distribution of radiation in concentrating solar power (CSP). Similar to SolTrace, Tonatiuh supports multiple geometric shapes and has a GUI. However, the analysis and the processing results should be treated with an external program such as Mathematica or R. Tonatiuh has a Universal GNU Public License, which allows free access to the code for any user and contribute to its development. About the ray-tracing methodology, the solar radiation distribution can be considered as a pillbox, or as the Buie model (Buie et al., 2003). As for the optics of materials, Tonatiuh considers refractive materials (e.g. glass covers) and specular materials (e.g. mirrors). The refractive materials are defined by the transmittance (a constant value), and the slope error. It should be noted that the electromagnetic Fresnel optics equations are not implemented. The reflective materials are defined by the reflectivity and the slope error.

Despite the variety of programs meant for optical simulation of solar systems, there is no open source software capable of taking into account the most relevant effects of the radiation-matter interaction that occur in solar energy systems, such as: electromagnetic Fresnel optics equations, the real behavior of dielectric materials, the wavelength dependence, the incidence angular dependence of selective and anti-reflective materials, the multivariate Gaussian function for the reflection direction, the volume scattering effects, among others. For this reason, the authors of this study are developing an open source code to simulate the optical behavior of solar collectors that takes into account the most relevant optical effects in optical solar systems.

To achieve the goals of the project, first a study of the most relevant effects related with the radiation-matter interaction of the common materials used to construct solar concentrating collectors has been conducted. Results are presented in another study at the EuroSun 2016 (Hertel et al., 2016b). All the interaction effects should be modeled by the Monte Carlo approach in order to consider the stochastic nature in the energy harvesting process of solar collectors.

On the other hand, a GUI will be provided with the tool to facilitate the visualization of the scene, and also be able to import the geometry of the solar collector from other formats. The interface software should allow working with open file formats such as STEP, STL, DXF, and OBJ.

An important part of the project is the availability under an open source license (GPL, freeBSD or similar). Finally it can be mentioned that the project is supported by the Plataforma Solar de Almería (PSA), the Spanish institute Instituto para la Diversificación y Ahorro de la Energía (IDAE), The solar Energy Research Center (CIESOL), TECNALIA Corporation, and SOLARUS Sunpower Sweden AB.

2. Previous results in ray-tracing analysis

The team of the project has a lot of experience in ray-tracing simulations. It can be noted that the first code developed was implemented in 2006 (Martínez Moll et al., 2006; Pujol et al., 2006) where the Fixed Mirror Solar Concentrator (FMSC) (Russell John L., 1977) was analyzed with simple optical models. The results showed the most interesting geometries of the FMSC based on two design parameters (the number of mirrors and the focus/width ratio). The simulations were conducted with simple models, such as a point source for the sun model, ideal specular reflectivity for mirror surfaces, a constant value for the transmittance of the cover, and a constant value for the absorptance of the receiver surface. As for the code, the geometry of the system only could be defined by triangles with ASCII files. Hence, only one algorithm was required to detect the intersection between a line and a triangle in 3D space. The algorithm used is the one exposed in the book (David H. Eberly, 2006). About the ray-tracing program developed at 2006, it can be concluded that the ray blocking effect was the most important phenomenon for the analysis of the optical efficiency of the solar collector. The code was implemented in FORTRAN.

It was not until 2012 when the first results with a more accurate ray-tracing model were presented by the

authors (Pujol Nadal and Martínez Moll, 2012). The major improvements implemented at this stage were: the Fresnel equations for the electromagnetic waves (Hetch and Zajac, 1999), the Buie model for the solar radiation distribution (Buie et al., 2003), the incidence angle dependence for the absorptance surfaces according to the model exposed in (Tesfamichael and Wäckelgård, 2000), and a one-dimensional radial distribution for the normal deviations from an ideal specular reflection (Johnston, 1995). All the effects were modeled with the Monte Carlo methods. The tool was used to analyze the FMSC and its curved mirrors version, the Curved Slats Fixed Mirror Solar Concentrator (CSFMSC) (Pujol Nadal and Martínez Moll, 2013). The most promising geometries of both designs were identified for medium temperatures ranges in other works (Pujol-Nadal et al., 2013; R Pujol-Nadal and Martínez-Moll, 2014).

It can be noted that a difference of 25% was observed between the optical efficiency calculated by simple models (studies presented in 2006) and the one based on more accurate models (presented in 2012). Even though the more promising geometries were in both cases very similar. Hence, if it is true that simulations with simple optical models can be used to compare different designs of the same concept (the FMSC and the CSFMSC), the absolute value of the energy collected by the system can only be determined if the simulations take into account accurate models which are based on the most important effects in the energy harvesting process of the solar collectors.

In order to evaluate the importance of a high-resolution ray-tracing model with respect to a simple ray-tracing tool, an optical simulation of a parabolic through collector (PTC) has been conducted. The PTC chosen for the analysis was the NEP PolyTrough 1800 collector exposed in (Sallaberry et al., 2015). The simulations have been done using two different models: Model 1 and Model 2. The first one takes into account the Buie model for the Sun (Buie et al., 2003), one-dimensional radial distribution for the normal deviations from an ideal specular reflection (Johnston, 1995), Fresnel optics equations for electromagnetic waves, the extinction coefficient of the glass tube for the transmittance, and the angular dependence of the absorber surface (Tesfamichael and Wäckelgård, 2000). On the other hand, Model 2 considers a point source model for the sun, ideal specular reflectivity, a constant value for the transmittance of the glass tube, and a constant value for the absorptance of the receiver. The results are shown in Fig. 1, for transverse and longitudinal angles of incidence. It can be seen that if a simple model for the radiation-matter interaction is considered in a ray-tracing simulation, an overestimation of the optical efficiency is obtained.

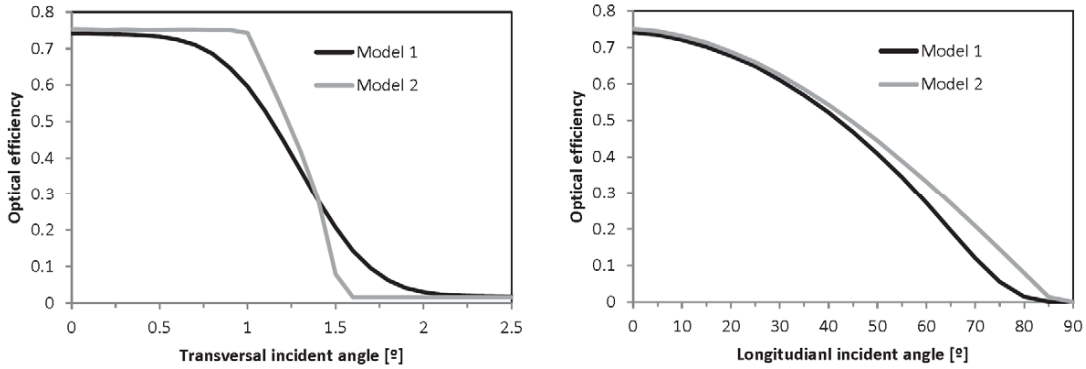

Fig. 1: Ray-tracing results of a PTC for transverse and longitudinal planes using simple and more accurate models

3. The ray-tracing code

The current code, written in FORTRAN, is under development. New models from 2012 are implemented in order to consider optical models based on the interaction of light and matter. The main description of the code in the actual state is described below.

In the current version the geometry has to be defined by surface objects. In a subsequent step different physical models with its respective parameters can then be assigned to each surface object.

For any type of model, the lay of energy conservation is always satisfied. There are consequently only three

possible ways of interaction. The incident ray can be either reflected, transmitted, or absorbed according to Eq. 1.

$$R(\theta_i, \lambda) + T(\theta_i, \lambda) + A(\theta_i, \lambda) = 1 \quad (1)$$

All coefficients depend on the wavelength, the incidence angle and the polarization of the light. With Eq. 1 in mind it is possible to classify common materials of solar concentrating collectors into three different groups: Reflective (mirrors), transparent (envelope, covers etc.) and absorbing (receiver) materials. As illustrated in Fig. 2, the simplifying assumptions are zero transmittance for reflective and absorptive materials, and zero absorptance for transparent materials. The latter only goes for the surface itself, because in the medium (after passing through the interface) there will be absorptance of the propagating electromagnetic wave, see Fig. 3.

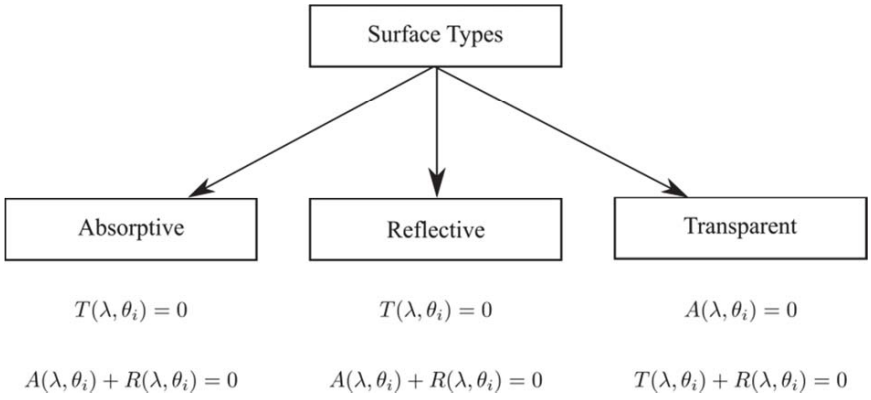

Fig. 2: Classification of typical solar thermal material: absorptive material (receiver), reflective material (mirrors) and transparent material (covers, envelopes)

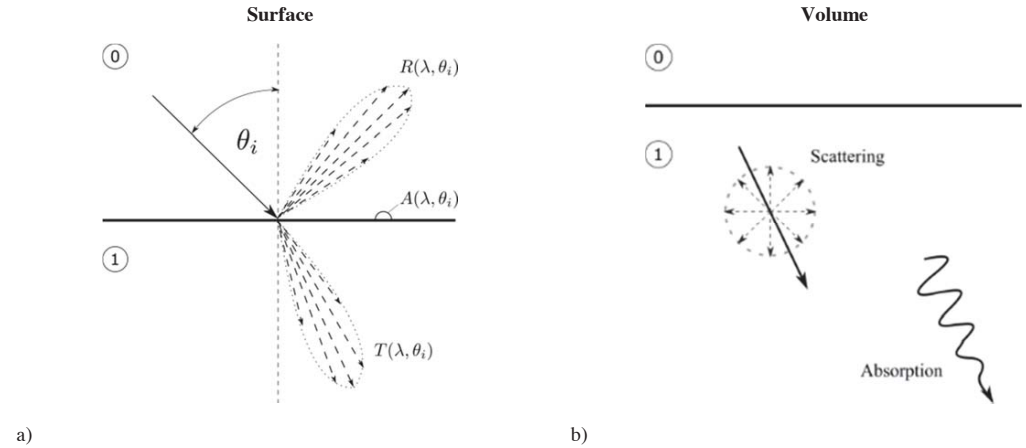

Fig. 3: Radiation-matter-interaction phenomena: a) Reflection, transmission and absorption on surfaces. b) Scattering and absorption within volume (Hertel et al., 2016b)

As far as conservation of energy goes, the interaction of an incident ray with a surface can be fully described by a surface reflectance model. What is then still missing for a more accurate description is the spatial dispersion of the reflected energy due to random microscopic surface textures. This phenomenon called

scattering can be described by a scattering model.

In summary, all radiation-matter interaction models that our ray-tracing code contains can be categorized into:

- Surface effects
  - Reflectance models
  - Scattering models
- Volume effects (only transparent material):
  - Volume absorption.

3.1 Reflectance models

Fig. 4 shows all surface reflectance models, which are currently implemented in the OTSun ray-tracing code. For more details see (Hertel et al., 2016b). It is important to comment here on the accuracy of the reflectance model. As mentioned before, the surface reflectance is a function of the wavelength and the incidence angle of the ray, as shown in Eq. 1. Depending on the purpose of the study, the surface reflectance can also be defined as a constant value, only depending on the incident angle, or depending on both the incidence angle and the wavelength.

In any case, sufficient experimental data has to be available. As for selective materials, often manufacturers provide a constant value. If such a value is not available, (Tesfamichael and Wäckelgård, 2000) proposed an empirical model of $R(\theta_i)$. This model was derived from measurements of an Al2O3-Ni/Al2O3 and NiO3-Ni-composite selective surfaces. Unfortunately, there was no other data obtained apart from these two samples. The model of (Grena, 2010) is a good alternative to derive the incidence angle dependence if the absorption coefficient is known for normal incidence.

Alternatively, accurate information about reflectance can be obtained from refractive index data bases. Based on this information, the Fresnel equations for single interfaces or the Transfer-Matrix method for more complex multi-layers (coatings) are common approaches in other fields such as PV or optics design (Macleod, 2010).

3.2 Scattering models

At the moment there are three options for scattering implemented: no scattering, Lambertian (isotropic) or Gaussian scattering (Fig.). Isotropic dispersion is typical for matte surfaces, while a Gaussian curve describes the reflection pattern of specular surfaces such as mirrors. In reality, the result is often a combination of isotropic and specular reflection and is described by a bidirectional reflectance distribution function (BRDF).

In solar concentrating applications the Gaussian model was found to be sufficiently accurate to describe the reflection of mirrors. OTSun uses a more general superposition of two bivariate normal distributions (Eq. 2).

$$f = Ke^{\left(-\frac{\varphi^2}{2\sigma_{21}^2}-\frac{\varphi^2}{2\sigma_{22}^2}\right)} + (1-K)e^{\left(-\frac{\varphi^2}{2\sigma_{11}^2}-\frac{\varphi^2}{2\sigma_{12}^2}\right)} \quad (2)$$

with K the ratio between distributions, σ_{ij} the respective variances and φ the acceptance angle. Moreover, it is possible to define wavelength and incidence angle dependent data for the variances σ_{ij} such as defined e.g. by (Good et al., 2016).

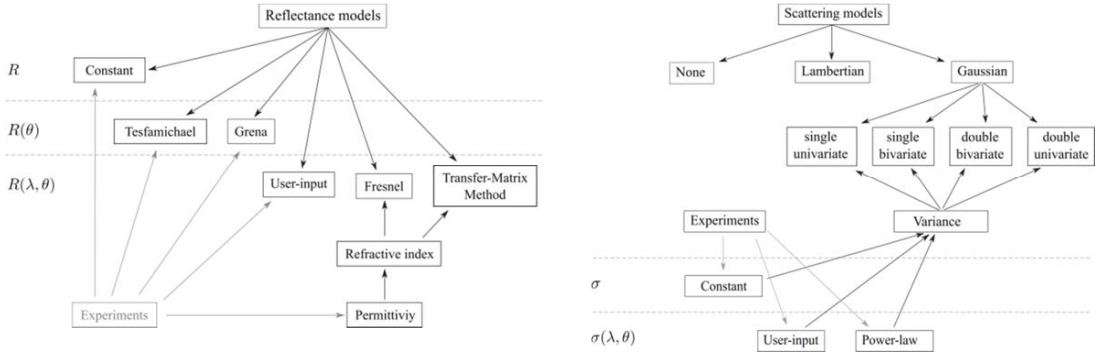

Fig. 4: Schematic of implemented reflectance (left) and scattering models (right) in the current version of the OTSun ray tracing code

4. Objectives and methodology

The improvement of the FORTRAN code is the first task of the OTSun project. The optical models are first proved and validated in the FORTRAN code, and then they will be implemented in the new version of the program.

The general objectives covered by the OTSun project are:

- Developing a computational tool for the high-resolution optical analysis of solar collectors.
- Validating the computational tool by comparison with theoretical and experimental results.
- Applying the computational tool in real cases.
- Distributing the tool as an open source code.

To achieve the general objectives, the next set of tasks will be developed during the project:

- Task 1: Current Status and improvements of the actual ray-tracing tool (FORTRAN).
- Task 2: Implementation of new algorithms of ray-intersection.
- Task 3: Implementation of a general algorithm for the energy distribution on the receiver.
- Task 4: Types of sources, spectrum and its implementation.
- Task 5: Models for specular reflective surfaces.
- Task 6: Radiation-matter interactions of materials.
- Task 7: Simulation of real cases.
- Task 8: Web and documentation platform.

General requirements for the simulation tool are a graphical interface for the visualization of the scene (GUI), and a programming language accessible to future improvements and developers. With this in mind, during the initial stage of the project we explored possible tools to start from; tools that were already developed with regard to these specifications. It should be clear that it is not beneficial to develop a visualization tool from scratch, but rather incorporate the physical models into an already existing visualization tool. Such a tool could be a computer aided design software (CAD), or any other 3D data visualization programs.

As discussed in previous sections, the geometry of the system only can be introduced by triangles in the actual FORTRAN code. It is possible to generate any geometry with the desired precision at the expense of an increasing number of triangles. Consequently, constructing curved surfaces with triangles has the disadvantage of requiring a large number of elements, which means increasing computation time. For this reason we explored new algorithms for ray-intersection with surfaces in task 2.

In view of the general specifications, and the need to reduce the CPU time, we explored the FreeCAD software (“FreeCAD,” n.d.). FreeCAD is a parametric 3D modeler made primarily to design real-life objects of any size. Parametric modeling allows to easily modifying the design by going back into the model history and changing its parameters. FreeCAD is open source and highly customizable, scriptable and extensible, it

runs on multiple platforms (Windows, Mac and Linux), and supports many open file formats such as STEP, IGES, STL, SVG, DXF, OBJ, IFC, DAE among others. It has the great advantage that almost all of FreeCAD's functionalities are accessible to Python, hence it is possible to easily extend these functionalities, automatize them with scripts, build self- made modules, or even embed FreeCAD in your own application.

Finally, it can be noted that Python is a widely used high-level, general-purpose, interpreted, and dynamic programming language, and that FreeCAD has implemented methods for the intersection between faces and lines (very useful for the ray-intersection problem mentioned above and to decrease the CPU time). For all of these reasons, we decided to develop the OTSun project as an extension of the FreeCAD software.

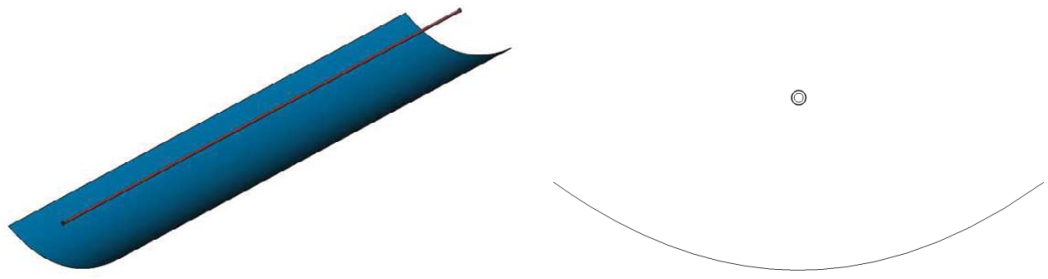
5. First results using the FreeCAD software

A ray-tracing simulation of a solar collector using the FreeCAD software has been conducted and validated. To do so, first the creation of the geometry of the NEP PolyTrough 1800 collector exposed in (Sallaberry et al., 2015) was modeled using the functions available in the *Part Module* of FreeCAD. Then, the skeleton of a simple ray-tracing procedure written in Python was implemented and executed. Only simple effects of optics have been implemented in this stage of the project. The main objective of this work was to evaluate the extensibility of FreeCAD software for ray-tracing simulations applied to solar collector systems.

5.1. Creating a PTC in FreeCAD

The *Part module* of FreeCAD allows accessing and using the OpenCasCade objects and functions. OpenCascade is a software development platform providing services for 3D surface and solid modeling, CAD data exchange, and visualization ("Open CASCADE Technology: Overview," n.d.). Most of its functionality is available as C++ libraries.

The *Part Module* has implemented tools for creating primitive objects, such as: box, cone, cylinder, torus, parabola and sphere among others. The ones that we used for creating the PTC were the parabola, the circle and the cylinder. Then, the *Part Module* has also implemented tools for modifying existing objects in the document, such as: booleans, union, common, extrude and cut among others. The extrude tool was used to create the parabolic mirror and the absorber tube from the primitives mentioned above. Since the glass tube has volume effects from the optical point of view, it was generated using the cut tool subtracting one cylinder from another. This way a solid object was obtained for the glass cover of the evacuated tube. A Python package with all the instructions mentioned above was written to create the geometry of the PTC in FreeCAD. Figs. 5 and 6 show the PTC created. Note that the parabolic mirror and the absorber cylinder are faces, but the glass tube is a solid.



(a) (b)

Fig. 5: (a) General view of the PTC. (b) Frontal view of the PTC

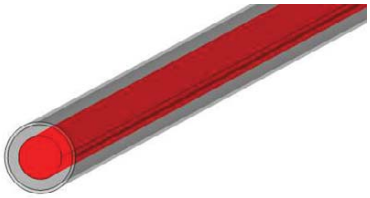


Fig. 6: Evacuated tube of the PTC

5.2. The ray-tracing procedure

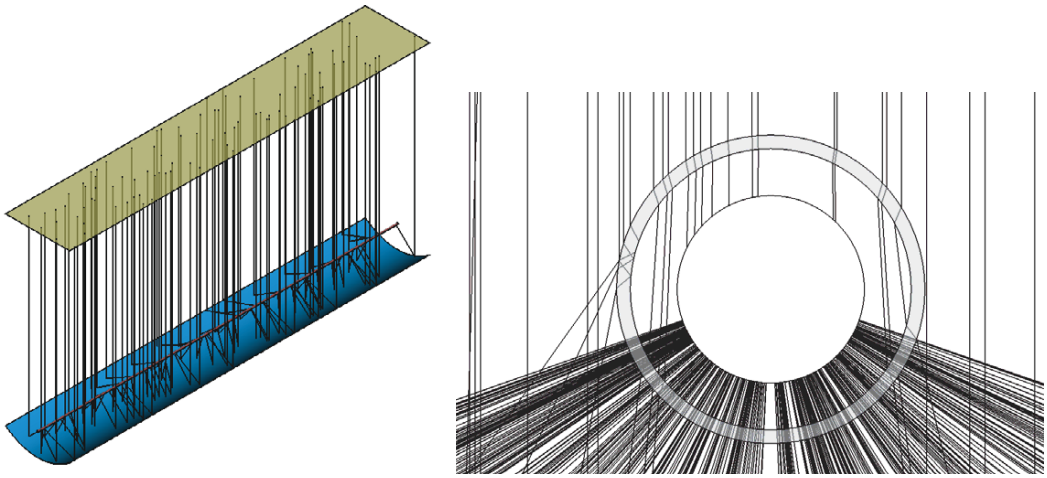
The program calculates ray trajectories originating from one source (called sun window) that emits rays to all surfaces of the system. We have created a Python package that uses the classes provided by FreeCAD and extends them in order to model scenes and implement the ray-tracing procedure.

At this stage of the project, the core of the computation is implemented via three main classes, Scene, Ray and SolarCollector. An object of the class Scene collects all the information related to the physical objects present in the active document (the solar collector constructed).The physical objects are represented using *Shapes* in FreeCAD with some extra information regarding their materials. At this stage of the project, only simple models for the optics are considered.

An object of the class Ray collects the path that a solar ray describes while it interacts with the objects present in its scene; it is initialized by giving its source and direction. For now, only a punctual source is considered. We have implemented algorithms to compute, step by step, the points that the object passes through while it is reflected, refracted or absorbed in the surfaces present in the scene. These two classes are used by the third; SolarCollector, that implements the overall computation of the optical efficiency of the scene as a solar collector, making an estimation of the overall energy that it gets absorbed when the scene is exposed to the source.

5.3. Ray-tracing simulations

Fig. 7(a) shows a visualization of a ray-tracing simulation of the NEP PolyTrough 1800 collector done with the package mentioned above. This simulation was done emitting 100 rays, and it can be see how the sun window emits rays to the solar collector system. In Fig. 7(b) a front projection of the same ray-tracing simulation is shown. Also visible are the path trajectories of the rays according to the refraction law. Another case is shown in Fig. 8, for the longitudinal angle equal to 45º.



(a) **(b)**

Fig. 7: Ray-tracing simulation with 100 rays emitted. (a) Total view of the concentrator, sun rays, and sun window. (b) Frontal projection of the same ray-tracing in the region of the receiver.

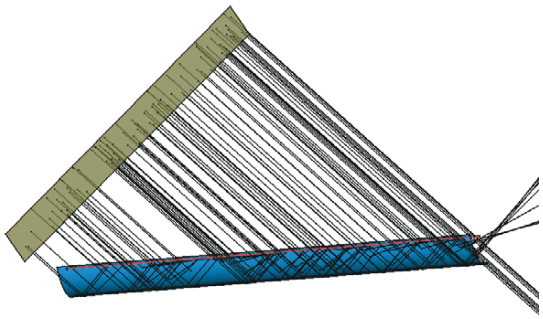


Fig. 8: Ray-tracing simulation with 100 rays emitted for the case of longitudinal angle equal to 45º

In order to validate the results of the new code generated, a simulation with 20000 rays has been conducted considering the same assumptions of Model 2 in Section 2. In Fig. 9 the optical efficiency obtained with the new code (OTSun_FreeCAD) and with the FORTRAN code (OTSun_FORTRAN) is shown. In view of the results, we can conclude that the new OTSun code calculates the optical efficiency with same accuracy as the FORTRAN version. Moreover, as the FORTRAN version was validated with experimental results in (Pujol-Nadal et al., 2015; Ramon Pujol-Nadal and Martínez-Moll, 2014), hence the code implemented in FreeCAD is also validated.

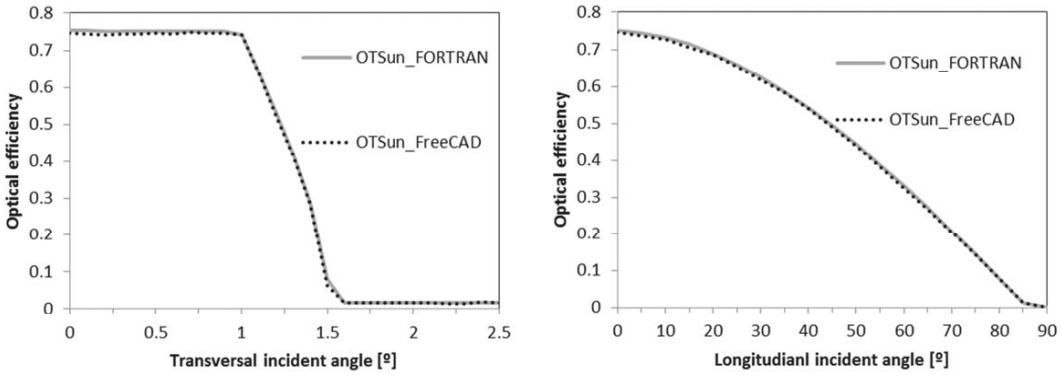

Fig. 9: Ray-tracing results of a PTC for transverse and longitudinal planes using simple models with FORTRAN and FreeCAD versions.

6. Conclusions

Ray-tracing simulations show great benefit for the optical analysis of solar collectors, and in order to achieve high-resolution results the consideration of the radiation-matter interaction is needed. In this contribution the authors describe the OTSun project, where the main goal is to develop a computational tool for high-resolution optical analysis of solar collectors. The tool will be developed under a free license (GPL, freeBSD or similar). Due to the general requirements for the tool, the authors decided to develop the OTSun project as an extension of the FreeCAD software which has the advantage that almost all of its functionalities are accessible to Python. A Python package has been written in order to explore the viability of making a ray-tracing simulation of a solar concentrating collector using the FreeCAD functions. In view of these experiences, it has been demonstrated that the FreeCAD program is suitable to extend its functionality and use it for a ray-tracing simulation of solar energy systems.

Abstract

The International Standard ISO 9459-5 describes the characterization of thermal performance for domestic water heating systems. The objective of this paper is to analyze the influence of measurement accuracy of some input parameters (inlet water temperature, outlet water temperature and solar radiation) during the test sequences on resulting solar fraction of a domestic water heating system, type thermosiphon, on the different European reference locations (Athens, Davos, Würzburg and Stockholm). A study of the measurement accuracy according to Standard ISO 9459-5 and other values has been carried out. The long-term prediction (solar fraction) for each of the input measurements was determined, and according to these results, a less restrictive measurement accuracy could be propose for a future revision of Standard ISO 9459-5.

Keywords: *solar system, dynamic testing, certification*

1. Introduction

According to the Spanish Technical Building Code (CTE) and Ministerial Order ITC/71/2007, all solar thermal systems on the Spanish market must be homologated by the Ministry of Industry to be eligible for government subsidies. For this reason, they must pass the EN 12976-1 and -2 (2006) European Standard tests. This Standard stipulates durability, safety and efficiency tests and user and installer documents checking.

The CENER (National Renewable Energy Centre) and GTER (Group of Thermodynamic and Renewable Energies) Accredited Solar System Testing Laboratory in Seville has been performed all the tests for factory-made solar thermal systems according to the European Standard since 2008. Before that, solar systems had been tested in this laboratory for 25 years. The European Standard efficiency test refers to two ISO Standards, ISO 9459-2 (2008) (CSTG method) and ISO 9495-5 (2007) (DST method). The CSTG method "Complete System Testing Group" makes use of an input-output method, while the DST method, called the "Dynamic System Test", makes use of dynamic software for parameter identification of the system characterization.

These International Standards provide information about measurement accuracies for each experimental measure (ambient temperature, inlet water temperature, outlet water temperature, flow-meter and solar radiation). The objective of this paper is to analyze the influence of measurement accuracy of some input parameters (inlet water temperature, outlet water temperature and solar radiation) on solar fraction in four different locations (Athens, Davos, Würzburg and Stockholm) for a factory made solar heating system, type thermosiphon, testing according to Standard ISO 9459-5.

doi:10.18086/eurosun.2016.06.07 Available at http://proceedings.ises.org

2. Description of testing method (ISO 9459-5)

The efficiency test of the DST method (also called dynamic method) consists in several test sequences with different system behaviors: S-Sol for characterizing the collector array performance at high efficiencies and acquire information about store heat losses and collector array performance at low efficiencies, S-Store for characterizing store heat losses and S-Aux for determining the heat losses and the volume fraction of the auxiliary heated portion of the storage tank. All the significant parameters (solar radiation, inlet and outlet water temperature, ambient temperature and flow-meter) are recorded. The mathematical model of the system energy output is based on a partial differential equation.

2.1. S-Sol Sequence

The aims of these sequences are to characterize the collector array performance at high efficiencies and acquire information about store heat losses and collector array performance at low efficiencies. The tests consists in conditioning the system and then letting the solar system operates normally for several days and finally the system is conditioned again to make uniform the tank temperature. Those sequence types are the called Test A and Test B. During those sequences, a series of 5 (Test A) or 7 (Test B) draw-offs are executed with different durations according to the system characteristics and at different times of the day. The Test A is supposed to let the system work at high efficiencies with enough closed draw-offs to not let the collectors heat too much. The Test B is supposed to let the system work at low efficiency leaving the tank as warm as possible.

Within those sequences, there should be a minimum of valid days with enough daily solar radiation and outlet temperature higher than a minimum for Test B.

2.2. S-Store Sequence

This sequence aims to characterize the store heat losses parameter of the system. It consists of a Test B sequence for at least 2 days and a cooling period of between 36 and 48 h.

2.3. S-Aux Sequence

This sequence aims to characterize the volume fraction of the auxiliary heated portion of the store. But it is not used in the tests of solar-only system.

2.4. Identification of system parameters and prediction of long-term performance

The identification of the characteristics parameters of the system is done using all the measured data recorded during the whole testing sequences. It is made by the validated commercial software InSitu (version 2.7) referred in the Standard ISO 9459-5. Figure 1 shows the flow chart of InSitu program

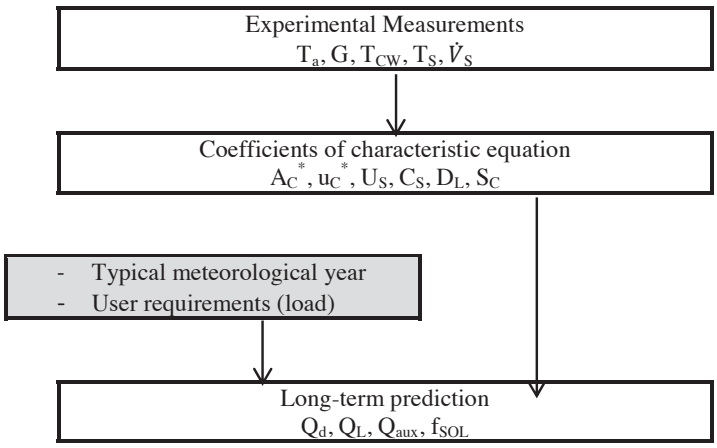

Fig. 1: Flow chart, InSitu program

The results consist in the coefficients A_c* (effective collector area), u_c* (effective collector loss coefficient), U_s (total store heat loss coefficient), C_s (total store heat capacity), D_L (mixing constant), Sc (store stratification). Each of those parameters is a coefficient of the terms in the physical model used for the thermosiphon.

The same software is used to calculate the yearly performance of the system for different reference locations and load demand using hourly meteorological data [H, T_a].

The solar fraction (f_{SOL}) is defined as the energy supplied by the solar part (Q_L) divided by the total system load (Q_D = heat demand).

3. Description of influence of the input parameters measurement accuracy

This section analyzes the influence of measurement accuracy of some the input parameters (inlet water temperature, outlet water temperature and solar radiation) on solar fraction in four different locations (Athens, Davos, Würzburg and Stockholm) for a factory made thermosiphon solar system. Table 1 shows the measurement accuracies according to Standard ISO 9459-5, as well as the accuracies proposed for this analysis. A prediction of long-term performance for each of the measurement accuracies has been carried out.

Tab. 1: Measurement accuracies

Parameter	Measurement accuracy according to Standard ISO 9459-5	Measurement accuracy analysed in this study
Inlet temperature	± 0.1 ºC	± 0.2 ºC, ± 0.5 ºC
Outlet temperature	± 0.1 ºC	± 0.2 ºC, ± 0.5 ºC
Solar radiation	± 1.0 %	± 1.5 %, ± 3.0 %

4. Influence of the input parameters measurement accuracies

4.1 Testing sample

A thermosiphon system with a storage tank of a volume of 300 l. and 2 flat-plate collectors with an aperture area of 4.46 m^2 is selected for analyzing the influence of input parameters measurement accuracies.

The results of these system parameters obtained according to Standard ISO 9459-5 are shown in Table 2

Tab. 2: System parameters

Parameter	Value	Unit
A_C*	2.619	m^2
u_C*	8.191	$Wm^{-1} K^{-1}$
U_S	2.504	$W K^{-1}$
C_S	1.114	$MJ K^{-1}$
D_L	0.125	--
S_C	0.515	--

The results of the long-term performance are presented in the following graphs

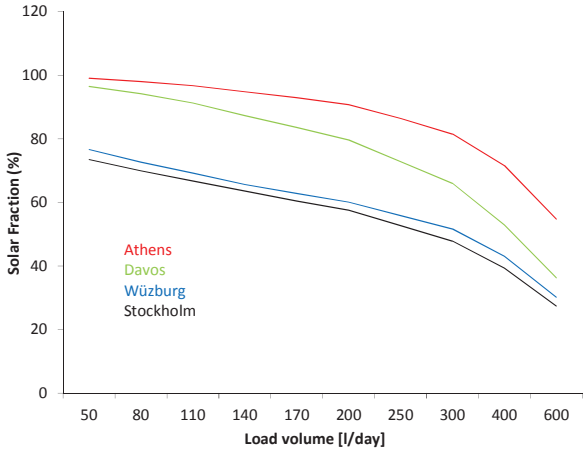

Fig. 2: f_{SOL} results

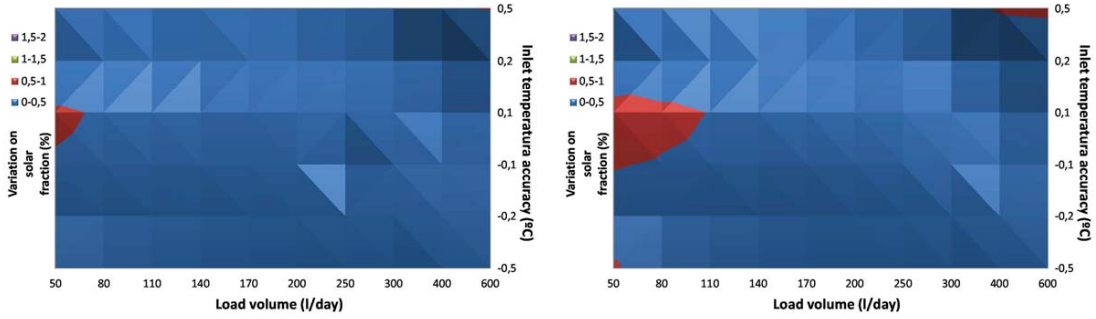
4.2 Comparative analysis

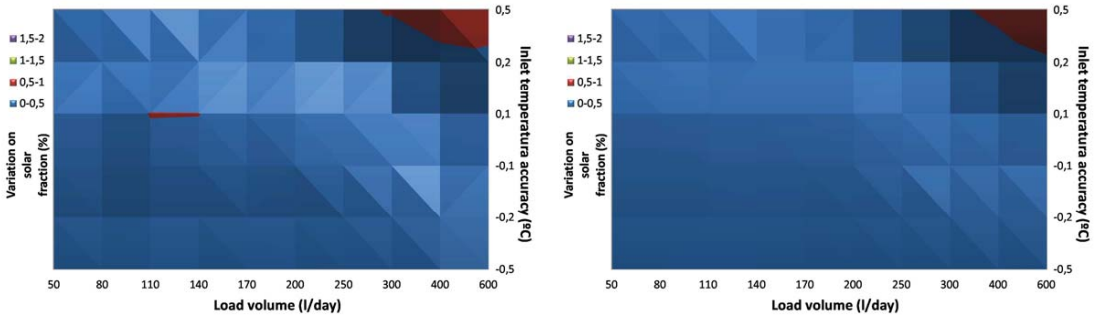
This section describes the variation on the solar fraction as a function of the load volume for every reference locations in order to modify the measurement accuracy of each parameter proposed in Table 1. Similarly, the average relative error of the solar fraction in every input parameter will be represented.

a. Inlet temperature

As shown in Figure 3, the maximum difference of the solar fraction obtained between the results to testing sample and the results in all intlet temperature measurement accuracies (table 1) is lower than 0.9 % in different reference locations. The maximum difference in variation on solar fraction is lower than 0.7 % to measurement accuracies according to Standard ISO 9459-5 (± 0.1 ºC) and 0.9 % to other measurement accuracies proposed (± 0.2 ºC, ± 0.5 ºC).



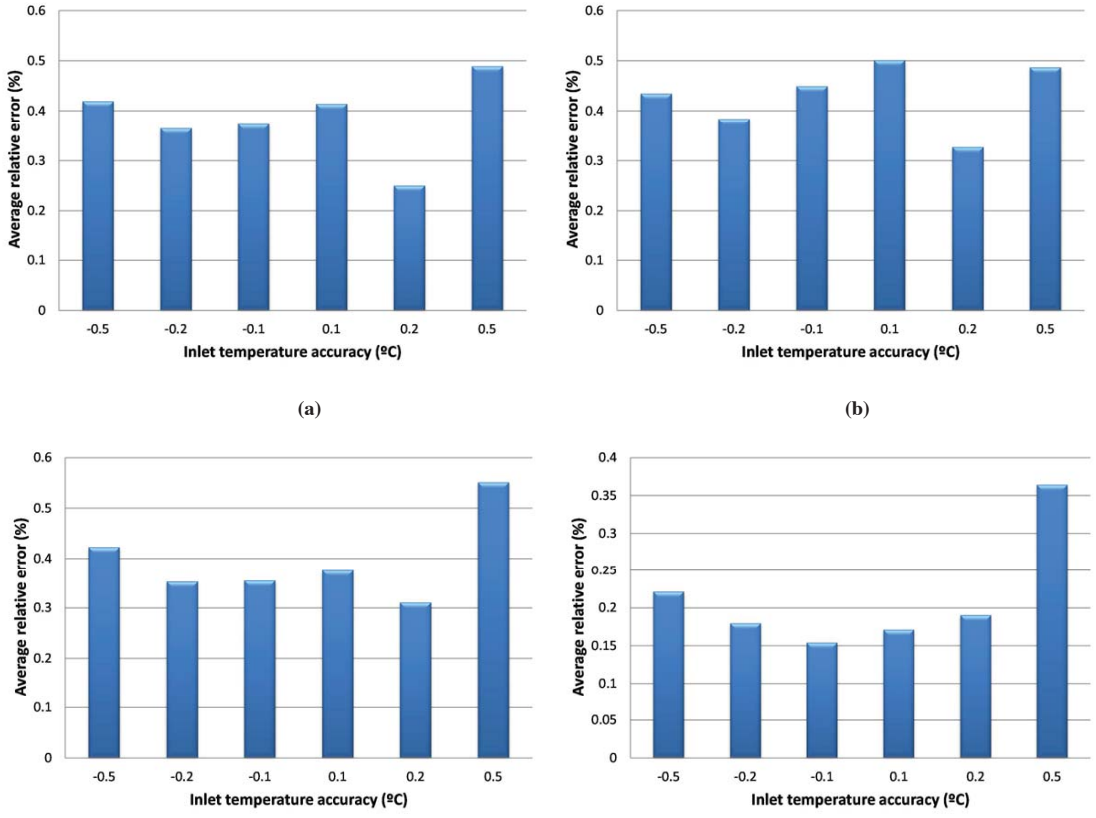
(a) **(b)**



(c) (d)

Fig. 3: Variation on f_{SOL} to modify inlet temperature measurement accuracy in Stockholm (a) Würzburg (b) Davos (c) and Athens (d)

Figure 4 shows the average relative error of solar fraction with respect to inlet temperature accuracy in all reference locations. The maximum average relative error on solar fraction is lower than 0.6 % for all measurement accuracies studied (table 1). The minimun values of average relative error on solar fraction occurs on Athens location.



(a) (b)

(c) (d)

Fig. 4: Average relative error on solar fraction to modify inlet temperature measurement accuracy in Stockholm (a) Würzburg (b) Davos (c) and Athens (d)

b. Outlet temperature

As shown in Figure 5, the maximum difference of the solar fraction obtained between the results to testing sample and the results in all outlet temperature measurement accuracies (table 1) is lower than 1% in different reference locations. The maximum difference in variation on solar fraction is lower than 0.4% to measurement accuracies according to Standard ISO 9459-5 (± 0.1 ºC) and 1% to other measurement accuracies proposed (± 0.2 ºC, ± 0.5 ºC).

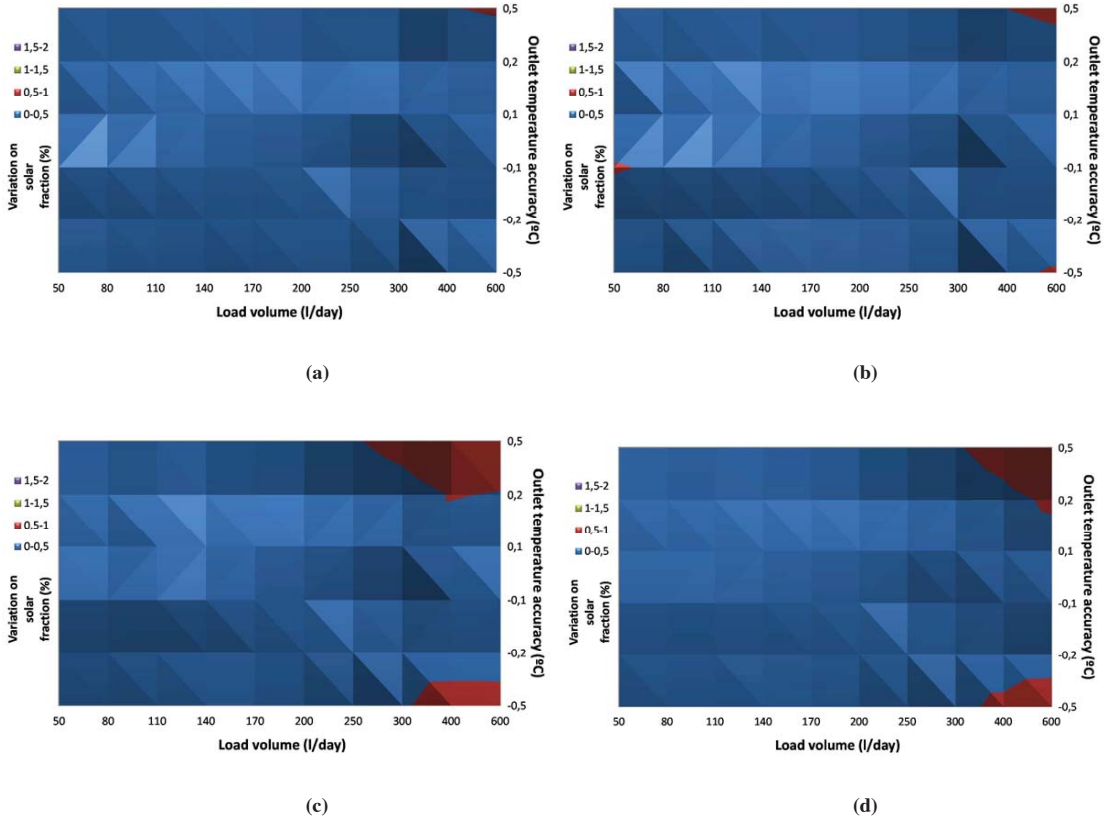


Fig. 5: Variation on f_{SOL} to modify outlet temperature measurement accuracy in Stockholm (a) Würzburg (b) Davos (c) and Athens (d)

Figure 6 shows the average relative error of solar fraction with respect of outlet temperature accuracy in all reference locations. The maximum average relative error on solar fraction is lower than 0.4% for the measurement accuracies according to Standard ISO 9459-5 (± 0.1 ºC) and 0.7% for other measurement accuracies analized (± 0.2 ºC, ± 0.5 ºC). The minimun values of average relative error on solar fraction occurs on Athens location.

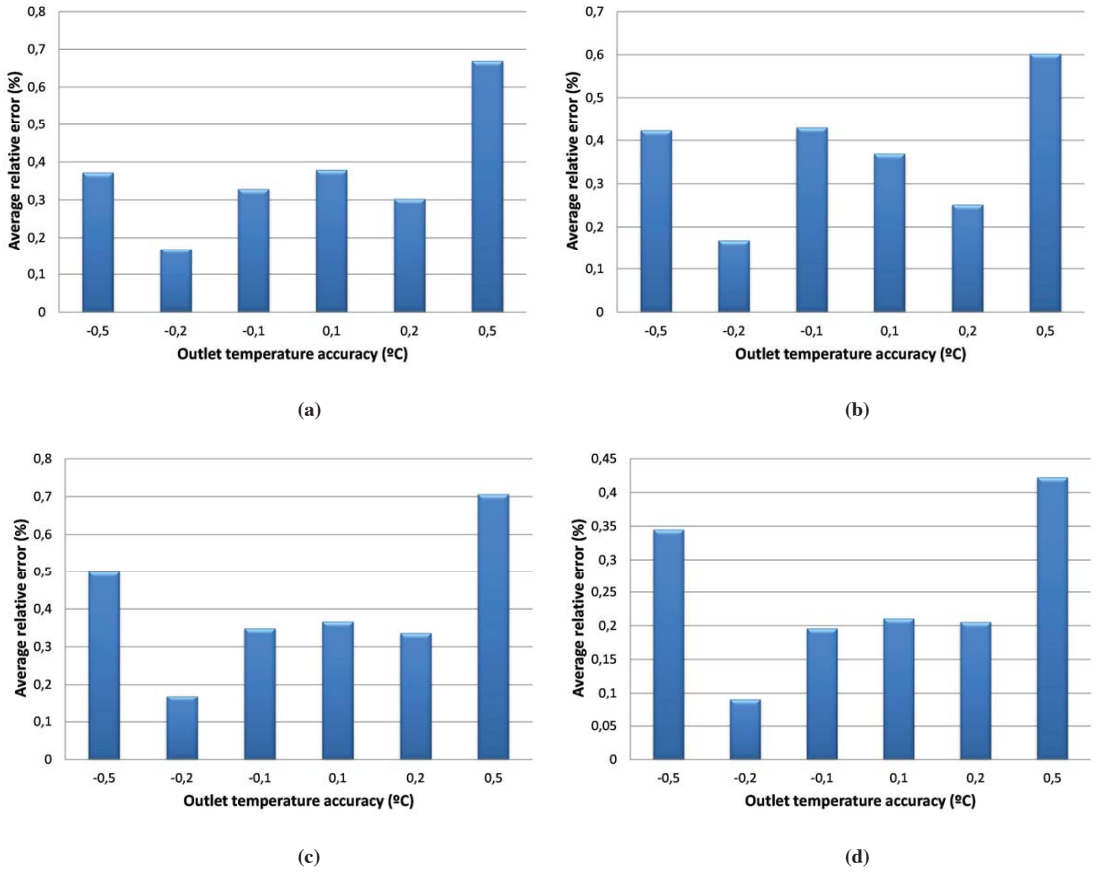

Fig. 6: Average relative error on solar fraction to modify outlet temperature measurement accuracy in Stockholm (a) Würzburg (b) Davos (c) and Athens (d)

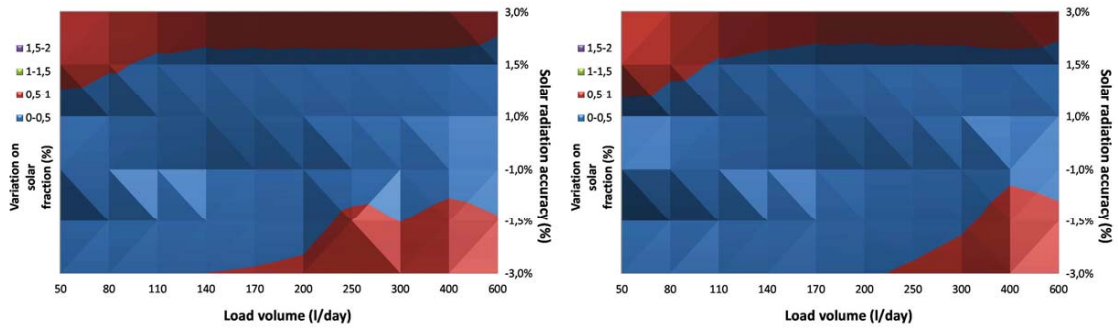
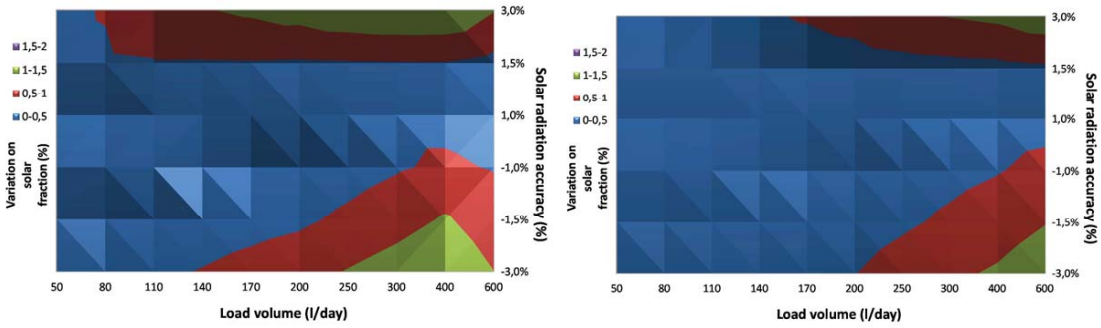
c. Solar radiation

As shown in Figure 7, the maximum difference of the solar fraction obtained between the results to testing sample and the results in all solar radiation measurement accuracies (table 1) is lower than 1.3% in different reference locations. The maximum difference in variation on solar fraction is lower than 0.7% to measurement accuracies according to Standard ISO 9459-5 (± 1.0 %) and 1.3% to other measurement accuracies proposed (± 1.5 %, ± 3.0 %).

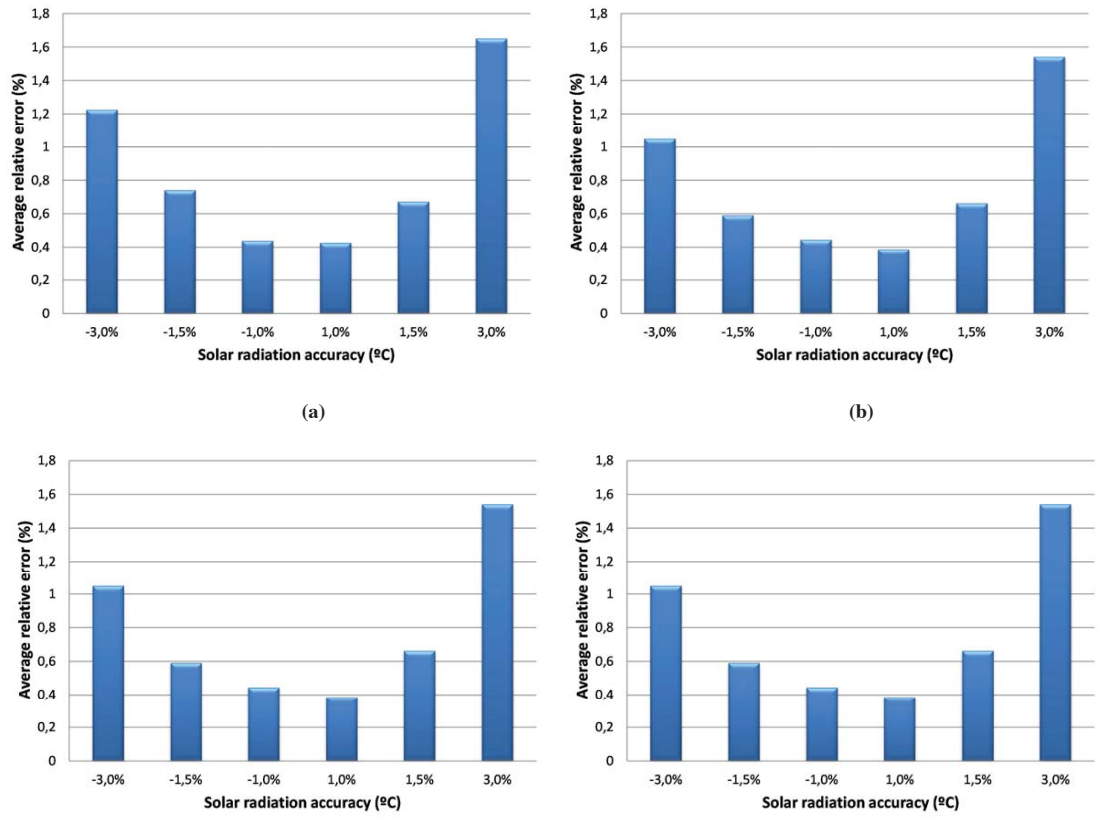




(c) (d)

Fig. 7: Variation on f_{SOL} to modify solar radiation measurement accuracy in Stockholm (a) Würzburg (b) Davos (c) and Athens (d)

Figure 8 shows the average relative error of solar fraction with respect of solar radiation accuracy in all reference locations. The maximum average relative error on solar fraction is lower than 0.5% for the measurement accuracies according to Standard ISO 9459-5 (± 1.0 %) and 1.6% for other measurement accuracies proposed in this study (± 1.5 %, ± 3.0 %).



(a) (b)

(c) (d)

Fig. 8: Average relative error on solar fraction to modify solar radiation measurement accuracy in Stockholm (a) Würzburg (b) Davos (c) and Athens (d)

5. Conclusion

The influence of measurement accuracies of some input parameters is analyzed (inlet water temperature, outlet water temperature and solar radiation) obtaining the following conclusions:

- The maximum differences on solar fraction when using the measurement accuracy according to Standard ISO 9459-5 varies between 0.4% (for the outlet temperature) and below than 0.7% (for the inlet temperature and solar radiation) considering all load volumes in the reference locations.
- The maximum differences on solar fraction when using the new measurement accuracies proposed in this study varies between 1% approximately (for the inlet temperature and outlet temperature) and 1.6% (for the solar radiation) considering all load volumes in the reference locations.
- The maximum average relative error on solar fraction when using the measurement accuracy according to Standard ISO 9459-5 is approximately 0.5% (for the inlet temperature, outlet temperature and solar radiation) in the reference locations.
- The maximum average relative error on solar fraction when using the new measurement accuracies proposed in this study varies between approximately 0.6% (for the inlet temperature and outlet temperature) and 1.6% (for the solar radiation) in the reference locations.
- This study shows that it is possible to increase the measurement accuracies range required in Standard ISO 9459-5 without losing effectiveness on the results obtained in long-term prediction (solar fraction).

A Comparison Study of Solar Thermal Collector Performance in the Tropics

Arifeen Wahed[1] and Thomas Reindl[1]

[1] Solar Energy Research Institute of Singapore, Singapore

Abstract

Over the recent years, awareness on integration of a solar thermal system for industrial process heating applications has been increased. In the Tropics, a huge potential on similar applications has been identified due to availability of abundant solar energy throughout the year. However, challenges lie on selection of an appropriate solar thermal collector for supplying required thermal energy to the industrial processes in tropical conditions with fluctuation irradiance and ambient high moisture air.

A test methodology has been developed in order to evaluate the solar thermal collector efficiency via measured data, a model based time resolved simulation analysis. In this analysis, collectors were tested at an outdoor test facility in the tropical condition. Collector model was developed and optimized the collector parameters for validating the experimental results. The validated collector model was then utilized to determine the efficiency parameters of the collector. Thus, the proposed method of comparing the collector performance would provide a valuable basis for selection of the appropriate collector technology to be utilized in a large-scale solar thermal system for industrial heating applications.

Keywords: *Solar thermal collector performance, tropics, industrial process heat.*

1. Introduction

Solar energy has emerged as a competitive source of energy compare to the conventional source of fossil energy due to concern of economic and environmental considerations. Utilization of solar thermal energy for industrial heating applications is one such targeted areas. At present, about two hundred large scale solar heating plants have been identified for industrial heating applications [SHIP] all around the world. Solar thermal collector is one of the key components of solar heating systems. Thus, selection of right type of solar thermal collector is crucial for industrial heating applications.

Collector thermal performance is generally tested either by steady-state test (SST) method or by quasi-dynamic test method. Researchers have been working on development of new and more effective test methods [Amer et al., 1997; Perers, 1997; Kratzenberg et al., 2006; Kong et al., 2012a, 2012b; Xu et al., 2012] that could predict the collector performance more accurately. In general, solar thermal collectors are certified by a specific test standard such as ISO 9806. This certificate provides the general basis for comparing different collector performances. However it is of particular interest to compare different collector performance for a particular condition such as the tropical climatic conditions in Singapore, where fluctuation irradiation and high humidity exists. The present study of the collector performance is thus not to redefine the existing test methods; rather to develop a test methodology for comparing the collector performance by outdoor testing over a period of time in the tropical climate. Thus the proposed study provides input for selection of the right type solar thermal collector, which is very much important for industrial heating applications.

In this study, solar thermal collectors' outdoor performance has been tested; and an evacuated model based on time resolved simulation has been developed to evaluate the collector thermal performance from the dynamic test performances. This method is an effective way of comparing collector outdoor thermal performance in the

doi:10.18086/eurosun.2016.06.02 Available at http://proceedings.ises.org

tropics, where a high fluctuation of irradiation has been observed.

2. Collector outdoor test

An experimental test facility, as shown in Fig. 1 of a solar thermal collector system has been installed at the roof top of the Solar Energy Research Institute of Singapore (SERIS).

Fig. 1: Solar Thermal collector testing system at the roof top of the Solar Energy Research Institute of Singapore (SERIS). Three different solar thermal collectors were installed for the test operation.

2.1. Experiments setup

For collector testing, three different collectors were setup in parallel. Other components of the test facility were a thermostat system including water tank, chiller, heater and temperature controller, three water flow pumps with variable speed drive for each collector, power control panel and data acquisition system. The testing collectors comprise of different technologies – (i) flat plate collector incorporated with evacuated technology, (ii) evacuated tube collector, and (iii) evacuated tube with heat-pipe technology. Testing area of each collector was approximately 4 to 5 m^2.

During experiments, the heat generated by these solar thermal collectors was discharged via the thermostat. The thermostat, controlled by the temperature controller via temperature sensors was heated up or cooled down the water in the storage tank, if required. Collector pre-set input water temperatures were supplied to the collectors from the storage tank. Water flow through each collector was controlled by the variable speed driven water pump. To measure water temperature and water flow, temperature sensors and water flowmeters were installed at the different positions of the system. A silicon sensor and a temperature sensor were installed to measure radiation and ambient temperature respectively. During test operation, data acquisition, processing and system control were achieved by utilizing the National Instrument systems through LabVIEW program.

For measurements, instruments such as (i) four-wire Class A type PT100 Resistance Temperature Detectors (RTD) for temperature measurement, (ii) magnetic flowmeters with low volumetric flow rate in the range of 0 to 1 $m^3.h^{-1}$ for flow measurement, (iii) silicon sensor (transducer set range 0 – 70 mV) for irradiance measurement and (iv) National Instrument (NI) equipment for control, data acquisition and processing were installed for test operation. A graphical user interface (GUI) of the solar thermal test system was developed in the LabVIEW for the purpose of the data processing, analyses and control with high flexibility. For data acquisition, one (1) second time resolution was set for all experiments.

Calibration of these sensors was performed in order to achieve a higher accuracy of the measured data. RTD temperature sensor, water flow meter and silicon sensors were calibrated before deployed for experiments. RTD (PT-100, 4-wire, Class A) sensors correction had been performed against a calibrated Platinum Resistance Thermometer (PRT). The magnetic flowmeter and the silicon sensor were also calibrated with a correction formula for higher accuracy. Even though the sensors were calibrated, there were systematic uncertainties in the systems. Tab. 1 lists the sensors' systematic uncertainties to be considered.

Tab. 1: Measuring sensors systematic uncertainties

Parameters	Sensor type	Range	Uncertainty
1. Temperature	RTD (PT-100, 4-wire, Class A)	0 to 200 ºC	0.02 ºC *
2. Water flow	Magnetic flowmeter (Rosemount 8732)	0 to 0.9 m^3/h	max. deviation ±0.025% of max. reading +
3. Solar irradiance	Silicon sensor (Mono-Si PV Cell)	0 to 1600 W/m^2	± 2.0% #
4. Data logging	NI analog input connector	4 to 20 mA	Gain error (reading): 0.76%

* Based on calibration report by A* Star Metrology Centre
\+ Flowmeter calibration test report by POLYCONTROLS
\# Test report – precision measurement of a PV irradiance sensor, Fraunhofer ISE

2.2. Test procedures

In order to determine the yield of the solar thermal collectors – in particular comparing the yield of different type of collectors in parallel against each other, an experimental test procedure, 'constant collector flow', had been followed. Under the experimental boundary conditions, collector flow was fixed but different minimum flow rates through each collector type according to the recommendation of the manufacturer. And the inlet temperature was same for all collectors during experiment and could be varied in the range of 80 to 100°C.

Tab. 2: Experiments conditions for fixed flow and constant inlet temperature for each collector

Collector	Irradiation, W/m^2	Ambient temperature, ºC	Water flow, m^3/h	Collector inlet water temperature, ºC		
Collector A	Ambient condition 100 - 1000	Ambient condition 30 - 34	0.10 – 0.12	80	90	~ 100
Collector B			0.17 - 0.20			
Collector C			0.13 – 0.16			

As observed from Tab. 2, the inlet water temperature boundary condition was relatively high during experiments, 80 to 100°C. Because the collectors were tested for industrial process heating application and such inlet water temperature range could represent the actual industrial process heating applications. Collector yield performance results were discussed in Section 4.2.

2.3. Stagnation test

In a tropical climate, supply of solar thermal heat may far exceed the heat demand due to the stagnation condition of the solar thermal system. This may raise the collector temperature above 200°C. Increasing stagnation temperature may lead to thermal stress of the collector. In order to determine the collector performance after such stagnation condition, tests were performed on the collectors.

For stagnation test, collector pumps were switched off and all three collectors were exposed to the ambient irradiance condition for continuously seven days. During this stagnation test, all the collector loops were filled with water.

After the stagnation test, a visual inspection had been performed to figure out any physical damage, wear and tear of the collectors including the corresponding joints. No visual defects including any wear and tear had been observed on these collectors. After visual inspection, experiments were performed with the same boundary conditions for all three collectors, as stated in the Tab. 2

3. Solar collector model

In order to evaluate the collector efficiency via measured data, model based time resolved simulation analyses have been developed. The method is well adapted to the fluctuating solar radiation conditions in the tropics. It allows for determining various collector parameters under non equilibrium conditions.

3.1. Collector mathematical model

During experiments three different technologies were investigated – (i) Collector A: flat plate vacuum solar thermal panel, (ii) Collector B: evacuated tube collector, and (iii) Collector C: evacuated tube collector with heat pipes. Even though these collectors use different technologies to absorb solar thermal heat, the mechanism of harnessing solar thermal heat is almost similar – evacuated technology and selective absorbers are used for all these collectors. In case of Collector A and Collector B, solar thermal heat is conducted by the absorbers directly to the collector fluid. In case of Collector C collector solar thermal heat is conducted indirectly to the collector fluid through heat pipe.

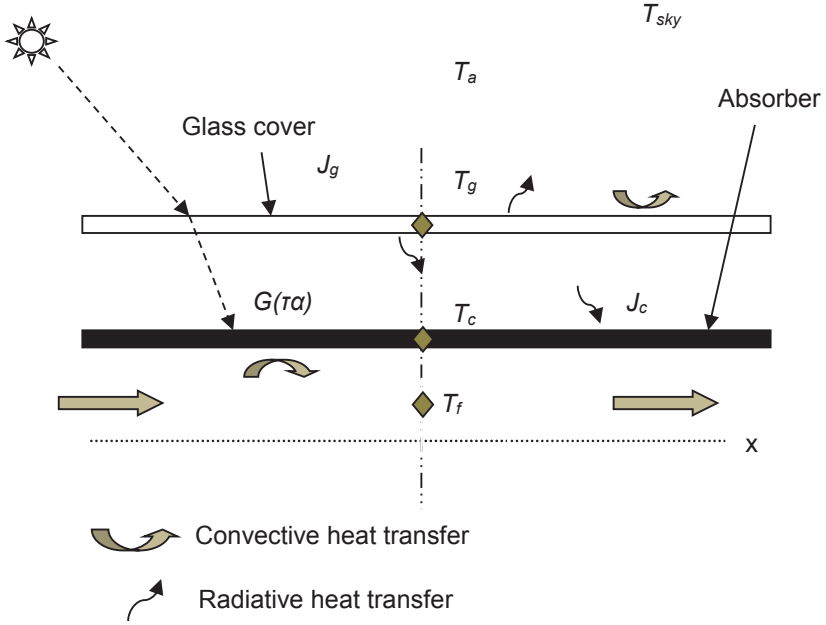

Fig. 2: Evacuated tube collector model. T_g, T_c, and T_f are the temperature of glass, absorber and fluid respectively. T_a is the ambient temperature and T_{sky} is the radiation temperature of the sky. G is the solar irradiance, α is the optical absorptance and τ is the transmittance coefficient. J_g and J_c are the heat capacity of glass and absorber respectively

An evacuated collector model as shown in Fig. 2 is considered to describe the different types of heat energy coupling between the absorber of the collector and the fluid applied for heat transfer. The assumption for these simplifications is the sufficiently accurate conformance between measured and modelled (simulated) time series of collector data, as shown in Section 4. Additional assumptions in the model are – (i) flow of the heat transfer fluid is unidirectional, along one axis (ii) properties of glass and absorber are independent of temperature (constant) (iii) thermo-physical properties of the water are temperature dependent (iv) no heat is supposed to be transported in the fluid moving direction by heat conduction (v) effect of the varying incidence angle of the solar radiation on the collector performance is neglected (vi) infrared emissivity of the sky is one (ε_{sky}=1).

As shown in Fig. 2, radiated heat transfer between the sky and the glass cover is taken into account. Heat transfer between the back cover and the ambient is assumed to be dominated by convection (radiative and conductive heat transfer is neglected here). Since there is almost no medium (vacuum) between the cover and the absorber, the heat transfer between these two components is assumed to be purely due to radiation.

Evacuated tube collector modelling is done following the publication of Praene et al. (2005). The model consists of 3 thermal nodes, namely, the transparent glass cover, the absorber plate and the heat transfer fluid. It is considered that the temperature of the fluid is a function of x (flow direction along x - axis) and the fluid is moving in an effective single channel with a velocity u (u=function of distance x, and time, t). Thus the thermal nodes can be expressed as,

For the transparent glass cover:

$$J_g \rho_g \frac{dT_g}{dt} = \varepsilon_g \sigma(T_{sky}^4 - T_g^4) + h_{g,a}(T_a - T_g) + \frac{\varepsilon_c \varepsilon_g}{\varepsilon_c + \varepsilon_g - \varepsilon_c \varepsilon_g} \sigma(T_c^4 - T_g^4) \quad \text{(eq. 1)}$$

The sky temperature of (eq. 2) can be obtained from the ambient temperature by using Swinbank's formula [Deacon, 1970],

$$T_{sky} = 0.0552 T_a \quad \text{(eq. 2)}$$

For the absorber plate:

$$J_c \rho_c \frac{dT_c}{dt} = G(\tau\alpha) + \frac{\varepsilon_c \varepsilon_g}{\varepsilon_c + \varepsilon_g - \varepsilon_c \varepsilon_g} \sigma(T_g^4 - T_c^4) + h_{f,c}(T_{fx,t} - T_c) \quad \text{(eq. 3)}$$

For the heat transfer fluid:

$$C_f \rho_f \frac{\pi d_{in}^2}{4} \left(\frac{dT_{f\,x,t}}{dt} + u \frac{dT_{f\,x,t}}{dx} \right) = \pi d_{in} h_{f,c}(T_c - T_{f\,x,t}) \quad \text{(eq.4)}$$

The collector heat removal channel is modelled as a single fluid channel, which is divided into N segments. The temperature values $T_f(x,t)$, $T_g(t)$ and $T_c(t)$ at every segment are obtained by solving the equations- (eq. 1), (eq.2), (eq.3) and (eq.4).

3.2. Collector parameter identification and model validation

Input parameters for identification in the model are (i) infrared emissivity of glass cover, (ii) glass heat capacity (specific heat of glass times glass thickness), (iii) absorber tube diameter, (iv) heat transfer co-efficient between glass and ambient, (v) heat transfer co-efficient between water and absorber, (vi) infrared emissivity of absorber, (vii) transmittance-absorptance co-efficient of the absorber, and (viii) absorber heat capacity (specific heat of absorber times absorber thickness). Tab.3 shows the input values obtained from data sheets (Engineering toolbox) and own assessment (Mahbubul 2013) for sensitivity analysis.

Tab. 3: Input parameter values for sensitivity analysis

Input parameter	Unit	Value
Collector absorber specific Heat capacity	J/kg K	400
Collector absorber thickness	m	0.001
Collector absorber emissivity	-	0.09
Collector absorber pipe diameter	m	0.0135
Heat transfer coefficient absorber-fluid	W/(m^2 K)	10
Transmittance-absorptance coefficient		0.86
Collector glass specific heat capacity	J/kg K	840
Collector glass thickness	m	0.0025
Collector glass emissivity	-	0.9
Heat transfer coefficient glass-air	W/(m^2 K)	9

The following steps are considered to identify the corresponding collector parameters in order to validate the model with experimental results (water is used as heat transfer fluid).

Step 1: Set the constant parameters (i) collector dimensions, (ii) collector glass and absorber densities, (iii) water properties as function of temperature, (water properties are determined for the mean fluid temperature T_m (average water temperature of collector inlet and collector outlet) at any time, using interpolation in the

water properties table.

Step 2: Input the experiment's data (time resolution one minute) into the model (i) mass flow rate, (ii) ambient temperature, (iii) irradiance, (iii) collector inlet water temperature.

Step 3: Perform sensitivity analysis of the identified parameters on the model (detailed discussion on the top of this section). Only the sensitive parameters – change of RMSE $\leq$ 1K with respect to the change of input parameter values in the range of ±10%, are considered for the optimization process. Else, input the parameter values (as constant) in the model.

Step 3a: In the optimization process, input an upper range value and a lower range value for each parameter selected for optimization. After optimization, input the optimized values to the model.

Step 4: Run the model. Compare the collector outlet temperature (simulated values) with the corresponding experimental values of the collector outlet temperature

Step 5: Calculate the root mean square (RMSE) of collector outlet temperature between the simulation value and the experiment value. Set the stopping criteria 10-6 K (a threshold to terminate the iteration when the successive iteration of the defined RMSE function does not satisfy the condition). This iteration process continues until the stopping criteria are satisfied.

Step 6: After optimization, the parameter values of the validated model are checked with another set of experimental data and step 4 and step 5 are repeated. If this condition is satisfied, the optimized parameters of the model are identified; else, repeat the procedures outlined in step 3a to step 6.

The parameter identification and model validation approach was adopted for three different collectors analysed – Collector A, Collector B and Collector C. The corresponding results obtained are discussed in the Section 4.2.

3.3. Collector efficiency parameter

In a dynamic model, the collector efficiency is defined as a ratio of the useful energy gain to the incident solar radiation power, as mentioned in (eq. 5),

$$\eta(t) = \frac{\dot{m} C_f(t)[T_o(x,t) - T_i(x,t)]}{G(t)A} \qquad \text{(eq. 5)}$$

The water temperature at the collector inlet, $T_i(x,t)$ and the collector outlet, $T_o(x,t)$ are obtained from the valid model, (eq. 4).

In a stationary model, the collector efficiency is usually defined as the function of collector efficiency parameters (η_0, a, and b) as mentioned in (eq. 6),

$$\eta = \eta_0 - a\frac{(T_m - T_a)}{G} - b\frac{(T_m - T_a)^2}{G} \qquad \text{(eq. 6)}$$

Collector validated dynamic efficiency model of (eq. 1) to (eq. 5) were used to determine the efficiency parameters η_0, a, and b of the stationary model from (eq. 6). By applying a multiple linear regression method on the simulation results these coefficients (η_0, a, and b) can be determined. The corresponding results for three different collectors – Collector A, Collector B and Collector C, are discussed in Section 4.2.

4. Results and discussions

Outdoor testing of the collectors was performed over a period of time. Collector experiment results were used to validate the collector models via fitted identified parameters. The collector models were then utilized to identify the efficiency parameters for collector performance analysis.

4.1. Outdoor test performance

According to the test procedures described in Section 2.2, experiments were performed for each of the three collector for three months. After that testing, a stagnation test as described in Section 2.3 followed by each collector performance test were performed.

During experiments, collector flows were maintained at the minimum flow condition recommended by the collector manufacturers as shown in Tab. 2. Minimum flow condition of the collector had been chosen to attain maximum temperature gain across the collectors. Since each collector technology has different specifications, minimum flow condition recommended by the manufacturer had been considered for experiments.

Thermal performances of the each collector, as shown in Fig. 3, were recorded by measuring the collector water temperature at the inlet and at the outlet. As observed from Fig. 3 collector inlet temperatures were maintained constant at ~80°C and the collector outlet temperature varies due to the fluctuation of irradiance during operation. Similar experiments with different collector inlet temperatures such as 90°C and ~100°C as described in Tab. 2, had also been performed.

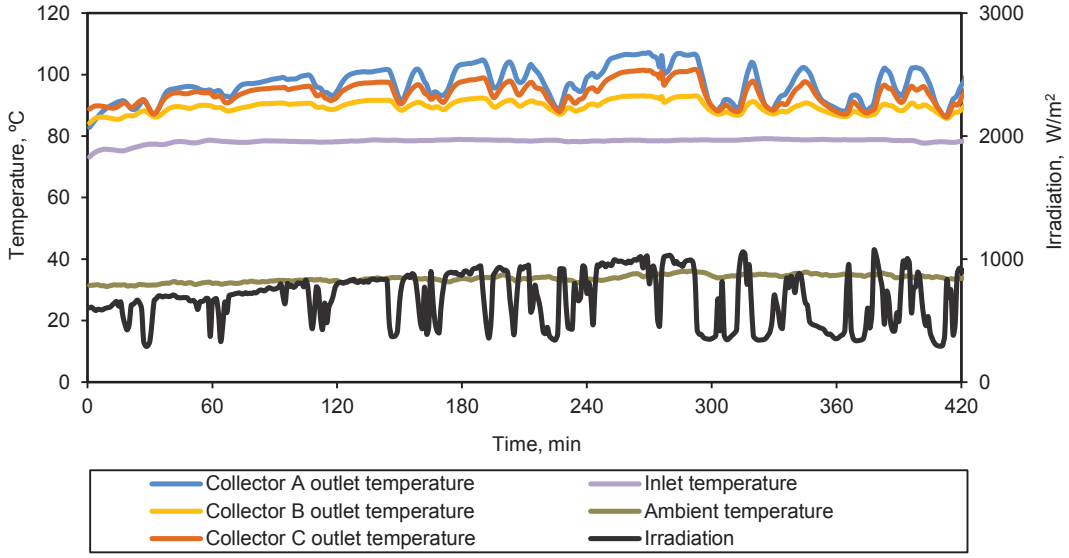

Fig. 3: Solar thermal collector performance for maintaining of the inlet water temperature of each collector at ~80°C. Collector outlet water temperatures, irradiation and ambient air temperature are shown in the figure. Caveat: "0 minute" considers the starting time of the experiments measurement. This time is generally between 9:30 to 10:00 a.m.

Since aperture area and water flow of each collector are different, the collector thermal performance could not be compared with this data alone. Therefore, collectors yield energy, i.e., thermal energy gain per unit collector aperture area has been analysed, as shown in Fig. 4.

As observed from Fig. 4, thermal energy gain per unit aperture area is different for each collector. Collector A is more responsive to the fluctuating irradiation followed by Collector B and Collector C. Collectors' materials properties and heat transfer mechanism of each collector attributes the difference of thermal energy gain of each collector. This comparison study provides the required data to consider the appropriate collector for industrial solar heating application in the tropics.

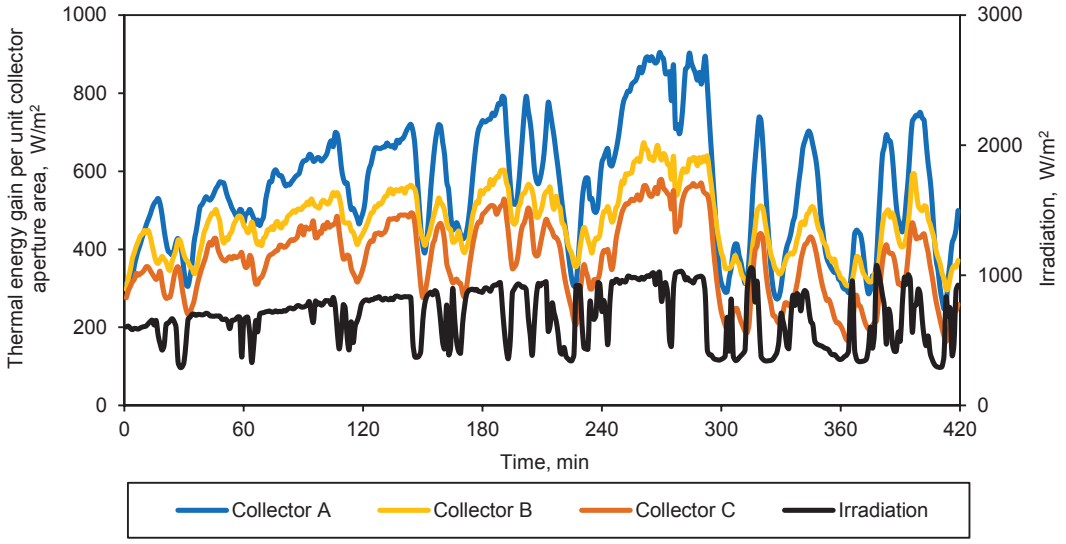

Fig. 4: Solar thermal collector thermal energy per unit collector aperture area when each collector inlet water temperature was maintained at ~80°C. Collector thermal energy gain per unit collector aperture area and irradiation are shown in the figure.
Caveat: "0 minute" considers the starting time of the experiments measurement. This time is generally between 9:30 to 10:00 a.m.

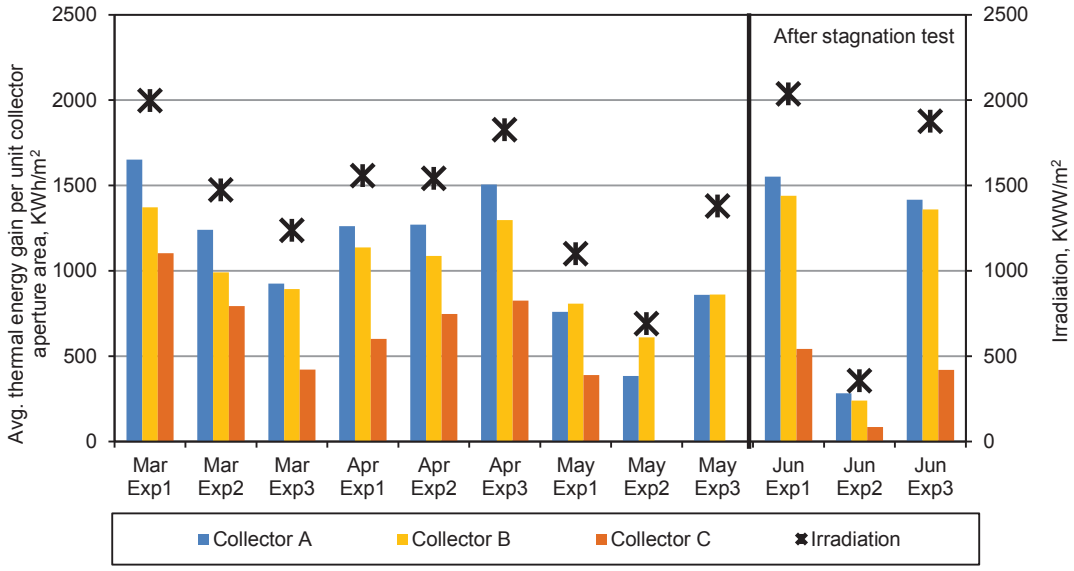

Fig. 5: Tested solar thermal collector thermal energy gain per unit collector aperture area when each collector inlet water temperature was maintained at 80°C (Exp1), 90°C (Exp2), 100°C (Exp3) on the month of March, April, May and June. June experiments were conducted after the stagnation test. Operating conditions of these experiments are given in Tab.2.
Caveat: Due to to technical failure some expermient results could not be recorded properly. Therefore, those data were not considered for analysis.

4.2. Outdoor test performance

Solar yield performance of the three collectors were analysed based on the experimental results. Average solar thermal gain for each month has been considered for this analysis. In the later part, collector efficiency parameters are compared on a monthly basis.

Yield energy

According to EN 12975 standard, the best way to compare different types of collectors is to compare the useful energy from a square meter of collector under equivalent circumstances (Standard 12975). Even though the present experiments of the three different types of collectors would not comply with the procedures of the mentioned standard, thermal energy gain per unit aperture area of each collector has been calculated for analysis purposes.

Fig.5 presents the comparison of thermal energy gain per unit collector aperture area among the three collectors under different operating conditions. As defined, the thermal energy gain by the collector depends on two factors – collector water temperature rise (delta T) and collector flow. Collector water temperature rise (delta T) is attributed to the solar irradiation absorbed and the collector heat losses. In the experiments, collector minimum flow according to manufacturer was attained for maximum temperature gain across the collector (highest delta T). It is observed from Fig.5 that the performance of the collector A and Collector B was the significantly higher than Collector C thermal performance under those boundary conditions. The difference of the collector performance would be due to the difference of technologies of heat gain and heat losses of these collectors. After stagnation test, Collector C performance was decreased significantly. Thus, the experimental findings would provide yield performance of the collectors before and after the stagnation test. But, these results would not be sufficient for comparison of the collector performance. For this reason, collector efficiency parameters had been analysed in the later sections.

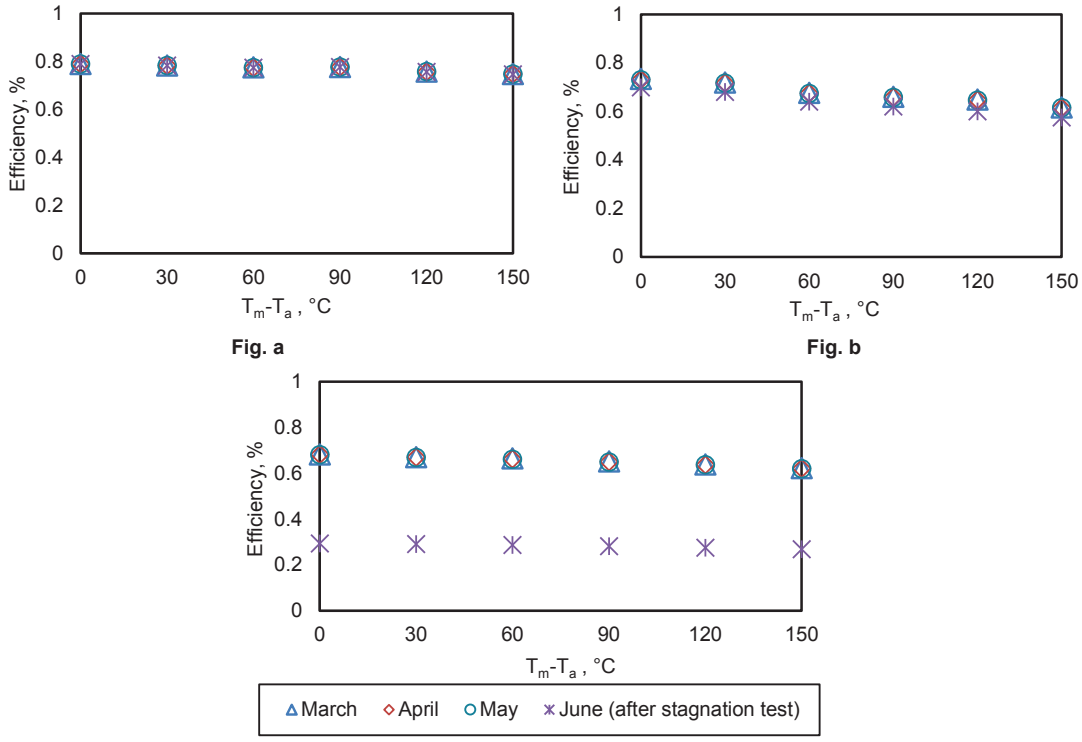

Fig. a

Fig. b

Fig. c

Fig. 6: Comparison of η vs (T_m-T_a) curve for unit aperture area and solar irradiance (G = 1000 W/m^2) values for testing months (March, April, May and June) of the collectors – Collector A (Fig. a), Collector B (Fig. b) and Collector C (Fig. c). June results present the collectors performance after the stagnation test.

Collector efficiency

The solar thermal collector models were validated with the experimental results, as discussed in section 3. In order to validate the collector models, the comparison of the collector outlet temperature between experimental and simulated values for the three different collectors were performed. The root mean square error (RMSE) of

the collector outlet temperature values between the simulated models and the experiments were found RMSE≤ 1K, which is not significant. The validated collector models, as presented in Section 3.3, were used to determine the efficiency parameters η_0, a, and b of the stationary model from (eq. 6). Applying the least squares approach, the coefficients η_0, a and b were determined for analysis of collectors performance

Fig.6 shows the calculated collector efficiency of the three different collectors for the temperature difference ($T_m - T_a$) when solar irradiance G=1000 W/m^2 on the collector plane. The efficiency functions are a result of a least square fit of the simulated values with a second order polynomial. This efficiency functions takes into account that the heat loss coefficient of the collectors is a function of temperature.

Comparison of the Collector A efficiency, as shown in the Fig. 6(a), revealed no degradation of the collector performance during testing from March to May. Even after the stagnation test on June, Collector A performance degradation has not been observed.

Comparison of the Collector B efficiency, as shown in the Fig. 6(b), revealed no degradation of the collector performance during the actual testing from March to May. After the stagnation test, a small order of degradation of the collector performance has been observed. After stagnation test, no defects were noted from outer inspection during collector operation. Thus, it might suspect that the collector materials, presumably the absorbent layer, could have degraded due to the high temperature of the stagnation test.

Comparison of the Collector C efficiency, as shown in the Fig. 6(c), revealed that here was a significant degradation of the performance after stagnation test. In this collector field, there are heat pipes which could be damaged and/or spoiled due to the excess heat during stagnation test. Because of this, the Collector C performance degraded after stagnation test.

Though the analyses of these collectors provide an insight of the collector performances for the given duration of the outdoor testing in Singapore, degradation of the collector performances for a longer period of operation could not be determined from these analyses.

5. Summary

This paper describes a test methodology for comparing collector performance in tropical climatic conditions like Singapore. An outdoor test facility has been setup at the roof top of SERIS facility, where different collectors performance can be tested side-by-side for different operating conditions. Experimentally measured data is used to validate the collector dynamic model. The model is then utilized to identify the collector efficiency parameters.

In this paper, three different collectors- Collector A, Collector B and Collector C were studied. Based on the experiments and simulation results of the three collectors, the following findings can be summarized:

- Solar thermal yield (energy performance) of the Collector A and the Collector B are higher than the solar yield (energy performance) of the Collector C.
- There was no degradation of the Collector A, Collector B and Collector C performance was observed during first three months of outdoor testing (before stagnation test). The reason is that three months outdoor testing would not enough duration to observe any collector performance degradation.
- After the stagnation test, no degrading of the Collector A had been noticed. The Collector B performance showed some degradation of collector performance, while the Collector C showed a considerable performance degradation.

Performance analyses of the three different collector show that the Collector A and Collector B could consider for industrial heating applications in Singapore.

Finally, the present analysis of the collector performances for outdoor testing in Singapore provides a valuable basis for the selection of the relevant collector technologies for a large-scale solar thermal systems. Other factors such as, relevant costs associated with the collector (including installation and maintenance costs) and the long-term durability have to be considered though in order to design, implement and operate a large scale solar thermal installation.

Erosion experimental system design and experimental research of high temperature molten salt

Yao Fan[1], Bi Qincheng[1]

[1] The State Key Laboratory of Multiphase Flow in Power Engineering, Xi'an Jiaotong University, Xi'an 710049, China

Abstract

The erosion behavior of two types of stainless steel in mixtures of sodium nitrate ($NaNO_3$) and potassium nitrate (KNO_3) is presented. The erosion resistance can be used to evaluate the lifetime of heat exchange tubes for solar thermal applications. A molten salt erosion experimental system was established for this purpose. Erosion tests were conducted for approximately 750 hours with type 304 and 321 stainless steel at 500 ºC and 400 ºC with different molten salt wash velocities, ranging from 1.09 m/s to 2.98 m/s. Erosion rates were determined by mass losses, and the results indicate that short-term erosion rates of the two types of stainless steel can be described in term of parabolic kinetics. The annual rates of metal loss were measured to be 10.8 to 18 μm/year for 304 stainless steel at 500 ºC depending on the wash velocities. Metal loss for 321 stainless steel at 500 ºC is about 7.68 to 10.92 μm/year. Based on these results, we confirm that the erosion resistance performance of 321 stainless steel is better than that of 304, which may be related to the titanium in 321 stainless steel.

Keywords: *Erosion behavior, molten salt, 321stainless steel, 304stainless steel*

1. Introduction

The two primary components of Concentrated Solar Power (CSP) are the receiver and heat exchanger. In a CSP system, the receiver structure consists of tubing panels through which heat transfer fluid circulates as it is heated by sunlight focused by an array of computer-controlled mirrors. The heat exchanger constitutes of a number of tubes transferring heat in fluid cross-flow tube banks that is steam cooled on the tube side. It has been suggested that a higher performance material should be used to construct these devices, such as stainless steel. We chose to study 300 series stainless steels; previous work has demonstrated that they exhibit good corrosion resistance and no degradation in mechanical properties after relatively long-term exposure to molten nitrates at the temperatures of interest.

The chosen heat transfer fluid is one of the most important aspects of a successfully operating power plant. Solar Two utilizes a molten salt consisting of 60 wt.% $NaNO_3$ and 40 wt.% KNO_3 as the heat transfer fluid, which has a melting point of 238 ºC and an intended working range of 290 ºC to 560 ºC. This mixture optimizes a number of important properties, including heat capacity, thermal conductivity, corrosivity, ease of handling and storage, and cost.

While the previous studies mentioned above have established the static corrosion behavior of stainless steel immersed in molten salt, there is little information regarding the dynamic erosion behavior at different flow rates of molten salt. Recent papers concerning stainless steel immersed in different mixtures of molten salt reported that pitting type corrosion occurs on the material's surface. Pitting corrosion of stainless steel is a critical form of corrosion in engineering structures and most equipment fabricated from stainless steel fail due to pitting. Moreover, the flow rates of molten salt could aggravate pitting corrosion. Therefore, the dynamic erosion behavior may be worse than static corrosion behavior. One specific goal of the current work is to address the question of molten salt velocity on corrosivity.

2. System description

In order to research the dynamic erosion behavior of heat exchanger tubes at high temperature due to molten salt, the author independently designed and established a high temperature molten salt erosion experimental system, as shown in Fig. 1 and Fig. 2.

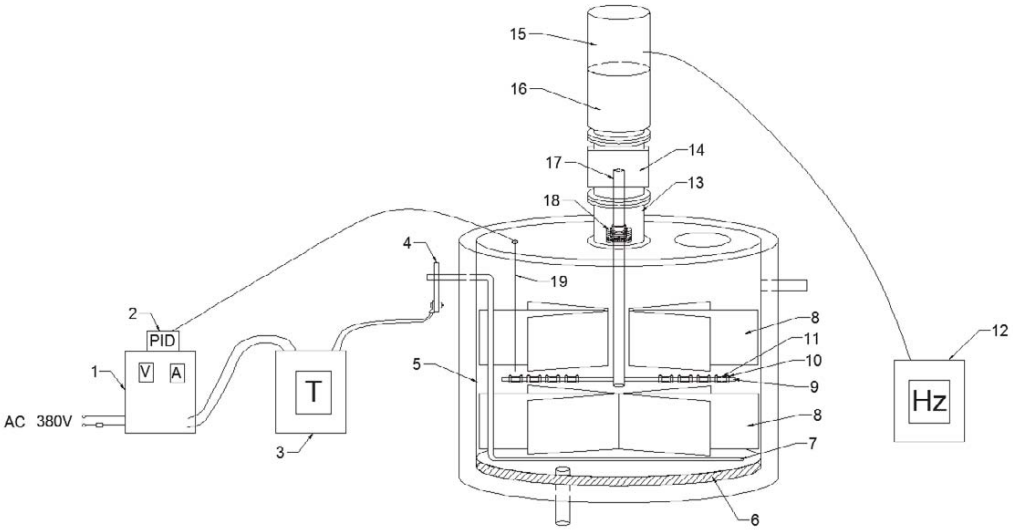

Fig. 1: Experimental system diagram 1：SCR voltage regulator；2：PID regulator；3：transformer；4：electrode plate；5：molten salt storage can；6：fire brick；7：heating element； 8：baffle；9：agitating shaft；10：ferrule ；11：experimental test；12：inverter；13：metal stent；14：reducer；15：encoder；16：motor；17：motor shaft；18：coupling；19：thermocouple

Fig. 2: Experimental system picture

The high temperature molten salt erosion experimental system consisted of an electrical heating system and erosion system. The electrical heating box was made of thick stainless steel for the internal surface, a middle layer filled with insulating cotton and an external surface containing an iron sheet. A layer of firebricks was spread on the bottom of electrical heating box. Two terminals of heating tubes were placed on the firebrick directly by welding with electrical heating plates. Ceramic tubes acted as insulators between the extension of the heating tube and electrical heating box. The transformer was connected with a silicon controlled voltage regulator by cable. One side of the cable was connected with electrical heating plates by four screws; the other side was link with a transformer. The silicon controlled voltage regulator includes a voltmeter,

amperage meter and PID controller. PID controller adjusted the output current from the silicon controlled voltage regulator in real time and controlled the heating power of the entire system by receiving a temperature signal from the sensors. The other side of the silicon controlled voltage regulator was linked to a 380 V alternating current by cable connections, which were installed with an electrical leakage protector to prevent short-circuiting. The erosion system was comprised of a motor shaft with accessory components. One side of the motor shaft was immersed in molten salt and installed as an agitating shaft. Coupons were installed on the agitating shaft according to the expected design distance are shown in Fig. 3. Both sides of the coupons were locked by card sleeves to prevent rolling while the agitating shaft was moving.

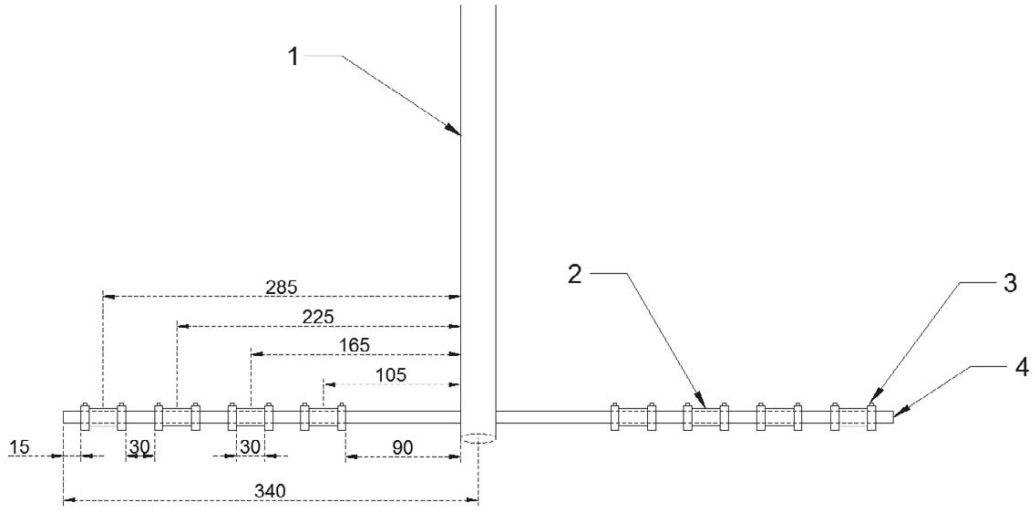

Fig. 3: Testing section distributions

1：motor shaft；2：experiment test；3：ferrule；4：agitating shaft

A coupling was installed on an extension from the motor shaft's electrical heating box. The upper side of the coupling was connected with the motor shaft using a keyway structure and a thrust bearing supported the bottom side. The motor shaft was connected with a reducer. The other side of the reducer was connected to a motor. The top of the motor was set up with an encoder, which was linked to a frequency converter, by signal wires. Baffles were installed on both sides of the agitating shaft in the electrical heating box in order to decrease the effect of turbulent flow in the vertical direction. The rotation speed of the motor was controlled by adjusting the operation panel of the frequency converter. This control allowed us to simulate the erosion behavior of stainless steels at different velocities of molten salt. In this experiment, the rotated speed of motor was set to 100 $r \cdot min^{-1}$, moreover the calculated velocities of each coupon are reported in Table 1. For maintaining precise experimental temperature, the thermocouple was installed on the same flat surface with the coupons.

Tab. 1: Locations and velocities of coupons

Number	Radius(m)	Velocity($m \cdot s^{-1}$)
1	0.105	1.099
2	0.165	1.727
3	0.225	2.355
4	0.285	2.983

Based on the commercial applications of the heat exchanger, we chose two types of stainless steel (SS) as coupons: 304SS and 321SS. The coupons, measuring approximately 30 mm × 25 mm× 3 mm in thickness, were cut from stainless steel tubes, polished, cleaned, alcohol rinsed, and weighed prior to immersion in salt. Two specimens of each alloy were immersed at 500 ºC and removed from nitrate mixtures at intervals of 168, 336, 504, and 720 hours for examination and analysis. Before starting the analysis the samples were washed

in distilled water, and cleaned ultrasonically in alcohol. The coupons were weighed after immersion to measure loss due to erosion process.

3. Data collection and discussion

Corrosion kinetics refers to the variable quantity of coupons per unit area in the experimental process. This study provides descaled mass loss measurements per unit area after conducting analysis and calculations. Mass loss measurements are an easy and direct way to represent the erosion behavior. Dissolvability of corrosion products and corrosion product adsorption onto coupons were not considered. Next, values of M are established using the descaled mass loss of metal alloys according to Equation. 1.

$$M = \frac{W_0 - W_1}{S} \qquad \text{(eq. 1)}$$

In Equation 1, M is the descaled mass loss of coupons per unit area. W_0 and W_1 represent the original mass and the post-experiment mass of coupons, respectively, and S is the surface-area of coupons. In this case, the value of S is 23.55 cm^2.

Adding the time factor to the Equation 1, the descaled mass loss of coupons per unit interval (erosion rate) is calculated according to Equation. 2.

$$V = \frac{W_0 - W_1}{S * t} \qquad \text{(eq. 2)}$$

In Equation 2, V is the erosion rates of coupons and t is the erosion time.

Fig. 4 is a plot of the average mass loss data versus time for 304SS based on different molten salt velocities. The mass losses were between 1.08 and 1.76 mg/cm^2 after 720 hours of erosion. The kinetics appear closely to follow parabolic rate laws initially and later become linear after prolonged exposures. In the absence of uniform erosion kinetics for the entire duration of coupon immersion, a conservative approach based on a linear extrapolation of the data seems warranted for estimating erosion-induced metal loss over longer timescales. For 500 ºC isothermal exposures, such linear extrapolations yield annualized mass losses of 12.96-21.12 mg/cm^2. We emphasize that these estimates are based on the flow velocity of molten salt used in this experiment.

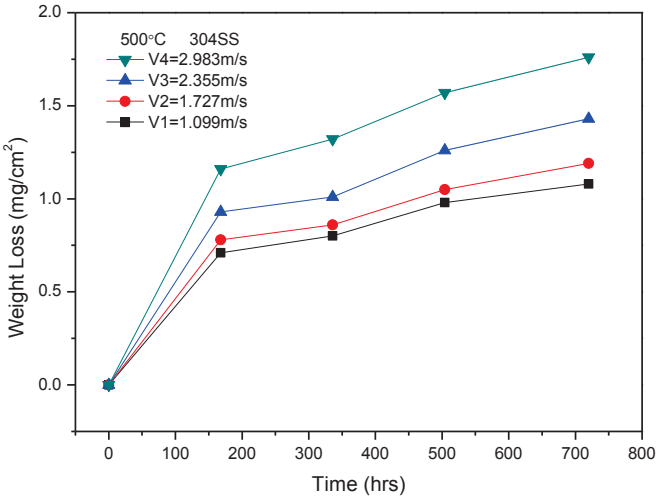

Fig. 4: Descaled weight loss measurements for 304 stainless steel specimens exposed to nitrate salt mixtures at 500 ºC

Based on Fig. 5, mass loss rate curve can be clearly observed. Mass loss velocities were $6.9 \cdot 10^{-3}$ mg·cm^2·h^{-1} after 168 hours and $2.4 \cdot 10^{-3}$ mg·cm^2·h^{-1} after 720 hours with a molten salt flow velocity of 2.983 m/s. Therefore, we hypothesize that steel erosion is based on a high corrosion rate at the beginning of the experiment and decreases slightly as time elapses. The erosion rate then became constant and dropped to a minimum erosion rate. The corrosion is possibly due to chemical or electrochemical processes that take place on the surface of the material. The electrochemical reaction is reduction and oxidation or can be simplified as a redox coupled reaction. Metal and alloy were used to form an oxide layer on the metal surface in air. The oxide layer is responsible for protecting the surface and retarding diffusion of oxidants to the reaction interface of the metal or alloy. The 304 stainless steel, with chromium and iron ions, tends to form Cr_2O_3 and Fe_2O_3 as its protective oxide layer. After a period of time, the coupons are immersed in molten salt, and anions will gather at points on the surface of coupons; moreover, certain points have negative potential. Electrons will move between certain anions points and their surroundings due to the potential difference, as if forming primary cells. The Cr_2O_3 and Fe_2O_3 of the protective oxide layer and iron atoms will exchange in an ionic state dissolved in molten salt. This reaction can induce pitting type erosion and cause an interruption or breakdown of the protective oxide film on the surface of the metal. The high corrosion rate at the beginning is likely due to impurities on the surface of coupons, such as carbon, which are prone to induce the redox reaction. After the conclusion of impurity reactions, the erosion rate is reduced with time. We hypothesize that the minimum erosion rate is achieved once the erosion rate is equal to the protective oxide layer self-regeneration.

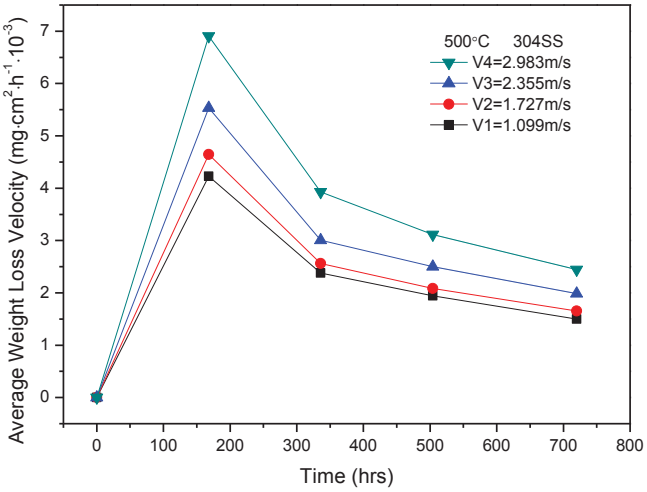

Fig. 5: Descaled weight loss velocity measurements for 304 stainless steel specimens exposed to nitrate salt mixtures at 500 ºC

Descaled mass loss measurements for 321SS coupons removed from nitrate salt mixtures at different flow velocities and 500 ºC are presented in Fig. 6. The mass losses range from 0.78 to 1.29 mg/cm^2 after 720 hours of immersion. Overall, 321SS exhibited more effective erosion resistance compared to 304SS. The mass loss data for 321SS reveal differences due to titanium. The 321 stainless steel has chromium, titanium and iron ions, which form Cr_2O_3, Ti_2O_3 and Fe_2O_3 as its protective oxide layer. According to standard electrode potentials shown in Table 2, the standard electrode potential of chromium is higher than that of titanium and the standard electrode potential of iron is highest of the three elements.

Tab. 2: Standard electrode potentials (25 ºC, 101.325kPa)

Number	Electrode process	Standard electrode potential(V)
1	Fe^{3+}+3e═Fe	-0.037
2	Cr^{3+}+3e═Cr	-0.744
3	Ti^{3+}+3e═Ti	-1.37

The higher the standard electrode potential element, the stronger its ability to capture electrons in the element's oxidation state. The Cr_2O_3 and Fe_2O_3 conduct electrochemical reaction captures electrons when the accumulation of ionic potential on the surface of coupons is higher than the equilibrium potential of chromium. This reaction deteriorates the protective oxide layer. However, this potential is too low for Ti_2O_3 to respond. The Ti_2O_3 electrochemical reaction proceeds when the accumulation of ionic potential on the surface of coupons is higher than the equilibrium potential of titanium. Therefore, the protective oxide layer of titanium has a more effective erosion resistance performance.

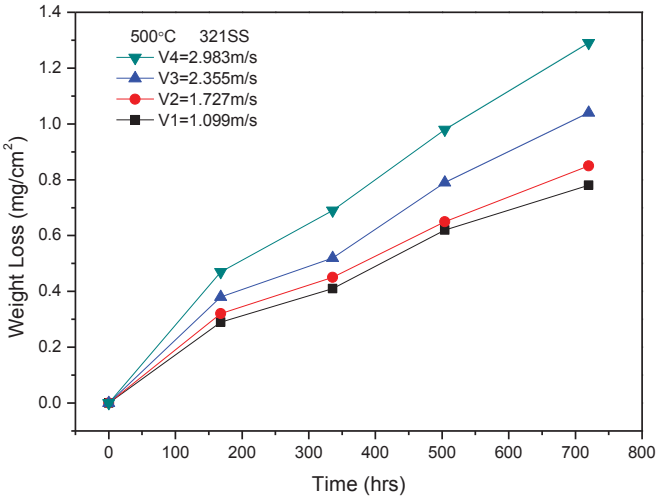

Fig. 6: Descaled weight loss measurements for 321 stainless steel specimens exposed to nitrate salt mixtures at 500 ºC

The descaled mass loss rate data for 321SS due to molten salt at different flow velocities and 500 ºC are shown in Fig. 7. Mass loss rates were $2.8 \cdot 10^{-3}$ mg·cm^2·h^{-1} after 168 hours and $1.8 \cdot 10^{-3}$ mg·cm^2·h^{-1} after 720 hours at 2.983 m/s molten salt flow velocity. The erosion rates curve for 321SS also generally shows slower rates after the initial high erosion rate. On the whole, the lower erosion rates for 321SS coupons than that of 304SS coupons potentially demonstrates that 321SS erosion resistance is stronger than 304SS erosion resistance.

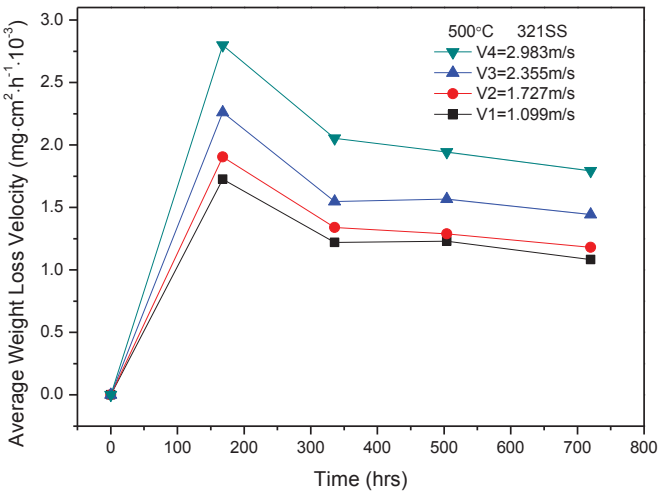

Fig. 7: Descaled weight loss velocity measurements for 321 stainless steel specimens exposed to nitrate salt mixtures at 500 ºC

4. Conclusions

The 300 series stainless steels are the most important materials to be used in solar thermal applications. The experimental data presented in this study indicate that flow velocities and temperature of molten salt play important roles in the erosion process of stainless steel. For the two sets of coupons made from different types of stainless steel, both rate of mass losses increased as flow velocities increased. However, erosion rates for SS321 were less sensitive to molten salt flow velocities than that of 304SS, due to the presence of titanium, which provides a protective oxide layer on the surface. The erosion kinetics of SS304 present a parabolic tendency, while that of SS321 exhibit approximately a linear one. Future work on the influence of different molten salt compositions on erosion behavior is warranted, in order to further develop an understanding of erosion behavior of 304SS and 321SS.

Abstract

The purpose of this project is to investigate an innovative technology for sustainable preservation of juicy fruits in developing countries with the aid of simple solar thermal drying technology. Approximately five million tonnes of citrus fruit produced in Mozambique is annually wasted (FAOSTAT, 2015). A large solar energy potential and large fruit spoilage in Mozambique present the opportunity to implement a simple method for fruit preservation, combining solar thermal drying with a semipermeable membrane bag containing fruit juice. A small-scale indirect passive solar air dryer for drying the membrane bags was constructed and evaluated in terms of drying flux as a function of temperature, relative humidity and air flow rate. Measurements were initially carried out in the laboratory and later complemented with a field study in Mozambique. The dryer achieved a temperature interval that was required for high quality fruit drying and lowered the relative humidity. However, it was further found that air flow passing over the bags acted as an important parameter in the drying meaning that an increased air flow rate increased the drying flux to a larger extent than first assumed. The findings provide insight on the drying process and on how to improve the design of the solar air dryer.

Keywords: *Solar Thermal, Indirect Solar Dryer, Semipermeable Membrane, Fruit Drying, Food Waste, Development Project.*

1. Introduction

Fruit is abundant in Mozambique, both farmed and wild, yet much of it spoils post-harvest or is never even picked due to the large amounts that ripen during a short harvesting season. Long-term storage possibilities are uncommon since industrial preservation technologies require large amounts of clean water and power – something limited in rural Mozambique (Phinney et al., 2015). One contributing solution to this problem could be the combination of solar thermal dryers with a newly developed breathable membrane bag to facilitate drying of fruit juices and purées in Mozambique. This means that juicy fruits, such as oranges and tangerines, that are difficult to dehydrate using traditional open-air sun drying, could also be dried. Preservation with the membrane bags only requires suitable ambient conditions since the drying process is largely driven by a lower relative humidity in the air surrounding the bags. The objective of using a solar dryer is to protect the bags from external disturbances and supply the process with more heat than the ambient conditions can provide (Ekechukwu and Norton, 1997), increasing the temperature and thus decreasing the relative humidity. This technological combination results in a system independent of external electric power and large amounts of clean water and thus is more suitable for rural areas lacking developed infrastructure (Ekechukwu and Norton, 1997; Otte, 2014). To ensure fruit preservation of high quality, the drying has to be performed using an adequate temperature interval. The aim of the research is to construct a solar dryer for enhancing the drying of the membrane bags and to understand the underlying mechanisms behind this drying process so that future dryers coupled with membrane bags can be properly optimised.

2. Theory

2.1. Theory behind the technique

Drying is the process of removing water from a product. In this study, drying of a liquid product was achieved using a membrane bag and a technique called Solar Assisted Pervaporation (SAP) (Phinney et al., 2015). Pervaporation is a process in which a non-porous semi-permeable membrane is used to separate one or more chemical species from one or more other chemical species. The species that diffuses through the membrane also has an affinity for it, or in other words the species "wets" the membrane (Néel, 1991). In the case of Solar Assisted Pervaporation, the membrane is hydrophilic and water molecules are able to diffuse through the void spaces of the polymer molecules that make up the membrane. The membrane acts as a selective barrier, letting water vapour molecules through while keeping the liquid water and other nutrients inside the bag (Phinney et al., 2015).

The SAP process is driven by a water vapour partial pressure difference across the membrane, where the partial pressure is a function of temperature (i.e. it increases with increasing temperature) (Pervatech BV, 2014). Inside the bag, the initial water vapour partial pressure is close to the saturation pressure whereas outside the bag, the partial pressure corresponds to the relative humidity (RH) of the surrounding air. If the RH of the surrounding air is less than 100%, a water vapour partial pressure gradient across the membrane will exist and drying will proceed (Saravacos and Kostaropoulos, 2002). Solar energy enhances the process by supplying the latent heat of evaporation and reducing the RH of the air surrounding the bag. As the second law of thermodynamics states: diffusion of a species will occur as long as a difference in saturation exists, striving for an equilibrium (Cengel and Boles, 2011).

The amount of mass transferred from the bag to the surrounding air over time, $\dot{m}$ (kg·s^{-1}), due to diffusion through the membrane is a function of the overall mass transfer coefficient, K (kg·m^{-2}·s^{-1}·Pa^{-1}), the total membrane surface area, A_s (m^2), and the difference in water vapour partial pressure (with units of Pa) on the inside ($p_{w,sat\ @\ T_1}$) and outside ($p_{w,\infty\ @\ T_2}$) of the bag, where T_1 is the surface temperature and T_2 is the surrounding air temperature in degrees Celsius (Bergman et al, 2007). The heat and mass transfer phenomena taking place can be compared to the case of an open dish with water where in both cases, water vapour is assumed to be an ideal gas. Since RH is equal to the ratio between $p_{w,\infty}$ and $p_{w,sat}$ at a given temperature, the RH on the inside of the bag is 100% and in the surrounding air is $p_{w,\infty\ @\ T_2}$ divided by $p_{w,sat\ @\ T_2}$ and then multiplied by 100 (note: $p_{w,sat\ @\ T_1}$ and $p_{w,sat\ @\ T_2}$ are only equal if T_1 and T_2 are equal, which is not always the case). The main differences between our case and that of an open water dish is a resistance provided by the polymer membrane (which reduces K), and that the open dish has only one drying surface whereas the bag has two (which means A_s is twice as large for a bag of the same length and width). Equation 1 shows how the mass transfer rate is affected by the mass transfer coefficient, surface area and water vapour partial pressure. Mass transfer flux is defined as $\dot{m}/A_s$ and is the quantity referred to in the remainder of the paper.

$$\dot{m} = K \times A_s \times (p_{w,sat\ @\ T1} - p_{w,\infty\ @\ T2}) \qquad \text{(eq. 1)}$$

2.2. Temperature as a function of flow rate

As relative humidity is a function of temperature, the speed of water removal in the dryer is dependent on temperature. In addition, the quality of the end-product (e.g. related to vitamin losses) requires a set temperature interval. The small-scale solar thermal dryer's gained energy over time, absorbed by the collector, can be calculated by measuring global irradiance, G (W·m^{-2}), for an angle of incidence normal to the glass of the dryer, on the collector area, A_c, (m^2). A thermal efficiency ($\eta_{thermal}$) is introduced to include the heat losses, the material properties and the optical losses into account. This efficiency only serves as a rough estimate on how much energy is put to use in the dryer as hot air. An equation for the power transfer from the sun to the air can be written as:

$$\dot{Q}_{gain} = G \times \eta_{thermal} \times A_c \qquad \text{(eq. 2)}$$

The amount of useful energy over time can also be calculated by looking at the collector as a control volume with a temperature difference over the absorber area.

$$\dot{Q}_{gain} = A_{cs} \times v \times \rho \times c_p (T_{out} - T_{in}) \qquad \text{(eq. 3)}$$

where A_{cs} (m^2) is the cross section area, v is the flow rate normal to the cross section, ρ ($kg \cdot m^{-3}$) is the fluid's density, C_p ($J \cdot kg^{-1} \cdot K^{-1}$) is the specific heat capacity at a constant pressure, T_{in} is the temperature of the air entering the collector and T_{out} is the outlet temperature of the collector. The velocity varies spatially due to the flow profile in the collector. Therefore, a mean has to be calculated, based on reference measurement points over the cross section width, from measurement standard SS-EN-1505 (Johansson and Svensson, 1998). Combining equations 2 and 3 and isolating T_{out}:

$$T_{out} = T_{in} + \frac{G \times \eta_{thermal} \times A_c}{A_{cs} \times v \times \rho \times C_p} \qquad \text{(eq. 4)}$$

Which results in the outlet temperature as a function of the flow rate in the dryer. The flow rate can be adjusted by regulated the air outlet opening size.

3. Method

3.1. Construction of the solar dryer

A prototype small-scale solar thermal dryer was constructed in Lund before the field study was conducted. The result is presented in Figure 1 with a schematic illustration of the basic technique of natural ventilation, along with dimensions. The implementation of the solar dryer would take place in a developing country, something the design of the dryer had to account for. This means that complexity had to be minimized and user friendliness maximized. Furthermore, the design of the solar dryer had to meet the posed criteria of temperature and size. A temperature interval defined by a lower temperature of 50 ºC to prevent microbial growth and a higher limit of 65 ºC to minimise degradation of ascorbic acid was set as desirable (Rab et al, 2015). The size, presented in Table 1, is limited to a small-scale solar thermal dryer, possible to transport on conventional flights.

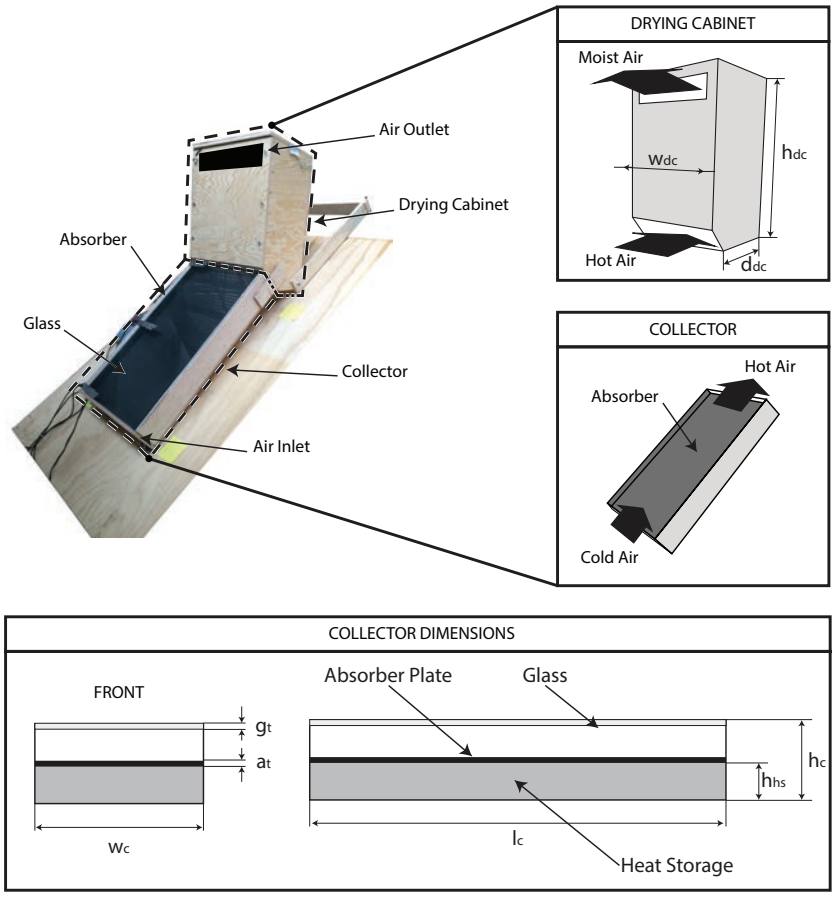

Fig. 1: Picture of the constructed solar dryer, with a schematic illustration of the collector, to illustrate the dimensions of the dryer.

Tab. 1: Table of the small-scale solar thermal dryer's dimensions.

Collector Parts	**Dimensions**
Length, l_c	0.700 m
Outer width, w_o	0.424 m
Width absorber plate, w_a	0.376 m
Height collector, h_c	0.082 m
Distance absorber-glass, $d_{a\text{-}g}$	0.035 m
Height heat storage, h_{hs}	0.035 m
Thickness absorber, a_t	0.012 m
Thickness glass, g_t	0.003 m
Drying Cabinet Parts	
Height, h_{dc}	0.500 m
Width, w_{dc}	0.400 m
Depth, d_{dc}	0.200 m

3.2. Measurement setup

The semi-permeable bag consists of a breathable polymer that is permeable to water vapour but not liquid water, as stated in the theory section. This means that during drying, all of the liquid water is contained in the bag, while water vapour is able to diffuse through the membrane and then escape to the surroundings. For a more detailed description of the procedure and SAP technique, please refer to Phinney et al., 2015. Previous

testing from the mentioned study with a bag prototype suggested a constant drying flux is achieved at the beginning of drying if the product to be dried is very watery (e.g. fruit juice). Wind speed was not found to play a crucial role in previous testing due to the nature of the equipment used where the air flow was able to pass horizontally over both sides of the bag. Figure 2 presents a picture of the membrane bags filled with water. The height of the bags are 19 cm, and width of 7.5 cm. Thickness varied depending on different amount of water in the bags, between 2 to 4 cm.

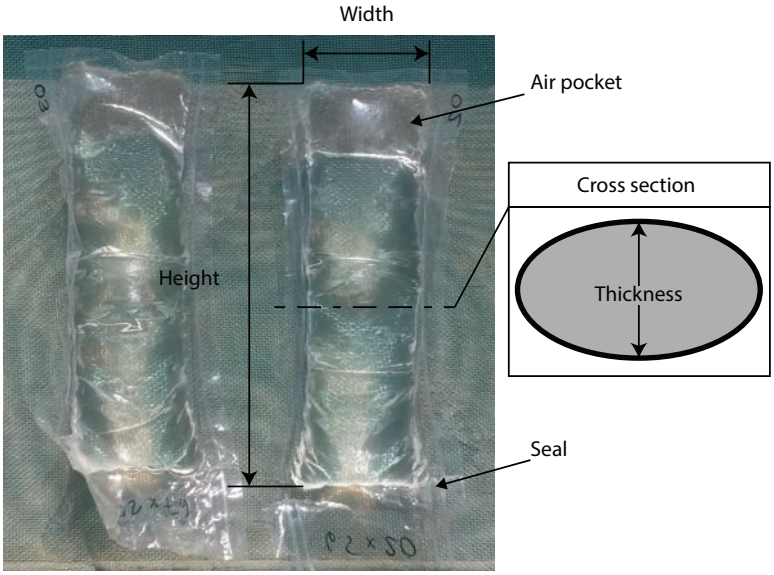

Fig. 2: Picture of the transparent membrane bags filled with water that were dried on-site in Mozambique..

The measurement equipment was setup to gather data on temperatures in the collector and drying cabinet, the relative humidity in the ambient environment and inside the drying cabinet, mass loss, wind speed and irradiance. The equipment was installed at the following points illustrated in Figure 3. The measurement points used in this article are points number 3, 9 and mass loss found by the hand scale represented at point 12.

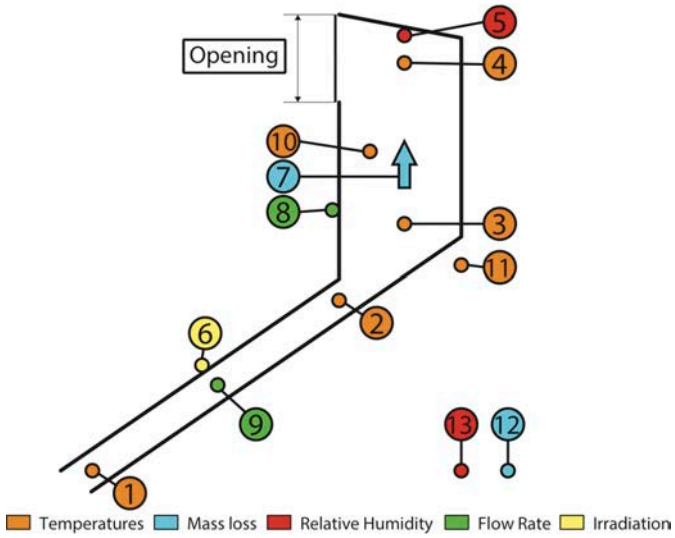

Fig. 3: A schematic figure of the measurement setup for the field testing.

3.3. Performance testing

The performance tests consisted of investigating the drying flux ($\dot{m}/A_s$) of the bags in the dryer over the course of a day. The separate tests are referred to as Run 1 to 6. The test runs begun by weighing the bags before they were inserted in the drying cabinet and ended by weighing after removal from the same space, in order to identify a linear representation of the mass loss over time per unit surface area. All membrane bags used were rectangular with dimensions of 0.19 ± 0.005 m times 0.075 ± 0005 m. The bags consisted of two sides, resulting in a total active surface area of 0.0266 ± 0.0025 m^2. The bags were filled with water, not fruit juice, since the aim of the project was to investigate how the conditions in the dryer affected the drying flux, and water was deemed easier to handle than fruit juice. The drying process of water in the bags is similar to the first stage of drying juice, otherwise known as the constant rate or constant flux period, when the water at the surface of the juice is still plentiful and internal mass transport is not yet dominating (Phinney et al., 2015).

The test aimed to reach a stable input of solar energy, by rotating the dryer along the solar azimuth angle every hour and regulating the temperature and air-flow in the dryer by adjusting the opening of the air outlet. These parameter changes are presented in Table 2. The resulting drying fluxes were later analysed to identify how drying flux could relate to temperature and air flow rate regulation in the dryer. The drying flux of the bags was later compared to a reference bag placed out in the open beside the dryer to evaluate the relative speed.

Tab. 2: Table representing the approximated amount of time each air outlet opening was used during Runs 1-6.

Opening /%	Run 1	Run 2	Run 3	Run 4	Run 5	Run 6
0	2 h					
16	2 h	1 h		3.5 h		
33	1 h	2 h		2 h		
50		2.5 h	4 h		5.25 h	3.5 h
100			3 h			2.5 h

3.4. Design changes

The dryer's design was examined after Runs 1, 2 and 3 and then the drying cabinet's volume was decreased by reducing the depth to 7 cm instead of 20 cm to increase the flow rate through the drying cabinet, illustrated in Figure 4. The hypothesis was that an increased flow rate passing the bags would increase the drying flux. The bag was hung vertically to fit in the smaller space, leading to a change in the characteristic length of flow passing over the bag.

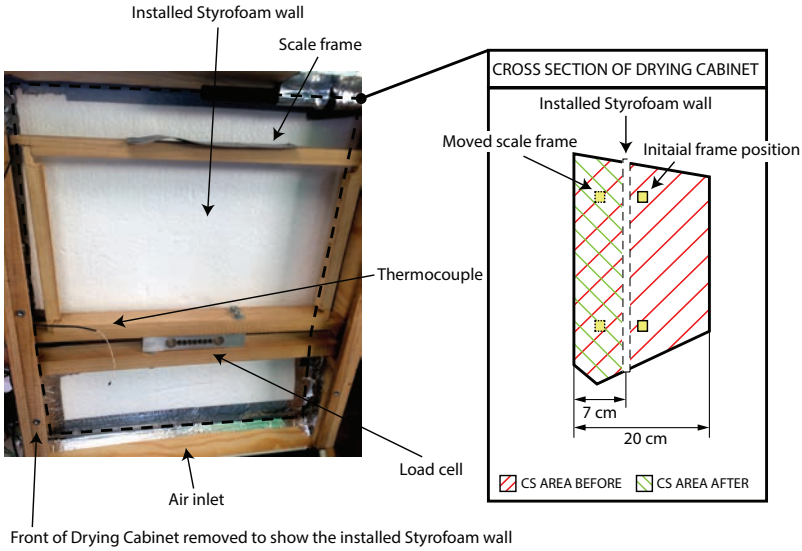

Fig. 4: Illustration of how the design change decreased the cross-sectional area of the drying.

4. Results

Table 3 presents measurement results of the drying flux of the bags as a function of the mean temperature (measurement point 3) in the drying cabinet and the air flow rate passing over the bags. Runs 1 to 6 are shown and compared to the reference bag dried at outdoor ambient conditions. Results for the drying flux are averaged over the course of a day. The results are presented ranging from the lowest to highest percentage of air outlet opening, where the first three runs represent the original design and Runs 4-6 represent the implemented design change with a smaller cross-sectional area. The air flow velocity is not corresponding entirely as it is higher for run 5 than run 6, which can be due to ambient weather conditions. Another anomaly is the drying flux for Run 2, which is not following the trend, since three bags were present in the dryer as opposed to the other runs where only one bag was present. Figure 5 and Figure 6 present the results in a graphical manner, where the values for the drying flux is plotted over air flow velocity. A linear approximation is introduced to illustrate the relationship between these variables. To be noted, the drying flux inside the dryer system never exceeded that of the reference bag, as presented in Table 3, but the run with the highest air flow rate reached approximately the same value.

Tab. 3: The results are presented ranging from the lowest to highest percentage of air outlet opening.

Test	Opening /%	Time	Drying Flux /g·m^{-2}·h^{-1}	Temperature /ºC	Air Flow Velocity /m·s^{-1}
Run 1	16 & 0	10:38-15:39	182.3	45.8	0.0190
Run 2	33 & 50	09:47-15:13	142.2	49.8	0.0436
Run 3	50 & 100	09:20-16:03	247.3	46.6	0.0783
Run 4	16 & 33	10:10-15:43	265.7	44.3	0.0871
Run 5	50	10:31-16:07	359.0	45.1	0.157
Run 6	50 & 100	10:23-16:41	369.7	50.2	0.144
Reference bag	N/A	N/A	372.0	30.0	N/A

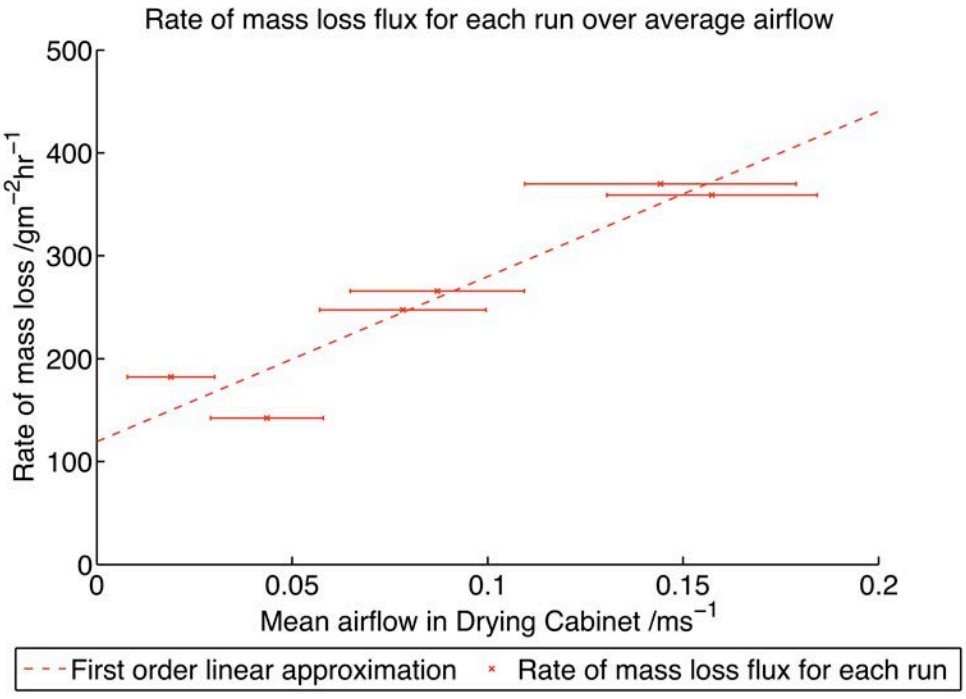

Fig. 5: Graphical representation of the drying flux versus air flow velocity from the values represented in Table 3 to identify the relationship between drying flux and flow rate. The points in Figure 5 and 6 are from corresponding runs.

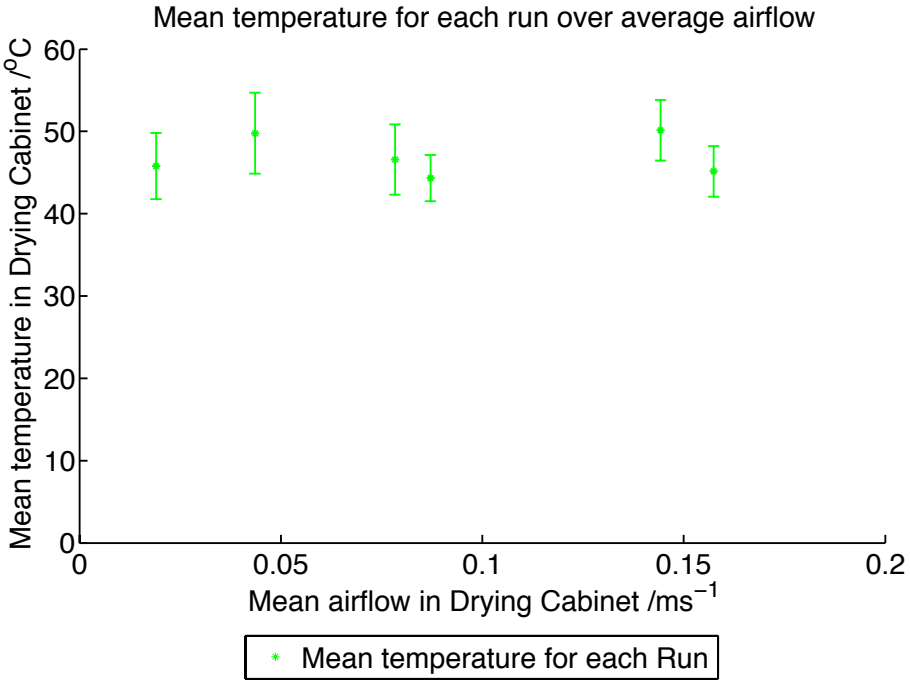

Fig. 6: Graphical representation of the temperature versus air flow velocity from the values represented in Table 3. The points in Figure 5 and 6 correspond, and with a small variation in temperature, a clear relationship between drying flux and flow rate is identified.

5. Measurement Uncertainties

Measurements with the hand anemometer to measure the air flow rate in the collector had complications due to fluctuating values with random variations in intervals. The fluctuation was affected by external wind which can create regions of turbulence and affect the measurements. The anemometer can only operate in laminar regions (Operation and Service Manual, Model 8330 VELOCICHECK 1994). The air flows measured in the collector were low, and small variations in wind led to large relative errors.

6. Discussion & Conclusion

6.1. Discussion

As can be seen in Table 3, the mass loss fluxes in the solar dryer never exceeded that of the reference bag. When this was discovered, during Runs 1 to Run 3, the driving forces of the drying process that differed between the dryer and ambient environment were analysed in order to identify the limiting factor on mass transport for the system. The temperature in the drying cabinet had increased by around 20 degrees compared to the ambient temperature, as seen in Table 3, and the relative humidity was lowered from 59.9 % (ambient) to 26.3 % (drying cabinet) on the 11th of May. This is one data point logged and the relation is similar during all performed tests. This corresponded with our predicted requirements for drying, but effectively it showed little effect. The most crucial parameters that differed between the drying cabinet and ambient environment were the direct sunlight on the reference bag in the sun and ambient wind passing over all reference bags. Direct sunlight was deemed to play a certain role in increasing the temperature of the reference bag. However, since it is transparent, it was not thought to have increased the temperature more than the 20

degrees which was the case in the drying cabinet. Ambient wind, or air flow passing over the bags, was thus investigated further.

The increased airflow velocity had a positive effect on the drying flux, as the drying flux was doubled between Run 1 and Run 6 which can be seen in Table 3 and Figure 5. If we relate the drying flux to eq. 1 in the Theory section, this suggests that the limiting factor for mass loss inside the drying cabinet was the mass transfer coefficient K, which is the only parameter dependent on airflow velocity. When the flow rate was actively increased in later test runs, the results showed an increase in drying flux. A hypothesis we suggest is that the limiting factor was not the diffusion of water through the membrane during the simulated "constant rate drying period" (i.e. when the drying flux is normally constant at the beginning of juice drying). If this was the case, an increased temperature would have led to an increased diffusion as it is driven by the difference in partial pressure as a function of relative humidity on the different sides of the membrane. However, the problem faced was not getting water to the surface of the membrane, but rather removing the already surfaced water.

6.2. Conclusion

Higher temperatures and a lower relative humidity inside the solar dryer did not increase the drying flux to the level of the reference bag placed in ambient conditions where passing wind and direct sunlight were available. A drying flux of 247.3 $g \cdot m^{-2} \cdot h^{-1}$ was reached during Run 3 compared to the drying flux of 372.0 $g \cdot m^{-2} \cdot h^{-1}$ for the reference bag. The solar dryer seemed to be missing the capacity to remove the vapour from the surface of the bag to continue the pervaporation process through the membrane. One hypothesis is that the air flow velocity was limiting the drying. A design modification, increasing the flow rate by 100%, by decreasing the volume of the drying cabinet doubled the drying flux between Runs 1 and Run 6, from 182.3 $g \cdot m^{-2} \cdot h^{-1}$ to a drying flux of 369.7 $g \cdot m^{-2} \cdot h^{-1}$. The hypothesis of air flow rate acting as an active parameter during the beginning stages of drying using Solar Assisted Pervaporation with membrane bags seems to be correct, but further research should be done to confirm this. It was concluded that the drying flux in the cabinet increased with the increased air flow rate due to a smaller cross section area, while temperature was maintained around the lower limit of the required temperature interval and a lower relative humidity than ambient was achieved.

A Fracture Mechanics Based Lifetime Assessment Approach for Polyamide used for Integrated Storage Collectors

Patrick R. Bradler[1], Joerg Fischer[1], Mathias Schlaeger[1], Gernot M. Wallner[1] and Reinhold W. Lang[1]

[1] Institute of Polymeric Materials and Testing, Johannes Kepler University of Linz, Linz (Austria)

Abstract

A novel test method simulating the superimposed mechanical, thermal and environmental service loads representative for single-loop integrated storage collectors (ICS) was developed. Engineering polyamide (PA) grades with glass fiber reinforcement, which are of high relevance for endcaps of steel-pipe ICS absorbers and all-polymeric absorbers and storage-tanks, were characterized on laboratory specimen level. An in-situ testing facility for fracture mechanics specimen was used on an electrodynamic testing machine. By in-situ characterization in hot water, a significant decrease in crack growth resistance compared to air (same temperature) was detected. For these specific loading conditions, an extrapolation to static loading was performed to better resemble the loading situation in the ICS and to calculate critical stress levels for cylindrical pipes.

Keywords: *integrated storage collector; polyamide; superimposed loading; lifetime assessment approach; fatigue crack growth kinetics*

1. Introduction

An objective in previous research projects (e.g. SCOOP – Solar Collectors made of Polymers) was to develop and implement advanced testing methods for the evaluation of the long-term behavior of polymeric materials for solar collectors under service relevant loading conditions (Wallner et al., 2004; Kahlen et al., 2010; Köhl et al., 2012; Geretschlaeger, 2015; Geretschlaeger and Wallner, 2016; Steffen et al., 2017). To fulfill the application requirements for pressurized integrated storage collectors, maximum internal pressures of 6 bar and maximum application temperatures of 90°C should be considered (Solecrafte, 2015). While in a previous paper, fatigue crack growth kinetics of PA under superimposed mechanical, thermal and environmental loads were described properly (Fischer et al., 2016), this paper deals with a lifetime assessment approach considering the previously determined most critical crack growth behavior. Special attention is given to an extrapolation procedure simulating a static loading case, as originally proposed for plastics pressure pipes (Lang et al., 2005).

2. Background

The entire discipline of fatigue crack growth (FCG) behavior in plastics is fundamentally based on the concept of linear-elastic fracture mechanics (Hertzberg and Manson, 1980; Lang, 1980; Lang et al., 1982; Hertzberg et al., 2013). The failure mechanisms are frequently described by two different regimes, the crack initiation and the subsequent crack growth regime (Lang et al., 1997; Haager et al., 2004).

Based on cyclic tests which allow an accelerated material characterization, the calculation of FCG kinetic curves is possible. In these FCG curves three different failure modes are apparent in a double logarithmic plot (see Fig. 1). Region I represents the threshold, region II the stable crack growth region typically obeying a power law (representing a linear increase in the double logarithmic scale), and finally region III which corresponds to unstable crack growth approaching ultimate failure.

doi:10.18086/eurosun.2016.07.05 Available at http://proceedings.ises.org

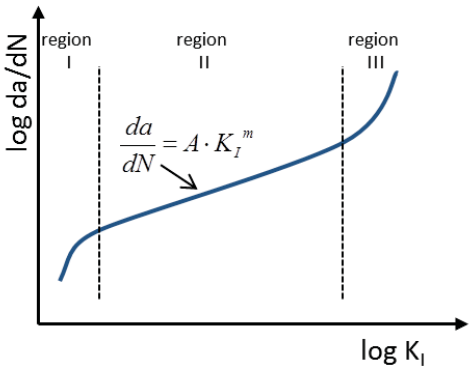

Fig. 1. Crack growth rate da/dN as a function of the stress intensity factor K_I.

However, for a lifetime prediction based on fracture mechanics, a static loading case representing creep crack growth is necessary. This requires a transformation of FCG data to static loading data with a procedure presented elsewhere (Lang et al., 2005; Frank et al., 2008; Frank et al., 2009). This procedure, in principle, also allows a prediction of lifetime of components, whereby a component and dimension dependent stress intensity factor K_I has to be simulated via finite element analysis.

3. Methodology and experimental

Materials

The test program was performed by using two semi-crystalline fiber reinforced polyamide (PA) grades. An overview of selected grade specific information as to the materials is given in Table 1. The grades are seen to vary in the glass fiber content as well as in the chemical composition. PA66-GF30 is an aliphatic PA, and PA6T/6I-GF50 is a semi-aromatic co-PA. Both material grades offer a high potential for the substitution of metals in integrated storage collectors.

Table 1. Materials with specific information

Material designation	Matrix polymer type	Glass fiber content	Commercial grade name	Manufacturer
PA66-GF30	Polyamide 66	30 w%	SCHULAMID® 66 GF 30	A. Schulmann GmbH, Germany
PA6T/6I-GF50	Polyamide 6T/6I-GF50	50 w%	Grivory HT1V-5 FWA	EMS-Chemie AG, Switzerland

Specimen and specimen preparation

The crack growth tests on the specimen level were conducted using compact-type (CT) specimens (see Fig. 2). The materials were first injection-molded to plates, which were then milled to the desired specimen geometry and subsequently notched with a razor blade for obtaining an initial crack. To cover the expected lower bound crack growth resistance of the specimens with a layered fiber orientation pattern caused by the injection molding process, the notched direction was chosen to be parallel to the main melt flow direction when injection molding the plates (Schlaeger, 2015; Fischer et al., 2016). Hence, the loading direction in these specimens is perpendicular to the main fiber orientation direction.

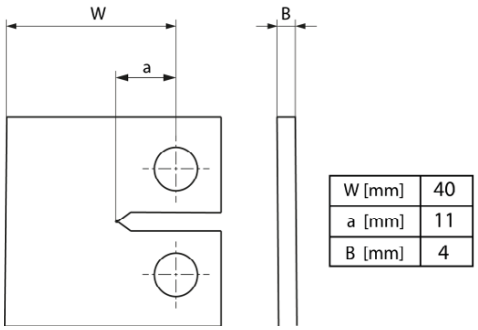

Fig. 2. Compact type (CT) specimen with test specific dimensions.

Fatigue testing and data reduction

Both PA grades were investigated in a previous research work (Fischer et al., 2016) as to their fatigue crack growth resistance under various, service relevant conditions. It has been shown that elevated temperature and liquid media are influencing and accelerating the failure kinetics of these PA-types (Hahn et al., 1982; Fischer et al., 2016). Hence, the testing conditions in this paper were chosen with a temperature of 80°C and deionized water (referred to as H_2O). In order to ensure water-saturation of grades tested in H_2O, a pre-conditioning procedure with a saturation time of 7 days in the testing-similar surrounding media was carried out (Schlaeger, 2015). To allow for extrapolation of cyclic crack growth data to static loading, the cyclic tests were performed with various R-ratios ranging from 0.1 to 0.7, with R being defined as the ratio between the minimum and maximum applied force in the sinusoidal, cyclic loading profile.

The tests were conducted in the superimposed in-situ testing media containment device originally designed and implemented by Schoeffl et al. (Schoeffl, 2014; Schoeffl et al., 2014). In contrast to tests with highly ductile materials, the camera system and the software device for crack length evaluation was especially adapted for less ductile materials. All FCG tests were conducted with an electro-dynamic testing machine of the type ElectroPlus E3000 (Instron; Nordwoos, USA) under sinusoidal loading and a frequency of 5 Hz. R-ratios were set to 0.1, 0.3, 0.5 and 0.7, respectively. To reduce overall testing times while simultaneously ensuring quasi-brittle, stable crack growth, the initial stress intensity factor levels were suitably chosen by pretesting some specimens. The calculation of the stress intensity factor K_I was done as described by Fischer et al. using eq. 1 and eq. 2 (Gross and Seelig, 2011).

$$K_I = \frac{F}{B \cdot \sqrt{W}} \cdot f\left(\frac{a}{W}\right) \qquad \text{(eq. 1)}$$

$$f\left(\frac{a}{W}\right) = \frac{\left(2+\frac{a}{W}\right)}{\left(1-\frac{a}{W}\right)^{3/2}} \cdot \left(0.886 + 4.64 \cdot \left(\frac{a}{W}\right) - 13.32 \cdot \left(\frac{a}{W}\right)^2 + 14.72 \cdot \left(\frac{a}{W}\right)^3 - 5.6 \cdot \left(\frac{a}{W}\right)^4\right) \qquad \text{(eq. 2)}$$

Lifetime assessment approach for a cylindrical ring

By using a quantitative comparison between the internal pressure loading conditions in ICS and the characterized FCG behavior, the probability of crack growth can be assessed. Therefore, calculations were carried out with eq. 3 and eq. 4 postulated by Yan (Yan and Nguyen-Dang, 1994). These equations allow a calculation of the K_I-values for a cylindrical ring under static internal pressure and small defect sizes, whereby p is the internal pressure, a the defect size and F a factor for considering different geometries relations of the cylinder. This factor contains the inner radius r of the cylinder (r=130 mm), the outer radius

R or the wall thickness. Representative values for the calculations were chosen with p=10 bar, a defect size of 0.5 mm and wall thicknesses of 2.0, 2.5 and 3.0 mm.

$$K_{I,critical} = p \cdot \sqrt{\pi \cdot a} \cdot F\left(\frac{a}{r}, \beta\right) \qquad \text{(eq. 3)}$$

$$F = 1.12 \cdot \frac{\beta^2 + 1}{\beta^2 - 1} \quad with \quad \frac{a}{r} \approx 0 \quad and \quad \beta = \frac{R}{r} \qquad \text{(eq. 4)}$$

As mentioned before, to obtain creep crack growth curves for static loading (R=1) from FCG curves, a procedure proposed by Lang et al. was followed (Lang et al., 2005; Frank et al., 2008; Frank et al., 2009). It allows for an extrapolation of FCG tests at different R-ratios to creep crack growth (CCG) curves under static load. If the K_I-values of these extrapolated CCG curves are higher than the calculated stress intensity factor K_I, FCG curves may be extrapolated back to those calculated component typical, calculated K_I-values, assuming no threshold regime occurs in the extrapolated range. In any case, this calculation remains on the safe side should such a threshold regime occur in the extrapolated range.

4. Results and discussion

The effect of R-ratio on the FCG resistance of PA66-GF30 is shown in Fig. 3 in terms of the da/dN vs. $K_{I,max}$. This illustration (rather than a ΔK diagram) was chosen as it is more prone to extrapolate the data directly to the static case. Clearly, the crack growth lines for constant R-ratios shift towards higher $K_{I,max}$-values as the R-ratio is increased.

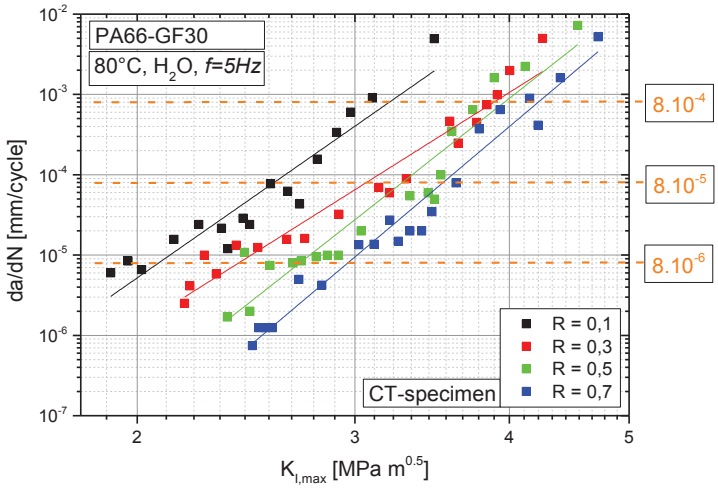

Fig. 3. Measured FCG kinetics for PA66-GF30S under various R-ratios.

In Fig. 4, the corresponding $K_{I,max}$ values at constant crack growth rates are plotted as a function of the R-ratio. Based on an exponential curve fitting and extrapolation using the existing data sets, values for the static loading conditions are achieved. The coefficient of determination R^2 was consistently above 0.9. By using the extrapolated data sets a CCG curve under static load was derived. Hence, a quantitative "synthetic" kinetic law for static loading (R=1) is obtained, which is shown in Fig. 5 together with the experimental kinetic laws at lower R-ratios. The results are in good agreement with expectations and results from previous studies with other materials (Lang et al., 2005; Pinter et al., 2007; Frank et al., 2009).

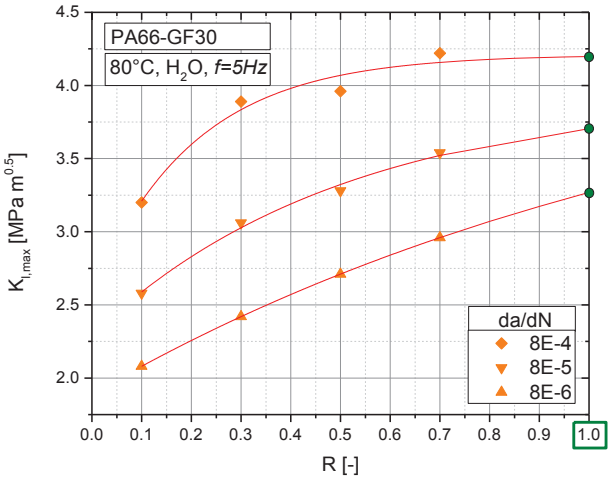

Fig. 4. Extrapolation of $K_{I,max}$-values at different R-ratios to R=1.

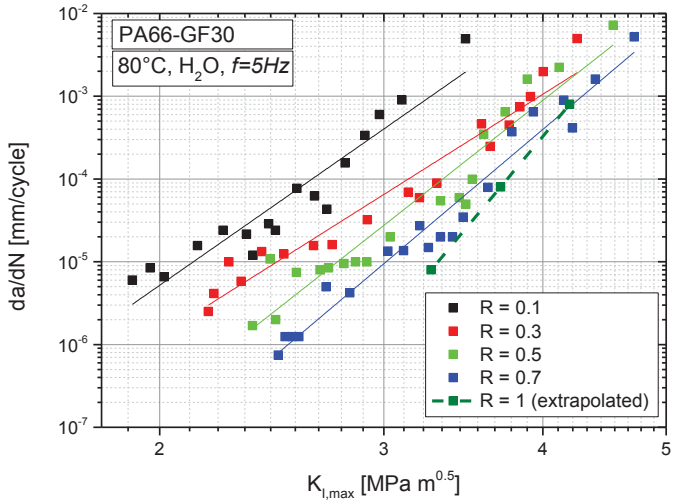

Fig. 5. Measured and calculated fatigue crack growth kinetics for PA66-GF30 under various R-ratios .

Using the assumptions for a pressurized ring component under service conditions described above (pressure p=10 bar; inner cylinder radius r of 130 mm; defect size a=0.5 mm; wall thicknesses of 2.0, 2.5 and 3.0 mm), "initial" K_I-values for the component level were calculated and are listed in Table 3.

Table 3. Calculated "initial" stress intensity factors under internal pressure for a cylindrical ring

Wall thickness (mm)	K_I-values ($MPa.m^{0.5}$)
2.0	1.47
2.5	1.17
3.0	0.97

These "initial" K_I-values are depicted in Fig. 6 together with the extrapolated "synthetic" CCG curves for both materials investigated. It appears that the CCG curves, when linearly extrapolated to lower stress intensity factors, would intersect the lines for initial stress intensity factor values at crack growth rates substantially below 10^{-8} mm/cycle. Considering that in a crack growth threshold may actually exist as one

moves towards such low crack growth rates, it is feasible to assume that the material inherent crack growth resistance may be sufficient for such an application. This conclusion, at least at this stage, does not necessarily apply to weld-bonded areas, an aspect which needs to be looked at in detail separately.

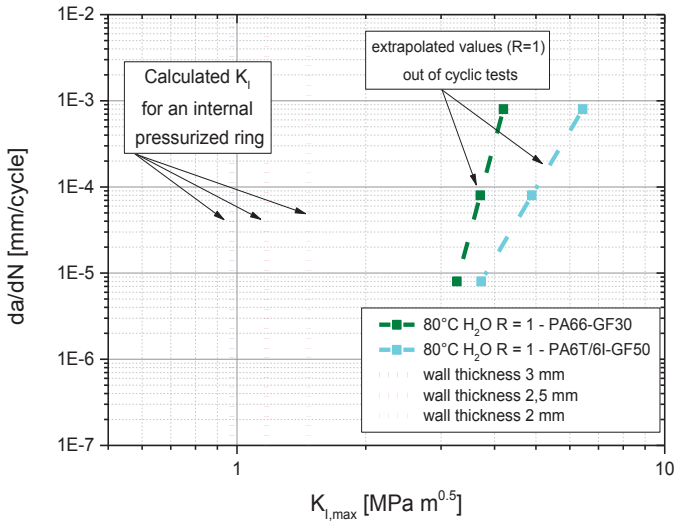

Fig. 6. Comparison of K_I-values of an internal pressurized cylinder with generated crack kinetics curves (R=1) for PA66-GF30 and PA6T/6I-GF50 at 80°C in water.

5. Summary and outlook

In this paper, based on a lifetime assessment approach for two polyamide grades with different glass fiber contents, the probability of crack growth under application conditions was investigated. Fatigue crack growth (FCG) experiments at different R-ratios (ratio of minimum to maximum force) were conducted at a temperature of 80°C in deionized water. The loading was applied to the injection molded compact-type (CT) specimens perpendicular to the main fiber orientation direction, i.e. the most critical case. Experimental data show that the FCG curves are strongly affected by the R-ratio, showing higher $K_{I,max}$-values with increasing R-ratio at a given crack growth rate. The experimental results were used to extrapolate towards a "synthetic" creep crack growth curve for both materials, which in turn were utilized to assess the long term performance capability of pressurized ring components in service such as in a single-loop integrated storage collector. While both PA material grades investigated seem to exhibit sufficient material-inherent crack growth resistance under service conditions, the crack growth resistance of weld-bonded sections remains a topic of further studies.

Influence of maritime/industrial atmosphere on solar thermal collector's degradation

M. J. Carvalho[1] S. Páscoa[1] R. Gonçalves[1] N. Mexa[1] T. C. Diamantino[1]

[1] LNEG – Laboratório Nacional de Energia e Geologia, Lisbon (Portugal)

Abstract

Influence of atmospheric corrosivity on solar thermal collector's degradation was studied by exposure of flat plate collectors to two different corrosivity environments, one urban Outdoor Exposure Testing (OET) site with medium corrosivity (C2-C3) and a very high/extreme corrosivity (industrial and marine) (C5-CX) atmosphere highly polluted and simultaneously with highly airborne salinity. This OET site is a natural laboratory and can be considered as an accelerated test site. Results of thermal performance measurements after two years of exposure in the OET site with very high/extreme corrosivity (C5-CX) are presented, as well as the characterization of collectors inside environment with reference materials (zinc) in terms of corrosion rate.

Measurement of thermal performance of the collectors exposed in the OET site with very high/extreme corrosivity (C5-CX) are also presented for 13/14 months and 26 months of exposure. Collectors were dismantled and optical properties of the absorbers were measured.

Keywords: *Solar thermal collectors, atmospheric corrosivity, thermal performance degradation*

1. Introduction

Solar thermal collectors (STC) have to withstand stress conditions like high temperatures, high humidity, ultraviolet irradiance or wind and snow loads depending on the geographic location. Literature points out to dependence on other influences like prevailing wind conditions, contaminants like chlorides, SO_2 and NO_x, global solar irradiation, wetness time and precipitation (Köhl, M., et al, 2004; Slamova, K et al, 2016).

Although for certification of solar thermal collector (e.g. Solar Keymark, SRCC), the testing standards applied, namely ISO 9806:2013, consider a set of tests which address testing of collector resistance to most common adverse conditions when collectors are in use, these tests do not address long term collector durability.

In order to better know how different environmental conditions influence STC, as well as collector components, two OET (Outdoor Exposure Testing) sites were used to expose collectors and collector components. The two OET sites represent an urban climate (Lisboa-Lumiar) and a maritime climate with industrial influence (Sines). The results of full collector exposure will be presented in this work for one of the OET sites where the highest corrosivity levels are present.

In section 2 the collectors exposed are described, as well as the test methodology for thermal performance evaluation of the collector. In this section the method for evaluation of corrosivity inside the collectors is also presented. A short presentation of Sines OET site characterization is given based on detailed work of Diamantino, T. et al., 2016.

In section 3 thermal performances of collectors before and after exposure are presented. In this section the corrosivity inside the collectors is also presented.

Conclusions are presented in section 4.

doi:10.18086/eurosun.2016.07.04 Available at http://proceedings.ises.org

2. Exposure of STC at OET sites

STC studied were Flat Plate collectors with tempered glass cover. Their main characteristics are described in Table 1.

Tab. 1: Main collector characteristics

Reference of collector model	Main collector characteristics
A *	Aluminum absorber surface with PVD coating (mirotherm ®); Aluminum box.
B	Copper absorber surface with PVD coating (mirotherm ®); Aluminum box.
C *	Aluminum absorber surface with PVD coating (Eta plus ®); Aluminum box.
D *	Copper absorber surface with selective paint coating (SUNCOLOR TS S Black); Stainless steel box.

*one (1) replicate with zinc metal samples (reference materials)

For each collector model, two samples were exposed in each OET site (see Fig. 1).

Fig. 1: Installation of collector in OET- Maritime/Industrial

Thermal performance was measured in one collector of each collector model before exposure. For three of the models, zinc standard samples (reference materials) were installed in one of the collector samples to evaluate the corrosivity inside the collector.

2.1 STC thermal performance evaluation method

Originally it was decided that after two years of exposure, thermal performance would be measured for all collectors. However, considering the need to have a longer exposure period it was decided to measure only the thermal performance of collectors exposed at the Sines OET site since it has the highest corrosivity levels. It was decided to keep the collectors exposed at Lisboa-Lumiar for a longer period, except those with zinc standard samples (reference materials) which will be measured after completing similar exposure time as those in Sines OET site (26 months). The results of the performed measurements for collectors exposed in Sines are presented in this paper.

Thermal performance tests of solar thermal collectors were performed according ISO 9806:2013, using quasi-dynamic test method. The comparison is made based on the power curve as defined in ISO 9806:2013 for normal incident irradiance of 1000 Wm^{-2} (Direct irradiance = 850 Wm^{-2}; Diffuse irradiance = 150 Wm^{-2}).

Initial thermal performance was measured only in one collector of each reference. Final results of thermal performance were measured for all collectors exposed. The collectors with installed reference materials were dismantled for inspection and for evaluation of the corrosivity in zinc samples.

2.2 Optical properties of absorbers

Optical properties of absorbers were also measured. Information on optical properties of absorbers used in each collector exists and will also be presented and compared with the performed measurements of the absorber samples extracted from collectors.

The optical properties measured were solar absorptance (α_s) and thermal emittance (ε_t). The solar absorption (α_s) was measured using a Perkin Elmer's Spectrophotometer Lambda 950 UV/VIS/NIR with a 150 mm integrating sphere according to equation (1):

$$\alpha_s = \int_0^{\infty} \frac{[1-\rho(\lambda)]S_\lambda}{S_\lambda} d\lambda \qquad \text{(eq. 1)}$$

where S_λ is the spectral solar irradiance according to ASTM G173 – 03(2012) and $\rho(\lambda)$ is spectral hemispherical reflectance of the absorber coating between 300 and 2500 nm (ISO 22975-3:2014). For measurement of the spectral reflectance a spectralon ® coating reference not calibrated is used.

The thermal emittance (ε_t) was initially determined with a portable emissometer, Devices & Service Company model AE-AD3, which measures a surface emittance at 80°C of temperature and corrected for a temperature of 100ºC based on later measurements using a Spectrophotometer Frontier IR/NIR of Perkin Elmer, with integrating sphere. The thermal emittance is determined according to equation (2):

$$\varepsilon_t = \int_0^{\infty} \frac{[1-\rho(\lambda)]P_\lambda(T)}{P_\lambda(T)} d\lambda \qquad \text{(eq. 2)}$$

where $P_\lambda(T)$ is the Planck function for the black-body at a temperature T equal to 373 K and $\rho(\lambda)$ is spectral hemispherical reflectance of the absorber coating between 2.5 and 20 μm (ISO 22975-3:2014). For measurement of the spectral reflectance, a diffuse gold coating reference calibrated by Avian Technologies LLC is used.

2.3 STC inside corrosivity evaluation

In the collectors referenced in Table 1 with * five (5) replicates of zinc metal samples were put in the air gap between absorber and glazing according to Fig. 2, to evaluate the corrosivity of the micro-climate after approximately 2 years (26 months). Zinc metal samples are equal to the zinc metal samples placed outdoors to comparatively evaluate the atmospheric corrosivity. The corrosion categories of outdoor exposure test sites were obtained by determination of the corrosivity based on corrosion rate measurement of standard specimens (carbon steel, zinc, copper and aluminum) according to ISO 9226:2012. Three (3) replicates of standard specimens were exposed in support structures fixed with ceramic screws at an angle of 45° facing South (S). After exposure, corrosion products of each metal (inside and outside the collectors) were removed in accordance with ISO 8407:2009 and the corrosion rate was determined by weight loss according to ISO 9226:2012, considering the mass loss, total surface area and exposure period.

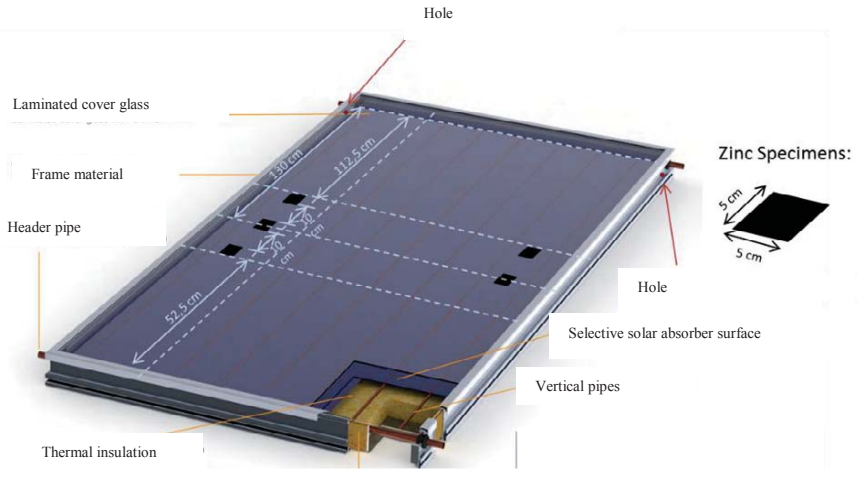

Fig. 2: Zinc specimens put in air gap between absorber and glazing.

To avoid contact with the absorber, the zinc samples inside the collector were fixed on the absorber with specially designed polymeric sample holders to ensure that the samples were galvanically isolated.

2.4 Short description of Sines OET site

Detailed description of OET site characterization can be found in Diamantino, T et al. (2016). A short description of Sines OET site is presented in Table 2. The values presented were obtained for one year (2014).

Tab. 2: Climate characterization in Sines OET site (2014) (Diamantino et al, 2016)

Location	Latitude	Longitude	Altitude [m]	Ambient temperature [°C] (average)	Solar irradiance tilt 45° G_h [W/m^2]	average relative humidity [%]	Cl^- [mg.day^{-1}.m^{-2}]	SO_2 [mg.day^{-1}.m^{-2}]
Sines, Portugal	37,95°N	8,88°W	17	16,9	351	78,7	191,8	139,1

In Table 3 are presented the results of atmospheric corrosion rates in Sines OET site. Detailed presentation of these results can be seen in Diamantino, T. et al. (2016).

Tab. 3: Corrosion rates of carbon steel, copper, zinc and aluminum and corrosion categories measured after 1 year of exposure for (exposed in 2 orientation – N and S) Sines OET site (Diamantino et al, 2016)

Sines OET site									
Reference materials		Carbon steel		Copper		Zinc		Aluminum

3.1 STC thermal performance results after approximately one and two years of exposure

After approximately one year of exposure (see Exposure time in Table 4) in Sines OET, two collectors were tested for thermal performance and dismantled after. Measurement of optical properties was made in one section of the absorber.

After approximately two years of exposure (see Exposure time in Table 4) in Sines OET, the collectors with zinc metal samples were also tested for thermal performance and dismantled after. Measurement of optical properties was made to one or two sections of the absorber.

One collector of type B was also tested for thermal performance. The other collector is still exposed in Sines.

Fig. 3 to 6 show the collector's power curve according to the definition of ISO 9806:2013, comparing the

thermal performances after exposure with the initial thermal performance, measured in collectors of the same type before exposure.

Fig.3 and 5 show the thermal performance after one and two years for collectors with aluminum absorbers and PVD coatings (Mirotherm ® and Eta plus ®, respectively) (Models A and C). After one year there was almost no change in thermal performance. After two years, a difference can be observed mainly due to change in optical efficiency.

Fig. 4 shows the impact of two years of exposure on a collector with copper absorber and PVD coating (Mirotherm ®) (Model B). In this case, optical efficiency does not show differences but thermal losses are higher and a loss in power for higher temperatures is visible. The collector was not dismantled and no information is yet available on optical properties of the absorber or on other degradation factors that can explain this behavior.

Fig. 6 shows the impact of two years of exposure of a collector with copper absorber and Paint coating SUNCOLOR TS S Black (Model D). Two collectors were tested after two years. The collector with installed zinc metal samples does not show significant decrease in the power curve. This collector was dismantled and information on optical properties are available in Table 5.

The collector without zinc samples was not dismantled but shows a difference on the power curve. Further analyses will be made to this collector.

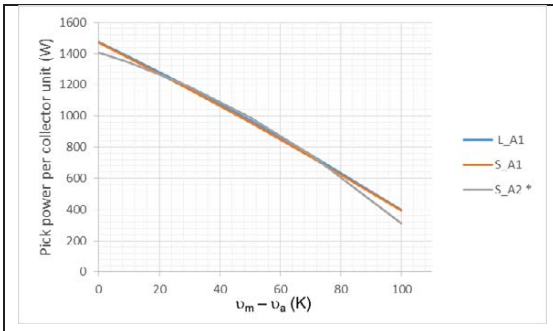

Fig. 3: Power curves of collector model A (L_A1 – initial measurement: S_A1 – measurement after one year; S_A2 * - measurement after two years).

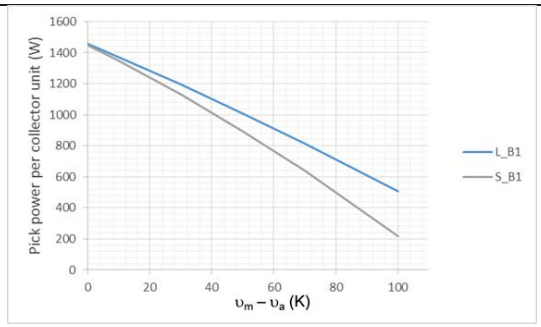

Fig. 4: Power curves of collector model B (L_B1 – initial measurement; S_B1 - measurement after two years).

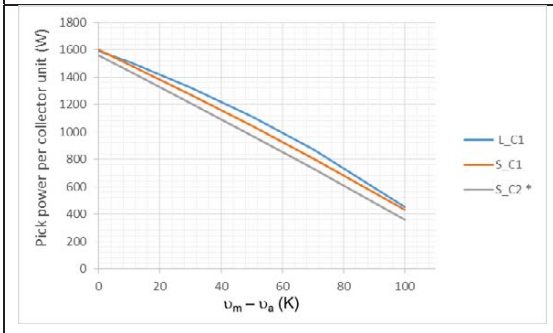

Fig. 5: Power curves of collector model C (L_C1 – initial measurement: S_C1 – measurement after one year; S_C2 * - measurement after two years).

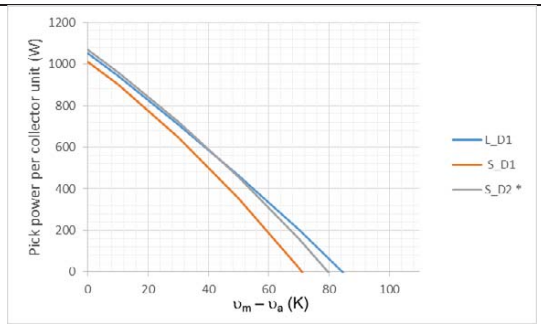

Fig. 6: Power curves of collector model D (L_D1 – initial measurement: S_D1 – measurement after one year; S_D2 * - measurement after two years).

In Table 5 the average relative difference between the power curves is presented.

Tab. 5: Average difference of power curve relative to initial peak power (%) in the temperature range 0-100 K.

Collector sample	Exposure time (month)	Average difference of power curve relative to initial peak power (%) in the temperature range 0-100 K
S_A1	14	0,6
S_A2 *	26	1,8
S_B1	26	7,7
S_C1	13	2,2
S_C2 *	26	6,2
S_D1	26	12,4
S_D2 *	26	0,0 (temp. range 0-70 K)

In Table 6 the optical properties of the absorber of the four collector models are listed. Initial values were obtained from measurement of thirty samples of the absorber used in each collector. The values after one and two years of exposure were measured in section of the collector absorber after dismantling.

The initial values of the optical properties correspond to average values of thirty samples with corresponding standard deviation. The values after 13/14 months correspond to only one measurement in one sample of the absorber of the collector dismantled. The values after 26 months correspond to values of measurements made on two different samples of the absorber (side and bottom) and, when more than one measurement was made, the standard deviation is given.

For collectors A with aluminum substrate and PVD coating, the variation in the solar absorptance is in agreement with the change in peak power (see Fig. 3). The thermal emmitance shows a higher change and after two years the bottom part of the absorber has higher thermal emittance values. For collectors C the solar absorptance does not show significative difference although some change in peak power measured (see Fig. 5) is observed. A change in glass transparency may be the reason for this. Also in this case a higher change in thermal emmitance can be observed and this change is not uniform. The bottom part of the absorber shows higher thermal emmitance values.

Tab. 6: Optical properties of collector absorber coatings.

Note: Figures in parentheses indicate that the standard deviation observed is lower than the measurement uncertainty.

Collector sample	Exposure time (month)	Location inside collector	α	σ_α	ε	σ_ε
	Initial	---	0,96	0,00(1)	0,11	0,00(2)
S_A1	14	---	0,95	---	0,11	----
S_A2 *	26	side	0,94	0,00(1)	0,13	0,01
		bottom	0,94	0,00(1)	0,12	0,00(2)
	Initial	---	0,96	0,000(2)	0,11	0,00(3)
S_C1	13	---	0,95	---	0,14	---
S_C2 *	26	side	0,95		0,11	
		bottom	0,95		0,14	
	Initial		0,95	0,00(1)	0,72	0,02
S_D2 *	26	side	0,93		0,56	
		bottom	0,93	0,00(1)	0,56	0,00(4)

The high difference of initial thermal emittance of collector D absorber when compared with the thermal emittance of absorber sections measured may result from different application procedures in initial samples and collector absorber.

3.3 Corrosivity rates

After dismantling the collectors with zinc specimens installed, the determination of the corrosivity based on corrosion rate measurement was obtained according to ISO 9226:2012 and ISO 8407:2009.

The results are presented in Table 7. Although five samples were installed, only three were used for corrosion rate measurement. The two additional samples will be used for morphological and chemical characterization of corrosion products formed. The average corrosion rate obtained inside each collector is presented in the Table below, as well as the categories obtained according to the classification described in ISO 9223:2012.

Tab. 7: Corrosion rates and corrosion categories obtained inside collectors

Collector	Corrosion rate inside collectors $r_{corr\ (g/m^2.a)\ (SD)}$	Corrosion category according to ISO 9223:2012
A	90,31 (9,53)	CX
C	99,91 (10,63)	CX
D	4,56 (0,55)	C2

Collector model A and C show corrosivity levels almost equal to outdoor (89,87 g(m^2/a) (category CX). Collector D shows low corrosivity values. These differences may be explained by different ventilation rates and higher temperatures in the collectors A and C. Further investigation will be performed on this aspect.

4. Conclusions

A first evaluation of STC exposure impact to a very high/extreme corrosivity (C5-CX) (Maritime/Industrial) was performed after one year and two years of exposure by measuring thermal performance of four collector models and comparing it with the initial thermal performance measured. Simultaneously measurement of the absorbers optical properties after dismantling of the collectors was performed. The change in thermal performance was evaluated based on the power curve of each collector for normal incidence with 1000Wm^{-2}.

In one replicate of each collector model, zinc metal samples (reference material) were installed in the air gap between absorber and glass cover. These zinc metal samples were collected after the two years of exposure of the collectors and allowed measurement of corrosion rate inside collectors.

For two of the collector models, the thermal performance was measured after one year of exposure of each collector model and did not show high impact. The average difference in the power curve relative to initial peak power (%) in the temperature range 0-100 K was of the order of 0,6 and 2,2 % for collector samples S-A1 and S-C1, respectively. The reduction in thermal performance after two years was higher for collector model C (6,2%) than for collector model A (1,8%). These differences can be correlated with the measured optical properties of the absorbers.

Collector model B showed a higher difference (7,7%) which is related with higher change in thermal losses. Future dismantling of the collector will help to identify causes for this change in thermal performance.

Collector model D showed low and high differences for the same exposure period. Also in this case for the collector showing higher difference, future dismantling of the collector will help to identify causes for the change in thermal performance.

The corrosion rate inside collectors and evaluation of the corrosion category according to ISO 9223:2012 showed for models A and C corrosion rates very close to atmospheric corrosivity measured at Sines OET site

(89,87 g(m^2/a) (category CX). For model D the corrosion rate was much lower. These differences may be explained by different ventilation rates and higher temperatures in the collectors A and C. Further investigation will be performed on this aspect.

The corrosion rates inside the collectors installed in Lisboa-Lumiar OET site will be measured for approximately the same time as for Sines OET site and will allow comparison between corrosion category inside the collectors and atmospheric corrosion for this test site.

5. Acknowledgements

This work was carried out under the Project FCOMP-01-0124-FEDER-027507 (Ref. FCT RECI/EMS-ENE/0170/2012) and the Project POCI-01-0145-FEDER-016709 FCT (PTDC/EMS-ENE/0578/2014). The authors would like to thank to industrial partners (FogãoSol, Hempel, OpenPlus and Permasolaris), by the supply of samples and the means for performing this work.

Abstract

The optical modelling of concentrating solar collectors is nowadays of great importance for a variety of applications. In this study two major goals have been achieved: First, the current market of materials for solar thermal applications was reviewed; and second, the most commonly used optical models for radiation-matter interaction were summarized. In the future, the study could be interesting for ray tracing implementations in order to adequately simulate solar concentrating or PVT collectors, which employ innovative materials and show more sensitive behavior towards incidence angle and wavelength dependent input.

1. Introduction

The optical characterization of concentrating solar collectors is of paramount importance. To mention only some of possible applications, such simulations are nowadays irreplaceable for designing and optimizing conventional or even completely new collector concepts; they allow to economically determining the error tolerance margins for real operating collectors or they could serve to complement testing procedures where laboratory settings cannot reproduce real conditions. Apart from these most common applications, optical modelling might gain even more importance with the increasing success of photovoltaic-thermal (PV/T) applications, which on the one hand have a wavelength sensitive receiver (PV-cells), but at the same time often have complex designs such as concentration collectors.

Undeniably, the core part of each optical simulation is the underlying mathematical radiation-matter interaction models. During the last decades a remarkable progress has been experienced in the field of solar

doi:10.18086/eurosun.2016.07.08 Available at http://proceedings.ises.org

materials research. New types of polymers, tailor designed coatings or surface structures are only some indicators for an increasingly changing market. The question is raised whether state-of the art models for radiation-matter interaction are still suitable to describe newly developed materials.

For this reason, a literature review has been conducted in order to first make a comprehensive list of commonly used solar materials and materials that show great potential to be used in the near future. The focus will be on solar thermal concentrating technologies, but the analysis applies to reflective and transparent materials used in PV and PVT collectors as well. The outcome of this review about solar materials will be presented in section 2. Section 3 will be related to section 2 describing physical models for radiation-matter interaction as they are often applied in order to simulate different materials.

A problem that was observed in this regard was to obtain reliable information about incidence angle dependent data of the material or material compounds that could serve as an input to optical models. It is not clear, what parameters a manufacturer or research group should provide in order to allow accurate simulations. We consider this a necessary debate in order to bring together the field of solar material research and development and the field of optical modelling.

2. Solar thermal material for concentrating applications

This section will provide a general overview on materials which are nowadays commonly used and such materials that show great potential to be used in the near future. Since the focus will be on concentrating solar collectors, materials are divided into the following groups: “transparent and semi-transparent”, “reflective”, “absorptive materials” and “coatings”.

2.1. Transparent and Semi-Transparent

Transparent and semi-transparent materials are mainly used as covers for protection and heat loss reduction. Doubtlessly, such covers come at the cost of a lower optical efficiency, which makes it even more important to model this part of the collector adequately.

At this point, the most employed material for covers is solar/optical glass, which is made of borosilicate with a low content of iron. One conventional example for such glass is the Schott BK-7 type (Schott, 2014). But there are also more innovative approaches to give glass more favorable properties for the use in solar applications, such as introducing gas bubbles to reduce the thermal conductivity and increase the transmittance (Cai et al., 2016).

While for a long time solar glass was the only choice for solar covers it has become more popular recently to employ semi-transparent polymeric materials. The advantages are manifold: low costs, less weight and almost no restrictions on the design. When it comes to essential optical properties such as the transmittance, polymers perform still poor in comparison to glass. However, due to its good mechanical properties polymer covers can be made extremely thin, which makes this drawback less significant. A good example for such an application is the parabolic trough collector (PTC) prototype of (Bader et al., 2011), which has a pressurized chamber with an ETFE-membrane as top-cover.

(French et al., 2011) and (Köhl et al., 2012) give an overview of polymeric materials which are promising for the use in solar thermal applications (ST). Some of them are:

- Fluoropolymers: ETFE, FEP
- Ethylene backbone polymers: PV1400 EVA
- Polyimides: Kapton H

2.2. Reflective

Reflective material is used for mirrors. To be interesting for the use in concentrating solar collectors, they need to be stable, stretch- and soil-resistant, durable and highly reflective in the wavelength range of the solar spectrum. Three types of mirrors are commercially available:

Glass mirrors

Glass mirrors are the most used type of mirrors. They usually have a 4mm thick solar glass layer with a thin reflective silver layer beneath. A paint layer protects the silver from environmental impacts such as corrosion. This type of mirror is very resistant and durable but rather expensive and heavy. Moreover, the 4 mm glass substrate reduces the mirror's reflectance. To improve optical performance there are versions with a 1mm thick substrate, which, however, comes at the cost of reduced rigidity. An additional metal sheet on the back side of this mirror can compensate this loss.

Polymer mirrors

This type of mirror comes as a thin foil. The core part of the mirror is a reflective silver or aluminum layer protected by a copper layer at the backside. Finally, a thin polymer film at the front and the back side further protects the metal stack from environmental impacts. Polymer mirrors are extremely light, flexible and cheap, but also less durable and resistant than glass mirrors. For the parabolic trough collector in (Bader et al., 2011) MyLar polymer mirrors are used.

Aluminum mirrors

Aluminum mirrors start from an anodized aluminum substrate that has either a pure aluminum or silver layer on top for reflection. To protect the reflection layer from corrosion and abrasion the mirror is also provided with a reflectance enhancing, protective coating. The advantage of aluminum mirrors is a comparably low weight at a still high rigidity. The overcoat of the mirror plays an important role for the optical performance and will be explained more in detail in the following.

2.3. Absorptive

Solar absorbers are mostly made of stainless steel, copper or ceramics (solar tower) or less common of polymeric material (pool collector or flat plate collector) (Köhl et al., 2012). The substrate of the absorber has to guarantee a high heat transfer coefficient. The most important part of the absorber is, however, its selective overcoat. This one should show high absorption in the short wavelength region (UV-Vis region), but low absorption/emission in the long wavelength region (Infra-red thermal radiation (IR)). According to Kirchhoff's law, a low absorption is equivalent to a low emission, which allows making use of most of energy of the incident radiation. The other main requirements to a selective coating are thermal stability at the operating range, good adhesion to the absorber substrate and resistance to corrosion. In fact, commercially available coatings are only designed for a specific temperature range (Selvakumar and Barshilia, 2012).

2.4. Coatings

As already mentioned in the previous sections, coatings or thin-films are single or multi-layers placed on top of a substrate with the purpose of giving a material certain optical properties. Today's processing methods allow designing coatings with a high degree of accuracy which give a lot of freedom for property design. Their importance for solar thermal technologies is paramount. In fact, nowadays coatings are employed in basically all parts of a solar thermal collector: Absorbers have a selective overcoat to allow better exploitation of energy of the incident solar spectrum; anti-reflective layers on covers reduce their reflectance and simultaneously enhance transmittance while mirrors have a high-reflectance coating to improve reflectance further sometimes to an even higher extent than the pure metal and at the same time protect the reflective layer.

Anti-reflectance and high-reflectance coating

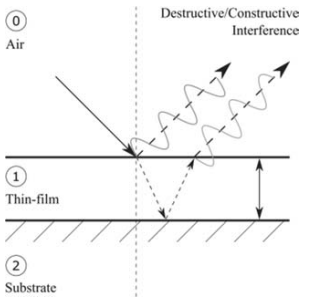

Fig. 1. Single layered optical coating: Controlled destructive or constructive interference by multiple reflections.

While anti-reflectance (AR) coatings are applied to reduce surface reflectance and enhance transmittance of covers such as e.g. the envelope of a PTC, high-reflectance (HR) coatings try to achieve exactly the contrary and are used on mirrors. Even though the effect of both coatings is exactly the opposite, their underlying principle is the same. These coatings consist of one or multiple layers. As an electromagnetic wave is propagating through the thin-film assembly it is partially reflected at the layer interfaces according to Fresnel's equations (Eq. 2). Given a specific refractive index for each layer, their thickness can be adjusted for a specific wavelength such that interference of the reflected light is either destructive (AR coating) or constructive (HR coating), as illustrated in Fig. 1. The resulting overall reflectance of the stack is then low or high. Absorption within the thin-film assembly is not desired which is why they consist of dielectrics.

The simplest version of an AR coating is a single MgF_2 of the thickness of a quarter of the target wavelength. When constructing a single HR layer on a metal surface it has to be taken into account that the substrate material has a complex refractive index (Macleod, 2010).

Coatings only perform well at the range around the wavelength and incidence angle they were designed for. In order to enable broadband AR or HR behavior for a coating, it is common practice to use multiple quarter-wavelength layers of alternating low (L) and high (H) refractive indices. In this sense, LHL…LHL would form an anti-reflective and HLH…HLH a highly-reflective structure. Commonly used dielectric materials are: MgF_2, SiO_2, TiO_2 (Choi et al., 2014; Jeong et al., 2004; Sutter et al., 2012), HfO_2, Si_3N_4, Al_2O_3 or ZnO (Macleod, 2010; Mazur et al., 2015).

Other increasingly popular low-refractive materials are sol-gels. The sol-gel process allows manufacturing porous layers with an almost tailor-designed refractive index (Atkinson et al., 2015; Prado et al., 2010; Sutter et al., 2010; Xin et al., 2013).

Selective coating

Selective coatings show low reflectance in the short wavelength range and high reflectance (low emission) in the long wavelength range. Most coatings incorporate metal which functions as an infra-red reflector, while the dielectric matrix substrate mainly absorbs in the UV-Vis spectrum. It can be distinguished between four types basic of selective surfaces: Intrinsic, metal-semiconductor tandem, metal-dielectric composite (e.g. cermets) or textured surfaces (Atkinson et al., 2015; Selvakumar and Barshilia, 2012; Soum-Glaude et al., 2013). To reduce reflection losses, selective coatings often also have an AR coating on top. The principle of textured surfaces differs from the other methods in such a way that short wavelength radiation is "trapped" in a complex structure and finally absorbed after multiple reflections (see Fig. 2).

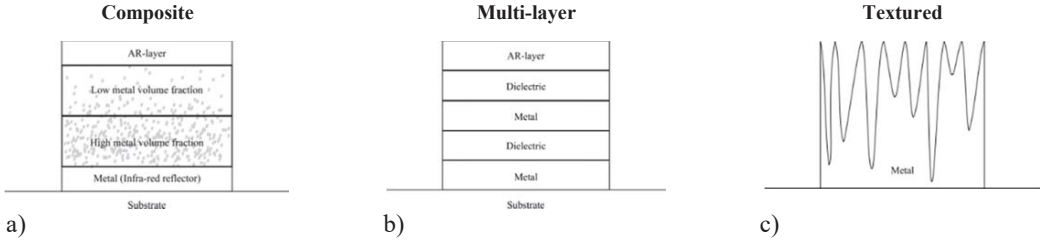

Fig. 2. Structures of selective coatings: a) dielectric-metal-composites b) dielectric-metal multi-layers c) textured surface.

The most widely used concepts nowadays are the composites or dielectric-metal multi-layers (Selvakumar and Barshilia, 2012). Selective coatings are designed for a narrow operation range. High temperature coatings are often based on Al_2O_3 as dielectric due to its high thermal resistance. Other dielectric matrix materials are: AlN, SiO and MgO (Selvakumar and Barshilia, 2012). Also possible for high-temperature resistant selective coatings is the assembly of the metallic-like TiAlN with the semiconductor TiAlON on top of a metallic IR reflective layer or directly on the substrate (An et al., 2015; Barshilia et al., 2008; Rebouta et al., 2012) or composites of $MoSi_2$ (conductor) and Si_3N_4 (dielectric)(Hernández-Pinilla et al., 2016).

Anti-soiling coating (AS)

Another positive effect of coatings is to make materials more resistant against soiling. In this light, TiO2 needs to be highlighted as a dielectric material with a couple of additional favorable properties. Not only does TiO_2 show high scratch resistance, its photocatalytic properties accelerate the decomposition of organic particles, which leads to a self-cleaning effect (Atkinson et al., 2015; Mazur et al., 2015).

3. Optical models for solar materials

After having summarized some of the most important materials and new structural concepts that are employed in concentrating solar collector nowadays, we will discuss some of the optical models in order to simulate material response on incident radiation. It will be distinguished between surface, volume and thin-film (coating) effects.

The propagation of an electromagnetic wave (radiation) through a medium is described by the Maxwell equations and the Lorentz force law. Where complex optical devices are used and results with a high degree of accuracy are needed, it is necessary to employ computational methods to solve these equations. However, if the properties of a medium are approximately constant and its dimensions are several times larger than the considered wavelength, the wave front can be represented by rays (geometrical optics). As a ray is passing through a solar thermal collector and interacting with different materials the finally absorbed energy is subject to a complex coupling of different physical correlations. The overall optical performance of a collector is then best approached by tracing an arbitrary number of rays separately according to the Monte Carlo method until the result is statistically stable. This is the principle description of how ray tracing work, the most commonly applied method for simulation of solar concentrating collectors.

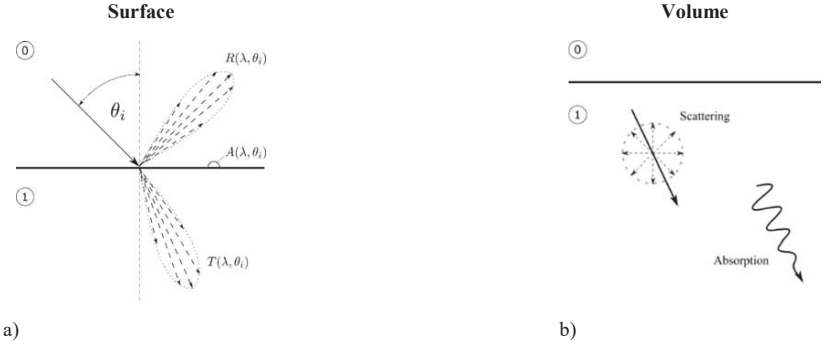

Fig. 3. Radiation-matter-interaction phenomena: a) Reflection, transmission and absorption on surfaces. b) Scattering and absorption within volume.

3.1. Surface effects:

In ray tracing, when a ray hits a surface there are only three possible ways it can interact with it. It can be either reflected, transmitted or absorbed (Fig. 3). According to the law of energy conservation all fractions over the incident energy add up to 1.

$$R(\theta_i, \lambda) + T(\theta_i, \lambda) + A(\theta_i, \lambda) = 1 \tag{1}$$

All coefficients depend on the wavelength, the incidence angle and the polarization of the incident light. Making some approximations regarding Eq. 1, helps to group the previously presented materials into different categories according to their surface type. Fig. 4 illustrates these categories. It is valid to assume zero transmission for absorptive and reflective materials such as receivers and mirrors. On the other hand, transparent materials like covers can be assumed to have zero absorption, since even if they are coated they only employ dielectric materials. This only goes for the surface itself. In the volume there will be absorption. The main advantage of this simplification is that a material is optically fully characterized when determining its reflectance beside its scattering properties, which will also be discussed.

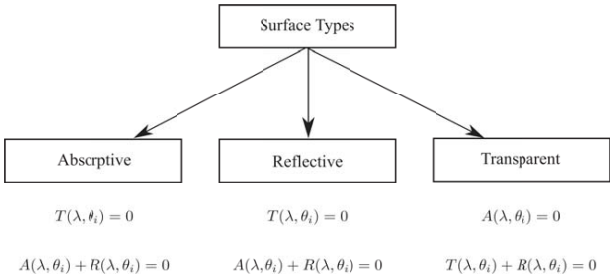

Fig. 4. Classification of typical solar thermal material: absorptive material (receiver), reflective material (mirrors) and transparent material (covers, envelopes)

Reflectance - $R(\theta_i, \lambda)$

One solution of Eq. 11 is given by the Fresnel equations, which result from the boundary condition of a balance of the electric and magnetic fields across the surface. The Fresnel equations therefore present a solution of the simplified Maxwell equations (Macleod, 2010).

$$R = \left(\frac{\eta_0 - \eta_1}{\eta_0 + \eta_1}\right)\left(\frac{\eta_0 - \eta_1}{\eta_0 + \eta_1}\right)^* \tag{2}$$

$$T = \frac{4\eta_0 Re(\eta_1)}{(\eta_0 + \eta_1)(\eta_0 + \eta_1)^*} \tag{3}$$

η is the optical admittance of the material and depends on the polarization of the incident light. It is also common to use a modified "tilted" version of the optical admittance that also incorporates the angle of propagation θ of the particular medium.

$$\eta_i = \begin{cases} \dfrac{N_i \cos\theta_i}{Z_0} & \text{, for s-polarization (TE)} \\ \dfrac{N_i}{Z_0 \cos\theta_i} & \text{, for p-polarization (TM)} \end{cases} \tag{4}$$

with Z_0 the optical impedance of free space. TE refers to a plane wave with the electric field vector perpendicular to the plane of incidence and TM with the magnetic field vector perpendicular to the plane of incidence.

$$Z_0 = \sqrt{\frac{\mu_0}{\varepsilon_0}} \tag{5}$$

And N the complex refractive index

$$N = n + i\kappa \tag{6}$$

It should be noted that the refractive index can be complex as is the case for non-dielectric matter such as metals. This becomes important for the analysis of mirrors. The refractive index and the angle of incidence are also the only non-Natural constants and hence fully describe the reflectance at an interface.

The angle of propagation of each medium θ_i is related to the angle of incidence θ_0 by Snell's law:

$$n_0 \sin\theta_0 = n_i \sin\theta_i \tag{7}$$

In the case of dielectric materials ($\kappa \neq 0$) Schlick proposed an approximation of the incidence angle dependence of the reflectance given by Eq. 2 (Schlick, 1994). Schlick's alternative equation is computationally less expensive.

$$R(\theta) = R_0 + (1 - R_0)(1 - \cos\theta)^5 \tag{8}$$

Scattering

Beside de Fresnel effect, scattering is another important phenomenon of radiation-matter interaction on a surface. While the former is the result of an energetic balance, the latter is instead due to surface texture. The microscopically random surface structure has influence on the direction of the reflected photon and disperses the energy flux spatially (see Fig. 5).

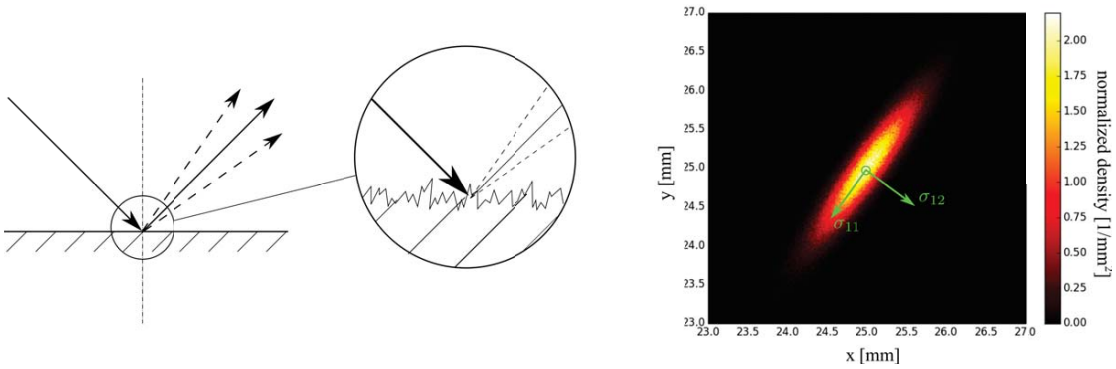

Fig. 5. Microscopic surface errors lead to narrow-angle dispersion of specular reflection (left). Right: reflection pattern on target. Due to systematic errors brought into by e.g. processing methods of the material, dispersion can have a preferred direction.

In general, it can be distinguished between two ideal cases of reflection: isotropic reflection (maximum dispersion) and specular reflection (no dispersion). In reality, the reflection pattern is a combination of both cases and is described by a bidirectional reflectance distribution function (BRDF). Many different BRDFs have been proposed to meet the variety of many different surface types (Montes and Ureña, 2012).

From the perspective of Monte Carlo ray tracing, it is necessary to express the direction of reflection in terms of probabilities. Isotropic or Lambertian reflection in this regard is the simplest case, since the probability for each reflection direction on the surface hemisphere is the same. This is the case for highly rough or matte surfaces.

Most of BRDF models are based on a Gaussian distribution. Especially when it comes to modelling the specular reflection of mirrors for solar thermal collectors, this is a well-established probability function (Gee et al., 2010; Good et al., 2016; Pettit, 1977; Sutter et al., 2016).

$$f = Ke^{\left(-\frac{\varphi^2}{2\sigma_{21}^2} - \frac{\varphi^2}{2\sigma_{22}^2}\right)} + (1 - K)e^{\left(-\frac{\varphi^2}{2\sigma_{11}^2} - \frac{\varphi^2}{2\sigma_{12}^2}\right)} \tag{9}$$

Eq. 9 essentially incorporates four basic forms of Gaussian specular reflection (Gee et al., 2010):

- Single univariate ($K = 0, \sigma_{11} = \sigma_{12}$)

- Single bivariate ($K = 0, \sigma_{11} \neq \sigma_{12}$)
- Double univariate ($K \neq 0, \sigma_{11} = \sigma_{12}$, $\sigma_{21} = \sigma_{22}$)
- Double bivariate ($K \neq 0, \sigma_{11} \neq \sigma_{12}, \ \sigma_{21} \neq \sigma_{22}$)

The multivariate Gaussian function accounts for a preferred reflection direction, which in reality appears on reflective material. It is caused by the respective processing method, so for example the rolling process in the manufacturing of aluminum mirrors. The superposition of two Gaussian distributions better represents the combined effect of microscopic and macroscopic surface errors. In practice, as long as macroscopic errors (slope, shape, alignment, tracking) are considered random, they are all summed up to a total surface variety σ_{tot} (Rabl, 1985).

$$\sigma_{tot}^2 = \sum_{i=1}^{n} \sigma_i^2 = \sigma_{spec}^2 + 4\sigma_{slope}^2 + 4\sigma_{shape}^2 + 4\sigma_{align}^2 + 4\sigma_{track}^2 \tag{10}$$

It is important to state that the dispersion itself depends on the wavelength and the angle of incident light as well ($\sigma = \sigma(\lambda, \theta)$). This dependency significantly depends on the material type (Good et al., 2016; Sutter et al., 2016). Since there is still no standardized experimental method for the complete spectral assessment of specular material (SolarPACES, 2013), little can be found on wavelength and incidence angle dependency of σ. One relation is the power law that can be derived from (Good et al., 2016) is given by Eq. 11.

$$\sigma(\lambda, \theta) = \sigma\left(\lambda_{ref}, \theta_{ref}\right) \cdot \left(\frac{\lambda}{\lambda_{ref}}\right)^{p} \cdot \left(\frac{\cos\theta}{\cos\theta_{ref}}\right)^{q} \tag{11}$$

3.2. Volume effects:

When an electromagnetic wave is propagating through a medium it will experience both scattering and absorption (Fig. 3). Scattering can be important if the medium contains particles or inclusions as for example in the case of (Cai et al., 2016). Volume scattering can also play an important role in polymeric material (French et al., 2011) or atmospheric calculations such as for solar tower applications. If the medium is mainly homogeneous, however, volume scattering in comparison to surface scattering is rather small and absorption will have most influence on the radiation intensity (Wallner et al., 2005).

The absorption coefficient α is correlated with the extinction coefficient κ – the complex part of the refractive index of a material (Eq. 6).

$$\alpha(\lambda) = \frac{4\pi\kappa}{\lambda} \tag{12}$$

A rough relation between a material's absorbance and the wavelength can be obtained by an exponential Urbach fit. However, this approximation is not accurate in all cases (French et al., 2011).

In order to get from experimental data to usable input for ray tracing, one challenge is to separate between volume and surface effects, as in reality they can only be measured together. This was also pointed out by the work of (Good et al., 2016) and (Wallner et al., 2005).

3.3. Thin-film effects (coatings):

The most common approach to model the reflectance, transmittance and absorptance of a thin-film assembly (coating) is the transfer-matrix method (TMM). Within a layer the electric and magnetic field is the sum of the total forwards and backwards (reflected) waves propagating according to a phase factor. This assumption is described by M_p, the characteristic matrix of a thin-film. Since the continuity condition of the electric and magnetic field across the boundary of the layer p and its adjacent layer is also applies here, the characteristic matrices can be multiplied. Theoretically, this can be done for an infinite number of layers. The result correlates the electric and magnetic field on top and at the bottom of the assembly (see Eq. 13) (Macleod,

2010).

$$\begin{pmatrix} B \\ C \end{pmatrix} = \left\{ \prod_{p=1}^{q} \underbrace{\begin{bmatrix} \cos\varphi_p & (i\sin\varphi_p)/\eta_p \\ i\eta_p \sin\varphi_p & \cos\varphi_p \end{bmatrix}}_{M_p} \right\} \begin{pmatrix} 1 \\ \eta_q \end{pmatrix} \tag{13}$$

with the phase factor φ_i (Eq. 14), the number of layers q (including the substrate) and the optical admittance of the substrate η_q

$$\varphi_i = \frac{2\pi N_i d_i \cos\theta_i}{\lambda} \tag{14}$$

From Eq. 13 an optical admittance of the assembly can be derived.

$$Y = C/B \tag{15}$$

And in the same way as done for the Fresnel equations, the reflectance, transmittance and absorptance of the stack can be calculated.

$$R = \left(\frac{\eta_0 - Y}{\eta_0 + Y}\right)\left(\frac{\eta_0 - Y}{\eta_0 + Y}\right)^* \tag{16}$$

η_0 is the optical admittance of the incidence medium.

$$T = \frac{Re(\eta_q)(1-R)}{Re(BC^*)} \tag{17}$$

$$A = 1 - R - T \tag{18}$$

The transmittance of the assembly is always independent of the direction of the propagation (propagation from the incidence medium to the substrate or from the substrate to the incidence medium (Abelés, 1950)). For the reflectance, however, this is only the case if there is no absorption in any of the layers (only dielectric material), which is usually satisfied for AR coatings, since here absorption is not desired.

Eqs. 13 to 18 present the basis for all thin-film performance simulations and design.

AR/HR coatings

There are many ways to design AR and HR coatings. One possibility is to make them out of multiple quarter wavelength layers. In this case the quarter wavelength condition $\varphi = \pi/2$ has to be satisfied for each layer, so that

$$d_p = \frac{\lambda}{4n\cos\theta_p} \tag{19}$$

and with a successively increasing refractive index according to

$$N_p = \sqrt[p+1]{\frac{n_0}{n_{sub}}} \tag{20}$$

It is however more common, in practice, to use layers with alternating refractive indices. Some examples for the analytical assessment of such layers are (Choi et al., 2014; Mazur et al., 2015; Sahouane and Zerga, 2014) for ST and (Saylan et al., 2015; Sikder and Zaman, 2016) for PV applications.

Especially for single layer AR coatings low refractive material are needed. Promising here are porous sol-gels, because the refractive index is related to the porosity (Prado et al., 2010; Xin et al., 2013).

$$n_p = [(1-p)(n^2-1)+1]^{1/2} \tag{21}$$

where p is the porosity volume fraction and n the refractive index of the base material.

Selective coatings

As described in the previous section, selective coatings are often based on dielectric-metal composites. Eqs. 13 to 18 are only valid for layers with homogeneous properties. It is therefore necessary to approximate the effective refractive index of the composite from the refractive indices of the base materials. This can be done by the Maxwell-Garnett relation.

$$\frac{\varepsilon_{eff} - \varepsilon_m}{L(\varepsilon_{eff} - \varepsilon_m) + \varepsilon_m} = f \cdot \frac{\varepsilon_i - \varepsilon_m}{L(\varepsilon_i - \varepsilon_m) + \varepsilon_m} \tag{22}$$

with the dielectric constants ε_m of the matrix, ε_i of the inclusions and ε_{eff} of the composite. f is the volume fraction of inclusion and matrix and L the depolarization factor.

Some examples for the analytical analysis and design of high-temperature resistant selective thin-film assemblies using the previously described transfer matrix method are (An et al., 2015; Cardenas, 2015; Hernández-Pinilla et al., 2016; Rebouta et al., 2012; Soum-Glaude et al., 2013; Yang et al., 2016).

Particularly interesting for ray tracing applications is the approach of (Tesfamichael and Wäckelgård, 2000) and (Grena, 2010). In their studies they tried to describe the absorptance (reflectance) of a selective solar receiver as a function of the angle of incidence only. Tesfamichael et al. proposed a modified version of the incidence angle modifier law for solar thermal applications (Duffie and Beckmann, 2006)

$$\alpha_{SW}(\theta_i) = \alpha_{SW}(\theta_0) \cdot b_0 \left(\frac{1}{\cos\theta_i} - 1\right)^c \tag{23}$$

Where $\alpha_{SW}(\theta_0)$ is the absorption coefficient at normal incidence.

$$\alpha_{SW}(\theta_0) = \frac{\int_0^\infty s(\lambda) \cdot \alpha(\lambda, \theta_0)\, d\lambda}{\int_0^\infty s(\lambda)\, d\lambda} \tag{24}$$

This model is able to describe different selective surfaces by adjusting the characteristic parameters b_0 and c. Unfortunately, the only available results are those provided by the authors themselves, which were those measured for a Al_2O_3-Ni/Al_2O_3 assembly and a NiO_3-Ni-composite layer.

(Grena, 2010), on the other hand, defines a more general power law based on experimental data from different selective absorption material.

$$\alpha_{SW}(\theta_i) = \alpha_{SW}(\theta_0) \cdot \left[1 - \left(\frac{2\theta}{\pi}\right)^8\right] \tag{25}$$

4. Discussion and Outlook

During the last decades significant progress has been experienced in the development of new materials and collector designs. Especially coatings have gained in importance for the use in solar thermal collector technologies due to more sophisticated processing methods and the possibility of application specific design, but also the increasing success of PV and PVT technologies make great demands on optical simulations.

In this study two major goals have been achieved: First, the current market of materials for solar thermal applications was reviewed; and second, the most commonly used optical models for radiation-matter interaction were summarized.

The outcome of this study could be particularly interesting for implementations of ray tracing optical simulation tools. It could be shown that most ray tracing programs do not consider the option of a more accurate spectral analysis. Whether such an analysis is necessary, might depend on the types of material that are employed. Glass mirrors e.g. do not show very strong variations of scattering with the wavelength, but aluminum and polymer mirrors do. It is also noticed that there is a lack of models that reflect incidence angle dependencies, most of all for selective surfaces.

The radiation-matter interaction models that were presented are a summary of what can be found in current

literature. A key parameter to optically define materials is their refractive index. There are extensive data bases that contain refractive information based on ellipsometry and dispersion relations for many different materials. Such data bases could provide valuable input to optical simulations. Nevertheless, a general problem one faces when trying to get from experimental data to usable input for ray tracing e.g., is to separate between volume and surface effects. This might be important in order to model compounds such as e.g. glass mirrors.

Experimental and CFD investigations on full volumetric flow to a solar flat-plate glass collector

Pascal Leibbrandt, Thomas Schabbach, Michael Dölz, Martin Rhein

Institut für Regenerative Energietechnik, University of Applied Sciences Nordhausen (Germany)

Summary

In the project solar flat-plate glass collector, a new type of solar collector will be developed which, simplified, consists of 4 glass plates. As subgoal of the project the full volumetric flow and heat transfer in the fluid layer and the collector filling have been examined experimentally and numerically. The experimental setup and the CFD settings are presented. By comparison of experimental data and CFD results the simulation results were checked. It appeared that the CFD simulations are able to model the flow well, so an optimization of the flow and heat transfer in the layer can be carried out numerically.

Keywords: glass collector, fluid distribution, CFD, validation, filling process

1. Collector construction and function

In context of the research project "Nurglassolarflachkollektor" a collector with lower production costs will be developed, which consists primarily of glass. Due to the simplified construction cost intensive production steps such as the absorber welding will be unnecessary and enable an automated production process with fewer production steps. Manufacturing costs can thus be reduced by approximately 20% compared to conventional standard flat-plate collectors. Another advantage is the reduced collector height of <50 mm, which allows a simplified installation and collector field connection, so that other application areas (especially in facade) can be opened up.

The glass collector consists of four planar glass plates, which are glued and sealed by a frame and a fluid layer structure. As shown in Fig. 1 the heat transfer medium passes directly through the middle rectangular disk-space. The coatings on the glasses ensure optimal radiation absorption in the fluid layer and minimize the radiation losses due to reflection and emission, see also Leibbrandt et al. (2014). Insulating gas layers minimize convective heat losses to the front and back. As also shown in Fig.1, the heat transfer fluid has to be distributed full volumetric from the circular collector connection through the flow channel. Without adequate installations in the fluid layer a short-circuit flow would be the follow. The fluid layer structure should also be able to absorb inner/outer forces from/to the fluid layer.

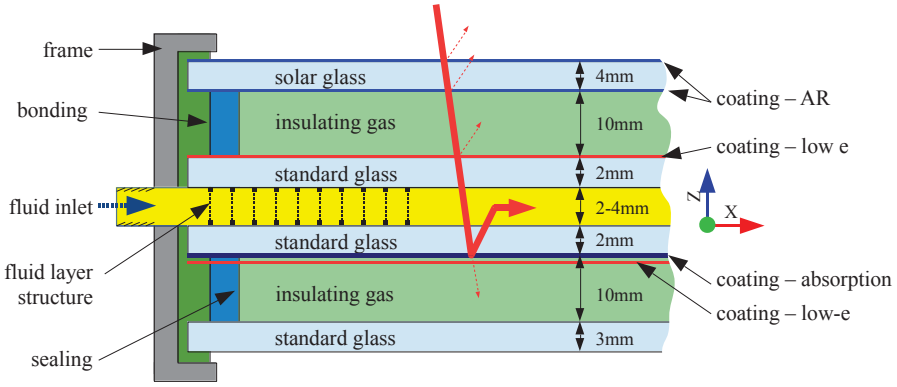

Fig. 1: Construction of the glass collector

Beside the presented problem of the fluid layer flow also the flow in the insulating gas layer, see Leibbrandt et al. (2016) and structural mechanical questions about the glass loads (Rhein et al. (2016)) are investigated in the project. With a specially developed collector test rig collector prototypes are investigated parallel to the project (see Dölz et al. (2016)).

doi:10.18086/eurosun.2016.07.02 Available at http://proceedings.ises.org

2. Full volumetric flow and heat transfer

The flow in the fluid layer should be optimized so that the absorbed radiation energy is transported ideally from the absorption layer to the heat carrier fluid. The collector efficiency factor is:

$$F' = \frac{U_{int}}{U_{int} + U_{loss}} \qquad \text{(eq. 1)}$$

U_{int} is the internal heat transfer coefficient, which describes just the forced convection in the fluid layer here, U_{loss} describes the overall heat transfer losses of the whole collector. So, F' is the theoretical ratio of the useful energy gain to the useful gain that would result if the absorbing surface would be at the fluid temperature, Duffie Beckman (2013). The collector efficiency factor is at its maximum if the flow would be full volumetric. For flat-plate collectors with a fin width of 90-120 mm, the collector efficiency factor is about 88-94%, Wesselak et al. (2013). The heat transfer is at its maximum when the flow is fully homogeneous (without flow areas with no/low flow velocity) and turbulent.

At the same time the pressure drop and the filling/drainback performance must be ensured for a potentially drainback system application.

The rectangular flow channel has a length L, a width B and a thickness of s_F (see Fig. 2). For the analysis presented here the collector size is LxB = 2000x1000 mm, the fluid layer thickness s_F varies between 2 and 10 mm. The fluid layer is inclined at an angle φ against the horizontal.

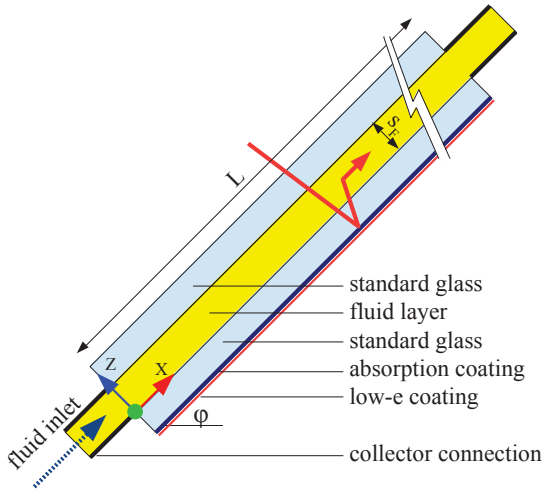

Fig. 2: Problem definition

Starting from a circular collector connection the heat transfer fluid should be distributed ideally. The flow velocity $\overrightarrow{u_i}$ at any point i of the fluid layer field consists of the flow velocity components u_i, v_i and w_i - see Fig. 3(a).

$$\overrightarrow{u_i} = \begin{pmatrix} u_i(x,y,z) \\ v_i(x,y,z) \\ w_i(x,y,z) \end{pmatrix} \qquad \text{(eq. 2)}$$

In case of homogeneous flow, the flow velocity $\overrightarrow{u_{i,opt}}$ is the same at all points of the fluid layer and consists only of velocity components in the main flow direction - see Fig. 3(b).

$$\overrightarrow{u_{i,opt}} = \begin{pmatrix} u_i(x) \\ 0 \\ 0 \end{pmatrix} \qquad \text{(eq. 3)}$$

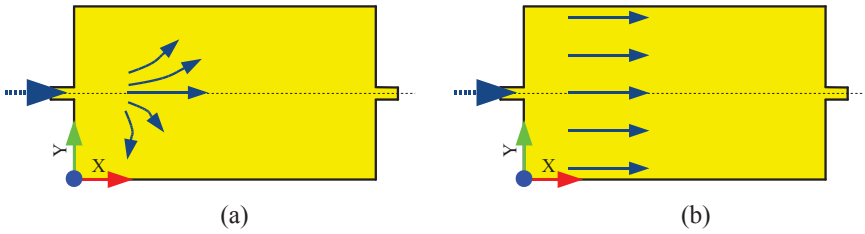

Fig. 3: Flow types in the fluid layer

For the experimental investigation of the flow behavior in the fluid layer 2 glasses in size of 2000x1000x4 mm each were glued and sealed with a 10 mm aluminum spacer in between. Later, the fluid film thickness will be reduced to up to 2-4 mm. For stabilization of the fluid layer the glasses were fixed with mounting rails in the experimental setup – see Fig. 4.

For volume flow generation and pressure control a laboratory thermostat was used, so that the fluid temperature could be adjusted and kept constant. Volume flow rate, in-/outlet temperatures and the pressure drop were determined.

The fluid was enriched with particles before the collector inlet via an injector pipe to visualize the flow behavior. The particle selection was based on a number of preliminary tests. Based on practicality, slip behavior and density expanded glass granulate, ceramic microspheres, polyester plates and soda-lime glass balls were tested. The particles had to be able to reflect the incoming light well. They should be small enough to have no effect on the flow and ensure a slip-free behavior in contrast to the fluid. Also different lighting media, such as halogen spotlights, fluorescent lighting tubes and led were tested.

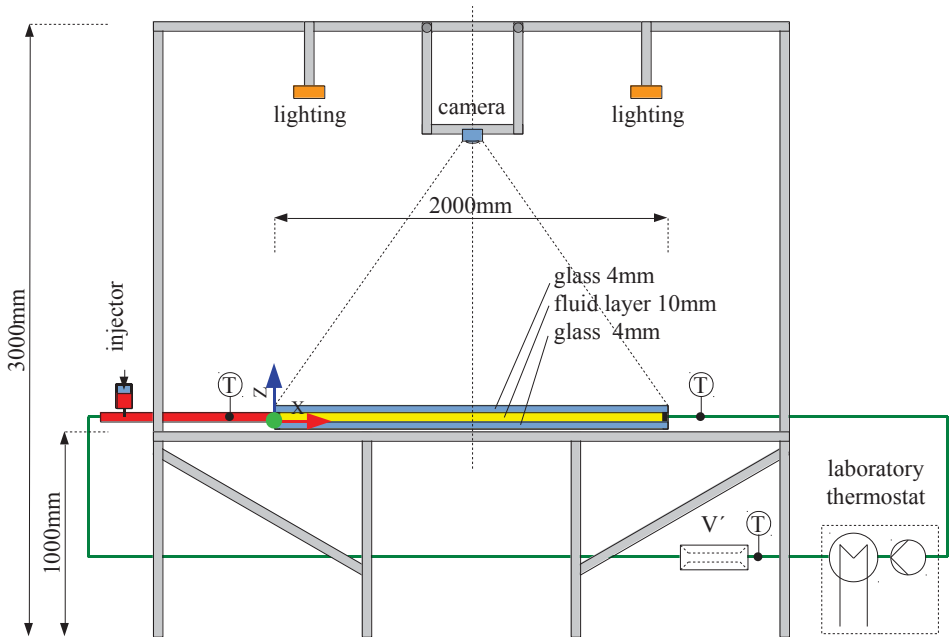

Fig. 4: Test setup full volumetric flow

The flow field was recorded with an HD-camera (50 frames/sec) from above. The generated single images were aligned, optimized and transferred to an image stack by using an image processing program. That image stack was transformed to a single image by subtraction, so it was possible to visualize the trail of the particles and to identify areas with low velocity. Ideally, the flow velocity should be identical in all points in the layer (see above).

So, three versions of different fluid layer structures (V00 - V02, see Fig. 5) were initially investigated experimentally. The inlet and outlet was located centrally on the short side of the fluid layer.

- In version V00 the fluid flows through the fluid layer without any internals.
- In version V01 the fluid is slowed right after the inlet with a central small barrier (width = 100 mm) and is so distributed sideways.
- Version V02 features a wide barrier (width = 900 mm) which directs the fluid to the long fluid layer wall.

Moreover, the experimental investigated versions V00 - V02 were simulated numerically using a simplified 2D CFD model. By preliminary investigations, the numerical discretization, the choice of flow and turbulence models and the admissibility of the 2D simplification ($z = 0$) were tested and validated. The boundary conditions were in all experimental analysis and simulations set identical to

$$\dot{V} = 140\,\frac{l}{h} \qquad p \approx 1\ bar \qquad T \approx 20°C.$$

As shown in Fig. 5, there is a good correlation between experimental and numerical data. In version V00 qualitatively similar flow swirls are identifiable. In versions V01 and V02 the distribution of the fluid to the edges agrees qualitatively in experiment and CFD results. Therefore, it can be assumed for additional versions that the CFD model provides sufficiently results and can be used to optimize the fluid distribution better than in the reference experiment V00. In addition, the option will be tested, to measure the velocity field locally with Prandtl tubes for example.

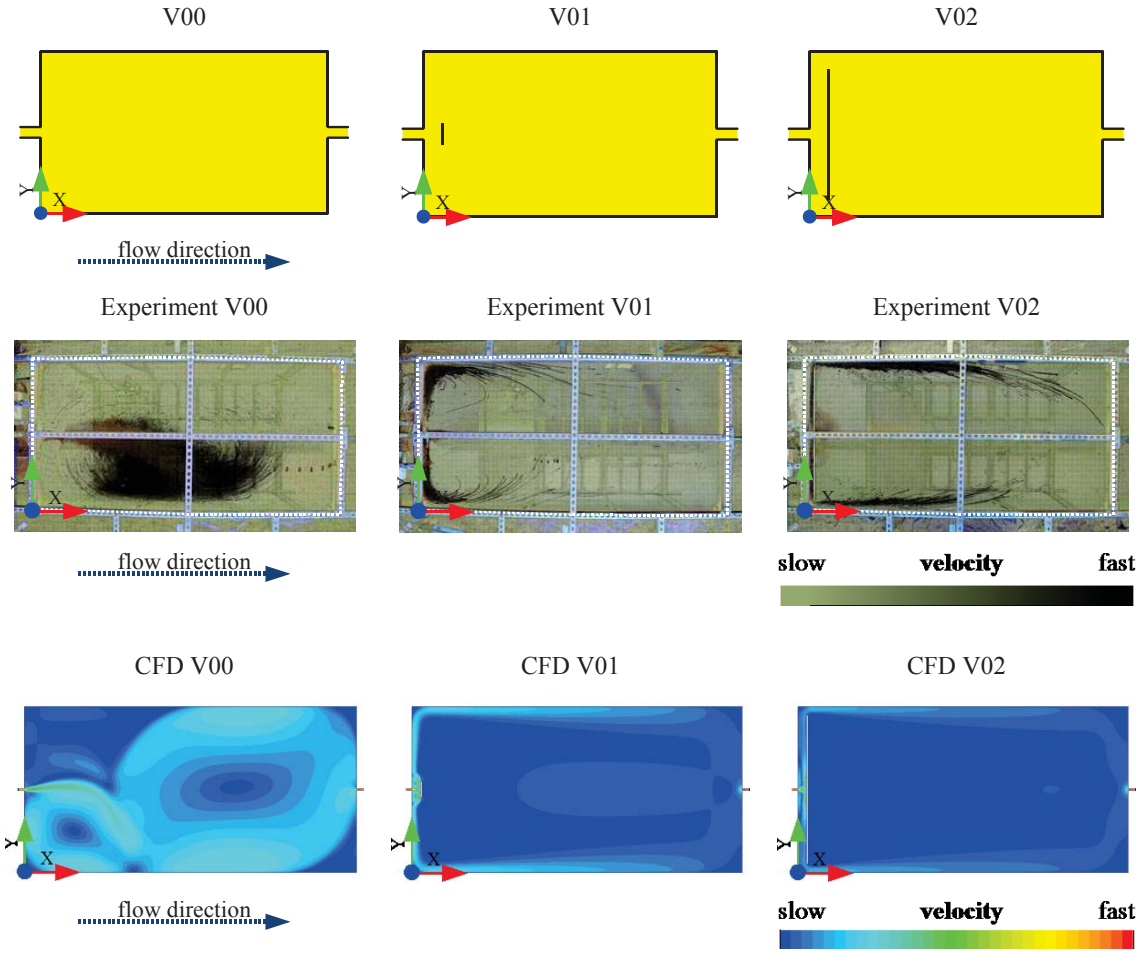

Fig. 5: Comparison of velocity distribution (middle: experiment, bottom: CFD)

After the qualitative validation of the CFD simulations additional fluid layer structures (V03-V08) were investigated numerically. So the optimization could be done more quickly. The experimental investigations took about 2-3 days per version, the simulation time was about a few hours per version.

The analysis of the homogeneity was carried out with the qualitative evaluation of flow visualization and the standard deviation of flow velocities u_i from the CFD simulations. It is:

$$std = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(u_i - \frac{1}{n}\sum_{i=1}^{n} u_i\right)^2} \qquad \text{(eq. 4)}$$

Also the pressure loss was read from the simulation data. In these 2D simulations, the pressure loss is determined over a reference layer thickness without any boundary layer influence. It is:

$$\Delta p = p_{inlet} - p_{outlet} \qquad \text{(eq. 5)}$$

For better overview these criteria are represented relative to the reference version V00.

Tab. 1: Velocity distribution, standard deviation and pressure loss V00 – V08

V00  std = 100% Δp = 100%	**V01**  std = 100,2% Δp = 102.3%	**V02**  std = 95.4% Δp = 101.6%
V03  std = 99.2% Δp = 104.1%	**V04**  std = 82.5% Δp = 124.3%	**V05**  std = 92.5% Δp = 101.0%
V06  std = 98.2% Δp = 105.0%	**V07**  std = 88.1% Δp = 106.7%	**V08**  std = 77.6% Δp = 159.6%

Results:

- V00, V03: In fluid channels with central inflow on the short collector side without fluid layer structures occur a flow expansion and thus a lowering of the average flow velocity. Generally, two flow swirls arise. The main flow direction tends thereby to a collector side, the other is barely flowed. For s_F = 2 mm and ideal distribution is Re = 78.
- V01, V02 and V05: In fluid channels with central inflow on the short collector side with fluid layer structures at the collector inlet a flow distribution to the long collector sides occurs. The fluid layer structures at the inlet are not able to distribute to the fluid over the whole collector length.

- V04, V06 – V08: In fluid channels with inflow on the short collector side with fluid layer structures the fluid is distributed optimally. From reasons of material saving, manufacturability and an ease of installation, fluid layer structures with lateral inlets (V06-V08) are appropriate preferable. The choice of the resultant channel width and geometry influence can be made regarding to flow homogeneity and thus to heat transfer. For s_F = 2 mm and good distribution (V08) is Re = 1213.

Also other structures have been tested so far, which are capable to distribute the heat transfer fluid quite well. As expected the pressure loss rises for more complex fluid layer structures. Especially in the versions V04, V06-V08 the fluid layer structure is able to connect the fluid layer glasses. The result is a sandwich structure which is able to carry internal and external loads from/to the fluid channel.

The CFD optimized fluid layer structures will be investigated experimentally in the further proceeding of the project. In addition, there are first collector prototypes under construction, which also will be tested on the collector test rig. This prototype studies will be supported by additional 3D CFD and FEM investigations with regard to the fluid distribution and the glass loads analysis.

After the optimization of the fluid layer structure, the influence on heat transfer was investigated. For this purpose, a 3D CFD model with the boundary conditions, as shown in Fig. 6, was used. The fluid layers' dimension was set to LxBxs_F = 2000x1000x10 mm. The inclination of the layer was 45°. For these simulations 3 fluid layer structures, similar to versions V00, V06 and V07 were analyzed. The backside of the fluid channel has been set up with a constant heat flow density $\dot{q}_{abs}$ which corresponds to the absorbed solar radiation power. At the front convective heat transfer with a constant heat transfer coefficient and fixed ambient temperature was assumed. In reality the convective heat transfer coefficient depends on the front side temperature. The edges of the fluid channel have been supposed to be adiabatic. The fluid inlet temperature was set to 20°C; the inlet velocity was varied between 0.25 – 1.00 m/s (35 – 140 l/(m² h)).

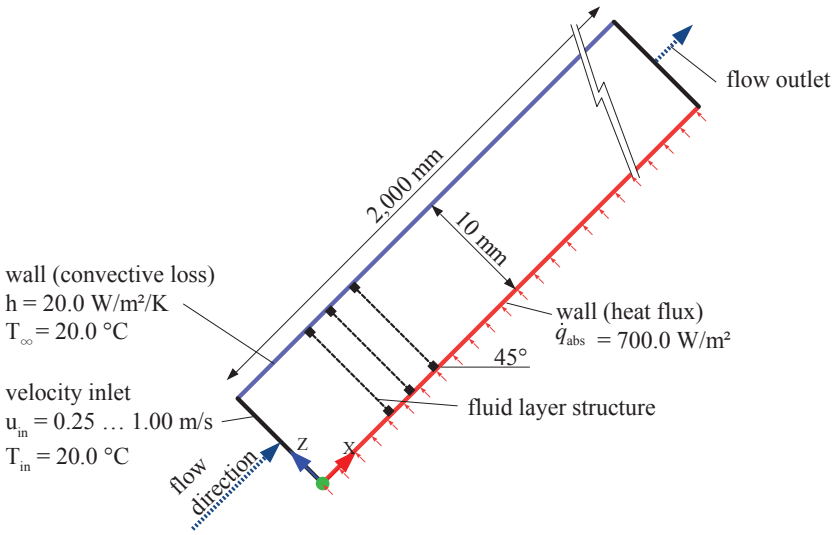

Fig. 6: CFD setup heat transfer

To rate the quality of the heat transfer through the fluid layer the useable enthalpy-flow $\dot{q}_{use}$ at the layer outlet was set into relation to mean fluid temperature difference. It is:

$$h_f = \frac{\dot{q}_{use}}{\overline{T_{abs}} - \overline{T_f}} \qquad \text{(eq. 6)}$$

To compare the collector efficiency factor of the fluid layer F_f' with standard flat-plate collectors it is assumed, that the overall loss heat transfer coefficient $U_{loss} = 4\ W/(m^2K)$. U_{loss} describes the collector heat losses over the sides and the back of the collector which are not part of the presented CFD simulations. The efficiency factor of the fluid layer F_f' is:

$$F_f' = \frac{h_f}{h_f + U_{loss}} \qquad \text{(eq. 7)}$$

Tab. 2: Influence of fluid layer structures on heat transfer (3D CFD results)

		u_{in} in m/s		
		0.25	0.50	1.00
fluid layer structure V00	$\dot{q}_{use}$ in W/m²	565.95	630.53	657.35
	h_f in W/m²/K	372.86	365.07	360.68
	$\boldsymbol{F_f'}$	**98.9%**	**98.9%**	**98.9%**
fluid layer structure V06	$\dot{q}_{use}$ in W/m²	558.99	628.45	658.76
	h_f in W/m²/K	337.87	327.60	405.85
	$\boldsymbol{F_f'}$	**98.8%**	**98.8%**	**99.0%**
fluid layer structure V07	$\dot{q}_{use}$ in W/m²	556.11	617.33	651.18
	h_f in W/m²/K	343.25	421.14	625.53
	$\boldsymbol{F_f'}$	**98.8%**	**99.1%**	**99.4%**

The temperature distribution is shown in Fig. 7. In the versions V06 and V07 a temperature inhomogeneity can be seen especially at the end of the individual fluid channels. They are formed due to the lower flow velocity and lead to local temperature maxima (hot spots). They should be minimized by a suitable flow guidance. At these hotspots the heat transfer reduces and high temperature gradients occur which also lead to stresses in the glasses.

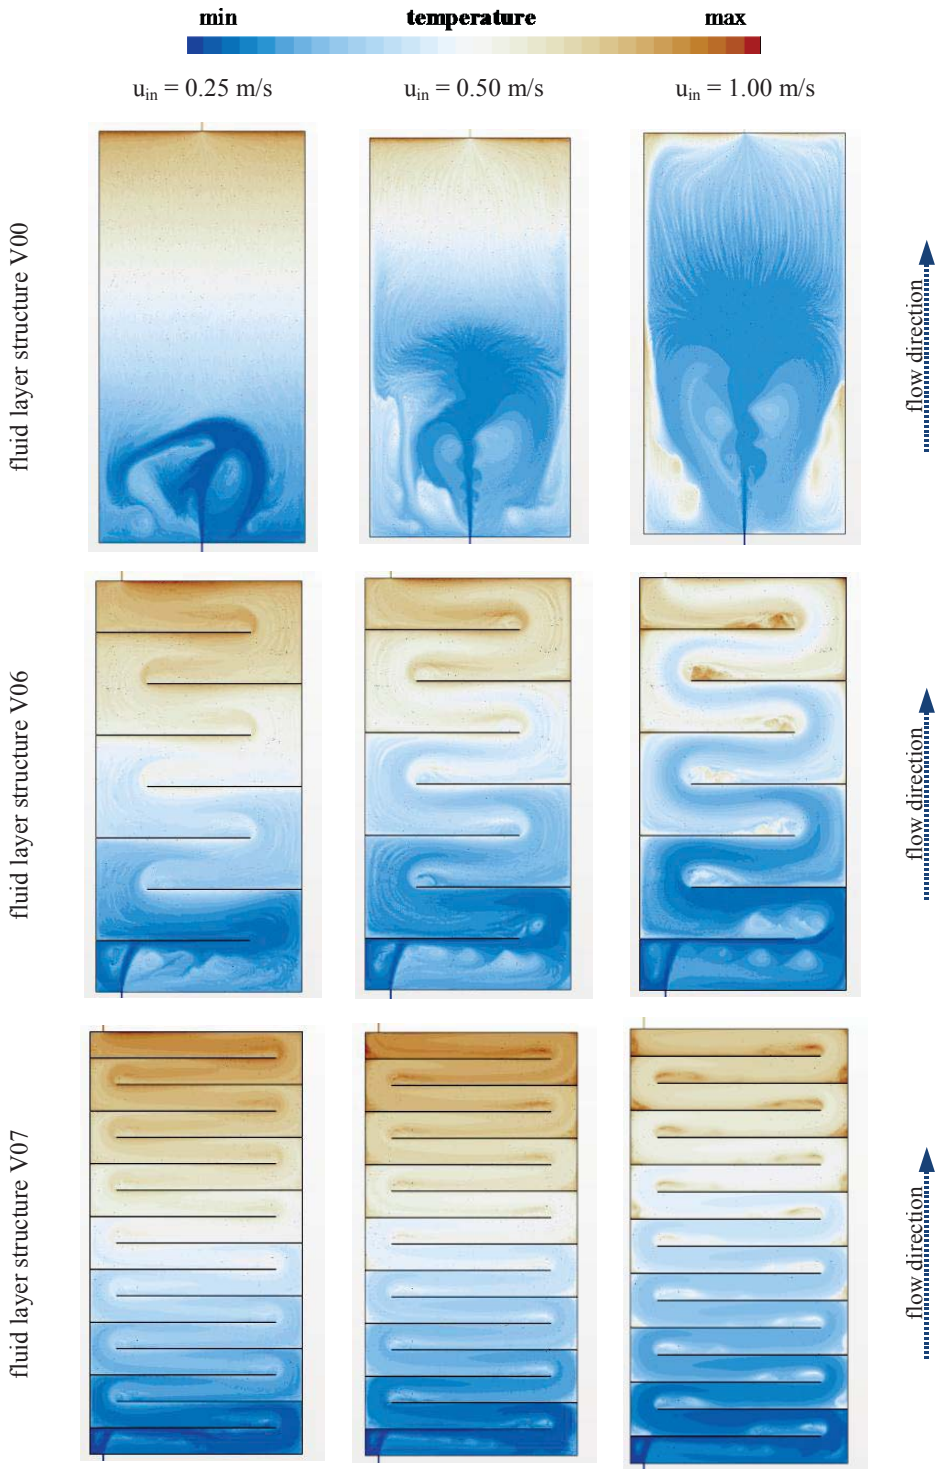

Fig. 7: Influence of fluid layer structures on temperature distribution (3D CFD results)

The versions with fluid channels as fluid layer structures lead to the best results for fluid distribution and heat transfer. This was shown by using experimental investigations and CFD simulations of the fluid layer.

These results are used as input quantities for experiments and FEM simulations to optimize structural behavior of the collector and are used as guidelines for first collector prototype design.

3. Collector filling

As mentioned above, the collector should also be suitable for a potential drain back use. The fluid layer structure should not only ensure a homogeneous flow and a good heat transfer but should also allow a fast and gas-free filling and completely emptying of the collector.

For first assessment the filling behavior was tested on a smaller version of the fluid layer with the measurement of $LxBxs_F$ = 500x250x10 mm. The fluid layer was confined with 4 mm single pane safety glass in the experiment. Target was an air-free filling in the least possible time. For this a simplified drainback system with open drainback reservoir, as shown in Fig. 8, was realized. A HD-camera gave the opportunity to have a detailed look to the fluid layer, detect gas bubbles and ascertain the filling time.

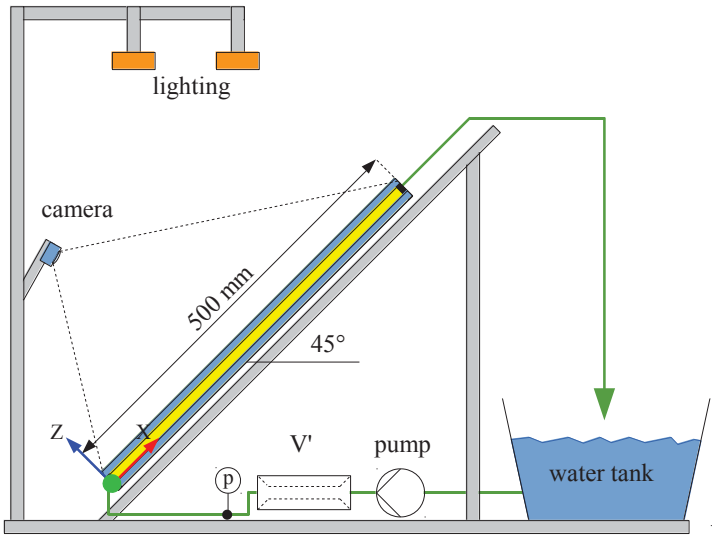

Fig. 8: Test setup collector filling

The lighting and contrast enhancement for better visualization of the bubbles were done with led spotlights and an all-around led belt on the glasses. The volume flow was generated with a pump after the drainback reservoir and was identified with an impeller counter.

The filling process is shown for different inlet velocities by single pictures in the interval of 10 seconds in Fig. 10.

- With the inlet velocity of u_{in} = 2 m/s the filling time was under 10 seconds. In addition to that, it is demonstrated, that a big amount of air bubbles is captured in the fluid layer. These air inclusions remain for several minutes in the collector. By internal flow rolls the air bubbles are circulated periodic in the fluid layer. Only by a short stop of the pump, the air bubbles can partially escape.
- With an inlet velocity of u_{in} = 1 m/s the filling time increased up to 12 seconds. The entry and circulation of air bubbles were reduced compared to the higher filling velocity. After 30 seconds of filling time there were just little bubbles at top of the fluid layer.
- Regarding to the proportionality the filling time increased up to 24 seconds with an inlet velocity of u_{in} = 0.4 m/s and after 30 seconds there are just a minimal amount of air inclusions left in the fluid layer. Compared to the higher filling velocities there was a worse venting of the upper corners to observe.

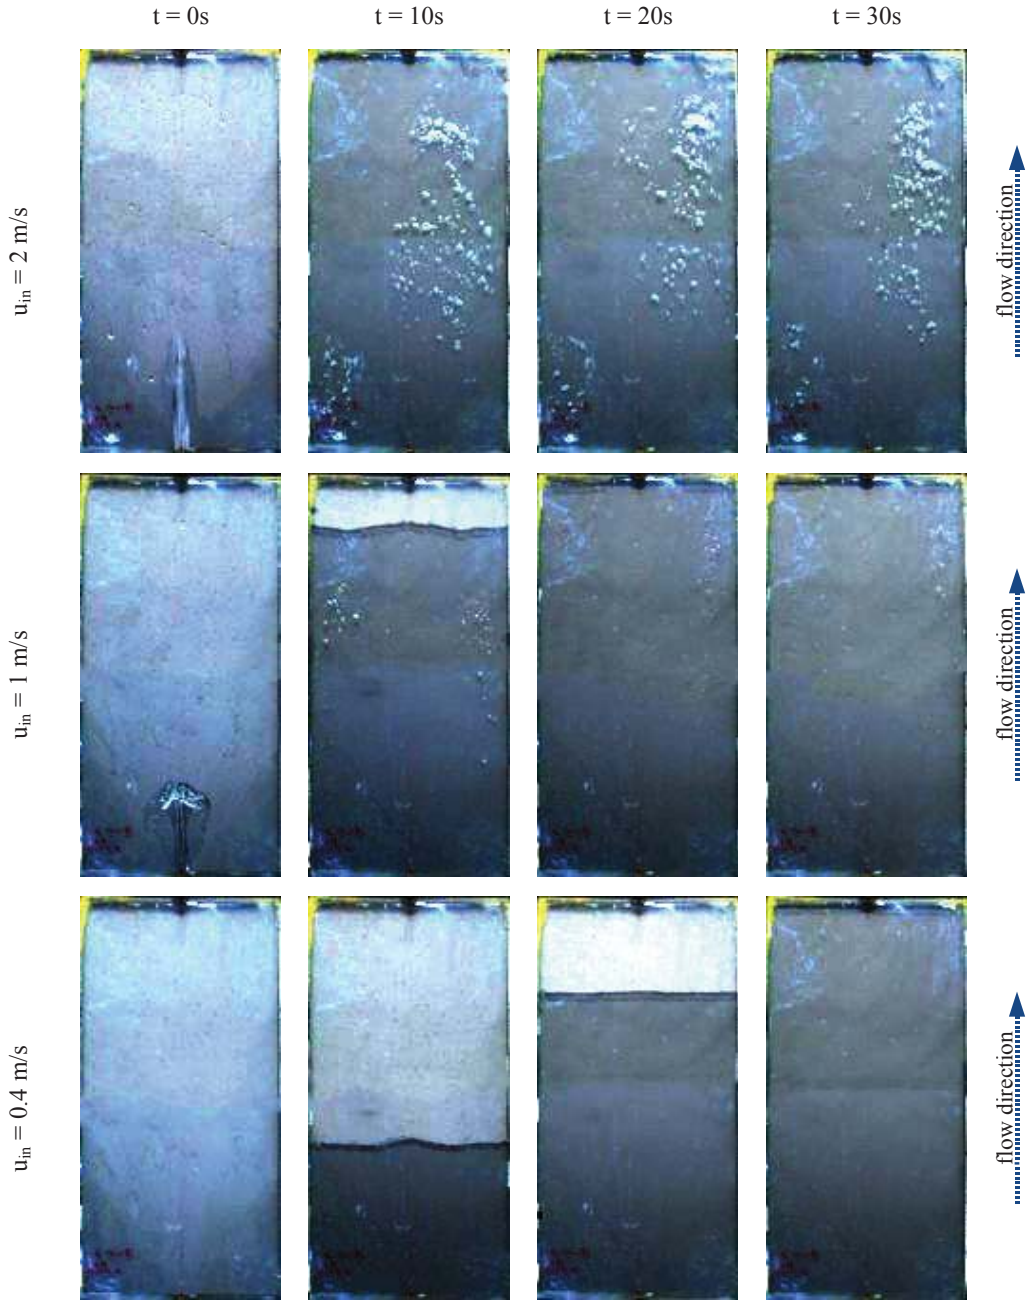

Fig. 9: Experimental results filling tests

In addition to these experimental investigations also CFD simulations on the filling behavior were carried out. In the simulations the fluid layer thickness was varied to check these influence on the filling behavior, too. For this purpose, a 3D CFD model inclined at an angle of 45° was used. Also a two-phase model which considered the interaction of the water and the air in the filling process was used. For better comparison of filling processes at different fluid layer thicknesses the fill level l_F was defined. This is the relationship of water volume in the fluid layer to the entire fluid layer volume.

$$l_F(t) = \frac{V_{water}\,(t)}{V_{total}} \qquad \text{(eq. 8)}$$

Tab. 3 and Fig. 10 illustrate the results of the filling process with different fluid layer thicknesses and variable inlet velocities. For this simulations the inlet velocities were decreased in contrast to the experiments.

Tab. 3: Influence of filling velocity and fluid layer thickness on filling level l_F (3D CFD results)

		u_{in} in m/s		
		0.25	0.50	1.00
l_F (t=140s) in %	s_F = 10 mm	99.3	98.5	87.6
	s_F = 4 mm	99.8	96.9	78.1
	s_F = 2 mm	99.1	89.5	53.3

- For s_F = 10 mm there are good filling results for the both low filling velocities. Of course the filling process takes longer for the lowest velocity. Even for this fluid layer thickness a vent at the highest filling rate is only partially possible because of the forming of circulating air bubbles – see also experimental results.
- The behavior and the trend of poor ventability is proofed for smaller fluid layer thicknesses. For s_F = 4 mm an air free filling is even not possible for medium filling velocity. An air free filling for s_F = 2 mm is only possible with quite slow filling velocity.

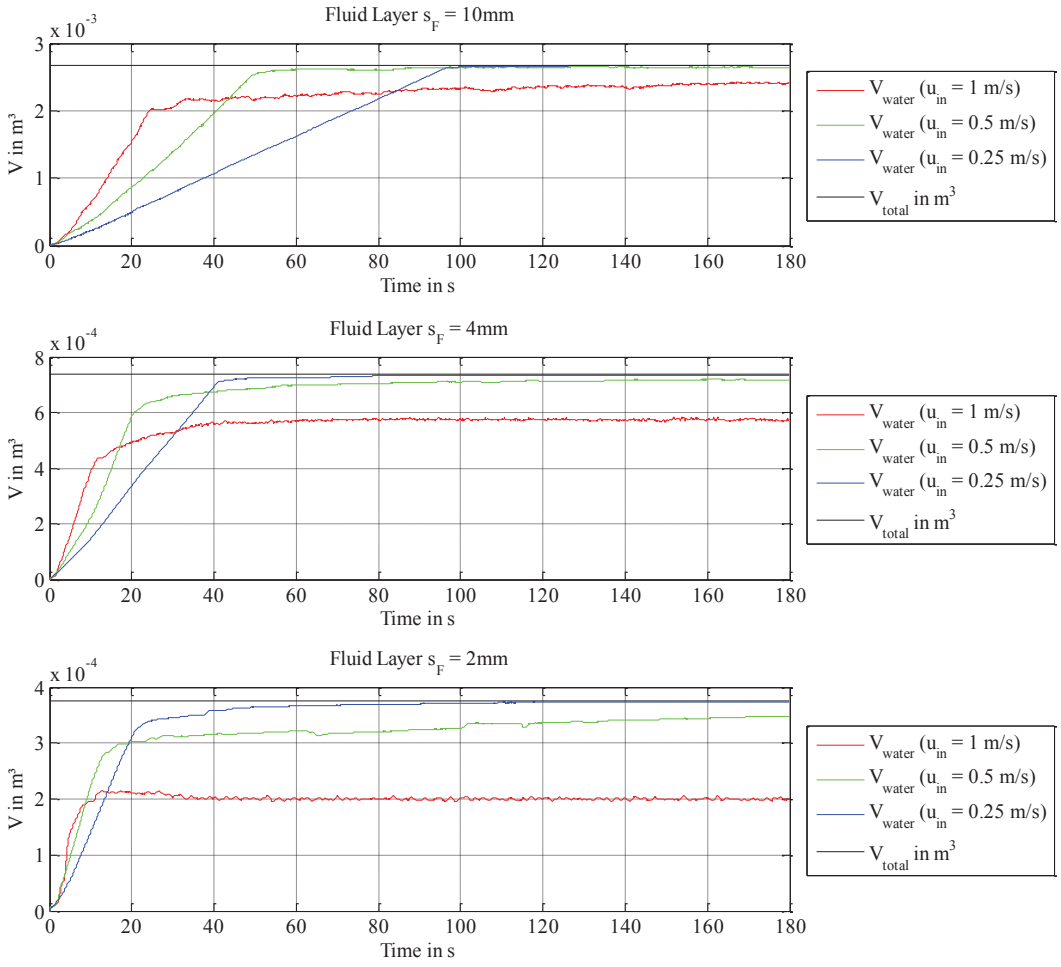

Fig. 10: Influence of filling velocity and fluid layer thickness on filling level (3D CFD results)

For the filling process therefore the lowest possible filling velocity should be chosen. In collectors and whole systems, the overall filling time will be the limiting factor. Further studies are needed to validate the filling behavior of collectors in the original scale with integrated fluid layer structure in addition to the presented results. Moreover, there will be a different filling behavior with water glycol mixture because of the varying material data.

4. Outlook

In continuation to the project additional fluid layer structures will be investigated experimentally and numerically. Target will be to increase the flow homogeneity, heat transfer and stability of the fluid layer. The pressure loss, manufacturability and long term stability must also be considered. The performance of the entire collector will be checked during QDT-testing in dependence of the different fluid layer structures. Mechanical load tests with internal and external forces will also take place.

5. Acknowledgement

The project “NUGLACOL – Development of a low cost solar flat-plate collector system based on glass”, FKZ 0325557, is carried out in cooperation with the companies Wagner Solar, Energyglas and Kömmerling and funded by the German Federal Ministry for Economic Affairs and Energy (BMWi) based on a decision of the German Federal Parliament. The authors are grateful for the financial support.

CFD analysis were carried out with the flow simulation software STAR-CCM+ by CD-adapco. Thanks for the support.

Effect of collector self-shading on the performance of a Biomass/Solar Micro-CHP system

Ana I. Palmero-Marrero and Armando C. Oliveira

University of Porto – Faculty of Engineering, Porto (Portugal)

Abstract

This paper describes an exhaustive study concerning solar geometry and the effect of shading between collectors in the overall performance of a new biomass/solar micro-CHP system. The system is a new prototype of a 6 kWe plant, based on a micro-cogeneration Organic Rankine Cycle (ORC) system, driven by a combination of solar thermal and biomass sources. Both sources may be used separately or combined. The solar thermal energy is obtained through medium-temperature concentrating compound parabolic solar collectors (CPC) with evacuated tubes. The system simultaneously produces electrical energy and low/medium temperature heat. In this study, five scenarios are presented: no shading; shading when the collector tilt is seasonally adjusted; and shading when the collector tilt is fixed in three positions during the year. Results of system simulation under the different operating modes are presented. Namely, a comparison of solar fractions and global electrical efficiencies of the system, with and without shading, is carried out.

Keywords: *collector shading, organic Rankine cycle, micro-cogeneration, solar energy, biomass*

1. Introduction

Micro-generation is the decentralised production of electricity, through different means with an electrical power output up to 50 kW. Micro-cogeneration, or micro-CHP, is the combination of micro-generation with useful heat (Pehnt et al., 2006). Among the several existing technological solutions for micro-cogeneration, Organic Rankine Cycle (ORC) systems are an interesting solution in cases where the heat demand is significantly larger than electricity needs, which is the case of residential and also other buildings (Oliveira et al., 2014). Micro-ORC systems driven by renewable energy sources have attracted the attention of many researchers. Either theoretical or experimental works have been carried out, including developments and improvements in system components (Facão et al., 2008), (Palmero-Marrero and Oliveira, 2009), (Quoilin et al., 2011), (Qiu et al., 2011), (Twomey et al., 2013), (Jradi et al., 2014).

A micro-cogeneration ORC system driven by a combination of solar thermal and biomass sources was simulated by the authors (Palmero-Marrero et al., 2015), (Oliveira et al, 2014). In the simulations, high efficiency vacuum-CPC solar collectors were used, and the power cycle used a highly efficient rotary lobe expander. The results obtained allowed the prediction of system annual performance. The system is under development and the prototype will be installed and tested in Benguerir (Morocco) during this year, in the framework of the REELCOOP project, funded by the EU (REELCOOP, 2015). For solar resource assessment purposes, Meteonorm software was used to generate climatic data of Benguerir.

The previous simulation of the overall system was performed considering no shading between the collectors. However, limitations in the available space may recommend shorter distances between collectors. Taking into account the dimensions of the vacuum-CPC collectors and the layout of the solar field, an extensive study about shading effects was developed.

The performance of the overall system is analyzed, taking into account the shading effects between collectors. Namely, a comparison of solar fractions and global electrical efficiencies of the system, with and without shading, is carried out. Five scenarios are presented: no shading; shading when the collector tilt is seasonally adjusted; and shading when the collector tilt is fixed in three positions during the year. When shading occurs, the reduction in incident solar radiation must be compensated by an increase in the boiler input energy. With

doi:10.18086/eurosun.2016.07.03 Available at http://proceedings.ises.org

that in mind, the biomass consumption for all scenarios was also calculated for different operating periods. In the next sections, detailed numerical simulations for specific climatic and operational conditions are presented.

2. Description of the system and numerical model considering shading

2.1 System description

A computer model of the overall system was developed by combining EES (Engineering Equation Solver) with TRNSYS software. EES was used for the power cycle calculations and TRNSYS for simulating the solar circuit and overall system. The system, including its main components, is schematically represented in Figure1 (Oliveira et al., 2014).

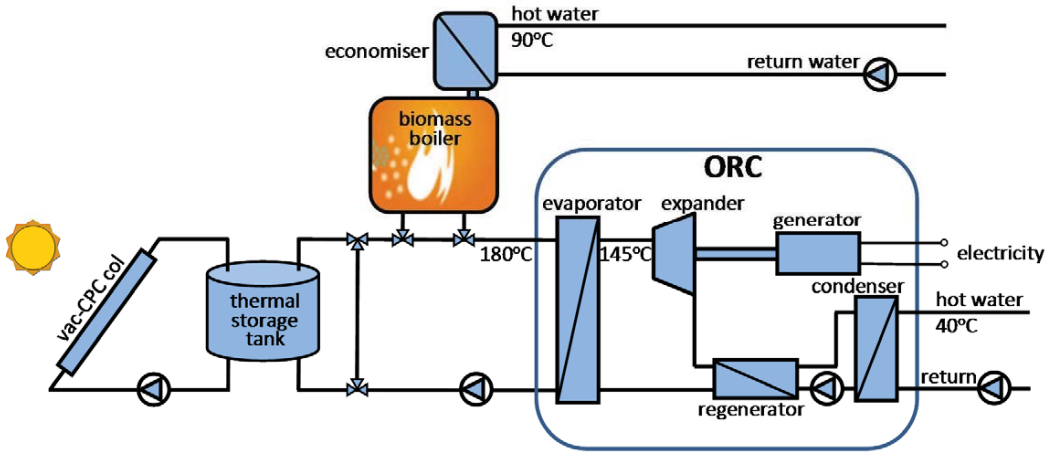

Fig. 1: System schematic representation.

The ORC/power cycle model consists of a set of algebraic equations representing the thermodynamic behavior of each ORC component. The ORC simulated by EES includes the following main components: evaporator, expander, generator, regenerator, condenser and pump. For an electrical output equal to 6 kW, a maximum temperature for the solar circuit of 180ºC is assumed. It is expected that the ORC operates under almost steady-state conditions, as the cycle driving temperature is kept approximately constant. However, the simulations in TRNSYS are transient, as they reflect changes in solar radiation and ambient temperature. The solar circuit simulated by TRNSYS includes the following main components: solar collector, boiler with economizer, thermal storage, pumps and control system. Different working fluids are used in the system: thermal oil for the solar sub-system, water for the condenser, and Solkatherm (SES36) fluid for the ORC.

The inputs of TRNSYS components and EES components are shown in Table 1.

Table 1: Definition of the inputs for each component

Programs	Components	Inputs
TRNSYS	Climatic data (Meteonorm)	Local: Benguerir (Morocco); Latitude = 32.13ºN, Longitude = 7.98ºW.
	Vacuum-CPC collectors (vac-CPC)	A_{coll} = 145.92 m^2; 32 modules (4 in series, 8 in parallel) Concentration factor (C) =2.573 Efficiency curve parameters: η_0=0.623; a_1=0.59 $Wm^{-2}K^{-1}$; a_2=0.004 $Wm^{-2}K^{-2}$ Tested flow rate = 0.0274 kg $s^{-1}m^{-2}$ Maximum total flow rate = 0.557 kg/s Collector tilt: seasonally adjusted at **51º** (from October to February), **29º** (March, April and September) and **8º** (from May to August), optimised according to period of the year and manufacture. Collector azimuth = 0º Fluid specific heat = 2620 J/kgºC (oil TERMOL 5HT) IAM data: file created through the numerical simulation of the novel CPC collector
	Thermal storage	Tank volume = 8000 l Thermal stratification modelled with 6 fully-mixed equal volume layers Tank losses: negligible Cold-side temperature (from Evaporator) = 140ºC Cold-side flowrate (from Evaporator) = 0.412 kg/s
	Boiler	Rated capacity = 60 kW Set point temperature = 180ºC Boiler efficiency = 0.9
	Pump	Maximum power = 0.6 kW
EES	Evaporator	Useful heat: 40 kW Outlet temperature = 145ºC Superheating = 5ºC
	Expander	Efficiency (η_{exp}): 0.75
	Generator	Efficiency = 0.95 Net electrical power = 6 kW
	Regenerator	ΔTmin = 10ºC Efficiency = 0.82
	Condenser	Condenser temperature = 45ºC

2.2 Climatic data

For solar resource assessment purposes METEONORM (Meteotest, 2015) was used to generate data of Global Horizontal Irradiation, GHI, solar azimuth and height, and ambient temperature (Ta), on an hourly basis for a typical year. The chosen location was Benguerir (Morocco), with a latitude = 32.13ºN and a longitude = 7.8ºW. For this city, the data from Meteonorm and local data were compared - see Fig. 2. In this case, the Meteonorm data were obtained with interpolation from nearby meteorological stations.

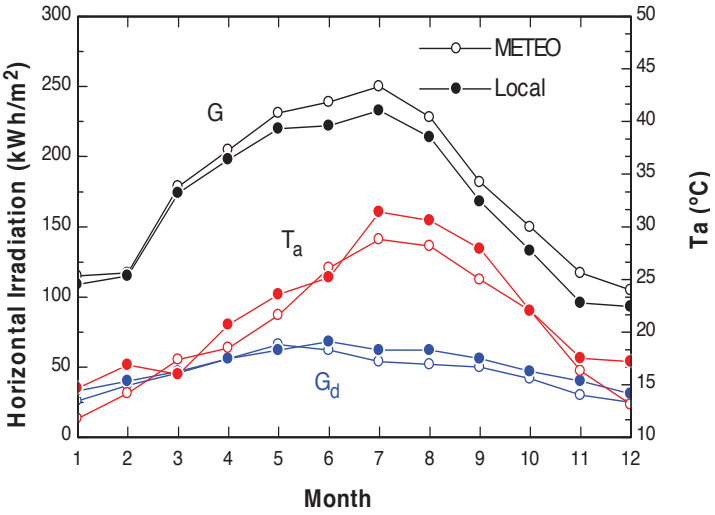

Fig. 2: Global (G) and diffuse (Gd) solar radiation on horizontal surface and ambient temperature (Ta) with Meteonorm data and local data for Benguerir.

The major differences between Meteonorm and local data concern horizontal global irradiation (G) and ambient temperature (Ta) for July, August and September (difference lower than 10% for these months).

2.2 Solar geometry analysis

A solar geometry analysis was carried out, considering the collector dimensions together with the location. Figure 3 shows the dimensions used to calculate the shading effect between the evacuated-CPC collectors, where L_{aper} is the collector aperture (L_{aper} = 0.437 m), d is the collector row separation (d = 0.7 m), tilt is the collector tilt ($tilt$ = 51°, for the most unfavourable situation) and h_{sun} is the solar altitude angle.

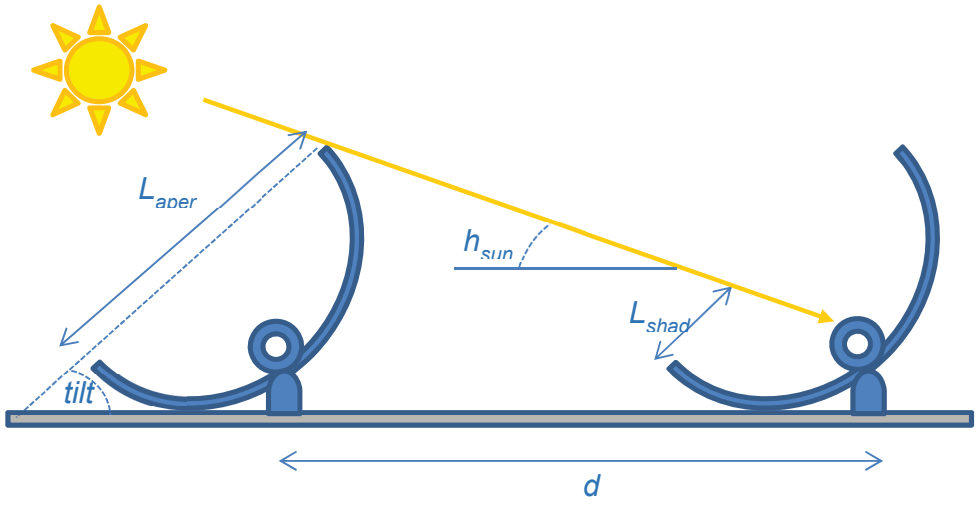

Fig. 3: Schematic view of the evacuated-CPC collectors with some parameters used for the solar geometry analysis.

Using the geometric relationship between a plane of any orientation and the incoming beam solar radiation for the specific latitude (Benguerir's latitude = 32.13ºN), it is possible to calculate the relations of the position of the sun relative to that plane. Considering the worst scenario for shading, when the solar altitude angles are lower (winter period) and the collector tilt is 51°, the shading effects were analysed, and the results will be shown in the next section.

3. Simulation results

Figure 4 shows the shaded length on the collector (L_{shad}) and the percentage of insolated length (*%insolated*) for each solar altitude angle, defined as (see eq. 1):

$$\%insolated = 100 \cdot (L_{aper} - L_{shad})/L_{aper} \quad \text{(eq.1)}$$

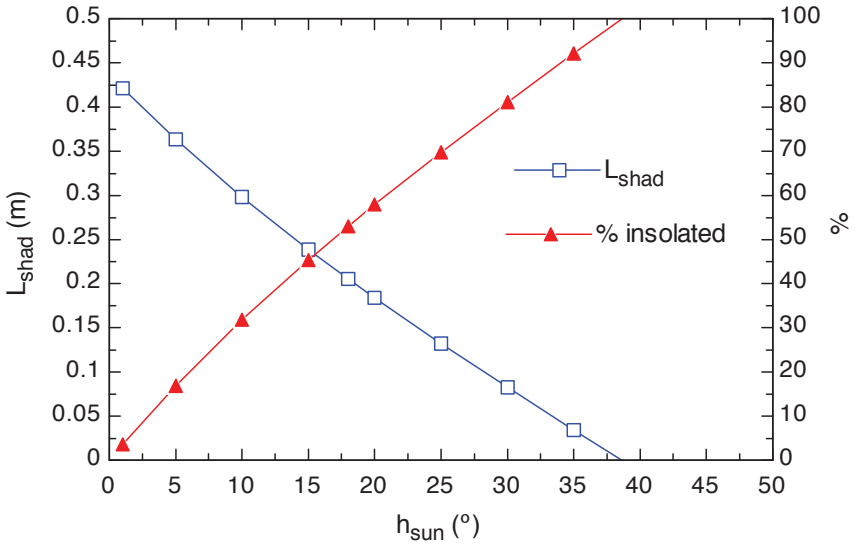

Fig. 4: Shaded length and insolated percentage on the CPC collector depending on solar altitude angle (h_{sun})

As can be seen, for the considered dimensions, the collector surface is completely insolated for a solar altitude angle above about 40º. To know in which months and hours shading occurs, it is necessary to combine the information with a solar chart (solar altitude angle and solar azimuth angle for different days and hours).

Figure 5 shows the solar chart for Benguerir, using an average day for each of the months, and results when the collector tilt is equal to 51º (from October to February).

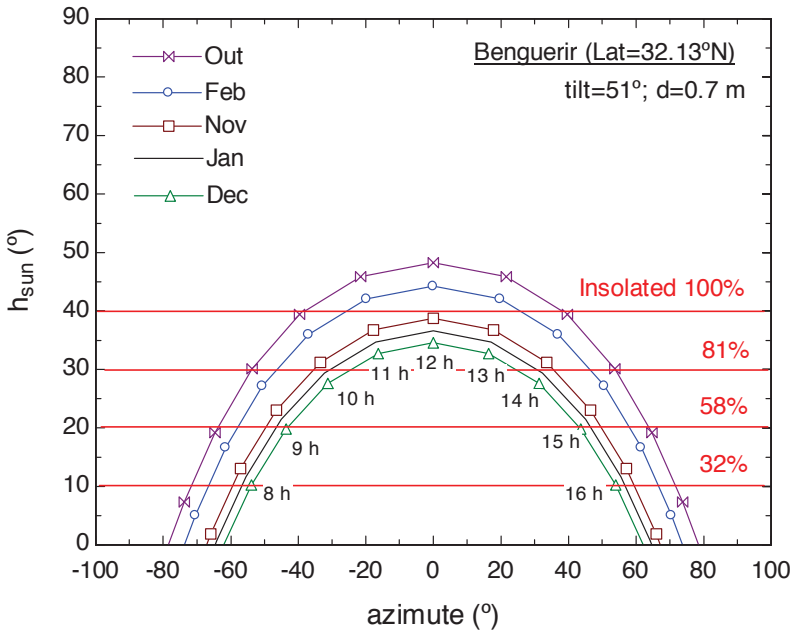

Fig. 5: Solar chart for Benguerir (months when the collector tilt is equal to 51º)

As can be seen, during the average day of November, December and January, part of the collectors behind the first row are always shaded.

Now, it is necessary to evaluate the performance of the system when the shading effect is considered. In the next section, the overall system performance is analysed.

3.1 Overall system performance

The monthly and annual performances, with and without shading, are shown in Table 2.

The table contains values of solar radiation incident on the collector surface (G_{coll}), useful heat gain on the solar collectors (Q_{usef_coll}), energy supplied by the boiler (Q_{aux}), and solar fraction (f), considering that no shading occurs and when the effect of shading is taken into account. The solar fraction can be defined as (see eq. 2):

$$f = Q_{usef\_coll}/(Q_{usef\_coll} + Q_{aux}) \quad \text{(eq. 2)}$$

Table 2: Monthly and annual performance results

Month (tilt)	G_{coll} (MWh)		Q_{usef_coll} (MWh)		Q_{aux} (MWh)		F

The annual thermal performance can be related to the annual net electricity generation of the power block. Assuming that the solar driven CHP plant is running non-stop throughout the year (helped by the boiler), the annual generated electricity value is 52.6 MWh, with an operating period of 24 h/day. The annual global electrical efficiency ($\eta_{electr,annual}$) is defined as the total electrical energy generated during one year (E_{elec}), divided by the sum of all annual energy inputs – boiler input energy (Q_{boiler}) plus incident solar radiation (G_{coll}), as can be seen in eq. 3:

$$\eta_{electr.annual} = E_{elec}/(Q_{boiler} + G_{coll}) \quad \text{(eq. 3)}$$

Figure 6 shows the annual solar fraction (f_{annual}) and annual global electrical efficiency for 5 scenarios: no shading, with shading when the collector tilt is seasonally adjusted (3 tilts), and when the collector tilt is fixed during the whole year at 51º, 29º and 8º.

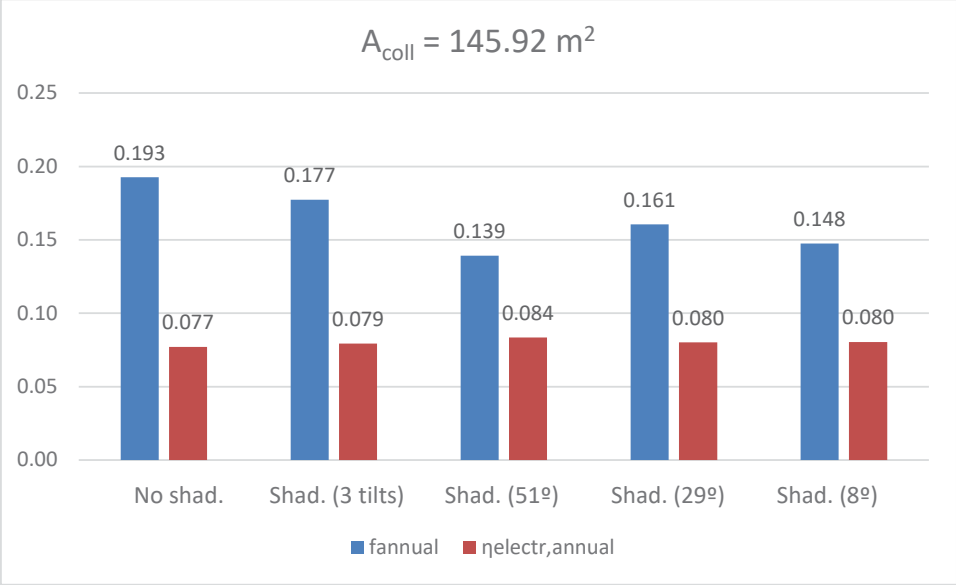

Fig. 6: Annual solar fraction and annual global electrical efficiency for the 5 scenarios.

Shading reduces the annual solar fraction from 0.193 to 0.177 (a relative reduction of 8%). When shading and solar fractions are analysed, the best scenario is when the collector tilt is seasonally adjusted (three times per year): the annual solar fraction with 3 tilts is equal to 0.177. If a single constant tilt of 29º is used, the resulting solar fraction is equal to 0.161, which means a relative reduction of 9%. This will be the best tilt for a constant inclination throughout the year.

A higher solar fraction does not imply a higher global electricity efficiency, since the reduction in incident solar radiation is compensated with an increase in the boiler input energy (with a higher efficiency). On the other hand, biomass consumption increases with the increase in boiler input energy. For that, the biomass consumption for all scenarios was also calculated. For 24 hours/day operation, the biomass consumption will be equal to 69.41 tons/year (3 tilts), 72.62 tons/year (tilt=51º), 70.82 tons/year (tilt=29º) and 71.92 tons/year (tilt=8º).

4. Conclusions

In the present paper, an exhaustive study concerning solar geometry and the effect of shading between collectors in the overall performance of a new biomass/solar micro-CHP system was presented. The performance of the overall system was analyzed, taking into account the shading effects between collectors and the location where the prototype will be installed and tested (Benguerir, Morocco). Five scenarios were considered: no shading, with shading when the collector tilt is seasonally adjusted (3 tilts), and when the collector tilt is fixed during the whole year at 51º, 29º and 8º.

Considering the worst scenario for shading, when the solar altitude angles are lower (winter period) and the collector tilt is 51º, the study shows that the collector surface is completely insolated for a solar altitude angle above about 40º. Then, during the average days of November, December and January, part of the collectors behind the first row are always shaded. To evaluate the performance of the system when shading is considered, annual solar fractions (f_{annual}) and annual electrical efficiencies ($\eta_{electr,annual}$) were assessed. The best performance corresponds to a collector tilt that is seasonally adjusted (three times per year): f_{annual} with 3 tilts is equal to 0.177 and $\eta_{electr,annual} = 0.08$. When shading occurs, the reduction in incident solar radiation must be compensated by an increase in boiler input energy, and so the $\eta_{electr,annual}$ remains practically constant for the different scenarios analysed. Biomass consumption increases with the increase in boiler input energy: for an operating period of 24 hours/day, biomass consumption will be equal to 69.41 tons/year (3 tilts), 72.62 tons/year (tilt=51º), 70.82 tons/year (tilt=29º) and 71.92 tons/year (tilt=8º). After the results, if a single constant tilt throughout the year is used, the best tilt is 29º.

Abstract

This research work deals with the thermal analysis of a hermetically sealed flat plate collector with a gas-filled cavity between absorber and glazing. Published scientific work in this field is discussed and compared to own laboratory testing and simulation results. The impact of the mechanical absorber deflection for small gap sizes between absorber and glazing on the collector efficiency are investigated. A parameter study for gas-filled collectors with a fully adhesive edge bond was conducted. Four different types of functional models were built and tested to validate the simulation model. Impacts affecting the thermal efficiency such as the absorber deflection of solar collectors with a fully adhesive edge bond were analysed and evaluated. A system simulation was conducted analysing the components temperatures and the annual collector yield.

Keywords: *solar thermal; absorber; gas-filled; edge bond;*

1. Introduction

In a standard flat plate solar collector, the highest heat loss is caused via the front loss (Tabor 1958, Beikircher 2009). This loss, in turn, can be split up into a radiative and a convective part. Modern collectors are equipped with a high selective coating with absorbance values of 0.95 respectively emission values of less than 0.05. This means 95 % of the short-wave sunlight is absorbed and only 5 % of the heat radiation (long-wave) emitted. Consequently, the highest loss in a flat plate collector with a high selective coated absorber is caused by the convection between absorber and glazing (Platzer 1988, Beikircher 2009, Tabor 1958). Consequently, reducing the convective heat transfer is a promising approach to increase the efficiency.

A common and successful method to reduce the convective front heat loss is the use of transparent insulation material. In particular, a transparent component is put between absorber and the ambient retarding the convection process. The measures can be classified according to their geometrical position to the absorber (Platzer 1988, Kaltenbach 2003) – structures parallel and perpendicular to the absorber, chamber structures and quasi-homogenous structures. The exhibit for a collector with a structure parallel to the absorber is the ordinary glazed flat plate collector. Yet, there were several approaches to use two or more layers to suppress free convection. Usually, plastic foils or glasses were used as layer material. Remarkable boosts in efficiency were calculated and demonstrated (Rommel et al. 2003, Beikircher 2010, Föste 2013). Absorber parallel structures such as multi-covers are finding infrequent use in solar collectors.

Structures perpendicular to the absorber are, amongst others, honeycomb structures. A wide field of valuable publications on the convective heat transfer itself and on honeycomb structures have been published. There might be still some challenges concerning the long-term stability as well as problems during stagnation but a decent performance level was demonstrated (Hollands 1965, Tabor 1969, Buchberg et al. 1976, Kessentini et al. 2013). However, due to the demanding requirements in solar collectors concerning the long-term stability and costs, these measures are not widely spread. Chamber structures are closely linked to absorber perpendicular and parallel structures and are usually made out of multiple wall sheets. The method

doi:10.18086/eurosun.2016.07.07 Available at http://proceedings.ises.org

retards convection in a similar way to the other structures mentioned above but results in a deterioration of the solar transmission coefficient. Since the chambers are usually made out of plastics the negative effects of ageing and long-term stability applies here as well as on the honeycomb insulation.
Svendsen and Jensen (1987), Svendsen (1992) respectively Nordgaard and Beckman (1992) investigated the use of monolithic silica aerogel in solar collectors. Aerogel is a highly porous solid body in which more than 95 % of the volume is air. Hence, it is an outstanding insulation material. Up to date, the use of aerogel insulation in solar collectors is linked with no economic advantages, as the material costs are exorbitant.
Beside transparent insulation between absorber and glazing, the possibility of evacuating this gap was analysed as well. In theoretical studies, an efficiency of 41 % at an operating temperature of 150 °C was calculated (Eaton and Blum 1975). Benz and Beikircher (1999) concluded in a laboratory testing that the convective heat coefficient is reduced by up to 65 % in the continuum range compared to air. Buttinger et al. (2009, 2010) analysed an evacuated compound parabolic collector (CPC) and confirmed efficiencies above 50 % for working temperatures of more than 150 °C. A significant drawback of these collector types can be seen in the complex design, the high requirements concerning mechanical loads and sealing methods, which prevents a low-maintenance lifetime.
A gas-filled interspace between glazing and absorber is a promising approach in reducing the convective heat loss. Vestlund et al. (2009) analysed the thermal performance of a gas-filled solar collector at ambient pressure. In their work, a parameter analysis was carried out including the variation of the inclination angle and the gas type. Based on simulations, a considerable reduction of the overall heat loss by 20 % was shown. Despite of the discussed paths, gas-filled collectors at ambient pressure are not yet as explicitly analysed as the other discussed approaches. The charm of this measure is that there is no additional hardware needed. In return, an efficiency on the level of a well-designed collector with a honeycomb structure or even an evacuated flat plate collector needs to be proven. The aim needs to be in a collector design, which is suitable for a highly automated production with a decent performance level and a cost structure competitive to a conventional solar collector.

2. Design of a collector with an all-round supported absorber with a fully adhesive edge-bond

Within this paper, a collector with an all-round supported absorber with a fully adhesive edge bond was analysed in terms of its thermal behaviour respectively convective heat loss. The basic collector construction was intended to be simple and as similar to an insulated glazing unit as possible in order to produce the collector on a highly automated insulated glazing unit production line. A butyl sealant (primary sealing) was applied directly on the absorber sheet. Subsequently, it was bonded to the glazing to achieve a gastight cavity. During the assembly process of the absorber and the glazing, the gap was filled with an inert gas to lower the convective heat loss. Fig. 1 shows a schematic cross section of the proposed collector design.

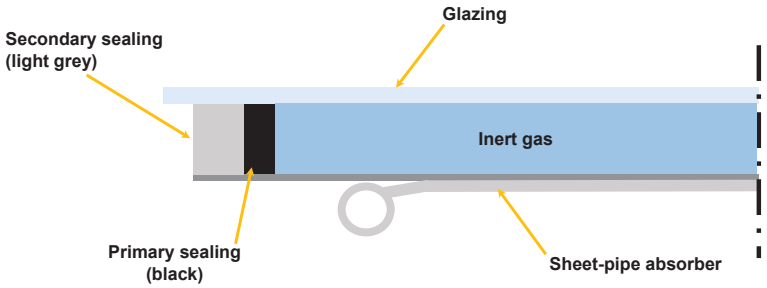

Fig. 1: Schematic cross section of the assembly group of absorber and glazing

In this work, it was favourable to achieve a short distance between absorber and glazing. On the one hand, a shorter distance between absorber and glazing reduces the adhesive costs, which cannot be ignored, as those are a considerable part of the total collector costs. On the other hand, a lower convective heat loss might be achievable by adjusting the gap size to the transition region between conduction and convection, i.e. Nusselt number is still 1 respectively very close to 1. Furthermore, it needs to be considered that less volume is enclosed between absorber and glazing and, thus, a lower mechanical load is applied on the collector

components due to the pressure change (Riess et al. 2014, Vestlund et al. 2009, 2012). Conventional flat plate collectors are designed to have a gap size between 25 and 35 mm whereas in this approach an absorber glazing distance at first of 10 mm for Argon was intended. In a later stage of the research work, gap sizes of up to 20 mm were considered and analysed as well. Even though Xenon and Krypton are allowing very short spacing distances in comparison to Argon or air (Vestlund et al. 2009), those inert gases are of no practical interest. Whilst Krypton is by a factor of 100 times more expensive than Argon, Xenon is even more costly than Krypton. An Argon filled interspace with a gap size of 15 mm for an aperture area of 2 m² causes costs of about 0.06 €. In theory, Krypton enables a shorter distance between absorber and glazing cutting the filling costs down to about 3.5 €. However, own results showed that it is not rational to achieve shorter gap sizes than 15 mm with conventional sheet-pipe absorber (Riess et al. 2014). Beyond that, it needs to be analysed whether the higher filling costs can be justified by an increased annual yield. Consequently, Argon was chosen as a filling gas in this approach whereas air served as the main reference. However, Krypton was used in some considerations as a further reference to Argon and air. Xenon was of no further interest due to its uneconomic pricing and very limited availability.

The principal theory concerning the convective heat loss in a flat plate collector is not discussed in this paper but can be found in (Eismann 2015, Hollands et al. 1976, Tabor 1959).

3. Thermal collector model

Over the decades, there have been plenty contributions in the modelling of flat plate solar collectors. In the early 1940s, Hottel and Woertz (1942) analysed the thermal performance of flat plate solar collectors and presented an analytical calculation approach of the collector efficiency. In 1958, their analytical approach was refined by Tabor (1958). In the same year, Hottel and Whillier (1958) published a linear efficiency model of the correlation between test results and analytical description. Cooper and Dunkle (1980) introduced a non-linear flat plate collector model in which the efficiency is plotted in dependence of the difference between ambient temperature and the mean fluid temperature to the solar irradiation. Klein et al. (1974) presented their investigations on the transient collector behaviour and pointed out the differences to a steady state collector model. Ultimately, the collector simulation model was refined by two heat capacities resulting in a two-node model. Matuska and Zmrhal (2008) as well as Koo (1999) published a collector simulation model that can be downloaded and used without a license fee. The mentioned models are sophisticated and established simulation approaches. A drawback of those approaches is that the component temperatures are not available at all or only very limited. In the case of a hermetically sealed flat plate collector with a fully adhesive edge bond new materials are being used. Moreover, the adhesive is by its nature sensitive to high temperature loads, i.e. temperature magnitude, period and occurrences. Against this backdrop, beside the collector efficiency it was essential to analyse the thermal loads on the components. Finally, in the mentioned freeware simulation models a gas-filled cavity cannot be simulated. Therefore, the simulation model by Reiter et al. (2015) was adapted for the conducted thermal analysis. This collector model was implemented for the development of full polymeric collectors and, hence, the temperature loads were in the focus of Reiter's research (2014). The principle equations, assumptions and simplifications used in this model can be found in Reiter et al. (2015) and, thus, are not further described. However, the convective heat transfer between absorber and glazing was modified. Reiter et al. (2014, 2015) used an approach to calculate the convective heat transfer between absorber and glazing from Matuska and Zmrhal (2009). In contrast to this, the widely used convection theory according to Hollands et al. (1976) was applied in this approach at first.

During the research program it turned out that, there is a considerable discrepancy between the applied convection theory and the laboratory testing results. The thermal influences that led to this deviation are discussed within the next chapters.

The convective heat transfer is amongst other parameters affected by the inclination angle of the collector. However, the inclination effect was not of interest within this research program. Hence, the standard inclination for testing and simulation was always set to 45°.

The inert gas properties as well as the change of the material properties such as viscosity or density depending on the present gas temperature were approximated by polynomials and can be found in the VDI Heat Atlas (Stephan 2010).

4. Thermal simulation according to the convection theory after Hollands et al. (1976)

The efficiency tests of the functional model were conducted on the institute's own indoor solar simulator according to the standard DIN EN 12975-2 (2006). During the complete research programme all parameter relating to the collector efficiency were referenced to the aperture area – unless otherwise stated.
Even though deviations between simulation results and measured efficiency curves were expected, the deviations were surprisingly high. Fig. 2 shows the simulated efficiency curve and the tested efficiency conducted on an indoor solar simulator. The collector parameters are found in Tab. 1.

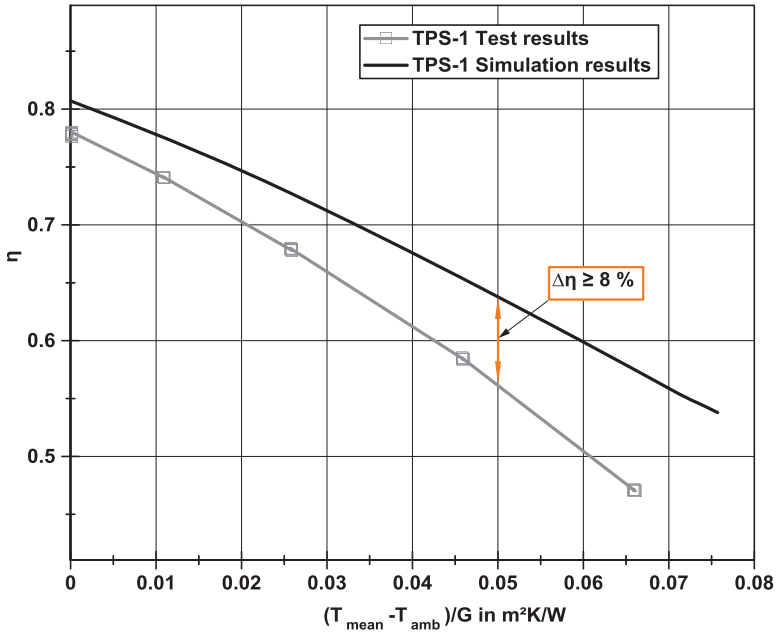

Fig. 2: Comparison between the first simulation model result of a hermetically sealed and gas-filled collector (convection theory according to Hollands et al. 1976) and the measured collector efficiency of the corresponding experimental collector

Tab. 1: Collector parameters used in both laboratory testing and simulation

Parameter	Value
Optical efficiency η_0	0.782
Linear loss coefficient a_1 in W/m²K	3.215
Quadratic loss coefficient a_2 in W/m²K^2	0.023
Aperture area in m²	1.9
Initial gap size in mm	10
Insulation thickness (back) in mm (mineral wool; λ = 0,04 W/mK)	40
Insulation thickness (side) in mm	--
Absorber type	Sheet-pipe
Absorber piping	Harp
Material absorber sheet	Aluminium
Material absorber piping	Aluminium
Gas filling	Argon

The simulated efficiency curve shows a higher performance over the complete operating range. Close to η_0 the deviation between the curves is only 2.4 %. Even though η_0 is called the optical efficiency there is also the fin efficiency F' contributing to this value and, thus, the collector heat loss is affecting this parameter as well. With rising collector working temperatures, the deviation between the two curves increases. For a typical working point of a space heating supporting solar system of $(T_{mean} - T_{ambient}) / G = 0.05$ m²K/W the deviation is more than 8 %. Reiter et al. (2015), however, validated the simulation model for a conventional collector with a double-harp absorber and a gap size of 30 mm. According to their results, the model showed a good correlation between laboratory testing and simulation results. Within this research study, the

simulation model code was modified in terms of the convective heat transfer, smaller gap sizes and gas fillings. Consequently, it can be concluded that the deviation is rather an underestimation of the actual convective heat loss or a failure in the experimental setup than a bug in the model code. At first, it seemed plausible to examine the experimental setup to exclude possible mistakes. As the institute's solar simulator is regularly checked by testing the same reference collector, it was ensured that the test rig was not faulty. Therefore, the collector was further analysed. The gas concentration of the functional model was measured thrice – right after its production, two hours later and 24 h after the production. All measurements gave values well over 95 % Argon concentration. The collector test was conducted 36 h after the production. It can be, therefore, concluded that a high Argon concentration (< 95 %) was in the interspace. However, several observations were made on the absorber. The thin absorber sheet showed a considerable deflection during collector operation. Instead of the intended 10 mm gap between absorber and glazing a mean distance between the two plates of only 6 mm was measured. It turned out that the initial absorber shape has a significant impact on the absorber deflection as its shape is magnified during collector operation (Riess et al. 2014). Consequently, this means absorber areas that had already a shorter distance than 10 mm to the glazing are getting even closer during collector operation and vice versa. Those absorber deflections were hard to spot by a visual inspection through the glazing due to the dark absorber coating and the glass reflections. Instead, holes were drilled through the back of the insulated back plate to conclude on the actual distance of the absorber to the glazing. This was possible as the collector dimensions, e.g. glass thickness and total collector height, were known and measurable. This investigation led to the result that the absorber deflection has a considerable effect on the difference of the collector efficiency prediction. Fig. 3 clarifies the impact of a small deviation in the gap size on the convective heat transfer respectively the collector efficiency for collectors with a small gap size, i.e. within the transition area between heat conduction and convection.

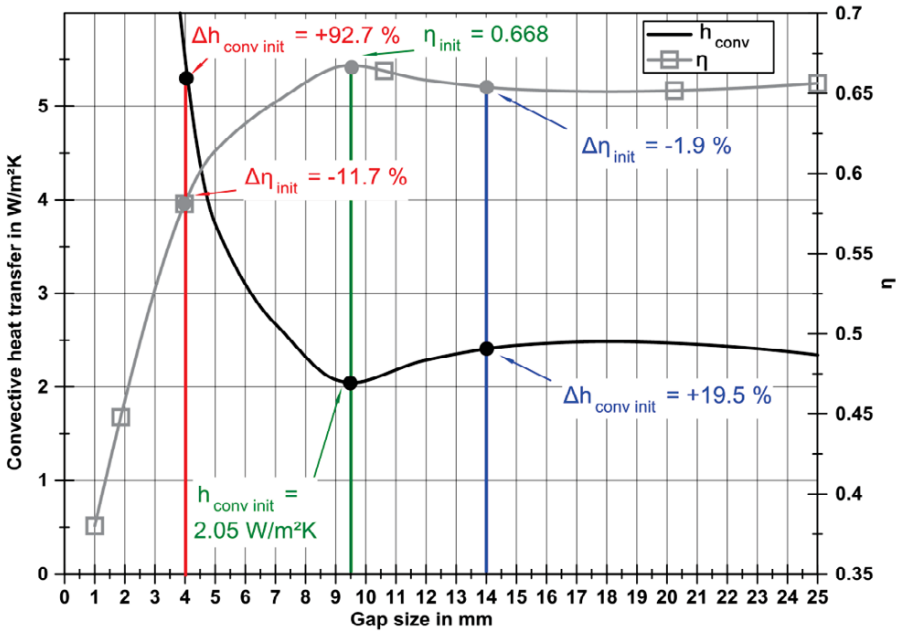

Fig. 3: Simulated change of collector efficiency depending on the gap size after the convection theory of Hollands et al. (1976) for a mean fluid temperature difference of 60 K

For a mean fluid temperature difference of 60 K and Argon as gas filling, the local minimum in the convective heat transfer is at 9.5 mm. If the gap size is decreased by only 5.5 mm the convective heat transfer is increased by almost 93 %. Ultimately, this means an efficiency loss in this typical working point of 11.7 %. In contrast to this, an increased interspace of 5.5 mm to 14 mm is followed only by a slight increase of the convective heat loss of 19.5 % which correspondents to an efficiency loss of less than 2 %. However, the interaction between absorber deflection and convective heat transfer cannot be implemented in to the applied thermal collector model. Reiter et al. (2015) showed that the simulation model was valid for conventional flat plate collector with a normal gap size; it is doubtful whether it is possible to predict the

precise convective heat loss for such short distances between absorber and glazing due to the absorber deflections. Furthermore, it is problematic if not impossible to adjust the gap between the glazing and a conventional sheet-pipe absorber to the local minimum of the convective heat transfer.
As a model validation with this experimental was not conductible another set of functional models with a wider spacing between absorber and glazing and different absorber types was produced and tested.

5. Discussion of different convection theories and model validation

Bartelsen et al. (1993) measured with an own experimental collector under various inclinations the convective heat transfer between absorber and glazing down to gap sizes of 15 mm and compared the results to the one published by Hollands. Their results showed a 25 to 60 % higher convective heat loss than the results computed according to Hollands. Föste (2013) measured the convective heat loss of a collector with a double-glazing unit. In his approach, a collector prototype was equipped with temperature sensors along the glass panes and the absorber. Subsequently, the absorber piping was perfused by hot water (> 150 °C) and the temperature difference between inlet and outlet was measured to conclude on the total collector heat loss. His results showed a deviation of the convective heat loss coefficient between the values derived by the literature and the measured results by up to 32 % between absorber and glazing unit respectively up to 15 % in the glazing interspace. Recently, Eismann (2015) published an extended correlation for the convective heat transfer in the cavity between absorber and glazing. In his study, 22 standard collectors were modelled based on the specifications provided by producers respectively test reports. As the common convection correlations were stated for isothermal plates, Eismann's focus was to extend the Hollands' equation for the convective heat loss for non-isothermal absorbers with a high selective coating. This is in particular of interest as the Hollands equation is only valid for Rayleigh numbers up to 105. The Rayleigh number, however, are by a factor of three higher in the case of coated absorber surfaces (Eismann 2015). According to the author, those facts are resulting in an underestimation of the convective heat loss in solar flat plate collectors. Eismann extended in his approach the convection equation according to Hollands by fitting it to the equation of ElSherbiny et al. (1982). This results in a better accordance for selective coated absorber surfaces.
For the author's own model validation, an experimental test was setup in which the convective heat transfer between absorber and glazing was measured. The collector 'TPS-AlCu20' was, therefore, in addition to the already applied 55 mm thick mineral wool further insulated on the back and on the side with polystyrene (t = 80 mm, $\lambda = 0.038$ W/m²K). The collector was equipped with temperature sensors to conclude on the thermal collector losses (Fig. 4).

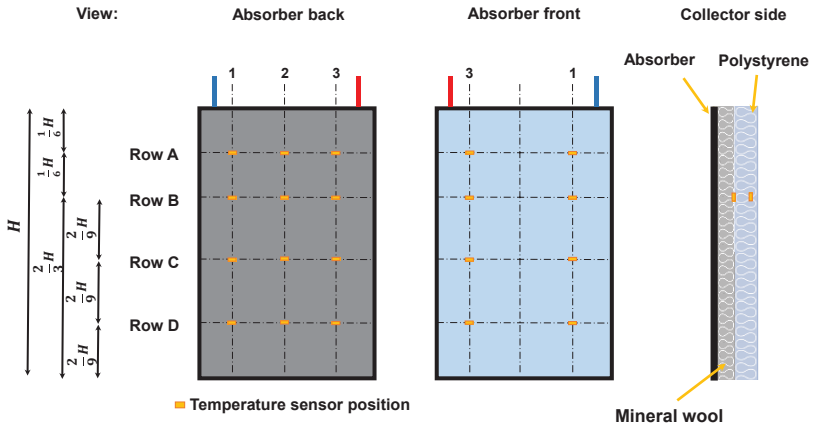

Fig. 4: Sensor positions on the experimental collector

Subsequently, the functional model was put under the solar simulator to measure the efficiency for certain collector inlet temperatures, i.e. 70, 80 and 89 °C. The testing rig is equipped with two pyranometers, a magnet-inductive flow meter and two matched PT100 sensors to log the collector inlet and outlet temperature. Hence, the useful collector energy respectively collector loss can be calculated. The conduction loss via the back insulation and the radiative absorber loss is calculated based on the collector temperature

measurements, the ambient temperature and the known physical collector properties. The sidewall losses are neglected, as the collector side surface is small compared to the collector's aperture area. Beyond that, the collector sides are very well insulated and, thus, considered as adiabatic. The collector model was enhanced by the convection equation according to Eismann (2015):

$$Nu = 1 + 1.44 * \left(1 - \frac{1708}{Ra\emptyset + 1708R_c}\right) * \left(1 - (\sin(1.8\emptyset))^{1.6} \frac{1708}{Ra\emptyset + 1708R_c}\right) + \left(\left(\frac{Ra\emptyset + 5830R_c}{5830}\right)^{0.39} - 1\right)(1 + C * R_c)$$

Eismann (2015) suggests a C-value of 0.29 with a mean deviation of ±0.17. For the here conducted calculation C was set to 0.46 whereas R_c was 1. Subsequently, the author's own convection loss measurements were compared to the calculation results according to the equations of Hollands et al. (1976) and Eismann (2015) in Fig. 5.

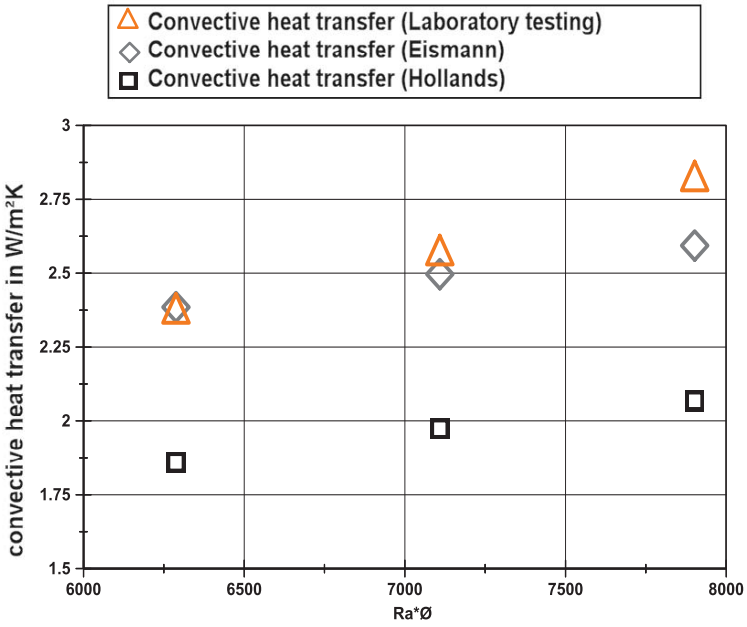

Fig. 5: Comparison of the calculated heat transfer according to Eismann and Hollands et al. and the own test results

The own results differ clearly from Hollands' approach. However, the measured deviations are in a similar range with the results obtained by Bartelsen et al. (1993) and Föste (2013). Beyond that, the results for the convective heat loss are in good accordance with the values from Eismann. The measured points with an inlet temperature of 70 °C and 80 °C are differing only -0.9 % respectively 2.5 % from the values derived by Eismann's approach. Yet, the value for the point with an inlet temperature of 89 °C differs by 7.8 %. Based on this experimental setup the used collector model was enhanced by the extended convection equation. Fig. 6 shows the tested results and the simulated efficiency curve according to Eismann's respectively Hollands' approach of the collector TPS-AlCu20 (Tab. 2).

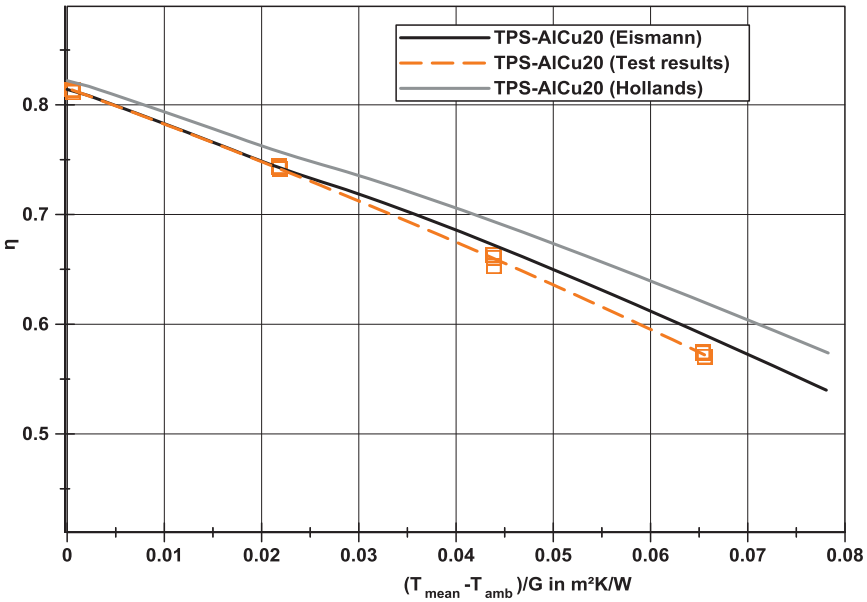

Fig. 6: Model validation by comparison of the measured and simulated collector efficiency with a calculation approach according to Eismann (2015) respectively Hollands et al. (1976)

Tab. 2: Used collector parameters in simulation

Parameter	Value
Aperture area in m²	1.84
Absorber type	Sheet-pipe
Absorber piping	Double-harp
Material absorber sheet	Aluminium (Al)
Material absorber piping	Copper (Cu)
Absorption absorber	0.95
Emission absorber	0.05

Thickness absorber sheet in mm	0.5
Fin width in mm	99
Outer diameter riser in mm	7
Absorber length in mm	1,857
Absorber width in mm	990
Insulation thickness in mm	50
Gap size in mm (unless stated otherwise)	20
Gas filling	Argon / Krypton

For the typical operation point of 0.05 m²K/W the deviation of the simulated values are 7.5 % (Hollands) respectively only 3 % (Eismann). The deviation of the complete temperature difference between the measured values and the simulated values is shown in Fig. 7.

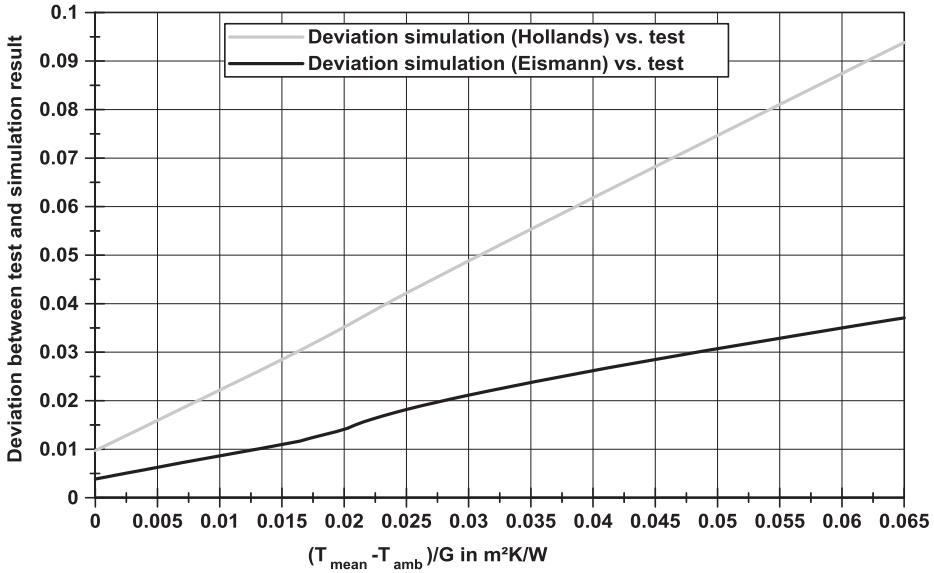

Fig. 7: Deviation between simulation and measurement results

The smallest deviation for the Hollands' approach is about 1 % in the region of the optical efficiency. Again, this is owed to the impact of the fin efficiency factor F' that affects this value. As the total collector losses are included in F' and the convection losses are slightly different, a rather small deviation exists. However, with increasing operation temperatures the deviation gets more obvious. For an ordinate value of 0.065 m²K/W the difference is almost 9.5 %. The extended correlation after Eismann shows only a deviation of 0.5 % for values close to η_0 and 3.5 % at max for higher operating temperatures. The deviation with increasing temperature ranges were also observed in the own conducted convective heat loss measurement. As the mean collector gap size varies, the convective losses differ as well. Ultimately, this behaviour is not included in an equation.

Beside the satisfying results of the efficiency comparison, the measured component temperatures showed as well a good correlation to the simulated results. In this second test setup, the functional model TPS-AlCu20 without the additional polystyrene insulation was equipped with the temperature sensors and put under the solar simulator. The collector's absorber and glazing temperatures were measured for three different inlet temperatures (70, 80 and 89 °C). During this steady-state test, the average insolation was 881.7 W/m² with a mean wind speed across the glazing of 2.5 m/s and an ambient temperature of 24.9 °C. In addition to the varying inlet temperatures, a further measurement series in dry stagnation (I = 879.8 W/m²; v_{wind} = 2.5 m/s) was conducted. Finally, the measured temperatures for absorber and glazing were averaged and compared with the simulation results. The deviation between the stagnation test and the simulated values were between -1.7 up to +0.1 % for the absorber respectively -1.7 to -0.2 % for the glazing. As for the good correlation between test and simulation results, the model is considered to be working properly and, thus, validated.

6. Efficiency analysis, thermal loads and annual yield of a gas-filled collector

Derived by the parameter study above, a gap size of 20 mm for an efficiency comparison between gas-filled collectors (Krypton, Argon) and an identical but vented collector was conducted (Fig. 8).

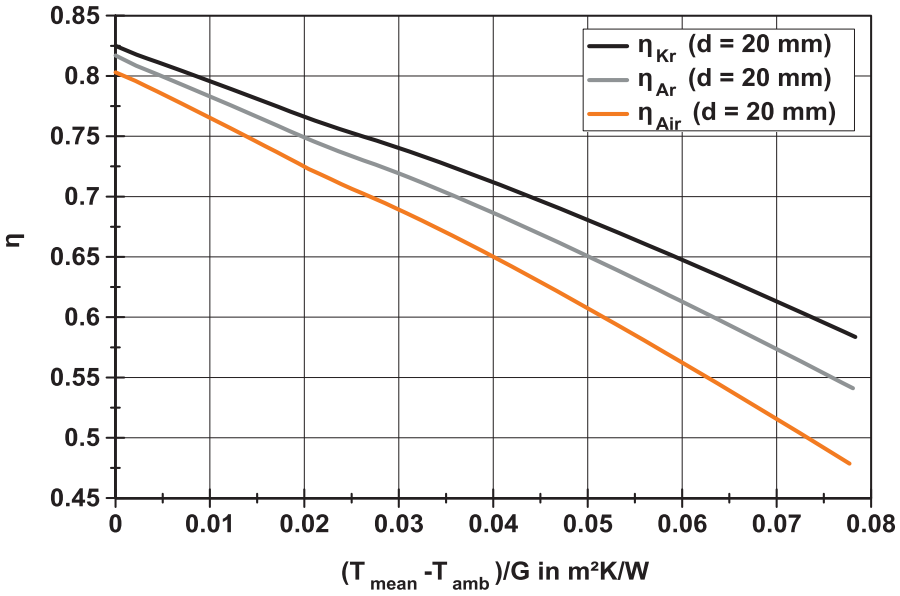

Fig. 8: Efficiency comparison of an Argon and Krypton filled respectively vented collector with a gap size of 20 mm (convection theory according to Eismann (2015))

The collector setting with the Krypton filling outruns the two other simulation results over the complete temperature range. For an ordinate value of 0.05 m²K/W, the efficiency difference between the Krypton and vented collector results in a 7.2 % higher performance whereas the second gas-filled collector version (Argon) lacks 3 % compared to the Krypton variant but outperforms the vented collector by 4.3 %. The predicted efficiency increase by Vestlund (2009, 2012) cannot be confirmed.

Beside the analyses of the collector's efficiency, a system simulation in Carnot (Hafner et al. 1999), an open source toolbox in Matlab / Simulink, and a simulation of the maximum temperature in dry stagnation was conducted. Therefore, the introduced collector model was embedded in a system simulation to derive the magnitude and occurrences of thermal loads during a normal system operation in Germany, maximum temperature during dry stagnation and the annual yield. For this evaluation, a typical solar thermal system for a single-family house in Germany was chosen and implemented in Matlab / Simulink. Since the maximum temperature occurs at the fin end (Duffie and Beckman 2009) and the edge bond was applied in this region, these absorber temperatures were analysed for the thermal load on the primary sealing. However, the edge bond temperatures are slightly lower than the simulated absorber temperatures due to higher edge losses. Yet, it is assumed that this effect is negligible as of the thick side insulation (20 mm). Tab. 3 comprises the used system parameters.

Tab. 3: Applied parameters in the system simulation

Parameter	
Location	Wurzburg (Germany)
Building	Single-family house
Annual heat energy demand in kWh	16,239
Space heating in kWh	2,539
Domestic hot water in kWh	13,700
Heating	Floor heating
Furnace	Oil (15 kW)
Domestic hot water storage volume in litre	130
Buffer storage volume in litre	1,000
Solar collectors in m²	14.4
Collector azimuth	South
Collector parameter TPS-AlCu20	
Optical efficiency	0.815
Linear heat loss coefficient in W/m²K	3.19
Quadratic heat loss coefficient in W/m²K²	0.009
Collector parameter Reference collector	
Optical efficiency	0.815
Linear heat loss coefficient in W/m²K	3.52
Quadratic heat loss coefficient in W/m²K²	0.012
Mass flow in l/m²h	40

Fig. 9 shows the maximum temperatures that occurred during a regular system operation throughout the year.

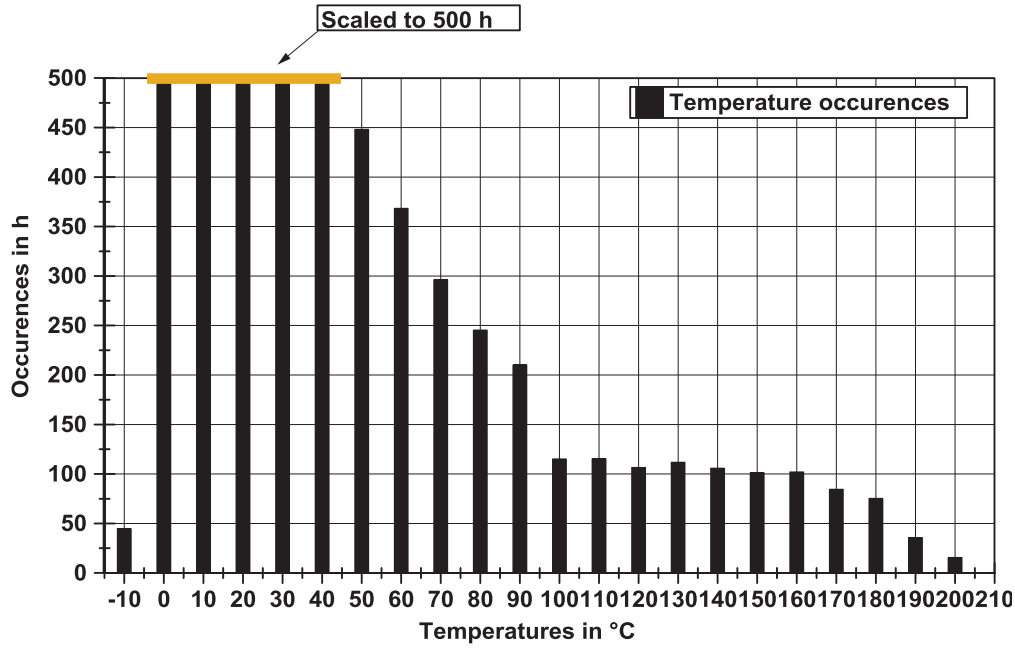

Fig. 9: Temperature load and duration of the absorber temperature during a year in system operation in Wurzburg, Germany

The adhesive service temperatures are not available in public. The temperature range between 100 and 130 °C were defined as short service temperature; however, the idle time cannot be stated. Temperatures exceeding 130 °C are critical and leading to an accelerated ageing effect. In total a dwell time for an absorber temperature between 100 to 130 °C of 449 h respectively 520 h for temperatures above 130 °C were detected. This means 5.9 % of the complete collector operation time the short-term service temperature was exceeded. The higher temperatures, i.e. > 200 °C, are badgering the adhesive more than temperatures close to

130 °C. A temperature amplitude between -13 °C and up to 207 °C was derived by the system simulation. Unlike the high temperatures, this minimal temperature is not afflicted with an ageing effect. To what dimension the temperature magnitude and periods exceeding the service temperature are affecting the material needs to be thoroughly tested, e.g. in outdoor tests.

The gas-filled solar collector achieved an annual solar yield of 5,386 kWh, which corresponds to a specific solar yield of 374 kWh/m²a. In contrast to this, the annual yield of the reference collector is 5,525 kWh (352 kWh/m²a). Further studies with Krypton as gas filling will be conducted as the Argon filled variant only shows a 6 % higher annual yield per collector area than the reference collector.

7. Summary

An existing collector simulation model was adapted, enhanced for gas-filled solar collectors and validated by laboratory testing. The convective heat transfer between absorber and glazing was analysed and compared to recent findings from other scientists. The results confirm the extended convection correlation after Eismann (2015) and show that the use of the convection calculation approach in solar collectors according to Hollands et al. (1976) underrates the heat loss. An efficiency increase of more than 4 to 7 % at a collector working temperature of 0.05 m²K/W for gas-filled collectors was demonstrated. Compared to the values stated in the literature, the efficiency increase of a gas-filled solar collector falls short of expectations (Vestlund 2009, 2012). Short gap sizes of less than 15 mm are critical due to the absorber deflection and, thus, not recommended.
In a system simulation, the thermal loads on the absorber edges and the annual yield of an Argon filled collector were derived. Whether the calculated temperature loads are critical for the adhesive needs to be analysed in a following paper. However, this collector type outruns a vented collector in terms of the annual yield by 6 %. Finally, the proposed collector is produced on a highly automated production line that offers a cost effective assembly for mass production (Riess et al. 2014a, b).

Abstract

For a wide range of operational temperatures, the solar thermal collectors can use optical concentration systems to optimize their efficiency. However, as optical concentration relies on direct solar radiation, it is necessary to use a solar tracker following the sun direction to maximize the amount of useful solar radiation received. The selection of the appropriate tracking systems matching the optical concentration factor is essential to achieve optimal collector efficiency. Otherwise, the concentrator would experience high optical losses due to the inadequate focusing of the direct solar radiation onto its receiver, regardless of its quality. This paper gives the state-of-the-art of the methodologies available to characterize the tracking error of a concentrating collector, a summary of different previous studies done in this subject and of the standardization regarding the tracking accuracy and its influence on the solar collector efficiency. The methodologies and results of the tracking accuracy, incidence angle modifier and optical losses due to tracking errors are presented in this paper for the five collectors studied.

Keywords: *Collector testing; Optical characterization; Solar tracking accuracy; Optical losses*

1. Introduction

Several predictions induces a change in the energy model and the one possibility for serving the world energy demand is the use of renewable and clean energies that are the only one that can support sustainable development by its inexhaustible nature, preserving the environment and distributing the resources locally. The solar energy is one of the main renewable energies with great benefit. Solar thermal energy is able to provide a considerable fraction of the current and future energy demand in both industrial and domestic sectors. This fact is reflected by the growing interest during the last decade in the design of new solar collectors in order to satisfy the increasing electricity and heating demands and replace fossil fuels.

The purpose of a solar tracker is to orient a solar system during the day in order to optimize the incident solar radiation. However, while using optical concentration devices on a solar collector, it is important to use a solar tracker with adequate precision compared to the optical concentration factor and the acceptance angle of the concentrator. Otherwise, the concentrator would sustain high optical losses due to the inadequate focusing of the solar radiation onto its receiver, despite having a good optical quality.

Even though the concentrating solar collectors are mentioned in the International Standards (ISO 9806:2013), the general testing methods cannot always be easily applied to unusual collector designs.

doi:10.18086/eurosun.2016.07.10 Available at http://proceedings.ises.org

Moreover, those testing methods consider the solar tracker as part of the solar collector so they do not characterize the impact of its precision on the overall efficiency. Additionally, the international technical committee IEC/TC 117, created in 2012, is dealing with the same issues related to thermal performance and durability of concentrating/tracking CSP systems and their components considering inputs from experts of various countries. In this committee, two working group has been created at the end of 2014 in order to define the testing standards for PTC (future standard IEC 62862-3-2) and for LFR (future standard IEC 62862-5-2), but no characterization of the tracker accuracy is proposed.

Bendt et al. (1979) considered different optical losses when calculating the flux on a receiver for a parabolic trough collector (PTC). The total effective root mean square (RMS) of a surface optical error results by adding quadratically the individual standard deviation of: the deviation of contour from design direction $\sigma_{contour}$, the imperfect specularity of reflector material $\sigma_{specularity}$, the imperfect placement of the receiver $\sigma_{displacement}$ and the imperfect tracking $\sigma_{tracking}$ as schemed in Fig. 1.

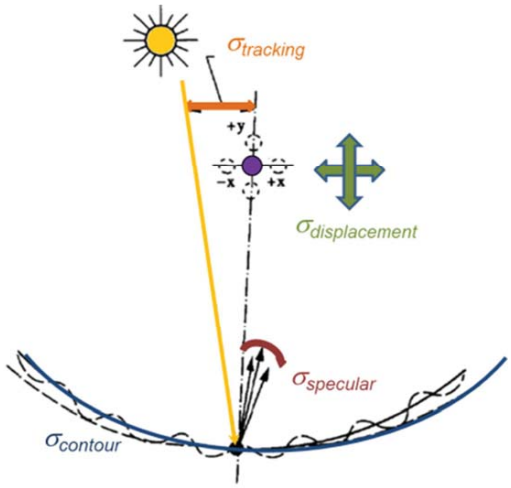

Fig. 1: Optical error from the individual standard deviation

Although the tracking error is not taken into account in current Standards for solar thermal collectors, several studies tried to characterize the tracking error. To do so, some devices could be used in a similar way to the sun-sensors on a closed-loop actuation tracker. But to qualify precisely the tracking error, an accurate electronic device is necessary. Gee (1982) defined a testing procedure and analyzed the angular pointing error on a parabolic through collector (PTC). An encoder was used to record the instantaneous tracking errors with a resolution of 0.03° and then to calculate the RMS (root mean square) of the error. Hession and Bonwick (1984) designed and tested a sun sensor composed of three photo-transistors mounted in a simple structure. This device allowed a solar tracking precision in double-axis better than 0.1°. Bhatnagar et al. (1987) measured experimentally the average tracking error of a tracking system at different solar hours. It was done using their own collector sun-sensor, which consisted in two silicon solar cells placed on either side of a rectangular plate. The error value at noon for the solar tracker characterized in this study was 0.93°. Kalogirou (1996) designed a single-axis tracker using a sun sensor made of three light-dependent resistors (LDRs). The tracking accuracy was estimated of 0.2° for cloudy days (solar radiation of 100 W/m^2) and of 0.05° for sunny days (solar radiation of 600 W/m^2). Arboiro and Sala (1997) presented an improved sun sensor and new strategies for the control unit of solar tracking, using both closed loop and open loop mode. The solar tracker prototype was monitored for one year and presented an accuracy of 0.2°. Sun et al. (2014) used a beam characterization system to evaluate the tracking error of two heliostats from a central tower plant with an estimated accuracy of better than 2% of the positioning angle measurement. Bentaher et al. (2014) analyzed a tracking system for PV panels using a sun sensor composed of two photo-resistors separated on two inclined planes.

Among all the previous studies, none has characterized the tracking error of a linear solar thermal concentrator in actual operation. Moreover, no testing procedure has been developed as the basis for a future standard. As explained before, the tracking system is a critical point of concentrating collectors. In Kalogirou

et al. (2004), the importance of an accurate tracking was clearly verified in the experiment. Those experimental data showed the influence, of the incidence angle deviation from the ideal angle, on the collector efficiency of a parabolic trough. For this PTC, a deviation of only one degree in the transversal incidence angle implies an incidence angle modifier (IAM) of 0.8, which means that the energy efficiency decreases by 20%. In some studies, the optical losses due to the tracking deviation was analyzed and discussed. In Hughes (1980), the pointing error was clearly identified as a source of efficiency reduction. The theoretical intercept factor losses due to the tracking error of a point focusing solar collector with ±0.1º error were calculated using a statistical analysis, but no experimental measurements were performed. Grass et al. (2004) mentioned that the tracking error of a collector with a small acceptance angle can have a significant effect on performance. It was also estimated in that study a value of 0.6 % for the tracking error for evacuated tubes collectors (ETC) with integrated tracking reflector, but with no more experimental details.

For all of those reasons, and the previous results mentioned in the previous sections, due to the lack of characterization test procedures, for single-axis tracking solar concentrators, a testing procedure for solar collectors with single-axis solar tracker is defined in this paper. The main objective is to determine the adequacy of the solar tracking system together with the actual concentration optics of the collector. Moreover, the optical losses due to the tracker were calculated on different concentrating tracking collectors in order to estimate the percentage of reduction on the concentrator efficiency. This study aims to contribute to the improvement of tracking errors estimation on single-axis solar trackers for a solar thermal collector, in particular linear trough collectors. And therefore, it also aims to estimate the optical losses resulting from the tracker.

2. Review of the equipments for measuring the tracking error

A review of all the commercial devices which use the “Machine-Vision” method (MV), based on image treatment. Those equipments already existing in the market are designed to characterize the deviations of the trackers and are not part of the actuator or tracking system.

The first device using MV method, the model Trac-Stat SL1 was developed by the company GreenMountain (Fig. 2a) (Pract Engineering & Consulting webpage). This system was composed of two separate independent sensors, one with a narrow acceptance angle and one with a higher acceptance angle. The first sensor has a field of view angle of 5º with an accuracy of ±0.02º. The second sensor has a field of view angle of 60º with an accuracy of ±0.5º. This device is now commercialized by the company Pract Engineering.

The model SunSpear, developed by the company Inspira and based on the patent 2008/0258051 (Heredia, et al., 2008), is a sensor for measuring the pointing error using an image sensor positioned within a collimator tube (See Fig. 2.b). According to the technical specifications, this equipment has a resolution of 1/10000th of angle with a field of view of 1º (Cervantes and Luque-Heredia, 2008; López et al., 2012; Luque-Heredia et al., 2006). Inspira S.L. was bought by the American company SolFocus.

The model TA1 is manufactured by the German company Black Photon (http://black-photon.de/) (See Fig. 2.c). According to the technical specifications, the measurement range is ± 1.2º, the linearity is ± 1.8 % of full scale and the accuracy is ± 2.4 % of full scale (for temperature between 5ºC and 45ºC). Missbach et al. (2012) presented the results of this sun sensor, with a high accuracy showing a standard deviation of 0.01% of full scale with the measurement of a stable LED (light-emitting diode) light source.

The model LAB is manufactured by the company AKKUtrack (http://akkutrack.com/lab/) (protected by the following patents: BO2010A000361, GE2014A000006, WO2011 /154872). According to technical specifications, the field of view is 4.5º per 2.9º, the resolution is ±0.01º and the relative accuracy is ±0.01º (see Fig. 2.d).

The model Heliosensor is manufactured by the German company PSE (Projects in Solar Energy) (http://www.pse.de) in collaboration with the Black Photon company (see Fig. 2.e). According to technical specifications, the field of view is 55º, the resolution is less than ± 0.02º, and the accuracy is less than ± 0.05º for angles less than 15º and less than 0.5 % for the entire acceptance angle.

Fig. 2: (a) Tract-Stat SL1 by Pract Engineering (Pract Engineering & Consulting) (b) SunSpear by Inspira (Heredia, et al., 2008) (c) Model TA1 by Black Photon (black-photon.de) (d) Model LAB by AKKUtrack (akkutrack.com/lab) (e) Heliosensor by PSE (www.pse.de)

Table 1 summarizes the specifications of the different devices exposed above. In particular, it compares the accuracy and field of view of several commercial devices

Tab. 1: Characteristics of commercial optical device for tracking error measurement

Model	Manufacturer	Accuracy	Field of view angle
Trac-Stat SL1	GreenMountain Engineering	± 0.02º ± 0.5º	5º 60º
Solar Tracker Tester	Proxima Systems S.L	±1º	20º
TA1	Black Photon	± 2.4% of full scale	1.2º
LAB	AKKU track	± 0.01º	4.5º x 2.9º
SunSpear	Inspira	1/10000th	1º
Heliosensor	PSE	± 0.05º	55º

Most of those optical devices characterize the pointing error on a double-axis tracker and could not be used for a linear concentrator because of their reduced field of view. The GreenMountain Engineering device has a field of view up to 60º but its accuracy (±0.5º) is not suitable for the characterization of the tracking error of a PTC tracker in order to estimate the optical losses.

In order to measure the tilt and orientation of a solar tracker, different sensors could be used, such as the angles sensors, the rotary encoders, the tilt sensors or inclinometers (Prinsloo and Dobson, 2015). Within the angular sensors, there are two types: the absolute encoder and the incremental or differential encoder. The main advantage of those devices is that they keep the information of the position even when the power is off. The magnetic encoders are angle sensors connected to a motor actuator drive, which convert the motor rotation pulse into tracking angles. The differential or incremental encoder record the change in the shaft position of a system, but do not keep the information if the power is off. This encoder needs a microprocessor or a software in order to calculate the position angle and to record this data. Table 2 presents the specifications of the different commercial devices.

Tab. 2: Characteristics of commercial inclinometers

Model	Manufacturer	Repeatability	Resolution	Absolute accuracy	Measure angle
IM 60-2	FIAMA	±0.05º	--	--	±60º

3. Materials

This section presents the main characteristics and particularities of the five solar collectors studied during this work. Those collectors have different tracking types and concentrating geometries. The first collector called Sunaitec, from a Portuguese company that manufacture it, is composed of several elliptical concentrators that act synchronized. The second collector is a prototype of variable geometry collector, designed and built by the university of Balearic island (UIB). It is composed of 32 parabolic mirrors, 8 sets of four receiver tubes and a structure that moves the array of receivers with a circular trajectory to maintain the focussing. The third collector is a small size PTC, commercial model PolyTrough 1800, manufactured by the Swiss company NEP Solar AG. The fourth collector was designed for the DIGESPO European project. It is a small size PTC consisting of 4 modules with 4 receivers. The last collector was designed for the EUROTrough European project. It is a large size PTC. All the experiments were carried out in different European facilities. Fig. 3 shows a map with the location of all the collectors and testing bench used during this study.

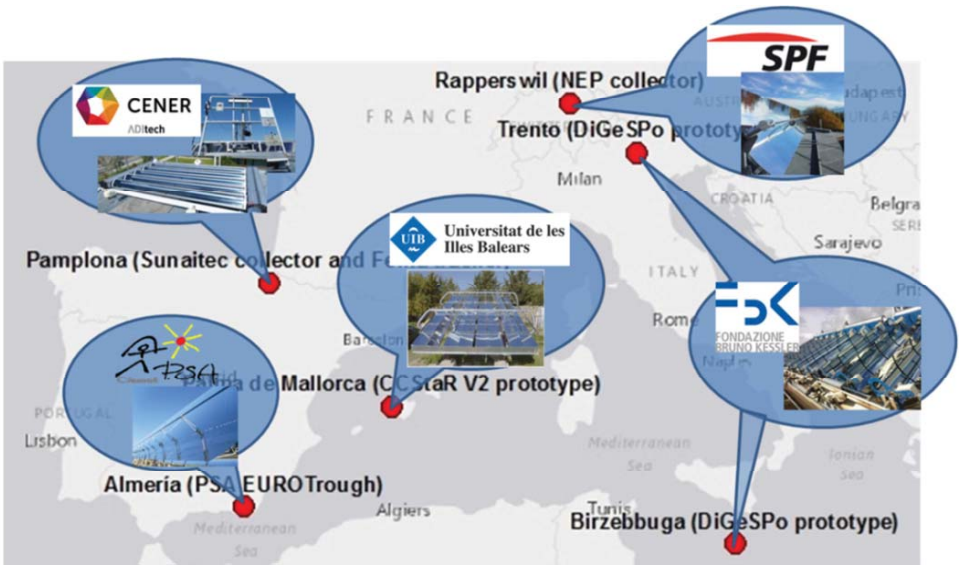

Fig. 3: Defining acceptance angle and relationship between tracking error and optical losses

Table. 3 shows a summary of the main characteristics of the solar collectors used for this study.

Tab. 3: Summary of collector characteristics studied

Solar collector	Sunaitec	CCStaR	NEP	DiGeSPo	EUROTrough
Concentrator type	Elliptic	Fixed-Mirror (fixed reflector and mobile receiver)	Small PTC	PTC with fixed receiver and mobile reflector	Large PTC
Focal length [mm]	Not specified	--	647	200	1710
Collector length L [m]	2.337	576.95 mm	10.347	2.0	75 meters
Receiver tubes	5	4*8	4	4*4	18
aperture area [m2]	1.82	37.4	19.1	12.8	409.9
Concentration factor	4.48	14.4	17.27	33.33	26.2

Axis and orientation	horizontal EW	tilted NS	horizontal EW	tilted polar NS	horizontal EW

4. Methodology

The optical losses due to the solar tracking are an important characteristic of a solar tracker and need to be characterized experimentally by defining a testing procedure. Thus, the main objective of this study is the characterization of those optical losses on a linear solar concentrator and unconventional collectors, for low and medium temperature applications. The test procedure is based on the angular tracking error θ_{track} and the profile of dependency of the optical efficiency on the tracking error, as scheme in Fig. 4.

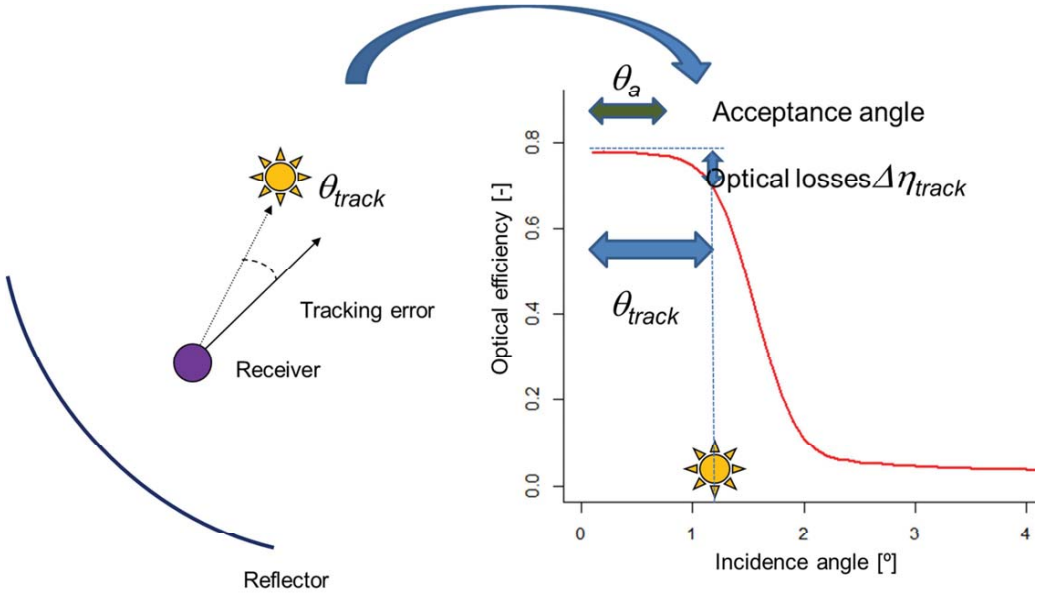

Fig. 4: Defining acceptance angle and relationship between tracking error and optical losses

To achieve this main objective, the following partial objectives were considered:

- Objective 1: Determination of the tracking error θ_{track} on a single-axis solar tracker and analysis for different environmental conditions like wind speed and wind direction. Development of a testing procedure for the characterization of this angular error.
- Objective 2: Characterization of the angular dependency of the optical efficiency to the tracking error, namely incidence angle modifier (IAM) by theoretical simulation and experiment. Demonstration of the utility of ray-tracing techniques in unconventional solar concentrators to determine its optical behavior.
- Objective 3: Calculation of the optical losses due to the tracking error. Determination of the acceptance angle, a key parameters of a solar concentrator, in order to check the accuracy required for the solar tracker to minimize the optical losses of the whole system (tracker and collector).

To reach the objective 1, different testing methodologies were described to quantify the tracking error of solar tracking in single-axis mode. The ad-equation between the precision of the device used to measure the tracking error and the accuracy of the tracker tested was determined. An experimental methodology for the tracking error characterization on a PTC, in the case of horizontal rotation axis, has been proposed, based on the international standard (IEC 62817, 2014) for the design qualification of solar trackers for photovoltaic systems. This proposal leads to the creation of a standard working group in November 2014 within the committee IEC/TC 117 (prIEC 62862-3-2). A statistical analysis was performed to estimate the mean angular error of each tracker.

To reach the objective 2, the optical efficiency was determined for different linear concentrators. The IAM parameter, regarding the beam solar irradiance $K_b(\theta_{track})$, is the one used to estimate the optical losses due to tracking error. The first method to characterize the optical efficiency was done experimentally using International Standards (ISO 9806:2013), the so-called quasi-dynamic test (QDT), monitoring the inputs and outputs of the collectors. The test benches and sensors used for the different collectors are summarized in Table 4.

Tab. 4: Summary of testing facilities

Solar collectors	Sunaitec	CCStaR	NEP	DiGeSPo	EUROTrough
Test location	Pamplona (Spain)	Mallorca (Spain)	Rappeswil (Swizerland)	Malta	Almeria (Spain)
Direct irradiance	Pyranometer - Shaded pyranometer	Pyrheliometer	Pyrheliometer	Pyranometer - Shaded pyranometer	Pyrheliometer
Diffuse irradiance	Shaded pyranometer	Shaded pyranometer	Shaded pyranometer	Shaded pyranometer	--
Temperature	Pt100	Pt100	Pt100	Pt100	Pt100
Flow	Mass flowmeter (Endress Hausser)	Volume flowmeter (Kamstrup)	Volume flowmeter (Endress Hausser)	Mass flowmeter (Micro Motion)	Flowmeter Emerson

The second method was by simulation, using a ray-tracing program OTSun that was developed in Fortran by the UIB, exposed in Pujol Nadal and Martínez Moll (2012) and compared to other commercial software in Osório et al. (2015). From the IAM profile $K_b(\theta_{track})$ was also determined the acceptance angle qa, which is an important factor of the concentrator.

To reach the objective 3, the long-term optical losses due to an imperfect tracking were estimated; an estimation of the long-term and average weighted optical losses due to the tracking error of a solar concentrator. The experimental and simulation results of the IAM on the tracking plane are used to determine the optical losses due to the tracker ($\Delta\eta_{track}$) using the transversal IAM fit $K_b(\theta_{track})$ and the tracking error (θ_{track}), according to Eq. 1.

$$\Delta\eta_{track} = \left(1 - K_b\left(\theta_{track}\right)\right) \cdot 100 \qquad \text{(eq. 1)}$$

As not all the collectors were studied in the same way, Table 5 summarized methodologies used for each sub-objective and collector.

Tab. 5: Methodologies used for each collector and objective

Sub-objetives / Solar collectors	Sunaitec	CCStaR	NEP	DiGeSPo	EuroTrough
1-Tracking error θ_T	Estimation from manufacturer	--	Experimental + Inclinometer	Optical device+ Estimation from orientation	Experimental + Inclinometer
2-IAM $K_b(\theta_T)$	Experimental	Experimental + Simulation	Simulation	Simulation	--
3-Optical losses due to tracking $\Delta\eta_{track}$	Calculation + Experimental	--	Calculation + Experimental	Estimation	--

5. Results

For the first objective, a testing procedure was defined for solar trackers by adapting a testing method from an International Standard IEC for photovoltaic double-axis trackers. The experiments were carried out using a simple procedure to determine the tracking elevation error. In Sallaberry et al. (2014a), a methodology for measuring elevation tracking error using an inclinometer has been defined and tested on a simple double-axis solar tracker at CENER. In Sallaberry et al. (2015a), the same methodology using an inclinometer has been tested on the NEP small-size PTC with EW single-axis solar tracker. In Sallaberry et al. (2015b), the same methodology using an inclinometer has been tested on the EUROTrough large-size PTC with EW single-axis solar tracker. On the DiGeSPo, a prototype device, based on the MV concept, had been designed and tested (Sallaberry, 2015d).

Second, the optical characterization of different concentrating solar collectors was performed through simulation and experiments. In particular, its dependency to the transversal incidence angle along the tracking plane is characterized. The IAM on the tracking plane was studied experimentally on the Sunaitec elliptic trough collector. In Sallaberry et al. (2015b), the IAM testing procedure for tracking collector has been defined and the asymmetrical product behavior for the Sunaitec asymmetric collector has been verified experimentally on a low concentrating/ tracking collector. In Sallaberry et al. (2015a), the IAM was obtained by simulation for the NEP collector. In Sallaberry et al. (2014b), the IAM testing procedure for the CCStaR nonconventional collector has been defined and a simulation ray tracing has been validated experimentally. A good agreement was found between the simulation and the experimental results considering the measurement uncertainties. In Sallaberry et al. (2015c), a theoretical model has been presented to specify the range of the incidence angles which should be tested on variable-geometry collectors to validate the IAM terms in the energy equation balance used on the CCStaR collector. In Sallaberry et al. (2014c) the IAM profile of the NEP collector was also determined by simulation. See Fig. 5 for IAM results in color surface by simulation and in black dot for experiment.

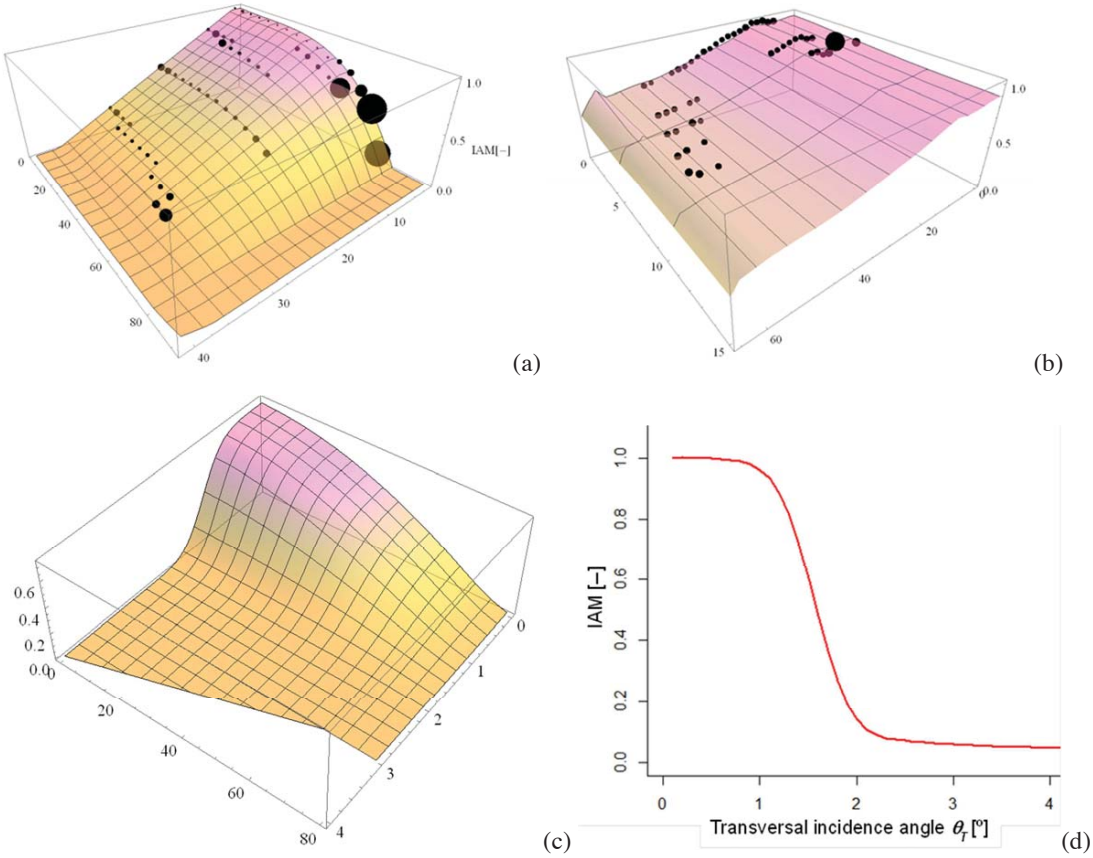

Fig. 5: IAM results by simulation (color surface and red line) and experiment (black dots) for (a) Sunaitec (b) CCStaR (c) NEP (d) DiGeSPo

Third, the long-term optical losses due to the tracking error were estimated using the transversal IAM obtained previously by raytracing simulation or by experiment, and the tracking errors distribution estimation. The impact of the maximum tracking error angle upon the optical efficiency has been determined on different concentrating/tracking collector types. In Sallaberry et al. (2015b), the long term calculation of the optical losses due to a tracker has been defined on the Sunaitec small low-concentration collector. In Sallaberry et al. (2014c), a sensitivity analysis has been performed about the possible source of tracking errors caused by an incorrect positioning of the DiGeSPo concentrating/tracking collector. In Sallaberry et al. (2015a), the average optical losses caused by the solar tracker has been calculated on the NEP small-size PTC. Table 6 summarized the results obtained for the three different sub-objectives,

Tab. 6: Summary of results

Results	Sunaitec	CCStaR	NEP	DiGeSPo	EUROTrough
1-Tracking error θ_T	Estimated ± 5°	Not estimated	± 0.4°	Experimental: between -0.6° and 0.1° / Estimation: ± 0.6°	± 0.3°
2-IAM $K_b(\theta_T)$: Acceptance angle θ_a	2.8°	Variable geometry	0.58°	0.9°	--
2- IAM $K_b(\theta_T)$: Optical efficiency η_{0b}	Experimental 67.7%	Simulation: 68.8% Experimental: 68.7% /	Simulation: 74%	Simulation: 77.7% Experimental: 30.9%	Experimental: 65.6%

3-Optical losses due to tracking $\Delta\eta_{track}$	$\Delta\eta_{track,year}$ = 1.01% 62% of data lower than 1%.	--	$\Delta\eta_{track,weighted}$ = 0.317% 95% of data less than 2.5%	$\Delta\eta_{track}$ up 0.5%	--

Finally, this work (Sallaberry, 2015e) describes the points defined in the International Standards that should be improved in order to ascertain the influence of the tracking accuracy on the overall efficiency of concentrating/tracking solar collectors. Some points have been proposed for a future Standard testing procedure on trackers for solar thermal collectors

6. Conclusions

In this work, solar collectors with different typologies have been tested; all with single-axis tracking and optical concentration (CCStaR V2 prototype with fixed reflectors and mobile receiver; Sunaitec collector with elliptic trough concentrators; NEP PTC single-axis solar tracker; DiGeSPo collector with fixed receiver tube and mobile reflectors). Unlike conventional solar collectors, such as flat plates and evacuated tubes, in the case of concentrating/tracking collectors, there is no clear specific testing procedure from a standard organisation. Furthermore, no testing procedure for the tracking precision exists and the efficiency testing procedures do not take into account all the special features of those collector types. More precisely, the IAM characterization is not completely standardized for unconventional concentrating/tracking collectors.

The main conclusions of this work, related to the three objectives in section 4 are given beneath:

- The characterization methodology of the angular error of tracking systems have been developed and validated experimentally on different solar trackers. The instantaneous angular tracking errors obtained by a simple procedure using digital inclinometer can be implemented and characterize statistically the tracking error distribution.
- The use of ray-tracing simulation has been validated for different types of concentrating solar systems, in which the optical efficiency for some solar incidence angles are difficult to obtain experimentally. Hence, the simulation by ray-tracing programs allowed determining the optical efficiency at any incidence angle. The simulation results have been compared to the experimental ones obtained during testing campaigns using the procedure presented. The agreement was very good.
- The IAM profile obtained previously has been compared to the maximum angular tracking error. In this way, the connection between the concentration optics and the tracker precision has been checked for two collectors.
- Finally, the optical losses of concentrators have been estimated using both the instantaneous angular tracking error measurements and the IAM results. Thus, valuable parameters, the weighted or the long term optical values, could be calculated to quantify the effect of the solar tracker on a concentrator performance.

7. Acknowledgements

I would like to thank the companies Sunaitec, TSC Tecnología Solar Concentradora S.L., NEP for letting me use the data of their collectors for my PhD and the institutes FBK and Ciemat-PSA for welcoming me in their facilities. Part of the experimental work on the EUROTrough collector were performed during an exchange of two weeks at PSA European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 609837 (Scientific and Technological Alliance for Guaranteeing the European Excellence in Concentrating Solar Thermal Energy, STAGE-STE).

Performance Evaluation of scheffler Concentrator

Praveen J. Sanga[1], Arbind Kumar[2] and Sabin K. Mishra[3]

[1] Waljat College of Applied Sciences in academic partnership with Birla Institute of Technology, Muscat (Oman)

[2] Birla Institute of Technology, Mesra, Ranchi (India)

[3] Higher College of Technology, Ras-Al Khaimah (UAE)

Abstract

Scheffler concentrator, used widely for cooking purpose, is simple in design and efficient, hence performance analysis of the reflector is essential. In this regard, an experiment is conducted to evaluate its performance. A lateral section of paraboloid having fixed focus at a distance is taken as a reflector to minimize the effect of the shadow of the receiver. The water contained in a dome shaped receiver located at fixed focus, gets converted into steam and collected in the steam header until ample pressure is reached and further, it can be utilized for cooking purpose.

Keywords: *Scheffler concentrator, receiver, fixed focus, steam header, solar energy*

1. Introduction

Over the past few years solar energy has been strongly recommended as a feasible source of energy both economically and its availability in abundance. Almost all the fossil fuels (coal, wood, natural gas, oil, etc.) have originated from solar energy as they have been formed due to high pressures and temperatures over a long period of time. Also, the increasing rate of consumption of oil and gas would not be able to meet the future demand in energy. In this situation one of the alternative source of energy is solar energy, available free of cost. In recent years, solar energy is being utilized in power generation, water desalination, cooking purpose etc. (Sanga 2013). Solar energy is also pollution free and in present context it is one of the major advantages for the society.

Concentrators designed and developed by Delaney (2003) are suitable for medium temperature applications because of their ability of delivering temperature in the range of 300^0 C. One of the major properties of solar concentrator is its fixed focus, which is desirable for domestic and industrial application. Munir et al. (2010) concluded that it is possible to construct a concentrator having fixed focus for all the days of the year. In this regard, a Scheffler concentrator was constructed and tested by Solare Bruecke (2010). In the study, a thermal storage device is constructed for storing heat that could further be utilized in the evening. It has also been showed that the available energy in the cooking vessel fixed at the focal point of the reflector is approximately half of the energy falling over the reflector.

2. Experimental Description

The experimental set up consists of a dome shaped receiver, steam header, Scheffler reflector, pressure relieve valve and pressure gauge as illustrated in Fig. 1. The specification of the complete set up is mentioned in table 1. The Scheffler reflector is exclusively used for cooking application because of fixed focus and single axis tracking. The shape of the concentrator chosen is a lateral section of a paraboloid having reflectivity of 90% and

doi:10.18086/eurosun.2016.07.01 Available at http://proceedings.ises.org

above. Protection of the mirror coating has been taken into consideration at the time of fixing the mirrors. The purpose of this break is to have reflectivity equal to conventional secular's anodized finishes and resistant to ultraviolet light like glass. The axis of daily rotation of the reflector is fixed at an angle equal to the latitude angle of the site (Ranchi, India) with horizontal in north-south direction parallel to the earth axis and runs through the centre of gravity of the reflector. It helps the reflector to maintain its gravitational equilibrium, hence it requires less force to rotate it. The performance of the concentrator depends upon the efficiently utilization of tracking system coupled to a gearbox which runs with the help of digital timer and a DC motor.

Table 1: Experimental set up specification

Parameter	Specification
Inner base diameter of receiver	337 mm
Outer base diameter of receiver	355 mm
Height of the receiver	150 mm
Inlet Pipe diameter	0.5 inch
Outlet Pipe diameter	1 inch
Inner diameter of steam header	255 mm
Length of steam header	800 mm
Thickness of steam header	19 mm
Length of mirror	225 mm
Breadth of mirror	170 mm
Total mirror used	212
Total cutting mirror used	20

Table 2: Nomenclature and symbols

Quantity	Symbol	Unit
Enthalpy	h	kJ/kg
Volume	V	m^3
Density	ρ	kg m^{-3}
Beam Radiation	I_b	W m^{-2}
Concentration ratio	C	
Area	A	m^2
Efficiency	η	
Time	t	s

The steam generated in the receiver gets collected in the cylindrical steam header. The working pressure of the steam header is about 15 kg/cm^2. A Bourdon tube pressure gauge is used for measuring the pressure inside the steam header. The range of the pressure gauge used is 0 kg/cm^2 to 15 kg/cm^2. Pressure-relieve valve controls or limits the pressure, if it exceeds the desired pressure. The temperature gauge attached with steam header is having range varies from 0^0 C to 200^0 C. The interconnecting pipe between steam header and receiver is insulated with glass wool having minimum thickness of 50 mm.

The concentration ratio of the reflector is the ratio of aperture area to the receiver area and is given by Sukhatme et al. (2013).

$$C = \frac{\text{Aperture area}}{\text{Absorber area}} \qquad \text{(eq. 1)}$$

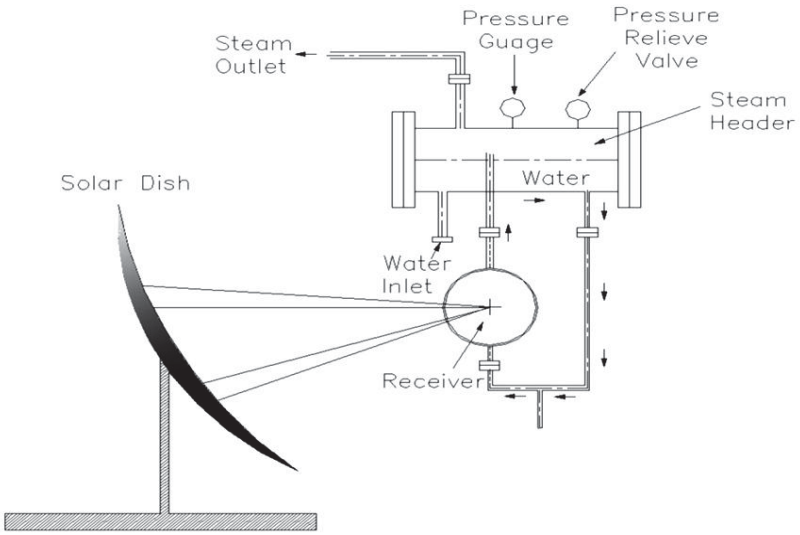

Fig. 1: Schematic of experimental set up

The effective area of the aperture is obtained by the total number of mirrors used. The enthalpy of the steam stored in the steam header is determined by steam table using linear interpolation. The experiment was carried out in February, 2015 and the average readings were taken at the time interval of 15 minutes as given in table 3. Beam and diffused radiation were measured with the help of precision pyranometer. The performance of the system is determined by the effective utilization of the reflected radiation. Therefore, efficiency of the system is defined as a ratio of energy stored in steam header to the energy reflected on the receiver.

$$\eta = \frac{h \times V \times \rho}{I_b \times C \times A \times t} \qquad \text{(eq. 2)}$$

3. Results and Discussion

The variation of beam radiation and temperature with respect to time is depicted below in Fig. 2. Both of them increase with respect to time. It has been observed that there is an increase in temperature of the steam stored in header even if the beam radiation falls down.

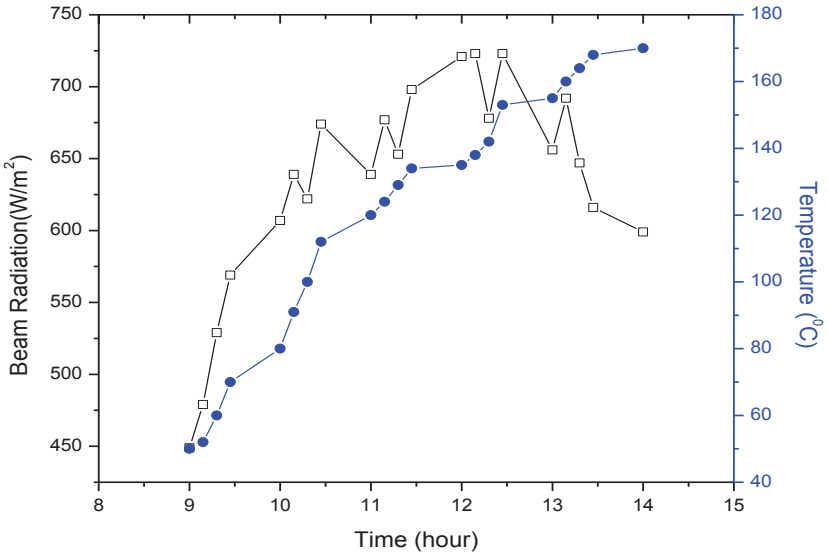

Fig. 2: Variation of beam radiation and steam temperature

The pressure and temperature of the steam collected in steam header is used to evaluate the physical state of the steam. It was also observed that the temperature of the steam is slightly more than the saturation temperature in the steam header after 12 p.m. as shown in Fig. 3, which is vital as the saturated steam has high heat transfer coefficient than the superheated steam.

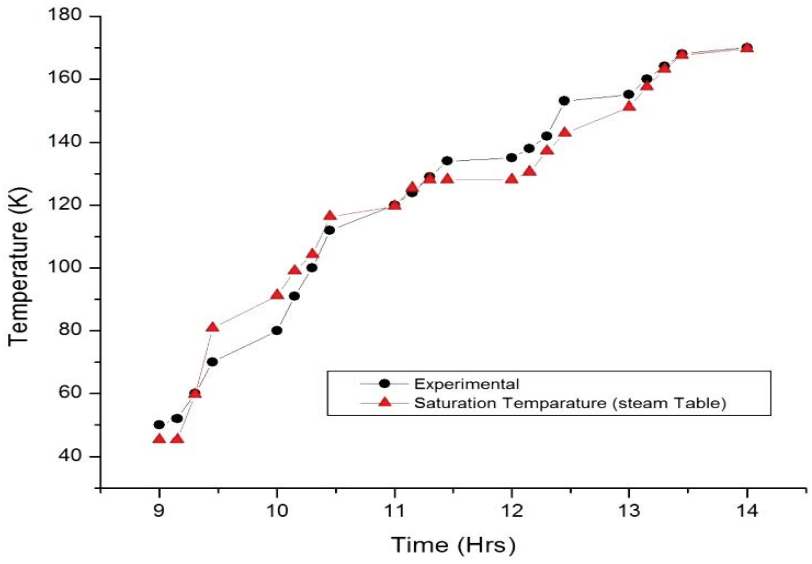

Fig. 3: Comparison of steam temperature at steam header with saturation temperature

The performance of the system is also evaluated. Maximum efficiency of the system was calculated to be 35 %.

4. Conclusion

The study suggests that the system can produce enough steam after 12 p.m. which can further be utilized for cooking purpose. It is also required to have a proper well insulated storage system to minimize the heat loss. As far as cooking place is concerned, it should be decided on the basis of the length of the pipe needed to maintain its temperature without any significant change or loss. The efficiency of the system can also be increased by minimizing heat loss.

Theoretical Analysis of Vacuum Flat-plate Solar Collector with a Detailed Model

Viacheslav Shemelin[1,2], Tomas Matuska[1,2]

[1] University Centre for Energy Efficient Buildings, Czech Technical University in Prague

[2] Faculty of Mechanical Engineering, Czech Technical University in Prague

Abstract

Flat-plate collectors are generally designed for applications with typical working temperatures between 40 °C and 60 °C, which is mostly the case for domestic hot water systems. The major effect on the performance of flat solar collector has heat loss through glazing. The reduction of front side heat loss and consequently increasing efficiency can be achieved by using vacuum glazing. The paper presents a theoretical analysis of flat-plate solar collectors with a vacuum glazing. Different configurations of the collector have been investigated by a detailed theoretical model based on combined external and internal energy balance of the absorber. Performance characteristics for vacuum flat-plate collector alternatives have been derived. Subsequently, annual energy gains have been evaluated for a selected variant and compared with state-of-art vacuum tube collectors. The results of modeling indicate, that in case of using advanced vacuum glazing with special low-emissivity coating (emissivity 0.20, solar transmittance 0.85), it is possible to achieve efficiency parameters similar to or even better than vacuum tube collectors.

Keywords: *flat-plate collector, vacuum glazing, detailed model*

1. Introduction

Flat-plate solar collector (FPC) is the most widely used solar collector type in Europe. Simple structure, high optical efficiency, low cost, and safe operation are its main features. However, FPC is generally designed for a low temperature level between 40 °C and 60 °C, which is mostly the case for domestic hot water system. Any shifts to a higher temperature level could bring the extension of applicability range of FPC. Hence, efforts aimed to improve the performance of flat plate solar collectors are ongoing. The performance of a flat plate solar collector is largely influenced by the thermal losses from the absorber to the ambient via the transparent cover. One way to reduce this heat loss is to reduce the natural convection heat transfer in the space between the absorber and the cover by its partitioning with the use of additional glass pane, plastic film, or transparent insulation materials (TIM). Another way to reduce this heat loss is to use gas with lower thermal conductivity rather than air or by evacuating the space.

During the last 60 years a great number of research works have been done with the aim to develop new designs of solar flat-plate collector able to yield good performance at medium temperature range. The proposed designs are mainly centered around the objective to reduce heat losses, especially front side heat losses, e. g. by using transparent insulation materials (TIM), moderate vacuum, and high vacuum.

Veinberg and Veinberg (1959) investigated the use of “deep narrow meshes” as solar transparent honeycomb insulation. Further, Hollands (1965) presented the theoretical performance characteristics of a cellular honeycomb as a convection suppression device placed between the absorber and the outer glass cover of the FPC. Tabor (1969) presented a brief picture of cellular (honeycomb construction), indicating successful use of honeycomb insulation should wait for material with better physical properties and manufacturing technique. Later, Rommel and Wagner (1992) demonstrated that FPC containing 50-100 mm polycarbonate honeycomb

doi:10.18086/eurosun.2016.07.06 Available at http://proceedings.ises.org

layers function well with fluid working temperature between 40-80 °C. Higher working temperatures up to 260 °C are also possible using glass honeycombs, since plastic covers are susceptible to melting at temperatures above 120 °C. Svendsen and Jensen (1987) and Svendsen (1989) experimentally showed that solar FPC efficiency can be significantly improved by filling the air gap between absorber and cover with monolithic silica aerogel and evacuating to 10 kPa. Later, Duan (2012) studied the reduction of front side heat loss by placing the aerogel layer between the transparent cover and the absorber plate showing an increase of 21% in the collector efficiency respecting to the conventional collector.

However, most of the available transparent insulation materials are still not a good choice for high temperature flat plate collectors (Brunold et al., 1994). They either cannot withstand high temperature levels because they are made of plastics (most of honeycomb and capillary materials), they are hygroscopic and cannot withstand the humidity inside the collector (aerogels etc.), or they are very expensive (glass capillaries).

The use of a moderate vacuum in flate-plate collectors is known to reduce front side heat losses since the work of Eaton and Blumn (1975). The concept of an evacuated flat-plate collector was commercially realized and is available of the market. Apart from the higher thermal output, these collectors have the advantage of longer lifetime compared to nonevacuated collectors, because no humidity and condensation problems occur within the casing. Typical interior pressures, which can be maintained economically, lie between 1 and 10 kPa. It means that although convection losses are suppressed, gas conduction remains fully developed. Further, Benz and Beikircher (1997) constructed a prototype collector based on the commercially available flat-plate collector. To implement high thermal efficiency in the medium temperature range, the thermal losses of the absorber have been reduced using a low emissive selective absorber, a low pressure krypton filling (5 kPa) in the collector casing. The prototype collector has been dynamically tested and has showed very high efficiencies of more than 60% at 100 °C. Later Benvenuti (2005) presented a FPC, which is able to reach 300 °C. That has become possible by ultrahigh vacuum (1.33 x 10^{-7} Pa) maintained by a getter pump powered by the sun. After few years SRB Energy, with the support of CERN experts and facilities, has started the production of these collectors.

This paper presents the idea of replacing single glazing, which is used in most of flat solar collectors, with flat vacuum glazing, which, on the one hand, will show a low level of heat losses (low-emissivity coating, high vacuum) and, on the other hand, will demonstrate a high solar energy transmittance. Flat-plate solar collectors with low heat loss (at the level of vacuum tube collectors) and with a sufficiently high optical efficiency could be effectively used for integration into building envelopes (residential, industrial), which are widely available.

2. Vacuum glazing as a glazing cover of solar collector

Vacuum glazing consists of two glass sheets sealed together around the periphery. Glass sheets are supported by a pillar array arranged on a regular square grid pattern, and space between sheets is evacuated to a pressure lower than 0.1 Pa, thus effectively eliminating both gaseous conduction and convection. The pillars have a dimension of about 0.5 mm in diameter and behave like thermal bridges. Three different heat transfer mechanisms contribute to the total heat transfer coefficient $h_{g1\text{-}g2}$ of the glazing: thermal conduction through residual gas (h_{gas}), thermal conduction through spacers (h_{spac}), and radiation heat transfer between the two sheets (h_{rad}) in vacuum glazing. The total heat transfer coefficient $h_{g1\text{-}g2}$ between the glass sheets of a vacuum glazing can be approximated by the simple addition of individual heat transfer coefficients as (Weinlader et al, 2005; Collins and Simko, 1998)

$$h_{g1-g2} = h_{gas} + h_{rad} + h_{spas} = 0.8P + 4\varepsilon_{eff}\sigma T_{mean}^3 + \frac{2\lambda r}{d^2} \quad \text{(eq. 1)}$$

where P is internal pressure, σ is Stefan Boltzmann constant (5.67 x 10^{-8} W/(m^2.K^4)), T_{mean} is the average of temperatures T_1 a T_2 of the glass sheets, λ is the thermal conductivity of glass pillars, r is thr radius of glass pillars, d is the distance between pillars and, the effective emittance, ε_{eff}, is conventionally written as follows:

$$\varepsilon_{eff} = \frac{1}{\frac{1}{\varepsilon_1}+\frac{1}{\varepsilon_2}-1} \quad \text{(eq. 2)}$$

The relationship (eq. 1) is valid for the space with pressure less than 0.1 Pa, that is, high vacuum.

Vacuum glazing already appears in the portfolio of windows suppliers for use in buildings (Fig. 1). Commercially available vacuum glazing with configuration 3-0.2-3 mm has a transmittance of solar radiation of τ = 67 % and glazing center-of-glazing transmittance U value of 1.1 W/(m^2.K) (e.g. Pilkington Spacia).

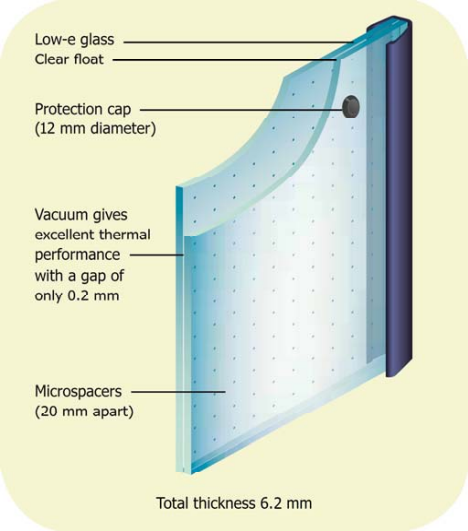

Fig. 1: Vacuum glazing (Pilkington Spacia)

Commercially available low-e coatings have been almost exclusively developed for architecture. To uphold the thermal and visual comfort in buildings, coating systems based on silver are primarily used, which can provide for extremely low emissivity (less than 0.03) and high visible transmittance (up to 0.90). Solar transmittance, however, is rarely higher than 0.60. A low solar energy transmittance, caused by reflectance of low-emissivity coating for the near infrared radiation (NIR) in the solar spectrum, is unsuitable for use in solar collectors. However, values up to 0.80 and corresponding higher emissivity (between 0.15 and 0.20) can be achieved using very thin silver layers, which have been developed in the last years for triple glazing, or with metal oxides (Fig. 2). It is also possible to use the external glass antireflection coatings on both surfaces and thus reduce reflection at the two boundary surfaces air-glass.

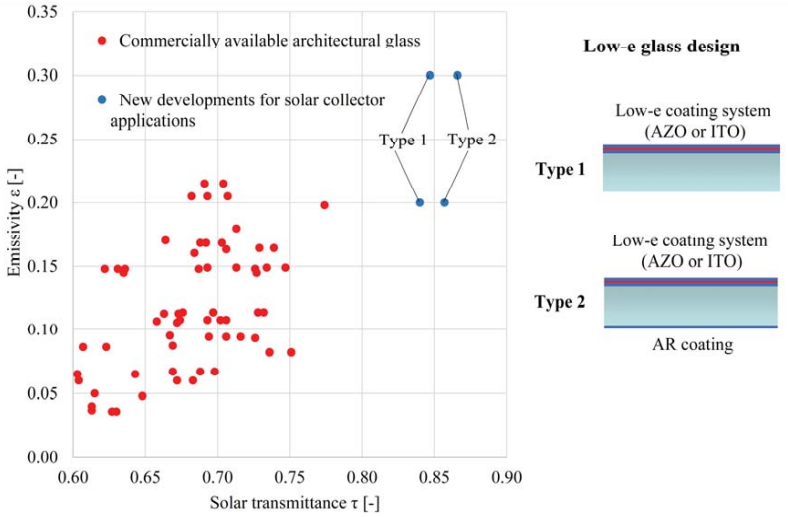

Fig. 2: Optical properties of spectrally selective glass with high solar transmittance for architecture and solar collector applications (Giovannetti et al, 2012)

To evaluate the potential of vacuum glazing application in solar thermal collector design, detailed simulations for three different variants of the collector cover glazing have been carried out. Reference variant (REF) is a simple solar low iron glass. The second variant (VG1) has a vacuum glazing based on two low iron glass without any coating. The last variant (VG2) is an advanced vacuum glazing with low-emissivity coating on

the outer surface of the inner glass (position 3). The optical properties of the coating are IR emissivity of 0.2 and solar transmittance of 0.85. Configurations of considered collector glazings are shown graphically in Fig. 3. The parameters of the cover glazings used for the comparative study are listed in Tab. 1.

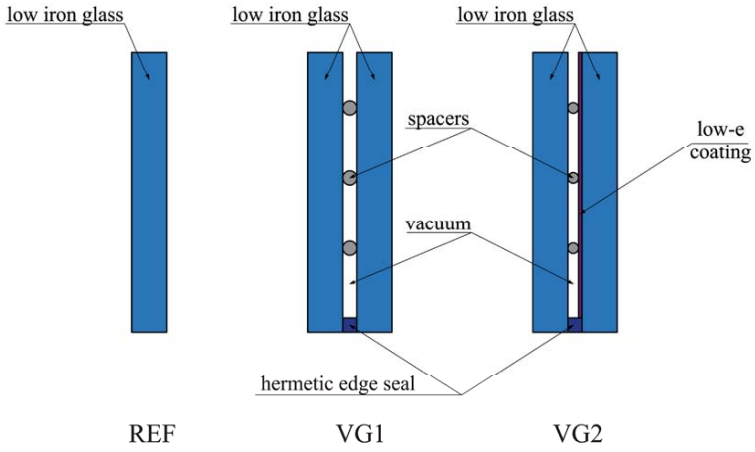

Fig. 3: Configurations of the investigated cover glazings

Tab. 1: Comparison of cover glazing physical properties

Properties	REF	VG1	VG2
Thickness of layers (mm)	4	4-0.2-4	4-0.2-4
Emissivity of surfaces (-)	0.85/0.85	0.85/0.85/0.85/0.85	0.85/0.85/0.2/0.85
Solar transmittance of glazing (-)	0.92	0.85	0.79

Since the thermal conductance is dependent on the temperature of the glazing, the heat transfer coefficient should be determined as a function of mean glazing temperature $T_{g1\text{-}g2}$ (Fig. 4)

$$h_{g1-g2} = f\left(T_{g1-g2}\right) = f\left(\frac{T_{g1}+T_{g2}}{2}\right) = h_{g0} + h_{g1}T_{g1-g2} + h_{g2}T_{g1-g2}^2 \qquad \text{(eq. 3)}$$

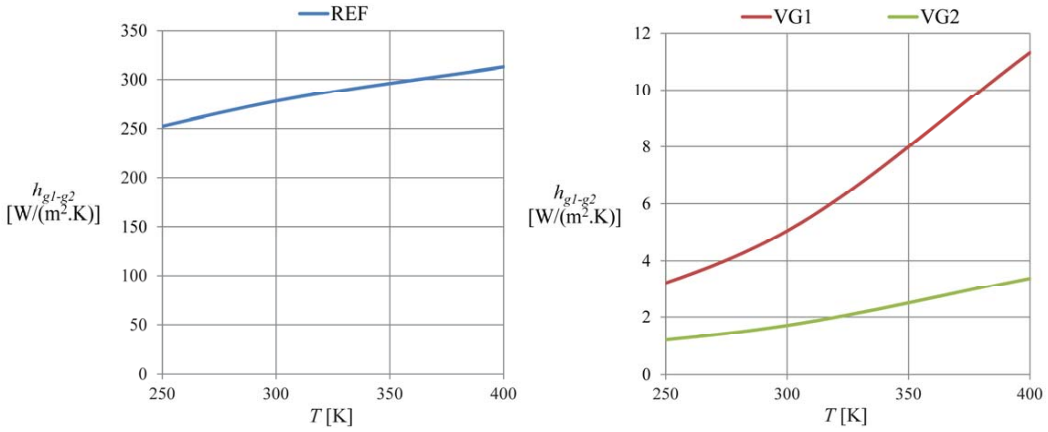

Fig. 4: Thermal conductance of the glazing as a function of mean temperature

3. Theoretical model of solar flat-plate collector

3.1. Description of the model

In order to analyze the thermal performance of FPC with considered variants of the transparent cover, a detailed theoretical model of the flat-plate collector Type 205 has been used and implemented into TRNSYS simulation software. The TRNSYS type is a successor of design tool KOLEKTOR 2.0 (Matuska and Zmrhal, 2009) originally developed as the Visual Basic program.

To compare the performance of given glazings the flat-plate collector has been considered consisting of an absorber placed in the insulated box covered with a given transparent cover. There is an air gap between the absorber and the cover and between the absorber and its back insulation, both defined by thickness and slope. The absorber is designed as a harp with distribution and riser pipes (defined by length, distance, and diameter). Transparent cover and back thermal insulation are defined by temperature dependent thermal conductance (see eq. 3).

The detailed model of flat-plate solar collector allows concluding a detailed calculation of heat transfer in the solar collector. Energy flow from the absorber surface to ambient and from the absorber surface to a heat transfer liquid, together with a temperature distribution in the collector, are calculated in the iteration loops. A solar collector can be specified by a number of detailed parameters, optical properties of glazing and absorber, and thermophysical properties of the main components of solar collector (frame, absorber, and transparent cover) in the model.

The implementation of the model in TRNSYS environment offers the parametric analysis for different construction alternatives for annual solar collector performance in the given solar system application. There is also a possibility to change a mathematical models describing the fundamental heat transfer phenomena (closed gap convection, wind convection, forced convection heat transfer in pipes etc.) and perform sensitivity analysis for selection of the models.

3.2. Basic equations

Mathematical model for solar flat-plate liquid collector solves one-dimensional heat transfer balances. Hottel and Woertz, Hottel and Whilier, and Bliss developed the simplest assumptions: thermal capacities, are neglected and a single value of collector overall heat loss coefficient is considered. Based on these assumptions and considering that the heat transfer is mainly one-dimensional and predominant in the direction normal to the absorber, Duffie and Beckman developed a simplified model (with electrical analogy) to characterize the solar collector in steady-state conditions.

The mathematical model in general consists of two parts: external energy balance of absorber (heat transfer from absorber surface to ambient environment) and internal energy balance of absorber (heat transfer from absorber surface into heat transfer fluid). The model solves the energy balance of the solar collector under steady-state conditions according to the principle Hottel-Whillier equation for usable thermal output

$$\dot{Q}_u = A_{abs} F_R [\tau_n \alpha_{abs} G_t - U(T_{in} - T_{amb})] \quad \text{(eq. 4)}$$

In this equation, A_{abs} is the absorber area, F_R is the collector heat removal factor, τ_n is the solar transmittance of the collector cover, α_{abs} is the solar absorptance of the absorber, G_t is the total solar irradiance, U is the overall heat loss coefficient of collector, T_{in} the inlet fluid temperature and T_{amb} is the ambient temperature.

The main planes of the collector are cover exterior surface (f_2), cover interior surface (f_1), absorber (abs), back insulation interior surface (b_1), back frame exterior surface (b_2), edge insulation interior surface (e_1), and edge frame exterior surface (e_2). A surface temperature is determined for each plane of collector during the calculation procedure. The main collector planes are schematically outlined in Fig. 5.

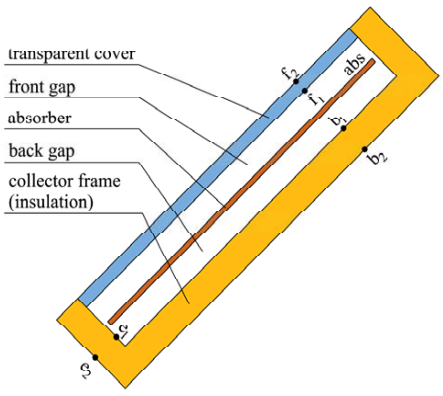

Fig. 5: Main temperature planes (surfaces) in solar collector model

Both external and internal energy balances are mutually dependent. The overall collector heat loss coefficient U as the main output from external balance is one of the inputs for internal balance. On the other side, mean absorber temperature T_{abs} as one of the outputs from internal balance is used as necessary input for external balance. Iteration loop has been introduced to transfer the results from external balance to starting internal balance and results from internal balance are put to external balance. Loop iterates as long as the difference between absorber temperatures calculated in two adjacent iteration steps higher than required minimum.

3.3. External energy balance

The external energy balance consists of:

- the heat transfer by radiation and by natural convection in the gap between absorber surface and transparent cover (respectively back insulation and edge insulation);
- the heat transfer by conduction through transparent cover (respectively back insulation and edge insulation);
- the heat transfer convection and radiation from exterior cover (respectively back frame and edge frame) surface to ambient.

To calculate the heat transfer coefficients properly (Fig. 6), temperatures for main collector planes (surfaces) should be known, but on the other side the temperature distribution in the collector is dependent on the heat transfer coefficients values. Therefore, external energy balance of absorber is solved in an iteration loop starting from first estimate of temperatures for each main surface based on given input temperature T_{in} and ambient temperature T_{amb}.

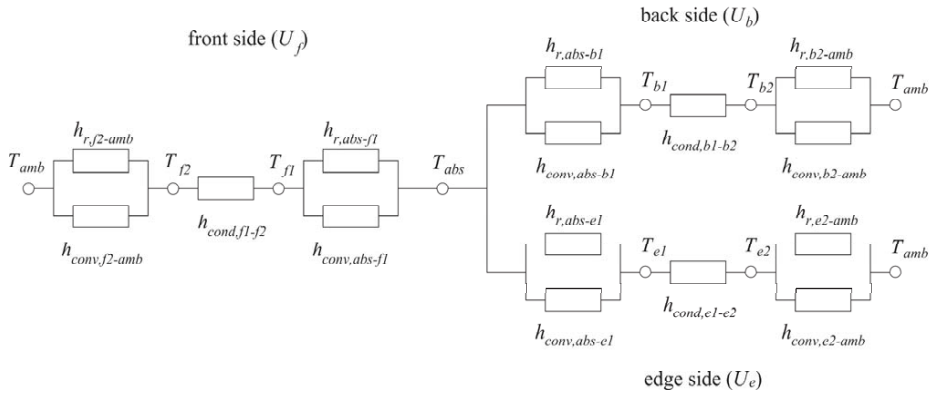

Fig. 6: Schematic detailed layout of external energy balance of absorber

3.4. Internal energy balance

The internal energy balance considers:

- the fin heat transfer by conduction;
- the heat transfer by conduction through the bond between absorber and pipes;
- the heat transfer by forced convection from interior surface of pipe to fluid.

Internal energy balance proceeds in its own iteration loop due to relationship between mean fluid temperature T_{mean} and forced convection heat transfer coefficients in absorber pipe register. The iterative calculation results of internal balance are collector efficiency factor F', collector heat removal factor F_R, usable thermal output and efficiency of solar collector.

3.5. Experimental validation

Type 205 has been experimentally validated in the frame of solar collectors testing according to European standard EN ISO 9806 in the accredited Solar Laboratory operated under University Centre for Energy Efficient Buildings, Czech Technical University in Prague. Solar thermal collectors have been tested to obtain steady state thermal output at constant operation conditions of inlet temperature (±0.05 K) and mass flow rate (±0.002 %) of heat transfer fluid (water) entering collector and at constant climatic conditions of solar irradiation (±1.4 %) and ambient temperature (±0.05 K).

Instantaneous efficiency has been calculated from collector thermal output related to total solar irradiation input (incident on collector reference area: gross area). Experimental data points of solar collector efficiency are coupled with uniform uncertainty bars in the graphs. Expanded uncertainty of efficiency and reduced temperature difference have been assessed for experimental data from both type A (statistical) and type B (instrumental) uncertainties considering the coverage factor $k = 2$ with 95% level of confidence (normal distribution).

The theoretical calculation of efficiency characteristic by the model is subjected to the uncertainty of input parameters. While geometrical parameters are easily available with high degree of confidence, the number of parameters defining the properties of collector parts is found uncertain within narrow range (e.g. absorber and glazing optical parameters, mostly ±2 %), middle range (e.g. conductivity of insulation layer dependent on its temperature and density, ±10 %), and quite broad range (e.g. emittance of absorber back side, insulation or collector frame, >10 %). Therefore, the results of theoretical calculation could be presented as two delimiting curves where the collector efficiency values can be found in reality.

The mathematical model has been validated in the field of atmospheric solar flat-plate collectors (top quality solar collectors with state-of-art copper laser welded absorber coated with a high performance selective coating and solar glazing as a transparent cover). Four different solar collectors have been used for detailed model validation. The majority of solar thermal collector parameters (e.g. thermal conductivity of insulation, the solar transmittance of the glazing, and the emissivity of the absorber) have been measured experimentally to reduce the uncertainty range. The model has also been tested in the case of various values of slope, mass flowrate, wind velocity, and incident radiation. More information about model validation could be found in (Shemelin and Matuska, 2015).

Fig. 7 shows experimentally measured efficiency points and theoretical modelled efficiency characteristics. It is evident from the results that simulated efficiency characteristics fit the measurements relatively well, which gives confidence about the developed model.

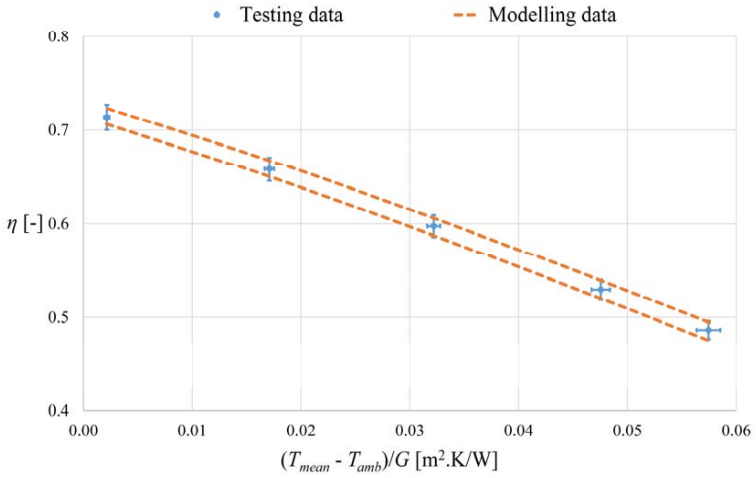

Fig. 7: Mathematical model validation

4. Results

Four configurations of FPC were modeled with dimensions 1 x 2 m. All variants have state-of-art copper laser welded absorber with a high performance selective coating with absorptivity of 0.95 and emissivity of 0.05. The thickness of the absorber is 0.2 mm and distance between pipes is 100 mm. Back thermal insulation and edge thermal insulation with thermal conductivity of 0.04 W/(m.K) have thickness 50 and 20 mm, respectively. The thickness of the air gap between absorber and glazing is 30 mm (except variant VC4, explained below). The difference between considered variants is only in the covering glazing.

The first configuration of FPC (RC) has a reference glazing (REF) as transparent cover with the parameters shown in Tab.1. The second configuration VC1 has a vacuum glazing VG1 instead of the reference glazing.

The third configuration VC2 considers variant VG2 as cover glazing. The last configuration VC3 has a principally different configuration. This variant has no gap between the absorber and the cover. Here, the absorber is bonded to the VG2 by permanently flexible, highly transparent silicone gel to reduce the whole thickness of the collector ("slim" collector alternative suitable for building envelope integration). Considered configurations of FPC collectors RC, VC1, VC2, and VC3 are shown in Fig. 8.

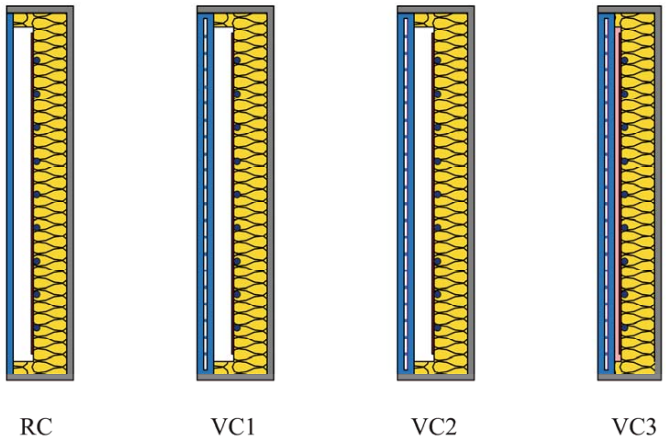

Fig. 8: Considered solar collector configurations

The graph in Fig. 9 shows the efficiency curves of considered solar collector variants. With respect to the EN ISO 9806 (2015) Standard "Solar energy-Solar thermal collectors-Test methods", the collector efficiency η is based on the collector gross area A_G. The calculations have been done with use of early described theoretical detailed model of FPC Type 205. The Graph shows the difference in energy quality of compared FPC variants. The low slope of the efficiency curve of the VC2 is due to the collector VC2 having two low-e coatings—the first inside the vacuum glazing and the second on the absorber surface. Other variants RC, VC1, and VC3 have only one low-e coating. Despite the vacuum layer, higher emittance of the glass low-e coating (0.2) in the VC3 variant instead of absorber coating with emittance 0.05 in the REF variant, brings the total top heat loss to similar value, but optical parameters of the VC3 configuration are lower (lower zero loss efficiency η_0). The resulting coefficients of efficiency characteristics η_0, a_1, and a_2 are listed in tab. 2.

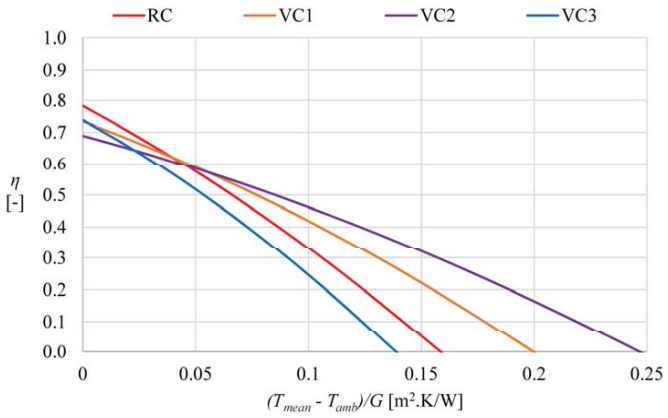

Fig. 9: Efficiency curves of different solar collector variants

Tab. 2: Summary of the collector simulation results

Collector variants	η_0 [-]	a_1 [W/(m^2.K)]	a_2 [W/(m^2.K^2)]
RC	0.783	3.788	0.006
VC1	0.734	2.634	0.004
VC2	0.689	1.919	0.003
VC3	0.738	3.890	0.009

On the other hand, solar collector variant VC3 has the lowest thickness between comparing variants – only 60 mm. Such thickness gives more possibility for integration of FPC into the building envelope because of the slim and compact design. Other variants RC, VC, and VC2 have thickness 87, 91 and 91 mm, respectively.

Fig. 10 presents the comparison of efficiency characteristics of flat-plate collector variant VC2 and vacuum tube collectors (with/without reflector, cylindrical/flat absorber) related to the gross area of collector. Thermal performance of solar flat-plate collector variant VC2 is comparable with that of vacuum tube collectors. Moreover, solar collector variant VC2 shows significantly higher efficiency than the majority of vacuum tube collectors (VT).

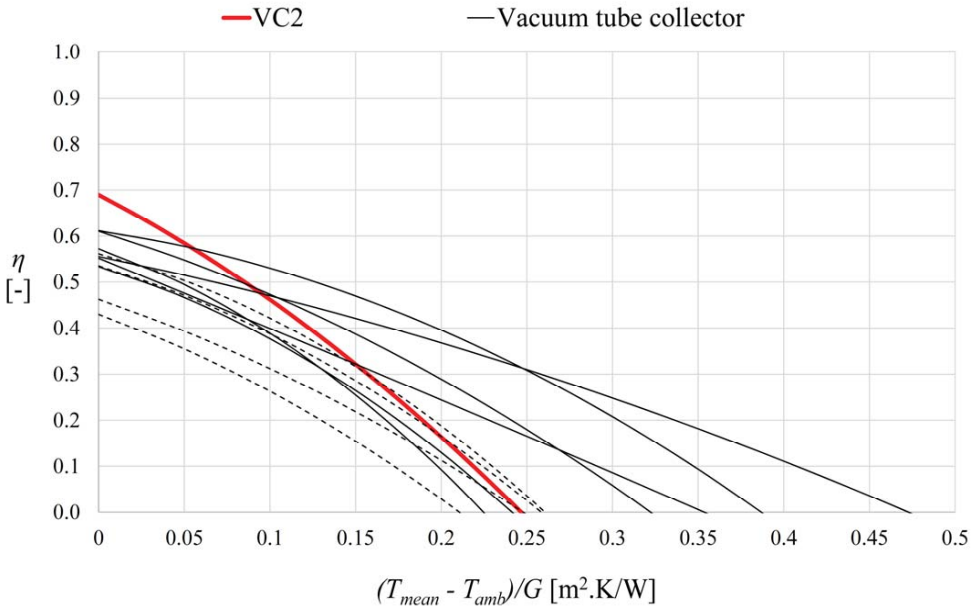

Fig. 10: Efficiency curves of different solar collector variants

To get a whole picture, the annual performance of the collector VC2 and VT collectors has been modelled using ScenoCalc software for constant operating temperatures 25, 50, 75, and 100 °C and climate conditions of Würzburg. The performance and optical characteristics of the compared collectors were used as input data. The results are shown in Tab. 3. The results of the modelling confirmed that the flat-plate solar collector variant VC2 has higher solar energy gains than the majority of vacuum tube collectors up to operating temperature 100 °C.

Tab. 3: Calculated annual solar collector gain with respect to the collector gross area

Solar gain [kWh/m^2]	25 °C	50 °C	75 °C	100 °C
VC2	697	548	422	320
VT1	653	**552**	**462**	**378**
VT2	586	480	386	303
VT3	527	465	390	308
VT4	603	511	421	**337**
VT5	616	515	416	320
VT6	577	478	386	304
VT7	**708**	**646**	**583**	**518**
VT8	607	493	400	318
VT9	626	**556**	**494**	**436**
VT10	667	**590**	**510**	**427**

5. Conclusions

Different designs of flat solar collectors based on a flat vacuum glazing have been theoretically investigated by using the detailed mathematical model to show the potential of vacuum glazing application in solar flat-plat collectors. The selected variant VC2 has been compared with state-of-the-art vacuum tube collectors by annual simulation of collector heat output in ScenoCalc. Results have shown, that there is a significant potential for increasing the efficiency of solar flat-plate collectors by using high performance vacuum glazing as a transparent cover. Collector variant VC2 shows higher performance than the majority of vacuum tube collectors up to operating temperature 100 °C.

Based on this analysis, now it is possible to proceed to the practical solution of the vacuum flat plate solar collector with vacuum glazing and low-emissivity coating (variant VC2). This collector promises to combine the low heat losses and the high solar energy transmittance.

Energy-economic Optimization of Flat-plate Collector

Viacheslav Shemelin[1,2], Tomas Matuska[1,2]

[1] University Centre for Energy Efficient Buildings, Czech Technical University in Prague

[2] Faculty of Mechanical Engineering, Czech Technical University in Prague

Abstract

The optimization of solar collector design may be based on energy, economic or energy-economic criteria. Obtaining maximum energy from a given collector area or determining the required minimum area of collector that produces a given amount of energy are examples of energy criteria. Designing a solar collector with a minimum cost is an example of economic criteria. The net present values, internal rate of return and payback period methods are examples of energy-economic criteria. This paper deals with the obtaining collector design parameters that provide the highest net present value. The following design parameters have been accepted as the decision variables: air gap size between the absorber and the cover glazing, emissivity of the absorber, frame insulation thickness, and distance between riser pipes. A detailed analysis is carried out for evaluating the thermal and optical performance, energy flows and losses for typical flat plate solar collector under given operating conditions – producing hot water for household needs. The high-quality flat-plate solar collector was chosen as a reference alternative. The results of modeling indicate that NPV value of solar collector variant with reduced to 50 mm distance between riser pipes is higher than in the reference variant, which indicates that a design change is economically justified.

Keywords: *flat-plate solar collector, optimization, sensitivity analysis, net present value*

1. Introduction

A wide spectrum of flat-plate collectors (FPC) is available on the market today, ranging from low-cost unglazed collectors to sophisticated selective-coated, single-glazed solar collectors. Up to now, a number of studies have been done in order to improve the thermal efficiency of FPC. The ways of increasing the energy performance of solar collector generally can be divided into two categories: effective absorption of solar radiation together with high rate heat transfer from the absorber to a transport media and reduction the heat loss of the collector to the minimum. The increase in optical efficiency can be achieved by application of glazing with antireflective coatings, use of extra clear low-iron glass instead of ordinary float glass together with spectrally selective absorber coatings. The heat transfer from the absorber surface can be maximized by fully wetted absorbers. Heat loss reduction can be achieved especially by using low emissivity absorber coatings, by increasing thickness of back, and by increasing thickness of the air gap between an absorber and collector glazing, alternatively using the low conductive gas instead of the air, or even by evacuating the space between absorber and cover glazing.

However, any improvement in the efficiency of solar collector has its cost. The use of new technologies and new materials always leads to an increase in collector price. Even given thickness of air gap between an absorber and covering glazing has an influence on the cost of the collector because it affects the overall depth of the collector and, thus, the amount of material used in the frame construction. On the other hand, while the solar PV modules price has dropped considerably in the last decades, the price of FPC collectors still remains high and there are no prospects for significant price reduction. Therefore, energy-economic optimization of the FPC has been taken into account in the present paper. Currently, there are not many studies in this area. A critical point, however, is that most of the published studies focused on energy optimization and did not take into account economic effects of the optimization.

doi:10.18086/eurosun.2016.07.12 Available at http://proceedings.ises.org

Furbo and Shan (2003) investigated the influence of antireflection treatment on the thermal performance of the solar system. Simulations showed that the thermal performance of SDHW systems with annual solar fractions of 25% and 60%, respectively, is increased by 10% and 4%, respectively, if a collector with a glass with an antireflective coating is used instead of a collector with a standard glass. Later, Kong et al. (2015) carried out the half-year measurement of the SDHW system with and without antireflective coating. The results show that solar gain for the system with solar fraction 75% and an antireflective coating is 2.4% higher in comparison to the solar system without an antireflective coating.

For achieving the maximum conversion efficiency, one important strategy is to use spectrally selective solar absorbers that exhibit a near-blackbody absorptance in the solar radiation region while suppressing emittance at infrared range. In particular, the new low-cost tandem absorber coatings have been extensively investigated by a number of groups. Feng et al. (2015) reported that TiAlN/TiAlSiN/Si_3N_4 coatings, deposited on stainless steel substrates can exhibit high absorptance of 0.938 and thermal emittance of 0.09. According to Liu et al. (2012), NbTiON/SiON absorber coating prepared on Cu substrate showed high selectivity with an absorptance value of 0.95 and emittance value of 0.07. Barshilia et al. (2008) studied NbAlN/NbAlON/Si_3N_4, and these tandem absorbers showed high absorptance of 0.956 and low emittance of 0.07. In a different work, Wu et al. (2015) reported that high absorptance of 0.948 and low emittance of 0.05 could be achieved by multilayered coating of Al/NbMoN/NbMoON/SiO_2 on stainless steel substrate. In another study, Zou et al. (2015) reported a CrAlN–CrAlON based tandem absorber that exhibited a high absorptance of 0.984 and a low emissivity of 0.07.

Brunold (1994) presented a prototype of a new FPC using glass capillary as transparent insulation. The results of the test indicated that an improved transparent insulated FPC could enter into competition with vacuum tube collectors. Further, Duan (2012) demonstrated that application of aerogel can greatly reduce top heat loss of FPC. Beikircher et al. (2015) presented advanced insulation methods for flat plate collectors. The collector front losses have been reduced by transparent insulation materials, the rear losses by an integrated vacuum insulation. The results of the experiment showed that the prototype with double fluorinated ethylene-propylene film and vacuum rear insulation, as well as prototype with transparent honeycomb insulation with ethylene tetrafluoroethylene film, has efficiency comparable to evacuated tube collectors.

Unfortunately, the main disadvantage of investigations presented above is a lack of cost data to show the profitability of the improvements in energy performance. The objective function for the optimization presented in the paper has been formulated according to the energy-economic criteria because it includes the investment costs (the cost of design changes) and also it includes the performance gains after design changes. The following analysis has been performed at first generally, and then in more detail for the most common application: solar domestic hot water system.

2. Variable design

To demonstrate the influence of the design changes on the collector performance, a detailed theoretical model of flat-plate collector Type 205 has been used. The detailed model of flat-plate solar collector allows a detailed calculation of heat transfer in the solar collector. Energy flow from the absorber surface to ambient and from the absorber surface into heat transfer liquid together with temperature distribution in the collector are calculated in the iteration loops. The solar collector can be specified by a number of detailed parameters, optical properties of glazing and absorber, thermophysical properties of main components of solar collector (frame, absorber, and transparent cover) in the model.

The implementation of the model in TRNSYS environment offers the parametric analysis for different construction alternatives for annual solar collector performance in the given solar system application. There is also a possibility to change mathematical models describing the fundamental heat transfer phenomena (closed gap convection, wind convection, forced convection heat transfer in pipes etc.) and perform sensitivity analysis for selection of the models.

A high-quality solar collector with solar glass as a transparent cover and selective absorber coating has been taken into account as an initial case. Specifications of the flat-plate solar collector used in the analysis are provided below.

Tab. 1: Design parameters of the FPC used in the analysis

Collector parameter	Value	Collector parameter	Value
Length	1175 mm	Air gap thickness	30 mm
Width	2017 mm	Absorber material	Aluminium
Height	87 mm	Absorber thickness	0.4 mm
Aperture area	2.25 m^2	Absorber emissivity	0.05
Absorber area	2.185 m^2	Surface treatment	PVD
Header pipe	Cu 22 x 1 mm	Number of riser tubes	11
Cover material	Solar glass	Distance between riser pipes	100 mm
Cover thickness	4 mm	Back insulation thickness	50 mm
Cover transmittance	0.92	Insulation material	Rockwool

Four decision changes in collector design have been investigated. The parameters discussed are back insulation thickness, absorber emissivity, air gap thickness, and distance between riser pipes. These parameters are known to have a significant influence both on the collector performance and on the collector price. Thus, it becomes possible to perform an energy-economic optimization aimed to reduce the payback period of flat-plate collector. For a series of simulations the evaluated parameter varies in the range of set values while the others parameters are kept fixed. The investigation provided below was based on the analysis performed by detailed theoretical model Type 205 available for TRNSYS environment.

2.1. Back insulation thickness

Nowadays, flat-plate collectors at the rear side are insulated by rock/mineral wool or similar insulation materials. Thermal conductivity of dry insulation amounts to 0.03-0.06 W/(m.K) for temperatures between 0 °C and 100 °C (see Fig. 1).

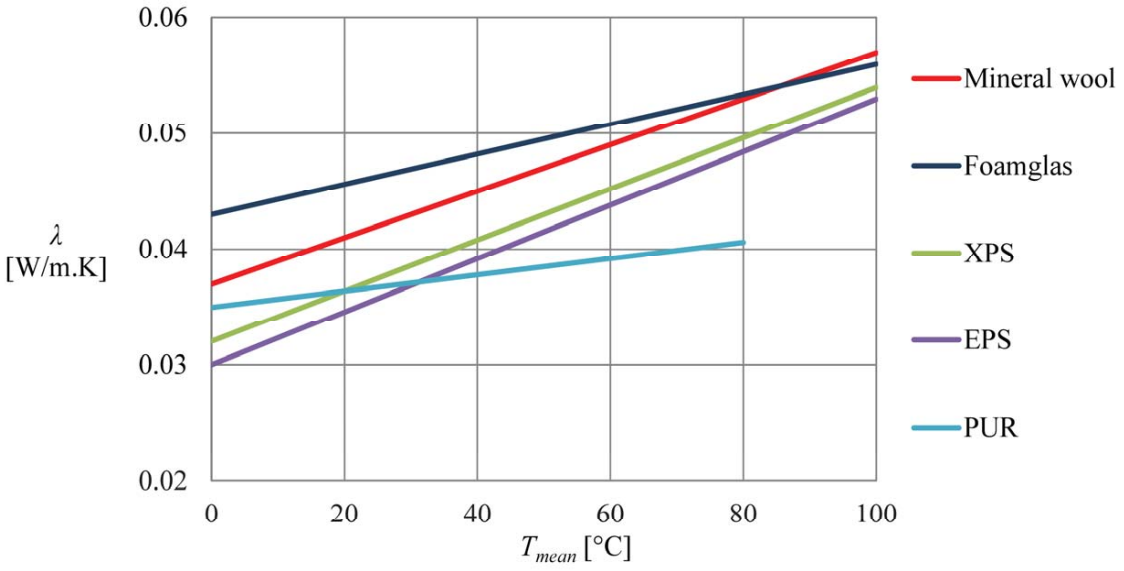

Fig. 1: Thermal conductivity as a function of mean temperature of insulation

For a typical insulation thickness of 40–60 mm, the backside collector heat losses amount to about 0.8 W/(m^2.K) from 3 to 5 W/(m^2.K) total losses. The question for the cost performance optimization is which insulation thickness is significant and which is not? Fig. 2 shows comparison of the efficiency curves for five solar collectors with the same geometrical and physical properties, but with varying thickness of the back insulation. It is apparent from the Fig. 2 that the thickness larger than 30 mm does not make significant improvement in the performance of FPC.

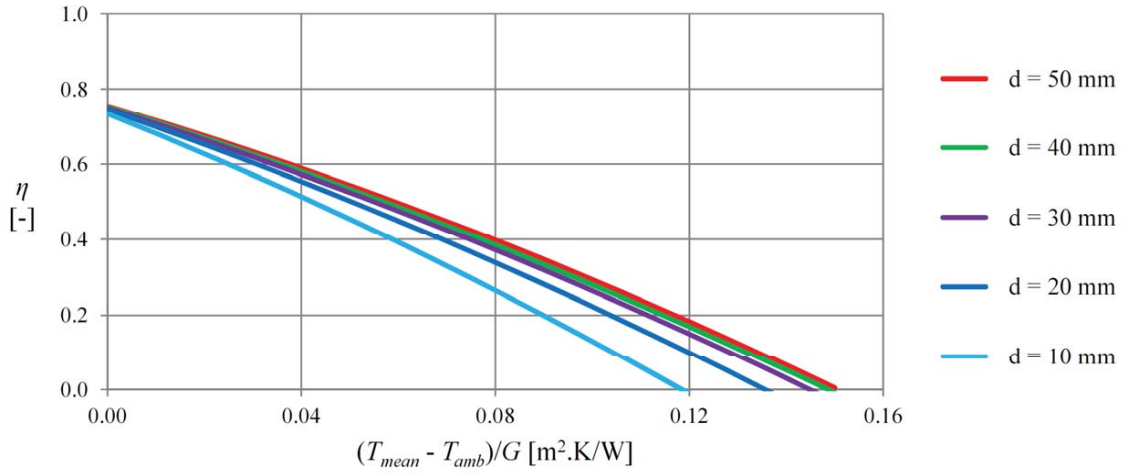

Fig. 2: Collector efficiency for considered design variants

2.2. Absorber emissivity

A solar absorber must have a high absorptivity α for solar (shortwave) radiation and a low emissivity ε for thermal (long-wave) radiation. Selective coatings are used to improve the performance of the solar collector by modifying optical properties both in the shortwave and longwave radiation ranges. For an absorber painted matt black without selective properties, absorptivity is 0.95 and IR emissivity is 0.85. Because of high ε values, such collectors have high heat losses by radiation and thus low efficiency, especially at high operation temperatures. Therefore, practically all single glazed collectors available on the market use selective coatings for the absorber (Tab. 2).

Tab. 2: Optical properties of selective coatings

Absorber coating	Absorptivity α in solar spectrum	Emissivity ε in infrared spectrum
Black chrome	0.95	0.12
Black nickel on polished nickel	0.92	0.11
Black anodized aluminium	0.93	0.07
Ceramic metal (cermet)	0.95	0.05

For the purpose of energy-economic optimization, two versions of absorbing coatings have been considered: a modern PVD coating with an emissivity of 0.05 or older and cheaper electrochemical (galvanic) coating with an emissivity of 0.12 both with the same absorptivity of 0.95. Fig. 3 shows collector efficiency characteristics of considered collector variations as a result of complex modeling. The difference between efficiency characteristics is obvious, especially at high operation temperatures.

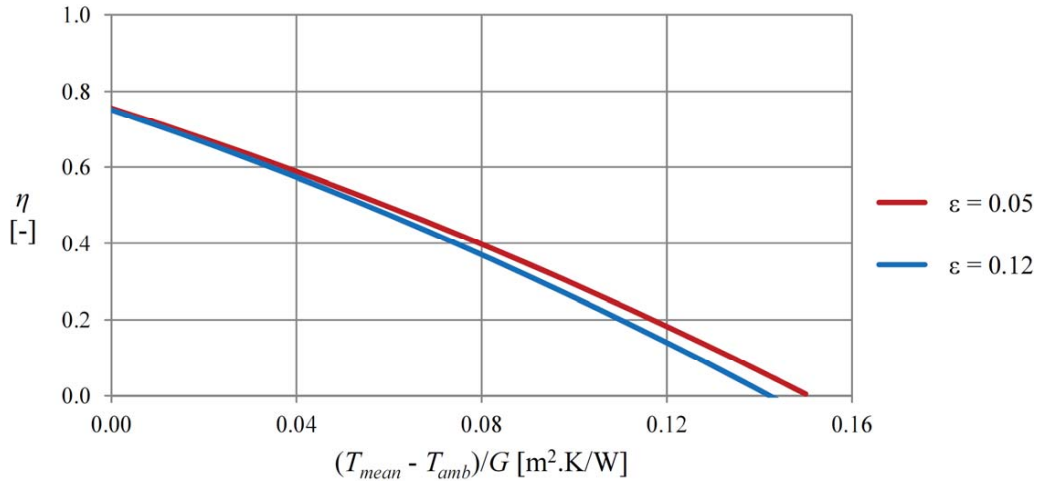

Fig. 3: Collector efficiency for the considered variants with ε = 0.05 and ε = 0.12

2.3. Air gap thickness

To have a good performance of a solar collector it is necessary to limit the thermal losses towards ambient through the front side of collector. Convective heat transfer through the air gap between the absorber surface and glazing has significant influence on these losses. The circulating air between absorber and cover, driven by temperature difference between absorber surface and interior glazing surface, transports the absorbed heat to the glazing. It depends on slope of the collector β and gap thicknesses L. The typical thickness of air gap is 30 mm. The goal is to investigate the influence of the air gap on the effectiveness of solar collector and to determine whether it makes sense to have 30 mm air gap in climatic conditions of Central Europe or the thickness of the air gap could be smaller. The graph in Fig. 4 shows natural convection heat transfer coefficient for closed layer between absorber and cover glazing as a function of the thickness of the air gap. Evidently, convection heat transfer coefficient decreases continuously with an increasing thickness of the air gap. However, Fig. 5 demonstrates a reduced influence of air gap thickness on the collector efficiency characteristics.

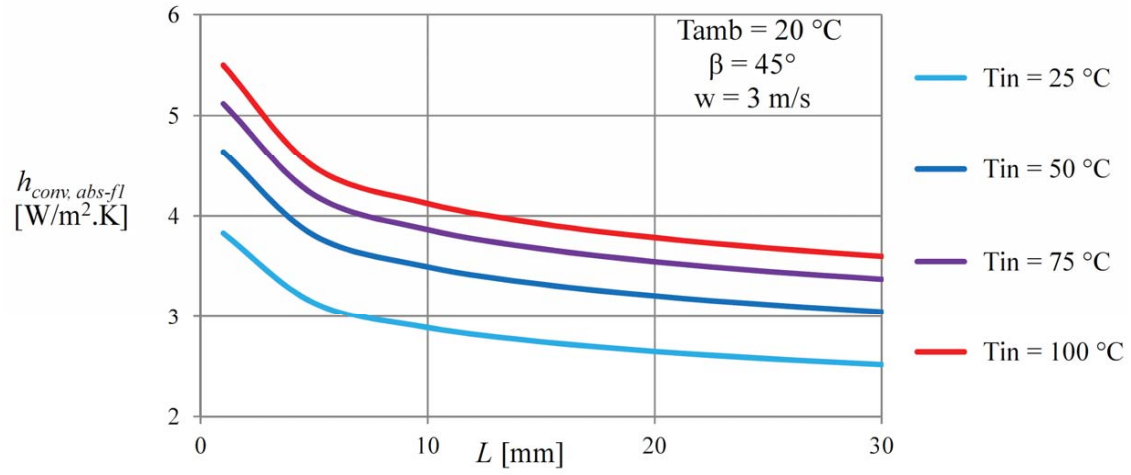

Fig. 4: Natural convection heat transfer coefficient as a function of the thickness of the air gap

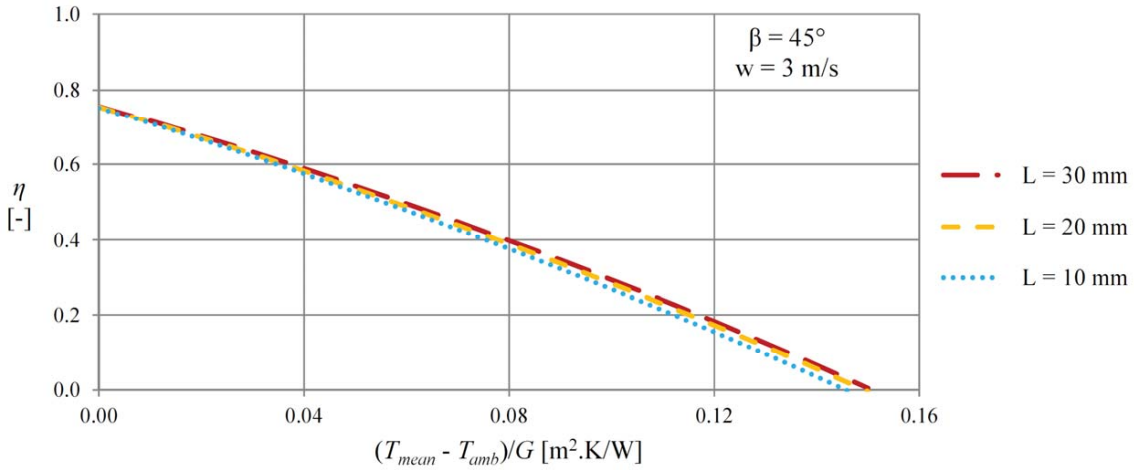

Fig. 5: Collector efficiency for the considered design variants

2.4. Distance between riser pipes

A typical design of the absorbers in solar FPC is represented by a tube and sheet configuration. Different hydraulic collector type (e.g. harp, double harp, or meander) can be used, but conductance of the sheet, conductance of the bond, forced convection heat transfer to the fluid, always have the crucial influence on the thermal performance (heat transfer from absorber surface to the fluid). As for distance between riser pipes, it has a direct impact on the heat conductance of the sheet and, therefore, on thermal performance of FPC. The typical distance between riser pipes is 100 mm. Reducing the distance between riser pipes increases fin efficiency F, collector efficiency factor F' (see Fig. 6) and consequently solar collector efficiency η (see Fig.7). As Fig. 6 shows that thermal conductivity and thickness of absorber also have a significant influence on the heat removal from absorber. For this reason,

the reduction of the distance of rising pipes from 100 mm to 50 mmin has been considered in the analysis. Fig. 7 demonstrates a significant increase in the efficiency characteristic of FPC with reduced pipe distance, especially for low operation temperature.

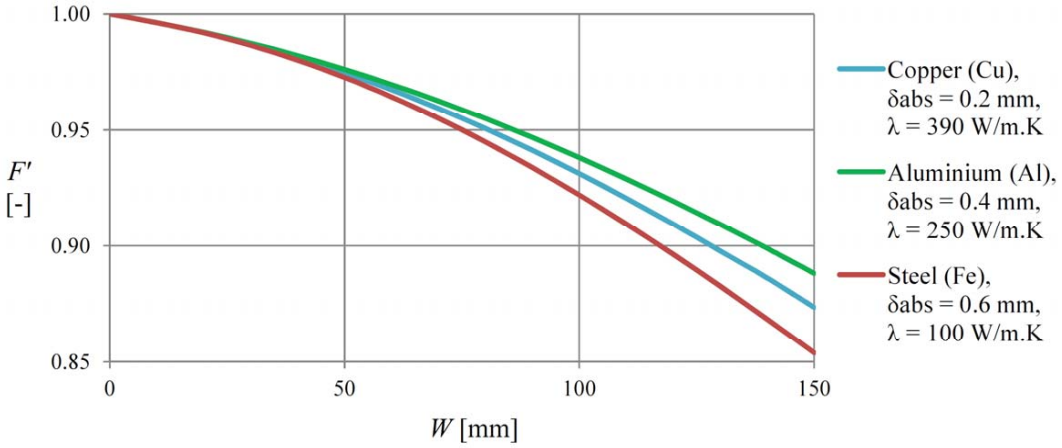

Fig. 6: Collector efficiency factor for different absorber materials as a function of pipe distance

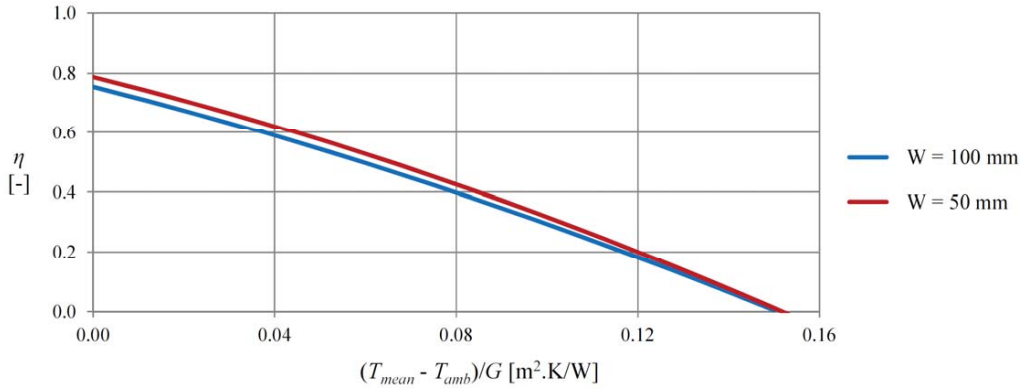

Fig. 7: Collector efficiency for the considered design variants

3. Energy analysis

The annual performance of the different solar collector variants has been evaluated by simulation of solar domestic hot water system with a given solar fraction 50 %. Scheme of the solar system is shown in the Fig. 8.

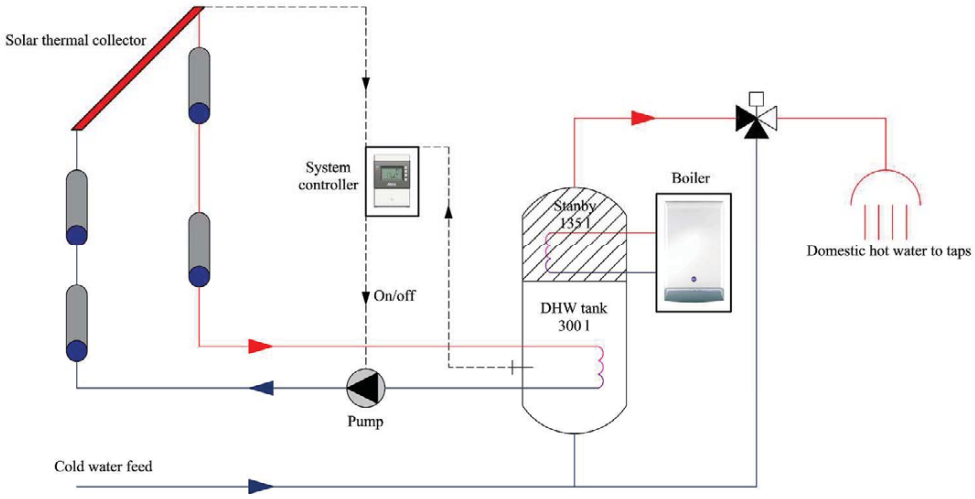

Fig. 8: Schema of simulated solar domestic hot water system

The system specification and the simulation results are shown in Table 4 and Table 5 consequently. The results show that the difference in the annual performance of compared solar collector variants decreases.

Tab. 4: Solar domestic hot water system parameters and operating conditions

Parameter	Description
Location	Athens, Würzburg, and Stockholm
Weather	TMY (Meteonorm)
Collector orientation	South, collector slope: Athens 25°, Würzburg 35° and Stockholm 45°
Collector area	Must cover 50% of domestic hot water heat demand (result between 49.5 and 50.5 %)
Reference area	Gross area
Collector mass flow rate	50 l/h.m^2
Heat transfer medium	Water
Pump control	Pump switching temperature is $\Delta T = 2$ *K* difference between collector output temperature and storage tank temperature in the area of heat transfer surface
Piping	Supply and return pipes are located in the internal and external environments: 7.5 each, DN 16 with 25 mm thermal insulation (λ = 0.04 W/m^2.K). Heat losses are determined towards the inside, respectively outside temperature.
Heat exchanger	Smooth tube heat exchanger with *UA* = 400 W/K (±15%) for 42 °C / 40 °C (outside temperature/tank storage temperature)
Tank storage	Volume: 300 l, heat loss: 2.2 W/K, height/diameter ratio: 2.5, standby volume 135 l with the temperature 60 °C
Cold water temperature	10 °C
Building interior temperature	15 °C
Hot water consumption	200 l/day (7.00 : 80 l; 12.00 : 40 l; 19.00 : 80 l), hot water temperature 45 °C, annual heat demand 2936 kWh/a

Tab. 5: Comparison of the annual energy gains for different solar collector variants

#	Collector design				Annual energy gain		
	back insulation thickness [mm]	absorber emissivity [-]	width of the air gap [mm]	distance between riser pipes [mm]	Athens [kWh/m^2.a]	Würzburg [kWh/m^2.a]	Stockholm [kWh/m^2.a]
RC	50	0.05	30	100	833	499	450
1	40	0.05	30	100	825	493	435
2	30	0.05	30	100	814	478	425
3	20	0.05	30	100	790	451	406
4	10	0.05	30	100	731	369	311
5	50	0.12	30	100	815	480	437
6	50	0.05	20	100	828	495	447
7	50	0.05	10	100	818	488	430
8	50	0.05	30	50	872	510	464

4. Economic analysis

The investigated design changes in the collector construction cause a change in the price of the collector. Based on the cooperation with the manufacturer of solar collectors, the influence of design changes on the price of the reference solar collector has been evaluated (Tab. 6). A negative value of the price change means the price

reduction, while positive value means the price increase. The energy-economic study has also been performed for three cities - Athens, Würzburg, and Stockholm.

Tab. 6: Effect of design changes on the collector price (relative to the gross collector area)

#	Collector design				Price change [€/m²]
	back insulation thickness [mm]	absorber emissivity [-]	width of the air gap [mm]	distance between riser pipes [mm]	
RC	50	0.05	30	100	0
1	40	0.05	30	100	-1.70
2	30	0.05	30	100	-3.37
3	20	0.05	30	100	-5.07
4	10	0.05	30	100	-6.78
5	50	0.12	30	100	-5.59
6	50	0.05	20	100	-0.50
7	50	0.05	10	100	-1.00
8	50	0.05	30	50	+6.07

Based on the full-year simulation results of SDHW system (Table 5) and on the effect of collector price changing (Table 6), the economic analysis has been carried out by using Net Present Value (NPV) method. NPV is a method used to determine the present value of an investment (collector price changing) by the discounted sum of all cash flows (additional energy gain, i.e. operation cost savings) received from the changed solar collector construction. A positive net present value indicates that the additional energy gain generated by a changing construction exceeds the cost of design changes. Generally, an investment with a positive NPV will be a profitable one and one with a negative NPV will result in a net loss. This concept is the foundation for the Net Present Value Rule, which dictates that the only investments that should be made are those with positive NPV values.

The formula for the discounted sum of all cash flows could be written as

$$NPV = -C_0 + \sum_{i=1}^{T} \frac{C_i}{(1+r)^i} \quad \text{(eq. 1)}$$

where C_0 is an initial investment costs, C_i is net cash inflow during period T, r is discount rate and T is time.

To calculate NPV profitability indicator, the following parameters have been assumed:

- Calculation of NPV for all collector variants has been carried out in relation to the reference variant.
- Additional energy gain multiplied by heat price has been used as a net cash inflow (Table 5).
- Collector price change has been used as an initial investment cost (Table 6).
- The following heat prices have been used in the analysis: 0.094 €/kWh for Athens, 0.085 €/kWh for Würzburg and 0.146 for Stockholm with annual growth rate 1%. These prices were derived from statistics on average natural gas prices in Greece, Germany, and Sweden (Eurostat) divided by a boiler efficiency of 0.80.
- A discount rate of 0.1% (average interest for private time accounts in Europe) has been used in the analysis.
- The service life of the collectors has been set at 20 years.

The results of calculation are shown in Table 7. The results of the modelling indicate that the only flat-plate solar collector with reduced to 50 mm distance between riser pipes has the positive value of NPV. That means that this design change is economically profitable. New PVD coatings with an emissivity of 0.05 are economically justified compared to old and cheap electrochemical (galvanic) coating with an emissivity of 0.12. Yet reducing the thickness of insulation to a level less than 50 mm or reduction of the air gap width to a level less than 30 mm, as can be seen from the results, does not make an economic sense as of today.

Tab. 7: Net present value for considered collector variants

#	Collector design				Net present value		
	back insulation thickness [mm]	absorber emissivity [-]	width of the air gap [mm]	distance between riser pipes [mm]	Athens [€/m^2]	Würzburg [€/m^2]	Stockholm [€/m^2]
RC	50	0.05	30	100	0		
1	40	0.05	30	100	-13	-8	-42
2	30	0.05	30	100	-32	-32	-69

6	50	0.05	20	100	-9	-6	-8
7	50	0.05	10	100	-27	-18	-57
8	50	0.05	30	50	67	12	34

5. Conclusion

The energy-economic analysis of flat-plate collector in SDHW system with yearly solar fractions of 50% has been carried out. In order to evaluate economically profitable design changes, numerical calculations have been made corresponding to the climatic and economic conditions of Athens, Würzburg, and Stockholm. The following design parameters were used as the decision variables: air gap size between the absorber and the cover glazing from 30 mm to 10 mm with the step 10 mm, emissivity of the absorber 0.12 and 0.05, rear insulation thickness from 50 mm to 10 mm with step 10 mm, and the distance between riser pipes 100 mm and 50 mm. At the end of the analytical study, there following conclusions can be drawn:

- There is a potential for increasing efficiency of the solar flat-plate collector by reducing the distance between rising pipes and, more importantly, this collector optimization is economically reasonable.
- The energy-economic analysis also shows that using new PVD coating with emissivity 0.05 instead of the electrochemical (galvanic) coating with an emissivity of 0.12 was economically justified.
- Back thermal insulation reduction or width of air gap reduction leads to a reduction of the initial price of the collector, but in the long term does not make any economic sense.

Electrodeposition of Co-Cr Black Coatings on Steel in an Ionic Liquid, For Solar Collection Applications

Gregorio Vargas, Ana P. García, Juanita Cerda and Jorge López

CINVESTAV-IPN, Unidad Saltillo, Calle Industria Metalúrgica No. 1062, Parque Industrial Saltillo - Ramos Arizpe, Ramos Arizpe, Coahuila, México, CP 25900

Abstract

The electrodeposition of Co-Cr black coatings on AISI 304 stainless steel substrates was studied using a solution of Co and Cr salts in an ionic liquid as electrolyte. The electrolyte was prepared employing choline chloride (ChCl) and ethylene glycol (EG) in molar ratios of 1:2, 1:8 and 1:16, as well as Co and Cr salts in molar ratios of 1:1, 2:1 and 4:1. The electrodeposition times were 30, 45 and 60 min. Cyclic voltammetry was used in order to define the potential window in an interval from -1.93 to 1.12 V. The electrodeposition was carried out by chronoamperometry. Scanning Electron Microscopy (SEM) was used to characterize the microstructure and chemical composition of the coatings. Their optical properties were characterized by using UV-Vis spectroscopy and Fourier-Transform Infrared spectroscopy (FT-IR). Homogeneous black coatings having absorptivities (α) of 0.98 and emissivities (ε) of 0.03 were obtained, which were suitable for their application in solar thermal collectors.

Keywords: *Black Co-Cr coatings, deep eutectic solvents, optical properties.*

1. Introduction

Spectrally selective surfaces for applications in solar thermal collectors must have high absorptivity (α) and low emissivity (ε) values. Electrodeposition of black Cr has been widely studied for applications in solar collectors due to their good optical properties (α = 0.97 and ε = 0.19) (Grimmer and Collier, 1981; Eugenio et al., 2011). The toxicity of Cr (VI) has incentivized the study of systems using instead Cr (III) in less toxic water-based electrolytes (Eugenio et al., 2011). However, the success of such systems has been limited by the chemical complexity of the Cr (III) ions in such solutions (Ferreira et al., 2013), as well as due to the hydrogen embrittlement underwent by the coatings (Saravanan and Mohan, 2012). Recently, a new family of ionic liquids, including Deep Eutectic Solvents (DES), has been developed (Abbott, 2006). These liquids are generally composed by two or more environmentally friendly components that are able to associate freely, often through hydrogen bonds (Abbott, 2006). The aim of the present work is to show that the electrodeposition of Co-Cr black coatings on stainless steels, using Co-Cr salts and an ionic liquid as electrolyte, allowed us to obtain spectrally selective coatings that are suitable for applications in solar thermal collectors.

2. Experimental Method

The electrolyte was prepared employing ethylene glycol (EG), choline chloride (ChCl), chromium chloride hexahydrate ($CrCl_3 \cdot 6H_2O$) and cobalt chloride hexahydrate ($CoCl_2 \cdot 6H_2O$). ChCl and EG mixtures (ethaline) were used in molar ratios of 1:2, 1:8 and 1:16, and the Co and Cr salts were used in molar ratios of 1:1, 2:1 and 4:1. The electrodeposition times were 30, 45 and 60 min. Cyclic voltammetry was used in order to define the potential window. The electrolyte was kept at a constant temperature of 60 °C. The studies were carried

doi:10.18086/eurosun.2016.07.11 Available at http://proceedings.ises.org

out using a three-electrode electrochemical cell, employing a vitreous carbon electrode (A = 0.007 cm^2), a stainless steel counter electrode (A = 0.785 cm^2) and an Ag/AgCl reference electrode. The electrodeposition was carried out on AISI 304 stainless steel substrates. Both, the electrochemical studies and the electrodeposition were carried out using a PARSTAT 4000 potentiostat/galvanostat, controlled by the Versa Studio 2.43 software. The employed electrochemical techniques were voltammetry and chronoamperometry. The optical properties of the coatings were characterized using a LAMBDA 850 UV/Vis spectrophotometer, fitted with a 150 mm integrating sphere for the determination of the absorptivity (α). The emissivity (ε) was determined employing a Frontier FT-IR spectroscope fitted with an accessory for diffuse reflectance spectroscopy, which allowed us to obtain the spectral reflectance curves (reflectance vs. wavelength) for the studied coatings.

The values of α were calculated employing equation 1 (Li, 2000):

$$\alpha = \frac{\int_{0.3\mu m}^{2.5\mu m}(1-R)I_{sol}d\lambda}{\int_{0.3\mu m}^{2.5\mu m}I_{sol}d\lambda} \qquad \text{(eq. 1)}$$

where I_{sol} is the solar radiation taken from the ASTM AM1.5 standard (ASTM AM1.5, 2012), while R and λ are reflectivity and total hemispherical wavelength, respectively.

The values of ε were calculated at 100 °C employing equations 2 and 3 (Li, 2000):

$$\varepsilon = \frac{\int_{2.5\mu m}^{25\mu m}(1-R)I_{p}d\lambda}{\int_{2.5\mu m}^{25\mu m}I_{p}d\lambda} \qquad \text{(eq. 2)}$$

$$I_p = \frac{2x10^{24}hc^2}{\lambda^5}\frac{1}{e^{\frac{10^6 hc}{\lambda kT}}-1} \qquad \text{(eq. 3)}$$

where I_P is the black body radiation at 100 °C, c is the speed of light ($2.998x10^8$ m s^{-1}), h is Planck's constant (6.628×10^{-34} J s = 4.136×10^{-15} eV s), and k is Boltzmann's constant (1.381×10^{-23} J K^{-1} = 8.617×10^{-5} eV K^{-1}).

Scanning Electron Microscopy (SEM) was used to characterize the microstructure and chemical composition of the coatings. This was carried out using a PHILIPS XL30ESEM apparatus, with a voltage of 20 KeV and a working distance of 10 mm.

3. Results and Discussion

Cyclic voltammetry allowed us to define the potential window (electrochemical stability range for the electrolyte) in an interval from -1.93 to 1.12 V (see Figure 1). At potential values higher than 1.15 V (anodic side), current density is rapidly increased, which is attributed to the decomposition of the medium, i.e., oxidation of Cl^-. At potential values smaller than -1.5 V (cathodic side), a reduction process is observed with a decrement in the current density, which indicates a reduction of hydrogen (Souza et al., 2007). An additional event occurring at 0.72 V, corresponding to the reduction of ethaline, was also identified. The potential window determined in this work agrees with previously published research (Binder, 2010) for ethaline.

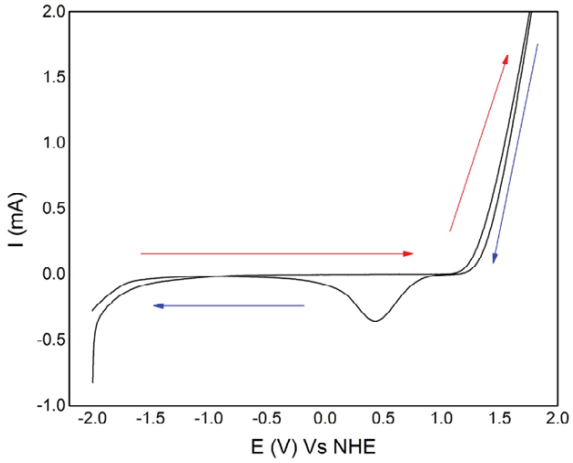

Fig. 1: Cyclic voltammetry curve of Ethaline obtained at 65 °C and V = 25 mVs^{-1} in vitreous carbon.

According to Figure 2, when $CoCl_2 \cdot 6H_2O$ and $CrCl_3 \cdot 6H_2O$ were present in a molar ratio of 2:1 in ethaline, a displacement was observed in reduction peak I (dotted line), which corresponds to reduction of ethaline, towards more anodic potentials (from 0.72 to 0.88 V), which was due to the presence of Cr (III) and Co (II) ions in the solution.

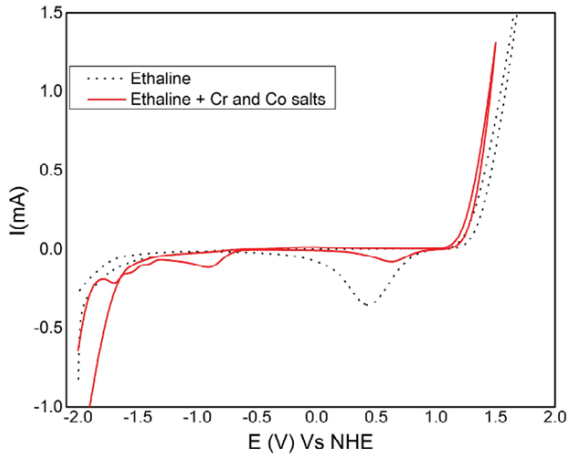

Fig. 2: Cyclic voltammetry curves of ethaline and ethaline + $CrCl_3 \cdot 6H_2O$ + $CoCl_2 \cdot 6H_2O$ obtained at 65 °C and V = 25 mVs^{-1} in vitreous carbon.

In this case, three reduction processes were observed in the potential window, which were located at -1.05, -1.38 and -1.6 V. The first one corresponded to the reduction of Cr (III) to Cr (II), the second one to the reduction of Cr (II) to Cr (0), and the third one to hydrogen embrittlement underwent by the coatings. These results are consistent with those reported by Eugenio et al. (2011).

To confirm the existence of the reduction processes observed when the electroactive species were added to ethaline, linear-sweep voltammetry tests were carried out at more electronegative potentials. Figure 3 shows the corresponding voltammetry curve in which three different processes can be appreciated: the first one was located at -1.06 V & Ag/ AgCl (1), the second one appeared at -1.38 V & Ag/ AgCl (2), and the third one was found at -1.6 V & Ag/ AgCl (3).

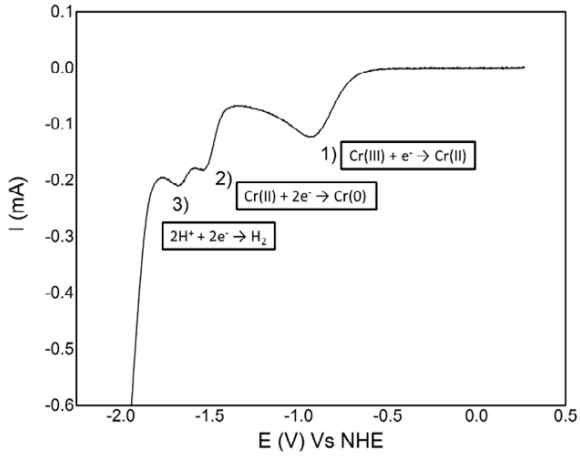

Fig. 3: Linear-sweep voltammetry curve of ethaline + $CrCl_3 \cdot 6H_2O$ + $CoCl_2 \cdot 6H_2O$ obtained at T = 65 °C with a sweep speed of 25 mVs^{-1}.

Chronoamperometric runs were carried out at the potentials identified in the voltammetric studies in order to select the working potential, which was based on the observation that uniform black deposits were obtained only at the potentials of -1.06 and -1.38 V. In contrast, black deposits were not obtained at a potential of -1.6 V due to the evolution of hydrogen at the metal surface. Furthermore, an excesive formation of bubbles was visible in the electrolitic solution in the cell, which apparently caused that the deposit layers became fractured, and thus, the electrodeposition was hindered, resulting in a damaged electrode.

Table 1 shows the factors and levels used to study the effect of the processing variables on the optical properties of the coatings.

Tab. 1. Factors and levels used in the employed L9 orthogonal array Taguchi experimental design.

Factors	Level 1	Level 2	Level 3
ChCl: EG molar ratio in the electrolyte	1:2	1:8	1:16
Co:Cr salt molar ratio	1:1	2:1	4:1
Voltage (V)	-1.06	-1.22	-1.38
Time (min)	30	45	60

Table 2 shows the employed L9 orthogonal array Taguchi experimental design, as well as the α and ε values obtained for the coatings deposited on the AISI 304 stainless steel substrates.

Tab. 2. L9 orthogonal array Taguchi experimental design.

Experiment	Independent variables				Dependent variables	
	Electrolyte	Co:Cr salt molar ratio	Voltage (V)	Time (min)	α	ε
1	1:2	1:1	-1.06	30	0.59	0.07
2	1:2	2:1	-1.22	45	0.55	--
3	1:2	4:1	-1.38	60	0.85	0.08
4	1:8	1:1	-1.22	60	0.90	0.16
5	1:8	2:1	-1.38	30	0.97	0.19
6	1:8	4:1	-1.06	45	0.95	0.18
7	1:16	1:1	-1.38	45	0.77	0.03
8	1:16	2:1	-1.06	60	0.98	0.03
9	1:16	4:1	-1.22	30	0.94	0.09

As it can be seen, the stainless steel substrates without electrochemical treatment showed an α value of 0.55, while the substrates with electrodeposited coatings achieved α values of up to 0.98. The best α values were achieved employing a deposition potential of -1.06 V for 60 min, with a ChCl:EG molar ratio of 1:16 and a

$CoCl_2$•$6H_2O$:$CrCl_3$•$6H_2O$ molar ratio of 2:1. Sample 8 showed a value of α = 0.98 and a value of ε = 0.035. The lowest ε value obtained corresponded to sample 7 (ε = 0.0309). This sample was coated using a deposition potential of -1.38 V & Ag/AgCl for 45 min, with a ChCl:EG molar ratio of 1:16 and a $CoCl_2$•$6H_2O$:$CrCl_3$•$6H_2O$ molar ratio of 1:1. However, this sample showed a value of α = 0.77. According to Malhotra and Chopra (1986), an increment in the value of α is considerably more favorable than a reduction in the value of ε. Mar et. al. (1976), in a similar previous work, reported values of α = 0.91 and ε = 0.07 (T = 100 °C). In this work, higher values of α and ε were achieved.

Sample 8, which showed the best optical properties, was characterized by SEM/EDS in order to identify and quantify the composition of the areas of interest. The SEM studies revealed that the black deposits were composed of Cr and Co oxide particles, whose chemical composition and morphology varied in the sample's cross section (Tab. **3. Results of the SEM/EDS analysis carried out in the cross-section of sample 8.**3).

Tab. 3. Results of the SEM/EDS analysis carried out in the cross-section of sample 8.

Sample	Analyzed zone	Elemental Composition (wt.%)				
		O	Cr	Co	Cu	Fe
8	I	15.97	20.3	56.28	-	7.45
	II	17.58	19.68	60.93	-	1.81

The SEM micrograph and photograph of Figure 4 correspond to sample 8. At a glance, it can be observed that the formed coating was uniformly distributed throughout the substrate surface, showing a black coloration.

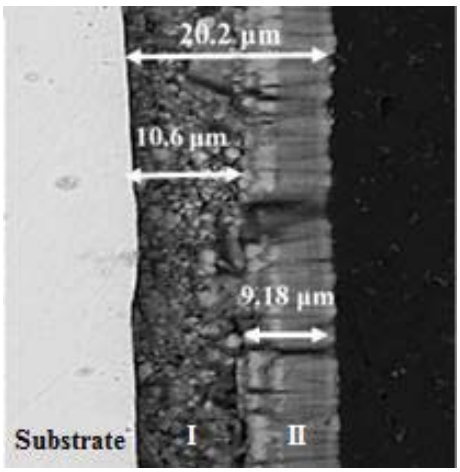

Fig. 4: SEM micrograph and photograph taken for the sample for which the best coating was obtained (sample 8).

The SEM micrograph of Figure 4 shows the morphology of the coating obtained on the surface of sample 8, in which the presence of equiaxed (zone I) and columnar (zone II) particles can be noticed. According to Table 3, it can be seen that both zones had a high content of Co and Cr, and thus, it was deduced that they were composed by a mixture of Co and Cr oxides. The main compositional difference among both zones was a higher Fe content in zone I and a higher Co content in zone II. Saravanan and Mohan (2012), who investigated a similar system, observed the formation of nodular particles. Probably in this study the variation in the composition of the used electrolyte and salts, as well as the applied potential, influenced the composition and morphology of the coatings. The coating formed on the surface of sample 8 was dense and compact, with zone I with a thickness of 10.6 µm, and zone II with a thickness of 9.18 µm. The coating thickness was dependent on the time of deposition.

4. Conclusions

The electrochemical study of the system ethaline/Co-Cr chloride salts allowed us to establish the conditions required to obtain uniform and well-adhered black Co-Cr oxide coatings on AISI 304 stainless steel

substrates, with excellent optical properties suitable for their application in solar thermal collectors ($\alpha = 0.98$ and $\varepsilon = 0.03$).

The efficiency of the process was controlled mainly by the molar composition of the electrolyte.

The conditions employed to obtain the electrochemical coating having the best optical properties were: a ChCl:EG molar ratio of 1:16, a Co:Cr salt molar ratio of 2:1, and a deposition potential of -1.06V.

The SEM characterization of the best deposited coating revealed that it was composed by two layers formed by particles with different morphologies, which probably consisted of a mixture of Co and Cr oxides. The total thickness of the coating was approximately 20 μm.

Abstract

This study presents the design and optical simulation of a circular trough solar concentrator with a trapezoidal secondary reflector using the SolTrace Software. The circular curve of this concentrator approaches the curve of a parabola with an edge angle of 45°. Due to the spherical aberration, the reflective surface introduces optical errors in such a way that it is necessary to use a second reflective stage that allows most of the rays that fall outside of the receiver to be reflected towards the latter. It is not necessary to obtain an even distribution of the concentrated solar radiation because the application of this solar concentrator is towards the generation of process heat. The ratio of rays intercepted by the cylindrical receiver to those intercepted by the primary reflector was 0.847. This study made a comparison of the collection efficiency according to the slope errors and misalignment for a parabolic trough and a circular trough collector, with and without a trapezoidal secondary reflector.

1. Introduction

Various processes in industry require heat in a temperature range between 90° C to 250° C (Kalogirou, 2003); solar collectors of medium temperature, such as parabolic troughs (PTC), Compound Parabolic (CPC), and Linear Fresnel (LFC) Collectors, can generate heat within this temperature range. Solar concentrators are optical systems that are subject to errors in their shape, slope, and surface, this causes a portion of the rays reflected by the concentrator not to impact the receiver. In order to increase the concentration or improve the intercept of rays, second stages of reflection are often used.

Mills (1995) presents a comparison via the ray tracing technique of different configurations of second concentration stages. In Singh et al. (1999), a linear fresnel concentrator was developed and the amount of heat absorbed by the used oil was assessed with 10, 15, and 20 mirrors; the absorber was surrounded with trapezoidal mirrors on three sides. Spirkl et al. (1997) presented a numerical optimization of the secondary reflectors for parabolic troughs using an involute and a flat section. Their performance was determined by ray tracing and by taking into account the reflective losses, shading, and the solar shape. In Chemisana et al. (2011), the development of a solar concentrator consisting of a fresnel lens, a CPC secondary concentrator, and a photovoltaic thermal module was presented; the latter was analyzed and characterized both electrically and thermally. Chen and Ho (2013) used an analytical method to obtain the geometrical shape of a secondary

doi:10.18086/eurosun.2016.07.09 Available at http://proceedings.ises.org

mirror of non-image in the application of photovoltaic with solar concentration. In Cheng et al. (2014), the ray tracing technique was used for the estimation of the concentrated irradiance using secondary reflectors of non-image. Zheng et al. (2014) developed a cylindrical solar concentrator composed of an arc-shaped fresnel lens, a fresnel mirror, and a secondary reflector. The collection efficiency of the concentrator (based on the tracking error and the longitudinal angle of incidence) was obtained using ray tracing along with a comparison with the experimental results. In Rodriguez Sanchez and Rosengarten (2015), a theoretical analysis was made on a parabolic trough with a flat secondary reflector that increased the concentration ratio (up to 80%); ray tracing was conducted to validate the developed equations. The curves of energy received in the receiver, as a function of the misalignment angle for different reflectivities, and the ratio of local concentration in the receiver were obtained. In Abbas et al. (2016) a ray tracing code was developed to compare the efficiencies of the parabolic trough technology against that of the linear Fresnel technology. The results showed that the parabolic trough is more efficient, however, the leveled cost of generation is lower than that of the linear Fresnel system.

This work presents the optical design of a Circular Trough Collector (CTC) with a trapezoidal secondary reflector by making the approximation in the paraxial region of a circular profile with a parabolic profile. It was taken into consideration that the fabrication of a rib with a circular profile is less expensive than a rib with parabolic profile, this is because the rib can be formed using a rolling process. Using the technique of ray tracing, a comparison of the collection efficiency of the circular trough and the parabolic trough is made.

2. Optical design

The PTC is one of the most developed solar concentration technologies, however, it still faces the challenge of cost reduction in its manufacturing with a good optical performance. Conversely, from the manufacturing viewpoint, it is easier to manufacture a circular section rather than a parabolic one, and a section of the circumference can be virtually indistinguishable in the paraxial region of a parabola (Hetch, 2000). Figure 1 shows both geometries. The circular section is given by

$$x = \frac{y^2}{2R} + \frac{1y^4}{2^2 2! R^3} + \frac{1 \cdot 3 y^6}{2^3 3! R^5} + \ldots \quad \text{(eq. 1)}$$

On the other hand, the normal equation of a parabola with vertex at the origin and whose focus is at a distance f towards the right is

$$y^2 = 4fx \quad \text{(eq. 2)}$$

Comparing equations (1) and (2), one can see that if $4f = 2R$ (i.e. if $f = R/2$), the first contribution in the series of equation (1) can be considered parabolic while the remaining terms are the deviation. This difference will be noticeable when y is relatively large in comparison with R.

The circumference introduces aberrations into the concentrated image, therefore, a part of the rays reflected by the circular reflective surface won't impact the focal region. Because of this, it is necessary to use a secondary reflector that redirects the rays so that most of these impact the cylindrical receiver. Figure 2 shows a diagram of the trapezoidal secondary reflector and receiver, in which the secondary reflector and the glass cover form a cavity. Additionally, Figure 2 shows an outer shell which, aside from giving support to the secondary reflector and receiver, serves as a cover whose interior space is filled with a thermal insulator.

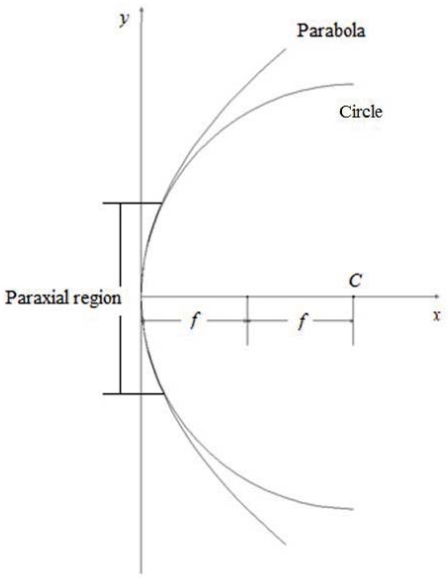

Fig. 1: Paraxial region of the circular and parabolic profiles

A way to evaluate the optical performance of a solar concentrator is by using the ray tracing technique. This study employed the Soltrace software developed by NREL. The width of the opening of the trapezoidal cavity was determined by taking into account that the image formed in the focal region should be less than the opening, thus ensuring that most of the rays pass through said opening. In addition, an almost right angle between the horizontal and lateral surfaces was used to ensure that the rays reflected by the latter strike on the receiver. The determination of the angle that should have the lateral reflectors must have with respect to the horizontal reflector was conducted in an iterative manner using the Soltrace program. To carry out the ray tracing, data from a parabolic trough developed in (Venegas et al., 2012) were used. The optical properties of the reflective surface can be seen in Table 1.

Tab. 1: Concentrator data used in the ray tracing

Variable	Quantity	Units
Circle radius R	1.432	m
Focal distance f	0.716	m
Aperture	1.21	m
Sheet curve perimeter S	1.22	m
Reflectance ρ	0.95	
Slope error σ_{slope}	3.73	mrad
Specularity error σ_{ref}	3.0	mrad
Receiver diameter	0.0254	m
Aperture of second reflector	0.08	m

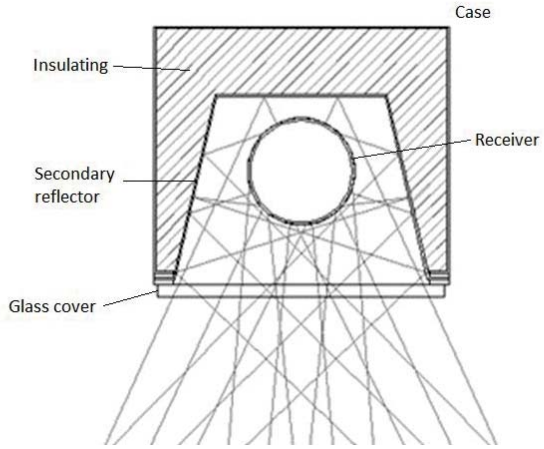

Fig. 2: Trapezoidal secondary reflector and receiver

3. Ray tracing results

Ray tracing was carried out with the Soltrace software by considering a Gaussian solar flux distribution and the data contained in Table 1. Figure 3 shows the trajectories of the ray tracing, where one can observe that most of the traced rays fall into the cavity that is formed by the secondary reflector. The intercept factor between the receiver and the primary reflector is 0.847, of which 7.8% of the incident rays in the cylindrical receiver are redirected by the trapezoidal secondary reflector. Table 2 shows a comparison of the intercept factor for different studies, where one can observe that the intercept factor was slightly higher in the proposed collector than in other developed collectors.

Tab. 2: Intercept factor for different collectors

	Intercept factor	C
This work	0.847	11.47
(Brooks et al., 2005)	0.823	15.92
(Coccia et al., 2015)	0.829	9.25

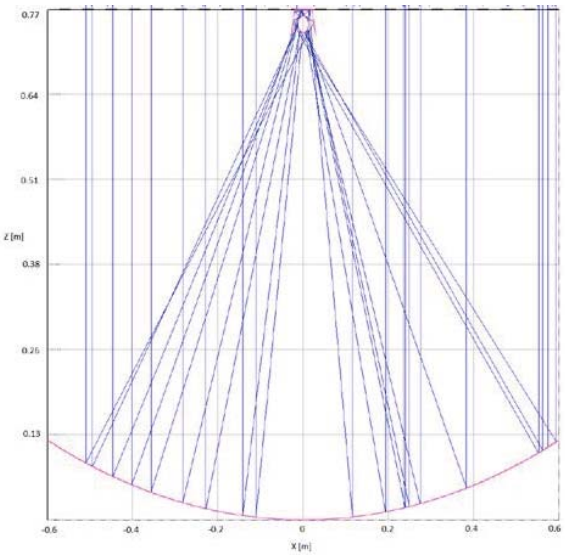

Fig. 3: Ray tracing paths of circular trough and trapezoidal reflector

Figure 4 shows the radiative flux distribution in the cylindrical receiver. The highest radiative flux density was found at the bottom of the cylindrical receiver (with peak values of approximately 25,000 W/m^2). At the top part of the receiver, one can see a slight increase in the radiative flux due to the rays that are redirected by the secondary reflector (with peak values of approximately 5,000 W/m^2). It is important to note that in Figure 4, the abscissa is zero at the top of the tube, which means that most of the amount of radiative flux impacts at the bottom part of the receiver.

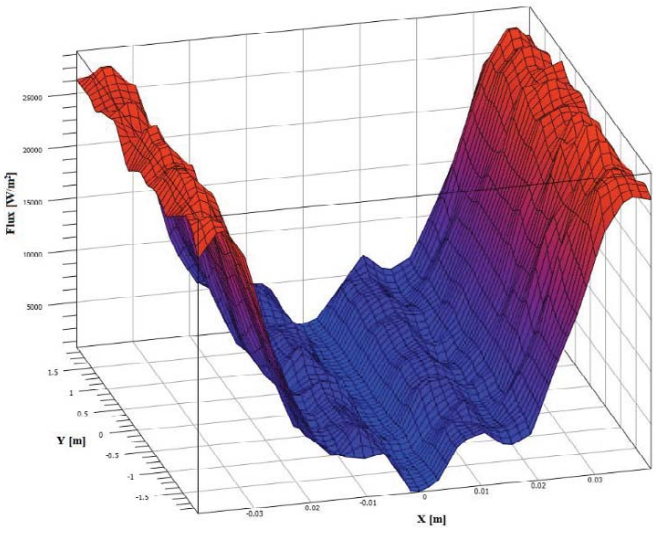

Fig. 4: Flux distribution in the receiver

The collection efficiency was obtained as a function of the slope error for a specular surface error of 3 mrad. The PTC, the CTC without a reflector, and the CTC with a trapezoidal secondary reflector were compared. It is important to note that, for the circular trough, the receiver was moved so that the opening of the secondary reflector remained in the focus, thus improving the collection efficiency. In Figure 5, one can see that the collection efficiency was greater in both the circular trough without a reflector and in the parabolic trough; however, as the slope error increased, the collection efficiency decreases in a more pronounced manner in these than in the circular trough with a secondary reflector. It is easy to observe that the trapezoidal secondary reflector reduced the optical losses due to the scattering caused by the slope error. For the case in which σ_{slope} = 10 mrad, the collection efficiencies of the PTC and CTC were close to 0.5 while the efficiency for the same slope error for the CTC with secondary reflector was 0.62 (i.e. more than 0.1). This implies that the trapezoidal secondary reflector can minimize the optical losses due to scattering caused by slope errors and other types of dispersion (e.g. profile errors).

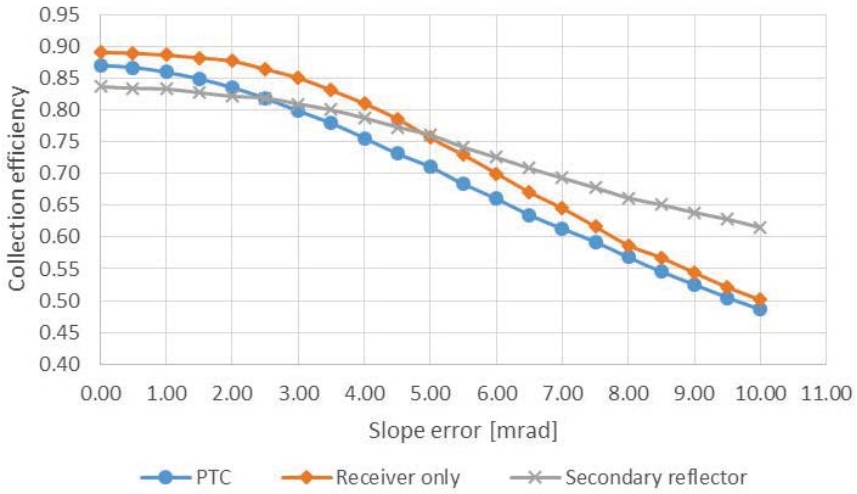

Fig. 5: Collection efficiency on the basis of the slope error

Figure 6 shows the collection efficiency as a function of the misalignment error angle for the parabolic trough collector, the cylindrical trough, and the cylindrical trough with a secondary reflector. It can be seen that the decreasing slopes were higher for both the PTC and CTC than for the CTC with a secondary reflector. It is important to note that the optical errors from Table 1 were taken into account to obtain this graph (Figure 6).

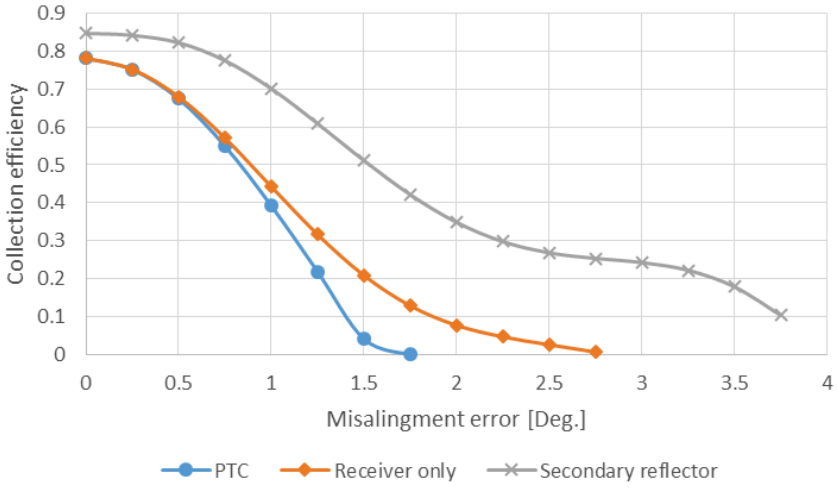

Fig. 6: Collection efficiency as a function of the misalignment angle

The collection efficiency appears with a minimal change until the misalignment angle reaches 0.3 degrees; therefore, the tracking error should be less than this value. When the misalignment angle reaches 0.5 degrees, the intercept factor goes down to 0.82, which is relatively close to 0.847 for a 0 degree angle. Even when the misalignment error angle reaches a value of 1, the collection efficiency reaches a value of 0.7 when compared to an approximate value of 0.4 for the other two configurations.

4. Conclusions

Ray tracing showed that the circular trough solar concentrator with a trapezoidal secondary reflector has an acceptable collection efficiency when compared to other devices in literature. A contribution of the present

study is to achieve a collection efficiency comparison between a parabolic trough and a substitute (so to speak), which is the CTC with a trapezoidal secondary reflector. The secondary reflector allows to reduce the losses caused by the slope error, which tends to disperse the reflected rays. At the same time, the secondary reflector allowed for a greater average misalignment error than if one only has the receiver. This demonstrated the utility of this system to minimize the dispersion effects, which improved the collection efficiency and therefore the optical efficiency of the solar concentrator under appreciable error conditions. Finally, the thermal losses of the solar concentrator are expected to be reduced than if one only has the bare receiver; this is thanks to the envelope that is formed by the secondary reflector and the glass of its opening.

Abstract

Pressure drop is known to be an important factor for the efficacy of thermosiphon systems. Accordingly, in this paper a flat-plate PV/T solar collector is studied to predict the pressure drop over it. First, a numerical model of the collector is presented and fluid dynamic concepts are introduced. This is done in order to determine an expression of pressure drop for a given water flow rate over both the collector's channels and manifolds. Then, an algorithm is presented to predict the pressure drop over the whole collector. The effect of the manifold size on the induced pressure drop is investigated. Finally, three flat-plate solar collectors with different manifold dimensions were used as a test case in which the model was validated within 3-8% in terms of normalized root-mean-square deviation. For the case of flat-plate PV/T solar collectors to be used in thermosiphon water systems, this model can be used to investigate trade-offs between fabrication choices and the thermosiphon performance.

Keywords: *Pressure drop, PV/T collector, solar energy, heat exchanger, thermosiphon, DualSun module*

1. Introduction

A solar photovoltaic-thermal (PV/T) collector is a combination of a solar photovoltaic panel (PV) and solar thermal (T) collector which simultaneously convert solar energy into electricity and heat in one integrated system. The photovoltaic cells are in contact with a thermal collector. When the system is operating, the energy from the sun is converted to electricity by the photovoltaic cells on the front side of the panel while a coolant fluid removes heat from the cells on the back side of the panel, generating a double benefit: (1) the collected heat can be used in domestic hot water systems and (2) the cooling of the photovoltaic cells increases the total electricity output as the efficiency of the photovoltaic cells decrease as a function of temperature (Wysocki and Rappaport, 1960).

Thermosiphon water systems are typically less expensive than active pump-driven systems and there is a growing interest to use PV/T collectors in thermosiphon water systems. Also, pressure drop over a solar collector gains importance since pressure drop is known to be an important factor for thermosiphon systems efficacy (Kalogirou, 2013). On the other side, flat-plate solar collectors are the usual type of collector for hybrid PV/T systems technology using water as coolant (Kalogirou and Tripanagnostopoulos, 2006). Accordingly, this paper presents a study made by DualSun on pressure drop in parallel flow flat-plate collectors in order to adapt the DualSun module, an innovative photovoltaic-thermal (PV/T) collector (Brottier et al. 2016), to be used in thermosiphon water systems. Fig. 1 shows a thermosiphon water system testbed where a DualSun module was installed in Marseille, France.

In this paper, first, a numerical model of a parallel flow collector is presented. Then, several fluid dynamic concepts are reviewed to calculate pressure drop over both the collector's manifold and the collector's channel. Next, an algorithm is used to calculate pressure distribution and pressure drop over the collector. Finally, the results of pressure drop measures over three flat-plate solar collectors with different manifold dimensions are presented and compared with the model results.

2. Mathematical Model

2.1 Variables and Flow distribution.

Parallel flow heat exchangers, or solar collectors, consist of an inlet and outlet manifold joined by a series of parallel channels where both inlet and outlet fluid flow are in the same direction, as shown in Fig. 2.

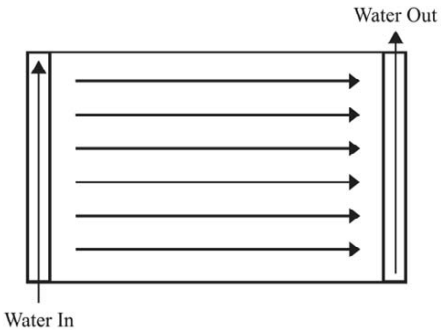

Fig. 2: Parallel flow collector diagram.

Several papers have analyzed the pressure drop over compact heat exchangers (Camilleri et al. 2015) and gas manifolds of a fuel-cell stack (Koh et al. 2003). In this paper an N-channel collector will be considered, and the channels will be numbered from the highest (1^{st}) to the lowest (N^{th}) position, where the input edge of the inlet manifold is in front of the N^{th} channel, and the output edge of the output manifold is in front of the 1^{st} channel, as shown in Fig. 3. Here $P_{in}^{(i)}$ denotes the pressure at the entrance of the i^{th} channel, $P_{out}^{(i)}$ denotes the pressure at the exit of the i^{th} channel and q_x^i is the water flow rate through the same channel. With this expression, pressure drop over each channel (i) is expressed by $\Delta P_x^{(i)}$, as shown in eq. 1.

Local pressure drop over the i^{th} inlet manifold section is expressed by eq. 2, and by eq. 3 for the case of the i^{th} outlet manifold section. Here, a manifold section (i) is defined from the entrance of the $(i-1)^{th}$ channel until the entrance of the i^{th} channel for inlet manifolds ('in' subscript and '(i)' superscript), and from the exit of the $(i-1)^{th}$ channel until the exit of the i^{th} channel for an outlet manifold section ('out' subscript and '(i)' superscript)

$$\Delta P_x^{(i)} = P_{in}^{(i)} - P_{out}^{(i)}, \quad (i = 1, \dots, N) \qquad \textit{(eq. 1)}$$

$$\Delta P_{in}^{(i)} = P_{in}^{(i)} - P_{in}^{(i-1)}, \quad (i = 2, \dots, N) \qquad \textit{(eq. 2)}$$

$$\Delta P_{out}^{(i)} = P_{out}^{(i)} - P_{out}^{(i-1)}, \quad (i = 2, \dots, N) \qquad \textit{(eq. 3)}$$

Then, cumulative flow rates $Q_{in}^{(i)}$ and $Q_{out}^{(i)}$ are defined as follows, where Q_F is the total inlet feed flow rate.

$$Q_{in}^{(i)} = \sum_{j=1}^{i} q_x^j = Q_{in}^{(i-1)} + q_x^i, \quad (i = 1, \dots, N) \qquad \textit{(eq.4)}$$

$$Q_{out}^{(i)} = \sum_{j=1}^{N} q_x^j = Q_{out}^{(i+1)} + q_x^i, \quad (i = 1, \dots, N) \qquad \textit{(eq. 5)}$$

$$Q_{in}^{(N)} = Q_F \qquad \textit{(eq. 6)}$$

2.2. Pressure Drop and Pressure Loss

In fluid mechanics, *pressure drop* is defined as the difference in pressure between two points of a fluid carrying network and which is due to the dissipation of mechanical energy into heat. Bernoulli's principle in fluid dynamics states that if there is conservation of energy, the following expression remains constant at any cross-sectional area A of a flowing fluid:

$$\int_A \left(\frac{P}{\rho} + \frac{v^2}{2} + gz\right) \rho \vec{v}.\vec{N}.\, dA \qquad \textit{(eq. 7)}$$

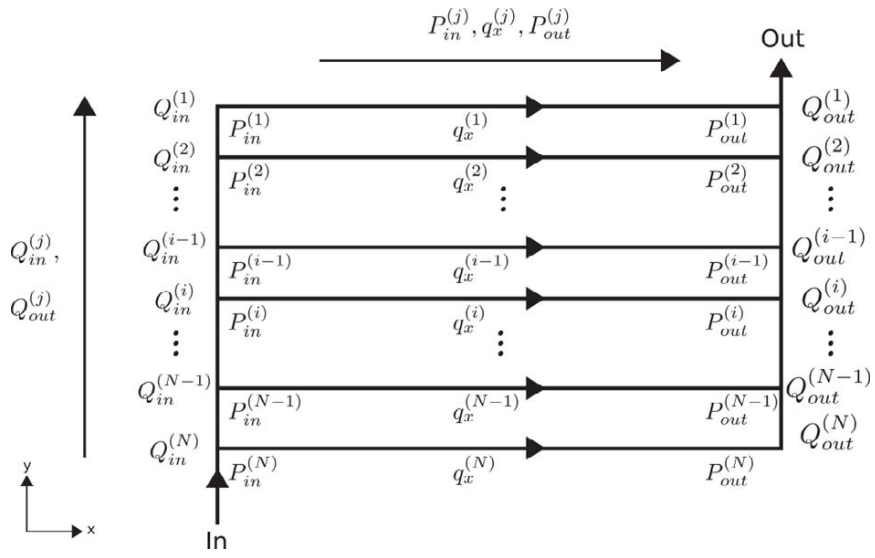

Fig. 3: Pressure and flow variables in the collector

Where P is pressure, ρ is the fluid density, v is the fluid local velocity, g is the acceleration due to gravity and z is the fluid height. Then, $\frac{P}{\rho}$ represents the flow work per unit mass, $\frac{v^2}{2}$ represents the kinetic energy per unit mass and gz represents the potential energy per unit mass. Some authors prefer to express eq. 7 in terms of energy per unit weight dividing it by the acceleration due to gravity. Considering the fluid pressure, fluid velocity and fluid height values as their mean values, along with assumed energy dissipation, the expression is no longer constant, and eq. 7 could be written in terms of energy per unit weight as:

$$\frac{\overline{P}_1}{\rho g} + \frac{\overline{\overline{v}_1^2}}{2g} + \overline{z}_1 = \frac{\overline{P}_2}{\rho g} + \frac{\overline{v}_2^2}{2g} + \overline{z}_2 + H_f \qquad \textit{(eq. 8)}$$

Here H_f represents the frictional work done per unit weight of a fluid element while moving from a point 1 to another point 2. H_f is called *head loss* and has a dimension of height. For simplicity, *frictional pressure loss* will be referred to as Δp_L , defined as:

$$\Delta p_L = \rho g H_f \qquad \textit{(eq. 9)}$$

Then, from eq. 2 we can calculate the *pressure drop*, defined as the pressure difference (in mean value) of a fluid while moving from a point 1 to a point 2, expressed then as the following:

$$\Delta P = \overline{P}_1 - \overline{P}_2 = \rho \frac{\overline{v}_2^2 - \overline{v}_1^2}{2} + \rho g(\overline{z}_2 - \overline{z}_1) + \Delta p_L \qquad \textit{(eq. 10)}$$

Pressure loss depends on any type of head loss H_f as described in eq. 9. Head losses, on their side, are divided in two main categories: *major head losses* (H_M) due to viscosity and wall friction along a pipe, and *minor head losses* (H_m) due to changes in the cross-section of the flow such as junction and bends. Major head losses can be calculated using the Darcy-Weisbach equation as shown in eq. 11, where f is the *Darcy friction factor*, L is the length of the pipe and D_h is the hydraulic diameter of the pipe. Minor head losses, for their part, depend on the *local loss coefficient K,* as shown in eq. 12.

$$H_M = f\frac{Lv^2}{2gD_h} \qquad \textit{(eq. 11)}$$

$$H_m = K\frac{v^2}{2g} \qquad \textit{(eq. 12)}$$

Having explained each type of head loss, the *total head loss* H_f is defined as the sum of major head losses and minor head losses, and total pressure loss becomes:

$$\Delta p_L = \rho g(H_M + H_m) = f\frac{\rho L v^2}{2D_h} + K\frac{\rho v^2}{2} \qquad \textit{(eq.13)}$$

Combining eq. 10 and eq. 13, pressure drop can then be written as:

$$\Delta P = \rho\frac{\bar{v}_2^2 - \bar{v}_1^2}{2} + \rho g(\bar{z}_2 - \bar{z}_1) + f\frac{\rho L v^2}{2D_h} + K\frac{\rho v^2}{2} \qquad \textit{(eq. 14)}$$

2.3. Darcy friction factor f and the loss coefficient K

The Darcy friction factor f and the loss coefficient K of the last expression (eq. 14) have been widely studied (Hager, 2010; Koch, 2000). The Darcy friction factor is a function on the dimensionless Reynolds number Re and depends on whether the flow is laminar or turbulent. The Reynolds number is defined as shown in the following equation, where ν is the kinematic viscosity of the fluid:

$$Re = \frac{vD_h}{\nu} \qquad \textit{(eq. 15)}$$

Here, an approximate way to calculate the Darcy friction factor is presented. For laminar flow ($Re < 2300$), the Darcy friction factor can be calculated as eq. 16; and for turbulent flow ($Re > 2300$), the Blasius equation is used as shown in eq.17

$$f = \frac{64}{Re}, \qquad Re < 2300 \qquad \textit{(eq. 16)}$$

$$f = 0.3164\, Re^{-0.25}, \qquad Re > 2300 \qquad \textit{(eq. 17)}$$

Koch (2000) has made a survey of available data of the pressure loss coefficient K for elbows and tees of pipework. The survey shows that in tee joints the K factor depends considerably on the tee configuration (converging flow, diverging flow) and which flow is being considered (from the branch, along the straight, etc.). The velocity used to calculate the minor head loss shown in eq. 12 is the velocity of the combined flow. For further information, see the articles listed in the Reference section.

2.4 The solar collector and pressure drop

In order to calculate pressure drop over the solar collector, an expression will firstly be given to calculate the pressure drop in each channel and in each manifold, based on the variables defined before.

Pressure drop over each channel strongly depends on the channel geometry and the presence of tee junctions or bends as explained in the previous section. If we consider the *channel flow* as the flow starting from the inlet manifold until the outlet manifold, both the tee junction diverging the flow from the inlet manifold and the tee junction converging the flow at the outlet manifold should be considered as minor head losses, each one with its own loss coefficient K. In the following, the subscript *Txin* will be used to describe the effects of the tee junction at the entrance of the channel, while the subscript *Txout* will be used to describe the effects of the tee junction at the exit of the channel. As there is no change in the flow, the fluid velocity through the channel (v_x) remains constant. Using the pressure drop expression introduced in eq. 14, and assuming that there is no change in height, eq. 1 becomes:

$$\Delta P_x^{(i)} = \Delta p_{L_{Tin}}^{(i)} + \Delta p_{L_x}^{(i)} + \Delta p_{L_{Tout}}^{(i)} = \frac{\rho}{2}\left(f_x\frac{L_x {v_x^{(i)}}^2}{D_{h_x}} + K_{Txin}^{(i)} {v_{y_{in}}^{(i)}}^2 + K_{Txout}^{(i)} {v_{y_{out}}^{(i)}}^2\right) \qquad \textit{(eq.18)}$$

Here, the fluid velocity through both intlet ($v_{y_{in}}$) and outlet ($v_{y_{out}}$) manifold are used to calculate the minor head losses since for tee junctions the velocity of the combined flow should be considered. However, the same superscript is used to simplify the solution algorithm. For the first and the last channel, the loss coefficient corresponding to elbows should be considered (Koch, 2000). Velocities are defined as the flow rate divided by the cross section flow area.

For the case of manifolds, the fluid flow rate decreases from the feeding position to the other end, with an inverse effect for the outlet manifold as the flow from each channel is sequentially added to the main flow.

Thus, the fluid velocity change should be considered. Additionally, only one tee junction will be taken into account. For simplification in the following, the subscript *Tyin* will be used to describe the effect of the diverging-flow tee junction (with flow going to the branch) for the inlet manifold, while the subscript *Tyout* will be used to describe the effect of the converging-flow tee junction (with flow coming from the branch) for the outlet manifold. Using the pressure drop expression introduced in eq. 14, and assuming that there is no change in height, eq. 5 and eq. 6 becomes eq. 19 for the local pressure drop in an inlet manifold section, and eq. 20 for the local pressure drop in an outlet manifold section, where L_e is the distance between two channels.

$$\Delta P_{in}^{(i)} = \rho \frac{\bar{v}_{y_{in}}^{(i-1)^2} - \bar{v}_{y_{in}}^{(i)^2}}{2} + \Delta p_{L_{Tyin}}^{(i)} + \Delta p_{L_y}^{(i)} = \frac{\rho}{2}\left(v_{y_{in}}^{(i-1)^2} - v_{y_{in}}^{(i)^2} + f_y \frac{L_e v_{y_{in}}^{(i)\ 2}}{D_{h_y}} + K_{Tyin}^{(i)} v_{y_{in}}^{(i)\ 2} \right) \quad \textit{(eq. 19)}$$

$$\Delta P_{out}^{(i)} = \rho \frac{\bar{v}_{y_{out}}^{(i-1)^2} - \bar{v}_{y_{out}}^{(i)^2}}{2} + \Delta p_{L_{Tyin}}^{(i)} + \Delta p_{L_y}^{(i)} = \frac{\rho}{2}\left(v_{y_{out}}^{(i-1)^2} - v_{y_{out}}^{(i)^2} + f_y \frac{L_e v_{y_{out}}^{(i)\ 2}}{D_{h_y}} + K_{Tyout}^{(i)} v_{y_{out}}^{(i)\ 2} \right) \textit{(eq. 20)}$$

2.5 Solution algorithm

In the following, a modified algorithm first introduced by Koh et al (2002) is presented to calculate pressure distribution and pressure drop over the collector.

Starting from an equally-divided channel flow rate ($q_x^{(i)} = Q_F/N$), the cumulative local flow rates in manifolds $Q_{in}^{(i)}$and $Q_{out}^{(i)}$ are obtained from eqs. 4 and 5. To continue, a reference local pressure in the outlet manifold $P_{out_{ref}}^{(1)} = P_{ref} = 0$ is defined, defining also a channel pressure drop reference $\Delta P_x^{(1)}{}_{ref}$ and a local pressure in the inlet manifold $P_{in}^{(1)}{}_{ref}$ using eqs.1 and 2. Then, sequentially, the pressure drop in outlet manifold $\Delta P_{out}^{(i)}$ and local pressure $P_{out}^{(i)}$ are calculated. $\Delta P_{out}^{(i)}$ is calculated using eq.20, while $P_{out}^{(i)}$ is calculated using eq. 3. The next step is to calculate sequentially the local pressure in the inlet manifold $P_{in}^{(i)}$ using eqs. 19 and 2.

In the following, a *flow distribution factor* $\alpha^{(i)}$ shown in eq. 22 is defined to be used as a redundant parameter in order to sequentially adjust channels flow rates in each iteration step until convergence is reached.

$$\alpha^{(i)} = \frac{P_{in}^{(i)} - P_{out}^{(i)}}{\Delta P_x^{(1)}} \quad \textit{(eq. 21)}$$

The adjustment correlation is developed from the definition of the flow distribution factor:

$$\sum_{i=1}^{N} \alpha^{(i)} = \frac{\sum_{i=1}^{N}\left[P_{in}^{(i)} - P_{out}^{(i)}\right]}{\Delta P_x^{(1)}} \quad \textit{(eq. 22)}$$

From this expression, a new value of the pressure drop over the first channel is obtained to adjust all local pressure and pressure drop values systematically as shown in the following expression:

$$\Delta P_x^{(1)} = \frac{\sum_{i=1}^{N}\left[P_{in}^{(i)} - P_{out}^{(i)}\right]}{\sum_{i=1}^{N} \alpha^{(i)}} \quad \textit{(eq. 23)}$$

By substituting the pressure drop terms, $P_{in}^{(i)} - P_{out}^{(i)}$ in eq. 23 by the equation for pressure drop over channels $\Delta P_x^{(i)}$ (eq.18), the expression becomes:

$$\Delta P_x^{(1)} = \frac{\sum_{i=1}^{N}\left[P_{in}^{(i)} - P_{out}^{(i)}\right]}{\sum_{i=1}^{N} \alpha^{(i)}} = \frac{\sum_{i=1}^{N} \Delta P_x^{(i)}}{\sum_{i=1}^{N} \alpha^{(i)}} = \frac{\sum_{i=1}^{N} \frac{\rho}{2}\left(f_x \frac{L_x v_x^{(i)^2}}{D_{h_x}} + K_{Txin}^{(i)} v_{y_{in}}^{(i)\ 2} + K_{Txout}^{(i)} v_{y_{out}}^{(i)\ 2} \right)}{\sum_{i=1}^{N} \alpha^{(i)}} \quad \textit{(eq. 24)}$$

Here, it is important not to replace the flow distribution factor by its formula, but to use the already calculated values. Once all local pressure and pressure drop values are adjusted, the flow distribution factor should be adjusted as well. Finally, new channel flow rates are then calculated from the adjusted inlet manifold pressure values using the flow rate definition (eq. 25) and eq. 18, as shown in eq. 25 and 26, whereA_x is the channel cross-sectional area.

$$q_{x\ new}^{(i)} = A_x v_{x\ new}^{(i)} \quad \textit{(eq. 25)}$$

$$q_{x\ new}^{(i)} = A_x \sqrt{\frac{D_h}{fL_x}\left(\frac{2}{\rho}\left(P_{in\ adj}^{(i)} - P_{out}^{(i)}\right) - K_{Txin}^{(i)} v_{y_{in}}^{(i)\ 2} - K_{Txout}^{(i)} v_{y_{out}}^{(i)\ 2}\right)} \quad \textit{(eq. 26)}$$

Note that the outlet manifold pressure is not adjusted because the exit pressure is known and is equivalent to the outlet reference pressure *($P_{out_{ref}}^{(1)} = P_{ref} = 0$)*. Once new channels flow rates are determined, they are compared with the initial or the previously calculated channel flow rates. The calculation continues with a new set of channel flow rates until the $q_x^{(i)}$ values are close to the old values within an error limit. The entire solution algorithm is summarized in Appendix A.

3. Experimental

Three flat-plate solar collectors as shown in Figs.4 and 5 with different manifold dimensions where used to measure pressure drop, using water columns to measure pressure and an electronic flow meter to measure the water flow rate in the collector inlet. The width and depth of the manifolds where respectively: 0.035x0.035m (collector N°1) 0.02x0.007m (collector N°2) and 0.045x0.045m (collector N°3). All other dimensions where equal as shown in Table 1.

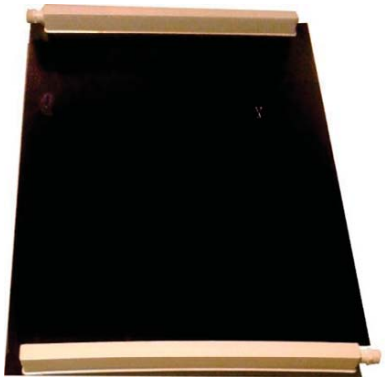

Fig. 4: Parallel flat-plate solar collector with rectangular manifold.

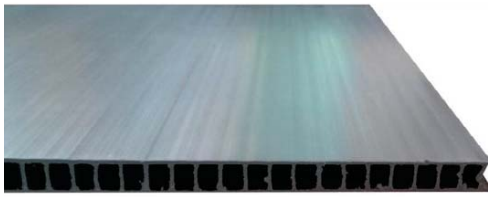

Fig. 5: Cross-sectional view of the collector channels.

Tab. 1: Manifold Dimensions

	Manifold Width [m]	Manifold Depth [m]	Manifold Large [m]	Channel Large[m]	Channel Width [m]	Channel Depth [m]	Number of Channels
Collector N°1	0.035	0.035	0.954	1.4	0.004	0.0044	165
Collector N°2	0.02	0.007	0.954	1.4	0.004	0.0044	165
Collector N°3	0.045	0.045	0.954	1.4	0.004	0.0044	165

4. Results

The three collector pressure drop measurements and simulations are compared in Fig. 6-9. The model is compared with the experiment values using the normalized root-mean-squared error (NRMSE) as defined in eq. 25. Finally, a pressure drop prediction is made for four solar collectors with different squared manifold dimensions (Fig. 4) in order to show the influence of the manifold size on the solar collector pressure drop.

$$NRMSE = \sqrt{\frac{1}{n}\sum_j^n (\Delta P_{exp} - \Delta P_{mod})^2} \,/\, (\Delta P_{mod}^{max} - \Delta P_{mod}^{min})$$

(eq. 27)

It can be seen that at some point (a=0.045m), pressure drop becomes less sensitive to increasing manifold width or depth in 0.005m when comparing to a smaller manifold (a=0.020m). This is probably because manifold size becomes proportionally less important and the analysis must be extended to the channels dimensions.

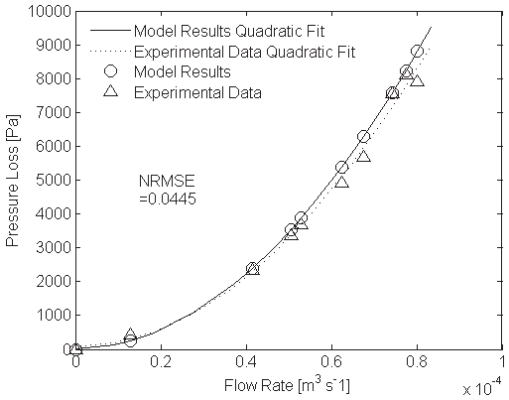

Fig. 7: Comparison of the predicted and measured pressure drop for the collector N°2

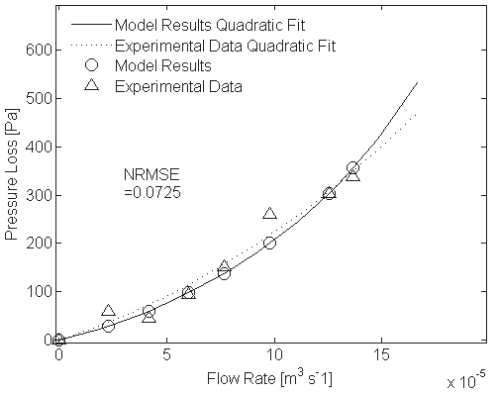

Fig. 8: Comparison of the predicted and measured pressure drop for the collector N°3

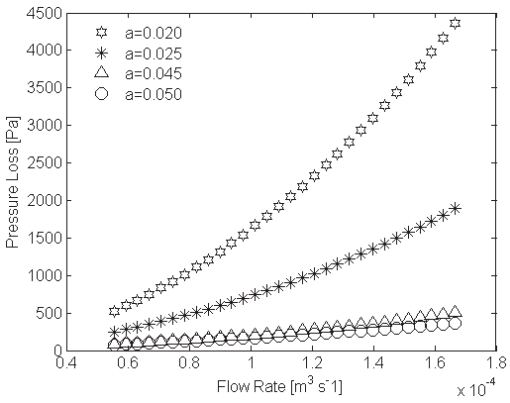

Fig. 9: Pressure drop predictions for different squared manifold dimensions (width=depth=a).

5. Conclusions

This paper presents a reliable numerical model and solution algorithm to calculate the pressure drop over parallel flow flat-plate solar collectors. The model gives the possibility to simulate pressure drop over exchangers at an early design stage and investigate the effects of geometric dimensions such as manifold or channel size. For the case of flat-plate PV/T solar collectors to be used in thermosiphon water systems, this model can be used to investigate trade-offs between fabrication choices and the thermosiphon performance.

Three flat-plate solar collectors with different manifold dimensions were used as a test case in which the model was validated within 3-8% in terms of normalized root-mean-square deviation. Also, the influence of the manifold size on the solar collector pressure drop was analyzed. It is shown that for smaller manifold size, the incremental pressure drop is higher than for larger manifolds. A channels size sensibility was not studied and should be take into account in further studies.

Appendix: **Algorithm to calculate pressure drop over flat-plate solar collectors**

Step 1: Initial guess of channel flow rates and a reference inlet pressure drop.

$$q_x^{(i)} = \frac{Q_F}{N}, \quad (i = 1 \text{ to } N) \qquad \textit{(eq.A.1)}$$

$$v_x^{(i)} = \frac{q_x^{(i)}}{A_x}, \quad (i = 1 \text{ to } N) \qquad \textit{(eq.A.2)}$$

$$\Delta P_{x\ ref}^{(1)} = \frac{\rho}{2}\left(f_x \frac{L_x v_x^{(i)^2}}{D_{h_x}} + K_{Txin}^{(i)} v_{y_{in}}^{(i)\ 2} + K_{Txout}^{(i)} v_{y_{out}}^{(i)\ 2} \right) \qquad \textit{(eq.A.3)}$$

Step 2: Calculate flow rates and linear velocity in manifolds and Reynolds numbers.

$$Q_{in}^{(i)} = Q_{in}^{(i-1)} + q_x^i, \quad (i = 1, \dots, N) \qquad \textit{(eq.A.4)}$$

$$Q_{out}^{(i)} = Q_{out}^{(i+1)} + q_x^i, \quad (i = 1, \dots, N) \qquad \textit{(eq.A.5)}$$

$$v_{y_{in}}^{(i)}, v_{y_{out}}^{(i)}, Re_{y_{out}}^{(i)}, Re_{y_{out}}^{(i)}, Re_x^{(i)}$$

Step 3: Calculate outlet manifold pressure.

$$P_{out_{ref}}^{(1)} = P_{ref} = 0 \qquad \textit{(eq.A.6)}$$

- *Loop 3.1: For i= 2 to N:*

$$\Delta P_{out}^{(i)} = \frac{\rho}{2}\left(v_{y_{out}}^{(i-1)^2} - v_{y_{out}}^{(i)^2} + f_y \frac{L_e v_{y_{out}}^{(i)\ 2}}{D_{h_y}} + K_{Tyout}^{(i)} v_{y_{out}}^{(i)\ 2} \right) \qquad \textit{(eq.A.7)}$$

$$P_{out}^{(i)} = \Delta P_{out}^{(i)} + P_{out}^{(i-1)} \qquad \textit{(eq. A.8)}$$

Step 4: Calculate inlet manifold pressure.

$$P_{in\ ref}^{(1)} = \Delta P_{x\ ref}^{(1)} + P_{out_{ref}}^{(1)} \qquad \textit{(eq.A.9)}$$

- *Loop 4.1: For i= 2 to N:*

$$\Delta P_{in}^{(i)} = \frac{\rho}{2}\left(v_{y_{in}}^{(i-1)^2} - v_{y_{in}}^{(i)^2} + f_y \frac{L_e v_{y_{in}}^{(i)\ 2}}{D_{h_y}} + K_{Tyin}^{(i)} v_{y_{in}}^{(i)\ 2} \right) \qquad \textit{(eq.A.10)}$$

$$P_{in}^{(i)} = P_{in}^{(i-1)} + \Delta P_{in}^{(i)}, \qquad \textit{(eq. A.11)}$$

Step 5: Calculate flow distribution factors.

$$\alpha^{(i)} = \frac{P_{in}^{(i)} - P_{out}^{(i)}}{\Delta P_x^{(1)}}, \quad (i = 1, \dots, N) \qquad \textit{(eq. A.12)}$$

Step 6: Calculate a new value of the pressure drop over the first channel

$$\Delta P_{x\ new}^{(1)} = \frac{\sum_{i=1}^{N} \frac{\rho}{2}\left(f_x \frac{L_x v_x^{(i)^2}}{D_{h_x}} + K_{Txin}^{(i)} v_{y_{in}}^{(i)\ 2} + K_{Txout}^{(i)} v_{y_{out}}^{(i)\ 2} \right)}{\sum_{i=1}^{N} \alpha^{(i)}} \qquad \textit{(eq. A.13)}$$

Step 7: Adjust local inlet manifold pressure from new pressure drop over the first channel

$$P_{in\ adj}^{(1)} = \Delta P_{x\ new}^{(1)} + \Delta P_{out}^{(1)} \qquad \textit{(eq. A.14)}$$

$$P_{in\ adj}^{(i)} = P_{in\ adj}^{(i-1)} + \Delta P_{in}^{(i)}, \quad (i = 2, \dots, N) \qquad \textit{(eq. A.15)}$$

Step 8: Adjust flow distribution factors from new pressure drop over the first channel.

$$\alpha^{(i)}{}_{adj} = \frac{P^{(i)}_{in\,adj} - P^{(i)}_{out}}{\Delta P^{(1)}_{x\,new}}, \quad (i = 1, \ldots, N) \qquad \textit{(eq. A.16)}$$

Step 9: Calculate new set of channel flow rates form adjusted inlet manifold pressure.

$$q^{(i)}_{x\,new} = A_x \sqrt{\frac{D_h}{fL_x}\left(\frac{2}{\rho}\left(P^{(i)}_{in\,adj} - P^{(i)}_{out}\right) - K^{(i)}_{Txin} v^{(i)\,2}_{y_{in}} - K^{(i)}_{Txout} v^{(i)\,2}_{y_{out}}\right)}, \quad (i = 1, \ldots, N) \qquad \textit{(eq. A.17)}$$

Step 10: Check convergence.

$$ERR = \sum_{i=1}^{N} \left[\frac{q^{(i)}_{x\,new} - q^{(i)}_{x}}{q^{(i)}_{x}}\right]^2 \qquad \textit{(eq. A.18)}$$

In $ERR > \epsilon$, update $\Delta P_x^{(1)}$ and $q_x^{(i)}$, and go to Step 2. If $ERR < \epsilon$, stop.

Abstract

A building integrated holographic concentrating photovoltaic-thermal system has been optically and energetically simulated. The system has been designed to be superimposed into a solar shading louvre; in this way the concentrating unit takes profit of the solar altitude tracking, which the shading blinds already have, to increase system performance. An energetic simulation has been conducted for Avignon (France), which is a European representative location suitable for solar applications with available atmospheric parameter and irradiance experimental data sets. The simulation tool utilized has been TRNSYS, coupled with MATLAB (where the ray-tracing algorithm to simulate the holographic optical performance has been implemented). In the frame of the simulation, a comparison with a conventional photovoltaic-thermal (PVT) module installed on the blinds and with the same area than the concentrator aperture one is conducted. The concentrator achieves an annual mean optical efficiency of 43.0%, an electrical energy production of 148.2 kWh/kWp and a thermal energy of 250.4 kWh/m^2. On the other hand, the reference PVT module behaves very similar in terms of the thermal energy yielding 294.2 kWh/m^2 but almost doubles the electrical annual production with 281.7 kWh/kWp.

Keywords: *solar energy, solar concentration, photovoltaics, PVT, holographic optical elements (HOE), building integration, energy dynamic simulation.*

1. Introduction

Energy consumption in the building sector represents 40% of the total energy consumed in the European Union. The European Commission, in order to decrease energy consumption, defined (considering buildings as a priority) the directive which states the "20-20-20" objectives: greenhouse gas emissions reductions (20%), the share of renewable energy (20%) and improvements in energy efficiency (20%) (*Directive 2010/31/EU of the European Parliament and of the Council of 19 May 2010 on the energy performance of buildings.*, 2010). In this regard, building integrated solar hybrid Concentrating Photovoltaic-Thermal (CPVT) systems are a technology which perfectly addresses the objectives defined by the European Union, as may cover both the thermal and the electrical consumption needs.

CPV systems replace part of the cell area by cheaper and more environmentally friendly materials, the optical elements, which can lead to more cost-efficient systems from both, economic and environmental aspects (Menoufi et al., 2013). On the contrary, when increasing the concentration ratio the percentage which is not converted into electricity becomes much higher in absolute terms. This could cause PV overheating and thus, problems related with efficiency reduction, stress of materials, etc. arise. A strategy to profit the removal heat which negatively influences system performance is to use a hybrid Photovoltaic-Thermal (PVT) receptor. A PVT module controls PV temperature while simultaneously produces thermal energy. Another strategy to prevent the PV warming up is the spectral selection of the incident irradiance. A technology able to concentrate sunlight and at the same time to spectrally select irradiance is holography.

Among the different types of Holographic Optical Elements (HOEs), volume holograms have been studied as solar concentrators attending to some interesting properties as the high optical efficiency achieved (they can reach 100% efficiency for a selected wavelength). They may be utilized in different configurations (Collados et

doi:10.18086/eurosun.2016.08.03 Available at http://proceedings.ises.org

al., 2016): plane gratings, that are not concentrating elements but as they operate directing light toward the same area the incident irradiance is concentrated (Castillo, 2011; Castro et al., 2010; Zhang et al., 2011) or concentrating optical elements (lenses) either cylindrical (Chemisana et al., 2013; Ludman et al., 1997) or spherical (Ludman, 1982; Vorndran et al., 2015; Zhang et al., 2013).

HOEs present two main characteristics that affect their performance: angular and chromatic selectivity, in other words, their efficiency depends on the angle of incidence and the wavelength. Consequently, the solar spectrum and the spectral sensitivity range of the photovoltaic cell, among other parameters, need to be taken into account in the design of the HOE, in order to optimize its behavior for the wavelength range of interest. The chromatic selectivity of holograms provides an important advantage in comparison with refractive elements, since the concentration of undesired wavelengths on the photovoltaic cell is avoided. If the HOE is designed to diffract infrared wavelengths with very poor efficiency, the cell is prevented from overheating, which could cause a worsening on the cell's performance (Chander et al., 2015; Xiao et al., 2014). The chromatic selectivity also allows spectrum splitting, if a configuration with more than one kind of receiver (either different photovoltaic cells (Ludman et al., 1997; Zhang et al., 2013) or a hybrid photovoltaic-thermal receiver (Froehlich et al., 1993; Iurevych et al., 2012; Vorndran et al., 2015; Xia et al., 2011)) is chosen.

More specifically, regarding holographic PVT designs: Vorndran et. al. (Vorndran et al., 2015) proposed a spectrum-splitting holographic system in which a holographic lens diffracts a narrow bandwidth towards a photovoltaic cell. The transmitted spectrum is reflected on a parabolic mirror towards a thermal tube. The solar concentrator described by Froehlich et. al. (Froehlich et al., 1993) is formed by two stacked holographic lenses, each composed by a holographic grating to correct the incident direction and a holographic lens. Each holographic lens directs a different spectral range of the incoming light to a photovoltaic cell, sensitive to one of these two spectral bandwidths. The transmitted spectrum reaches a thermal absorber, which also refrigerates the PVs. Xia et. al. (Xia et al., 2011) proposed a solar concentrator formed by a holographic grating, which would split the incident spectrum into visible and infrared range, and a Fresnel lens, which would concentrate the visible spectrum onto a set of PV cells and the IR spectrum onto a heat exchanger. Iurevych et. al. (Iurevych et al., 2012) simulated the performance of a solar concentrator constituted by a reflection holographic grating. Incoming rays with wavelengths of a certain range are reflected by the HOE and the surfaces of the system, reaching a PV cell, whereas the rest are transmitted through the HOE and reach a thermal absorber.

Based on the previous studies found in the literature, it can be noted that even though there are some works conducting optical and energetic simulation of holographic concentrators, there is no research dealing with the energy simulation of the system performance in a building integrated configuration. In this regard, the present research is the continuation of that presented by the authors in (Marín-Sáez et al., 2016b) and aims at covering an important gap in the frame of Holographic Concentrating Photovoltaic-Thermal (HCPVT) solar generators, which is their dynamic energy simulation. For this purpose, the electrical and thermal energy productions of the proposed HCPVT are simulated and compared with those obtained by a conventional reference PVT system.

2. System description

The analyzed building integrated concentrating PVT system is designed to be superimposed on the blinds of a solar louvre shading system. In this manner, the concentrator is benefitted from the solar altitude tracking of the shading blinds and thus increasing the optical efficiency. Figure 1 illustrates the architectural configuration proposed, indicating in light blue the blind area where the concentrating system is placed (top-left). The blinds' size is 9 meters long by 0.4 meters wide and by 0.065 m high. The simulated building is considered to be 5.8 m height, starting the blinds at the ground floor window level (1 m height), therefore the number of blinds is 12. On the top-right, a schematic of a blind section shows the location of the holographic lenses and the PVT module, which is placed in the interior space. Both elements are assembled in a single unit forming a modular system with two parallel layers, the HOEs and the PVT module. At the bottom, a diagram of the cross section indicates the main dimensions of the module.

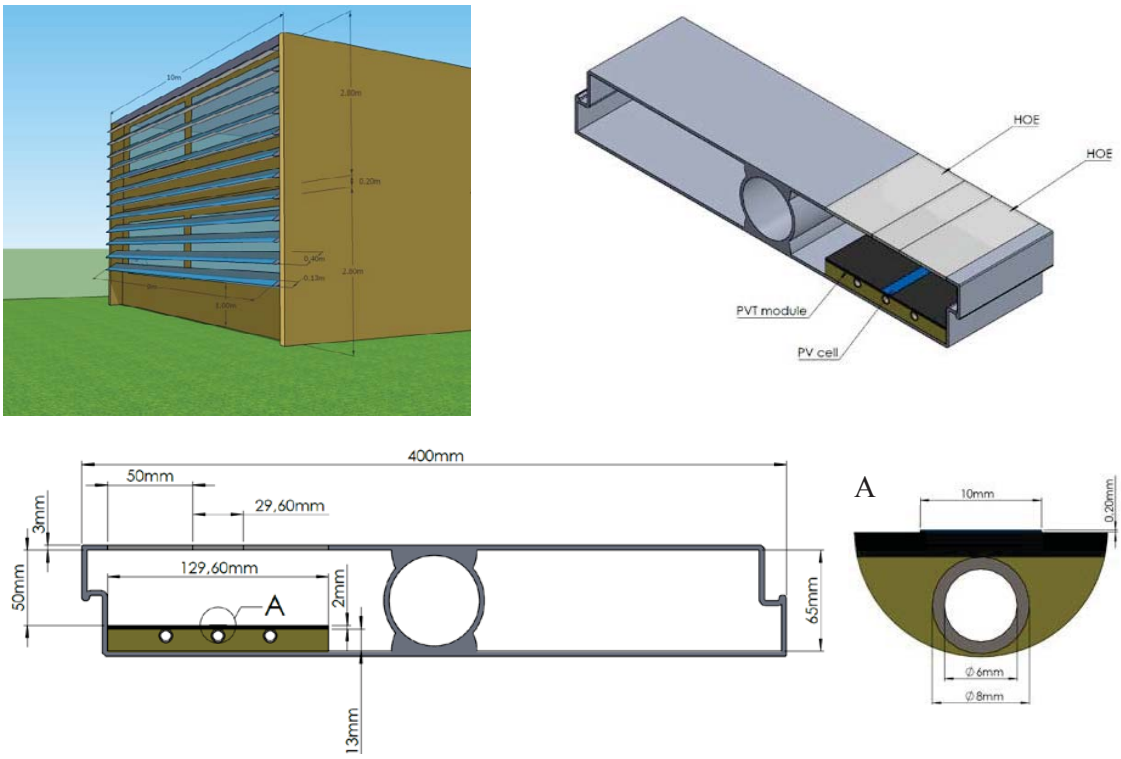

Figure 1. Architectural image of the building integrated concentrator (top-left), section of the blind where the PVT concentrator in placed (top-right) and cross-section and detail of the blind with the PVT concentrator (bottom). (Marín-Sáez et al., 2016b)

The concentrating system consists of two holographic lenses that focus incident irradiance toward the PVT module. Both lenses are attached to the same glass substrate, which at the same time closes the space between them. In figure 2a, a diagram of the ray-tracing is represented. Three different wavelengths in the range of maximum spectral response of the Si PV cell are depicted to show the rays' spatial distribution at the *YZ* plane.

2.1. Holographic optical element

A cylindrical holographic lens is chosen as a solar concentrator HOE. The recording of such lens is carried out by means of the interference of a plane wave and a cylindrical wave onto a photosensitive medium, as shown in Figure 2b. This turns into variations of the refraction index along the material.

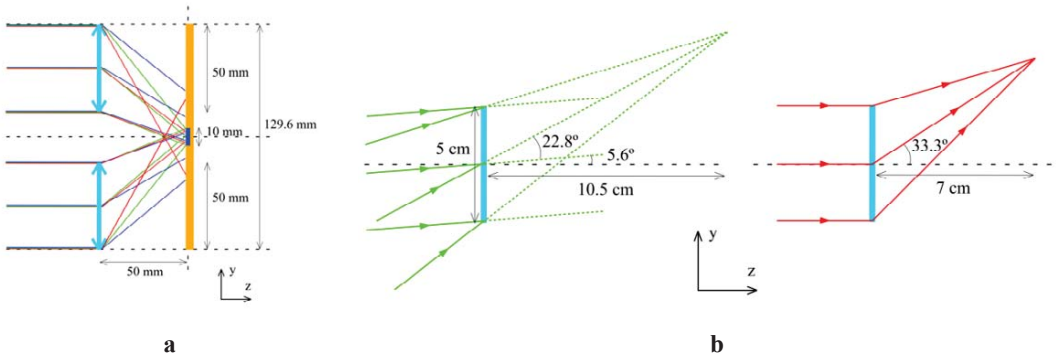

Figure 2. a) Schematic of the HCPVT generation unit (right), with ray-tracing for rays with three different wavelengths: 700 (depicted with blue lines), 800 (green lines) and 900 nm (red lines); b) Sketch of the recording (center, at 532 nm) and reconstruction (right, at 800 nm) schemes of the holographic cylindrical lens simulated in this study. (Marín-Sáez et al., 2016b)

When illuminating a volume hologram at the reconstruction stage, only two waves are found at its output: the transmitted wave and the diffracted wave. With the adequate incident conditions (wavelength and angle), the efficiency of the diffracted beam is maximal, and it can reach 100 % for a selected wavelength if the design is also optimum. When illuminating a holographic cylindrical lens with a plane wave, the resulting diffracted wave is a cylindrical one, as it is shown in Figure 2b.

The reconstruction wavelength for which the HOE will be most efficient is set at 800 nm. This value results from a compromise between the incident solar spectrum (with maximal intensity at wavelengths around 500-800 nm most of the day) and the photovoltaic cell sensitivity (optimum around 700-1000 nm for mono-Si cells). Incident light at 800 nm will focus at a line parallel to the x-axis, 7 cm away from the HOE, as it is shown in Figure 2b. However, the PVT module is placed at 5 cm away from the HOE, in order to collect more energy of the desired wavelength range, since rays with different wavelengths are led towards different directions, as it is illustrated in Figure 2a.

Holograms present higher angular selectivity when the incidence direction varies in the plane formed by the two recording beams, and lower in the perpendicular plane. Taking advantage of this effect, a cylindrical lens offers the possibility of suppressing tracking in one direction. Therefore, tracking is only necessary along the direction with higher angular selectivity.

The proposed recording material of the HOE is Bayfol HX, a photopolymer manufactured by Covestro AG (Berneth et al., 2014), adequate for holographic recording with solar photovoltaic applications (Marín-Sáez et al., 2016a).

In the configuration chosen for this study, two HOEs are placed separated in the same *XY*-plane, so that the spatial distributions of the diffracted beams are symmetrical. A glass plate located in this plane serves as a substrate for the photopolymer, covers the space between the two HOEs and is assumed to have the same refractive index as the photopolymer. The distance between the two lenses, and therefore, the position of the PV cell in the y-axis, was optimized so that it would receive more energy at the most favourable wavelength range for the cell. The ratio between the x dimension of the HOEs and the PV cell was chosen to avoid vignetting on the cell of its optimal wavelength range (700 - 1000 nm).

2.2. Hybrid photovoltaic-thermal module

The PVT module units for the holographic system are considered to be 100 cm long by 12.96 cm wide; thus every shading blind of 9 m is composed of 9 PVT modules. Every PVT module is formed by 7 cells connected in series of 14.29 cm long by 1 cm wide each. The photovoltaic cells considered in the simulation are based on commercial mono-crystalline cells by Sunways ("Sunways," n.d.), whose main electrical characteristics are summed up in table 1. The characteristics of the thermal receiver are detailed in section 3.2.

In the case of the reference PVT module, it presents the same dimensions as the HCPVT one and is considered to be composed of the same type of cells (table 1) and with the same thermal receiver characteristics. The difference between both is that the reference PVT module is placed at the same position than the optical system, thus receiving the same incident irradiance.

Table 1. Parameters of the PV cells ("Sunways," n.d.).

V_{OC} [1] (V)	J_{SC} (A/m^2)	FF (%)	γ (%/°C)	T_{NOCT} (°C)
0.635	377.6	78.4	-0.44	45

[1] V_{OC} = Open circuit potential; J_{SC} = Short circuit current density; FF = Fill factor; γ = Power temperature dependence losses; T_{NOCT} = Nominal operating cell temperature.

3. Methodology

3.1. Spectra simulation

The direct normal irradiance spectrum is calculated with the SMARTS radiative model (Gueymard, 2001), whose main atmospheric input parameters are (listed by order of importance): Air mass (AM), aerosol optical depth (τ), precipitable water (PW) and Ångström exponent (α).

Measured values of Z , τ , PW and α, can be obtained from the Aerosol Robotic Network (AERONET) database ("Aerosol Robotic Network (AERONET)," n.d.). For this study, only AERONET's level 2.0 data are used to guarantee the highest possible data quality (after cloud screening, calibration and degradation correction (Holben et al., 1998)).

Detailed information on the sunlight spectrum is required for at least a complete year in order to accurately estimate the energy output of the PVT modules. Therefore, a preliminary search on AERONET's database has been done to select only those locations and years with a high density of atmospheric retrievals. These retrievals

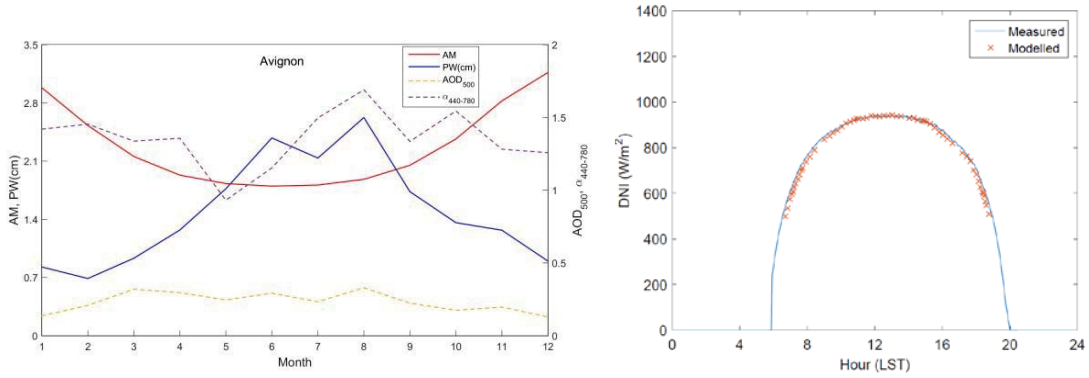
are performed at least every 15 minutes for AM less than 5. Following the procedure described by Chan et al. (Chan et al., 2014), measurement gaps longer than 15 minutes are considered to be caused by extended cloudiness, not computing this time for the annual yield. In addition, the selected locations should be suitable for CPVT systems and have a high direct normal irradiance (DNI).

The location has been selected according to two criteria: (i) It should provide high-quality data over an extended period of time (a constraint satisfied by only a small fraction of AERONET sites); and (ii) it should have co-located and simultaneous DNI measurements, in order to validate the simulated spectra. Based on the above criteria, Avignon, France, (2003) has been chosen.

Table 2. Characteristic parameters for Avignon.

Location	Simulated year	Lat. (°)	Long. (°)	Elevation (m)	Mean daily DNI (kWh/m^2/day) [25]	Annual mean atmospheric parameters AM | τ | PW | α
Avignon	2003	43.93	4.88	32	5-5.5	2.16 | 0.25 |1.76 | 1.37

Figure 3a illustrates the monthly variation of the most representative atmospheric parameters obtained by AERONET at the selected location. This graph conveniently displays the amplitude with which each variable varies throughout the simulation year.



a b

Figure 3. a) Monthly-average values of the main atmospheric variables for the simulated sites, obtained from AERONET. In the case of AM, the values are limited to AM < 5, in agreement with AERONET measurements; b) DNI data validation on the 1st of August in the selected simulated year. LST: Local standard time. (Marín-Sáez et al., 2016b).

Finally, the validation of the spectra generated by SMARTS is undertaken by comparing the calculated broadband DNI to reference irradiance measurements obtained from the Baseline Surface Radiation Network (BSRN) ("World Radiation Monitoring Center – Baseline Surface Radiation Network homepage.," n.d.). A good agreement is achieved between the simulated and the measured data, as depicted in Figure 3b, showing the irradiance profiles for a cloudless typical day. The validation has been conducted using DNI data from BSRN station in Carpentras, located 28 km away.

3.2. Optical simulation

The performance analysis of the holographic lens is based on Kogelnik's Coupled Wave Theory (Kogelnik, 1969) and the approximate scalar theory established by Syms (Syms, 1985). A ray-tracing algorithm has been developed (Bañares-Palacios et al., 2015), which allows the calculation of the output directional cosines and the spectral energy associated with each ray, for the transmitted and the diffracted wave delivered to the PVT module.

The propagation wave vectors of the recording beams, $\vec{k}_1$ and, $\vec{k}_2$ with modulus $k_1 = k_2 = \frac{2\pi}{\lambda_R}$ (where λ_R is the recording wavelength), determine the grating vector $\vec{K} = \vec{k}_1 \pm \vec{k}_2$, illustrated in Figure 6. Since one of the recording beams is a cylindrical wave, its propagation wave vector has a different direction at each point along the *y*-direction, and the angle between beams is also different. Therefore, the vector $\vec{K}$, which is perpendicular

to the planes with constant refractive index variation, is spatially dependant. Its modulus is $\frac{2\pi}{\lambda}$, where Λ is the spatial period of a grating with vector $\vec{K}$, and also different at each point. Each point of the holographic lens behaves differently; thus, each point is treated as a local holographic grating.

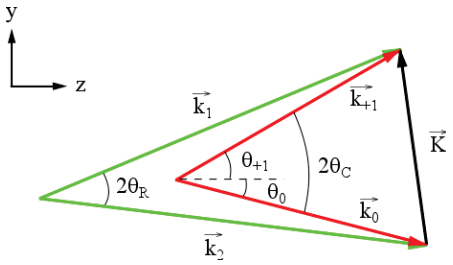


Figure 4. Sketch of the relation between the grating vector $\vec{K}$ and the wave vectors of the two recording beams, $\vec{k}_1$ and $\vec{k}_2$, and the transmitted and diffracted waves, $\vec{k}_0$ and $\vec{k}_{+1}$.

When illuminating the HOE with a wave with vector $\vec{k}_0$ and a certain wavelength λ_C, the resulting diffracted wave has a vector $\vec{k}_{+1}$, which has the same modulus as $\vec{k}_0$ and direction determined with $\vec{k}_0$ and $\vec{K}$. This relation is shown in Figure 4. Thus, if the vector $\vec{K}$ along the hologram is known, the direction of the diffracted ray originated with each incident reconstruction ray at a certain point can be calculated.

The energy of the diffracted wave from each point is calculated with equation 1:

$$\eta = \frac{\sin^2\left[\left(\nu^2 + \xi^2\right)^{1/2}\right]}{1 + \frac{\xi^2}{\nu^2}} \tag{1}$$

The parameters ν and ξ are given by:

$$\nu = \frac{\pi d \Delta n}{\lambda_C c_0 c_{+1}} \tag{2}$$

$$\xi = \frac{d\vartheta}{2c_{+1}}, \tag{3}$$

where d is the thickness of the recording material, Δn is the refraction index modulation, λ_C is the reconstruction wavelength, and c_0 and c_{+1} are the directional cosines with respect to the z-axis of the reconstruction and diffracted wave, respectively. ϑ is a parameter that determines the variation from Bragg's law, that is, the condition of maximal efficiency. Bragg's law is met when the next equation is fulfilled:

$$2\Lambda \sin\theta_C = \lambda_C, \tag{4}$$

where θ_C is the semiangle between the transmitted and the diffracted beam, shown in Figure 6. When Bragg's condition is not fulfilled the efficiency of the diffracted wave decreases, and the efficiency of the transmitted wave increases.

The energy of the transmitted wave is calculated as the remaining available energy that is not taken by the diffracted wave, at each point and for each reconstruction wavelength.

The rays entering the system through the glass plate between the two HOEs are also considered.

The simulation considers direct normal irradiance solar spectrum, generated by SMARTS, as the incident irradiance input parameter. Nevertheless, due to the implicit difficulty and computational time required, the solar semiangle and the diffuse irradiance fraction are not considered at this stage. Further research will be conducted to define the algorithm containing the particular angles of incidence and polarization constraints of the diffuse radiation, jointly with the implementation of the solar semiangle. Therefore, it should be taken into account that the irradiance delivered by the holographic concentrator is underestimated in a percentage proportional to the diffuse fraction. Losses due to Fresnel reflections on the surface and to total internal

reflection (Hecht, 1998) are taken into account in the simulations.

3.3. Energetic simulation

The energetic simulation is conducted in TRNSYS, evaluating the HCPVT performance under the weather conditions of Avignon. Figure 5 charts the monthly cumulated DNI values and the monthly average ambient temperatures. The annual cumulated DNI is 1860 kWh/m^2 and the annual mean temperature is 14.7 °C. It should be noticed that, in agreement with AERONET criteria, values with AM > 5 (solar altitude below 11.5°) are not considered and, taking into consideration the optical efficiency limitations of the concentrating system, the direct beam irradiances accepted by the HCPVT module will be significantly lower than the DNI values. Results regarding optical efficiencies are included in section 4.

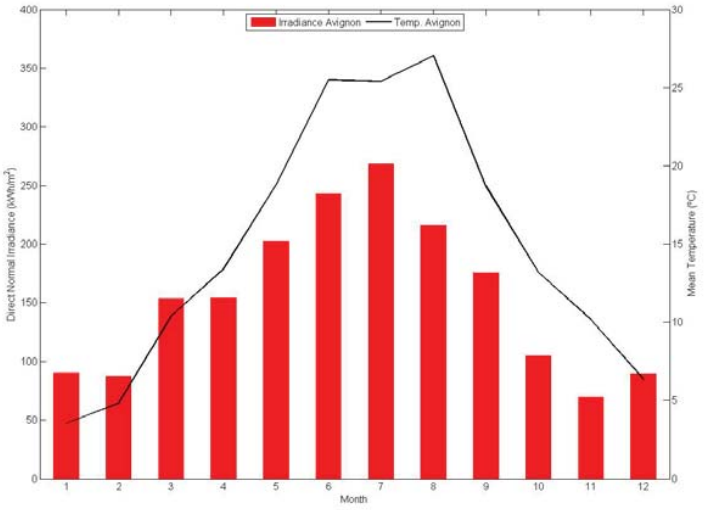

Figure 5. Monthly cumulated DNI and mean temperature values.

The optical simulation program described in subsection 3.2, which is programmed in MATLAB, is linked to TRNSYS delivering at every time step (1 minute) the irradiance impacting on the PVT module. From the irradiance received on the module, the thermal energy produced is calculated by a MATLAB code which determines the electrical power (P'_{mpp}) coupled with the thermal generator *type 1b*, as a function of the solar cell electrical parameters and the cell temperature, calculated with the following equation (5) (Marion, 2002). In the case of the reference module, the simulation is conducted in the same way but with no optical simulation.

$$P'_{mpp} = P_{mpp}\left[1+\gamma\left(T_{cell}-25\right)\right], \tag{5}$$

where P_{mpp} is the electrical power generated by a PV cell without taking into account losses due to the temperature, γ is a temperature coefficient equal to -0.44 %/°C for the PV cells considered in this study, and T_{cell} is the temperature of the cell in °C. The temperature of the cell of the PVT module is estimated with equation 6 (Amrizal et al., 2013):

$$T_{cell} = T_{in} + \frac{P_{th}}{F'U_L A}\left(1-F'\right), \tag{6}$$

where T_{in} is the input temperature of the water circulating at each module, P_{th} is the power generated by the thermal absorber, F' is the collector efficiency factor, U_L is the overall convective heat loss coefficient of the collector and A is the surface of the collector. T_{in} and P_{th} values are obtained from the previous time step, considering the error to be minimum.

The electrical power of the cell P_{mpp} without temperature effects is calculated with:

$$P_{mpp} = J_{SC}V_{OC}FF \tag{7}$$

The short circuit current, J_{SC} is calculated taking into account the spectral response curve of the mono-crystalline silicon solar cell manufacturer. The values of the open circuit voltage V_{OC} and the fill factor FF are assigned from the technical characteristics of the simulated solar cells (see Table 1).

Table 3. Parameters of the thermal collector [33].

η_0 [2] (%)	U_L (W/m^{2}K)	k_2 (W/m^{2}K^2)	$F' = \eta_0 / \tau\alpha$	ε (%)	α (%)	τ (%)
79.9	3.97	0.016	0.913	5.0	95.5	91.6

[2] η_0 = Efficiency; U_L, k_2 = Coefficients of heat loss; ε = Emission; α = Absorption; τ = Transmission and F' = Collector efficiency factor ($F' = \eta_0 / \tau\alpha$).

4. Results

The optical efficiency of the concentrating holographic system is defined in Eq. (8) as the ratio between the irradiance received at the generator surface, differentiated in the area where the PV is situated (A_{PV}) and the rest of the area where it is the thermal absorber (A_T), and the irradiance at the entrance pupil area of the system (A_E). The irradiances on the PV, thermal absorber and entrance pupil are respectively I_{PV}, I_T and I_E.

$$\eta_{opt} = \frac{I_{PV} A_{PV} + I_T A_T}{I_E A_E} . \tag{8}$$

The average optical efficiency obtained each month is presented in Figure 6. The fact that the system works better during the winter months than the summer months may seem counterintuitive. However, it is due to the lack of tracking of the system in the azimuth direction, since the maximum optical efficiency is reached when the azimuth angle, φ, is zero (at solar noon), and decreases when the absolute value of this angle increases. The azimuth angle reaches greater values in summer; therefore, the optimum incident angle range is found during less time each day, which results in lower optical efficiency, because of the angular selectivity of the HOEs.

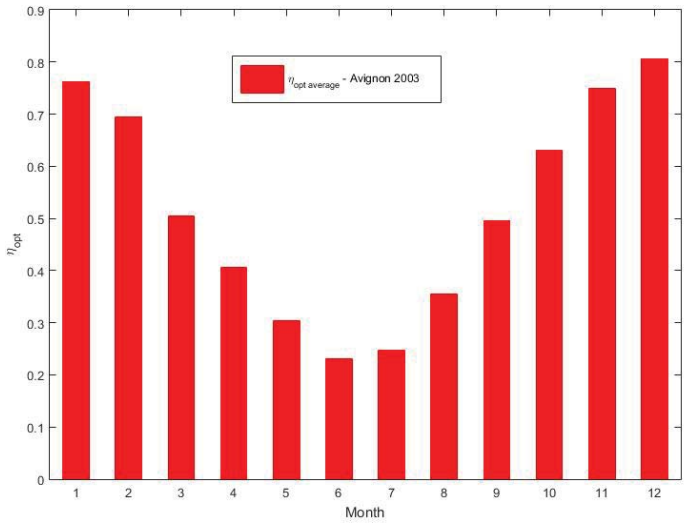

Figure 6. Average optical efficiency of the concentrating holographic system obtained each month with incident radiation of Avignon (2003).

The incident mean annual spectral irradiance received at the surface of the PV cell and at the surface of the thermal absorber, determined by means of the optical simulation described in section 3.2, is plotted in Figure 7, together with the incident solar spectral irradiance received at the entrance of the system. One of the most remarkable aspects of this graph is the shift of the peak wavelength of the spectrum that reaches the PV cell, compared to the solar spectrum. This effect is caused by the chromatic selectivity of the HOEs, which are designed to perform more efficiently around 800 nm. The shape of the spectral irradiance received by the thermal absorber is rather similar to the solar spectrum, except for the optimum wavelength range of the PV

cell.

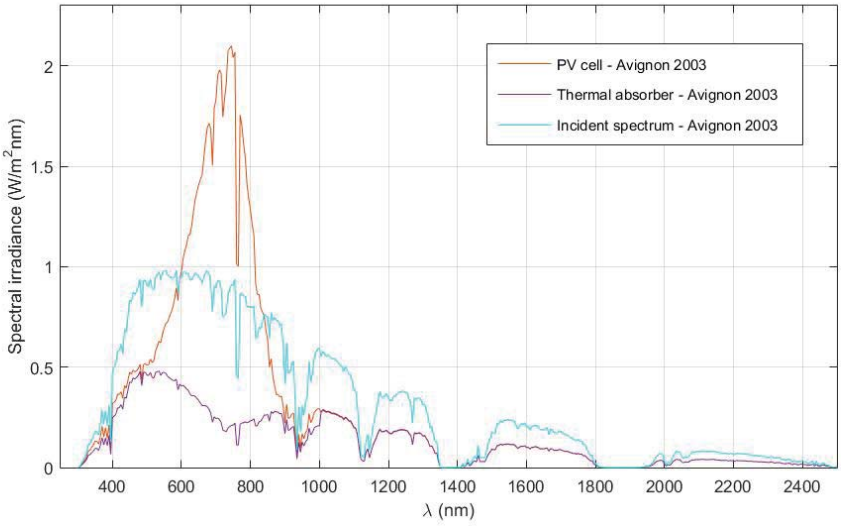

Figure 7. Average spectral irradiance at the entrance of the system, at the PV cell and at the thermal absorber at both locations.

The electrical energy produced by the HCPVT module expressed in terms of the PV cell area outperforms clearly the one delivered by the reference PVT system as it can be observed in Figure 8 a. More specifically the productions are 275.8 kWh/m^2 and 144.8 kWh/m^2 for the HCPVT and the reference PVT respectively. These values denote a mean effective optical concentration of about 2 for the whole spectrum where the PV cell is sensitive. In addition, figure 8b represents the results in a more widespread manner for PV systems that is in terms of the kilowatt pic (kWp). Conversely, in this case the energy values are the opposite: the reference system delivers almost twice the electric energy than the HCPVT (563.3 vs 296.4 kWh/kWp). This behavior is attributed to the low annual efficiency achieved by the concentrating system for all the spectral response bandwidth of the PV cell (43%) and it is a key indicator that further research in the optical design should be conducted to increase the average optical efficiency and therefore to obtain either similar or higher electrical yield values than in the reference module. On the other hand, it is worthy to mention that in terms of environmental impact the ten times reduction of the PV cell area, even the production to be the half than for the reference case in terms of kWp, reduces considerable the impact of the system as polymeric materials (used for the lenses) present in most of the cases and with all the particularities of each environmental indicator a much lower impact (Lamnatou et al., 2016).

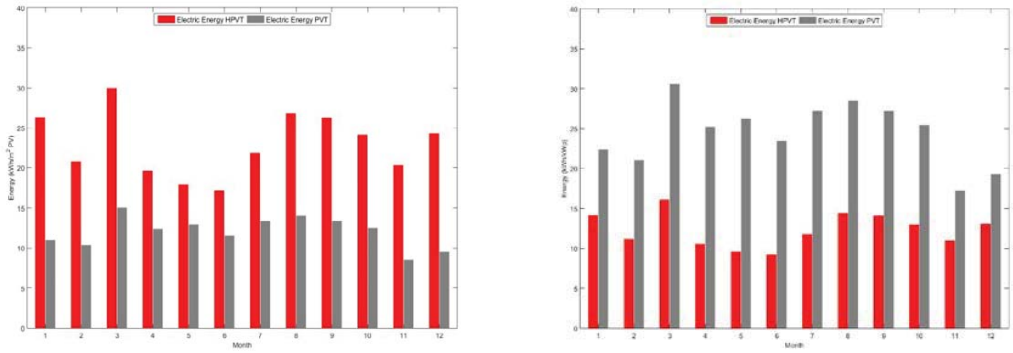

Figure 8. Electric energy output of the HCPVT system (grey bars) and the PVT system (red bars) along the year, expressed in terms of kWh/m^2 (left) and kWp (right).

The thermal energy output in both systems is quite simimilar, as it can be seen in Figure 9, reporting annual values of 250.4 and 294.2 kWh/m^2 of thermal collector area for the HCPVT and the reference PVT respectively. Therefore, the system proposed reports satisfactory values with respect to the thermal energy, however, concerning the electrical production further research is necessary not only from the energetical point of view but also considering environmental aspects.

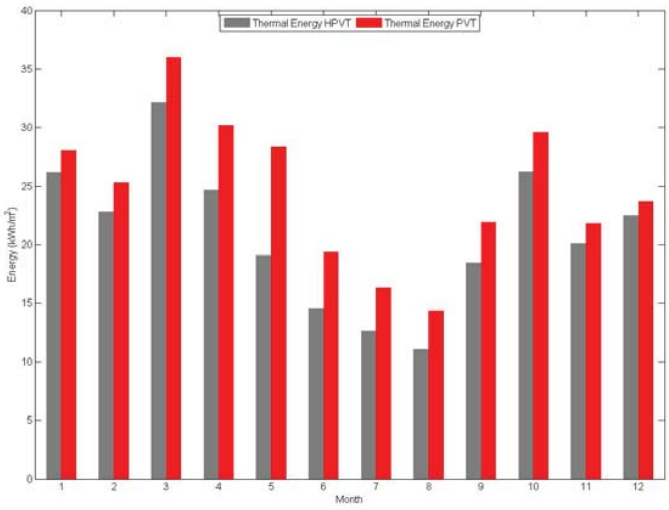

Fig 9. Thermal energy output of the HCPVT system (grey bars) and the PVT system (red bars) along the year.

5. Conclusions

A building-integrated holographic concentrating photovoltaic-thermal system has been designed and simulated. The module has been placed on the blinds of a solar louvre, which track the solar altitude movement of the sun along the day, on a south-oriented façade.

The direct normal irradiance solar spectra along one year have been calculated with the SMARTS radiative model, utilizing AERONET atmospheric parameters to test the concentrating system proposed under different spectral conditions. These spectra have been verified with direct irradiance measurements obtained from the Baseline Surface Radiation Network (BSRN), which proved the high accuracy of the simulations.

The behavior of the holographic concentrator, based on two holographic cylindrical lenses, was simulated by means of a ray-tracing algorithm. It concentrates toward the cell mainly its optimal wavelength range and also distributes the rest of the spectral irradiance on the thermal absorber, reaching a total optical efficiency. The annual average optical efficiency obtained is 43.0%.

A MATLAB-TRNSYS coupling was implemented to run simultaneously the optical, the thermal and the electrical simulations.

In the comparative study with respect to a reference photovoltaic-thermal conventional module installed with the same characteristics as the concentrating one, a similar thermal output was observed (~15% difference) but the electrical energy delivered by the reference module doubled the electricity production of the concentrating one (563.3 vs 296.4 kWh/kWp)

A future work of the present study is the improvement of the optical design to achieve higher mean optical efficiencies to obtain better electrical efficiencies mainly. In addition, environmental criteria should be considered to adequately estimate the differential performance of the holographic concentrator proposed.

[1] University of Gävle (Sweden)

[2] University of Zaragoza (Spain)

Abstract

Partial shading decreases the performance of PV modules due to the series connection between the solar cells. In the recent years, several new technologies have emerged within the photovoltaics field to mitigate the effect of shading in the performance of the PV modules. For an accurate assessment of the performance of these devices, it is required to evaluate them comparatively in different circumstances.

Three systems with six series-connected PV modules (each containing 60 cells) have been installed at the University of Gävle. System One comprises a string inverter system with 6 PV modules; System Two features a DC-DC optimizer per panel and a string inverter; System Three incorporates three micro inverters for six modules.

A major conclusion of this study was that under partial shading of one (or more) modules both System Two (DC-DC optimizers) and System Three (micro inverters) perform considerably better than System One (string inverter), as long as the Impp of the shadowed module is lower than the Impp of the unshaded string. It is also important that the Vmpp in the shaded module is higher than the lowest allowed voltage of the DC-DC optimizer or module inverter. The economic implications of the usage of these devices were also analyzed.

Keywords: Shading; PV-cells, DC-DC, inverter, installation, Impp, Vmpp, Pmax

1. Introduction

It is well known that partial shading decreases the performance of PV modules due to the series connection between solar cells in a string. In the recent years, several new technologies and devices have emerged within the photovoltaics field to mitigate the effect of shading in the performance of the PV modules. In order to make an accurate assessment about how such devices affect the overall efficiency of the PV-systems, it is necessary to evaluate them comparatively.

1.1. A standard PV system

The investigated modules have 72 series connected cells divided into 6 columns and 12 rows. There are three by-pass diodes connected between column 1 and column 2, column 3 and column 4 and between column 5 and column 6. This means that each diode is connected in parallel with 24 cells.

1.2. How shading affects PV

There are several reasons that can lead to the reduction of produced power on PV panels such as manufacturing defects, degradation of cells, high solar cell temperatures, or partial shading (Stuart R. Wenham, 2012). This project has been focused on the significant decrease of power that can be caused by shading.

doi:10.18086/eurosun.2016.08.25 Available at http://proceedings.ises.org

A cell can be seen as a combination of a current generator and a diode. Current is generated in the reverse direction of the diode. If a cell is partially shaded, it will produces less current than a cell that is fully illuminated. Voltage is practically not affected by the level of illumination, as long as a minimal level is present. During partial shading of one cell of a string, the shaded cell will not be able to generate as much current as the remaining cells of the string. Since the photo current flows in the reverse direction of the diode the unshaded cells cannot force current through the shaded cell. This means the shaded cell will limit the output of all cells in that string. Since cells are normally series connected in a string in order to raise module voltage, this causes a significant power reduction. However, if a by-pass diode is connected over the cell this will allow the surplus current to pass through the diode permitting the unshaded solar cells of the string to produce current unrestrained by the low current production caused by the shaded solar cell.

2. Method

The effect of shading was evaluated by controlled shading of different cells in a string of six modules.

2.1 The four PV installations at Gävle University

At the University of Gävle, there are four different solar systems installed. This paper is focused on the three PV systems that are shown in the picture below. Each of these three systems has 6 EOPLLY 125M/72 200 W monocrystalline modules with 72 cells and 3 bypass diodes per module (3 circuits of 24 cells per panel). There are 18 PV modules in total.

Figure 1. Systems 1, 2 and 3 at University of Gävle

2.2.1 The PV panels

The electrical specifications are shown in the table below. Each panel measures 1580x808 mm.

Table 1 Electrical specifications of the modules (Energy, n.d.)

Open circuit Voltage Voc	45.73 V	Measured at STC: 25ºC, 1000 $\frac{W}{m^2}$
Rated Voltage Vmpp	37.00 V	
Short Circuit Current Isc	5.589 A	
Maximum Power	200 W	
Operating Temperature	-40ºC to 85ºC	
Cell Efficiency	15.67%	
Module Area	1580mm x 808mm	

2.2.2 System description and schematics

- **System One:** Comprises six standard PV modules series connected to one central inverter. The string inverter contains a Maximum Power Point Tracker (MPPT) that finds out the maximum power voltage and maximum power current (Vmp and Imp) by a trial and error algorithm for the PV array. A schematic drawing can be observed on the following picture:

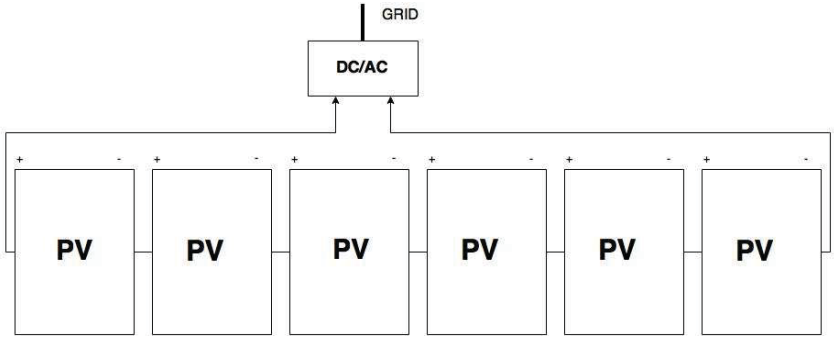

Figure 2. Schematics of System 1 (String inverter)

It is important to mention that this central inverter has a maximum DC voltage of 400V and the range of the MPP tracking in the inverter is between 100V to 320V.

- **System Two:** Comprises of the same six standard PV modules and the same string inverter as system 1. However, on this system each panel has a DC-DC optimizer. Since the output from an array of PV panels is limited by the weakest producing panel, a good solution to obtain the maximum output is to install DC-DC optimizers. They basically work as an individual MPPT for each PV panel. The DC-DC optimizers are series connected and the string inverter collects the output from the optimizers. The following figure describes how the system is connected:

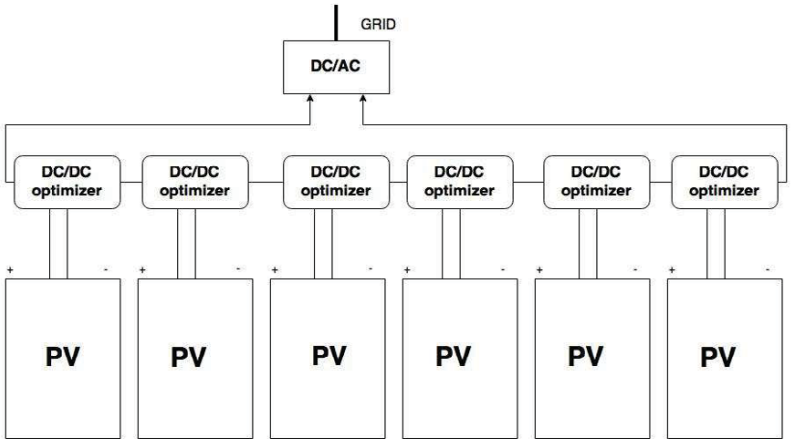

Figure 3. Schematics of System 2 (String inverter with additional DC/DC optimizers)

The following table describes the electrical specifications of the DC-DC optimizers:

Table 2. Electrical specifications for the optimizer (Tigo Eenergy, 2012)

Maximum power	375 W
Maximum Voc	52 V
Vmpp range	16-48 V
Maximum Imp	9.5 A
Maximum Isc	10 A

It is important to mention that the optimizers include a function that allows the users to monitor the power as well as the voltage and current outputs during the day on the manufacturers´ web page.

- **System Three**: Comprises three micro inverters for six modules, resulting in one micro inverter with a MPPT built-in for each two PV panels connected in parallel between themselves. The three inverters are connected to the grid like the above system. The following picture explains how the system is installed:

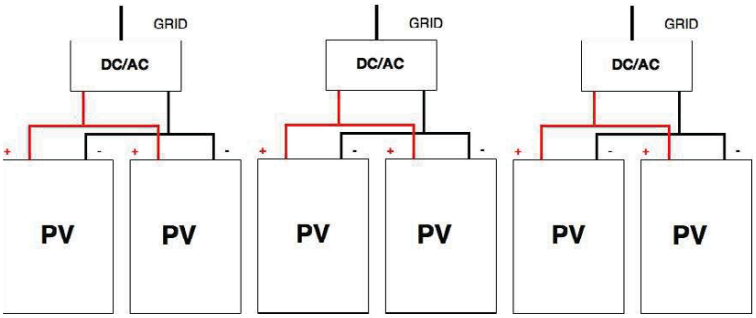

Figure 4. Schematic of system 3 (Micro inverters)

The electrical features of the micro inverters are:

Table 3. Electrical specifications of one micro inverter (Anon., n.d.)

Maximum PV power	250 W
Maximum V_{OC}	45 V
Vmp range	20-40 V
Maximum I_{SC}	10 A

- **System four:** This system was installed slightly above the location of system one, two and three at the University of Gävle. This system consists of nine thin film modules that where only utilized as reference in order to compare the output at the same irradiance level when the remaining systems were shaded.

Figure 5. System 4 (Thin film modules)

2.2.3 Components of the Systems

In order to compare the different prices of the systems that are going to be investigated, its components need to be enumerated. The table below describes each system:

Table 4. Systems components

SYSTEM	COMPONENTS
System 1	6 PV modules + 1 String Inverter
System 2	6 PV modules + 1 Maximizer Management Unit + 1 Optimizer Energy Gateway + 1 Inverter (Tigo Eenergy, 2012)
System 3	3 Micro Inverters + 6 PV Modules

2.3 Testing Procedure

In order to know how the different systems work under shading, the performance was monitored during different shading configurations. Two different procedures have been carried out:

- **Procedure 1:** System 1 was measured with the help of a solar sensor and an IV tracer which provided the IV curves. System 2 was evaluated thanks to the website of the Tigo optimizers which gave us the voltage, current and power output. Both of these systems were always evaluated with a solar irradiance

exceeding 750W/m^2. None of these procedures was available for system 3. These measurements were taken under 4 cases:

1. No shading.
2. One cell covered in one module in each system.
3. Two cells covered in different circuits in one module for all systems.
4. Three cells covered in different circuits in one module per system.

- **Procedure 2:** A data logger was collecting the power output of the three systems continuously. This data was used in a comparative analysis. Since there was no permanent pyranometer installed on site, system 4 was used as a solar radiation reference allowing us to conclude that all analyzed cases always took place during sunny days with a solar radiation exceeding 600W/m^2. The measurements were performed under 5 different cases:

1. No shading.
2. One cell shaded in one module in each system.
3. Two cells shaded in different circuits in one module for both systems.
4. Three cells shaded in different circuits in one module per system
5. 30% of a row shaded in one module per system

The following figures illustrate how the modules were shaded

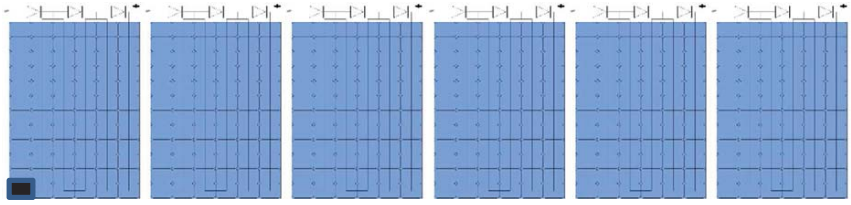

Figure 6 Case 1: No shading

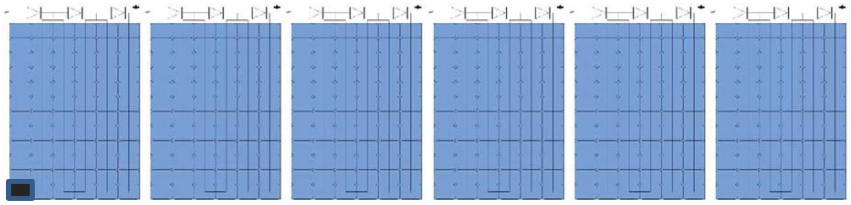

Figure 7 Case 2: One cell shaded

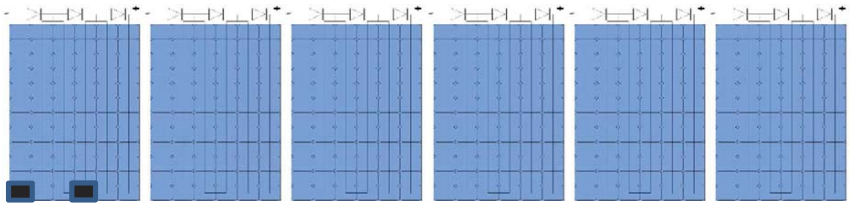

Figure 8 Case 3: Two cells shaded

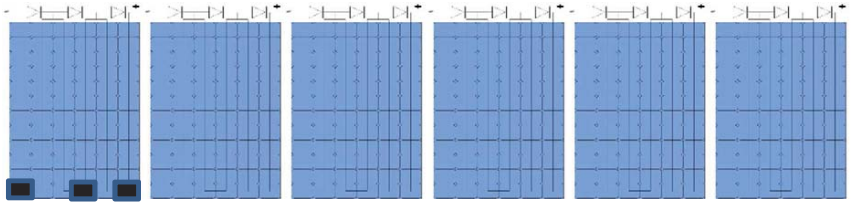

Figure 9 Case 4: Three cells shaded

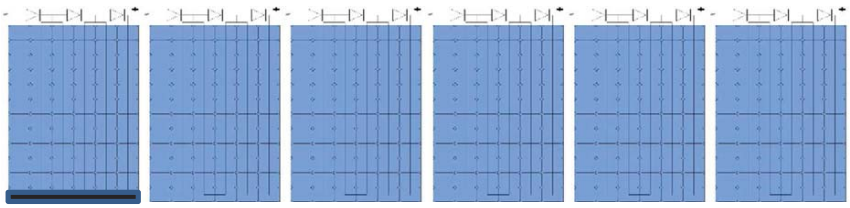

Figure 10 Case 5: 30% of a row shaded

Measurements Limitations

In order to avoid the influence of clouds, the analysis of measured data were limited to sunny days around solar noon. Only days with high output from the modules were considered. In procedure 2, the system with thin film modules were used as a reference, instead of a pyranometer.

3. Results

3.1 Procedure 1

An IV tracer was used to measure the IV curves for system 1 for each case above. For system 2, the optimizer's webpage showed the power output of the system. A solar sensor was used in order to be able to compare the results between each case and each system. Since the module current is proportional to the irradiance on the module (Alberto Dolara, 2013), it was possible to normalize the obtained results to the irradiance level of 1000 W/m^2, as shown in the following table:

Table 5. Comparison between the power output for systems 1 and 2 normalized to the same irradiation level of 1000W/m^2

28/05/2015	Irradiation level [W/m^2]	**System 1**			**System 2**	
		Normalized Power [W]	**Power relative to no shading (in %)**	Vmpp[V]	Normalized Power [W]	**Power relative to no shading (in %)**
No shading Case 1	762	1094	**100.0**	198	1089	**100.0**
1 cell shaded Case 2	815	1021	**93.3**	185	1034	**95.1**
2 cells shaded Case 3	877	948	**86.6**	171	887	**81.6**
3 cells shaded Case 4	1040	887	**81.1**	167	909	**83.6**

3.2 Procedure 2

The output during different time periods has been analyzed in order to get a comparison between the three systems which was not possible to do using procedure 1. In order to avoid influence of clouds, a careful choice

of the time periods when the output was high was made. The next graph shows the power output for the reference day with no shading based on a 10 minute resolution.

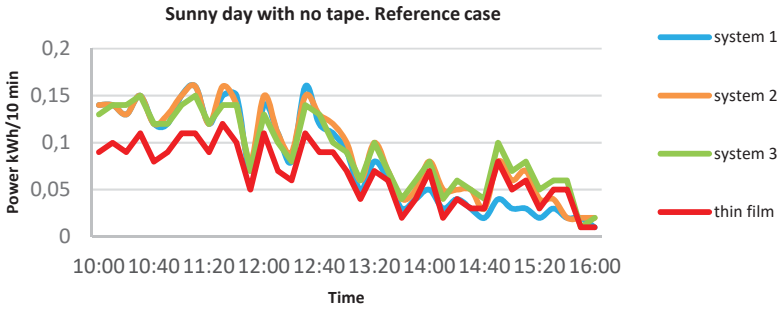

Figure 11. Power during the reference day with no shading

The following figures show the power during time periods with high power under 3 different shading cases:

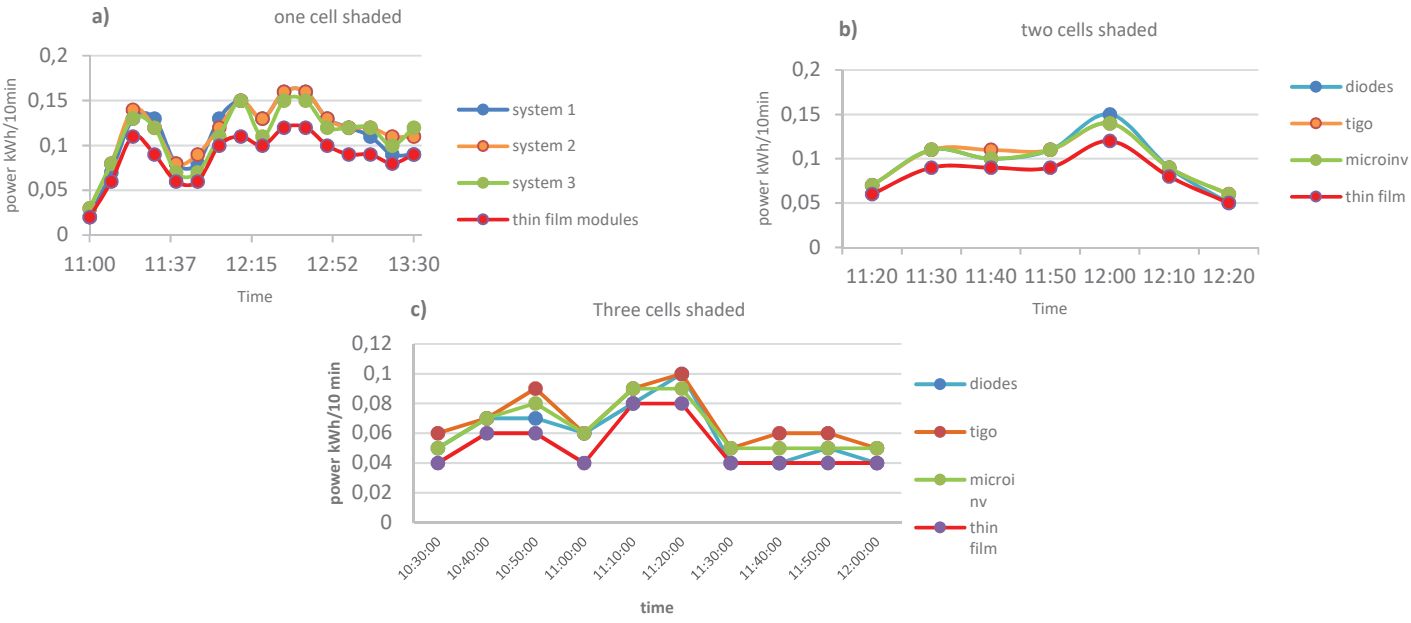

Figure 12. Power output for the cases: a) Case 2, One cell shaded, b) Case 3, Two cells shaded, c) Case 4, Three cells shaded

The following tables show the output values for each case and system. The column "percentage relative to the reference case" shows us the performance drop suffered by each system under different shading conditions. The thin film modules (system 4) where never shaded.

Table 6. Panel output in kWh during 150minutes for the case of one cell shaded in one string

ONE CELL SHADED	150 min output [kWh]			
From 11.00 to 13.30 (150 minutes)	**Reference (No tape)**	**Measurement**	**Normalized Value**	**Power relative to no shading (in %)**
System 1	1,80	1.78	1,72	**95.6**
System 2	1.89	1.85	1,78	**94.2**
System 3	1.76	1.75	1,69	**96.5**
Thin film system (reference)	1.35	1.40	1.35	**100**

Table 7. Panel output in kWh during 60 min for the case of two cells shaded in two different strings

TWO CELLS SHADED	60 min output [kWh]			
From 11.20 to 12.20	**Reference (No tape)**	**Measurement**	**Normalized Value**	**Power relative to no shading (in %)**
System 1	0.82	0.64	0.71	**86.5**
System 2	0.85	0.64	0.71	**83.5**
System 3	0.78	0.63	0.70	**89.7**
Thin film system (reference)	0.60	0.54	0.60	**100**

Table 8 90 min output. Case of three cells shaded in the three different strings

THREE CELLS SHADED	90 min output [kWh]			
From 10.30 to 12.00	**Reference (No tape)**	**Measurement**	**Normalized Value**	**Power relative to no shading (in %)**
System 1	1.33	0.6	1.12	**84.2**
System 2	1.36	0.62	1.16	**85.3**
System 3	1.28	0.59	1.10	**85.9**
Thin film system (reference)	0.97	0.52	0.97	**100**

As it can be observed in the following table, the daily output of the thin films system remains stable. This is because the measured days (the reference and the studied cases) were sunny with no clouds. Therefore, the output of the different systems in the different cases is comparable.

Table 9. Daily output with a tape covering 30% of a row in one module

30% of a row shaded	Daily output [kWh]			
Case	System 1	System 2	System 3	Thin film system
No tape (no shading)	5.9	6.0	6.2	4
Tape 30% row covered	4.9	5.6	5.8	4
Comparison to "no tape case"	83.2%	93.7%	94.6%	100%

The following table summarizes the comparison results obtained:

Table 10. Comparison between the three systems during different shading configurations

	% of the power relative to no tape		
	System 1	**System 2**	**System 3**
No tape (no shading)	100	100	100
Tape on one cell	95.6	94.2	96.5
Tape on two cells	86.5	83.5	89.7
Tape on three cells	84.2	85.3	85.9
Tape covers 30% of a row	83.2	93.7	94.6

3.3 Summary of both procedures and comparison with theoretical results:

The following table summarizes the experimental results, the relative power decrease, and compares it with the theoretically expected results.

Table 11 Percentage of the power relative to no shading. Comparison Theoretical Vs Experimental.

	Experimental results Power relative to no shading (in %)					Theoretical power relative to no shading case (in %)		
	System 1		System 2		System 3	System 1	System 2	System 3
	Procedure 1	Procedure 2	Procedure 1	Procedure 2	Procedure 2			
No shading	**100**	**100**	**100**	**100**	**100**	**100**	**100**	**100**
One cell shaded	**93.3**	**95.6**	**95.1**	**94.2**	**96.5**	**94,5**	**94,5**	**94,5**
Two cells shaded	**86.6**	**86.5**	**81.6**	**83.5**	**89.7**	**88,8**	**83,3**	**88,8**
Three cells shaded	**81.1**	**84.2**	**83.6**	**85.3**	**85.9**	**83,3**	**83,3**	**83,3**
30% of a row shaded	**---**	**83.2**	**---**	**93.7**	**94.6**	**83,3**	**95**	**95**

3.4 System costs

The performance of PV modules connected to different shading mitigation systems has been shown in the above tables. However, this is analysis would not be complete without looking into the costs.

This way, the investment cost for each system has been calculated. The following tables show the price of each component of the three systems installed at Gävle University.

Table 12. Costs of the devices

DEVICE	PRICE	PRICE [SEK]
Inverter	450£ (direct, n.d.)	5784
Optimizer Maximizer	111$ (Solar, 2015)	903
Optimizer Energy Gateway	113$ (Solar, s.f.)	918
Optimizer Energy Maximizer Management Unit	343$ (direct, s.f.)	2780
Micro inverter	249€(Anon., n.d.)	2345
PV modules	3720€(Gomes et al., 2014)	39466

Table 13 System Cost

System	Price [SEK]	Added cost
System 1	18 330	**0%**
System 2	27 446	**50%**
System 3	19 581	**7%**

4. Discussion and Conclusions

The influence of shading in solar panels is difficult to measure since both power output and the energy collected are strongly dependent on factors like the weather, time of the year, latitude and others. Table 5 shows the decrease in Vmpp for each shading case of procedure 1. The current produced by the panel, after normalization to the solar radiation, remained fairly stable and thus was not included in table 5. Therefore, in the evaluated cases, the power decrease correlates very well with the voltage decrease.

In system 1 (the string inverter), when one cell is shaded, the MPP tracker finds the point that leads to the highest power production in all the series connected PV modules, which means that the five modules are working at maximum power while the shaded module is working only at 2/3 of its maximum power. This means that the maximum current possible will pass through the six panels and one bypass diode will be activated to bypass one string. The theoretical percentage of power collected from the six panels will be 95% which corresponds to 5.67 out of six modules working at full power. The data collected from the measurements in procedure two supports the above statement. Table 6 shows the same 95% percentage of power production in all systems. Likewise, system 2 (with the DC-DC optimizers) with one cell shaded shows a similar power reduction (from 100% to 95%), as shown in table 5. This means five optimizers will collect the maximum power output from five unshaded modules while the shaded one will produce only 2/3 of its maximum power output. Finally, system 3 (parallel connected micro inverters) also shows a 5% power reduction. When one cell is shaded the DC-DC optimizer and the microverter will not increase the power and all systems will produce the same power.

In the case of two cells shaded, it can be observed that in system 1, the shaded panel only produces 1/3 of the power which corresponds to two strings producing no power. In this case, the theoretical power output is about 88% of the power collected with no shading, since 5.33 out of 6 modules are working. However, using procedure 1, it can be seen that the optimizer collects slightly lower output, about the 83% of the output collected from the unshaded case. This is shown by optimizer's webpage (procedure 1) in figure 10 where it is visible that one module (in black) is basically not working:

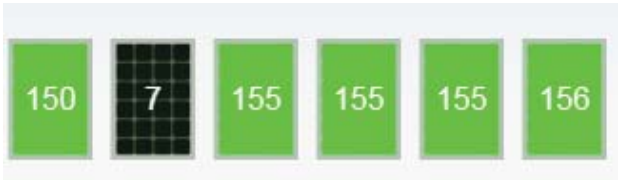

Figure 10. Power in Wp from each panel of system 2, in the case where two cells shaded. Each square represents the PV panel and the number inside is its power output in W.

This is a result of the limited Vmpp range of the optimizers being between 16-48V. If two strings in one module are shaded, the maximum voltage output is 1/3 of the PV module voltage (about 12V) which is below 16V, the minimum operating range of the optimizers. Hence the optimizer will go to a point in the IV curve where the voltage is bigger than 16 V and consequently sacrifice the current output, collecting almost no power from the PV module like shown in figure 10. It was expected that system 3 (with the micro inverters) would have the same problem since the Vmpp range is between 20-40V and the expected voltage was 12V. However, looking at table 7, the output obtained is about 90% of the output with no shading in the system which means that 5.33 out of 6 modules are working. This is probably due to the fact that the total voltage of the two mismatched parallel modules is between the Vmpp range of the MPP tracker of the micro-inverter.

In the case where three cells are shaded in each string of one module, all of them behave in the same way; Five module produce at full power and the shaded module is not working. This can be observed in table 8.

Finally, in case 5 (where a tape was covering the 30% of the module), it can be observed that the system 1 produces less output than the other two systems. In this case, the MPP tracker of system 1 has two options: to get the power output with a current about 70% of the total generated or collect the power output with five modules working while the bypass diodes of the shadowed one are working. The MPP tracker in the string inverter will take the last option since it produces more power.

This way, the main conclusions from this paper are:

1) If the shaded module gives full current at MPP then optimizers and the micro inverters will not increase the output. The module gives full current, if one of the three circuits in the module are not shaded.

2) The Vmpp range of the optimizers and inverters are important. If the Vmpp is out of range then the module will give either no or a low output.

3) The optimizers and the micro inverters will increase the output if the shaded module gives lower current than the non-shaded modules. This occurs under partial shading of all circuits in one (or more) modules. In this situation both System two (DC-DC optimizers) and System Three (micro inverters) perform considerably better than System One (string or central inverter), as long as the Impp of the shadowed module is lower than the Impp of the string. It is also important that the Vmpp in the shaded module is higher than the lowest allowed voltage of the DC-DC optimizer or module inverter.

4) There is a good agreement between the experimental results and the theoretically expected results for all cases.

From an economic perspective, considering the impact of shading, since system 2 (DC-DC optimizer) does not collect more energy that system 3 and it is 50% more expensive, it should not be selected as an option. System 1 (string inverter) is the cheapest and for this reason, it is preferable in all situations when one can be certain that there will be no shading. When one is uncertain if shading will occur, the extra 7% cost (difference between system 1 and system 3 with micro inverters) will probably be justified since the increase in annual energy produced should be superior to 7%.

Abstract

Modeling and simulation of photovoltaic systems represent an essential task for the integration of photovoltaic panels in current power applications. At the present time, there are sizing tools of photovoltaic systems available on the market, taking into account the proposed energy consumption, site localization and system cost. Many of the specialized programs are relatively simple and allow the user to solve automatically the energy balance calculations, basing on different components of the photovoltaic system.
In this article, there were considered the most common specialized programs namely SAM, SOLARIUS PV and PVSyst; it was analysed the sizing of a photovoltaic system. The results obtained through numerical modeling were compared with the existing data from a photovoltaic park installed in the South of Romania. In this way, it was identified the most efficient program for sizing.

1. Introduction

In the recent years, the share of the energy produced from renewable energy sources has grown considerably. This kind of energy presents numerous advantages, which lead to the sustainable development of society, but it has a major drawback: it is very fluctuant. This drawback becomes more and more an issue, since the increase in the percentage of total energy production using renewable energy sources could have a negative impact on energy distribution equipment, as well as on the quality of energy.
In the case generated by photovoltaic systems based on small or large photovoltaic power plants, energy quality varies not only in annual cycles (different angles of the incident solar radiation depending on the season), or day-night cycle, but also depends on the spontaneous factors such as clouds, nebulosity, aerosols, etc. For these reasons, the present work proposes a comprehensive study on the most interesting software packages used for simulation and analysis of a photovoltaic system developed for energy purposes and to compare the obtained results in order to identify the most efficient way for estimations and forecasts (Fara, et al., 2009; Sharma, et al., 2014)

2. Presentation and results of the SAM software (Solar Advisory Model)

SAM, called "Solar Advisory Model" was firstly developed (for internal use only) by the National Renewable Energy Laboratory (NREL), in cooperation with the Sandia National Laboratories, in 2005 (https://sam.nrel.gov; Wagner and Gilman, 2011). NREL has released the first public version of SAM in August 2007, in order to be used by solar energy experts for the technical – economical analysis of PV systems. The program allows the performance forecasts and energy estimates for photovoltaic systems, both for grid connected or mixed photovoltaic systems, and stand alone ones, based on the technical and economical parameters to be used as input for analysis.
The aim of the program is to facilitate the decision making for persons involved in the renewable energy industry. It could be used by the project managers, researchers, engineers, financial experts and developers of new technologies (Klise and Stein, 2009; Wagner and Zhu, 2011). SAM makes performance forecasts and estimates the cost of power installations connected to the grid or stand-alone, based on the costs of installing,

doi:10.18086/eurosun.2016.08.18 Available at http://proceedings.ises.org

operating and specific design parameters. National Renewable Energy Laboratory (NREL) distributes the software SAM at: https://sam.nrel.gov. https://sam.nrel.gov/content/sam-publications
Based on this program, it is possible to calculate the electricity output of the PV systems from hour to hour; it can be exploited the performance characteristics of the system by visualization of the hourly and monthly data from the tables and graphs in order to establish the system performance and annual capacity (Wagner 2012; Gilman and Flat 2013). The input data from our study are represented by the main specifications of the Photovoltaic Park sited in the South of Romania (see **Tab. 1**); they are compared with the data obtained from numerical modeling using SAM program. The meteorological parameters interesting for the PV Park's location are: direct irradiance - 1 [kWh/m^2/day], average annual temperature – 11.5 [˚C], average annual wind speed – 3.2 [m/s] and Albedo – 0.2. These parameters were introduced to describe a general view of the site where the PV system is located. The comparative study between the measured data and simulated ones by means of specialized software programs for determination of monthly/yearly electricity production does not take into account the meteorological parameters of the analyzed existing PV Park because the simulation programs have own meteorological data and different models were used for calculation of electricity production; the authors' main objective was to interfere as little as possible in the characteristics of the simulation programs.

Tab. 1: The main specifications of the PV system for the studied PV Park

Installed power	**9934 kW**
PV panel power	245 245 Watt Suntech Power
Total number of panels	40551
Number of panels on string	21
Number of strings	1931
Number of inverters	20 - Green Power PV500
Used area	33 ha

The PV power plant is composed from 1931 strings, each string having 21 Suntech panels of 245W each. Totally there are 40551 PV panels having an installed power of 9934 kW. The solar radiation data are measured done by 2 pyranometers and 10 cells for calibration. The pyranometers are located within the weather station in the PV Park and the cells for calibration are placed at each transformation center. PV panels are made of 72 solar cells based on Si polycrystalline. The I-V characteristics of a PV module is presented in **Fig. 1.** The PV module main parameters are considered for Standard Test Conditions (STC): total irradiance of 1000W/m^2 and cell temperature of 25^{o}C (See **Tab. 2**).

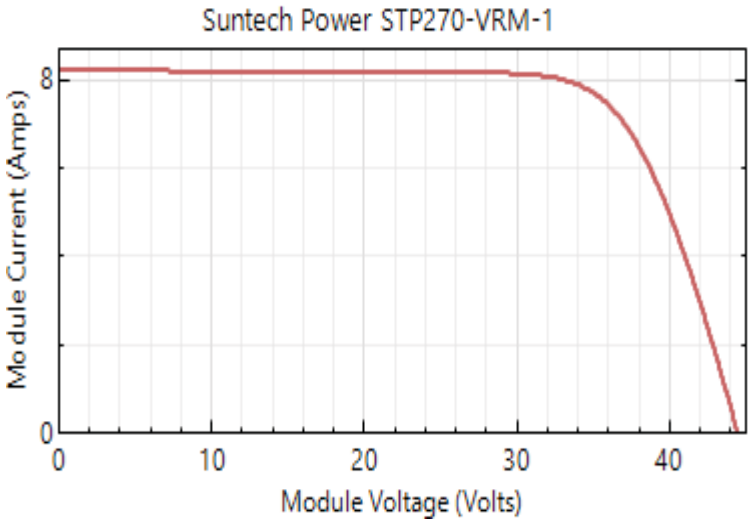

Fig. 1: I-V characteristics of the PV module

The PV system includes, too 20 Green Power inverters of PV500 type (the efficiency curve of an inverter is shown in **Fig. 2**). Each transformation center contains 2 inverters. The inverter main parameters are presented in **Tab. 3.**

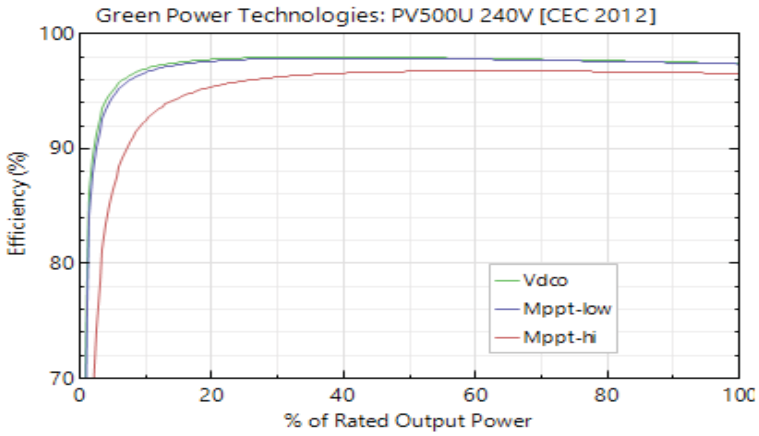

Fig. 2: The PV500 Green Power Inverter Efficiency

Tab. 2: Main parameters for PV module

PV module	
Nominal efficiency	13.9098%
Maximum power	269,850 W dc
Maximum voltage	35 V dc
Maximum current	4.8 A dc
Voltage in open circuit	44.5 V dc
Short-circuit current	8.2 A dc

Tab. 3: Main parameters for inverter

Inverter	
CEC Efficiency	97,733%
EURO Efficiency	97,656%
Max. power output ac	500000W ac
Maximum power dc	513270 W dc
Normal operating power consumption	998,728 W dc
Night operating power consumption	140.4 W ac
Nominal voltage ac	240 V ac
Maximum voltage dc	1000 V dc
Minimum current dc	1250 A dc
Minimum voltage MPPT	425 V dc
Nom. voltage 12v dc	395,616 V dc
Maximum voltage MPPT	825 Vdc

In **Fig. 3** is represented simulated monthly energy production using SAM software. The simulation was carried out over a period of a year; the results are adjusted using an annual degradation coefficient of 0.5% per year.
The losses caused by various factors-both technical, and external ones from the environment of the system location were taken into account. In order to make a comparison between actual and simulated data, the components of the existing PV system and those used in simulation are identical.
In terms of losses arising in the system functionality, the program calculates their estimates based on the existing literature and data on the technical details of the used components. In addition to the technical factors, the program estimates other type of losses that may be due to the environment in which the system is located. All of

these losses are represented in a Sankey diagram, (see **Fig. 4**) and according to this, the user can estimate the future problems and differences between the installed power of the system and the energy actually delivered to the local grid of energy distribution.

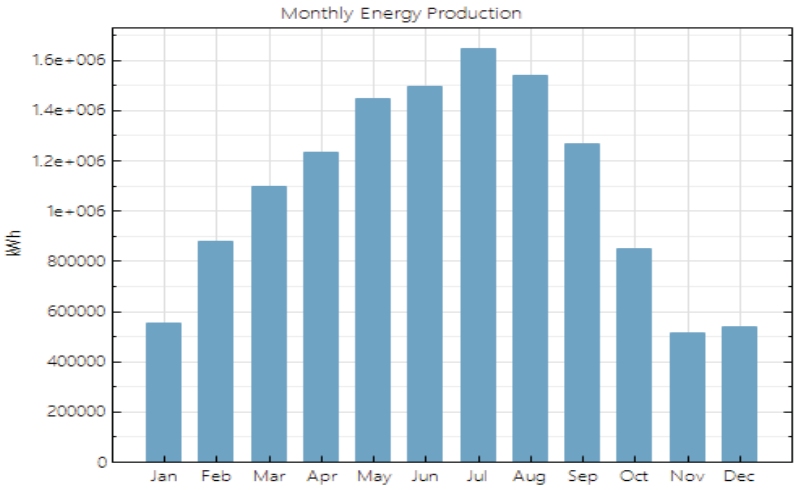

Fig. 3: SAM monthly energy production

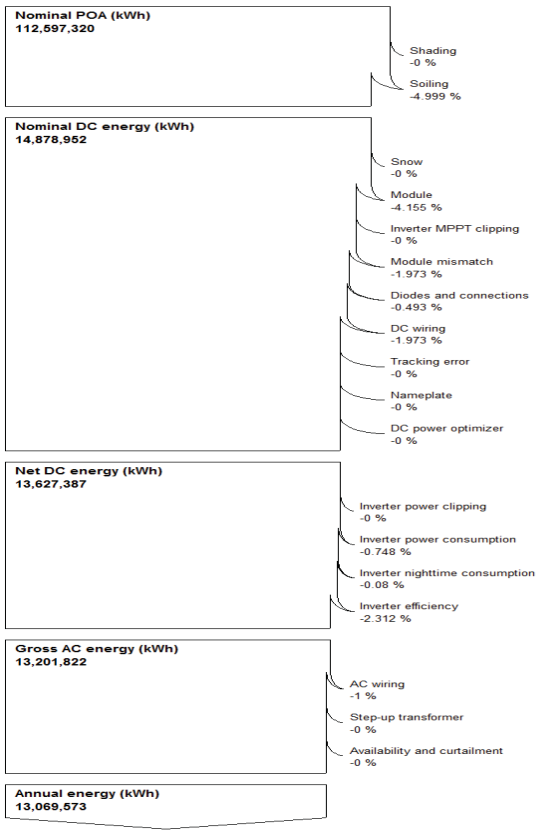

Fig. 4: Sankey diagram for energy losses

In the database relating to the sizing program, the same types of panels, strings, inverters from the studied PV Park have used. We have to mention that the weather data from the SAM software are different from those existing in the database of meteorological station of the PV Park.
The energy to be injected in SEN (National Energy System) based on the SAM software presents an annual difference of 1020 MWh compared with the actual one.

3. Presentation and results of the software SOLARIUS-PV

The program SOLARIUS – PV represents a software package for the design and simulation of energy production for PV systems connected to the grid (http://www.acca.it). It has multiple functions to be fulfilled for a better sizing (ACCA Software, Solarius PV, User's Guide, 2011):

a) **Calculator for estimation of solar irradiance.** The SOLARIUS software guides the user for the sizing process in order to obtain the best technical and financial solutions. The program provides the ability to view real-time possible benefits of changes that the user could enter. For example, the benefits obtained by the optimum changing of the tilt angle for PV panels on a monthly time period of one year, could be remarked
b) **The CAD (computer aided design) input files parameters**
c) **Calculations of the efficiency rate of the PV system.** The SOLARIUS software calculates annual and hourly energy production for a PV system. In this way there is obtained its profitability based on the recovery period that determines the PV system simulated performance (**Fig. 5**). This technical and financial evaluation is simple and fast, the program generating system yields through various charts and tables, easy to understand even for new users.
d) **Analysis of the losses**
e) **Automatic sizing and positioning of the photovoltaic panels**. The SOLARIUS software works in graphic mode to be faster and easier for understanding. The program sizes and automatically places the PV panels on the selected location (roof, fixed mounting systems or solar trackers). The panels to be used in the construction of the system can be selected from an existing archive, which can be updated easily and from which you can extract information about the technical specifications of these panels. Within the framework of appropriate size and location of the PV system, it is possible to sketch the site plan and PV panel location.
f) **Auto - size of the inverters.** The PV systems can be sized by SOLARIUS software, integrating single phase or three phase inverters or inverters based on MPPT (Maximum Power Point Tracking) technology. In order to achieve maximum efficiency, inverters can be chosen from a list of components but, depending on the characteristics of the system, the program can propose the best options to maximize the yield of the inverters.

The reflection capacity of solar energy within the incident surface is characterized by *albedo*. The albedo depends on many factors such as soil nature, its degree of roughness and soil color. In this study the albedo value was considered to be 0.2. The monthly energy production based on SOLARIUS software is shown in **Fig. 5.**

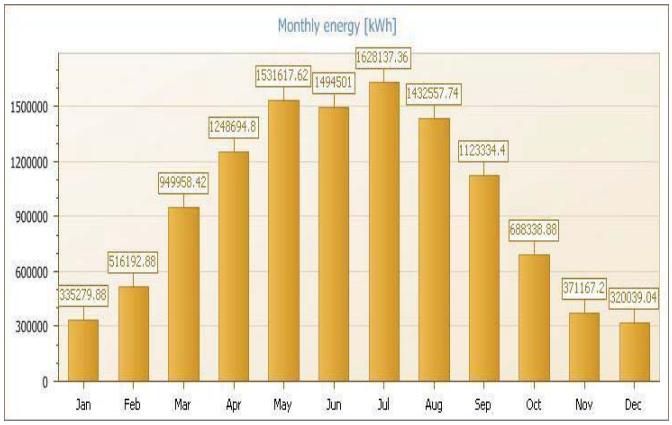

Fig. 5: SOLARIUS – PV monthly energy production

The simulated annual energy to be injected into the SEN is 11639 MWh. The BOS components are identical to those of the existing PV Park. There is a difference of 410 MWh between the simulated values and existing ones. In terms of annual energy production, we conclude that the SOLARIUS software has better results in comparison with the SAM one because the energy production value provided by SOLARIUS is approaching to the value supplied by the PV Park.

4. Presentation and results of the software PVSyst

The PVSyst software is a package intended for study, sizing and data analysis of a photovoltaic system (grid connected or stand-alone PV systems). For analysis, meteorological global database and databases containing detailed specifications of the system components are used. The software holds two expertise technical levels for sizing of a PV system, each level corresponding to different stages in the development of a real system (http://www.pvsyst.com; Chikh et al., 2011).

Preliminary Design - is appropriate to the pre-dimensioning stage. In this level, the PV system performance is assessed using the average monthly values, without detailed specification of the components of the system. For PV systems connected to the grid, in particular for BIPV systems, this level has architectural guidance, requiring information on available space, photovoltaic technology used (color, transparency, etc.), the required power and financial details (Karki et al., 2012; Iftakhar et al., 2012). For stand-alone systems, a sizing of power generated or storage batteries, taking into account the load profile and loss of load probability could be achieved (Irwan et al., 2015).

Project Design – The project aims to carry out a detailed examination using hourly simulations and selection of different specific components of PV system. The program helps the user in sizing the PV system (number of PV modules used and their layout-in series or in parallel); there are considered data related to the inverters, batteries or project needs. On this basis, the PVSyst software is developing monthly energy production (see **Fig. 6**), and losses Sankey diagram (see **Fig. 7**).

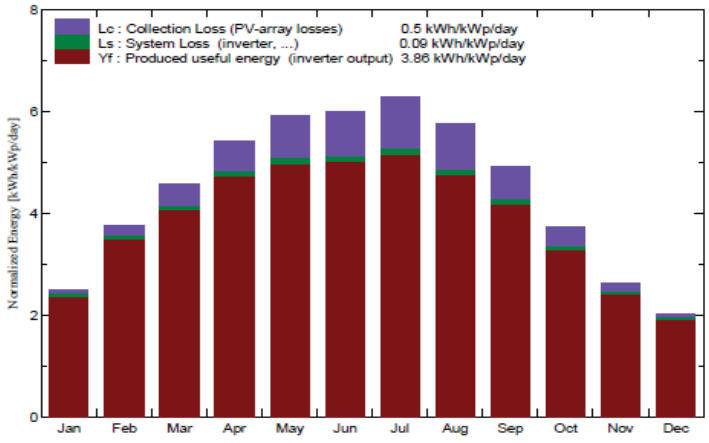

Fig. 6: PVSyst monthly energy production

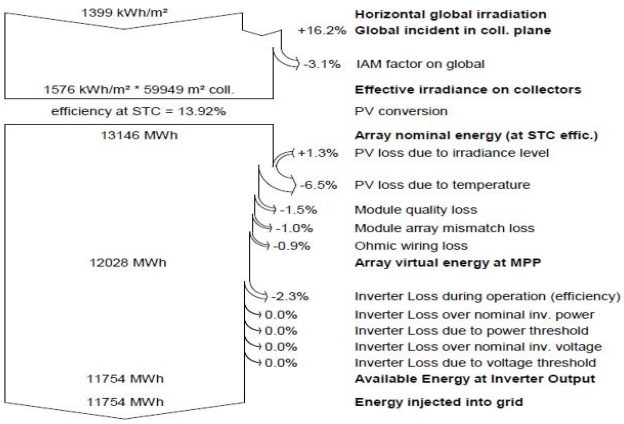

Fig. 7: Sankey diagram for energy losses

There is a difference of 395 MWh between the simulated yearly energy (injected into the SEN) and the real one supplied by the PV Park. This value of 11758 MWh obtained using the PVSyst software is the closest to the value obtained in situ, respectively 12049 MWh, thus the PVSyst software, is the most corresponding for estimation of annually energy production by a PV Park.

5. Analysis of the results

The simulated results using the three software programs: SOLARIUS, SAM and PVSyst were compared with the measured data for the studied PV Park (see **Tab. 4** and **Fig. 8**). There were obtained too, the absolute and relative errors for annual energy production estimation using the analyzed simulation programs, namely: 1) For SAM software the absolute error is 1020 MWh and the relative error is 8.47 %, 2) For SOLARIUS software the absolute error is 409.62 MWh and the relative error is 3.4 %, 3) For PVSyst software the absolute error is 290.80 MWh and the relative error is 2.41 %. According to the obtained results the PVSyst software has the smallest error in comparison with the measured data; it is the most efficient program to be used in the simulation of energy production estimation on long term (annually).

Tab. 4: Monthly/annually energy injected into to the grid: measured data and simulated results by three programs SAM, SOLARIUS and PVSyst

Month / Database	Measured energy production [MWh]	Simulated energy production with SAM [MWh]	Simulated energy production with SOLARIUS [MWh]	Simulated energy production with PVSyst [MWh]
January	347.33	556.07	335.28	613.12
February	585.39	880.84	516.19	816.08
March	1273.83	1095.69	949.96	1049.45
April	1094.03	1235.40	1248.69	1183.21
More	1442.60	1447.85	1531.61	1286.56
June	1422.56	1495.60	1494.50	1254.12
July	1507.23	1646.23	1628.14	1334.63
August	1671.89	1542.12	1432.55	1229.47
September	1197.59	1267.53	1123.33	1044.16
October	922.31	849.48	688.34	849.58
November	217.65	513.89	371.16	605.01
December	367.05	538.76	320.09	493.27
Total annual	**12049**	**13069**	**11639**	**11758**

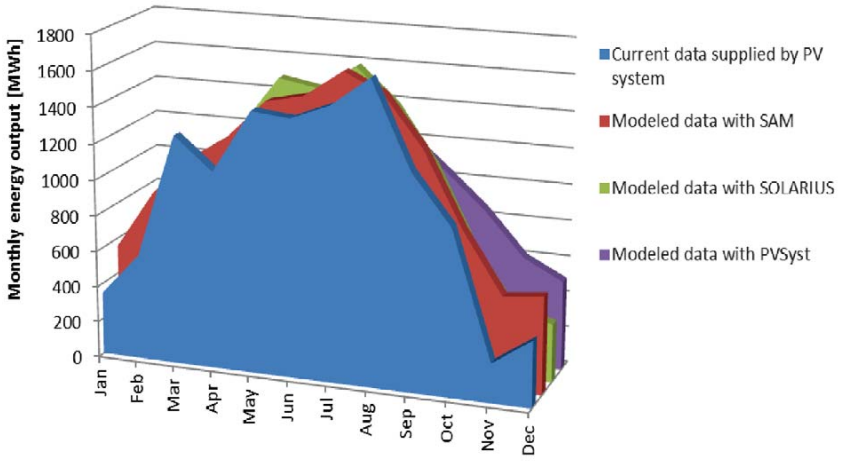

Fig. 8: Monthly energy production related to the analyzed PV Park using three specialized software (SAM, SOLARIUS – PV and PVSyst) compared with the monthly energy production registered by the PV system, all results are obtained within one year (2015)

6. Conclusions

- The comparative analysis shows that for the annual level, the closest results from the measured ones in the analyzed PV Park are based on the PVSyst software.
- The SAM Program could be recommended to optimize the existing PV Park, because it offers the highest annual simulated energy production. A reconditioning of the actual PV Park could be taken into account.
- The programs could not be used for forecasts on short and medium term because the errors are significant in these cases, but on the long term (one year) they would offer an acceptable perspective of the results.

Abstract

In the photovoltaic (PV) system, relations between current, voltage and power generated by system can be illustrated by photovoltaic characteristics, and it can be developed experimentally and/or theoretically. In this work, characterization of a PV module in Bandung – Indonesia, as one of tropical climates area, will be shown based on experimentals. Our works were carried out using a Laboratory scale PV system. Three sub systems, i.e. a PV module, measuring instruments and data acquisition, and PC for the monitoring system, were identified and determined. An Electrical Solar Module (ESM) of 50 Wp was used as the object. As an output of this work, characterization of a PV module in a tropical climate, represented by current-voltage-power relation will be shown.

Keywords: *current, voltage, power, experimental test, laboratory scale.*

1. Introduction

Presently, research in the photovoltaic (PV) field becomes interesting topic for many institutions, universities and companies, as a response to the crisis of energy and environmental problem all over the world.

Testing through experiments, modelling through numerical method or simulation using software package are typical to quantify the physical phenomenon. Testing and modelling of a PV system performance are very complicated and influenced by a variety of interactive factors related to the environment (temperature and irradiance), besides to solar cell physics (Rusirawan and Farkas, 2014).

In designing power generation system that incorporates PV modules, there is a basic requirement to accurately estimate outputs from the proposed PV system under a particular operating condition. PV modules are given a power rating at standard test conditions (STC) of 1000 Wm^{-2}, AM 1.5 and a module temperature of 25 ^{o}C, but these conditions do not represent what are typically experienced outdoor (Carr and Pryor, 2004).

A PV system (cell/module/panel/array) naturally exhibits non-linear *I-V* (current – voltage) and *P-V* (power – voltage) characteristics which vary with the radiant intensity and PV cell temperature (Tsai et al., 2008).

Referring to the state of arts of PV modules technology, currently, proven technologies in the commercial market are crystalline technology and thin film technology. From the PV module performance point of view, the eficiency of thin film technology is lower than crystalline technolgy. Nevertheless, an additional issue is the lower energy consumption for the production of thin film technology and consequently a shorter energy payback time for these technology. One should bear in mind that the total energy payback time for a given PV module does not only depend on the solar cell used, but also on the module design, e.g. framed module, glass/glass, metal foil, EVA, etc. The general features of commercial wafer based crystalline silicon and thin film are presented in the working material of Greenrhinoenergy (2012).

In this work, characterizations (*I-V-P*) of a PV module by experiments will be shown for some operating condition (solar irradiance and module temperature) in Bandung – Indonesia condition, as one of tropical/hot climate regions. As the first, characterizations of crystalline technology of PV module is performed.

doi:10.18086/eurosun.2016.08.02 Available at http://proceedings.ises.org

In the near future, characterization of thin film technology will be performed as well, therefore a comparison of two PV technologies between crystalline technology (mono and/or poly crystalline silicon) and thin film technology (amorphous silicon) can be performed.

As an outcome of this work, all required informations, especially related to characteristics of different types of PV modules technology can be acquired. Based on this outcome, a depth consideration in order to choose a type of PV module can be defined by countries in tropical region, as a response to the controversy in selecting the proper PV modules, based on their climates.

2. System Description and Methods

The photovoltaic module experiments apparatus is shown in Fig. 1 and the schematic diagram for photovoltaic module experiments along with the measuring features can be seen in Fig. 2.

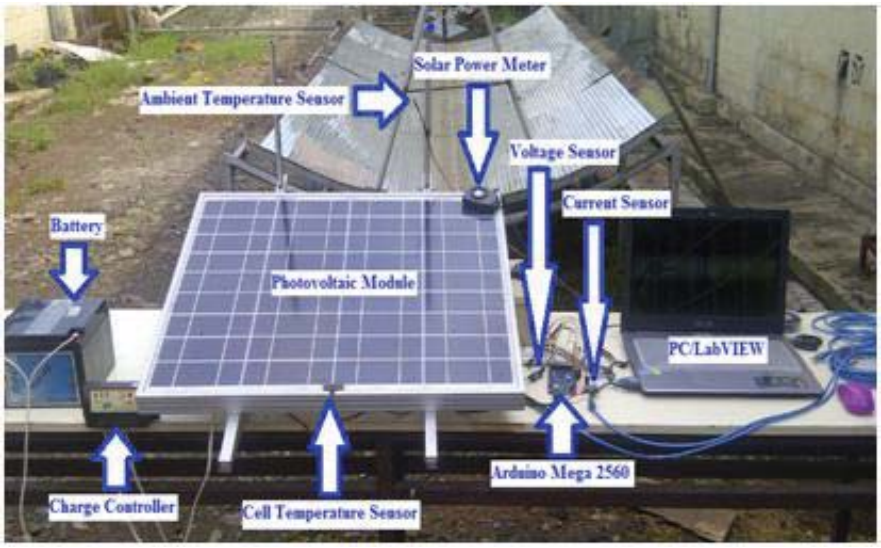

Fig. 1: The PV module experiment test

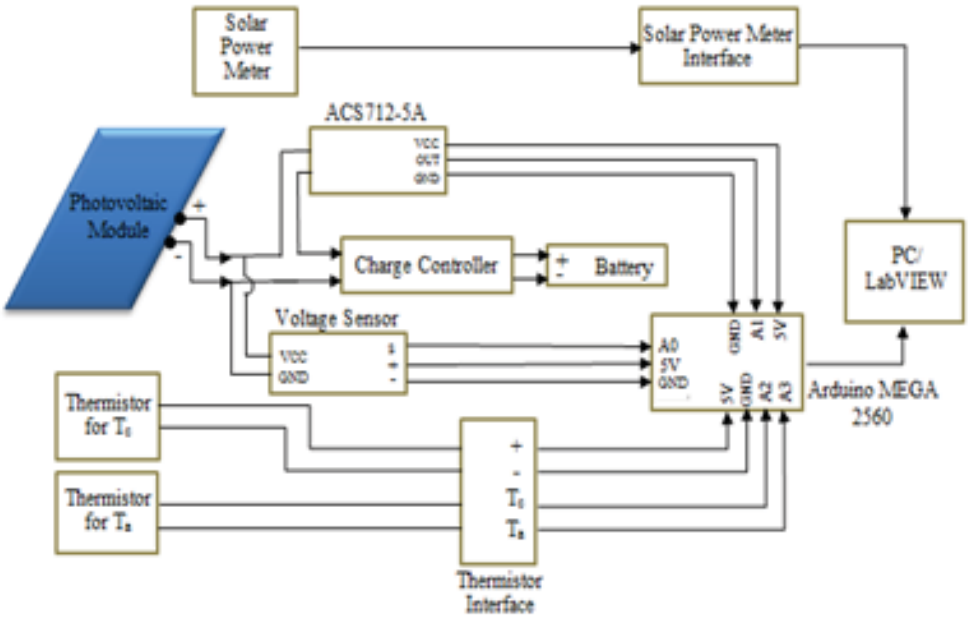

Fig. 2: Experimental test schematic diagram

The location for experiments is Bandung, West Java-Indonesia, with latitude 06°54'S and longitude 107°36'E. The type of the PV module in this research is ESM (Electrical Solar Module) 50 Wp with the optimum operation voltage 17.2 V and optimum current operation 2.91 A. The data acquisition system is Arduino

MEGA 2560 with LABVIEW Programming, and the sensors for: voltage, current and temperature are VCC<25V, ACSC712-5A, thermistor 10 kOhm, respectively. The system is equipped by solar power meter and its sensor.

Additionally, two LED lamps (with the same specification: 12 V and 3.5 W) are provided as an external load.

The specifications of all component used in the experimental test are shown in Figs 3-8.

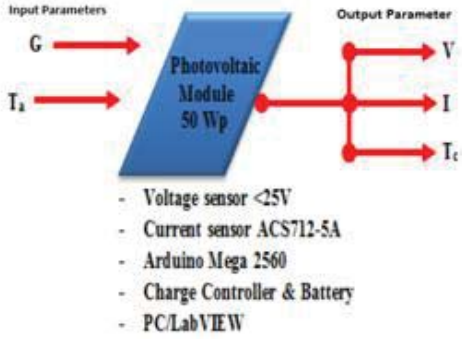
Results

The PV module experimental system was installed in the ITENAS campus area in Bandung. The data acquisition was performed during 1 day experiments, January 16, 2016, from 09:00 a.m. to 05:00 p.m. The input – output parameters and the principle of measurement can be seen in Figs 9 and 10.



G : Global irradiance ($W.m^{-2}$)

T_a : Ambient temperature (^oC)

V : Voltage (Volt)

I : Current (Ampere)

T_c : Cell temperature (^oC)

Fig. 9: Input – output parameters

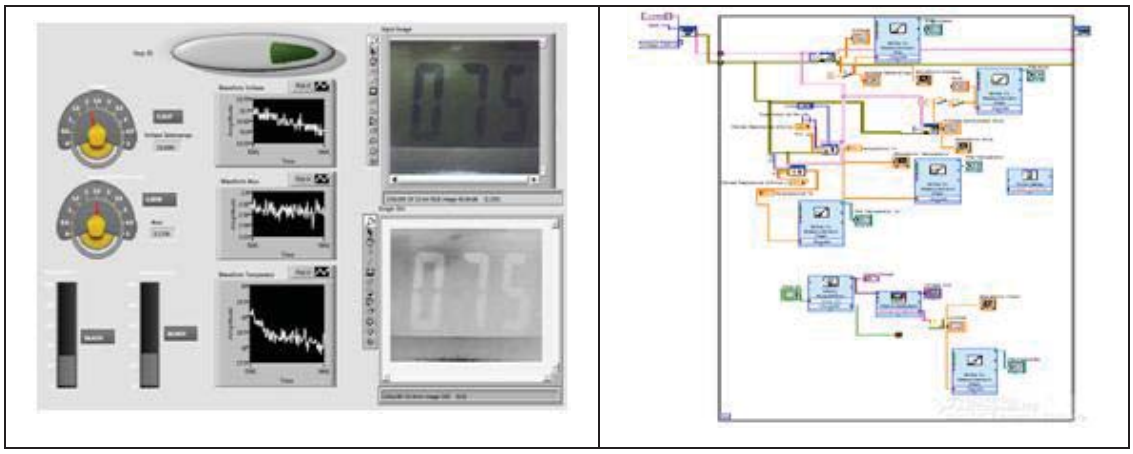


Fig. 10: Data acquisition method and block diagram

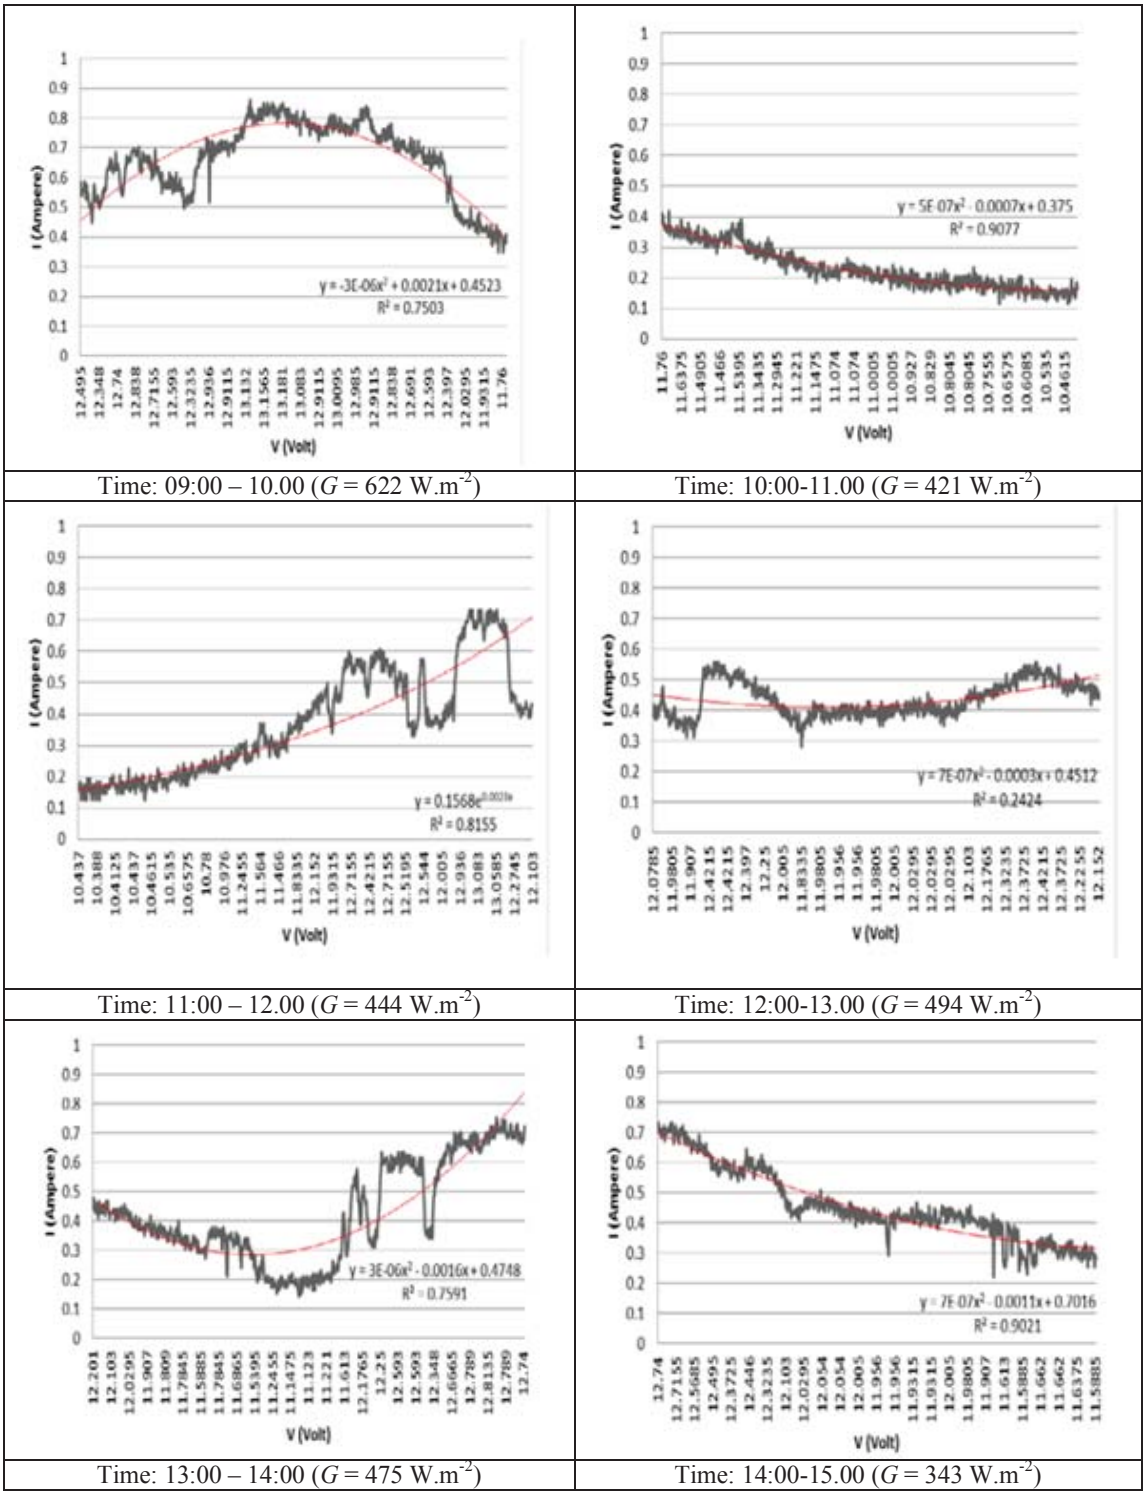
Input parameters, G, T_a and output parameters I, V, P and T_c recorded. All parameters data was taken every 3 minutes, for 8 hours (09:00-17:00), except solar irradiance data. The solar irradiance data was taken manually every hour, because the signal from solar power meter could not be processed by Lab VIEW. Figs 11-13 show the relationship between *I-V-P* data based on the experiments.The average of all data at each hour is summarized in Table 1.



Time: 09:00 – 10.00 (G = 622 W.m^{-2})	Time: 10:00-11.00 (G = 421 W.m^{-2})

3. Conclusions

A progress on characterization of a PV module in tropical climate is reported in this paper. The PV module observed was polycrystalline and the type was ESM (Electrical Solar Module) 50 Wp. In this preliminary experiments, characterization of the PV module was performed in the real Bandung weather condition in one day, for 8 hours. It is found that current, voltage and power of PV module is influenced by the fluctuation of temperature and solar irradiance. Conducting to main purpose, in the future work, characterization of PV modules based on thin film technology will also be performed.

Performance Evaluation and Trial Making of a Compact Solar EV

Toru Fujisawa[1] and Takashi Kawaguchi[1]

[1] Kanagawa Institute of Technology, Atsugi (Japan)

Abstract

In this study, we built a compact solar electric vehicle (EV) converted from a Honda Gyro Canopy, which is a three wheel scooter widely used in Japan for delivery services, and installed bifacial c-Si PV modules on the surface of its delivery box. The power generated from the photovoltaic (PV) modules was controlled using a quad peak power tracker (PPT) system in the solar EV. In this paper, we discuss three types of PPT systems that can maximize the charging power from PV modules to the four valve-regulated lead-acid storage batteries. Moreover, we evaluated the energetic performance of the solar EV running on a Li-ion storage battery of 5 kg. The outdoor experiments clearly showed that four series–parallel PPT systems produce better electrical energy than the other systems. The average energy consumption by the solar EV circling a building on a flat asphalt pavement road was 1.06 kW at an average speed of 15.9 km/h (peak speed was 25.1 km/h).

Keywords: *Solar EV, EV conversion, PV system, bifacial c-Si, multiple peak power tracker.*

1. Introduction

In 2015, the number of Honda Gyro (GYRO) Canopy vehicles manufactured in Japan was over 240,000 (Honda Gyro, 2015). The GYRO is a three-wheel scooter, popular for delivery services in Japan, and has an engine displacement of under 50 cc.

Fig. 1 shows a solar electric vehicle (EV) converted from the GYRO Canopy with bifacial c-Si photovoltaic (PV) modules on its delivery box. The powertrain of the solar EV is a surface-mounted permanent magnet synchronous motor (SPMSM; outer rotor type, with 12 poles, 18 teeth, and 6 coils in parallel with a Y connection, as indicated in Table 1), as shown in Fig. 2. Its reduction gear ratio was 29.86 after the conversion.

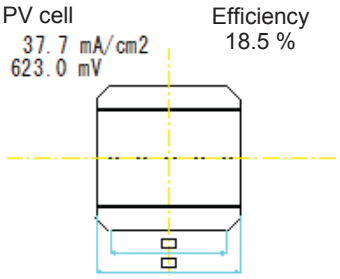
Tab. 1: Specification of the blushless DC motor.

Item	Value
Core diameter	94.7 mm
Core thickness	27.0 mm
Air gap	0.85 mm
Permanent magnet	FB6B (Br = 420 mT)
Slot／Pole	18／12
Turns of 1 slot	25 turns
Wire type	Polyester enamel wire
Wire diameter	1.0 mm
Winding and Connection	3 phase 6 parallel, Y connection

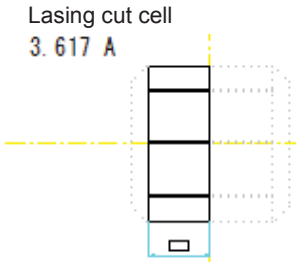
2. PV system

2.1. PV cell and PV module

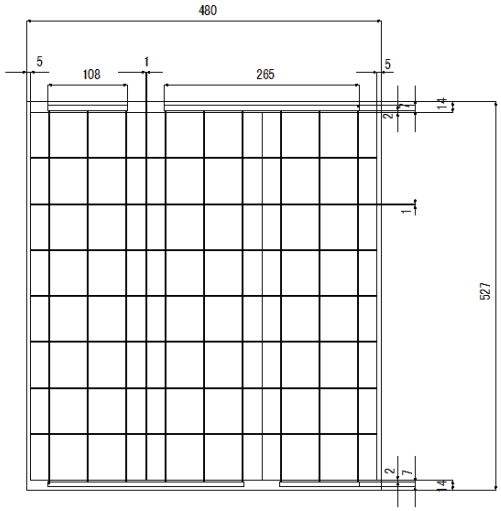
Fig. 3 shows the unit cell of bifacial c-Si PV produced by bSolar (2012) comprising a cut cell, laminated cell layout, and weight of the module. The laminated modules are installed on four surfaces (top, back, left, and right) of the delivery box. Table 2 lists the ratings as typical values of bifacial c-Si PV module under the standard test condition (STC) of 1kW/m^2, A.M.1.5, and 25 °C.



(a) 156 × 156 mm cell



(b) 156 × 61.5 mm cut cell



(c) Laminated PV module made from the cut cell (24 cell types)

(d) Weight of laminated module (approx. 0.5 kg for a 24-cell module)

Fig. 3: Laminated PV module of bifacial c-Si

Tab. 2: Ratings of bifacial c-Si PV module (Typical value for 24 cells)

surface	Voc [V]	Isc [A]	Vmax [V]	Imax [A]	Pmax [W]	FF [-]
Primary	14.50	3.52	11.74	3.31	38.87	0.76
Secondary	14.36	2.82	11.77	2.67	31.41	0.78

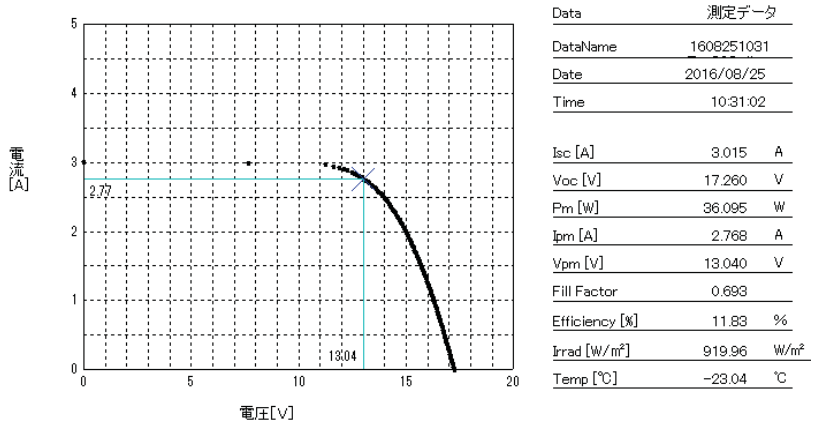


Fig. 4: I–V characteristic curve of the top 32 cells obtained from outdoor experiments (25th AUG, 2016; 10:31)

Fig. 4 illustrates the I–V characteristic curve of the 32-cells PV module on the top surface of the delivery box. A temperature sensor was not connected, and the PV module is second hand. However, a smooth curve and a peak power current of 2.8 A were obtained in outdoor (with reduced irradiance and increased temperature).

2.2. PV system (Peak Power Tracker)

On the delivery box, PV modules on the top surface consist of 32 cells, and the other three vertical surfaces (back, left, and right surfaces) have 24 cells each. We used four boost dc–dc type peak power trackers (PPTs; of one-chip and an efficiency of up to 98%, as developed by STMicroelectronics, 2012) for those PV modules (Fig. 5). A distributed PPT in stationary PV array, evaluation and introduction has discussed by Youhei et al. (2013). Takanori et al. demonstrated a distributed PPT on a racing solar car (2014). To evaluate a multiple PPT system, we tested three connections (Fig. 6). In addition, a series PPT system and series–parallel PPT system were compared through outdoor experiments at the north parking (as shown in Fig. 6). The series–parallel system consists of a pair of parallel PPTs in series with other PPTs; this arrangement is aimed at recovering lower power of the PV module by adding current to the left, right, back, and top of the delivery box.

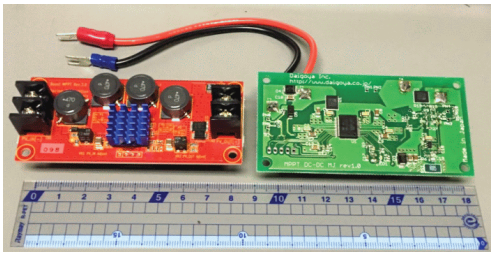

Fig. 5: Boost-type peak power tracker (SPV1020)

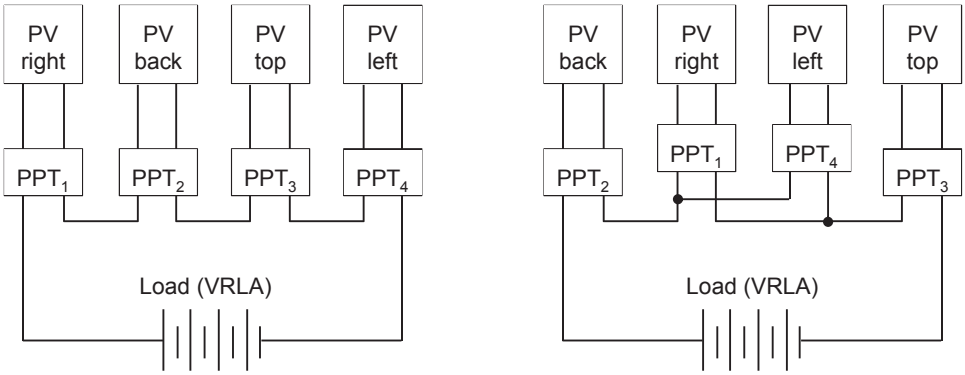
3. Outdoor experiments

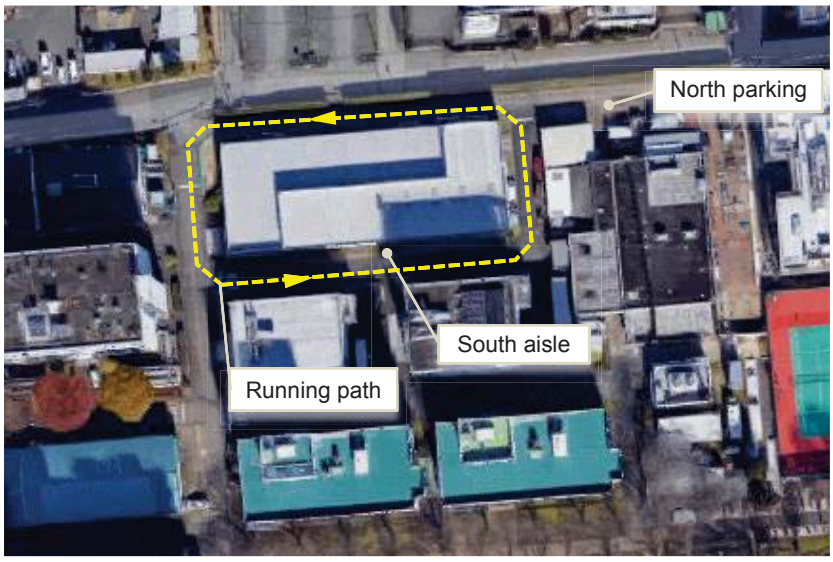
3.1. Trial experiment of PV power generation

Fig. 7 and Table 3 show some results of outdoor experiments of the series and series–parallel PPT systems. For these experiments, the solar EV was tested at the north parking with the PV module of its back side facing the south; the measuring period was 10:30–15:30 (logging data by every 10 s). As indicated in Fig. 7 and Table 3, every output power was kept low in the trial experiments because few protection settings in the PPT circuit board, such as the input voltage, output current, and output voltage, were not suitable. Thus, the PV module's current was limited to less than 0.3 A based on the PPT settings. However, every PPT system can function for

different surfaces and irradiance conditions. In Table 3 and Fig. 7, the measured powers are normalized based on the top surface's PV module.



(a) Series **(b) Series–Parallel (Left//Right)**



(c) Experimental location

Fig. 6: Different connections of the multiple PPT system

Tab. 3: Results of outdoor experiments at the north parking in winter from 10:30 to 15:30. (PPT outputs were limited because of the PV voltage setting)

Averaged values	Series PPT system on 9th DEC	Series–Parallel PPT system	
		Left//Right on 18th DEC	Top//back on 22nd DEC
Horizontal irradiance	377.4 W/m^2	389.9 W/m^2	344.3 W/m^2
PPT input power from the top PV	1.00	1.00	1.00
PPT input power from the left side PV	0.62	0.50	0.81
PPT input power from the right side PV	0.28	0.30	0.65
PPT input power from the back side PV	0.62	0.69	0.37
Output power of the four PV modules	2.61	2.48	2.83

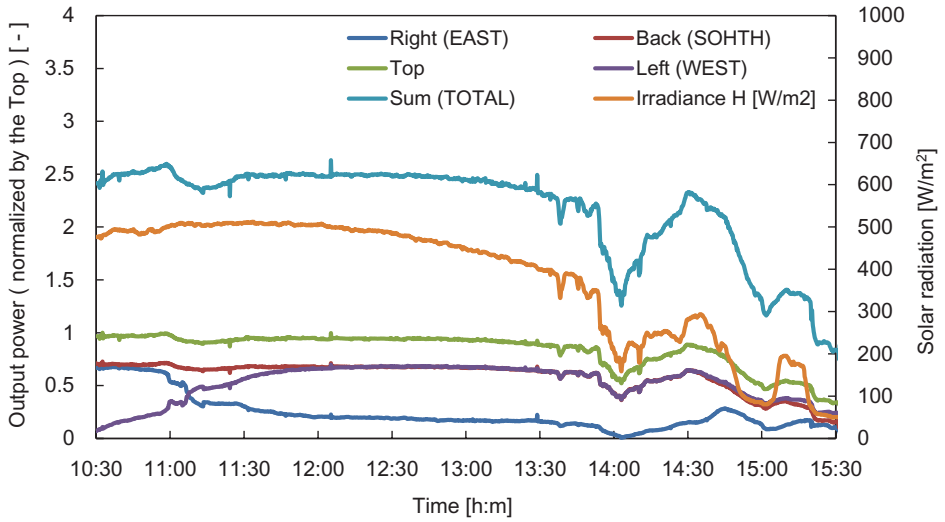


Fig. 7: Output power of PV modules on Dec 9, 2015 (Series PPT system)

3.2. Battery charging data in summer

To fix the setting problem mentioned earlier, actual charging was tested for various connections by means of the summer sunlight at the south aisle (Fig. 6). Four valve-regulated lead-acid (VRLA) batteries of 12 V/27 Ah (5 h) were connected to the PPT output as system load. Fig. 8 shows a series PPT system, in which the east PPT underwent the through-mode from the beginning, the west PPT underwent the through-mode at noon. And after 15:00, when the shadows from surrounding buildings appear on the east and south PV, at around 15:30, the overall output power decreases rapidly because of the presence of the shadows of the surrounding buildings. Fig. 9 shows the result of the series–parallel PPT system. The west and east PPTs were connected in parallel; thus, the output currents for both are confluent with those of the top and south PPT. Except after 15:00, no PPTs underwent the through-mode.

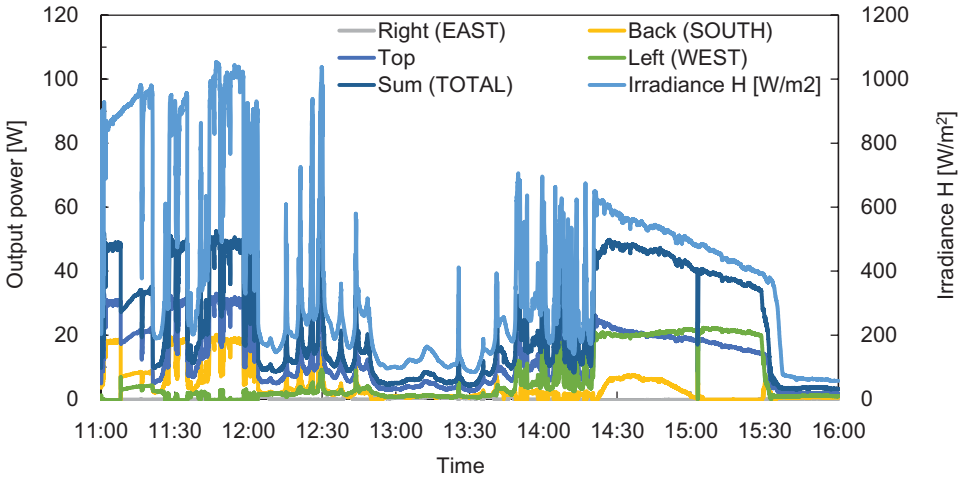

Fig. 8: Output power of PV on Sep 27, 2016 (four series PPTs for four VRLA systems)

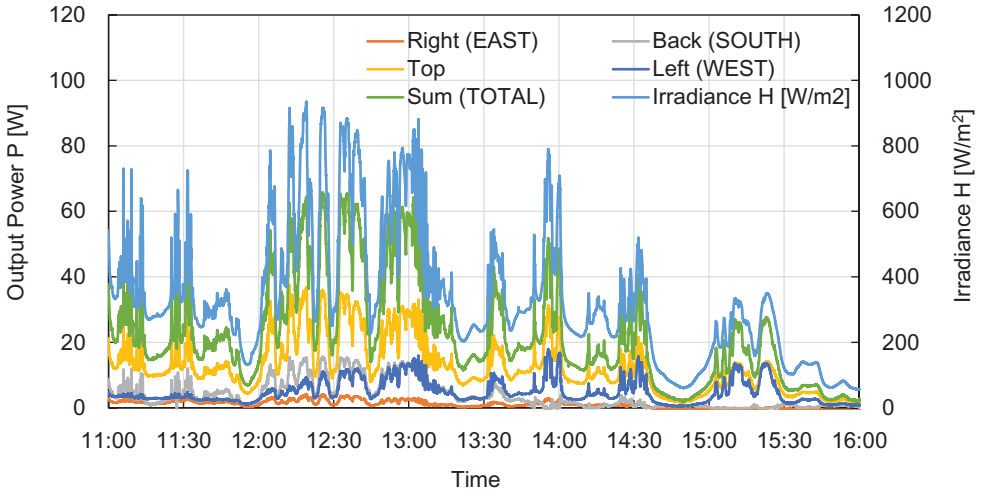

Fig. 9: Output power of PV modules in Sep 26, 2016 (Series–Parallel PPT system)

3.3. Irradiance on vertical surfaces

The output power is proportional to the PV current, which is proportional to the irradiance. Therefore, we must determine how to utilize the irradiance on three vertical surfaces. Different azimuth angles of the vertical surface imply an increase in the peak-time difference. In a calculation, it seems easy to add solar irradiance at different angles; however, in an actual system, it is difficult to collect the generated power through simple summation. This is because a low power implies low voltage output of a PPT in a system, and the load voltage is much higher than that of PV modules.

$$P \propto I_{SC} \quad \text{(eq. 1)}$$

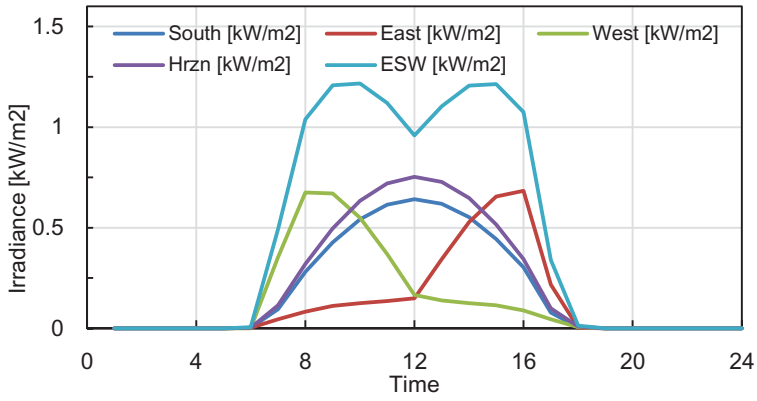
$$I_{SC} \propto Irr \quad \text{(eq. 2)}$$

$$E = \sum Irr \quad \text{(eq. 3)}$$

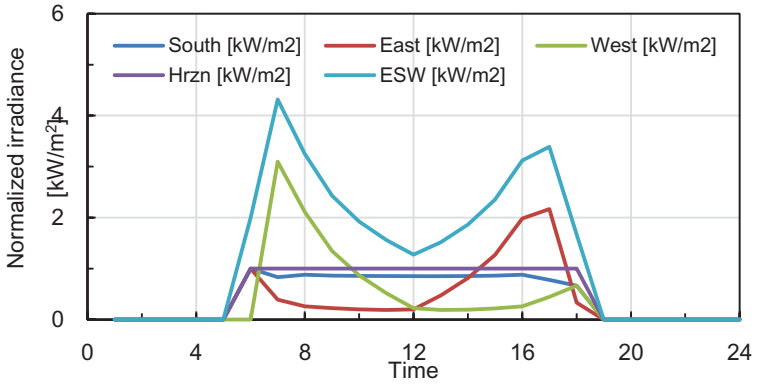
$$k = \frac{E_{Hrzn}}{E_{ESW}} \quad \text{(eq. 4)}$$

where P (W) is the output power of the PV module, I_{SC} (A) is the short-circuit current of the PV module, Irr (W m^{-2}) is the solar irradiance onto the PV module, E (W m^{-2}) is the summation of the irradiance on different angled surfaces, and k is the imbalance ratio between horizontal irradiance and three vertical surfaces.

Fig. 10 shows the hourly output data of solar irradiance from METPV-11 as a standard meteorological data in Japan released by NEDO/JMA (2016). The figure shows the mean data of a clear day near the university (distance is less than 10 km) in Ebina city, with an irradiance from four directions. Yoshio (2016) recently showed energy utilization in four directions in an architectural study. To utilize a vertical surface efficiently, irradiance on the three walls can be added for collecting PV module's current in the East, South, and West (ESW) directions. As indicated in Fig. 10(b), ESW can function accurately with respect to the horizontal surface. Especially, within few hours before or after noon, the imbalance ratio of irradiance between the horizon and ESW surfaces is less than two.



(a) Irradiance



(b) Normalized Irradiance (Imbalance ratio)

Fig. 10: Meteorological data for 25th September in Ebina city (N35°26.0, E139°23.2/METPV)

When imbalance ratio is smaller, other combination circuitries of the multiple PPT system are also possible (Figs. 11 and 12). PV modules on the three vertical surfaces are connected to a single PPT in parallel. Further, for the PV module on the delivery box's top surface, another PPT is connected to the PPT in series or parallel.

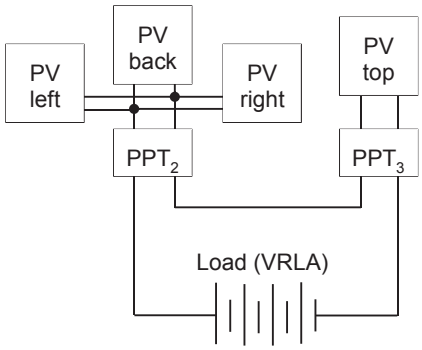


Fig. 11: Series PPT system for collecting individual current (three vertical PV modules are connected in parallel to one PPT, and another PPT is connected at the top surface)

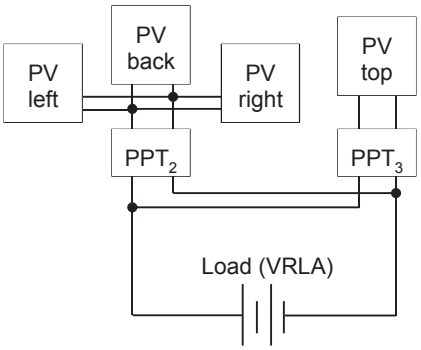

Fig. 12: Parallel PPT system to collect individual current (three vertical PV modules are connected in parallel to one PPT, and another PPT is connected at the top surface)

Fig. 13 shows the charging results of a 2-series PPT system on a fine summer day. In the figure, the load comprises four VRLA batteries in series. As shown, the system does not work well even though enough irradiance was present. The PPT output was less than 0.5 A and the boost voltage was imbalanced; thus, the PV modules were unable to operate at the peak power point. The averaged output power was 25.1 W for 5 h. Fig. 14 shows the charging results of a 2-parallel PPT system on a clear summer day; the load comprises four VRLA batteries: two units in series and two units in parallel. As shown, the output power was unstable from 11:00 to 11:10; however, this fluctuation was due to the opening of the back hatch of the delivery box. From 11:10 to 16:10, the PV system of the solar EV generated 51.1 W on an average. It was found that a 180-min

PV charge produces 150 Wh (= 540 kJ) of electrical energy into the load battery even when the irradiance decreased.

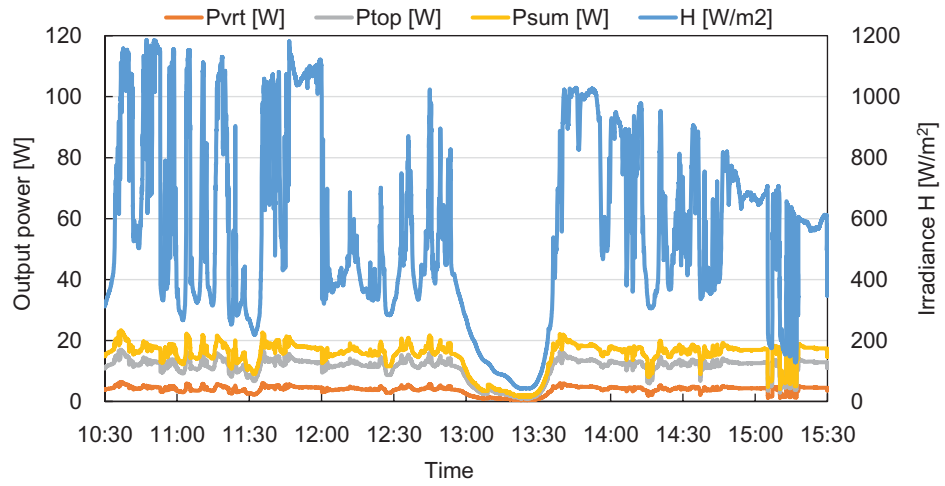

Fig. 13: Output power of PV on Aug 24, 2016 (2 series PPTs for a 4-series VRLA system)

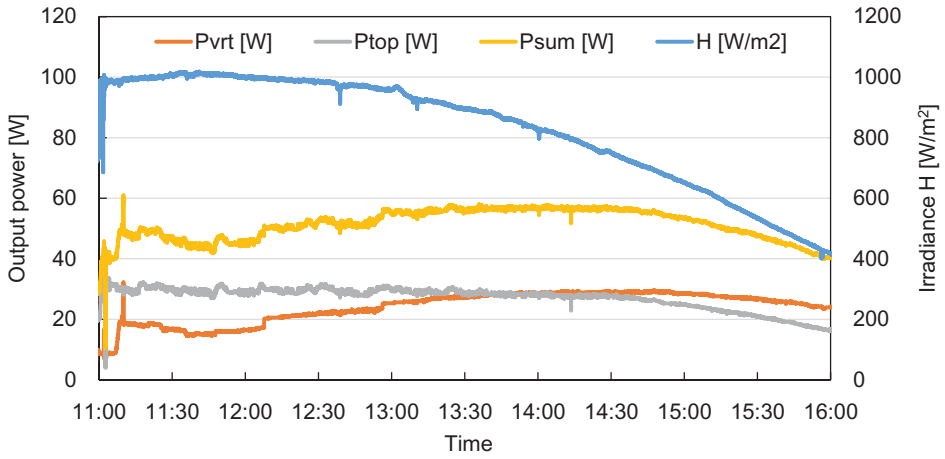

Fig. 14: Output power of PV on Aug 26, 2016 (2 parallel PPTs for a low voltage VRLA system)

Table 4 shows the results of the overall experiments at the south aisle in summer; the parallel PPT system showed a slightly better performance. However, the scattering irradiance affects the vertical surfaces, and more data must be collected to discuss an optimum system.

Tab. 4: Results of outdoor charging experiments of 5 h at the south aisle in summer.

PPT System / Average values	Series on 27th Sep	Series–Parallel (left/right) on 26th Sep	Series (top, vertical) on 24th Aug	Parallel (top/vertical) on 26th Aug
Horizontal irradiance	389.6 W/m^2	332.7 W/m^2	560.1 W/m^2	811.5 W/m^2
Charged Power	23.7 W	22.1 W	25.1 W	51.1 W
P/*H*	6.1%	6.6%	4.5%	6.3%
	(Scattering irradiance effect)			(Low voltage load)

3.4. Running experiment

Power and energy consumptions of the solar EV were measured through an experiment by using a 5 kg Li-ion rechargeable battery. Fig. 15 shows the measurement result of the scooter riding around a building on a flat asphalt road in winter. As indicated in the figure, the top speed reached 25.1 km/h and the peak current was 30 A, approximately. In addition, the average power consumption was 1.09 kW. This result shows that the solar-

energy-charging time would be at least 20 times longer than running time in fine weather.

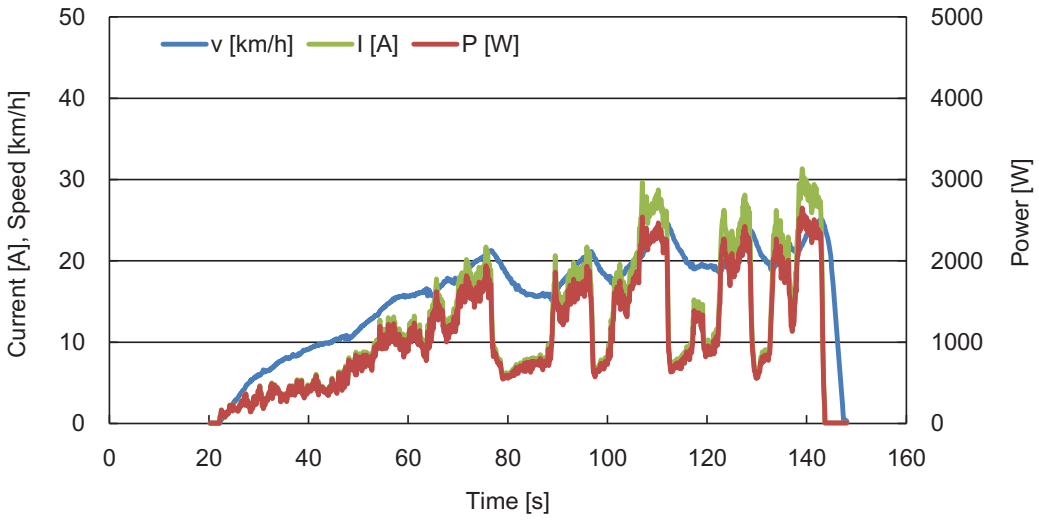

Fig.15: Test data of travelling 0–25 km/h around the building (Feb 18, 2016).

4. Conclusions

In this paper, we discussed about the solar EV converted from the three wheel scooter Honda Gyro Canopy widely used for delivery service in Japan. The limited data of outdoor experiments showed that the series–parallel PPT system produced more energy than the series or parallel PPT systems at the south aisle in summer. There is more room to discuss the optimization of a multiple PPT system. However, we must also consider the system load voltage of the VRLA battery and the effect of scattering irradiance. Experiments were conducted in which the solar EV was driven with the help of a 5 kg Li-ion rechargeable battery around a building on a flat asphalt road. The result showed that the average power consumption was 1.06 kW at an average speed of 15.9 km/h (the peak speed was 25.1 km/h), electric energy consumption ratio was 15 km/kWh.

In photovoltaic and automotive industry, 100 thousand delivery boxes with PV system for the Solar EVs means creating at least 10 MW new PV business market. With amount of 100 thousand Solar EV utilizing solar energy, if the ratio of charging time / running time was 3-4, 15-20 thousand Solar EVs are equivalent to zero energy vehicle (ZEV).

4.1. Remaining Problems

- For the PPT, both optimum connection and protective limit settings must be discussed.
- Optimum PPT control at the running state must be discussed. (Direction of sunlight and shading area will be variable.)
- The installation area of the PV modules, such as the rooftop and front fairing, must be increased.
- The vehicle's weight must be reduced, and the rolling resistance of the tires and air flow drag should be improved.
- The delivery box needs an advertisement area, and strong reflective sunlight due to the PV modules must be avoided for the benefit of other drivers.
- The merits for bifacial PV cells should be investigated.

Design Options for Uncovered Photovoltaic-Thermal Glass-Glass Panels

Federico Giovannetti, Maik Kirchner and Marc Albert

Institut für Solarenergieforschung Hameln (ISFH), Emmerthal (Germany)

Abstract

The use of glass-glass photovoltaic modules in uncovered photovoltaic-thermal (PVT) panels can provide for a longer durability of the solar cells and for higher design flexibility compared to other encapsulating technologies, thus representing an attractive solution for building integration. After giving an overview of available design options and of their impact on the efficiency of the PVT, the paper presents and analyzes the thermal performance of different prototypes by means of measurements in open circuit (OC) mode according to ISO 9806. The customized panels are assembled from commercially available components and intended for the integration into ventilated glass façades. As cell technology, wafer-based crystalline silicon (c-Si) and thin film copper indium diselenide (CIS) are implemented. For the front cover, clear glass with high and low iron content as well as special low emissivity and colored glass with high solar transmittance developed for solar applications are considered. In combination with c-Si solar cells, we additionally compare the use of black enameled rear glass and multilayer black encapsulant as a solution to mask the heat exchanger. The results show the significant impact of the design on the thermal performance of the PVT panels: we report zero-loss efficiency values between 0.61 and 0.78 and heat loss coefficients $b_{1.5m/s}$, evaluated at a wind speed of 1.5 m/s, between 10.2 and 17.8 W/m²K. Concerning both performance and aesthetics, the best results are achieved with CIS photovoltaic modules and low-emissivity front glass panes.

Keywords: *photovoltaic-thermal collectors, hybrid collectors, uncovered collectors, building integration*

1. Introduction

Photovoltaic-thermal (PVT) collectors have been regarded since longer than 40 years as a promising solution to supply both for renewable electricity and heat with a single device. Compared to the common separate installation of solar thermal and photovoltaics, a higher solar yield and lower costs per unit area, a more appealing design as well as an improvement of the electrical efficiency of the solar cells in case of low-temperature applications with uncovered panels can be mentioned as main advantages. Still far away from being an established technology, PVT collectors have been receiving a renewed interest in the last time, not only in research works but also among manufacturers and end users, as a consequence of the recent development of the photovoltaic market and the energy performance requirements set by the new European building regulation.

Similarly to the case of solar thermal and photovoltaics, building integration represents a very efficient way to improve the architectural quality and reduce the cost of the installations, by replacing existing building components and their associated embodied energy with active solar ones. Both aspects represent a key approach for a successful deployment of these renewable energy systems. Most of the available design and integration options (type of cell technologies, glass, encapsulants, coatings, etc.) are known from previous experiences with photovoltaics (Farkas, 2013; Jelle et al., 2013) and their effects have been commonly investigated with regards to the electrical efficiency or to the reliability of the solar cells. Furthermore, developments aiming at improving the design of the modules are often carried out for specific commercial projects and seldom comprehensively documented in the scientific literature (Perret-Aebi et al., 2014).

γ	temperature coefficient of the maximum power	[%/K]
η	thermal efficiency	[-]
η_0	zero-loss thermal efficiency	[-]
η_{el}	electrical efficiency	[%]
ε	thermal emittance	[-]
τ	solar transmittance	[-]

In the framework of a current research project we have been investigating the design and the integration of uncovered liquid-based glass-glass PVT panels into ventilated glass façades (s. Figure 1). The specific façade system consists of vertical aluminum profiles screwed to the main bearing wall and equipped with clip fasteners able to support glass claddings with different thickness, size and geometry and, thus, best suitable also for PV and PVT panels.

The glass-glass encapsulating technology can generally provide for a longer service life of the solar cells thanks to the higher mechanical durability and the improved degradation behavior, thus representing a reliable choice if combined with an additional heat exchanger as for photovoltaic-thermal applications. The wider range of design options makes it furthermore an attractive and flexible solution for building integration. As drawbacks, higher costs and a higher thermal resistance due to additional rear glass have to be taken into considerations if compared to the common use of thin plastic backsheets or to the direct lamination of the PV cells on the heat exchanger, a manufacturing approach already tested in previous research works (Rockendorf et al., 1999; Dupeyrat et al., 2010; Matuska et al. 2015).

Fig. 1: Examples of ventilated glass façades with common glass panels (left, source: Konvortec) and PV panels (center, source: Konvortec) as well as schematic representation of the ventilated façade with glass-glass PVT panels under development (right)

After giving an overview of relevant design options for glass-glass PVT panels and analyzing their correspondent impact on the collector performance, the work presents and discusses selected results of thermal efficiency measurements on different large-sized prototypes, assembled on the basis of commercially available components.

2. Overview of design options

Liquid-based, uncovered glass-glass PVT panels basically result from the combination of a glass-glass PV-module and a heat exchanger, which can be connected to each other by using different mechanical or/and adhesive fixings. This section briefly describes the single components of PVT panels, mainly considering

commercial products and focusing on the influence of possible design configurations on the thermal efficiency of the panels.

2.1. Solar cell technology

Solar cells represent the core of PVT panels and can have a strong impact both on their energy performance and their design. They are basically distinguished in wafer-based silicon and thin film cells; under this last category amorphous silicon (a-Si), cadmium telluride (CdTe), copper indium diselenide (CIS) and copper indium gallium selenide (CIGS) are the most common and commercially relevant ones. Due to the different manufacturing processes implemented, the choice of a specific technology also affects the module assembly itself, i.e. the number and type of components used, as shown in Figure 2.

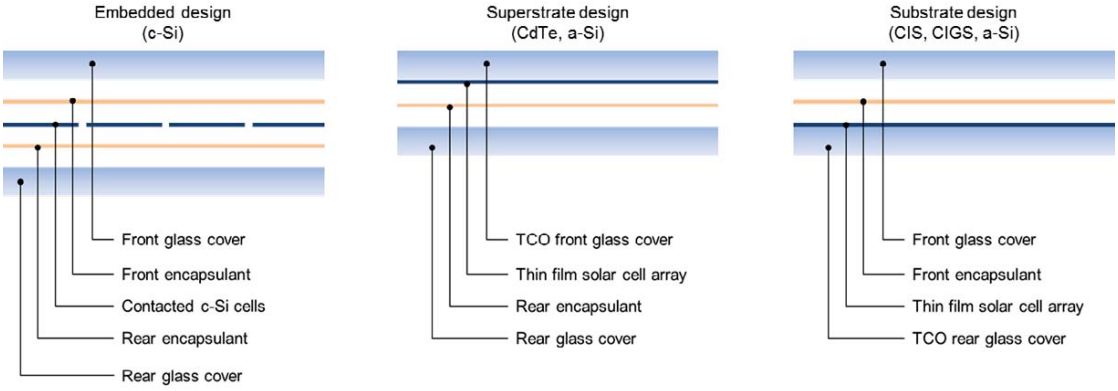

Fig. 2: Design of glass-glass photovoltaic modules for wafer-based (left) and thin film (center, right) solar cells

The photovoltaic performance is commonly characterized by the electrical efficiency η_{el} measured under standard conditions STC (irradiance: 1000 W/m²; spectrum: air mass AM 1.5; module temperature: 25°C). In commercially available PV modules it ranges between 10% (a-Si) and 16% (CdTe or CIGS) for thin films and between 16% (polycrystalline) and 20% (monocrystalline) for wafer-based silicon cells (Fraunhofer ISE, 2015). The electrical efficiency exhibits a significant temperature dependent behavior. The temperature coefficient γ, which describes the relative change of the power output of the module in %/K compared to measurements under standard conditions, roughly varies from - 0.45%/K (c-Si) to - 0.20%/K (CdTe). A lower coefficient is generally considered a negative property for common PV installations, as it can lead to lower energy production under operation. In typical applications with uncovered PVT panels, such as solar assisted heat pump systems, on the contrary, it can even be energetically advantageous, as the solar cells usually operate at temperatures below 25°C.

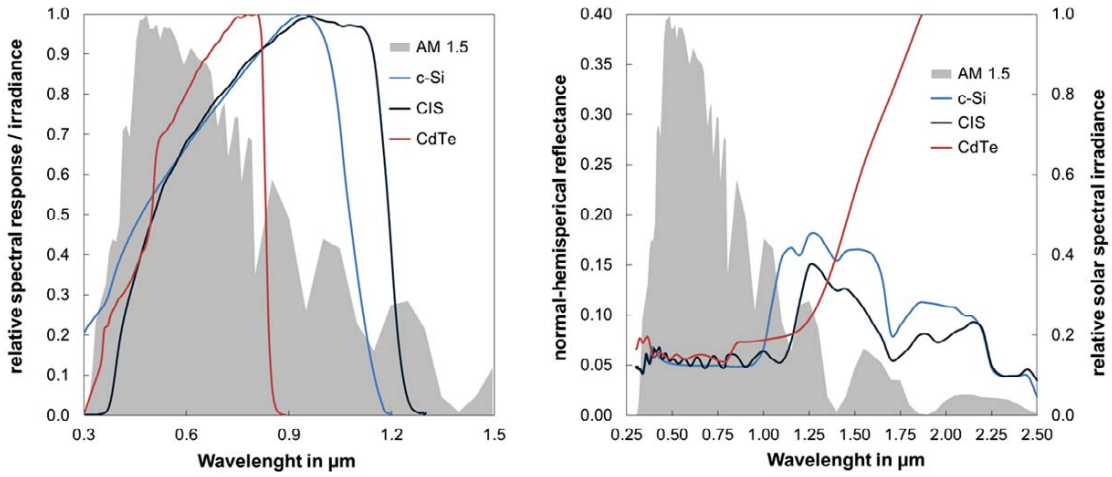

Fig. 3: Relative spectral response (left, data provided by manufacturers) and spectral reflectance (right, ISFH measurements) of PV modules based on different solar cell technologies.

To assess the impact of the PV cell as well as of other module components on the thermal performance of the PVT collector, more detailed data than the electrical efficiency are required: the spectral optical properties over the whole solar wavelength range and the spectral response of the PV module, describing the amount of current coming out of the device per incoming photon of a given energy and wavelength (or alternatively the quantum efficiency). Figure 3 compares exemplarily spectral response and reflectance of three PV modules based on different cell technologies. The modules' data were provided by manufacturers, the optical measurements were carried out at ISFH with a commercial double-beam spectrometer equipped with an integrating sphere.

The graphs show the different wavelength dependent behavior of the technologies especially in the near-infrared range, which has to be considered if combining the cells with spectral selective front covers or encapsulants. The reflectance measurements report otherwise similarly low integral values, ranging between 0.09 and 0.06, thus proving their suitability for the use as solar thermal absorbers.

The choice of a defined cell technology can also significantly influence the color and the final aspect of the module, thus playing an important role for building integration. Wafer-based silicon cells are typically available in dark blue or black and feature a homogenous or non-homogenous appearance, depending on the crystalline structure of the cell itself (mono or poly). The color is determined by the material and by the antireflective coating, which is usually optimized to achieve maximum electrical power under solar irradiation. Many research works have addressed the manufacturing of colored cells with low power losses by tuning the antireflective coating (Selj et. al., 2011; Chen et. al., 2012; Vogt et al., 2015) and several commercial products developed for building integration are already available on the market in different colors (green, red, etc., s. Figure 4). Beside the color, the shape and size of the cell still remain a limiting factor for the module design, affecting both its characteristic patterned appearance and its geometry.

Due to the specific manufacturing process, thin film technology presents a much more homogenous aspect and enables a customized and very flexible dimensioning of the modules, which make them more attractive as components of the building envelope. The cells are generally matt black, blue or brown. Different grades of transparency can be achieved by reducing the cell thickness and/or by removing small areas of the cell with laser treatment, which implies a correspondent efficiency loss. The combination of semitransparent cells with colored rear glass panes or films significantly extends the design options of this technology as shown in Section 2.3.

Fig. 4: Typical appearance of wafer-based c-Si and thin film cells. Left: common monocrystalline c-Si cell; center: colored mono- and polycrystalline c-Si cells (source: Loft Solar Corporation); right: CIGS cell

Reliability of solar cells is finally a complex and crucial aspect to be considered in the development of PVT panels, which is not specifically addressed by the present work. Manufacturers of photovoltaic modules generally guarantee 90% and 80% of the performance (power output) after 10 years and 25 years operation respectively, independently from the cell technology used. The operation in PVT systems can primarily lead to higher mechanical and thermomechanical stress, depending on the heat exchanger and bonding technology chosen. Comparative investigations on long-term reliability of PVT panels are not known to the authors. Degradation mechanisms and behavior of different PV modules are on the contrary well documented in the literature, for example in a recent work by Jordan et al. (2016).

2.2. Front and rear cover glass

The front cover of glass-glass PVT modules should provide for high mechanical stability and low optical

losses. In case of PV modules with superstrate design (s. Figure 2), it also represents the substrate for the deposition of the thin film cell array. Tempered, soda-lime glass panes with a thickness of 3 to 4 mm and low-iron content are generally used both for photovoltaic and solar thermal applications (s. Figure 5). The impact of the iron content (mainly Fe_2O_3) on the PVT module performance depends on the spectral sensitivity of the considered cell technology and on the referred spectral range, as explained in section 2.2. For monocrystalline c-Si modules a power output decrease between 1% (Fe_2O_3 = 0.1 ‰) and 10% (Fe_2O_3= 1‰) compared to an ideal iron-free glass is reported for commercially available 3.2 mm samples in a recent work (Vogt et al, 2015). The thermal efficiency of uncovered PVT is less influenced by the iron content of the glass, as part of the solar radiation absorbed in the glass bulk is transferred by thermal conduction to the fluid and contributes as secondary heat gain to an increase of the conversion factor η_0.

To further reduce the optical losses of solar modules antireflective coatings are commonly deposited on the external surface of the front cover of premium products. In most cases porous SiO_2 layer stacks are used, which can improve the efficiency of photovoltaic and thermal collectors by about 0.02 for each side.

Aiming at improving the thermal performance of PVT collectors, the use of low emissivity, high transmittance coatings to reduce the radiative heat losses represents an additional option. This approach has been already investigated in previous works for different kind of flat plate collectors (Giovannetti et al., 2014) as well as for covered PVT (Lemmle et al. 2016). To minimize the optical losses and ensure long-time reliability in uncovered collectors coatings based on metal oxides (e.g. indium, tin or zinc) are suggested. The impact of the low-e coating for low-temperature applications is strongly dependent on the specific heating system design and on the operation mode: if the collector is working as heat exchanger below ambient temperature, the use of the coating can even lead to a lower performance if compared with non-selective panels.

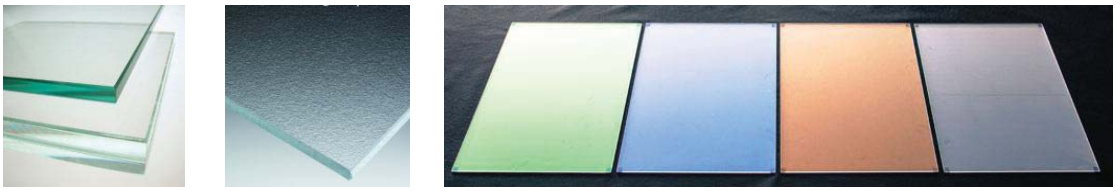

Fig. 5: Examples of front glass for solar applications. Left: clear glass with different iron content (source: Euroglas); center: textured clear glass (source: Interfloat Corporation); right: colored glass with high solar transmittance (source: Swissinso)

For architectural purpose, the use of colored or patterned glass is of high interest: most of the available products exhibit a considerably lower transmittance compared to common covers (in best case about -10%). Special spectrally selective coatings for solar glazing with improved optical properties were developed at the École polytechnique fédérale de Lausanne (EPFL) and are now manufactured by the Swiss company Swissinso (Schüler et al., 2005; Swissinso, 2016). These interference thin films can reflect a very small selected portion of the visible spectrum while letting the rest of the energy pass through. The glass panes are supplied in several colors, which according to manufacturers' data reduce the performance of thermal collectors by approximately 1% (grey) to 4% (yellow) and of photovoltaics by 2% to 6% (Swissinso, 2016). An additional light diffusing layer, achieved by etching the outside surface of the glass makes it possible to completely hide the absorber and obtain stable quality colors (s. Figure 5). Independently from the coloration, textured glasses and acid etching treatments are since long in use for solar applications with the aim of partially masking the solar absorber or the solar cells and improve the module appearance.

Rear cover glass is used similarly to front glass to ensure the durability of the glass-glass PV-modules and represents in case of PV modules with substrate design (CIS, CIGS or a-Si) the substrate for the cell deposition. The optical properties as well as the aesthetics play a role only in combination with wafer-based silicon or with semitransparent thin film cells. Colors or patterns can in these cases be used to hide the heat exchanger and better match the façade design, while affecting the solar absorptance of the glass and, thus, the thermal performance of the PVT panels.

2.3. Encapsulants

Encapsulants are primarily used in glass-glass PV modules to embed the solar cells between the glass panes and protect them from environmental stress. To provide for high performance and long-term durability several requirements have to be fulfilled, such as optical transparency, mechanical adhesion, electrical isolation, resistance to UV radiation, temperature and moisture penetration. For aesthetical purposes, colored or patterned encapsulants are also available on the market. These products are mainly combined with wafer-based silicon or semitransparent thin film cells in building integrated photovoltaics (Perret-Aebi et al., 2014) as shown in Figure 6 and can be similarly implemented in PVT panels to hide the heat exchanger. As for the glass panes, different colors result from different optical properties and can thus affect the energy efficiency of the panel.

Concerning the typical materials, ethylene vinyl acetate (EVA) represents today the most common choice for photovoltaics, thanks to its high transmittance, good durability but especially low cost. EVA films are transparent, white or black and supplied in different thickness. Silicon-, polyefine- or ionomer-based films offer alternative solutions for EVA products and exhibit even better optical performance and weatherability. Due to their higher costs, they haven't been able to gain a significant market share so far. The use of colored silicon films for solar energy applications is documented in recent research activities (Vogt et al., 2015). Finally polyvinylbutyral (PVB), commonly known as interlayer in laminated safety glass is also implemented as encapsulant material. These films are manufactured in many different colors, thus representing an attractive option for architectural applications. Furthermore, according to the current European building regulation PVB is the only material that can be integrated into façades without a special construction permit, which explains its prevalent use in building integrated photovoltaics. As relevant drawbacks, it exhibits inferior performance and durability if compared to the previously mentioned products.

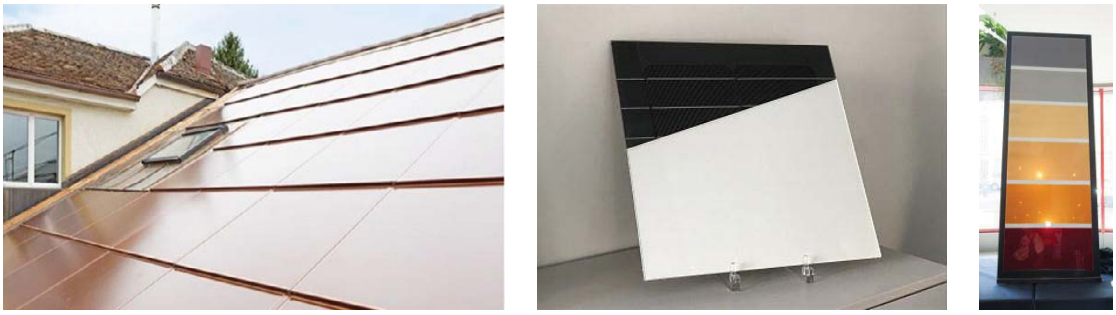

Fig. 6: Colored solutions developed for building integrated photovoltaics: Left: thin film PV with rear encapsulant as roof tile (source: NexPower). Center/right: Samples of modules with white and colored multilayer front encapsulants (source: Solaxxes)

Additionally to these standard encapsulants, special multilayer solutions embedding interference filters for tuning the color of the modules have been recently introduced to the PV market, on the basis of the research work carried out at the EPFL and at the Centre Suisse d'Electronique et Microtechnique (Perret-Aebi et al., 2015): deposited on microstructured films, these filters can selectively scatter visible light while transmitting infrared radiation, thus enabling the manufacture of perfectly homogenous colored and even white modules (Figure 6). Combined with heterojunction c-Si cells, which are particularly sensitive in the IR range, electrical power losses by about 40% were measured for white samples. For PVT applications also a significant decrease in thermal efficiency is expected.

2.4. Heat exchanger

Aim of the heat exchanger in PVT panels is to efficiently transfer the solar energy absorbed in the PV module to the fluid. For the challenging design two main aspects have to be taken into consideration: the low thermal conductivity of glass (λ = 0.8÷1.0 W/m*K), which requires a large contact area between the heat exchanger and the rear pane of the PV module in order to provide for a reasonable internal heat transfer coefficient; the combination of components consisting of different materials, which on the other side calls for an appropriate solution able to avoid critical thermo-mechanical stress under typical operation, and over the service life of the panels. One approach is to use materials for the heat exchanger exhibiting mechanical properties similar to those of glass as well as a suitable geometrical configuration. A second approach is to

fix the heat exchanger to the PV module in a way that can tolerate and/or compensate the different thermo-mechanical behavior of the components. Commercially available products adopt for the heat exchanger materials (copper, aluminum, steel and plastics) and assemblies (sheet-and-tube, roll-bond, etc.) common in solar thermal collectors as well as customized designs (s. Figure 7). For the fixing, mechanical or adhesive solutions are used (Brotje et al., 2016).

Fig. 7: Examples of heat exchangers used in commercially available uncovered PVT-panels (sources from left to right: Fototherm, AnafSolar, DualSun, Poly Solar Solutions, CGA Technologies)

3. Experimental investigations

Our investigations focused on the thermal performance of different photovoltaic-thermal glass-glass modules. This section presents the selected assemblies as well as the details of the efficiency measurements.

3.1. PVT-panel design

The prototype panels were manufactured on the basis of commercially available components. Figure 8 gives an overview of the design selected for our investigations. Additional technical data are reported in Table 1.

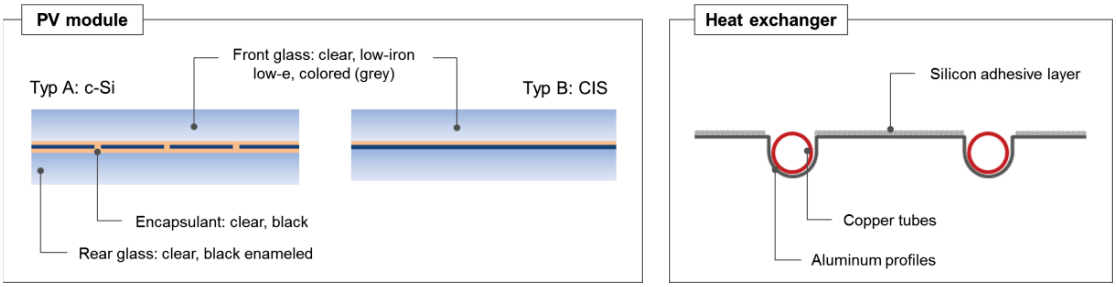

Fig. 8: Design of the investigated PVT panels

As solar cell technologies wafer-based crystalline silicon and thin film CIS were implemented. For the heat exchanger we chose a composite construction consisting of copper tubes with a serpentine geometry and aluminum omega-profiles, which enclose the tubes and are glued to the rear glass cover with a temperature resistant, two-component silicon adhesive layer (thickness about 0.8 mm; thermal conductivity λ = 0.3 W/m·K). This heat exchanger is produced by the German company Schmoele for heating and cooling panels as well as for solar absorbers of flat plate collectors. It enables an efficient and uniform heat transfer from the glass pane to the fluid and can compensate the thermo-mechanical stress originated by the different thermal expansion coefficients of glass ($\alpha = 9 \cdot 10^{-6}$ K^{-1}) and aluminum ($\alpha = 23 \cdot 10^{-6}$ K^{-1}) or copper ($\alpha = 17 \cdot 10^{-6}$ K^{-1}) more effectively than other common solutions. The long-term durability of the fixing over the expected operating temperature range has been successfully proved at ISFH both by accelerated weathering laboratory tests on small samples (Seitz M., 2015) and by outdoor exposition tests on large-sized prototypes.

Tab. 1: Selected technical data of the investigated PVT panels

Module type	Area [m²]	Nominal power [W]	Packaging factor [-]	Coeff. γ [%/K]	Area HTX / Area glass	Distance tubes [mm]
c-Si	1.26	171 ÷ 175	0.71	-0.45	0.86	0.95

CIS	0.84	91 ÷ 94	-	-0.39	0.81	0.85

To analyze the impact of the front cover glass on the thermal performance of the PVT-panels four different panes were taken into consideration. Beside common clear glass typically used in architecture and glass with low iron content, two functional glasses with high solar transmittance specially developed for solar applications and already mentioned in Section 3 were selected: a colored (grey) glass intended for building integration and a low emissivity glass for improved thermal performance. Both coatings are deposited on a substrate with low iron content. The correspondent optical properties calculated according to ISO 9050 (solar spectral range) and EN 12898 (infrared spectral range) are reported in Table 2. The data of the clear and the grey glass were supplied by the manufacturers, the low iron and low-e glass were measured at ISFH by using the equipment already mentioned in Section 2.1 and a commercial Fourier transform infrared spectrometer.

Tab. 2: Relevant optical properties of the investigated front glass covers

Cover type	Solar transmittance τ	Solar absorptance α	Thermal emittance ε
Clear glass	0.85 ± 0.01	0.07 ± 0.01	0.84 ± 0.02
Low-iron glass	0.90 ± 0.01	0.02 ± 0.01	0.84 ± 0.02
Grey glass	0.88 ± 0.01	-	0.84 ± 0.02
Low-e glass	0.86 ± 0.01	0.07 ± 0.01	0.30 ± 0.02

For the PVT-modules with crystalline silicon cells, we further investigate two alternative solutions for the standard combination clear glass + clear encapsulant, with the purpose to effectively mask the portion of the heat exchanger visible through the cell interspaces, thus providing for a more homogeneous appearance, and to increase the solar absorptance of the panel. In the first case we use an opaque black enameled glass (color RAL 9005), with the enamel layer facing the heat exchanger. In the second case, the PV module was laminated with a multilayer encapsulant consisting of a black fluoropolymer backsheet embedded between two transparent EVA films. Spectrometric measurements on the two modules report very similar results, which exclude a possible different optical impact of the films on the thermal efficiency of the PVT panels.

3.3 Performance measurements

The performance of the PVT panels was investigated by means of indoor and outdoor measurements according to ISO 9806, both in open circuit (OC) and with the PV modules operating in maximum power point (MPP). As the panels are intended for the integration into ventilated glass façades, additional measurements were carried out by closing the air cavity (40 mm) between the rear side of the test specimen and the mounting plate, which is otherwise open to allow free air circulation. The paper presents and discusses the results in OC mode, thus focusing on the impact of the design on the thermal efficiency of the panels.

For the eight prototypes, we report zero-loss efficiency values η_0 between 0.61 and 0.78 (0.58 and 0.76 if referred to the hemispherical irradiance G and not to the net irradiance G", as displayed in Figure 9 and 10) as well as heat loss coefficients $b_{1.5m/s}$ (heat loss coefficients evaluated at a wind velocity w = 1.5 m/s) between 10.2 and 17.8 W/m²K. The correspondently calculated stagnation temperature (G = 1000 W/m²; ambient temperature = 30 °C; no wind) ranges between 84 °C and 126 °C. Compared to the performance of commercially available products (Brötje et al., 2016) or to previous research works, the results attest the potential of this reliable PVT assembly, in spite of the additional thermal resistance due to the rear glass pane and show at the same time the strong impact of the considered design options. Further performance improvements are technically feasible by optimizing the thickness of the silicon-based adhesive layer or by more efficiently coupling the heat exchanger to the PV module (larger contacted area of the aluminum profiles, smaller distance of the copper tubes). For a comprehensive assessment, also economic and long-term reliability aspects are to be taken into consideration. The influence of the single design options is displayed in Figure 9 and 10 and can be summed up as follows:

- Low-emissivity coating (Figure 9, left): in comparison to an identically assembled module equipped with common low-iron glass, the use of a low-emissivity front cover improves the heat loss coefficient $b_{1.5m/s}$ of the panel by 2.0 W/m²K. Thanks to the high solar transmittance of the coated pane and the better thermal insulation, also the conversion factor η_0 is positively affected by the replacement of the cover. With refer to the specific boundary conditions (sky temperature T_{sky}) improvements up to 0.04 (0.07 if referred to the hemispherical solar irradiance G and not to the net irradiance G) are reported.

- Colored cover (Figure 9, right): the influence of grey glass was investigated on PVT modules both with c-Si and CIS solar cells. The performance results remain slightly below our expectations: In combination with c-Si cells, for example, we measured a lower η_0 than that of the module equipped with clear glass ($\Delta\eta_0$ = - 0.01), despite the higher solar transmittance declared by the manufacturer ($\Delta\tau$ = 0.03). This special combination of interference coating and light-scattering finishing proves to be an effective solution to modify the appearance of thin film modules and adapt them to the specific building design. In case of wafer-based silicon modules, on the contrary, the masking effect is not as satisfactory and the solar cells are still clearly visible under the cover. The aesthetical results are of course restricted to the selected glass and not transferable to other colors.

- Rear cover glass (Figure 10, left): non-transparent rear glass or encapsulants were used in combination with c-Si solar cells to mask the metallic heat exchanger and to enhance the solar absorptance of the PV module. The best performance was achieved by the panel equipped with a black enameled pane. Due to the higher thermal resistance between the heat sources (solar cell and black absorbing layer) and the fluid, the use of a fluoropolymer backsheet embedded between two EVA films leads to a decrease of the conversion factor by 0.04. The significant difference results not only from the position of the absorbing layer and the number of the sheets, but also from the low packaging factor of the PV module (71.4%). By using a single black EVA film as rear encapsulant and increasing the packaging factor lower deviations are expected. As further advantage of enameled glass the easier and more reliable processing has to be mentioned, which doesn't differ from the standard lamination procedure.

- Rear ventilation of the panels (Figure 10, right): Convective heat losses at the rear side of the PVT modules confirm to have a significant impact on their thermal performance. By closing the air gap and suppressing the ventilation between the modules and the mounting panel, we report a well reproducible reduction of the heat loss coefficient $b_{1.5m/s}$ between 5.6 W/m²K and 5.7 W/m²K, which corresponds to an increase of the stagnation temperature by about 15 K.

- Cell technology: due to the different size of the c-Si and CIS PV modules and the correspondently different configuration and tube distance adopted for the heat exchanger (s. Table 1), the results are not directly comparable. Assuming identical size and configuration, similar zero-loss efficiencies are expected and the discrepancy will depend more on the solution used to mask the heat exchanger in the c-Si module and on the packaging factor than on the photovoltaic technology itself. The choice of the solar cells has a much more significant impact on the aesthetics than on the performance of the panels.

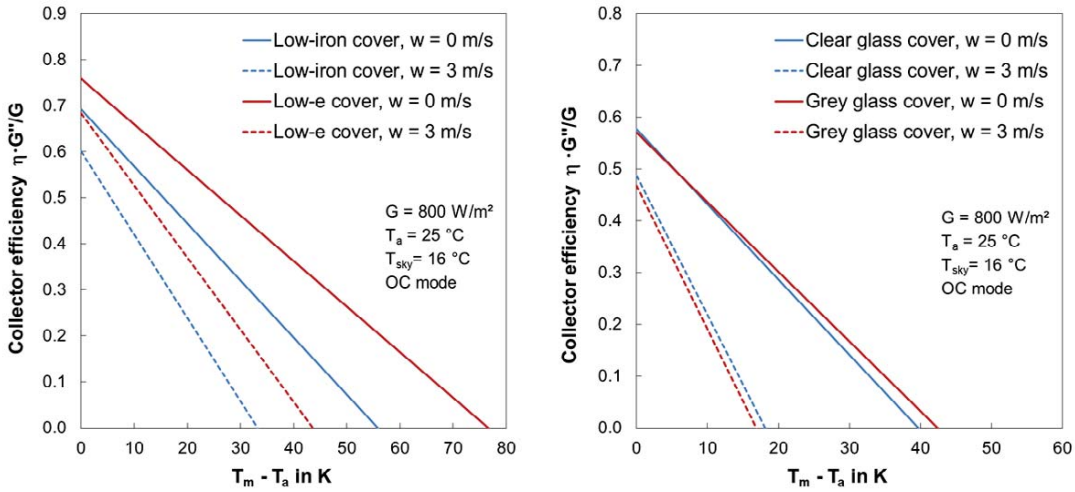

Fig. 9: Measured thermal efficiency of the investigated PVT panels. Left: comparison between prototypes with CIS PV modules featuring a low-iron and a low emissivity front glass cover (closed rear air cavity). Right: comparison

between prototypes with c-Si modules featuring a clear and a grey front glass cover (open rear air cavity). The results are displayed with refer to the hemispherical solar irradiance G and not to the net irradiance G".

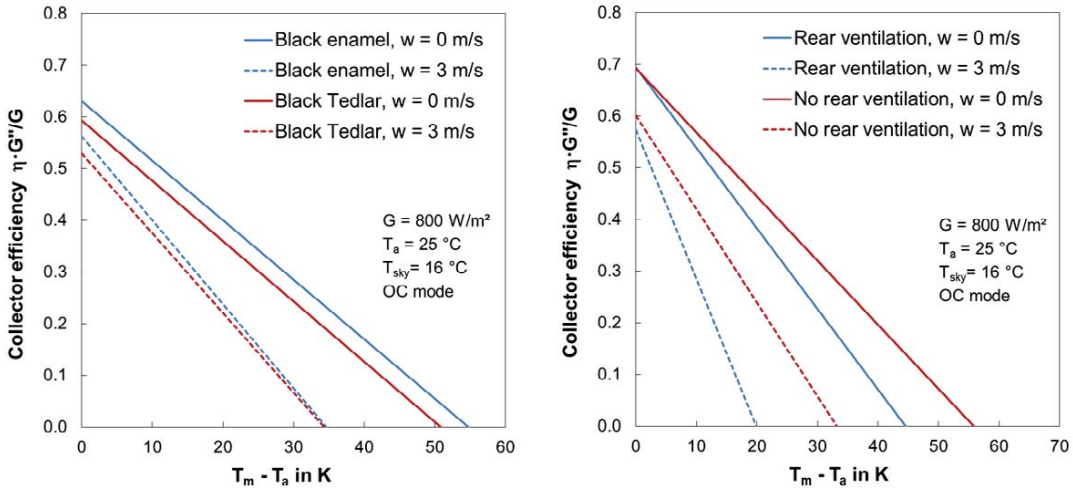

Fig. 10: Measured thermal efficiency of the investigated PVT panels. Left: comparison between prototypes with c-Si PV modules using a black enameled rear glass and a multilayer encapsulant embedding a black sheet to mask the heat exchanger (closed rear air cavity). Right: comparison between measurements on a prototype with a CIS PV module with and without ventilation of the rear air cavity. The results are displayed with refer to the hemispherical solar irradiance G and not to the net irradiance G".

4. Conclusion

Uncovered glass-glass PVT-modules offer a high design freedom by combining different types of solar cell technologies, front and rear cover glass as well as encapsulating sheets. We investigate the performance of 8 different modules by means of thermal efficiency measurements in open circuit mode. The results show the strong impact of the design options as well as the potential of this PVT assembly. We report conversion factors η_0 between 0.61 and 0.78 as well as heat loss coefficients $b_{1.5m/s}$ between 10.2 and 17.8 W/m²K. Considering both performance and aesthetics, the best results are achieved by combining a high transmittance low-emissivity front cover with a CIS thin film photovoltaic module.

5. Acknowledgments

The project underlying this publication is funded by the German Federal Ministry for Economic Affairs and Energy, on the basis of a decision of the German Federal Parliament ("Solar Glas - Development of a cost efficient solar activated glass façade for heat and electricity production", reference number: 16KN014827). The investigations are carried out in cooperation with the companies Konvortec GmbH and Energy Glas GmbH. The PV-modules were manufactured and supplied by the company Antec-Solar GmbH. The authors are grateful for the support and responsible for the content of the paper.

Profitability of Solar Photovoltaic Rooftop Systems in Buildings with Medium Sized Loads

Maria Haegermark[1], Peter Kovacs[2] and Jan-Olof Dalenbäck[1]

[1] Chalmers University of Technology, Gothenburg (Sweden)

[2] SP Technical Research Institute of Sweden, Borås (Sweden)

Abstract

In Sweden, it is generally most feasible to install solar photovoltaics (PV) primarily for self-consumption, as long as there either is a large enough load when the sun shines or that over-generation is generously compensated. Currently there are two support schemes for PV: a capital subsidy and a tax rebate for grid feed-ins. However, the latter is not available for systems above 100A, thus making self-consumption highly important for these systems. This paper studies the profitability of systems connected to loads from 100 to 700 MWh, most of them above 100A. In particular, it compares multi-family buildings to other building types. Analyses were based on measured electricity use matched to simulated PV yield and current market conditions. Calculations were conducted with and without consideration of existing roofs. In general, the supply points in multi-family buildings had less favorable load profiles than the ones in other buildings, which resulted in lower self-sufficiencies as well as relatively lower profitability and smaller system sizes. The support schemes turned out to be crucial for the profitability in most cases, but not all. For supply points in other building types with loads above 300 MWh profitable systems were found also without a subsidy. Taking areas and orientations of existing roofs into consideration drastically decreased the share of profitable systems.

Keywords: *solar photovoltaics, buildings, profitability, support schemes, Sweden, self-consumption*

1. Introduction

Sweden has a small but growing solar photovoltaic (PV) market with a majority of installations made on buildings (Lindahl, 2015). As in the rest of the world, system prices has decreased drastically the last few years, but due to low electricity prices, PV system investments are generally still in need of financial support to reach profitability. Sweden has an REC (Renewable Energy Certificates) system in place since 2003 and since 2009 there is also a direct capital subsidy program available for all PV installations connected to the grid. After a few years of discussions about a support scheme based on net billing, a tax rebate system for renewable electricity generated in small plants was introduced in 2015. A tax rebate of 0.60 SEK is achieved per kilowatt-hour electricity fed into the grid up to an equivalent amount that is bought from the grid during one calendar year. The tax rebate is only available for systems with a main fuse size of maximum 100A. After years of falling prices and with the new support scheme in place, the relevance of the investment subsidy has been questioned and there are ongoing discussions about the appropriate subsidy level for the near future.

The effects of current market conditions and support schemes were previously examined by the authors of this paper in an economic feasibility study of solar PV systems in Swedish multi-family buildings. Economic analyses were then conducted for 108 electricity supply points with loads ranging from 0 to 370 MWh and fuse sizes from 16 to 250A. The study has been presented in the article "Economic feasibility of solar photovoltaic rooftop systems in a complex setting: A Swedish case study" submitted to Energy earlier this year. Today, it is generally most feasible to install solar PV primarily for the purpose of self-consumption, as long as there either is a large enough load during hours with high insolation (in Sweden mainly daytime April – September) or over-generation of PV electricity is generously compensated. However, it was shown that the

doi:10.18086/eurosun.2016.08.10 Available at http://proceedings.ises.org

profitability of a PV system is highly affected by both building specific parameters and load characteristics.

In this paper, the profitability analysis was expanded to comprise also other types of buildings and it focuses on electricity supply points with medium sized loads (100 – 700 MWh). Most of the studied supply points have main fuses above 100A, and are therefore not entitled to the tax rebate described above. The paper examines the importance of an investment subsidy under different circumstances and aims to show how the profitability as well as self-sufficiency of a PV system is affected by the size of the load and load profile. In particular, the results of multi-family buildings are compared to the results of other buildings. Moreover, the influence and potential limitations of existing roofs were studied.

2. Method

Economic analyses were conducted for 35 PV systems based on measured electricity use matched to simulated PV electricity generation. For each of the electricity loads a PV system was sized according to highest system profitability. First, the analyses were carried out for optimally oriented systems (oriented to give a high annual yield) and thereafter consideration was taken to the slopes and orientations of existing roofs.

The method used in this paper has previously been used and described in the article "Economic feasibility of solar photovoltaic rooftop systems in a complex setting: A Swedish case study" (Haegermark, Kovacs and Dalenbäck), which was submitted to Energy 2016. Therefore, a condensed version of the methodology description is given below along with input data used in this study.

This study comprises 22 electricity supply points in multi-family buildings and 13 supply points in buildings with other types of activities (e.g. office, museum and warehouse). It was limited to supply points with yearly electricity loads between 100 and 1000 MWh and the main fuse sizes range from 80A to 750A. Some of the supply points only include electricity for facility management, while others include all electricity use within the building (e.g. electricity for facility management and household electricity).

The buildings are all situated in Gothenburg, Sweden (57° 42' N, 11° 58' E). Measured data of electricity use were collected from a database owned by the local grid company (Göteborg Energi Nät AB) with the consent of the property owners. Hourly data from 2014 were used in all cases but one. For the last supply point, data from 2013 were used.

The electricity use in each of the electricity supply points was matched to simulated electricity generation from a fictive PV system on an hourly basis. Solar electricity generation was achieved from simulations in Polysun with a poly-crystalline PV system and local climate data. A summary of the input parameters used for the simulations are shown in Table 1.

Table 1 Summary of input parameters for simulations in Polysun

Input parameter	Value	Unit
Weather data	Gothenburg	n/a
Module	Yingli YL205P	n/a
Module type	Polycrystalline	n/a
Module nominal peak power	250	W
Efficiency at STC (standard test conditions)	15.3	%
Module area	1.633m^2 (1.65m*0.99m)	m^2
Soiling losses	2	%
Cable losses	2	%
Module mismatch	1	%
Inverter	Sunny Tripower STP 25000TL-30	n/a
Inverter efficiency	93.5	%
Performance ratio	88	%
Degradation	0	%
Module orientation (base case)	0 (south)	°
Module tilt (base case)	45	°

The PV system sizes were decided according to highest system profitability. For this, net present value (NPV) (eq. 1) was used as the decisive financial metric. The NPV approach is considered appropriate when choosing between mutually exclusive investments (Berk and DeMarzo, 2014). It includes all future cash flows, considers time value of money and recognizes the size of the project.

$$\mathrm{NPV} = \mathrm{PV(benefits)} - \mathrm{PV(costs)} = \mathrm{PV(all\ project\ cash\ flows)} = \sum_{n=0}^{N}(C_n/(1+r)^n) \quad \text{(eq. 1)}$$

C= cash flow (positive or negative)
n= year of cash flow
N= total number of years of cash flows
r= discount rate

Table 2: Summary of input parameters for economic calculations. The table presents all cash flows excluding VAT.

	Input parameter	Value	Source
PV system parameters	Lifespan of PV system	30 years	
	Salvage value	0 SEK	
	Degradation of PV modules	0.5%/year	Jordan and Kurtz, 2013
General	Real discount rate	4%	
	VAT	25%	
Investment costs	PV system incl. BoS and installation (year 0)	$I_0 = 11000 + 3200 \times P^{(-0,0033 \times P)}$ (where P=peak power)	Assumptions based on Lindahl, 2015
	Meter for green certificates (year 0)	4800 SEK	
	Inverter replacement incl. installation (year 15)	15% of investment	
Annual costs	Operation and maintenance costs	0.75% of investment	Keating et al., 2015
	Grid metering fee	1500 SEK	Göteborg Energi, 2015a
	Metering fee for green certificates	Sold certificates up to 1000 SEK: 0.2 x income Sold certificates above 1000 SEK: 0.1 x income	Egen el, 2015
Value of self-consumed electricity	Green certificate trading (first 15 years)	0.20 SEK/kWh for 15 years	Energimyndigheten, 2015
	Avoided spot price	0.29 SEK/kWh (Nord Pool Spot price for SE3 2014) first year and increasing with 2.4% per year	Nord Pool Spot, 2015. Spot price assumed based on Lindahl, 2015
	Avoided grid fee	0.07 SEK/kWh	Göteborg Energi, 2015b
	Avoided energy tax	0.29 SEK/kWh	Lindahl, 2015
	Avoided green certificate fee (excl. VAT)	0.03 SEK/kWh	
	Avoided trading surcharge (excl. VAT)	0.05 SEK/kWh	
Value of sold electricity	Green certificate trading (first 15 years)	0.20 SEK/kWh for 15 years	Energimyndigheten, 2015
	Selling price	0.29 SEK/kWh (Nord Pool Spot average price for SE3 2014) and increasing with 2,4% per year	Nord Pool Spot, 2015. Sales at spot price was assumed based on Lindahl, 2015.
	Grid benefit compensation	0.037 SEK/kWh	Göteborg Energi, 2015a
Economic incentive	Investment subsidy	20% of PV system cost (maximum 800 000 SEK)	Assumption based on current subsidy (Lindahl, 2015)

The profitability was calculated from the perspective of a building owner. The costs include the initial investment, a replacement of the inverter, operation and maintenance costs, and other additional costs associated with the PV electricity generation. The basic benefits include cash inflows from sold electricity, tradeable green certificates, and savings from reduced electricity purchases from the grid. Calculations were performed with and without PV-specific benefits currently available in Sweden, that is, investment subsidy and tax rebate. All economic input parameters were chosen to reflect current market conditions.

A summary of the economic parameters used in the base case is given in Table 2. In addition, the following sensitivity analyses were conducted:

No subsidy. The current capital subsidy is available for all grid-connected PV systems. However, due to a discrepancy between supply and demand, the waiting period before a subsidy request is granted can be very long. Moreover, the subsidy scheme is today only planned to continue until 2019 and the level for upcoming years has not yet been decided. For these reasons, profitability was also calculated without a subsidy.

Value-added tax: The owners of multi-family buildings, which mainly have private customers, are generally not allowed to deduct value-added tax (VAT) from their expenses. Hence, in the base case scenarios VAT was added to all costs for these buildings. Economic calculations for buildings other than multi-family houses were conducted without value-added tax (VAT). This difference between multi-family buildings and other buildings is one of the factors that affects the system profitability. Hence, additional calculations without VAT were carried out for the multi-family buildings in the scenario with 20% subsidy in order to separate this effect from the influence of other parameters.

Tax rebate for systems ≤ 100A: There is today no plan for how long the current tax rebate program will be in place and it was therefore not included in the base case scenario. However, a sensitivity analysis including a tax rebate of 0.60 SEK/kWh during the first 10 and 30 years respectively was carried out for systems with a main fuses of 100A or less. The tax rebate is received for solar electricity fed into the grid up to a maximum of 30 MWh. However, it does not apply for more than the amount of electricity that is bought from the grid.

Discount rate: Besides the costs benefits associated with the installation of a PV system, the profitability of the investment will also vary with the chosen discount rate. In the base case scenario in this study a discount rate of 4 is used. For the systems in multi-family buildings, results from the base case were compared to scenarios with no subsidy, but a discount rate of 2 and 3 respectively.

Roof-tops: Initially, the study focuses on how the profitability of a PV system is affected by the size and type of electric load as well as current support measures. Calculations in the base case scenarios are therefore performed without consideration of the size and orientation of available rooftop areas. Instead, the economic analyses are based on a PV system oriented towards the south with a 45° slope, which gives a high yearly energy output per kilowatt peak. As a sensitivity analysis, the characteristics of existing roofs were included in the economic calculations, and reductions of PV generation and profitability due to less beneficial system orientations were determined.

3. Results

The results presented below are based on data from 35 real electricity supply points, all with unique load profiles. Some main characteristics of these loads are displayed in Figure 1. Figure 1a shows the load factor (highest hourly electricity use to yearly electricity use) as a function of yearly electricity use. Here, no difference can be seen between the supply points in multi-family buildings and other buildings. Figure 1b on the other hand, shows a divergence in how large share of the electricity use that coincide with hours of sunshine. Especially, the share of load that occurs during daytime is generally lower in multi-family buildings than in other buildings.

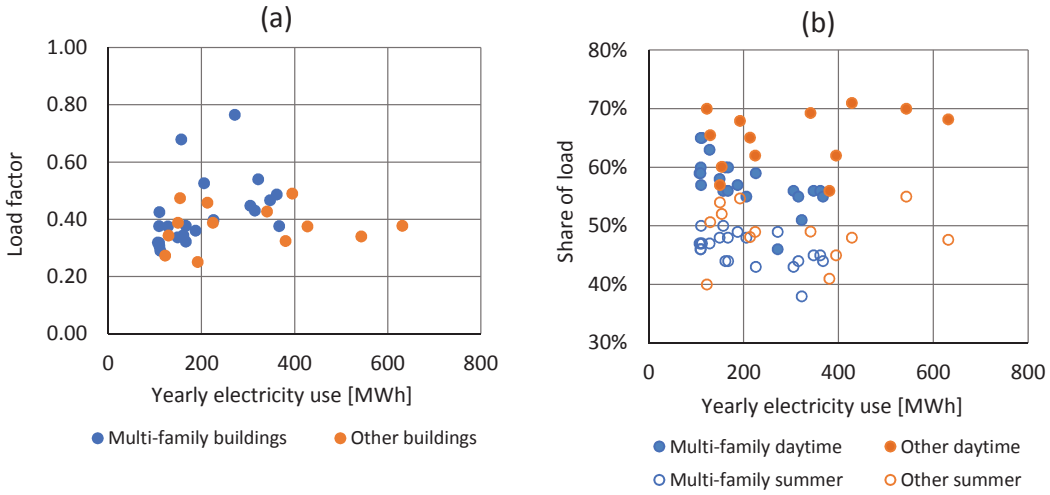

Fig.1: Characteristics of the studied electricity loads. Figure (a) shows the highest measured hourly energy as a function of yearly electricity use. Figure (b) shows the share of the load that occurs during daytime (07h-18h) and summer half-year (April – September) respectively as a function of yearly electricity use.

3.1 Profitability and sizing

This section gives the results from economic analyses with and without a capital subsidy of 20%. The highest achieved profitability (in NPV) for PV systems connected to each of the studied electricity supply points are shown in figure 2, while figure 3 shows the corresponding system sizes.

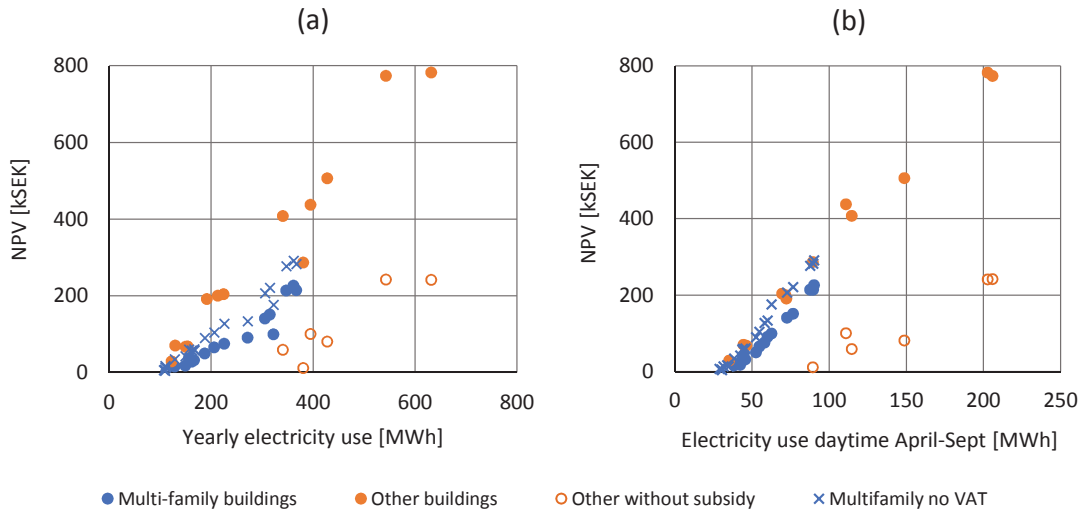

Fig. 2: The highest net present values (NPV) for PV systems connected to the studied electricity supply points. Profitability is shown as a function of (a) early electricity use and (b) electricity use during daytime (07h-18h) April – September. For multi-family buildings, the results are all with subsidy but with and without VAT. For systems in other buildings, results are shown with and without subsidy. Only systems with positive NPVs are included.

In relation to yearly electricity use, PV systems in multi-family buildings results in lower net present values (figure 2a) and lower system sizes (figure 3a) compared to the systems in other buildings. This can partly be explained by the fact that the profitability in multi-family buildings was calculated with VAT added to all cost. However, also when excluding VAT for the cost (as for other buildings), the results show lower values for multi-family buildings. It can be seen that excluding VAT makes the largest difference on optimal system size, while there is only a small increase in system profitability.

Comparing NPV or system size to the part of electricity load that occurs during daytime April through September (figures 2b and 3b) shows even stronger correlations than when comparing to the yearly load. Also, now there is no difference between multi-family buildings calculated without VAT and other buildings, indicating that the previous gap was due to differences in the load profiles (figure 1b).

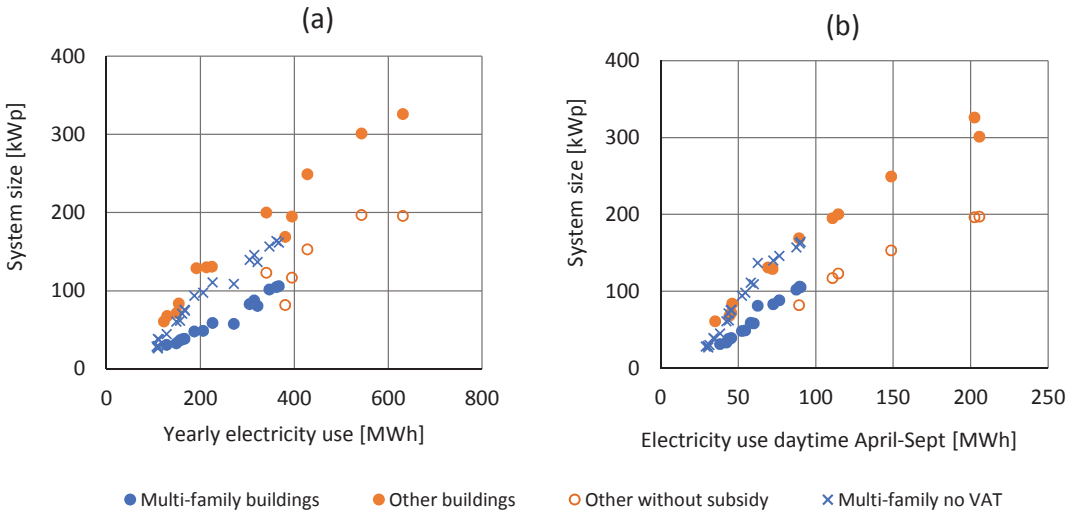

Fig. 3: Solar PV system sizes that results in the highest net present values (NPV) as a function of (a) total early electricity use and (b) electricity use that occurs during daytime (07h-18h) April – September. For multi-family buildings, the results are all with subsidy but with and without VAT. For systems in other buildings the results are shown with and without subsidy. Only systems with positive NPVs are included.

Without an investment subsidy no profitable system sizes were found for supply points in multifamily buildings, but for half of the supply points in other buildings. It can be seen that a daytime summer load of about 90 MWh, or yearly loads above 300 MWh, was required for the PV systems in other buildings to reach profitability. Regarding the supply points in multifamily buildings with yearly loads above 300 MWh, system sizes around 60 kW were close to being profitable.

3.2 Self-sufficiency and grid feed-ins

In this section, the share of the yearly electricity load that is covered by solar electricity, so called self-sufficiency, as well as solar electricity grid feed-ins are shown for the system sizes previously displayed in figure 3.

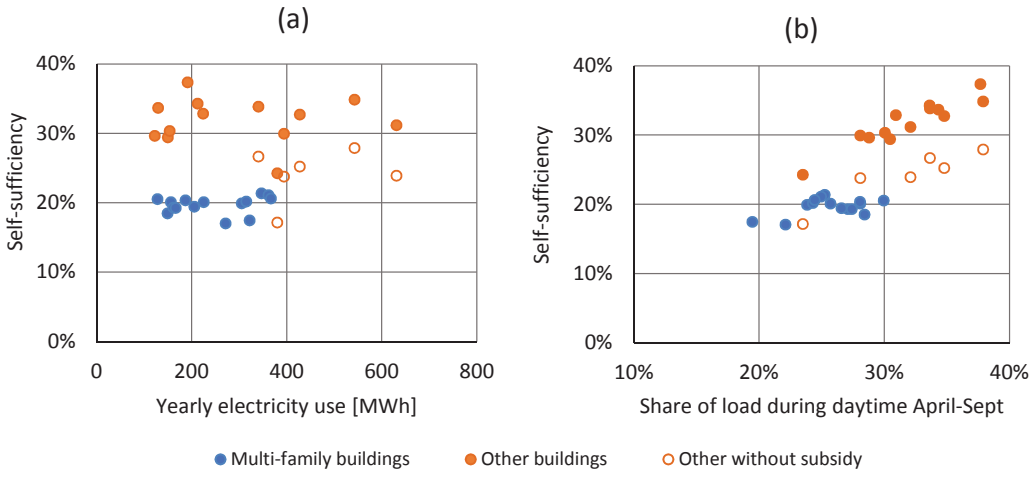

Fig. 4: Self-sufficiency (self-consumed solar electricity to total electricity use) as a function of (a) yearly electricity use and (b) share of the load that occurs during daytime (7h-18h) April-September.

Figure 4 shows that the PV systems optimally sized for supply points in multi-family buildings all result in a self-sufficiency around 20 %, while for the systems in other buildings it varies from above 20 to almost 40 %. For buildings other than multi-family houses, figure 4b shows a trend with increasing self-sufficiency with increase share of electricity load during daytime from April through September.

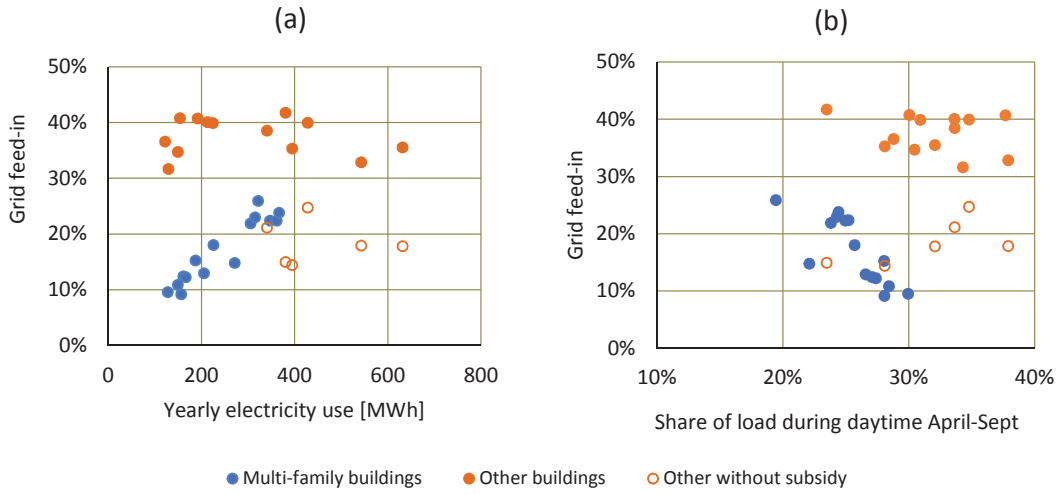

Fig. 5: Grid feed-in (over-generation of solar electricity to total solar electricity generation) as a function of (a) yearly electricity use and (b) share of the load that occurs during daytime (7h-18h) April-September.

Figure 5 shows the share of electricity that is fed to the grid, thus over-generation of solar electricity. The grid-feed-ins are about 10-25 % for systems in multi-family buildings and as much as 30-40 % for systems in other buildings (with subsidy) (figure 5). For multi-family buildings, the grid feed-ins increases with increased yearly use (figure 5a), but decreases with increased share of the load that occurs during daytime April through September. The same trends cannot be seen for other buildings.

3.3 Tax rebate

Eight of the electricity supply points in multi-family buildings and one of the supply points in other buildings have a main fuse smaller or equal to 100A, which makes them entitled to a tax rebate based on solar electricity fed to the grid (see section 2). Optimal system sizes for scenarios with 20% subsidy and tax rebate during 0, 10 and 30 years respectively are shown in figure 6.

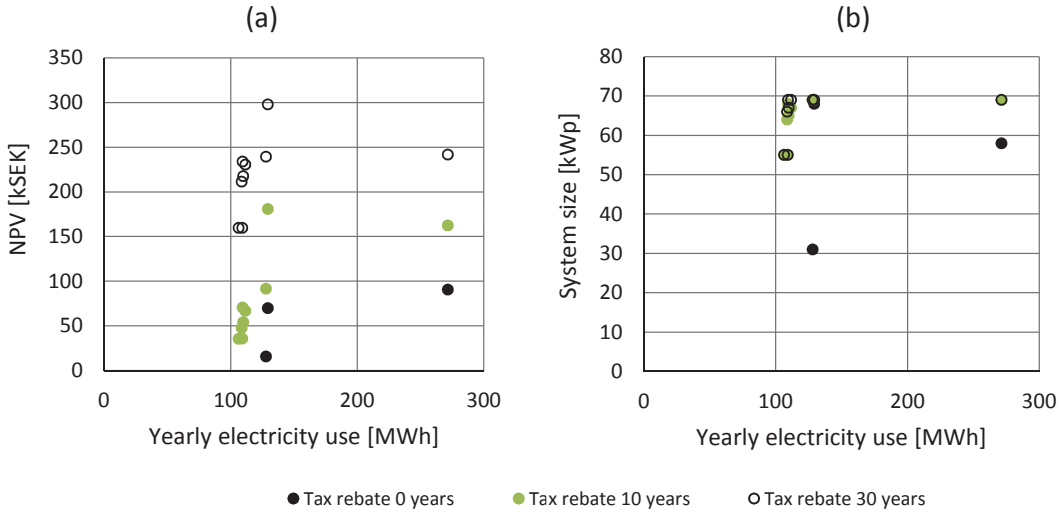

Fig. 6: Diagrams showing (a) maximum net present values (NPVs) and (b) corresponding system sizes for electricity supply points ≤ 100A, when the economic analyses are carried out with an investment subsidy as well as a tax rebate during 0, 10 or 30 years. Only systems with positive NPVs are included.

Only considering an investment subsidy, and no tax rebate, profitable PV systems were found for three of the supply points within this group (≤ 100A). With a tax rebate during 10 or 30 years on the other hand, all of the systems were profitable. As seen in figure 6, these two scenarios resulted in similar optimal system sizes, but with higher NPVs when including the tax rebate during a longer period of time.

3.4 Discount rate

A sensitivity analysis of the discount rate was carried out for all supply points in multifamily buildings. Figure 7 displays the resulting optimal system sizes and corresponding NPVs.

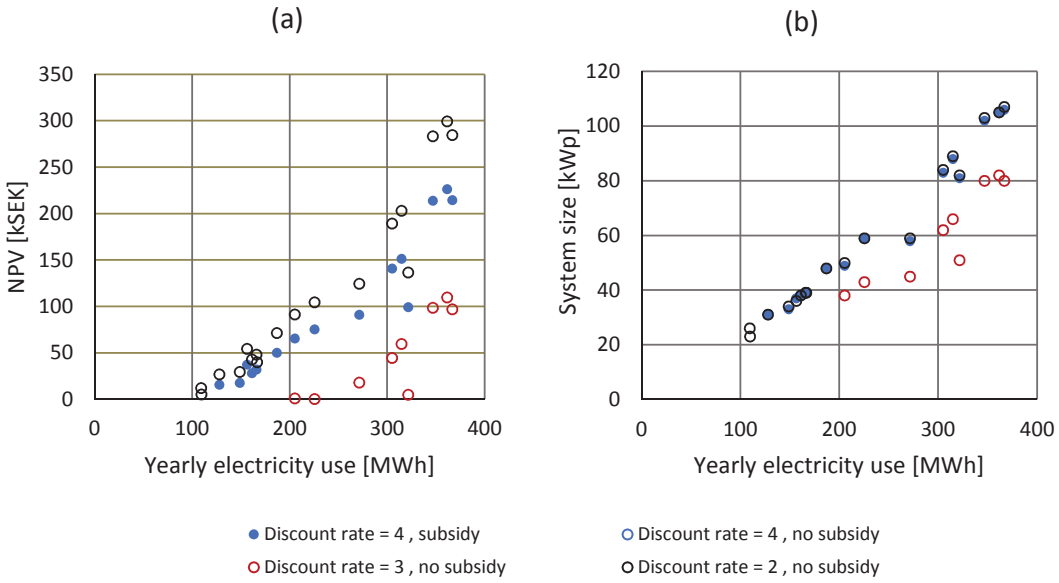

Fig. 7: Diagrams showing (a) maximum net present values (NPVs) and (b) corresponding system sizes for electricity supply points in multifamily buildings for economic analyses based on different discount rates. Only systems with positive NPVs are included.

Using a discount rate of 4 (base base), there were no profitable systems when the subsidy was excluded from the analysis. Accepting a discount rate of 3 would result in 9 profitable systems and with a discount rate of 2, twice as many are profitable. Moreover, figure 7 shows that with a discount rate of 2, the optimal same system sizes are the same as with a discount rate of 4 and a subsidy. However, the corresponding NPVs are higher in the former case.

3.4 Existing roofs

The results shown in previous sections were all were based on PV systems oriented to give a high yearly output and with an unrestricted system size. Since this is not often the circumstances in reality, this section explores the available areas offered by existing roofs and their effect on system profitability.

Figure 8 shows the optimal PV system sizes as well as the practically possible system sizes after consideration has been taken to available roof areas. The previously calculated PV system sizes for supply points in multi-family buildings (section 3.1) were generally small enough to fit the available roof areas. Only 3 out of 22 systems would have to be reduced (if sized with both subsidy and tax rebate). On the contrary, the systems sized for electricity loads in other building types were generally too large. When assuming a 15 degree module slope on flat roofs, all but one of these systems had to be downsized, 40% of them as much as 5 times or more. This is a result of relatively larger system sizes in combination with generally higher electricity use per floor area for these supply points, compared to the ones in multi-family buildings. Also, a large share of these buildings have a very small usable roof area relative to the floor area.

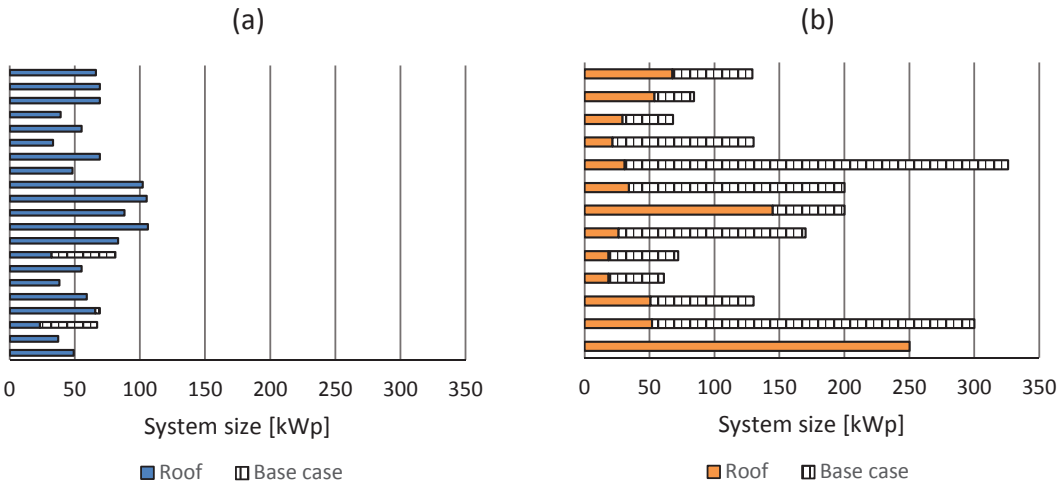

Fig. 8: System sizes before (base case) and after considering available roof areas in (a) multi-family buildings and (b) other buildings.

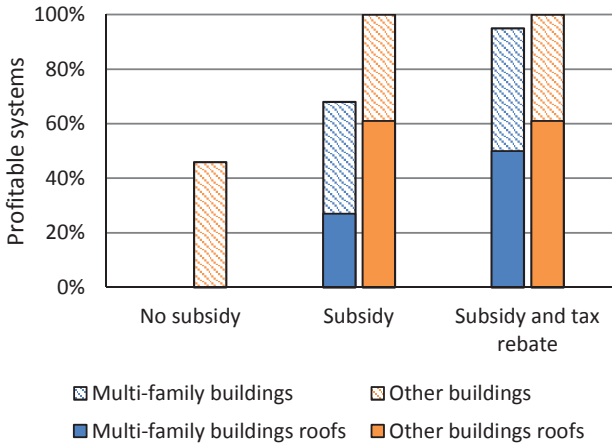

Fig. 9: Share of profitable PV systems in multi-family buildings and other buildings respectively before and after consideration of existing roofs. The results are shown for three different support scheme scenarios.

Reduced system sizes as well as adjustments of the module orientation to the slopes and directions of existing roofs affect the profitability of the PV systems. The shares of profitable systems before and after consideration of existing roofs are shown for different scenarios in figure 9. With a 20% investment subsidy, the number of profitable systems (positive NPVs) in multi-family buildings decreased from 15 to 6 and in other buildings from 13 to 8.

4. Conclusions

In general, the share of electricity use during hours of sunshine is lower for the studied multi-family buildings, compared to the buildings with other types of activities, thus giving them a disadvantage when matched to the electricity generation from a solar PV system. The effects of this difference can be seen as a lower self-sufficiency, as well as relatively lower profitability and smaller system sizes for supply points in multi-family buildings, compared to other buildings.

The currently available support schemes for solar PV in Sweden – an investment subsidy and a tax rebate based on net billing – turned out to be crucial for the profitability of a PV system investment in most of the studied buildings, but not all. Without any of the two, no profitable system sizes were found for the supply points in

multi-family buildings. Among the supply points in other building types on the other hand, the ones with a yearly electricity use above 300 MWh resulted in profitable systems also without additional financial support. With an investment subsidy of 20 %, more than half of the systems in multi-family buildings were profitable and all of the systems in other buildings. A fourth of the studied supply points had a main fuse smaller than or equal to 100A and were thereby also qualified for the tax rebate program. How much this would influence the profitability depends on the number of years that the program will be in place, which at this point is unknown. However, it was shown that with a subsidy, an additional tax rebate during either 10 or 30 years resulted in similar optimal system sizes. Taking the areas, slopes and directions of existing roofs into consideration drastically decreased the number of profitable systems both among the multi-family buildings and other buildings.

The economically optimal self-sufficiency (electricity use covered by solar electricity) was around 20 % for multi-family buildings and from 24 % up to almost 40 % for other buildings. Self-sufficiency was shown to be linked to the share of load that occurs during daytime April-September, rather than the size of the yearly load.

Abstract

The main goal of this research is to design and assess a new heat recovery (absorber-exchanger) configuration for a hybrid PVT solar panel with a geometry and from a material that maximises heat transfer while reducing weight and cost. To this end, firstly, potential configurations and materials for the absorber-exchanger unit that have the potential to meet the aforementioned aim are considered. The selected configurations (plus a benchmark reference case) are then applied to the same PVT panel in order to compare their performance. Once these configurations are defined in detail, they are modelled in 3-D finite-element and multiphysics (FEM and CFD) software, specifically COMSOL. The objectives are to: i) maximize the heat transfer performance of the different absorber-exchanger configurations, ii) obtain characteristic curves that describe the steady-state performance of the PVT panel in each case, and iii) compare the different alternatives with the reference case. The results show that a polymeric flat-box configuration is a promising alternative to commercial PVT panels, being able to achieve an improvement in the thermal performance of the PVT unit compared to the reference case (up to 5.1% higher optical efficiency and up to 48.7% lower heat loss coefficient), while also lowering the weight (up to 12%) and investment costs (up to 22%) of the PVT panel.

Keywords: *hybrid PVT panel, absorber-exchanger unit, heat transfer, energy efficiency, energy modelling*

1. Introduction

Currently, PV systems only use ~15% of the solar radiation, losing the remaining 85% as heat which, if recovered, could be used to heat a circulating fluid such as air or water. This has been the main motivation behind the development of hybrid PVT systems, which simultaneously generate electricity and a thermal output, and are considered a very promising technology for electricity and heat provision in buildings (Herrando et al., 2014). In particular, PVT-water (PVT-w) systems can increase the efficiency of PV panels by up to ~15% while generating hot water suitable to provide Domestic Hot Water (DHW) or space heating, so it is believed that this technology has an important potential in the residential sector, which accounts for 25% of the total electricity and 29% of the final energy consumption in the European Union (Antonanzas et al., 2015).

Previous research undertaken by the authors concluded that PVT-w systems can cover up to 50% of the total electricity demand and 35% to 50% of the DHW demand of a typical household located in London (the UK) (Guarracino et al., 2016c; Herrando et al., 2014), while completely covering the electricity demand and around 70% of the DHW demand if located in a household in Larnaca (Cyprus) (Guarracino et al., 2016a). Furthermore, as previous authors noted (Allan et al., 2015), the most desirable aspect of the PVT technology is the more efficient use of the roof space compared to stand-alone PV and solar collector systems.

Since their appearance, commercial PVT systems have been made available with increased in efficiency, making these panels an interesting option for integration in buildings. However, there are still very few companies worldwide that commercialise this type of PVT panel (Herrando and Markides, 2016) and most of the products available on the market do not have an optimised design for PVT applications. For this reason, the International Energy Agency (IEA), in its Task 35 for the development of PVT systems, insists on the need to optimise these systems from the manufacture and performance points of view, by developing projects that accelerate their economic viability to compete with current renewable energy technologies.

The main goal of this research is to develop an improved hybrid PVT module, with an optimal balance of energy efficiency, weight, cost, and ease of manufacturing. A number of alternative heat recovery (absorber-

doi:10.18086/eurosun.2016.08.22 Available at http://proceedings.ises.org

exchanger from now on) configurations are designed and compared with a reference case, all of them integrated in the same panel, for which a 3-D model is developed in COMSOL to model their energy performance, obtain their corresponding characteristic curve, and finally identify the design parameters which optimise the performance. The main focus is the study of a new absorber-exchanger configuration made of polymer and with a geometry that maximises heat transfer, while reducing the cost and weight of the PVT panel.

A detailed 3-D model of the PVT module is required to predict the non-uniform temperature distribution on the solar cells. In a previous work of Guarracino et al. (2016a), the 3-D PVT model showed a temperature gradient on the surface of a sheet-and-tube PVT module of ~10 °C during normal operating conditions, which led to a 5% drop in cell efficiency at the hot spots compared to cooler points, with a consequent loss in the PVT panel electrical performance. Therefore, the aim here is to achieve a uniformly cooled PVT module through the identification in the 3-D PVT model of the solar cells' hot spots and their elimination as far as possible.

In this work, a commercially available PVT sheet-and-tube collector (ECOMESH panel) model is implemented in COMSOL and validated with experimental results provided by the panel manufacturer, EndeF Engineering. COMSOL allows the investigation of more complex geometries which are not easy to model mathematically without a graphic tool, thus once the COMSOL model of the commercial PVT panel is validated, the model can be used with confidence to evaluate the temperature distribution and the thermal performance of different geometries of absorber-exchanger of the PVT unit. Specifically, a flat-box configuration is investigated in the present paper, and other more complex geometries will be considered in future work.

2. Hybrid PVT panel selection

In the last decades, significant research has been undertaken giving rise to a large number of PVT water (PVT-w) system configurations, both in terms of material and geometry. Copper is the most widespread material used for several reasons, such as its high thermal conductivity. Among all the absorber-exchanger configurations found in literature, parallel tubes (sheet-and-tube) is the most common (Chow, 2003; Chow et al., 2007; Herrando et al., 2014; Kalogirou, 2001; Tripanagnostopoulos et al., 2005; Zondag et al., 2003), also used in various commercially available PVT panels. Regarding the PVT panel cover, several configurations have been studied: uncovered, with one or two covers, with or without gap between the cover and the PV cells, as well as different filling gases: air, inert gases or vacuum. The authors decided to use as benchmark reference case a commercial copper parallel tubes PVT panel, ECOMESH (EndeF Engineering), with an innovative Transparent Insulating Cover (TIC), with which the thermal efficiency is significantly improved while maintaining the electricity generated (Antonanzas et al., 2015; del Amo et al., 2016).

On the other hand, other authors (Chow et al., 2006, 2007; He et al., 2006) have studied other PVT configurations, such as the flat-box structure made of extruded aluminium alloy, with the aim to improve the fin efficiency and bonding quality, and hence the heat transfer. Therefore, as a first alternative to the reference case, aluminium flax-box is considered in an attempt to reduce the weight and cost of the absorber-exchanger unit, while improving (or at least maintaining) the thermal efficiency of the panel.

However, the main innovation and focus of this work is the study of a new absorber-exchanger configuration made of polymer, as it is believed that some polymeric materials such Polycarbonate (PC) or Polyamide (PA) have several properties that make them an interesting option for PVT collectors, such as (Cristofari et al., 2009): low density, mechanical strength, no special surface treatment required, no corrosion, ease of manufacturing at mass production as there are fewer components to assemble, and lower production cost because the material is generally cheaper and the manufacturing time is reduced. Nonetheless, there are also some disadvantages, such as the low thermal conductivity, large thermal expansion and limited service temperature. Specifically, the ideal polymer for this application should have the following properties: UV protected, high thermal conductivity, water-resistant and glycol-resistant, good thermal range of utilization (-10/+150°C), a good mechanical strength and be chemically stable (Cristofari et al., 2002, 2009, 2012). Bearing in mind this, two types of polymer are considered in the present research: Polycarbonate (PC), as suggested by previous authors (Cristofari et al., 2002, 2012; Huang et al., 2001) and Polyamide (PA) without and with additives to improve its thermal conductivity (Ghaffari Mosanenzadeh et al., 2015). Regarding the geometry, flat-box structure is the most common configuration studied with different channel dimensions. Examples are Huang et al. (2001) who considered channels of 6×4 mm (W×H), or Cristofari et al. (2009) who studied bigger channels of 10×10 mm (W×H), based on the results of parametric analysis undertaken in previous research (Cristofari et al., 2002), which concluded that the highest thermal energy gain is achieved with a fluid layer

thickness of 1 mm. The study also concluded that, to collect more than 90% of this energy, the collector should have a fluid layer thickness smaller than 10 mm.

Although some of the absorber-exchanger configurations proposed in this work were studied previously, this research is innovative in the following aspects: i) these configurations were not implemented in high efficiency PVT units such as the one proposed (ECOMESH panel), but in PVT panels uncovered or covered with an air gap; ii) none of the studies found proposed a detailed study through 3-D FEM and CFD software of the absorber-exchanger alternatives considered in this work, integrated in the same PVT panel; iii) so far it has not been found any work that studied Polyamide with additives for the absorber-exchanger unit.

3. Methodology

Firstly, each absorber-exchanger configuration is defined in detail (geometry, technical specifications, etc.), integrated in the same PVT panel, and the energy balance of the PVT unit considering radiation, convection and conduction heat exchanges among the layers is developed. The reference PVT unit is then graphically implemented in COMSOL, together with its parameters and physics associated. Thanks to the symmetry of this sheet-and-tube geometry, only one riser tube of the PVT unit is implemented, significantly lowering the computation time and computational resources required by the 3-D model. The performance curve obtained is then compared with the empirical results provided by the PVT panel manufacturer (EndeF Engineering). Once the detailed 3-D model is validated, the different absorber-exchanger configurations are modelled to obtain the characteristic curve that describes the steady-state performance of the PVT panel in each case, i.e., the value of the optical efficiency (η_o) and linear and quadratic heat loss coefficients (a_1 and a_2). Finally, a simple cost analysis is undertaken to evaluate the different configurations studied from a cost perspective.

3.1 PVT panel modelling

The two main components of the PVT unit are the PV module and the rest of the solar collector, which can be further divided into the glazing, the thermal absorber and the riser water tubes (referred to, in the present work, as the absorber-exchanger or heat recovery unit) and the insulation layer (see Figure 1). Similarly to previous work by the authors (Herrando et al., 2014) and other PVT modelling attempts (Notton et al., 2005; Zondag et al., 2003), energy balances were written in order to evaluate the heat fluxes and temperatures throughout the unit. The equations were applied separately to each layer of the unit, instead of using global equations to find the average absorber plate temperature and energy flows (Kalogirou, 2004; Zondag et al., 2002). This allowed an estimation of the average temperatures of all the separate unit layers. Figure 1 shows the main heat transfer mechanisms of the PVT unit as well as the section with the different layers considered in the present work.

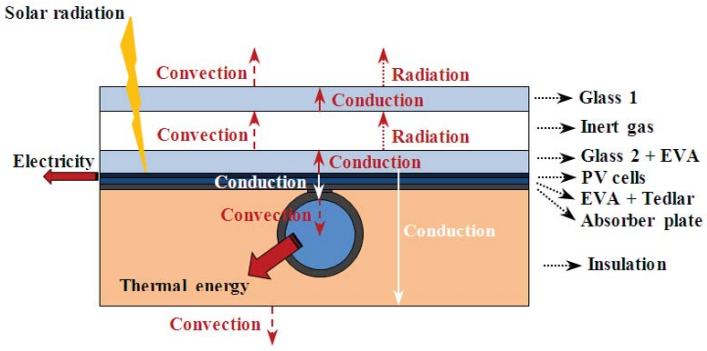

Fig. 1. PVT collector cross-section.

The PVT model was developed under the following main assumptions: i) Solar radiation is absorbed only by the collector (Agarwal and Garg, 1994); ii) the fraction of solar irradiance that is not converted into electricity in the PV cells and is not lost to the environment, is transmitted and absorbed in the absorber plate (Chow, 2003; Cristofari et al., 2009; Zondag et al., 2002, 2003), where most of it heats the water flowing through the collector and the rest is lost as heat (Agarwal and Garg, 1994); iii) the ambient temperature is considered uniform around the module (Cristofari et al., 2009; Notton et al., 2005) and heat transfer (losses) at the sides of the PVT collector are negligible (Notton et al., 2005), iv) the heat capacities of the PVT panel components (PV cells, Tedlar and insulation) are negligible compared to the heat capacity of water (Tiwari and Sodha, 2006); v) the water mass flow-rate is divided equally among all tubes of the collector (Bhattarai et al., 2012; Cristofari et

al., 2009), the water flow-rate within the collector tubes is uniform and heat is transferred to the tubes by forced convection; and vi) radiative thermal exchanges between the sides of the solar collectors' channels are neglected (Chow, 2003; Cristofari et al., 2009; Sandnes and Rekstad, 2002; Zondag et al., 2002). The model was run under steady state conditions (Tiwari and Sodha, 2006; Zondag et al., 2003).

To compare the performance of the different absorber-exchanger configurations studied, the thermal efficiency of the PVT unit is calculated, following both the ASHRAE method (ASHRAE Standard, 2013) and the ISO method (ISO, 2013) for the performance testing of solar thermal collectors, as there is currently no standard method to assess the performance of a PVT collector (Allan et al., 2015).

The former is used to determine the heat removal factor (F_R) and the overall heat loss coefficient (U_L) of the PVT collector (Allan et al., 2015), by measuring or calculating (as in this case) the thermal efficiency of the collector at different inlet temperatures in steady state conditions (Antonanzas et al., 2015; Collins and Zondag, 2009; Sandnes and Rekstad, 2002; Vokas et al., 2006),

$$\eta_{th} = \frac{q_u}{G_i} = F_R(\alpha\tau)_{PV} - F_R U_L \frac{T_{in}-T_a}{G_i}; \qquad \text{(Eq. 1)}$$

where η_{th} is the thermal efficiency of the PVT unit, q_u is the useful thermal energy extracted (W/m^2), G_i is the Incident irradiance (W/m^2), $(\alpha\tau)_{PV}$ is the combined transmission-absorption coefficient, T_{in} is the inlet water temperature and T_a is the ambient temperature.

Alternatively, in the ISO method, the PVT collector is also tested under steady state conditions but in this case the difference between the mean fluid temperature (T_{fm}) and the ambient temperature (T_a) is considered (Allan et al., 2015; Antonanzas et al., 2015; del Amo et al., 2016),

$$\eta_{th} = \frac{q_u}{G_i} = \eta_o - a_1 \frac{T_{fm}-T_a}{G_i} - a_2 G_i \left(\frac{T_{fm}-T_a}{G_i}\right)^2; \qquad \text{(Eq. 2)}$$

with $T_r = \frac{T_{fm}-T_a}{G_i}$; (Eq. 3)

where η_o is the optical efficiency, a_1 is the heat loss coefficient which accounts for the linear heat loss variation, a_2 is the temperature dependence of the heat loss coefficient which accounts for the quadratic heat loss variation, T_{fm} is the mean fluid temperature and T_r is the reduced temperature.

One of the main limitations of detailed CFD-FEM 3-D simulations is the significant amount of both time and computational resources required, especially in problems involving multiple processes, e.g. thermal, fluid flow, etc. This is the case of hybrid PVT panels, where heat transfer and fluid-dynamic equations should be solved simultaneously. Furthermore, surface-to-surface radiation should also be considered to properly model covered PVT units, which adds an extra complexity to the model. Consequently, to lighten the problem without simplifying the physics (which would reduce the accuracy of the 3-D model), some simplifications are required. In the configurations studied in the present research, both the reference case (parallel riser tubes) and flat-box collectors have in common that all the riser pipes behave likewise, as the water mass flow-rate is divided equally among all tubes of the collector (Bhattarai et al., 2012; Cristofari et al., 2009), therefore symmetry can be applied to solve this problem. As consequence, only one pipe was implemented in COMSOL, applying symmetry boundary conditions on both sides of the model. However, even though the 1-pipe 3-D model worked for an uncovered PVT collector, when the Transparent Insulating Cover (TIC) was implemented, together with the physics involved (heat transfer in fluids in the gap and surface-to-surface radiation between PV glass and glass cover), the problem became too heavy to compute. Consequently, an additional symmetry was applied, considering half of the pipe with its corresponding half fin width (see Figure 2). To ensure the validity of this assumption, the results obtained in COMSOL for half pipe were validated with those of an entire pipe for the uncovered PVT panel.

Fig. 2. (Left) Cross section of a pipe and its fin and (right) half a pipe modelled in COMSOL Multiphysics

In the case of the flat-box structure, the geometry is simpler so it was possible to model a whole channel (20×10 mm, 40×10 mm), or two in the case of smaller dimensions (10×10 mm, 6×4 mm and 3×2 mm).

Examples of the type of results obtained from the COMSOL simulations are presented in Figure 3, where it is possible to observe on the left the PV layer temperature distribution and on the right 10 slices at different collector lengths of the temperature profile of the PVT layers throughout half of a pipe's fin, for the reference case. The results obtained for the reference PVT unit in the COMSOL model where validated with the experimental performance curve provided by the PVT panel manufacturer (EndeF Engineering).

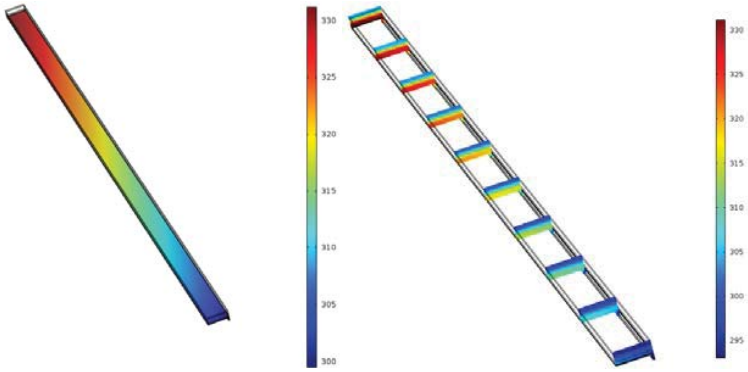

Fig. 3. (Left) PV layer temperature and (right) slices of the temperature profile in the different layers.

3.2 PVT unit parameters

The PVT unit taken as the reference case and modelled in this paper is the commercially available ECOMESH panel (EndeF Engineering), which consists of (from top to bottom): a Transparent Insulating Cover (TIC) comprising a transparent cover (glass) and an insulating gas (del Amo et al., 2016), a poly-crystalline (pc-Si) PV module, an EVA encapsulating film, an absorber-exchanger which transforms the solar radiation to heat and transfers it to the collector fluid (heat recovery unit), and a layer of insulation material at the bottom (see Figure 1). The absorber-exchanger unit consists of a sheet-and-tube heat exchanger in which water flows in (nine) copper parallel pipes (Antonanzas et al., 2015). The main PVT panel features are shown in Table 1. In order compare the different absorber-exchanger configurations studied in the present research, all the PVT parameters of the different layers were kept constant (panel dimensions, cover layers, PV cell, etc.), varying only the absorber-exchanger unit.

[*] *(Cristofari et al., 2009, 2002);* [+] *(Ghaffari Mosanenzadeh et al., 2015);*

[†] *The same heat capacity is considered for all Polyamides (PAs) as the addition of hBN does not significantly influence this physical property and its effect on the absorber-exchanger performance (within this order of magnitude) is negligible.*

[$] *An hypothetical polymer with a high thermal conductivity (30 W/(m·K)) is considered to study to which extent it is possible to improve the thermal performance of the absorber-exchanger unit with additives.*

As alternative to the reference case, flat-box structure was considered. First of all, aluminium alloy was studied with two different channel dimensions, 20×10 mm (*W*×*H*) as suggested by several authors (Chow et al., 2006, 2007; He et al., 2006), and 10×10 mm (*W*×*H*), both with wall thickness of 2 mm. The properties of the aluminium alloy considered as those provided by Chow et al. (2006) (c_p = 903 J/(kg·K), ρ = 2702 kg/m^3, k = 237 W/(m·K)). Regarding polymeric materials for the absorber-exchanger unit, two main types of polymers were considered: Polycarbonate (PC) and Polyamide (PA), studying also some variations of the latter with different loadings of hexagonal Boron Nitride (hBN) particles (additive) (Ghaffari Mosanenzadeh et al., 2015). Table 2 summarizes the physical properties of different polymers considered.

Table 3 summarises all the geometric absorber-exchanger configurations considered in the present research.

Tab. 3. Summary of the absorber-exchanger configurations studied

Copper	Aluminium	Polymer		
3×2 mm 10×10 mm	10×10 mm 20×10 mm	3×2 mm • PC • PA30-33 6×4 mm • PC • PA30-33	10×10 mm • PC • PA • PA90-15 • PA30-33 • PA ideal	20×10 mm • PA • PA30-33 40×10 mm • PA • PA30-33

All the PVT configurations detailed in Table 3 as well as the reference case are studied at steady state with the same initial conditions, detailed in Table 4. It should be noted that, even though according to the PVT manufacturer of the reference case the nominal flow-rate for the sheet-and-tube configuration is 0.0083 kg/s (30 L/h), the same collector flow-rate than for the flat-box configurations has been considered in this study to compare the alternatives under the same operating conditions.

Tab. 4. Initial conditions and other important constant system parameters

G_i	Incident solar irradiance	1000	W/m^2
T_a	Ambient temperature	25	°C
v_w	Wind velocity	1	m/s
T_{in}	Mains water temperature	20.2	°C
$\dot{m}_c$	Collector flow-rate	0.00533[†]	kg/s

[†]*Optimum flow-rate for the 10×10 mm flat-box configuration according to Cristofari et al. (2002, 2009)*

To complete the technical assessment, a simple cost analysis was undertaken in which the investment cost of each configuration was estimated, and the electricity and heat generation were converted to the same unit (€/h per PVT panel), so as they can be added up. To this intend, the actual electricity and natural gas price (€/kWh) in Spain were considered (see Table 5).

Tab. 5. Cost factors for the economic analysis

Cost analysis		Reference
Natural gas price	€/kWh	0.0508
Electricity price	€/kWh	0.14
Polymer cost	€/kg	2.3-3*
Additive (hBN) cost	€/kg	150
Aluminium 20×10 mm flat box cost	€/m	2.33
Ratio copper/aluminium cost	-	1.27
Extrusion production cost	€/m	2

**Price varies slightly between this range for PA, PA30, PA90 and PC*

The aim of the economical assessment is the estimation of the payback time (PBT) of the panels with Eq. (4) from the cost savings (€/h per PVT panel) and the investment costs (C_0). The payback time is estimated at constant weather conditions (Table 4) and represents a simple figure that can be used for comparison. The

investment cost of the polymeric absorber-exchanger configuration is estimated from the cost of the raw polymeric material and the cost of adding the additive (hBN) where applicable, including also an estimation of the extrusion production cost. For the aluminium configurations, the price of off-the-shelf square channel tubes was considered, which was then extrapolated to the copper square channels considering the price ratio of both materials (Table 5).

$$PBT = \frac{C_0}{cost\ savings \cdot 24} \quad \text{(Eq. 4)}$$

4. Results and discussion

4.1 Model Validation

The 3-D model developed in COMSOL was validated against a manufacturer's performance curve. In Figure 4 the thermal efficiency (η_{th}) is plotted against the reduced temperature (T_r). The 3-D model fits the experimental results with an average error of 19%, when the inlet water temperature is in the range 10-80°C, being the thermal performance overestimated with the largest deviation at high temperatures of operation. It should be noted that for inlet water temperatures lower than 30°C, the error is below 10%. This suggests that the heat losses are underestimated in the model. It should be noted that the model assumes a perfect thermal contact between the PV module and the rear copper sheet, and between the absorber and the pipe which are bonded, both assumption might explain the overestimation of the thermal performance. Guarracino et al. (2016b) found that that a poor thermal contact between the PV module and the thermal absorber, which resulted in an insulating air gap between the layers, reduces the thermal performance of the module up to 30%.

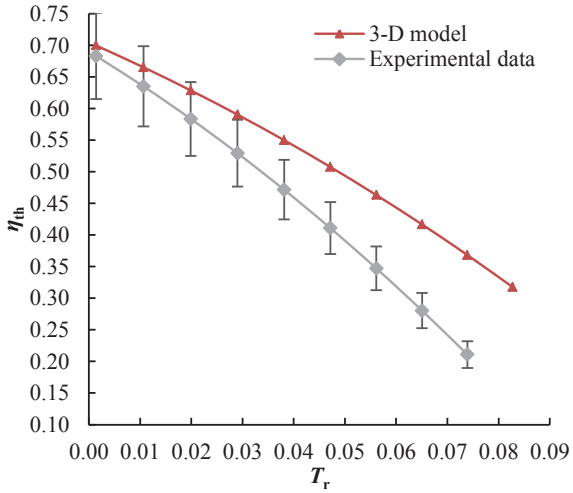

Fig. 4. Performance curves of the reference sheet-and-tube PVT unit for the COMSOL model, as well for the commercial ECOMESH panel (EndeF Engineering)

Regarding the heat transfer from the copper absorber to the tubes, a uniform bond made of copper and with fixed dimensions throughout the pipe is assumed, and both parameters influence the heat removal factor (F_R) and the overall heat loss coefficient (U_L) and hence the linear (a_1) and quadratic (a_2) heat loss coefficients. However, in reality depending on the bonding method (welding, ultrasounds, etc.) these will vary and hence the heat conduction will be achieved at lower or higher extent. Furthermore, lateral losses are not considered in the theoretical models. Finally, it should be noted that to obtain the experimental performance curve, the different experimental points are plotted in a T_r vs. η_{th} graph obtaining a cloud of points, and depending on which ones are selected to fit the curve, this might considerably vary .

4.2 Performance curve analysis

From the different PVT configurations studied and detailed in Table 3, first of all the effect of the material on the thermal efficiency of the PVT panel was assessed for the same channel dimensions (10×10 mm). First of all, it should be noted that, even though the thermal conductivity of all the polymers considered is lower than the one for copper, the heat transfer area between the polymer and the fluid is significantly larger than the sheet-and-tube configuration where the pipe is in contact with the copper only thought the bond. Furthermore, while for the sheet-and-tube collector the temperature on the PV cells reaches a maximum between two pipes, the temperature distribution on the PV surface is more uniform for the flat-box configuration, resulting in lower

thermal losses (top thermal losses for the sheet-and-tube q_{top} = 138.06 W/m^2, while for the copper 10×10 flat box, q_{top} = 95.04 W/m^2). This is in agreement with the results found by previous studies that used polymeric flat-box absorber-exchanger units (Cristofari et al., 2009; Sandnes and Rekstad, 2002). As consequence, Figure 5 left shows that all flat-box configurations have better thermal performance than the sheet-and-tube collector, with a higher optical efficiency (η_o) (up to 4.3% better) and significantly lower heat loss coefficient (a_1) (up to 28.4% lower) in all the cases.

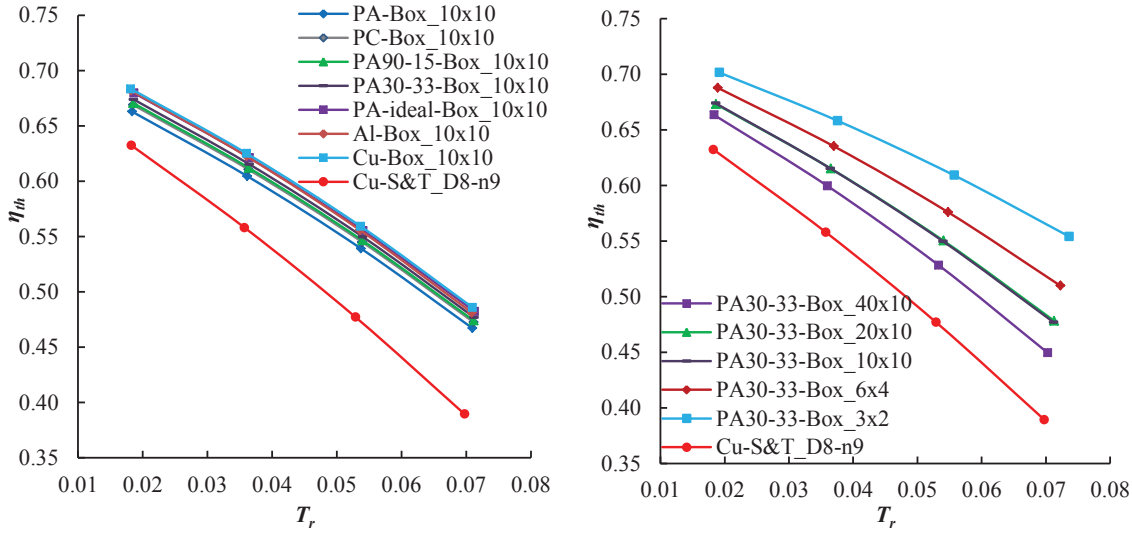

Fig. 5. Performance curves of the different PVT configurations studied for (left) same channel dimensions with different materials and (right) same material with different channel dimensions. In the legend, Cu-S&T_D8-n9, refers to 9 copper pipes of 8 mm external diameter.

It can also be observed that for the same channel dimensions, the difference in the performance curves between the best configuration (made of copper) and the worst one (made of Polyamide) is less than 5%, which implies that in this type of configuration the material selected is not determinant in the thermal performance of the PVT collector. This can be attributed to the small thickness of the polymeric absorber plate (1 mm).

On the other hand, Figure 5 right shows that the channel dimensions (for the same material) have a significantly higher influence on the thermal efficiency of the PVT panel. It is possible to observe that the smaller the channel is, the higher optical efficiency (η_o) (up to 5.1% better) and the lower heat loss coefficient (a_1) (up to 48.7% lower) compared to the reference case. The reason is that, as the total collector flow-rate was maintained constant in all the cases, the water velocity through smaller channels is higher as well as the convention heat transfer coefficient (which depends on the hydraulic diameter for laminar flows) (h = 1,141 W/(m^2·K) for the best case (3×2 mm) *vs*. h = 171 W/(m^2·K) for the worst case (40×10 mm)), so more heat can be extracted.

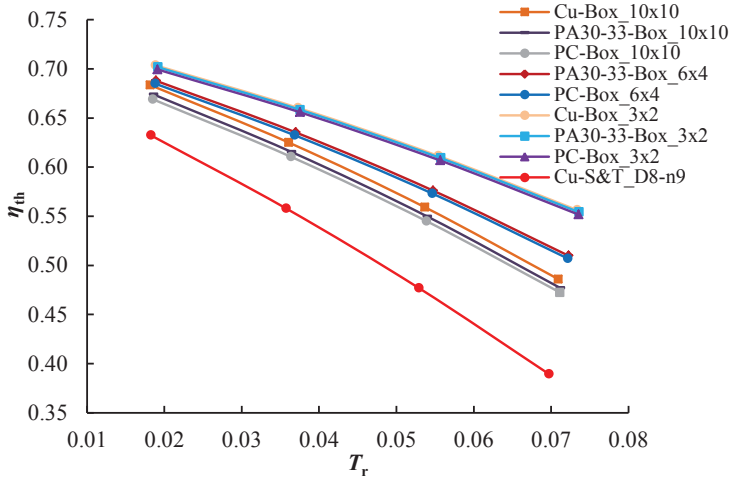

Fig. 6. Performance curves of the most promising PVT configurations studied.

In Figure 6, the most promising PVT configurations studied are presented, which are for channel dimensions of 10×10 mm or lower. These results corroborate that the channel dimensions are determinant in the thermal

performance of the PVT panel, while the material does not influence as much. Consequently, it is believed that, in the case of polymeric materials, the higher complexity and costs of loading the polymer with additives might not be outweighed with the increase in thermal performance of the PVT unit. Besides, even though the copper flat-box configuration has the highest thermal performance, the improvement achieved compared to off-the-self polymers (such as Polycarbonate (PC) or Polyamide (PA)) for the same channel dimensions is considerably small. Therefore, a techno-economic analysis is required to bring into consideration other factors such as investment cost and weight to draw conclusions.

4.3 Techno-economic analysis

Table 6 shows a summary of the techno-economic results obtained for the different PVT configurations studied. The heat removal factor (F_R) and the overall heat loss coefficient (U_L) are obtained with Eq. (1), plotting the thermal efficiency (η_{th}) for different water inlet temperatures (T_{in}), and fitting the points to a line (in all fittings, R^2 is higher than 0.997). The results obtained are equivalent to those shown in Figures 5 and 6, with the lowest heat loss coefficient (U_L) and the highest heat removal factors (F_R) in the PVT configurations with smaller channels.

Tab. 6. Summary of the techno-economic results of the different PVT configurations studied.

The highest average temperature of the PV cells (T_{PV}), and hence the lowest electrical output (w_e) and electrical efficiency (η_e), are obtained for the reference case, which is operating at lower collector flow-rate than the recommended one by the manufacturer, while if it is operated at the nominal flow-rate (0.0083 kg/s (30 L/h)), the PV temperature decreases to 318 K, value lower than for the rest of the configurations. Regarding the flat-box configurations, as expected, the highest PV cell temperatures are reached for the Polyamide (PA) absorber-exchanger, as it has the lowest thermal conductivity (see Table 2). In terms of channel dimensions, the electrical output and electrical efficiency increases as the channel dimensions decreases, as more heat can be extracted (higher useful heat obtained (q_u)) and hence lower PV temperature is reached. On the other hand, it is observed that outlet water temperature (T_{out}) and hence the increment in the water temperature throughout the PVT collector (ΔT) is higher for all flat-box configurations compared to the sheet-and-tube panel, as more heat can

be extracted (higher q_u), thanks to the higher heat transfer area of the channels.

Figure 7 shows the total cost savings (€/h) *vs*. the total investment cost (€) of each PVT panel alternative. It is possible to observe that there are two points which differ significantly from the rest (red diamonds) which correspond to the copper flat-box configurations, due to the significantly higher investment cost (as the cost of copper is higher than the aluminium and polymer costs) which is not outweighed by the higher cost savings. Similar results are obtained for the aluminium configurations (green squares). The lowest investment costs are for the polymers without additives, as expected, due to the lower cost of the raw material (dots on the left of the graph), and among them, the best results are obtained for the Polycarbonate (PC) flat-box configuration, in particular the 3×2 mm and 6×4 mm (upper and lower purple triangles respectively) with which high cost savings are achieved, compared to the rest of the channel configurations.

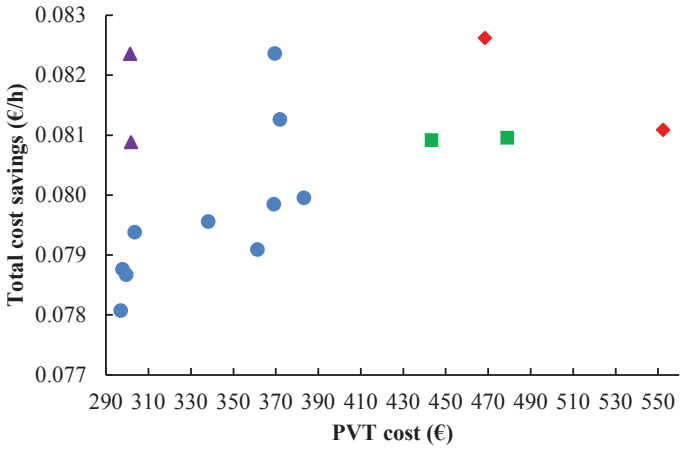

Fig. 7. Total savings (€/h) *vs*. total investment cost of the PVT panel for the different configurations studied. (Red diamonds = copper flat-box, green squares = aluminium flat-box, purple triangles = PC 3×2 mm and 6×4 mm flat-box configurations).

Finally, it is noted that the weight of all polymeric panels can be reduced by 7.5-12%, while the weight of the aluminium flat-box panels increase by 6% and 12% for the 20×10 mm and 10×10 mm configurations, and of the copper flat-box by 48% and 59% for the 3×2 mm and 10×10 mm configurations respectively, compared to the reference case; the absorber-exchanger unit accounts for 17.3% of the total PVT panel weight in the reference sheet-and-tube panel.

5. Conclusions

In this work, 17 different flat-box configurations for the absorber-exchanger unit (plus a benchmark reference case) are applied to the same PVT-w panel in order to compare their performance. The results show that all flat-box configurations have better thermal performance than the copper sheet-and-tube (reference) collector, which is attributed to the larger heat transfer area between the absorber and the fluid in the former configurations. Furthermore, with the flat-box configurations proposed, the temperature distribution on the PV surface is more uniform, avoiding the maximum PV cell temperatures reached between two pipes that appear in the sheet-and-tube collector. As a consequence, although the thermal conductivity of all the polymers considered is lower than the one for copper, all of them achieve a higher optical efficiency (η_o) (up to 5.1% better) and a lower heat loss coefficient (a_1) (up to 48.7% lower) compared to the reference case.

Amongst the different flat-box configurations studied, the results show that for the same channel dimensions, the material does not significantly affect the thermal performance of the PVT collector, with a variation of less than 5% in the performance curves between the best (copper) and worst (Polyamide) configuration. Conversely, the channel dimensions (for the same material) have a significantly higher influence on the thermal efficiency of the PVT panel, varying from around 7% at low water inlet temperatures up to 25% at higher temperatures, between the best (3×2 mm) and worst configuration (40×10 mm). This is attributed to the significantly higher heat transfer coefficient of the water flowing through the channels in the former case (nearly 7 times higher).

Finally, a basic economic consideration of the PVT panels showed that the slightly better thermal performance of the copper and aluminium flat-box configurations do not outweigh their significantly higher investment costs (as the cost of copper and aluminium are higher than the polymer costs). Similarly, among the different polymeric absorber-exchanger alternatives studied, it is observed that the loading of additives considerably

increases the investment costs, while only achieving marginal cost savings. Consequently, it can be concluded that the polymeric flat-box configuration is a promising alternative to commercial PVT panels, being able to achieve an improvement in the thermal performance of the PVT unit, while also lowering the investment costs (by up to 22%) and weight (up to 12%) of the PVT panel. However, further work is required to study the thermal expansion of these configurations and its effects on the PV module as well as the performance of the PVT panels under real weather conditions at short and medium term.

Abstract

The rapid ageing of the population of Asian countries presents a demand for increased agricultural labor productivity. We are currently investigating the potential of a renewable energy-operated, energetically autonomous, sunlight combination-type plant factory for meeting this demand. In the factory, electricity is generated from translucent solar cells (TSCs) while improving the marketability of the horticultural crops cultivated within by supplementing the crops with monochromatic light using a portion of the generated power. Evaluation of the energy characteristics in a model glasshouse using TSCs revealed that sufficient electricity could be secured for supplementary monochromatic illumination. Subsequently, ultraviolet radiation–induced color change in chrysanthemum flowers and red light–induced early maturation of pea plants were investigated to evaluate the potential improvement of crop marketability from monochromatic light irradiation. The results demonstrated that the products' marketability could be improved with only minute power consumption.

Keywords: *crop marketability, monochromatic lighting, plant factory, translucent solar cell*

1. Introduction

Traditional family farming with low labor productivity has historically been practiced in many Asian countries, including Japan. However, as the population of Asian countries is aging rapidly, increasing the labor productivity of agriculture is a pressing issue. To solve this issue, the automation of agriculture, that is, the widespread use of plant factories, will become necessary. We have previously investigated the realization of a renewable energy-operated, energetically autonomous, sunlight combination-type plant factory (Watanabe *et al*., 2005). A conceptual diagram is shown in Figure 1. In this plant factory, translucent solar cells (TSCs) are installed in the roof of a glasshouse. Part of the incident solar energy is harnessed for power generation, while the light energy that passes through is used for by crops for photosynthesis. The electricity generated is used for management of the cultivation environment, such as ventilation of the glasshouse and operation of monochromatic lighting.

Plants use light not just for photosynthesis, but also as a signal of changes in their surroundings. Making use of this latter characteristic, we previously investigated the effect of supplemental blue light (460 nm) on the production of functional components in perilla planted in an unheated glasshouse, and found that the content ratio of a functional component, perillaldehyde, in plants grown with blue light was 60% higher than in control (Horibata *et al*., 2013). In this way, sunlight supplemented with additional monochromatic lighting has been shown to improve crops' marketability. Based on research revealing the specific photoreceptors present in plants, ultraviolet light (Christie *et al*., 2012), blue light (Ahmad *et al*., 1998, Christie *et al*., 1999), red light, and far-red light (Butler *et al*., 1959) are candidate wavelengths for supplementary monochromatic light expected to favorably affect crops. Crop marketability indicates superiority quality or value added in the market, such as early harvest time, unique flower color, excellent taste, or good nutritional properties. The specific properties important in the market depends on the type of crop, which span diverse categories such

doi:10.18086/eurosun.2016.08.08 Available at http://proceedings.ises.org

as flowers and ornamental plants, fruits and vegetables, or medicinal plants. Therefore, it is necessary to examine the effect of different kinds of supplementary lighting on various kind of crops with different economic values in order to refine and spread the use of supplementary monochromatic light.

In this study, we investigated the effect of supplementary monochromatic lighting in chrysanthemum flowers and pea plants for improving crop marketability, as well as the energy use characteristics of a sunlight combination-type plant factory equipped with TSCs.

2. Material and Methods

2.1 Measurement of power output using a model glasshouse equipped with translucent solar cells

A model glasshouse (width 3.0 m, length 2.0 m, height 2.6 m; Kinokawa, Wakayama, Japan) was set up to evaluate the energy characteristics of a sunlight combination-type plant factory equipped with TSCs. As shown in Figure 2, TSCs totaling 6 square meters were mounted on the roof of the model glasshouse. Six plate of TSC model KN38 (Taiyo Industrial Co., LTD., Osaka, Japan) were used in this study. KN38 is originally a kind of the TSCs for building use and has been used for the outer wall of Suwon City Labor Welfare Center in Korea. Since numerous narrow slits (0.1 mm width) are in the non-transparent amorphous silicon layer at intervals of 8 mm × 1 mm, the overall light transmittance is about 10%. The output characteristics in one unit of about 1 square meter are as follows; the maximum power voltage is 54.5 V, the maximum power current is 0.66 A, and the maximum power is 36 W. Thus, the electromotive force of the entire 6 square meter panel is calculated at 3.96 A, 54.5 V. In terms of crop cultivation, a light transmittance of 10% is quite low, but as this was a preliminary model and as the incident scattered light from the normal-glass sides of the glasshouse may also be used in photosynthesis, tests were carried out in this light transmittance for the time being. In addition to the slit TSCs used in the present study, other TSCs designs with fine pores in the amorphous silicon solar cell (Takeoka *et al*., 1993) or using an organic thin-film solar cell (light transmittance 50%) (Lin *et al*., 2012) have been developed, but these were not yet available at the time that the present glasshouse was designed.

We performed model studies on the relation between insolation and power output and other parameters. A set of sensors for measuring solar operating current, solar operating voltage, amount of solar radiation, ambient air temperature, and humidity was affixed to the glasshouse. Data from each respective sensor were acquired at 10-minute intervals and transmitted to a monitoring system via wireless LAN. Unfortunately, due to system malfunctions, we were able to obtain the data of a consecutive few days only in March, August,

November, and December in 2015. Despite this, however, we were able to establish approximate trends for the amount of power generated by the TSCs over one year.

2.2 Improvement of marketability of horticultural crops by monochromatic lighting

2.2.1 Improvement of flower color of spray-type chrysanthemum by UV irradiation

Following this, we investigated the effects of supplementary monochromatic lighting on horticultural crops' marketability. Our first subject of investigation was flower color improvement in spray-type chrysanthemums (*Chrysanthemum morifolium* Ramat.), a flower with a history of symbolism tied to Japan. Spray-type chrysanthemums, as shown in Figure 3, are a category of cut flower that are tufted and of medium size. Colors range from reddish colors (purple, red, pink) generated anthocyanin-related pigments, yellowish colors (yellow, cream) generated by carotenoid-related pigments, orange colors, generated by both pigments, and white, without either pigment. Anthocyanin have superior antioxidant function and so are sometimes accumulated at high concentrations in tissues to be protected, such as young leaves. Biosynthesis of anthocyanin is particularly induced with oxidative stress due to UV irradiation (Chalker-Scott, 1999, Zhou *et al*., 2007). In light of these findings, we considered that darker color in chrysanthemum flowers would be induced by

UV irradiation.

Figure 3. Spray-type chrysanthemum.

Preliminary studies in red, red-purple, and yellow chrysanthemum varieties showed that flower color darkens upon UV irradiation in only those varieties that owe their color to anthocyanin-related pigments (red and red purple). Change in flower color was not observed at all in yellow carotenoid-related color varieties (data not shown). From this, the present study was targeted at anthocyanin-related chrysanthemums and two experiments were conducted to clarify the timing and intensity of UV irradiation required to induce a change in flower color.

In the first experiment, UV light of various intensity was used to irradiate buds before blooming and flowers after blooming in order to observe changes in flower color. A pink chrysanthemum variety, 'Elite Pink', was used, and 50 flowers cut at time of shipping, when the top terminal flower was just flowering (before-blooming) or at 1 week before shipping (after blooming) were obtained from Kinosato Agricultural Cooperative (Kinokawa, Wakayama, Japan). Before UV irradiation, in the before-blooming plot, all already-opened flowers were excised to retain the buds only, and in the after-blooming plot, all buds and partially opened flowers were excised to retain the newly bloomed flowers only. Here, different UV intensity conditions were effected by placing cut flowers at various distances from a single blacklight (FL40SBLB; Toshiba Lighting & Technology Co., Yokosuka, Japan; wavelength 270–430 nm, peak wavelength 350 nm). The UV irradiation intensity of the high- and medium- intensity plots were four and two times that of the low-intensity plot, respectively. UV irradiation was performed for 3 h (4–7 AM) daily. Petal color was evaluated from day 3 to day 12 after beginning UV irradiation in the before-blooming plot, and from day 1 to day 12 after beginning irradiation in the after-blooming plot. Color evaluation was performed using a fiber multichannel spectrometer (USB-4000; Ocean Optics Inc., Dunedin, USA) and the light reflected off petals upon irradiation with a standard halogen lamp was analyzed spectroscopically. Red color index was evaluated by using the relative intensity of red (wavelength; 645 nm) against green (wavelength; 500 nm) in the reflected light.

Based on findings that UV irradiation of buds was effective in changing flower color, in the following experiment, we attempted to assess the most effective developmental stage for inducing color change in flowers with UV irradiation in order to explore whether more efficient use of UV light could reduce irradiation. In this experiment, we used a different, pink-colored chrysanthemum variety, 'Kyonkyon'. A total of 150 flowers cut 2 weeks before shipping were obtained from Kinosato Agricultural Cooperative.

We designed 6 experimental plots, which each received 4 consecutive days of UV irradiation beginning at either 6, 8, 10, 12, 14, or 16 days before blooming; additionally, a control plot that received no irradiation was established. Due to the shorter UV irradiation period compared to the previous experience, the irradiation intensity and exposure hours per day were increased. Irradiation intensity was doubled by using two of the aforementioned 40 W blacklights, and exposure hours per day was doubled to 6 hours per day; however, this time was divided into three 2-h periods (5–7 AM, 1–3 PM, 9–11 PM) due to concerns about tissue damage caused by continuous UV exposure. After 5 days of blooming, redness of petals was evaluated as in the previous experiment.

2.2.2 Accelerated flower formation in pea plants using red light

Our second subject of investigation is the acceleration of flower formation in garden peas (*Pisum sativum* L.). This variety of pea is the same species as green peas, but is eaten at a slightly more mature phase of development. In Japan, forced pea culture is practiced using incandescent lamps, allowing for harvest to occur from early spring to early summer. Earlier flower formation leads to earlier harvesting and shipment, as well as higher market value due to the ability to supply a savored spring vegetable to expectant consumers earlier in the season. Flower formation in plants is controlled by the length of the continuous dark period. When plants are exposure to light for a short duration during the night, the continuous dark period is interrupted and shortened, falsely creating conditions that mirror the arrival of spring. In the case of peas, this manipulation leads to flower formation. One red light receptor pigment, phytochrome, plays a principal role

in measurement of the length of the continuous dark period, and we therefore attempted to accelerate flower formation in peas by exposure to red light at nighttime.

In this experiment, we used two pea varieties, 'Kishu-usui' and 'Kinokagayaki'. 'Kinokagayaki' is an improved variety of 'Kishu-usui' developed for with earlier flower formation. An LED array (1200 × 600 mm) was established using 230 high-brightness Flux LEDs (CH-LB3B-2; Peace Co., Koshigaya, Japan; 645 nm) as the red light source. A series of test plots with different red light intensity was established by placing 8 parallel plant containers (700 × 300 mm) at various regularly spaced intervals from the array, with the closest at 1500 mm. A control plot was also placed in an unexposed location. A total of 8 pea seeds were planted in each container on October 28th, and days from seeding to first bloom was observed. All experimental plots were irradiated with red light for 3 h nightly (1–4 AM), resulting in a continuous dark period of less than 8 hours, which is even shorter than the dark period on the shortest night of the year, the summer solstice.

3. Result and Discussion

3.1 Power output measurement using a model glasshouse equipped with a translucent solar cell

Figure 4 shows the monthly insolation for an average year in Wakayama, Japan, and the estimated amount of power generation calculated based on this solar radiation and the standard parameters of the TSCs provided by the supplier. The maximum estimated monthly power generated was 20 kWh in August, and the minimum was 8 kWh in December. Figure 5 shows the diurnal variation in power generation measured during 4 consecutive days in August or December, 2015. The maximum value of power generated in one day reached about 40 W in summer and about 20 W in winter. Of course, power generated on cloudy and rainy days was lower than that generated on days with clear weather.

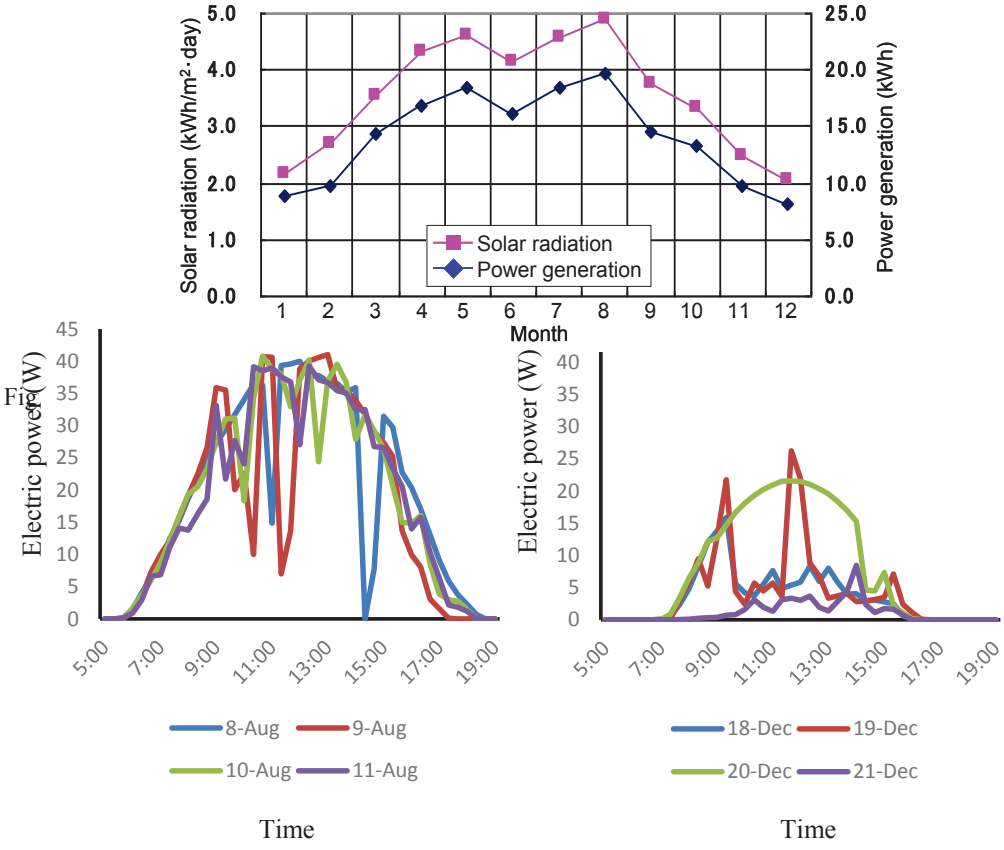

Figure 5. Diurnal variation of power obtained from TSCs at Kinokawa, Wakayama.

Table 1 shows the amount of global solar radiation and daily power generation measured for 2 or 4 consecutive days in March, August, November, and December, 2015. Global solar radiation shown is based on the public database of the regional meteorological observatory located closest to the experimental site, in Osaka, Japan (Japan meteorological agency website, http://www.data.jma.go.jp/gmd/risk/obsdl/). On a clear day, the amount of daily power generated was 0.827 kWh in summer (8 August) and 0.351 kWh in winter (20 December). On a cloudy/rainy day, daily power generated declined to as low as 0.051 kWh (21 December). Figure 6 shows the correlation of the amount of global solar radiation and the amount of daily power generation. The amount of daily power generation increased proportionately to the amount of global solar radiation. The conversion efficiency of the entire apparatus was calculated to be about 2%.

Table 1. Global solar radiation and daily power generation measured in continuous 2 or 4 days in March, August, November and December 2015.

Date	Global solar radiation (MJ/m^2・day)	Daily power generated (kWh)
28 March	22.80	0.618
29 March	4.49	0.120
8 August	23.96	0.827
9 August	25.78	0.760
10 August	22.74	0.821
11 August	23.30	0.813
13 November	5.13	0.131
14 November	3.24	0.080
15 November	7.12	0.192
16 November	13.10	0.401
18 December	6.16	0.149
19 December	8.42	0.183
20 December	11.34	0.351
21 December	2.20	0.051

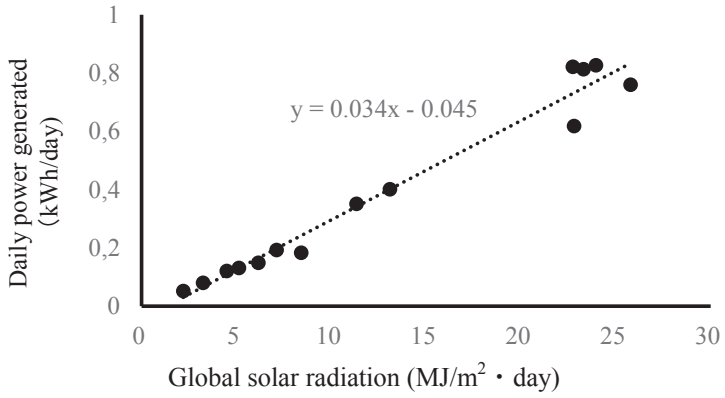

Figure 6. Correlation between the amount of global solar radiation and the amount of daily power generation.

3.2 Improvement of flower color in spray chrysanthemums by UV irradiation

Figure 7 shows the flower color of chrysanthemums subjected in various intensities of UV irradiation before or after blooming. For the group irradiated before blooming, the color of the high- and medium-intensity plots, but not the weak-intensity plot, was significantly more intense than that of the control plot. In contrast, in group irradiated after blooming, no significant differences in flower color were observed between any of the plots and the un-irradiated control. These results suggest that UV irradiation before blooming is necessary for induction of change in flower color in chrysanthemums.

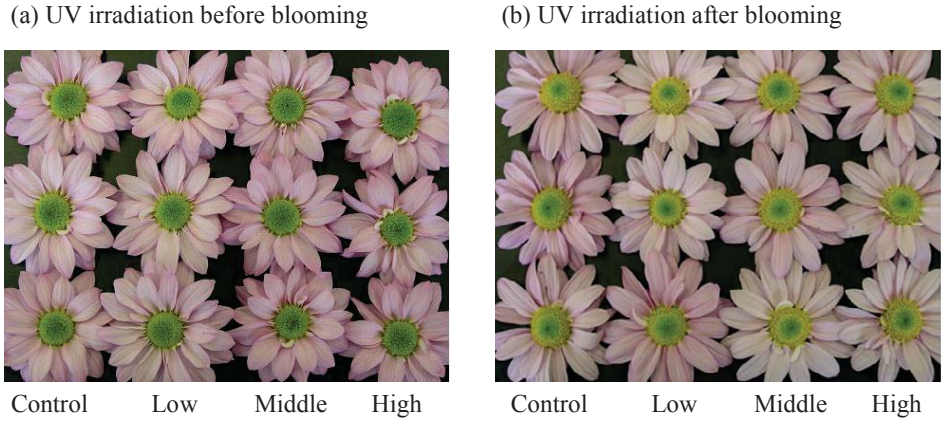

Figure 7. Flower color of chrysanthemums subjected to different intensities of UV irradiation before blooming (a) or after blooming (b).

In light of this result, we irradiated buds with UV light for 6 h/day for 4 consecutive days beginning between 19 and 6 days before blooming. Figure 8 shows the change in flower color in each plot. UV irradiation 13 to 10 days before blooming or 11 to 8 days before blooming resulted in significant change in flower color compared to the control plot. Taken together, this indicates that the period of 11 to 10 days before blooming, the overlapped period of these two plots, results in marked change in flower color. Because this period is equal to a few days prior to the general shipment time for cut flowers, it is economically preferable to perform UV irradiation for cut flowers harvested at a slightly earlier time than performing UV irradiation for an entire greenhouse.

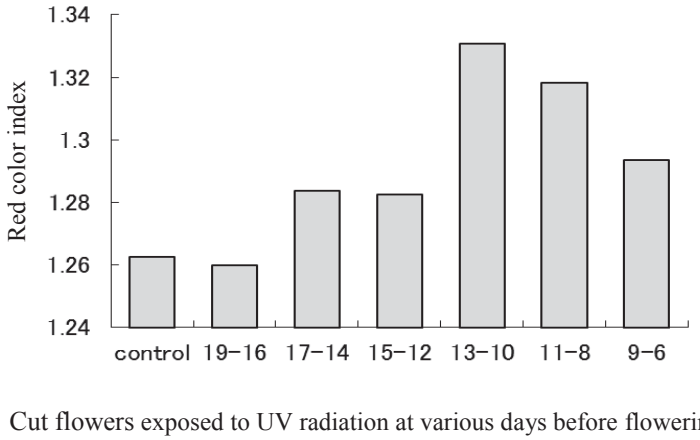

Figure 8. Flower color of chrysanthemums when buds were exposed to 4 days of UV irradiation at different developmental stages.

3.3 Accelerated flower formation in pea plants using red lighting

Figure 9 shows the effect the intensity of red light used for dark period interruption on the duration from seeding to blooming of the first flower cluster. In 'Kishu-usui', days to blooming was approximately 150 days in the control group, which was reduced by 10 days by dark period interruption. In 'Kinokagayaki', this reduction of the days to blooming in groups with dark period interruption was about 20 days. In both varieties, this reduction was maximized by irradiation intensity of 2 μmol/m^2/s, but no further effects were observed when the intensity increased beyond this point up to about 10 μmol/m^2/s. This suggests that the

minimum value of the red light intensity used in dark period interruption required to accelerate flower formation in peas is as low as 2 μmol/m^2/s.

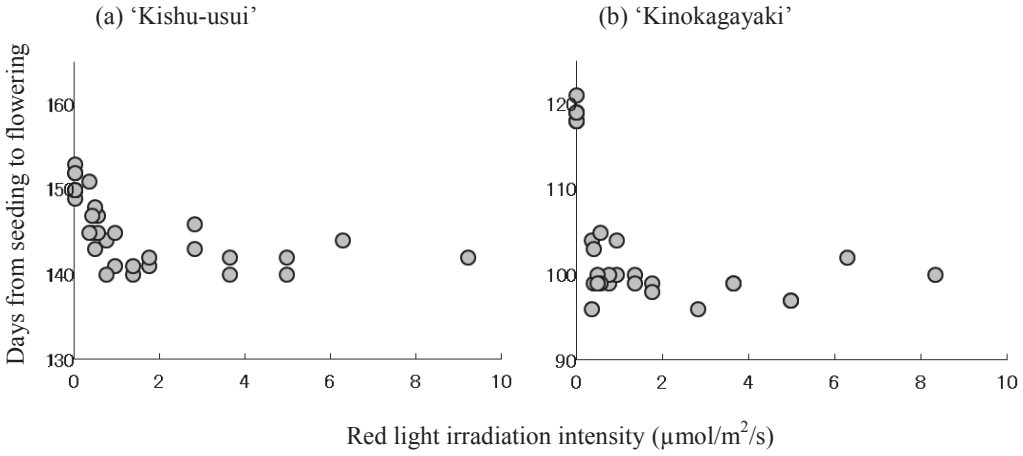

Figure 9. Effect of intensity of red light used for dark period interruption for promoting flowering in pea plants.

4. Conclusion

The power output of the model glasshouse equipped with TSCs, as investigated in 2015, was greatest on 8 August, at 0.827 kWh/day, and lowest in 21 December, at 0.051 kWh/day. In comparison, 0.240 kWh/day (40 W × 6 h/day) of electricity was used to induce chrysanthemum flower color change and 0.099 (33 W × 3 h/day) kWh/day was required to accelerate pea plant flower formation. Because we used a 40 W fluorescent tube (blacklight) with relatively high power consumption for chrysanthemum experiments, power consumption per day was as high as 0.240 kWh/day. However, since it was possible to narrow the irradiation period to only 4 days, the power supplied over multiple days would still be sufficient to power the lights for 4 days, even in winter, if appropriate energy-storage systems are available. For peas, we used daily irradiation consuming 0.099 kWh/day of electricity; however, as the required irradiation intensity necessary for acceleration was determined to be 2 μmol/m^2/s, the actual amount of electricity needed is estimated to be only 0.050 kWh/day. The present TSCs are capable of supplying this amount of electricity, and generally speaking, are fully capable of providing energy within this range.

The TSCs used in our study were amorphous solar cells with slits to give 10% transmittance; however, to grow healthy crops under TSCs, light transmittance of around 50% is desired. As stated by Lin *et al*. (2012), although TSCs with around 50% transmittance have been produced experimentally, their power generation performance is corresponding lowered as light transmission is increased. In the future, we must investigate the economic performance of our cultivation method when higher transmittance units are used.

The average amount of solar radiation in the plain part of Japan is about 1300 μmol/m^2/s. In contrast, up to about 800 μmol/m^2/s can only be used for photosynthesis of crops. Excessive solar radiation will increase leaf temperature, accelerate respiration, inhibit growth of the crop, and cause various obstacles due to production of active oxygen species. Therefore, in this study, we proposed to convert a part of excessive solar energy into electric energy by TSCs. And we expected to obtain some economic benefits by irradiating crops with red light that regulates the circadian rhythm of plants, or with ultraviolet light that induces the production of secondary metabolites. As a result of this study, we have shown that characteristics of horticultural crops can be changed by minute photostimulation of plants. The electricity required for these processes was obtainable from TSCs equipped within the cultivation facility. The marketability of products from sunlight combination-type plant factories can be expected to improve when these methods are used.

Forecasting Models for an Intelligent Use of Renewable Energy Based on the Prediction of PV Energy

Alexander-Nicolai Köhler[1], Markus Fischer[1] and Steven Lambeck[1]

[1]University of Applied Sciences Fulda, Fulda (Germany)

Abstract

Renewable energy has many advantages, such as low environmental impact and endless resources. However, there are also some disadvantages. For example, such energy can be highly weather-bound and therefore not always available. This sometimes makes it necessary to store this time-dependent energy. On the other hand, it would be ideal to adjust the power consumption to the power generation. Forecasting the produced energy in order to plan its use in advance is thus highly advantageous. In photovoltaic technology (PV), forecast-based operation is very helpful to both electricity suppliers and plant operators. It prevents both the unwanted load peaks and the economic losses of the system. In this paper, a mathematical forecasting model is presented and validated. The main focus is on the forecast of energy production with PV systems. Electrical load forecasts are not examined here.

Keywords: *forecasting models, prediction, PV energy*

1. Introduction

Renewable energy has many advantages, such as low environmental impact and endless resources. However, there are also some disadvantages. For example, such energy can be highly weather-bound and therefore not always available. This sometimes makes it necessary to store this time-dependent energy. On the other hand, it would be ideal to adjust the power consumption to the power generation. Forecasting the produced energy in order to plan its use in advance is thus highly advantageous. In photovoltaic technology (PV), forecast-based operation is very helpful to both electricity suppliers and plant operators. Through the rapid expansion of PV and the fluctuating amount of electricity, the existing electricity network increasingly pushes its limits. To avoid damaging power peaks in the electricity network, various laws to limit the maximum feed-in capacity and to regulate the expansion of PV systems have been agreed upon in Germany. The operator of plants for generating electricity with PV are obliged to operate in accordance with feed-in management regulations or to limit the maximum active power feed to 70 percent of the installed capacity at the network transfer point. (EEG, 2014) Limiting the output means economic losses for the plant operator. This could be avoided by a forecast-based operating method of the PV system. Thus the energy consumption of the produced energy can be tracked by PV forecasts and suitable activation of electric loads. This prevents both the unwanted load peaks and the economic losses of the system. The basis for forecast-based operations are particular methods of predicting the PV production in order to plan the usage of the generated energy better. In this paper, a mathematical forecasting model is presented and validated. The main focus is on the forecast of energy production with PV systems. Electrical load forecasts are not examined here.

2. Forecasting methods

A forecast is defined as a statement about one or more events, conditions or developments in the future, based on information in the past (Theil, 1966). This information is usually in the form of time series, which are needed to calculate future values of the process (Schlittgen, 2001). Forecasts of load profiles of energy

doi:10.18086/eurosun.2016.08.04 Available at http://proceedings.ises.org

consumption and power generation are very important in the energy sector. Because the production and consumption of energy in the electricity grid have to be in balance at all times, forecasting methods are used to predict the energy consumption.

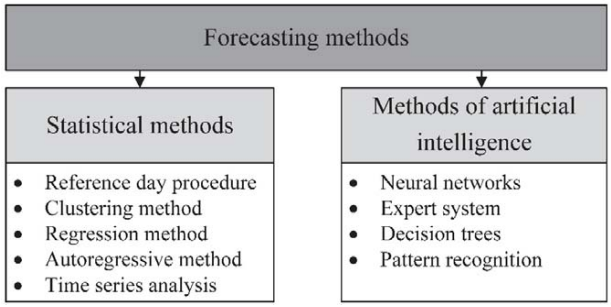

Fig. 1: Overview of typical forecasting methods

As shown in Figure 1, there are two typical types of forecasting methods. Statistical methods use mathematical combinations of historical data combined with information on the influencing variables to predict the behavior of consumers. However, if, due to the lack of information about influencing factors, no expedient prediction can be made, it could be helpful to use methods of artificial intelligence. Some artificial intelligence processes involve learning patterns of behavior with the help of historical data and project these patterns as a function of the expected operating conditions into the future. To select the optimal forecasting method for a particular application, it is also important to look for the required time horizon of the forecast. Short-term forecasts (forecast horizon of one day) can be created on the basis of measurements and current data. In contrast to long-term forecasts (forecast horizon of several months), mostly methods of artificial intelligence are used. These learn the different patterns of behavior based on historical data and project them into the future. Various forecasting methods can work differently depending on the influencing factors, such as climate or weather. Because of this, combined or cascaded models are increasingly used. Each of them operate for certain input variables and complement each other. A combination of different methods for a forecast can improve accuracy. (Prokhorova and Heimel, 2013)

3. Forecast of the PV capacity

The production of energy with a PV system is, in contrast to the electric load profile of a building, not affected by stochastic factors and can be described mathematically. A forecast of PV capacity can be done on the basis of weather forecasts and the characteristics of the PV system (type of assembly, module orientation, location, ...). The output of the generating PV system depends mainly on the available solar radiation at the place of installation, the installed modules and the efficiency of the inverter. The necessary basics for the calculation of the solar radiation range and the related performance calculation will be explained in the following sections with reference to Quaschning, 2015, Blank, 2005 and Schumacher, 2005.

3.1. Global radiation

The extra-terrestrial irradiance E_e varies due to the non-constant distance between sun and earth, which is between 1321 $\frac{W}{m^2}$ and 1412 $\frac{W}{m^2}$. Therefore, methods for the calculation must be chosen with care. An exact calculation of E_e is possible via the factor of eccentricity E_0, which can be determined by Duffie/Beckmann (Baehr and Stephan, 1994). The extraterrestrial irradiance is reduced by various influences as it passes through the earth's atmosphere. The horizontal extra-terrestrial irradiance $E_{e,hor}$ is reduced by the terrestrial atmosphere because of

- reduction by reflection at the atmosphere
- reduction by absorption of the atmosphere,
- reduction by Rayleigh scattering,
- reduction by Mie scattering.

All these influences can be analyzed though the transmittance τ. Determining the size of the influences is usually difficult, so it is possible to substitute the influences with a factor of the clearness index k_T. This is the ratio of the global irradiance $E_{G,hor}$ and the extra-terrestrial irradiance parallel to the surface of the earth $E_{E,hor}$.

The light on the surface of the earth is composed of a direct radiation component and a diffuse radiation component. Direct radiation $H_{dir,hor}$ comes directly from the sun and strikes in a certain point. The diffuse radiation $H_{diff,hor}$ is caused by scattering and reflection in the atmosphere and reaches a certain point indirectly. The sum of direct and diffuse radiation results the global radiation $H_{G,hor}$.

3.2. Calculation of the solar altitude

The current position of the sun, which is relevant for many calculations, can be determined for any place on earth. For this determination, two angles, the sun height γ_S and the solar azimuth α_S, are needed. According to DIN5043, the height of the sun is defined as the angle between the center of the sun and the horizon from the observer's perspective. The solar azimuth is the angle between geographic north direction and the vertical circle by the center of the sun (Fig. 2a).

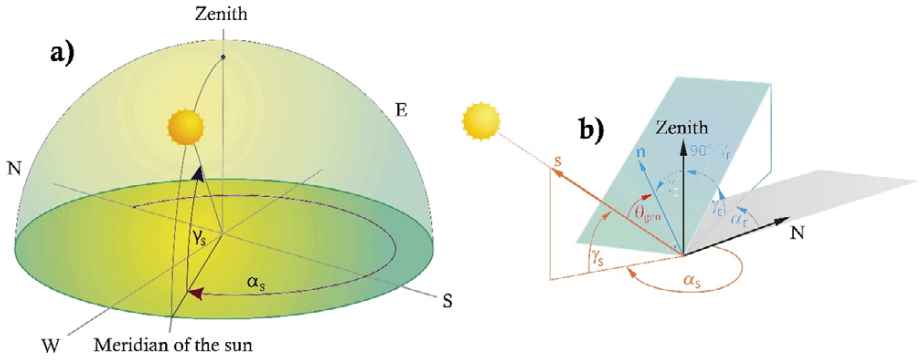

Fig. 2: Overview of typical forecasting methods (Figures based on Quaschning, 2011)

The height of the sun and the sun's azimuth also depend on date and time. The angle between the center of the sun and the celestial equator, also known as the solar declination δ, is an important variable. The position of the sun can be calculated with various algorithms. Some examples are SUNAE (Walraven, 1978), SOLPOS and SPA (Reda, 2008). In this paper, a method according to DIN 5034-2 is used to calculate the position of the sun. For each given point in time, it yields the height of the sun and the azimuth as a function of longitude λ and latitude φ.

To calculate the angle of incidence θ_{gen} at an oblique plane, the angle of inclination γ_E and the angle of rotation α_E is needed (Fig. 2b). Depending on the orientation of the generator surface and the angle of incidence of the sun, it is possible to calculate the direct radiation θ_{gen} on the PV modules. For this, the direction of irradiation $\vec{s}$ and the normal vector $\vec{n}$ of the surface are determined. The angle of incidence θ_{gen} can be calculated on the dot product of the two vectors $\vec{s}$ and $\vec{n}$. For detailed information, please refer to Fischer, 2016.

3.3. Radiation on oblique and aligned surfaces

The global irradiance $E_{G,gen}$ on an oblique plane is composed of a direct, a diffuse and a reflective component:

$$E_{G,gen} = E_{dir,\mathrm{gen}} + E_{diff,gen} + E_{refl,gen} \qquad \text{(eq. 1)}$$

Because it is a geometric problem, the determination of the direct irradiance $E_{dir,gen}$ on the oblique plane can be solved mathematically based only on the sun. The direct irradiance can be determined on the geometric relationships below (Fig. 2b), where $E_{dir,\mathrm{hor}}$ is the direct horizontal irradiance:

$$E_{dir,\mathrm{gen}} = E_{dir,\mathrm{hor}} \cdot \frac{cos\theta_{gen}}{sin\gamma_S} \qquad \text{(eq. 2)}$$

The calculation of the diffuse irradiance $E_{diff,gen}$ on an oblique plane differentiates between an isotropic and anisotropic approach. The isotropic approach means that there is always the same proportion of sky radiation in all directions. The radiance is neglected. For an exact calculation, the anisotropic approach is needed, because the radiance, especially in a clear sky, is very different. For this, Temps and Coulson, 1977, Klucher 1979 and Perez, 1987 proposed some calculation models. Temps/Coulson's anisotropic radiation model for a clear sky was expanded by Kulcher, who introduced the weather factor F_K for general sky conditions. Several studies, such as Jakhrani, 2016, show that this model provides good results when calculating diffuse irradiation. Therefore, the calculation of the radiation components is based on the Temps/Coulson/Klucher model.

The reflected radiation $E_{refl,gen}$ of the ground depends on the reflectivity of the surface and can be determined by using the albedo value A. The albedo value describes the reflectivity of the surface, which depends on its texture. Blank, 2005 provides an overview of different albedo values.

3.4. Calculation of performance

The performance of PV modules is specified in watt peak (Wp). This is achieved under standard test conditions (STC) and corresponds to the rated output of a module. The STCs are defined by DIN EN 60904-3 and correspond to an irradiance of $1000\frac{W}{m^2}$ and a module temperature of 25°C. Under normal conditions, the specified power value is rarely achieved in Germany. Despite this, it can sometimes be exceeded. How high the power value depends on the method of installation, module temperature, season and ambient temperature. The influence of the spectral distribution of light and the reduction in performance by shadowing and pollution is neglected in the model.

Deviation of the temperature is a crucial factor. If it deviates from STC, the performance will vary. The temperature coefficient that describes the deviation of the STC is about $-0.43\frac{\%}{K}$ on current PV modules (Fischer, 2016).

The dimensions of a PV system a usually chosen so that the nominal DC output is higher than the nominal AC output. This is common because the theoretical generator power under (STC) is achieved only a few days of a year. In addition, system losses like cable resistances between modules and inverters have to be taken into account. Because of this, it is common to make the power of the inverter smaller than the power of the generator.

4. Verification of the forecast

In order to verify the forecasts of the PV simulation program, the comparison of the results with measurements of real systems is necessary. In this case, the measurements are from a conventional single-family house in the center of Germany. In the following, the results of the PV forecast are compared with the real measurements and the results achieved are evaluated.

The weather data "global radiation" and "temperature" required for the simulation are available at local weather stations that are provided by Weather Underground, 2016. In each case, a summer and a winter day are used to compare simulation and measurements of the PV system. A disadvantage is that there are no forecast data for global radiation and temperature for the periods in which measurements of PV systems are available. Instead of this, the actual weather data is used in each case.

The measurement (measuring station 1) of the global radiation takes place very close to the aforementioned building. This provides an optimum condition for the verification of the PV forecasting model. The data can be measured in the immediate vicinity of the generator field and thus represent the global radiation that exists near the generator field.

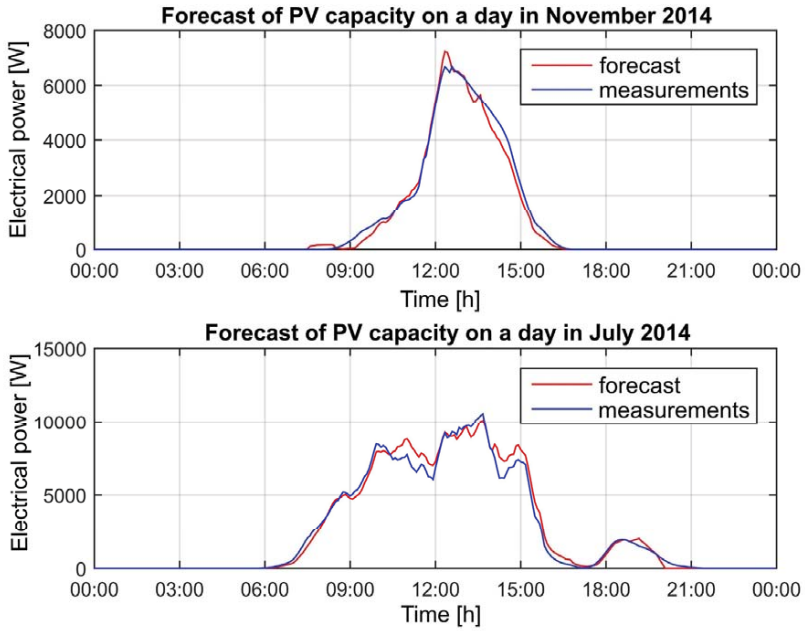

Fig. 3: Comparison between simulation and measurements on two days

Figure 3 shows the results of the forecast for a winter day (top) and a summer day (bottom) compared to the measured power values of the PV system. It can be seen that the calculated forecasts and the measured power curve correspond closely. The basic course of the calculated curve corresponds to the measured curve. Since the global radiation measurements were taken immediate vicinity of the PV system, it can be concluded that the existing minor forecast errors are caused by the calculation model or inaccurate measurements.

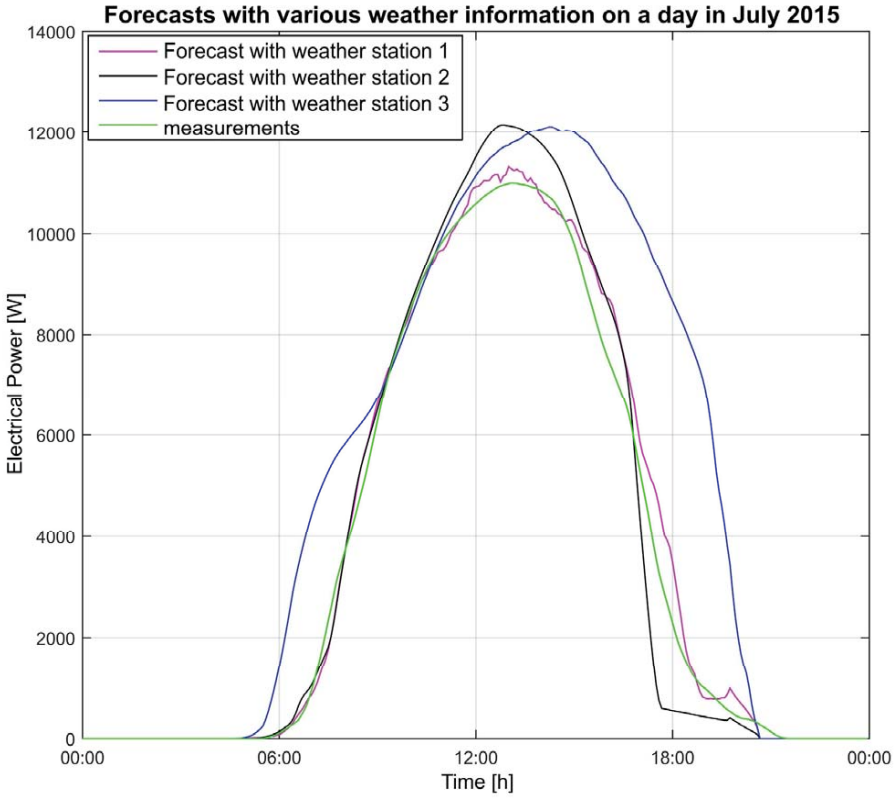

Fig. 4: Comparison between different forecasts depending on different weather stations

The above forecast with weather data from three different stations is useful for investigating the effects of the global radiation values on the forecast result. Figure 4 shows the measured curve of the power (green), and the forecasts based on the measurements of station 1 (magenta), station 2 (black) and station 3 (blue). It can be seen that the power curve of the forecast based on the measurements of station 1 is best predicted. The influence of the global radiation on the forecast results are clearly recognizable in the different weather stations. If the station is further away from the PV system, the differences between the measurements and the forecast are larger.

5. Conclusion and prospect

Due to the verification of the forecast model with data from the immediate vicinity of the PV system, it can be seen that the power curve of the PV system can be accurately predicted if the measurements and forecast data are of equivalent quality. The simulation program developed for the current paper makes it possible to predict the power of a PV system for a day with sufficient accuracy. In a near-optimal forecast, only negligible differences occur between forecast and real value. The simulations of a real pilot house at various summer and winter days clearly show that the forecasting model is highly dependent on the global radiation or temperature data.

Deviations between the forecast data and real measurement can be explained by simplifications in the calculation model, the neglect of shading losses and pollution and measurement inaccuracies. However, these deviations were not significant and the forecasting model is sufficient for the scope and requirements of this paper. Furthermore, since the input for and characteristics of a PV system are variable, a flexible and universal forecasting model such as the one developed for the current paper is also necessary and appropriate in other contexts and will be used in a further paper in conjunction with forecast data of global radiation and temperature.

Heat Pump System Performance with PV System Adapted Control

Tomas Matuška [1,2], Jan Sedlář[1], Bořivoj Šourek[1]

[1] University Centre for Energy Efficient Buildings, Czech Technical University in Prague

[2] Faculty of Mechanical Engineering, Czech Technical University in Prague

Abstract

Combination of heat pumps with PV systems could significantly reduce the use of grid electricity from external supplier for space heating and hot water application. The paper presents an analysis of using PV adapted control for heat pump operation in two different alternatives and compares such advanced approach with conventional static approach. Both alternatives of the adapted control for the heat pump system achieve high solar fraction about 39 % compared to conventional approach (16 %) and more than 30 % higher seasonal performance factors.

Keywords: *heat pump, PV system, adapted operation*

1. Introduction

There is a number of measures to increase the energy performance of modern buildings today. Space heating demand has been minimized to limits of technical and economical possibilities in case of passive houses (envelope insulation, triple glazings, ventilation heat recovery, etc.). Domestic hot water systems use energy saving showers, insulation of hot water piping, time and temperature control of hot water circulation run, etc. Further savings can be expected with use of heat recovery from waste water. Electricity demand has been continuously reduced with an introduction of appliances with energy class A and better and implementation of modern daylighting principles together with proper control of LED artificial lighting.

Logical step ahead to decrease the energy demand in buildings is application of renewable energy sources. Heat pumps use the renewable energy from ambient environment, however they also need grid electricity to valorise the renewable heat to useful temperature level for space heating and hot water preparation. Grid electricity in Europe in general has high primary energy conversion factors (Molenbroek, 2011) dependent on the share of renewables in the grid in each country. The grid electricity in Czech Republic originates from non-renewable fuels (brown coal and nuclear power plants) which disqualifies the use of such electricity in heating applications within the frame of building certification. Simultaneously, the associated high CO_2 emission factor for electricity (Ecometrica, 2011) has a direct impact on the environmental assessment of the heating systems in subsidy schemes. Both implications lead to the effort of minimizing grid electricity use as an energy carrier for space heating and hot water preparation, despite the fact that costs of electric heating systems are the lowest.

Current trend in increasing the effectiveness of electricity use by the heat pumps is complemented by local production of renewable electricity by PV systems. The supply of local electricity production to a public grid has been complicated in several countries already (huge administration, negligible feed-in tariffs) and new installations are focused on the local use of renewable electricity from PV systems integrated into buildings. Production of electricity by PV systems and use of electricity by heat pumps seems to be an ideal combination to significantly reduce the external supply of electricity from public grid for space heating and hot water systems (IEA, 2014). However, the reality is not that simple as can be evident on first sight. The paper shows the potential of conventional state-of-art heat pump systems to use local PV electricity to increase the effectiveness of space heating and hot water preparation.

2. Family house

Energy efficient family house under construction (2016) has been chosen for an analysis of potential to combine the heat pump and PV system under climate of Czech Republic. Family house has two floors with a space volume of 935 m^3 and total living floor area 190 m^2. Family house has a passive house concept, *U*-values of individual envelope constructions meet the recommended values for such high performance buildings. Saddle roof has a slope of 40° with south-north orientation. Design heat loss of the house is 4.5 kW. Low temperature floor space heating system has been used with design flow/return water temperatures 40/35 °C. Ventilation is provided by air handling unit with maximum flowrate 275 m^3/h using a heat recovery.

Ground source heat pump unit has been designed for the heat supply to house. Investor considered the PV system installation to increase the energy independency of the house operation. Analysis of different size of PV system and different control of heat pump operation has been performed by computer simulation to provide maximum use of electricity production from PV system to cover the heat pump needs and thus to minimize external supply from public grid. System simulations have been performed in TRNSYS with use of detailed mathematical models of building (type56), storage tank (type340) and heat pump (type250) with a borehole (type451). Simulation has been performed with time step of 2 minutes to evaluate the match between the the electricity load by heat pump and electricity production by PV system properly. Two subsequent identical years of system operation have been simulated to provide the balance in the ground source, only second year has been used for evaluation.

3. Conventional static approach

Conventional solution for the improvement of energy effectivity for heat supply in considered passive house has been based on combination of ground source heat pump of capacity 5.5 kW without speed control and PV system. PV system has been considered in different alternatives of installed nominal power without any advanced system control to adapt the operation of the heat pump according to available PV production. Heat pump is hydraulically connected to combined water storage tank with volume 900 l. Bottom part of the storage is connected to space heating system (SH zone) and is charged to required flow temperature according to outside air temperature (OTC control). Storage tank involves the integrated tube heat exchanger with surface area 6 m^2 for hot water preparation. Top part of the storage tank is dedicated to water heating (HW zone) and maintained at required temperature at minimum required set-point the whole year.

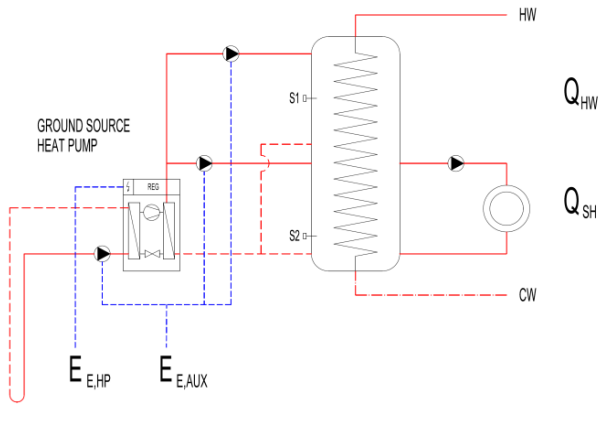

Fig. 1: Scheme of the conventional ground source heat pump system

The heat pump system delivers 3429 kWh/a of heat for space heating and 3063 kWh/a of heat for hot water to satisfy the energy demand of house. The heat loss of the storage tank amounts more than 550 kWh/a which degrades the performance of the whole system. Electricity use of the heat pump system is 2446 kWh/a, i.e. system seasonal performance factor *SPF* is 2.7. This is a value common for heat pump applications in passive houses because annual effectiveness is significantly influenced by high ratio of hot water preparation demand (47 % in given case) to be supplied at high required temperature 45 °C at any part of the year. Such temperature available at integrated heat exchanger output results in hot water set-point for HW zone permanently 55 °C.

Improvement of the system performance could be achieved by a combination with PV system. The PV electricity production can partially cover electricity use of the heat pump system. Tab. 1 presents the results of computer simulation in TRNSYS for different alternatives of PV system size: 1 kW_p, 3 kW_p and 6 kW_p. Except the grid electricity use and *SPF* the parameters monitored and evaluated were solar fraction f_{PV} (coverage of electricity use by PV system) and degree of PV electricity utilization r_{PV} (ratio of used PV electricity to produced PV electricity). The results show that installation of PV system slightly improves the total effectiveness of heat supply, however utilization of PV electricity is very low, at level of several percents. The explanation can be shown in two profiles of the electricity load and production including the temperatures in the storage tank for two typical weeks, first for summer season (see Fig. 2) and second for winter season (see Fig. 3).

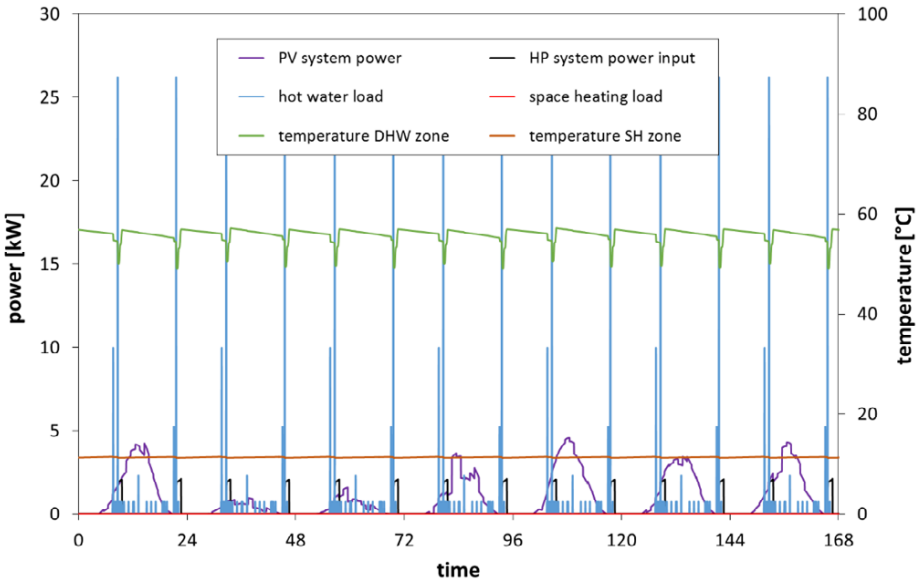

Fig. 2: Production and load profile of the conventional PV heat pump system in summer (6 kW_p)

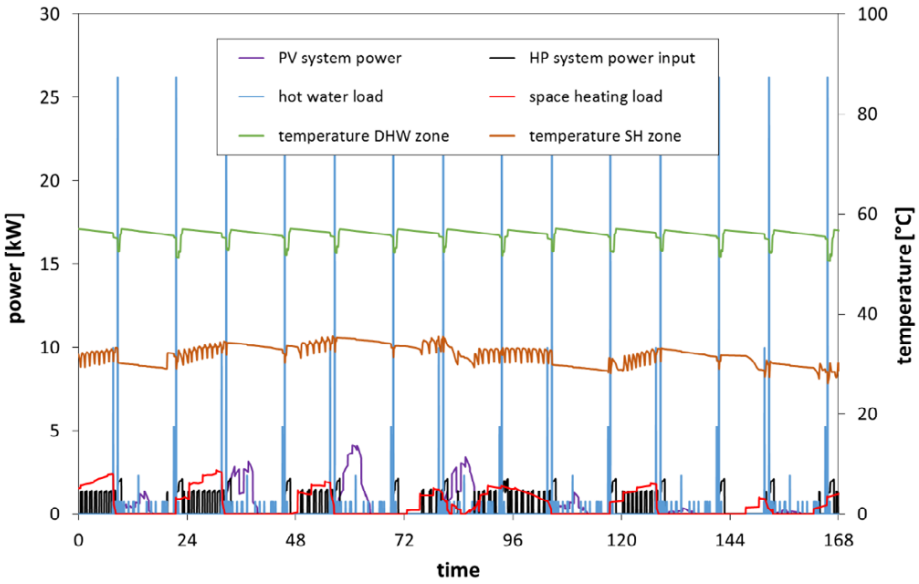

Fig. 3: Production and load profile of the conventional PV heat pump system in winter (6 kW_p)

As shown in Fig. 2 for summer season, the heat pump starts and uses electricity if temperature in HW zone decreases due to hot water load. Hot water load has the morning peak and the evening peak. Match between time of PV electricity production and electricity load by heat pump happens only partially during the HW zone

charging by heat pump after morning peak of hot water load (in optimum case).

Tab. 1: Results of TRNSYS simulation of PV heat pump system with conventional approach

Parameter	Reference alternative (no PV)	Alternative 1 kW_p (4 modules)	Alternative 3 kW_p (12 modules)	Alternative 6 kW_p (24 modules)
Electricity from grid W_{el} [kWh/a]	2446	2370	2217	2061
System *SPF* [-]	2.7	2.7	2.9	3.1
Solar fraction f_{PV} [%]	-	3	9	16
PV utilization r_{PV} [%]	-	8	8	6

From the point of the match between heat pump electric load and PV system electricity production (see Fig. 3) the situation is not more favourable in winter. Heat pump for space heating starts and uses electricity if temperature in SH zone decreases due to space heating load. The space heating in passive house occurs practically only during the night because the heat loss of the passive house is effectively compensated by solar heat gains during the day. Morning and evening hot water peak loads occur mostly within the time periods with no PV production.

4. Advanced approach – PV adapted operation of heat pump

An adaptation of heat pump operation to time period of PV system production ca be used in order to increase the utilization of PV electricity to cover heat pump electricity use. If the PV system actual power overcomes at given time a certain power threshold, algorithm of the system controller shifts the set-point for charging the storage tank and thus forces the heat pump to start. It practically means that in case of sufficient PV electricity production the heat pump is started, heats up the defined volume of storage tank to higher temperature than the required set-point (zone overcharging). The heat produced by the heat pump is stored in the combined storage tank for later use. The question of optimization process is the value of the power threshold for adapted operation of the heat pump system to minimize the annual electricity demand of the system. There were two alternatives for the control by set-point shift considered:

- PV-HW – alternative where the control shifts the required temperature 55 °C to 60 °C (considering the temperature limit of the heat pump) in the hot water zone of storage tank and sensor S3 is used as relevant temperature sensor (see Fig. 4 left) to enlarge the heated volume of the HW zone in storage tank;
- PV-SH – alternative where the control shifts the required temperature to 50 °C in the space heating zone of storage tank (see Fig. 4 right).

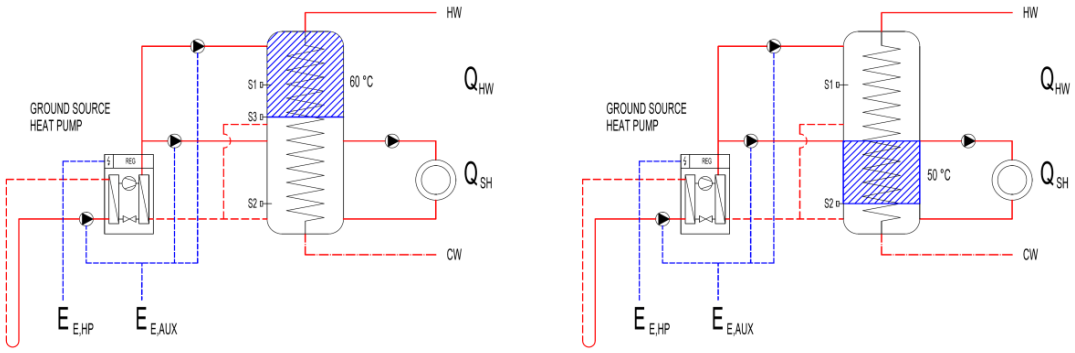

Fig. 4: Alternatives of adaptive control for heat pump system: PV-HW (left) and PV-SH (right)

To find an optimum power threshold for both adapted control alternatives a parametric analysis has been

performed. The results are shown in Fig. 5 and Fig. 6. While the system power input in regime of overheating the storage to high temperatures 50 to 60 °C overcomes the value of 2 kW, the optimum threshold found for both alternatives ranges around 1.0 kW for 3 kW_p PV system and around 1.25 kW for 6 kW_p PV system. Analysis for PV system with installed power 1 kW_p wasn't considered.

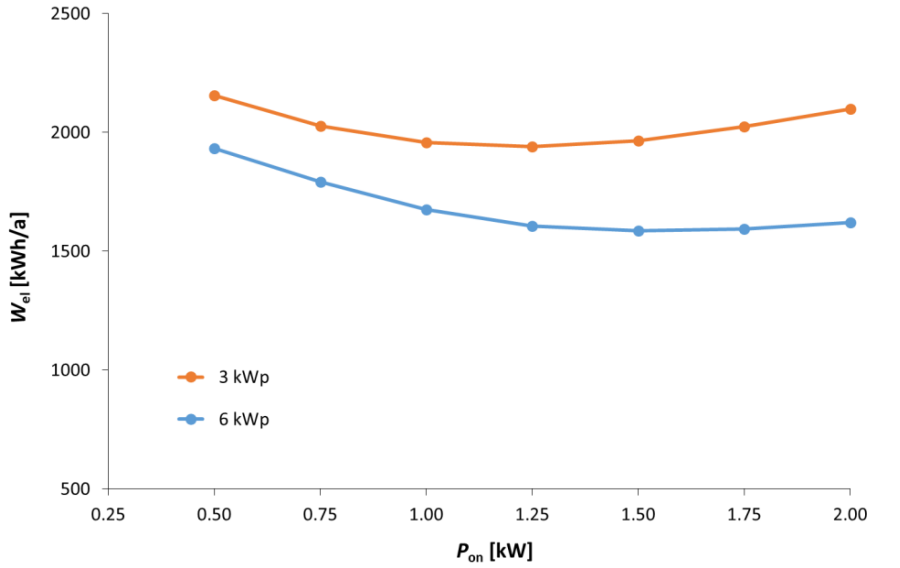

Fig. 5: Optimum value of power threshold for alternative PV-HW

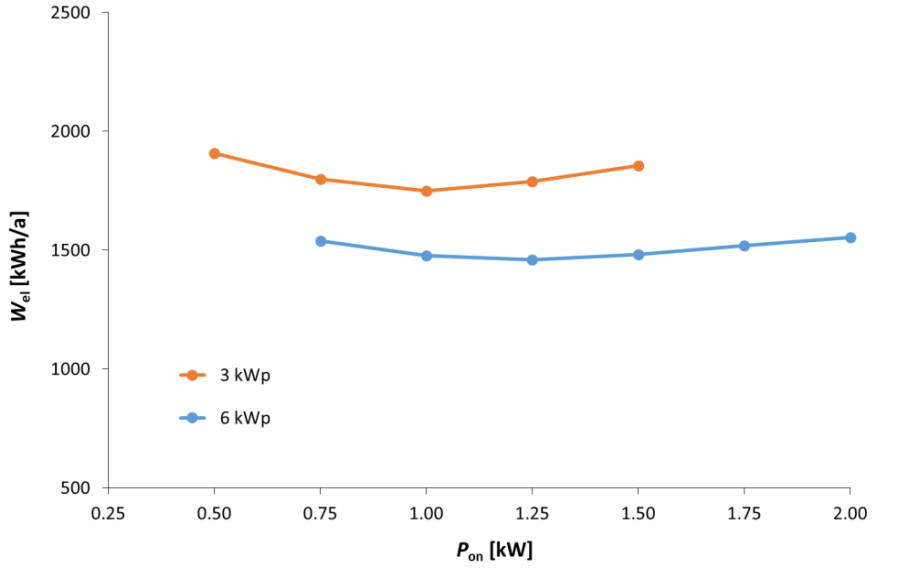

Fig. 6: Optimum value of power threshold for alternative PV-SH

Results of simulations with optimized thresholds are presented in Tab. 2 for both alternatives of the adaptive control and PV systems with nominal power 3 kW_p and 6 kW_p. Fig. 7 and 8 shows the profile of the electricity load and production, including the temperatures in the storage tank for adaptive system alternative PV-HW in the identical two typical weeks as it has been shown for reference system with PV system of nominal power 6 kW_p. Compared to the reference (shown in Fig. 2), there is obvious shift of heat pump operation to the daytime with PV electricity production due to adaptive control in summer season (see Fig. 7). Increased temperature and larger heated volume has a direct consequence that despite the evening and morning hot water peak load from the storage, the temperature in the HW zone of the storage (required temperature sensor) doesn´t decrease under the standard set-point value and the heat pump doesn´t start out of the daytime. Only the days without available power of PV system sufficient to forced starting the heat pump show the decrease

of required temperature in the HW zone in the evening hours and operation of the heat pump consuming the grid electricity. Similar function can be seen within the winter season (see Fig. 8 and compare it with Fig. 3), but with respect to lower PV system production the charging of HW zone in the storage tank to higher temperatures is not so frequent.

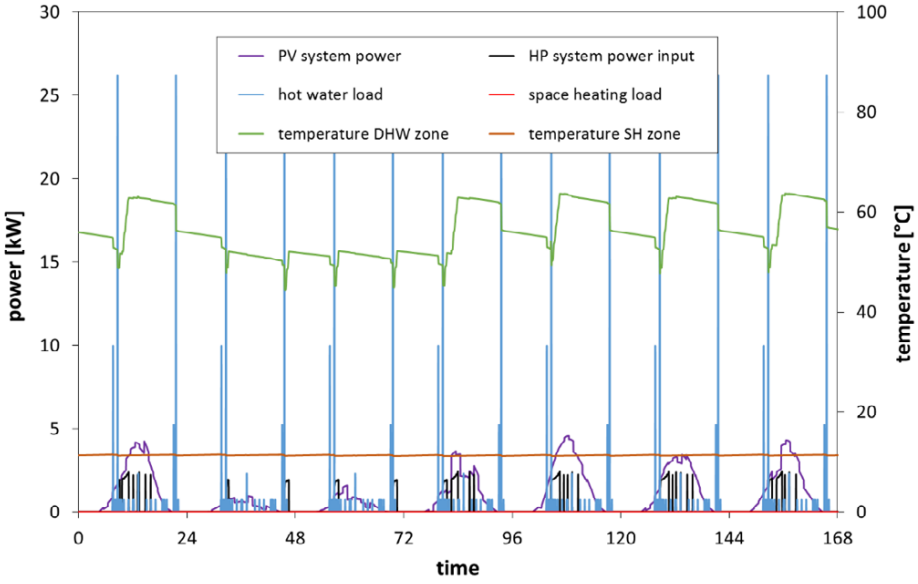

Fig. 7: Production and load profile of the PV heat pump system in summer (6 kW_p) – alternative PV-HW

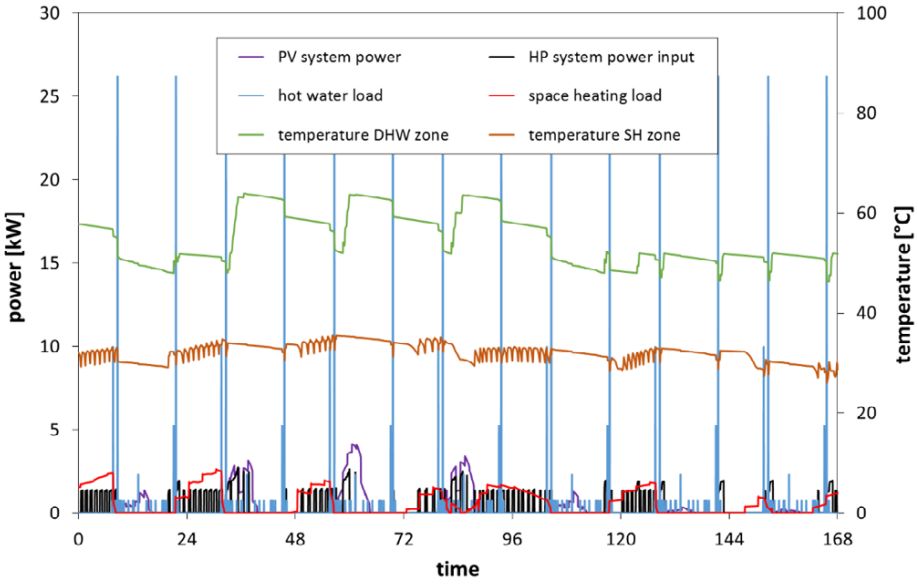

Fig. 8: Production and load profile of the PV heat pump system in winter (6 kW_p) – alternative PV-HW

Similar trend in system operation can be monitored also in adaptive control alternative PV-SH. Heat pump charges the SH zone of the storage tank to 50 °C whole year if the sufficient PV power is available. Hot water is preheated by integrated tube heat exchanger already in the SH zone. Therefore the temperature in HW zone doesn´t decrease significantly during the hot water loads (see Fig. 9 and 10). A very detailed comparison is shown in Fig. 11 where the PV system power and electric power input of the system for selected sunny winter day are presented for a conventional alternative without adaptation (above) and for PV-SH alternative with adapted control (below). Use of the PV electricity for overcharging of the storage tank by heat pump can shift significant amount of "night demand" of grid electricity to daytime and cover it from PV system. Temperatures shown in graphs belongs to temperature sensors positions dedicated to control of storage tank charging in both

zones (HW, SH).

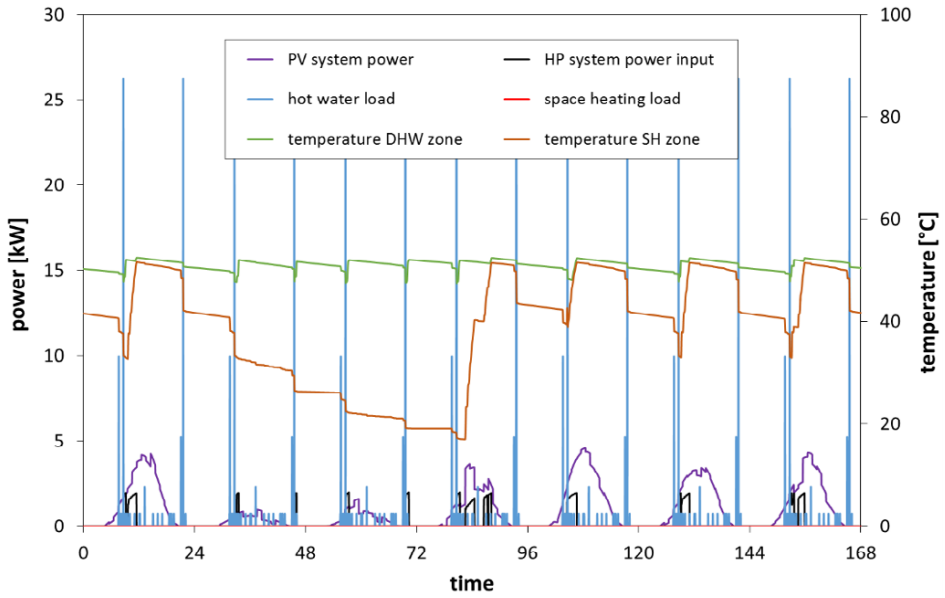

Fig. 9: Production and load profile of the PV heat pump system in summer (6 kW_p) – alternative PV-SH

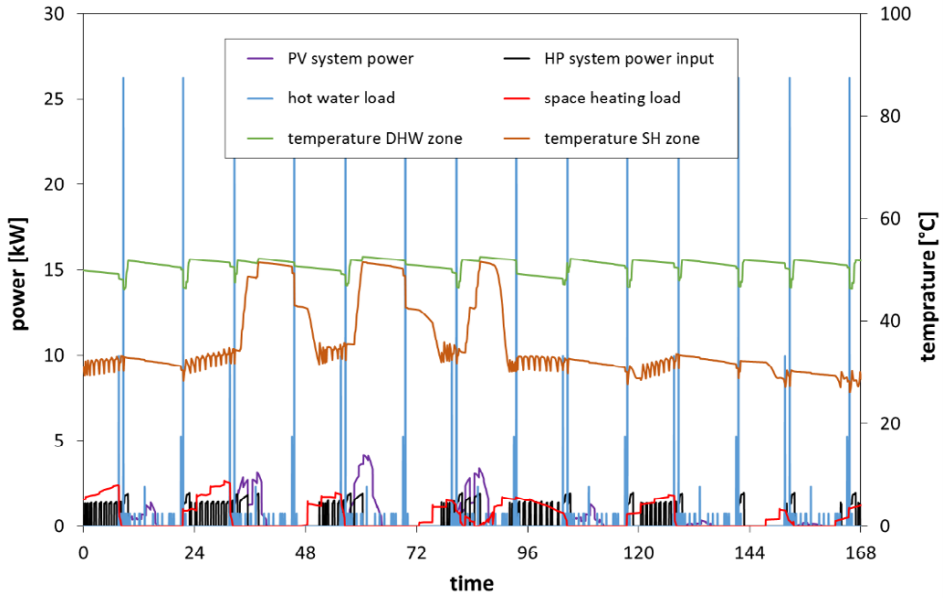

Fig. 10: Production and load profile of the PV heat pump system in winter (6 kW_p) – alternative PV-SH

Tab. 2: Results of TRNSYS simulation of PV heat pump system with adaptive control

Parameter	Alternative PV-HW		Alternative PV-SH	
	3 kW_p	6 kW_p	3 kW_p	6 kW_p
Electricity from grid W_{el} [kWh/a]	1941	1586	1749	1459
System *SPF* [-]	3.3	4.1	3.7	4.4
Solar fraction f_{PV} [%]	26	41	32	44
PV utilization r_{PV} [%]	22	19	27	19

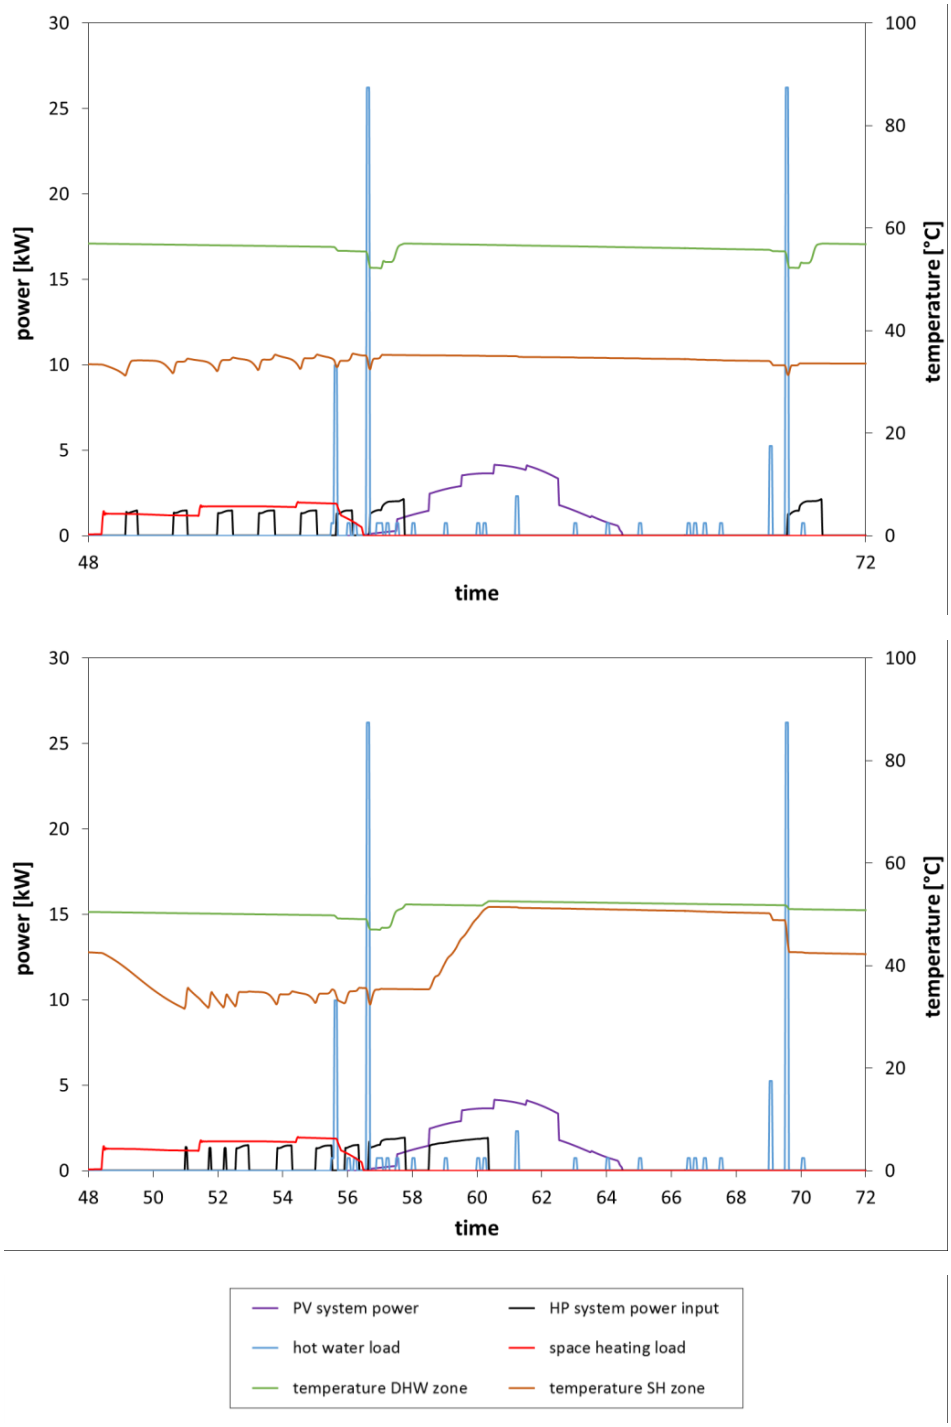

Fig. 11: Detailed comparison of production and load profile of the PV heat pump system in winter for conventional alternative and adapted PV-SH alternative (6 kW_p)

Computer simulations have shown that both alternatives of adapted control can significantly reduce the grid electricity use of heat pump system combined with PV system. The alternative PV-SH with overcharging the SH zone of the storage tank is more favourable thanks to lower annual use of grid electricity and higher seasonal performance factor *SPF* of the system for both PV systems with installed power 3 kW_p and 6 kW_p. Heat pump system alone works more effectively in time of using PV electricity due to charging the storage volume to lower temperature (50 °C) and finally the larger volume of the storage tank which is charged due to natural convection too.

5. Conclusions

Paper has indicated possibility of combination of heat pump and PV system by means of advanced adaptive control which already appears on the market. Computer simulation in TRNSYS has shown the benefits in energy performance of the PV heat pump systems for space heating and domestic hot water preparation. Simple adaptive control allows a significant increase in solar PV fraction and reduction of grid electricity use when compared with static control of conventional system. I has been shown that power threshold for adapted operation of heat pump to PV system lies significantly lower than maximum power input of the system. PV-SH control alternative with overcharging of space heating zone in storage tank has shown better results for the energy performance of the system at conditions of given passive house than alternative with overcharging of the hot water zone.

Abstract

Solar PV cells may be mainly divided into two parts as crystalline and thin film. Mono-crystalline silicon (e.g. Mono-Si) and microcrystalline based amorphous silicon and other thin films (e.g. µc-Si/a-Si and CdTe thin films) are widely used PV cells in the arrays. The outdoor performances of these systems depend on some climatic parameters and conditions, and it is important to understand how the monthly efficiencies vary with these parameters. In the present study, the data obtained from three grid connected PV arrays of Mono-Si, a-Si/µc-Si and CdTe thin film that were operated for 41 months in Ankara-Turkey is analyzed. The results showed that Mono-Si array performance depends on the 5 parameters of outdoor climatic conditions while a-Si/µc-Si and CdTe thin film arrays performances are not significantly affected by the variation of the climatic parameters. The possible reasons are discussed in details.

Keywords: *Photovoltaic system, climatic parameters, efficiency*

1. Introduction and Methodology

Performances of solar PV systems are affected by meteorological parameters and ambient climatic conditions. Some examples from the literature are: (Bhattacharya et al., 2014; Sabri et al., 2007). In fact, all these references mainly discuss the temperature and wind speed variations of the PV system performances and with relatively for a period of short term data. Present study is the monthly performance variations of three PV systems installed in Ankara, Central Anatolia, with 5 monthly averages of climatic parameters, using a data set of 41 months. To the best of our knowledge, such an extended study for the monthly averages did not appear in the literature, both in terms of the length of the time period and number of climatic parameters analyzed. Such works are important in simulating feasible and optimum PV installations, toward the transition to clean energy policies for the decision makers, investors and end-users.

Fig. 1: Mono-Si, micro-crystalline based amorphous silicon and CdTe grid connected PV systems.

The specifications of the systems are as follows: The first one is Mono-Si array of 1.14 kWp and its total area is 7.584 m^2; the second one is µc-Si / a-Si array (thin film) with installed capacity of 1.26 kWp and its total area is 14.4 m^2 and the last one is CdTe thin film of 1.215 kWp and its total area is 12.96 m^2. There are

doi:10.18086/eurosun.2016.08.21 Available at http://proceedings.ises.org

three inverters connected to each PV array. The inverters are identical and the outputs are directly connected to the grid. The systems and the inverter specifications are presented in Table 1 and 2, respectively.

Tab.1: Mono-Si, CdTe and µc-Si / a-Si thin film PV systems properties.

Specifications	Mono-Si	CdTe	µc-Si / a-Si
Module brand	IBC	Abound	Kaneka
Module type	190 MS	AB1-67B	U-EA105
P_{MAX} [W]	190	67.5	105
V_{OC} [V]	45.2	46.6	71
I_{SC} [A]	5.56	2.2	2.4
V_{MPP} [V]	36.6	36.1	53.5
I_{MPP} [A]	5.19	1.9	1.96
Connection	6 series	6 series x 3 parallel	4 series x 3 parallel

Their performance and degradation analysis were carried out and presented before (Ozden et al., 2015 and 2016). As mentioned above in the present work, we analyzed the variation of the monthly performances of the arrays with respect to different climatic parameters. These parameters are monthly averages of ambient temperature (T_a, °C), relative humidity (RH, %), air mass at the noon of the average day (M) and solar irradiation on tilted arrays (H_t, kWh/m2). In this paper we present only the effects of two of these parameters: T_a and H_t.

Tab.2: Inverter properties.

Specifications	Energy Input Values [DC]	Energy Output Values [AC]
Inverter Brand	SMA	
Inverter type	SB 1200	
V_{MAX} [V] / V_{nom} [V]	400	105
V_{MPP} [V] / f_{nom} [Hz]	100-320	50/60
I_{MAX} [A] / I_{nom} [A]	12.6	5.2
--- / P_{nom} [V]	---	1200

Monthly efficiency (η) calculations are carried out using the hourly values I_t of solar irradiation on tilted panels and the hourly outputs of the systems by the equation:

$$\eta = \frac{\sum_j^N \left(\sum_i^{day} (hourly\ output)_i\right)_j}{\sum_j^N \left(\sum_i^{day} (hourly \quad I_t)_i\right)_j} \qquad \text{(eq. 1)}$$

where N is the number of days in the month and i and j are the indices that stand for the hour in a day and day in a month, respectively. The output and input in equation 1 are inserted in unit of kWh/m^2. In the previous analysis (Ozden et al., 2017, 2015) and in the present study, the calculation of hourly solar irradiation on tilted panels using anisotropic sky model HDKR, as named in (Duffie and Beckman, 2013), is used as it was demonstrated to be relatively better among one isotropic and another anisotropic model (Ozden et al., 2017, 2015).

Monthly performance ratio, R_P is defined as the ratio of the final monthly energy yield of the PV system, Y_f, to the monthly estimated reference yield, Y_r:

$$R_p = \frac{Y_f}{Y_r} \qquad \text{(eq. 2)}$$

In this equation, Y_f is calculated as the ratio of the monthly yield (Wh) of the PV array, E_{out}, to the installed array's rated output power P_{STC} (Wp), provided by the manufacturer. Y_r is calculated by dividing the total monthly tilted PV surface irradiation (Wh/m^2) E_t by the reference irradiance G_{STC} = 1000 W/m^2.

Variations of the monthly efficiency and performance ratio with the parameters H_t, T_a, M and RH are analyzed using IBM SPSS software package. The calculations of the monthly parameters H_t, T_a ve RH are simply carried out by averaging the hourly values in a full month. We used the noon air mass for a specific month calculated at the average day of the month (Duffie and Beckman, 2013).

Next section gives the graphical results and the discussion of these results. Section 3 is conclusion and future prospects.

2. Results and Discussions

2.1. Variation with temperature

Figure 2a and 2b depict the efficiency and performance ratio variation with respect to T_a. As it can be seen clearly, the temperature has negative effect on the monthly efficiency of the PV system with mono crystalline cells as expected. This is mainly due to the well-known band gap decrease with the increasing temperature which mainly affects the open circuit voltage and thus decreasing the efficiency.

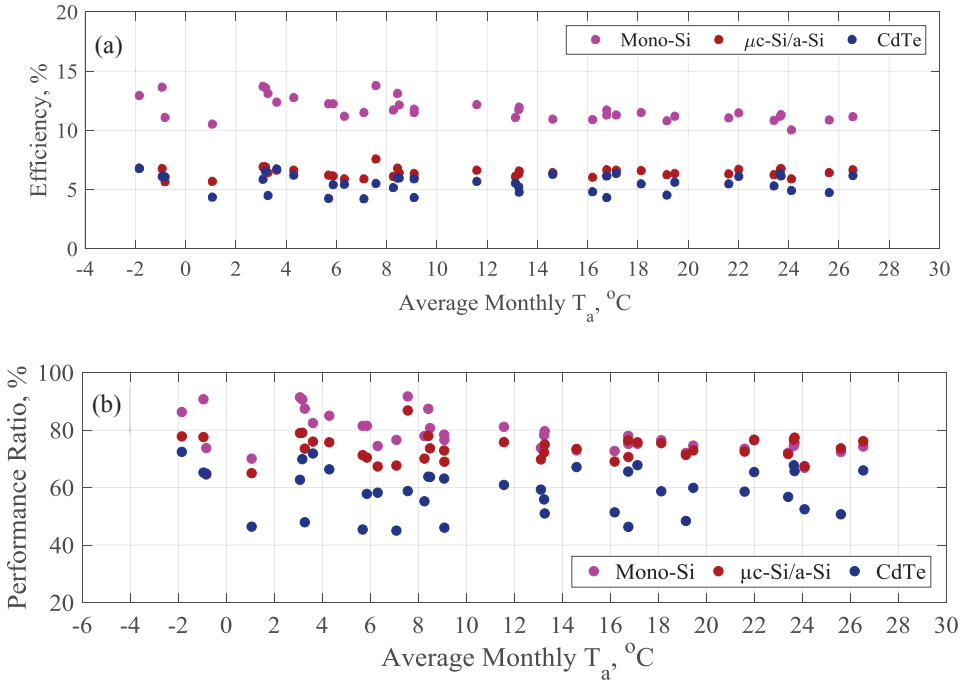

Fig. 2: Variation with temperature for Mono-Si, micro-crystalline based amorphous silicon and CdTe grid connected PV systems, (a) efficiency and (b) performance ratio.

For the systems with thin film solar cells however, the variation of the performances with the temperature is not that obvious as can be seen from Fig. 2. Although this is an unexpected result, we should note that the figure is obtained using the monthly performances and monthly average ambient temperature. Another reason may be the relatively narrower range of monthly average ambient temperatures in the outdoor testing conditions. We should note that in the laboratory, efficiency experiments with wider ranges of ambient temperatures (ambiance of the laboratory) would reveal the temperature variation clearly.

2.2. Variation with solar irradiation on tilted arrays

Similar to the variations with the temperature can be observed in the variation of the performances with the incident monthly average solar irradiation on tilted array as can be observed in Figure 3a and b. This can be attributed to the increase in the temperature of the ambient with the increase in solar irradiation. However, it seems that the thin film systems, especially in the variation of the performance ratio are also affected, as the monthly average incident solar irradiation is increased the performance ratio seems to decrease. To clarify, we calculated coefficient of Pearson correlation for all the variations and present in Tables 3 and 4. In the first columns of Table 4 one can observe that this variation is clearly revealed and the significance of correlation values given in Table 4 are also noteworthy. We discuss this result in the following sub-section.

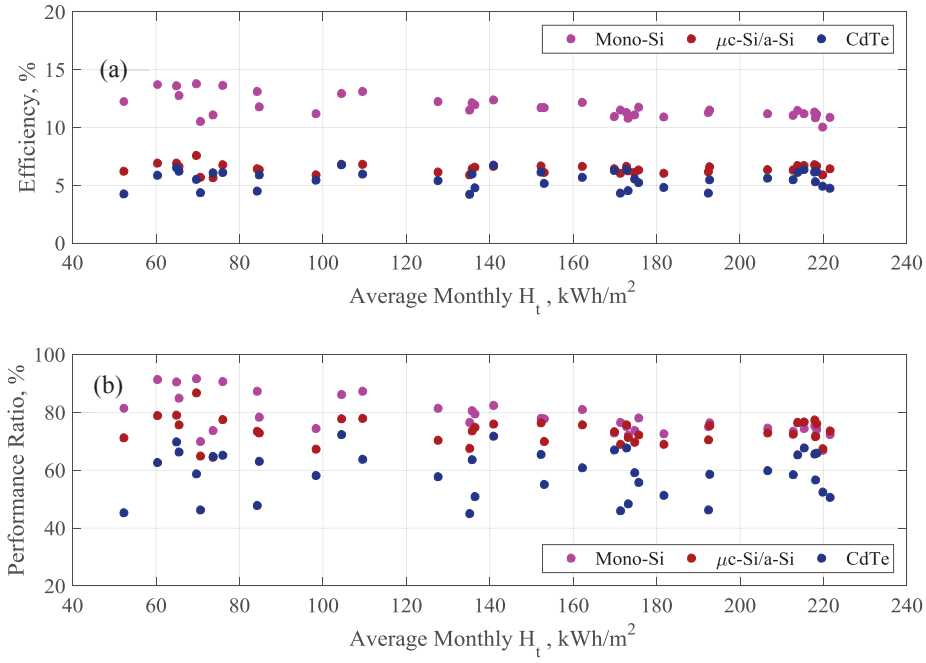

Fig. 3: Variation with solar irradiation on tilted arrays for Mono-Si, micro-crystalline based amorphous silicon and CdTe grid connected PV systems, (a) efficiency and (b) performance ratio.

2.3. Variation with air mass

Figures 4a and b present the variations with monthly average noon air mass. These variations follow very similar trends as in the variations with H_t. This conclusion can also be reached using Table 4 again. Of course, it is also a validation of the observed variation with H_t since it is clear that larger the air mass means the morning and evening hours so is smaller the solar irradiation and the ambient air temperature, and so increased performance. We should here note that these dependences of the thin film systems performances on H_t and M could not be clearly revealed in the efficiency variations (Figure 3a and 4a). Although this situation needs further test data and analysis to clarify, one might attribute it to the obvious difference between the laboratory test conditions and outdoor climate conditions.

Tab. 3: Coefficient of Pearson Correlation for grid connected PV systems (efficiency).

Module type	Pearson Correlation Coefficients				Significant of Correlations			
	H_t	T_a	RH	M	H_t	T_a	RH	M
Mono-Si	-0.682	-0.637	0.546	0.666	0.000	0.000	0.000	0.000
µc-Si / a-Si	-0,067	0.027	-0.060	0.112	0.683	0.868	0.718	0.498
CdTe	0.071	-0.054	-0.034	-0.062	0.669	0.746	0.839	0.708

Tab. 4: Coefficient of Pearson Correlation for grid connected PV systems (performance ratio).

Module type	Pearson Correlation Coefficients				Significant of Correlations			
	H_t	T_a	RH	M	H_t	T_a	RH	M
Mono-Si	-0.460	-0.468	0.324	0.446	0.003	0.002	0.037	0.003

CdTe	-0.250	-0.282	0.141	0.277	0.110	0.071	0.375	0.075

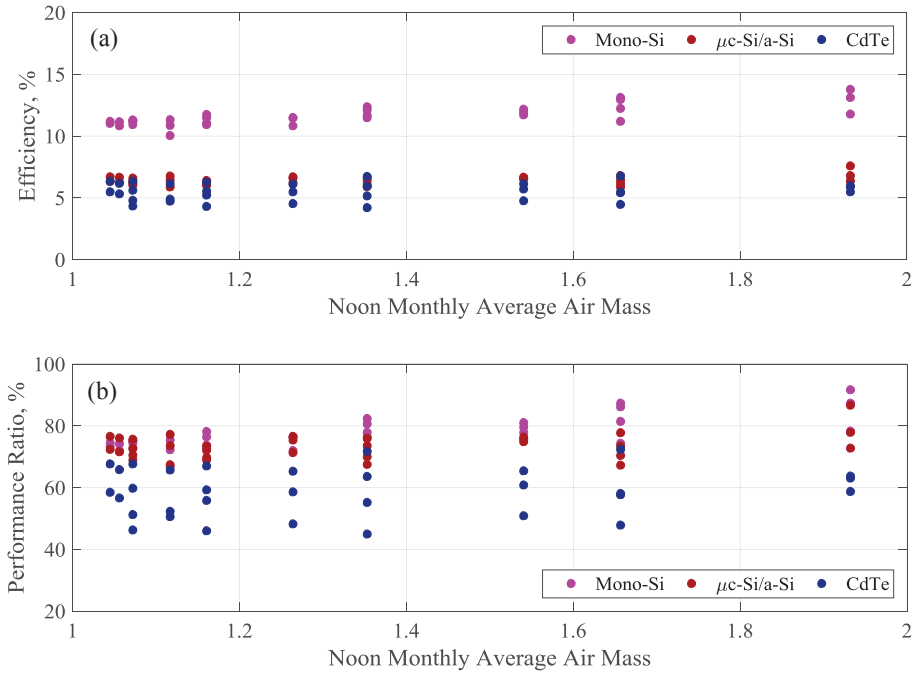

Fig. 4: Variation with air mass for Mono-Si, micro-crystalline based amorphous silicon and CdTe grid connected PV systems, (a) efficiency and (b) performance ratio.

2.4. Variation with relative humidity

Figures 5a and b are the variations of the monthly performance with the average monthly relative humidity. It is quite interesting that for the mono-Si system there exist considerable correlation between RH and system performance (Figure 5a and b, and see also Table 3 and 4). However, this can be attributed to the correlation between the monthly average ambient temperature and relative humidity as depicted in Figure 6.

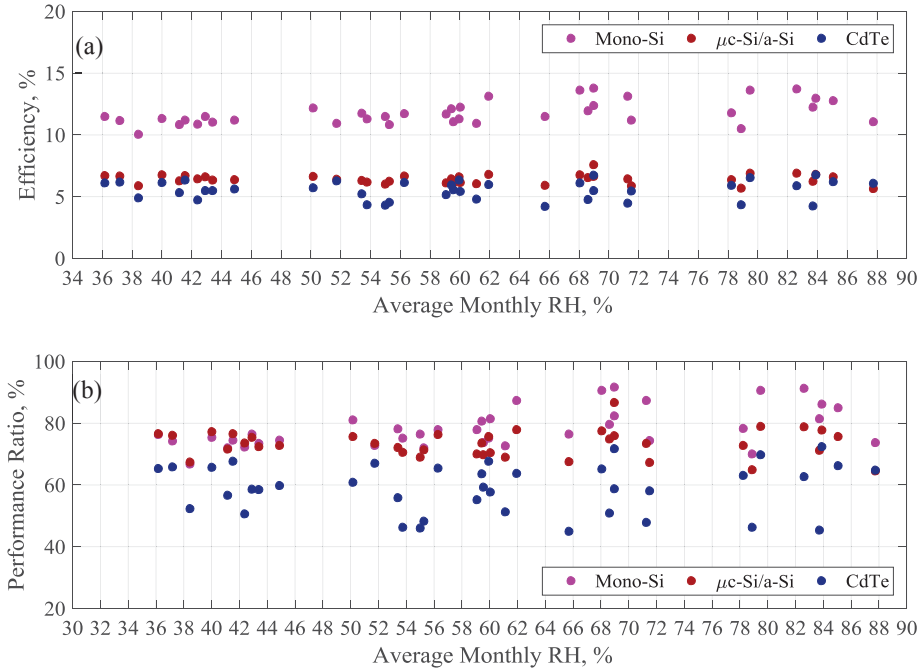

Fig. 5: Variation with relative humidity for Mono-Si, micro-crystalline based amorphous silicon and CdTe grid connected PV systems, (a) efficiency and (b) performance ratio.

The nature of this relation between T_a and RH is specific to the region of the installations and therefore, the correlation between performance and RH for mono-Si system should not be treated to be a physical effect of RH on the performance. That is, the correlation with RH for mono-Si is rather an artificial one which results due to increase in temperature with decreasing RH of the location. In any case, further data and analysis are needed to reach clearer conclusions. Similar to the T_a independence of the performance of the thin film systems, no considerable dependence on RH can be observed (Figure 5, and Table 3 and 4).

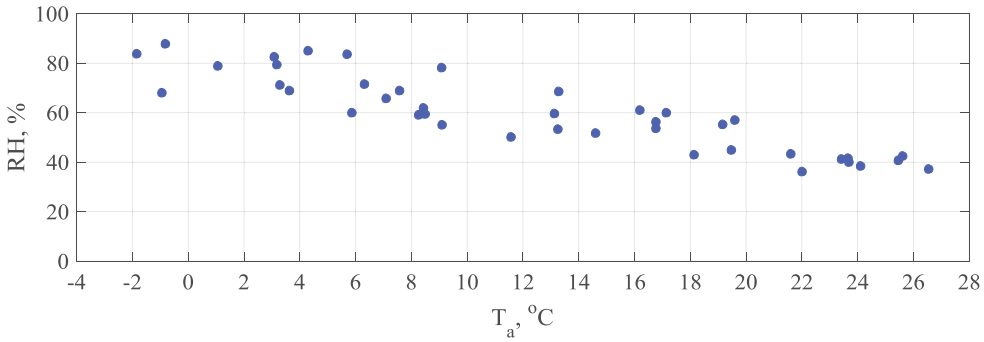

Fig. 6: RH with respect to T_a.

3. Conclusion

In this work, we analyzed the effects of all aforementioned monthly performance variation with climatic parameters and discuss the possible reasons of obtained correlations. As mentioned above, Mono-Si array performance depends on the outdoor climatic conditions while a-Si/µc-Si and CdTe thin film arrays performances are not significantly affected. Although one would expect decrease in efficiency with increasing temperature, we demonstrated that, a-Si/µc-Si and CdTe thin film array performances seems independent of T_a, while a decrease in the efficiency can be clearly observed for Mono-Si array. Similarly, H_t value affects the efficiency of Mono-Si while does not effect a-Si/µc-Si and CdTe thin film array efficiencies. In fact, Pearson's correlation coefficients for H_t independence are in accord with these findings for a-Si/µc-Si and CdTe thin film array monthly efficiencies. However for the performance ratio R_p, it seems that there is rather a significant correlation with H_t and we attributed this dependence to the obvious differences between the laboratory and outdoor climatic conditions. Air mass dependences of the performances are in accord with T_a and H_t dependences. There exists a dependence of the performances on the relative humidity RH however, this dependence should not be due to some unobvious physical effects but instead, it should be due to the interdependence of the T_a to RH specific to the region.

The results of the present work are important in planning and deciding the large scale PV installations to the regions with dry continental climate as in Central Anatolia. Further analysis of efficiency, performance and degradation of some larger number of different types of PV modules at the outdoor conditions of Ankara-Turkey are our future prospects.

4. Acknowledgments

The authors would like to thank B. Aksoy and MGM for the supply of meteorological data. The helps of Mr. C. Güvenç Oğulgönen, Mr. Harun Tanık and Mr. Ugur Yardım during installation, maintenance and data handling are acknowledged. One of the authors thanks to TUBITAK for the support from 2218 program.

Abstract

Glazed liquid photovoltaic-thermal collectors with polysiloxane encapsulation of photovoltaic cells have been developed and fabricated to generate both electric and heat energy simultaneously. The purpose of this study is to present the monitoring of the solar domestic hot water system with the new photovoltaic-thermal collector prototypes and compare the results with data simulated by a dynamic mathematical model of glazed liquid photovoltaic-thermal collector. The detailed dynamic model enables the optimization of the construction design and has been implemented into TRNSYS as a new type to allow the system simulations. Experimental measurement of solar domestic hot water system with two glazed photovoltaic-thermal collectors has been done for 6 days. Thermal energy difference for whole measured period of monitoring was less than 1.5 % compare to dynamic model. Difference between measured electric energy output and modelled was 8.1 %.

Keywords: *Solar energy, glazed PVT collector, SDHW system*

1. Introduction

Hybrid solar photovoltaic-thermal (PVT) collectors have attracted a large interest in last decade. Increase of energy production from given receiving area at the building envelope can bring higher solar fractions both for electricity and heat demand. While unglazed PVT collectors show excellent electric yields, their poor thermal performance results in lower total energy production when compared with combination of conventional PV modules and photothermal collectors(Matuska, 2014). Glazed PVT collectors could offer a good compromise between electricity and heat production, the total energy production is higher than for conventional combination of identical area (Matuska et al., 2015). The principle barrier for the glazed PVT collectors development is the weak resistance of common ethylene-vinyl acetate (EVA) encapsulation to excessive thermal exposure. Maximum operation temperature of EVA laminate is around 85 °C (Zondag et al., 2002) while the stagnation temperature for glazed solar collectors ranges from 120 to 180 °C. At these temperatures EVA encapsulation decomposes to acetic acid, which causes the corrosion of PV cell contacts, delamination and degradation of layer transparency. Nevertheless, majority of published papers focused on development of new glazed PVT collectors consider PV cells encapsulated in EVA lamination (Zondag et al., 2002; Chow et al., 2006; Dupeyrat et al., 2011). Research in the area of glazed PVT collectors resulted into two approaches. One is focused on the increasing heat losses during stagnation period (Lammle et al., 2016) and second focuses on the temperature resistant material as replacement for EVA lamination (Matuska, 2014). In this paper new concept of solar PVT collectors is presented where PV cells are encapsulated between double glazing and metal heat exchanger by means of polysiloxane gel. Polysiloxane gel as PV encapsulant offers a large range of operation temperatures (from -60 to +250 °C), high transparency for solar radiation and allows the compensation of thermal dilatation stresses thanks to low modulus of elasticity (Poulek et al., 2012).

Developed PVT collector presented in this paper uses temperature resistant material as encapsulant for PV cells. Moreover, the paper presents a detailed numerical model convenient for the optimization of glazed PVT collector design. Several glazed solar PVT collector prototypes based on the polysiloxane encapsulant have

doi:10.18086/eurosun.2016.08.20 Available at http://proceedings.ises.org

been fabricated. Prototypes have been tested in outdoor conditions and under conditions of artificial sun. The developed mathematical model has been validated for steady-state conditions (Pokorny et al., 2015) both for electrical and thermal performance and it has been implemented into TRNSYS as a new type. Reason of the implementation to the TRNSYS was to have a model which includes sufficient amount of parameters for the optimization in the PVT collector design process (glazing properties, dimensions and physical properties of sheet and tube absorber, properties of insulation etc.). Currently available types in TRNSYS is type 563 (unglazed) and type 50 (glazed). Only type 50 is suitable for glazed PVT collectors but type 50 do not consider a detailed construction parameters of the collector as well as do not consider change of important collector parameters during the varying operation conditions. Several steady-state models (Bergene and Løvvik, 1995; Zondag et al., 2002)and dynamic models of glazed PVT collector (Chow, 2003; Haurant et al., 2015; Guarracino et al., 2016) were published but not available for TRNSYS. The work presented here extends the steady-state model by a dynamic term to allow the system performance simulations at realistic conditions. The new type has been used for the simulation of solar domestic hot water system and the results were compared with an experimental installation of solar DHW system equipped with the developed glazed PVT collectors.

2. Theoretical model of glazed liquid PVT collector

In order to optimize construction of the glazed PVT collector, a detailed mathematical model has been developed and implemented into the TRNSYS. The advantage of implemented model is that model calculates energy flow from PVT absorber surface to ambient and energy flow from PVT absorber surface to liquid, all in every time step. The detailed model of glazed PVT collector allows to define a number of construction and physical parameters of collector configuration. Inputs of the model are climatic and operation conditions. Main outputs of the model are: thermal output, electric output, absorber temperature and outlet temperature. For instance, type 50 available in TRNSYS has effective heat loss (eq. 3) constant for whole simulation. Equally collector efficiency factor (eq. 4) is constant because model does not consider variable forced convection in pipes. Also type 50 does not consider thermal capacity of the PVT collector. Mathematical model of glazed PVT collector has been developed on the basis of Florschuetz approach (1979)). A detailed calculation of the heat transfer from the collector absorber to ambient (heat loss) and from the collector absorber to the heat transfer liquid (internal balance) is performed within the iterative loops. The model inputs are the detailed geometrical, thermal, electrical and optical properties (about 40 parameters) of individual segments of the PVT collector together with operation and climatic conditions. Temperature distribution in the solar collector is calculated in the iteration loops. Original steady-state model has been extended to a dynamic model by the introduction of the effective thermal capacity term available from testing or calculation. The dynamic term is used for the thermal calculations, the calculation of the electric output doesn't consider dynamic change of the temperature in the PVT collector so far. Moreover, non-uniform distribution of PV cells temperature which could have impact on the electric performance is not taken into account in the electric part of the model.

The photoelectric efficiency to establish electrical performance in Florschuetz approach is estimated as a function of ambient temperature t_a, using the relation of the form

$$\eta_a = \eta_{ref}\left[1-\beta_{ref}(t_a - t_{ref})\right] \qquad \text{(eq. 1)}$$

where β_{ref} [-] is the temperature coefficient of the PV cells, η_{ref} is the reference efficiency of PV cells, and t_{ref} [°C] is the reference temperature, all at standard testing conditions (STC). The incident solar energy converted to heat can be calculated as

$$\tilde{S} = G \cdot \alpha \cdot \tau_g \cdot \left(1 - \frac{\eta_a \cdot r_c}{\alpha}\right) \qquad \text{(eq. 2)}$$

where G [W·m^{-2}] is the incident irradiance, α [-] is the solar absorptance of the PVT absorber, τ_g [-] is the transmittance of the glass cover and r_c [-] is the packing factor (related to aperture area).

Effective heat loss coefficient of the PVT collector can be calculated as

$$\tilde{U} = U - r_c \eta_{ref} \tau_g G \beta_{ref} \qquad \text{(eq. 3)}$$

where U [W·m^{-2}·K^{-1}] is the PVT collector heat loss coefficient from absorber to ambient related to aperture area. The collector efficiency factor $\tilde{F}'$ [-] for upper bond of absorber to riser pipes is given as

$$\tilde{F}'=\frac{1/\tilde{U}}{W\cdot\left[\frac{1}{\tilde{U}\left[2a+(W-2a)\cdot F\right]}+\frac{1}{C_b}+\frac{1}{h_i\cdot\pi\cdot D_i}\right]} \quad \text{(eq. 4)}$$

where W is distance between risers, C_b [W·m^{-1}·K^{-1}] is bond thermal conductance, a [m] is the average bond width and h_i [W·m^{-2}·K^{-1}] is forced convection heat transfer coefficient in the riser pipe.

Heat removal factor $\tilde{F}_R$ [-] is defined as

$$\tilde{F}_R=\frac{\dot{m}\cdot c}{A_a\cdot\tilde{U}}\left[1-\exp\left(-\frac{A_a\cdot\tilde{U}\cdot\tilde{F}'}{\dot{m}\cdot c}\right)\right] \quad \text{(eq. 5)}$$

where $\dot{m}$ [kg·h^{-1}] is the mass flow rate, c [J·kg^{-1}·K^{-1}] is the specific heat capacity of the fluid and A_a [m^2] is the aperture area. Thermal output $\dot{Q}_t$ [W] is given by

$$\dot{Q}_t=\tilde{F}_R\cdot A_a\left[\tilde{S}-\tilde{U}\cdot(t_{in}-t_a)\right]-C\cdot A_a\cdot\frac{dt_m}{d\tau} \quad \text{(eq. 6)}$$

where t_{in} [°C] is the inlet fluid temperature to the collector, C [J.m^{-2}.K^{-1}] is the effective thermal capacity of PVT collector, t_m [°C] is mean fluid temperature, and $d\tau$ is time step of simulation. Electric output $\dot{Q}_e$ [W] is given by formula

$$\dot{Q}_e=\tau_g\cdot G\cdot A_A\cdot r_c\cdot\eta_a\cdot\left\{1-\frac{\beta_{ref}\cdot\eta_{ref}}{\eta_a}\cdot\left[\tilde{F}_R(t_{in}-t_a)+\frac{\tilde{S}}{\tilde{U}}\left(1-\tilde{F}_R\right)\right]\right\} \quad \text{(eq.7)}$$

3. Steady-state testing of prototypes and model validation

The prototypes of glazed liquid PVT collector have been developed and constructed based on the new concept (Matuska, 2014)to be further investigated and used for the validation of the mathematical model. The construction is based on sandwich structure with monocrystalline PV cells encapsulated in the polysiloxane gel layer between double glazing (see Fig. 1) and copper sheet with pipe register (conventional solar thermal absorber technology). Double glazing with a gap between glass panes 24 mm filled with argon has been used. No optical coatings have been applied for glass surfaces. Transmittance of the glazing is 0.91 and emissivity of the PVT absorber is 0.84. Average absorptance of the PVT absorber is 0.93. In total 6 x 11 polycrystalline PV cells at size 125 x 125 mm have been used. Gross area of the collector has been filled with PV cells for 60 % (packing factor related to gross area). Absorber has been made from copper sheet (0.2 mm) soldered to pipe register made from risers of 8 mm in diameter with thermal conductivity 200 W.m^{-1}.K^{-1}. Distance between the copper risers was 50 mm. Absorber has been insulated by 30 mm of mineral wool on the back, edge side was insulated by 10 mm of mineral wool (thermal conductivity 0.04 W.m^{-1}.K^{-1}). The frame of the PVT collector has been made of aluminum profiles.

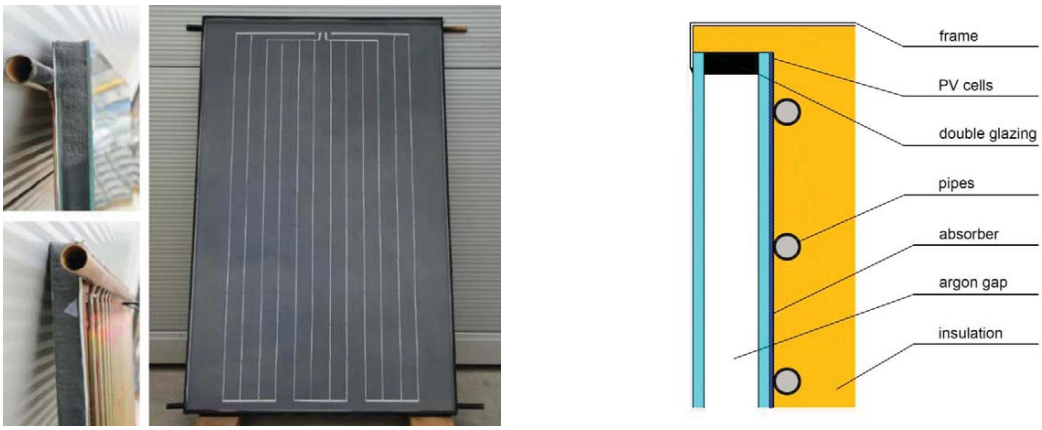

Fig. 1: Compact sandwich of double glazing, encapsulated PV cells and copper heat exchanger (left) and the schematic layout of the whole PVT collector (right)

The sample of developed glazed PVT collector have been tested at Solar laboratory (UCEEB CTU) with use of indoor solar simulator. Solar simulator consist of 8 metal halide lamps with power 4.5 kW. Solar simulator can achieve irradiance up to 2000 W.m^{-2} with guaranteed homogeneity 5 % on the area 1 x 2 m. Required inlet temperature to the collector is supplied by thermostat with tolerance ±0.03 K. The thermal performance has been determined according to EN ISO 9806. Required accuracy of measurement according to EN ISO 9806 was respected. Characteristic of thermal efficiency has been tested in two modes. In the hybrid mode, the PV part was connected to MPP tracker with measured load. In open circuit mode, the PVT collector thermal performance was tested without electric load. Thermal and electric characteristics have been related to gross area of the PVT collector which is 1.71 m^2 (1.04 m x 1.64 m). The global irradiance was kept at the average value 931 W.m^{-2} during the test. The collector tilt angle was set up to 45°. Ambient temperature was fixed at 17 °C. Collector zero loss thermal efficiency was evaluated 65 % and the electrical efficiency 9.1 % (both related to gross area). Moreover, the thermal capacity of the PVT collector was assessed 14.5 kJ.m^{-2}.K^{-1} by the testing.

Individual electric test of the PV part of PVT collector was carried out with PASAN tester at standard test conditions (G = 1000 W.m^{-2}, t = 25 °C, AM1,5). The results of the PV test are: U_{OC} = 40.7 V, I_{SC} = 5.1 A, U_{MPP} = 31,4 V, I_{MPP} = 4.81 A, P_{MPP} = 151 W, η_{STC} = 8.8 %.

To validate the mathematical model the thermal and electric efficiency characteristics have been modelled and compared to steady-state tested data. There is natural uncertainty in the parameters data for the model, e.g. real thermal conductivity of the insulation, real transmittance of the cover glazing, real absorptance and emissivity of the full absorber area, etc. For example, uncertainty of thermal conductivity value for the insulation could be considered about 10 % if not determined from special testing, transmittance of cover glazing was considered with uncertainty about 2 % according to datasheet of the manufacturer, etc. Therefore the efficiency characteristics have been modelled as two boundary lines expressing the full range of parameters uncertainty and creates the model uncertainty band for given PVT collector. This band could be diminished if there is a knowledge of the parameters with better precision. The experimental data derived for steady-state laboratory test of the PVT collector in hybrid mode lie within the model uncertainty band (see Fig. 2, red lines), however there is still potential to improve the model further.

The measurement uncertainty of thermal efficiency was determined by methodology published in (Mathioulakis et al., 1999). Results of experimental uncertainties are in Tab 1. Uncertainty of the model is much bigger compare to uncertainties of the measurement. For this reason uncertainties were not plotted in the chart in Fig. 2.

Tab. 1: Measurement uncertainties for thermal efficiency (related to gross area)

	η	η + σ	η - σ
η_0 [-]	0,645	0,649	0,640
a_1 [W.m^{-2}.K^{-1}]	5,391	5,141	5,640
a_2 [W.m^{-2}.K^{-2}]	0,011	0,008	0,014

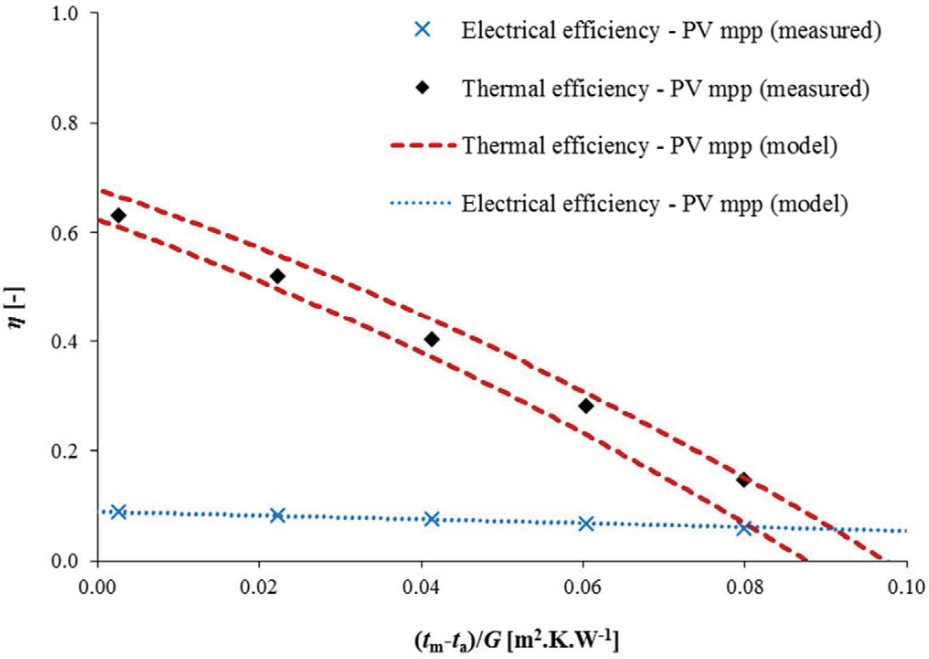

Fig. 2: Measured and calculated thermal and electrical performance in hybrid mode under steady state conditions

4. Solar system with glazed PVT collectors

Solar domestic hot water system with glazed nonselective PVT collectors has been realized to prove the applicability of the technology in real environment. Moreover, the developed dynamic model has been used for parallel simulation of the energy output in TRNSYS to continue with the validation process. PVT collectors were installed in the outdoor part of Solar laboratory on the roof of the Faculty of Mechanical Engineering, CTU in Prague and rest of the technology was placed in the adjacent room. Scheme of the system is shown in Fig. 3. Solar system consists of two glazed PVT collectors with gross area 3.42 m^2, storage water tank with volume 400 l, basic control components (circulation pump, closing and safety fittings, pressure and temperature sensors) and pipelines with thermal insulation. Heat transfer fluid was water. PVT collectors were installed on the metal construction of south orientation with tilt angle 45°. Solar system is dedicated to the preparation of domestic hot water in central storage tank but it does not fit to realistic design (high volume of the storage to collector area ratio). It was set up as laboratory system to provide the experimental testing of continuous PVT collectors operation under realistic climate conditions with dynamic behavior. Solar PVT collectors are directly connected to storage water volume, hot water is taken from integrated tube heat exchanger (similar to combined storage tanks). Conventional controller has been installed with the monitoring of the temperature difference and switching on and off the circulation pump of the system. Mass flow in the collector loop was set to 180 l.h^{-1}. Hot water load has been emulated by time-controlled electromagnetic valve representing the tapping device. Simple hot water load profile consisted from 4 loads with duration from 5 to 10 minutes was used at flowrate 5 l.min^{-1}. Daily hot water draw off was 200 l to provide sufficient load for the storage. Solar system works as solar only system for water preheating and auxiliary heater was not installed. For measurement was used pyranometer Kipp & Zonen (type CMP 6), wattmeter Hioki Power HiTester -3334, magnetic flowmeter TCM 142/02/3715, anemometer, and temperature sensors Pt100. For the electric part there

is hybrid inverter INV (with MPP tracker), two batteries BATT (24 V x 140 Ah = 3360 Wh) and continuous electric load (see Fig. 3) for PV electricity. Energy from batteries was used continually in order to avoid full charged battery and reduction of useful PV electricity generation.

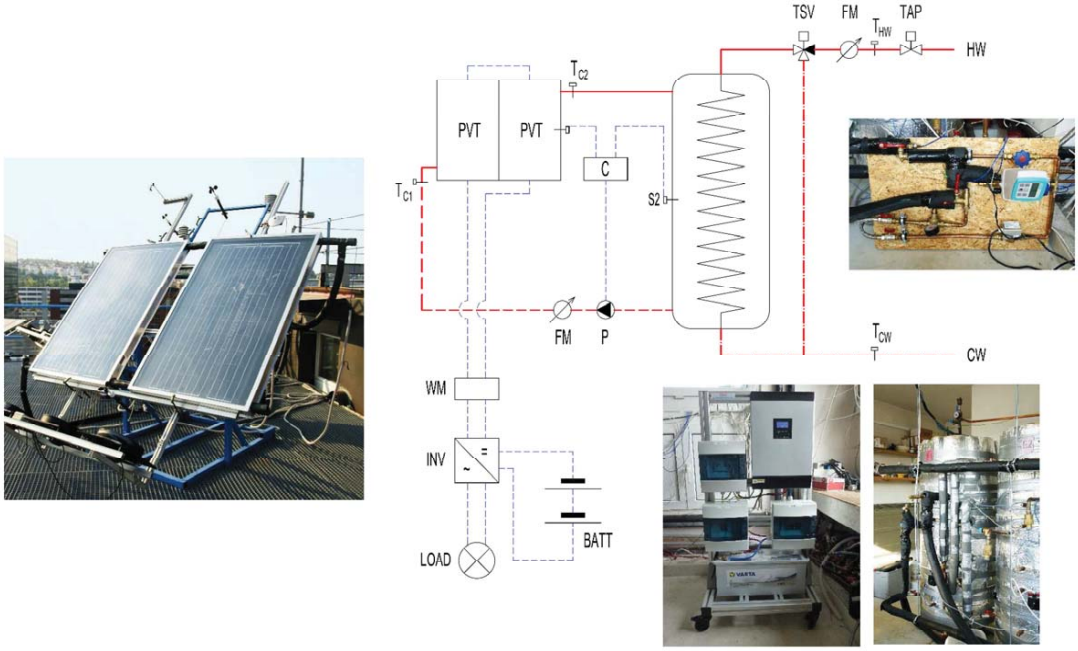

Fig. 3: Scheme of the solar DHW system with PVT collectors

5. Comparison between measured and simulated data

Thermal and electric output generated by solar PVT collector field has been evaluated for 6 days (from 18.5.2016 to 23.5.2016). Electric power, collector flowrate and temperatures at input and output of the collector field has been monitored in 30s time step together with climatic data (solar irradiance, ambient temperature, wind velocity). Electric power of PVT collectors was measured by digital wattmeter WM. Flowrate was measured by electromagnetic flowmeter FM and temperatures were monitored with Pt100 sensors.

Measured thermal and electric output data typical for clear and cloudy day is shown in Fig. 4 and Fig. 5. Heat output peaks are caused by switching the circulation pump on and off. For example at 9.00 am mean fluid temperature in the collector is higher compare to temperature in storage therefore pump is turned on. Although in short time temperature in collector is cooled because irradiation is not sufficient high, the same phenomena is during the evening. Fluctuation of thermal performance during the day is caused by cloudiness. These dynamic states are convenient for observation of the dynamic behavior and comparison with the steady state and dynamic model. During the clear day the heat output peaks are present only at morning and evening. Cloudy day leads to frequent heat output peaks during the whole daytime.

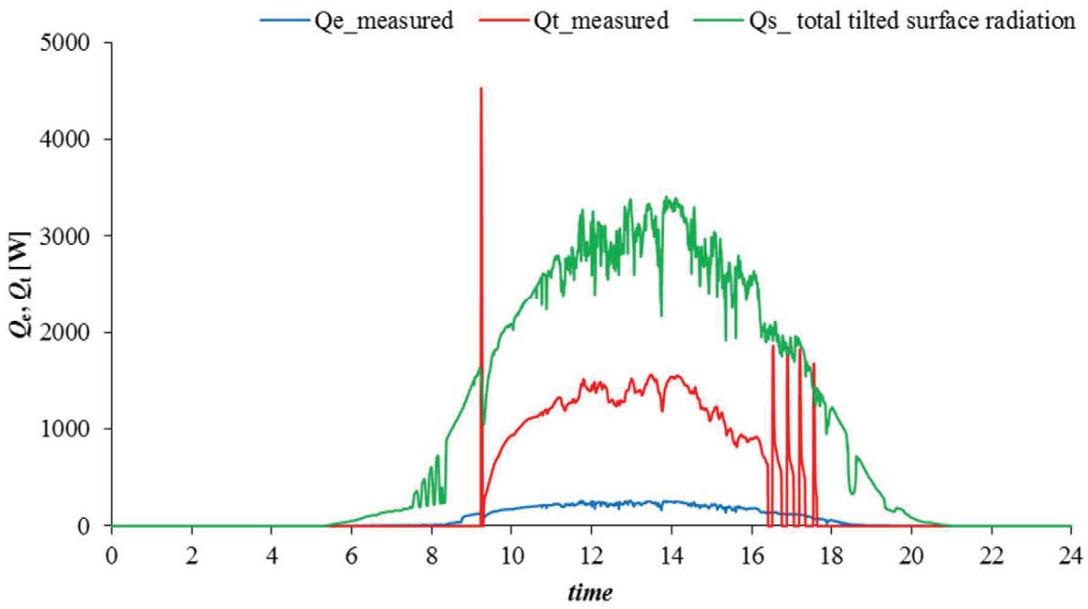

Fig. 4: Thermal and electric performance during clear day (22.5.2016)

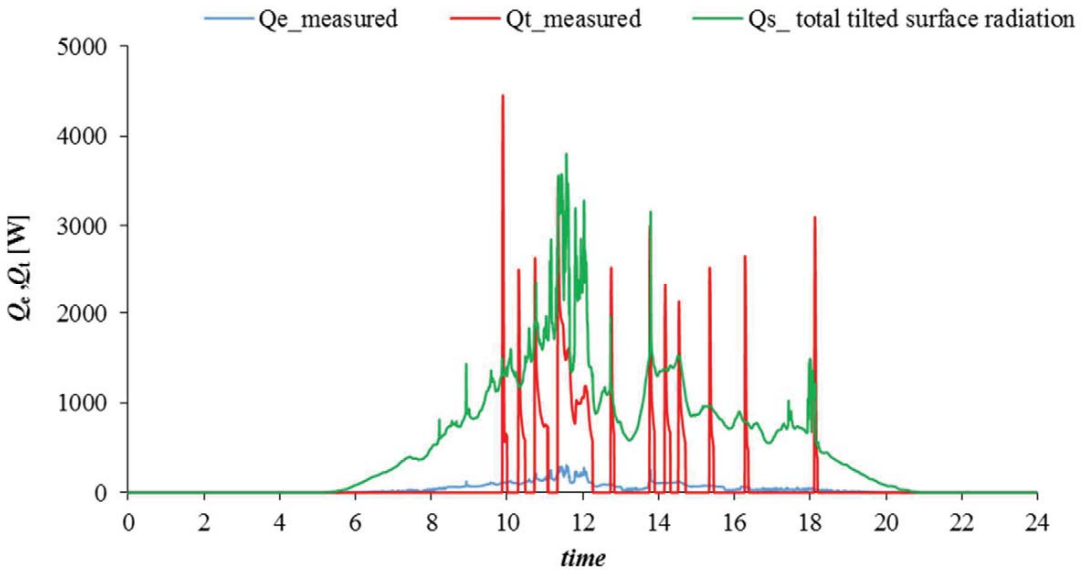

Fig. 5: Thermal and electric performance during cloudy day (18.5.2016)

Tab. 2: Measured data on the SDHW system with PVT collectors (for area 3.42 m^2)

Date	Incident solar irradiation Q_s [kWh]	Measured electric gain Q_e [kWh]	Electric efficiency η_e [%]	Measured heat gain Q_t [kWh]	Thermal efficiency η_t [%]
18. 5. 2016	12,8	0,91	7,1	2,93	22,9
19. 5. 2016	17,4	1,18	6,8	5,84	33,6
20. 5. 2016	16,6	1,17	7,0	4,98	29,9
21. 5. 2016	19,3	1,41	7,3	6,46	33,4
22. 5. 2016	24,3	1,76	7,2	9,05	37,2
23. 5. 2016	16,7	1,23	7,4	5,80	34,6

Tab. 2 shows the measured data from SDHW system. Daily thermal and electric gain was evaluated and daily efficiency of the collectors related to gross area has been determined. Tab. 3 shows the theoretically determined data by simulation model (steady-state, dynamic) and differences between modeled and measured values. Thermal energy difference for whole 6 days period of testing was -7 % for steady-state model and less than 1.5 % for dynamic model. Difference in modelled and measured electric energy was 8.1 % for the whole testing period. Maximum daily difference of the heat output are present during cloudy days but still less than 10 % for dynamic model, while quite large difference has been monitored for the steady-state model. Maximum difference between electric output modelled and measured is 15.7 %. This overestimation of electricity production by the model especially for cloudy days could be caused not only by quality of the model but also by operation out of the range of used hybrid inverter and power point tracker. This will be further investigated.

Tab. 3: Simulated daily energy output by model including difference from measured energy

Date	$Q_{e,stac}$ [kWh]	$\Delta_{e,stac}$	$Q_{t,stac}$ [kWh]	$\Delta_{t,stac}$	$Q_{t,dyn}$ [kWh]	$\Delta_{t,dyn}$
18. 5. 2016	1,02	12,3 %	1,83	-37,5 %	3,17	8,5 %
19. 5. 2016	1,37	15,9 %	5,60	-4,2 %	5,93	1,5 %
20. 5. 2016	1,30	11,0 %	4,22	-15,2 %	5,21	4.7 %
21. 5. 2016	1,48	5,6 %	5,95	-7,8 %	6,36	-1,5 %
22. 5. 2016	1,83	3,8 %	9,20	-1,6 %	9,03	0,2 %
23. 5. 2016	1,28	3,7 %	5,83	0,7 %	5,76	-0,5 %

Fig. 6 shows a detailed comparison between measured and modeled data for part of the clear day. To show the difference the steady-state and dynamic modeled data are put together with measured data in the graph. Dynamic model corresponds to measured data quite well in the whole period including the heat output peaks at the end of the day. Heat gain modelled with steady-state model without PVT collector capacity term oscillates during the operation and this results in worse precision of the model when compared to measured data.

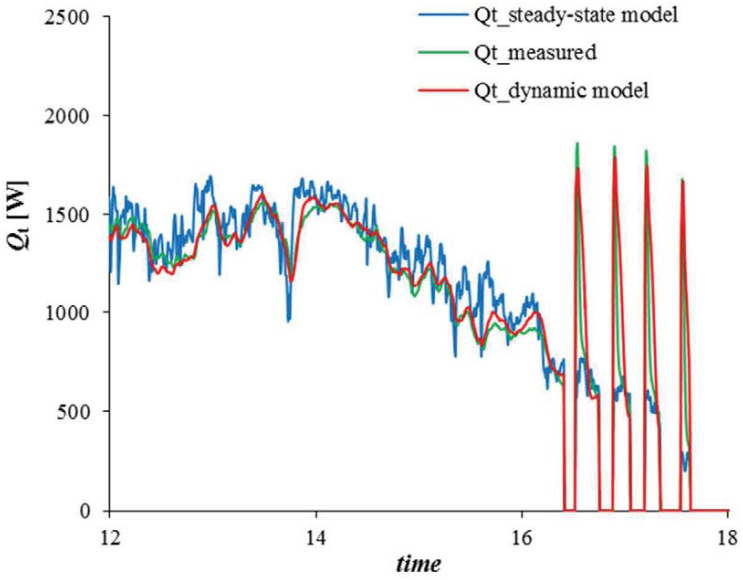

Fig. 6: Comparison between measured and modelled thermal performance (22.5.2016)

Fig. 7 shows the comparison of measured and modeled electric output. Significant differences of electric output are obvious particularly during the morning and evening. One possible reason of discrepancy is that hybrid

inverter works out of his range as mentioned above. Due to this fact measured electric output is lower than modeled electric output. However the electric model could be improved further. Currently, the electric model does not consider non-uniform temperature distribution across the collector plane. Temperature difference between the area close to inlet and the area close to outlet can be more than 5 K.

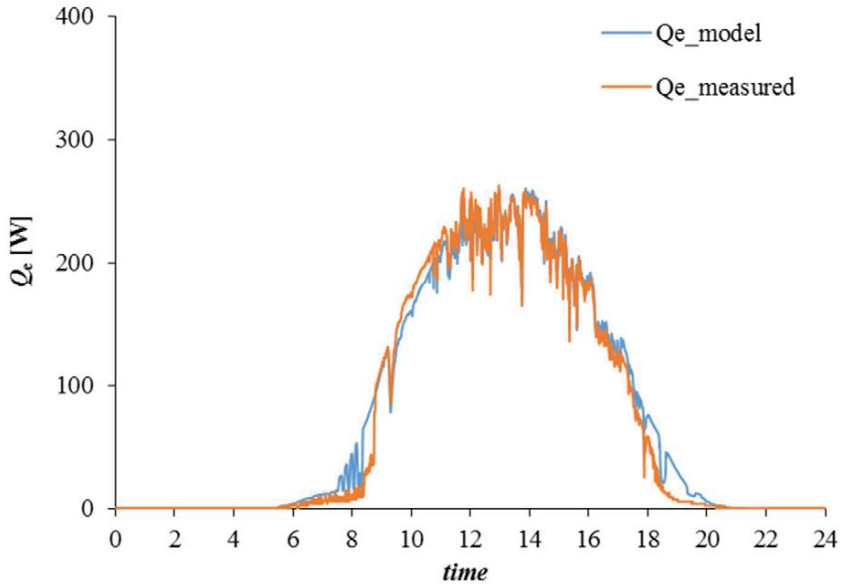

Fig. 7: Comparison between measured and modelled electric performance (22.5.2016)

6. Conclusion

The detailed mathematical model of new concept of glazed PVT collector has been validated by steady-state testing and further extended to dynamic model. The prototypes of the developed glazed PVT collectors has been fabricated and used in laboratory system for domestic hot water preparation. The performance PVT collectors in the system has been monitored and results have been compared with a simulation using the developed dynamic model implemented into TRNSYS. The comparison has shown a good agreement for the thermal part of the model (compared to steady-state model) and relatively good agreement with electrical part during the sunny days.

Main findings

- Prototype of PVT collector with durable lamination over high operating temperatures
- Dynamic model of PVT collector implemented into the TRNSYS as a new type

Abstract

Photovoltaic-thermal (PVT) collectors are commonly designed for use in domestic hot water systems, however it can be interesting to incorporate them into ground source heat pump (GSHP) systems. Because of the historically narrow use case, many PVT models are created with a collection of assumptions which may not apply to novel collectors designed for use in PVT+GSHP systems. The aims of this study are to review existing PVT collector models for use in TRNSYS, identify any potential error sources, and test for possible improvements. Type 560 is found to be the most promising theoretical model, however two potentially limiting features are identified; the radiation absorption model and the confinement to sheet-and-tube configurations. The absorption is tested using a recreation of Type 560 in Matlab where two alternative models developed specifically for PV modules are compared. The results show a marked increase in power during low angle, low light hours, and a 14.36% increase in electrical energy and a 10.91% for the thermal energy over the course of a day with one of the models. Collector geometry is tested by creating a 1D model in EES and comparing it to several geometries in Type 560. A method of packing as many tubes as possible together is shown to give comparable results as the 1D model. The results of these simulations will be compared with empirical data from currently ongoing testing.

1. Introduction

With the increasing interest in improving the energy efficiency of buildings, solar assisted heat pumps (SAHP) have been gaining attention. There are numerous potential configurations, but one of particular interest to heating dominated climates combine photovoltaic-thermal (PVT) hybrid solar collectors with ground source heat pumps (GSHP). Series configurations, where the solar collector is integrated on the source side of the heat pump, have been identified as a promising systems solution for PVT (Hardorn, 2015).

In this case, working fluid temperatures may often be lower than the ambient air which can lead to some non-conventional operating cases. For example, the collector can also be used as an air-to-water heat exchanger, capturing heat from the air in sensible and latent forms. The lower temperatures can also lead to lower PV cell temperatures, which may result in higher electricity production. Being on the source side may also limit the acceptable temperatures to be delivered to the evaporator, meaning higher flow rates during times of high irradiance may be necessary to avoid overheating.

Since these operating conditions are significantly different from PVT used for domestic hot water or direct space heating, it stands to reason that typical PVT designs may need to be modified for use with a GSHP. For example; larger or alternative flow channels from fin-and-tube, enhanced heat exchange on the rear of the panel rather than insulation, or accommodations for condensation.

Because of the interactions between components, it is critical to use a comprehensive modeling tool when designing hydraulic configurations and testing control strategies for a PVT+GSHP system. TRNSYS is a widely used and accepted, transient simulation tool for solar energy systems with many additional models for additional building components (Klein et al., 2009). Several solar thermal, PV, and PVT models have been

doi:10.18086/eurosun.2016.08.19 Available at http://proceedings.ises.org

incorporated, however they were developed with more traditional usage cases in mind and may not be as appropriate for PVT+GSHP applications. Therefore, the objective of this study is to develop a state-of-the-art PVT collector model for use in TRNSYS which can be incorporated into GSHP systems.

To meet this objective, a comprehensive review of existing PVT models is made with a focus on those which have already been implemented in TRNSYS. The study is limited to theoretical models rather than experimental since it is the general modeling of PVT that is of interest, rather than a particular module. Any critical limitations that are identified are tested by building new models or co-simulating with modifications to existing types in Matlab and EES, or using a combination of TRNSYS Types to overcome limitations to stand-alone models. The impact of the modifications will be tested against the existing TYPEs. Steady-state as well as quasi-steady state simulations are performed. The nomenclature used throughout is given in Tab. 1.

Tab. 1. List of nomenclature

Quantity	Symbol	Unit
Collector Area	A_c	m^2
PV air mass coefficient	a_k	-
Air mass	AM	-
Incidence angle modifier coefficient	b_o	-
Bond conductance	C_b	$Wm^{-1}\,K^{-1}$
Specific heat at constant pressure	c_p	$Jkg^{-1}K^{-1}$
External diameter of the tubes	D	m
Hydraulic diameter	D_h	m
Collector efficiency factor	F'	-
Collector heat removal factor	F_R	-
Total radiation on horizontal surface	G	Wm^{-2}

2. Review

PVT modeling in TRNSYS is by-in-large based on solar thermal collectors with the PV layer added to the front. This section reviews these models in detail as they have been applied to PVT models, as well as modifications made by succeeding authors.

2.1. Type 50

Type 50 is a modification of the Hottel-Whillier (1955) model used in Type 1 and is presented by Florscheutz (1979). It is available in the default TRNSYS library, can be used with glazed and unglazed modules, and is the most widely used PVT Type (Pressiani, 2016). The model is built on the assumption that the PV cells are laminated directly to the absorber plate, and thus the cells and the absorber are considered to have the same temperature.

The electrical power output Q_{el} is calculated with eq. 1.

$$Q_{el} = A_c \tau G_T \eta_a \left\{1 - \beta_a \left[F_R\left(T_{fi} - T_a\right) + \frac{S_{abs}}{U_L}(1 - F_R)\right]\right\} \quad \text{(eq. 1)}$$

Eq. 2 defines the useful thermal output Q_{th} of the combined collector.

$$Q_{th} = F_R A_C [S_{abs} - U_L (T_{fi} - T_a)] \quad \text{(eq. 2)}$$

Where F_R is the collector heat removal factor shown in eq. 3.

$$F_R = \frac{\dot{m} c_p}{A_c U_L} \left[1 - \exp\left(- \frac{U_L F' A_c}{\dot{m} c_p} \right) \right] \quad \text{(eq. 3)}$$

The absorbed radiation S_{abs} is calculated using eq. 4.

$$S_{abs} = G_T \left(1 - \frac{\eta_a}{\alpha} \right) (\tau\alpha) \quad \text{(eq. 4)}$$

There are eight different operational modes: modes 1 to 4 simulate flat-plate collectors with an increasing level of complexity in the heat loss calculations, modes 5 to 8 are used to model concentrating solar collectors, which is outside the scope of this study. In mode one the heat loss coefficient (U_L) and the angular dependence of ($\tau\alpha$) are set as constant values. This mode is recommended for all cases except those for which the assumption may introduce significant error in the calculated performance. Mode two calculates U_L as a function of the operating temperatures, the wind speed and the collector geometry using Klein's equation (1975). In mode three U_L is set as a constant and τ is considered using Hottel-Woertz (1944). Mode four is a combination of modes two and three, however it can only be used with glazed collectors.

Shortcomings of Type 50 have been noted by several authors over the years. A significant source of error is the lumped temperature of the absorber and the PV cells, which when measured was found to be up to 12K different and result in electric overproduction of 10% (Raghuraman, 1981). Later simulations would demonstrate that the temperature gradients between cooling tubes are much higher when a thermal resistance is added between the layers, also identifying a greater average temperature difference (Mazara, 2009). The collector efficiency factor (F') in eq. 3 is an input in Type 50 and constant throughout the simulation, even though it is a function of irradiation, wind speed, and internal temperature of the collector layers. This assumption may be appropriate for glazed collectors, but will likely lead to greater errors in unglazed PVTs (Bilbao and Sproul, 2012). An issue directly related to the PVT+GSHP concept is the calculation of the top loss coefficient (U_t), which uses the mean absorber temperature rather than the fluid temperature, potentially causing increased errors when the fluid temperature is lower than ambient (Bilbao and Sproul, 2012). Type 50 doesn't consider the thermal resistance of the bond between absorber and the tube ($C_b = \infty$).

The algorithm used in Type 50 may also be a source of error. The Florscheutz model requires multiple iterations to converge on a solution. Type 50 is hard coded to perform only three iterations, which may not be enough to reach an acceptable convergence (Bilbao and Sproul, 2012). Additionally, a floating point error can cause the simulation to fail (Collins, 2009).

2.2. Type 560

Type 560 has been created as a dedicated unglazed PVT model using heat transfer equations derived by Duffie-Beckman (1991) based on energy balances of the PV layer, absorber fins, and absorber tubes. Like Type 50, it uses an iterative approach to solve the analytical equations until convergence is reached and is also based on a fin-tube absorber design.

The electrical power output Q_{el} is defined with eq. 5.

$$Q_{el} = (\tau\alpha)_n (IAM) G_T \eta_{PV} A_c \quad \text{(eq. 5)}$$

The thermal power output Q_{th} is calculated with eq. 6.

$$Q_{th} = \dot{m} c_p (T_{fo} - T_{fi}) \quad \text{(eq. 6)}$$

The outlet fluid temperature T_{fo} can be written using eq. 7.

$$T_{fo} = \left(T_{fi} + \frac{C_1}{C_2} \right) exp\left(\frac{N_{tubes} C_2 L}{\dot{m} c_p C_3} \right) - \frac{C_1}{C_2} \quad \text{(eq. 7)}$$

The coefficients C_1, C_2, and C_3 are based on the fin-tube geometry and material properties, as well as the heat transfer coefficients with the surroundings.

A notable feature of Type 560 is that it considers the PV and absorber layers separately, allowing the user to

define the thermal resistance between them. It also considers convection coefficients as inputs. In Type 50, wind speed is an input and the convection coefficient on the front of the collector is calculated using the linear relationship defined by McAdams (1954). This allows users to calculate convection externally using Type 1232 or a custom equation. Convective and radiative heat transfer is also considered on the back side of the module in Type 560, which is of particular interest in a PVT without insulation.

2.3. Modifications to Type 50 and 560

Upon the identification of limitations to Type 50, a small library of modified Types were created as a part of the IEA Solar Heating and Cooling Task 35 and are freely available for download (Collins, 2009). Type 250 is the flat plate, water cooled model in the library and is a modification of Type 50d. Modifications to the model include the correction of the floating point error which lead to a division by zero and the correction of an error in the PV efficiency equation related to the temperature coefficient.

Several authors have created their own versions of Type 50 by connecting their own PV electrical equations with Type 1. For calculating PV output, Elswijk et al. (2004) used a linear temperature relationship similar to Types 50 and 560 and used the mean fluid temperature from Type 1 to determine cell temperature. Kalogirou and Tripanagnostopoulos (2006) use the same linear relationship to temperature, however they use a combination of standalone PV module temperature models with the PVT fluid temperature to determine cell temperature.

Type 563 is an alternative version to 560 which relies on the same thermodynamic model but is intended for building integrated PVT. The modification connects the back side temperature to the interior air node in a multi-zone building model. This allows the building model to take into consideration the heat transfer of the PVT modules on the building energy balance.

2.4. Other PVT Types

A number of researchers have created custom PVT models in recent decades using a variety of approaches. Some of these have been adapted for use in TRNSYS. Kalogirou (2001) created Type 49 based on the work of Bergene and Lovvik (1995). Their approach is similar to Duffie-Beckman but use a 2D steady state model which considers temperature gradients in the surface plane of the module. Like Type 50, temperature gradients through the thickness of the PV and absorber are not considered. Fraisse et al. (2007) used an electrical current analogy applied to heat transfer to create Type 105. The model is capable of glazed and unglazed PVT collectors and is described by 12 nodes with heat capacities that handle the dynamic behavior of each layer. Bilbao and Sproul (2012) developed Type 850 which is mathematically similar to Type 50 in that it assumes the PV cell temperature is the same as the absorber, however it uses a numerical solving approach and a top heat loss coefficient model by Akhtar and Mullick (1999). Dupeyrat et al. (2014) use Type 832, a thermal collector model original developed by Perers and Bales (2002) and extended most recently by Haller et al. (2012) which relies on experimental data to determine its coefficients. They modify it to include the electrical portion using an experimentally derived relationship between temperature and PV power.

2.5. Review conclusions

There have been numerous studies towards the goal of modeling PVT collectors, many of which are directed towards use in TRNSYS due to its ability to model complete solar energy systems. The vast majority of work has been based on the original solar thermal model by Hottel-Whillier and integrated into Type 50. As noted above, Type 50 has a number of computational shortcomings as well as physical limitations. Two significant issues are the matching PV cell temperature with the absorber layer and the limited modeling capabilities of heat transfer with the surroundings. In PVT collectors where the PV cells are laminated directly to the absorber with very high conductivity, then the single temperature assumption is more reasonable. However, this limits the type of collectors which can be explored. Similarly, the heat transfer with the surroundings is unique with PVT+GSHP systems given the potential for collector temperatures well below ambient. These issues limit the applicability of Type 50 and its derivatives to PVT+GSHP system models.

Type 560 offers a multi-layered model which solves the major shortcomings of Type 50. Surprisingly, it is not used by nearly as many researchers as Type 50, and there is little documentation to validate its performance with experimental data. However, the theoretical foundations make it a more promising tool for use with novel PVT collector designs in GSHP system simulations.

Nevertheless, Type 560 does have artifacts which may be a source of error for unglazed and uninsulated PVT

collectors. There are several which have been identified (Pressiani, 2016), only two are discussed here. First, the model used for absorbed radiation is derived from a glazed thermal collector, rather than an unglazed PV module. Second, the model is entirely based on the traditional fin-tube design, which may not be representative of other configurations, such as roll bond construction, that could have other flow patterns.

3. Models and Results

In consideration of the artifacts listed above regarding Type 560, alternative models are tested to see if there are any impacts on electric and/or thermal production. The alternative models are only tested against the default 560 model. To make the modifications, the Fortran code from Type 560 has been recreated in Matlab and EES.

3.1. Absorbed radiation

Testing the absorbed radiation is performed with transient simulations over the course of one day, using TMY2 weather data for Stockholm-Arlanda from June 1st, and a time step of 10 minutes. The model used to calculate the total amount of incident radiation absorbed by the PV surface in Type 560 is based on Liu and Jordan's (1963) isotropic sky method and represented by eq. 8.

$$S_{abs} = (\tau\alpha)_n (IAM) G_T = (\tau\alpha)_n \left(G_{b,T} K_{\tau\alpha,b} + G_d K_{\tau\alpha,d} \frac{1+\cos\beta}{2} + G\rho_g K_{\tau\alpha,g} \frac{1-\cos\beta}{2} \right) \quad \text{(eq. 8)}$$

Where $K_{\tau\alpha,i}$ is represented by eq. 9.

$$K_{\tau\alpha,i} = 1 - b_0 \left(\frac{1}{\cos\theta_i} - 1 \right) \quad \text{(eq. 9)}$$

And $G_{b,T}$ with eq. 10.

$$G_{b,T} = G_T - G_d \frac{1+\cos\beta}{2} - G\rho_g \frac{1-\cos\beta}{2} \quad \text{(eq. 10)}$$

While developing an improved PV generation model, De Soto (2004) proposes a PV specific absorption term described in eq. 11.

$$S_{abs} = (\tau\alpha)_n M (IAM) G_T = (\tau\alpha)_n M \left(G_{b,T} k_{\tau\alpha,b} + G_d k_{\tau\alpha,d} \frac{1+\cos\beta}{2} + G\rho_g k_{\tau\alpha,g} \frac{1-\cos\beta}{2} \right) \quad \text{(eq. 11)}$$

Where $K_{\tau\alpha,i}$ is represented by eq. 12. that defines light refraction passing through a single pane of glass without an air gap on the other side. This better represents a standard PV module, similar to what would be found in an unglazed PVT.

$$K_{\tau\alpha,i} = \frac{(\tau\alpha(\theta_i))_i}{(\tau\alpha)_n} \quad \text{(eq. 12)}$$

$G_{b,T}$ is also modified and shown in eq. 13.

$$G_{b,T} = G_b R_b = \frac{\cos\theta_b}{\cos\theta_z} (G - G_d) \quad \text{(eq. 13)}$$

A new term, *M*, represents the air mass modifier to account for changes in spectral distribution due to air mass, and is described with eq. 14 (King et al., 2004). The coefficients a_k are constants based the cell material (De Soto et al., 2006).

$$M = \sum_{k=0}^{4} a_k (AM)^k \quad \text{(eq. 14)}$$

For zenith angles between 0° and 60°, the air mass is represented with eq. 15, and for angles beyond 60° is described by Kasten and Young (1989).

$$AM = \frac{1}{\cos(\theta_z)} \quad \text{(eq. 15)}$$

In most absorption models, the PV cell is the only material considered even though there are gaps and busbars which are also present. Santbergen and van Zolingen (2008) consider the absorptivity of the multiple surfaces of a PV module using a dedicated optical model. The absorptivity model is represented by eq. 16.

$$\alpha = \tau\left(\xi\alpha_{cell} + (1-\xi)\alpha_{space\ between\ cells}\right) \quad \text{(eq. 16)}$$

$G_{b,T}$ is calculated using eq. 10 and the effective absorptivity with eq. 17. The packing density ξ is the ratio of the module area that are active PV cells to the total area of the module.

$$S_{abs} = \alpha\left(G_{b,T} + G_d\frac{1+\cos\beta}{2} + G\rho_g\frac{1-\cos\beta}{2}\right) \quad \text{(eq. 17)}$$

The three radiation absorption models (Type 560, De Soto, Santbergen) are tested using identical conditions and input values where possible. In cases where model specific terms are considered, values representing a typical mono-crystalline PV module are used.

The results in Fig. 1 show that Type 560 has the lowest electrical power output. Relative to 560, the De Soto model is higher across the entire day, while Santbergen has notably higher output during the morning and evening hours when there are low incident angles. The peak difference occurs in both models during the morning, with De Soto being 38.1% greater and Santbergen 44.5%. During the midday when there is much greater production, the De Soto model is about 13% greater. In terms of electrical energy generation, Type 560 produced 1.692 kWh, De Soto 1.798 kWh, and Santbergen 1.975 kWh for the day, suggesting that over a year there could be significant differences in this portion of the model.

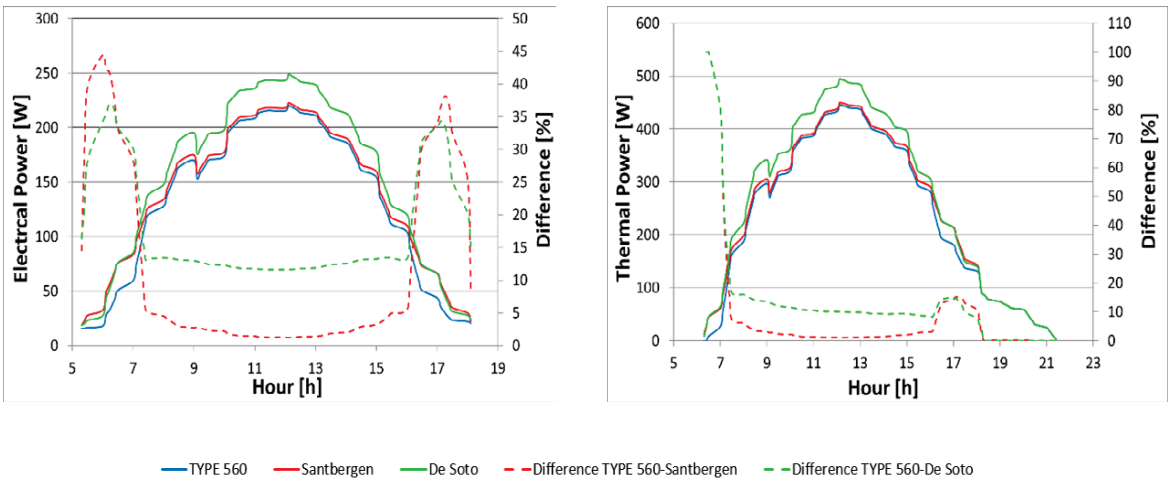

Fig. 1. Electrical and thermal output comparison of Type 560, De Soto, and Santbergen radiation absorption models

The thermal output results show once again that De Soto is shown to have significantly higher output throughout most of the day. The differences in the early and late hours are less pronounces as in the electrical generation, particularly in the later hours where all three models match exactly. During the midday, De Soto gives a 10-18% higher output while Santbergen is usually under 5% greater. Total thermal production for the day from each model is 3.575 kWh for Type 560, 3.713 kWh for De Soto, and 4.012 kWh for Santbergen.

3.2. Alternative Collector Geometry

One of the main limitations of Type 560 is that the only absorber design is a sheet and tube, represented by Fig. 2a. If another geometry is considered, like the rectangular channel absorber in Fig. 2b, then it is possible to use the hydraulic diameter. In Type 560 there's the assumption that the temperature (T_b) around the tube is uniform. This may not be true for all types of design, for example with a single channel like in Fig. 2c where there is direct contact on one side and no insulation on the rear, $T_{b,1}$ could have a significantly different value from $T_{b,2}$.

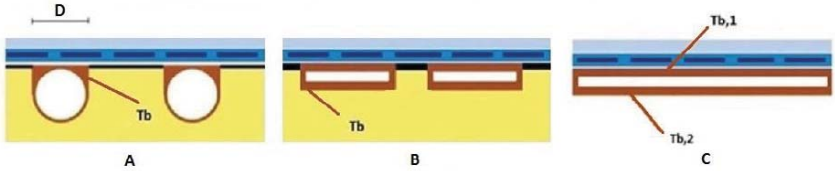

Fig. 2. Different absorber geometry

A 1D steady state model is built with EES in order to simulate the geometry with one single rectangular channel (Fig. 2c). The single channel configuration is used as a way to examine designs which do not have large gaps between the parallel tubes. The proposed model is then compared with several configurations of Type 560 which attempt to mimic the single channel design. A cross section of the layered construction which the 1D model is based on is shown in Fig. 3, and is based on a prototype collector currently in development. The model is built using energy balances over multiple layers within the collector; the top glass, PV, bottom glass, and the metal back layer.

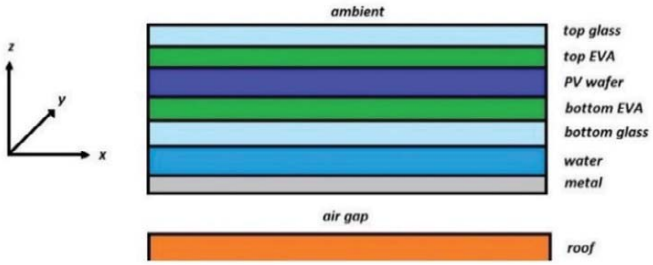

Fig. 3. PV/T collector representation

The energy balance on the top glass cover is given by eq. 18.

$$\frac{T_{PV} - T_{top-glass}}{R_{top-glass} + R_{top-eva} + R_{PV}} - h_{rad}\left(T_{top-glass} - T_{sky}\right) - h_{conv-top}\left(T_{top-glass} - T_a\right) = 0 \quad \text{(eq. 18)}$$

Where h_{rad} is represented with eq. 19:

$$h_{rad} = \varepsilon_g \sigma \left(T_{top-glass} + T_{sky}\right)\left(T_{top-glass}^2 + T_{sky}^2\right) \quad \text{(eq. 19)}$$

Eq. 20 gives the energy balance on the PV cells.

$$S_{abs} - \frac{T_{PV} - T_{top-glass}}{R_{top-glass} + R_{top-eva} + R_{PV}} - \frac{T_{PV} - T_{bottom-glass}}{R_{bottom-eva} + R_{bottom-glass}} - \frac{Q_{el}}{A_c} = 0 \quad \text{(eq. 20)}$$

Where Q_{el} is represented with eq. 21. S_{abs} is described with eq.8.

$$Q_{el} = G_T \eta_{\mathrm{PV,ref}}\left[1 - \gamma\left(\mathrm{T_{PV}} - \mathrm{T_{PV,ref}}\right)\right] A_c \quad \text{(eq. 21)}$$

The energy balance on the bottom glass is given by eq. 22.

$$\frac{T_{PV} - T_{bottom-glass}}{R_{bottom-eva} + R_{bottom-glass}} - h_{fl}\left(T_{bottom-glass} - \overline{T_{fl}}\right) = 0 \quad \text{(eq. 22)}$$

Eq. 23 and 24 represent the energy balance on the metallic backing on the fluid channel.

$$\frac{\left(T_{back} - T_{metal}\right)}{R_{metal}} - h_{fl}\left(T_{metal} - \overline{T_{fl}}\right) = 0 \quad \text{(eq. 23)}$$

$$h_{conv-back}\left(T_{amb} - T_{back}\right) - \frac{\left(T_{back} - T_{metal}\right)}{R_{metal}} = 0 \quad \text{(eq. 24)}$$

The convective heat transfer coefficients $h_{conv-top}$ and $h_{conv-back}$ follows Cole and Sturrock's formula (1977).

The average working fluid temperature in the collector $\overline{T_{fl}}$ is calculated with eq. 25.

$$\overline{T_{fl}} = \frac{\frac{T_{bottom-glass} + T_{metal}}{2} - T_{fi}}{\frac{2h_{fl}L_1L_2}{\dot{m}cp}}\left(\exp\left(-\frac{2h_{fl}L_1L_2}{\dot{m}cp}\right) - 1\right) + \frac{T_{bottom-glass} + T_{metal}}{2} \quad \text{(eq. 25)}$$

The convective heat transfer coefficient h_{fl} is calculated for laminar and turbulent flow using Nusselt correlations.

The final output for thermal power Q_{th} is given by eq. 26.

$$Q_{th} = \dot{m}cp\left(T_{fo} - T_{fi}\right) \quad \text{(eq. 26)}$$

Where the outlet temperature T_{fo} is given by eq. 27:

$$T_{fo} = \left(T_{fi} - \frac{T_{bottom-glass} + T_{metal}}{2}\right)\exp\left(-\frac{2h_{fl}L_1L_2}{\dot{m}cp}\right) + \frac{T_{bottom-glass} + T_{metal}}{2} \quad \text{(eq. 27)}$$

There are three configurations of Type 560 tested; a single tube approach (I), a packed tube approach (II), and a typical collector design (III). The single channel approach considers one tube with a diameter equal to the width of the module, which is similar to the adaptation that can be made for designs like Fig. 2b. The packed channel approach places the tubes directly next to each other across the entire width, effectively removing the fins, which is represented in Fig. 4. The typical collector uses 10 tubes with diameters of 0.015 m in parallel, which result in absorber fins between them much like Fig. 2a, and is included as a control.

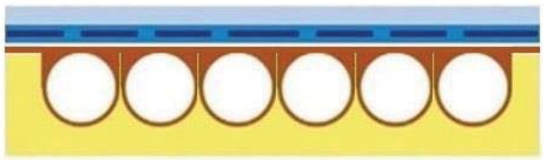

Fig. 4. Approximation of a rectangular water channel using the packed tube approach

To represent the single fluid channel directly in contact with the rear glass, the bond conductance between the tubes and absorber plate in all of the Type 560 models is set very high (10^{10}) and the thickness very low (10^{-10}). The resistance of the back glass in the 1D model is then incorporated into the absorber plate conductivity setting. The front and back convection coefficients in Type 560 are set to match the values used in the proposed 1D model. This means adding resistance to the front since Type 560 does not consider the glass and EVA layers on top of the PV. The convection coefficient inside the tubes are set using eq. 28 and 29.

$$h_{fl} = \frac{h_{fl}^{*} D_h}{D} \quad \text{(eq. 28)}$$

$$h_{fl}^{*} = f\left(Nu(D_h)\right) \quad \text{(eq. 29)}$$

The four geometries are run using steady state simulations across a range of operating conditions. A range of inputs are considered for three external variables; wind velocity, ambient temperature, and mass flow rate. The default value for the wind is 1 m/s, ambient temperature is 10 °C, and the flow rate is 0.05 kg/s.

The electrical and thermal production results are shown in Fig. 5, with electrical on the left and thermal on the right. In both cases the packed tube approach (II) is the closest to the 1D model. The difference in electric output is only 0.63% and in thermal output 3.77%. The greatest difference is found in the traditional collector design, highlighting the differences between the design concepts.

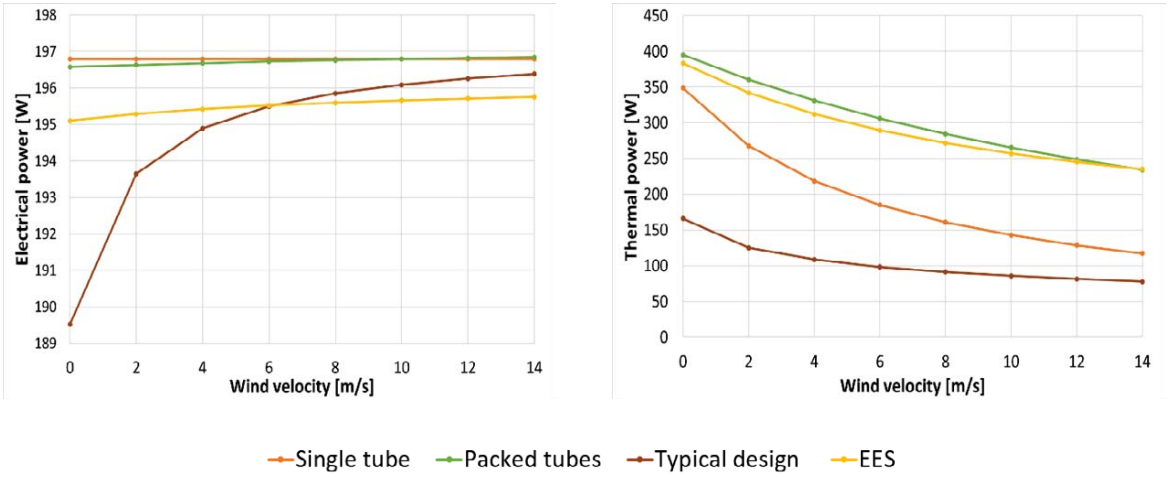

Fig. 5. Electrical and thermal power outputs with wind velocity variation for multiple geometries

The relationship between power and ambient temperature are shown in Fig. 6. Once again the packed tube concept and 1D concept are best matched in both thermal and electrical output. The average difference is 1.20% for electrical and 8.36% in thermal. In this case the traditional collector had the greatest error again, but this time is significantly greater, with a variation of 59.92% for the thermal part.

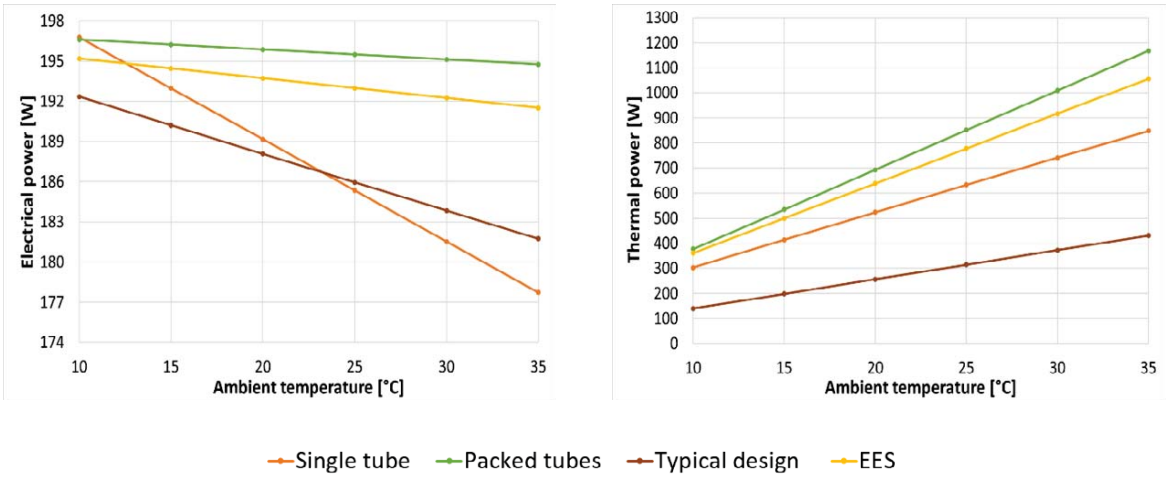

Fig. 6. Electrical and thermal power outputs with ambient temperature variation for multiple geometries

Fig. 7 shows the trends in output related to mass flow rate.

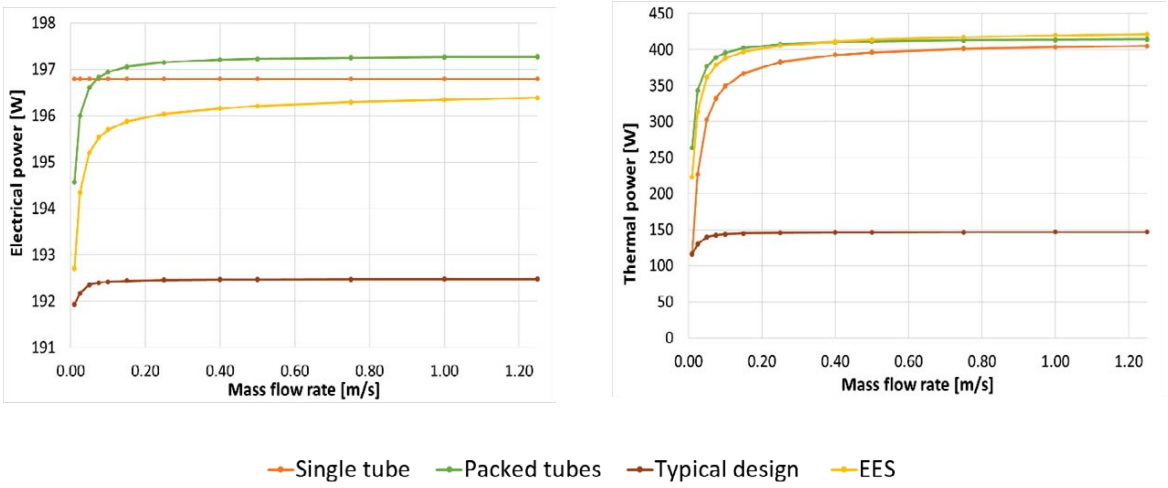

Fig. 7. Electrical and thermal power outputs with mass flow rate variation for multiple geometries

The difference in electric production is small between each geometry, but again the packed tubed concept (II) matches the 1D model most closely. There's a difference of 0.62% for the electrical power output and 3.62% for the thermal one. A notable feature in these results is the deviation of the single tube concept (I) from the patterns of the others at low flow rates. This may be caused by an error in the way the convection coefficient is being calculated for the single tube. Once again in thermal output, the traditional collector geometry is significantly lower than the others, with a 62.07% of deviation.

3 Discussion and Conclusions

Upon review of the two most prominent TRNSYS models for PVT collectors, Type 50 and Type 560, the later model has been identified as the most promising representation for novel PVT designs. Type 850, which incorporated the thermal model Type 832 would also be a good choice, however it requires the construction and testing of a collector prior to use. Type 560 is a theoretical model and provides the most flexibility and control. Type 50 and its derivations are limiting by not considering resistance between the absorber and PV cells and the relatively basic convection interaction with the environment.

For exploring novel PVT collectors Type 560 is not without limitations, however, two of which have been explored here; radiation absorption and collector geometry. Two absorption models dedicated to PV modules demonstrated significant differences in electrical and thermal power output during low angle, low light conditions. One of the models, from De Soto (2004) showed increased power output during nearly all hours of the day. These differences require most testing given the limited results presented here. The impact on annual or lifetime production should be investigated. Validation with experimental data is also necessary.

The collector geometry limitation has been tested considering two possibly modifications with Type 560 and compared with a 1D model created in EES. The results showed that collector geometry has significant impact on output, and that is must be taken into consideration in the model. A method which places as many working fluid tubes together as possible gave the most similar results between Type 560 and the 1D model, and are close enough to recommend 560 for use in this collector design. This is beneficial since construction of a new Type can be a lengthy and difficult process.

A limitation to this work is that all of the results presented here are theoretical. Development and testing of a prototype PVT collector specifically for use with GSHP systems is currently being performed. Once completed, the results from this modeling can be compared to the empirical data to confirm and validate the models.

Abstract

In this study a detailed model of a single-family house with an exhaust air heat pump and photovoltaic system is developed in the simulation software TRNSYS. The model is used to evaluate three control algorithms using thermal and electrical storage in terms of final energy, solar fraction, self-consumption and seasonal performance factor. The algorithms are tested and compared with respect to energetic improvement for 1) use of the heat pump plus storage tank for domestic hot water and space heating, 2) use of the electrical storage in batteries and (3) use of both electrical and thermal storage. Results show the highest increase of self-consumption to 50.5%, solar fraction to 40.6% and final energy decrease to 6923 kWh by implementing the third algorithm in a system with 9.36 kW PV capacity and battery storage of 10.8 kWh. The use of electrical energy storage has higher positive impact compared to the thermal storage with the settings and component sizes used. The combined use of thermal storage and batteries leads to final energy savings that are nearly the same as the combined savings of thermal storage and batteries separately, showing that they are mostly independent of one another for the settings of this study.

Keywords: Photovoltaics, heap pump, thermal storage, electrical storage, solar fraction, self-consumption

Nomenclature

COP	Coefficient of performance
DHW	Domestic hot water
FE	Final energy
HP	Heat pump
SC	Self-consumption [%]
SF	Solar fraction [%]
SH	Space heating
SPF	Seasonal performance factor
PV	Photovoltaics

1. Introduction

The energy consumption in the building sector has increased steadily in developed countries for several years, reaching 20-40% of the total energy consumption with Sweden in the upper end of the scale in 2015 (Heier et al., 2015; Pérez-Lombard et al., 2008; Swedish Energy Agency, 2015a). Domestic hot water (DHW) and space heating (SH) accounted for more than half of the sector's total energy use (Swedish Energy Agency, 2015a). There are several options for supplying thermal energy for DHW and SH in the

doi:10.18086/eurosun.2016.08.13 Available at http://proceedings.ises.org

building stock, including district heating, electric heating, biofuels and fossil fuels. In Swedish single-family houses electric heating is the most common option with a share of 45% of the total heat demand in the sector in 2014 (Swedish Energy Agency, 2015b). For houses with electric heating, a heat pump (HP) combined with a hot water storage tank is an efficient way to lower the electricity demand for heating in an electrically heated house (Hirvonen et al., 2016; Swedish Energy Agency, 2015a).

1.1 Energy management in buildings

There are two ways to reduce the need of buying electricity in a household: either using solutions for energy savings or producing own electricity. This paper focuses on the latter method to lower the need of buying electricity from a retailer by using photovoltaics (PV) for in-house electricity production. PV for residential applications is becoming more popular in Sweden due to lower prices for turnkey systems and enhanced economic supporting schemes for micro-producers of electricity (Lindahl, 2016). The cumulative installed PV capacity in Sweden has increased remarkably during the past years, from a total of 11 MW in 2010 to 127 MW at the end of 2015, of which 30% was residential grid-connected PV systems.

With an electric HP more of the PV electricity can be used in the house in comparison to non-electric heated houses. This can be an advantage both from an economical point of view and from a power system's perspective. If the buying prices of electricity exceed the selling prices, it is more profitable to replace bought electricity by own PV electricity than to sell the excess production to the power grid. A higher use of the PV electricity also lowers the excess electricity from the PV system, which might reduce the stress on the power grid in areas with a large penetration of PV.

Apart from converting electricity to heat via a heat pump, batteries for electricity storage or load shifting of electric appliances can be used to increase the use of PV electricity in the house (Castillo-Cagigal et al., 2011; Widén, 2014). The advantage of batteries is the possibility to store electricity for later use, while heat pumps can convert electricity into heat but not back again. Heat pumps can, however, have a higher thermal output than electric output, known as the coefficient of performance (Binder et al., 2012). This means that the efficiency of converting and storing electric energy as thermal energy can exceed 100% whereas the efficiency of battery storage always is below 100% due to conversion and storage losses. By time-shifting electric appliances such as washing and drying machines to times when there are high PV production, both self-consumption and solar fraction can be improved. The economic benefit for load shifting in the Swedish single-family building stock might, however, be low. A study of 200 houses in Sweden showed the economic benefit of load shifting to be maximum 20 Euro per house and year (Widén, 2014).

1.2 Final energy, solar fraction, self-consumption and seasonal performance factor

Apart from the electricity production, there are three measures that are useful to evaluate the energy performance of a residential PV system, namely, final energy consumption, self-consumption and solar fraction. Furthermore, a heat pump can be evaluated based on its seasonal performance factor.

Final energy (FE) consumption refers to the energy supplied to a customer (European Environment Agency, 2016). In this study the final energy is the electricity that needs to be bought from an electricity retailer over the studied year. Self-consumption is defined as PV electricity production that is directly consumed in the house, i.e. self-consumed electricity, relative to the total PV electricity production (Baetens et al., 2012). Solar fraction is defined as the self-consumed PV electricity production relative to the total load (Lund, 2005).

A mathematical description of self-consumption and solar fraction can be found in Luthander et al. (2015). If $L(t)$ denotes the instantaneous electric load including appliances, heat pump and auxiliary heater, and $P(t)$ is the instantaneous power from the PV system, the directly consumed PV power $M(t)$ can be defined as

$$M(t) = \min\{L(t), P(t)\} \quad (1)$$

if no electric storage is used. When adding battery storage to the system, this can be extended to

$$M(t) = \min\{L(t), P(t) + S(t)\} \quad (2)$$

where $S(t) < 0$ denotes power to storage (charging) and $S(t) > 0$ denotes power from storage (discharging). The final energy for the simulation period is equal to the electric load that cannot be supplied by PV

electricity:

$$FE = \int_{t_1}^{t_2} L(t)\,dt - \int_{t_1}^{t_2} M(t)\,dt \quad (3)$$

Self-consumption and solar fraction can then be defined as:

$$SC = \frac{\int_{t_1}^{t_2} M(t)\,dt}{\int_{t_1}^{t_2} P(t)\,dt} \quad (4)$$

$$SF = \frac{\int_{t_1}^{t_2} M(t)\,dt}{\int_{t_1}^{t_2} L(t)\,dt} \quad (5)$$

Strategies for improving PV self-consumption and solar fraction in residential buildings are a rapidly expanding research field (Luthander et al., 2015). The majority of the studies focus on PV in combination with battery storage but heat pumps plus hot water storage have also attracted some interest in recent years (Binder et al., 2012; Hesaraki and Holmberg, 2013; Hirvonen et al., 2016; Luthander et al., 2015; Thygesen and Karlsson, 2014).

Seasonal performance factor (SPF) is a measure of the efficiency of the heat pump, defined as the heat output relative to the electric input. In this study two definitions are used, the first SPF_{HP} includes only the HP compressor electric input and the second SPF_{HP+aux} includes both the HP compressor electric input and the auxiliary input. Since the use of a heat pump system in cold regions is higher in the winter months when the solar irradiance and thus PV electricity production is low, the SPF of the heat pump may have a large impact on the yearly final energy. SPF can be defined as:

$$SPF_{HP} = \frac{\int_{t_1}^{t_2} [Q_{SH}(t) + Q_{DHW}(t)]\,dt}{\int_{t_1}^{t_2} P_{el,HP}(t)\,dt} \quad (6)$$

$$SPF_{HP+aux} = \frac{\int_{t_1}^{t_2} [Q_{SH}(t) + Q_{DHW}(t)]\,dt}{\int_{t_1}^{t_2} [P_{el,HP}(t) + P_{el,aux}(t)]\,dt} \quad (7)$$

Where $Q_{SH}(t)$ is the instantaneous heating power for the SH and the $Q_{DHW}(t)$ is the instantaneous heating power for the DHW respectively. $P_{el,HP}$ denotes the instantaneous power of the HP's compressor and $P_{el,aux}$ the instantaneous power of the auxiliary input.

1.3 Aim and novelty

In this paper, control algorithms for residential PV, heat pump and battery storage systems are evaluated for a single family house in Sweden in terms of self-consumption, solar fraction and final energy. A detailed model of a new single-family house with a typical grid connected PV system, exhaust air heat pump and hot water storage tank is defined and modelled on the simulation software TRNSYS 17. The model is further developed by regulating the heat pump based on PV power production and by using battery energy storage.

The aim of the study is to maximize the self-consumption and solar fraction and to minimize the final energy by using control algorithms for the heat pump and battery storage. The novelty of this study is the combined use of a detailed and validated house model, measured high-resolution weather data and detailed load profiles for both DHW and electric load. The stochastical load patterns are based on monitoring data for single family houses (Widén et al., 2012, 2009). All these are implemented in the simulation software TRNSYS where the components are designed to meet the specifications of existing products of a house, heat pump, hot water tank and battery storage available on the market today.

2. Models and boundary conditions

This section describes the models of the house and PV system, heat pump and hot water storage tank, battery storage as well as the boundary conditions of the whole system.

2.1 House model and boundary conditions

The modelled house is a typical Swedish single floor, single family house (SFH) with a gabled roof, an overall U-value of 0.2 W m^{-2} K^{-1} and 143 m^2 heated floor area, see Tab. 1. A detailed model of the house

with six zones using space heating, developed in the simulation software TRNSYS, is described in detail and validated by Persson and Heier (2010). TRNSYS' type 56 is used for the house model. A schematic figure of the house with its zones is found in Fig. 1. The set temperatures in the zones (rooms) differ from 20°C in zone 3, 5 and 6, 21°C in zone 1 and 2, and 22°C in zone 4 (Persson and Heier, 2010). The SH is switched on when the temperature falls 1°C below the set temperatures in either of the zones.

Tab. 1: Geometrical and thermal properties of the studied house (Persson and Heier, 2010)

	Total area [m^2]	**U-value [W m^{-2} K^{-1}]**
Outer walls	107	0.23
Roof	153	0.09
Floor	143	0.10
Windows	24	1.27
Doors	5	0.54
Mean U-value		0.20

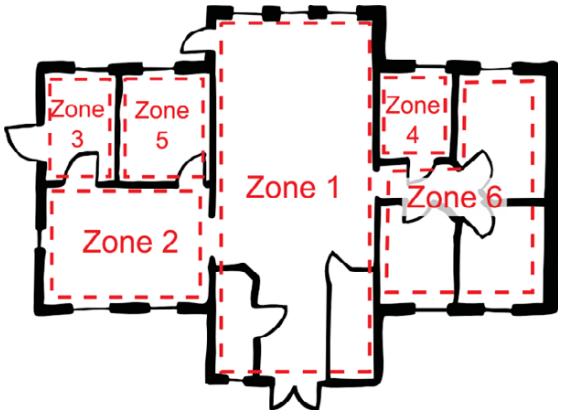

Fig. 1: Schematic figure of the house and the temperature zones (Persson and Heier, 2010)

The location of the house is Norrköping, Sweden (58.6°N, 16°2E). Measured high-resolution (one minute) meteorological data by the Swedish Meteorological and Hydrological Institute (SMHI) from the year 2007 in Norrköping is used in the simulations. The weather data is used both for calculation of the PV electricity production and for calculations of energy gains and losses in the house.

Fresh water temperature, which affects the heating demand, is dependent on the time of the year and modelled on a function described by Heimrath and Haller (2007). Two adults and two children are living in the house, and the internal heat energy gain, assumed to be the same as the electricity consumption for appliances, are calculated using a Markov-chain model for occupancy and energy use described in Widén et al. (2009). The DHW demand is derived from the MacSheep project and adjusted for this study, see Table 2 (Bales et al., 2015). All variables are in a 2 minute resolution over the period of one year.

Tab. 2: DHW and appliance data (Bales et al., 2015)

2979	Discharge energy [kWh $year^{-1}$]
70.9	Discharge volume [m^3 $year^{-1}$]
45	Discharge temperature [°C]
194.2	Daily Average draw-off [kg]
2.44 – 972.2	Flow [kg h^{-1}]
3437	Electricity for appliances [kWh $year^{-1}$]
5650	Max load for appliances [W]

2.2. Hot water storage tank, heat pump and auxiliary heater

A variable speed, exhaust air HP delivers heat both for SH and DHW but cannot supply them both at the same time. The HP model is based on the performance map of the HP, with heat capacity and power input as dependent variables together with inlet air temperature, inlet air flow rate and compressor speed as independent variables. SH is turned on in each zone when the room temperature falls below a lower limit, see Section 2.1. This means that the SH can be on for one zone but not for the rest. A hot water storage tank of 180 litres is used for DHW whereas the SH is supplied by the HP through a buffer store of 25 litres. The HP is activated according to a heating curve and compensatory control algorithm dependent on the SH supply temperature. An electric auxiliary heater is activated when the thermal power provided by the heat pump is insufficient to meet thermal power need. The auxiliary heater is inactivated during the predefined summer period. Preferences that are used for this study of the DHW storage, heat pump and auxiliary heater can be found in Table 3. The models for HP including storage and control algorithms are based on one of the most common commercial products on the market.

Tab. 3: Specifications of hot water storage tank, exhaust air heat pump and auxiliary heater

Preference	Quantity/name
DHW storage tank capacity [litre]	180
Electric compressor power [kW]	0.27-2.05
Thermal power of HP [kW]	1.14 – 4.99
Heat pump COP	2.4 – 4.7
Electric auxiliary heater [kW]	0.5 – 6.5

2.3. Battery storage and PV system

Three PV system sizes and three battery storage sizes are used to study the impact on the performance in terms of self-consumption, solar fraction and final energy, see Tab. 4. The tilt angle is defined by the roof of the building whereas the azimuth angle is chosen to optimize the yearly PV electricity production. The PV panels, inverter and batteries are modelled on products available on the market.

Tab. 4: Specifications of the PV system and battery storage

Preference	Quantity/name
Capacity PV [kW]	3.12, 5.7, 9.36
Inverter efficiency [%]	97.7
PV tilt [°]	27
PV azimuth [°]	0
Capacity battery [kWh]	3.6, 7.2, 10.8
Battery technology	Lithium-ion
Battery losses [%]	10%

3. Control algorithms for increased self-consumption

A base case and three control algorithms for improving the energy performance of the system are developed and evaluated:

- The base case includes the house equipped with a PV system and a heat pump for DHW storage and SH. The HP is controlled solely by the need of SH and the temperature in the DHW storage tank.
- First control algorithm is applied to the base case system. The heat pump is controlled by excess PV production to increase self-consumption.

- Second control algorithm is applied to the base case system with added battery storage. Charging and discharging of the batteries are controlled by excess PV production to increase self-consumption whereas the HP is controlled solely by the need of SH and temperature in the DHW storage tank.
- Third control algorithm is for the base case system with usage of both thermal storage and batteries. Excess PV power production is first used to charge the batteries, thereafter the HP is switched on if possible.

A flow chart showing the control scheme for on-off control of the HP for the case of algorithm 3, can be found in Figure 2. Moreover, since the algorithm 3 is the combination of algorithm 1 and 2 the flow chart contains all the three algorithms.

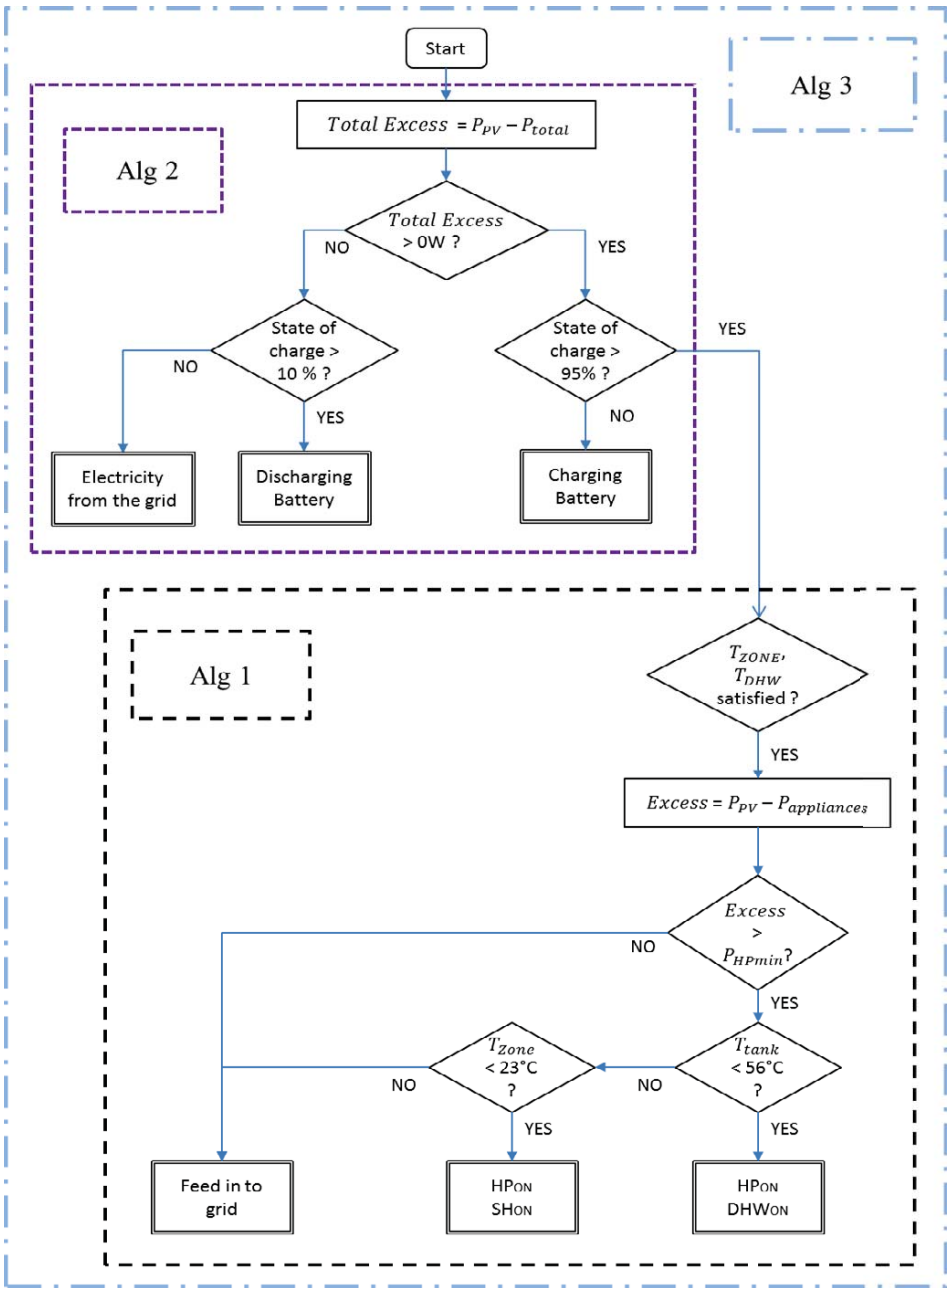

Fig. 2: Flow chart for control scheme to utilize excess PV power combining electrical with thermal storage (algorithm 1-3).

In algorithms 1 and 3, excess PV power production can switch on the HP even if no SH is needed and the DHW storage temperature is above the lower temperature limit. This is used to increase the self-consumption of PV electricity production and lower the demand of buying electricity at later times. The temperature in the DHW storage must be below than the upper temperature limit as well as the maximum allowed individual zone temperature, to allow the HP to be operated based on PV excess production. In order for the HP to be activated and increase the thermal storage either by DHW or by SH a minimum power limit of the excess PV electricity is required which is the P_{HPmin}.

4. Results

A comparison of the key figures such as self-consumption, solar fraction and final energy is given in Table 6 for base case, while Table 5 gives the heat and electricity use of the building and its occupants. For the base case system the self-consumption varies from 43 to 23% while solar fraction varies from 12 to 19% with increasing PV size. The SPF of the HP is 2.67 while that for the system (HP plus auxiliary electrical heater) is only 2.35 due to the relatively large amount of auxiliary energy used.

Tab. 5: Heat and electricity use of the base case

Electrical energy	**kWh year-1**
Electrical appliances	3437
Heat pump	6506
Auxiliary heater	1380
Thermal energy	**kWh year-1**
SH load	14923
DHW load	2979
DHW tank losses	669

Tab. 6: Key results for the base case system

PV capacity	3.1kW	5.7kW	9.3kW
Electrical energy		**kWh year-1**	
PV production AC	3123	5914	9370
Measure		**Quantity**	
PV SC (annual)	43%	30.6%	23.3%
PV SF (annual)	11.9%	16%	19.3%
Final energy	9981	9499	9116

The system was simulated for each of the algorithms with the three different PV sizes, each with its own storage size chosen according to the PV capacity (3.1 kW/3.6 kW, 5.7 kW/7.2 kWh, 9.3 kW/10.8 kWh). The results can be seen in Figure 3, where FE, SC and SF are shown for the base case and the three algorithms for all three PV sizes. Algorithm 2 (batteries) gives far greater savings (reduction in FE compared to base case) than algorithm 1 (thermal storage), and this difference is greater for larger PV sizes. For the largest PV size, algorithm 2 saves three times as much FE as algorithm 1 does. The savings for algorithm 3 are only slightly less than the sum of the savings of the algorithms 1 and 2 separately. This shows that the two algorithms are compatible and additive and hardly competing for the PV electricity. The savings in final energy for algorithm 3 (compared to base case) are 837, 1573 and 2193 kWh for the 3.1, 5.7 and 9.3 kW PV sizes respectively.

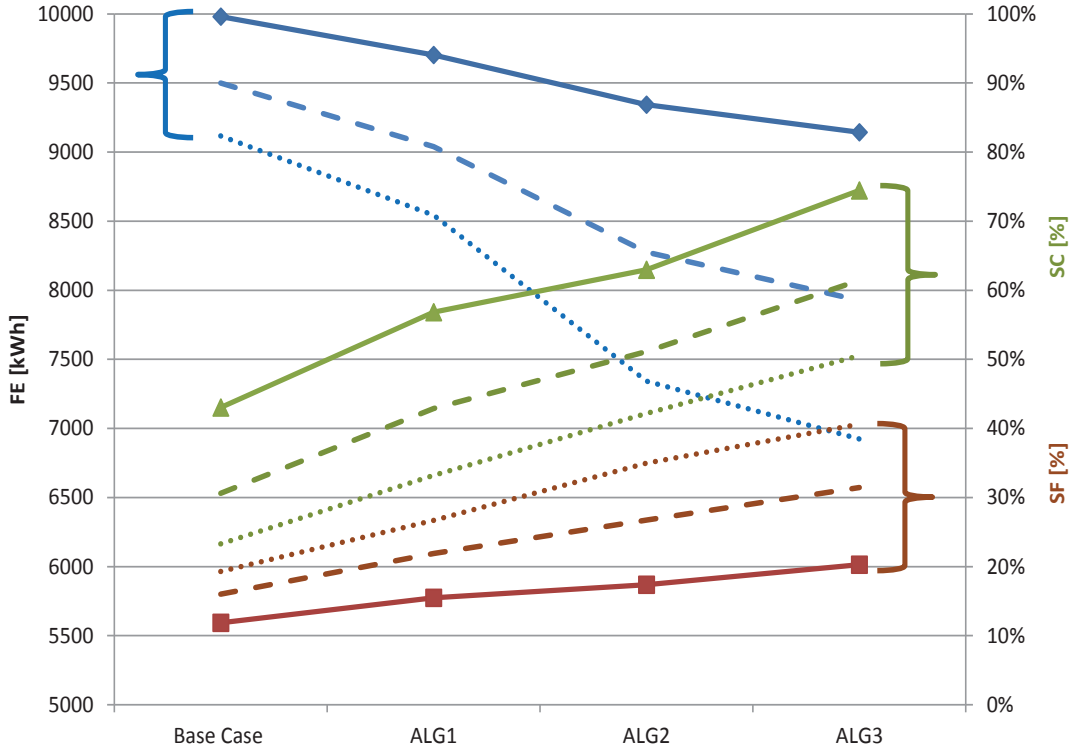

Fig 3: Comparison of the key figures between the base case and the control algorithms 1, 2 and 3. Final energy in blue (diamonds), self-consumption in green (triangles) and solar fraction in brown (squares). The PV sizes are denoted with solid lines (3.1 kW), dashed lines (5.7 kW) and dotted lines (9.3 kW).

The annual electricity production is 3120 kWh for a system of 3.1 kW. Key figures for the base case and the same PV system size using the third algorithm are presented in Table 7. SPF_{HP} is lower for algorithm 3 than for the base case, while the values for SPF_{HP+aux} are the same. This is because the algorithm using thermal storage leads to increased operating temperatures in the HP, reducing the COP. However, the auxiliary does not have to supply as much energy, which in this case happens to cancel out the negative effect of lower COP.

Tab. 7: Key figures for the base case system of 3.1 kW PV and the control algorithm 3 with 3.1 kW PV.

	Base case	Alg3
Electrical energy	**kWh year-1**	
PV production AC	3123	
Heat pump	6506	6805
Auxiliary heater	1380	1223
Measure	**Quantity**	
PV SC (annual)	43%	74.5%
PV SF (annual)	11.9%	20.3%
Final energy	9981	9144
SPF_{HP}	2.67	2.59
SPF_{HP+aux}	2.35	2.35

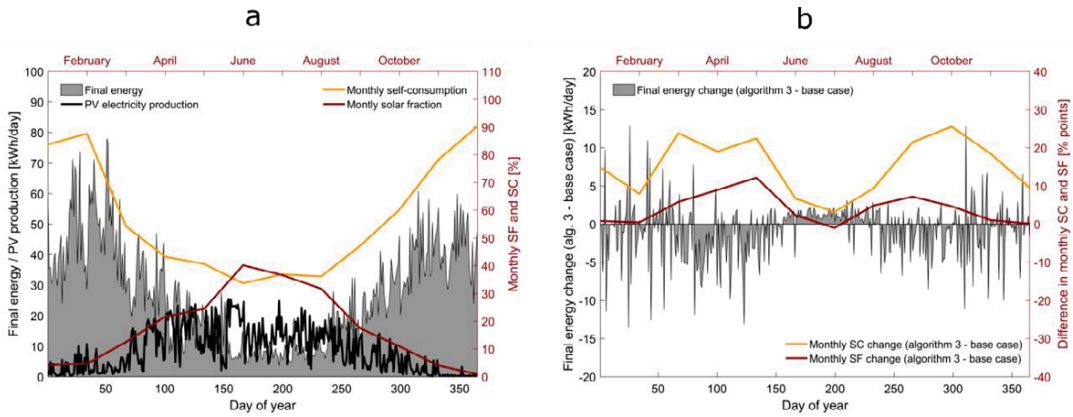

Fig 4: Daily final energy and production and monthly solar fraction and self-consumption for the base case (a) and the result with the third algorithm applied (b).

The monthly solar fraction varies much over the year, reaching 40% in June but is below 10% in November to February as seen in Figure 4a. With the third algorithm the solar fraction, as well as self-consumption, can be improved, most notably in the spring, see Figure 4b. Solar fraction, self-consumption and final energy are calculated with minute values of production and consumption. If aggregated monthly values would be used instead for the calculations, the solar fraction would get near to 100% in the summer.

5. Discussion

In order to increase the self-consumption, the temperature in the DHW tank is sometimes exceeding the set temperature during periods with high excess PV power production. Although the total electricity consumption by the HP is increasing due to higher heat losses, the final energy will be reduced due to a lower need of HP operation during periods without excess PV production.

Figure 4b shows that there are times during the year when the final energy is greater with algorithm 3 than for the base case, but for the whole year there are significant savings (837 kWh for 3.1 kW PV system). This shows that there is still some potential for improving the algorithms.

The climate conditions in Sweden with negative seasonal correlation between irradiance and outdoor temperature make it difficult for a regular single-family house to be completely independent of the power grid. For an off-grid system either large storage units or a drastically changed behavior are needed. Therefore, a reliable power grid that can handle both high power demand as well as high power production is needed for a larger integration of PV in the Swedish power system.

The performance map of the HP is defined for constant water flow rate, but in practice the system flow for SH and DHW is variable, which will affect both the capacity and COP of the HP. This effect has not been taken into account in the study.

To minimize the final energy the solar fraction should be high and to minimize excess PV electricity production the self-consumption should be high. The highest PV power production occurs in the summer which coincides with low electricity demand, see Figure 4. The need of thermal energy for space heating is low in the summer but there is still a need of DHW. For the Swedish climate and indoor temperature of 22 °C in the bathroom, there is only a short period when no heating is required. The heat pump and thermal storage can therefore be operated to minimize both final energy and excess PV electricity

6. Conclusion

This study shows the potential of increasing the self-consumption of a residential PV system and reducing the final energy. The base case with a PV system of 3.1 kW and a heat pump operating independently of PV excess power production has a self-consumption of 43%, final energy of 9981 kWh and solar fraction of 12% for the simulated year.

- The use of the existing thermal storage gives a decrease in final energy of 279 to 573 kWh per year for the PV sizes of 3.1 to 9.3 kW.
- The use of battery gives far greater decreases in FE than the use of the thermal storage, with the used settings and sizes of components.
- The combined use of thermal storage and batteries leads to final energy savings that are nearly the same as the combined savings of thermal storage and batteries separately, showing that they are mostly independent of one another for the settings of this study.

Abstract

A flat panel Integrated Collector-Storage Solar Water Heater (ICSSWH) incorporating a photovoltaic-thermal (PVT) absorber and a Planar Liquid-Vapour Thermal Diode (PLVTD) was fabricated. Tests indicate zero temperature rise instantaneous thermal and electrical efficiencies of 60% and 9% respectively, dropping to 40% and 6% under nominal intended operating conditions (600 Wm^{-2} irradiance, 50°C storage tank, 20°C ambient temperature). Measured overall heat loss coefficient was 0.85 $Wm^{-2}K^{-1}$ and thermal diode conductances were typically 45 $Wm^{-2}K^{-1}$ during solar collection periods and 1.7 $Wm^{-2}K^{-1}$ during heat retention periods. The work demonstrates that ICSSWH, PVT and PLVTD concepts can be successfully combined to create a scalable flat panel solar collector suitable for integration within a multifunction building facade.

1. Introduction

This paper presents key findings of experimental investigations undertaken to characterise behaviour of a flat panel Integrated Collector-Storage Solar Water Heater (ICSSWH) incorporating a photovoltaic-thermal (PVT) absorber and a Planar Liquid-Vapour Thermal Diode (PLVTD). This new hybrid solar collector type is intended for integration within multifunction building façades to provide low temperature hot water and electrical power to buildings. The paper briefly introduces the concept and cites influential prior work. The theoretical basis for the concept is outlined and modelling results are presented which demonstrate how collection, retention and diurnal thermal efficiencies are influenced by diode thermal conductances. Methodology and results of the experimental investigation are presented. Measurement results are compared to those typically achieved by comparable collector types and recommendations are made for future work.

1.1. Thermal and photovoltaic solar collectors

The Renewable Energy Directive (EU, 2009) sets a target of 20% of EU gross final energy consumption to be supplied from renewables by 2020. Increasing solar energy utilization plays a key role in meeting the target. Solar Thermal (ST) systems are expected to make a significant contribution to renewable heat targets in addition to renewable electricity supplied by already popular PhotoVoltaic (PV) systems. Traditionally, building mounted ST competes with PV for suitable roof or façade space. Combining technologies gives rise to PhotoVoltaic-Thermal (PVT) solutions which deliver low to medium temperature solar heat at efficiencies marginally lower than conventional ST collectors and generate electricity similar to standard PV modules.

doi:10.18086/eurosun.2016.08.14 Available at http://proceedings.ises.org

Careful design is necessary as most building thermal demands require heat to be delivered at temperatures significantly above ambient which reduces both thermal and electrical efficiencies. Domestic hot water, space heating and cooling systems which combine, ST, PV or PVT collectors with heat pumps appear to be a promising development area and a popular subject for current applied research (Good et al., 2015; Aguilar et al., 2016; Calise et al., 2016; Poppi et al., 2016; Qu et al. 2016).

Zondag (2008) gives a comprehensive review of PVT collector development, covering both air and water heating variants. More recent reviews are given by Michael et al. 2015 and Besheer et al. 2016. Santbergen et al. (2010) and Dupeyrat et al. (2011) specifically examine module design, construction, and heat transfer aspects of PVT-water collectors for domestic hot water production. Most PVT-water collectors take the form of photovoltaic cell laminates glued or bonded to sheet-and-tube, flow channel, or roll-bond type solar thermal absorbers. Packing Factor (PF) is the ratio of PV cell area to total absorber area. Thermal efficiency is maximized by ensuring absorber substrates are matt black or selectively coated to maximize solar thermal input. Bonding layers between PV cells and absorber substrates should be thin and thermally conductive. Convective heat transfer within the working fluid should be promoted. Zondag (2008) cites PVT-water collector examples featuring overall cell-to-fluid conductances in the range 40 to 250 $Wm^{-2}K^{-1}$. Low conductances increase PV cell temperatures which reduce both electrical and thermal efficiencies. Thermal efficiencies of PVT collectors are typically lower than those of dedicated ST collectors due to lower absorption coefficients of encapsulated PV cells ($0.7 \lesssim \alpha \lesssim 0.9$ as opposed to $\alpha=0.95$ for matt black surfaces) and also because some of the available energy ($15<\eta_{E(0,mpp)}<20\%$ typically for crystalline silicon cells) is extracted as electricity. Silicon cells produce a nominal voltage of 0.55V per cell but this reduces significantly with increasing temperature (~0.45%/°C) and falls markedly under low irradiance conditions (below about 200 Wm^{-2}). Photovoltaic current is directly proportional to irradiance and only slightly temperature dependent. Temperature nonuniformities across PVT absorber surfaces can significantly reduce electrical efficiency if cells are connected in parallel but generally have minimal effect on series connected cells.

Smyth et al. (2006) present a thorough review of Integrated Collector-Storage Solar Water Heaters (ICSSWH). These collectors can be significantly more cost effective than conventional ST systems because they have fewer components and require less floor space for water storage tanks. However, inherent exposure of the thermal storage to the outdoor environment (via the absorber surface) means that ICSSWH collectors suffer from heat loss at night and during periods of low insolation, particularly if installed in cold and windy climates. Most ICSSWH designs utilize one or more transparent covers to reduce heat loss. Various researchers have examined the use of novel techniques to improve heat storage effectiveness in ICSSWH collectors, including use of reflectors, concentrators, inlet diffusers, baffles, sleeves, phase change materials and thermal diodes. A recent review by Singh et al. (2016) attempts to categorise ICSSWH designs according to whether they are non-concentrating (eg flat plate or tank box systems), concentrating (eg compound parabolic) or employing phase change materials. Performance comparisons between different ICSSWH collectors are commonly made by considering collection efficiencies (typically $15<\eta_{col}<50$ %), overall heat loss coefficients (typically $2<U_{sys}<7$ $Wm^{-2}K^{-1}$), and maximum daily stored water temperatures (typically $30<T_{max}<60$°C).

Façade mounted Building Integrated (BI) solar collectors (BIST, BIPV and BIPVT) offer viable alternatives to bolt-on roof mounted collectors if structural, functional, aesthetic and cost considerations are addressed holistically to achieve high quality architecturally integrated solutions. Combining façade integrated BIPVT with improved ICSSWH technology potentially offers attractive and cost effect solutions for new buildings and refurbishments, particularly in multi-tenanted dwellings, hotels, and hospitals which have significant demands for low temperature heat and typically have limited roof-space available for solar collectors.

1.2. Thermal diodes and development of the PVT-PLVTD-ICS concept

A thermal diode is a unidirectional heat flow device analogous to an electrical semiconductor diode which offers low resistance to heat flow in one direction and higher resistance in reverse. Most studies involving thermal diodes focus on liquid convective devices (Kolodziej et al., 1997; Mohamad, 1997; Chen et al., 1998; Smyth et al., 1999; Faiman et al., 2001; Sopian et al., 2004; Fang & Xia, 2010; Rhee et al., 2010) but few consider phase change diode concepts. De Beijer (1998) proposed a horizontal cylindrical building integrated roof-ridge ICSSHW employing a liquid-vapour-liquid phase change thermal diode. Studies from Ulster

University (Quinlan et al., 2008; Quinlan, 2010; Souliotis et al., 2011) fabricated and tested similar devices in both horizontal and vertical orientations. The best of several ~25 L/m^2 prototypes investigated by Quinlan (2010) was DVICS Mark VI which achieved η_{col} =38 %, T_{max}=44°C and U_{sys}=1.3 Wm^{-2}K^{-1} during solar simulator tests. These performances (particularly heat loss coefficients) compare favourably with values reported in Section 1.1. Calculations based on Quinlan's results suggest that the x≈25mm wide thermal diode in DVICS Mark IV offered U_{12f}≈20 Wm^{-2}K^{-1} during collection periods and U_{12r}≈2 Wm^{-2}K^{-1} during retention periods. Boreyko et al. (2011) and Boreyko & Chen (2013) investigated planar jumping-drop liquid-vapour-liquid thermal diodes primarily aimed at microelectronics cooling applications, but recognised their potential use in solar collectors. High conductances of U_{12f}=40500 Wm^{-2}K^{-1} and U_{12r}≈165 Wm^{-2}K^{-1} were reported, seemingly enabled by highly effective evaporator wetting, thorough removal of non-condensable gases, and small diode cavities (x≈2.5mm). Thermal diode behavior is eminently suited to ICSSWH applications which inherently require rapid heat transfer from absorber to storage tank during sunny daytime periods (collection/forward mode) and thermal insulation to minimise tank heat losses during cloudy and overnight periods (retention/reverse mode). Unfortunately, the reverse mode conductances achieved by Boreyko et al. are unlikely to be beneficial in reducing tank heat losses. Recent work at Ulster University has progressed the patented vertical cylindrical liquid-vapour-liquid phase change thermal diode ICSSWH concept (Smyth, 2015) and evaluated commercial feasibility (Solaform, nd). Several design variants are currently evolving, aimed at cost reduction, improved evaporator wetting, and flattened forms compatible with PVT and building façade integration (Smyth et al., 2015 & 2016; Pugsley, 2017). The present paper details results of tests undertaken on the first truly flat panel prototype, the design of which is shown in Figure 1. Unlike previous design variants, the prototype examined in this study features resin-bonded PV cells and the liquid-vapour thermal diode has a much wider cavity (x=70mm) than any others encountered in the literature with the aim of reducing overnight heat losses. The diode is planar in form to facilitate building façade integration and features a novel internal support structure similar to that employed in vacuum glazing (Fang et al., 2004).

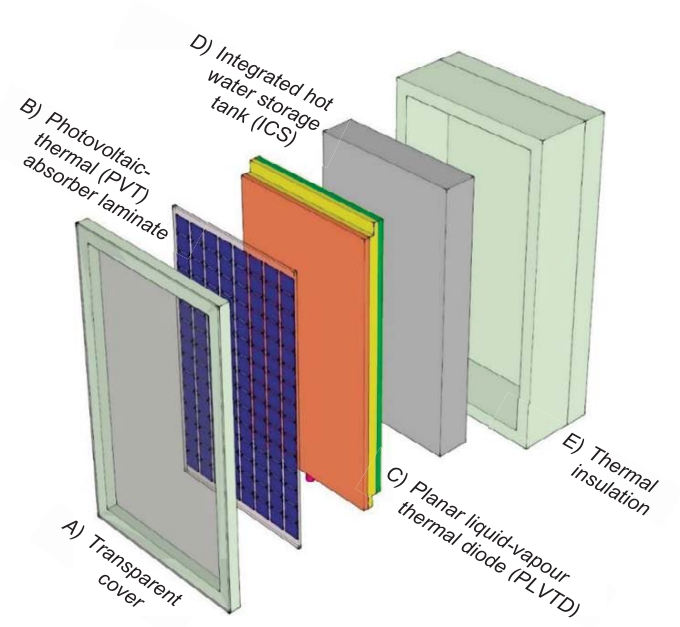

Figure 1 – General arrangement of a PVT-PLVTD-ICS solar collector

2. Theory

Heat collection (η_{col}) and retention (η_{ret}) efficiencies and system heat loss coefficients (U_{sys}) for ICSSWH collectors can be defined (after Smyth et al., 1999 and Faiman et al. 2001) using Equations 1 to 3 based on total heat capacity (C_{tot}), water storage tank temperatures ($T_{3[t]}$) at dawn ($t=t_0$), dusk ($t=t_0+t_{col}$) and the subsequent dawn ($t=t_0+t_{col}+t_{ret}$), retention period average ambient temperatures ($\tilde{T}_a$), collection period average

incident irradiance ($\tilde{G}$), and collector area (A). The overall diurnal efficiency ($\eta_{T+E,24}$) of a PVT-ICSSWH can be expressed in terms of the product of the collection and retention efficiencies plus the electrical efficiency, as per Equation 4, where instantaneous electrical power is determined from the product of current (I) and voltage (V) supplied to an electrical load. Diurnal thermal efficiency is a relative performance measure where $\eta_{T24}=1$ indicates perfect solar thermal collection and retention without losses and $\eta_{T24}=0$ implies either no heat collection, total overnight heat loss, or both. Values of $0<\eta_{T24}<1$ indicate potential for useful net heat gain provided that Equation 5 is satisfied.

$$\eta_{col} = \frac{C_{tot}\left(T_{3[t=t_0+t_{col}]} - T_{3[t=t_0]}\right)}{\tilde{G}A} \quad \text{(eq. 1)}$$

$$\eta_{ret} = \frac{T_{3[t=t_0+t_{col}+t_{ret}]} - \bar{T}_a}{T_{3[t=t_0+t_{col}]} - \bar{T}_{a[t=t_0+t_{col}]}} \quad \text{(eq. 2)}$$

$$U_L = \frac{C_{tot}}{A.t_{ret}} \ln \frac{1}{\eta_{ret}} \quad \text{(eq. 3)}$$

$$\eta_{T+E,24} = \eta_{T24} + \eta_{E24} = \eta_{col}\eta_{ret} + \frac{\int_{t_0}^{t_0+t_{col}+t_{ret}} IV}{\tilde{G}A} \quad \text{(eq. 4)}$$

$$\eta_{T24}\tilde{G}A + C_{tot}\left(\overline{T_{3[t=t_0]} - T_a}\right)(\eta_{\text{ret}} - 1) > 0 \quad \text{(eq. 5)}$$

Equations 6, 7 & 8 describe how ICSSWH collector instantaneous thermal efficiencies ($\eta_{T,col}$ during collection and $\eta_{T,ret}$ during retention periods) are determined by the solar power input (GA); transmission-absorption product ($\tau\alpha$); and the absorber (T_1), tank (T_3), and ambient (T_a) temperatures. These equations were derived by Pugsley (2017) based on a lumped parameter model which considers the thermal resistances associated with absorber-to-tank heat transfer ($R_{123}=R_{12}+R_{23}$), absorber-to-ambient heat loss (R_{1a}) and insulated tank envelope heat losses (R_{3ia}). Conductance $U_{12}=1/(A\cdot R_{12})$ describes diode behaviour and conductance $U_{23}=1/(A\cdot R_{23})$ represents water storage tank natural convection. Conductance $U_{1a}=1/(A\cdot R_{1a})$ represents combined radiative heat transfer and air mass natural convection effects occurring between the absorber and its transparent insulating cover, and also between the transparent cover and the external environment.

$$\eta_{T(col)} = \frac{{}^{(T_1-T_3)}/_{R_{123}} - {}^{(T_3-T_a)}/_{R_{3ia}}}{GA} \quad \text{(eq. 6)}$$

$$\eta_{T(ret)} = \frac{C_{tot}(T_3-T_a) + t_{ret}\left[{}^{(T_3-T_a)}/_{R_{123}} - {}^{(T_3-T_a)}/_{R_{3ia}}\right]}{C_{tot}(T_3-T_a)} \quad \text{(eq. 7)}$$

$$T_1 = \frac{R_{123}T_a + R_{1a}T_3}{R_{1a}+R_{123}} = \frac{R_{123}R_{1a}\tau\alpha GA + T_aR_{123} + T_3R_{1a}}{R_{123}+R_{1a}} \quad \text{(eq. 8)}$$

The theoretical relationship between diurnal thermal efficiency and water storage tank temperature is shown on Figure 2 for various diode performance scenarios. The analysis was undertaken by calculating the product of Equations 6 & 7 for nominal G=500 Wm^{-2}, t_{ret}=64800s, A=1m^2, $\tau\alpha$=0.81, and U_{3ia}=0.3 $Wm^{-2}K^{-1}$ using temperature dependent values of $3<U_{1a}<5$ $Wm^{-2}K^{-1}$ and $100<U_{23}<1000$ $Wm^{-2}K^{-1}$ which were evaluated using well known Rayleigh-Nusselt convection and Stefan-Boltzmann radiation heat transfer equations (Cengel, 2006). Equilibrium absorber temperatures (T_1) during collection periods were found by iteration to satisfy Equation 8. Temperature dependent collection/forward mode (U_{12f}) and retention/reverse mode (U_{12r}) diode conductances (see legend of Figure 1) were determined from experimental and theoretical work on PLVTDs by Pugsley (2017). Figure 2 indicates that the benchmark single glazed collector with no thermal diode (A) achieves η_{T24}=37% when the tank temperature is low (close to a zero daytime heat loss operating condition $[T_3-T_a]/G=0$) and a nominal mild-climate night-time heat loss condition $[T_3-T_a]$=15°C occurs. Performance decreases with increasing tank temperature such that η_{T24}=9% occurs for a hypothetical daytime condition of $[T_3-T_a]/G=0.1m^2KW^{-1}$ followed by a cold night-time period where $[T_3-T_a]$=70°C. Addition of a basic thermal diode (B) yields a 1.5 times improvement in low temperature performance (η_{T24}=56%) and doubles the high

temperature performance (η_{T24}=18%). Use of a high performance diode (E) yield a 1.7 times improvement in low temperature performance (η_{T24}=61%) and a 2.3 times improvement in high temperature performance (η_{T24}=21%). These improvements in diurnal thermal efficiency are primarily due to improved (reduced) reverse mode conductance (D) which improves heat retention efficiency, rather than increased forward mode conductance (C) which has only a limited effect on collection efficiency.

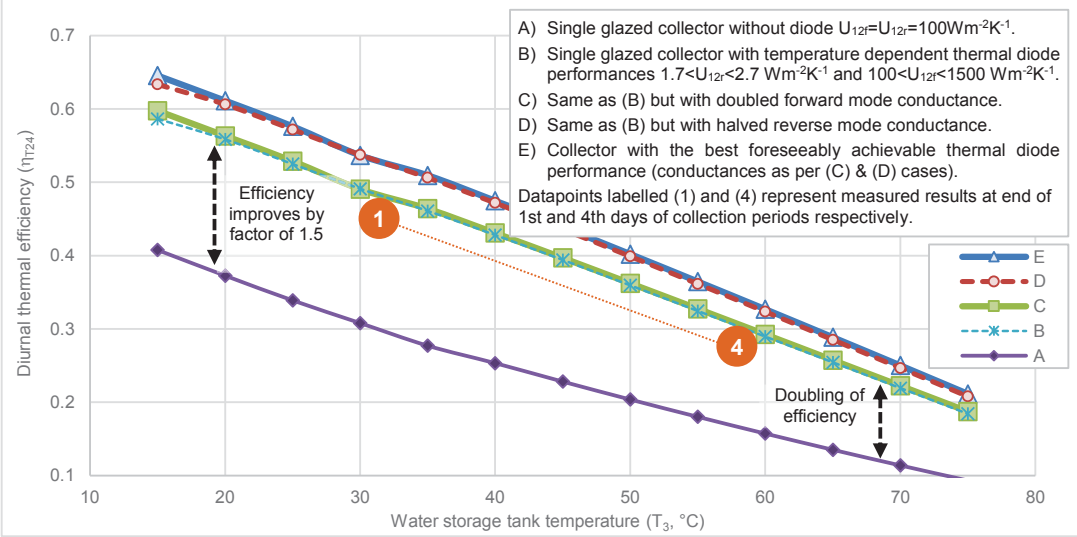

Figure 2 – Effect of diode thermal conductance upon diurnal thermal efficiency of an ICS collector

3. Experimental methodology

A prototype taking the form shown in Figure 1 was fabricated. The thermal diode and water storage tank (see Figures 3, 5a and Table 1) were formed of folded and welded stainless steel sheet supported internally by an array of stainless steel tubular struts. A welded vacuum flange was added to enable working fluid addition and chamber evacuation through the top of the unit. A stainless steel manifold plate was welded to the bottom to enable connection of the evaporator wetting mechanism (Intellectual Property considerations prevent us from describing this in detail). The completed steelwork was tested for storage tank water leaks and diode vacuum leaks (Figure 5c). The PVT absorber was then formed on the diode's absorber-evaporator plate (see Figure 4, 5b and Table 1) using matt black paint, double-sided adhesive foam tape, quartered mono-crystalline silicon cells, transparent silicone resin, and transparent Perspex cover plates. The series-parallel interconnected PV cells were connected to a 5.2Ω resistive load bank. Prior to resin casting, T-Type Thermocouples (TTC) producing measurement results with standard uncertainty ±0.3°C in the range 0 to 100°C were attached to the rear of four PV cells (T_0) and to the absorber-evaporator plate surface at twelve locations (T_1). Fourteen TTCs were bonded to the condenser-tank plate surface (T_2) within the tank, along with five TTCs mounted along a thin vertical wire suspended in the water (T_3). Thirteen TTCs were bonded to outer surfaces of diode sidewalls (T_4) and sump (T_S) and three were placed in shaded and sheltered locations to measure ambient temperatures (T_a). All TTCs were connected to a Delta-T Devices DL2e datalogger sampling continuously and recording average temperatures at 5 minute intervals. Thermally insulating polystyrene foam was applied to the rear and sides of the prototype along with a transparent Perspex sheet to cover the absorber.

The diode was filled with 1 kg of working fluid and evacuated to ~2.5 kPa (close to saturated vapour pressure of water at 20°C) using an Edwards XDS5 scroll vacuum pump and a Druck DPI-104 vacuum pressure gauge. The completed prototype was initially tested for heat retention performance by filling the tank with hot water at T_3=70°C and measuring the rate of temperature reduction overnight. The test was repeated with additional polystyrene insulation over the absorber which enabled tank back and sides heat loss to be quantified as U_{3ia}=1.1 $Wm^{-2}K^{-1}$ at 70°C and U_{3ia}=0.6 $Wm^{-2}K^{-1}$ at 40°C (estimated standard uncertainty ±0.2 $Wm^{-2}K^{-1}$). The tank was then drained and the prototype moved to Ulster University's solar simulator facility (Zacharopoulos et al., 2009). The main tests under the simulator followed similar methodologies and procedures to those used

by Quinlan (2010) and Smyth et al. (2015) although the test duration was significantly extended to account for the relatively high volume-to-absorber area ratio (100 L/m^2) of the prototype:

1. Adjust solar simulator for irradiance of G≈600 Wm^{-2} by taking readings at locations across the entire absorber surface with a Kipp and Zonen CMP6 pyrometer.
2. Fill tank with cold mains water. Activate evaporator wetting mechanism and remove temporary shading from absorber.
3. Disconnect resistive load bank from PV terminals. Measure characteristic IV performance curve of PV module using Daystar DS1000 tracer. Reconnect resistive load bank.
4. Repeat Step 3 after 2, 4 & 6 hours of illumination then immediately switch off the solar simulator and leave to cool overnight.
5. Repeat Steps 1 to 5 on subsequent days until no significant day-to-day change in daily minimum and maximum tank temperature occurs.

The procedure featured 6 hour collection periods (t_{col}=21600s) and 18 hour retention periods (t_{ret}=64800s) repeated over four consecutive 24 hour periods. Recorded temperature time history results were error-checked and spatially averaged to determine overall average values of T_0, T_1, T_2, T_3, T_4, T_S and T_a. These results were then used to determine heat transfer rates, corresponding thermal conductances and subsequently to determine thermal efficiencies according to Equations 1, 2 & 3. Photovoltaic performance results (V_{oc}, I_{sc}, V_{mpp}, I_{mpp}, Q_{Empp} and FF) were produced directly by the Daystar DS1000 along with characteristics IV curves.

Table 1 – Specifications of the prototype

Parameter		*Value*		*Basis / Reason*
Tank and diode envelope and structure construction material		**Stainless steel**		High strength, low vacuum outgassing, relatively low thermal conductivity and emittance.
Diode cavity depth	$x = x_w = x_s$	*mm*	70	Optimum value for compromise between forward and reverse mode performance.
Absorber-evaporator & condenser-tank plates height and width	z	*mm*	1400	Slender cavity aspect ratio (z/x=20) and modest plate aspect ratio (y/z=0.5) to minimise reverse mode vapour convection and optimise high temperature liquid-vapour-liquid conductance.
	y	*mm*	700	
Plate thickness	x_1	*mm*	1.2	Chosen for compromise between structural integrity, cost and weight, whilst minimising number of struts.
Sidewall thickness	z_w	*mm*	0.9	Chosen for compromise (z_w≈0.1x_w) between structural integrity and minimal sidewall thermal conductance, rounded up to nearest available gauge.
Centre-centre spacing of struts	d_{ss}	*mm*	70	Chosen to be similar to cavity depth and strut length
Strut tube diameter	d_s	*mm*	8	Compromise between structural integrity and minimising structure thermal conductance.
Strut tube wall thickness	d_{sw}	*mm*	0.9	
Mass of diode and tank	m_{1234s}	*kg*	8.1	Construction material and liquid masses determined from dimensions given above together with densities for stainless steel and liquid water (7900 and 1000 kg·m^{-3} respectively).
Mass of diode working fluid	m_{Lv}	*kg*	1.0	
Mass of water stored in tank	m_{3L}	*kg*	100	
Total mass	m_{tot}	*kg*	131	
Photovoltaic cells		**Monocrystalline silicon**		Bosch M-2BB high efficiency pseudo-square cells.
Number of cells	N	8 x 15 = 120		Formed of 30 whole cells cut into quarters.
Cell size	A_0	*m*^{2}	78 x 78	Quarter of a standard 6x6 inch whole cell.
Wiring scheme & voltage	V_{oc}	*V*	23	Series-parallel configuration of 8 cells per string with 3 strings connected in parallel to form each bus (V_{oc} ≈ 4.5V). Module consists 5 buses in series.
Cell packing factor	PF	%	72%	Thermo-electrical efficiency compromise. Absorber surface behind PV cells was painted matt black.
Encapsulation		**Silicone resin PlatSil® 71-20**		Low cost, highly transparent, pourable resin, resists UV degradation and high temperatures.
Bonded cover (on top of encapsulation) **Thermal cover (for air gap)**		**Clear Perspex**		Low cost, robust, resistant to UV degradation.
Thickness of encapsulation and bonded cover (x_{15}=x_{01}+x_{05})	x_{15}	*mm*	5	Perspex sheet minimum 2mm available thickness. Resin thickness determined by pour viscosity and adhesive foam tape spacer thickness.
	x_{01}	*mm*	1.5	
	x_{05}	*mm*	3.5	
Thickness of thermal cover	x_6	*mm*	2	
Thickness of air gap	x_{56}	*mm*	35

4. Results and discussion

Recorded temperature time histories are shown on Figure 6. Tests began with T_3=17°C tank temperature which rose by 21°C during the first collection period and fell by only 5°C during the first overnight retention period. The final (fourth) day of collection saw only 11°C gain before reaching T_3=57°C. This gain was almost entirely lost during the fourth overnight retention period. Ambient temperatures were T_a≈25±5°C during collection and T_a≈20±3°C during retention periods. Instantaneous thermal and electrical efficiencies were 60% and 9% respectively at zero increased temperature (T_3-T_a=0), dropping to 40% and 6% respectively at a nominal intended operating condition ~0.05 m^2KW^{-1} corresponding to T_3≈50°C, T_a≈20°C and G≈600 Wm^{-2}.

Dependence of the instantaneous thermal and electrical efficiencies upon the water storage tank temperature are shown on Figure 7 to be reasonably linear. Scatter in the data is primarily a manifestation of absorber heat-up and cool-down transients which occurred at the beginning and end of each collection period due to the diode's significant thermal mass (sensible and latent). These transients were observed to affect PV module efficiency as well as absorber heat loss and diode thermal conductance. Electrical efficiencies recorded at the start of each day of testing, immediately after illumination whilst the absorber was cool ($T_1 \lesssim T_a$+15°C), were consistently higher than values recorded at other times when the absorber was warmer (typically $T_1 \approx T_3$+8°C). Recorded collection efficiencies each day were η_{col}=65, 46, 44 and 40%. Overnight retention efficiency was η_{ret}=71% with corresponding overall loss coefficient U_{sys}=0.85 $Wm^{-2}K^{-1}$ (estimated standard uncertainty ±0.1 $Wm^{-2}K^{-1}$). With reference back to Figure 2, diurnal thermal efficiencies recorded for Days 1 and 4 were slightly lower than predicted because of poorer than expected forward mode diode thermal conductances, but as predicted, were significantly higher than for the benchmark ICSSWH without thermal diode.

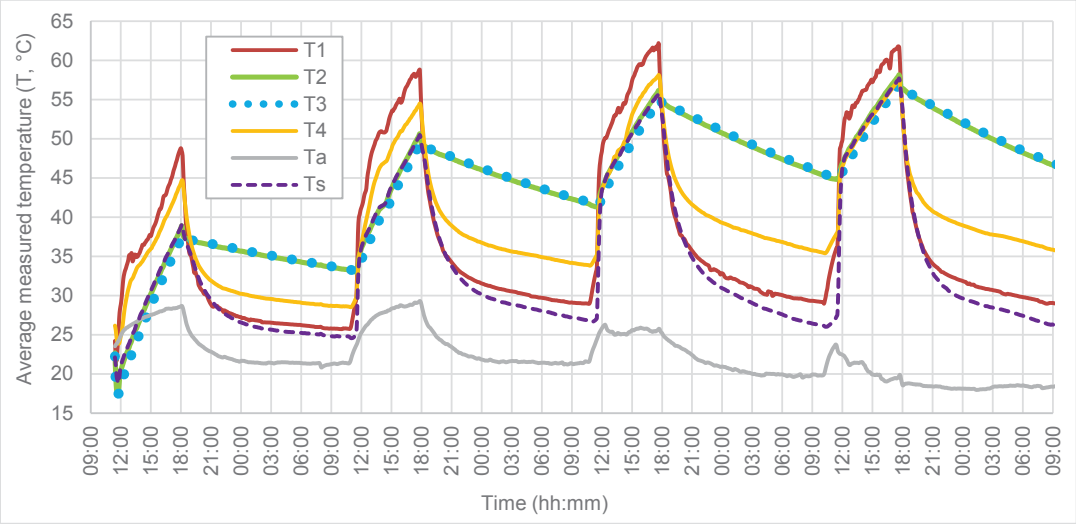

Figure 6 – Recorded temperature time history

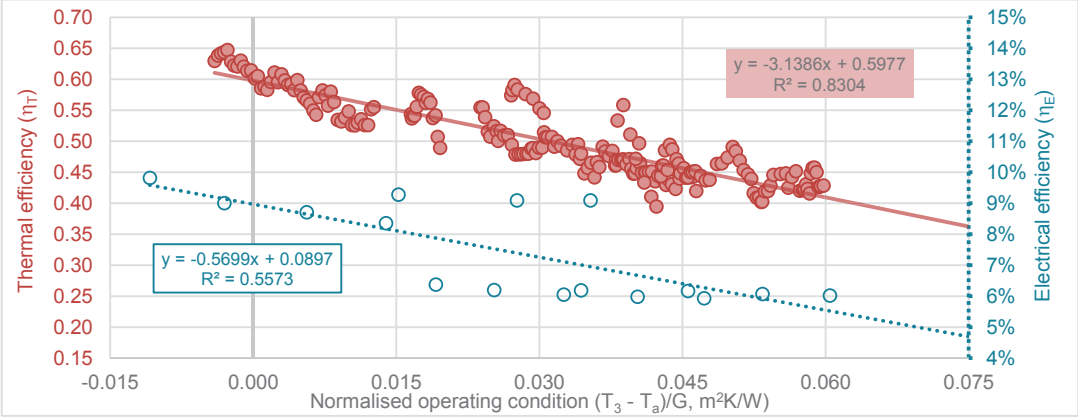

Figure 7 – Instantaneous thermal and electrical efficiencies

Table 2 – Comparison of measured photovoltaic characteristics against manufacturers data

Characteristic	***Manufacturer's data for single cell***	***Expected module performance***	***Actual module performance*** *(with encapsulation and bonded cover*)*
Maximum Power at STC (Q_{Empp}, W)	4.24	127	83*
Cell efficiency at STC ($\eta_{E(0,mpp)}$, %)	17.6%	17.6%	11.4%*
Module efficiency at STC ($\eta_{E(ec,mpp)}$, %)	-	13.7%	8.9%*
Open Circuit Voltage at STC (V_{oc}, V)	0.616	24.6	24.1*
Short Circuit Current at STC (I_{sc}, A)	8.9	6.7	4.8*
Fill Factor (FF, %)	78% (G=1000 Wm^{-2})		74% (G=610)
Voltage temperature coefficient (%V_{oc}/K)	-0.37%		-0.37%
Current temperature coefficient (%I_{sc}/K)	+0.03%		-0.19%
Maximum power temperature coefficient (%Q_{Empp}/K)	-0.49%		-0.55%

** Photovoltaic performance was measured under a variety of irradiances (G=350, 610 and 870 Wm^{-2}) and a variety of temperatures, with the transparent thermally insulating cover removed. No measurements were made under strict Standard Test Conditions (STC) of G=1000 Wm^{-2} and T_0=25°C but the data obtained enabled STC open circuit voltage, short circuit current, maximum power, and efficiency values to be determined by extrapolation.*

Forward mode diode thermal conductances were typically an order of magnitude lower (worse) than expected, but the predicted temperature dependence was clearly apparent with U_{12f}=30 $Wm^{-2}K^{-1}$ occurring when the water storage tank was cold, rising to U_{12f}=70 $Wm^{-2}K^{-1}$ when it was hot. Considerable spatial variation in absorber surface temperature was observed during collection periods. Detailed investigations (Pugsley, 2017) found that the relatively poor forward mode diode performances were primarily caused by poor evaporator wetting. Wetted parts of the absorber-evaporator plate were typically observed to be $T_1 \approx T_3$+3°C (as expected) whereas "dry spots" were markedly hotter (typically $T_1 \approx T_3$+30°C) due to the lack of evaporative cooling.

Reverse mode diode thermal conductances were generally slightly lower (better) than predicted being typically U_{12r} =1.7 $Wm^{-2}K^{-1}$. Other measured forward and reverse mode conductances were broadly as expected, being typically U_{23f}=250 $Wm^{-2}K^{-1}$ and U_{23r}=100 $Wm^{-2}K^{-1}$ within the water storage tank; U_{1af}=3.5 $Wm^{-2}K^{-1}$ and U_{1ar}=2.5 $Wm^{-2}K^{-1}$ between the absorber and ambient; and $U_{01} \approx$100 $Wm^{-2}K^{-1}$ through the silicone resin encapsulation bonding the PV cells to the absorber. Water storage tank thermal conductances (U_{23}) and absorber heat loss thermal conductances (U_{1a}) were higher during forward mode than during reverse mode because heat fluxes and plate temperatures were inherently higher during solar collection periods than they were during retention periods. The estimated combined standard uncertainty of the aforementioned thermal conductance results is about ±30%.

Measured PVT absorber electrical performance is summarised in Table 2. Short circuit current (I_{sc}), maximum electrical power yield (Q_{Empp}), and efficiency (η_E) were all 30-35% lower than expected, despite results of pilot tests on individual cells being broadly consistent with manufacturer's data. Measured temperature coefficients for whole-module power (%Q_{Empp}/K) and short circuit current (%I_{sc}/K) were also notably worse than manufacturers single-cell values. Analysis described in detail by Pugsley (2017) identifies several potential causes for the poor current yield, of which the most significant is accidental cell damage (to approximately a quarter of all cells) which occurred during absorber laminate fabrication. Cell fractures function as electrical resistances which limit (or completely eliminate) the flow of current between broken cell fragments and the main body of each cell. Detailed inspection of the test data indicated an abrupt worsening of current loss above $T_1 \approx$45°C which is thought to be due to absorber thermal expansion widening fractures and increasing associated electrical resistances. In addition to cell fractures, the following effects are also likely to have contributed to current and power loss:

- Uneven distribution of light emitted by the solar simulator (±10% for high irradiance tests) causing some cells to produce less current than others, thereby limiting overall string currents.
- Optical losses associated with delamination of the encapsulation material, which was particularly notable in locations where the aforementioned hot "dry spots" occurred.

- Non-uniform absorber surface temperatures which caused voltage mismatches between parallel connected cell strings. The hot "dry-spots" on the absorber-evaporator plate were observed to be most pronounced when the absorber and/or the tank were cool and irradiance levels were high.

Despite the lower than expected diode forward mode thermal conductance and underperforming PV cell array, the solar thermal collection and retention performances of the prototype are amongst the highest reported anywhere in the ICSSWH literature (see Sections 1.1 & 1.2) providing strong evidence that incorporation of a planar liquid-vapour thermal diode yields a significant performance benefit. This finding is echoed in the comparative study reported by Smyth et al. (2016).

5. Supporting analyses

In addition to the work presented above, a considerable amount of additional experimental and theoretical work and supporting analyses have been undertaken as part of this study (Pugsley, 2017) and will be the subject of several anticipated future papers:

- **Theoretical behavior of PLVTDs:** A lumped parameter thermal resistance model enabling prediction of PLVTD heat transfer was developed and experimentally validated. The model was used to undertake a parametric study examining PLVTD behaviour under different heat flux, temperature, and tilt angle conditions. The model was also used to optimize the PLVTD design in respect of material choices; working fluid types and flow rates; dimensions and aspect ratios.
- **Economics:** Materials for the prototype cost £600/m^2. This cost is comparable to typical retail prices of flat plate and evacuated tube solar thermal collectors and is considerably less than most commercially available packaged solar water heaters. Estimated labour costs were very high (£2000/m^2) due to reliance on labour intensive processes required to fabricate a one-off prototype. Significant value engineering and manufacturing process optimization would be required to make the device commercially viable and mass-manufacturable.
- **Building integration:** Feasibility studies were undertaken to examine how the PVT-PLVTD-ICSSWH concept might be integrated into different building façade constructions, allowing for key considerations such as structural loading and aesthetic/dimensional compatibility with building structural grids. The compatibility of the device in respect of integration into building electrical and heating services systems was also examined.

6. Conclusions

A flat panel Integrated Collector-Storage Solar Water Heater (ICSSWH) incorporating a photovoltaic-thermal (PVT) absorber and a Planar Liquid-Vapour Thermal Diode (PLVTD) was fabricated and tested under Ulster University's solar simulator. The collector primarily consisted of a sealed evacuated thermal diode and a vented water storage tank, both constructed of welded and folded stainless steel sheet. The absorber-evaporator plate was painted black and 120 quartered monocrystalline photovoltaic cells were encapsulated and bonded to it using clear silicone resin. Cells were interconnected in a series-parallel configuration to produce an open circuit voltage of ~24V. The absorber was insulated by a transparent Perspex cover and air gap. Collector rear and sides were insulated by polystyrene foam.

Test results indicate instantaneous thermal and electrical efficiencies of 60% and 9% respectively under zero temperature rise conditions (when stored water temperature equals ambient temperature), dropping to 40% and 6% at the nominal intended operating condition (~0.05 m^2KW^{-1} at 20°C ambient). Water temperature of 57°C was achieved in the 100 Litre tank after four days of consecutive 6-hour collection periods (G=610Wm^{-2} irradiance on ~0.95m^2 absorber) and 18 hour retention periods (T_a≈20±3°C). Daily solar thermal collection and overnight heat retention efficiencies of η_{col}=65% and η_{ret}=71% were achieved, corresponding to diurnal thermal efficiency of up to $\eta_{T+E,24}$=46% and an overall heat loss coefficient of U_{sys}=0.85 $Wm^{-2}K^{-1}$. Measured thermal diode conductances were typically U_{12f}=45 $Wm^{-2}K^{-1}$ in forward mode (during collection periods) and U_{12r}=1.7 $Wm^{-2}K^{-1}$ in reverse mode (during retention periods). These thermal performances are comparable to

the best ICSSWH collector designs encountered in the literature. Photovoltaic performance was lower than expected, primarily owing to accidental damage to PV cells during fabrication, together with temperature and irradiance non-uniformities, and optical losses associated with delaminated encapsulation.

Overall, the work demonstrates that ICSSWH, PVT and PLVTD concepts can be successfully combined to create a scalable flat panel solar collector suitable for integration within a multifunction building facade. Changes to fabrication procedures could reduce or eliminate breakage of PV cells. Improved evaporator wetting, reduced PV cell encapsulation thickness, and better bonding of PV cells to the absorber plate would all increase conductance during collection periods yielding improvements to both thermal and electrical efficiencies. It is recommended that further work focusses on implementing the aforementioned improvements and undertaking further studies to optimize the design for building façade and services systems integration.

7. Nomenclature

Meanings of symbols:

A	Area
α	Solar absorption coefficient
C	Heat capacity
d	Distance or dimension
FF	Fill Factor of current-voltage characteristic curve
G	Irradiance or solar power flux
η	Efficiency with subscripts $_{E, T, col, ret, 24, 0, ec, mpp}$
I	Current (subscript $_{sc}$ for "short circuit")
m	Mass with subscripts $_{Lv, 3L, 1234s, tot}$
N	Number of PV cells
PF	Packing Factor of PV cells
Q	Power (Q_{Empp} = electrical at maximum power point)
R	Thermal resistance with subscripts $_{12, 123, 1a, 23, 3ia}$
t	Time or duration with subscripts $_{0, col, ret}$
T	Temperature with subscripts $_{0, 1, 2, 3, 4, a, s}$
τ	Optical transmittance
U	Thermal conductance with subscripts $_{12f, U12r, 23f, 23r, 1af, 1ar, 3ia, sys}$
V	Voltage (subscript $_{oc}$ for "open circuit")
x	Distance parallel to collector depth with subscripts $_{01, 05, 1, 15, 56, 6, s, w}$
y	Distance parallel to collector width
z	Distance parallel to collector height (subscript $_{w}$ for "sidewall thickness")

Meanings of subscripts:

a	Ambient
col	Collection
E	Electrical
f	Forward mode / collection periods
Lv	Diode working fluid at liquid-vapour saturation
r	Reverse mode / retention periods
ret	Retention period
s	Strut
S	Sump
sys	System heat loss coefficient
tot	Total
T	Thermal
0	Photovoltaic cells (T_0, A_0) or Start of period (t_0)
1	Absorber-evaporator plate
2	Condenser-tank mantle plate
3	Water in storage tank
4	Diode sidewalls
5	Absorber laminate bonded cover plate surface
6	Transparent thermally insulating cover
12	Between Plates 1 and 2
123	Between absorber and bulk of stored water
1a	Between absorber and ambient
23	Between Plate 2 and bulk of stored water
24	Diurnal value over a 24 hour period
3ia	Between "3" and "a" via foam insulation
56	Air gap between absorber & transparent cover

Abstract

In this work, the Optimal Power Flows (OPF) for the tertiary control problem in microgrid is studied. The objective is to find the optimal dispatch of energy which maximize the benefit. Such energy can come from renewable sources, storage devices or the main power grid. To this aim, a unified model of the microgrid, which is operated in non-autonomous mode, has been developed. This model is composed by basic submodels of the distribution system, the photovoltaic panels, the wind turbines and the batteries for energy storage. The optimization problem is solved using three different methods provided by the optimization toolbox of MATLAB®. More precisely, an interior point method, a genetic algorithm and the direct search method have been considered. The performance of those optimization methods is analyzed in terms of efficiency and effectiveness. Some good results are depicted. The case study considers the microgrid connected to the main power system with the photovoltaic panels, the wind turbines and the batteries for energy storage. In this test, the power supplied by the grid is mostly due to the size of each renewable source, but it is possible to see the contribution of the microgrid in the cost graphics.

Keywords: *optimal power flow, microgrid, distributed power systems*

1. Introduction

Nowadays the electricity sector worldwide is subject to meet strict environmental policies that promote the use of renewable energy sources, with the aim to contribute with the environmental and global energy sustainability. The operation modes of a microgrid are two: i) non-autonomous (connected to the main power grid) and, ii) autonomous (not connected to the main power grid) [Olivares, 2014]. In any of these operation modes, the microgrid is controlled through a three-level hierarchical control system which can be split in a primary controller, a secondary controller and tertiary one [Bidram, 2012]. This work is part of the tertiary controller of the microgrid operating in non-autonomous mode. In this scenario, the objectives that are mainly considered for the tertiary controller are the minimization of the energy cost from the main grid and the optimization of the voltages profile within the microgrid among others, through different optimization methods [Katiraei, 2008]. As a result, Optimal Power Flows (OPF) analysis is the cornerstone of the tertiary controller. Taken it into account, this paper is particularly focused in implement a model of optimal power flows of the microgrid for non-autonomous operating mode and three different optimization methods for the resolution of OPF. Based on the profiles of electric demand curves and solar radiation from the cities of Salamanca and Guanajuato, Mexico, and the predicted wind speed for a period of time T, the analysis of optimal power flows can be used to determine the optimum dispatch for the energy storage devices and the optimal quantity of power imported from the main grid, with the aim of maximizing the benefit of the energy generated by the Distributed Energy Sources (DES) installed in the microgrid and, at the same time, reducing the cost of the energy imported from the main grid [Levron, 2013]. In a microgrid framework,

doi:10.18086/eurosun.2016.08.24 Available at http://proceedings.ises.org

different models of optimal power flow, optimization algorithms and strategies for the energy management have been proposed [Olivares et al 2014, Levron et al 2013, Gill et al 2014]. Despite this, there is not any strategy of optimal power flows that can be considered as the ultimate tool for the implementation of a tertiary controller. Therefore, the problem of optimal flows for microgrids is a topic of current research and of relevant importance in this context.

This work presents three different optimization methods for a unified model of optimal power flow for microgrids, which considers basic models of the elements of the distribution system, photovoltaic panels, wind turbines, as well as batteries for energy storage. The model is solved by three different methods of optimization: i) interior point, ii) genetic algorithm and, iii) direct search provided by the optimization toolbox included in MATLAB®. The solutions obtained allows us to evaluate the optimal dispatch of energy storage devices and the optimal amount of power imported from the main grid. The mathematical basis of this work and the generic model of OPF for microgrid are presented in the Section 2. Section 3 shows the mathematical models of the different components of the microgrid as a wind turbine, photovoltaic module, battery, load, and the components of the distribution lines. In Sections 4 and 5 the explicit model of OPF and its solution are described, respectively. In Section 6 are described, showed and compared the results obtained with the different methods of optimization for the proposed case study. Finally, the conclusions of this work are presented in Section 7.

2. Generic model of OPF for Microgrid

For electric demand curves, solar radiation and predicted wind speed for an interval of time T, the general model of OPF is given by eqs. 1-4. It should be noted that, in this model, it is considered that the period of time T is composed of a set of time stages t_z ($\forall z = 1,..., end$), such that $T = [t_1,..., t_{end}]$.

$$\text{Minimize} \quad F_T = \sum_{t_z=1}^{t_{end}} f^{t_z}(\boldsymbol{y}^{t_z}) \qquad \text{(eq. 1)}$$

$$\text{Subject to} \quad \boldsymbol{h}^{t_z}(\boldsymbol{y}^{t_z}) = \boldsymbol{0}\ ;\ \forall t_z \in T \qquad \text{(eq. 2)}$$

$$\boldsymbol{g}^{t_z}(\boldsymbol{y}^{t_z}) \le \boldsymbol{0}\ ;\ \forall t_z \in T \qquad \text{(eq. 3)}$$

$$\underline{\boldsymbol{y}} \le \boldsymbol{y}^{t_z} \le \overline{\boldsymbol{y}}\ ;\ \forall t_z \in T \qquad \text{(eq. 4)}$$

Taking into account that, t_z represents the *z-th* time stage, the description of the terms of the model, eqs. 1-4, is as follows: F_T is the objective function to optimize along the interval T, $\boldsymbol{h}(\boldsymbol{y})$ is a set of equality constraints, which represents the balance equations of active power and reactive on all the nodes in the microgrid, as well as other operating conditions that must be fulfilled unconditionally, $\boldsymbol{g}(\boldsymbol{y})$ is a set of constraints of inequalities that represents the physical limits and operating of the elements that make up the microgrid, $\boldsymbol{y}$ is the set of decision variables (to be optimized) composed of subsets $\boldsymbol{y}_{RD}$, $\boldsymbol{y}_{MF}$ and $\boldsymbol{y}_B$ such $\boldsymbol{y}=[\boldsymbol{y}_{RD}, \boldsymbol{y}_{MF}, \boldsymbol{y}_B,]$. Where $\boldsymbol{y}_B$, $\boldsymbol{y}_{RD}$ and $\boldsymbol{y}_{MF}$ represent batteries variables, distribution grid and photovoltaic modules, respectively. The upper and lower limits, $\overline{\mathbf{y}}$ and $\underline{\mathbf{y}}$, of these variables are formulated through the inequality constraints, see eq. 4.

3. Model for microgrids components

The models for microgrid components presented in this section are considered to formulate explicitly the unified model of OPF for microgrid presented in Section 4.

3.1. Points of Common Coupling

It is considered that the microgrid operates in non-autonomous mode, such that is connected to the main grid in N_{pac} ($N_{pac} \ge 1$) Points of Common Coupling (PCC). It is assumed that each PCC is electrically robust and is an interface for the unlimited exchange of both, active and reactive power between the microgrid and the main grid. In this context, the PCC are modeled as generation sources that operate at voltage levels

magnitude $V_j^{t_z}$ and angle $\theta_j^{t_z}$ within the limits given by eq. 5:

$$\left.\underline{V}_j \le V_j^{t_z} \le \overline{V}_j ; \underline{\theta}_j \le \theta_j^{t_z} \le \overline{\theta}_j \right\} \forall t_z \in T \;\; ; \;\; \forall j \in PAC \qquad \text{(eq. 5)}$$

For time t_z, the cost of active total power exchanged through the PCC is modeled by eq. 6. Where a_j, b_j and c_j are weight constant coefficients for the *j-th* PCC. The variable $P_{RPj}^{t_z}$ means the power exchanged through the *j-th* PCC. The decision variables associated with the PCC are $\left[V_j^{t_z}, \theta_j^{t_z}, P_{RPj}^{t_z}\right] \in \boldsymbol{y}_{RD}$ ($\forall t_z \in T, \forall j \in PCC$).

$$f^{t_z}(\boldsymbol{y}^{t_z}) = \sum_{j=1}^{N_{pac}} a_j + b_j (P_{RPj}^{t_z}) + c_j (P_{RPj}^{t_z})^2 \quad ; \; \forall t_z \in T \qquad \text{(eq. 6)}$$

3.2. Feeders

Each feeder is modeled as a line of transmission, as is illustrated in Fig. (1) Where $\boldsymbol{I}_i$ and $\boldsymbol{E}_i$ are the phasors of the injected electricity and voltage, respectively, on the node i ($i = k,m$) of the microgrid. R, L and B_c represent the parameters of resistance series, inductance series and shunt susceptance, respectively, of the feeder. The relationship electricity-voltage of the equivalent circuit is given by eq. 9 [Acha, 2004]. Where admittance matrix elements are evaluated in eq. 8 and eq. 9.

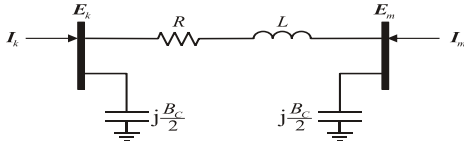

Fig. 1: π circuit for the feeders

$$\begin{bmatrix} \boldsymbol{I}_k^{t_z} \\ \boldsymbol{I}_m^{t_z} \end{bmatrix} = \begin{bmatrix} \boldsymbol{Y}_{kk} & \boldsymbol{Y}_{km} \\ \boldsymbol{Y}_{mk} & \boldsymbol{Y}_{mm} \end{bmatrix} \begin{bmatrix} \boldsymbol{E}_k^{t_z} \\ \boldsymbol{E}_m^{t_z} \end{bmatrix} \quad \forall t_z \in T \qquad \text{(eq. 7)}$$

$$\boldsymbol{Y}_{kk} = \boldsymbol{Y}_{mm} = (\boldsymbol{y}_{km} + j0.5Bc) = G_{kk} + jB_{kk} ; \boldsymbol{Y}_{km} = \boldsymbol{Y}_{mk} = -\boldsymbol{y}_{km} = G_{km} + jB_{km} \qquad \text{(eq. 8)}$$

$$G_{km} = R/R^2 + (\omega L)^2 ; B_{km} = -\omega L/R^2 + (\omega L)^2 \qquad \text{(eq. 9)}$$

Starting from Fig. 1 and eq. 7 it is possible to obtain expressions that model the injection of active and reactive power, eq. 10 and eq. 11 respectively, on the node i ($i = k, m$) at each moment $t_{T \in} z$ [Acha, 2004]. Where $j = k, m$, being $j \neq i$. The variables $V_n^{t_z}$ and $\theta_n^{t_z}$ ($n=i, j$) represent the magnitude and the angle of the nodal voltage phasor $\boldsymbol{E}_i$.

$$P_{inyi}^{t_z} = (V_i^{t_z})^2 G_{ii} + V_i^{t_z} V_j^{t_z} \left[G_{ij} Cos(\theta_i^{t_z} - \theta_j^{t_z}) + B_{ij} Sin(\theta_i^{t_z} - \theta_j^{t_z}) \right] \qquad \text{(eq. 10)}$$

$$Q_{nyi}^{inj\ t_z} = -(V_i^{t_z})^2 B_{ii} + V_i^{t_z} V_j^{t_z} \left[G_{ij} Sin(\theta_i^{t_z} - \theta_j^{t_z}) - B_{ij} Cos(\theta_i^{t_z} - \theta_j^{t_z}) \right] \qquad \text{(eq. 11)}$$

The decision variables associated to these feeders correspond to the nodal voltages in its terminals $\left[V_k^{t_z}, V_m^{t_z}, \theta_k^{t_z}, \theta_m^{t_z}\right] \in \boldsymbol{y}_{RD}$ ($\forall t_z \in T$).

3.3. Transformer

The primary winding is considered an ideal transformer with relation of complex tap T_v:1 and T_i:1 in series with the impedance Z_p (refers to Fig. (2)). Where $\boldsymbol{T}_v = \boldsymbol{T}_i^* = T_v \angle \phi_{tv}$, the symbol * denotes complex conjugate. The secondary winding is also represented as an ideal transformer with relation of complex tap $\boldsymbol{U}_v$:1 and $\boldsymbol{U}_i$:1 in series with the impedance $\boldsymbol{Zs}$. Where $\boldsymbol{U}_v = \boldsymbol{U}_i^* = U_v \angle \phi_{uv}$. The relationship between voltage $\boldsymbol{V}_p$ and electricity $\boldsymbol{I}_p$ of the primary winding and the voltage $\boldsymbol{V}_s$ and electricity $\boldsymbol{I}_s$ of the secondary one is given by eq. 12 [Acha, 2004].

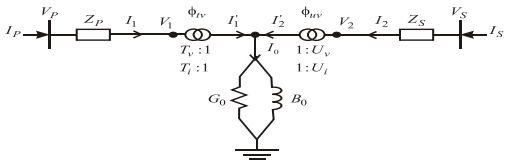

Fig. 2: T model for the transformers

$$\begin{bmatrix} \boldsymbol{I}_p^{t_z} \\ \boldsymbol{I}_s^{t_z} \end{bmatrix} = \begin{bmatrix} G_{PP}\ G_{PS} \\ G_{SP}\ G_{SS} \end{bmatrix} + j \begin{bmatrix} B_{PP}\ B_{PS} \\ B_{SP}\ B_{SS} \end{bmatrix} \begin{bmatrix} \boldsymbol{V}_p^{t_z} \\ \boldsymbol{V}_s^{t_z} \end{bmatrix};\ \forall t_z \in T \qquad \text{(eq. 12)}$$

where:

$$G_{PP} = \frac{F1(U_v^2 + R1) + F2R2}{F1^2 + F2^2},\ B_{PP} = \frac{F1R2 - F2(U_v^2 + R1)}{F1^2 + F2^2}$$

$$G_{SS} = \frac{F1(T_v^2 + R3) + F2R4}{F1^2 + F2^2},\ B_{SS} = \frac{F1R4 - F2(T_v^2 + R3)}{F1^2 + F2^2}$$

As the feeders, the injections of active and reactive power in the connection nodes *i* and *j*, where *i = p, s; j = p, s; i≠j,* are represent by eqs. 10 and 11, but considering the conductance and susceptance matrices of eq. 12. It is important to highlight that, the decision variables associated with transformers correspond to the nodal voltages in its terminals $\left[V_p^{t_z}, V_s^{t_z}, \theta_p^{t_z}, \theta_s^{t_z}\right] \in \boldsymbol{y}_{RD}$. ($\forall t_z \in T$).

3.4. Batteries

The batteries are elements that can operate in charge or discharge mode to provide or consume a net amount of active power in their connection node. Then, the *j-th* battery is represented by two sources of active power, as shown in Fig. 3 [Gill, 2014]. One of them represents the charge power $P_{Bc\,j}^{t_z} \leq 0$ and the other the discharge power $P_{Bd\,j}^{t_z} \geq 0$, the sum of both powers represents the net power $P_{Bn\,j}^{t_z}$ provided or consumed by the battery in their connection node.

$$P_{Bn\,j}^{t_z} = P_{Bc\,j}^{t_z} + P_{Bd\,j}^{t_z};\ 0 \leq P_{Bd\,j}^{t_z};\ P_{Bc\,j}^{t_z} \leq 0;\ \forall t_z \in T \qquad \text{(eq. 13)}$$

In addition, the voltage phasor in the connection node is represented by its magnitude $V_j^{t_z}$ and its angle $\theta_j^{t_z}$. Thus, the decision variables of the *j-th* battery are $\left[P_{Bd\,j}^{t_z}, P_{Bc\,j}^{t_z}\right] \in \boldsymbol{y}_B$ ($\forall t_z \in T$), while $[V_j^{t_z}, \theta_j^{t_z}] \in \boldsymbol{y}_{RD}$ ($\forall t_z \in T$). Moreover, the State Of Charge of the *j-th* battery (SOC) in the time t_z ($SOC_{B\,j}^{t_z}$) can be approximated by means of eq. 14.

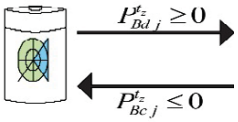

Fig 3. Battery model

$$SOC_{B\,j}^{t_z} = SOC_{B\,j}^{t_0} - \frac{\varepsilon_{c\,j}\Delta t}{E_{Bnom\ j}} \sum_{t=1}^{t_z} P_{Bc\,j}^{t} - \frac{\Delta t}{E_{Bnom\ j}\,\varepsilon_{d\,j}} \sum_{t=1}^{t_z} P_{Bd\,j}^{t} \qquad \text{(eq. 14)}$$

It is assumed that the energy provided by the batteries has not cost, since it is absorbed and provided in the same node of connection. However, since the optimization algorithm will manage the power, batteries will be charged in periods of low-cost energy and it will be discharged in periods of high cost. This fact involves an economic benefit in the operation of the microgrid.

3.5. Wind turbine

For the aim of the stationary analysis, the wind turbine can be considered like a source of non controlled

active power $P_{Aj}^{t_z}$, depending on its density δ_w, wind speed $S_w^{t_z}$, as well as of the area A_w covered by the blades of the wind turbine [Wang, 2009]

$$P_{Aj}^{t_z} = \delta_w A_w \left(S_w^{t_z}\right)^3 \Big/ 2, \forall t_z \in T \qquad \text{(eq. 15)}$$

Since it is considered that the power delivered by the wind turbine is not controllable; this element does not introduce decision variables. However, eq. 16 is required to assess the contribution of the power *j-th* of the wind turbine for a wind speed curve, $S_w^{t_z}\ \forall\ t_z \in T$, density, δ_w, and area, A_w, given. Clearly, the magnitude $V_j^{t_z}$ and angle $\theta_j^{t_z}$ of the voltage phasor of the connection node are considered as decision variables, such that $[V_j^{t_z}, \theta_j^{t_z}] \in \boldsymbol{y}_{RD}$ ($\forall t_z \in T$). Finally, it is assumed that the energy provided by the wind turbine has no cost. In addition, it is considered available a good forecast for wind speed curves.

3.6. Photovoltaic modules

Figure 4 shows the schematic model of a photovoltaic module connected to the node *k-th* through a converter DC/AC 4 [Bellini, 2009]. The implicit expression eq. 16 models the behavior of the current DC in $I_{CD\,k}^{t_z}$ panel terminals. Where I_{ph}, I_0, $V_{CD\,k}^{t_z}$, R_s, n_s and n_p represent the current of the panel photovoltaic, the current of saturation, the DC voltage in the module terminals, the resistance in series, and the number of cells in series and in parallel, respectively. The term R_s is evaluated from eq. 17, where V_{oc}, V_{mp}, I, I_{mp} represent the open circuit voltage, the voltage of the point of maximum power, short circuit electricity and maximum power point electricity, respectively. Terms I_{sc} and V_{oc} are evaluated through eq. 18 and eq. 19, respectively. Where $I_{sc,\,stc}$, G, G_{stc}, k_i, T, T_{stc}, $V_{oc,\,stc}$, and k_v represent the short circuit electricity standard under conditions of test, irradiance under test, electricity temperature coefficient, temperature of the panel, standard temperature under test, standard low open circuit voltage conditions test and voltage and temperature coefficient, respectively.

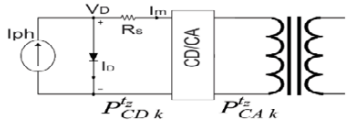

Fig. 4 Schematic model of a photovoltaic module

$$I_{CDk}^{t_z} = \left[I_{ph} - I_0 \left(\exp\left(\frac{\frac{V_{CD\,k}^{t_z}}{n_s} + \frac{I_{CDk}^{t_z}}{n_p} R_s}{V_{CD}^{t_z}} \right) - 1 \right) \right] n_p; \forall t_z \in T \qquad \text{(eq. 16)}$$

$$R_s = \frac{\frac{V_{oc} - V_{mp}}{n_s} + V_{CD}^{t_z} \ln\left(\frac{I_{sc} - I_{mp}}{I_{sc}}\right)}{\frac{I_{mp}}{n_p}} \qquad \text{(eq. 17)}$$

$$I_{sc}(T,G) = I_{sc,stc} - \frac{G}{G_{stc}}\left[1 + \frac{k_i}{100}(T - T_{stc})\right] \qquad \text{(eq. 18)}$$

$$V_{oc}(T) = V_{oc,stc}\left[1 + \frac{k_v}{100}(T - T_{stc})\right] \qquad \text{(eq. 19)}$$

In this work, the photovoltaic module parameters involved in eqs.16-19 were taken from the features of the polycrystalline module Solartec S60PC-250 [Bellini, 2009]. Moreover, a good forecast of solar irradiance curves is considered available.

According to the model of the Fig. 4, the injected power in DC terminals (generated by module) can be expressed directly as:

$$P_{CD\,k}^{t_z}\left(V_{CD\,k}^{t_z},\, I_{CD\,k}^{t_z}\right) = I_{CD\,k}^{t_z} V_{CD\,k}^{t_z};\ \forall t_z \in T \qquad \text{(eq. 20)}$$

Moreover, the balance of power between the terminals of AC and DC of the inverter must also be fulfilled. If the losses of the converter are rejected:

$$P_{CA\,k}^{t_z}\left(V_k^{t_z}, V_m^{t_z}, \theta_k^{t_z}, \theta_m^{t_z}\right) = P_{CD\,k}^{t_z}\left(V_{CD\,k}^{t_z}, I_{CD\,k}^{t_z}\right);\ \forall t_z \in T \qquad \text{(eq. 21)}$$

where $P_{CA\,k}^{t_z}$ is the active power injected at the terminals of the primary transformer coupling module. $V_k^{t_z}$ and $\theta_k^{t_z}$ are the magnitude and the angle, respectively, of the voltage phasor for such terminals. $V_m^{t_z}$ and $\theta_m^{t_z}$ represent the same but for the secondary terminals. Therefore, $P_{CA\,k}^{t_z}$ in eq. 21 is formulated explicitly by means of eq. 11, but considering the matrix of conductances and susceptances of eq. 13. It is important to mention that, due to it is considered a DC/AC converter multipulse with 48 pulses, the following relationship must also keep [Zúñiga, 2006]:

$$V_{CD\,k}^{t_z} = \frac{\pi}{16} V_k^{t_z};\ \forall t_z \in T \qquad \text{(eq. 22)}$$

It is important to highlight that, the decision variables introduced by the photovoltaic module are $\left[V_{CD\,k}^{t_z} I_{CD\,k}^{t_z}\right] \in \boldsymbol{y}_{MF}$ ($\forall t_z \in T$), whereas $[V_k^{t_z}, V_m^{t_z}, \theta_k^{t_z}, \theta_m^{t_z}] \in \boldsymbol{y}_{RD}$ ($\forall t_z \in T$).

3.7. Electrical load

Energy consumption in load nodes of the microgrid is represented by a model of constant power for any interval of time T. The power *i-th* $\boldsymbol{S}_{li}^{t_z}$ complex consumed in the node is then represented by eq. 23. Where $P_{li}^{t_z}$ and $Q_{li}^{t_z}$ represent the power consumption active on that node at the instant t_z, respectively.

$$\boldsymbol{S}_{li}^{t_z} = P_{li}^{t_z} + jQ_{li}^{t_z}\ \ \forall t_z \in T \qquad \text{(eq. 23)}$$

Model of energy demand does not introduce decision variables to the optimization problem, but the magnitude $V_i^{t_z}$ and angle $\theta_i^{t_z}$ of the connection node phasor voltage must be considered as decision variables, such as $[V_i^{t_z}, \theta_i^{t_z}] \in \boldsymbol{y}_{RD}$ ($\forall t_z \in T$). In addition, it is considered that a good forecast of the energy demand curves is available ($\boldsymbol{S}_{li}^{t_z} \forall i, t_z \in T$).

4. Explicit model of OPF

Models of the microgrid components described in Section 3 are considered in this section to formulate explicit model of OPF for non-autonomous microgrid. For this purpose, is considered one generic microgrid composed of a number of N_{bAC} nodes in AC, N_{bCD} nodes in DC, N_{Al} feeders, N_T transformers, N_B battery, N_A wind turbines, N_{MF} photovoltaic modules and N_{CE} electrical loads. Noted that, the N_{pac} points of common coupling are a subset of the N_{bAC} nodes in AC. In addition, the nodes in DC represent DC terminals of the photovoltaic modules, such N_{bCD}=N_{MF}.

4.1. Objective function

The intention is to minimize eq. 1, which is formulated explicitly taking into account eq. 6, as follows:

$$F_T = \sum_{t_z=1}^{t_{end}} \sum_{j=1}^{N_{pac}} a_j + b_j\ (P_{RP\,j}^{t_z}) + c_j\ (P_{RP\,j}^{t_z})^2 \qquad \text{(eq. 24)}$$

Note that eq. 24 denotes that the objective is to minimize the cost of the total energy imported through the PCC during the period of time T to supply the demand curves predicted $\boldsymbol{S}_{li}^{t_z} \forall i, t_z \in T$.

4.2. Equality constraints

The set of equality constraints **h(y)** in eq. 2 is expressed explicitly as follows. The constraints of power active, $\Delta P_{RDi}^{t_z}$, and reactive, $\Delta Q_{RDi}^{t_z}$, balance corresponding to the nodes of the microgrid in AC are written in the first block of eq. 25.

$$\boldsymbol{h}^{t_z}(\boldsymbol{y}^{t_z})=\left\{\begin{array}{c}\left.\begin{array}{c}\Delta P^{t_z}_{RD\,i}=P^{t_z}_{RP\,i}+\sum\limits_{\forall j\in i}P^{t_z}_{Bc\,j}+\sum\limits_{\forall j\in i}P^{t_z}_{Bd\,j}+\sum\limits_{\forall j\in i}P^{t_z}_{A\,j}+\\ \sum\limits_{\forall j\in i}P^{t_z}_{CD\,j}-\sum\limits_{\forall j\in i}P^{t_z}_{lj}-\sum\limits_{\forall j\in i\,|\,j\in N_{AI},N_T}P^{t_z}_{inj\,j}(\boldsymbol{V},\boldsymbol{\theta})=0,\\ \Delta Q^{t_z}_{RD\,k}=-\sum\limits_{\forall j\in k}Q^{t_z}_{lj}-\sum\limits_{\forall j\in k}Q^{t_z}_{inj\,j}(\boldsymbol{V},\boldsymbol{\theta})=0\\ i=1,2,\ldots,N_{bAC}\;;\;k=1,2,\ldots,N_{bAC}\,|\,\forall k\notin N_{GEN}\end{array}\right\}\\ \left.\begin{array}{c}\Delta I^{t_z}_{CD\,k}=I^{t_z}_{CD\,k}-f_{CD}(V^{t_z}_{CD\,k},I^{t_z}_{CD\,k})=0,\\ \Delta P^{t_z}_{CD\,k}=P^{t_z}_{CAk}(\boldsymbol{V},\boldsymbol{\theta})-P^{t_z}_{CD\,k}(V^{t_z}_{CD\,k},I^{t_z}_{CD\,k})=0,\\ \Delta V^{t_z}_{CD\,k}=V^{t_z}_{CD\,k}-(\pi/16)V^{t_z}_{k}=0\\ k=N_{bAC}+1,\ldots,N_{bAC}+N_{bCD}\end{array}\right\}\forall t_z\in T\end{array}\right. \qquad \text{(eq. 25)}$$

4.3. Inequality constraints functions

According to the elements models introduced in Section 3, the only inequality constraints function $\boldsymbol{g}(\boldsymbol{y})$ in eq. 3 corresponds to the batteries, as follows. The batteries have finite capacity of charge and discharge. With this point in mind, the SOC is modulated over the period of time T through eq. 26 [Gill, 2014].

$$\boldsymbol{h}^{t_z}(\boldsymbol{y}^{t_z})=\left\{SOC^{\min}_{B\,j}\le SOC^{t_z}_{B\,j}\le SOC^{\max}_{B\,j}\right\}\forall j\in N_B;\forall t_z\in T \qquad \text{(eq. 26)}$$

4.4. Equality constraints variables

Should be taken into account that, the decision variables must acquire admissible values, otherwise, the solution provided by the OPF model could not make sense from a practical point of view. For this reason, the decision variables $\boldsymbol{y}$ are limited during the interval of time T by means of the constraints set in eq. 27.

$$\left\{\begin{array}{c}\underline{\boldsymbol{y}}_{RD}\le\boldsymbol{y}^{t_z}_{RD}\le\overline{\boldsymbol{y}}_{RD}\\ \underline{\boldsymbol{y}}_{MF}\le\boldsymbol{y}^{t_z}_{MF}\le\overline{\boldsymbol{y}}_{MF}\\ \underline{\boldsymbol{y}}_{B}\le\boldsymbol{y}^{t_z}_{B}\le\overline{\boldsymbol{y}}_{B}\end{array}\right\}\forall t_z\in T \qquad \text{(eq. 27)}$$

5. Solution of the OPF model

The OPF model eqs. 24-27 corresponds to a non-linear optimization model with constraints, which could be not continuous or differentiable. For this reason, is solved by means of three different optimization methods provided by MATLAB® optimization toolbox. The methods are: i) interior point method, ii) genetic algorithm and, iii) direct search method. For this purpose, the objective function, eq. 24, and the constrains, eqs. 25-27, are written in two separate functions, which are provided as input arguments to the above-mentioned functions. For the interested reader a detailed description of the use of these tools can be found in [MathWorks et al 2002, MathWorks et al 2013].

5.1. Interior Point Method

The interior point method is applied through the *fmincon* function which belongs to the MATLAB® 'Optimization Toolbox' [MathWorks, 2002]. It is considered as a tool for local search with constraints for non-linear multivariable functions. Therefore, it fits well for the OPF problem in microgrids.

5.2. Direct Search Method

The direct search method is applied through the function *patternsearch* which belongs to the MATLAB® 'Direct Search and Genetic Algorithm Toolbox' [MathWorks, 2013] and, like *fmincon*, can be classified as a tool for local search with non-linear constraints for multivariate functions such as the OPF problem in microgrids.

5.3. Genetic Algorithm Method

The genetic algorithm method is applied through of the *ga* function which belongs to the MATLAB® 'Direct Search and Genetic Algorithm Toolbox' and is especially thought for the optimization of global non-linear problems with or without constraints. Also, provides a great flexibility since contains multiple parameters of configuration.

6. Results

In this section, the analysis of optimal power flows for the microgrid showed in Fig. 5 is presented with the aim of showing and comparing the different optimization methods used in this work. The microgrid is connected to the main grid through the only PCC (node 1). Note that, the elements of the network between pair of nodes 1-2, 3-6, 4-7 and 5-8 are transformers. The other elements are feeders. The parameters of the network distribution models, photovoltaic module, wind turbine components, as well as the cost coefficients of associated at the energy import are presented in the Appendix. For the case of study has been considered the unit variables in per unit (pu), for which it took a base power and voltage of 100 VA and 100 V, respectively.

For the analysis, the forecasted curves of active power demand, wind speed and solar irradiation from the city of Salamanca (Mexico) are considered. These signals are displayed in Fig. 6a, 6b and 6c, respectively, and were provided by the Center for Atmospheric Sciences of the University of Guanajuato. The limits of the magnitudes for the AC voltage for all nodes in the microgrid are 0.95≤V≤1.05 pu. The limits of batteries SOC are 0.2 ≤SOC (t_z) ≤0.95 (in %) while the initial SOC is $SOC(t_0)$ = 0.2 (in %). The results, which have been obtained with a PC DELL with 8 GB of RAM and an Intel processor i5 - 3230 M CPU @ 2.40 GHz, from the solution of the OPF model are shown and discussed below.

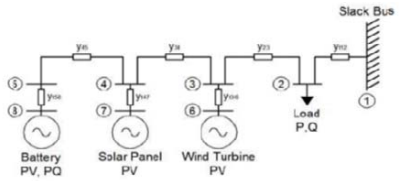

Fig. 5 Microgrid scheme

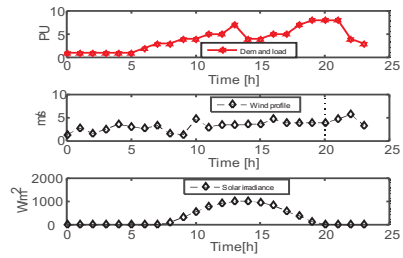

Fig. 6 Forecasted signals: a) active power demand, b) wind speed, c) solar irradiance

Figure 7a shows the active power provided by the battery, wind turbine, module PV and the imported one from the main grid. There is a greater percentage of the demand curve, see Fig. 6a, which is supplied from the main grid. It is important to highlight that, the panel photovoltaic has a relevant role in the contribution of energy between the 10:00 and 18:00 hours, which coincides with the period of high irradiation, see Fig. 6c. It is clear that the power provided by the wind turbine has a similar shape than the wind speed shown in Fig. 6b. The battery experiences periods of charge ($P_{Bnj}^{t_z} < 0$) and discharge ($P_{Bnj}^{t_z} > 0$). In particular, it is possible to see that in periods with high wind power generation (e.g. at hours 4 and 10) the battery is charged ($P_{Bnj}^{t_z} < 0$). This power is useful to reduce the energy cost in hours of peak demand (e.g. at hours 13 and 20). This fact fits with the battery SOC shown in Fig. 7b

Figure 7c shows the cost in $/h of the total energy imported from the main grid. It is clear that the cost varies depending on the imported power from main grid and has its highest value around the 20 hour, which is

where the high peak demand happens. Moreover, in the same figure it is possible to compare the energy cost if there would be no renewable power sources, clearly, without renewable sources the energy cost increases.

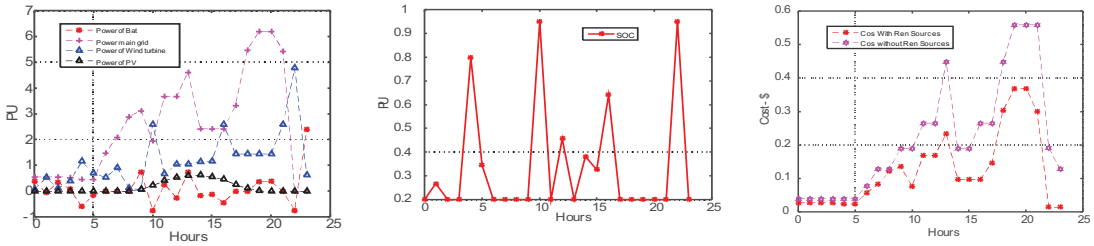

Fig. 7 Case study solved with the interior point method a) generated power b) battery SOC c) cost of the energy from the main grid

These results were obtained by means of the interior point method. In this work, the solution of this problem will be analyzed with the three different optimization methods explained in the section below.

6.1 Results of the different methods of optimization

To carry out this study, tests have been done taking into account the following points:

- It has been repeated several times the execution of each configuration and have taken into account all the results through the arithmetic mean and the standard deviation.
- It has been evaluated the most important parameters and those ones that fit better to this problem, maintaining fixed the rest.
- For each tool, it has been selected for this study those parameters that are relevant to the problem, setting the rest to their values by default.

6.1.1 Interior Point Method (fmincon)

Because this is a deterministic method for a given problem, its performance depends mainly of the initial condition. However, the initial condition for the OPF problem for the tertiary control of microgrids is completely defined, so arbitrary modification makes no practical sense. However, it is possible determine the CPU time required for the complete execution of the OPF analysis and the value of the objective function ("fitness") associated. The last results will serve as reference like comparison with them associated to them methods meta-heuristics. In this case, the convergence, the solution provided by the interior point method is associated to a fitness of $3 units currency, while the time of computation is of approximately 3630 s.

6.1.2. Direct Search (patternsearch)

As can observe in Figs. 8a and 8b for the parameter *Pollingorder* of the function *patternsearch*, the option *Consecutive* is the one that obtains best results in the fitness value. But, in cost time terms, the option that is the fastest is *Random*. On the other hand, Figs 9a and 9b show the effect of the parameter *Pollmethod*. In this case the option that gives best results for both, as in fitness values as at runtime, is *MADSPositiveBasisNp1* that is the option will be used during the optimization.

Fig. 8 Effect of *PollinfOrder* parameter: a) value of the fitness function b) time spent

Fig. 9 Effect of *PollMethod* parameter: a) value of the fitness function b) time spent

6.1.3. Genetic Algorithm (GA)

As is shown in Fig. 10a and 10b, in general to increase the population size gets a better result in the fitness value but, at the same time, it implies a higher computational time. Therefore, searching a tradeoff between fitness value and computational cost, the population size has been set to 25. Figure 11a and 11b show the evaluation of the parameter *selectionFCN* where is possible to see that for both, the fitness value and the computational cost, the best option is *selectiontournament*. Finally, in Figures 12a and 12b evaluate the parameter *crossoverFCN* where it is shown that the best result for the fitness value is the option *crossoverscartered* whereas the option *crossoverheuristic* is the best one in computational cost terms. Since in this work the execution time of the algorithm is a priority the last option, *crossoverheuristic*, will be selected.

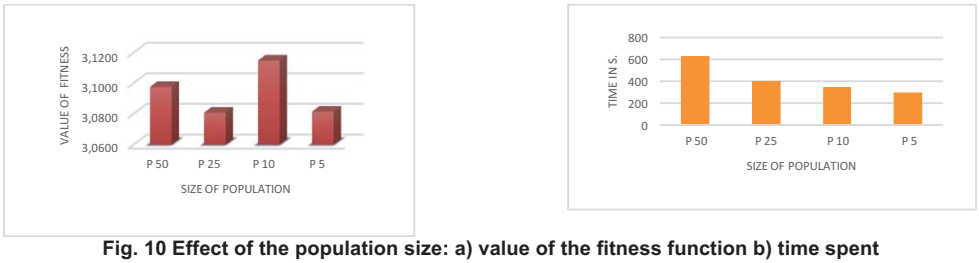

Fig. 10 Effect of the population size: a) value of the fitness function b) time spent

Fig. 11 Effect of *selectionFCN* parameter: a) value of the fitness function b) time spent

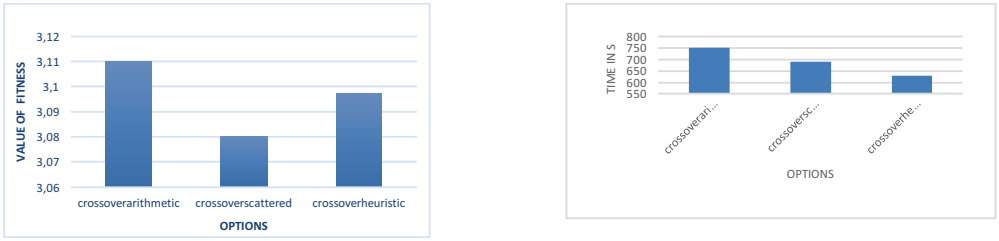

Fig. 12 Effect of *crossoverFCN* parameter: a) value of the fitness function b) time spent

6.1.4. Comparison of results between the different methods

As is possible to see in Fig. 14 the method that achieves the best result in the fitness value is the interior point through the *fmincon* function. In computational time terms the genetic algorithm method is the one that obtains a smaller computational cost. Finally, the direct search method through the *patternsearch* function is the one that gets a worst value for the fitness value and intermediate results in computational cost. Therefore, three different methods have been tested and can be used to solve the optimization problem of OPF in micro-grids each one with its advantages and disadvantages. It is important to note that, the interior point method is the one that best result obtains in the fitness function and its value will be used for continuous functions, but also, the genetic algorithm can solve not continuous fitness functions which is important since can evaluate cost functions which different behaviors between day and night.

Fig. 14 Comparison of the different optimization methods: a) value of the fitness function b) time spent

Figure 15 shows the results of the optimization of the microgrid presented in Fig. 5 with the three methods, Fig. 15a depicts the power of the main grid whereas Fig. 15b the costs of the imported power compared to the cost of the total energy load. It is important to highlight that, the solutions given for the three methods varying only in a percentage of 2% for the genetic algorithm and a percentage of 4% for the direct search method with respect to the interior point one.

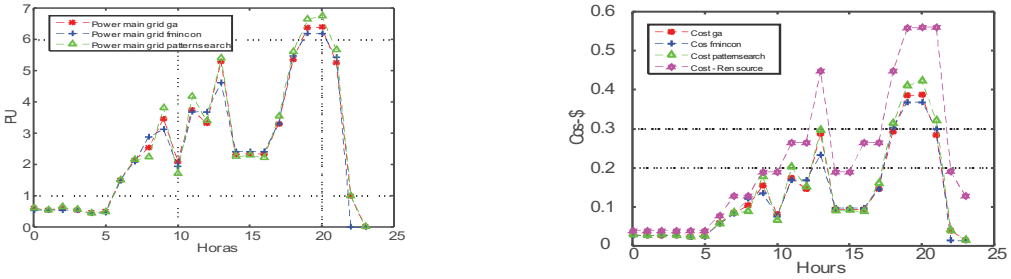

Fig. 15 Results obtained with the three optimization methods: a) Comparison of power main grid b) Comparison of cost of the imported power compared to the cost of the total energy load

7. Conclusions

In this work a model for the analysis of OPF microgrids is presented. The model allows us to manage the energy storage elements to improve the economic operation of the microgrid. Likewise, through it is possible to determine the optimal amount of power imported from the main grid. The model considers basic models of the elements of the distribution system, photovoltaic panels, wind turbines, as well as batteries for energy storage. The model is solved by three different optimization methods: i) interior point, ii) genetic algorithm and, iii) direct search. The presented numerical results illustrate the potential analysis of OPF to determine values that could be used as a reference by the secondary controller of a microgrid. In addition, the validation of the optimization methods has been performed through the evaluation of a case study which has been efficiently solved.

8. Acknowledgments

This work has been possible thanks to the collaboration of CONACYT in conjunction with the University of Guanajuato Mexico and the CIESOL center of the University of Almeria Spain. Luis O. Polaco Vásquez, Cristian A. Carreño Meneses, Alejandro Pizano Martínez are fellows of Universidad de Guanajuato and CONACYT. This work has been funded by grants from the Spanish Ministry of Economy and Competitiveness (TIN2015-66680-C2-1-R and ENERPRO DPI 2014-56364-C2-1-R), Junta de Andalucía (P11-TIC7176 and P12-TIC301). Abstract

This research is oriented towards improving energy efficiency in the cooling of greenhouses equipped with pad fan system. Once the least amount of energy was achieved, it was installed and evaluated the performance of a hybrid photovoltaic system inexpensive. Two of the most important branches of research related to agricultural greenhouses were unified to achieve the objective, namely, 1) the mathematical modeling of greenhouse climate and 2) experiments of solar energy for greenhouses. The results of the mathematical model allowed selecting the adequate ventilation rate and avoiding unnecessary consumption of electrical energy in the exhaust fans. After determining the optimal ventilation rate, it was calculated the energy required by fans depending on the hours of operation. A hybrid photovoltaic system with backup was evaluated with a solar resource of 5.5 kWh per day (Central region of Mexico). The main objective of the hybrid system is not to provide all the energy required for extraction fans, but reduce the power consumption from the local grid. The reduction of energy consumption was 32% and the total cost of hybrid system was USD $3,400.00.

Keywords: *agricultural greenhouse, photovoltaics, mathematical modeling, saved energy*

1. Introduction

In general, mathematical models applied to agricultural greenhouses have two main objectives: 1) to get knowledge about greenhouses systems, without the need to reproduce expensive experiments, 2) to optimize the greenhouses processes of operation and management. In literature, mathematical models predict variables such as natural ventilation rate, temperature, relative humidity, carbon dioxide concentration, growth of crops, among others (Tiwari, 2003). However, their practical application to solving real specific problems of agricultural engineering is limited by their low reliability. On the other hand, photovoltaic systems are a source of electrical power also with low reliability, mainly because generated energy is variable along the day and year (Duffie, 1993). The above objections foster distrust the implementation of photovoltaic systems in greenhouses. The objective of this work is to solve these problems in order to reduce the electric power consumed by the cooling system of a greenhouse. First, a mathematical model is used to predict the energy required by the cooling system and its reliability is increased by validating with experimental data. After, the performance of a hybrid photovoltaic system that supplies electric energy for fans from solar panels and local grid was evaluated.

Greenhouses without cooling systems often have 11 °C higher indoor temperatures than the surrounding environment. The detrimental effects of high temperatures on crops are characterized by loss of strength in the stem, reduced flower size, delay flowering, among other (ASABE, 1995). The pad fan system can lower the temperature of incoming air by about 80 percent of the difference between the dry and wet bulb temperatures, by example, air at a dry bulb temperature of 32 °C and relative humidity of 20%, the wet bulb temperature would be of 17 °C and the pad fan system could lower temperature to approximately 20 °C. To generate the cooling effect, it is required a ventilation rate created by exhaust fans located on the opposite side wall of the evaporative pad. There are different technical methods based on experience for calculating this ventilation rate, for example, the National Greenhouse Manufacturers Association (NGMA) indicates in its 1993 standards for cooling greenhouses that a rate of removal of 13.6 m^3 per hour per m^2 is sufficient. Nelson (1998) suggests a method of applying correction factors to the previous value considering, elevation

doi:10.18086/eurosun.2016.08.16 Available at http://proceedings.ises.org

above sea level of greenhouse, light intensity and distance between fans and evaporative pad. Likewise, several authors have shown that steady-state mathematical models describe with high level of accuracy the thermal behavior of a greenhouse with pad fan system (Jain et al (2002), Ganguly, Kittas (2001)). In the field of energy efficiency applied to pad fan systems, Franco and Valera (2014) used a steady state model to describe the operation parameters of three different materials for evaporative pads. Since that results they concluded that evaporative cooling boxes are better option than cellulose pads for cooling non-hermetic greenhouses such as those most frequently used in the Mediterranean basin. The use of steady-state models has yielded practical results for the improvement of operation of greenhouses.

In reference to the use of photovoltaic systems in greenhouses, Al-Helal (2004) realized a study of pad-fan performance for a photovoltaic application and his results showed that electricity consumption increased non-linearly as the ambient temperature increased, only through experimentation and without modeling. Ahmed (2011) evaluated a standalone photovoltaic system for cooling a greenhouse, he proposed the design of isolated photovoltaic system to supply power to the fans of greenhouses in remote areas, however, the system is expensive and its main objective is to provide all energy, since it is off-grid and electrical loads are inductive decreases the reliability of the battery bank, jeopardizing the control of the depth of discharge and decreasing the life of the same. There are several studies related to photovoltaic for cooling greenhouses, Al-Shamiry et al (2007), Carlini et al (2012), Ganguly et al (2010), Al- Ibrahim et al (2006), however, none of them involves mathematical modeling to calculate electrical energy consumed by the fans, i.e. that the dimensioning of the photovoltaic system is not a function of the greenhouse temperature or ventilation rate.

2. Materials and methods

2.1 Instrumentation for greenhouse climate study.

The experiment was conducted in an experimental even-span greenhouse equipped with a pad-fan system (height: 5 m, length: 30 m and width: 11 m) of the Center for Plant Breeding Research of Autonomous University of Chapingo, located in Texcoco, Mexico (19.30 °N, 98.53 °W). The greenhouse is equipped with two fans located on the opposite side to the pad and their function is exhaust air, sucking there through pad. The rated power of each electric fan motor is 1.125 kW, and the electric motor of the water pump is 0.375 kW, all them work at 220 V. Greenhouse instrumentation was performed to measure air temperatures inside the greenhouse on a typical day at high temperatures (01/03/2015). Campbell Scientific datalogger (CR1000) was used. Variables recorded were: air temperatures (seven sensors, model108, Camp. Sc.) (before and after the pad and along the greenhouse), relative humidity (four sensors, model HMP50, Camp. Sc.). For measurements of solar radiation a sensor CMP3 (Camp. Sc.) was used.

2.2 Thermal modelling for energy demand.

In order to predict the thermal behavior inside agricultural greenhouses when ventilation rate varies, different mathematical models have been studied. Jain and Tiwari (2002) developed a detailed model in order to predict the temperatures inside the greenhouse divided in two zones (Eqs. 1-2), where $T_{r,i}$: temperatures of zones, I_i: solar radiation on various walls and roof (W/m^2), V_1: volume of greenhouse under zone-I (m^3), $\boldsymbol{H_{z2}}$: height of walls in zone II, $\boldsymbol{A_{nw1}}$: area in north wall (m^2), $\boldsymbol{U_i}$: overall heat transfer coefficient from cover zone-II to ambient air, A_i: area of walls and roofs of greenhouse (m^2) , $\boldsymbol{T_a}$: ambient temperature (°C), $\boldsymbol{h_{r1r2}}$: convective heat transfer coefficient of air from zone-I to zone-II (W/m^2°C), $\boldsymbol{A_g}$: area of floor under greenhouse (m^2) , $\boldsymbol{T_{r2}}$: room air temperature in zone-II (°C) , L: length of greenhouse (m) , a: constant value , $T_{r2,0}$: room air temperature in zone-II at 0 m (°C) . The model can be simplified and applied for the greenhouse of case study of this research which is equipped with pad-fan system (Eq. 3), from an energy balance Kittas (2001) developed the model solution. Ganguly and Ghosh (2006) compared the results of this model with other similars, demonstrating that steady state models described with acceptable accuracy the interior temperatures of greenhouses.

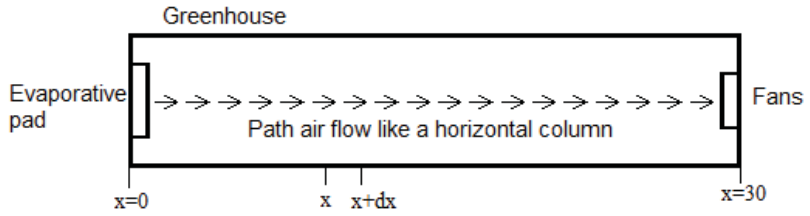

Fig.1. Greenhouse cross section scheme used for mathematical modeling. The main assumption is that air flow moves only in the horizontal direction. No temperature gradients in the vertical direction.

$$\boldsymbol{T_{r,1}} = \frac{I_1 V_1 + I_2 H_{z2} A_{nw1} + (U_{r2a} A_{nw1} + \sum U_i A_i) T_a + h_{r1r2} A_g T_{r,2}}{h_{r1r2} A_g + \sum U_i A_i + U_{r2a} A_{nw1}} \qquad \text{(eq. 1)}$$

$$T_{r,2} = \frac{1}{L}\int_0^L T_{r,2}\,dx = \frac{F(t)}{a}\left[1 - \frac{1 - e^{-aL}}{aL}\right] + T_{r,2,0}\,\frac{1 - e^{-aL}}{aL} \qquad \text{(eq. 2)}$$

Where $F(t) = \frac{T_{r2}}{dx} + aT_{r2}$, and the simplified model applied to this case study is:

$$T_{in}(x) = \left[T_o + \frac{\tau(1-\alpha)R_o w_{gh}}{K_c L_{cov}}\right]\left[1 - e^{-\left(\frac{K_c L_{cov}}{\dot{V}\rho C_p}[x]\right)}\right] + T_{pad}\, e^{-\left(\frac{K_c L_{cov}}{\dot{V}\rho C_p}[x]\right)} \qquad \text{(eq. 3)}$$

In Eq. 3, $T_{in}(x)$ is the interior temperature at x position (Fig. 1), T_o is exterior dry bulb temperature, τ is transmissivity of the plastic cover; α: coefficient representing the fraction of radiation incident on the plant that is directly converted into latent heat by transpiration and losses of radiation through soil, R_o: outside solar radiation in W/m^2, w_{gh}: greenhouse width en m, K_c: coefficient of sensible heat losses through the plastic cover in $W/m^2\,°C$, L_{cov}: length of cover proportional to the width of greenhouse to obtain the differential heat transfer area, $\dot{V}$: ventilation rate generated by fans; C_p: heat capacity of air in $J/kg°C$; ρ is air density, T_{pad} is air temperature when leaves evaporative pad.

This model can describe the temperature of a completely sealed greenhouse without evaporative pad, this is achieved when the ventilation rate, $\dot{V}$, approaches zero, this way the temperature is not a function of x, and there is only one temperature along greenhouse:

$$T_{in} = \left[T_o + \frac{\tau(1-\alpha)R_o w_{gh}}{K_c L_{cov}}\right] \qquad \text{(eq. 4)}$$

The term x represents the length of the greenhouse, that is, the distance between the pad and the fans. This term is limited by the exponential function, so it is expected that the model cannot be applied to great lengths greenhouses because the exponential function generates an asymptote and the value of the temperature would be the same. This asymptote is physically correct. Since for large distances between the evaporative pad and the fans, there would be no cooling effect inside the greenhouse. In general, the model describes physically a greenhouse with or without pad fan system. The main results of interest for research will be the temperature depending on the ventilation rate. That is, it is necessary to know the ventilation rate required to obtain a given temperature of 25 °C, which is most recommended for crops.

2.3 Hybrid photovoltaic system.

The amount of energy obtained from the mathematical model served as the first parameter design of a hybrid system. The hybrid system consists of four PV modules of 200 W each one, one hybrid inverter charger of 3.0 kW and four batteries of 150 Ah each one. The operation mode of Fig. 2 is described below:

t1: To ensure the battery is at full capacity, when the inverter is turned ON, the CPU will execute the bypass

mode automatically connecting the AC main to the load. In the meantime, it will activate both the AC charger and solar charger to simultaneously charge the batteries.

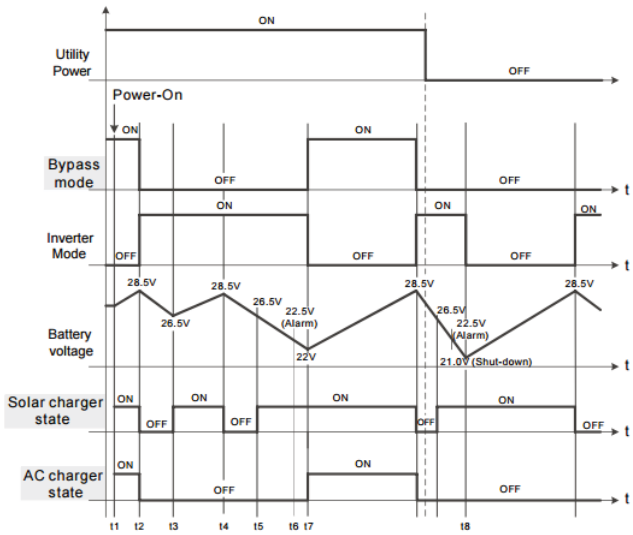

Fig. 2. Diagram of hybrid photovoltaic system mode control logic.

t2: When the batteries are full (battery voltage around 28.5 V), both the AC and solar charger will be turned OFF by the CPU to prevent overcharging and reducing battery lifetime. The CPU will also switch to inverter mode and the AC electricity provided to the loads will be coming from the batteries.

t3: When the batteries are depleted to around 90% of their capacity (battery voltage around 26.5V), CPU will start up the solar charger but not the AC charger to achieve the goal of energy saving.

t4: If the energy provided by the solar panels is larger than the load requirement, voltage of the battery bank will increase gradually until reaching battery voltage around 28.5 V and then the solar charger will shut off to prevent the batteries from overcharging.

t5: When the capacity of batteries goes down to battery voltage around 26.5 V, solar charger will restart and begin charging.

t6: If the energy provided by the solar panels is lower than consumed by the loads, voltage of the battery bank will decrease gradually to battery voltage around 22.5 V. The built-in buzzer will sound to inform the user that battery power is very low.

t7: If the power consumption of the loads does not decrease and the AC main is normal, the CPU will detect this and the unit will be transferred to "bypass mode." The utility will provide electricity to the loads and charge the battery bank at the same time in order to prevent the unit from shutting off. If the solar current is higher than 3 A, the CPU will not activate the AC charger and just let the solar changer charge the batteries to achieve energy saving target.

t8: When there is no AC main, the CPU will shut down the whole system if the external battery bank voltage is less than 21 V in order to prevent over-discharging and reducing its lifetime. After shutdown, the CPU will still provide LED indication so the user knows why the inverter has shut off.

Fig. 3: PV array and hybrid inverter with battery bank.

Fig. 4: View of PV system outside greenhouse.

3. Results and discussion

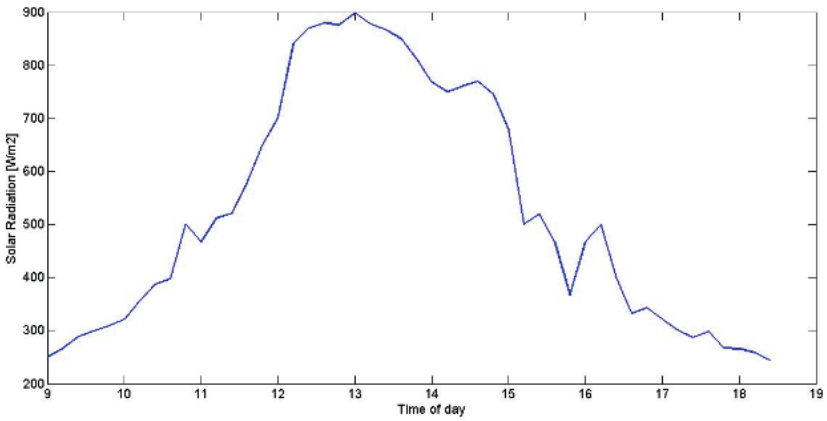

Fig. 5: Variation of exterior solar radiation on experimentation day (03 june 2015)

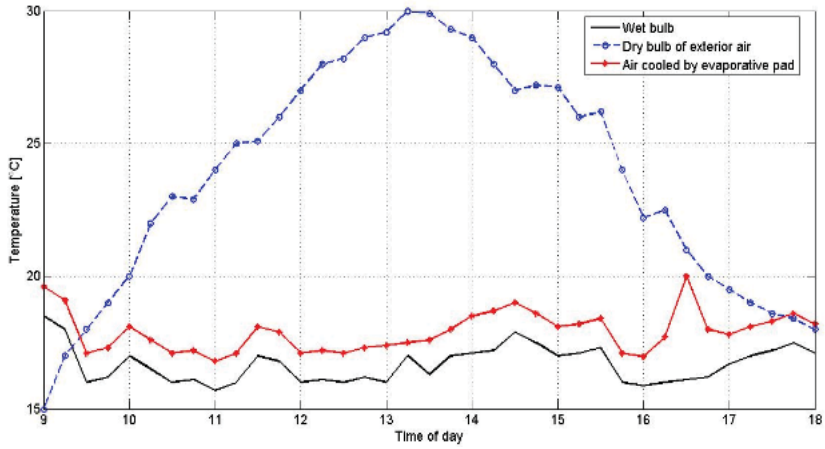

Fig. 6: Operation air temperatures involved in performance of evaporative pad on experimentation day.

The mathematical model does not include factors such as partial cloudy, rain and outside wind speed and these represent sources of random errors that generates uncertainty of non-reproducible measurements. For that reason, it was taken a specific day with the least influence of these factors, environmental conditions and operation temperatures of evaporative pad are shown in Figs. 5 and 6.

MatLab software was used to program solution. Figures 5 and 6 shows that when exterior dry bulb temperature was 30 °C the outside solar radiation achieve 890 W/m^2, and the wet bulb temperature was 17 °C. The average dry bulb air temperature leaving the pad was 18 °C. That means 85% of pad efficiency. This value is less than the common pads and could rise with an increase in ventilation rate, however the temperature of 25 °C is reached successfully with the current rate of ventilation. Here lies the importance of implementing energy efficiency plan to avoid consuming more energy than necessary.

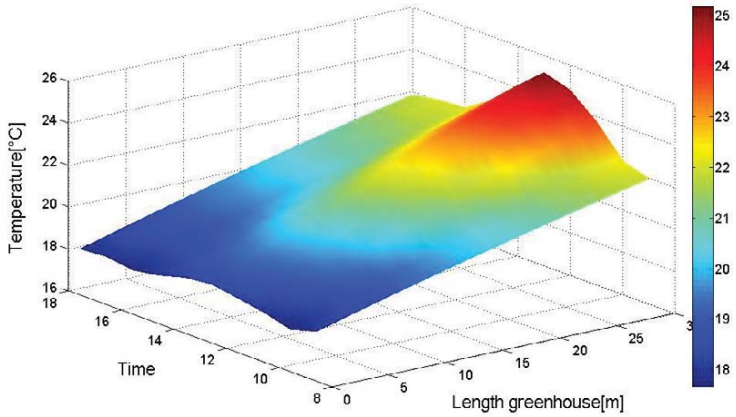

Fig. 7: Spatial temperature distribution inside the greenhouse during experimentation.

With the steady-state model it can obtain a spatial temperature distribution inside the greenhouse along the day when operating the evaporative wall and exhaust fans. To determine the temperature versus time, experimental data of radiation was used in the model along the day while keeping constant the ventilation rate. Fig. 7 shows the spatial temperature distribution inside the experimental greenhouse along the experimentation day. Fig. 8 shows predicted temperature inside greenhouse at x = 30 m, ie maximum temperatures at outlet in fans.

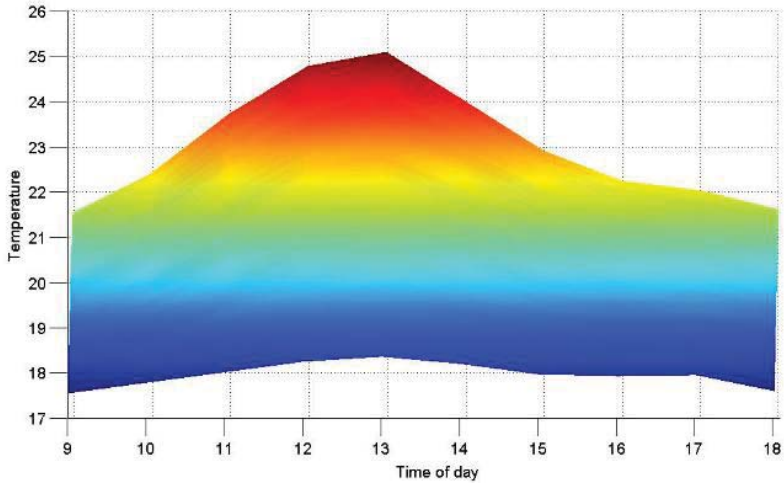

Fig. 8: Predicted temperature inside greenhouse at x= 30 m, ie maximum temperatures at outlet in fans.

To improve the energy efficiency of exhaust fans is necessary to determine the value of adequate ventilation rate, then to know the number of fans and power to meet that ventilation rate. As an example, in Table 1, three models of fans are proposed:

Tab. 1: Characteristics of three models of fans commonly used for pad fan system

Model	Power W	Airflow rate $m^3/h - m^3/s$
1	563	24666 - 6.9
2	746	27630 - 7.7
3	1119	31663 - 8.9

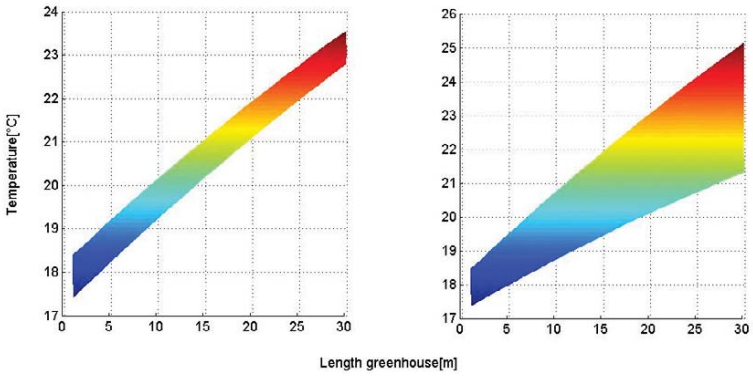

Fig. 9: Temperature profiles along greenhouse with 16 m^3/s (left) and 14 m^3/s (right).

Under same exterior conditions but different ventilation rate, it can obtained different temperature profile. It is expected that energy consumed is proportional to cooling effect. Fig. 9 shows two different temperature profiles generated from two ventilation rates. It is necessary to select fans to meet these ventilation rates of 16 and 14 m^3/s from the models proposed in table1. Table 2 shows results:

Tab. 2: Fans selected for different ventilation rates

Ventilation Rate [m^3/s]	Maximum temperature obtained at x=30 [°C]	Fans selected	Energy consumed in 1 hour kWh
16	23.5	Two fans of model 3	2.22
14	25	Two fans of model 2	1.49

In order to create a flow as uniform as possible, ASABE (2008) suggest that the fans should have the same air flow capacity and technical features, that is, they are the same model. For that reason, it is important to select just necessary ventilation rate, it would be creating more cooling effect than necessary for crops. Also, it would be wasting electrical energy. The ventilation rate of 14 m^3/s is sufficient to maintain 25 °C or lower temperature. If we use this design parameter, for 5 hours of operation of the pad fan system during the hottest part of the day, the energy consumed would be 7.45 kWh/day.

Fig. 10. Fans in opposite face to evaporative pad.

Theoretically energy generated by solar panels at Central Region of Mexico during experimentation is 3.3 kWh per day (5.5 sunshine hours equivalent to 1000 W/m^2 multiplying 600 W of power pv array). However, the energy measured with a Power Quality Analyzer (Fluke 434 Three phase power) during the 30 days of 2015 summer, the percentage of energy saving was 32%. The specific technical characteristics and unit prices of all major components shown, including also expenses for construction and installation of the support tower of photovoltaic modules, electrical cables, and labor. The total cost of the installed system was USD$3,400.00 and the recovery time is 10.5 years. After that the system will have an estimated 15 years additional life.

4. Conclusions

If a pad works at maximum efficiency, it does not guarantee that energy consumption is minimal. The increased pad efficiency could cause unnecessary energy consumption, this is because the optimum temperature inside a greenhouse can be obtained with a ventilation rate lower than that corresponding to the maximum ventilation pad efficiency. Consequently, the power of the fans must be lower and energy consumption as well. After this energy analysis, a hybrid photovoltaic system of low cost and high reliability was obtained. Energy savings of nearly a third of the total are obtained by keeping the greenhouse temperature close to 25 °C during the hours of maximum solar radiation. 32% of the energy saved is the best choice because other settings create more cost and time of return is achieved close to the life of the system. Even when AC utility is available, the main source of power will still be solar, AC utility will supplement only when necessary. This type of design cuts back the use of paid electricity thus reaching the goal of energy conservation.

Abstract

In this work, we investigated temperature regulation of concentrating photovoltaic (CPV) and thermal energy storage using solid-liquid phase change material (PCM) under tropical dry climatic conditions. A finite element based heat transfer model is developed that includes the optical behavior of incident irradiance, solar to electrical conversion and online calculation of heat loss coefficients. The model's results are in good agreement (±3 ºC) against indoor experimental results. The validated model is used to predict the thermal behavior of PV and CPV incorporating PCM by varying melting point (35 ºC to 75 ºC), ambient temperature (30 ºC to 50 ºC) and concentration ratio (2× - 4×). It is found that a PCM with melting temperature in the range of 45 ºC to 65 ºC is suitable for temperature regulation and thermal energy storage for a CPV system in a tropical dry climate for up to ~ 4×. The choice of an appropriate PCM in melting temperature range of 45 ºC – 65 ºC depends on energy utilization requirement. The overall efficiency of the CPV system with a PCM makes it an attractive choice for a CPV thermal application in a tropical dry climate.

Keywords: *Phase change material, concentrated photovoltaic, finite element, heat transfer*

1. Introduction

Concentrating solar radiation onto photovoltaic (PV) cells generates more electricity but concomitantly raises the PV cell operating temperature thereby decreasing solar to electrical conversion efficiency by 0.08 %/K for crystalline silicon PV (Radziemska, 2003). Solid-liquid phase change material (PCM) is a promising technology to regulate the temperature of PV along with enabling thermal storage of energy (Hasan et al., 2015). A PCM stores energy during phase change otherwise acts as a sensible heat storage material. The absorption, storage and releasing capability of a PCM depends on its geometrical configuration and its thermophysical properties (Sarwar and Mansoor, 2016). A comprehensive review of integration of a PCM for thermal management of photovoltaic has shown that the PCM is not only useful for non-concentrating PV but has particular potential for temperature regulation of concentrated photovoltaic (CPV) application (Browne et al., 2015).

Recently, several researchers have experimentally and numerically investigated the performance enhancement of CPV using a PCM. For example, an in-door experimental investigation of a low concentrated, geometrical concentration ratio of 2.7, building integrated CPV containing a paraffin wax (RT42) has been carried out. It is reported that the PCM effectiveness depends upon the incident irradiance intensity and the integration of PCM reduces module center temperature by an average of 3.8 ºC (Sharma et al., 2016). An outdoor investigation of another low concentrated CPV system integrated with a paraffin wax (melting temperature of 47 ºC) has shown a decrease in PV temperature and increase in solar to electrical conversion efficiency (Ceylan et al., 2016). A theoretical investigation of application of a PCM in a photovoltaic-thermoelectric system has

doi:10.18086/eurosun.2016.08.12 Available at http://proceedings.ises.org

been undertaken to determine PCM influence on electrical conversion (Cui et al., 2016). The results are compared with a photovoltaic-thermoelectric system without a PCM. It is reported that introduction of a PCM increases the electrical conversion efficiency and mitigates the temperature fluctuations of a PV cell. It is also discussed that the selection of an appropriate PCM depends on desired operating temperature conditions (Cui et al., 2016). A combination of heat spreading and PCM cooling method has been employed to experimentally investigate the temperature regulation of a PV cell under concentrated irradiance (optical concentration ratio of 4). It is reported that the introduction of PCM (Fatty acids and salt hydrates) reduces the peak PV cell temperature in the range of 9 ^{o}C – 20 ^{o}C (Sarwar et al., 2013). An indoor and outdoor investigation of a CPV using a V-trough as a concentrator and a PCM having melting temperature of 57 ^{o}C has also reported the temperature regulation ability of the PCM (Maiti et al., 2011).

Although, temperature controlling ability of a PCM is well established but selection of an appropriate PCM is critical to design an efficient system that can work over the whole year. The PCM used should have a large latent heat of fusion, reversible phase change and melting point within a range of operation (Cabeza et al., 2011). On the other hand, ambient conditions play an equally important role in selection of a PCM in extreme conditions such as a tropical dry climate (i.e. Qatar, Middle East). Nocturnal ambient or radiative cooling temperatures must fall below the melting temperature to solidify the PCM for operation the next day. A multi-year (1978-2012) analysis of the weather data for Qatar showed that during summer night, temperature can go as high as up to 32 ^{o}C while peak temperature during summer day can reach up to 50 ^{o}C. In this preliminary analysis we considered the effect of ambient temperature (e.g. no humidity) and melting temperature. Therefore, we consider PCMs with a melting point in the range of 35 - 75 ^{o}C for the temperature regulation and calculate the electrical and thermal energy storage performance of selected system. The ambient temperature is considered in the range of 30 - 50 ^{o}C while the concentrated flux intensity is considered up to 4 kWm^{-2}.

2. Optical-thermal model

A finite element based heat transfer model is coupled with an optical model to evaluate the thermal, optical and electrical behavior of a photovoltaic cell integrated with a phase change material. The schematic illustration of different physical phenomena within the system is shown in Fig. 1.

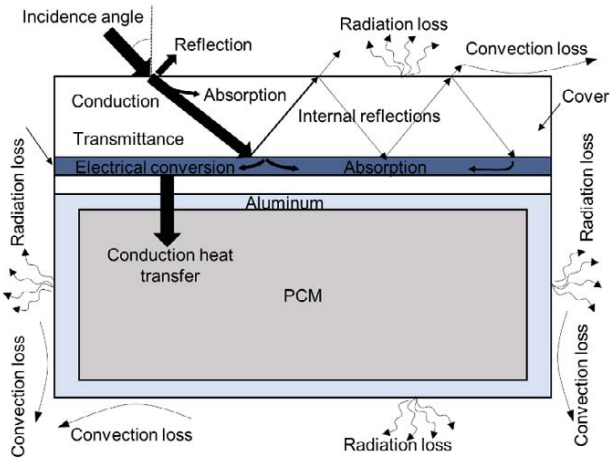

Fig 1: Physical phenomena within the photovoltaic/phase change material system

The principles of the optical-thermal model are as follows:

- A 2D differential heat diffusion equation is used to develop the finite element based heat transfer model. The weak formulation is developed using a test function and integrating it over the domain and its boundary. Green-Gauss theorem and divergence theorem are used to simplify the formulation. An 8-node Serendipity element is used to transform physical coordinates to natural coordinates. The elements are assembled using direct addition of components method to form the domain of the system.

- Latent heat of fusion effect is introduced via an effective heat capacity method.
- The temporal discretization is carried out using a Crank-Nicholson method.
- Convection and radiation losses are considered on all sides of the system.
- Reflectance, transmittance and absorptance is calculated using Fresnel equations method.
- Angle of incidence of sun's irradiance is found via a methodology proposed by Hoang et al. (2014).
- Temperature dependence of electrical conversion is considered for calculations of electrical power generation by incident irradiance.

The following assumptions are made to simplify the calculations:

- Multiple reflections up to 3 are considered in the cover.
- Incident diffuse and direct radiations are considered un-polarized.
- Effective thermal conductivity of the PV cell is used instead of using thermal conductivity of each layer of the PV cell.
- Only conduction heat transfer in the PCM is considered.

2.1 Thermal model

A two-dimensional differential heat diffusion equation governing transient heat transfer in the system shown in Fig. 1 is as follows:

$$\rho c \frac{\partial T}{\partial t} - \left[\frac{\partial}{\partial x_i}\left(k_{ij}\frac{\partial T}{\partial x_j}\right)\right] = 0 \qquad \text{(eq. 1)}$$

The convection and radiation heat losses at the boundary of the system are given by following equations:

$$H = h_c A \Delta T \qquad \text{(eq. 2)}$$

$$R = h_r A \Delta T \qquad \text{(eq. 3)}$$

The energy balance of the system is obtained using equation eq. 1 – eq. 3 and multiplied by a test function δT and integrated over the domain to get its weak formulation. The Green-Gauss theorem and divergence theorem is applied on the relevant equations to obtain simplified form of the weak formulation which is given as:

$$\int_\Omega \delta T \rho c \frac{\partial T}{\partial t} \partial\Omega + \int_\Omega \left[k_{11}\frac{\partial \delta T}{\partial x_1}\left(\frac{\partial T}{\partial x_1}\right) + k_{22}\frac{\partial \delta T}{\partial x_2}\left(\frac{\partial T}{\partial 2}\right)\right]\partial\Omega - \int_\Gamma \delta T q \partial A + \int_\Gamma \delta T (H+R)\partial A = 0 \qquad \text{(eq. 4)}$$

The differential of temperature and test functions are transformed from physical coordinates into natural coordinates by using chain rule and an 8-node Serendipity element. After transformations, the energy balance equation becomes as:

$$\mathbf{M}\dot{T} + \mathbf{K}T - \boldsymbol{q} + (\mathbf{H}+\mathbf{R})T = 0 \qquad \text{(eq. 5)}$$

where $\dot{T}$ is the time derivate of temperature while **M**, **K**, **H**, **R** and $\boldsymbol{q}$ are the mass, conductivity, convection, radiation and irradiance matrices. These matrices are calculated as:

$$\mathbf{M} = \int_{-1}^{1}\int_{-1}^{1} \rho c N^T N |J| h \partial\xi_1 \partial\xi_2 \qquad \text{(eq. 6)}$$

$$\mathbf{K} = \int_{-1}^{1}\int_{-1}^{1} B^T k B |J| h \partial\xi_1 \partial\xi_2 \qquad \text{(eq. 7)}$$

$$\mathbf{H} = \int_{-1}^{1} h_c N^T N |J_i| h \partial\xi_{1\ or\ 2} \qquad \text{(eq. 8)}$$

$$\mathbf{R} = \int_{-1}^{1} h_r N^T N |J_i| h \partial\xi_{1\ or\ 2} \qquad \text{(eq. 9)}$$

$$\mathbf{q} = \int_{-1}^{1} q N^T N |J_i| h \partial\xi_{1\ or\ 2} \qquad \text{(eq. 10)}$$

N represents an 8-node Serendipity element, B is the B-operator, ξ is the natural coordinates, J is Jacobian matrix and h is the width of the system. The physical discretization of the domain is obtained by assembling

the elements using direct addition of components method. The temporal discretization of the system is carried out using a Crack-Nicholson scheme. The convection and radiation heat transfer coefficients are calculated at each time step using following equations:

$$h_c = 2.9v + 4.5 \quad \text{(eq. 11)}$$

$$h_r = \sigma \varepsilon F \left(\frac{T^4 - T_a^4}{T - T_a}\right) \quad \text{(eq. 12)}$$

Where v is the velocity of the air, σ is the Stefan-Boltzmann constant, ε is the emissivity and T_a is the ambient temperature. In current calculations, the ambient temperature is considered equal to the sky temperature (Kumar and Mullick, 2012) and view factor is considered as 1. For indoor calculations, velocity of the air is considered as zero. The latent heat effect of the PCM is introduced using an effective heat capacity method (Lamberg et al., 2004) which is as follows:

$$c_e = \begin{cases} c_s & T < T_1 \\ c_s + \frac{L}{T_2 - T_1} & T_1 \le T \le T_2 \\ c_l & T > T_2 \end{cases} \quad \text{(eq. 13)}$$

Where c_e is the effective heat capacity of the PCM, c_s and c_l are the heat capacities of solid and liquid PCM respectively. L is latent heat of fusion while T_1 and T_2 are the melting onset and solidification temperature respectively.

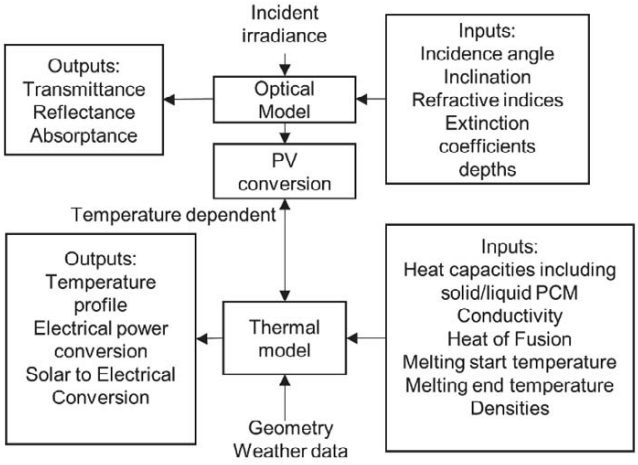

Fig. 2: Flow chart representation of the optical-thermal model

2.2 Optical model

The irradiance incident on the PV cover goes through the series of reflections and absorptions in the cover, as shown in Fig. 1, before absorbing in the PV cell. The reflectance, absorptance and transmittance in the system is calculated using Fresnel equations (Hecht, 2002).

$$\begin{aligned} &\rho = \tfrac{1}{2}(\rho_\parallel + \rho_\perp) \quad \rho_\perp = -\frac{sin(\theta_i - \theta_t)}{sin(\theta_i + \theta_t)} \quad \rho_\parallel = \frac{tan(\theta_i - \theta_t)}{tan(\theta_i + \theta_t)} \\ &\tau = \tfrac{1}{2}(\tau_\parallel + \tau_\perp) \quad \tau_\perp = \tau_a \left(\frac{1-\rho_\perp}{1+\rho_\perp}\right)\left(\frac{1-\rho_1^2}{1+\rho_1^2\tau_a^2}\right) \quad \tau_\parallel = \tau_a \left(\frac{1-\rho_\parallel}{1+\rho_\parallel}\right)\left(\frac{1-\rho_\parallel^2}{1+\rho_\parallel^2\tau_a^2}\right) \\ &\alpha = \tfrac{1}{2}(\alpha_\parallel + \alpha_\perp) \quad \alpha_\perp = (1-\tau_a)\left(\frac{1-\rho_\perp}{1+\rho_\perp\tau_a}\right) \quad \alpha_\perp = (1-\tau_a)\left(\frac{1-\rho_\perp}{1+\rho_\perp\tau_a}\right) \\ &\tau_a = e^{\frac{-Kx}{cos\theta_t}} \end{aligned} \quad \text{(eq. 14)}$$

A transmittance angle (θ_t) is calculated from an incident angle (θ_i) by using Snell's refractive law. For indoor calculations, the incident irradiance is assumed normal to the cover but for the outdoor calculations, the incident angle is found using a methodology available in literature (Hoang et al., 2014). The formulae for

calculations of incidence angle, sun declination angle (δ) and hour angle (ω) are presented in eq. 15.

$$\cos\theta_i = \sin\delta \times \sin l \times \cos s - \sin\delta \times \cos l \times \sin s \times \cos\varphi + \cos\delta \times \cos l \times \cos s \times \cos\omega + \cos\delta \times \sin l \times \sin s \times \cos\varphi \times \cos\omega + \cos\delta \times \sin s \times \sin\varphi \times \sin\omega$$
$$\delta = 0.38 + 23.26 \sin\left(\frac{2\pi J'}{365.24-1.395}\right) + 0.37 \sin\left(\frac{4\pi J'}{365.24-1.457}\right) \quad \text{(eq. 15)}$$
$$\omega = 15 \times \left(H_l - \Delta H_l + \Delta H_g - E - 12\right)$$
$$E = 7.5 \times \sin\left(2\pi \frac{J'}{365.24} - 0.03\right) + 0.99 \times \sin\left(4\pi \frac{J}{365.24} + 0.35\right)$$

Where J' is the rank of the day after the first of January 2013 while J is the Julian day of the year. The local time is represented by H_l, time lag between the given time zone and UTC is represented by ΔH_l and time lag due to the longitude variation is denoted by ΔH_g.

2.3 Coupling of optical-thermal model

The flow chart representation of the optical-thermal model is shown in Fig. 2. The irradiance available at the PV after going through series of reflections and absorption losses in the PV cover is obtained via following equation:

$$q_{aol} = (1 - \rho - \alpha) q_i \quad \text{(eq. 16)}$$

The part of the irradiance available at the PV is converted in to electricity while rest is converted in to heat. The irradiance after accounting for electrical conversion is shown in equation 17.

$$q = q_{aol} - [\eta + \mu(T - T_a)] q_{aol} \quad \text{(eq. 17)}$$

Where η is the efficiency and μ is the power output temperature coefficient of the PV cell under standard test conditions.

The irradiance (q) is updated at every time step to include temperature dependence properties of the PV cell and incidence angle variations over the day. The electrical power produced from the PV cell is calculated using following correlation:

$$P = q_{aol}\, A\, \eta\, [1 - \mu(T - 298)] \quad \text{(eq. 18)}$$

Furthermore, the thermal efficiency of the CPVPCM system is calculated by calculating the ratio of thermal energy stored in the PCM (Hasan et al., 2015) to the incident energy.

2.4 Input parameters of the optical-thermal model

The electrical, thermal and optical properties of the materials that serve as an input in the optical-thermal model are presented in table 1.

Tab. 1: Thermal parameters of the materials used in the system for the optical-thermal model

	Thermal parameters of the materials					
	ρ (kg m^{-3})	k ($Wm^{-1}K^{-1}$)	c ($kJkg^{-1}K^{-1}$)	ε	H ($kJkg^{-1}$)	T_m (K)
Perspex	1190	1.9	1.3	0.9	×	×
PV	2205	125.4	0.8	0.9	×	×
Aluminium	2700	205.0	0.9	×	×	×
PCM	880	0.2	1.3 (s) 1.8 (l)	×	190	303 - 323
	Electrical characteristics					
	η			μ ($^oC^{-1}$)		
	12.7			-0.005		
	Optical parameters of the materials					
	n		K (m^{-1})		x (m)	
Perspex	1.5		10		3×10^{-3}	
PV	4		4710		5×10^{-4}	

A clear sky broadband solar radiation model (Bird and Hulstrom, 1981) is used to simulate the direct beam and global horizontal irradiance. The latitude and longitude of the selected location (Education city, Doha, Qatar) are 25.314779° N and 51.43978° E respectively. Four days (January 1, March 30, June 29 and September 29) belonging to each season of a year 2015 are selected to predict the electrical, thermal and optical behaviour of the selected system. The weather data including wind speed and ambient temperature for the selected days is obtained from experimentally measured data by meteorological department, Qatar. The variations in irradiance, ambient temperature and wind speed on selected days are shown in Fig. 3. Thermal and electrical output of the system under concentrated irradiance, referred as CPVPCM in subsequent text, is predicted and compared with non-concentrated PV. The inclination angle of the PV for non-concentrated system is considered equal to the latitude of the location while dual-axes tracking is considered for CPVPCM system with an error of ±0.1°.

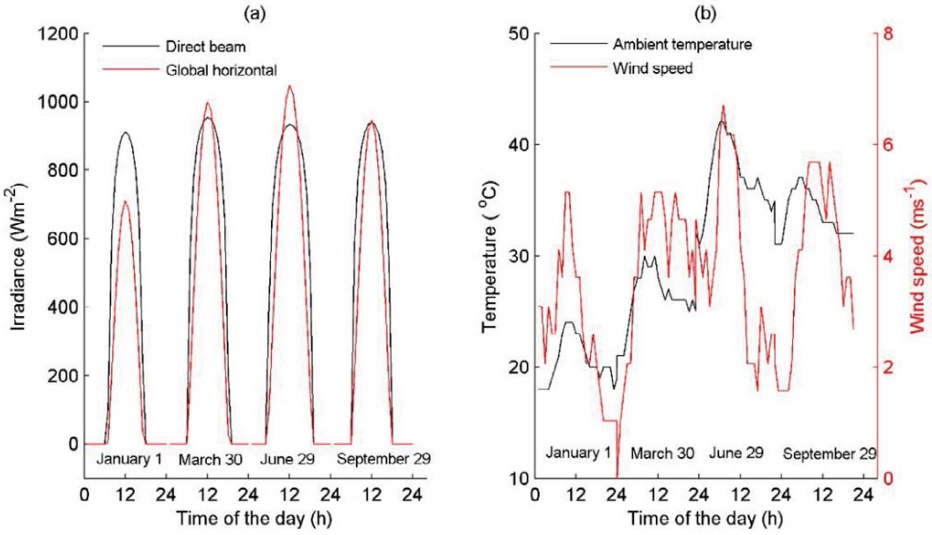

Fig. 3: The irradiance, ambient temperature and wind speed variations on selected days

3. Experimental setup and model validation

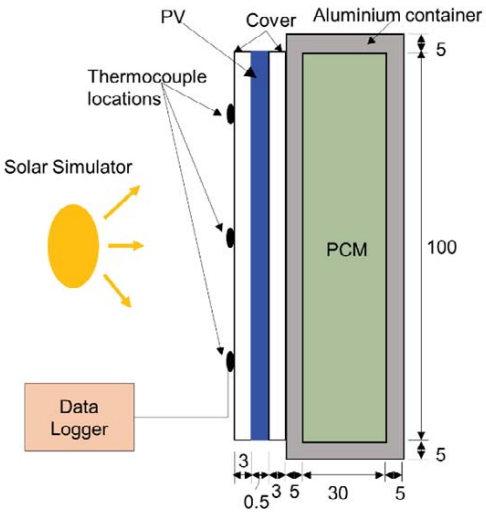

Fig. 4: Schematic illustration of the experimental setup

The schematic illustration of experimental setup is shown in Fig. 4. Polycrystalline silicon PV cell, Suntech power STP065-12/Sb, (Solar, 2013) with the dimensions of 100 mm × 100 mm × 0.5 mm encapsulated in a 3 mm thick Perspex imitated the PV cell. The volume of PCM required for temperature regulation of the PV cell, was calculated using an energy balance equation presented by Huang et al. (Huang et al., 2004) by

considering RT20 as a PCM. A 5 mm thick aluminium sheet was used to fabricate a 30 mm thick aluminium container encapsulating a PCM having a volume of 0.3 litres. Five T-type copper-constantan thermocouples with a maximum measurement deviation of ±0.2 °C were attached to the front surface of the system to measure the temperature at a sampling rate of 100 Hz using a data logger. The system is irradiated at 1000 Wm^{-2} using a Griven GR262 solar simulator and the flux is measured using a Kipp & Zonen CM6B pyranometer. The height of the solar simulator and PV cell was adjusted to keep the irradiance normal to the centre of the PV cell. The experiments were performed three times to ensure repeatability and to quantify the uncertainty in the experimental results. The average of the measured experimental PV cell temperature along with error bars depicting uncertainty was compared with numerically predicted temperature under same irradiance to validate the numerical model.

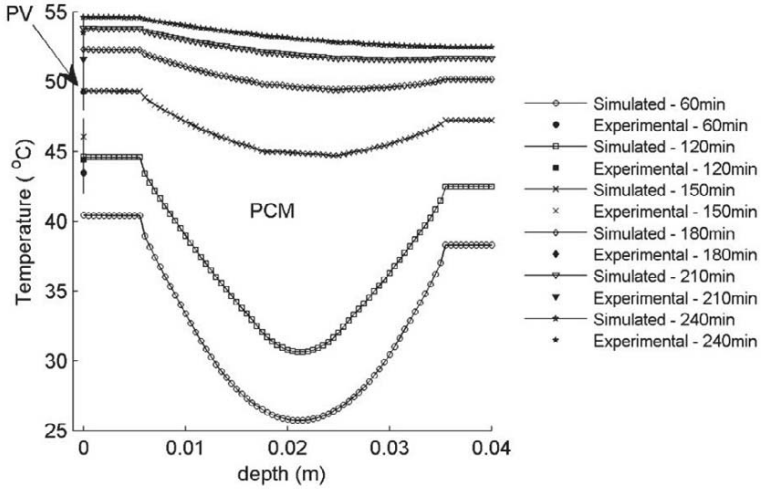

Fig. 5: Comparison of experimental and numerical temperature along with melting behavior of a phase change material

It is shown in figure 5 that the temperature of the PV cell is in agreement with numerically predicted temperature. The experimental temperature of the PV cell increases to 43.4 °C in one hour while it increases to 53.9 °C while exposed to 1000 Wm^{-2} for four hours. The corresponding numerical temperatures are 41 °C and 54.6 °C respectively. A maximum standard deviation of ±3 °C is achieved between experimental and numerical temperatures thereby, validating the optical-thermal model. The melting behavior of the system is also shown in Fig. 5 which indicates that heat is transferred to the PCM from both front and back side. Although irradiance is incident on the PV cell only but heat is transmitted to the back of the container fast through the aluminum containment due to its high thermal conductivity. Therefore, the melting of the PCM starts from each side of the container and completes in the center of the container.

4. Results and Discussion

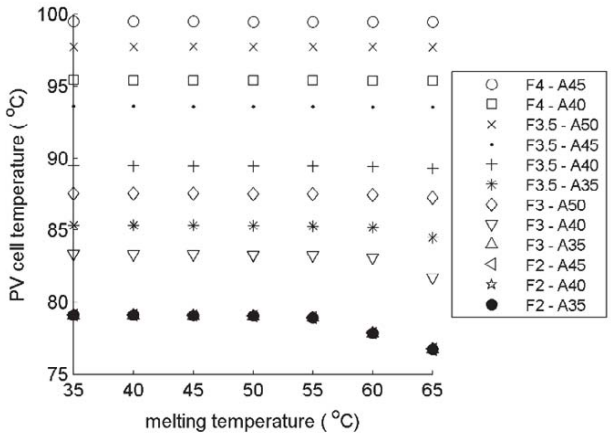

Fig. 6: Temperature of the CPVPCM system under variable concentrated irradiance, ambient and melting temperature

The temperature of the CPVPCM system under in-door conditions has been investigated using developed optical-thermal model for variable incident concentrated irradiance up to 4 kWm^{-2}. The ambient temperature has been varied in the range of 35 ºC – 50 ºC while melting temperatures of the PCM are varied in the step of 5 ºC from 35 ºC to 65 ºC. The result is shown in Fig. 6.

The temperature of the PV cell increases with the increase in ambient temperature and increase in concentrated irradiance. The PV cell temperature decrease with the increase in the melting temperature but the difference is more pronounced at lower concentrated irradiance up to 3 kWm^{-2}. The temperature of the PV cell in the CPVPCM system can be maintained below 85 ºC up to concentrated irradiance of 3.5 kWm^{-2} under indoor conditions. To investigate the electrical and thermal behavior of the CPVPCM system under out door conditions, the temperature evolution and electrical output of the system is simulated for PCM melting temperatures of 45 ºC and 65 ºC. The simulated irradiance, ambient temperature and wind conditions, as shown in Fig. 3, of selected days of a year 2015 are used for that purpose. The incident concentrated and non-concentrated irradiance on the CPVPCM system and PV only after optical losses is shown in Fig. 7(a) while corresponding temperature evolution is shown in Fig. 7(b).

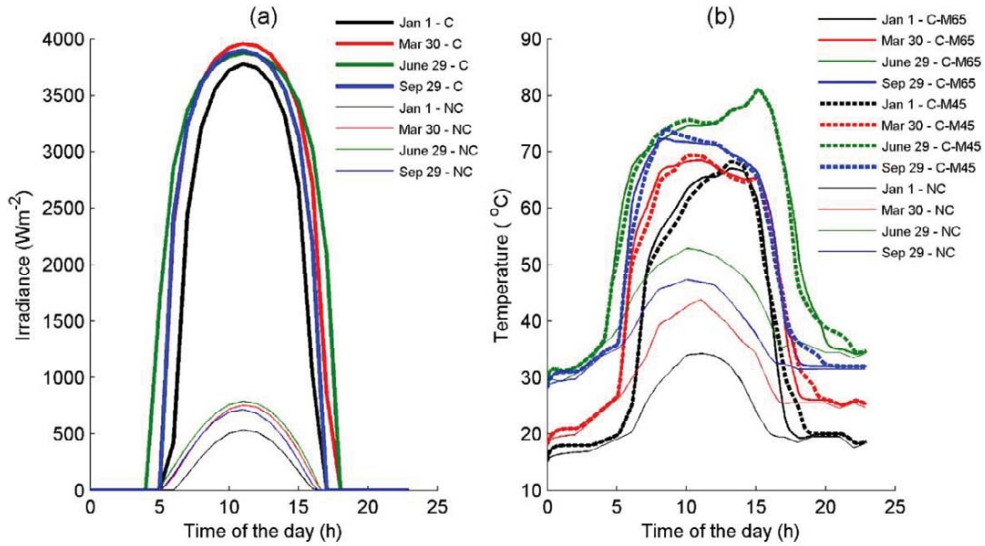

Fig 7: (a) Concentrated and non-concentrated irradiance after optical losses (b) Temperature evolution of the selected system and PV only

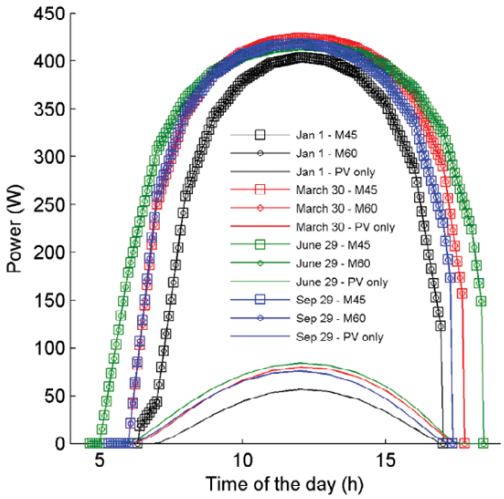

Fig 8: Electrical output of the system and PV only for a unit cell area

The peak concentrated irradiance varies in the range of 3.7 kWm^{-2} – 3.9 kWm^{-2} while non-concentrated irradiance varies in the range of 534 Wm^{-2} – 787 Wm^{-2}. The peak temperature of ~81 ºC for the CPVPCM system is found in June while minimum peak temperature of ~68 ºC is found in January. The change in melting

temperature of the PCM results in slight temperature increase of ~2 ºC for the melting temperature of 45 ºC. The peak temperature of PV only system varies in the range of 35 ºC – 53 ºC for selected days of the year. The hourly averaged incident irradiance and ambient temperature are used in the current investigations and the peak hourly average ambient temperature is ~ 40 ºC in June. The difference between peak PV temperature for PV only system and ambient temperature is ~ 13 ºC for incident irradiance of 787 Wm^{-2}. This difference is reasonable compared to a previous outdoor simulated analysis carried out by author, where the temperature difference between ambient to PV cell is obtained as 22 ºC for peak incident irradiance of ~ 980 Wm^{-2} (Hasan et al., 2015). There is a peak shifting in the temperature of the PV cell in the CPVPCM system is observed which is due to the integration of the PCM. This behavior is also consistent with previously reported experimental and simulated results (Hasan et al., 2015). The electrical output of both systems is investigated using equation 18 and result of electrical output is shown in Fig. 8. It is found that the electrical output of the system integrated with PCM remains almost same. The peak output of 424 W is obtained in March while peak output of 84 W is obtained for PV only system in June. The electrical output of the concentrated systems increases disproportionally with the increase in the incident irradiance. The incident irradiance increases by ~ 7 times but corresponding increment in electrical output is just ~5 times which is due to the temperature effect of the PV cell. Nevertheless, in current configuration, the electrical output remains unchanged by changing melting temperature from 45 ºC to 60 ºC but thermal behavior changes with the change in melting temperature of the PCM as shown in Fig. 9.

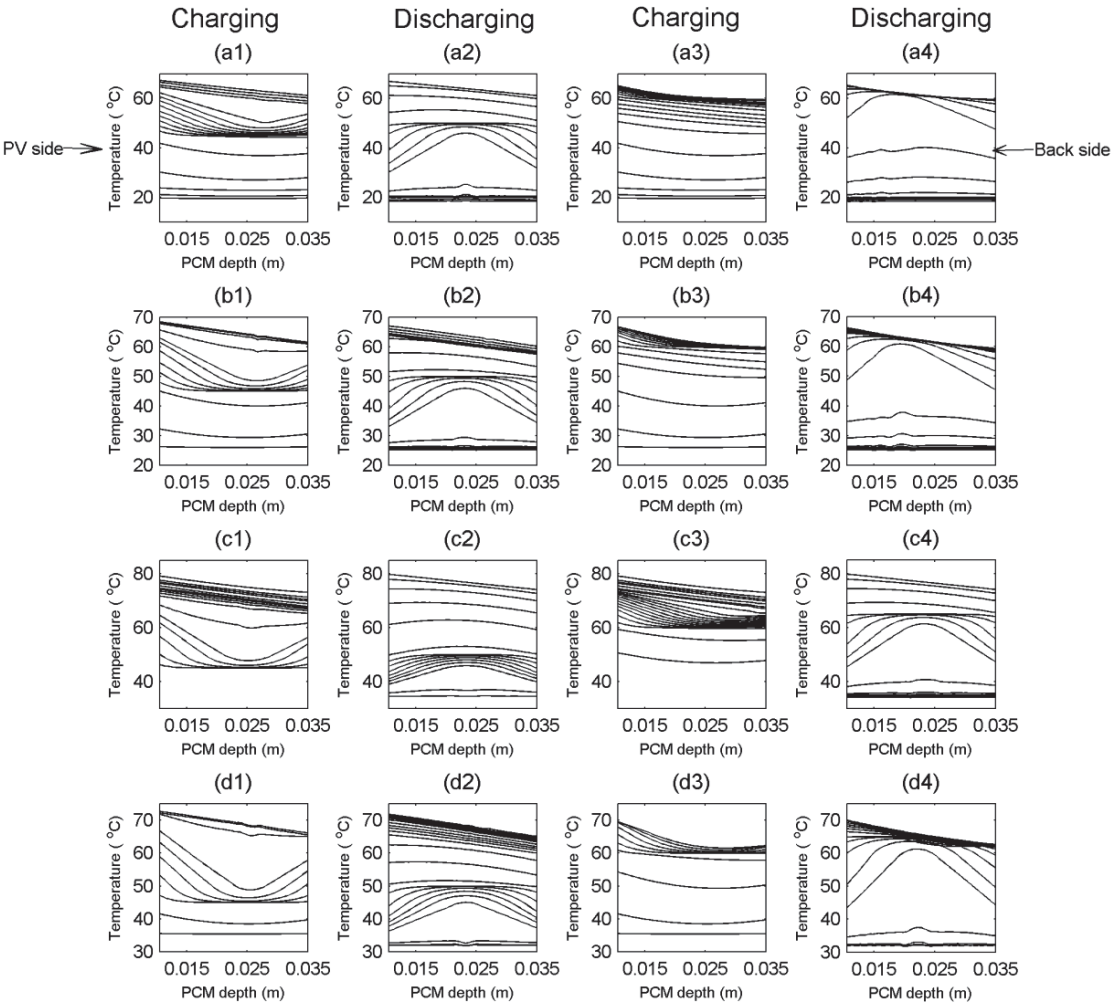

Fig. 9: Temperature curves in the PCM for every 30 minutes during charging and discharging (a) January 1 (b) March 30

(c) June 29 (d) September 29

The thermal energy storage in the PCM takes place at the melting temperature of the PCM as shown in Fig. 9. For the PCM, having melting temperature of 45 ºC, the temperature curves in the PCM shows energy storage and an extended temperature maintenance in the melting temperature range of 45 ºC – 50 ºC. The similar behavior is shown in Fig. 9 for the PCM having melting temperature of 65 ºC. This result shows that the PCMs having melting temperatures in between 45 ºC to 65 ºC are suitable for temperature regulation of a CPVPCM system. Thus, the selection of a PCM, in current configuration, also depends upon energy utilization requirement of the system. For example, if stored energy is required to be extracted at 45 ºC than PCM with a melting temperature of 45 ºC is appropriate and so on. The results of the electrical and thermal efficiencies of the systems are shown in Fig. 10.

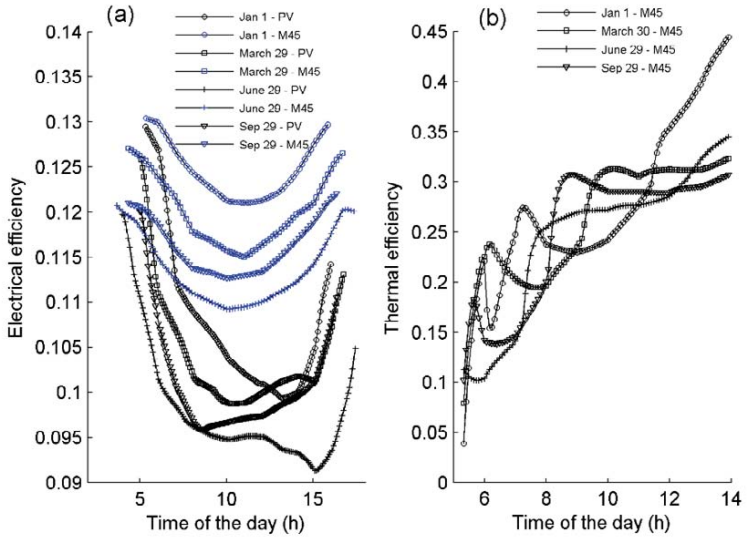

Fig. 10: (a) Electrical efficiency of the PV only and the system having PCM (b) thermal efficiency of the system

Despite increase in electrical power output for a unit area of CPVPCM system as compared to PV cell (as shown in Fig. 8), the overall electrical efficiency of the CPVPCM system decrease by ~16.5% than the PV system. But, the storage of thermal energy provides an advantage for the CPVCPM system and its thermal efficiency is found up to 45% during charging (Fig. 10). Therefore, the overall efficiency of the CPVPCM system is higher than the PV only system that makes it an attractive choice for a hybrid concentrated photovoltaic thermal application. Further studies are required to investigate the combined effect of other parameters of the CPVPCM system such as thermophysical properties of PCMs, geometry, containment thickness etc.

5. Conclusions

Following conclusions can be drawn from this work:

1. Developed optical-thermal model is a suitable tool for optical, thermal and electrical behavior of the system.
2. Ambient temperature and concentrated irradiance intensity effects the selection of a suitable PCM. A PCM with melting temperature in the range of 45 ºC to 65 ºC is suitable for temperature regulation and thermal energy storage for a CPV system in a tropical dry climate.
3. The utilization of stored energy from a PCM is another criterion for the selection of a PCM under limiting ambient and concentrated irradiance conditions.
4. The overall efficiency of a CPV system integrated with a PCM makes it an attractive alternative to a conventional PV system.

SOLAR PV FOR SWEDISH PROSUMERS – A COMPREHENSIVE TECHNO-ECONOMIC ANALYSIS

Nelson Sommerfeldt

KTH Royal Institute of Technology, Stockholm, Sweden

nelson.sommerfeldt@energy.kth.se

Abstract

Like many countries around the world, Sweden is experiencing an exponential growth in PV installations, driven largely by building mounted systems. As prosumers become significant actors in the electricity market, questions about how to integrate them technically, economically, and politically are becoming more critical. A recently concluded, three-year research effort dedicated to the techno-economic analysis of PV prosumers has identified some of the major challenges for multi-family housing owners in designing PV systems in light of uncertainty in the market and policies. This paper highlights the primary results and conclusions from the project, including; PV system sizing, strategies for electricity metering to maximize revenues, a Monte Carlo analysis to understand market and policy risks, and several case studies. The overall conclusion is that PV installations can be a profitable investment in Swedish multi-family houses, however it is important to have a roof with good solar resources, a well designed and installed system, and to capture as many available economic support programs as possible. While primarily focused on multi-family houses, much of this work can be used as a practical guide for many Swedish prosumers towards developing practical systems integration solutions and increasing renewable energy usage in buildings.

Keywords: Solar PV, Techno-economic, Monte Carlo analysis, Systems integration, Self-consumption

1. Introduction

The continued reduction in the cost of solar photovoltaics (PV) is making it increasingly easier for building owners to turn their properties into small scale, renewable energy power plants. These new actors in the energy system are transitioning from being solely consumers to both consumers and producers, often called prosumers. As subsidies continue to be reduced in parallel with reduced costs, prosumers will increasingly be subject to market conditions which will likely come with increased risk, particularly in the deregulated markets commonly found in Europe.

The PV market in Sweden is often overlooked given its small size, however the trend has been towards exponential growth (Lindahl, 2015). Solar PV is only 0.1% of total electricity generation, but it is popular with the public and if trends continue could significantly influence the power system, particularly in buildings. The low cost of electricity but high consumption and VAT taxes make prosumers the most economically interesting installation point under the current market structure.

From the prosumer's perspective, there is considerable uncertainty both inherent in the deregulated electricity market, as well as the rapidly changing policies. When considering a PV investment, there are several economically related questions which can come to mind:

- What size should the PV system be?
- What is the chance I will make a profit on my investment?
- How have others done it?
- Are there any special considerations with regards to the building?

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/eurosun.2016.08.01 Available at http://proceedings.ises.org

There are many concerns around designing and building a PV system, and it is important to prepare and execute in the best possible way to boost the chances of profitability. For example, sufficient pre-studies to ensure good solar resources, keeping costs down, and capitalizing on available subsidies. Multi-family houses (MFH) can be particularly challenging due to the coordination of tens if not hundreds of actors (Muyingo, 2015). A recently concluded, three-year study has examined PV opportunities and risks for Swedish MFH prosumers in detail (Sommerfeldt et al., 2016). This paper is a summary of the primary results and conclusions, and covers issues regarding system sizing and electricity metering with regards to self-consumption, market and policy risks, and case studies from some first movers in this emerging market.

2. Background

Multi-family housing makes up 51% of all households in Sweden, of which 41% are resident-owned cooperatives and 59% are corporate owned and rented to tenants (Statsitics Sweden, 2013). Building electricity usage can be split into two categories; communal and private. Communal electricity consists of HVAC, exterior and stairwell lighting, garages, and laundry rooms. Private electricity is that which is used inside of apartments. Under the European Commission's energy efficiency directive (2012/27/EU), all apartments must have individual electricity meters, however billing methods can vary. Some MFH will own the apartment meters and include electricity usage with other utilities in a monthly fee, while others will allow the apartments to have electricity contracts directly with utilities and thus have their own meter. The aggregating of meters has the advantage of only one connection point with the utility that covers the entire load of the building, thus making the MFH one large customer which can save on fixed network connection fees. Independent metering gives apartment owners the freedom to select their own electricity supplier and contract to fit their needs.

Electricity supply in Sweden is dominated by hydro and nuclear power, with wind and biomass fueled co-generation plants making up the majority of the balance (Swedish Energy Agency, 2015). Demand peaks during the winter months due to a high fraction of electric heating. The wholesale and retail electricity markets are both deregulated. Most electricity is traded on the wholesale market, Nord Pool Spot, where it is purchased by retailers and delivered to end users. A variety of economic pressures have been placed on the nuclear industry, both in the market and by the government, which is likely to lead to the premature closure of several reactors (World Nuclear Association, 2015). Renewable energy development is primarily supported through a technology neutral quota system, where demand is set by the government and prices for green certificates are set by the market based on supply. This program has largely benefited the wind and biomass industries (Swedish Energy Agency, 2015).

The Swedish solar market is relatively small compare to many others in Europe. In 2015, 47 MW_p were installed resulting in a cumulative total of 127 MW_p. Fig. 1a shows how the market has expanded rapidly in recent years, which is correlated with the rapid decline in costs (shown in Fig. 1b) and favorable financial support from the government. Solar PV systems can qualify for a 20-30% capital rebate (depending on the owner), earn green certificates to sell on the quota market, and earn a 0.06 €/kWh feed-in bonus on over-production sold to the network. The future of the feed-in bonus is highly uncertain, placing emphasis on self-consumption as a way to maximize revenues. A PV system in Sweden facing south with little shading can usually expect to produce 900-1000 kWh/kW_p.

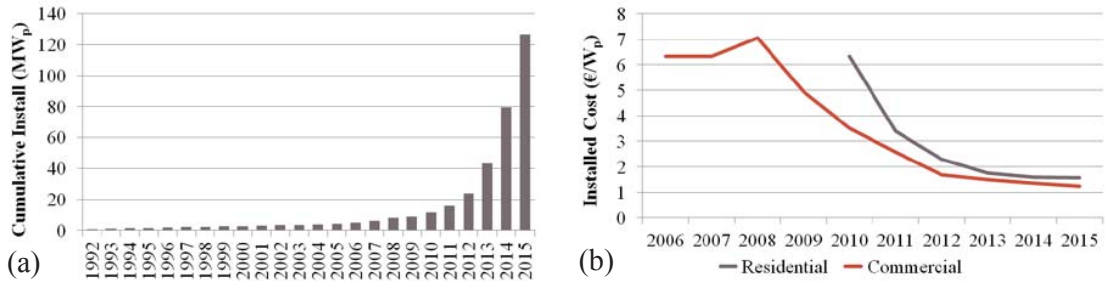

Fig. 1. Cumulative installations (left, a) and installed cost (right, b) for PV in Sweden (Lindahl, 2016)

3. System Sizing

Sizing a PV system for maximum economic benefits is difficult to generalize across buildings. Differences in building load profile, system orientation, or personal economic factors can all play a role in sizing optimization. To demonstrate this, two buildings with the same annual load but significantly different load profiles are presented with a sizing sensitivity analysis. Measured building load data is used and compared to modeled PV production values from System Advisor Model (Blair et al., 2014) using TMY2 climate data from Gothenburg, Sweden. The PV systems are set facing south with a 30° tilt and no shading, resulting in an annual production of 970 kWh/kW_p. The loads for each building are given in Tab. 1. with the key difference being that building one has a laundry rooms while two does not. The system sizes are increased in 1 kW_p increments until reaching 100% load coverage. Net present value (NPV) is used as the key performance indicator and is reported as a function of self-consumption, demand coverage, and system size.

Tab. 1: Building parameters for sensitivity analysis

Building	Laundry	Annual Demand	Maximum Size
1	Yes	27,490	28 kW_p
2	No	27,974	29 kW_p

The results are shown in Tab. 2 and Fig. 2 using three discount rates, where it can be seen that the discounting has a significant effect on optimal sizing of the PV systems. For example, the optimal size for building 1 moves from 11 kW_p to 17 kW_p to 28 kW_p with a change from 3% to 1.5% to 0% discounting, respectively. The wide range signifies the difficulty in generalizing rules for all owners. Even if those owners have nearly identical buildings, they could have different discounting preferences.

Comparing the two buildings, it is clear the optimal system sizes and corresponding demand coverage varies considerably between them. This highlights the difficulty of recommending a rule of thumb for all buildings based on a single load value, even if those buildings are of the same type like a MFH. The optimal self-consumption values are much more consistent however, which is logical since self-consumption rates scale with system size and directly affect revenues whereas demand coverage is only a sizing indicator. The curves in Fig. 2 are notably flat, with optimal size ranges being approximately ±50% of the peak to remain within 5% of the maximum NPV. However, the ranges between the two buildings do not overlap.

Tab. 2. Optimal PV system sizing results comparing a MFH with and without laundry rooms

Building	Discount Rate	Optimal System Size	Demand Coverage	Self-Consumption	Size Range Within 5% of NPV Max.
1	3.0%	11 kW_p	39%	75%	8.5 - 14 kW_p
1	1.5%	17 kW_p	60%	59%	12 - 23.5 kW_p
1	0%	28 kW_p	99%	42%	19 - 28 kW_p
2	3.0%	3 kW_p	10%	75%	2 - 4 kW_p
2	1.5%	4 kW_p	14%	64%	3 - 6 kW_p
2	0%	8 kW_p	28%	39%	5 - 13 kW_p

While it is difficult to extract a hard rule of thumb, some broad guidelines can be suggested for early stage design. In MFH with laundry rooms, the PV system can be sized such that annual production is between 30-50% of the annual demand, which will often correlate with 60-80% self-consumption. In buildings without laundry, a 15-35% ratio can be sought for similar self-consumption rates, however more care must be taken not to oversize since NPV declines more rapidly with increases in system size. In summary, before any final system decisions it is important to review hourly demand and production profiles to estimate self-consumption. It may also be the case that the investors are more focused on goals other than economic optimization. For example, in a case where an owner wishes to maximize their solar production, they could choose to cover 70-80% of their demand and still have a positive NPV, even if it is not the maximum value. More detailed analysis can be found in the project's final report (Sommerfeldt et al., 2016).

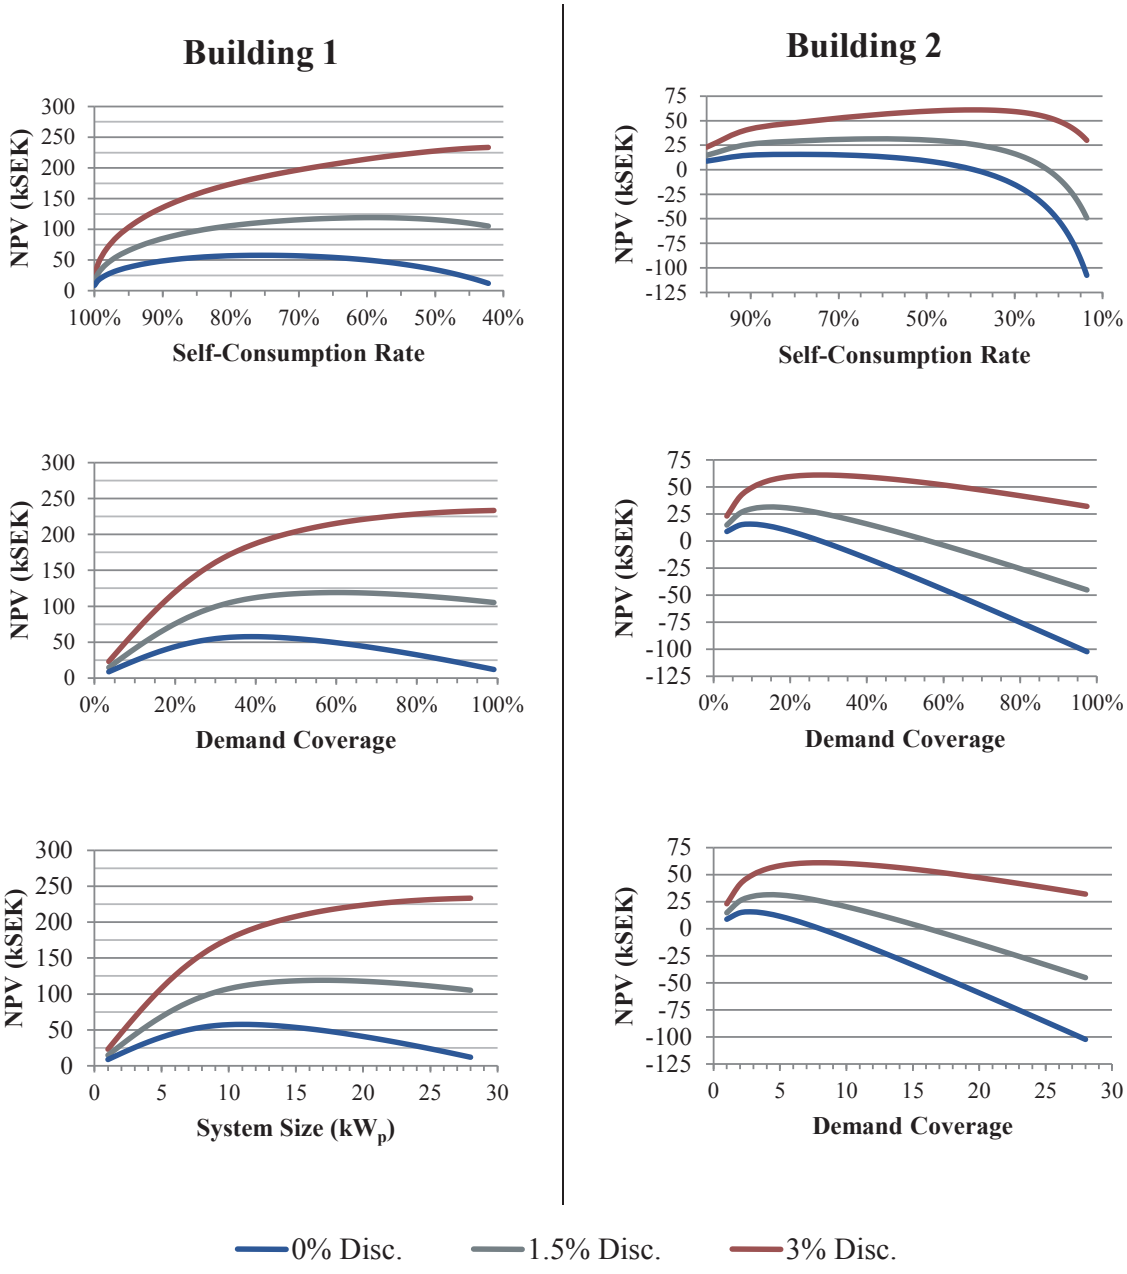

Fig. 2: PV system sizing sensitivity results for two buildings with similar demand but different load profiles

4. Electricity Metering

As mentioned in the background, MFH have options for how their building and apartments are metered by electric utilities; aggregated or independent. The metering configuration determines load volumes and profiles, which was shown in the previous section to impact PV system sizing and profitability due to changes in self-consumption. The effect of metering is tested for a six building housing cooperative considering four configurations, which are visualized in Fig. 3 and described as followed:

- Default: each building is metered separately and includes only communal loads
- Horizontal: all buildings are metered together and includes only communal loads
- Vertical: each building is metered separately and includes communal and apartment loads
- Combined: all buildings and all loads are combined into a single load

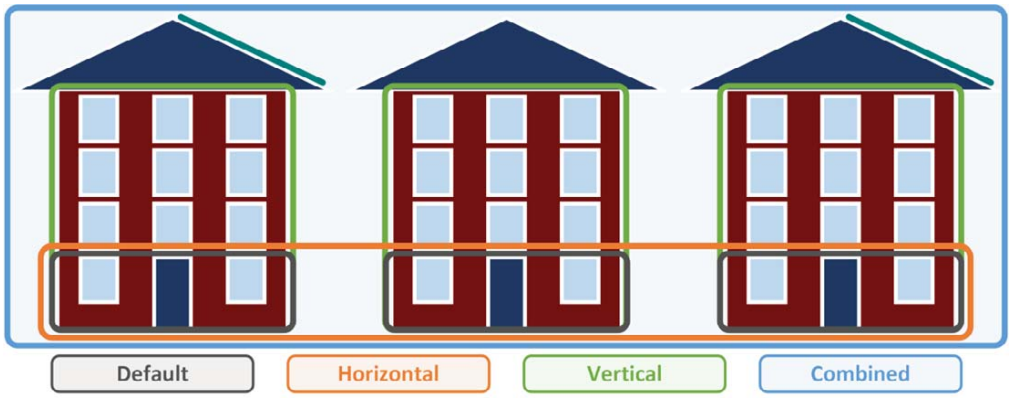

Fig. 3. Diagram of the tested metering configurations (Sommerfeldt, 2015)

Two years of measured communal load data is averaged together to create a single load curve for each of six buildings. Apartment loads are created using a Markov chain model developed by Widén and Wäckelgård (2010). Total communal and apartment demand is 264 MWh-yr^{-1} and 705 MWH-yr^{-1}, respectively. Solar production is modeled using System Advisor Model (Blair et al., 2014) with TMY2 climate data from Gothenburg, Sweden for a PV system facing due south with a 30° tilt. The buildings have identical 16 kW$_p$ systems producing 15.5 MWh-yr^{-1} each and 93 MWh-yr^{-1} in total. The economic impacts of metering are compared to the three prominent subsidies currently available in Sweden; capital rebate, green certificates, and the feed-in bonus.

Increasing self-consumption is the primary motivation for changing metering schemes, and it is found that a vertical scheme is more effective than horizontal. The default self-consumption is 60% whereas the horizontal configuration increases to 77% and the vertical to 97%. This is not entirely surprising given the significantly greater load found in the apartments. When combined the self-consumption rate reaches 100%. The effect on profitability is shown in Fig. 4, where NPV is shown to increase by €60,000 in the vertical configuration. This is significantly more than any of the subsidies which are €44,000 when combined (the subsidies are added cumulatively moving from left to right).

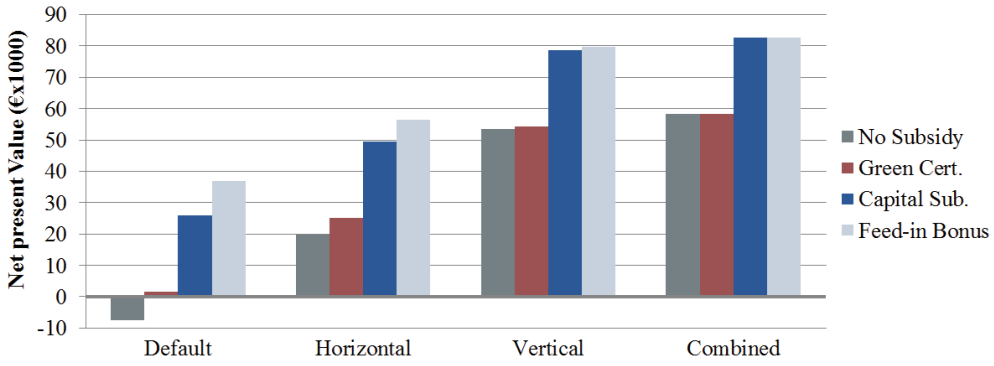

Fig. 4. Net present value of each metering scheme compared to various subsidies (Sommerfeldt, 2015)

Vertical and combined metering configurations are not entirely uncommon in Sweden due to the savings on network fees. However many MFH would need to convert, which would require the replacement of utility meters with those owned by the cooperative. The cost of this conversion would be approximately €35,000 which significantly reduces the benefit as it relates to the PV installation, but should also be compared to the saving in network fees which must be done on a case by case basis. The results also place the importance of metering in context with state subsidies. If it were easier to share generation between prosumers and consumers (i.e. removing tax and market structure barriers), then it might be possible to save on direct subsidies. Alternatively, energy service companies could see this as an opportunity to create micro-grids on housing campuses with solar PV. A more complete analysis can be found in a recent ISES Solar World Congress paper (Sommerfeldt, 2015).

5. Monte Carlo Analysis

Monte Carlo analysis (MCA) is a mathematical modeling method which uses traditional performance indicators but selects inputs at random from predefined distributions to perform repeated iterations and create a distribution of results. The MCA process can be viewed like an outer layer surrounding the inner deterministic layer, as shown in Fig. 5. Presenting the results as a distribution rather than a point value is an improvement over common sensitivity analyses in that it can give the results in a way that tells the investor *what is likely to happen* rather than *what could happen*. This is particularly relevant for PV and other renewables, which are typically subject to long payback times.

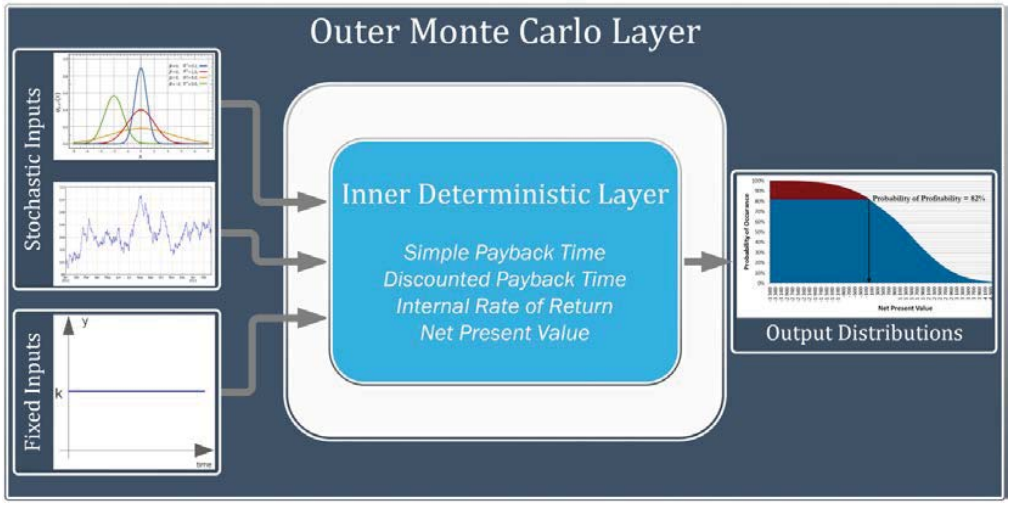

Fig. 5: Diagram of the MCA method in relation to traditional deterministic methods (Sommerfeldt and Madani, 2016)

At the core of the probabilistic method are the traditional deterministic, cost-benefit calculations based on discounted cash flows (Short et al., 1995). The outer MCA layer selects input values at random from a distribution to be fed into the deterministic models. Only the most critical factors are considered for probabilistic input, which includes electricity price, installation cost, annual generation, self-consumption rate, system lifetime, and the real discount rate. Electricity price is treated with a novel geometric Brownian motion model, while the remaining inputs are given distributions.

The output from the MCA is a distribution of NPV values. This is used to create two metrics; the probability of profitability (PoP) and probability of principle return (PPR). Profitability in this case is defined as earning the desired real discount rate (in this case a 3% real return), and thus the PoP represents the chance that NPV will be greater than zero. PPR is found the same way, however with the discount rate at 0% and thus representing only the return of the original investment.

The case presented here is intended to be representative of the most common PV installations currently in Sweden. Nominal values are annual generation at 900 kWh/kW$_p$, an installation cost of 1.81 €/kW$_p$, a system lifetime 30 years, and a self-consumption rate of 60%. The primary subsidies (capital rebate, green certificates, and the feed-in bonus) are examined in three policy scenarios, shown in Tab. 3, to give a practical assessment from the prosumer perspective. They are also examined separately to identify their individual impact.

Tab. 3: Policy scenario descriptions

Scenario	Capital Rebate	Green Certificates	Feed-In Bonus
Unsubsidized	None	None	None
Common Case	15%	Overproduction	5 Years
Best Case	20%	All production	15 Years

The results in Fig. 6 show that under a common case of policy support, a prosumer with a well-designed and well-oriented system has an approximately 70% chance of earning a profit. Without subsidies the probability falls to 8% and in a best case scenario there is a 97% chance of profit. Interestingly, the PPR is 100% in all cases, even without any policy support.

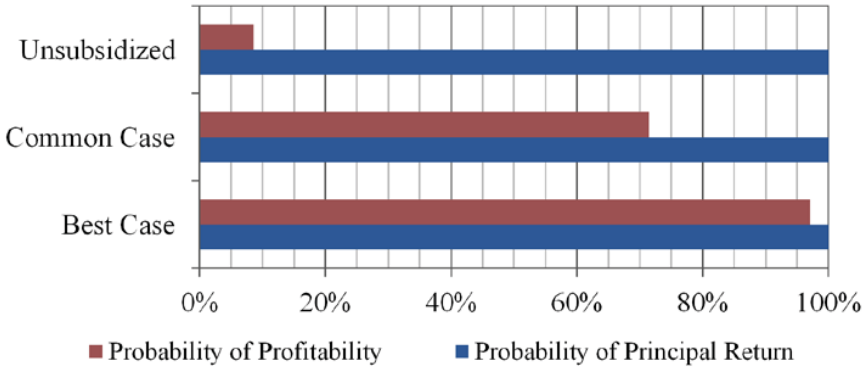

Fig. 6: Probability results for the policy scenarios (Sommerfeldt and Madani, 2016)

Comparing results from the various policies, shown in Fig. 7, indicates that the capital subsidy is the strongest tool for profitability in Sweden. The 20% capital subsidy alone is capable of lifting the PoP from 8% to nearly 60%. The feed-in bonus is the next valuable while green certificates are the least, however the feed-in bonus' future remains highly uncertain. The impact of the capital subsidy on profitability is in large part due to the immediate payment, which has no discounting applied and thus carries more value to the investor than payments extending into the future.

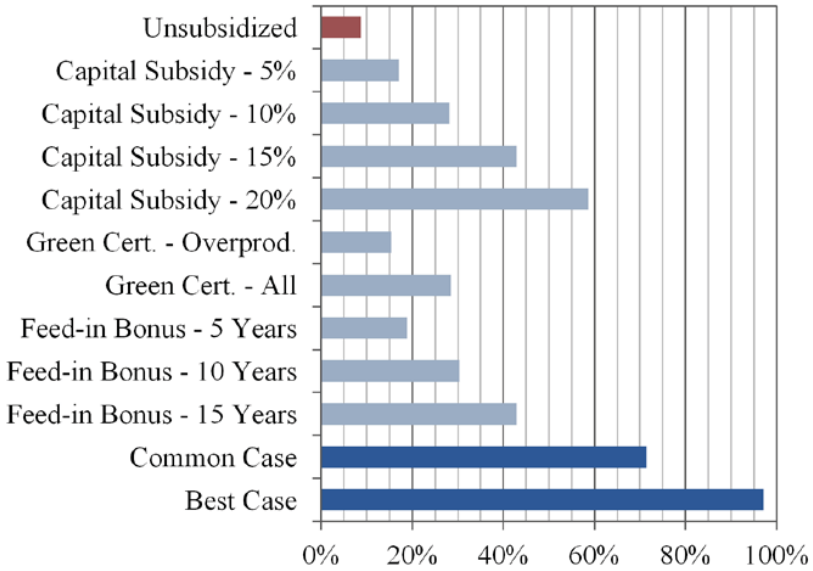

Fig. 7: PoP values for a range of subsidy levels for the most direct PV support policies (Sommerfeldt and Madani, 2016)

It is important to note that the applicability of these results are limited to the assumptions and models used, most important of these being the current market structure. There are a number of possible exogenous risks which are not easily incorporated into a single MCA which could significantly alter the probabilities presented here. These abbreviated results and further detailed analysis is presented in a recently submitted article currently under review (Sommerfeldt and Madani, 2016).

6. Case Studies

Like the remainder of the Swedish market, the number of MFH installing solar PV systems is small but growing. The boards of directors from three early adopting MFH cooperatives agreed to interviews to discuss their experiences and are used as case studies to learn about the ideation, planning, execution, and conclusions about installing a PV system. The results are summarized here and a more complete description can be found in (Sommerfeldt and Muyingo, 2015).

In all cases, the motivation for installing a PV system is rooted in a desire to improve the economic position of the cooperative. This would primarily be achieved through reduced energy costs, but in some cases it was believed that the system would create a positive image for the cooperative and subsequently improve property prices. All of the cooperatives were presented with a financial analysis from an outside party prior to construction; in two cases from the contractor installing the system and in the other the economics were simply estimated without calculation. Naturally these reports indicated positive returns for their investment such that they wanted to move forward. Since the time of the original analyses, the electricity prices collapsed by 40% and significantly altered the economic outlook. In one case it is highly unlikely that they will earn a return and may even lose some principle.

The unforeseen downturn has not dissuaded the boards from considering their projects a success. This could be because economic factors are not as critical as originally claimed, or that their opinion is biased since they have little choice but to accept the installations. The boards also see their PV as positive advertisement for their community, which has been confirmed by two of the cases being given awards by the Solar Energy Association of Sweden for their pioneering efforts (Solar Energy Association of Sweden, 2015). All of the communities have received media attention in some form, which could very well result in higher property prices since the environmental awareness in Sweden is relatively high (TNS Opinion & Social, 2014).

These cases highlight the challenges that can arise with early adopters and there is a need for improved financial assessment for PV, particularly in deregulated markets like Sweden where forecasts have a high uncertainty. However the general attitude towards PV suggests a continued increase on installations, particularly if environmental and social benefits are highlighted. As one chairman put it, “the long term sustainability of the cooperative is more important than the short term economics.”

7. Conclusions

While the volume of the Swedish PV market is still small, awareness and interest are growing such that more and more building owners are considering becoming prosumers. The results here show that PV investments can be profitable, but without dedicated policy support the chances of earning an acceptable return are low. Even with positive investment indicators, it is important for prosumers to keep in mind that PV is a long term investment and that a well design and installed system are necessary. Policy towards prosumers is highly uncertain, however high levels of self-consumption have been identified as a good way to hedge against policy changes and maintain profitability.

From a policymaker’s perspective; of the policies currently in place, the capital rebate is the most powerful and valuable to the prosumer. The receipt of the money earlier in the investment results in less discounting costs and in less uncertainty about the value. By comparison, green certificates can be earned for 15 years and have a moving price based on market conditions. Green certificates and the feed-in bonus can also act against the development of flexibility via storage or demand response. Policies should support the transition to a flexible electricity system. Therefore emphasis should be placed on the capital rebate with a long term, transparent plan for phase out that encourages stability for investing.

REVIEW OF SOLAR PV/THERMAL PLUS GROUND SOURCE HEAT PUMP SYSTEMS FOR EUROPEAN MULTI-FAMILY HOUSES

Nelson Sommerfeldt*, Hatef Madani

KTH Royal Institute of Technology, Stockholm, Sweden

*Corresponding author: nelson.sommerfeldt@energy.kth.se

Abstract

The combination of photovoltaic-thermal (PVT) hybrid modules with ground source heat pumps (GSHP) has the potential to increase renewable fractions of heating, cooling and power generation in buildings. The concept benefits each component in the system; the solar collector can be more efficient; collected heat can be stored in the boreholes and recovered in both short and long term; and the elevated temperatures of the boreholes improves the efficiency of the heat pump. System optimization is challenging due to the number of possible configurations, options in component designs and system control, and the close interrelation of performance between components. This study presents several system configurations which are designed to be a balance of performance, practicality, and cost. The designs are based on a state-of-the-art literature review from multiple fields (solar collectors, heat pump controls, seasonal thermal storage, and solar assisted heat pumps) and consultations with heat pump and PVT collector manufacturers.

Keywords: Solar PV/thermal, Ground Source Heat Pump, Seasonal Thermal Storage, Systems Integration

1. Introduction

In light of environmental challenges, throughout Europe there is an increased interest in integrating solar power with the built environment. At the same time, heat pumps are often considered an environmentally sound method for producing heat or domestic hot water and are often part of low-energy or net zero energy building (NZEB) concepts (Cao et al., 2016). The combination of the two, known as a solar assisted heat pump (SAHP), has been investigated for decades (Andrews, 1981a; Freeman et al., 1979; Threlkeld, 1953) with the idea that the two technologies can complement each other and improve the system as a whole. Recently, research on the subject has accelerated as environmental and regulatory pressures to reduce energy demand in buildings increase.

SAHP systems are complex both in design and operation. For the heat pump, there are multiple potential heat sources (air, ground, water, aquifer, solar) and sinks for delivering space heating and domestic hot water (hot water tanks, traditional radiators, floor heating, combi-stores, etc.) that result in a multitude of design options. Likewise, solar collectors have several designs and configurations, such as thermal and/or photovoltaic, insulated (glazed) or not, and liquid or air based. The hydronic connection can be done in series, parallel, or both and can also include regeneration of a seasonal thermal store. All together, the options are quite broad.

The recently concluded IEA project on solar assisted heat pumps (Solar Heating and Cooling Task 44 / Heat Pump Program Annex 38, hereafter referred to as T44A38) resulted in a useful handbook for guiding engineers and researchers (Hardorn, 2015). While successful examples of most configurations could be found, the most promising solutions tended towards insulated (glazed) solar collectors working in parallel with the heat pump. At the same time, the best examples also tended to be the ones where components were specifically designed for a SAHP configuration and where the control strategy was well planned.

doi:10.18086/eurosun.2016.08.15 Available at http://proceedings.ises.org

The majority of the IEA project research, and the research on SAHP in general, has been done considering solar thermal collectors in single family houses (Haller et al., 2014). However, as noted in the handbook, photovoltaic/thermal (PVT) hybrid collectors are an interesting prospect that merit further investigation. The co-generation of heating, cooling, and electricity can produce more renewable energy per roof area than other solar solutions and will likely result in alternative control strategies to thermal-only systems (Dott et al., 2012). Multi-family houses (MFH) are often overlooked since 90% of European heat pumps are installed in single family houses (EHPA, 2015), even though 40% of Europeans live in multi-family houses (Eurostat, 2015). Space for heat sources, in particular ground sourced systems, is a common limitation for MFH which are often located in denser urban areas. Regenerating the ground with solar heat could make ground source heat pumps (GSHP) a possibility for more MFH with limited space (Reda, 2015).

A recently initiated research project at KTH Royal Institute of Technology aims to fill a research gap for PVT plus ground source heat pump (GSHP) systems in MFH (Sommerfeldt, 2016). As a first step in the project, this study's objective is to identify PVT+GSHP systems with a high probability of implementation through improved performance, ease of integration, and cost efficiency. This is done primarily through a state of the art review. However given the relative lack of examples for this type of system, guidance must be inferred from similar SAHP systems as well as reviewing the relevant literature of each component.

The application for this system is in heating dominated climates, therefore less inspiration is taken from systems with significant cooling loads given their different operating conditions. There is also considerable interest in the ability to store the excess of solar energy from the summer to the winter, which is made easier with the use of boreholes in the GSHP. Direct-expansion collectors, i.e. those which use the PVT as the heat pump evaporator, are not considered due to their relatively low technology readiness for commercial use, higher cost, and risk for environmental impact. The strengths, weaknesses, and motivations for each design will be presented and the study concludes with an outline of the future work planned for the chosen systems.

2. State-of-the-Art Review

The investigation of PVT+GSHP systems dates back to 1981, where series, parallel, and even ground regeneration were all considered (Andrews, 1981b). The conclusions were that in no case could PVT be economically justified over solar thermal due to the lower thermal efficiency and that all or most of the electricity is degraded into heat. It's important to note, however, that PV modules in 1981 had a typical efficiency of 6-10% and cost 25 USD/W_p. Today's commercial PV modules can routinely be 15% efficient for 0.75 USD/W_p (Fraunhofer ISE, 2015).This rapid decline in the cost of PV has significantly altered the approach designers take in adding solar generation to buildings, and could have a similar impact in the economics of SAHP systems.

Perhaps the most comprehensive review of SAHPs comes from Haller et al. (2014), which summarized the studies performed under T44A38 and was then adapted for the SAHP handbook. As previously mentioned, solar thermal systems working in parallel with heat pumps of any source typically have the best energy performance. This correlates with the types of product available on the market, which are dominated by glazed solar thermal collectors working in parallel with air or ground source heat pumps (Hardorn, 2015).

Kamel et al. (2015) reviewed the fundamentals of SAHP systems and corresponding collector designs with an objective of identifying promising systems for cold climates. Their focus was drawn towards PVT collectors, where it was found that most studies consider the collector as the evaporator (direct-expansion) and that most SAHP systems in cold climates use liquid as the working fluid. Buker and Riffat (2016) performed a review of SAHP for low temperature water heating with a focus on system classification and performance. They concluded that an optimal configuration cannot be identified for a given climate and application due to the wide range of possible system designs and methods for measuring performance, which is similar to the conclusions from T44A38. In light of this, they call for developing a standardized method for defining performance that can capture all designs.

The work performed under T44A38 is extremely helpful as a foundation, but additional input is necessary to guide system design. The remainder of this chapter will review specific PVT+GSHP systems, as well as relevant literature which can give important insights.

2.1. PVT + GSHP Systems

Although not as common as solar thermal systems, there have been several PVT+GSHP studies performed in recent years. To be certain, there are several other SAHP oriented studies which have included PVT collectors and are not considered here. This is due to the structures of those studies not lending themselves as well to be used for system design inspiration.

Bertram et al. (2011) studied the measurements from a single family house near Frankfurt, Germany with 39 m^2 of unglazed PVT collectors, a 12 kW GSHP, and 225m (3 x 75 m each) of borehole heat exchangers (BHE) for delivering space heating and DHW. Fig. 1 shows how the PVT collectors are connected in series to the BHE loop after the heat pump, thus delivering heat to the ground first and then to the evaporator. The measurements showed that heating demands were underestimated, thus resulting in an undersized BHE. TRNSYS simulations were used to estimate long term performance. After 20 years, the system without solar showed temperature degradation in the BHE whereas the solar equipped system did not, resulting in a 13% improvement in the seasonal performance factor (SPF) in year 20. Had the BHE been sized correctly however, the improvement would only be 6%. The electrical output of the PVT was also compared to uncooled PV modules on the same roof, which showed the PVT to produce 4% more electricity.

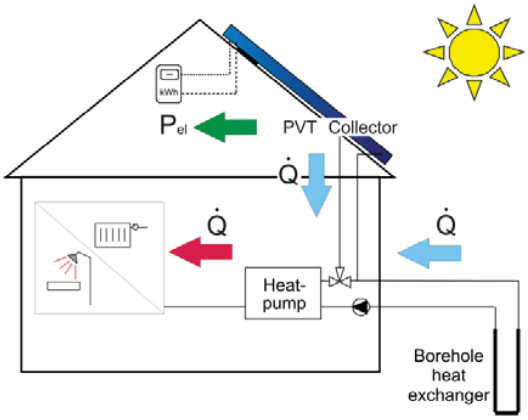

Fig. 1: PVT used to boost brine temperatures to the BHE (Bertram et al., 2011)

Another single family house in Montreal, Canada was simulated by Brischoux and Bernier (2016), shown in Fig. 2, which included a 140 m BHE with independent dual u-tube circuits, where one tube was connected to a 10 m^2 unglazed PVT array and the other to a 10 kW heat pump. The annual SPF only increased from 2.82 to 2.88. The mild performance increase was attributed to the unglazed collectors providing little benefit during the heating season, only having a single borehole (such that it could not act as a seasonal store), and that the BHE was appropriately sized. The cooled PV cells produced 7.7% more electricity than a traditional PV module. It is also worth noting that when the system boundaries are moved to include the PV production the SPF improves by 18%. This demonstrates the importance of defining relevant performance indicators, particularly when considering electrical and thermal co-generation.

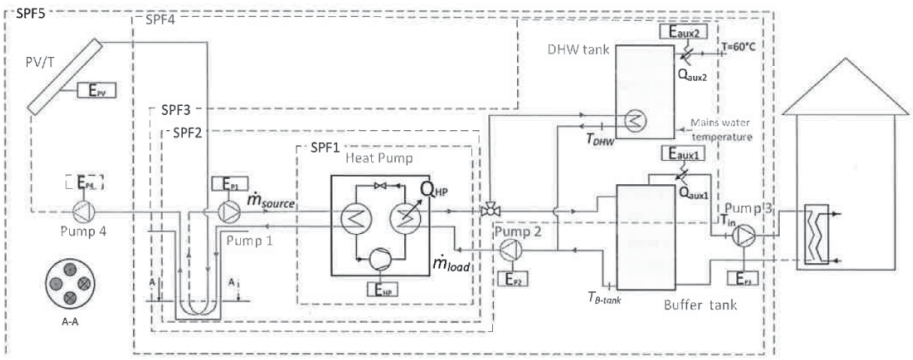

Fig. 2: PVT+GSHP concept using dual u-tubes in a single family house (Brischoux and Bernier, 2016)

In Switzerland, a low-exergy building concept presented by Meggers et al. (2012) and Baetschmann and Leibundgut (2012) includes unglazed PVT collectors combined with a novel dual-depth BHE where there are a set of 400 m boreholes for higher temperatures and a set of 200 m boreholes for lower temperatures. As shown in Fig. 3, the PVT collector heat can be used directly (in parallel) as a boost for the heat pump (in series) or to recharge the boreholes (regeneration). The concept focuses on low temperature differences between all components in the building energy system and requires a specially designed low-lift heat pump. The simulations suggest that the average coefficient of performance (COP) could be near eight and an SPF during the heating season of six. This is about double what is typically expected in European GSHP systems and highlights the performance opportunities in taking a systems approach to building energy supply.

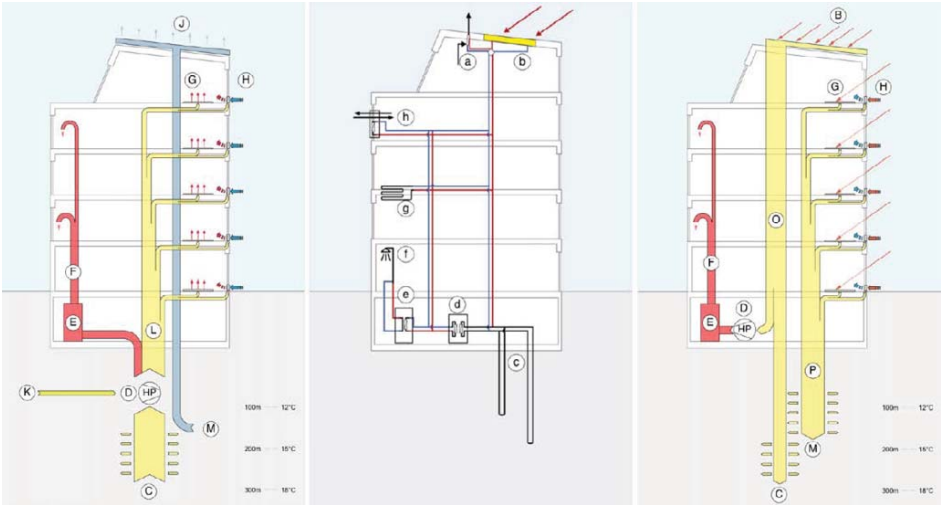

Fig. 3: Low exergy building concept configuration (center) in heating (left) and cooling modes (right) (Meggers et al., 2012)

2.2. PVT Collectors

PVT collectors come in an extremely varied range of configurations and designs (Michael et al., 2015; Riffat and Cuce, 2011; Tyagi et al., 2012; Zondag, 2008). In building applications, flat plat collectors using a liquid working fluid are the most common, leaving the primary categorization in designs being between glazed and unglazed (Kamel et al., 2015). A glazed collector typically has greater thermal efficiency but lower electrical efficiency than unglazed, so the design choice is partially influenced by which energy form is more important. In the case of unglazed collectors, there is also the choice to insulate the rear side of the panel.

The operating condition of the collector in conjunction with the GSHP is an important factor since temperatures can fall outside the typical operating conditions (Haller et al., 2012). In a series or regenerative configuration, collector temperatures can be below ambient thus making glazing or insulation a barrier to added heat gains from the ambient air. Bunea et al. (2012) tested four collector designs (flat plat, evacuated tube, unglazed-insulated, unglazed-uninsulated) with low inlet temperatures. The results show that unglazed collectors have higher efficiency during periods of low temperature or irradiance. They also showed that condensation gains can be a significant portion of the energy gains during periods of low or no incident radiation. This can be particularly helpful during winter months when heating demands are highest, but on an annual basis condensation is not likely to be a significant heat source (Bertram et al., 2010). From a product reliability standpoint, condensation does need to be attended to.

2.3. Borehole Thermal Energy Storage

Several SAHP studies have shown that borehole regeneration using a single BHE is not energy efficient due to the heat dissipating too rapidly in the earth (Bertram, 2014; Bertram et al., 2012a, 2012b; Kjellsson et al., 2010). Additionally, appropriately sized boreholes (i.e. those which would operate successfully without solar regeneration) do not significantly benefit the heat pump's SPF (Kjellsson et al., 2010; Reda, 2015). In a MFH, it is usually expected that there will be multiple boreholes and thus there is the opportunity for creating a borehole thermal energy store (BTES). The design of these stores depends on many local factors, but some general design principles can be garnered from previous work.

Most solar BTES have been designed for low mean temperatures (10-40 °C), are usually supplied by glazed solar thermal collectors, and are used in combination with heat pumps (Dalenbäck, 1990; Rad and Fung, 2016). These systems are usually designed for a high solar fraction (50-90%) and often have relatively short boreholes (30-65 m) in order to give a compact volume for minimizing heat losses. Thermal stratification, which is done radially rather than vertically as in a hot water tank, is helpful for reducing losses and improving collector efficiency but can be difficult to achieve in the ground (Dalenbäck, 1990). Nordell and Hellström (2000) state that the heat losses, and thus the efficiency, of a BTES depend primarily on the size and shape of the store, average cycle temperature (more specifically, the temperature at the boundary of the store), and the thermal properties of the ground. The optimal BTES volume is highly dependent on size of the heating demand and the desired supply temperature, and the most efficient conditions are with large loads and low temperatures (Nordell, 1994; Pahud, 2000). It is suggested that only systems with high thermal loads (greater than 500 MWh/yr) can be built cost effectively (Dalenbäck, 1990; Pahud, 1996).

Drake Landing, a solar community of 52 single family houses in Alberta, Canada, uses flat plate collectors with a high temperature BTES that feeds directly to the buildings (McClenahan et al., 2006; Wong et al., 2006). The BTES is a 35,000 m^3 cylinder with 144, 35 m deep boreholes, 2.5 m spacing, six boreholes in series, a maximum storage temperature of 80 °C and was expected to have an efficiency of 40%. Measurements after five years show that the system is performing very close to the simulations and the BTES has an efficiency of 36% with an operating temperature range of 45-70 °C (Sibbitt et al., 2012).

Chapuis and Bernier (2009) examine a redesign of Drake Landing by lowering the store temperature to have a range of 10-16 °C and then combine with a GSHP. The solar collector area is reduced by 75% and the BTES volume enlarged nearly 300% by increasing the borehole spacing to 4.5 m. The result is greater collector efficiency (58% vs. 23%) due to the lower inlet temperatures and reduced heat losses by over 70%. This configuration does require significantly more auxiliary energy input (144 vs. 11 MWh) thus lowering the solar fraction to 78% from 98%. Unfortunately no economic comparison was performed to compare the savings from the solar collectors to the cost of the heat pump and electricity.

In addition to the BTES, Drake Landing uses short term thermal storage in the form of two hot water buffer tanks with a total volume of 240 m^3. A buffer tank is a common component in a solar thermal system, and Pohud (1996) identified that a BTES only becomes economically interesting when targeting solar fractions higher than 60%. Since some solar collectors are capable of producing heat faster than the BTES can absorb it, the buffer tanks can play an important role in the control of the system and increase the efficiency of the storage system as a whole. The size of the buffer tank is predominantly linked to the collector area, and less so with the heating load type and the size of the BTES (Pahud, 2000).

2.4. Control Strategies

With the increased deployment of solar PV in buildings, there has been a decrease in financial support schemes in many countries which make it less profitable to sell overproduced electricity to the grid. It can also be the case that high penetrations of PV in a power grid will erode the tariffs during these hours and thus reduce profitability. Therefore increasing self-consumption of solar generation using load shifting and/or energy storage is likely to be increasingly important in coming years (Luthander et al., 2015).

The use of a heat pump makes it possible to convert excess electricity into thermal energy for use in the building later on, and is a concept which has seen increasing research interest. Thygesen and Karlsson (2014) compared the cost effectiveness of storage using a hot water tank with a direct electric element for DHW to lead acid batteries. For an equivalent increase in self-consumption for both technologies (from 56% without storage to 88% with) the PV + battery system was found to cost double the PV + thermal storage. Thygesen and Karlsson (2016) went on to study a weather forecasting control for the GSHP, foregoing any direct electric storage. In this case self-consumption increased from 56% without predictive control to 63% with, however heat pump demand also increases due to additional running time called for by the controller.

Control systems, particularly with a complex hydronic configuration such as in a PVT+GSHP, can create difficult optimization problems. Salpakari and Lund (2016) presented a non-linear, cost-optimization algorithm considering appliance load shifting, battery storage, and GSHP control for a single family NZEB in Helsinki. The method was compared to a baseline building without controls and found to perform

significantly better, with self-consumption increasing by as much as 30 percentage points and annual electricity costs decreasing 13-25%. A simpler rule based control algorithm was also tested and increased self-consumption, but usually resulted in higher annual costs due to increased storage losses and less efficient heat pump operation. The best performance was found with combined thermal and battery storage, however investments were not considered in a cost-benefit analysis. Storage was found to be more effective than load shifting towards improving PV self-consumption, which correlates with previous work (Widén et al., 2009).

Dar et al. (2014) compared several simple air source heat pump control strategies with PV in Oslo, considering; self-consumption maximization, electricity cost minimization, and grid import/export limitations. For a given system configuration, it was found that self-consumption could be improved by six percentage points and as much as 12 points if larger thermal stores were considered. Using spot price signals as a control input, the annual electricity cost could be reduced by up to 19%. These two objectives are currently at odds with each other, as the lowest electricity prices are currently during the night when there is no solar production. It was also shown that SPF of the heat pump was made worse in every case by 10-20% and that self-consumption by the heat pump is limited to about 35% without the use of seasonal storage.

3. Resulting System Configurations

Prior to the review, there were some design features which were planned to be a part of the system, such as the use of PVT modules, a GSHP, and a BTES. The method(s) in which these components would be connected and controlled however was unknown. In light of the review, it is clear that the complexity of the system makes objectively selecting a single best SAHP design difficult if not impossible. There are some overarching design principles which guide system design in this study to help identify a configuration. The focus is techno-economic, meaning that cost-optimized solutions are important, not only performance optimized. This places emphasis on relatively simple components and configurations, which has been previously highlighted as a design goal for future SAHP systems (Dalenbäck, 1990).

The design process can begin with the PVT collectors and the decision to use glazed versus unglazed. Glazed collectors can be more thermally efficient at the expense of electrical efficiency, but are likely to be restricted to the sink side of the heat pump (parallel configuration) due to the risk of condensation inside the collector from the low inlet temperatures of the BHE loop. Unglazed collectors have the advantage of acting as an air-to-water heat exchanger during periods of low irradiance, having lower cost due to less materials and can more easily integrate with PV systems (physically and aesthetically).

Having access to seasonal storage via the BTES is a major element in the design considerations. The elevated temperatures will supply the heat pump higher source temperatures, thus improving efficiency, but not without limits. The BTES core temperatures should be planned to be low enough such that it can continue to work with the heat pump during the summer when temperatures are highest. Integrating the collectors on the source side makes it easier to access the BTES for regeneration. It also has the advantage of being relatively easy to integrate into existing systems, as there would be no need to change the hydronic system between the heat pump and the building. A series configuration also pairs well with the unglazed PVT collectors, since much of the time outlet temperatures from the PVT will likely be too low to supply the building directly.

Considering the economic goals of the system and the inclusion of a seasonal BTES, a series/regenerative configuration is chosen for this project. Not using the solar energy directly may lead to a less energy or exergy efficient system (Haller and Frank, 2011), however it may be that the cost efficiency will be greater. The integration of the PVT collectors to the BHE loop remains an open question, and there are several possibilities to do this that are difficult to rank without more information. Therefore the following four design concepts will be simulated to determine performance and cost effectiveness; PVT-in-loop, heat exchanger, buffer tank, and dual u-tube.

The first concept, shown in Fig. 4 places the PVT collector in the same hydronic circuit as the connection between the heat pump and BHE, similar to the system presented by Bertram et al. (2011). The strengths of this configuration are its simplicity and low cost, where only one three-way and one check valve are required. The weaknesses include lack of control over flow rate or fluid properties, as the PVT collector is directly bound to the requirements of the heat pump and BHE.

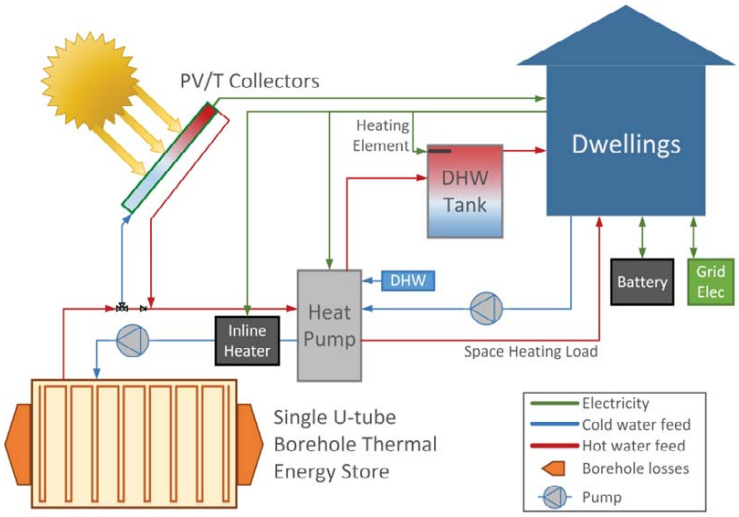

Fig. 4: Concept One using PVT in the BHE loop to boost incoming fluid temperature to the HP

There are two additional components that appear in every concept; batteries and an inline heater connected to the BTES. These allow the storage of electricity with the batteries being short term chemical storage and the BTES being long term thermal storage. While there may be large amounts of exergy destruction by heating the BTES with electricity, the heat is reducing the need for electricity from the heat pump in the winter thus acting as a method for storing electricity rather than simply converting it to heat. It can also test the cost efficiency of the BTES in comparison to selling electricity to the market.

Another consideration for all concepts is the connection point for the PVT collectors, which can go in either the supply or return lines from the BHE to the heat pump. Thermodynamically it would be the most logical to use the heat to boost the temperature supply into the heat pump, however they have a source temperature limit that could cause faults. Therefore a pre-study will need to be made to determine the appropriate connection point, which will then be used in all concepts.

Concept two uses a liquid-to-liquid heat exchanger to integrate the PVT collectors, as shown in Fig. 5. This configuration overcomes a weakness of concept one by allowing the PVT circuit flow rate to be controlled independently from the BHE circuit. It also allows for a separate working fluid, which may be important in later years when the BTES is fully charged and it's possible to reduce the fractions of antifreeze in the BHE circuit. The primary weaknesses are the additional cost of a heat exchanger and the higher pumping demands due to the additional pressure drop. From a practical standpoint, the integration of this concept into the physical system should be similar to concept one and does not require a prohibitive amount of space.

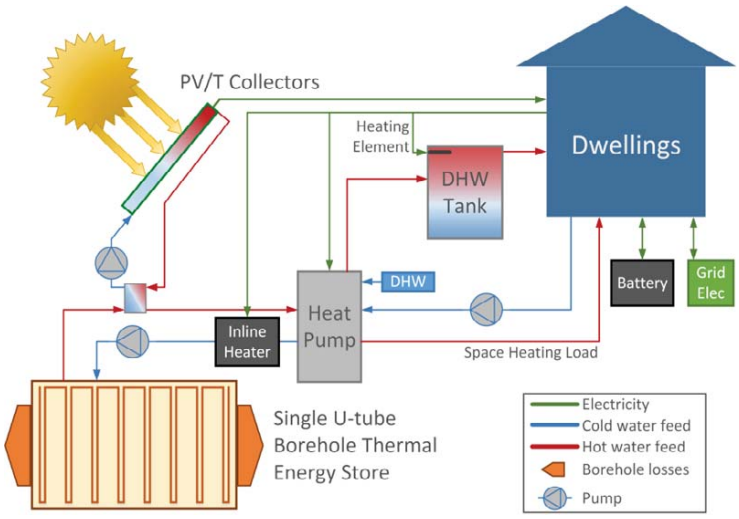

Fig. 5: Concept two using a liquid-to-liquid heat exchanger to boost incoming fluid temperatures to the HP

In concept three, the heat exchanger in concept two is replaced with a buffer tank as shown in Fig. 6. This concept's strength is that it could result in more efficient use of the solar heat by avoiding delivery to the BTES until there is an excess of solar energy beyond daily use, as recommended by Pahud (1996). The control of the buffer may require forecasting to decide when to release the heat into the BTES. This concept has the potential for improved control options over concept two, but has the weakness of the cost and space for space for the tank.

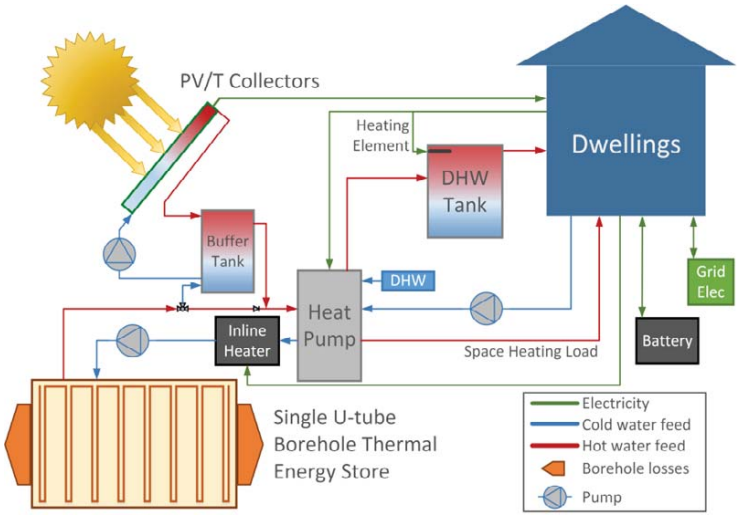

Fig. 6: Concept three using a storage tank to boost incoming fluid temperatures to the HP

Concept four, shown in Fig. 7, uses the BHE as the heat exchanger for the PVT collectors and the heat pump via a dual u-tube, similar to Brischoux and Bernier (2016). This configuration has the same strengths as concepts two and three, where independent working fluids and flow rates can be used. It also removes the need for valve control strategies since the circuits are completely separate and can be controlled independently. The greatest weakness for this concept is that it applies predominantly to new systems, since many existing systems only use a single u-tube and adding a second tube may be prohibitively expensive or impractical. There will also be high pumping losses in the PVT circuit since it includes the BTES as well.

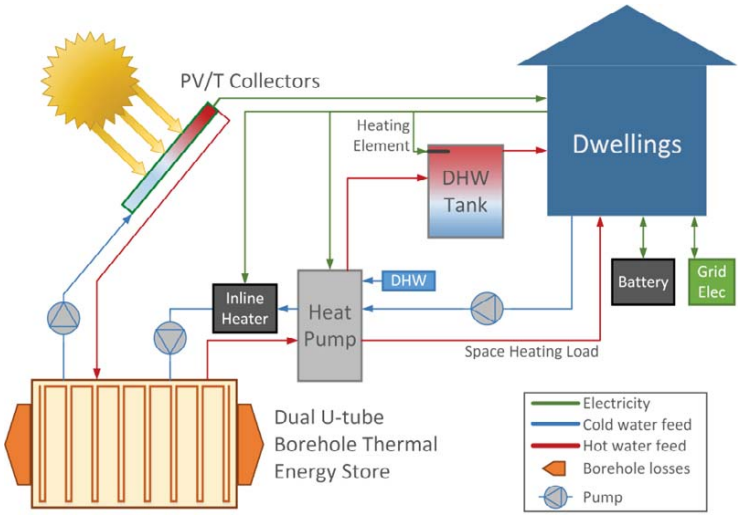

Fig. 7: Concept four using dual u-tubes as a heat exchanger and regeneration method

Recent market trends have seen new solar thermal system installations decline with the rise of solar PV, particularly on rooftops. PVT collectors have traditionally been used to create DHW directly but have never had a significant market share. In this application it is interesting to ask if the additional thermal energy collection justify the costs. Therefore a fifth concept, shown in Fig. 8, is considered which only uses PV

collectors that are coupled to the BTES. This concept tests the marginal value of adding a thermal component to the PV collectors and the associated hydronic complexities. In this concept, the battery acts as short term storage, similar to a thermal buffer tank, while the BTES is used as long term seasonal storage.

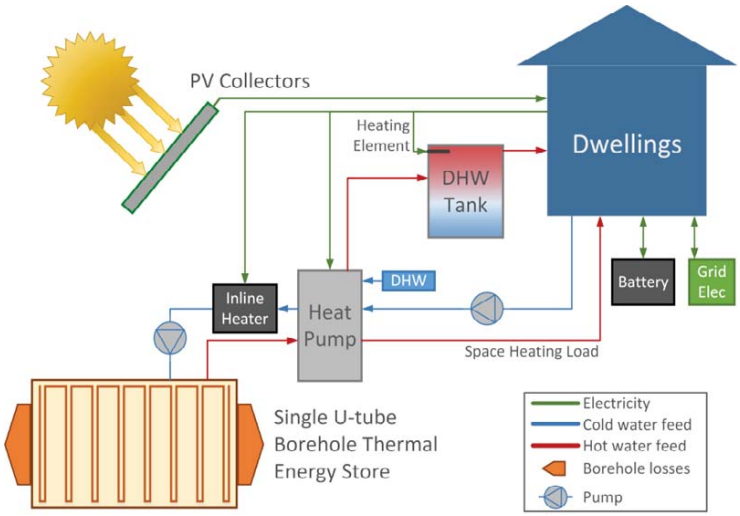

Fig. 8: Concept only considering PV and borehole regeneration

4. Discussion

A significant challenge when reviewing SAHP systems, particularly when comparing thermal to PV systems, is the lack of consistency between metrics used in studies (Buker and Riffat, 2016). Many authors use traditional key performance indicators (KPI) such as SPF, solar fraction, self-consumption, self-sufficiency, or renewable fraction, however the system boundaries are often not defined or do not capture the performance of the entire system as it relates to the owner. For example, if the indicator boundaries are limited to the heating system, the value of the PV generation to the rest of the building loads can be missed. The traditional indicators are still valuable to SAHP analysis, however care must be taken not to emphasize any particular one to the detriment of the others (Dar et al., 2014).

An extensive discussion surrounding the selection and use of KPI can be found in the SAHP handbook (Hardorn, 2015), and the top level systems definition of SPF is given by eq. 1. In the numerator is the total space (Q_{SH}) and domestic hot water (Q_{SH}) energy supplied to the building. The denominator includes the electricity used by the heat pump (E_{HP}), all auxiliary heaters ($E_{AUX,H}$), and all auxiliary pumps ($E_{AUX,P}$). One missing factor in this definition is electricity supplied from PV. In PV-HP literature there is often a focus on self-consumption and the definition for SPF is the same as in a non-solar HP, however as noted earlier, PV generation can make a significant improvement to SPF (Brischoux and Bernier, 2016).

$$SPF_{sys,grid} = \frac{\int Q_{SH} + Q_{DHW}}{\int [E_{HP} + \sum E_{AUX,H} + \sum E_{AUX,P}]} \qquad \text{(eq. 1)}$$

In a SAHP with PVT cogeneration, the handling of the electricity generation raises interesting questions about KPI. What fraction of PV generation should be applied to the heat pump? Is it necessary to make such a distinction in SPF? Are there other KPI (or combination of indicators) which would be more useful to the owner? Environmental or economic indicators can often be important to the purchaser of energy related equipment. In an economic KPI, it is important to capture the impact PV generation has on the entire building load and not limit it to the SAHP system. It is also necessary to capture all costs and benefits in order to make a fair comparison between options. Further research and careful consideration will be made towards the selection of KPI to ensure fair and relevant evaluation of the PVT+GSHP systems.

5. Summary and Future Work

Solar assisted heat pumps are complex in design, operation, and analysis. The review presented in this paper briefly captures some of the facets to be considered in the design of a PVT+GSHP system, including; collector design, borehole thermal energy storage, hydronic configurations and control strategies. The four PVT system concepts presented are focused on simplicity and practicality, and are of the series/regenerative configuration with various integration methods for the PVT into the BHE hydronic loop. They are designed primarily to maximize cost efficiency with the expectation that energy or exergy performance may not be as high as other designs. The marginal benefit of collecting heat from a PV array will also be tested by simulating a PV-only system which can also feed into the BTES.

The next steps in the project are to create system models in TRNSYS, finalize the remaining questions about system configuration, and identify appropriate ranges of component sizes. Input from component manufacturers for PVT collectors, heat pumps, and boreholes will be used to ensure that the practical limits of the components are respected and to identify opportunities for designs specific to this application. Care will be taken to ensure that most representative costs are used for the installed system, which is particularly important given the uniqueness of the concept. Control strategies will also be tested to optimize the use of the batteries, heat pump compressor speed, circulation pumps, etc. Effort will also go into defining meaningful KPI to evaluate and optimize systems that are relevant to the system owners. The primary area of application is in the Nordic region, therefore building construction, usage, and GSHP system designs will be taken from regional norms.

6. Acknowledgements

This research is funded by the Swedish Energy Agency through the Effsys Expand program, for which the authors are most grateful. Appreciation is also given to the private companies contributing to the project, including; Danfoss heat pumps, Solybrid i Småland, HP Borringar, Geobatteri, Bengt Dahlgren, Nowab AB, Avanti Drillers Association, housing cooperative Moranvikan, and housing cooperative Timmermannen 2.

Abstract

The typical number of subcells comprised in multijunction solar cells steadily increased over the last 25 years to achieve higher electrical efficiencies. However, these cells typically show increased sensitivity to the spectral content of sunlight, and the efficiency under real conditions can be significantly affected. This study investigates whether or not fine-tuning of MJ solar cells could lead to significant improvement in the energy yield of CPV systems comprising a high number of subcells. The average incident spectrum in several cities is obtained with SMARTS, using as an input the main atmospheric parameters from AERONET database. The optimal combinations of bandgaps for all the selected locations and cell architectures comprising up to 10 subcells was derived. In particular, the improvement in the energy output achieved when using fine-tuned MJ solar cells to a mean annual spectrum in a located area is investigated. Implications for future generations for multi-junction solar cells are also discussed.

Keywords: *Multi-junction solar cells, spectral distribution, fine-tuning, energy yield, optimization,*

1. Introduction

Multi-junction solar cells could potentially achieve ultra-high solar-to-electricity conversion efficiency (Pérez-Higueras and Fernández, 2015) and are seen as one of the most promising options toward affordable solar electricity. Cells comprising up to 5 different subcells have been reported in the litterature with efficiencies currently approaching 50%. Today, the world record is held by a quadruple-junction solar cell with a conversion efficiency of 46% under concentrated sunlight (Green et al., 2015).

Increasing the number of *pn* junctions with appropriate band gaps leads to a more efficient utilization of the solar spectrum and consequently better conversion efficiencies. Nonetheless, the spectral distribution of the light reaching the cells may affect dramatically the ability of MJ cells to efficiently convert sunlight into electricity. The photovoltaic conversion efficiency is usually provided assuming a spectral distribution of the incoming light described by the AM1.5 reference spectrum. However, the spectral distribution of light is likely to vary significantly due to changes in the atmospheric parameters, and the ability of MJ cells comprising a high number of subcells to accommodate changes in the spectral distribution was recently questioned (Chan et al., 2014; Vossier et al., 2015). In particular, the energy output of CPV systems was shown to be highly dependent on the climatic conditions to which it is exposed. Fine-tuning of solar cells is often mentioned as a promising strategy toward increasing the efficiency with which solar energy is converted into electricity: Fine-tuning basically consists in tailoring the combination of electronic gaps comprised in the MJ stack to the spectral distribution characteristic of a particular location. This raises the question of whether or not CPV systems involving fined-tuned MJ solar cells are likely to outperform conventional MJ cells designed according to the AM1.5D reference solar spectrum, taking into account the typical variations in working conditions over a long period of time.

2. Method

In order to tackle this question, the mean spectral distribution of the light received in several locations around the world was first assessed, using long time series of actual measurements of the main atmospheric variables at widely different sites. The locations investigated here were chosen for being representative of the large range of climatic conditions on the planet. They cover a wide range of latitudes (see details in Table 1), extending from Nauru (near the equator) to Palaiseau (near Paris, France). Xianghe (China) is characterized by a high pollution level resulting in systematically large AOD. Nauru is a tropical site with high PW, as opposed to arid sites, such as Sede Boqer. The latter is characterized by intermediate values of all variables, with however large daily excursions in AOD and α in the wake of regional dust storm activity.

The direct normal irradiance spectrum was calculated with SMARTS radiative model (Gueymard, 2001) whose main input parameters are the Air Mass (AM), the Aerosol Optical Depth (AOD), the Precipitable Water (PW), the Angstrom exponent (α),. The AM values were evaluated in SMARTS from the solar zenith angle (Z) for the location and time considered. Simultaneous values of Z, AOD, PW, α, were obtained from the Aerosol Robotic Network (AERONET) database (http://aeronet.gsfc.nasa.gov). From this set of data, the mean annual solar spectra were derived for each selected location, and compared to the AM1.5D (AM=1.5, AOD_{500} = 0.084 and PW = 1.416 cm) solar spectrum (from ASTM G173) commonly used as an input solar spectrum when designing solar cells.

Table 1: Characteristic parameters for the selected locations

Location	Simulated year	Lat. (°)	Long. (°)	Elevation (m)	Mean daily DNI (kWh/m2/day) [Source: (SWERA)]	Annual mean atmospheric parameters AM | AOD | PW |α
Nauru	2011	-0.52	166.92	7	6-6.5	1.72 | 0.09 | 4.17 |0.26
Sede Boqer	2004	30.86	34.78	480	6-6.5	1.92 | 0.18 | 1.34 |0.86
Xianghe	2009	39.75	116.96	32	2.5-3	2.07 | 0.53 | 1.01 |1.12
Palaiseau	2012	48.71	2.21	156	3–3.5	2.29 | 0.16 | 1.44 |1.15

Fig. 1 depicts the spectral distribution of the mean annual solar spectrum for each city investigated in this study, using the method described above. Some spectra are shown to deviate drastically from the AM1.5D Spectrum (bold purple curve). Places characterized by low latitudes and favorable climatic parameters (such as Sede Boqer or Nauru) show relatively high annual mean intensities. Conversely, places characterized by high latitudes (such as Palaiseau) and/or poor atmospheric parameters (i.e Xianghe), demonstrate modest values of the mean annual solar spectrum. Such a representation, however, does not allow a convenient analysis of the extent with which each range of wavelength is altered.

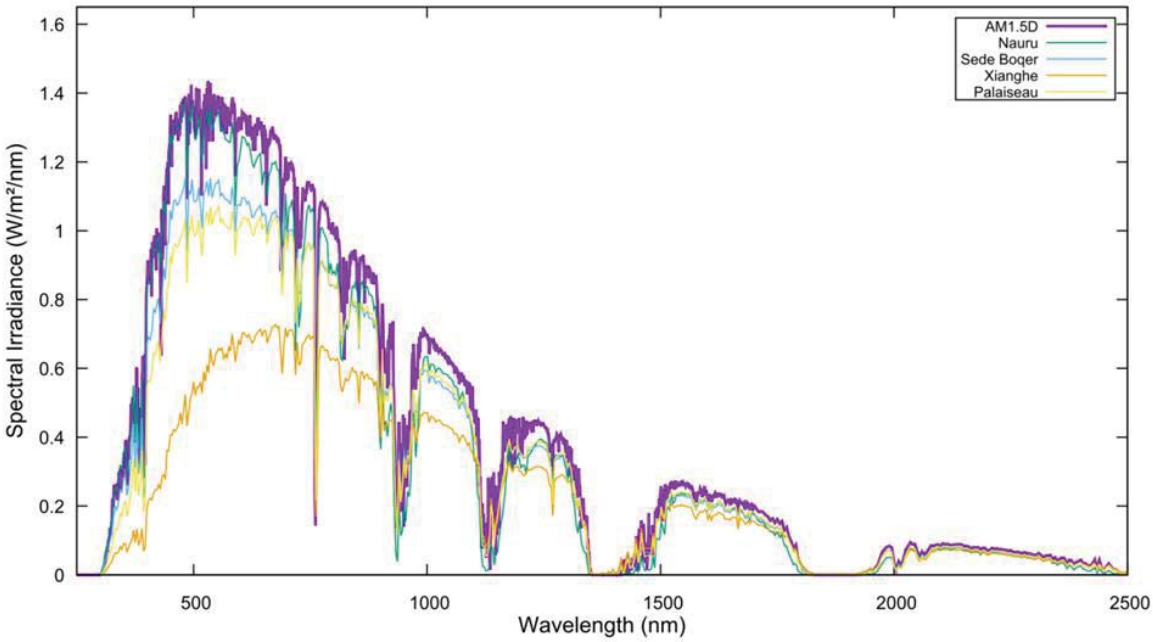

Fig. 1: Mean annual solar spectrum for each investigated city

For sake of clarity, the relative residual of the mean annual spectrum with the AM1.5D spectrum is reported in Figure 2. The spectra are normalized so that the total solar irradiance corresponding to each spectrum equals the power corresponding to AM1.5D solar spectrum (900W/m²). The deviation relative to the AM1.5 solar spectrum is represented as a red curve for each city investigated. The regions of the spectra corresponding to the absorption bands were removed from the graphs (the very low spectral irradiance values associated with these regions gave rise to high levels of noise). Several statements can be drawn from Fig. 2:

- First, for Xianghe and Palaiseau, the mean annual spectrum, calculated using the method described above, shows lower irradiance values in the UV-Vis range relative to the AM1.5D solar spectrum. From these first preliminary data values, it is expected that a fine-tuning of the MJ cells will lead to an optimal combination of subcells characterized by lower values of their electronic gaps, when compared to AM1.5-optimized MJ cells. On the other hand, Nauru exhibits higher values in the UV-Vis range and consequently higher electronics gaps are expected. The solar spectrum is mostly attenuated in this range by the air mass and the AOD which are particularly low in this city. Sede Boqer presents a spectrum similar to AM1.5 and significant differences in the bandgaps are not expected.

- Second, the amplitude of the spectrum alteration over a full year varies drastically from one place to the other. If Nauru and Sede Boker show modest variations in the annual spectral distribution of light (relative to AM1.5 spectrum), Palaiseau and Xianghe demonstrate significant changes in the spectral content of the light, and fine-tuned MJ cells should could lead to a noticeable improvement in the electrical efficiency of CPV systems in these locations.

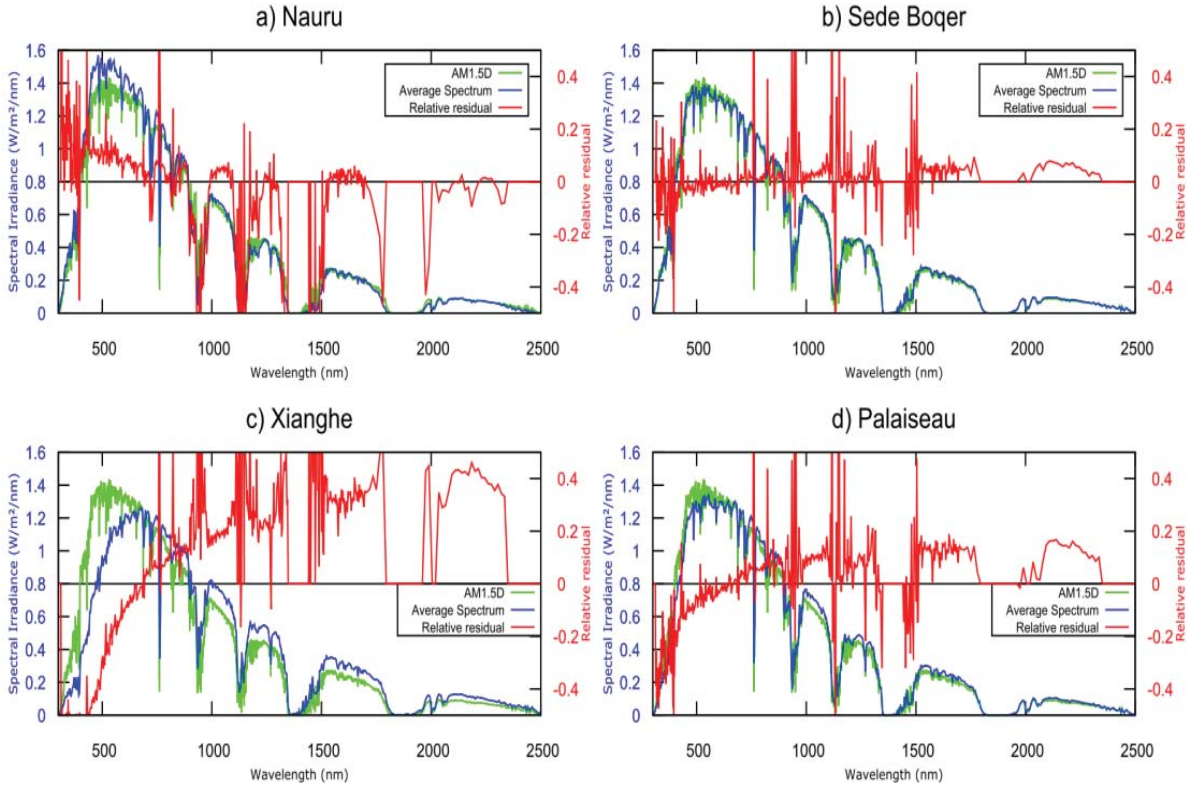

Fig 2: Relative residual of the normalized mean annual spectrum of each city (in red) compared to reference spectrum AM1.5D (in green) and the mean annual spectrum of each city (in blue)

The optimal combination of electronic gaps leading to the highest conversion efficiency was derived using the Shockley and Queisser (SQ) model with the mean annual spectra as an input spectrum for each selected location. The model considers the following assumptions:

- Each absorbed photon generates one single electron-hole pair
- There is no absorption of photons with energy less than the semiconductor band gap
- The only recombination process within the cell is radiative recombination; the other non-radiative processes (SRH, Auger) are thus neglected
- There are no resistive losses
- The cell temperature is kept equal to the ambient temperature (298 K).

The numerical method used here is based on the detailed balance model originally suggested by SQ. The conversion efficiency of these MJ cells was calculated using the detailed balance formalism (Brown and Green, 2002; Vossier et al. 2015) which only requires as an input a reduced set of parameters, namely the sun and the cell temperature, the spectral distribution of the light absorbed, and the electronic gaps of the semi-conductor materials used in the cell.

Basically, the maximum electrical power that can be extracted from a solar cell is obtained as the difference between the absorbed and emitted radiation. Both are conveniently described by the generalized Planck's law, as pointed out in (Brown and Green, 2002).
The maximum current (I) extractable from the cell can be obtained from:

$$I/q = \dot{N}_S - \dot{N}_R \quad (1)$$

where q is the elementary charge, and $\dot{N}_S$ and $\dot{N}_R$ are the current contributions associated with the absorption and emission of photons, which both are a function of the semiconductor bandgap, cell and sun temperatures, and other parameters, as described in (Vossier et al. 2015).

Using the SQ limit, the ultimate efficiency is given by:

$$\eta_{SQ} = \frac{\left\{qV\left[\dot{N}_S(\mu=0) - \dot{N}_R(\mu=qV)\right]\right\}_{\max}}{P_{in}} \quad (2)$$

where P_{in} is the incident power.

The optimal combination of electronic gaps leading to the highest solar→electricity conversion efficiency was investigated using a genetic algorithm, taking into account the current-constraint between each subcell (introducing such a constraint imposes the current generated by each individual subcell to be equal).

3. Results

The optimal bandgaps and the corresponding conversion efficiencies for MJ solar cells comprising up to ten subcells under the AM1.5D, 298K and 1 sun were obtained in (Vossier et al., 2015 b), and are reported here as a reference to show how the optimal bandgaps change as a function of the selected spectrum for the optimization (Table 2)

Table 2: Optimum efficiencies for MJ solar cells ten subcells comprising up to ten subcells under the AM1.5D spectrum of every city and 1-sun illumination.

Spectrum	Nb. Cells	E_{g1}	E_{g2}	E_{g3}	E_{g4}	E_{g5}	E_{g6}	E_{g7}	E_{g8}	E_{g9}	E_{g10}	Efficiency (%)

	9	2.35	1.96	1.69	1.47	1.26	1.09	0.94	0.74	0.53		61.4
	10	2.41	2.03	1.77	1.56	1.39	1.21	1.05	0.92	0.74	0.55	62

Table 3 summarizes the bandgap combinations for MJ cells optimized considering the mean annual spectra of every location investigated, rather than the AM1.5D reference spectrum.

As mentionned before, Xianghe and Palaiseau present lower bandgaps in the UV-Vis range than those obtained considering the AM1.5D spectrum. These 2 cities are located well above the equator and therefore the AM effect over the UV-Vis range is noticeable. In addition, Xianghe presents high pollution levels and thus even lower irradiance in this particular wavelength range.

The normalized average spectrum for Sede Boqer, depicted in Figure 2, shows negligeable differences compared to the AM1.5D reference spectrum. As a consequence, the optimized combination of bandgaps only shows slight variations relative to the AM1.5-optimized reference case, and fine-tuning would not bring any significant gain in the energy output for this location.

On the other hand, the optimized bandgaps for Nauru are energetically higher than the reference case for almost all the wavelengths considered. Nauru is practically located over the equator and characterized by low pollution levels (low AOD) but, as a tropical city, presents high PW. The water vapor absorption bands are mainly located in the near-infrared and infrared regions of the spectrum, accounting for the relative residual drops which can be seen in Figure 2 at around 940, 1100 and 1400 nm. Since the irradiance in the UV-Vis region is higher, the bandgap energies tend to be higher to enhance the conversion for these photon frequencies.

Table 3: Optimum efficiencies for MJ solar cells comprising up to ten subcells under the average spectrum of every city and 1-sun illumination.

The conversion efficiency for the MJ solar cell architectures reported in the previous Table 3 and for the corresponding annual mean spectrum are depicted together with the efficiency under the same spectrum but using the gaps optimized for AM1.5D in Figure 3.

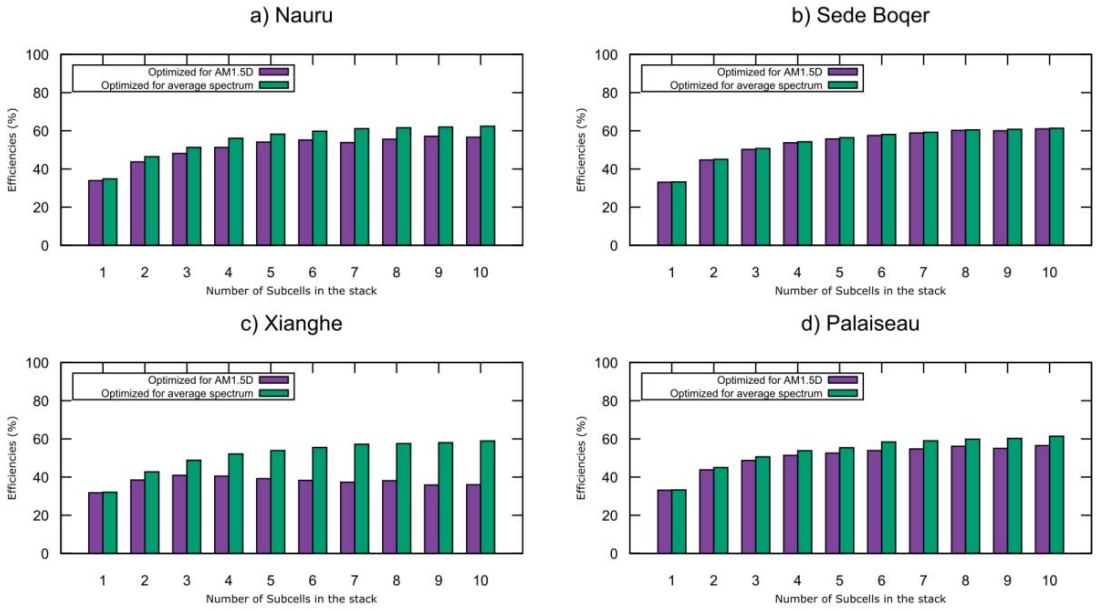

Fig 3: Efficiencies for MJ solar cells comprising up to 10 subcells with gaps optimized for AM1.5D (pink bars) or for average spectrum in every city (green bars)

Fig. 3 illustrates the potential benefits for fine-tuning in different locations around the world: some noticeable improvement in the conversion efficiency can be obtained with fine-tuned MJ solar cells, relative to the "reference" conversion efficiency achieved with AM1.5-optimized cells. However the extent to which fine-tuning may lead to noticeable improvement in the cell efficiency largely depends on the location. The benefit for fine-tuning is particularly strong in Xianghe: because of the noticeable alteration in the spectral distribution of light relative to the reference AM1.5 spectrum, fine-tuning is shown to lead to significant improvement in the cell efficiency, in particular for cell architectures involving a high number of subcells. Nauru and Palaiseau show a modest improvement in the cell efficiency with fine-tuned solar cells, as a result of the minor difference between the mean annual spectral distribution of light and AM1.5 reference spectrum. Finally, the gain in efficiency for fine-tuned solar cells appears to be very weak in Sede Boqer, the mean annual distribution of light and AM1.5 solar spectrum being very close. It should be finally stressed that all the selected locations tend to achieve maximum efficiencies around 60% for the 10 subcells stack, suggesting that fine-tuning of solar cell is a promising way to achieve ultra-high conversion efficiencies for a broad range of climatic and atmospheric conditions.

It was previsouly shown that the higher the number of subcells in the stack, the narrower the range of spectral characteristics for which the cells performs optimally (Vossier et al, 2016). To better grasp the spectral dependence of MJ cells as the number of subcells increases, the relative residual between the optimized and non-optimized efficiencies in the case of Xianghe is plotted in Figure 4 (see Eq. (3)). The relative residual grows sharply with increasing number of subcells, underlining the strong impact of AOD and the fundamental inability of MJ solar cells comprising more than 3 subcells to accommodate spectral variations. The relative residual is higher than 20% with more than 3 junctions and reaches 60% for 10 junctions. Thus, the benefit for tailoring the gaps in this specific case could lead to an efficiency increase of 60% with 10 gaps.

$$Relative\ residual(\%) = 100\left(\frac{Efficiency\ \ for\ the\ optimized\ gaps - Efficiency\ for\ the\ AM1.5D\ gaps}{Efficiency\ for\ the\ AM1.5D\ gaps}\right) \quad (3)$$

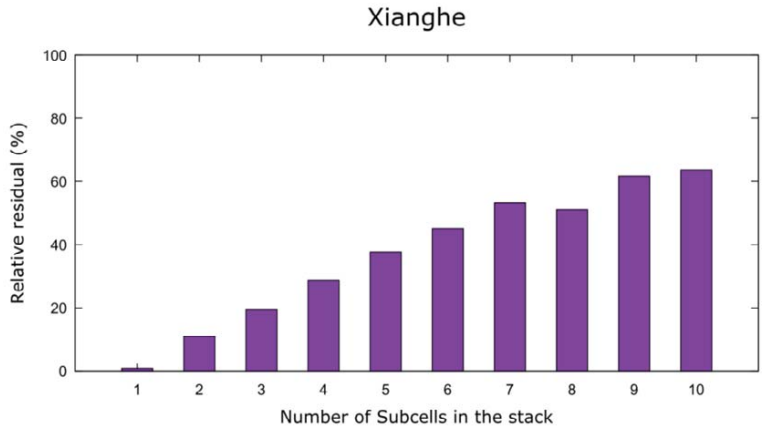

Fig 4: Efficiency relative residual in the case of Xianghe

4. Conclusions

Fine-tuning of solar cells can potentially increase the efficiency with which solar energy is converted into electricity, by tailoring the combination of electronic gaps to the spectral distribution characteristic of a particular location. The present results suggest that increasing the number of subcells in a MJ stack leads to increased conversion efficiency. However, locations characterized by a strong alteration in the mean annual spectral distribution relative to AM1.5 solar spectrum only show modest improvement in the maximum conversion efficiency achievable, when designing the cells using AM1.5 as a reference spectrum. In this work, we showed that fine-tuning of MJ solar cells may allow a significant increase in the cell conversion efficiency. The amplitude of the efficiency gain associated with fine-tuning largely depends on the variation in the mean distribution of light relative to AM1.5 spectrum. Locations characterized by minor difference in the spectral distribution of the light (relative to AM1.5) show a very weak improvement in the conversion efficiency of fine-tuned MJ solar cells. Conversely, locations characterized by a noticeable modification in the spectral distribution of light demonstrate a strong improvement in the efficiency of fine-tuned MJ cells. Finally, it was demonstrated that the maximum conversion efficiency achievable with fine-tuned MJ cells is around 60% for the 10 subcells stack, suggesting that this approach is a promising way to achieve ultra-high conversion efficiencies for a broad range of climatic and atmospheric conditions.

Thermal Behavior of Photovoltaic-Thermal Hybrid Collector

Hiro Yoshida, Shigetoshi Daidouji, Kazutaka Itako and Naoto Hagino
Kanagawa Institute of Technology, Atsugi (Japan)

Abstract

Thermal behavior of the PV-T hybrid collector was examined using a simulator, where the PV cell is backed by the thermal collector. Heating effect of the PV cell (Joule heating by internal currents) was a main interest in this study. For the hybrid PV-T system, the thermal collector coefficient was prone to be larger in the case without external electric loads (open PV circuit) than in the case with the loads (closed PV circuit). Such trend was able to be explained analytically in terms of the internal heating phenomenon of PV. Results of field experiment by Sandnes and Rekstad (2002) show similar trend to the present one. The maximum heating power of the PV cell was confirmed to be equivalent to the maximum electric power of it. This result seems quite reasonable from the physical point of view. In the present PV-T configuration, the thermal collector coefficient drops significantly due to the shade effect of the PV cell placed in front of the thermal collector.

Keywords: *Photovoltaic cell, Joule heating, thermal collector, PV-T hybrid collector / simulator*

1. Introduction

The solar energy gives us an irreplaceable benefit. It is well known that a part of the energy is converted into electricity by the photovoltaic (PV) cells. The conversion rate of the cells will be practically 10-20 %. Regarding the remaining 80 % of the solar energy, our choice for now seems to be confined to using it as heat. Thus not only the electricity but the clever application of the heat is important. In many cases, the electricity and the heat are collected by the separate surfaces to each. It is natural that people come to an idea of collecting both electricity and heat by one common surface. Such device generally called photovoltaic and thermal (PV-T) hybrid collector. In the hybrid collector PV cell is often backed by the thermal collector.

The first publication on the PV-T hybrid model appeared about 40 years ago (Florschuetz, 1978). Up to now, many papers, mostly on the field experiments, have been published (for example, Chen and Riffat, 2011, Ito and Miura, 1993, Ibrahim, Othman, Ruslan, and Sopian, 2011, Sandnes and Rekstad, 2002). In one of the latest international conferences, EuroSun 2014 for example, discussions on the PV-T hybrid system was very active. To date, however, the performance of the PV-T hybrid system is not necessarily well understood (Yandri, Hagino, Itako, and Yoshida, 2012). Namely, the thermal coefficients of the hybrid collector showed different trend depending on whether the PV cell was connected to the external electric loads or not, where the electric loads are the household appliances such as TV, air-conditioner or lighting equipment (Yandri, Hagino, Itako, and Yoshida, 2012, Sandnes and Rekstad, 2002). It has been suggested that the internal heating (Joule heating) of the PV cell is supposed to affect the thermal characteristics of the hybrid collector (Yoshida, Daidouji, Itako, and Hagino, 2013). Based on the field experiment data, Sandnes and Rekstad (2002) also commented qualitatively on an excess heat generated by PV cell. Here, it might be interesting to ask what occurs in the PV cell under the irradiation when the cell is not connected to the loads (i.e. electricity generated is not properly taken out). In any case, direct observation of such phenomenon will be important for quantitative discussion.

In this study, aiming at further understanding about the thermal behavior of the PV-T hybrid system accompanying the PV internal heating, the authors tried to measure directly the heating effect of PV cell. For this purpose, a compact PV-T hybrid simulator was employed (Yandri, Hagino, Itako, and Yoshida, 2012).

doi:10.18086/eurosun.2016.08.17 Available at http://proceedings.ises.org

Through a series of experiments by the simulator, the behavior of the hybrid system was able to be examined more quantitatively.

2. Photovoltaic-thermal (PV-T) hybrid collector simulator

Figure 1 shows the schematic diagram of the PV-T simulator. It consists of the light source, the water supplying unit, and the PV cell (KIS Co.Ltd., model GT434, mono-crystalline type) backed by the thermal collector unit. The size of the PV cell is 1 mm thick (or less) and 378 x 349 mm^2 surface area. Side of the PV cell and the thermal collector were heat insulated by a 5 mm thick styrene foam sheet. In the precise measurement of the PV internal heating (section 4.4), the back surface of the thermal collector was covered by a 20 mm thick foam rubber. The heat conduction coefficients of the styrene foam and the foam rubber are 0.03 J/(mK) (JSME Data Book, 2009). In the preliminary experiment in section 4.1, the foam rubber was not set. The normal maximum output of the PV module is 13 W at 25 ^oC under the sun light. The 16 halogen bulbs (Ushio, model JDR110V40W LW/K) were used as the light source. The bulbs are arranged in a 4 x 4 matrix at equal intervals in the light source plane. The light source was placed underneath the PV-T collector surface facing downwards (Fig.1). Such arrangement (collector top - light source bottom) was adopted for the convenience of arranging cooling pipes and temperature sensors. Actually, due to this arrangement, the temperature field on the PV back surface was easily monitored by an infrared thermal view camera (Yoshida, 2010). The thermocouples for T_{in} and T_{out} (Fig.1) were attached through brass T-joints to a silicon rubber tube for cooling water. The thermocouple for T_{in} was placed at 1 m tube length from the inlet of the thermal collector and that for T_{out} was at 0.3 m from the outlet of the collector (Fig.A1 in Appendix). The outer and inner diameters of the silicon rubber tube were 11 mm and 5 mm, respectively. The light collecting surface is 0.38 m x 0.35 m area. The base structure of the simulator is the same as Yandri, et al (2012). In the present setup, a few improvements were added: 1) A center aperture was made at the center of the thermal collector unit to monitor PV temperature correctly (Fig.2); 2) The thermal collector unit was replaced by an aluminum plate with machined channel of cooling water (Yoshida,Daidouji, Itako, and Hagino, 2013). The imbedded channel is covered with a flat aluminum plate. A sheet of silicon rubber is placed between the channel and the aluminum plate (Fig.2). A flat surface is easy to manage heat transfer and heat insulation. Due to those modifications, temperatures of the PV unit and the thermal collector were able to be monitored

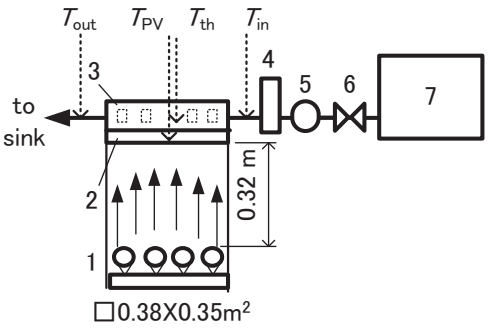

Figure 1 Schematic diagram of PV-T simulator: 1, light source (halogen light bulbs); 2, PV unit of 0.38 m x 0.35 m cross section; 3, thermal collector unit with cooling water channel; 4, flow meter; 5, circulating pump; 6, gate valve; 7, water tank. T_{in}, T_{out}, T_{th}, and T_{PV} are the temperatures of water at thermal collector inlet, outlet, center of the thermal collector and PV unit, respectively.

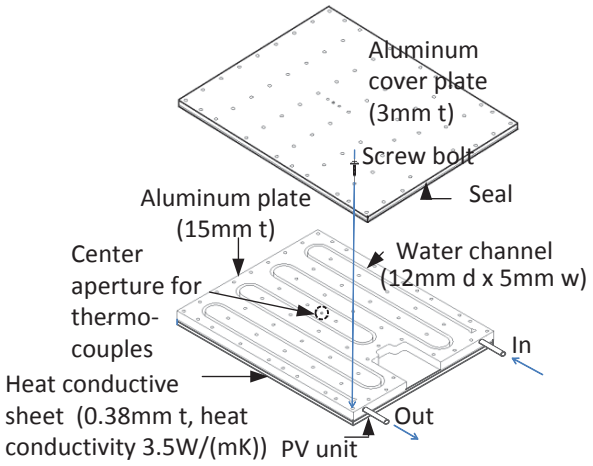

Figure 2 Aluminum plate thermal collector with cooling water channel. The center aperture was made for temperature measurement of PV and thermal collector.

simultaneously and correctly. Because the authors focused on the phenomena of internal heating of PV cell, effect of the light source position on the thermal collector performance was not examined.

Thermocouples of type T class 2 (CHINO, model 1STF013, precision measured by the authors was in the order of ∓0.2 ^{o}C) and a pyranometer (EKO INSTRUMENTS, model MS-42, internal resistance 500 Ω) were used for the temperature and the irradiation measurement, respectively. A float type flow meter (KOFLOC, RK1710-500/MIN) and a magnet pump for cooling water flow (SANSO, PMD-331B6K, 45W, 3L/min) were used. The temperature measurement was done when the simulator was under thermally steady state condition.

Regarding the convection heat transfer between the light source and the PV surface, the convection stream up to the PV surface was negligibly small, i.e. less than 0.3 m/s. As far as the light source and PV-T set (units 1 and 3 in Fig.1) was concerned, convection heat transfer was considered to be negligible. The effects of the room temperature and the convections on the piping tubes, attachments of thermocouples, and water tank (units 4 – 7 in Fig.1) will be concretely discussed later (section 4.4 and Appendix).

3. Thermal collector coefficient under additional heating in PV

In this section, we examine theoretically the thermal collector coefficient of the PV-T hybrid system for the case with an additional internal heating in the PV unit. It is quite reasonable to consider that the internal current in PV is prone to bring Joule heating effect. This effect is supposed to be maximized especially when the PV unit is not connected to the external electric loads. In the following, let us consider the thermal collector coefficient. The net thermal energy absorbed by the thermal collector unit, Q_{net}, is given as:

$$Q_{net} = Q_c - Q_{loss} \tag{1}$$

, where Q_c and Q_{loss} are the total thermal energy absorption and the total loss of the thermal collector unit, respectively. Referring to Huang and Du (1991), Q_c and Q_{loss} are defined as

$$Q_c = \alpha A I_0 \tag{2}$$

and

$$Q_{loss} = U\left(T_{out} - T_a\right) \tag{3}$$

In Eqs.(2) and (3), α, A, I_0, U, T_{out}, and T_{a} are, respectively, the non-dimensional effective solar absorptance, the collector surface area, the irradiation intensity incident upon the surface of the PV-T system, the coefficient of total heat loss, the temperature of water flowing out from the thermal collector unit, and the ambient temperature. In the present experiment, we took room temperature T_{room} as T_{a}. If there is an additional internal heating in the thermal collector, i.e. Joule heating in the PV unit, Eqs(2) and (3) can be modified as

$$Q_c^{'} = \alpha A\left(I_0 + \delta I\right) \tag{4}$$

$$Q_{loss}^{'} = U\left[\left(T_{out} + \delta T\right) - T_a\right] \tag{5}$$

, where δI and δT are the increments of the apparent irradiation and the water temperature at the thermal collector exit, respectively. Thus the thermal coefficient of the thermal collector, η'_{th}, under the additional heating is given as

$$\eta_{th}^{'} = \left(Q_c^{'} - Q_{loss}^{'}\right)/\left(AI_0\right) = \alpha^{'} - U^{'}\left(T_{out} - T_a\right)/I_0 \tag{6}$$

, where a' and U' are

$$\alpha^{'} = \alpha\left(1 + \delta I / I_0\right) \tag{7}$$

$$U^{'} = U\left[1 + \delta T /\left(T_{out} - T_a\right)\right] \tag{8}$$

In Eq.(6), let us name the term $(T_{out}\text{-}T_a)/I_0$ the temperature parameter. On the other hand, the thermal coefficient without the internal heating, η_{th}, , is given as

$$\eta_{th} = (Q_c - Q_{loss})/(AI_0) = \alpha - U(T_{out} - T_a)/I_0 \quad (9)$$

Comparing Eqs.(7) and (8), we easily see that

$$\alpha' \geq \alpha \text{ and } U' \geq U \quad (10)$$

Relationship (10) suggests that, if we plot η_{th} as a function of the temperature parameter $(T_{out}\text{-}T_a)/I_0$, the thermal coefficient of PV-T collector with the internal heating tends to be higher than that without it. More specifically, the inclination of the coefficient curve is steeper for the case with internal heating than that without it. This analytical examination will be confirmed experimentally in section4.3.

4. Experimental results

4.1 Starting behavior and various coefficients of PV-T simulator (*preliminary experiment*)

In this section a rough image of the general performance of the PV-T simulator was examined. In the experiment, back surface of the thermal collector was not covered by the rubber sheet. Effect of the room temperature will be discussed precisely in section 4.4. The irradiation intensity, I_0, was kept 1000 W/m^2 constant at the center of the PV surface, which was set 0.32 m above the light source (Fig.1). Distribution of irradiation intensity on the PV surface was measured by the pyranometer. On the surface, the irradiation was the largest at the center and smaller in peripheral area. The difference was less than 10 % (Takahashi and Nishiwaki, 2012).

Figure 3 shows temperature traces of PV unit for various cooling water flow rates, i.e. 100 – 600 cc/min. For those flow rates, the PV-T simulator reaches steady condition within an hour. After the steady condition, the temperature fluctuations around the mean value were less than ∓3 % for the flow rates of 100 cc/min and 200 cc/min, ∓6 % for 400 cc/min, and ∓10 % for 600 cc/min. The transition time of the present simulator is longer than that of the previous one (Yandri, Hagino, Itako, and Yoshida, 2012). However, as far as the steady state behavior is concerned, this is not the essential obstacle in the present study. To investigate non-steady behavior of the PV-T system, precise adjustment of the heat capacity of the collector will be necessary.

The PV power generation coefficient η_{PV} and the thermal collector coefficient η_{th} are compared in Fig.4, where η_{total} is the sum of them. The irradiation intensity was the same as the case of Fig.3, i.e. I_0=1000 W/m^2. In Fig.4, the coefficients at various PV temperatures 30.9, 32.7, 33.6, and 38.2 ^{o}C were obtained under the flow rates of 600, 400, 200, and 100cc/min, respectively. The higher flow rate tends to cause the lower PV temperature. In this figure, η_{PV} is about 0.05 for the temperatures considered and η_{th} ranges 0.4 to 0.55. As a result the total coefficient was around 0.5 – 0.6. It is clear that η_{th} is prevailing over η_{PV}. Although results are

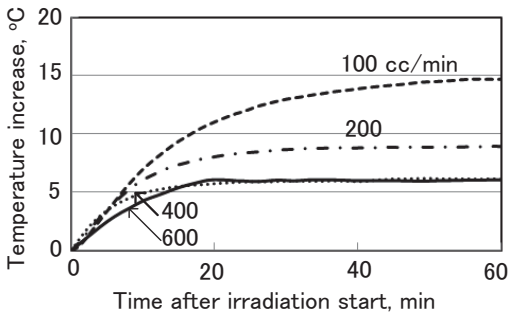

Figure 3 TempErature increase of PV unit after the irradiation start for various cooling water flow rate. Irradiation intensity is 1000 W/m^2.

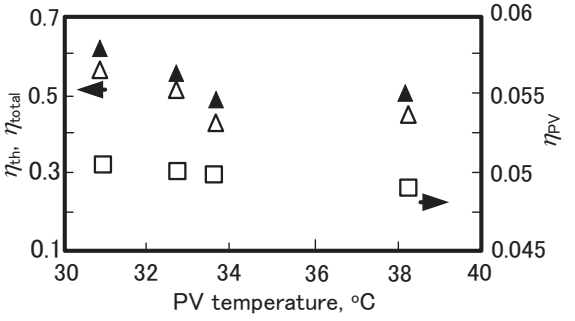

Figure 4 η_{PV}, η_{th}, and η_{total} vs PV temperature. Coefficients η_{PV}, η_{th}, and η_{TotaL} are designated by the symbols of open square, open triangle, and closed triangle, respectively. Irradiation intensity is 1000 W/m^2.

not shown here, our another experiment without PV cell in front of the thermal collector showed that η_{th} was above 80 % under the same flow rates and the irradiation conditions. Thus, in the present PV-T configuration, the thermal collector coefficient with PV cell dropped by roughly 40 % due to the shade effect of PV cell. This result seems quite understandable. The shading effect of the hybrid system is significant subject in future.

4.2. Internal (Joule) heating of PV cell

Hereafter, the open PV circuit and the closed PV circuit mean that the PV is connected to and not connected to the proper outside electric loads, respectively. Table 1 gives the measured data which are plotted in Figs.5 and 6. The irradiation intensity was set I_0=1000 W/m^2 constant as hitherto. Thus the actual irradiation input to the PV cell is 1000 W/m^2 x 0.378 m x 0.349 m = 132 W. The background temperature at each experiment was equal to the room temperature of the day. As can be read in Table 1, the temperature increase (T_{out}-T_{in}) for the open PV is larger than that for the closed PV by 0.2 ^{o}C - 1.2 ^{o}C for the flow rates considered. Those temperature increases are compared in Fig.5. As can be seen in this figure, the temperature increment in the open PV is distinguishable within the present experimental precision. At this stage, however, we can merely say that the Joule heating of PV may be detected. Amount of the Joule heating and effect of the room temperature will be discussed and handled more quantitatively in section 4.4.

Table 1 Data of PV open and closed, I_0=1000W/m^2

PV open

Flow rate	T_{PV}	T_{th}	T_{PV}-T_{th}	T_{in}	T_{out}	T_{out}-T_{in}	T_{room}	Power	$(T_{out}-T_{room})/I_0$	η_{th}

600	30.9	27.2	3.7	26.2	28	1.9	25.5	6.71	0.0025	0.57

Influence of the heat transfer between the simulator and the ambient air is considered as follows: The PV cell is irradiated in front surface. It transfers the heat to the ambient air in the room through the side surface and to the thermal collector through the back surface. If the coefficients of the heat transfer among PV, the ambient air, and thermal collector are the same in each experiment, it is reasonable to consider that the magnitudes of the heat releases from PV unit to the room and to the thermal collector must be proportional to the temperature differences i.e. (T_{PV}-T_{room}) and (T_{PV}-T_{th}). Thus amount of heat leaving from the side and the back surfaces of the PV unit can be estimated by A_s(T_{PV}-T_{room}) and A_b(T_{PV}-T_{room}), respectively, where A_s is the area of the side surface (1 mm thick x 2 x (378+349) mm periphery) and A_b is that of the back surface (378 mm wide x 349 mm height) of the PV unit. Using the data in Table 1, ratio of A_s(T_{PV}-T_{room}) and A_b(T_{PV}-T_{room}) was calculated as 0.02 – 0.03. That is, the heat release from the side surface of the PV unit is negligible compared to that from the back surface. The heat leaving from the thermal collector to the room is estimated by using the thermal property and geometry of the heat shield (section 2) and the temperature differences. Based on the above discussion and the data in Table 1, the heat loss from the back surface was calculated as 1 – 4 % of the thermal output, which was calculated by (mass flow rate) x (specific heat) x (measured T_{out}-T_{in}). On the other hand, the excess heat (difference of thermal outputs between open and closed PV cases) was 9 – 29 % of the thermal output in each experiment. Possibly, this result suggests that the internal (Joule) heating effect of PV might be maximized when it is not connected to the external electric loads.

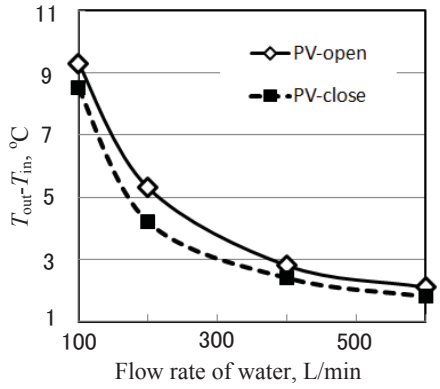

Figure 5 Temperature increase due to the internal heating of PV.

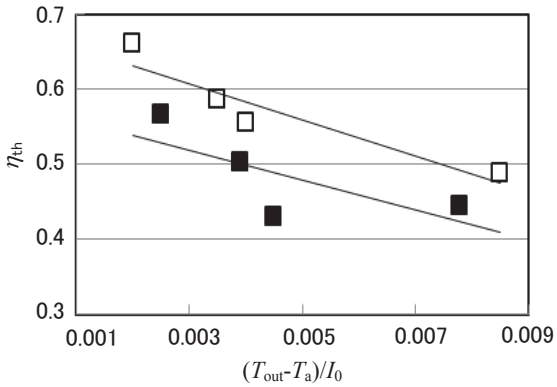

Figure 6 Thermal collector coefficient vs temperature parameter. Open and closed symbols indicate the cases of open and closed PV circuit, respectively.

The convection heat transfers were neglected and not taken into account in the present discussion. Effect of the room temperature and heat transfers including the convections will be discussed statistically in section 4.4 and Appendix.

In the case of the closed PV, the electric resistance of the circuit was controlled by the MPPT (Maximum Power Point Tracking) algorism (Itako, 2013) to generate maximum power output for various irradiation intensities. This algorism has been commonly applied already in the ordinary PV generation system.

4.3 Thermal collector coefficient with/without internal (Joule) heating of PV

The thermal coefficients of the open and the closed PV circuits are shown in Fig.6. As was forecasted in section 3, the coefficient of the open circuit is larger than that of the closed one. The regression lines in Fig.6 are: for the open circuit

$$\eta_{th} = 0.68 - 24(T_{out} - T_a)/I_0 \qquad (11)$$

, and for the closed circuit

$$\eta_{th} = 0.58 - 20(T_{out} - T_a)/I_0 \qquad (12)$$

In Eqs.(11) and (12), the ambient temperature T_a means the room temperature T_{room} in this study. Those equations indicate that $\alpha' = 0.68$, $U' = 24$ and $\alpha = 0.58$, $U = 20$, thus $\alpha' > \alpha$ and $U' > U$. This result is just the same as what suggested by Eq.(10). We can confirm that the experimental results by Sandness and Rekstad (2002) (Fig.5 in their paper) show the similar trend to the present results shown in Fig.6. Considering the Joule heating effect of the PV cell, we understand the reason of the trend of the thermal collector coefficient.

4.4 Joule heating and electricity output

In this section we examine the relationship between the thermal output of the PV cell when it is not connected to the outside electric loads (open PV) and the electric power output of it when it is properly connected to the loads (closed PV). To evaluate more correctly the heat generation by PV itself, influence of the room temperature on T_{in} and T_{out} (Fig.1) must be minimized. For this purpose the heat insulation of the thermal collector was improved: the back side of the thermal collector placed behind the PV cell was heat shielded by a foam rubber (section 2). Silicon rubber tubes connecting the inlet and the outlet of the thermal collector (Fig.A1) were left as they were. Three irradiation intensities of 800, 1000, and 1100 W/m^2 were chosen as I_0. At each irradiation the temperatures measured at least five times. The volume flow rate of cooling water was kept 200cc/min constant for each experiment. In Table 2 and 3 are given the measured raw temperatures and the modified temperature difference ($T'_{in} - T'_{out}$), where the effect of the room temperature was minimized. The procedure of calculation of the modified temperatures and the minimization is given in Appendix.

The data in Tables 2 and 3 are plotted in Figs.7 and 8. In Fig.7 are compared the raw temperature differences $\Delta T = (T_{out} - T_{in})_{open} - (T_{out} - T_{in})_{closed}$ and the corresponding modified temperature differences $\Delta T' = (T'_{out} - T'_{in})_{open} - (T'_{out} - T'_{in})_{closed}$. The suffixes "open" and "closed" indicate temperature differences under the open and the closed PV circuits, respectively. In the plot of ΔT and $\Delta T'$, the 1-σ (a standard deviation) error bars are superimposed. We can see in Fig.7 that both the raw ΔT (closed squares) and the modified $\Delta T'$ (open squares) tend to be positive. In the modified $\Delta T'$, a much clear dependency on I_0 can be seen. Those results indicate that the PV appreciably generates heat when it is not connected to the external electric loads. Figure 8 compares the thermal output of PV under unconnected circuit and the corresponding maximum electric power output under connected circuit. Within the present measurement precision, we can say that internal current of PV generates an appreciable amount of heat when it is not connected to the external electric loads. In other words, the maximum thermal output of unconnected PV is almost the same order of magnitude as the maximum electric power output of it under the same irradiation condition.

5. Concluding remarks

The thermal behavior of the photovoltaic-thermal (PV-T) hybrid collector was examined using a simulator, especially focusing on the cases when PV cell was connected to (closed) and not connected to (open) external electric loads. The main results are summarized as follows:

1) For the hybrid PV-T system: it was confirmed that the thermal collector coefficient was prone to be larger in the case without the external electric loads (open PV) than the case with them (closed PV). Such trend was well explained in terms of the internal heating phenomenon (Joule heating) of the PV cell. Field experiment by Sandnes and Rekstad (2002) show the similar trend to the present one. In the present PV-T configuration, thermal collector coefficient drops significantly due to the shade effect of the PV cell. Overcoming such defect and improving total coefficient may be an important subject in future study.

2) For the Joule heating of the PV cell: the heating phenomenon was directly observed by the simulator. The maximum heating power of the PV cell was confirmed to be equivalent to the maximum electric power of it. This result seems quite reasonable from the physical point of view.

In the last the authors would like to express their sincerer thanks to Messes E.Yandri, N.Nishiwaki, K.Takahashi, and S.Ono for their help in the experiments. The present study was performed under the special grant of Kanagawa Institute of Technology.

Appendix

1. Effect of room temperature and heat losses

We consider in section 4.4 that effect of the room temperature on T_{out} - T_{in} mainly originated from the heat exchange through the silicon rubber tubes of 0.3 m long and 1 m long. Shorter one is for the outlet and the longer one for the inlet of the thermal collector, respectively. The situation considered is depicted in Fig.A. Heat exchanges through the other units except those tubes are considered to be negligible. The thermal entrance region (length) of the tubes was estimated to be over 1.5 m in the present experimental condition. For a reference, Reynolds number and Prandtl number were ≈ 900 - 1100 and ≈ 5 - 7, respectively. Exact analytical approach for deciding the temperatures without the room temperature effect seemed difficult. Thus a statistical but mathematically reasonable method of data analysis was adopted in the following.

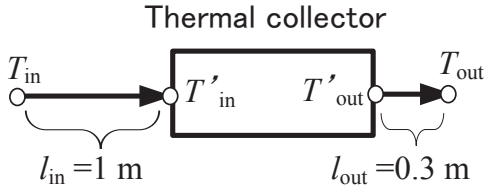

Figure A1 Silicon rubber tubes connected to the inlet and the outlet of the thermal collector. The main heat exchange between the simulator and the ambient is supposed to occur through the tubes.

Based on the observed data, we assume $T_{room} < T'_{in} < T_{out} < T'_{out}$ simply as an aid in the following procedure. The temperatures T_{room}, T_{in}, and T_{out} are the measured ones and T'_{in}, and T'_{out} are the modified ones, in which the room temperature effect is minimized. It is obvious that this

inequality assumption on the temperatures does not violate the validity of the present approach.

1. Heat transfer between the silicon tubes and the ambient

Let the heat transfers through the tube l_{in} and l_{out} be Q_{in} and Q_{out}, respectively. It seems reasonable to assume that those heat transfers are given as Eqs. (A1) and (A2):

$$Q_{in} = A_{in}h_{in}\left[\left(\frac{T_{in}+T_{in}^{'}}{2}\right)-T_{room}\right] \quad \text{(A1)}$$

$$Q_{out} = A_{out}h_{out}\left[\left(\frac{T_{out}+T_{out}^{'}}{2}\right)-T_{room}\right] \quad \text{(A2)}$$

, where h_{in} and h_{out} are empirical coefficients of heat transfer evaluated statistically and A_{in} and A_{out} are the surface area of the tubes given as Eq. (A3).

$$A_{in} = l_{in}\pi d,\ A_{out} = l_{out}\pi d \quad \text{(A3)}$$

, where d is the outer diameter of the silicon tube. Using mass flow rate m and specific heat C of the cooling water, Eqs.(A1) and (A2) are rewritten as

$$Q_{in} = mC\left(T_{in}-T_{in}^{'}\right) \quad \text{(A4)}$$

$$Q_{out} = mC\left(T_{out}-T_{out}^{'}\right) \quad \text{(A5)}$$

From Eqs. (A1), (A2), (A4), and (A5), modified temperatures T'_{in}, and T'_{out} are decided as follows,

$$T_{in}^{'} = \frac{-\left(\frac{1}{2}-\frac{mC}{ak}\right)T_{in}+T_{room}}{\left(\frac{1}{2}+\frac{mC}{ak}\right)} \quad \text{(A6)}$$

$$T_{out}^{'} = \frac{-\left(\frac{1}{2}+\frac{mC}{k}\right)T_{out}+T_{room}}{\left(\frac{1}{2}-\frac{mC}{k}\right)} \quad \text{(A7)}$$

, where a factor a is the ratio of the tube lengths $l_{in}/l_{out} \approx 3.3$ and a parameter k is given as $k = \pi d l_{out} h$, respectively. In Eqs.(A6) and (A7), we can easily confirm that $T'_{in} \rightarrow T_{in}$ and $T'_{out} \rightarrow T_{out}$ when $k \rightarrow 0$.

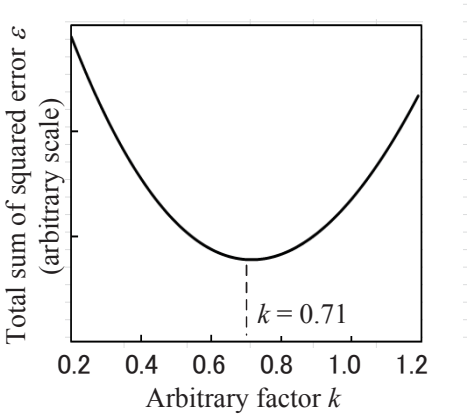

Figure A2 Total sum of squared errors vs k

2. Calculation of k and $T'_{out} - T'_{in}$

Using Eqs.(A6) and (A7), we can define the error in $T'_{out} - T'_{in}$ for experiments i and j done under the common irradiation condition. The error ε_{ij} and sum of squared ones ε are defined as

$$\varepsilon_{ij} = \left(T_{out}^{'}-T_{in}^{'}\right)_i - \left(T_{out}^{'}-T_{in}^{'}\right)_j \quad \text{(A8)}$$

$$\varepsilon = \sum_{i,j}\varepsilon_{ij}^{2} \quad \text{(A9)}$$

The factor k was calculated so as to minimize ε. In Fig.A2 is plotted ε for all temperature data given in Table 2 and 3 as a function of k. As can be seen in this figure, we find the error is minimum at $k \approx 0.71$. Using the relationship $k = \pi d l_{out} h$, the corresponding heat transfer coefficient h is evaluated to be $\approx$ 70 W/(m^2 K). The temperatures $T'_{out} - T'_{in}$ in Table 2 and 3 are calculated by using Eqs. (A6) and (A7) with k = 0.71.

Economic analysis of renewable energy production with photovoltaic- and solar thermal systems for small and medium-sized enterprises

Maximilian Zarte[1] and Agnes Pechmann[1]

[1] University of Applied Sciences, Emden (Germany)

Abstract

The economic benefits that photovoltaic and solar thermal renewable energy (RE) producers offer under Germany's current legislative conditions (EEG 2014) have been investigated for two cases involving small and medium-sized enterprises (SMEs). The energy demands of the case SMEs are very distinct in volume, type, and profile. With the aid of a simulation, the direct consumption of the expected RE generation and the resulting energy exchange with the grid have been calculated. The results have been analyzed from an economic standpoint using economic indicators and the LCCA (life-cycle cost analysis) method. For the two cases, the results are presented with their indicator values and the designs of the PV and solar thermal systems.

Keywords: Renewable energy; small and medium-sized enterprises; simulation; cost analysis; life-cycle cost analysis

1. Introduction

While energy supply is a constant subject of discussion, focus on it has intensified due to factors such as the prediction regarding the depletion of fossil fuels or nuclear accidents. The current driver of the discussion is climate change. Approximately 80% of the world's primary energy supply comes from fossil fuels that emit greenhouse gases such as CO_2 (International Energy Agency (IEA), 2015). CO_2 and other greenhouse gases modify the planet's absorption and emission of solar radiation and are associated with the observed warming of the climate and other serious environmental problems (Pachauri and Mayer, 2015). To initiate and maintain a decrease in CO_2 emissions, several targets have been set worldwide. For instance, for 2020, the European Union has set the 20/20/20 targets. These entail reducing greenhouse gas emissions by 20% (in comparison to the 1990 levels), increasing the share of renewable energy (RE) sources in final energy consumption by 20%, and increasing energy efficiency by 20% (European Commission, 2010). Installing RE plants could improve the first two targets but would result in further challenges. One such challenge involves the change of predominantly centralized energy systems into bi-directional, decentralized ones which integrate RE producers. Another challenge involves handling the fluctuating behavior of RE producers such as photovoltaic systems (PV) and/or wind stations (WS) due to their weather dependency. Energy production is difficult to predict. The fluctuating behavior and forecast errors would lead to instabilities in the grid, resulting in higher management control efforts. Like that of many other countries, the infrastructure of the German energy system must be modified to manage such challenges; such efforts will incur major costs. To finance them, several levies and taxes have been established based on the Renewable Energy Sources Act (EEG) (Deutsche Bundestag, 2014).

The German EEG manages the expansion of RE producers and sets tariffs for the feed-in of RE into the grid for new RE producer installations. The EEG was first introduced in 2000. Initially, investors benefit from the high feed-in tariffs and lower taxes. But the regulations are constantly revised over the years. Certain conditions have drastically reduced and restricted the feed-in tariffs, bringing self-consumption into focus.

doi:10.18086/eurosun.2016.08.07 Available at http://proceedings.ises.org

For SMEs which are willing to invest in RE, a complex decision problem has to be solved. Once the technical and legal feasibility of installing and operating one or more RE producers has been verified, the issue of how the optimal RE system fits the SME's energy demand and profile has to be decided: Does it consist of one type of RE producer or of different types of RE producers? In what combinations do they occur, and of what size are they? To what extent does the RE satisfy the energy demand? How is overproduction handled? Is it suitable to store it or can it be injected into the grid – and under which conditions are such efforts possible?

This paper investigates the optimal design of a PV and solar thermal system that will supply an SME consumer with electrical and thermal RE and fit its energy demand and profile. These results are compared with the original situation, which involves the 100% feeding of RE into the grid, to illustrate the higher benefits that self-consumption offers. Two distinct cases are investigated under the rubric to achieve the best financial return for the investment within the restrictions of Germany's 2014 EEG.

The optimal design of a RE producer is highly critical for maximizing energy cost savings. Tools have been developed to calculate the economic effects of RE producers. Available tools, such as pv@now (Deutsche Gesellschaft für Sonnenenergie (DGS)), base their calculations on average yearly values for RE production and company demand. Though the results are useful for rough estimations, they neglect the seasonality of RE generation and company demand, leading to considerable deviations in efforts to balance RE supply and demand and, consequently, to differences between the expected and true economic effects. To solve this problem, the research group, "Energy Efficiency in Production," at the University of Applied Sciences Emden/Leer has developed the agent-based simulation, PREmdeK (Pechmann). It simulates a local energy system that consists of one major industrial consumer (e.g., an SME), a multi-source renewable power plant (PV, wind station, CHP, solar heat), and storage entities. The simulation runs on data produced at 15-minute intervals for the duration of a year. For the two cases, historical data regarding energy demand and local weather conditions were used (Pechmann et al., 2016). The simulation employed various PV and solar thermal machine designs that were calculated to balance RE generation with the company's consumption while using storage entities and the grid. The scenarios served as input for an economic analysis that employed economic indicators and the LCCA (life-cycle cost analysis) method. The results of the economic analysis include supplying solutions that will maximize the SMEs' energy cost savings.

In the subsequent section, related work is discussed. Next, section three presents background information on "energy" business models (BM) for SMEs that are feasible under the German EEG 2014, the two case SMEs and energy supply scenarios, and the calculation methods that are applied in the economic analysis. Section four evaluates the case SMEs' results. Then the article ends with a conclusion and a description of possible future work, followed by the references.

2. Related Work

Choosing the right machine design is very important when investing in an RE plant for full or partial self-supply to achieve maximum energy cost savings. It is not sufficient to solely consider energy production costs per plant though they have been researched widely and calculated (Michaelis et al., 2013; Balks and Breloh, 2014; Oliveira e Silva and Hendrick, 2016).

Several conditions affect the benefits that the RE producer offers and should be analyzed for each specific consumer. An overview of possible methods is presented and reviewed in the recent article, "Decision-Making in Renewable Energy Investments," by Strantzali and Aravossis (2016). This literature review shows that the choice of the method mostly depends on the preferences of the decision-maker and the analyst. Industrialists prefer the use of economic indicators for decision-making, and LCCA is dominant in the fields of energy policy and management (Strantzali and Aravossis, 2016). To calculate the economic indicators and the LCCA value, the right input parameters (e.g., investment, installation, and operational costs) must be defined, depending strongly on the types and sizes (designs) of the RE producers and necessary storage devices. Studies on the methodologies that define the input parameters associated with the design and size of the RE producer exist as well (Baños et al., 2011; Erdinc and Uzunoglu, 2012). There is a need for case examples that present the technical design of the RE producer in relation to costs and benefits during the

operation of the system. Though there are a few such case studies, they focus on private households and buildings (Achtnicht, 2011; Marszal et al., 2012). Case studies that focus on manufacturing SMEs with real data are not publicly available. SMEs account for half of the industry's power consumption (BMWI, 2016). It is therefore expected that the results of this study will be of great interest to SMEs that are looking for ways to reduce their energy costs with RE.

3. Background and Methods

3.1 Feasible business models under the German EEG 2014

Generally speaking, the operator of an electrical RE producer has different ways to handle RE (see Figure 1): as a mix of self-consumption and feeding into the grid (BM1), as self-consumption alone (BM2), and as feeding into the grid alone (BM3–BM5). This paper investigates BMs for supplying an SME consumer within the operational scope; therefore, it does not take into further consideration the BM of selling to a third person. Only BM3 (market premium model) is considered to compare the benefits of self-consumption and those of 100% grid feed-in under the current EEG.

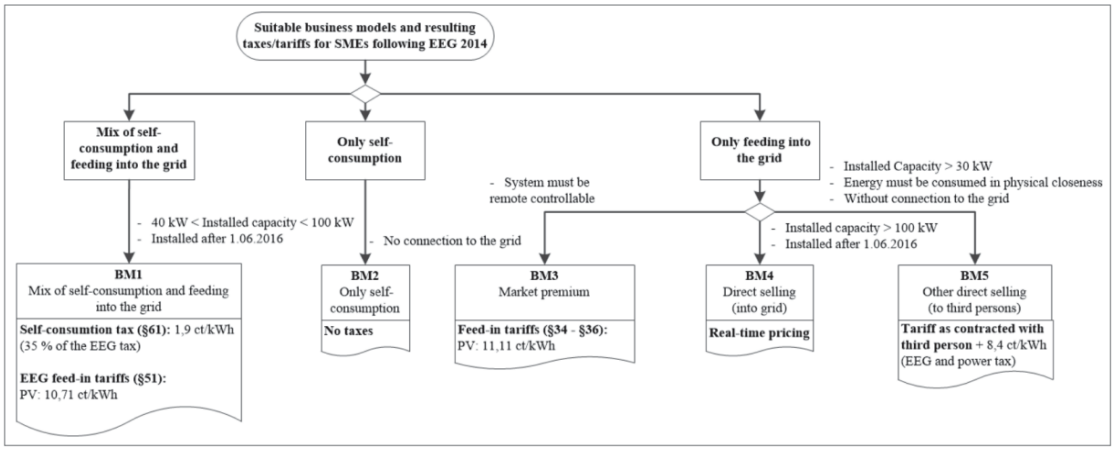

Figure 1: The range of possible applications for RE according to the German EEG

In **BM1**, the operator has the following options for using the electrical RE produced (P_{elRE}) (see Equation 1): consuming the RE ($P_{elRE\text{-}elC}$) and/or feeding the RE produced into the grid ($P_{elRE\text{-}G}$). Additionally, it is possible to temporarily save the energy in electrical storage ($P_{elRE\text{-}elS}$) for its later consumption and/or feeding in. According to the EEG 2014, BM1 is only possible if the machine design value of the RE producer is lower than 100 kW.

$$P_{RE} = P_{elRE-G} + P_{RE-ES} + P_{RE-elC} \quad \text{(eq. 1)}$$

Equation 2 calculates the cash inflows for BM1 (C_{BM1}). The operator gets the tariff for feeding RE into the grid from to §51 ($P_{elRE\text{-}G} * c_{RE,i}$). The self-consumption of electrical RE saves energy costs less the tax for own consumption of energy (($P_{elRE\text{-}elC} + P_{ES\text{-}elC}$) * ($c_{el}$ - c_{EEG})) according to §61. For electrical storage systems, special conditions are applied. The self-consumption tax must be paid twice: for charging the electrical storage and for discharging it.

$$C_{BM1} = P_{elRE-G} * c_{elRE,i} + (P_{ES-elC} + P_{elRE-elC}) * (c_{el} - c_{EEG}) + P_{elRE-ES} * c_{EEG} \quad \text{(eq. 2)}$$

If the machine design value is greater than 100 kW, the option of consuming and/or feeding the RE into the grid is not allowed. For **BM2**, the RE plant may not be connected to the grid. Therefore, in the event of the overproduction of electrical energy, it cannot be injected into the grid. If the consumer makes no demand and is not able to store the energy, it will be wasted. ($P_{elRE\text{-}EO}$) (see Equation 3).

$$P_{elRE} = P_{elRE-EO} + P_{elRE-ES} + P_{elRE-EC} \quad \text{(eq. 3)}$$

The advantage of BM2 over BM1 is that the tax for self-consumption does not apply to it. The operator saves the full purchasing costs for its own consumption of electrical energy ($P_{elRE\text{-}elC} * c_{el}$). The disadvantage lies with the overproduction: It is wasted. Hence, it does not lower any costs ($P_{elRE\text{-}EO} * 0$). Equation 4 calculates the cash inflows for BM2 (C_{BM2}).

$$C_{BM2} = P_{elRE-EO} * 0 + (P_{elRE-elS} + P_{elRE-EC}) * c_{el} \quad \text{(eq. 4)}$$

For the thermal RE producer, no regulation is in place due to the EEG 2014. The thermal energy supply via local and/or district heating grids is not considered in this paper. Because of this, no thermal energy is fed into a grid, and the calculations are made in analogy to those for BM2 (see Equations 5 and 6).

$$P_{thRE} = P_{thRE-EO} + P_{thRE-TS} + P_{RE-thC} \quad \text{(eq. 5)}$$

$$C_{BMTh} = P_{thRE-EO} * 0 + (P_{RthE-thS} + P_{thRE-EC}) * c_{th} \quad \text{(eq. 6)}$$

In the case of the market premium model (**BM3**), the grid operator must have access to remote control of the RE producers. The RE produced is completely fed into the grid (see Equation 7).

$$P_{elRE} = P_{elRE-G} \quad \text{(eq. 7)}$$

The operator gets a tariff according to §34 - §36 ($c_{PM,i}$). In case of a shutdown by the grid operator (for various reasons), the amount for the non-fed-in energy is reimbursed as it would have been if it were feed-in. Equation 8 calculates the cash inflows for BM3 (C_{BM3}).

$$C_{BM3} = P_{elRE-G} * c_{PM,i} \quad \text{(eq. 8)}$$

3.2 Characterization of case companies and scenarios

For two case SMEs, the capital and operating costs for energy supply are investigated for several scenarios for the year 2014. For each SME, the scenarios are then compared. All scenarios are technically feasible and applicable. The energy demand (see Table 1) is known, and load metering data from the SMEs' energy provider is used. Additionally, individual load metering is performed on the most energy-intensive machines using metering devices. The installation of these devices is part of a long-term effort by the PREmdeK Project (Ernst et al., 2013).

Tab. 1: Yearly energy demand of the case SMEs considered for 2014

SME	1	2
El. demand in [kWh] (day)	199.099	3.454.636
El. demand in [kWh] (night)	47.363	934.972
Th. demand [kWh]	1.236.802	-

SME 1 is a small production company that specializes in fruit processing. The company fills 10.000 bottles of different types of fruit juice per hour for five workdays in a one-shift system. The main energy consumer on the production floor is the bottle cleaning system, which cleans reusable glass bottles. The system works at water temperatures between 40 °C and 95 °C, and it is feasible to integrate thermal RE into it. The integration details are not relevant to the investigation and, therefore, are not explained further here.

SME 2 is a medium-sized manufacturing company that specializes in metal processing. The company produces mainly small to medium-sized product series with some repetitive orders on a five-day week in a two-shift system. The main energy consumers in production are big smelters. The smelters need to achieve about 1.500 °C to melt the metal and account for most of the energy costs (purchase of foundry coal, gas, and power). Because of the required high temperature level, the use of thermal RE is not feasible. In addition, the company has a waste heat system in place. Because of this, the amounts of gas and foundry coal used, and the location of the company site, this paper only considers the electrical supply and the demand side of the

company.

For the investigation, in addition to the load profiles of the SMEs, the weather conditions at the company sites are necessary for calculating energy generation. The PREmdeK simulation uses the following meteorological data: air temperature, air moisture, air pressure, global radiation, wind speed, and wind direction. The weather data is measured by a local weather station that the University of Applied Sciences Emden/Leer operates. The data is aggregated to 15-minute intervals (Ernst et al., 2012). Different scenarios for the RE supply have been investigated for the SMEs. The scenarios differ in terms of the composition of the RE plant (PV and solar thermal systems), the use of storage systems, and the machine design value (see Table 3 for elements used in the RE plant).

3.3 Cost calculation data and methods

For both SMEs, Table 2 lists the actual energy supply costs for 2014 and the $LCCA_{Reff}$ value. The costs are the product of the energy demand and the specific energy cost.

Tab. 2: Actual energy costs of the case SMEs in 2014

	Energy price c_i [ct/kWh]	**SME 1 [Euro]**	**SME 2 [Euro]**
El. energy cost (day)	20,5	40.752	707.095
El. energy cost (night)	18,5	8.747	172.671
Th. energy cost	6,5	56.892	-
Total cost	-	106.391	879.766
$LCCA_{Reff}$	-	1.172.275	9.693.702

For the alternative supply (according to the investigated scenarios) and for each RE producer and storage system different suppliers have requested offers related to machine design value (see Table 3), which industry experts have verified. Based on the weather and energy demand data (split into electrical demand data and thermal demand data), simulations have been run with scenarios involving different combinations and designs. For each scenario, the PREmdeK simulation gives values for the energy generated according to plant type, storage usage, and energy exchange with the grid.

Tab. 3: Overview of the capital and operating costs for the RE producer

RE producer	**Supplier**	**Machine design value (P_i)**	**Capital cost (CC_i)**	**Operating cost (OC_i)**
Photovoltaic	Heckert Solar NeMo 60P	40–2.000 kW	1036,9 * P_{PV} + 7309,6	2% of the capital cost
Solar heat	Paradigma Aqua Plasma 19/50	5,01–1002 m²	801,69 * P_{SH} + 63,934	2% of the capital cost
El. Storage	EP Solarpower EnergieS 18	18,4 kWh	26.983,09 Euro	-
	EP Solarpower EnergieS 55	55,2 kWh	59.769,20 Euro	
	EP Solarpower EnergieS 110	110,4 kWh	120.758,17 Euro	
Th. Storage	Paradigma Aqua Expresso ll 110	441–4410 kWh	13,831 * P_{ThS}	-

Based on these results, the following indicators have been calculated for the three BMs considered: net present value (NPV), internal rate of return (IRR), payback period (n_{dyn}), and life-cycle cost analysis (LCCA) value. The calculations of the indicators and the LCCA values are explained below. The NPV is used in capital budgeting to analyze the profitability of an investment ($CC_{RE\ plant}$) for a certain time (here k = 20a) at a specific discount rate (here j = 6.5%) (see Equation 9) (Poggensee, 2009).

The NPV is the difference between the present value of cash inflows and the present value of cash outflows ($C_{BMi} - OC_{RE\ plant}$).

$$NPV = \sum_{k=0}^{k=20} \frac{(C_{BMi} - OC_{RE\ Plant}) - CC_{RE\ Plant}}{(1+j)^k} \quad \text{(eq. 9)}$$

The IRR is the discount rate, where the NPV of all cash flows from a particular project equals zero. IRR calculation (see Equation 10) is similar to NPV calculation (Poggensee, 2009) but sets the NPV at zero.

$$NPV = 0 = \sum_{k=0}^{k=20} \frac{(C_{BM} - OC_{RE\ Plant}) - CC_{RE\ Plant}}{(1+IRR)^k} \quad \text{(eq. 10)}$$

The discounted payback period gives the number of years it takes to break even after undertaking the initial investment by discounting future cash flows and considering the value of money in relation to time (see Equation 11) (Poggensee, 2009).

$$NPV = 0 = \sum_{k=0}^{n_{dyn}} \frac{(C_{BM} - OC_{RE\ Plant}) - CC_{RE\ Plant}}{(1+j)^{n_{dyn}}} \quad \text{(eq. 11)}$$

The LCCA value takes into account all cash outflows related to future activities and the business model but does not consider cash inflows (Fuller and Petersen, 1996). The following cash outflows are considered: operation costs, taxes for self-consumption, and electrical and thermal energy costs. All costs are discounted and total to an NPV (see Equation 12).

$$LCCA = \sum_{k=0}^{k=20} \frac{CC_{RE\ Plant} + \text{cash outflows}}{(1+i)^{-k}} \quad \text{(eq. 12)}$$

For the evaluation, the ratio of the LCCA for the RE plant to the reference LCCA has been calculated (see Equation 13).

$$LCCA\ ratio = 100\% * \frac{LCCA}{LCCA_{Reff}} - 100\% \quad \text{(eq. 13)}$$

4. Evaluation of the Scenarios for the Case SMEs

4.1 Results of the economic indicators and LCCA for SME 1

Figure 2 shows the electrical RE self-consumption ratio in relation to the PV machine design value and the electrical storage capacity for SME 1. As expected, the self-consumption ratio increases as the storage capacity increases and decreases as the PV machine design value increases.

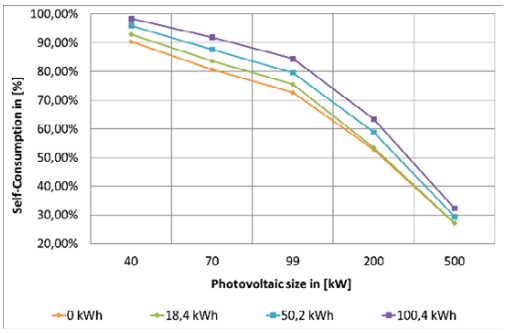

Fig. 2: Self-consumption ratio of the electrical RE for SME 1

Figure 3 shows the results for the IRR and payback period in relation to the PV machine design value and BM for SME 1. For easier comprehension, the figures only show the results for the electrical storage capacity of 18 kWh. It is not necessary to show all the results because the conclusion is the same for all the storage capacities. As expected, a comparison of BM1 and BM2 with BM3 shows that BM1 and BM2 offer higher benefits. Only with higher machine design values can BM3 achieve better benefits, but this is not applicable to SMEs. Typically, the SMEs do not have a sufficiently large free area for bigger PV machine design values and for the efforts required to operate big RE plants. BM2 has the best IRR and payback period at 40 kW. As Figure 2 shows, there is also a maximum point for the self-consumption ratio. BM1 has the best IRR and payback period at 70 kW. The combination of the high self-consumption ratio and RE overproduction feed-in lead to an enhanced benefit. In both BMs (BM1 and BM2), using storage systems leads to lower profitability. As Figure 2 shows, it is possible to increase the self-consumption of the electrical RE with storage systems, but that cannot compensate for the higher capital cost and higher taxes for self-consumption (BM1 alone).

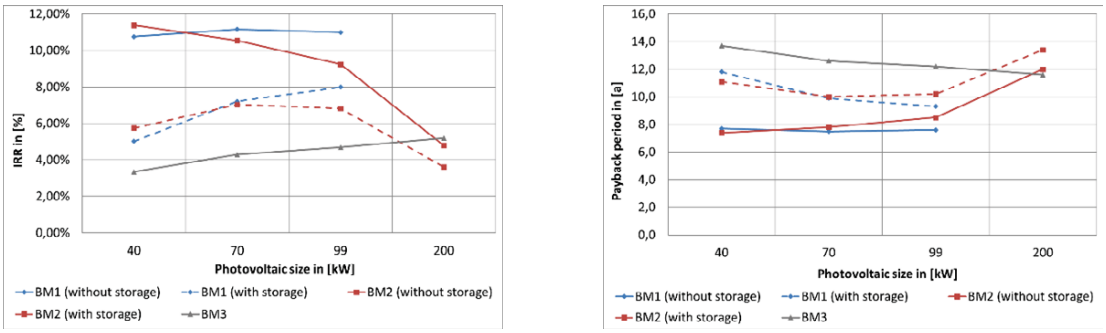

Fig. 3: Relationship between PV machine design value and IRR (left) and between PV machine design value and payback period (right) for SME 1 and all BMs

Figure 4 shows the results of the NPV and LCCA ratio in relation to the PV machine design and BM for SME 1. As Figure 3 shows, the profitability of BM3 and of the systems that have storage is lower than that of BM1 and that of BM2. In contrast to the IRR and payback period, the NPV achieves the maximum points at different machine design values: BM1 at 99 kW and BM2 at 70 kW. For BM1, the profit is higher because more electrical RE is fed in, and for BM2, more electrical energy is saved in total compared to the scenarios involving lower machine design values. Higher machine design values save more electrical energy in total, but the higher profit cannot compensate for the higher capital and operation costs, leading to a lower IRR. The LCCA ratio has the best value in BM2 at 70 kW. At this point, the combination of high cost savings and no taxes for self-consumption leads to a low operating cost for the electrical energy supply for SME 1.

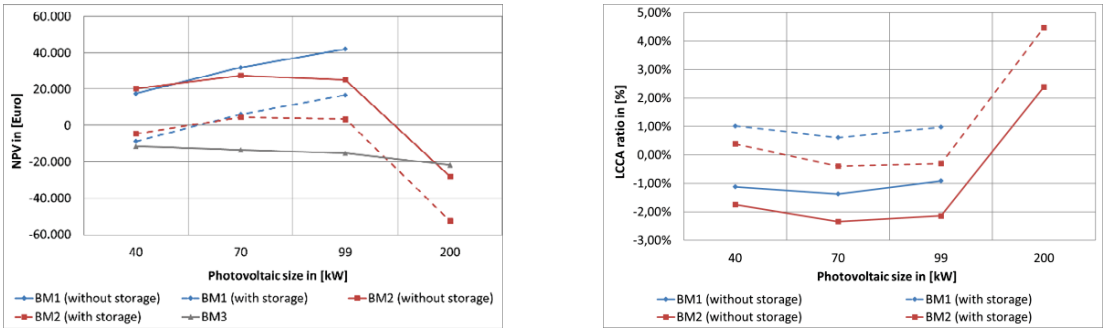

Fig. 4: Relation between PV machine design value and NPV (left) and between PV machine design value and LCCA ratio (right) for SME 1 and all BMs

Figure 5 shows the thermal RE self-consumption ratio in relation to the solar thermal machine design value and the thermal storage capacity for SME 1. As expected, the self-consumption ratio increases with the rise in the storage capacity and falls with the rise in the solar thermal machine design value.

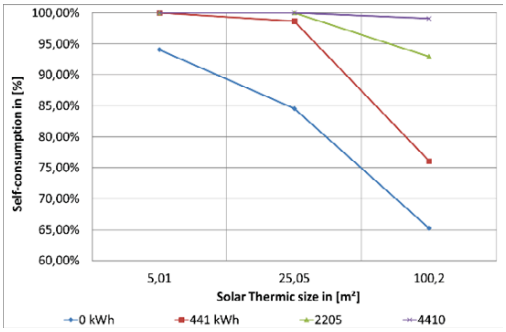

Fig. 5: Self-consumption ratio of the thermal RE for SME 1

Figure 6 shows the results for the IRR and payback period in relation to the solar thermal machine design value for SME 1. Contrary to expectations, the profitability of the thermal RE producer is in the negative range. In comparison to the PV system, the maximum point is experienced with this system, which has the highest self-consumption ratio. Moreover, the storage usage shows that the higher benefits due to higher self-consumption do not compensate for the higher capital costs.

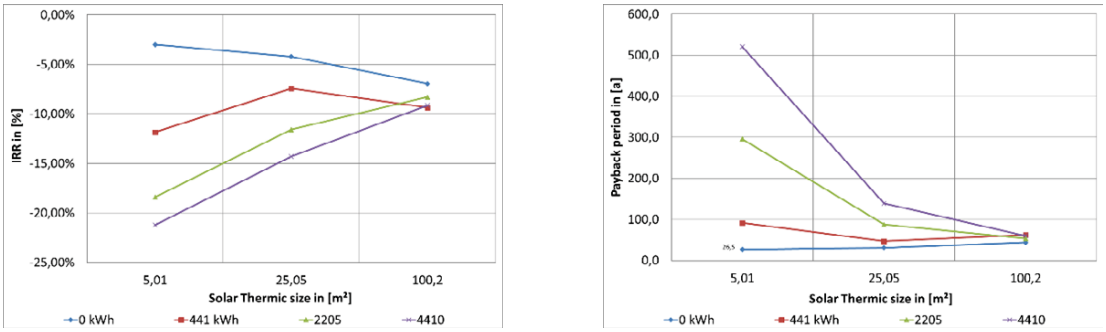

Fig. 6: Relation between solar thermal area and IRR (left) and between solar thermal area and payback period (right) for SME 1 and all BMs

Figure 7 shows the results of the NPV and LCCA ratio in relation to the solar thermal machine design value for SME 1. The NPV is like the IRR, and the payback period is in the negative range. The operation costs are at the lowest point (0,4 % higher than they would be without the solar thermal system). The problem is the low cost savings due to the low gas price. In comparison to the electrical energy price (20,5 ct/kWh), the thermal energy price (6,5 ct/kWh) is significant lower, which leads to lower profits.

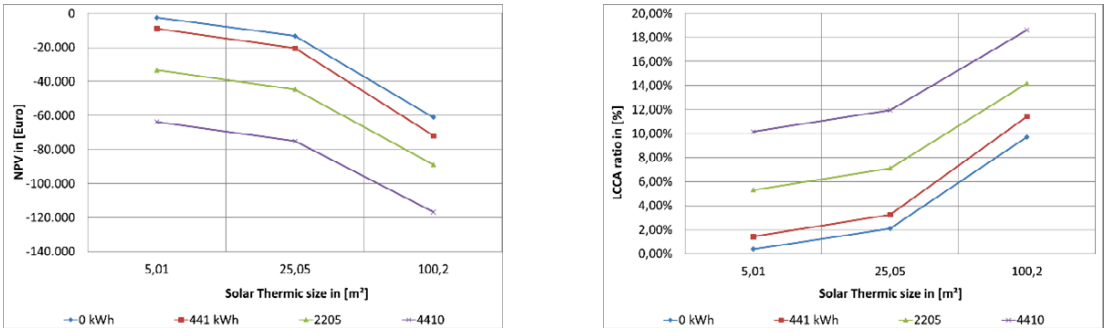

Fig. 7: Relation between solar thermal area and NPV (left) and between solar thermal area and LCCA ratio (right) for SME 1 and all BMs

4.2 Results of the economic indicators and LCCA for SME 2

Figure 8 shows the electrical RE self-consumption ratio in relation to the PV machine design value and electrical storage capacity for SME 2. As expected, the self-consumption ratio rises with the increase in the storage capacity and falls with the increase in the PV machine design value. In comparison to that for SME 1, the increase is lower because of the higher total electrical energy consumption.

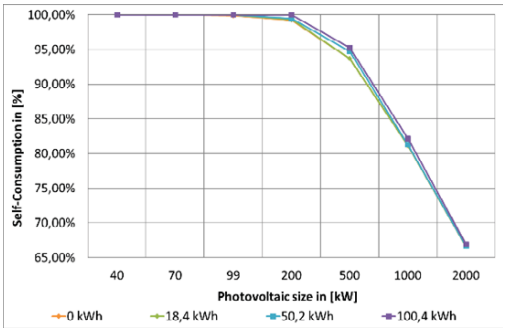

Fig. 8: Self-consumption ratio of the electrical RE for SME 2

Figure 9 shows the results of the IRR and payback period in relation to the PV machine design value and BM for SME 2. For easier comprehension, the figures for SME 2 only show the results for the electrical storage capacity of 55 kWh. In contrast to SME 1, BM2 always offers the best benefits. The advantage due to BM1's feeding of overproduced RE into the grid is not applicable because the self-consumption ratio (Figure 8) is still 100% for the 99-kW PV system. The best IRR and payback period are achieved at 200 kW. The results for the storage system are similar to those for SME 1.

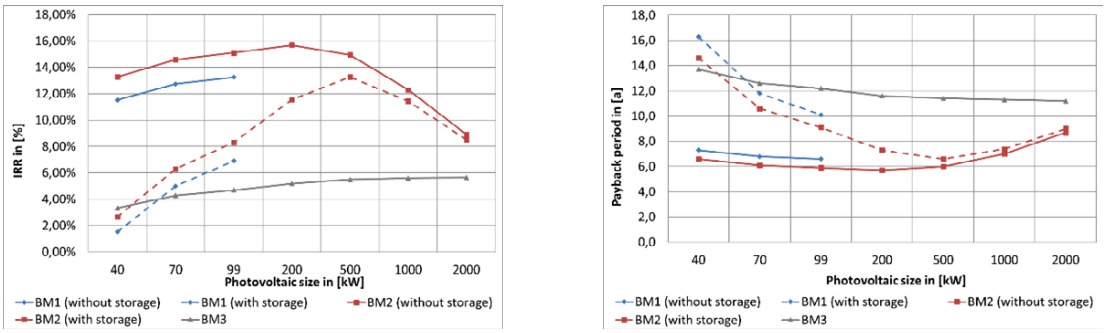

Fig. 9: Relation between PV machine design value and IRR (left) and between PV machine design value and payback period (right) for SME 2 and all BMs

Figure 10 shows the results of considering the NPV and LCCA ratio in relation to the PV machine design value and BM for SME 2. Similarly to those for SME 1, the best NPV and LCCA ratio occur at a different machine design value (like the IRR and payback period). The best NPV and LCCA ratio occur with the

1,000-kW PV machine design value.

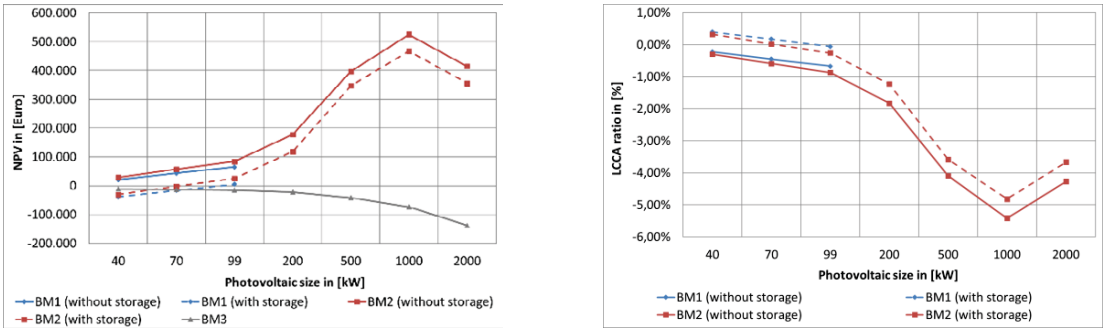

Fig. 10: Relation between PV machine design value and NPV (left) and between PV machine design value and LCCA ratio (right) for SME 2 and all BMs

5. Conclusion

The comparison of all investigated systems and BMs shows that the most beneficial scenarios are always the ones with high, direct, self-consumption of electrical RE from PV systems and the ones with minimal use of storage systems or no storage systems. The benefits that BM3 (which solely involves the feeding of RE into the grid) offers are too low to compete against those that BM1 (self-consumption and/or feeding into the grid) and BM2 (self-consumption alone) offer. The main reason for this is that the feed-in tariffs (10,7 ct/kWh) for the RE from PV systems are low compared to the cost savings due to self-consumption of electrical RE (20,5 ct/kWh). The use of storage systems in BM1 and BM2 is not economically reasonable. Though it is possible to increase RE self-consumption with a storage system, the following factors make it less profitable than a situation that involves no storage: The main problem in BM1 and BM2 is the high capital cost. The benefits due to higher self-consumption are too low to compensate for the higher capital costs. Another factor concerns BM1 alone: German´s EEG "double tax" for electrical storage systems decreases their profitability. Under the investigated conditions, if the PV system is optimally designed for RE self-consumption, no storage systems are required. For demand-side management or other applications, new analyses must be undertaken regarding the need for storage systems.

The use of solar thermal energy to decrease the SME's thermal energy cost makes cannot be recommended, the cost savings (6,5 ct/kWh) are too low to have a satisfying effect on overall energy costs.

Considering the currently electrical energy prices (including taxes and levies) and the political conditions that the EEG 2014 for RE producers promotes, SMEs warrant PV systems for self-consumption with no storage systems. The choice between BM1 and BM2 and the design of a PV system depends on the company's size and on the amount of energy that is consumed. The final decision regarding the most ideal machine design and BM should be analyzed individually for each SME.

6. Future Work

The legislation regarding RE and the grid system is in a state of constant change, at least with respect to the German EEG. The next version, EEG 2017, is currently under preparation and will need to be taken into account in future research. Controllable demand (e.g., demand-side management) and other business models (e.g., real-time pricing or selling to third persons) should also be considered in the future. This will become possible with a new PREmdeK simulation design. The verification of measured data and the easy use of historical local weather data via a direct connection and databases should constitute another future task.

Estimation of Global Solar Radiation from Air Temperature using Artificial Neural Networks based on Reservoir Computing

Miquel L. Alomar[1], Vincent Canals[1], Josep L. Rosselló[1] and Víctor Martínez-Moll[1]

[1] University of Balearic Islands, Palma de Mallorca (Spain)

Abstract

Solar radiation data are crucial for the design and evaluation of solar energy systems. For locations where measurements are not available, models to estimate solar radiation from more readily available data are required. In this paper, we introduce the use of the reservoir computing (RC) technique to model daily global solar radiation (GSR) as a function of air temperature. RC is a type of artificial neural network (ANN) with closed loops (recurrent neural network, RNN) particularly suited to process time-dependent information. The novelty of this work is the use of a recurrent network for modeling solar radiation, which allows including temporal correlations between the input and output variables. The proposed approach is used to estimate GSR using weather data from a location in Almeria, Spain. The results show higher accuracy than those obtained with conventional regression models.

Keywords: *Global solar radiation, modeling, artificial neural networks, reservoir computing*

1. Introduction

Reliable knowledge of solar radiation availability and variability is essential for the efficient and economical development and implementation of solar energy applications such as photovoltaic, solar thermal and passive solar systems. Long-term real measurements at the site of the proposed solar system are the ideal database for the simulations required to evaluate the performance of such application. However, solar radiation measurements are made at few locations due to the high cost of the equipment. This makes necessary the use of accurate models for locations where measured values are not available.

A number of empirical formulas have been developed to estimate solar radiation from more commonly available data at weather stations. A review of such models for global, beam and diffuse radiation is presented in Wong and Chow (2001). In the present paper, we focus on the estimation of daily global solar radiation (GSR) on the horizontal surface. Several methods for decomposing direct and diffuse irradiance from GSR can be found in the literature (Lam and Li, 1996).

The empirical models for the assessment of GSR use historical weather data of the location under study. The meteorological observations typically employed are sunshine, cloud and temperature. As cloud is routinely detected by satellites and strongly influences solar radiation, numerous accurate models have been proposed to estimate GSR through satellite images (Janjai et al., 2009). Nonetheless, sunshine and satellite-based cloud observations are not readily available in most locations. On the other hand, air temperature is measured (usually along with humidity and precipitation) in any weather station worldwide and has been shown to be an important meteorological parameter for the modeling of GSR (Almorox et al., 2011). This motivates the research to find precise models for GSR based only on the geographical location and in commonly available temperature measurements, such as maximum and minimum temperature registers.

Apart from standard regression models (see Almorox et al., 2011 for a review of empirical temperature-based GSR models), artificial neural networks (ANNs) have also been employed in recent years for the estimation of GSR from other available meteorological parameters (Rehman and Mohandes, 2008; Behrang

doi:10.18086/eurosun.2016.09.13 Available at http://proceedings.ises.org

et al., 2010). Conventional regression models are based on the use of empirical equations that define a relationship between the desired output function (daily GSR, H) and some input variables (for example, the extraterrestrial GSR, H_0, and the daily maximum, T_{max}, and minimum temperature, T_{min}). Some empirical coefficients in these equations need to be calibrated for the site under study with available measurements by means of a mathematical regression. On the contrary, ANNs represent a methodology that allows fitting an output function without a predefined structure (black box modeling). In this approach, a network of so-called artificial neurons with configurable connections is used to learn from data the desired nonlinear output function.

ANNs can be essentially classified into feed-forward neural networks (FFNNs) and recurrent neural networks (RNNs). A FFNN has its neurons organized in layers with no feedback or lateral connections. The input signal propagates through the network in a forward direction, on a layer-by-layer basis. On the other hand, RNNs present loops, feedback connections between neurons. Thus, information can propagate forward and backwards. The major advantage of RNNs over FFNNs is that they can implicitly learn temporal tasks. That is to say, an output function can be learnt such that it does not only depend on the current value of the input signal but also on the input history. In other words, RNNs are appropriate for processing time series.

A number of works have already proposed the use of FFNNs to model GSR (Mohandes et al., 1998; Rehman and Mohandes, 2008; Benghanem et al., 2009; Behrang et al., 2010). Here, however, we propose the use of a RNN for that purpose. More specifically, we make use of reservoir computing (RC, Lukosevicius and Jaeger, 2009), a particular approach for building and training RNNs that presents a conveniently simple learning algorithm. As records of GSR represent time-series values, we hypothesize that the RNN's capability of learning temporal features from the data may improve the accuracy of the GSR estimations. This idea was already suggested by the empirical model of Bristow and Campbell (Bristow and Campbell, 1984) where the estimated radiation at current time does not only depend on the current temperature value, but also on that at a different time step.

2. Methods

2.1. Empirical models

Among the existing methods that use empirical relationships to estimate GSR, two of them have been chosen as representative for comparing the accuracy of our RC-based proposed model with conventional regression ones. Namely, the Hargreaves model (Hargreaves and Samani, 1982) and the Bristow-Campbell model (Bristow and Campbell, 1984).

Daily total extraterrestrial radiation (H_0) is included in both models together with maximum (T_{max}) and minimum temperature (T_{min}) or other quantities derived from them. H_0 can be calculated using standard geometric procedures as described in Almorox et al. (2011). The only inputs required to calculate this value is the day of the year and the latitude of the location.

The equation to estimate daily GSR according to the Hargreaves model can be expressed as follows:

$$H = H_0 \cdot [A_{HG}(T_{max} - T_{min})^{\frac{1}{2}}] \qquad \text{(eq. 1)}$$

where A_{HG} is an empirical coefficient that usually ranges between 0.16 and 0.17, but must be derived for the particular site using the available data.

The Bristow-Campbell model is based on a function (ΔT) of the maximum and minimum temperatures and on three empirical parameters (A, B and C):

$$H = H_0 \cdot A \cdot [1 - \exp(-B \cdot \Delta T^C)] \qquad \text{(eq. 2)}$$

where ΔT is defined as the next function (i corresponds to the current day and $i+1$ to the next day):

$$\Delta T = T_{max,i} - (T_{min,i} + T_{min,i+1})/2 \qquad \text{(eq. 3)}$$

Typical values for the empirical coefficients are $A=0.7$, $B=0.004\text{-}0.001$ and $C=2.4$, but they can be determined using solar radiation data.

2.2. Reservoir computing approach

Artificial neural networks (ANNs) are a computational tool inspired by the way our brain seems to process information. Basically, an ANN is an interconnected group of processing nodes (neurons) that can be used to estimate or approximate functions that depend on a number of inputs. As in biological neural networks, ANNs can learn from experience adjusting the strength of the connections (weight values). That is, they learn from examples (data) constructing an input-output mapping without explicit derivation of the model equation. ANNs can be used for many different applications, such as pattern recognition (in speech, handwriting, etc.), optimization problems, prediction and control among others.

Reservoir computing (RC) is a particular type of ANN characterized by a recurrent network architecture with a high number of interconnected nodes as illustrated in Fig.1 (a). Contrary to conventional RNNs, where all connections need to be adapted, all connection weights in an RC system are randomly chosen and kept fixed except for a linear output layer, which is the only configurable part of the network. This design reduces the complex RNN training to a simple linear regression problem, which facilitates the practical application of RNNs.

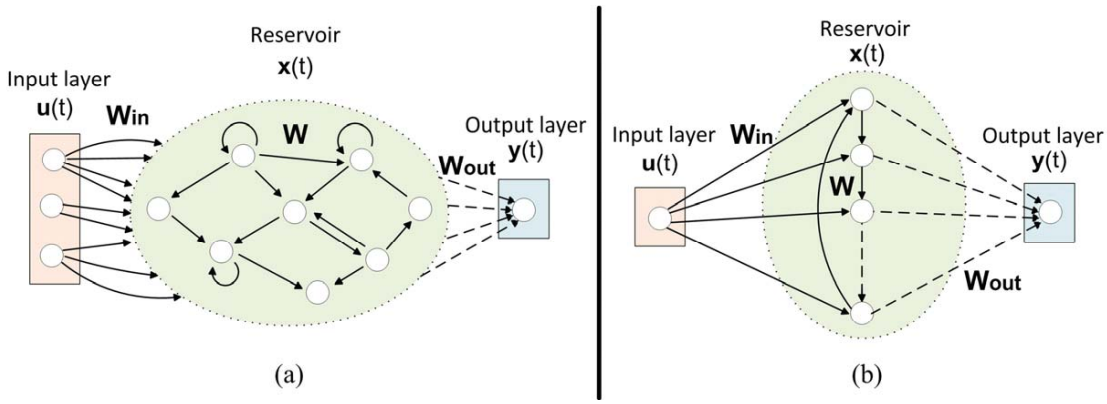

Fig. 1: (a) General architecture of an RC system. All connections are randomly chosen and kept fixed except the ones coupling the reservoir on the output layer (dashed arrows). (b) Particular RC architecture where the reservoir units are organized in a cycle.

An RC system consists of two clearly differentiated parts (apart from the input signals):

- The reservoir, a recurrent network that is randomly generated and remains unchanged.
- The output layer, a simple linear combination of the reservoir states. The weights of such combination are obtained through linear regression using a training set of data.

The general expression to estimate the neuron states in the reservoir at current time, $\boldsymbol{x}(t)$, as a function of the (multidimensional) input signal, $\boldsymbol{u}(t)$, and of the reservoir states at the previous time step, $\boldsymbol{x}(t\text{-}1)$, is given by eq. 4:

$$\boldsymbol{x}(t) = \boldsymbol{f}[\boldsymbol{W_{in}} \cdot \boldsymbol{u}(t) + \boldsymbol{W} \cdot \boldsymbol{x}(t-1)] \qquad \text{(eq. 4)}$$

where ***Win*** refers to the strength of the connections coupling the input signals with the reservoir and ***W*** corresponds to the reservoir internal weights (both matrixes of weight values are, in general, randomly generated). ***f*** denotes the nonlinear transfer function employed for the neurons. When a sigmoidal function is used for ***f***, such as the hyperbolic tangent function (it is the case of the present work), the reservoir is called an echo state network (ESN).

The output layer units (***y***) in RC (readouts) are computed as a simple linear combination of the reservoir states (***x***):

$$\boldsymbol{y}(t) = \boldsymbol{W_{out}} \cdot \boldsymbol{x}(t) \qquad \text{(eq. 5)}$$

where ***Wout*** corresponds to the matrix of output connection weights.

The recent study of Rodan and Tino (2011) shows that a simple reservoir where the neurons are organized in a cycle as illustrated in Fig.1 (b) is practically equivalent to the original reservoir structure with random connections of Fig.1 (a). The connections between internal units in the reservoir have the same weight value *r*. The input layer is fully connected to the reservoir with a connection weight that is positive or negative with equal probability and with the same absolute value for the weight (*v*). Parameters *r* and *v* must be scanned in order to find the best performing weight configuration. This conveniently simple RC topology, known as the simple cycle reservoir (SCR) is the one employed in the present article. For more details about this approach, see the work by Rodan and Tino (2011) or that by Alomar et al. (2016).

RC can be viewed as an expansion (or kernel) method similar to the support vector machine (SVM) approach (Burges, 1998) where the input signal is projected to a higher dimensional state space through the nonlinear dynamics of the reservoir recurrent network. The expanded feature vector (***x***) composed of the reservoir states can be finally readout with a linear method to get an estimation (***y***) of the desired output function. However, it must be noted that apart from producing a nonlinear transformation of the input signals, RNNs (unlike SVMs or FFNNs) have the capability to learn a temporal task. That is, to set a relationship between the desired output value and the input history.

2.3. Data description

A 5-year recording (from 1 July 2007 to 30 June 2012) of GSR and temperature values derived from satellite data for a location in Almeria has been used for training and testing the different models (conventional regression models and RC networks). These data are freely available on the internet (SolarGis, 2016). The original data provided with a 15-minute time basis have been integrated to obtain daily values. The resulting time-series are shown in Fig. 2 and Fig. 3. All input signals (T_{max}, T_{min}, H_o) have been normalized to the [0, 1] range before being processed by the RC network. The first 4 years of data have been used as training set for calibrating the models while the last year has been employed for testing them.

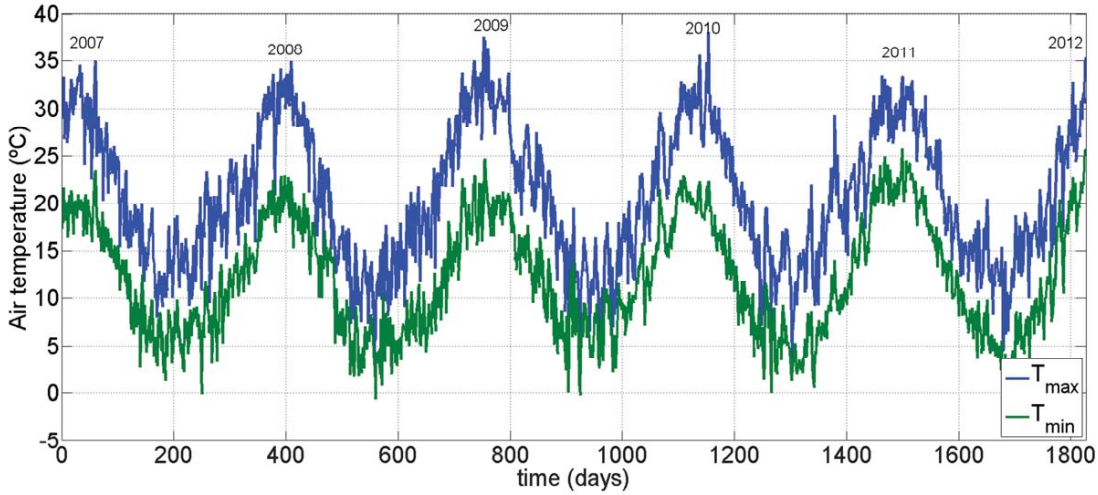

Fig. 2: Daily maximum and minimum temperature values employed as input data to estimate the GSR.

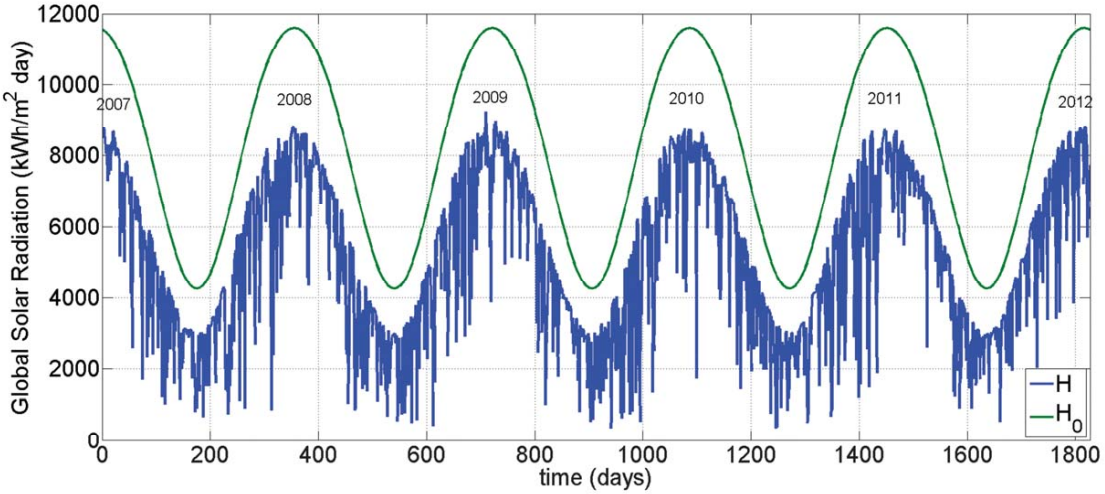

Fig. 3: Observed daily GSR (*H*) along with the daily total extraterrestrial radiation (H_0) calculated using standard geometric procedures from the latitude of the location.

3. Results

A number of network combinations using different parameters as inputs (T_{max}, T_{min}, T_{mean}, $\delta T=T_{max}$,- T_{min}, H_0) and different numbers of units (30, 50, 70 and 100 neurons) have been tested. The performance of the various models has been assessed according to various statistical errors: normalized mean-square error (NMSE), normalized root mean-square error (NRMSE), coefficient of determination R-squared (R^2), root mean-square error (RMSE), mean-square error (MSE), mean absolute error (MAE) and mean bias error (MBE).

Two network configurations have been found to perform the best, both using 50 neurons. The first model (which we call "RC-1") employs a single input (δT) to estimate the ratio H/H_0 (desired output). That is, a linear dependence between H and H_0 is assumed. The second model ("RC-2") utilizes two input signals (δT and H_0) for modeling H as output function. Any other combination of variables used as input signals have resulted in less accurate estimations. The test error results of both RC-based models compared to those of the standard regression methods are presented in Tab.1 where "Regress1" corresponds to the Hargreaves model and "Regress2" to the Bristow-Campbell model. It can be appreciated that both RC-based models are practically equivalent, which indicates that assuming that H is directly proportional to H_0 seems adequate.

On the other hand, it can be observed that, as expected, the proposed RC-based models exhibit a higher accuracy than the conventional regression-based empirical methods. Only for the case of the MBE one of the conventional models provides a lower error than the RC-based models. However, it must be mentioned that the MBE is not a good indicator of the estimations' accuracy but just of the error bias.

The function fitting performed by one of the proposed models ("RC-1") is finally illustrated for the test set (one year of data) in Fig.4.

Tab. 1: Statistical evaluation of the conventional (regression-based) and proposed (RC-based) models for the test data set.

Model	NMSE	NRMSE	R^2	RMSE ($Wh/m^2 \cdot day$)	MSE ($(Wh/m^2 \cdot day)^2$)	MAE ($Wh/m^2 \cdot day$)	MBE ($Wh/m^2 \cdot day$)
Regress1	0.2467	0.4967	0.7533	1053.90	$1.18 \cdot 10^6$	836.82	237.61
Regress2	0.2201	0.4691	0.7799	995.35	$9.93 \cdot 10^5$	823.73	535.26
RC-1	0.1940	0.4404	0.8060	934.49	$8.76 \cdot 10^5$	745.03	407.08
RC-2	0.1940	0.4404	0.8060	934.48	$8.76 \cdot 10^5$	771.49	426.06

4. Conclusions and future work

In this paper, we have proposed a convenient model for estimating daily global solar radiation (GSR) using temperature measurements commonly available at weather stations. The model is based on reservoir computing (RC), a particular type of recurrent neural network (RNN), which allows implicitly learning from time-series data the relation between the input and output signal. We have shown that the proposed neural approach outperforms other conventional empirical methods. The RC-based model can be calibrated for any particular desired location, which makes it useful for the simulation of solar energy systems.

Nevertheless, it is worth highlighting that the validity of the proposed approach has been tested using meteorological data derived from satellite observations assuming that such values present a similar complexity to those that might be obtained from direct physical measurements at a weather station. Therefore, it would be of high interest to further validate the proposed methodology with measured data.

Furthermore, although the presented RC models have been compared with standard methodologies (adjustable empirical equations), they have not yet been demonstrated to outperform other simpler kernel approaches, such as feed-forward neural networks (FFNNs). Finally, it could be an interesting step for the future analyzing whether GSR estimations can be improved by including other input parameters different from temperature, such as humidity and precipitation, which are also often available at most weather stations.

Abstract

To properly operate Central Tower Solar Power (CTSP) plants, collection systems must work under appropriate weather conditions. Therefore, knowing the state of the atmosphere, and more specifically the level of incident radiation, is a very valuable information for the operation, to adapt the system for electricity production to atmospheric conditions. Sky cameras have emerged as terrestrial point technologies that can observe the changes produced in short-time intervals. In this work, we have estimated Direct Normal Irradiance (DNI) using a total sky camera (TSI-880 model) under high dust load to study its effect in the DNI estimation, for next compare the results with a cloudless day without these attenuator particles. Furthermore, a CL-51 Vaisala ceilometer was used to identify the presence of this dust concentration in the atmosphere.

Keywords: *Solar radiation estimation, Atmospheric attenuation, Central tower solar power plants, Sky camera, LIDAR*

1. Introduction

The great majority of CTSP plants are in areas with low or medium probability of occurrence of clouds, but high probability of occurrence of episodes of high concentrations of aerosols or dust intrusion. That is why it is necessary to include both factors of a correct evaluation and prediction of the values of direct radiation in the receiver of the tower.

Sky cameras have been used to characterize the atmosphere from a terrestrial point. Its technology makes can be installed in any geographical location, providing a hemispheric view of the sky in real time. Subsequently, many researchers have used these cameras for cloud detection (Alonso et al., 2014) and solar irradiance estimation (Alonso-Montesinos and Batlles, 2015). In that case, atmospheric constituents play also an important role in the radiation attenuation and must be take into account in the solar irradiance estimation.

On 22nd February 2016, an intense episode of Sahara dust intrusion took place in almost all of the Iberian Peninsula, reducing visibility drastically and producing a remarkable dust deposition. In the southeast, Almería was particularly affected by the event (Alonso-Montesinos et al. 2016). Having a sky free of clouds, the DNI estimation was carried out, obtaining a results very distant than in a normal cloudless sky.

doi:10.18086/eurosun.2016.09.05 Available at http://proceedings.ises.org

Therefore, in this work, we present the influence of the concentration of dust particles in the DNI estimation using a total sky camera (TSI-880 model). To ensure the presence of this dust deposition in the lower atmosphere layers, LIDAR data were used from a CL-51 Vaisala ceilometer, obtaining different atmospheric parameters for the days studied.

2. Data

Radiation data were obtained from a radiometric station placed at CIESOL at the University of Almería, Spain (36.8ºN, 2.4ºW, at sea level), at the same time that total sky images (from TSI-880 sky camera) have also collected. The hemispheric vision was represented in JPEG (joint photographic expert group) images, with a 352x288 pixel-image resolution. Furthermore, CL51 Vailasa data were used. Fig. 1 shows the instrumentation in the rooftop of the CIESOL building.

Fig. 1: Total sky camera, TSI-880 model and CL51 Vaisala ceilometer placed in the rooftop of the CIESOL building at the University of Almería

3. Methodology and results

In this section, a particular episode occurred in the southeast of Spain is presented where dust particles appeared over Almería, provoking a decrease in the Direct Normal Irradiance (DNI). Therefore, a case study was performed for estimating DNI using a total sky camera under this special situation. The estimations for this turbid day were compared with the estimations for a clear day, obtaining representative conclusions. Furthermore, CL51 Vaisala ceilometer data were used to contrast the causes of the DNI decreasing.

The importance of this study comes from the special interest of CTSP plants, which need to measure the DNI attenuated in the lower layers of the atmosphere. Therefore, one of the main goal of these plants is to model the irradiance losses between the heliostats and the receiver placed at the top of the tower.

3.1 Turbid day vs clear day

As the idea of this paper is to determine the influence of dust particles in the estimation of DNI with total sky cameras, two contrasted days were selected. The first day was conditioned by a high concentration of Saharan dust particles in the atmosphere (22nd February 2016). For the second day, we tried to choose a clear day in the same date but in other years, obtaining it on 22nd February 2012. Fig. 2 shows the difference of DNI measurements for both days:

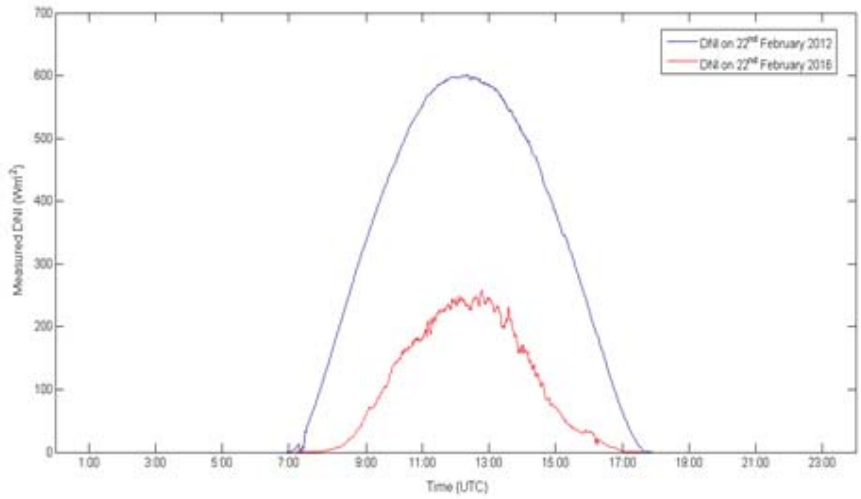

Fig. 2: Representation of measured DNI curves for the days 22nd February 2012 and 22nd February 2016

As seen, the DNI measured for the two days presented an important difference along the day. This difference was also captured by the total sky camera where the digital image levels were also very different. Fig. 3 shows the difference between the two sky camera images:

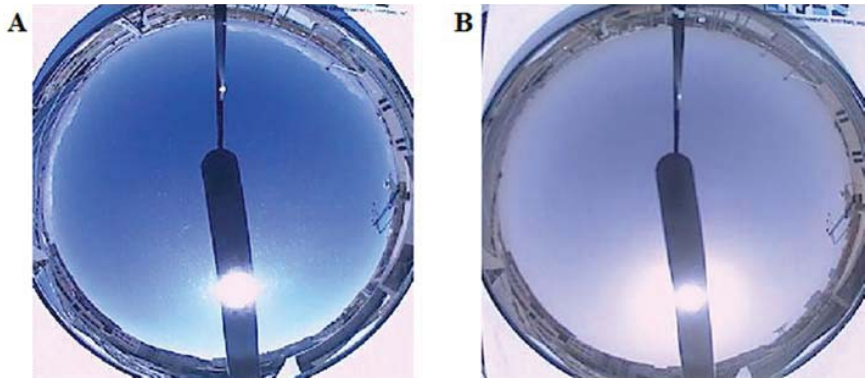

Fig. 3: Sky representation using a TSI-880 sky camera. The image A represents the sky on 22nd February 2012 at 12:00 Universal Coordinated Time (UTC), and image B on 22nd February 2016 at 12:00 UTC.

In the previous images, the blue sky presents a different appearance: in the picture A the sky appears in a more intense blue; whereas in the picture B, the sky appears with another blue tone (cloudier). Having this difference, the objective was to study the influence of the dust presence in the DNI estimation. Subsequently, the idea was to see how the atmosphere was composed in the lower layers with the CL51 Vaisala ceilometer. As Vaisala was installed in the CIESOL building in 2014, there was not data available from 2012. Then, a day with similar DNI was searched, finding 1st March 2016 like the most suitable. Figure 4 represents the DNI curves for 22nd February 2012 and 1st March 2016 to see that the DNI values had a similar trend in the two days:

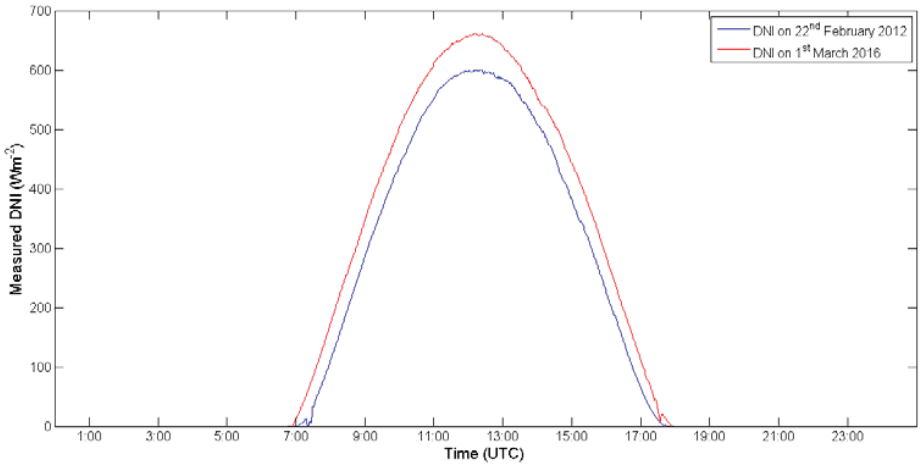

Fig. 4: Representation of measured DNI curves for the days 22nd February 2012 and 1st March 2016

The DNI on 1st March presented higher values than 22nd February, indicating a clearer day. Therefore, the first day of March was selected like the clear sky for comparing with 22nd February 2016 (dust episode). Figure 5 shows an image for the selected day, where blue sky does no present any perturbation in the atmosphere due to dust particles apparently.

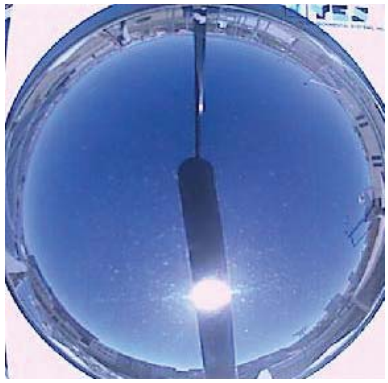

Fig. 5: Image from TSI-880 sky camera on 1st March 2016 at 12:00 (UTC)

3.2 DNI estimation using a total sky camera

According to methodology presented in Alonso-Montesinos and Batlles, (2015) and Alonso-Montesinos et al., (2015), the DNI was estimated using TSI-880 sky images for the two studied days: 22nd February 2016 and 1st March 2016. The first one presented the concentration of Sahara dust particles; whereas the second one was a cloudless sky where dust particles do not appear.

Digital image levels are used to estimate a DNI value. For DNI, not all pixels are processed; only pixels in the sun area. As the sun area has not always the same size, a radius which covers the solar area is obtained in function of the solar altitude angle (α), following the next expression:

$$Radius = -0.9646\,\alpha + 99.2986 \qquad \text{(eq. 1)}$$

Figure 6 represents the solar area detected for a cloudless moment, where the red circle represents the sun area to estimate the DNI.

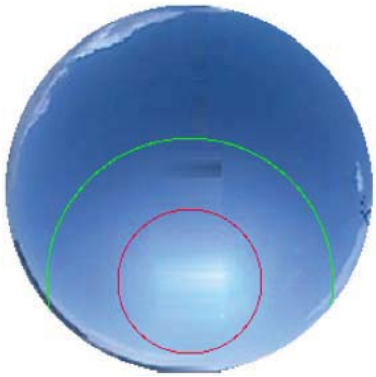

Fig. 6: Image from TSI-880 sky camera, where different areas are established to do the estimation of radiation.

After that, using digital image level correlations and the solar altitude angle, each pixel belonging to the red circle acquires a DNI value following the methodology described in the previous cites. Finally, the mean value of the total pixel estimations represents the DNI.

From sunrise to sunset, images from the sky cam were processed every minute. For all results, different parameters were obtained: RMSE given by Eq. (2) and expressed in (Wm^{-2}); nRMSE given by Eq. (3) in (%); MBE given by Eq. (4) and expressed in (Wm^{-2}); nMBE given by Eq. (5) in (%) and R given by Eq. (6) (dimensionless):

$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(DNI_{est} - DNI_{mea})^2} \quad \text{(eq 2)}$$

$$nRMSE = \left[\frac{RMSE}{DNI_{max} - DNI_{min}}\right] 100 \quad \text{(eq 3)}$$

$$MBE = \frac{1}{N}\sum_{i=1}^{N}(DNI_{est} - DNI_{mea}) \quad \text{(eq 4)}$$

$$nMBE = \left[\frac{MBE}{DNI_{max} - DNI_{min}}\right] 100 \quad \text{(eq 5)}$$

$$R = \frac{\sigma_{DNI_{est}DNI_{mea}}}{\sigma_{DNI_{est}}} \quad \text{(eq 6)}$$

where DNI_{est} is the DNI estimated, DNI_{mea} is the DNI measured, DNI_{max} is the maximum observed DNI value, DNI_{min} is the minimum DNI value, $\sigma_{DNI_{est}DNI_{mea}}$ is the covariance of the two input data sets (the estimated and measured radiations), $\sigma_{DNI_{est}}$ is the standard DNI_{est} deviation and $\sigma_{DNI_{mea}}$ is the standard DNI_{mea} deviation. Tab. 1 shows the numerical results:

Tab. 1: DNI estimation results for the two day analyzed: 22nd February 2016 (turbid day) and 1st March 2016 (clear day).

Day	RMSE (Wm^{-2})	nRMSE (%)	MBE (Wm^{-2})	nMBE (%)	R
22nd February 2016	192.87	50.36	-141.35	-36.91	0.27
1st March 2016	137.68	16.17	50.13	5.89	0.95

As seen, the results on February presented an nRMSE value higher than on March in a value of 30%. Furthermore, the nMBE presented a high difference; on February, the DNI was underestimated, with a mean value of -37%; whereas on March, the value was lower than 6%. The underestimation was consequence of the classification of pixels. In the February's case, the pixels were classified like overcast due to the digital image level of the pixels that belong to the red circle, and therefore, the DNI estimation was done for an overcast day. As seen, the DNI estimation model is only based on the image digital values without considering atmospheric measurements. By this reason, in a free cloud day, the appearing of dust situations provokes that the model presents results very far than for typical cloudless skies. Therefore, CL51 Vaisala ceilometer data were used to see the behavior of the atmosphere, having another tool which could improve the solar radiation estimation.

3.3 Determination of atmospheric factors using a LIDAR ceilometer

CL51 Vaisala ceilometer with LIDAR technology, provides atmospheric information (from 0 to 4 kilometers) related to aerosol presence and visibility, and gives indirect information to calculate some atmospheric factors. Therefore, with the data collected, it is possible to identify the main attenuation factors helping to improve the solar radiation estimation models.

In the case of study of this paper, the profiles for the two analyzed days were studied, and the complete distributions are presented in Fig. 7, where it is shown the evolution along the whole day of the attenuated backscatter intensity (ABI) profiles from ground up to 4 km:

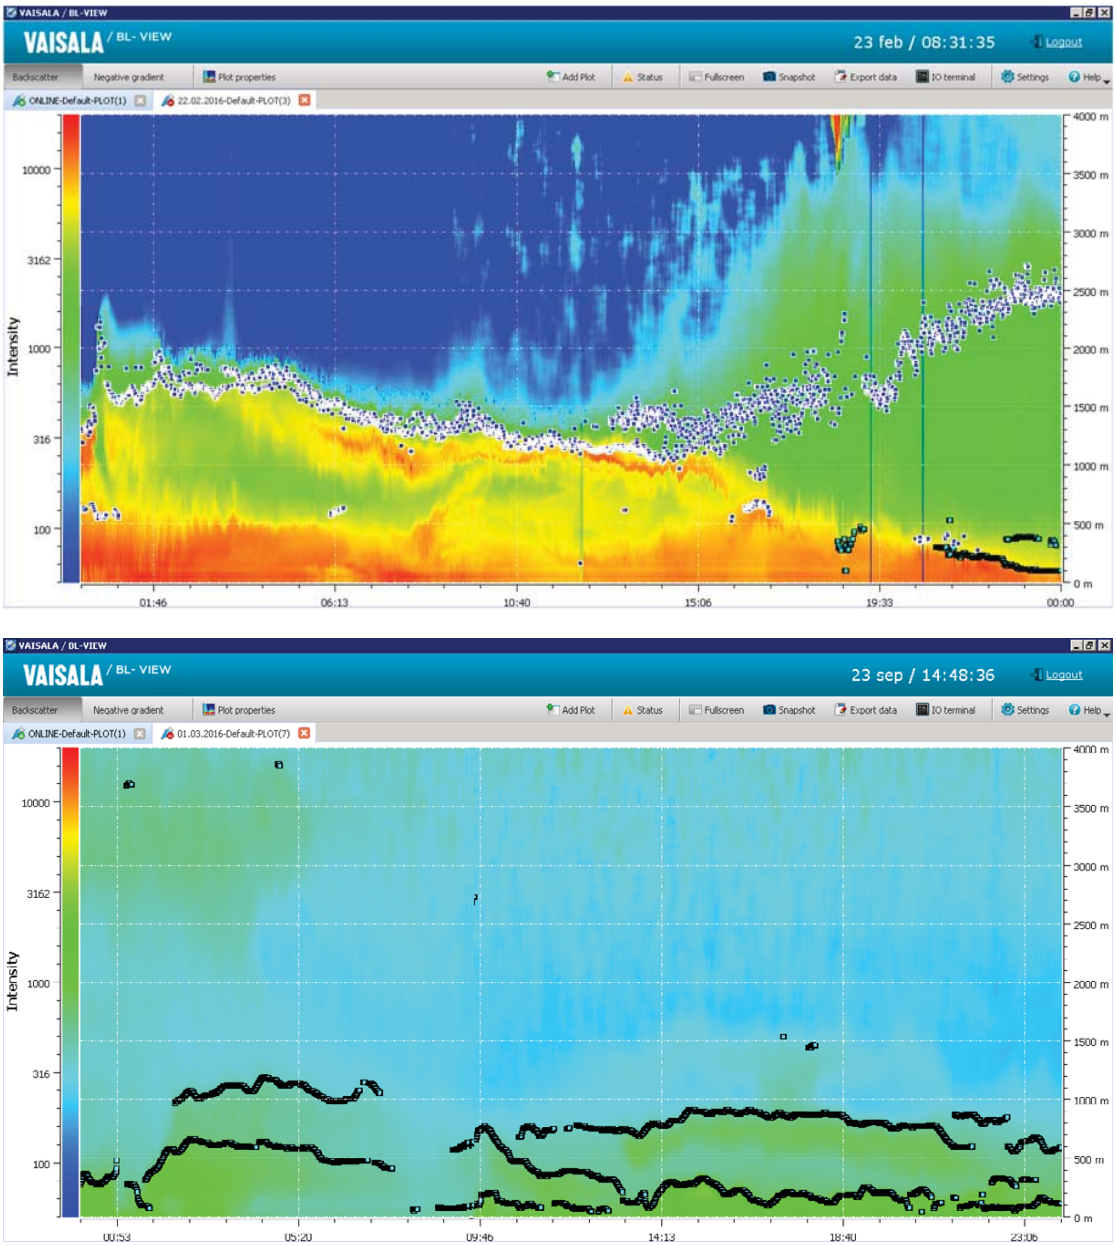

Fig. 7: CL51 Vaisala ceilometer profiles: the upper image represents the profiles on 22nd February 2016, and the other one represents the profiles on 1st March 2016

In this figure, important information is extracted for the two days. In the case of 22nd February, the most relevant data are presented below:
A nearly static dust layer 500 meters thick appears. With the sunrise, the surface temperature rises and this layer expands up to the boundary layer. Another thin layer, in the upper limit of the residual boundary layer appears floating on the boundary layer. From 16:00 UTC to the end of the day, the two layers precipitate progressively, appearing an expanding region of intermediate Attenuated Backscatter Intensity (ABI) values (in green) reaching up to 4 km in altitude.
For the analyzed case on 1st March, the atmosphere presents clear profiles (low intensity values) along the day. Perhaps, from 14:00 hours to midnight, a higher concentration of particles appears in the lower atmospheric layers (from 0 to 250 meters) but in a lower degree than on 22nd February. However, this first day of March can be considered like a very clear day.

As seen, the most important successes occurs in the lower layers (being more representative from 0 to 250 meters, approximately). Taking into account the interest of CTSP plants in the study of the sky conditions in these lower atmospheric layers to quantify the DNI losses between the heliostats and the receiver placed at the top of the central tower, these layer are analyzed. Furthermore, the first 250 meters are enough to measure the losses, covering the higher towers built in the plants.

Therefore, the inclusion of LIDAR information in DNI estimation models can improve the accuracy of that. For this reason, different atmospheric factors have been obtained from LIDAR measurements. Subsequently, ABI has been analyzed with the aim to determine the Meteorological Optical Range (MOR) and the Aerosol Optical Thickness (AOT) from 0 to 250 meters. Concretely, the profiles were obtained at midday (12:00 UTC) for an average time of 20 minutes in the two selected days.
The extinction coefficient (K_{ext}) is obtained solving the ceilometer equation, for a given profile, taking a particular Lidar Ratio (LR). The LR is a variable which depends on the aerosols and the water vapor, being 33 $(Wm)^{-1}$ for a cloudless sky by the manufacturer. Figure 8 represents the K_{ext} coefficient on 22nd February.

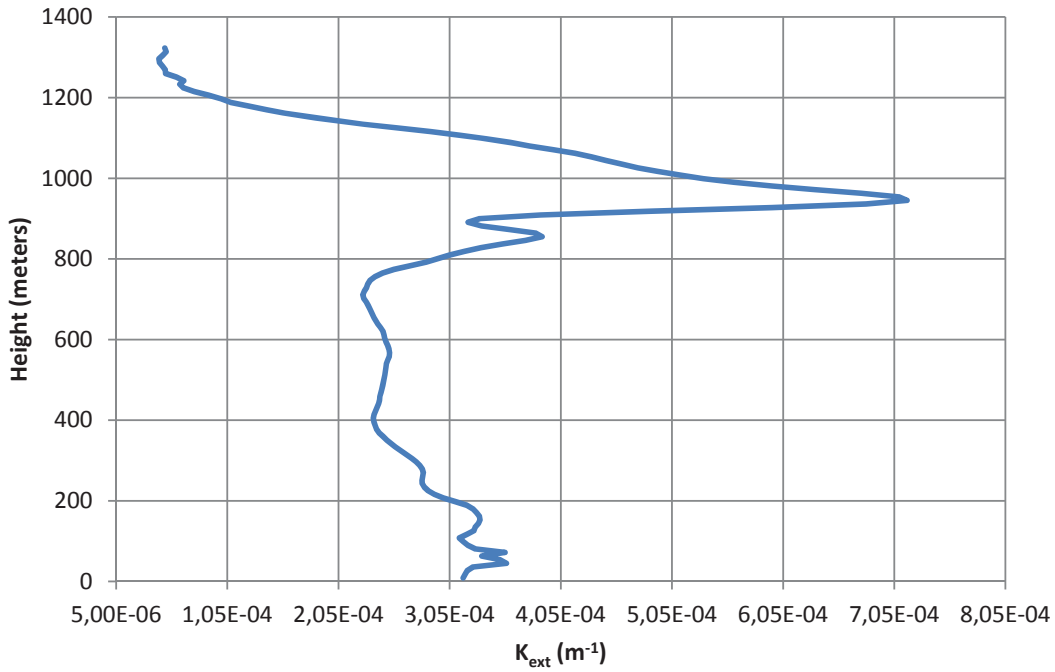

Fig. 8: K_{ext} profile obtained from CL51 Vaisala ceilometer on 22nd February 2016 at 12:00 UTC

Analyzing the graph, the coefficient shows similar values in the lower atmospheric layers (until 500-600 meters approximately), having a high dispersion from 800 to 1300 meters. It means that the atmospheric composition was homogenous in the low layers with a K_{ext} coefficient value between $2.5E^{-04}$ and $3.5E^{-04}$; and next, the homogeneity changed significantly. For comparing this day with the clear studied day, Figure 9 shows the K_{ext} profile on 1st March 2016:

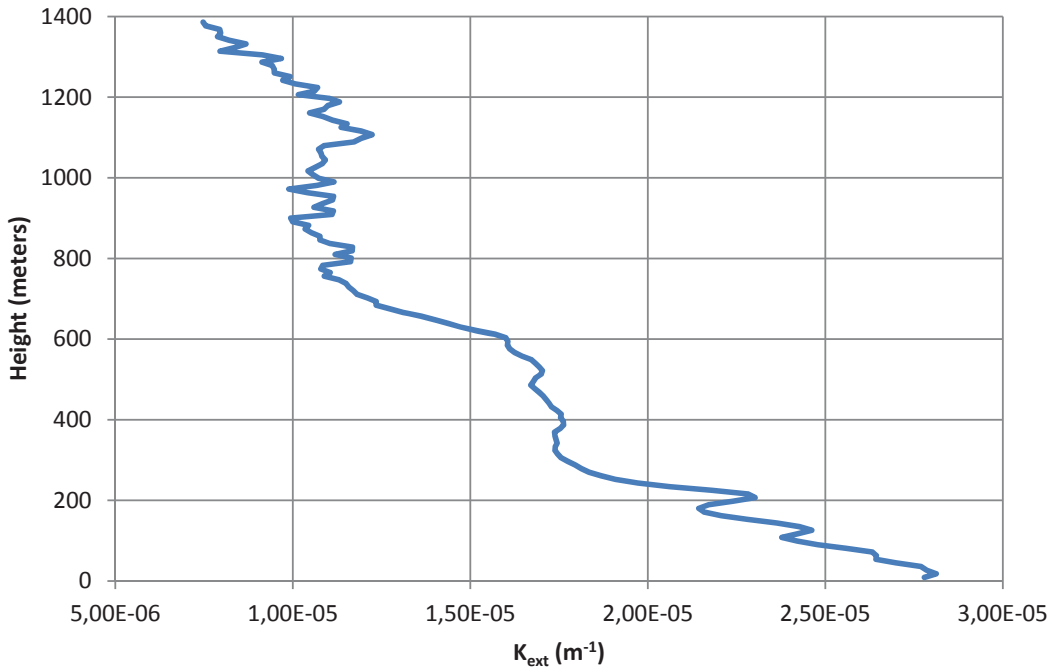

Fig. 9: K_{ext} profile obtained from CL51 Vaisala ceilometer on 1st March 2016 at 12:00 UTC

In this case, the K_{ext} values were lower than the values registered on February. For the first 250 meters, the K_{ext} values presented a decrease, reaching values between $2.8E^{-05}$ for 9 meters and $1.9E^{-05}$ for 250 meters.

The MOR (expressed in meters) was also calculated following the next equation:

$$MOR = \frac{3}{K_{ext}} \qquad \text{(eq 7)}$$

Together with the averaged K_{ext} values and the MOR parameter, the AOT was obtained integrating the K_{ext} into the first 250 meters. As the CL51 ceilometer profiles are retrieved every 9 meters, we integrated the coefficient from ground to 252 meters (multiple of 9). Table 2 shows the summary of variables for the two days:

Tab. 2: Atmospheric variables obtained from CL51 Vaisala LIDAR ceilometer from ground to 252 meters

Day	K_{ext} (m^{-1})	MOR (Km)	AOT (910nm)
22nd February 2016	$3.19E^{-04}$	9.40	$8.04E^{-02}$
1st March 2016	$2.40E^{-05}$	125.00	$6.05E^{-03}$

The results show a significant difference between the two analyzed days: in the case of 22nd February, the K_{ext} coefficient was higher than on March, and consequently, the MOR was different too. In the case of February, the dust particles provoked that the MOR decreased until 10 Km approximately, whereas for the case of March, with a clean atmosphere, the MOR was higher than 120 Km. The AOT obtained at 910 nm was also lower under a clear sky, presenting a value of $8.04E^{-02}$ with the presence of dust particles, and $6.05E^{-03}$ for a very clear atmosphere in the lower layers.

Therefore, considering LIDAR measurement, the DNI estimation can be improved taking into account the attenuation coefficients in the processing of total sky images. The coefficients calculated can help to determine the optical properties of sky cam images depending on the contamination degree which appears in the digital image levels. With that, the interpretation of the pixel like cloudless or overcast is improved, and the consequent DNI estimation too.

4. Conclusions

In this work, a Sahara dust episode occurred the last 22nd February 2016 has been studied and compared with a totally clear day (1st March 2016) using a TSI-880 total sky camera and a CL51 Vaisala ceilometer with LIDAR technology.

The DNI was estimated using the TSI camera for the two studied days using the digital image levels. On 22nd February, where the intensity of dust particles was very high, the nRMSE value was higher than 50%, whereas the nMBE value presented an underestimation of 37%. The other day, 1st March 2016, presented an atmosphere free of dust particles, and the DNI estimation presented better results, where the nRMSE value was of 16% and the nMBE was lightly overestimated, with a value of 6%. In this case, the R coefficient presented also good values. Therefore, the results show that the nRMSE can differ in more than 30% under cloudless skies, if particular episodes, like the scenarios presented on February, appear.

LIDAR data from the CL51 Vaisala ceilometer have been used to obtain atmospheric parameters. K_{ext}, MOR and AOT were obtained for the turbid and for the clear day, showing a high difference. In the case of K_{ext} and AOT the values were lower in the clear day, and the MOR presented lower values in the turbid day.

As seen, dust particles have an important impact in the solar irradiance. Depending on the particle load, the attenuation of solar radiation can be more or less important. Theferore, the DNI estimation with sky cams can be improved using LIDAR data, where the atmospheric parameters are quantified, helping to identify the correct classification of pixels and, consequently, improving the solar irradiance estimations.

Abstract

In this work we analyze the impact of a strong Saharan dust intrusion on the DNI registered at two sites in the southeast of Spain: University of Almería (UAL) and Almería Solar Platform (PSA) located in Tabernas (Almería). Direct normal irradiance (DNI) modelling with ESRA procedure presents high Linke turbidity values, being extremely high at the first site. DNI simulations using SMARTS code in the PSA emplacement, using AERONET data from PSA and maximum desert aerosol type, show a great accordance with the measured DNI values. In the UAL emplacement, SMARTS simulation of DNI values seems also to be compatible with maximum desert aerosol type aerosols. Visibility values are in good accordance with the extinction coefficients derived from the CL51 ceilometer profiles.

Keywords: *Aerosol optical depth, solar irradiance estimation, DNI simulation, atmospheric attenuation*

1. Introduction

On 21st and 22nd February 2016, an intense episode of Saharan dust intrusion took place in almost all of the Iberian Peninsula, reducing drastically the visibility and producing a remarkable dust deposition. Southeast, where the University of Almería (UAL) and the Almería Solar Platform (PSA) are located, was particularly affected by the event. Fig. 1 shows that relevant entrance of dust in the coast of Almeria region.

doi:10.18086/eurosun.2016.09.10 Available at http://proceedings.ises.org

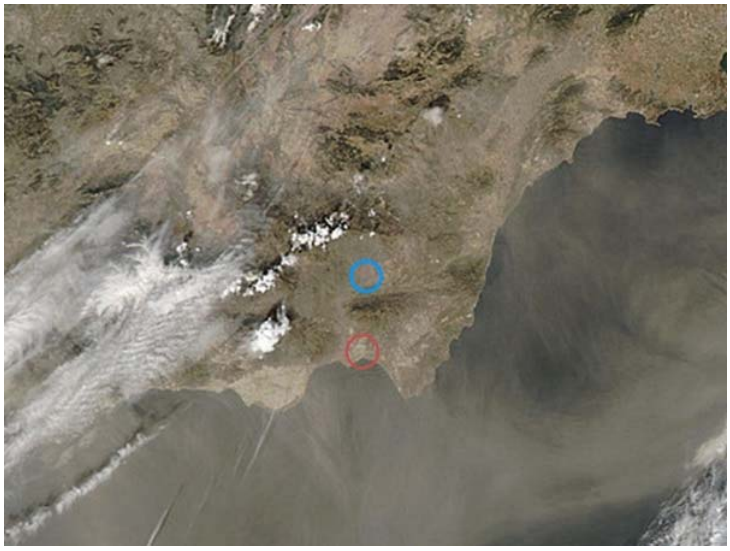

Fig. 1: MODIS satellite image for Almeria and surroundings on 22nd February 2016. Blue circle denotes PSA site. Red circle, the UAL site.

Observing the previous image, an evidence mineral dust load comes from the south, reaching a higher concentration of dust particles in the coast than in the PSA site. This feature can be also seen in the next image, where the sun reaches a heliostat and the sun's reflection is attenuated gradually due to the presence of concentrated Saharan dust.

Fig. 2: This figure shows the low visibility and the light scattered by the large particles in the atmosphere on 22nd February 2016 at 14:30 in PSA. Solar radiation reflected by the heliostats is attenuated by scattering.

Other African-dust episodes reaching Europe, even at high latitudes have been described so far (Kambezidis et al, 2012). 22nd February was a clear day, almost from sunrise to 14:00 h (when some high clouds appeared, affecting the DNI measurements), and this work analyzes the influence of the high turbidity on the DNI values for both sites. Figure 3 shows the HYSPLIT predicted back-trajectories for the studied area. The HYSPLIT model results corroborate the evidence of an air mass with coarse aerosols particles that enters the Iberian Peninsula from the Sahara desert.

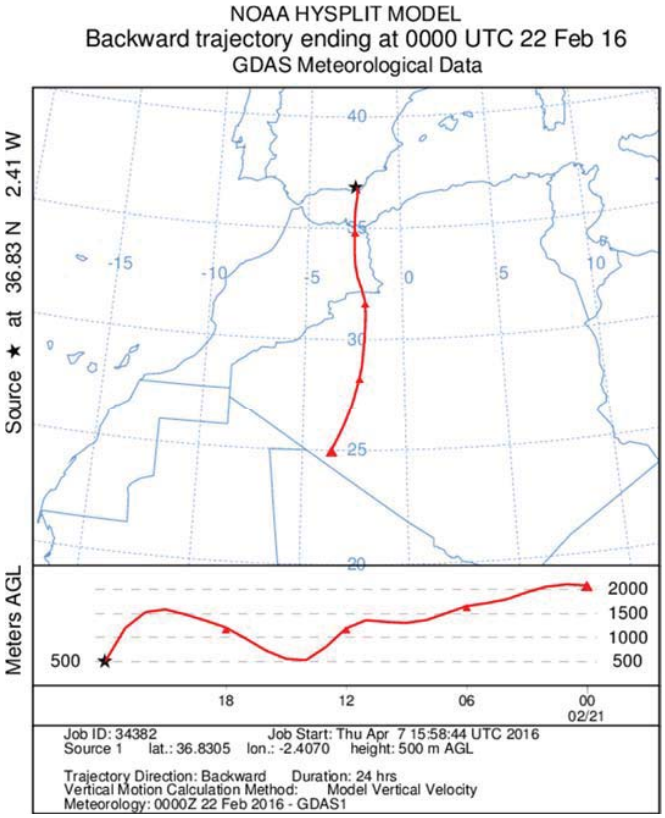

Fig. 3: HYSPLIT back trajectories

2. Data

DNI was measured at UAL station (36.8304º N, 2.4071º W, 0 m above sea level (ASL)), whereas, measurements at PSA (37.0949º N, 2.3614ºW, 550 m ASL) comprised both DNI and aerosol optical thickness (AOT) from the AERONET station.
Figure 4 shows the DNI ground measurements registered during 22nd February in both sites.

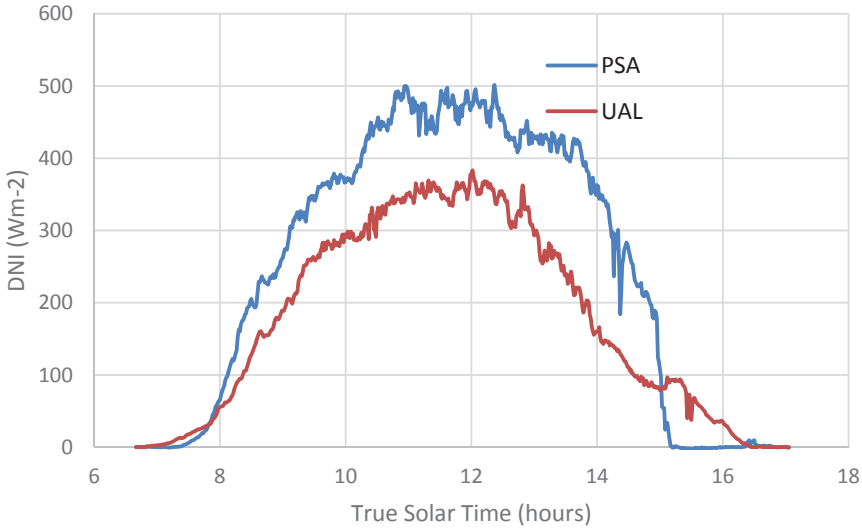

Fig. 4: DNI from PSA and UAL on 22nd February 2016

DNI values show that the daily profiles do not correspond to a clear sky situation for the whole day. After noon there is a clear decrease in DNI not related with an increase of dust concentration (as showed in Figure 4); when upper clouds appeared in the atmosphere. Figure 5 shows the presence of clouds in the solar area and in the surroundings at 16:00 True Solar Time (TST).

Fig. 5: Total sky image on 22nd February 2016 at 16:00 TST

In Figure 6, we show the evolution along the whole day 22nd of the attenuated backscatter intensity (ABI) profiles from ground up to 4 km registered by a CL51 ceilometer (Vaisala), located at the UAL.

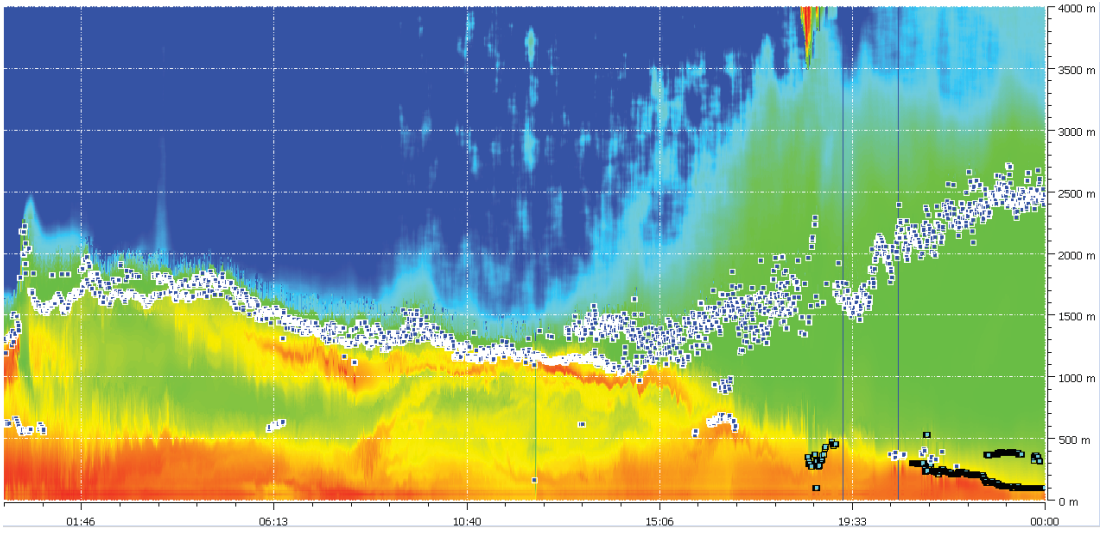

Fig. 6: Attenuated backscatter profiles from CL51 ceilometer at Almeria University

In this figure we observe:

- A nearly static dust layer 500 m thick from the previous day and through sunrise. As the surface temperature rises, this layer expands into the boundary layer.
- Another thin layer, in the upper limit of the residual boundary layer of the previous day, floating on the day 22nd boundary layer. Both layers together, progressively precipitate from 16:00 h through the end of the day.
- An expanding region of intermediate ABI values (in green) reaching up to 4 km in altitude.

3. Methodology and results

In this section the study of a particular case of Saharan dust is presented for two southeastern Spain locations: PSA and UAL.

Figure 7 shows the evolution of Aerosol Optical Thickness (AOT) at PSA site, where the measurements were offered by the AERONET station at 1.5 level for 22nd February.

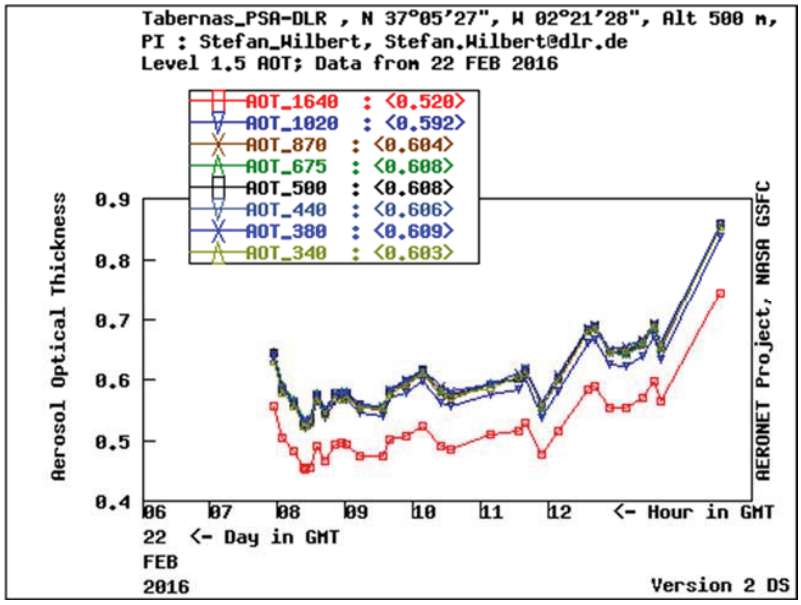

Fig. 7: AERONET AOT at 1.5 level measured at PSA

From the AERONET data, the mean daily value for the Angström turbidity parameter was $\beta \sim 0.6$, indicating an important load of coarse mode aerosols. According to Fig. 7, the AOT values showed an increasing trend along the day.

After that, the first goal was to determine the Linke Turbidity (T_L) under these particular sky conditions. Subsequently, the ESRA clear sky model (Rigollier et al., 2000) was used to obtain a representative T_L factor according to DNI values from PSA. The air mass was set to 2 and the results showed an average T_L of 8.2 (Fig. 8).

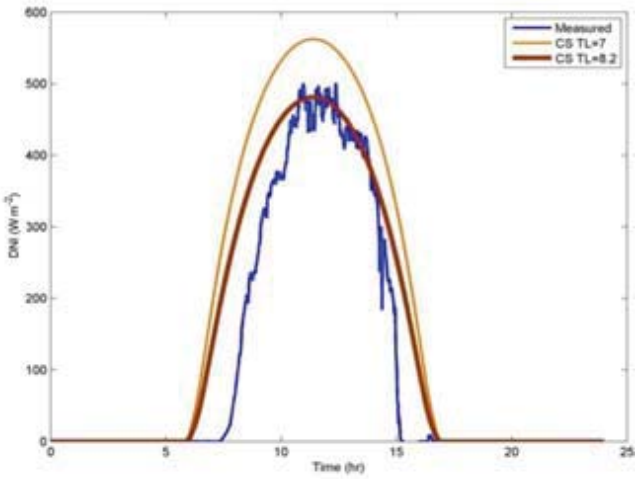

Fig. 8: PSA DNI and ESRA clear sky model using T_L factor of 7 and 8.2 for PSA site on 22nd February 2016

The use of ESRA model for computing Linke turbidity at air mass 2 is required for comparing the results with the estimation of T_L at air mass 2 from the AOT and water vapor using the Ineichen approach (Ineichen, 2008). The estimation of Linke turbidity from inverting the ESRA model is in agreement with the AERONET data. Thus, using the Ineichen model, T_L is computed from AOT and water vapor. AERONET measurements resulted in a mean T_L value of 7. The differences between the estimations of T_L from DNI data and from AERONET are expected taking into account the strong dynamism of the aerosol loading phenomena and the different time stamp between AERONET and pyrheliometer measurements.

Analyzing this factor at UAL emplacement, the estimated T_L was of 10.5, which is an extremely high value. Fig. 9 represents the measured and estimated DNI values using the T_L factor estimate of 10.5.

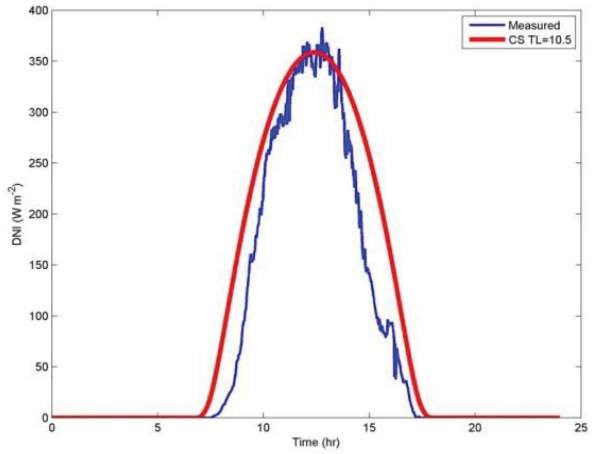

Fig. 9: UAL DNI and ESRA clear sky model using T_L factor of 10.5 for UAL site on 22nd February 2016

3.1 SMARTS simulations

Figure 10 shows the evolution of the AOT at 500 nm and the Angström exponent at (440-675) nm for 4 consecutive days, starting on 22nd February, date where the dust intrusion took place. The AOT values for 22nd February are extremely large, around 0.6, indicating the high aerosol concentration. After two days, the AOT levels diminish to values of about 0.05 corresponding to the clean conditions at the PSA. The atmospheric dust has a large attenuating effect on the solar energy reaching the ground, with a reduction of about 50%. To note, the effect of turbidity is only observed on the first half of the day. In the afternoon, the cloudiness fully blocks DNI, showing values near 0 Wm^{-2}. Besides, the Angström exponent provides useful information about the size distribution of aerosols (Eck et al., 1999). α- values obtained from the spectral band (440-675) nm close to 0 are mainly associated with desert dust. From Fig. 8 it is observed the temporal evolution of α, where zero values appear for the beginning of the dust intrusion increasing until reaching typical values of 1.2-1.3 on 25th February.

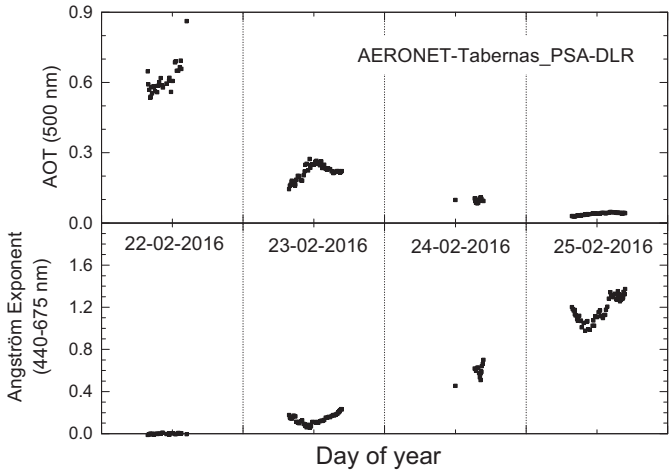

Fig. 10: Time-series of AOT at 500 nm (upper panel) and Angström exponent at (440-675) nm (lower panel) obtained with the AERONET-Cimel at Plataforma Solar de Almería (Spain). Cimel data are AERONET level 1.5 data.

To investigate the type of aerosol, DNI simulations using the SMARTS code (Gueymard, 1995) were carried out. Four different aerosol models available in SMARTS were selected (Tab. 1): the tropospheric aerosol model defined by Shettle and Fenn –"S&F Tropospheric"-, the Maritime aerosol model of the IAMAP preliminary standard atmosphere –"SRA Maritime"-, the "Desert_min" option corresponding to normal conditions in desert areas and "Desert_max" corresponding to extremely turbid conditions.

Tab. 1: Daily mean values of the Angström exponent and the meteorological optical range (MOR) given by SMARTS for the 4 aerosol models considered in this work and corresponding to 22nd February.

Aerosol model	α	MOR (km)
S&F Tropospheric	1.3	14
SRA Maritime	0.24	12
Desert_min	1.13	14
Desert_max	0.0	11

The turbidity coefficient was the AOT (500 nm) given by AERONET. Precipitable water data derived from the sunphotometer (Cimel) was also used. Atmospheric pressure measurements were available from the PSA radiometric station. The atmospheric profile and total column amounts of other atmospheric constituents are those specified by the Mid-Latitude Summer Atmosphere. Tab. 1 shows the daily averaged mean Angström exponent and the Meteorological Optical Range (MOR) obtained from SMARTS for the four aerosol models. The MOR is similar for the four options, however the Angström exponent is different.
The S&F Tropospheric and Desert_min models are not suitable to describe the existing size distribution of aerosols since the values are 1.3 and 1.13 respectively. To compare clear and turbid skies, Fig. 11 shows the DNI measured at PSA for the very turbid day 22nd February and for the day 25th February with the clean atmosphere.

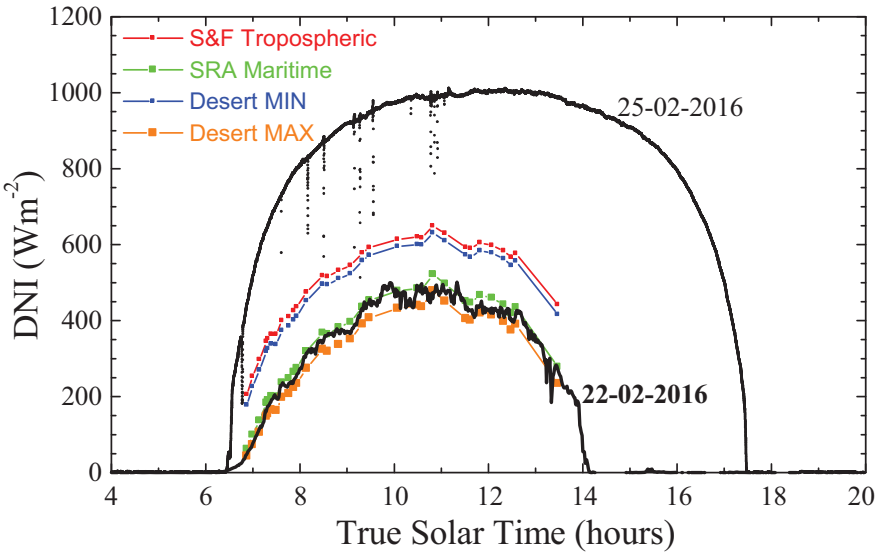

Fig. 11: DNI measured at PSA for the days 22nd February and 25th February (black dots). Simulations using Smarts code corresponding to four different aerosol models are included for the day 22nd February

In addition, the estimated DNI values using the four aerosol types for the 22nd February are also included. The DNI estimates corresponding to the two aerosol models with Angström exponent values close to the measured zero values, i.e. SRA Maritime and Desert_max, show a good agreement with the experimental pyrheliometric measurements. Since the simulated α value corresponding to the Desert_max model matches better the experimental one, this aerosol model is then selected to be representative of the main type of aerosol prevailing in this event.

In the case of UAL site, the Desert_max aerosol model was also used like in PSA site. We also used SMARTS for estimating DNI by using the AOT values derived from the Linke Turbidity factor. Using a MidLat-Summer atmosphere type, and atmospheric pressure and humidity data from the meteorological station placed at UAL, we have checked the influence on the DNI in the aerosol type:

Tab. 2: Cases for the simulation with SMARTS code of the event at UAL.

Aerosol type	AOT (500)	α	MOR (Km)
Desert_max	0.7	0.0	9.4

After obtaining direct normal irradiance values from SMARTS, the model was validated from sunrise to midday, because next to this moment the clouds appeared and SMARTS model works only under cloudless skies.

Estimated and measured values for the complete day are presented in the graph in Fig. 12:

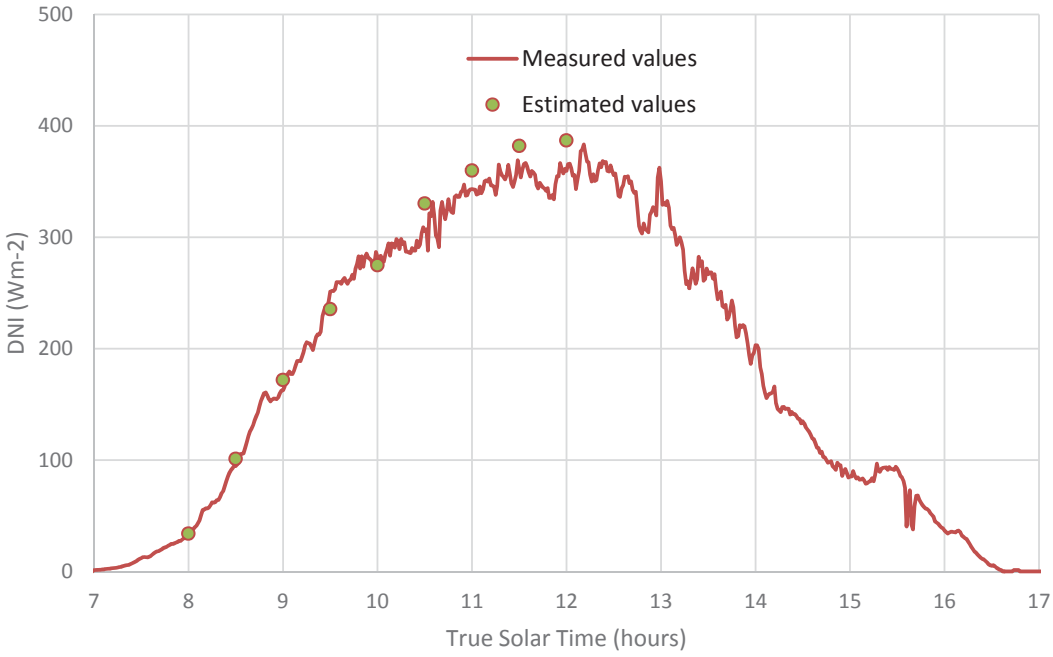

Fig. 12: DNI measured and estimated at UAL using Smarts code

Therefore, estimated DNI values show a good agreement with the measured ones in both cases, having a higher difference at 11:00 and 12:00. In these cases, the estimated values from SMARTS (green dots) presented a higher value than measured values (red line). Mainly, this difference was produced by the appearing of very thin clouds (see Fig. 1); for this reason, the DNI curve presented a different trend from sunrise to midday than from midday to sunset. Due to Saharan dust coming from the south, the saturation was higher at UAL than at PSA.

4. Conclusions

In this work we have made an exhaustive study for 22nd February 2016, with a high presence of dust particles from Sahara desert.

Linke turbidity factor was estimated for PSA and UAL through ESRA clear sky model and the measured DNI data in both sites. In the case of PSA, the best approximation was a TL value of 8.2, whereas for UAL the best value was 10.5, which are expected values for this type of phenomena.

DNI values were analyzed and estimated using SMARTS code by using AOT (500nm) measured at PSA, and desert type aerosols. Subsequently, DNI values were estimated for UAL using the Smarts code, also using desert type aerosols successfully.

In general, we have characterized an episode of turbidity using terrestrial measurements and simulations based on a clear sky radiative transference model in two south-east Spain sites, representing with satisfactory results the type of aerosol which appeared, and accurately modeling the direct normal irradiance during this phenomena. Furthermore, with the correct reproducibility of this extreme episode, the DNI estimation procedure acquires confidence and reliability under this particular sky condition.

STUDY OF SOILING ON PYRANOMETERS IN DESERT CONDITIONS

Dunia Bachour[1], Daniel Perez-Astudillo[1] and Luis Martin-Pomares[1]

[1] Qatar Environment and Energy Research Institute (QEERI), HBKU, Qatar Foundation, Doha (Qatar)

Abstract

This work presents a study of the degree of soiling on pyranometers in Qatar, a region with high amounts of dust in the atmosphere. The experiment was performed during several months including a dusty season. It consists of using two pyranometers to measure the global horizontal irradiance: one of the pyranometers was considered the reference sensor and was cleaned on a daily basis, and the other pyranometer was used as the testing one, on which different frequencies of cleaning were tested. In order to evaluate the losses in the measurements due to dust/dirt accumulation on the sensor dome, the ratio of the daily average of global horizontal irradiance measured by both sensors was calculated and analysed in function of the time passed after the last cleaning of the testing sensor. From day to day, the changes in this ratio are between 0.3% and 0.5% *per day* depending on the soiling environment of each season, with increasing changes towards summer. The relative errors (RMSE and bias) of the output of the testing sensor as compared to the reference one were also studied and show a linear increase with the time passed since the last cleaning, for the period under study. It is concluded that a schedule of daily, or every 2 days, cleaning of the pyranometer dome is advisable in order to avoid noticeable errors in the measurements. This study helps to develop an adapted quality assurance programme for sensors installed at remote sites in the desert, including an adapted cleaning schedule which takes into account the local environmental conditions.

Keywords: *solar radiation, solar measurements, pyranometers, soiling, GHI.*

1. Introduction

As solar-based projects multiply across the planet, the need for high-quality assessment of the available solar resources also increases. Solar resource assessment is needed throughout the lifetime of solar power projects, from the prefeasibility studies to the operation of the final system. Knowledge of the historical (long-term) solar climatology at the selected site is fundamental for plant sizing and bankability studies, and such historical solar data are usually obtained with the aid of long-term satellite observations site-adapted with direct, ground measurements. Real-time solar input data during the plant operation goes directly into the calculation of plant performance, as well as into forecasting methodologies. It is, therefore, evident that the solar measurements have to be accurate and trustable enough for the cited purposes.

Currently, the most accurate measurements of the solar resource can be obtained with thermoelectric radiometers. For projects based on photovoltaic (PV) technology, the solar resource is usually measured on the horizontal plane, in the form of the so-called global horizontal irradiance, using thermopile pyranometers. This type of radiometers is the one recommended by the International Organization for Standardization (ISO) and the World Meteorological Organization (WMO), to measure the global solar radiation. Pyranometers typically have one or two curved optical glass domes covering the sensor for protection and reduction of dirt or rain drop deposition. When they are used for solar resource assessment studies, the radiometers are usually installed at remote sites and left unattended to achieve continuous measurements. The instrument is exposed to the weather conditions and might accumulate substantial amounts of dirt on its dome, especially in desert

doi:10.18086/eurosun.2016.09.08 Available at http://proceedings.ises.org

regions; this is problematic since it affects the quality of the measurements and thus the resource assessment studies and solar projects relying on these data.

To obtain accurate measurements, two checks should be done daily on the sensors: alignment and cleaning of the dome. However, when the sensor is located at remote sites, it is usually difficult to follow this ideal maintenance schedule or at least to control that it is done the right way. Therefore, the study and quantification of soiling will result in a better management of a solar radiation network distributed across remote sites, and will help in terms of setting optimum rules for the frequency of sensor cleaning and for correcting the data before final processing.

While studies of the effect of soiling on PV panel performance are common (see, e.g., Urrejola et al., 2016; Maghami et al., 2016; a recent PV soiling study was carried out in Qatar by Abdallah et al., 2016), sensor soiling studies are not so abundant, but several examples can be found, like Hammond et al. (1997) in Arizona, Maxwell et al. (1999) in Saudi Arabia, Geuder and Quaschning (2006) in Spain and Morocco, Pape et al. (2009), and Wolfertstetter et al. (2014) in the north of Africa. Most of these studies focus on only determining a sensor cleaning frequency for specific sites; Geuder and Quaschning (2006) propose a method to correct for soiling which, however, requires the measurement of the beam, global and diffuse radiations and, along similar lines, Pape et al. (2009) describe an additional accessory to determine soiling rates. In a report of IEA SHC Task 46 (Wilbert et al., 2015), the soiling of a rotating shadow band irradiometer (RSI) and a pyrheliometer was studied during a period of one month in Almeria, Spain. After one month of not cleaning both sensors at this location, they found that the relative error of the uncleaned pyrheliometer follows a linear trend with an increase of around 0.7% per day, whereas the relative error of DNI measurements of the uncleaned RSI varies within the range of the reference uncertainty of ±2 %.

This work focuses on the study of pyranometer soiling and its characteristics in a region where dust is highly present in the atmosphere, and dust storms occur frequently. Qatar is embarking on its journey of using solar energy for power production and, to measure its solar resources, a network of 13 solar radiation monitoring stations will be deployed throughout the country (Mohieldeen et al., 2015). Due to the location of the stations in the desert, the sensors will be highly susceptible to soiling, thus affecting the accuracy and reliability of the measurements. In the present work, a methodology is described to determine the effects of soiling on the output of the pyranometer.

2. Methodology

The total or global horizontal irradiance (G) can be measured using a thermopile pyranometer mounted on a horizontal surface. In this work, two Kipp & Zonen CMP11 pyranometers mounted on the same horizontal platform, each provided with a ventilation unit and located at the same site in Doha, Qatar, are used (Perez-Astudillo and Bachour, 2014); one of the radiometers is considered the reference, on which the cleaning and alignment check are done on a daily basis, and the other pyranometer is used for testing, where only the alignment check is done every day, and the cleaning frequency followed different scenarios. During the first week of the experiment, both sensors were cleaned on a daily basis for calibration purposes to ensure that for the soiling study both sensors provide the same measured values. For the next three consecutive weeks, the testing sensor was left without any manual cleaning, only somewhat washed by some rain events. Afterwards, the cleaning frequency of the testing sensor varied following the schedule in Table 1, which shows the days when this sensor was cleaned. Note that for the month of July, the *reference* sensor was not cleaned from the 3rd until the 14th of July; these days are excluded from the data analysis of this soiling study.

Tab.1: Cleaning schedule of the testing sensor from March until September 2016. Note that the reference sensor was cleaned every day including the days shown in the table. *See also note for July in the text.

Dates of cleaning						
March	April	May	June	July*	August	September
12	1	--	--	2 & 15	1 & 21	25

It can be seen from Table 1 that the longest period in which the test sensor was left without cleaning is from

April through June (90 consecutive days without cleaning), followed by the period from August 21 until September 25 (35 days). The shortest period was in the second half of July (16 days). In March and August, the testing periods were of 19 days. For simplicity, the testing periods are called herein: A (Mar), B (Apr-Jun), C (Jul), D (1st half of Aug) and E (Aug-Sep). A future scenario consists of not cleaning the sensor for several months to test whether the losses due to soiling will reach a plateau.

The analysis of the difference between the two measurements under the different cleaning regimes stated above will be used to quantify the soiling of pyranometers and to understand its characteristics and the change of associated errors with time. This analysis will consequently lead to the establishment of independent benchmarks and procedures to control the data and the sensors, due to soiling in desert regions.

3. Results and discussions

3.1. Calibration of the two sensors

Since the current soiling study relies on the measurements of two independent sensors, it was deemed necessary to calibrate the sensors relatively to each other, in order to eliminate sources of errors related to a drift or variations in the response of the sensors and to ensure that for the same conditions, the data from both sensors are comparable.

The calibration was performed using the days when both sensors were cleaned, which consist of all days during the first week of the experiment and several other days representing different seasons across different months: one day in April, two days in July, two days in August and one day in September. Fig. 1 shows in black, for the calibration days, the 1-minute values G_test measured by the testing pyranometer (the one to be kept without cleaning afterwards) versus G_ref, measured by the reference pyranometer (the one used as a control, with daily cleaning). The testing pyranometer slightly underestimates G. This underestimation can be fitted using a linear function, shown in blue on the graph. The linear fit relates G_test to G_ref through the following equation:

$$G\_test = 0.996547 * G\_ref - 3.99292 \qquad \text{(eq.1)}$$

Equation 1 was then used to calibrate G_test, for the following data analysis.

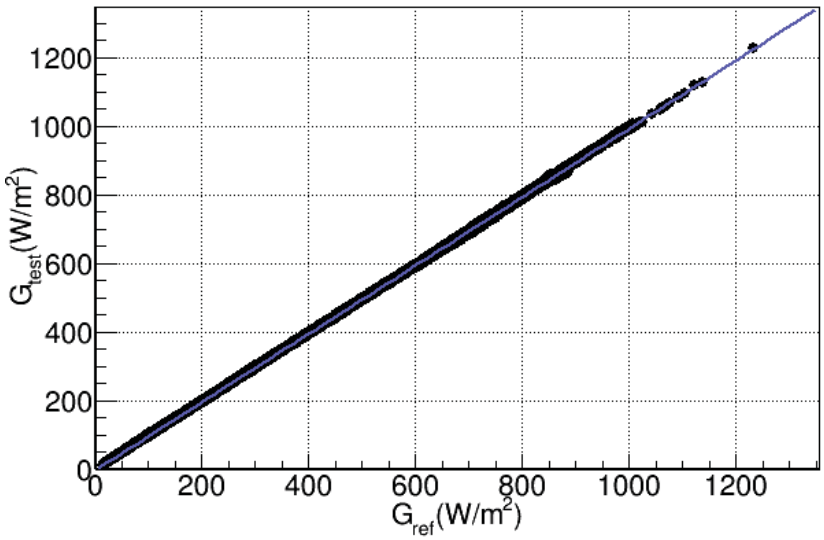

Fig. 1: Comparison of the G values (W/m2) measured by the testing and reference pyranometers.

3.2. Effect of pyranometer soiling on measured G

In order to study the effect of the soiling with the time passed since the last cleaning of the test sensor, the errors in terms of daily relative root mean square error (rRMSE) and relative bias (rBias) were studied for each of the testing periods. Fig. 2 and Fig. 3 show, respectively, rRMSE and rBias as function of time.

In Fig. 2, each point represents the relative RMSE between the two sets of 1-minute measurements during one day. It should be noted that the errors are calculated after calibration of the testing sensor against the reference one, as described in Section 3.1. The relative RMSE is calculated as

$$rRMSE = \frac{\sqrt{\frac{\sum_0^N (G\_test - G\_ref)^2}{N}}}{G\_ref_{mean}}, \qquad \text{(eq.2)}$$

where G_ref and G_test are the 1-minute values within one day, measured respectively by the reference pyranometer and the testing one. N is the total number of included minutes during that day and G_ref_{mean} is the mean value of G_ref during that same day.

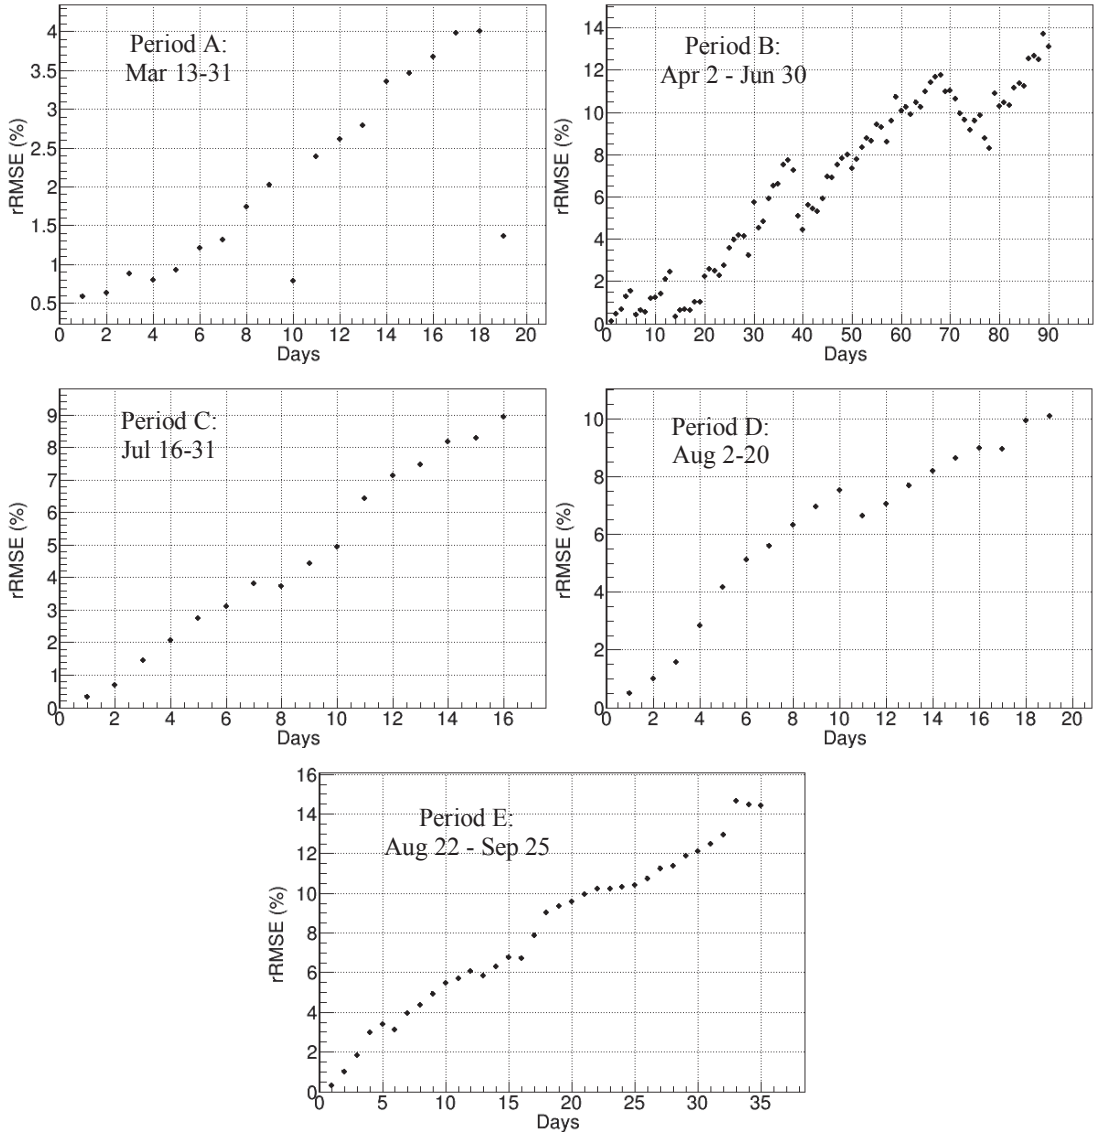

Fig. 2: Daily values of relative RMSE between G_test and G_ref for several days after cleaning the testing sensor, for different testing periods (shown on each of the plots).

It can be seen that for each of the testing periods the error due to soiling is continuously increasing with time; points showing deviation from the increasing trend correspond to rain events. The magnitude and speed of the increase in the error are different between the testing periods and depend on the season. For instance, the error in period 'A' grew at slower rate than in periods 'D' and 'E': it reached 4% after 17 days since the last cleaning in period 'A', whereas in period 'E' it reached the same level after 7 days. This is most probably due to more stable weather conditions, i.e., mostly clear days, in the summer months, but also due to the increasing dust

levels in the atmosphere during summer. It is to be noted that for each of the testing periods, the error due to the pyranometer soiling starts increasing from 0 (see Fig. 2 and 3), which means that the calibration factors were the same at the start of each period; in other words, after each cleaning event of the testing sensor, the signal is brought to the same level of the signal of the reference sensor.

In order to better understand this behaviour and be able to compare the differences in rRMSE within different periods, the average rRMSE for a span of 15 days after the last cleaning was calculated for each of the testing periods and is shown in Table 2.

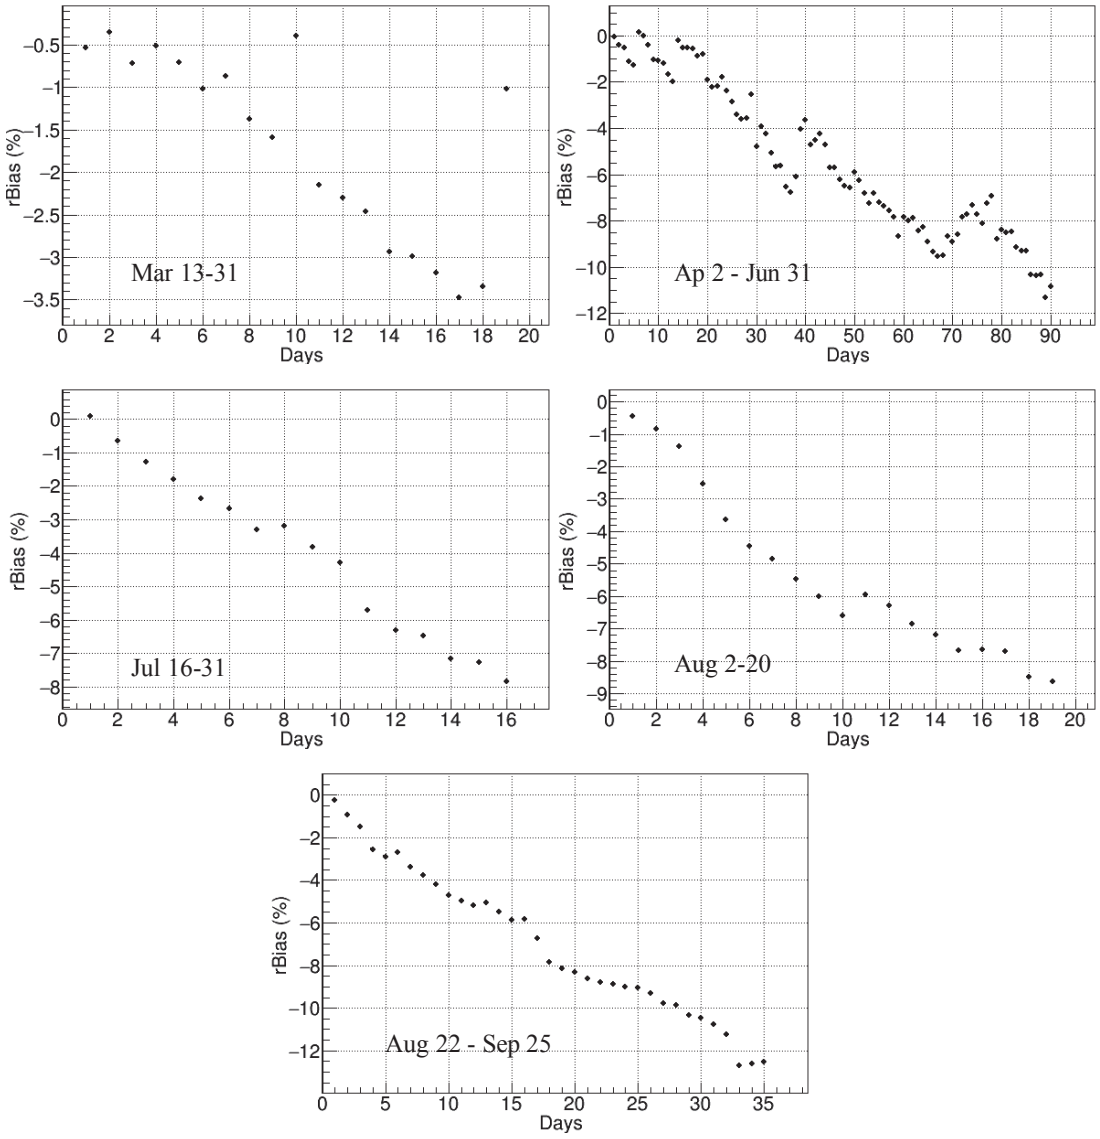

Fig. 3: Daily averages of relative Bias between G_test and G_ref for several days after cleaning the testing sensor, for different testing periods (shown on each of the plots).

Tab.2: Average of relative RMSE during 15 days after cleaning the testing sensor, for each of the testing periods.

rRMSE (%)				
March	April	July	Aug (first half)	Aug-Sep
1.71	0.99	4.32	5.32	4.13

Comparatively, it is noticeable that the averaged rRMSE during the first 15 days since the last cleaning is higher in the summer months. The low value of the averaged error in April is due to the frequent rainy days during this period, which resulted in a low average of rRMSE.

For comparison purposes also, Table 3 shows the quantification of the level of increase of rRMSE per day due to soiling, for each of the studied periods. These values were determined by establishing a linear relation between rRMSE and the days since the last cleaning, separately for each period. Although finding the relation was not straightforward due to changing weather conditions, especially in period 'B', an average rate was calculated using different series of consecutive clear days. The dependency of the soiling effect on the season is clear: the average increase of rRMSE is lower in March and April and higher in July and August, when dust is more abundant in the local atmosphere.

Tab.3: Average increase in relative RMSE, per day, for each of the testing periods.

rRMSE/day (%)				
A	**B**	**C**	**D**	**E**
0.25	0.33	0.6	0.5	0.4

In Fig. 3, each point represents the relative bias error between the two sets of measurements during one day, calculated using Equation 3, after calibration of the testing sensor against the reference one.

$$rBias = \frac{\frac{\sum(G_{test} - G_{ref})}{N}}{G\_ref_{mean}} \qquad \text{(eq.3)}$$

As expected, rBias increases as a function of time and this increase more or less follows the trend of the rRMSE. This can be explained by looking closely to the plot in Fig. 4, which shows the relative bias of each 1-minute pair (G_test vs. G_ref) as a function of time for the testing period 'E'. For clarity, the data shown were limited to minutes between hours 9 and 14 (local time). It is clear that the mean relative bias increases with time, similarly to Fig. 3, but it is noted too that the amplitude of each individual U-shaped curve (corresponding to one day) also increases with time and remains more or less constant after a certain time. The shape of each day's rBias depends on the spatial distribution of dust on the dome, as dust accumulates more on the top than on the sides of the dome, thus obstructing more direct sunlight (resulting in larger bias) when the sun is higher in the sky. The increasing amplitude with time contributes to the growing trend of the relative daily RMSE (as seen in Fig. 2).

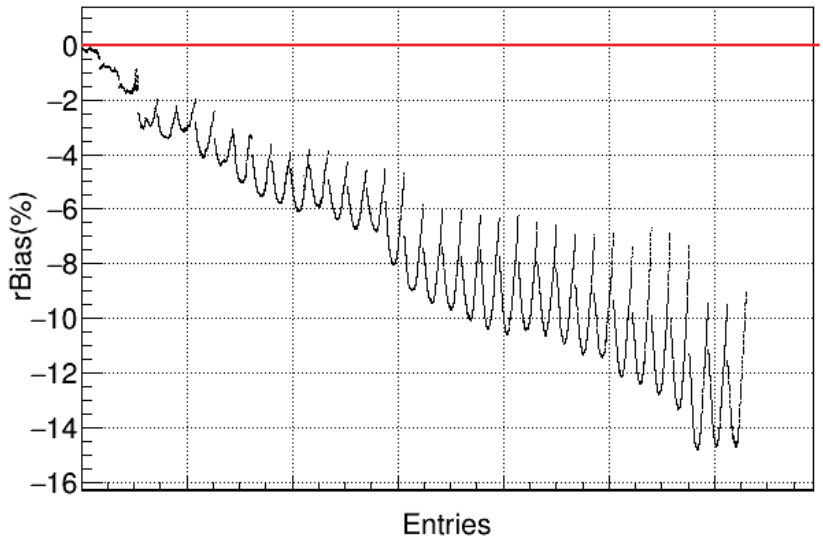

Fig. 4: Relative Bias of each one-minute value of G_test relative to G_ref for several days after cleaning the testing sensor, during the last testing period (22 Aug to 25 Sep).

Tab.4: Average change of relative bias, per day, for each of the testing periods.

rBias/day (%)				
A	**B**	**C**	**D**	**E**
-0.22	-0.3	-0.53	-0.43	-0.38

Table 4 shows the averaged increase per day of the relative bias due to soiling, for each of the studied periods. Similarly to the determination of the increase of rRMSE per day, this was determined by fitting a linear function on the plots in Figure 3, using consecutive clear days and excluding days with rain events. Here also, the rate of increase of the relative bias per day is higher in the summer months of July and August.

To obtain a quantitative evaluation of the loss in G due to sensor soiling, the ratio of the daily average of G_soil to G_ref (hereby called 'cleanliness') as a function of time since the last cleaning, is studied (shown in Figure 5, for period 'C'). The correlation between the cleanliness and time (the linear fit function shown in red) gives the value of the loss in output signal per day due to soiling. As in the previous cases, the loss was easily determined in periods of clear days. In periods with unstable conditions, it was determined using the average of the loss of one or several series of consecutive clear days (if found). As a result of this test, the loss per day in the global radiation due to soiling is around 0.2 to 0.3% in periods 'A' and 'B', from March to June, and is evaluated as 0.5% and 0.4% in July and August, respectively.

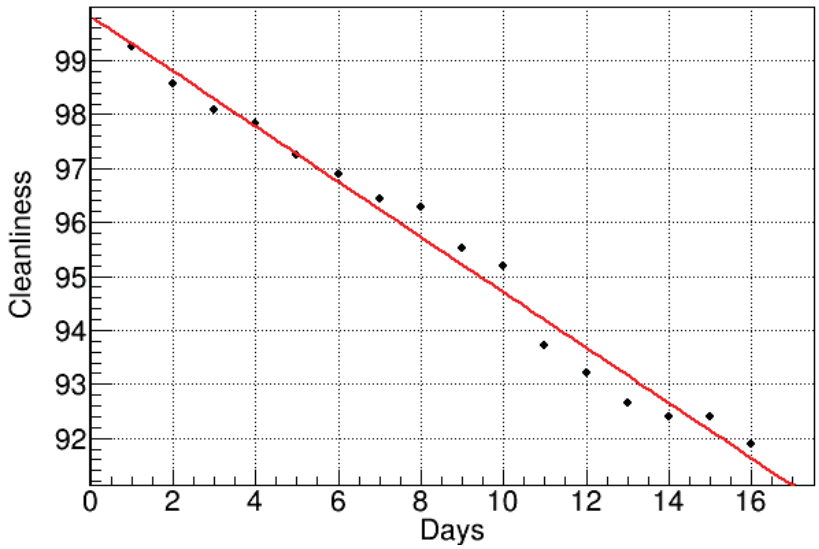

Fig.5: Decrease of measured global horizontal radiation per day due to sensor soiling, in period C. The red line is the fit of the cleanliness with time.

4. Conclusions

For the deployment of solar projects using photovoltaic systems, one of the key parameters to determine is the global horizontal irradiance, G, as part of the solar resource assessment studies for the project. G is usually measured on the horizontal plane using thermopile pyranometers. In this type of radiometers, the sensor is protected from the elements by a transparent dome, which only allows solar radiation to reach the sensor. Because the dome is exposed to the elements, it gets dirty, or soiled, as time passes, due to deposition of atmospheric dust and particulates, rain, snow, bird droppings, etc. This soiling obstructs the passage of sunlight to the sensor, resulting in erroneously low measurements, more obviously at locations with high amounts of dust in the atmosphere. Therefore, an important part of the routine maintenance of the sensor is the periodic cleaning of the dome. Ideally, this cleaning should be done daily; however, this is not always possible, for example, at remote unmanned sites, and also the costs (personnel, transportation, etc.) have to be considered, so in practice the instrument cleaning is commonly done at longer intervals, sometimes extending several

weeks or even months. The optimal cleaning frequency depends on each site's conditions, which are highly variable depending on atmospheric and any other surrounding events.

In this work, the assessment of the soiling rate of pyranometers was evaluated using two sensors: one with daily cleaning and another one following a cleaning schedule with varying intervals. The results show that the measurement errors due to soiling increase linearly with time, and the increase varies depending on the weather conditions, with a seasonal dependency. The average increases in rRMSE and rBias are, respectively, around 0.4% per day and 0.37% per day, for the studied period.

The actual decrease in the signal due to accumulation of dust on the dome of the pyranometer is evaluated as around 0.2 to 0.3% per day for the winter season, and around 0.4% to 0.5% per day for the summer season. This shows that the effect of dust and soil on the pyranometer signal is not negligible in dusty environments even in short intervals, frequent cleaning of the glass dome of the instrument should be followed in order to avoid dust accumulation and consequently larger errors on the measured data. According to the analysis shown here, and in order to ensure low deviations from the correct measurement (on the order of 1 to 2 %) in dusty regions, the pyranometer dome should be cleaned daily, or every 2 days.

Although the results presented here cannot be universally applied due to varying soiling conditions between different sites, they may be useful in regions with similar weather conditions.

Detailed information on irradiance characteristics in Central Africa (Rwanda) from a dedicated network of ground stations for characterizing statistics of the irradiance field and validation of satellite derived data

Hans Georg Beyer[1], Fabien Habyarimana[1,2]

[1]Inst. Of Engineering, University of Agder, Grimstad (Norway)

[2]Department of Physic, University of Rwanda, Kigali (Rwanda)

Abstract

In Rwanda as in most of the countries in central Africa in-situ empirical data on solar irradiance are sparse. This presents an obstacle for an increased application of solar energy to the coverage of the (increasing) energy needs of the country. These needs are given by both, the wish to increase the share of PV to bulk electricity and the application of PV for off-grid rural electrification. Required for a proper planning of both on- and off-grid applications are information beyond the knowledge of annual or monthly irradiance sums. For the layout of the off-grid systems the respective knowledge of the temporal variability is essential for e.g. the sizing of batteries. For on-grid systems the time and space characteristics of the irradiance field effect the interaction of PV-power plants with the conventional generation park. In Rwanda a new dedicated network of meteorological stations, that are logging the irradiance with a 5min time resolution has been set up to close this gap. For a more comprehensive approach the data from this network can be used to calibrate the satellite derived irradiance data for the continuous coverage of this region. This paper gives a short view on the use of the data for these two fields of application.

Keywords: *irradiance data, irradiance statistics, satellite derived data, ground station network*

1. Introduction

To increase the knowledge of the agro- and energy-meteorological conditions, the government of the Central African country of Rwanda initiated the setup of a fleet of Basic meteorological stations. The map in fig.1 shows the distribution of these stations operated by the Rwanda Environment Management authority (REMA) [Meteo Rwanda, 2014]. In operation since mid of 2013 (stable data delivery since mid of 2014). The stations are equipped with - among others sensors for the registration of the horizontal irradiance. The data are logged with a time resolution of 5min.

Fig. 1: Map of the network of Automatic weather stations setup in in Rwanda (Meteo Rwanda, 2014).

doi:10.18086/eurosun.2016.09.15 Available at http://proceedings.ises.org

This set offers - beyond the countywide information on the general solar potential - on one hand, information on the detailed statistics of the irradiance field in time and space needed as input for the detailed assessment of the performance of both, on-grid and off-grid solar energy systems. In addition these data form a unique basis for the check of the quality of satellite derived irradiance data extracted for this region. In the present paper exemplary applications of this data set should show its usefulness for these two fields of applications.

2. Quality of Data set

As initial analysis, the quality of the ground data set was checked by its consistency to the outcome of a clear sky model. As can be seen in the example given in Fig. 2 , the measured data are well in accordance with a clear sky irradiance calculated (Kasten 1983) for a Linke turbidity of 3.

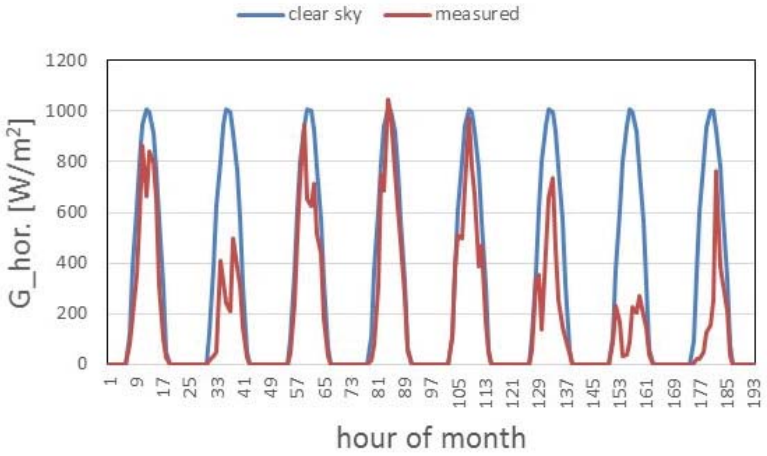

Fig. 2: Data quality from the weather stations in Rwanda, shown by consistency to modelled clear sky data (Linke turbidity:3) . Section of a time series of measured data from Location Gikomera, data from July 2014.

3. Analysis of irradiance statistics

As examples for more in depth analysis of the data sets, two examples are given here. The first concerns the investigation into short term statistics of the irradiance series that effect the performance of both on- and off-grid systems. For on-grid systems the magnitude and persistence of the irradiance fluctuations may challenge the stability of the grid. For off-grid systems the fluctuations cause stress to the storage devices.

3.1. Temporal statistics of short term data

From the 5min ground station data, the temporal variability of the irradiance re analysed. This is done here by extracting the daily standard deviation of the 5 min clear sky index (csi). Fig.3 gives for the location Kigali the daily standard deviation of the csi in dependence of the daily mean csi for the month of December 2013 and July 2014. It can be observed that there is no unique coupling of the daily standard deviation to the daily mean. This may call for a revisiting of both, schemes for the generation synthetic data sets based on daily averages (see e.g. Remund, Kunz 2004) and respective tools for the analytics system design (see e.g. Beyer, Langer 1996). In addition the autocorrelation coefficient of these csi series are inspected, indicating a general high correlation of the fluctuations on this time scale (Fig.4) which e.g. effects the cycling characteristics of the storages.

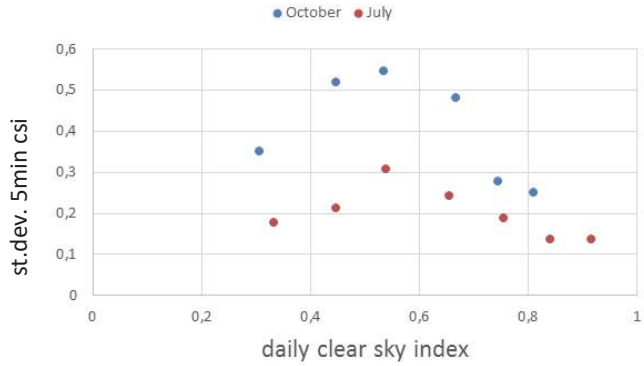

Fig. 3: Standard deviation of the 5 min clear sky indices csi, depending on the daily clear sky index for the location Kigale, month December 2013 and July 2014.

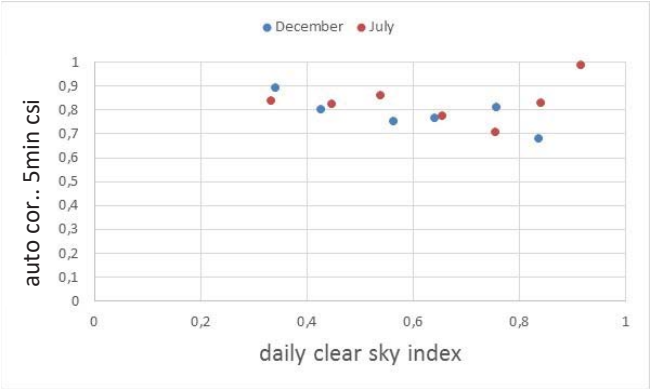

Fig. 4: Temporal correlation of 5 min. clear sky indices csi auto- correlation depending on daily clear sky index location Kigali, July and December - similar structure for both month indicate persistence of cloud situation for periods > 5min. Same data base data as Fig.3.

3.2. Spatial statistics of daily and hourly data

A second approach to investigate the details of the variability of the irradiance field with relevance for the large scale country wide integration of photovoltaics focusses on the large scale spatial correlation. Fig. 5a and 5b give a first qualitative view on the homogeneity of the irradiance field by showing the monthly time series of the daily clearness index for the months of July and December for 4 stations dispersed over the country (see map in fig.1).

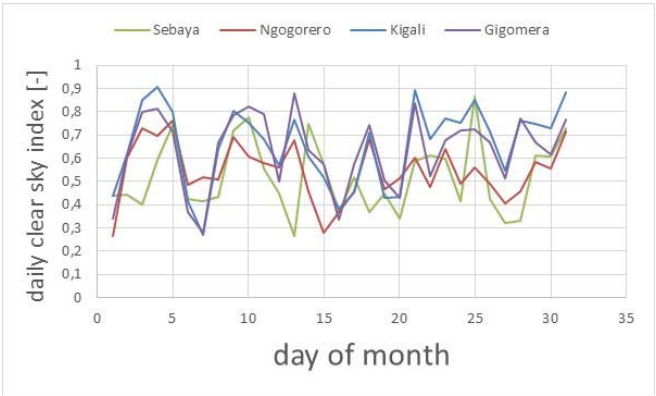

Fig. 5a:. : Monthly time series of the daily clear sky index at 4 stations (see map in fig.1). Given are the data for (July 14 5a)

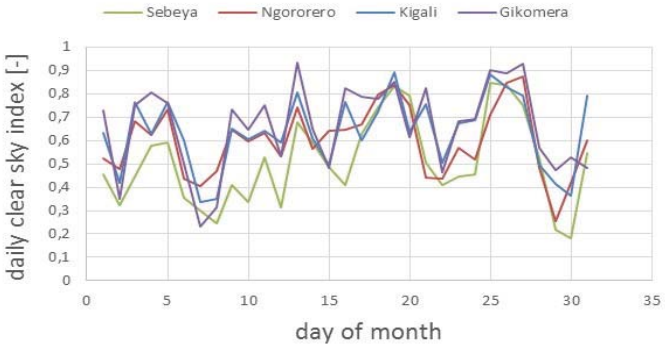

Fig. 5b: Same as fig.5 but for December 14 (5b)

It can be observed that days with an either completely clear of completely covered sky at all of the stations are rare. Thus it has to be expected, that a county wide PV-fleet will only rarely challenge the grid by delivering the rated power of all systems at one. The more fractures spatial structure of the irradiance field in Rwanda is also visible when looking at the cross-correlation of the hourly clearness index for pairs of stations.
Fig. 6 gives the correlation coefficients for pairs of stations in dependence of the interstation distances. Data for the month of July and December are analyzed. The strong decay with distance can be observed. For comparison, the characteristic of the decay of the interstation correlation (annual average) extracted from data sets for Germany (Wiemken et. al. 2001) are given. This indicates, that the fluctuations of the irradiance field in Rwanda show less spatial coherence that in northern Europe – leading to a more pronounced smoothing of the relative fluctuations of lumped power output from dispersed stations as compared to the fluctuations in single station data.

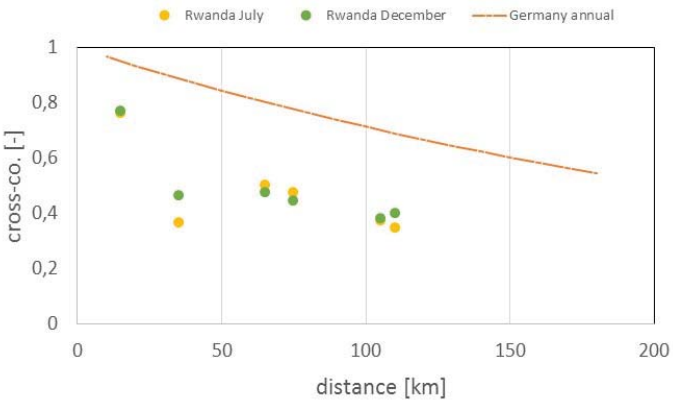

Fig. 6: Cross correlation of hourly clear sky indices compared to the correlation derived from a respective set from stations in Germany (Wiemken et al. 2001).

4. Application for the quality check of satellite derived data

A first qualitative assessment of the quality of satellite derived data for Rwanda had been done by Habyarimana, Beyer 2015. With the by then absence of time parallel ground and satellite data there was a comparison of the trace of monthly means for 5 years of satellite data (Geomodell 2013) with the 2014 ground data for the station of Kigali. It can be remarked that the satellite derived data are for most of the month clearly superior to that ground data.

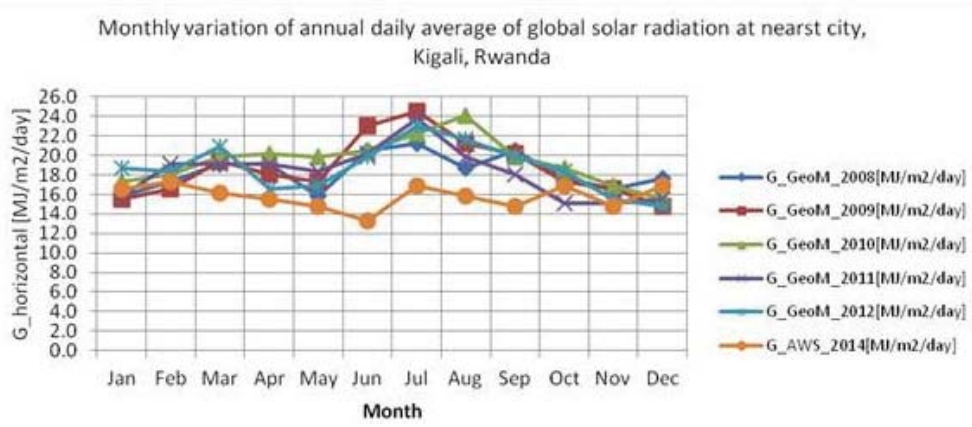

Fig. 7: Comparison of yearly traces of the monthly irradiance sum for Kigali from the 2014 ground data and 2008-2012 satellite derived data from Geomodel 2013.

This comparison is taken up here with the use of now available datasets with worldwide coverage offered by the SARAH service (Müller et al 2015). The following results refer to that source.
Fig.8 gives data for the station. Here the increase of the cumulative irradiance sum for the month of October is given. It can be observed that the satellite derived data give an overestimation of ~20%. A pattern that is qualitatively repeated for the month of November and December (fig. 9 and fig. 10).
For an explanation of this overestimation a first guess would call for an inspection of the assumptions taken for the estimation of the clear sky irradiance used in the calculation scheme for the satellite derived data. To get a qualitative impression of the influence of the assumptions on clear sky irradiance, it is assumed that a tuning of the clear sky irradiance may result in but a scaling of the modelled irradiance. Applying this assumption, one may test the use of a scaling to matching the final monthly irradiance sum.
The results of this procedure applied to the monthly sets are added in the figs.8-10.

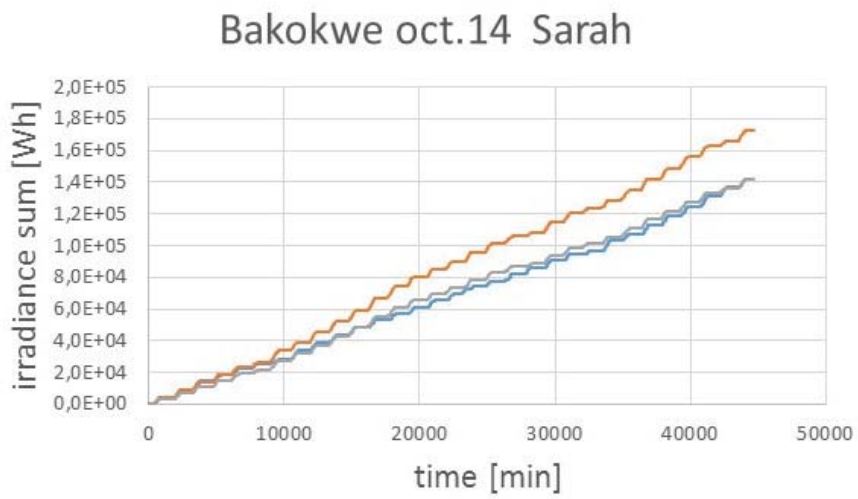

Fig. 8: Cumulative irradiance sum for the data from the station Bakokwe, month of October14 - Red line: satellite derived data, blue line: ground data, grey line: satellite derived data matched to meet the final monthly irradiance sum (see text).

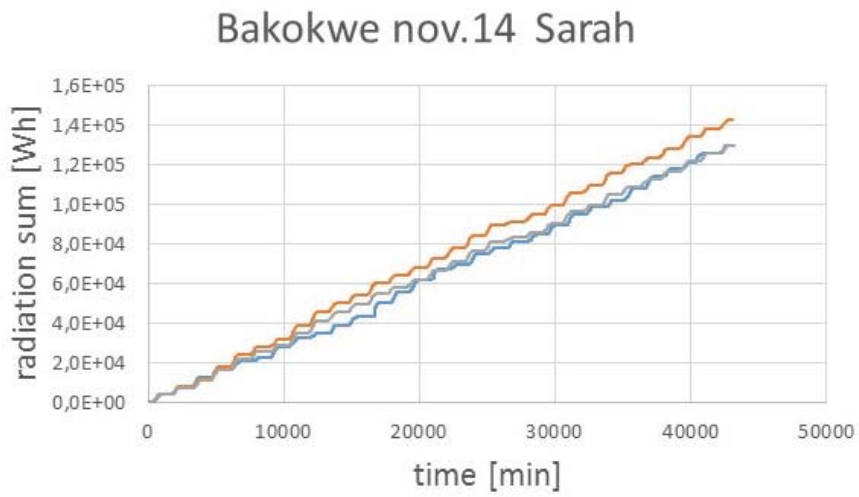

Fig. 9: Same as fig.8, but for the month of November 14.

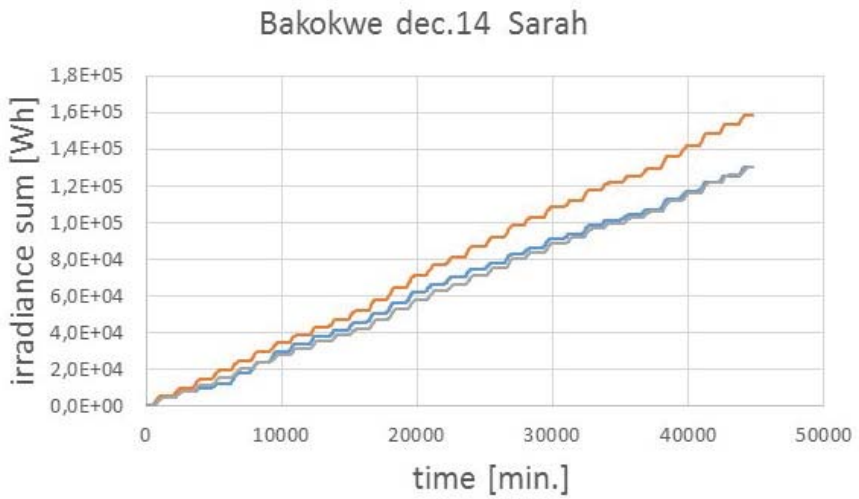

Fig. 10: Same as fig.8, but for the month of December 14.

In the figures 8-10 the grey lines present this adopted irradiance sums - a perfect match with the line for the ground data would indicate that errors are due to but a faulty scaling, i.e. incorrect assumptions on clear sky irradiances. As can be observed this is most likely the case for the December and October data. For November further inspection would be needed.

5. Conclusions

In view of the general lack of detailed irradiance data in central Africa, the opportunities offered by a network of meteorological stations in Rwanda logging highly time resolved respective data sets are obvious. This could be discussed for both, the application for the layout (e.g. sizing of storage) of small stand-alone PV systems and the assessment of large scale application of grid-connected PV-power stations with repercussion in the country wide power grid. An additional benefit of the set discussed is given by its applicability for the quality assessment of satellite derived information on irradiance. Here, a need for improved information on the local atmospheric turbidity could be identified.

6. Acknowledgement

Thanks are due to Meteo Rwanda for granting access to the ground data. The SARAH data are kindly supplied by Thomas Huld from JRC, Ispra, Italy.

Abstract

Short-term solar irradiance forecasting is of great importance for optimal operation and grid integration of photovoltaic (PV) plants. Morocco's Green Energy Park (GEP) of Benguerir is investigating the possibility of providing accurate solar forecasts for its own PV plant. However, to overcome the variability of solar resources under changing weather conditions, a reliable forecasting model is needed. In this context, this work provides a detailed research in short-term solar irradiance forecasting, an implementation and a technical analysis were performed in this study for a suitable and a reliable Global horizontal irradiance (GHI) forecasting model. Comparing the performance of different models such as ARIMA, Multiple linear regression, curve fitting and artificial neural networks, gave valuable information for further development of the final model. This final model is based on NARX ANN. In order to achieve meaningful results when comparing these different approaches as well as for NARX ANN model assessment, a standardized methodology for evaluation is used. NARX model outperformed all the approaches carried out in this study and it gave very satisfying results of 4,57 % MAPE error for Clear-sky and 14,67% MAPE error for Cloudy weather conditions.

1. Introduction

Solar power generation is gaining substantial prominence worldwide, especially Photovoltaic (PV) power technologies, with an average yearly growth rate of 50% over the last ten years (Jäger-Waldau, 2015), making PV one of the fastest growing industries at the present. However, while PV output is dependent on solar irradiance, natural intermittency and variability of solar resources poses limitations for a more stable grid integration. Furthermore, this variability of solar technologies output at higher grid penetration levels induces problems economically, regarding dispatchability, generation, and grid reliability in general (Rich H. Inman, 2013). While energy storage in large amounts on-site is very problematic, this limitation can be tackled by accurate solar irradiance forecasting, which is crucial for efficient integration of solar energy into the electric power grid and for improving its proportion in total energy consumption.

Solar irradiance at the ground level are highly variable mostly due to weather related variables like clouds coverage variability and their motion, and to a lesser extent aerosols and gases in the atmosphere. However, thanks to solar meteorology for renewable generation, a number of promising approaches for prediction have been developed in the past few years, such as Remote sensing based Numerical weather prediction (NWP) methods (Diagne, 2013) (Lima, 2016), Regression methods, Machine learning and artificial intelligence (AI) forecasting using data acquired by local sensing instrumentation such as total sky imager (Chi Wai Chowa, 2011) , pyranometers and local weather instrumentation (Rich H. Inman, 2013).

Regressive methods are not new to forecasting, beginning with pre-stochastic algorithms like Multiple Linear Regression (MLR), and Curve Fitting (CF) to newly developed nonlinear stochastic algorithms. Hard computing techniques like MLR and Curve fitting predict different types of data, the authors of (Jain, 2012) have carried out these techniques on variables like temperature, humidity and "day type" parameters to recognize load patterns in short-term load forecasting. Also, authors in (Sahin, 2012) have compared MLR based model with Artificial Neural networks (ANN) for estimating solar radiation, and they are generally very simplistic while maintaining the ability to model non-linear patterns. Nonetheless, a lot of models were developed based on Box-Jenkins model ARMA, such as ARIMA (Zhang, 2003) taking into consideration external information to the time-series under analysis. Also we can find many variations of such model like ARMAX and ARIMAX with the same philosophy.

doi:10.18086/eurosun.2016.09.02 Available at http://proceedings.ises.org

For solar radiation, many works have incorporated these methods like (Aguiar RJ, 1989) used clearness index K_t to model daily sequences of hourly irradiance with ARMA techniques, where K_t was obtained by multiplying a clear sky index values by a non-stationary fluctuation, with probability depending on the hour of the day.

Since the late 1990s, ANNs have seen an increase in solar forecasting applications. Several works proposed in literature modeled solar irradiance using various ANN's internal topologies, different inputs and for several time scales (Lopez, 2005) (Koca, 2011) .Al-Alawi and Al-Hinai used weather variables as inputs to an ANN to predict monthly values of Global Horizontal Irradiance (GHI) over a year (Al-Alawi S, 1998). Authors in (A. Di Piazza, 2013) have acquired very satisfactory forecasts using a feedforward Time delay Neural Networks called NARX. In addition, In the work of (Vaz, 2015) PV output forecast have been generated using NARX by employing meteorological variables as exogenous inputs and assed the influence of multiple PV neighboring systems.

In this context, a thorough methodology was undertaken for short-term global horizontal irradiance forecasting using local meteorological measurements. This paper is organized as follows. In section 2, the study overview and experimental data collection were presented. The methodology is illustrated in Section 3. Results and discussion in section 4 and finally this paper ends with a conclusion.

2. Study overview and Experimental setup

2.1 Overview and Objective.

The Research Institute for Solar Energy and New Energies (IRESEN) was established in 2011 to lead and promote Moroccan R&D in the field of renewable energy through applied R&D projects. To expand this leadership further, a research platform called "Green Energy Park" (GEP) was set-up in Benguerir by IRESEN and the OCP Group in 2014. The goal of this technical platform is to provide the means to characterize various PV technologies in local weather conditions and investigate their long-term behavior. The GEP's PV plant is facing the same limitations in regards to the export of electricity to the grid. Thus, the aim of this work is to provide a precise model for a short-term solar irradiance forecasting for optimal operation and a prospect grid integration in Morocco.

2.1 Experimental solar irradiance data

In the present study, we have selected some weather related variables that are directly or indirectly influencing global horizontal irradiance (GHI). GEP PV Plant is equipped with a Meteo-Station measuring accuratly various weather related variables like wind speed, temprature, pressure, ...etc. Also, a very accurate SOLYS2 solar monitoring station and it is composed of two pyranometers, one directly exposed to the sun and measures Global Horizontal Irradiance, one with a shading ball to help measure DHI the diffuse Diffuse Horizontal Irradiance and finally, one pyrheliometer measuring Direct Normal irradiance (DNI). When solar data are logged, they are sent via a Modbus data logger to GEP Servers. These data is then treated and organized in a SQL database. Data quality is checked and calibrated according to World Meteorological Organization (WMO).

For this study GHI data were aggregated with time, temprature and relative humidity. As an example Fig.1 present data of three days, 21th, 22th, 23th of april 2016 with 10 minutes lag.

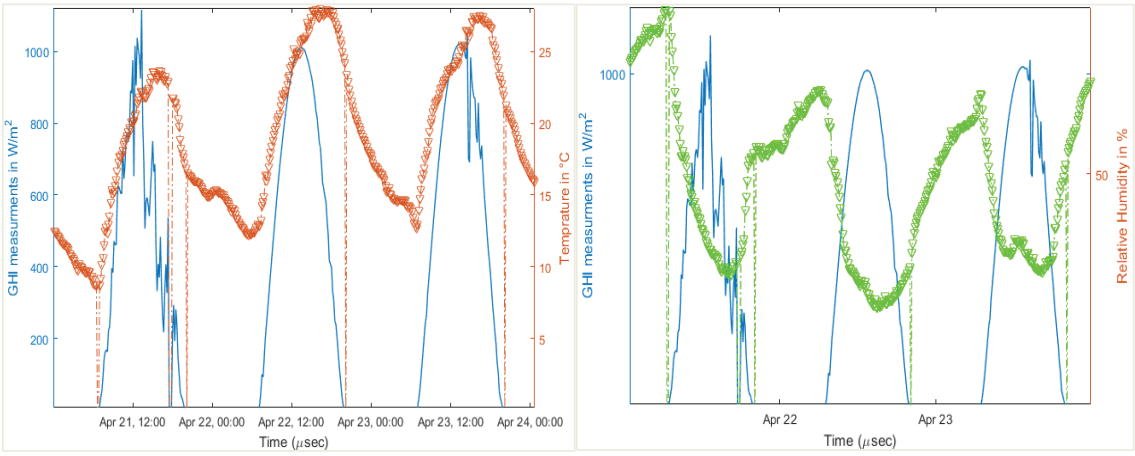

Fig. 1: Variability comparison of Temperature (Left) in red and relative humidity (Right) in green with GHI in blue.

Several datasets were created in order to investigate the influence of lags on the computation time, forecast error and finaly the choice of forecasting method.

3. Approach and implementation

3.1 Forecasting approach

The methodology undertaken was to choose two of the extreme scenarios (Clear-Sky and cloudy) of data and test them using ARIMA and time series analysis with different lags (1 min, 10 min, 1 hour) to assess the quality of forecast and for different forecast horizons. The developed ARIMA model was tuned up to see its capabilities for 48h forecast horizon.

The next step was to determine a suitable model from the different methods that deal with local sensing data, in order to do so, a MATLAB program was developed to benchmark 2 stochastic methods and one of the soft computing based on neural networks (Fig. 2).

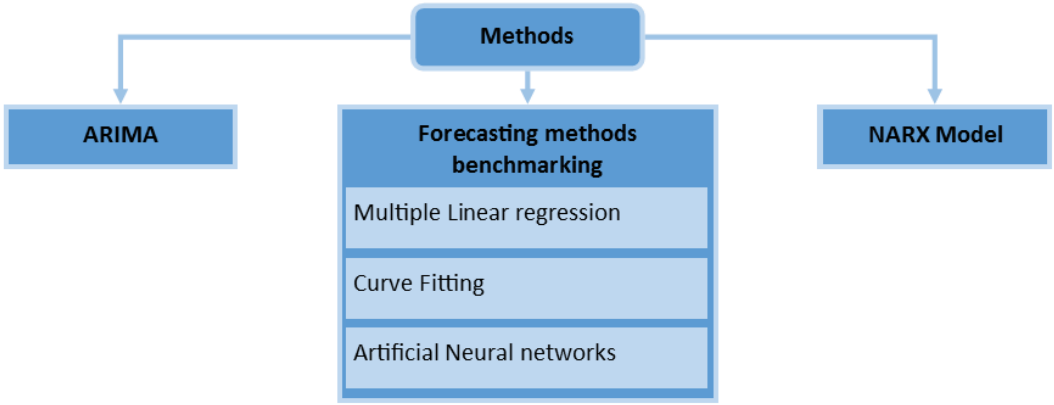

Fig. 2: Forecasting methods involved in this study.

3.2 ARIMA

Unlike the stationary model ARMA, ARIMA is a non-stationary regressive model. Non-linear methods would enable powerful structures with the ability to accurately describe complex non-linear behavior problems (Suykens JAK, 1996). This model has 3 orders, and it is known as ARIMA (p,I,q), AutoRegressive (AR), Moving average (MA) and I for the integrative part and it means that the model take into account the difference between response variable data, which is suitable for non-stationary values. This makes the model look like the following:

$$Y_t = (1-L)^d X_t \qquad \text{(eq. 1)}$$

With Y_t being forecasted values, L the lag, d seasonality exponent and X_t actual values. In a wide sense it can be written as such:

$$\left(1 - \sum_{i=1}^{p} \emptyset_i L^i\right) Y_t = \left(1 + \sum_{i=1}^{q} \beta_i L^i\right) \varepsilon_t \qquad \text{(eq. 2)}$$

Where β_j are Moving average ***MA*** coefficients and $\emptyset_i$ are AutoRegression ***AR*** coefficients. This equation creates a multitude of forecasting models, determining the orders of ARIMA was carried out by computing ACF and PACF functions provided by *autocorr* and *parcorr* in MATLAB, also this model was tuned up using an optimization for parameters like, ***SAR*** (Seasonal AutoRegression Coefficents), ***SMA*** (Seasonal MovingAverage coefficents) and Variance. Using *optimset* function in Matlab help estimate these coefficients by incorporating a nonlinear iterative optimization algorithm called Sequential quadratic programming (SQP).

3.3 Forecasting models benchmarking

For the sake of comparison a program had been developed to select the most suitable approach for our data‘s behavior. The program compares two well-known statistical methods against one based on Artificial Neural Network.

3.3.1. Multiple Linear regression (MLR) Model

In order to be able to predict accurately, and to fit data in the best way possible, regression models are often constructed based certain conditions that must be verified. The basic linear model is a simple linear regression

between dependent and independent variables. Linear regression model fits the data to a model of the following form:

$$y_i = \beta_0 + \beta_1 x_i + \varepsilon_i \qquad \text{(eq. 3)}$$

Where i is the number of measurements, (β_0, β_1) are coefficients and ε is a random error.

The term ε is a catch-all for differences between predicted and observed values of y. These differences are due to process fluctuations (changes in β), measurement errors (changes in x) and model misspecifications (for example, nonlinear relationships between x and y). It is usually assumed that ε is generated by an unobservable innovations process with stationary covariance $\Omega_t = Cov(\varepsilon_1, \ldots \varepsilon_t)$.

If the model has more than one independent variable, it will become a multiple linear regression model and will be in this form:

$$y_i = \beta_0 + \beta_1 x_i + \beta_2 x_i^2 + \beta_3 x_i^3 + \cdots + \beta_k x_i^k + \varepsilon_i \qquad \text{(eq. 4)}$$

Where β_i ($i = 1,2,3, \ldots, k$) are the coefficients of the model, this method is used to analyze the effect of more than one independent variable ($x_1, x_2, x_3, \ldots, x_k$) on the dependent variable (Solar Radiation). For a given dataset ($y, x_1, x_2, x_3, \ldots, x_k$) the multiple linear regression fits the dataset to the model according to (eq.4).

Assuming that ε are independent and identically distributed as normal random variables with $\overline{\varepsilon_i} = 0$ and the unknown variance of these random errors $\sigma^2 = Var(\varepsilon_i)$. In Order to minimize the $\|\varepsilon_i\|$ with respect to β_i, we solve the function:

$$\frac{\delta\, \varepsilon_i^T \varepsilon_i}{\delta \beta_i} = 0 \qquad \text{(eq. 5)}$$ Where ε_i^T is the transposed errors vector.

Which leads to the optimal coefficients $\hat{\beta}$ that are being estimated from the vector β by least squares method:

$$\begin{bmatrix} \widehat{\beta_0} \\ \vdots \\ \widehat{\beta_k} \end{bmatrix} = (X^T X)^{-1} X^T \qquad \text{(eq. 6)}$$

Matlab provides script driven tools to carry out multiple linear regression, the regression used returns a p-by-2 matrix of 95% confidence intervals for the coefficient estimates. The inputs were designed to bring about seasonality features in solar irradiance and to make sure that our forecasts revolve around the average of each hour.

3.3.2. Curve Fitting Model

Curve fitting finds an appropriate mathematical model that expresses the relationship between dependent and the independent variables and the parameters are estimated using nonlinear regression.

Using the historical data to find coefficients of an equation is the basic principle of Curve fitting; the equations could be multiple sin waves, Fourier or polynomial equations, etc. Matlab Curve fitting GUI is a good way to find the potential of this Model. In our case, our equation is fourier8 of the form (eq. 7):

$$Fit_{model}(x) = a_0 + a_1\cos(x * w) + b_1\sin(x * w) + a_2\cos(2 * x * w) + b_2\sin(2 * x * w) + a_3\cos(3 * x * w) + b_3\sin(3 * x * w) + a_4\cos(4 * x * w) + b_4\sin(4 * x * w) + a_5\cos(5 * x * w) + b_5\sin(5 * x * w) + a_6\cos(6 * x * w) + b_6\sin(6 * x * w) + a_7\cos(7 * x * w) + b_7\sin(7 * x * w) + a_8\cos(8 * x * w) + b_8\sin(8 * x * w) \qquad \text{(eq. 7)}$$

This model uses the same inputs in MLR model and all coefficients a_n, b_n and c_n will be found using "fit" function in Matlab.

3.3.3. Artificial neural network (ANN)

Artificial intelligence techniques use a symbolic approach to intelligent systems, it is a processing architecture based on the human brain focusing on information representation by its ability to learn and adapt. ANNs are constituted by a mathematical model of biological neuron called perceptron arranged in nodes and connected by weigh vectors or simply called weights (Fig.3).

ANNs can model any actual data variations by constantly changing the weights between the nodes based on information flow through the network during the learning phase.

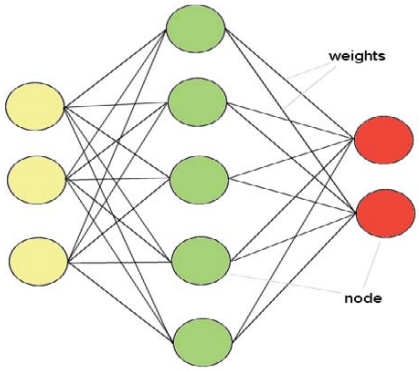

Fig. 3 : ANNs incorporate the two components of biological neural nets: Neurones (nodes) and Synapses (weights), inputs layer is in yellow, hidden layer in green and output nodes are in red.

ANN is well suited for modeling complex relationships between inputs and outputs with an ability to construct a map without explicit analytical equation, which is at the same time a very powerful tool to model nonlinear statistical data. The basic mathematical model of ANNs is shown below.

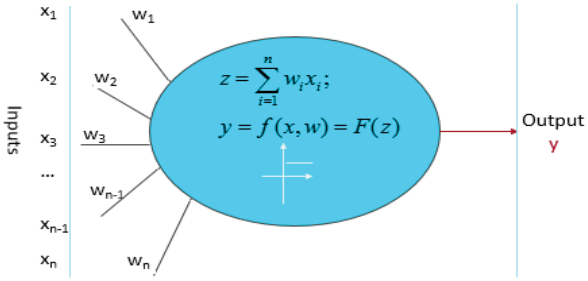

Fig. 4 : Neurons work by processing information as they receive and provide it in form of spikes.

(Fig.4) present the McCullogh-Pitts model, where x_i is an input vector, w_i are weights values, $f(x,w)$ an activation function and y is the output. The architecture used in this study is a feedforward neural network and is designed in a way to acquire a forecasts error less or equal to the error imposed by the user via a constraint imposed in a loop, so the program can reiterates until it finds the forecast with the minimum error. The training algorithm used is Levenberg-Marquardt, Training, Test and Validation dataset are divide randomly from the original data, the best results were acquired for 5 hidden neurons with a logistic sigmoid activation function and one output neurons with an adaptive linear function.

3.4 NARX model implementation

The Nonlinear AutoRegressive with eXogenoues inputs model or NARX in short, is a specific type of recurrent neural architecture (RNN), it was derived from derived from Autoregressive exogenous (ARX) model commonly used in time-series modeling. It is a recurrent dynamic network, with feedback connections enclosing several layers of the network. It has limited feedback architectures that come only from the output neuron instead of from hidden neurons.

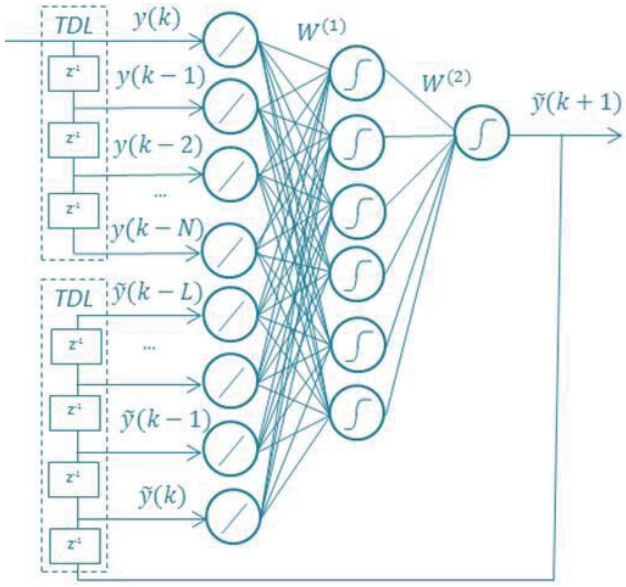

Fig. 5: NARX NEURAL NETWORK (Mladenov, 2013)

The NARX neural network structure is shown in Fig. 5 is equipped with both a tapped delay line (TDL) at the input y and global recurrent feedback connections $\tilde{y}$. It represents a Dynamic Multilayer Perceptron. The input vector can be written as such:

$$x(k) = [y(k) \dots y(k-N) \;\; \tilde{y}(k) \dots \;\; \tilde{y}(k-L)]^T \qquad \text{(eq. 8)}$$

Where N is the order of the input tapped delay and L is the order of the feedback tapped delay line. Long-term dependencies that solar radiation has with other exogenous input was the reason for choosing an ANN that uses TDL.

The output is then generalized by:

$$\tilde{y}(k+1) = g(\sum_j w_j{}^{(2)}(f(\sum_i w_i{}^{(1)} x_i))) \qquad \text{(eq. 9)}$$

Where $w^{(1)}$ and $w^{(2)}$ are weights of the hidden and output layers, $f(.)\ and\ g(.)$ are activation functions respectively of the hidden and the output layers.

NARX use taps to set-up the delays across the inputs. Also, it incorporates the past values of the output. Recurrent networks have loops within intermediate layers and incorporate memory via these loops.

The inputs for the NARX ANN are GHI time serie and as exogenous inputs we have chosen what might reflect the changes in GHI, variables like *relative humidity* and *ambient temperature* were often mentioned in literature as exegenous inputs for NARX ANN and as the fig.2 shows they follow to a certain extent solar irradiance‘s seasonality.

Also, we have divided our dataset to inputs and targets, target series are what we compare the response of the neural network to. So the first group is used to train the Neural Network while the second group of variables are Validation series, this new data is used for simulation. For this model we have used a 10 min resolution time-series from 1st of January 2016 to 1st of February 2016.

For learning process, ANNs training uses mathematical procedures to adjust the network’s weights and biases. The training function necessitates a global algorithm that affects all the weights and biases of our network. The algorithm used is *Levenberg-Marquardt algorithm* found in NN toolbox in Matlab. And then we have divided our dataset into 3 parts, Training, validation and test datasets by setting up ratios respectively 60%, 20%, 20% of input vectors. The training performance function is Mean squared error (MSE), minimizing this error while our network learns the dataset behavior. Also, we assigned *Tansig* activation function for hidden layers and *Purelin* for the output layer. Number of the hidden layers is determined by trial and error until the program converges at an error less or equal to the desired error entred by the user. The evaluation of each trial is carried out by Mean Absolute Percent Error (MAPE).

4. Results and discussion

4.1 Forecasting evaluation metrics:

A standardized performance evaluation was adopted to asset the accuracy of each model involved in this study, the metrics used are RMSE and MSE because they give more weight to the largest error and MAE was used to give the average of the magnitude of forecast error. Also we have used MAPE as a constraint over forecast iterations in our programs.

We define the forecast error: $e_i = y_{i,forecasted} - y_{i,observed}$ (eq. 10)

where $y_{i,forecasted}$ is the i[th] forecasted value, $y_{i,observed}$ the i[th] actual value and N is the length of the test dataset.

$$RMSE = (MSE)^{\frac{1}{2}} = \left(\frac{1}{N}\sum_{i=1}^{N} e_i^2\right)^{\frac{1}{2}} \quad \text{(eq. 11)}$$

$$MAE = \left(\frac{1}{N}\sum_{i=1}^{N}|e_i|\right) \quad \text{(eq. 12)}$$

$$MAPE = \left(\frac{1}{N}\sum_{i=1}^{N}\frac{|e_i|}{y_{i,observed}}\right) * 100 \quad \text{(eq. 13)}$$

4.2 ARIMA

The first set of experiments was carried out for intra-day forecasts with the horizon of 30 minutes. The two datasets used for clear-sky and cloudy day have a 1 min resolution. Running ARIMA gave us an error less than 5% MAPE for clear-sky and 10% cloudy day after the beginnig of each day. The dataset used was only one day of GHI. However, it seems very problematic if the program is supplied with more than two days of data. Taking into account the computing power of the processor (4 CPU 1.6 GHz, 8G RAM), running time average in this case around 15 to 30 seconds. If the dataset is too large, computation takes a lot more time to produce results. So we have concluded that it is best to reason with the length of the dataset, not with its duration.

For a Days-ahead forecast, we have begun the procedure by estimating the model through ACF and PACF, calculating residuals, testing residuals, running simulation and finally comparing results for the three data sets chosen. A constraint in the program has been integrated in order to stop it from running if the calculation was going to take a lot of time, this is the reason behind the poor results acquired for larger datasets.

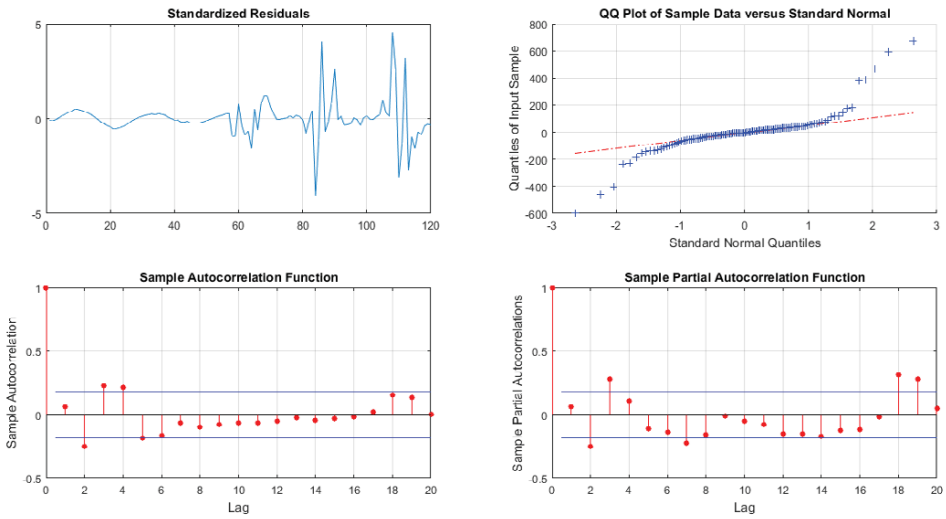

Fig. 6: Tuned up ARIMA Standarized Residuals and QQplot (1 Week 1 Hour)

After optimizing the process of getting ARIMA coefficient, we have noticed a reduction in standardized residuals amplitude and the evenly distributed quantiles on the references line (Fig. 6 Standarized residuals plot). However, there are fractions that indicate that our forecasted values is still greatly different from real measurements (Fig.6 QQ plot).

ARIMA results were evaluated and are presented in (Tab. 1):

Tab. 1: Tuned-up ARIMA Model results for the 3 chosen datasets

	1 Week 1 Hour	1 Week 10 minutes	1 Month 1 Hour
MAE W/m²	98,78	159,67	335,769
MSE W/m²	2,47E+04	7,85E+04	2,05E+05
RMSE W/m²	157,19	280,14	453,64

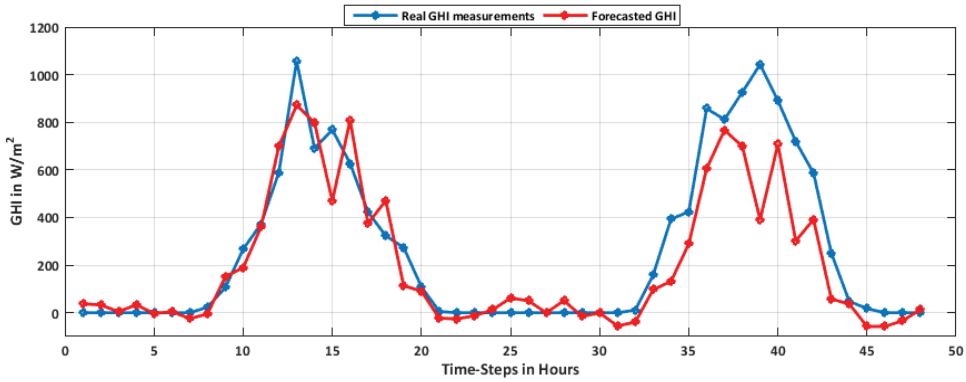

Fig. 7: Forecasted GHI results using 1 Week of data with 1 Hour resolution

The best results were recorded for one week of solar data with one hour resolution presented in (Fig. 7), the larger the dataset is the more time the computer takes to produce forecasts. A constraint over computational time was however put in place to have some rapidity while maintaining the same reliability. This constraint had largely increased the error on one Month dataset with the resolution of one hour. But it still gives relatively acceptable results if compared to the other datasets. In either ways, ARIMA seems incapable of producing reliable forecast for long periods. One limitation of ARIMA models is that they often overlook the physical behavior of time series objects, in our case sunrise and sunset. A study by (Moreno-Munoz, 2008) showed that ARIMA can accurately forecast hourly irradiance levels using data from a few previous hours. However, due to the discontinuity of solar irradiance, forecasts immediately adjacent to sunrise and sunset are problematic and increase forecast errors.

4.3 Benchmarking Program Results and Analysis

For this task we have used a year of historical GHI data with the resolution of 1 hour, the results are compared for clear-sky and cloudy conditions as presented in Fig.8:

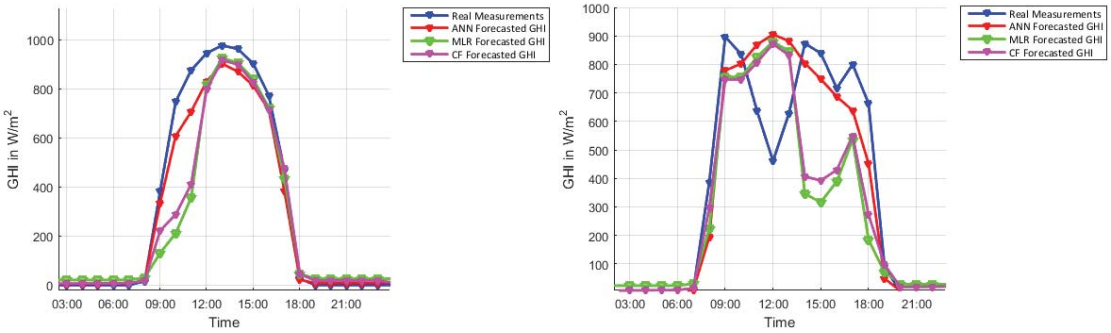

Fig. 8: Forecasting Benchmark results of a clear-sky day and cloudy day

Using the daily and hourly averages of solar irradiance of the previous day imposes that our MLR model to mimic yesterday's behavior, the choice of this procedure was taken because generally adjacent days follow relatively the same behavior. MLR model gave 56.352% MAPE for Validation dataset, this Error was reduce to 22.733% Using Curve Fitting model. ANN model is seeeminly independent of adjecent days but gives relatively satisfying results of 16, 264% MAPE.

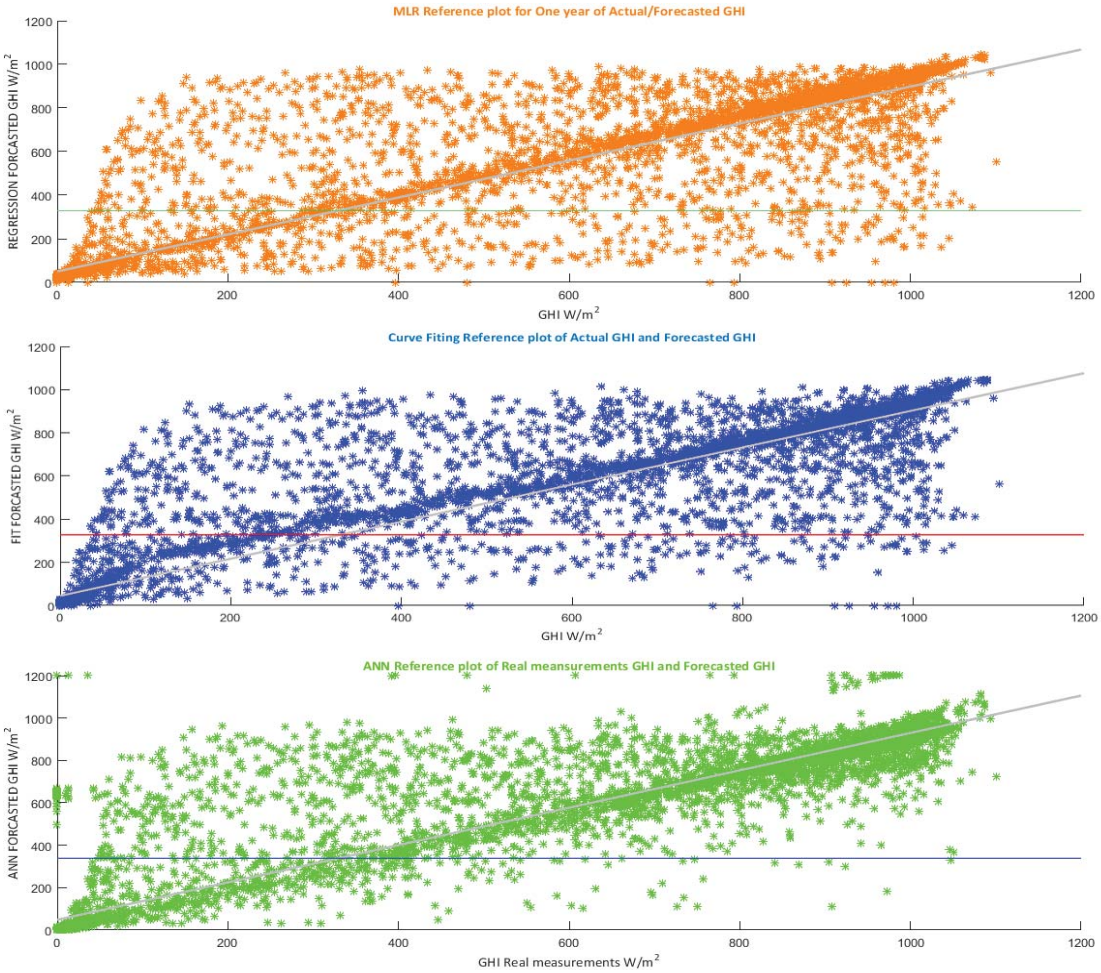

Fig. 9: Reference plot of the three benchmarked methods using 1 year of GHI with 1 hour resolution

For visual comparison we present in (Fig. 9) reference plot for MLR model in orange, Curve Fitting in blue and ANN model in green, horizontal line represent mean value, and the inclined line represent least-squares line.

If the diffenrence between forecasted and measured values was smaller the dots tend to be close to the least-square line, so we can notice that ANN response fits GHI historical data better than MLR and CF models, which is verified by (Tab.2) of Metrics presented in section 4.1:

Tab. 2: Benchmarking forecasting models evaluation using 1 year of GHI with 1 hour resolution

	Curve Fitting		Multiple Linear Regression		ANN	
	Validation Error	Historical Error	Validation Error	Historical Error	Validation Error	Historical Error
MAE W/m²	23,35	81,1673	29,94	75,57	20,77	66,87
MSE W/m²	1,05E+03	2,42E+04	1,48E+03	2,21E+04	0,77E+03	3,38E+04
RMSE W/m²	32,58	155,57	38,3	148,513	22,1	183,729
MAPE	22.733%	44.644%	56.352%	123.045%	16, 264%	331,11%

While regression barely gave admissible results, improving it with fitting curve has considerably enhanced it. But between the three combined models, the best is Artificial Neural Networks model as the Validation MAPE error indicates, even with the high error of historical GHI due the learning phase and night time values. Ergo tuning up Neural Networks model will surely produce a robust forecasting engine.

4.4 NARX ANN model

Mean squared Error MSE gives a huge proportion to the difference between predicted and real values, using it in as performance function in learning phase helped reduce the error drastically. However evaluating regression models is often done by MAE or MAPE as they only evaluate the difference between two data values. The

simulation were carried out and the Neural Network stopped training with ten layers at a delay of 2, in (Fig. 10) the NARX ANN is presented.

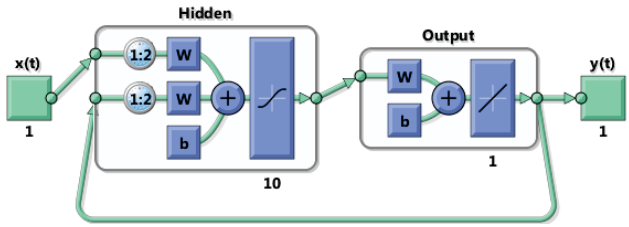

Fig. 10: NARX ANN Model architecture.

x(t) is a matrix containing historical data lagged by 10 minutes from 15th of April to 15th of May of GHI, Relative humidity and ambient Temperature and as an output y(t) is forecasted GHI. The choice of the input matrix was taken for examining various meteorological variables and how they change with GHI (Fig. 2).

We have tried this model for three Forecast Horizons, one day, two days and three days ahead results are shown in (Fig. 11) below:

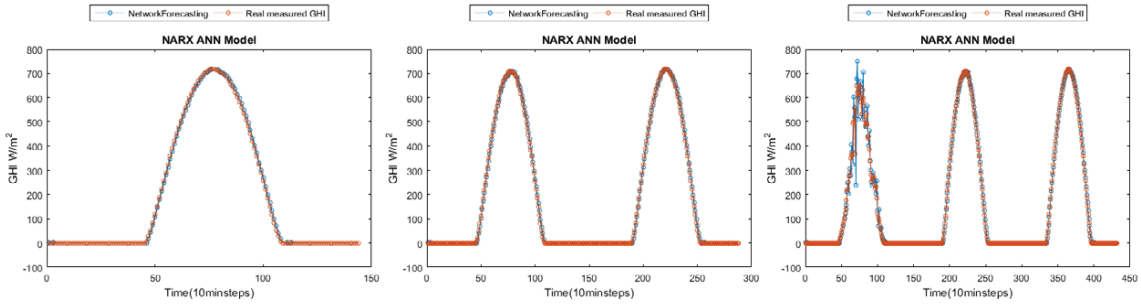

Fig. 11: Plot of forecasted values and real measurements of NARX model for the three Forecast Horizons

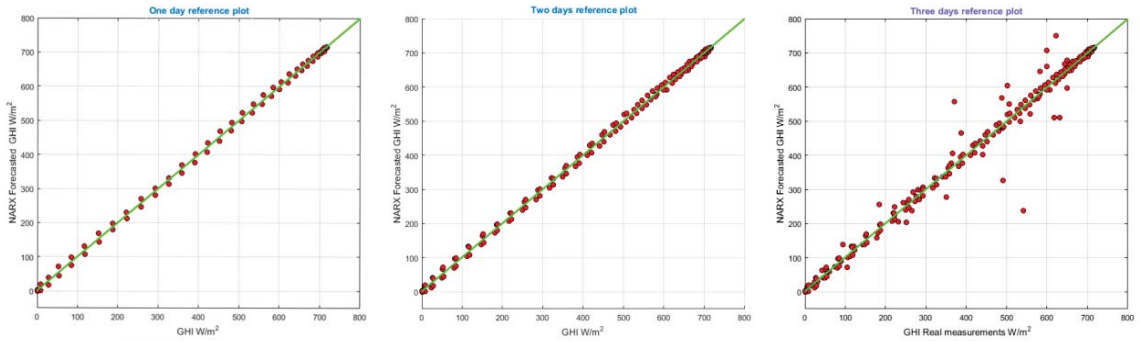

Fig. 12: Reference Plot of NARX model for the three Forecast Horizons

For a clear sky conditions, the results are near perfect as shown in (Fig.12) for one and two days forecast horizon, with less than 4,57 % MAPE error, however for cloudy day the minimum error acquired was 14,67% which by far less than the other models previously developed in this study. Also, as presented in (Tab. 3) we noticed that when the Forecast Horizons gets bigger the accuracy decreases, it was the same for all models, however for NARX model this lost of accuracy is really subtle and relative to cloudy days presence, but for clear sky the forecast is very good which demonstrates the robustness for NARX model.

Tab. 3: Evaluation metrics results for NARX model

	1 Days ahead	2 Days ahead	3 Days ahead
MAE W/m²	8,82	9,3126	4,21E+01
MSE W/m²	1,47E+02	1,64E+02	1,71E+04
RMSE W/m²	12,10	12,81	130,95

The results in Tab. 3 shows that NARX ANN model outperforms all the other models, and the best way to make a neural network learn seasonality and the trend is to make a construct of inputs that are related to each other to a certain extent, temperature and relative humidity gave better results if compared with clearness index.

For Clear-sky day the forecasted values seem to be close to real measurements as they follow the least squared error line, as for cloudy days the majority of values are near real measurements, the other minority have bigger differences from real measurements.

5. Conclusion

In this paper, a methodology has been undertaken for short-term globale horizontal irradiance forecasting for the case of Green Energy Park of benguerir. An ARIMA model was developed and showed its efficiency in Intra-hour forecasts and its inability to produce reliable forecasts for longer horizons. Other stochastic methods were also developed for the sake of comparison. Multiple linear regression (MLR) and curve fitting were compared with artificial neural networks. We also have demonstrated that MLR barely has the ability to determine the general trend of used solar data but it cannot model data non-linearities, MLR was tuned with curve fitting by trying to find coefficients for the Fourier polynomial equation, the improvement seen were barely noticeable. However, for ANNs, the results were promising and it was a better choice for further developments. For this reason, a new forecasting model was developed based on NARX ANN, the results were very satisfying as the forecast error (MAPE) was decreased to 4,57 % for Clear-sky day and 14,67% cloudy day.

To make a good use of enhancements made in GEP's forecasting model, using SANDIA PV library in Matlab, we have succeeded in modeling 12 photovoltaic systems with different photovoltaic technologies from different PV modules manufacturers. This precise model will be used as conversion process for solar irradiance forecasts to acquire DC power output predictions of GEP's PV power Plant.

6. Future work

In order to make the model developed in this study more reliable, a hybrid model based on satellite images and NWP is under development. As for the GEP PV power plant model, some enhancement are underway to make the model more responsive to real weather conditions.

Abstract

The design and optimization of solar power systems requires a detailed knowledge of the dynamic behavior of the meteorology at the site of interest, usually assess by one typical meteorological year (TMY). Even with today's technology, the computational effort to simulate solar energy system performance with one year of data at high frequency (as 1-min) may become colossal if a multivariable optimization has to be performed. This work evaluates a methodology based on cluster analysis for selecting number of individual days able to represent the long-term performance of a solar energy system. This procedure permits to drastically reduce computational effort related to the calculation of a solar power plant energy yield by simulating a reduced number of days from a TMY, facilitating a fast and optimal design of the plant.

Keywords: Cluster, Day selection, STE (Solar Thermal Electricity), Optimization

1. Introduction

Concentrating Solar Thermal Power (CSTP) technologies collect and concentrate the Direct Normal Irradiance (DNI) incident on the earth's surface to heat a working fluid and afterward producing electricity through a thermodynamic cycle. The mean power produced by a CSTP system often determines the viability of the Solar Power Project, which is calculated from energy yield simulation computer programs requiring weather data input to drive the optical and thermal models within the simulation tools.

The feasibility analysis of a CSTP plant project requires the estimation of the amount of energy that it will be able to deliver to the grid during its lifetime. A detailed knowledge of the Direct Normal Irradiation (DNI) is a critical point to perform an economical feasibility analysis of these plants, as it is the most determining variable in the final energy yield. This knowledge comprises a deep understanding of the availability and dynamics of the solar resource over different temporal scales (intraday, day, month, year) (Vignola et al., 2012). To achieve this, long time series of meteorological data are usually condensed into shorter series that typify the meteorological conditions at a specific location with the aim of data volume reduction and speeding-up of energy system simulations, considered as representative of the location of interest.

Currently, the typical year approach is by far the most widely used among the scientific and industry communities for the design and optimization of solar power plants. These datasets hold 8,760 hourly meteorological values that typify conditions at a specific location throughout a longer period. Accordingly, simulations are usually performed using one hour simulation steps, either with steady state models or somehow

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/eurosun.2016.09.03 Available at http://proceedings.ises.org

taking into account system dynamics to more accurately simulate the performance of the plant. Also, worst cases of solar resource availability are often analyzed in order to ensure the viability of the project. Frequently, these worst cases are evaluated by probability of exceedance scenarios, which provide an estimate of electric generation output that the solar resource consultant expects to be exceeded in any given year over the life of the debt with 90% confidence (P90) and 99% confidence (P99) (C.M.F. Peruchena et al., 2016).

TMY approach seems to be appropriate for rather detailed simulations of a specific solar power plant. Notwithstanding, DNI exhibits a great variability at high-frequency due to the dynamic effects of passing clouds, which is a key issue in the design and performance analysis of a CSTP system, given its nonlinear response to DNI caused by various thermal inertias due to their complex response characteristics (Fernández-Peruchena et al., 2015). DNI series of sub-hourly resolution (in the range of 1 to 10 minutes) permit an accurate modeling and analysis of transient processes in some CSTP technologies. For example, parabolic troughs with direct steam generation could be particularly sensitive to the cloud transients (Eck and Hirsch, 2007; Montes et al., 2009), and, therefore, better analyzed using DNI series with frequency resolutions much lower than 1-h (Meyer, 2010). This kind of simulations provides more accurate representation of the plant performance at the cost of larger computational effort leading to longer simulation times. Thanks to the powerful computers currently available, these transient simulations are being used not only for detailed simulations of the short term performance of the plant to improve the design and operation of specific aspects of the system, but also for the energy yield estimation over long periods of the plant (e.g. year simulation or even multi-year simulations) for a specific final plant design.

During the optimization of the large number of plant parameters before a final design is reached, a huge number of simulations are required. The computational effort to simulate a CSTP plant performance with 1-year series at high frequency (as 1-min) may become colossal if a multivariable optimization has to be performed. To overcome this problem, several approaches have been presented for reducing or condensing the data, as the Short Reference Year (SRY) (Hallgreen, 1983), which divides the calendar year into periods. However, in this approach, the selection of the representative days is left to the designer expertise, or they are selected emblematic days like the solstices. More recently, a novel approach based on cluster analysis has been proposed to optimally select individual days able to represent meteorological conditions at a site (Carlos M. Fernández Peruchena et al., 2016). The goal of this contribution is to apply this methodology in a location with high-quality and long term validated measurements, in order to evaluate if selected days can represent the performance of a CSTP plant throughout the complete year.

2. Experimental data and method

2.1. Experimental data

A 12-year series of hourly solar irradiance and meteorological parameters measured in Evora, Portugal by the University of Évora has been selected for this study. Table 1 below presents details about the location of the station, its pyrheliometer and the climatic conditions of the station location, according to the Köppen-Geiger classification (Peel et al., 2007).

Tab. 1: Radiometric station selected for this study.

Location (Country)	Coordinates (º)	Altitude (m)	Pyrheliometer	Period	Climate (Köppen classification)
Évora (Portugal)	38.567 N 7.911 W	290	Kipp&Zonen CHP1	2003-2015	Mediterranean (Csa)

The measured data set covers a 12-years period. The data has been recorded every 5 seconds and averaged every 10 minutes. DNI is measured with a Kipp&Zonen Pyrheliometer (model CHP1), a WMO First Class Pyrheliometer with an associated estimated uncertainty at daily scale of <1%. The pyrheliometer is calibrated every 2 years according to the standard ISO9059:1990.

2.2. Energy yield simulations

A 50 MWe Fresnel type power plant without thermal-energy storage and with a primary mirror area of 193.000 m^2 has been designed for Évora, Portugal. The software TRNSYS V.17 (www.trnsys.com) has been used for the estimation of hourly values of the energy produced by this system. TRNSYS is a validated, time-series simulation program that can simulate the performance of photovoltaic, concentrating solar power, water heating systems, and other renewable energy systems using hourly resource data (Wagner, J. M. and Gilman, P., 2011).

2.3. Day selection

In this work, a TMY series is generated from measured series available at the location. For selecting specific days of this yearly series, the following parameters have been calculated to characterize individual days: daytime mean temperature; daily cumulative DNI value; sum of the product of DNI · cos (SZA), being SZA the solar zenith angle; a wind-dependent variable that is zero if maximum daytime wind speed is lower than 12 m/s, 2 if percentile 90 of daytime wind speed is higher than 12 m/s, and 1 in any other case.

Cluster analysis comprises a wide variety of techniques for delineating natural groups (clusters) in data sets, so that observations within each group are similar to one another with respect to variables or attributes of interest and the groups themselves stand apart from one another. This technique is useful for summary and discovery:

- *Summary* refers to the reduced representation of the full data;
- *Discovery* refers to finding out patterns into the original data series.

In this work, the objective of applying cluster analysis is summarizing the data, by means of selecting a small number of days to represent the complete year.

Finally, the clustering method used in this work is the K-medoids algorithm, which selects points analyzed as the center of the clusters. Also, the gap statistic method (Tibshirani et al., 2001) is used for estimating the number of clusters (groups) in the daily series. The idea behind this technique is to find a benchmark (i.e., a *null distribution*) and to compare the observed value of W (the within-cluster variability) with the expected value under the null distribution (being large deviations from the mean evidence against the null hypothesis).

2.4. Method relevance

The aim of this method, using groups of data as clusters is to enable a faster analysis of a wide range of options when designing a Solar Plant. With today's computer processing capability this might seem outdated. However, engineers that design big plants usually do not have plenty of time to run multiple scenarios and in multiple locations. For that reason, reducing the computing time for one set of data for a specific location is an advantage specially in the pre-design phase. With the cluster analysis the computing effort in time is reduced in a magnitude of 15 to 20 times, thus enabling many other alternatives and configurations to be studied.

3. Results

3.1. Optimal number of days

In fig. 1 it is represented the gap statistics for the TMY at Évora, where 3 number of clusters cases are highlighted: 15 days (blue), 18 days (green) and 22 days (orange). These cases represent the maximum value of the gap functions in 5-clusters intervals (10-15 clusters; 15-20 clusters; 20-25 clusters), and they are candidates to be the optimal number of clusters to represent the TMY.

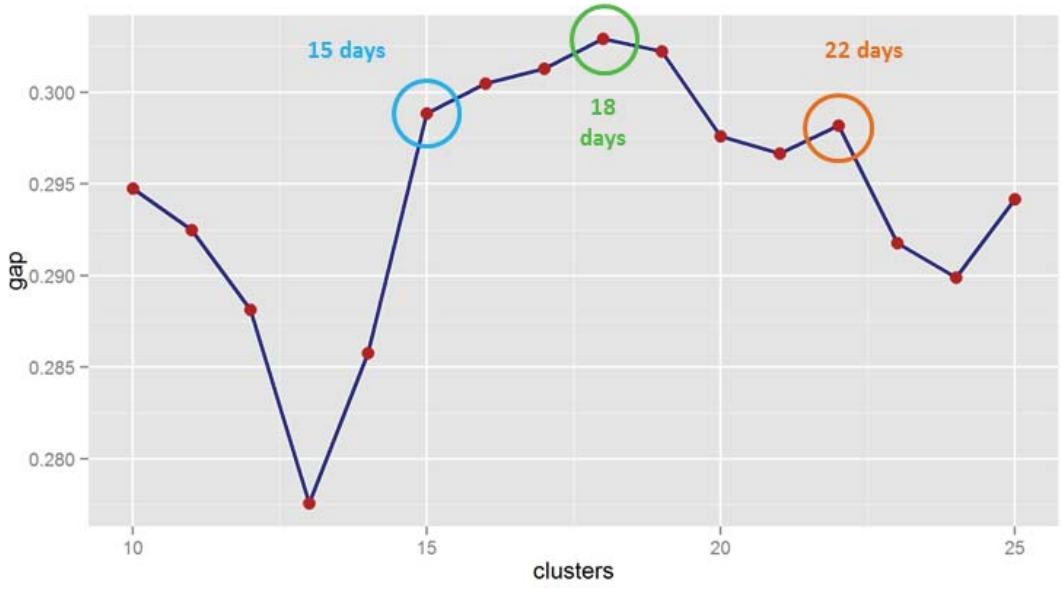

Fig. 1: Gap statistics for day selection

In the analysis carried out, the medoid of each cluster is selected as the most representative days, and also each of the 365 days of the TMY are assigned to one of these clusters. Table 2 shows the 18 selected days selected for representing the TMY at the site (this is expected to be the optimal case, as it reaches the highest Gap value), their DNI value and the number of days represented. This table also shows the maximal and average dissimilarity (max_diss and av_diss, respectively) between the observations in the cluster and the cluster's medoid, as well the *isolation* of the clusters: the maximal dissimilarity between the observations in the cluster and the cluster's medoid, divided by the minimal dissimilarity between the cluster's medoid and the medoid of any other cluster.

Tab. 2: Cluster parameters for the TMY representation

Specific days selected of TMY (1-365)	Daily DNI (kWh/m^2)	Number of days represented	max_diss	av_diss	Isolation
301	1.55	23	2.60	1.56	0.98
2	2.97	28	2.45	1.31	0.93
328	6.23	25	4.00	1.45	1.76
17	4.71	20	6.34	1.88	1.64
8	0.97	15	2.38	1.21	0.68
326	5.81	28	2.64	1.17	1.16
276	3.88	20	2.84	1.54	1.18
60	7.89	19	2.98	1.56	1.09
282	2.46	11	2.70	1.96	0.76

103	10.34	16	3.15	1.92	0.69
86	1.72	7	2.36	1.03	0.98
289	6.76	23	2.91	1.65	1.13
186	9.72	31	2.54	1.38	1.13
287	7.22	17	2.83	1.33	1.10
165	11.34	20	3.14	1.38	1.40
228	4.50	14	3.36	1.97	0.67
237	9.22	26	4.35	1.93	1.24

In fig. 2 it is plotted the selected days, representing its own typical DNI value varying along a 24h period. Clusters are numbered from 1 to 18, and also color-coded. As expected in a Mediterranean climate, most days of summer are represented by clusters 14-18 (characterized by high DNI values as well as long days), and most of winter days are represented by clusters 1-5 (characterized by shorter days and higher DNI variability).

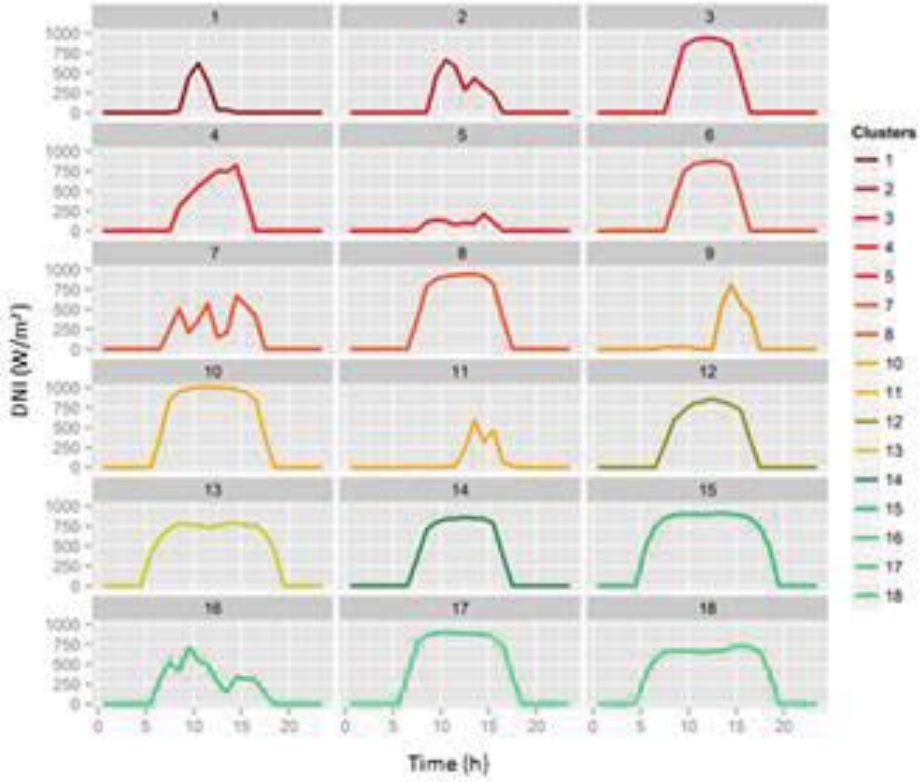

Fig. 2: left, days selected representative of the 18 clusters calculated for the TMY at Évora

This variability across the year can be observed in fig. 3 where which of the 18 typical days are represented throughout the whole year.

From fig. 3, it is clear that from November to February the representation is mainly obtained with clusters 1 to 6, while March, April and October are transition months with clusters 7 to 12 representing most of the period.

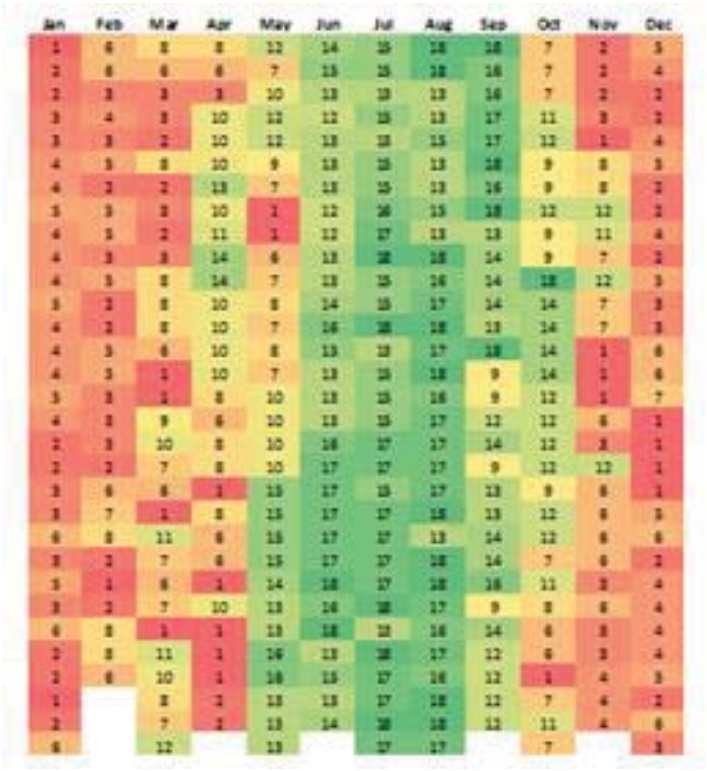

Fig. 3: Days throughout the year (January to December) represented by the selected days (#18 days)

The comparison of the annual energy yield provided by the days selected, multiplied by the number of days represented by each one of the cluster days, has been compared with the solar energy yield of the 365 days of the TMY, and their differences are shown in fig. 4 as a function of the number of clusters selected (from 10 to 183 days). These differences tend to decerase at increasing number of days selected, as expected. Very low differences (<1%) are found even for the selection of few days (15 or less).

Peaks are found in almost the whole range analyzed, as expected as a trend, the amplitude decays with an increasing number of days.

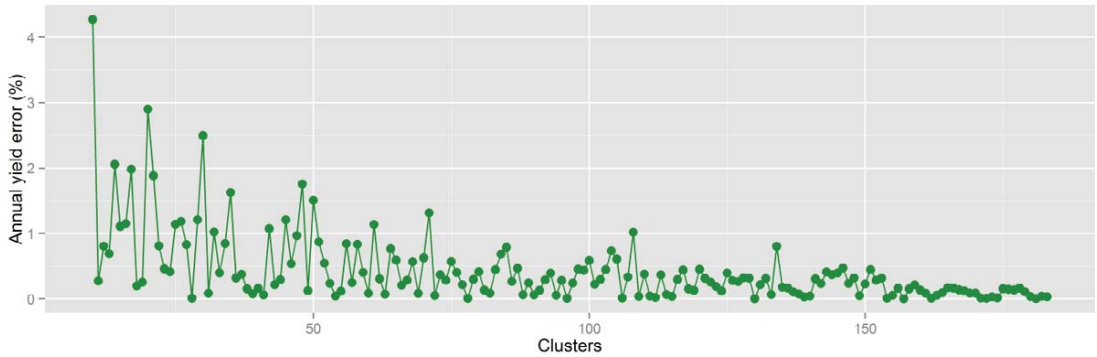

Fig. 4: Difference between annual energy yield calculated with clusters and TMY, as a function of the number of clusters selected

Even if a univocal relation between Gap function and accuracy of annual energy yield cannot be fully established, it has been found a more clear correlation by grouping clusters into intervals. Table 3 shows the optimal number of days selected as a function of the maximum number of days allowed in the cluster analysis, in 5-days intervals. It is shown the difference between TMY and days-selected electric yield, as a function of the maximum number of clusters allowed, showing a clear correlation between Gap function and accuracy in yield estimation.

Tab. 3: Results of cluster analysis as a function of the maximum number of clusters allowed

Maximum number of days allowed for the cluster	15	20	25
Optimal number of days selected	15	18	22
Gap function value	0.2959222	0.2996370	0.2949644
Difference between electric yield production using TMY data and using cluster selected days	1,1%	0,2%	0,8%

4. Conclusions

The methodology presented in this work allows a very significant reduction in the computational effort related to the calculation of a STE plant energy yield by simulating a reduced number of days from a high frequency TMY (90% of computing time can be reduced if 18 days are selected for representing the TMY). These days are the medoids of clusters selected according to gap statistic.

The energy yield produced by these selected days facilitates a fast and accurate, evaluation of the annual energy production of a STE plant. Concurrently, in the optimization phase of a solar plant design, many more configurations can be explored using these 18 days than using the whole TMY production analysis (with the same computing cost / time).

The computational effort of this evaluation depends on the uncertainty allowed: a tradeoff between inaccuracy (which is given at low numbers of clusters selected) and computational effort (which is given at low numbers of clusters) must be carried out in each specific analysis as it was shown for the specific location of Evora, Portugal where a STE research facility has been built, the EMSP (Evora Molten Salt Platform).

5. Acknowledgments

The authors would like to thank to ICT-Uni.Evora (Prof. Paulo Canhoto and Prof. Heitor Reis) for enabling the usage of solar radiation collected data, to project DNI approved by IPES (Portuguese Solar Energy Institute), as well as to the H2020 Program which funded Project PreFlexMS, the trigger for the study presented.

Abstract

In analyzing the solar energy systems, the first step is the accurate measurements/estimations of the input in the long term: solar irradiation incident on the panels. The measurements are lacking in many places so the estimation procedures should be developed using the measured data of the locations having similar climates and close in latitudes. In most life cycle assessments, monthly averages of daily values are utilized in the form of typical meteorological year or simply with the averages of a year or for a number of consecutive years. Although the beam component of the solar irradiation is usually higher than total of all diffuse components except in highly cloudy and overcast sky conditions, estimation of diffuse components is vital especially to determine the solar irradiation on tilted solar panels. In this study, with the final aim of developing the best procedures to estimate diffuse solar radiation component for all the locations of Turkey, we carried out a preliminary comparison and reached a best procedure of estimation for two locations in Central Anatolia. Our procedure is to compare a model based on a physical formalism developed before with four methods of estimation appeared in the literature, together with the data obtained by Meteonorm Software. As a result, our model has given one of the two best results together with Meteonorm Software when compared to measured values. It is in fact the best one according to the RMSE value.

Keywords: *Total, beam and diffuse solar radiation; solar energy; Turkey; MBE; RMSE*

1. Introduction

By courtesy of being in solar belt (EPIA, 2010), Turkey is a high potent country to utilize solar energy for daily needs of public body, such as heating, cooling, hot water and in particular electricity, *inter alia*. In that vein, there is an opportunity for developing countries like Turkey to meet their needs in more economical, social and environmental way in parallel to the necessities of sustainable development. Even if the current position of Turkey on solar electricity production is still low with 562 MW PV installed power which was just 249 MW in the beginning of the year (TEIAS, 2016), it carries huge potential when compared to global leaders. For instance, while 1 kW PV system installed at the south part of Germany, a region that has got the highest solar potential in the country, is able to produce 1190 kWh electricity annually, it ranges between 1350-1750 kWh in Turkey from north to south (SMS and Fraunhofer, 2015). Considering the leadership role of Germany throughout the development process of solar energy market, this situation in Turkey is an obvious measure of the potential of Turkey.

As for hot water production via solar energy, Turkey's performance is devastating as being world number 3 together with Germany after China and USA with respect to solar water heating collector capacity (REN 21, 2016).

On the other hand, Turkey has got increasing electricity production demand. Current electricity demand which is around 280 TWh is estimated to be 424 TWh by the year 2023 with more than 50% increase rate (DG for Renewable Energy, 2014). Furthermore, Turkey is obliged to condemn the pledges under Paris Agreement a legally binding document ratified in order to tackle with climate change.

Consequently, solar energy usage in various fields has vital importance for the country. Moreover, its sharply decreasing marginal costs and rapidly increased technological development strengthen the use of solar energy against its counterparts. To look more closely at the development on solar technologies and their prices, together with annual reduction of marginal cost of wafer-based silicon PV modules of about 9% since 1990 (Fraunhofer, 2016) it is expected to be declined 59% more till 2025 (IRENA, 2016). Furthermore, the

doi:10.18086/eurosun.2016.09.04 Available at http://proceedings.ises.org

efficiency of them is increased about 5% in the last 10 years (Fraunhofer, 2016).

In this manner, there are two necessities to be known accurately that can be identified by making correct calculations after defining appropriate estimation procedures. The first necessity is to know the solar potential which is directly depended on solar insolation exposure. Second is related to defining the methods/ways to exploit/utilize the potential. In other words, there is a need to make feasible, bankable, technically efficient projects to install solar energy systems for various purposes (Karaveli et al., 2015). In this respect, Karaveli et al. made calculation of monthly mean solar irradiation for horizontal and tilted surface for Konya province Karapinar district which has one of the highest solar potential in the country and owns Energy specialized industrial zone specific to solar energy . Then, solar photovoltaic system designed in an appropriate manner and compared it with nuclear power plant planned to be installed in Turkey. Consequently, this study has lead in showing the appropriate way to define the solar potential and the feasibility of solar energy (Karaveli et al., 2015).

In order to be able to attain these above mentioned two necessities, the most important step is to make accurate estimations of the input of the system with its all components. For solar energy, this input is the solar irradiation falling on tilted surfaces of solar energy systems; mainly its components: beam (direct) and diffuse (scattered) ones.

Of course, the most accurate way to know the solar radiation with its components is long-term measurements of it at each location taken into account. However, this option is not used for a current situation and not possible in a short-run. Moreover, this option may not be economically feasible and physically possible. Therefore, the possibility of using measurements of one location to estimate the irradiation values for another location which has similar coordinate (latitude) and climate features can make it possible to estimate the feasibilities of the applications. Accordingly, by using currently measured long-term solar irradiation values of some locations to attain the best estimation procedures of the solar energy for the other locations, on tilted panels are an important and a possible way to reach feasibilities of the solar systems.

The estimation procedures of solar irradiation incident on tilted surfaces necessitate the calculation of beam and diffuse components of solar irradiation on horizontal surface (Duffie and Beckman, 2006). There are quite a large number of methods developed in the literature as reviewed by (Khorasanizadeh and Mohammadi, 2016). In addition many comparative studies are carried out using the measured data set of a location or at most a region [see for example (Tasdemiroglu and Sever, 1991)]. The results of our preliminary comparisons showed that it is very important to determine the best procedure(s) for Turkey and for different regions of the country, due to the highly complicated nature of the diffuse component. We present here our preliminary results of these comparisons of various models using the data of two locations in Central Anatolia, as a preliminary work. We also compared a model that we developed based on a physical modeling approach that was outlined before by Akinoglu (1993, 2008) and updated by Karaveli and Akinoglu (2016).

We chose a pair of locations to work on this study located in Central Anatolia: Eskisehir (39.78^{o} N) and Ankara (39.95^{o} N). The climates of the two locations are semi-dry continental and typically similar in terms of mean temperatures, rainfall and hot and cold waves spatial distributions (SMS, 2016). The distance between these two locations is 235 km. and altitudes are 792 m and 938 m, respectively. The data is obtained from State Meteorological Service (SMS) of Turkey.

The correlations that we used for comparisons are as follows: The first expression was derived for twelve locations in Central Anatolia by Aras et al. (2006). They concluded that a cubic expression is relatively better than others. Ulgen and Hepbasli conducted similar analysis and proposes another cubic expression and they both depended on monthly average daily bright sunshine hours per day length ratio (n/N) and monthly average daily solar irradiation on horizontal surface divided by monthly average daily extraterrestrial solar irradiation on horizontal surface, that is clearness index (Ulgen and Hepbasli, 2009). Tasdemiroglu and Sever utilized experimental data of mean solar irradiation on horizontal surface and obtained forth order polynomial function for the diffuse ratio with respect to clearness index (Tasdemiroglu and Sever, 1991). In comparisons, we also used the expression obtained by Erbs et al. who utilized hourly pyrheliometer and pyranometer data of US locations and derived clearness index and sunset hour angle depended equation (Erbs et al., 1982, Duffie and Beckman, 2006).

Moreover, one of the most famous databases/methodologies used by some of the commercial software programs which are heavily used for solar system design in Turkey, namely Meteonorm, is also used for comparisons in this study. The aim is to find the accuracy that this software can reach in their performance

calculations of solar energy systems.

Lastly, we obtained linear correlations between monthly average diffuse ratio and monthly average daily fractional bright sunshine hours to estimate the diffuse component of monthly average daily solar irradiation, based on a physical modeling developed by Akinoglu (1993, 2008). In fact, we obtained a linear correlation for one of the locations: Eskisehir, and used this correlation to estimate the diffuse solar irradiation for Ankara.

In the view of above information, this study takes into account all the options to obtain the best estimation method for the diffuse part of solar irradiation. The results will be used in the short term and long term feasibility studies of the solar energy systems to be installed in the mentioned regions of the country.

The data used and exploited in the study provided from State Meteorological Service (SMS) of Turkey is as minute by minute values of total, diffuse solar irradiation and bright sunshine hours. These are the data measured through pyranometers and pyrheliometers in SMS measurement stations in the unit of watts per minute. Then, the measured data taken from the beginning of 2011 till the end of 2015 are analyzed and unreliable data are extracted. Moreover, the unit of the data is converted into MJ m^{-2} d^{-1} as needed for the models used in this study. Finally, the monthly averages of the compiled data are calculated and assigned as the value for monthly mean daily amounts.

In the comparisons, we used Mean Bias Error (MBE) and Root Mean Square Error (RMSE) values for the estimations of each procedure. MBE is a measure of under or over-estimation while RMSE can get high values even if the estimation only for one of the months considerably deviates from its measured value. Therefore, for both error values closer the value to 0 means better the estimation.

2. Solar Radiation Calculations

The study is on the estimation of monthly average daily solar irradiation on horizontal surface. To this aim, we calculated monthly average of daily extraterrestrial solar irradiation on horizontal surface using the equation given in Duffie and Beckman (Duffie and Beckman, 2006). Then, the diffuse component of the solar irradiation reaching the Earth on a horizontal surface after passing through the atmosphere is calculated using the aforementioned models.

These models (equations) are depended on H_0, H, H_d, n and N where H_o symbolizes daily value of the extraterrestrial (outside the atmosphere) irradiation incident on a horizontal surface; H is the estimated daily global solar irradiation; H_d is the daily values of diffuse component; n is daily bright sunshine hours (sunshine duration) and N is day length. The over-bar of the mentioned symbols refers to monthly average values. The models used in comparisons are given in Table 1.

In addition to these equations, to retrieve data from Meteonorm, the software is installed on the desktop. Ankara is selected from the tool bar. The diffuse solar radiation data for Ankara is given in the following screen that is revealed in Figure 1.

Tab. 1: Defined equations to find diffuse component of solar irradiation

Equation	Reference
$\frac{\bar{H}_d}{\bar{H}} = 1.6932 - 8.2262(\frac{\bar{H}}{\bar{H}_0}) + 25.5532(\frac{\bar{H}}{\bar{H}_0})^2 - 37.8070(\frac{\bar{H}}{\bar{H}_0})^3 + 19.8178(\frac{\bar{H}}{\bar{H}_0})^4$	Tasdemiroglu and Sever, 1991
$\frac{\bar{H}_d}{\bar{H}} = 1.7111 - 4.9062\frac{\bar{H}}{\bar{H}_0} + 6.6711\left(\frac{\bar{H}}{\bar{H}_0}\right)^2 - 3.9235\left(\frac{\bar{H}}{\bar{H}_0}\right)^3$ and $\frac{\bar{H}_d}{\bar{H}_0} = 0.2427 - 0.0933\left(\frac{\bar{n}}{\bar{N}}\right) + 0.1846\left(\frac{\bar{n}}{\bar{N}}\right)^2 - 0.2184\left(\frac{\bar{n}}{\bar{N}}\right)^3$	Aras et al., 2006
$\frac{\bar{H}_d}{\bar{H}} = 0.981 - 1.9028(\frac{\bar{H}}{\bar{H}_0}) + 1.9319(\frac{\bar{H}}{\bar{H}_0})^2 - 0.6809(\frac{\bar{H}}{\bar{H}_0})^3$ and $\frac{\bar{H}_d}{\bar{H}_0} = 0.1437 + 0.2151\left(\frac{\bar{n}}{\bar{N}}\right) - 0.1748\left(\frac{\bar{n}}{\bar{N}}\right)^2 + 0.0697\left(\frac{\bar{n}}{\bar{N}}\right)^3$	Ulgen and Hepbasli, 2009
$\frac{\bar{H}_d}{\bar{H}} = 1.391 - 3.560(\frac{\bar{H}}{\bar{H}_0}) + 4.189(\frac{\bar{H}}{\bar{H}_0})^2 - 2.137(\frac{\bar{H}}{\bar{H}_0})^3$	Erbs et al., 1982

From the table revealed in Figure 1, monthly mean daily diffuse solar radiation amount, as needed, is reckoned by dividing irradiation in the second column in the Table with the number of days in the specific month. The results are given in Table 3.

3. Linear Equation Derivation

As mentioned in previous parts of this article, the physical formalism derived and applied in this study was developed in Akinoglu (1993 and 2008) and adopted for the diffuse component by Karaveli and Akinoglu (2016). The development of the aforementioned model is launched by the consideration of the instantaneous fractional clear sky period n_i. Then the beam solar irradiation directly reaching the Earth's surface during n_i period, I_B, can be given as:

$$I_B = I_0 \tau n_i \qquad \text{(eq. 1)}$$

where I_0 is the extraterrestrial solar irradiation falling on horizontal surface during that certain time interval and τ is atmospheric transmission coefficient for clear-sky. In the mentioned time interval, there is not only beam but also diffuse part (sky and circumsolar) reaching to the surface that can be expressed as:

$$I_{D1} = I_0 (1-\tau) \beta' n_i \qquad \text{(eq. 2)}$$

where β' is the atmospheric forward scattering coefficient. The time remaining after n_i period is called as cloudy period. This period, as is nature, has diffuse radiation, I_{D2}, that can be expressed as:

$$I_{D2} = I_0 \tau \tau' (1-n_i) \qquad \text{(eq. 3)}$$

where τ' is a transmission coefficient of the clouds.
Then the linear model expression for the global solar irradiation [Akinoglu, 1993, 2008] is attained by adding Eqns. (1) to (3). Moreover, adding Eqns. (2) and (3) results in a linear expression for the diffuse part as:

$$I_D = I_0 (1-\tau) \beta' n_i + I_0 \tau \tau' (1-n_i) \ . \qquad \text{(eq. 4)}$$

We may then write equation (4) for daily integrated and then monthly averaged values of diffuse solar irradiation by assuming that the forms would not change and by replacing the coefficients with their effective monthly counterparts (Akinoglu, 1993, 2008 and Karaveli and Akinoglu, 2016). While structuring this approach, we should also consider that the ratio of monthly average of daily sunshine duration to day-length n/N will replace the fractional time period n_i. Accordingly, I_D and I_0 will be replaced with their monthly average daily values of $\overline{H}_D$ and $\overline{H}_0$. If these replacements are carried out, a linear correlation for the monthly average of daily diffuse irradiation from Eqn. (4) can be reached as:

$$\overline{H}_D / \overline{H}_0 = a_1 + a_2 (\overline{n} / \overline{N}) \qquad \text{(eq. 5)}$$

where $\overline{H}_D$ is monthly average daily diffuse solar irradiation, $\overline{H}_0$ is extraterrestrial solar irradiation, $\overline{n}$ is the monthly average daily bright sunshine hours and $\overline{N}$ is monthly average day length. In this approach, the parameters a_1 and a_2 can be written as:

$$a_1 = \tau_e \tau_e' \quad \text{and} \quad a_2 = \beta_e' (1-\tau_e) - \tau_e \tau_e' \ .$$

The sub-index e stands to indicate that the coefficients are monthly effective counterparts of the coefficients defined before. Accordingly, τ_e and τ_e' are effective monthly parameters of the transmission coefficient of the atmosphere during clear-sky condition and the transmission coefficients of the clouds, respectively, and β_e' is effective monthly forward scattering coefficient of the clear atmosphere.

In this modeling approach, knowing the value of the global and diffuse component for a location and by assigning a value to β_e' one can reach the monthly values of a_1 and a_2. Thus, in the present study we also used the calculated monthly values of a_1 and a_2 for one location to estimate the diffuse component of solar irradiation of the other location.

In fact, linear equation for the monthly-mean daily total solar irradiation, and monthly average daily fractional bright sunshine hours can also be obtained using this physical modeling approach as presented in ref. Akinoglu, 1993.

Applying above mentioned procedure and using measured SMS values for Eskisehir, we have found the constants specific to Eskisehir to calculate diffuse solar irradiation falling on a horizontal surface, namely a_1, and a_2 as presented in Table 2.

Tab. 2: Monthly specific constants for linear equations

Months	Constants	
	a_1	a_2
January	0.41	-0.26
February	0.28	-0.13
March	0.32	-0.18
April	0.33	-0.19
May	0.35	-0.21
June	0.28	-0.15
July	0.37	-0.24
August	0.33	-0.19
September	0.38	-0.24
October	0.39	-0.22
November	0.37	-0.21
December	0.28	-0.10

Then by using constants given in Table 3, we calculate diffuse solar radiation of Ankara as given in Table 3. Table 2 also gives the estimated values by the models together with the measured SMS data.

4. Results

The diffuse solar radiation values for Ankara calculated by using all the options to be compared are compiled in Table 3. So as to ease the comprehension of Table 3, models are numbered. Model 1 is reserved for the first equation coming from reference Aras et al. (2006), while Model 2 is the second equation of the same reference. Model 3 is the result of the first equation coming from reference Ulgen and Hepbasli (2009), while Model 4 is the second equation of the same reference. Model 5 and 6 constitutes the methodology of the references Tasdemiroglu and Sever (1991) and Erbs et al. (1982), respectively. Model 7 is reserved for Meteonorm values and finally Model 8 for the results coming from the procedure developed and used in this study.

Tab. 3: Diffuse solar radiation in MJ m^{-2} reckoned through all the models

Months	Models								Measured
	1	2	3	4	5	6	7	8	
January	3.45	3.47	2.88	2.87	3.43	3.05	3.25	5.24	3.93
February	4.53	4.54	4.31	4.23	4.96	4.05	4.76	4.73	5.68

5. Outcomes and Discussions

On the way to structure a formalism to determine specific equations for Turkey, the preliminary steps are carried out in this study by identifying equations for diffuse solar irradiation calculations for Eskisehir and estimating the diffuse component for Ankara by utilizing obtained monthly coefficients a_1 and a_2 for Eskisehir. Then, its accuracy is examined by comparing its results with other options in order to get estimations with the least error values.

Checking the results of the comparisons tabulated in Table 4, it can be clearly observed that the procedure used in this study is one of the two best methods. In fact, pursuant to RMSE comparison the procedure derived and used in this study is the best one. The larger value of RMSE for Meteonorm is due to quite high deviation of its estimation for the month May with the measurement as can be seen from Table 3.

The rationale behind this result can be identified with following reasons: The two previous methods (Aras et al., 2006 and Ulgen and Hepbasli, 2009) proposed for the estimation of diffuse irradiation was not derived using measured data of diffuse irradiation. And, the method proposed by Erbs et al. was derived using hourly pyrheliometer and pyranometer data from four U.S. locations and therefore, its lesser accuracy for locations in Turkey is reasonable. Although the model proposed by Tasdemiroglu and Sever was derived from the measured data of five different locations from various climates in Turkey, it is not better than the procedure explained and used in this study. This is because the equation of Tasdemiroglu and Sever, using regression analysis, obtained one equation that fits all the months however the linear equation derived in this study provides an opportunity to assign month-specific correlations.

Therefore, we concluded that better results we obtained by the procedure we used are reasonable and may be the procedure we should choose at the end. The results of Meteonorm Software are also good for diffuse values but our observations showed that global solar irradiation values of Meteonorm considerably deviate from the measured values. Nevertheless, some further analysis should be carried out to reach concrete conclusions.

As a result, our formalism has given one of the two best results together with Meteonorm Software when compared to measured values. It is in fact the best one according to the RMSE comparison. By sticking to the method derived in this study if this study is applied to all regions/locations/provinces in Turkey, the most accurate total and diffuse solar radiation results can be gathered/acquired for all over the Turkey. This paves the way for us to see the exact potential and enables to define the most feasible ways to utilize solar radiation.

Our further prospects are first to extend the present analysis to different locations covering all the climates/regions of Turkey to reach the best procedure(s) to be used in estimation of diffuse component of solar irradiation. Secondly, we will use these procedures to estimate the solar irradiation on tilted panels and evaluate the long term performances of solar energy systems.

Abstract

Many countries in the world plan to increase their share of wind and solar power. In order to efficiently utilize large amounts intermittent renewable power, flexible consumers such as buildings with heat pumps and chillers may play a crucial role. However, it is not clear how heat pumps and chillers should be operated in order to make the best use of the volatile renewable energy. For this purpose, the residual loads of 13 European countries, Great Britain, and Alberta in the year 2030 were simulated and analyzed. The term "residual load" refers to the electricity demand that is not covered with intermittent renewable systems and that, therefore, must be met by dispatchable electricity generation units. It was calculated as the difference of the wind and PV generation simulated as part of this study, and the electric load of 2011.

The results show a high relative variability in the residual load in almost all analyzed countries. In winter, the lowest residual loads (i.e. the most favorable times for electricity consumption) occur either around noon (particularly in the countries with the highest amount of wind and solar power), or at night. In summer, the residual loads are usually lowest around noon, which coincides well with the typical cooling load profile of a building. PV-dominated countries show stronger daily variations in the residual load, which can be managed even with relatively small storage capacities as typically found in buildings. In contrast, in wind-dominated countries, the residual load fluctuates on longer time scales, which requires larger storages.

Keywords: *energy system, residual load, energy scenario, demand response, heat pumps*

1. Introduction

In an effort to reduce the emissions of greenhouse gases and combat climate change, intermittent renewable energy sources such as wind and photovoltaics (PV) are gaining in importance in many countries of Europe and throughout the world. A large share of intermittent renewable energy in the electricity mix presents serious challenges to power systems, as load and generation must match at any time. However, the generation of intermittent renewables depends on the current weather conditions and, unlike in conventional plants, cannot be dispatched and controlled at will.

In order to promote an efficient integration of a large share of intermittent renewables into the electric energy system, a part of the electric consumers can be made flexible such that their consumption follows the renewable generation. This concept is known as 'demand response'. Demand response has been identified by (IEA, 2003) as a viable alternative to traditional supply side remedies and the most cost effective solution to integrate large amounts of renewable in the energy mix.

doi:10.18086/eurosun.2016.09.07 Available at http://proceedings.ises.org

Presently, many international research activities (e.g. as part of IEA EBC Annex 67) study how buildings can be used for demand response purposes by implementing special control strategies for heat pumps, chillers, CHP units and other technical systems in order to support the electric energy system.

Efforts in the recent years have been made to understand the interaction between buildings and grid, particularly with buildings that incorporates on-site renewable energy systems. Thus Salom et al. (2014) analyzed several indicators to study grid interaction of prosumer buildings, particularly Net Zero Energy Buildings and Cubí et al. (2015) proposed a method to incorporate GHG emissions intensity changes due to grid variability into building environmental assessment with the objective to encourage building systems that reduce electricity use during peak periods. Several solutions have already been investigated how buildings can be providers of flexibility in the grid and demand response agents. Hedegaard et al. (2012) studied the potential of individual heat pumps, using heat accumulation tanks or passive heat storage in the construction, for increasing wind power utilisation and providing cost-effective fuel savings in the Danish energy system. Results show that by displacing less efficient heating technologies and increasing electricity demand, the installation of heat pumps alone can contribute to the integration of wind power, providing significant reductions in excess electricity production and fuel consumption.

However, the load profiles that ideal flexible buildings should follow are unique for each country, because each country or region has a different combination of amount of wind and solar power to be integrated in the energy system, electric load profile, as well as weather conditions. Furthermore, the amount of energy that can be stored and shifted by buildings depends on the dynamics of the thermal load, which is influenced by the ambient temperature and irradiation and thus changes with the geographical location. It is thus relevant to analyze and compare the availability of renewable energy generation as well as thermal demand and deduce requirements to grid-friendly heating and cooling strategies in buildings for each location.

In the current paper, 15 geographies (more accurately: 13 European countries, Great Britain (i.e. UK sans Northern Ireland, which is part of the Irish power grid), as well as the Canadian province of Alberta, which is similar in population to the smaller European countries), are compared in terms of the projected residual load in the year 2030. The residual load is here defined as the electric load minus the generation of intermittent renewable plants (wind and PV). Therefore, it is the electric power that needs to be provided by conventional dispatchable plants in order to balance generation and demand, and can be used as an indication of the relative demand for conventionally-produced electricity.

2. Methodology

The methodological procedure and structure of this paper is illustrated in Fig. 1.

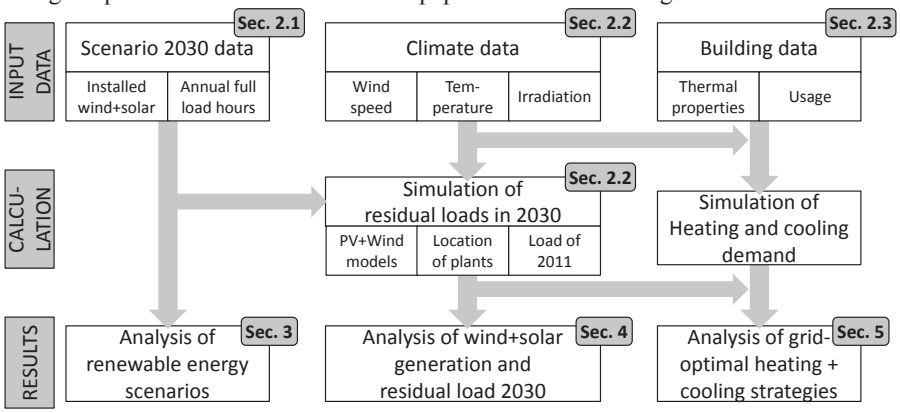

Fig. 1: Process flow, data and models used for this study.

The assumed scenario data are introduced in sec. 2.1, the climate data and models used for the simulation of renewable wind and PV generation in 2030 and calculation of the residual load are discussed in sec. 2.2. Building data and assumptions used for the simulation of thermal demand are given in sec. 2.3. The evaluation is done in three steps: First, the assumed energy systems of 2030 in the individual countries are characterized in terms of the installed capacity of solar and wind plants, as well as the share of renewable

energy generation in the energy mix (sec. 3). Following this, the residual loads for the year 2030 are analyzed in terms of their daily and seasonal characteristic (sec. 4). Finally, requirements to grid-supportive heat pump operation (in heating mode and in cooling mode) in the respective countries are deduced (sec. 5)

2.1 Scenario data for wind and PV energy in 2030

The assumed installed capacities of wind and PV plants in 2030 are mostly based on (Agora, 2016). For nearly all of the countries considered as part of the current paper, the assumed values from said study match (closely, if not exactly) with the "Vision 3" assumptions of (ENTSO-E, 2014). Some differing figures were used for the following countries. The complete data are given in Table 1 in the Appendix.

- For Germany installed capacities of 73.5 GW wind power and 66.3 GW PV power in 2030 were chosen according to the latest Grid Development Plan (Bundesnetzagentur, 2016; scen. B2030).
- For Denmark, there was a big mismatch between the assumed solar generation capacity in (Agora 2016) and (ENTSO-E, 2014). After consultation with Danish researchers which are familiar with the latest status in Danish energy policies, a third source was chosen (Energienet.tk, 2016).
- For Greece, assumptions from (ENTSO-E, 2014) were used as the country was not included in (Agora, 2016).
- For Alberta, a wind generation capacity of 5.5 GW was assumed in accordance with (Canadian Wind Energy Association, 2016). The province neither has nor plans to acquire significant amounts of solar generation power.

2.2 Simulation of wind and PV generation

The renewable energy generation is simulated using historic weather data of the numeric weather model COSMO-EU, run by the German Weather Service (DWD). COSMO-EU has a high spatial (average distance 7 km) and temporal (hourly) resolution and predicts the area of Europe. The meteorological values of irradiance, wind speed and temperature are allocated to a NUTS3 level, which covers different national counties. The processed weather data forms the basis of a PV and wind turbine power production estimation by additionally including their technical characteristics. In the case of PV, the simulation differs between azimuth and inclination angles as well as installation and module types. To represent the wide variety of wind turbines in reality, different power curves and hub heights are used and result in 61 individual specifications. Furthermore the roughness length of the ground is used to transform the wind speed to the individual hub height. The simulation procedure has already been employed with the COSMO-DE model on a national scale by (Killinger et al. 2015).

In order to simulate the total renewable energy generation of a country, it is assumed that the total installed capacity is evenly distributed over the NUTS3 regions, meaning that the regions are weighted by their area. The installed capacities of wind and PV plants assumed according to sec. 2.1.

Figure 2, left and right, show the simulated full load hours of wind and PV power in the examined European countries, respectively. Although these values are further aggregated and processed in order to derive the residual load within a country, the figures show clearly the large fluctuation within Europe. The full load hours of PV range between 700 in the North and 1489 in the South. In terms of wind power, this variability between the NUTS3 regions is even increased and differs between 174 and 4080 full load hours per year with the best locations close to the sea in the northern parts of Europe.

As becomes evident from Fig 2, the annual full load hours of wind and PV plants are highly inhomogeneous even within the respective countries. Since it is not known how the future installed capacity of wind and PV plants will be allocated to the individual NUTS3 areas, the following assumptions are made: First, it is assumed that the renewable generation units are distributed homogeneously throughout the country (i.e. proportional to the size of the NUTS 3 area).

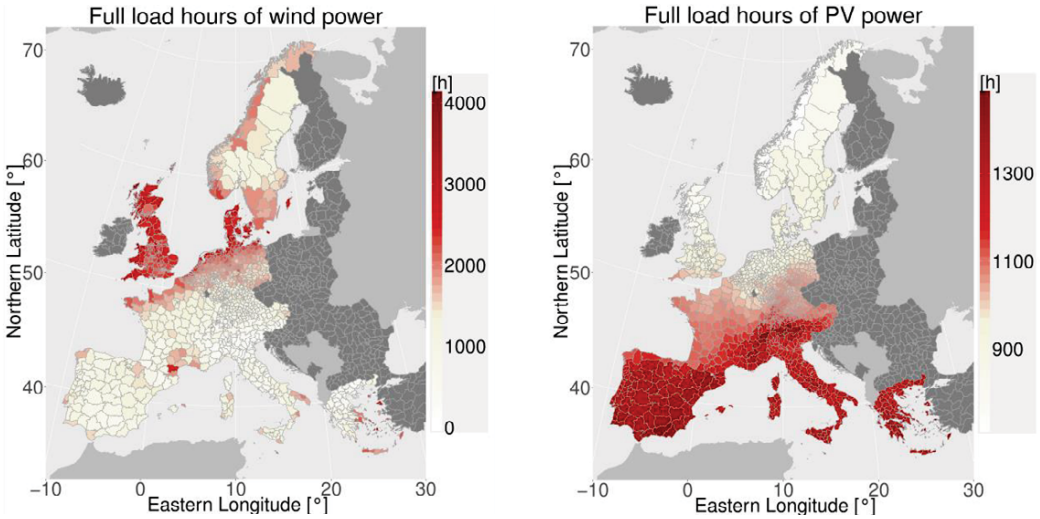

Fig. 2: Full load hours on NUTS3-level of PV (left) and wind power (right) based on the numeric weather model COSMO-EU and a power simulation with different technical specifications.

This procedure will in tendency underestimate the wind and PV yield potential, because in reality, the locations with the best conditions (i.e. most sunshine hours, most steady wind) will be preferred. In order to account for this, the generation curve is in a second step corrected by a factor such that the full load hours of wind and PV plants match those assumed by the national renewable energy plants of 2020 (European Commission, 2008).

For the load, data of the year 2011 from the European Network of Transmission System Operators for Electricity (ENTSO-E, 2016) are used, assuming that the oppositional effects of economic growth and advances in energy efficiency will lead to a similar electricity demand in 2030 as today. The ENTSO-E load data are corrected by a factor such that the official electricity consumption according to Eurostat is matched. For Alberta, which is not contained in ENTSO-E, the load data are obtained from the Alberta Electric System Operator (AESO, 2016).

2.2 Simulation of heating and cooling demand for an office building in each country

In order to analyze how a buildings should be heated or cooled in order to promote the integration intermittent renewable energy, the thermal energy demand must be known. Evidently, the heating and cooling demand differs between the studied countries depending on the ambient temperature and irradiation.

shading factor	0.4	(-)

c)

Fig. 3: Bulding model used for determination of thermal demand in each country. a) outside view of the building, b) geometry of the internal space usage, c) thermal properties of the building

The heating and cooling demand in the considered geographies is quantified using a simple single-zone model of a generic office building with a useful area of approximately 2430 m^2, which was described in

(Klein et al, 2015). It is assumed that the building is composed of two-person offices on the Northern and Southern façade with a connecting corridor in between. The building is modeled as a resistor-capacitor network in compliance with the ISO 13790 modeling standard. The insulation standard is based on the German building code EnEV 2014. The assumptions for usage (occupancy on weekdays from 7 a.m. to 6 p.m., six full-occupancy hours per day), the control of the external shading devices (activated above 200 W/m^2 irradiation onto the façade, deactivated below 150 W/m^2), the heat gains by human occupancy and appliances (100 W/pers. and 7 W/m^2, respectively), as well as the mechanical ventilation (30 m^3/hr·pers. during occupancy, heat recovery factor 0.75) are based on the DIN-V 18599 standard (DIN-V 18599, 2011). The interior temperature of the building is controlled using an ideal heater, such that the interior temperature does not fall below 20°C in heating operation and does not exceed 26°C in cooling operation. If the interior temperature assumes a value between these two limits (e.g. in the intermediate periods, spring and autumn), the building is neither heated nor cooled.

3. Characteristics of energy systems in 2030

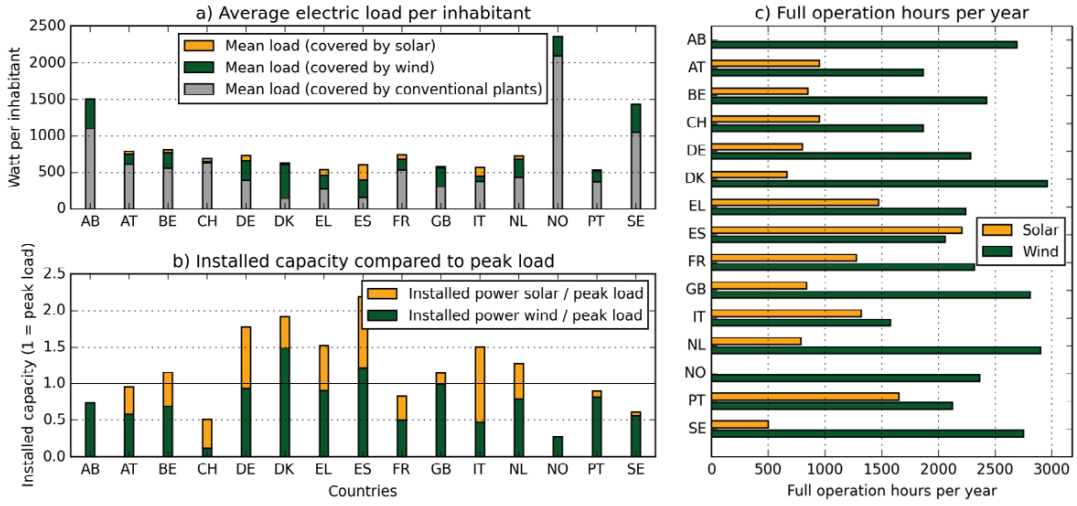

Fig. 4: Characteristics of the energy systems under evaluation. a) Mean electric load and share of solar and wind power in energy mix. b) installed power of solar and wind plants compared to peak load, c) annual full operation hours of solar and wind plants (from (European Commission, 2008)).

Fig. 4 a) shows the average electric power used by each inhabitant, which can be interpreted as an indication of how much a society relies on electricity. A glossary of the country codes is provided in Table 1 in the appendix. It becomes evident that Norway has the highest per capita electricity load, followed by Sweden and Alberta. The reasons for this are on the one hand the electricity-intensive heavy industries (notably the steel and aluminum production in Norway and Sweden, oil and gas industries in Alberta), and on the other hand the high share of electricity-based heating. Most other countries have a significantly lower mean load per inhabitant in the order of 500-700 W/person because they rely more on fossil fuels. Fig 4 a) also illustrates that Denmark and Spain are the countries with the highest share of intermittent renewable electricity, followed by Germany, Great Britain, the Netherlands and Sweden. Norway has a relatively large share of conventional electricity, however, is shall be noted that the renewable, but non-intermittent hydroelectric power accounts for nearly all of the conventional generation.

Fig 4 b) indicates the installed capacity of wind and solar plants in comparison to the peak load (determined here as the 98th percentile of the electric load). Interestingly, 10 out of the 15 countries have installed capacities close to or larger than the peak load. In Denmark, Spain and Germany, the installed wind power alone exceeds the peak load, closely followed by Great Britain and Greece.

In all countries except Spain, wind power provides more full operation hours per year than solar power, which is why it produces more electricity in proportion to the installed capacity than solar power. That said, the number of full load hours of both solar and wind varies greatly between the considered countries. The

countries along the North Sea reach close to 3000 full load hours per year, whereas Italy reaches just over half that number. Sweden gets around 500 full load hours for solar plants, while Spain, Portugal and Greece get nearly three times as many. Spain's exceptionally high solar full load hours are partly due to the fact that Spain plans to build concentrated solar power plants with storages which operate during part of the night.

4. Wind and solar generation and residual load in 2030 in 15 countries

4.1 Wind and PV generation in 2030

The aggregated daily profiles of the electric load are given in Fig. 5. The daily aggregation has been performed for the sample months January, April, July and October illustrating seasonal variations: the generation curve for January is most representative of the heating season, while July is most representative of the cooling season. April and October represent the intermediate seasons, spring and autumn.

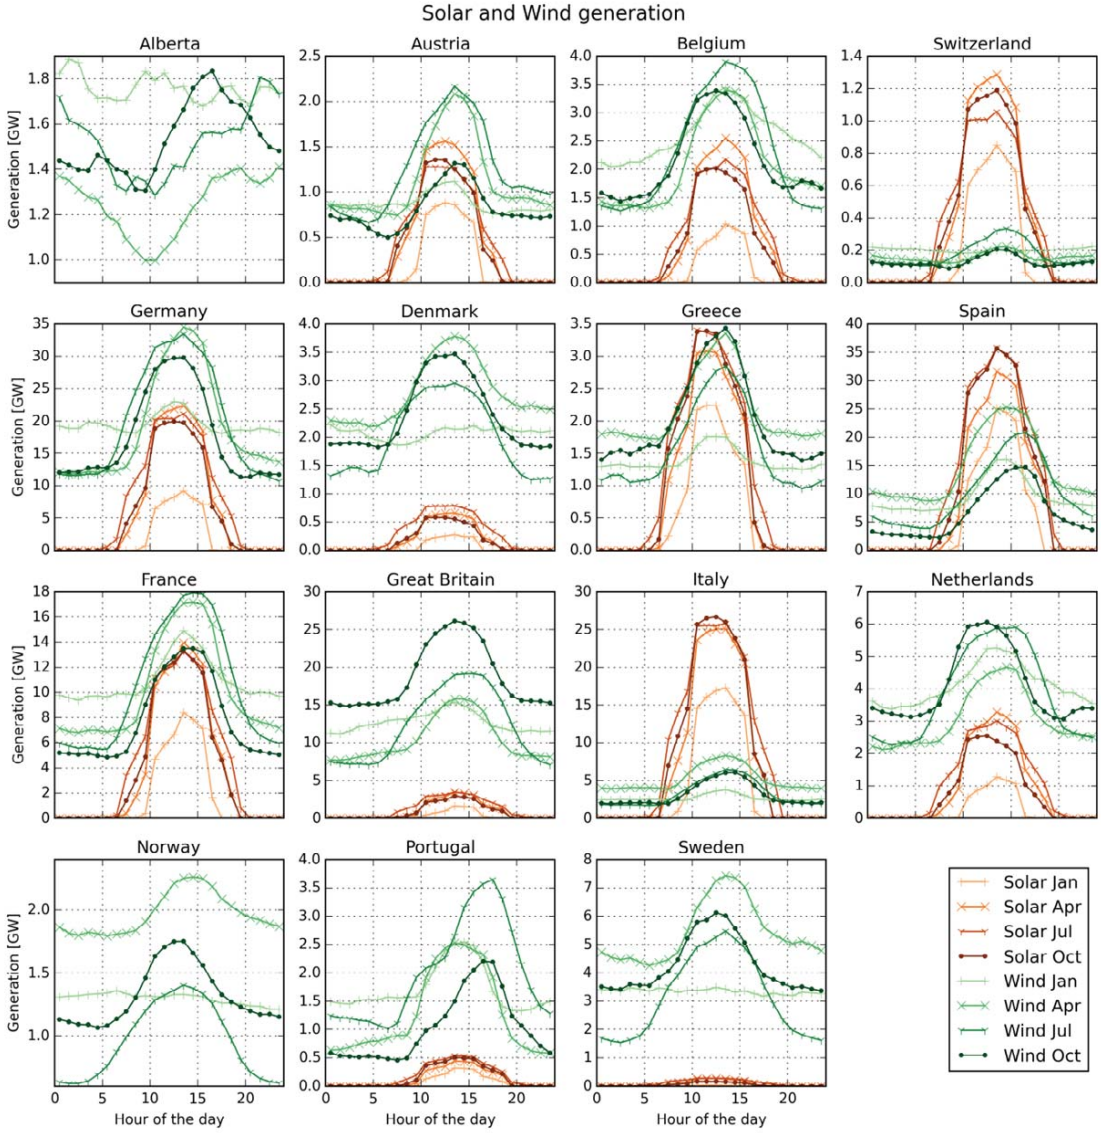

Fig. 5: Aggregated daily profiles of solar and wind generation 2030 for the months January, April, July and October.

As expected, solar generation peaks around noon and is highest in quantity in July, with April and October close behind. The Solar generation in January typically amounts to 50-70% of the generation in July. The time delay between the solar noons of Austria and Portugal due to their different longitudes is visible in the solar generation peaks. Note that Alberta and Norway have no solar plants and thus no generation.

Wind generation also peaks in the day and thus shows a high coincidence with solar generation, although a base generation usually occurs throughout the night. The daily generation peak is more pronounced in the summer than in the winter due to the larger share of solar irradiation in summer. Wind power seems to be partly overestimated during day in the summer. The explanation can be found in the methodology itself for two reasons. The wind speed is provided by COSMO-EU for a height of 10m, which is interpolated to the hub height by only including the roughness length of the ground. Nightly inversions in summer will strongly affect this ground layer and lead to almost no wind, although in reality there is significant wind potential close to hub height. Furthermore the stability of the atmosphere is unknown, but influences the growth of the wind speed with an increasing height. Unstable atmospherical conditions, which are likely to occur in the summer, will lead to an overestimation of the wind speed at hub height and the generated power as well (Focken and Heinemann, 2003).

4.2 Electric load

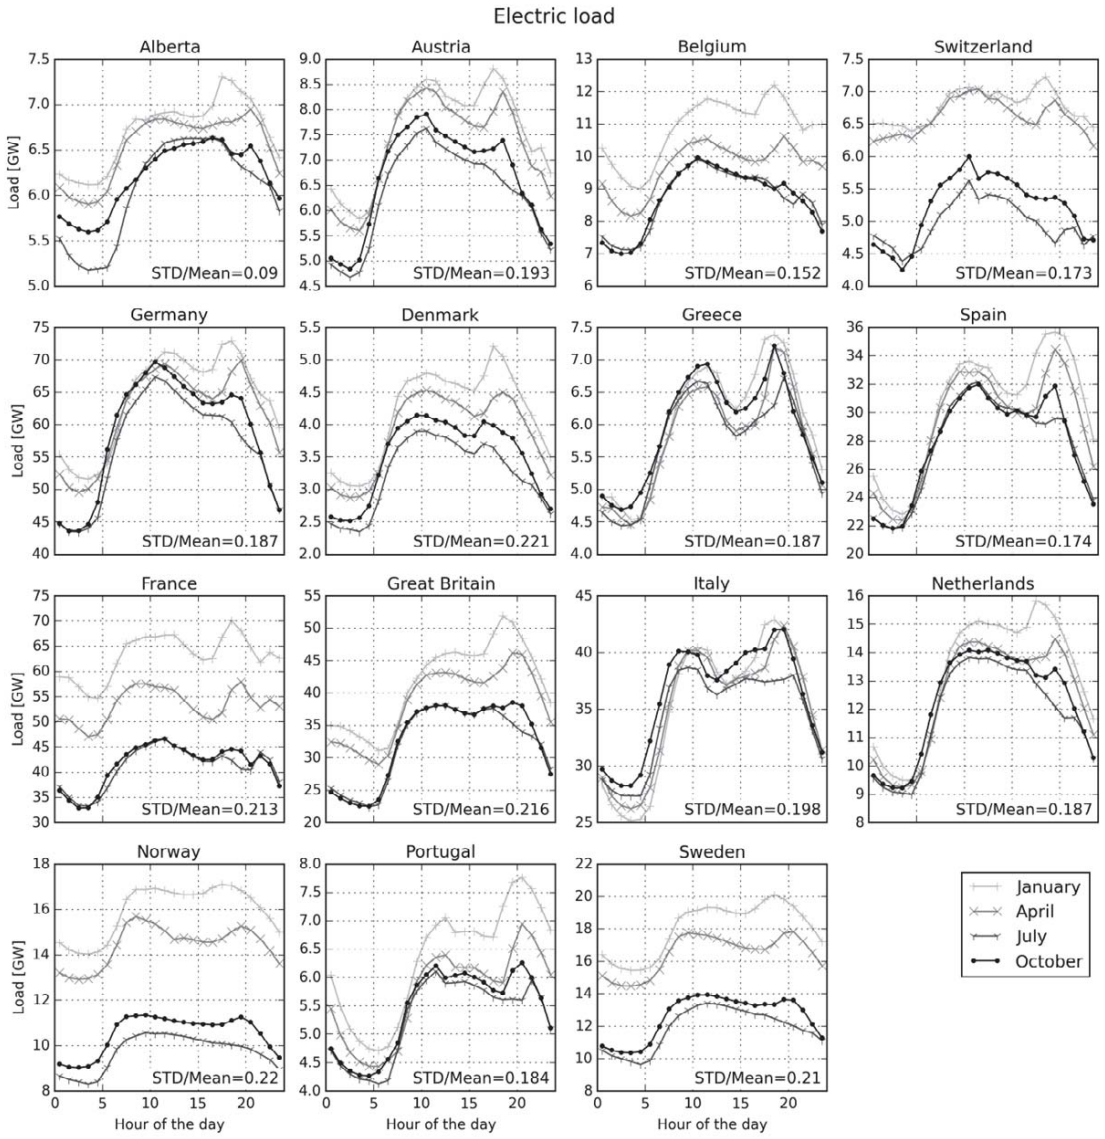

Fig. 6: Aggregated daily profiles of the electric load in 2011 for the months January, April, July and October.

The aggregated daily profiles of the electric load of 2011 are given in Fig. 6 for the same sample months as previously. The load of 2011 is used for the calculation of the residual load of 2030. In all considered countries, the electric load is significantly higher during the day than in the night. Typically, two demand peaks occur in the morning and in the evening. In some countries (Norway, Sweden, Switzerland, France,

Belgium) a notable seasonal difference in the electric load is observed, which is mainly attributable to a high share of electricity-based space heating using heat pumps or direct-electric heaters and a larger lighting demand due to longer nights in winter, while other countries (Greece, Italy) have a nearly identical load profile in the evaluated months. The relative fluctuation of the load, quantified here by the standard deviation (STD) of the load in relation to its mean value, assumes relatively similar values between 0.09 (Alberta) and 0.22 (Denmark, Norway). In absence of significant renewable energy capacities in a traditional energy system, the load is equal to the residual load. The relative fluctuation of the load is thus similar to the level of variability that most energy systems (and markets) were designed to deal with.

4.3 Residual load

The daily curve of the projected residual load 2030 for the four sample months is given in Fig. 7.

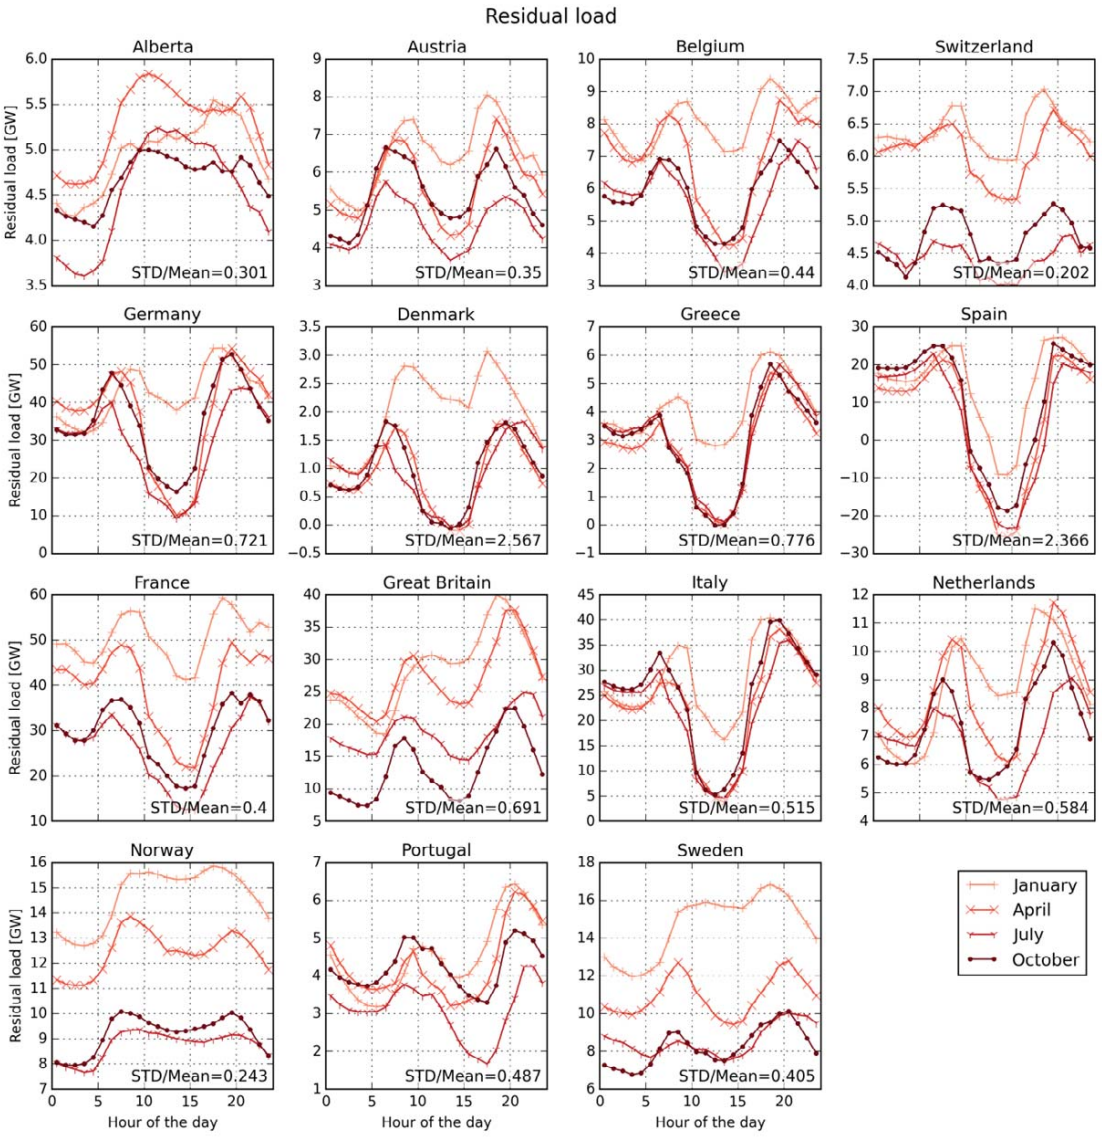

Fig. 7: Aggregated daily profiles of the residual load 2030 for the months January, April, July and October.

In most countries, the residual load shows its lowest values around noon as a consequence of peak solar and (on average) wind generation, as well as lower loads compared to the morning and evening. Even in the aggregated form shown in Fig. 7, residual loads close or below zero occur in Spain, Denmark, Greece and

Italy. This means that during especially sunny and/or windy days, extreme surpluses of renewable electricity (emission-free and at zero marginal cost) are expected. Storing this surplus or making it useful by demand response will be a major challenge and builds a strong case for considering variable grid conditions in heat pump and chiller control strategies.

Moreover, the residual loads in the analyzed countries show significant seasonal differences: they are typically lower and more volatile in summer than in winter. This is largely due to higher solar and wind generation and lower electric loads in summer. This means that daily variations in the availability of electricity, which justify grid-supportive building operation, are most prevalent during the cooling season.

Finally, it is noteworthy that the residual loads of 2030 of most of the analyzed countries have a much higher relative fluctuation (standard deviation/mean value) than the respective loads (Fig. 6). Particularly in the countries with the highest share of intermittent renewable energy, Denmark and Spain, the standard deviation of the residual load is over twice as large as its mean value, indicating rapid and substantial changes in the relative demand for electric energy – and thus the value of electricity. The relative fluctuations in residual load are up to ten times larger than those for the electric load – which underlines the necessity of demand response and other new measures to integrate intermittent renewables.

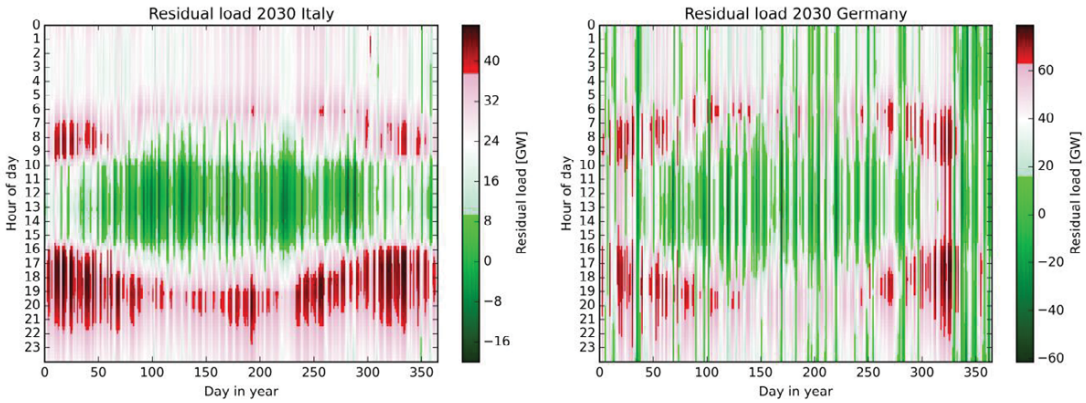

Fig. 9: Carpet plot diagrams of the residual load 2030 in Italy and Germany. For visual reference, highlighted areas residual loads above 80% of the peak load (red) and below 20% of the peak load (green).

Fig. 9 shows the residual loads of Italy and Germany in carpet plot diagrams For visual reference, the periods with very high demand (residual load > 80% of the peak load) and low relative demand (residual load < 20% of the peak load) are highlighted in red and green, respectively. It becomes clear that in Italy, which is characterized by a high amount of solar power, the relative demand for electricity varies very strongly and regularly within one day, between peak demands in the morning and evening and generation surplus around noon. This provides a strong incentive for intraday storage and load shifting. Germany, in contrast, has both a high amount of solar generation, which produces a similar pattern as in Italy, and additionally a significant amount of wind power generation, which causes sequences of entire operating days with surplus electricity. In addition, Germany has a stronger seasonal load variation than Italy, which leads to fewer peak load situations in summer. In such a situation, electricity needs to be stored for longer time periods, which is more challenging for conventionally designed building energy systems.

5. Requirements to grid-supportive heating and cooling

The annual heating and cooling energy consumption as well as the thermal peak loads (based on the 98th percentile) for are given in Fig. 10. Alberta, Norway and Sweden have both the highest heating energy consumption and the highest heating load. Greece has the highest highest cooling energy consumption and cooling load, followed by Italy and Spain. Portugal is the country with the lowest combined annual thermal demand of about 18 W/m^2·a, as well as the lowest combined heating and cooling load.

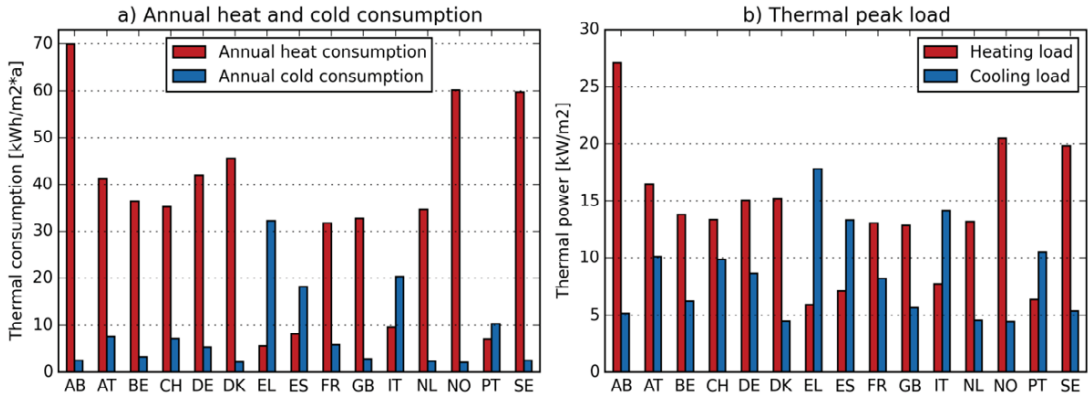

Fig. 10: Annual thermal consumption and peak heating and cooling loads

Figure 11 shows the aggregated thermal loads and the grid-optimized thermal generation trajectories for January (heating, red) and July (cooling, blue), i.e. the operation periods during the hours of the day with the lowest residual load. For calculation of the latter, 25% overdimensioned heating and cooling systems (according to Fig. 10 b)) and sufficient thermal storage capacity for intraday load shifting were assumed.

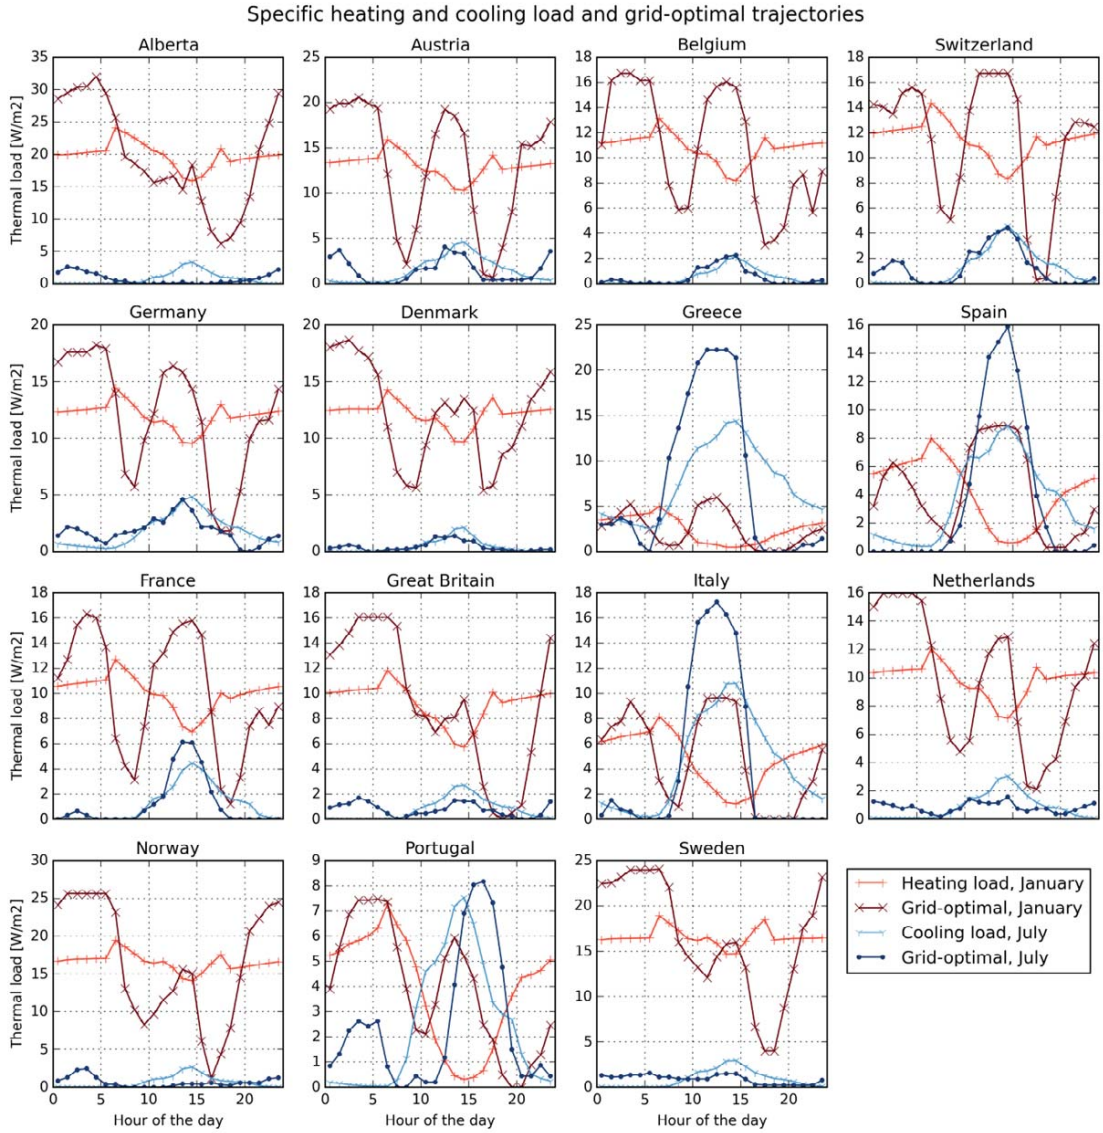

Fig. 11: Specific thermal loads and grid-optimal heating and cooling trajectories for January and July

As expected, the cooling loads assume their highest values around noon due to the high ambient temperatures and irradiation intensity. In nearly all countries, this coincides well with the generation and wind and PV and thus the residual load, which is why the grid-optimized cooling trajectory is similar to the load profile. Notable exceptions are Norway and Alberta, which lack solar generation and whose grid-optimal operation is scheduled at night when the load and residual load are lowest.

The heating load profile of the considered reference building is nearly constant throughout the day in the colder countries (e.g. Alberta, Norway, Denmark, Germany) and is more variable in warmer countries (Portugal, Spain), with the highest heating load occurirng in the morning (due to an increase in ventilation rate at the beginning of occupancy in the morning, when ambient temperatures are low) and the lowest heating loads occurring in the afternoon. The grid-optimal heating trajectory depends on the renewable energies mix: in wind-dominated regions such as Alberta, Norway and Sweden, it peaks in the night hours, whereas in PV-dominated countries such as Spain, it peaks around noon. Most countries, however, have a combination of wind and PV power, leading to two peaks in the grid-optimal heating profile at night and in the middle of the day. Their relative size depends on the mix of wind and PV in the energy system and the weather conditions of the individual day, which affects the thermal demand as well as wind and PV generation. This makes it difficult to derive general rules for grid-optimal scheduling of heat pump operation only based on the hour of the day. Note that for CHP units, which unlike heat pumps are electric generators rather than loads, the conclusions for grid-optimal scheduling of heating must be reversed: the most favorable times of the day for heating with CHP units are usually in the morning and evening.

6. Conclusions

This paper analyzes the dynamics of future renewable electricity generation and electricity demand profiles in a range of 15 geographies. The future scenarios (2030) are forecasted based on the current dynamics of the systems in combination with claims or commitments on PV and wind power installed capacities stated in the corresponding energy plans. At the core of this analysis, the “residual load” is defined as the electricity demand that must be met by conventional dispatchable electricity generation systems. This study explores short term and long term variability in the residual load, as a first step towards assessing the role that demand response systems (such as controls of heat pumps in buildings) might have in mitigating such variability and maximizing use of renewable generation.

Results show that, if the energy plans materialize, residual loads will be highly variable in 2030. The magnitude and variability of residual load varies across countries. However, some general trends can still be identified:

- Residual loads are lower and more variable in summer than in winter. In summer, electricity demand is generally lower (which helps lower residual load), and renewable generation is larger (which also contributes to reducing residual load, but adds variability)
- In summer, the lowest residual loads are seen around noon. This is good news, as the use of electricity in space conditioning devices (chillers, heat pumps) during the hottest periods of the day coincide in time with the lowest residual loads (i.e., when electricity use is the least disturbing for the electricity system)
- In winter, the lowest residual loads are either around noon or at night, none of which coincides well with the typical peak heating demand of a building. If heat pumps were to be used as a demand response system to accommodate variability in the grid, they would likely have to be accompanied by a thermal storage system.

It is interesting to note that one of the factors that make a difference in the dynamics of the residual load is the relative capacities of solar and wind power. In the European geographies, wind power peaks during daytime. However, unlike solar, generation does not necessarily drop to zero at night. Large solar generation capacities lead to strong daily variations in residual load, which can be more easily managed with short term storage systems. In contrast, variability of wind power is often in a longer time scale (days or even weeks). Managing variability in a longer time scale would require storage systems of higher capacity. The relative share of solar vs. wind power can, to some extent, be determined by the local jurisdictions. Electricity management and the opportunities for demand response could (and arguably, should) be among the criteria in defining renewable energy policies.

Multiscale Characterization of French Polynesia Climate for Dynamic Simulation of Buildings

Franck Lucas, Marania Hopuare, Charlotte Besnard and Pascal Ortega

Laboratoire GePaSud, Université de la Polynésie française, FAA'A Tahiti (French Polynesia)

Abstract

Performance assessment of buildings in tropical climates requires annual meteorological data files for an "energy approach" of air-conditioned buildings. It also requires localized climatic sequences allowing a real estimation of the natural ventilation potential of the sites for a "comfort" approach of non-air-conditioned buildings. The absence of this type of weather data in Polynesia considerably limits designer analysis means. This article presents two methods to establish meteorological sequences for both energy and comfort approaches. The first aims developing annual typical weather files from a reduced number of ground measurements. The missing meteorological variables are completed using a global to diffuse decomposition model of the solar irradiance. The second is based on a mesoscale climate model and a downscaling to obtain a characterization of localized natural ventilation potential and climatic data on a fine mesh. The weather sequences generated are used to perform energy calculation for air conditioned classrooms and wind potential and comfort assessment for cross ventilated classrooms of a primary school located in French Polynesia.

Keywords: *Weather data, tropical climate, dynamic simulations, natural ventilation.*

1. Introduction

The design of very low energy buildings or net zero energy buildings requires sophisticated analysis and forecasting tools. For assessing energy performance of buildings during the design phase, dynamic thermal simulation codes are now the most commonly used tools. These codes simulate building behavior using a physical description and weather data. Design methods have evolved in the last decades. At the beginning, the buildings performance analysis supposed steady states outside conditions, for example: the method of "outside based conditions" or the "Degree Days method". The more recent dynamics simulation tools propose building energy calculation on hourly or even lower time step. They account for a large number of input variables and parameters. Nevertheless, there are significant differences between energy performance of buildings estimated by dynamic simulation codes during the design phase and the real performance of the operating building. In his thesis, C Spitz (2012) evaluates all sources of uncertainty between the design and operating phase. Of course, "Design" phase calculations generate errors due to the assumptions on the building and its components description. But Spitz noted that the quality of meteorological data used in numerical simulations is also an important source of error that can cause deviations of up to 30% of the estimated consumption of an air conditioning system. To be representative of the building external loads meteorological data used by designers must meet specific standards. Several types of data can be used:

- "multi-year" data sets: they bring together all the meteorological data required for the simulation of buildings and over several years. They are complicated to use because of the large number of values they have. Example: SAMSON database 1961-1990 (NCDC 1993).

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/eurosun.2016.09.11 Available at http://proceedings.ises.org

- Typical weather annual files: the most commonly used data to estimate the average performance of a building. Example: Typical Meteorological Year (TMY), Weather Year for Energy Calculation (WYEC), Test Reference Year (TRY)...
- Short representative weather sequences: They can be used to study extreme weather conditions (very hot or cold, very sunny or very wet ...), localized weather (considering the influence of the relief on meteorology), the design of specific technical solutions (studying the potential for natural ventilation of a building) or the design of building components ("design day" sequences for the sizing of air conditioning systems).

The type of weather data to use and therefore generate, depends on the objectives for the design process. The French Polynesia like all island territories is facing a difficult situation because of energy supply difficulties and operating constraints of a non-interconnected electricity grid. The ambitious political commitment is to achieve a 50% renewable energy for electricity supply in 2020. Thus, an energy regulation is being drafted. This thermal regulation will target energy ratio for air-conditioned buildings but will also state minimum comfort performance for naturally ventilated buildings. In both cases, specific weather data are needed. For energy approach, annual weather sequences will assess the energy consumption of buildings. Short sequences are dedicated to the comfort evaluation. This paper presents the study to provide both types of meteorological data for French Polynesia. The first part addresses the creation of typical meteorological year for the energy approach. The chosen method uses a reduced meteorological database obtained from ground measurements. For the "comfort" approach, it is necessary to consider the high spatial variability of the meteorological inputs. In the second part, we use a climatic model to generate climate data on a fine mesh (around 1.3 km) compatible with the needs of dynamic simulations of buildings operating in natural ventilation. These weather sequences will then be applied to energy calculation and comfort evaluation for air conditioned classrooms and cross ventilated classrooms in French Polynesia.

2. Energy calculation with typical annual weather file

2.1 File Constitution

In preparation for the implementation of a thermal regulation in French Polynesia, the climatic sequences that seem most important and most urgent are the annual weather files. These sequences are very often used by building designers. They bring together all hourly climate variables needed for dynamic simulation of buildings for a period of one year. There are several possibilities to obtain these annual typical sequences. The first is based on the selection of the most representative month made in a database developed with ground measurements over long periods (between 10 and 30 years). The ground measurements are usually obtained from forecast utilities. For all the French territories, the first 200,000 digital values are provided free of charge for the public institutions by the French forecast utility Meteo France. Beyond, the data are charged. The second method is based on the use of stochastic models that generate time series climate data by extrapolation of measured data by ground stations. These tools are often called "weather generators." Developed by research laboratories since the 1980s (Van Passen, 1979) (Knight, 1990) (Adelard, 2000), (David, 2010), these methods were taken over by private providers for commercial services. Among them, for example Meteonorm (Remund, 2004) and Type 54 from TRNSYS (TRNSYS 2000) are commonly used by designers.

The annual typical weather data sets generated from ground measurements are the most widespread. It has been developed in several formats. The main ones are:

- TRY (Test Reference Year): One of the first weather data sets, developed in 1976.
- TMY (Typical Meteorological Year) developed from TRY format by especially adding global horizontal irradiance data. The TMY dataset includes measurements selected over the periods from 1945 to 1973. It evolved in 1995 in the TMY2 format by adding new weather variables such as direct solar irradiation and using more recent weather data (1961 to 1990). Then, the TMY3 format is built up with even more recent years, up to 2005.
- WYEC (Weather Year for Energy Calculation) were developed by ASHRAE. As for the TMY format, WYEC2 version was made from the WYEC files by adding additional variables, including the characterization of natural lighting.

Drury's study for US climates (Drury 1998) analyzes the estimation of the energy performances of a building according to the type of the weather files used. The performances are compared to the results of simulations with real weather data collected over 30 years. It notes that the climate data used in dynamic simulation of buildings can have a significant influence on the energy performance assessment and concluded by recommending the use of TMY2 formats (or TMY3) and the WYEC2. These two types of data sets are developed by selecting twelve typical meteorological months (TMM) from a multi-year weather database. The difference between the TMY and WYEC files comes with the TMM selection process. For TMY files, Hall (Hall 1978) presents a method for selecting the representative month by analyzing four climatic variables (global solar radiation, air dry temperature, dew-point air temperature, wind velocity) supplemented by daily maximum, daily minimum, daily mean air dry temperature and dew point temperature, daily maximum and daily mean wind speed, and daily global solar radiation. A total of 9 variables are required for the selection process. Each of these variables is weighted according to its importance on the behavior of buildings. The selection of each typical meteorological month in the database is operated following the Finkelstein-Shaffer statistical method. The weighting of each leads to several variants of the method (Hall 1978) (Yang 2007) (Yang, 2011). The drawback of this method is that the weighting process may seem subjective, but above all, it requires a large number of values in the selection database (over 1 million, just for the process selection). Crow (Crow 1984) proposes a method to generate annual typical weather files kinds requiring a smaller database for the selection of the TMM. It is based solely on the study of the dry air temperature. The selected representative month is the one whose monthly average dry bulb temperature is within a range of ± 0.3 ° C of the monthly average dry bulb temperature over the entire database. The choice of the TMM is done according to:

$$dx = \left| \overline{T}_x^i - \overline{T}^i \right| \qquad \text{(eq. 1)}$$

$\overline{T}_x^i$: Monthly average temperatures for the month i in year x.

$\overline{T}^i$: Monthly average temperatures for every month i on the entire database.

The selection process is carried out using only the values of the monthly average temperature over a period of 10 to 30 years. Once the TMM selection made, the values bought from the forecast utility to form the typical annual weather file are limited to the climatic hourly meteorological variables of the selected months. The total number of values required for the selection process is 360 and the file includes less than 44,000 values. On the available database for French Polynesia from 1997 to 2007, the weather typical year was formed by the months given in the table below:

Table 1: Selection of the TMM for the typical annual weather file for French Polynesia.

	J	F	M	A	M	J	J	A	S	O	N	D
Selected year	2006	2002	2001	1998	1997	1998	1999	1998	2001	1998	2004	1999

The meteorological data requested for each TMM are the hourly values of the following variables: dry air temperature, relative humidity, wind speed, wind direction, horizontal global irradiation. From these TMM a "Polynesian typical meteorological year" (PTMY) is then generated using the Matlab conversion tool "Weather xls to TMY2". However, the horizontal diffuse radiation has not been continuously measured by Meteo France in Polynesia and is no longer measured since 2006. It is, therefore, necessary to estimate the diffuse and direct irradiation form the other variables available.

a. Post processing of data: Decomposition of global irradiance

The creation of the typical annual weather file requires determining the diffuse and direct solar irradiance using the global horizontal irradiance. A decomposition model adapted to the climate of Polynesia is then necessary. A number of models are available in the literature. They are generally based on the use of the

index clearness index K_t and diffuse fraction K_d given by: $K_t = \frac{G_h}{G_o}$ and $K_d = \frac{G_{d,h}}{G_h}$

Where, G_h is the global horizontal solar irradiance, G_o is the extraterrestrial solar irradiance, and $G_{d,h}$ is the diffuse solar irradiance on a horizontal plane. Among the available models, a pre-selection of four mathematical models was made: Orgill & Hollands (Orgill 1977), Li Lam (Lam 1996), Erbs (Erbs 1982) and Reindl (Reindl 1990). This series model is complemented by the DIRINT model established by Perez (Perez 1992) which is available through a Matlab toolbox or in Python. An additional model was established in this study. It is derived from a correlation established by Meteo France. This latter model, designated "PF model" whose interest is to be simple and valid throughout the interval 0<kt<1 is given by:

$$K_d = \frac{1}{1 + \exp(c_0 K_t + c_1)} \qquad \text{(eq. 2)}$$

c_0 and c_1 are coefficients determined from the diffuse radiation measurements available in Polynesia. The global and diffuse radiation measurements of 1993, 199, 1998 and 1999 were previously screened by the method of BSRN (Long 2002) and c_0 and c_1 are determined by the least squares method. The values obtained are: c_0 =7.122 and c_1 = - 3.511.

The comparison between the measurements for the years when diffuse radiation is available (1993, 1997, 1998, and 1999) and the different models is given in the table below by the value of the relative root mean square error (rRMSE).

Table 2: relative root mean square error between measurements and the different models.

rRMSE (%)	Erbs	Lam & Li	Reindl	Orgill & Hollands	Perez	PF Model
1993	43,0	37,7	43,6	44,3	42,6	32,0
1997	38,0	35,0	39,4	39,8	37,9	27,6
1998	37,3	32,0	38,7	38,8	37,2	25,7
1999	46,4	39,7	48,0	48,2	46,1	30,9
Average	41,175	36,1	42,425	42,775	40,95	29,05

3. Downscaling of climate models

Climate models are a numerical representation of the climate system based on the physical, chemical and biological properties of its components and their interaction processes. It calculates all climatic parameters with a very fine spatial resolution. Weather and Research Forecasting (WRF) climate model (Skamarock 2008) used in this study is a non-hydrostatic limited area model to zoom in on a particular region. WRF is known to have high bias and isn't the best method and model for solar resource assessments. WRF is parameterized with localized convective scheme and thus, can show some discrepancies when assessing solar radiation. Anyway, it is a useful tool for estimating coherent coupled climatic variables (temperature humidity, wind and also radiation). It is, therefore, adapted to provide climatic weather sequences. A realistic parameterization of the subgrid processes has been assessed for French Polynesia by Heinrich. (2009). An experimental comparison is also provided by Hopurare. (2016) which compare small scale prediction with ground measurements.

The method used consists in increasing the resolution within an area of interest by embedding other smaller domains. We get what is called a "downscaling cascade" with increasing resolution nested domains until the desired spatial resolution is obtained in the inner domain (Fig. 1). The spatial resolution is the dimension in km of a grid. The calculations have been carried out on three interacting grids, with horizontal resolutions of 20, 4, and 1.33 km, respectively. The use of a mesoscale model provides short weather sequences to address specific building design issues. This study presents a specific analysis on wind regimes in Tahiti with the objective of a fine-scale characterization of the natural ventilation potential for low energy buildings.

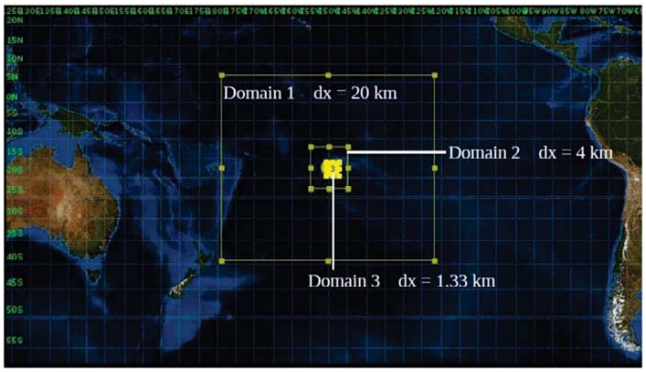

Fig. 1: Diagram of the downscaling with WRF positioned on a large central Pacific area, 20 km resolution and boundary conditions as the Interim reanalysis Era. A second domain is implemented with 4 km resolution centered on French Polynesia. A final domain (domain 3) is implemented in the domain 2 with a resolution of 1.3 km and centered on Tahiti.

3.1 Synoptic wind regimes in Tahiti and Moorea

ERA Interim dataset (http://apps.ecmwf.int/datasets) is a reanalysis product provided by the European Centre for Medium-Range Weather Forecasts (ECMWF). In this study, Era Interim reanalysis data were processed to identify the regimes of most frequent winds in Tahiti. A statistical method on a time series of 31 years (1979 to 2009) has highlighted six main synoptic wind regimes (fig. 2).

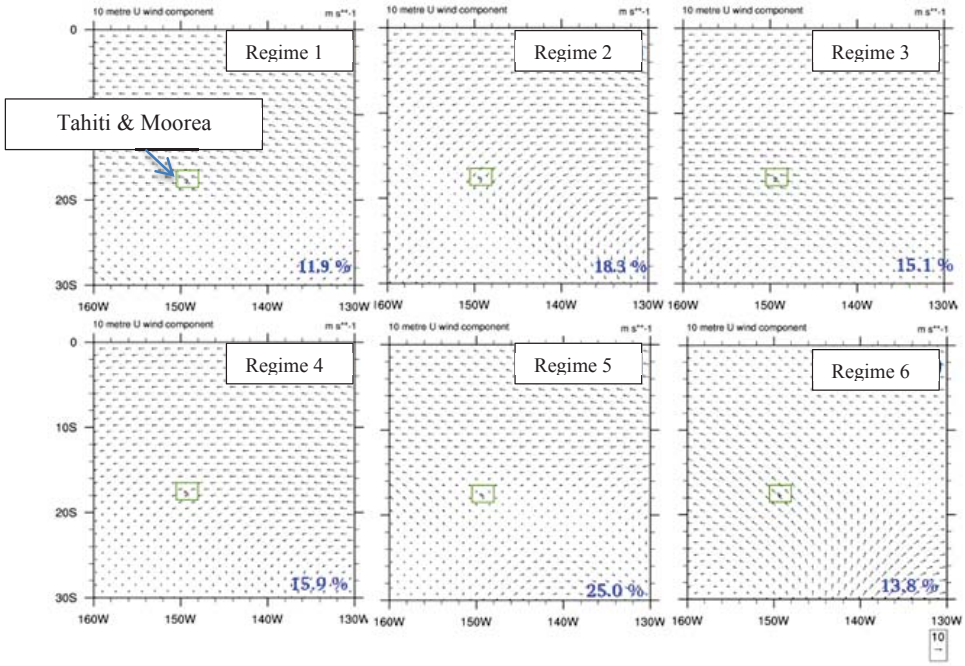

Fig. 2: Synoptic wind regime over French Polynesia obtained with 10m Era Interim reanalysis. The green square locates Tahiti.

The wind regime can be observed both on Tahiti and Moorea Islands with the following frequency of occurrence : Regime 1 (11,9%); Regime 2 (18,3%); Regime 3 (15,1%); Regime 4 (15,9%) ; Regime 5 (25,0%); Regime 6 (13,8%). It appears that at least 25% of a year, for the days of wind regime 5, the potential of natural ventilation is weak. The downscaling technique focused on a restricted area with a higher resolution gives a better estimate of the natural ventilation potential.

3.2 Downscaling

The Era Interim Reanalyzes data for five days for each of the six wind regimes were recovered and applied as boundary conditions of the WRF model domains. This provides five daily weather sequences simulated for each wind regime. The wind cartography for each regime at 1.3 km resolution is obtained by averaging the five days. The consideration of the relief is essential for small scales. Figure 3 shows the orographic

description considered by the model for Tahiti and Moorea Islands. The relief description level remains coarse as the maximum altitude considered is 1200m while the highest point of Tahiti is actually 2240 m. However, greater finesse requires very long calculation times.

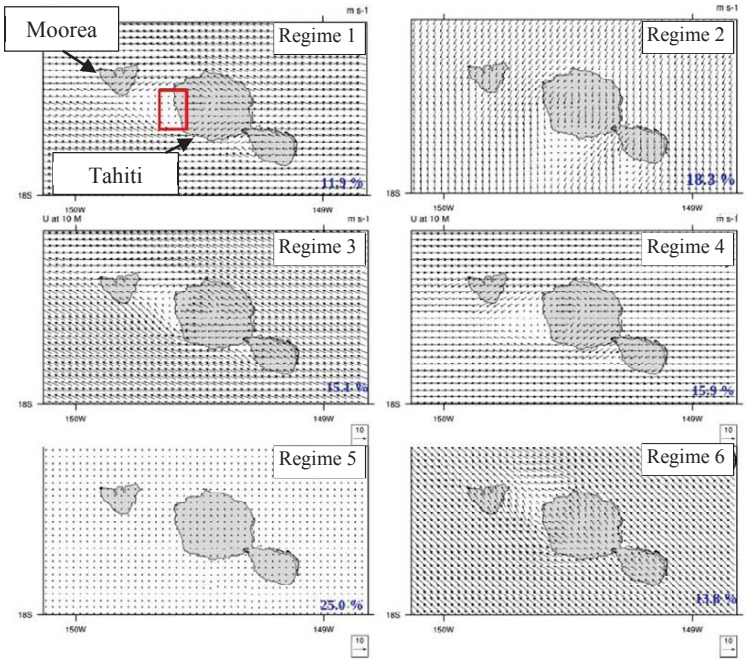

Fig. 3: Wind cartography at fine resolution (1.3 km) focused on Tahiti and Moorea islands and simulated with WRF model for the six wind regimes.

The downscaling with WRF has resulted in a more accurate and reliable wind cartography, showing the windward and leeward contrast for northeast, east and southeast wind regimes and is north. This study has highlighted the potential of natural ventilation throughout the islands of Tahiti and Moorea. It confirms that the main wind direction is South East with a frequency of 40% (regime 1, 3 and 6) and that for synoptic wind regime 5, natural ventilation of building might not be ensured as wind is very low. Moreover, for each coastal area, it evaluates the time percentages with light wind (<2.5 m/s) moderate wind (2.5 <wind <11 m/ s) and strong wind (> 11 m/s). The results are as follows:

- North and East Coasts: low wind 25%, moderate wind 34.2%; strong wind 40.8%
- South Coasts: low wind 43.3%, moderate wind 15.9%; strong wind 40.8%
- West Coasts: low wind 67.9%, moderate wind 13.8%; strong wind 19.3%

The downscaling approach provides also fine scale short weather sequences (typically one day) for each wind regime as the example shown on fig 4. These hourly sequences include all meteorological data needed for dynamic simulations of naturally ventilated building.

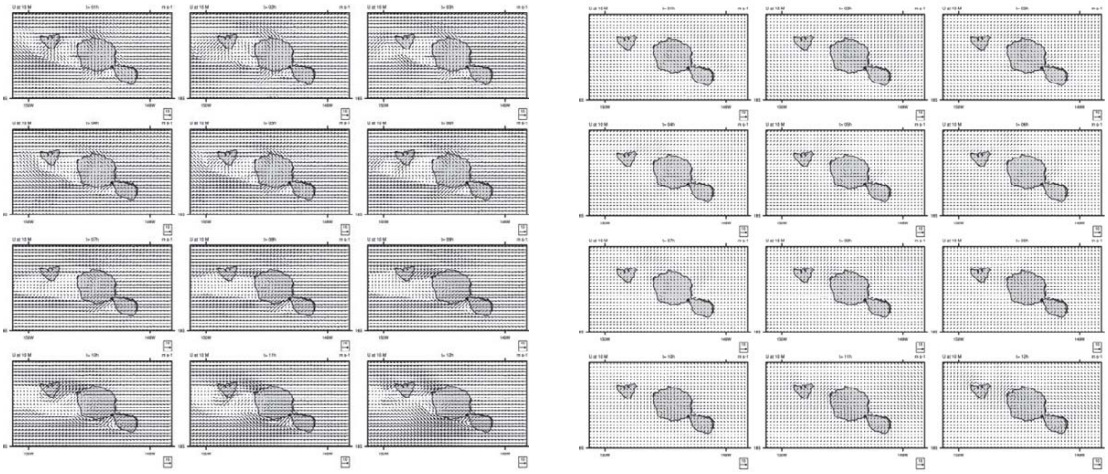

Fig. 4 : Example of hourly fine scale weather sequences. Hour by hour wind cartography for one day (from 0am to 12am) for a windy day (regime 1, on the left) and for day with low wind (regime 5, on the right)

4. Case study : building performance assessment using weather files

To compare the result of the weather sequences presented in this article, dynamic simulations using Energyplus software (Drury 2001) were carried out on a building located at Papetoai on the northwest coast of Moorea Island. (Fig 5). This building is a primary school building including 11 identical classrooms. Some classrooms are air conditioned whereas some are cross ventilated. Two different kinds of simulations where performed. The first simulations aim to compare the energy consumption of the air conditioned classrooms estimated with the PTMY weather file presented above and an annual weather file produced by Meteonorm. The second set of simulation includes simulations for each wind regime in order to estimate the comfort condition for the naturally ventilated classrooms. The one-day weather sequences used are generated hour by hour by the mesoscale model which perform a downscaling over Papetoai. All the simulations assess the classrooms are occupied with 20 people and their design is adapted to the tropical climate (solar shading, roof insulation, large openings equipped with louvers on opposite walls…) and to the operating mode. For the simulations of ventilated classroom the openings are supposed open all the time. For air conditioned rooms, these openings are closed and, according to sanitary regulations, mechanical ventilation provides 15m^3/h per person of outside air. The air conditioning system has a rated COP of 2.6 and the set point temperature is 26°C.

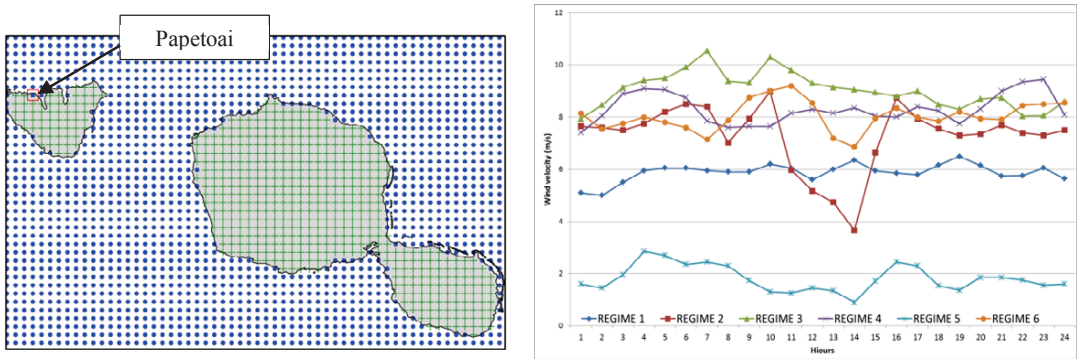

Fig. 5 : Location of the building under study on the north coast of Moorea plotted on the resolution grid of 1.33 km (left) and wind velocities for the short hourly sequences of the 6 wind regimes (right).

According to the Spitz's study mentioned in the introduction, the comparison of annual weather file will focus on the energy consumption and the cooling demand of the air conditioned classrooms. The output variables studied are the Air Conditioning sizing cooling load (kW), the annual cooling energy (kWh/year) and the annual electricity consumption of the AC system (kWh/year). The results are presented in table 3. The deviations observed are in the range of 10% for annual energies but rise to 18% for the cooling power required in the zone to reach the set point temperature. Consequently, the choice of the input weather file can

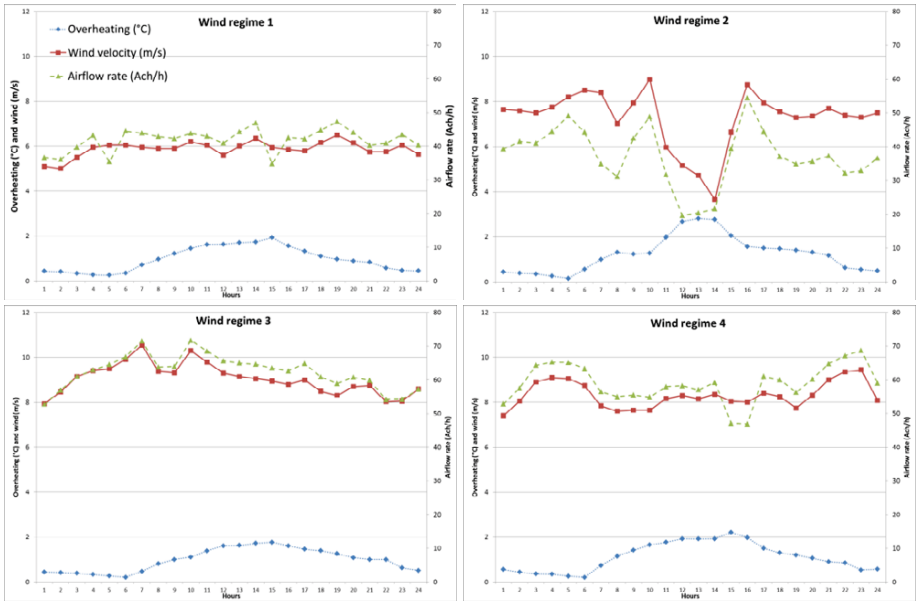
lead to overestimate the air conditioning system size.

Table 3: Cooling rate, cooling energy and electricity consumption for the two weather files

Weather file	System sizing cooling load (kW)	Annual cooling energy (MJ/year)	Annual electricity consumption of AC system (MJ/year)
Meteonorm	10.5	28 519	12 711
PTMY	8.6	25 603	11 397
Deviation (%)	18.0%	10.2%	10.3%

To ensure comfort in buildings, natural ventilation has two objectives: one is to evacuate thermal loads from the building and the second is to generate air velocity on occupants. The simulations performed for non-air conditioned classrooms aim to verify if natural ventilation can be an effective solution for building design in French Polynesia especially when the potential of ventilation is weak. As mentioned above, synoptic wind is low everywhere on Tahiti and Moorea the days of wind regime 5. It is also low on leeward coasts for all other wind regimes. Then, natural ventilation may not be sufficient to ensure comfort. The building studied being located on the North West coast; one can suppose that it is not exposed to the main synoptic South-East trade winds. However, the specific weather sequences generated for this location show that the wind velocity is most of the time moderate (Fig. 5). For these simulations, the effect of cross ventilation in the classrooms is estimated by the temperature difference between interior and exterior (overheating) and by the airflow rates through the zone. The target values for airflow rates depend on many parameters and among them the main one would be the population habits and their expectation in terms of comfort. Few targets values can be found in the literature for the populations in the islands of the Pacific Ocean. Le Bars (2010) mentions that an average airflow rate of 15 ach/h limits the overheating at only 4 to 5°C for an office building. To reduce the overheating to 2°C the airflow rate must be at least 20 to 30 ach/h. For classrooms, the same airflows and overheating values can be targeted if building design is adapted.

The simulation results (Fig.6) confirm that the natural ventilation potential is weak for wind regime 5, as the wind velocity is always less than 3m/s (the average during the day is 1.8 m/s) and the overheating goes up to 3°C (average is 1.5°C and the maximum is 3.26°C at 2pm). The airflow rate is always less than 25 ach/h (the average is 13 ach/h). The other wind regimes lead to moderate wind velocities with averages during the day ranging from 5.8 to 8.3 m/s. The average airflow rates range between 37 to 58 ach/h. The average overheating is less than 1°C, but its maximum values stay high (from 1.7°C to 2.8°C).



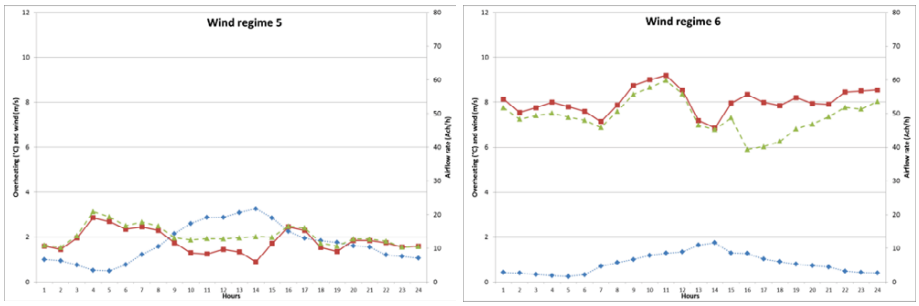


Fig. 6 : Simulation results with overheating, wind velocity and airflow rate for the 6 synoptic wind regimes

The use of localized short weather sequences shows that although the building is not located on the windward coast of Moorea, the local wind is most of the time moderate (between 2.5 and 11 m/s) and can be usable for effective natural ventilation. Thus, the airflows generated through the building are significant and overheating can be limited under 3°C all the days except for days of wind regime 5. Most of the time, comfort might be acceptable in ventilated classrooms, providing that the building design is suitable. From 1pm to 3pm during days of wind regime 5, the inside conditions are hot. In this case, ensuring an air velocity on occupants could be a solution to improve thermal comfort. The thermal simulation with Energyplus doesn't give access to air velocity in the thermal zone. Therefore a coupling with a CFD model should be investigated. At the last resort, ceiling fans could be added in the zone to generate the required air velocity.

5. Conclusion

Appropriate meteorological data is the first decision making tool that should be provided to building designers. This article presents the methods used to obtain climate data for addressing the building design in French Polynesia by following two approaches: an energetic approach for air conditioned buildings and a qualitative approach of comfort for naturally ventilated buildings. For the energy approach, the presented method proposes to establish a "Polynesian typical meteorological year" from a reduced ground measurement database. To complete the meteorological measurements on the ground, a global to diffuse decomposition model for solar irradiance was developed. This model presents interesting performances because it is easy to use by designers and has satisfactory accuracy. To carry out a qualitative analyzes of comfort in naturally ventilated buildings a climate model was used. This has highlighted six main synoptic wind regimes on Tahiti and Moorea Islands. The downscaling of this model has helped develop the wind cartography over a 1.33 km mesh and generate short weather sequences for each wind regime and for each point of the mesh. The weather sequences provided in this study have been used for energy calculation and wind potential assessment of a primary school building located in Moorea. For energy calculation, the "Polynesian typical meteorological year" is compared to an annual weather file from Meteornorm. The simulations of natural ventilation show that the fine mesh short weather sequences give a better evaluation of localized wind potential. To go further in this study, two directions must be investigated. The first is to carry on the downscaling toward a finer resolution (typically 100m) to better consider the orography and very localized climatic phenomenons. The second is to estimate the air velocities inside the building with CFD calculations using localized wind velocities as input. Considering the air velocities on the occupant will significantly improve the comfort assessment in the zone.

Abstract

Knowledge of the solar spectrum is essential for the design and study of numerous technologies based on the use of the solar resource. In spite of the fact that the Atacama Desert is in the spotlight of solar industry, there is not enough information about the spectral irradiance present on it. This fact and the special atmospheric conditions of Atacama cause an increasing interest of solar industry to know the spectral differences with other places of the world. Using a standard spectrum may represent very different results from the true. In this paper, direct and global tilted Atacama Desert Solar Spectra are derived from mean values of available satellite and model retrievals databases. Results are compared against the ASTM G173-03 Reference Spectra in order to know if the information provided by the standard is useful for solar energy applications. For that, solar spectra derived from SMARTS atmospheric transfer model in combination with the atmospheric information from the available databases are previously compared with several spectral irradiance measurements from the first spectral measurement campaign in Chile, developed on 2015. Later, the average of the atmospheric parameters for the whole Atacama Desert area is calculated from these data bases and is used to obtain the mean Global tilted Irradiance and Direct plus Circumsolar Irradiance solar spectrum.

Keywords: *Spectral Irradiance, Atacama Desert, Atmospheric Radiative Transfer Model, Solar Energy*

1. Introduction

Chile has experienced a rapid grow regarding the implementation of solar energy technologies. According to the Centre for Innovation and Promotion of Sustainable Energy (CIFES), the cumulative installed photovoltaic (PV) capacity in the country surpassed 1.5 GWp in June 2016, where 0.78 GWp will be added next. Concentrated Solar Power (CSP) is also reported with a 110 MW plant currently under construction (CIFES, 2016). Many of these solar projects are located in the Atacama Desert.

The Atacama Desert is located along the Pacific coast in South America. It has a hyper arid climate with annual precipitations lower than 50 mm (Larraín and Escobar, 2012). Characteristic mean temperatures range from 10ºC to 20ºC in winter and 20ºC to 30ºC in summer, whereas the air temperature keeps below 38ºC (McKay et al., 2003). In terms of chemical composition, nitrates represent 28% of the soil and water-soluble salts such as perchlorates and iodides. These salts rarely exist anywhere else (Navarro-González et al., 2003).

doi:10.18086/eurosun.2016.09.01 Available at http://proceedings.ises.org

Under clear sky conditions, the spectral distribution of solar radiation strongly varies during the day, mainly due to the distance that light must travel through the atmosphere, or air mass (M). It also depends on the climate conditions, which are responsible for the variation of the spectrum from one day to another and throughout the year. The most important parameters affecting the solar spectrum are the Solar Zenith Angle (SZA) related to M, cloudiness, the Total Ozone Column (TOC), the Precipitable Water (PW), the Aerosol Optical Depth (AOD), and the reflectance from the ground or albedo.

The Atacama Desert Solar Spectrum and environmental conditions can differ from what is usually found in northern hemisphere. The key factors responsible for these spectral differences are the high mean altitude, a large number of days with clear skies and low absorption ozone and water vapour columns (Cordero et al., 2016). Thus, this location receives highest surface irradiation. It was determined that the Global horizontal irradiation (GHI) can reach more than 8 kWh/m^2 per day resulting in more than 2500 kWh/m^2 per year (Escobar et al., 2014).

Knowledge of the solar spectrum at the earth surface can be important for the application of any solar energy technology but also for other disciplines. A spectral treatment of solar radiation can provide more accuracy since it incorporates more physical phenomena. The spectral irradiance can be essential for spectral, narrow-band and broadband applications. Among the spectral applications, the precise determination of the solar spectrum can be used for quantifying atmospheric parameters, for testing the performance of spectroradiometers, for defining a reference spectrum to certify PV technology, and for obtaining accurate spectra in the UV part of the spectrum. Narrow-band and broadband applications include UV radiation, illuminance and luminous, photosynthetically active radiation, filter radiometry as well as circumsolar radiation for pyrheliometers, assessment of broadband radiation models, turbidity determination from irradiance data and mapping and predictions of radiation fluxes (Gueymard, 2005).

Reference spectra were first generated as independent norms as E-891-82 and E-892-82, for the direct normal and global tilted irradiance, respectively. From June 1999 on, the subcommittee G3.09 of the American Society for Testing and Materials (ASTM) combines these two documents in the "Standard Tables for Reference Solar Spectral Irradiance at Air Mass 1.5: Direct Normal and Hemispherical for a 37 Degree Tilted Surface". This norm is based only on E891 and E892 standards and has the ISO 9845-1 certification. In January 2003, the G159 norm was reviewed and replaced by the G173-03. The current G173-03 was created by the North American PV industry together with ASTM (http://www.astm.org/) and research centers of the US government. They developed and defined two standard distributions of the ground solar spectrum. These spectra are the standards for direct normal and global tilted (at 37º) spectral irradiances (Myers, D. R.; Emery, K.; Gueymard, 2004).

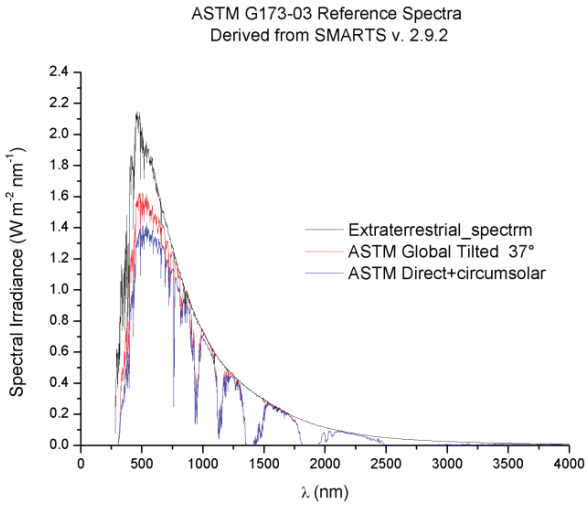

Fig. 1: ASTM G173-03 Reference Spectra Derived from SMARTS v.2.9.2, available in (American Society for Testing and Materials, 2012; Gueymard, 2004; Gueymard et al., 2002; NREL, 2015)

The calculation of the standard spectral irradiances was performed by means of the Simple Model of the Atmospheric Radiative Transfer of Sunshine (SMARTS) (Gueymard, 2001, 1995). SMARTS is a spectral model based in the Fortran programming language which can determine solar spectral irradiances under clear sky conditions for a set of given atmospheric parameters.

The ASTM G173 spectra, available in (NREL, 2015), represents the solar spectral irradiance at the earth surface which falls on a plane with specific orientation and specific atmospheric parameters. This spectrum provides the only reference for the evaluation of PV materials studied under natural and artificial light with different spectral distributions. However, the chosen atmospheric conditions were thought for the US during one year. Therefore, the tilt angle as well as the atmospheric conditions correspond to the national average values (Berman et al., 1999).

As the actual sunlight and environments, where PV systems operate, can be very different to those defined by standard testing conditions (STC), PV modules may not produce the maximum power output, as they should. The spectral effects need to be considered (Simon and Meyer, 2011; Topi et al., 2007). As reported in (Bücher, 1997) the efficiency of PV devices can differ up to 35% with respect to what is rated under STC due to the spectral differences. In order to demonstrate the relevance of the spectra, the photovoltaically active fraction (PAF) was defined (Berman et al., 1999). The effect of the solar spectrum was observed when using semiconductors with different bandgap energy. In order to quantify that impact on the absorbing materials, another parameter was defined, namely the useful fraction (UF) (Gottschalg et al., 2003). According these results, the need for a representative spectrum for Atacama Desert becomes clear.

In order to ensure optimal performance of PV technologies under specific conditions such as those of the Atacama Desert, PV module materials, solar cells and modules can be adapted and designed. Advances in this matter have been reported in (Cabrera et al., 2016, 2015; Ferrada et al., 2017) where different module materials were combined with several solar cell configurations and considering a preliminary calculated Atacama Solar Spectrum.

In order to achieve the aim of this paper, the Simple Model of the Atmospheric Radiative Transfer of Sunshine, or SMARTS (Gueymard, 2001, 1995), was chosen to estimate mean direct an global spectral irradiances for the Atacama Desert. Firstly, SMARTS model and the selected data bases were validated by comparison against global horizontal spectral irradiance measurements in north of Chile. Subsequently, the astronomic factors and long-term atmospheric parameters, available in satellite databases, were averaged for Atacama Desert area. Then, results were used to calculate mean solar spectra. Finally, the estimated Atacama spectra were compared with the ASTM G173-03 Reference Spectra.

2. Comparison with ground measurements

The SMARTS code is used for many applications in the solar industry and previously it has been widely validated by researchers. Some examples are (Eltbaakh et al., 2013; Gueymard, 2008, 2005, 2004, 1995; Kocifaj and Gueymard, 2011; Myers, D. R.; Emery, K.; Gueymard, 2004). However, estimated spectra derived from SMARTS and the available databases were compared against ground spectral measurements in order to know if it is reliable the use of SMARTS and the selected databases in this work.

A first campaign of solar spectral measurements supported by CIFES (CIFES, 2016) was performed in February 2015. The campaign focused on the spectral global horizontal measurement of solar irradiance at several places from Antofagasta and Iquique Regions, in north of Chile. The resulting information from the measuring campaign was not enough to obtain mean solar spectral irradiances for the Atacama Desert, because of the short time period of measurement at each place, around three days per each location, and the short covered area. However, the spectral measurements play an important role to validate the performance of atmospheric radiative transfer models and satellite databases..

The measurement campaign were carried out with a Bentham DTMS300 double monochromator spectroradiometer and a probe to measure the solar spectral global horizontal irradiance (G_λ), as described in (Cordero et al., 2016). The spectroradiometer measured the spectral irradiance between 290 and 1800 nm wavelengths, and took nearly 10 minutes to measure in this range. Consequently, only measurements taken under clear and stable sky conditions were considered. The measurement uncertainty was estimated around ±10% for the UV-B spectral range [290, 315] nm and ±4% for upper wavelengths, obtained from the comparison of the integral values for each spectral range, as reported by authors. Authors also point out that higher uncertainties may be found in atmospheric absorption bands but they did not quantity them.

To compare the estimation of solar spectral irradiances with the measurements, three places where chosen according to the availability of ground and satellite databases. Antofagasta, Calama and Caldera were the selected locations; and Era Interim (ECAD, 2016), Giovanni (NASA and Kempler, 2016) and the ground database of the National Air Quality Information System, SINCA (SINCA, 2015), were the consulted databases.

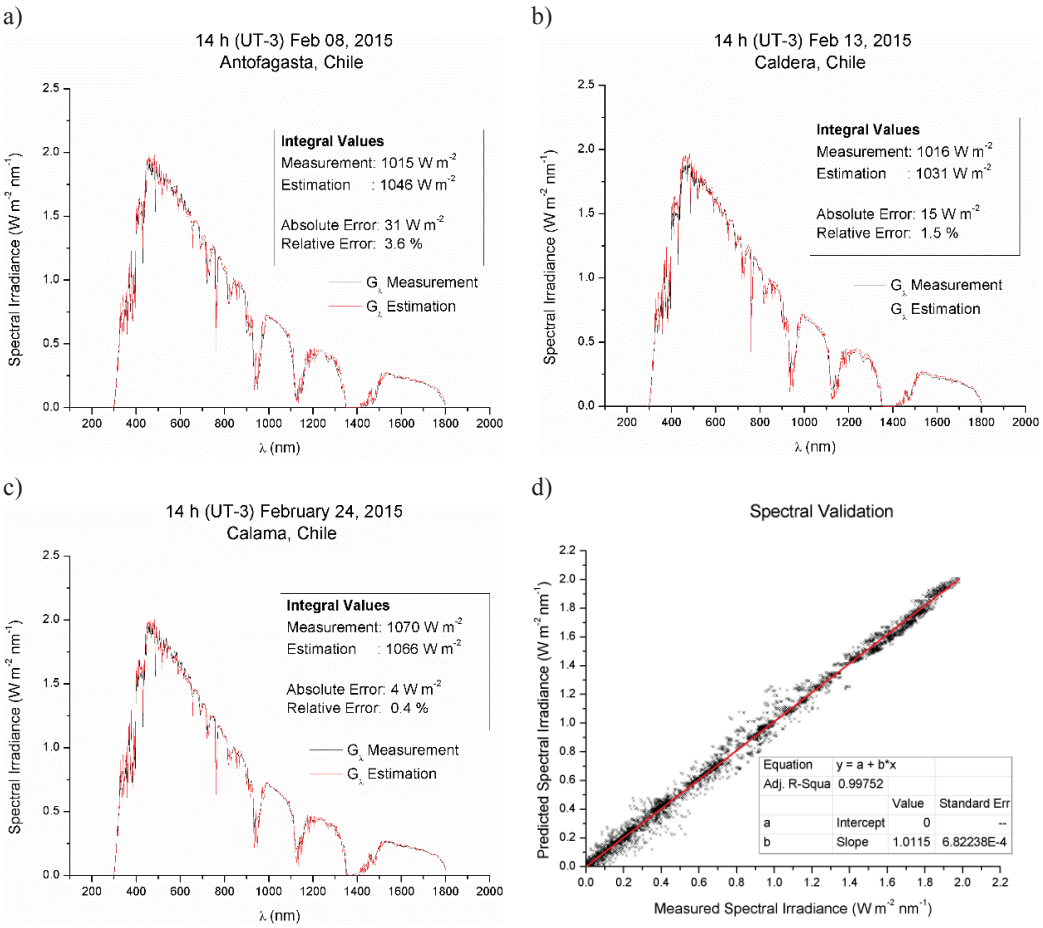

Fig. 2: Spectral global horizontal measurements (black) and spectral irradiance calculations using SMARTS (red) for Antofagasta (a), Caldera (b) and Calama (c). (d) Linear fit of the measured spectral irradiances against the calculations obtained with SMARTS model.

An example of the validation test for each place is shown in Fig. 2, as well as the fit of predictions and measurements for the spectral irradiance values (Fig. 2-d).

As shown in Fig. 2, some differences are presented in the bands relating to the water vapour and ozone absorption. This fact is in agreement with ground measurement reported by authors. A slight deviation can be

observed also at short wavelengths, where predictions overestimate the measurements. These differences may be due to the radiative transfer model or, aerosols or instrument uncertainty. An in-depth investigation will be developed in future works in order to improve the estimations. However, if the instrument uncertainty is taken into account, the results of the SMARTS predictions are in agreement with the measurements shown in Fig. 2 d, and Tab. 1.

Tab. 1: Averaged relative errors for the validation test according to the integration spectral range.

Spectral Range	**Comparison** *Relative error*	*Instrumental Relative* **Error**
[290, 316]	±3%	±10%
[316, 400]	±3%	±4%
[400, 700]	±1%	±4%
[700, 1800]	±3%	±4%
[290, 1800]	±2%	±4%

3. The Atacama Desert Solar Spectra

On one hand, several inputs, most of them characterized with a high temporal and spatial variability, are needed to predict or calculate a solar spectrum. On the other hand, different criteria can be considered to estimate the average values to calculate a representative spectrum for the area of interest. For these reasons, it is difficult to affirm that an average solar spectral irradiance is the representative mean spectra for a specific place, mainly for the direct normal component of the solar irradiance. However, this work intends to highlight the importance of considering local atmospheric parameters in spectral studies related to solar energy technologies instead of the global reference spectra.

The inputs considered to calculate an average of the Atacama Desert Solar Spectrum were: temperature, relative humidity, precipitable water, ozone, pressure, altitude at ground, carbon dioxide, turbidity (AOD at 550 nm), albedo, and surface tilt angle. Each one of the mentioned inputs was changed individually with respect the ASTM G173-03 Reference Spectra. The remaining inputs were left as the default values: Air Mass (M) and Shettle & Fenn aerosol model (rural). All atmospheric parameters were averaged for the area of interest before to be introduced as inputs in SMARTS to estimate mean solar spectral irradiances for Atacama Desert.

The surface tilt angle, β, for PV panels was calculated according to the following expression (Gallegos and R. Righini, 2012):

$$\beta = 3.7 + 0.69\,\phi \qquad \text{(eq. 1)}$$

where β results 18º when the ϕ value is 20.7º.

The average elevation of the area of interest for solar technologies in Atacama Desert is approximately 2 km. This value is derived considering that the elevated places, over 3.5 km, are not suitable for the installation of solar power plants due to their complex orography with steep slopes, difficult access, long distances to the distribution network and villages, and the disadvantages of working at height: altitude sickness, low atmospheric density and strict national safety regulations for these places. The atmospheric pressure value, 804.3 hPa, corresponds to the value of pressure at 2 km altitude for a sub-tropical reference atmosphere considering a pressure of 1013.25 hPa at sea level (Gueymard, 1995).

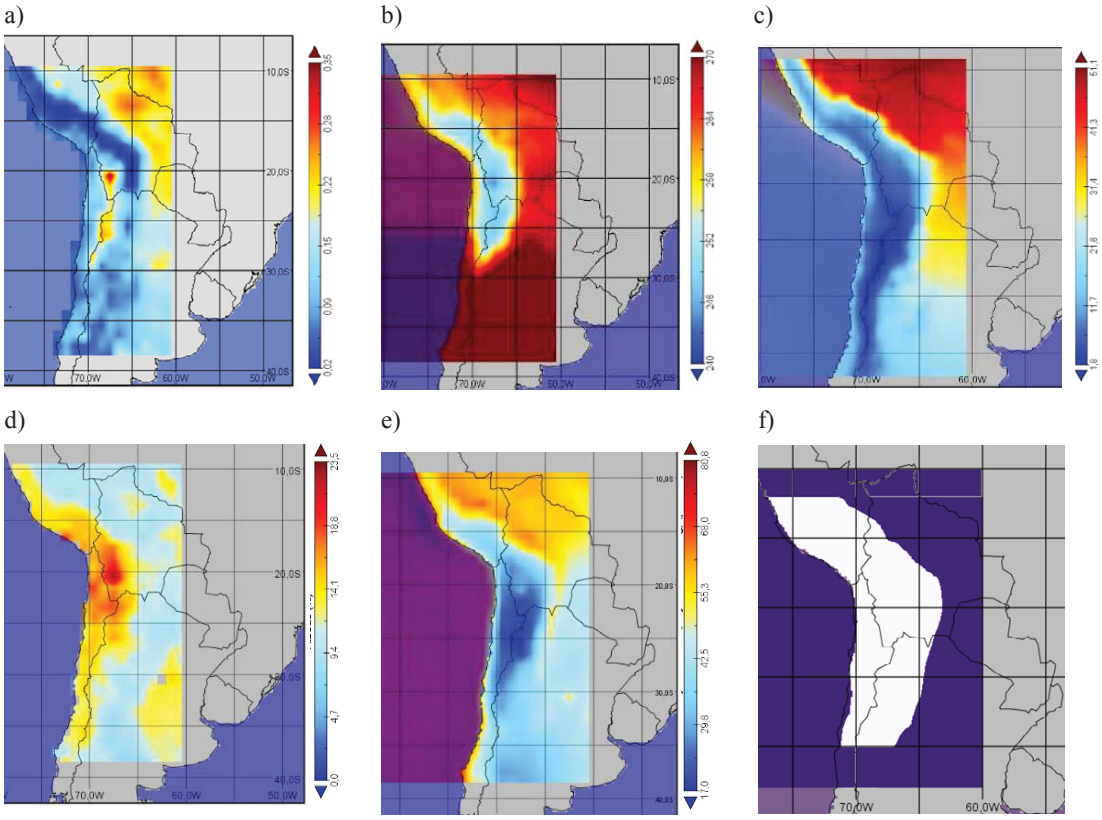

Fig. 3: a) Aerosol Optical Depth at 550 nm [no units]; b) Ozone Total Column [DU]; c) Precipitable Water Vapor [cm]; d) Albedo [no units]; e) Relative Humidity [%]; all parameters were averaged for a time-period of 10 years. f) The white region represents the area where parameters were averaged.

Other atmospheric parameters derived from long-term satellite databases were averaged for Atacama Desert area (Fig. 3), which is represented as a white region in figure 4 f. All parameters plotted in Figure 4 are available in (NASA and Kempler, 2016). Figure 4a and 4c show the MODIS retrievals for Atacama Desert Aerosol Optical Depth (AOD) at 550 nm and Precipitable Water (PW) values averaged from January 2006 to January 2016 (Bellouin et al., 2013; Kato et al., 2011; Remer et al., 2005). Figure 4b shows the Ozone Total Column (TOC) values over the Atacama Desert and figure 4e the Relative Humidity (RH), both from AIRS/Aqua L3 Daily Standard Physical Retrieval (Wang et al., 2012). Albedo (Figure 4d) was obtained from Global Land Data Assimilation System Version 2, bases on temporal averaging of the 3-hourly reprocessed data. It contains a set of land surface parameters simulated from the Noah Model 3.3 (Rodell and Beaudoing, 2015). Albedo values were calculated as an average for dates from January 1999 to January 2010.

Results of the average and the remaining inputs are shown in the table of Figure 4.

As results shows, low levels of TOC and PW are achieved. These results are in agreement with the ground measurements at several points of north of Chile (Cordero et al., 2016; Dirección Meteorológica de Chile, 2015; Galewsky et al., 2011; Kerber et al., 2014, 2012; McKenzie et al., 2015; Patat et al., 2010).

The Atacama Desert spectra derived from SMARTS and the average values of the atmospheric conditions are shown in Figure 4.

PARAMETER	VALUE	UNITS
P	804.3	*(hPa)*
T	22.54	*(C)*
RH	38	*(%)*
T_{MEAN}	14.25	*(C)*
PW	1.5	*(cm)*
TOC	257	*(DU)*
CO_2	400	*(ppmv)*
AOD at 550 nm	0.102	*(--)*
ALBEDO	0.18	*(--)*
β	18	*(°)*
M	1.50	*(--)*

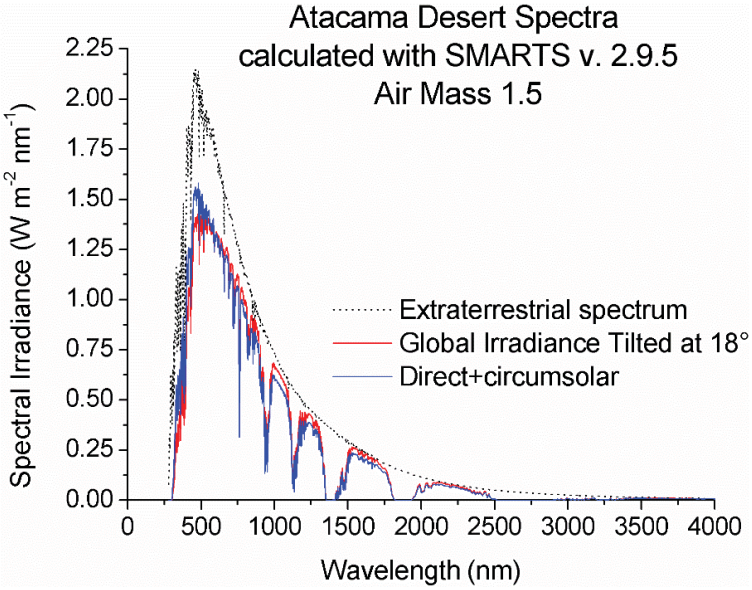

Fig. 4: At left, a table with the inputs resulting from data processing, considered to calculate the Atacama Spectra. Right, Atacama Spectra derived from SMARTS v 2.9.5. Black line represents the extra-terrestrial solar spectrum (Gueymard, 2004), the red line is the global irradiance for a tilted surface at 18°, and the blue line represents the direct and circumsolar irradiance assuming a half aperture angle of a simulated spectroradiometer of 2.5°.

4. Comparison with the ASTM G173-03 Reference Spectra

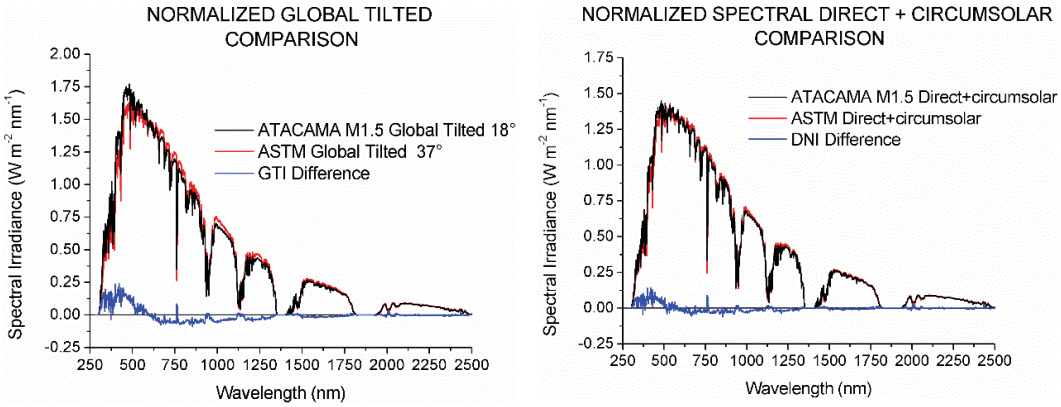

Fig. 5: Right, comparison of Atacama (black) and Reference (red) global spectral irradiances over a tilted surface at 18° and 37° respectively. Left, comparison of Atacama (black) and Reference (red) direct and circumsolar spectral irradiances.

Under the previously defined atmospheric and astronomic conditions, the integral values of the solar spectral global and direct plus circumsolar irradiances estimated for Atacama Desert were 893 and 903 W m^{-2} respectively, while the reference spectra have 1000 W m^{-2} and 900 W m^{-2}. The main different occurs in the global tilted spectrum and it is mainly due to the difference in the tilted angle of the surface where solar radiation is impinging on. A higher tilt angle permits a higher amount of solar radiation reflected from the ground to achieve the surface.

In order to show the differences on how the solar power is distributed along the electromagnetic spectrum, figure 5 shows the comparison of the normalized Atacama Desert spectra with the ASTM G173-03 reference for each solar irradiance component, namely Global (left) and Direct + Circumsolar (right), for M equal to 1.50. Normalization was performed to the integral values of the global tilted and direct plus circumsolar

spectral irradiances of the standard, 1000 W m^{-2} and 900 W m^{-2} respectively. In general, the greatest differences occur in the spectral range from 250 to 600 nm. Elevation above sea level (Pressure), AOD and TOC play an important role in light transmission at wavelengths below approximately 600 nm. The low levels of atmospheric ozone which play an important role in the atmospheric transmittance below the 340 nm, lead to higher UV-B irradiances, as ground measurements have shown, e.g. see (Dirección Meteorológica de Chile, 2015).

In the framework of solar energy technologies, the differences per wavelength do not play a role as important as the power distribution differences inside broadband ranges, excluding those processes, which occur at a given wavelength, such as for water treatment.

Figure 6 shows how much power there is in the ultraviolet (UV), visible (VIS) and near-infrared (NIR) ranges for each spectrum. In other words, it shows how the solar power is distributed for each spectral range. For that purpose, the integral of the spectral irradiance in each range was calculated and compared with the integral for the whole range in two cases: from 280 to 1200 nm (Fig. 6 left) and from 280 to 2500 nm (Fig. 6 right). Both spectral ranges were selected to provide useful information for Concentrated Solar Power (CSP) and Photovoltaic (PV) technologies, respectively.

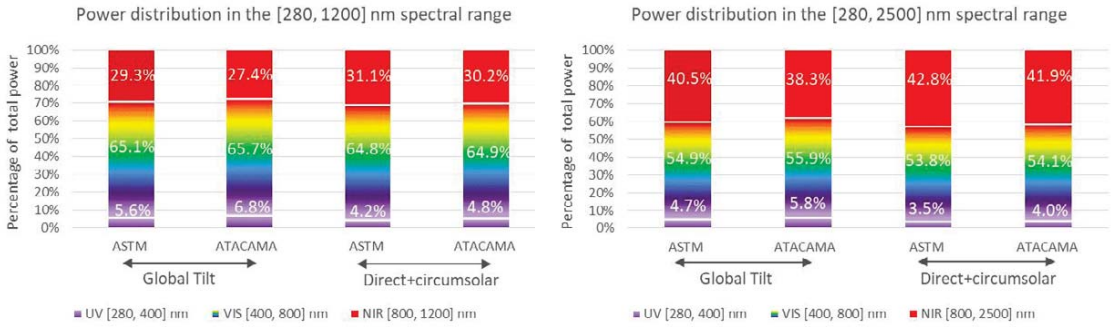

Fig. 6: Solar power distribution for each spectral irradiance according to the UV [290, 400] nm (violet colour), VIS [400, 800] nm (rainbow colour) and NIR [800, 2500] nm (red colour) ranges. Left: results for the [280, 1200] nm spectral range. Right: results for the [280, 2500] nm spectral range.

As figure 6 at left shows, 6.8% of the total hemispherical power received by a 18° tilted surface in Atacama Desert, is confined in the UV spectral range. Paying attention to the irradiance values in this spectral range, 58 W m^{-2} for Atacama and 46 W m^{-2} for the ASTM. It means that the predicted spectrum for Atacama differs 24% from the ASTM, and the difference is 93% higher if the same comparison is done in the UVB spectral range. Similar values can be obtained if the comparison is done for the direct plus circumsolar irradiance, 17% and 67%, respectively.

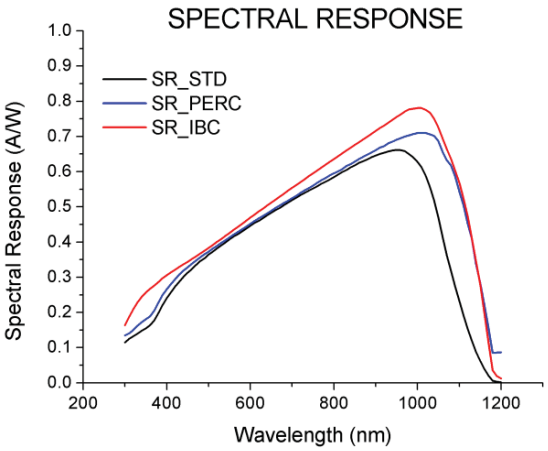

Fig. 7 Spectral Response of standard, PERC and IBC photovoltaic technologies

In order to know how these differences affect the development of solar technologies, three PV cells are studied under the influence of the solar global tilted reference spectrum and the average spectral irradiance estimated for Atacama Desert. The technologies used in this study were: a standard solar cell (STD), a passivated emitter and rear contact solar cell (PERC) and an interdigitated back contact solar cell (IBC) with spectral responses (SR(λ)) shown in Fig. 7.

A good indicator that helps to know about the influence of the solar spectrum shape on solar PV cells or devices is the spectral mismatch factor (MM). The MM is defined in the IEC 60904-7 norm (IEC, 2008) and describes the procedure for correcting the bias error introduced in the testing of a photovoltaic device, caused by the mismatch between the test spectrum and the reference spectrum and by the mismatch between the spectral responses (SR) of the reference cell and of the test specimen. The MM factor is defined in this work as follows:

$$MM = \frac{\int E_{ref}(\lambda) S_{Std}(\lambda) d\lambda \int E_{Ata}(\lambda) S_{sample}(\lambda) d\lambda}{\int E_{Ata}(\lambda) S_{Std}(\lambda) d\lambda \int E_{ref}(\lambda) S_{sample}(\lambda) d\lambda} \quad \text{(eq. 2)}$$

Where $E_{ref}(\lambda)$ is the irradiance per unit bandwidth at a particular wavelength, of the reference spectral irradiance; $E_{Ata}(\lambda)$ is the irradiance per unit bandwidth at a particular wavelength, of the spectral irradiance distribution estimated for Atacama; $S_{Std}(\lambda)$ is the spectral response of the standard PV device; $S_{sample}(\lambda)$ is the spectral response of the test PV device. The relative error (ΔMM) is calculated as a deviation from 1. Results are shown in table 2.

Tab. 2: Spectral mismatch (MM) and relative error of the spectral mismatch (ΔMM) in comparison with the reference global tilted spectrum and reference photocell

CELL	MM	ΔMM (%)
PERC	0.9989	0.11%
IBC	1.0004	0.04%

The calculations show low MM values, 0.998 and 1.000, and ΔMM values, 0.11% and 0.04%, for PERC and IBC solar cells, respectively. These low ΔMM values indicate that the changes in the shape of the spectra, estimated for the specific conditions previously defined in this work, are not significant for the PV cells performance.

The photo-generated current (J_{ph}) is defined as the maximum theoretical current that can be generated by a PV device. It is calculated as (Ferrada et al., 2017):

$$J_{ph} = \int E(\lambda)\, SR(\lambda)\, d\lambda \quad \text{(eq. 3)}$$

Where $SR(\lambda)$ is the spectral response of the considered PV device, E_λ is the incident solar spectral irradiance, and λ is the wavelength. The calculations were performed for both normalized and non-normalized solar spectra estimated for Atacama, and the reference solar spectrum. Results are shown in Fig. 8.

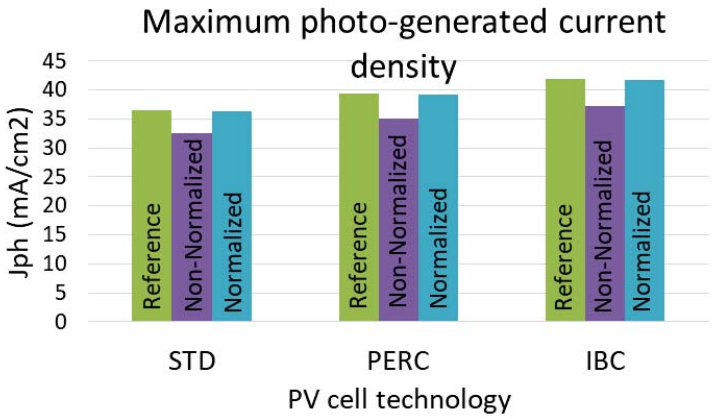

Fig. 8 Maximum photo-generated current (Jph) for different solar cells (STD, PERC and IBC). The green bar indicates the Jph calculated with the reference global tilted spectrum, the violet bar is the Jph for the Atacama Desert global tilted spectrum without normalization, and the cyan bar represents the Jph calculated with the normalized solar spectrum estimated for Atacama Desert.

The results indicate that the maximum difference occurs if the calculation is performed for a non-normalized spectrum, around 11%. On the contrary, the difference is minimum, less than 0.6%, if the comparison is done with normalized solar spectra. This result therefore agrees with the result of the MM comparison, indicating that the shape of the spectrum is not as important as the total amount of incident solar power, at least under the atmospheric and air mass conditions used in this work.

From the point of view of thermal processes, the differences in the energy distribution of the solar radiation do not play a major role. In CSP technologies, the aim is the production of process heat from the incident solar radiation. For this purpose, the receivers play an important role. In this context, receivers are designed to absorb the maximum of the incident solar power, which means pursuing absorptance values close to 1, usually in the 300-2500 nm spectral range. However, the aging of materials used may become a factor to be considered, especially at mirrors and receivers.

5. Conclusions

An estimation of the local solar irradiance spectrum for the Atacama Desert was conducted by deriving relevant atmospheric parameters from satellite databases, and then using those parameters as inputs for the SMARTS model. The atmospheric values were averaged for the area of Atacama Desert. These estimates represent a spectral distribution of the solar power for the specific conditions defined in this work.

The estimated spectra show changes with respect the world reference. These changes are in the amount of solar power and in the shape of the spectral power distribution. Changes are mainly due to the difference in the angle of the tilted surface and also because of the differences in the atmospheric parameters.

The main difference is found for short wavelengths, especially in the UV spectral range. The solar irradiance confined in the UV spectral range for the Atacama calculations resulted in 24 percentage points higher than the reference spectra for the global tilted component.

On one hand, the differences found in the shape of the solar spectrum, are not relevant for the solar technologies. The spectral mismatch calculation for three different solar cell types shown that the relative deviation from 1 is less than 0.11%. The maximum photo-generated current calculations indicates a relative error less than 0.6% respect the reference for the normalized spectrum calculated for Atacama. Both results are in agreement with themselves.

On the other hand, if the maximum photo-generated current calculations are performed with the non-normalized spectrum for Atacama, the relative error is around the 11%. This result indicates that what matters is the amount of energy and not the shape of its spectral distribution, at least under the specific conditions detailed in this paper which takes into account the same air mass than that defined for the world reference (M=1.5).

From the review of the available databases, it was noted that ground-based measurements of long-term atmospheric parameters in Atacama Desert is still necessary. The calculated spectral irradiances through SMARTS were in agreement with the spectral horizontal global measurements. However, an in-depth investigation is required in order to improve estimations, including more measurements for the improvement of the statistical methodology.

Abstract

During the last decade, worldwide deployment of solar photovoltaic power plants has registered an unprecedented growth owing to – initially – politically motivated support programs and – finally – economic competitiveness. India has also witnessed an exponential growth in solar PV installation during the recent years and has set an ambitious target of 100 GW solar PV installed capacity by 2022. In Rajasthan alone, a solar power capacity of around 5.8 GW is aimed to be achieved by that time. However, short-term solar variability can be a hindrance in the process of large scale solar power deployment, as this makes operation of large solar PV plants difficult and management of power grid challenging.

Here, the aim is to study the impact of short-term temporal variability of solar power in Rajasthan. Also, another motive is to observe the effect of spatial smoothing and to quantify the suppression of variability due to the same. The data sets used consist of 1-min solar irradiance data measured at ten time-synchronized solar radiation resource assessment (SRRA) sites dispersed across Rajasthan. The methodology includes calculation of clear sky index (K_t*) using Bird clear sky model, computation of site-pair correlation using the parameter 'Change in clear sky index' (ΔK_t*), evaluation of proposed parameter 'Percentage change in generation' to observe Dispersion-Smoothing effect and sample calculation of parameter 'Diversity Filter' to estimate suppression of variability due to regional smoothing.

Key Words: *Short-term temporal variability, Spatial smoothing, PV power ramps.*

1. Introduction

India, a country of around 1.3 billion population, is power starved. Today still around 22% of the Indian population has no access to electricity (The World Bank, 2015). The Indian government (GOI) has recognized the fact that renewable energy (RE) will play a very important role in reducing the percentage of people, who are deprived of electricity, by providing easier access to clean energy and is working assiduously to create a conducive environment for renewable energy infrastructure growth in the country. Last sexennial, India has witnessed an unprecedented growth in green energy installations. As of June 2015, India's net grid-connected RE capacity stood at 36.47 GW, of which almost 65 % came from wind, while solar PV contributed to nearly 11 % of total RE installed capacity (MNRE, 2015a). Though contribution of solar PV has been meagre compared to the share from wind previously, the scenario is about to change. By the year 2022, the GOI aims to achieve an updated target of 100 GW of solar PV capacity under its Jawaharlal Nehru National Solar Mission (JNNSM) program. In Rajasthan alone, the target is to achieve solar PV power installed capacity of 5.8 GW (MNRE, 2015b).

doi:10.18086/eurosun.2016.09.14 Available at http://proceedings.ises.org

However, short-term solar variability may be an impediment to the large scale solar deployment. Solar variability, which – on the very short-term time scale – happens mainly due to the movement of clouds, can drive a PV power plant from generation at rated power to nearly no generation mode or vice versa in matter of seconds. An array of cloud structures passing in front of the sun can cause an abrupt change in power generation, thus making the operation of solar PV power plants difficult and the management of electrical grids challenging.

In addition, a sudden variation in solar generation due to short-term solar resource variability can be a source of unprecedented challenges for power generation companies, transmission companies and distribution system operators (DSOs). Changes in solar irradiance over a short time scale (seconds) can create power quality problems like voltage flicker & harmonic distortion etc., which may be detrimental to critical, sensitive loads at consumer end. Serious grid level problems like issues with power quality and network outages may occur, when, due to sudden variation in solar power generation and unavailability of sufficient ramping capability, the grid fails to cater to system load. In addition to this, variable PV generation can also have a serious impact on local feeders and substations, which are highly specific to local conditions like demand profile, grid distribution and existing system constraints (CAT Projects, 2015). Tab. 1 lists different impacts on power system due to variable solar generation (IEA, 2015). The grid operator may sometimes need to take corrective actions like using voltage limiters, ensuring availability of ample operating reserve and ramping capability and load following etc.

Tab. 1: Potential impact on power system due to short-term solar variability (IEA, 2015)

Time interval of change in solar irradiance	Potential impact on power system
Seconds	Voltage fluctuation
Minutes	Regulation reserves
Minutes to hours	Load following

Hence, short term solar variability is a very important parameter to study, as the outcome of the study may throw light on the extent to which variability can be experienced and the balancing resources needed to lessen its impact. In recent years, this topic has attracted attention of a large number of researchers and there have been numerous publications on this topic, most notably by (Hoff & Perez, 2010, 2012a, 2012b), (Mills & Wiser, 2010) and (Perez et al, 2015). For most of these studies, synthetic data or satellite data has been used to evaluate the impact of short-term variability over a wide area. (Mills & Wiser, 2010) used ground measured irradiance data from 23 time-synchronized stations to study the event of solar variability in the Southern Great Plains area.

Here, a short-term solar variability study for the state of Rajasthan is conducted using 1-min resolution irradiance data, measured at the Solar Radiation Resource Assessment (SRRA) stations. This is the first time, a wide-area study on assessing the impact of solar variability has been conducted for any state in India using high-quality ground measured irradiance data sets. Also, another motive behind this study is to observe the effect of spatial smoothing and to quantify the suppression of variability due to spatial smoothing. The main rationale behind choosing Rajasthan for this study is the proposed development of solar energy infrastructure in the state in the coming years. Recently, the Indian government has proposed setting up of ultra-mega solar power farms at Sambhar, Bhadla and Jaisalmer of Rajasthan. In the years to come, Rajasthan is going to witness a steep increase in solar power generation and in that context, the selection of Rajasthan for a variability study can be justified.

2. Methods

2.1. Quantifying solar variability for a single site, for a fleet of solar generators & suppression of variability

For properly quantifying variability, the parameters needed to be defined are: (a) the physical quantity that varies (b) the time interval over which it varies and (c) the time period of variation.

The most important physical quantity under assessment can be solar PV power generated from a single site or from a fleet of PV plants, as it is of the highest concern for a solar power producer or grid operator. Solar power generated is also a linear function of solar resources available. Hence, researchers study variability of global horizontal irradiance (GHI) or direct normal irradiance (DNI) in case of unavailability of power generation data. Studying variability of DNI is more relevant for concentrating technologies, while the former is more important for non-concentrating flat plate solar systems. Short-term GHI variability considers variation due to both predictable solar geometry and unpredictable cloud motion. The effect of predictable

components can be excluded by analysing the clear sky index K_t^*, the ratio of GHI to clear sky GHI. This parameter is calculated by applying a clear sky irradiance model with a specific set of atmospheric parameters as input. K_t^* as a normalized quantity then clearly shows any deviation from this highly predictable clear sky situation – especially any cloud induced variability. In this work, the clear sky index K_t^* is used based on the clear sky irradiance model from (Bird, 1984; Myers, 2013).

Time interval (Δt) is the time over which the selected physical quantity, K_t^*, varies. ΔK_t^* is defined as the change that the clear sky index undergoes during the time interval Δt. The time interval can vary from few seconds to hours depending on the concern of the user. For large PV generators or regional grid operators, solar variability over few seconds may not be a serious matter to worry about, but it will be troublesome for a small PV generator or for a single site.

Time period is the time span over which variability is studied. Time span is always a multiple of time interval. Here, for this work, the time period of study is one year.

Now, a nominal variability metric for a single site can be defined as the standard deviation of the change in clear sky index ΔK_t^* during a time interval Δt over the selected time period (Perez & Hoff, 2013).

$$\sigma\ (\Delta Kt^*_{\Delta t}) = \sqrt{Var(\Delta Kt^*_{\Delta t})} \quad \text{(eq.1)}$$

The quantity $\sigma\ (\Delta K_t^*)$ is a normalized dimensionless quantity. This variability is directly proportional to the standard deviation of the change in generated power. Absolute power output variability is expressed by:

$$\sigma(\Delta P_{\Delta t}) = \sqrt{Var(\Delta P_{\Delta t})} \quad \text{(eq.2)}$$

Where $\Delta P_{\Delta t}$ = change in power generated during time interval Δt.

Again, normalized power variability is given by:

$$\sigma(\Delta P_{\Delta t})_{Norm} = \sqrt{Var(\Delta P_{\Delta t})}\ /P_{installed} \quad \text{(eq.3)}$$

Where $P_{installed}$ = net installed capacity at the site under study.

Ideally,

$$\sigma(\Delta Kt^*_{\Delta t}) = \sigma(\Delta P_{\Delta t})_{Norm} \quad \text{(eq.4)}$$

For a fleet of solar generators, the absolute power variability of N plants is given by (Perez & Hoff, 2013):

$$\sigma_{\Delta t}^{fleet} = \sqrt{Var(\sum_{n=1}^{N} \Delta P_{\Delta t}^{n})} \quad \text{(eq.5)}$$

Where $\Delta P^n_{\Delta t}$ = change in generation at n^{th} site during time interval Δt.

For a special case, when all the plants in the fleet have the same installed capacity, exhibit the same variability and their power output time series are uncorrelated, the above equation simplifies to:

$$\sigma_{\Delta t}^{fleet} = \sqrt{(N * Var(\Delta P_{\Delta t}))} \quad \text{(eq.6)}$$

For this special case, the relative normalized power variability for the fleet of generators is given as follows:

$$(\sigma_{\Delta t}^{fleet})_{Norm} = \sqrt{(N * Var(\Delta P_{\Delta t}))}\ /(N * P_{installed}) \quad \text{(eq.7)}$$

Where $P_{installed}$ is the net installed capacity of an individual power plant.

Hence, the relative variability for a fleet of identical generators with their power output time series uncorrelated, experiencing same variability equals each individual plant's relative variability divided by square root of the number of plants N (Perez et al, 2015).

$$\text{Fleet Relative Variability} = (\text{Single Relative Plant Variability})/\sqrt{\text{N}} \quad \text{(eq.8)}$$

Hence, the following equation mentioned in terms of clear sky index (K_t*) can be applied to the relative variability for a fleet of identical generators:

$$(\sigma_{\Delta t}^{fleet})_{\text{Norm}} = \sigma_{\Delta t}^{1}/\sqrt{N} \quad \text{(eq.9)}$$

Here, $(\sigma_{\Delta t}^{fleet})_{\text{Norm}}$ is the fleet's normalized variability and $\sigma_{\Delta t}^{1}$ is a single location's nominal variability. This event of suppression of variability is also known as spatial smoothing effect, which signifies suppression of power variability experienced (by a factor of 1/√N) at a single PV generator when integrated to a fleet of similar but uncorrelated PV power plants. The above equations hold good for a fleet of identical uncorrelated generators, but in actual case, there will be a correlation among any two sites under study, which is a function of distance between them, the time interval and the time period of analysis. Therefore, the key parameter to find is the site-pair correlation (ρ).

Now, considering a pair of identical stations with site-pair correlation ρ, (eq. 9) can be re-written as:

$$(\sigma_{\Delta t}^{pair})_{\text{Norm}} = \frac{\sqrt{(\rho+1)}}{\sqrt{2}} * \sigma_{\Delta t}^{1} \quad \text{(eq.10)}$$

This site-pair correlation parameter for a pair of sites can be evaluated by deriving the weighted mean of each individual day's correlation. Again individual day's correlation is found by correlating the change in clear sky index values between a pair of stations for different time intervals. The weighting factor is the day's variability quantified by the daily variance of ΔK_t* (Perez et al, 2012).

$$\rho_{\Delta t}^{L} = \frac{\sum_{j=1}^{n}(\rho_{\Delta t,j}^{L} * Var(\Delta Kt_{\Delta t}^{*}))}{\sum_{j=1}^{n} Var(\Delta Kt_{\Delta t}^{*})} \quad \text{(eq.11)}$$

Where $\rho_{\Delta t}^{L}$ = Site-pair correlation for a pair of sites separated by a distance L for a time interval Δt,
n = total number of station days analyzed.

In this work, the site-pair correlation between any two sites has been evaluated for n = 365 with Δt varying from 1 minute to 60 minutes and L ranging from 47 km to 532 km.

For a fleet of identical PV generators (whether correlated or uncorrelated), absolute power variability is given by the expression:

$$\sigma_{\Delta t}^{fleet} = \sqrt{Var(\sum_{n=1}^{N} \Delta P_{\Delta t}^{n})} = \sqrt{(\sum_{i=1}^{N}\sum_{j=1}^{N} \text{Cov}(\Delta P_{\Delta t}^{i}, \Delta P_{\Delta t}^{j}))} \quad \text{(eq.12)}$$

Relative Power Variability for a fleet of identical generators can be expressed as:

$$(\sigma_{\Delta t}^{fleet})_{\text{Norm}} = \sigma_{\Delta t}^{fleet}/(N * P_{installed}) \quad \text{(eq.13)}$$

$$(\sigma_{\Delta t}^{fleet})_{\text{Norm}} = \sqrt{(\sum_{i=1}^{N}\sum_{j=1}^{N} \sigma_{\Delta t}^{i}\sigma_{\Delta t}^{j}\ \rho_{\Delta t}^{i,j})} \quad \text{(eq.14)}$$

To quantify the suppression of variability, a factor termed as Diversity Filter (Mills & Wiser, 2010) has been introduced. Diversity Filter denotes the factor by which spatial smoothing takes place. It is expressed by the ratio of agglomerated variability of all sites to the sum of variability at individual sites.

$$\text{Diversity Filter} = \text{D} = \frac{\sigma_{\Delta t}^{fleet}}{\sum_{i=1}^{N} \sigma_{\Delta t}^{i}} \quad \text{(eq.15)}$$

So, for a group of N uncorrelated sites with same variability, Diversity Filter (D) is 1/√N, which is the theoretical maximum by which suppression of variability, for a group of PV generators, can take place. But, for a group of correlated sites the diversity factor can be calculated by using (eq. 15). In our study, we have evaluated Diversity Filter values for ten SRRA sites for time intervals, Δt = 1 minute, 5 minute, and 15 minute on a highly variable 165th day of the year 2014. This value signifies the suppression of variability that can be achieved, by combining outputs from PV plants at these ten different sites and feeding them to a common regional grid.

2.2. Experimental data

2.2.1. SRRA Stations

For this work, we have collected ground measured environmental parameter data-sets from ten solar radiation resource assessment (SRRA) stations in Rajasthan. SRRA stations are automatic stand-alone systems consisting of several high quality/high resolution instruments, which measure available solar radiation (global horizontal irradiance (GHI), diffuse horizontal irradiance (DHI), and direct normal irradiance (DNI)) along with other weather parameters like ambient temperature, relative humidity, atmospheric pressure, and wind speed etc. at a temporal resolution of 1 minute. In the year 2011, the erection and commissioning of 51 SRRA stations was started by the National Institute of Wind Energy (NIWE) with funding from the Ministry of New & Renewable Energy (MNRE), Government of India and technical assistance from the Deutsche Gesellschaft für Internationale Zusammenarbeit (GIZ GmbH) under the SolMap Project. The SolMap project was initiated under Indo-German Bilateral Cooperation and was supported by the German Ministry for Environment, Nature Conservation and Nuclear Safety (Bundesministerium für Umwelt, Naturschutz, Bau und Reaktorsicherheit, BMUB).

In the second phase, NIWE has established 60 more SRRA stations in 28 states and 3 union territories. As of May 2015, there is a total of 121 SRRA stations operating all over India being maintained by NIWE (Fig 1). The SRRA network with 121stations is one of the world's largest pyrheliometric networks and ensures the availability of a solid database of ground measured solar radiation data essential for the deployment of solar power plants in India.

All station data quantifying global, direct and diffuse irradiance as well as other environmental parameters are acquired at SRRA stations and stored in a server at Central Receiving Station (CRS) established at NIWE. The raw data sets are further processed by applying different quality control algorithms. If any errors or inconsistencies are detected, then corresponding data points are flagged. Quality control algorithms are based on Baseline Surface Radiation Network (BSRN) rules set by the World Meteorological Organization (WMO). The radiation data obtained is also compared to modelled clear sky irradiance and to the physical limits. Once, the data points have cleared all the tests, they are cached in another server at CRS (Kumar et al., 2014). For this work, the archived datasets for the year 2014 measured at some selected SRRA stations in Rajasthan, have been extracted from CRS.

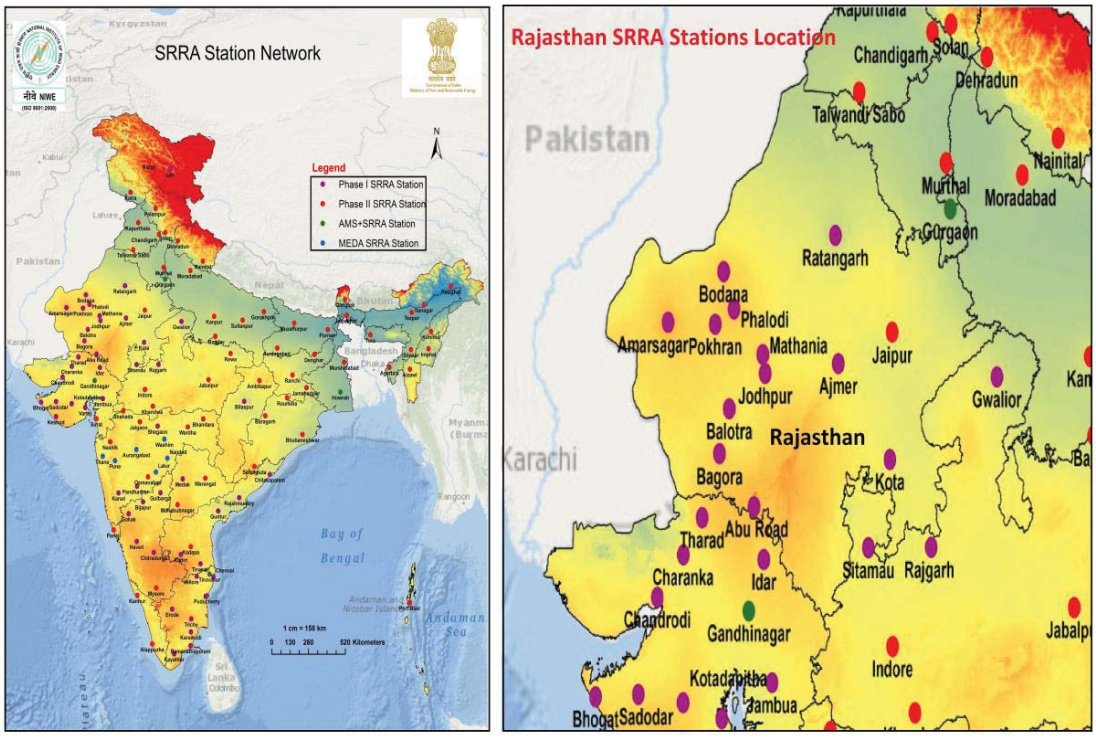

Fig.1: Map of the full SRRA network (left) and the SRRA stations in Rajasthan (right), as of May 2015.

2.2.2. Specification of used data sets

Mentioned below are different environmental parameters studied:

- Temperature (in deg. C), relative humidity (in %) and pressure (in hPa) data sets measured at ten different SRRA stations across Rajasthan for calculating clear sky GHI values.
- Measured GHI (in W/m2) values for calculating the clear sky index (K_t*).

Tab. 2 gives additional details about the quality, temporal resolution and time period of data sets used. As can be seen from the table, the data sets acquired from ten SRRA stations are of high quality as 98.62 % i.e. almost 99% of the meteorological data points pass the quality control tests (Kumar et al., 2014). The use of such high quality radiation data corroborates the authenticity and the validity of the study. Tab. 3 and Fig. 1 (right) provide more detailed information regarding the location of the SRRA stations under observation. Fig. 2 depicts different SRRA stations in Rajasthan. Tabled values of latitude, longitude and elevation at each location have been used to evaluate the Bird model clear sky GHI values, which are subsequently used to calculate the clear sky index (K_t*) at each time step (Bird, 1984; Myers, 2013).

Tab. 2: Detailed Specification of SRRA data sets used.

Details	Specification
Parameters studied	Temperature (in deg. C), relative humidity (in %), pressure (in hPa) and GHI (in W/m2).
Temporal resolution of data sets	1 Minute
Temporal horizon	1 year (analysis done for the year 2014)
Quality control statistics (Percentage of error free values)	98.62 %

3. Results

The objective here is to understand site-pair correlation and the factors upon which it depends. Another intention behind the study is to observe the effect of spatial smoothing and to quantify the factor by which suppression of variability takes place due to spatial smoothing.

3.1. Evaluating site-pair correlation

As mentioned before, site-pair correlation value is a very important parameter to evaluate, as it will help in understanding the impact of aggregation of outputs from several PV sites. Here in our study, we have obtained site-pair correlation values among different SRRA sites at Rajasthan for a time interval of 1 minute, 5 minutes, 15 minutes, 30 minutes, and 60 minutes with the time period of the study being one year.

Fig. 3 shows the correlation of change in the clear sky index across the time scales of 1 minute to 60 minutes for pair of sites at different distances from one another. Fit curves, as function of distance between the pair of sites and time interval, can be drawn for all these scattered plots and the equation of the curve can be used to find correlation for intermediate/other distance values.

In Fig. 3, a near-zero correlation for the 1-minute time interval is observed between all ten sites in SRRA network in Rajasthan. Even the closest sites in the network, separated by a distance of 47 km, exhibit zero correlation of change in the clear sky index values (of time interval of 1 minute). Similarly, for the 5-minute time interval, site-pair correlation values are almost zero. Hence, for 1 minute and 5-minute time intervals the ten sites under SRRA networks are almost uncorrelated. Now, if output from PV generators with the same installed capacity at these sites is combined and the power variability at these sites is identical, a smoothing by a factor of $1/\sqrt{N}$ (with N = number of PV generators) will take place. But for the 15-minute time interval, a slight increase in site-pair correlation values is observed with percentage correlation values hovering around 3% - 5% and for 30 and 60-minute time intervals, higher correlation between sites are more evident.

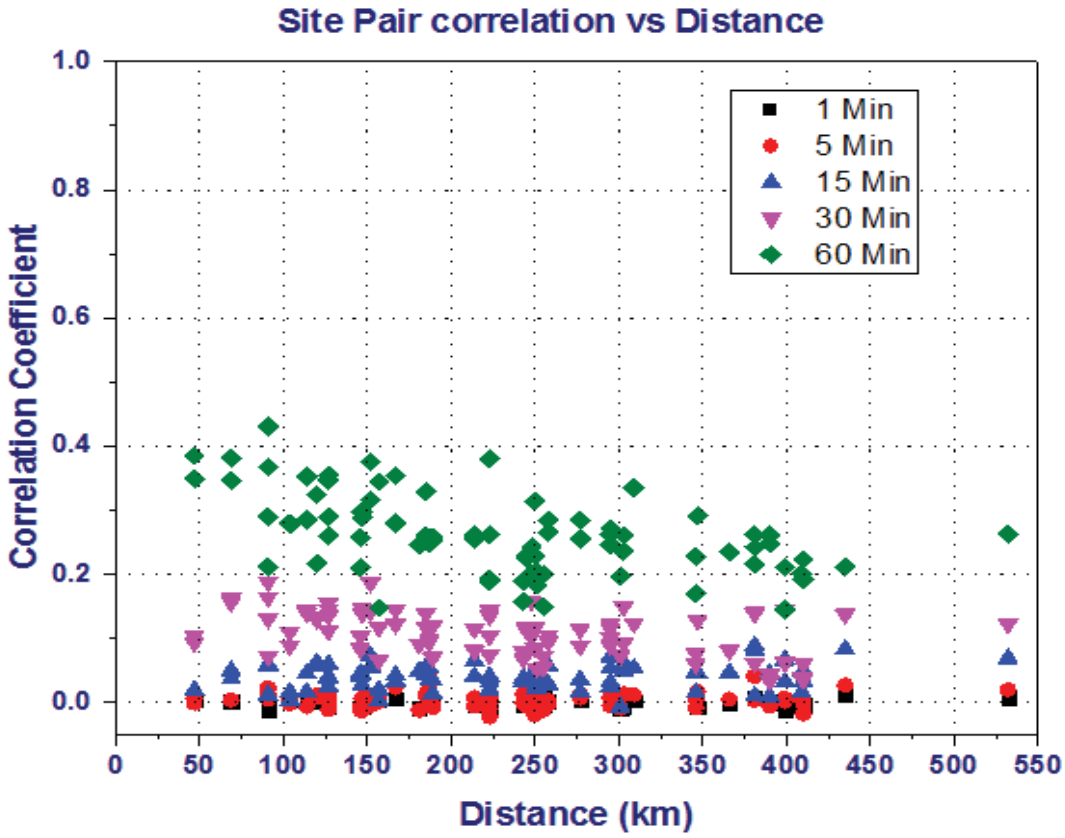

Fig. 3: Site-pair correlation as a function of distance for time intervals Δt = 1min, 5 min, 15 min, 30 min, and 60 min.

3.2. Dispersion-smoothing effect

To observe the pattern of spatial smoothing over a wide area with geographical diversity for a highly variable day, a parameter titled 'Percentage Change in Generation' has been introduced.

The 'Percentage Change in Generation' parameter is defined as:

$$\text{Percentage Change in Generation} = (GHI_2 - GHI_1) / GHI_1 * 100 \qquad \text{(eq. 16)}$$

Where, GHI_1 = GHI measured at time t_1
GHI_2 = GHI measured at time t_2
$t_2 > t_1$, Time Interval, $\Delta t = t_2 - t_1$

The above parameter is analogous to ramp rate (rate of change of power generation in a certain time) as change in solar resources results change in PV power generated and hence, the higher the 'Percentage Change in Generation' value, the higher will be the ramp rate. So, it is an appropriate parameter to demonstrate the effect of smoothing. The above equation has not been used for situations when, $(GHI)_1$ is equal to zero or of extremely small value as the calculation of 'Percentage Change in Generation' parameter would lead to infinity or an unrealistically high value.

We have calculated the 'Percentage Change in Generation' parameter for several days in the year 2014 and here, we have included our observations on a highly variable 165th day of the year i.e. on 14-06-2014. In Fig. 4, the 'Percentage Change in Generation' value for a single site is compared with the same quantity for all 10 sites combined for a certain 'time block' to observe the spatial smoothing effect over a wide area. The term 'time block' has been taken from Central Electricity Regulatory Commission (CERC) documents (CERC, 2011) and describes a time interval of 15 minutes. This value received increasing importance after

modification of the bidding time block from one hour to 15 minutes in the day-ahead market. Scheduling is also done on a 15-minute time interval.

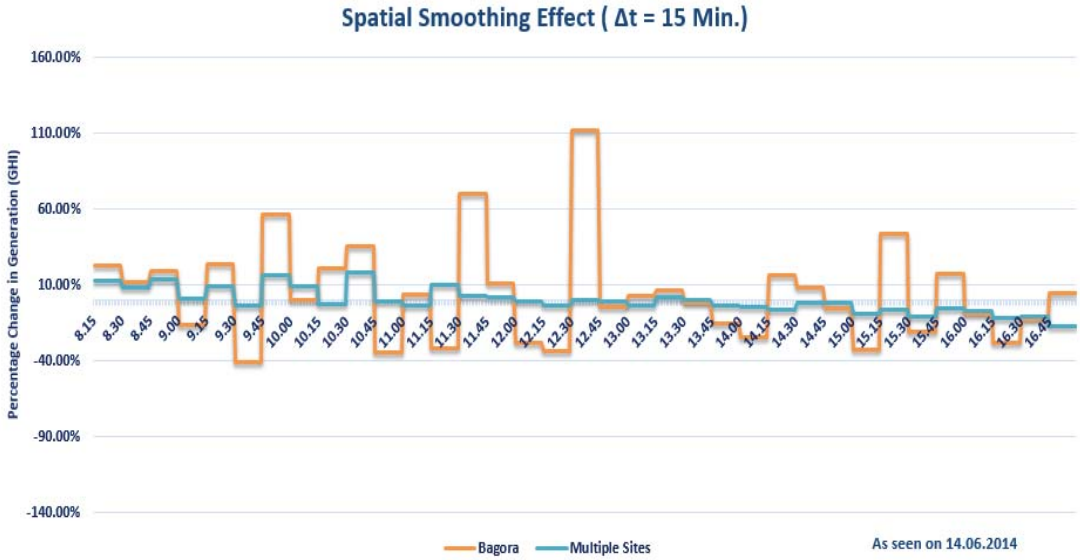

Fig. 4: Spatial smoothing effect observed for multiple sites for the time interval Δt = 15 min.

3.3. Results from sample calculation of diversity filter on a highly variable day

For the day chosen (day 165th of the year 2014), diversity filter values for 1 min., 5 min., and 15 min. time intervals have been calculated. Mentioned below are outcome of these evaluations:

3.3.1. Diversity filter calculation for Δt = 1 min.

Diversity Filter (considering 10 uncorrelated sites with the same variability) = $1/\sqrt{10} = 0.316$.

The theoretical maximum smoothing is achieved for a Diversity Filter of 0.316 i.e., around 68.4% of the variability will be suppressed.

Diversity Filter (considering the site-pair correlation obtained from graph) = 0.341, i.e., almost 65.9% of variability is suppressed. The small difference in the Diversity Filter value indicates that for a time interval of 1 minute the sites are nearly uncorrelated.

3.3.2. Diversity filter calculation for Δt = 5 min.

Diversity Filter (considering the site-pair correlation obtained from graph) = 0.365, i.e. almost 63.5% of variability is suppressed. Again, the small difference in the Diversity Filter value indicates that for a time interval of 5 minutes the sites are nearly uncorrelated.

3.3.3. Diversity filter calculation for Δt = 15 min.

Diversity Filter (considering the site-pair correlation obtained from graph) = 0.392, i.e., almost 60.8% of variability is suppressed. Also for a time interval of 15 minutes, only a slight increase in correlation is observed.

4. Discussion

The analysis that has been done to understand site-pair correlation leads to several points to ponder upon. Firstly, site-pair correlation values decrease with increasing distance between a pair of stations for a specific time interval. This means as the distance between a pair of sites increase, changes in output from PV plants at these locations become less correlated and outputs vary in an independent manner. When solar generation varies independently, maximum smoothing will occur when outputs from these plants are fed to a common grid. Also reduction in site-pair correlation signifies less Diversity Filter value, which indicates higher suppression of variability when the PV plants at sites under study are connected as a fleet. Secondly, site-pair correlation values increase with increasing time interval for a pair of sites. This denotes the significance of

selecting the time interval, which actually depends on the concern of the user. For a regional grid operator, solar variability during a time interval of a few seconds may not matter much, but it will be a reason to worry for a small PV plant. So, it is of utmost importance to study the site-pair correlation to estimate solar variability for a group of PV plants, whether clustered over a small area or dispersed over a wider region.

Another important observation has been the effect of spatial smoothing or dispersion-smoothing effect. As an example, the 15-minute time interval from 12.30 PM to 12.45 PM in Fig. 4 shows 'Percentage Change in Generation' values of +110% and +3% for the single site Bagora and for multiple sites, respectively. That is, a significant spatial smoothing for the time interval of 15 minute is observed, when generation from all ten sites is combined. This also means a substantial reduction in ramp rates for a wider control area compared to that for a single site, which can lead to the conclusion that, from better grid management point of view, wider control area holds greater significance compared to a single generator at a site.

We have also evaluated Diversity Filter values on a highly variable day for time intervals 1, 5, and 15 minutes. Here, the Diversity Filter value signifies the percentage by which variability is suppressed when the output from individual sites are fed to a common regional grid. For the 1-minute time interval, almost 66 % of variability was suppressed, while for 5 and 15-minute time intervals, the percentage values by which suppression took place were estimated to be around 64% and 61%, respectively. The values obtained from the sample calculation also denote the importance of considering the effect of smoothing while estimating reserves for balancing operation. Ignoring the same may lead to an overestimation of balancing requirements and hence, to extra costs.

Previously, we discussed several impacts of short term solar irradiance variability on power system. The same can be addressed by strengthening the grid and by efficient control and management of the power network. A strong, reinforced grid will facilitate evacuation of power from areas with high solar resources to locations where there is a power scarcity and will also enable grid operators to access a wide variety of flexible resources to manage ramps. In India, currently efforts are underway in this direction under the 'Green Energy Corridors (GEC)' project to build an advanced, robust grid infrastructure. Under this project, in addition to improved transmission facilities, it has also been proposed to establish, locate Renewable Energy Management Centers (REMCs) along with load dispatch centers where challenges pertaining to system operation, managing variable resources can be addressed through day-ahead forecasting, improved scheduling and ancillary services. Day-ahead solar power forecasting along with real time solar generation information can prepare grid operators for controlling ramps effectively, while ancillary services can compensate for the operating reserves. Also under GEC project, policies are being formulated to bring market reforms and strengthen power market for improving coordination, cooperation along balancing areas.

In the end, commenting about the usefulness of solar radiation data sets measured at SRRA stations, the high resolution 1-min solar irradiance data shows an excellent value and can be used for a Pan-India level solar variability study. If combined with satellite-based resource information and ground-based sky imagers at few selected sites, this could provide an invaluable information source for studying various aspects of solar power grid integration.

5. Acknowledgements

The work described here was funded by the Deutsche Gesellschaft für Internationale Zusammenarbeit GmbH (GIZ GmbH) on behalf of the Federal Government of Germany under Green Energy Corridors (GEC) of the Indo-German Energy Program (IGEN). The authors would also like to thank the National Institute of Wind Energy (NIWE), Chennai, and the Ministry of New and Renewable Energy (MNRE), Government of India, for providing environmental parameter data sets measured at the Solar Radiation Resource Assessment (SRRA) stations in Rajasthan.

On the linear relationship between daily relative sunshine duration and daily mean cloud cover

Heinrich Morf, Senior Member ISES

Buechraiweg 47, 5452 Oberrohrdorf, Switzerland

Abstract

This paper explores the relationship between daily relative sunshine duration – *S* and daily mean cloud cover – *C*. A theoretical model that leads to the idealized linear relationship *S=1-C* often encountered in literature is derived, based on well-defined simplifying assumptions. We demonstrate the application of the theoretical model to vertical visibility and cloud cover readings by ceilometer. We explore the deviations from linearity in the real world in the context of the theoretical model. An estimate of the relationship between measurements of *S* and *C* based on sunshine recorders, ground based human observers, and ceilometers is given.

Keywords: ceilometer, climatology, cloud cover, sunshine, stochastic modeling

1. Introduction

The opinion that the relationship between daily relative sunshine duration – *S* and daily mean cloud cover – *C* would be *S=1-C* under ideal conditions is often encountered in literature. This is a very convenient assumption because it opens the way for many elegant mathematical simplifications. However, in reality a non-linearity between S and C is observed. See Biga and Rosa (1980), Brabec et al. (2016), Gueymard et al. (1995), Hoyt (1977), Rangarajan et al. (1984), and Sarkar (2016). To our knowledge, no convincing description of the conditions leading to *S=1-C* was ever given. This paper fills this argumentation gap. First, the linear relationship is theoretically derived, based on well-defined simplifying assumptions. Then reasons for the non-linear relationship encountered in the real world are given.

We base our theoretical considerations on the stochastic solar irradiance model by Morf (2013). In this model cloud cover – *cc(t)* is modeled as a strictly stationary stochastic process that is invariant to the observation area. Then, sunshine – *ss(t)* is generated in a random experiment with probability *1-cc(t)*. We demonstrate that, over the period from sunrise to sunset – T_d, the mean of *ss(t)* – *S* can be approximated by the mean of *1-cc(t)* – *1-C*. As *S* and *1-C* are both random variables, this implies that ideally also their probability distributions are the same.

Our theoretical model takes a strict nadir view of the sky, and clouds have no vertical extent. To the contrary, real world observations take a single point view of the sky dome. In consequence, sunshine and cloud cover observations are affected by the vertical extent of clouds and the height of the cloud layers in the sky. This disrupts the ideal conditions assumed by the theoretical model and leads to the observed non-linear relationship between *S* and *C*.

2. Problem statement

Prior to going into details, some definitions are necessary.

Definition of daily relative sunshine duration – *S*:

$$S = \frac{\int_{SR}^{SS} ss(t)}{T_d} \qquad \text{eq. (1)}$$

ss(t) is the stochastic insolation function. As an indicator function, it is 1 when the sun is shining and 0 when the sun is hidden behind clouds. T_d is the time between sunrise – *SR* and sunset – *SS*.

doi:10.18086/eurosun.2016.09.09 Available at http://proceedings.ises.org

Definition of daily mean cloud cover – C:

$$C = \frac{\int_{SR}^{SS} cc(t) \cdot dt}{T_d} \qquad \text{eq. (2)}$$

$cc(t)$ is cloud cover. This is the fraction of the sky that is covered by clouds; 0 represents a completely cloudless sky, 1 a fully cloud covered sky. T_d is the time between sunrise – SR and sunset – SS.

Our objective is to demonstrate that the following approximation holds true:

$$S = \frac{\int_{SR}^{SS} ss(t) \cdot dt}{T_d} \approx 1 - C = \frac{\int_{SR}^{SS} (1 - cc(t)) \cdot dt}{T_d} \qquad \text{eq. (3)}$$

For this purpose, we prove that

$$\frac{\int_{0}^{T} ss(t) \cdot dt}{T} \sim \frac{\int_{0}^{T} (1 - cc(t)) \cdot dt}{T} \quad T \to \infty \qquad \text{eq. (4)}$$

The equation states that the two terms converge with increasing observation time T.

We then verify up to what degree the approximation by eq. (3) is met, when delimiting T by T_d in eq. (4).

3. A theoretical interpretation for the linear relationship between daily relative sunshine duration and daily mean cloud cover

We will prove eq. (4) by demonstrating that the expectation – μ of its first term is equal to its second term. Then, we will show that the variance – σ^2 of the first term converges towards 0 with growing T. The leading idea is that a random variable with zero variance is a certainty. Thus, the result of the two terms in eq. (4) must finally match.

For the proof we take a discrete approach, in concordance with the model of Morf (2013), where the random experiment for sunshine is periodically executed with a time interval Δt, corresponding to the minimum time resolution for sunshine encountered in the real world.

Morf (2013) models sunshine by executing a random experiment that generates sunshine from cloud cover with a probability equal to the complement to one of cloud cover:

$$P_{ss=1}(t) = 1 - cc(t) \qquad \text{eq. (5)}$$

$P_{ss=1}(t)$ is the probability for sunshine. $cc(t)$ is cloud cover.

Expectation and variance of $ss(t)$:

$$\begin{aligned} \mu(ss(t)) &= 0 \cdot cc(t) + 1 \cdot (1 - cc(t)) = 1 - cc(t) \\ \mu(ss^2(t)) &= 0 \cdot cc(t) + 1 \cdot (1 - cc(t)) = 1 - cc(t) \\ \sigma^2(ss(t)) &= \mu(ss^2(t)) - \mu^2(ss(t)) = (1 - cc(t)) \cdot cc(t) \end{aligned} \qquad \text{eq. (6)}$$

Integrating the expectation of $ss(t)$ over T and normalizing by T leads to the proof of the first proposition:

$$\mu\left(\frac{\int_{0}^{T} ss(t) \cdot dt}{T}\right) \approx \mu\left(\frac{\sum_{n=1}^{N} ss_n}{N}\right) = \frac{\sum_{n=1}^{N} (1 - cc_n)}{N} \approx \frac{\int_{0}^{T} (1 - cc(t)) \cdot dt}{T} \qquad \text{eq. (7)}$$

whereby $N = T/\Delta t$.

To demonstrate the convergence of the variance of the first term of eq. (4) towards zero we proceed as follows:

$$\sigma^2\left(\frac{\int_0^T (ss(t))\cdot dt}{T}\right) \approx \sigma^2\left(\frac{\sum_{n=1}^{N} ss_n}{N}\right) = \frac{\sum_{n=1}^{N}(1-cc_n)\cdot cc_n}{N^2} \qquad \text{eq. (8)}$$

whereby $N=T/\Delta t$. With increasing N the variance given by eq. (8) converges towards zero. Thus, one may write:

$$\frac{\int_0^T ss(t)\cdot dt}{T} \sim \frac{\int_0^T (1-cc(t))\cdot dt}{T} \quad T\to\infty \qquad \text{Q.E.D.} \qquad \text{eq. (9)}$$

As the two terms of eq. (9) converge, so will also their probability distributions. We refer the reader to Morf (2011) for an analysis and to Morf (2014) for an analytical expression of this probability distribution.

Executing the random experiment for sunshine every 30 seconds (corresponding roughly to the minimum time resolution of sunshine in the real world) in the model described by Morf (2013) leads to a spread in the plot of *S* against *C* that is smaller than *0.05* for both, *S* and *C*. Thus, on a daily basis, eq. (3) may be used with little loss of accuracy. See Fig. 1.

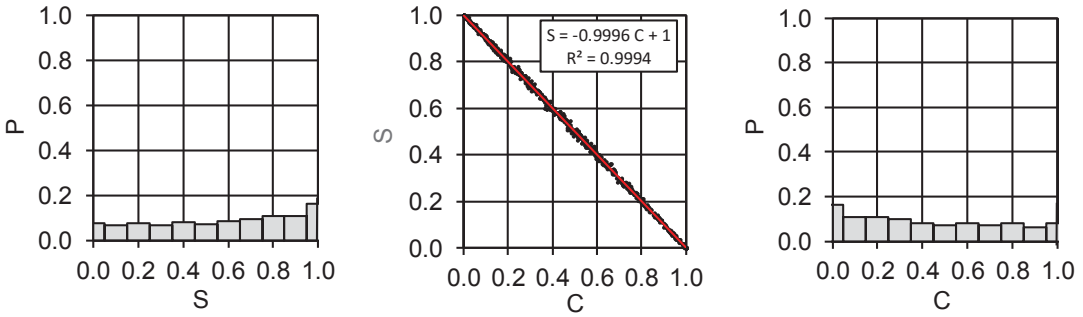

Fig. 1: Simulated plot *S=g(C)* of daily relative sunshine duration – *S* as a function of daily mean cloud cover – *C* and the probability bar charts of *S* and *C*. Observe the little spread of the plot, the high correlation coefficient of the least square fit, and the equality of the probability bar charts of *S* and *1-C*.
Simulation results for Payerne, Switzerland, in July. 300 points, roughly the July-days of 10 years, are shown. A time resolution of 30s was used for the simulation.

4. Vertical visibility and ceilometer readings

The model of Morf (2013) that generates sunshine – *ss(t)* by a random experiment with probability equal to the complement to one of cloud cover – *1-cc(t)* (which is the basis of our theoretical considerations) is an approximation of another model given by Morf (2011). It generates vertical visibility – *vv(t)* with a probability equal to the complement to one of cloud cover – *1-cc(t)*. *vv(t)*, as defined by Morf (2011), describes the state of the sky (0 for covered, 1 for clear) at the observer's zenith. The only difference between the two models is that one is defined for sunshine – *ss(t)* and the other for vertical visibility – *vv(t)*. As *vv(t)* takes a strictly zenithal view, the observations are not affected by the vertical extent of clouds. Therefore, it fits the theoretical model better than *ss(t)*.

Thus, under the assumptions of our theoretical model one may write for eq. (9):

$$\frac{\int_0^T vv(t)\cdot dt}{T} \sim \frac{\int_0^T (1-cc(t))\cdot dt}{T} \quad T\to\infty \qquad \text{eq. (10)}$$

The equation states that the two terms converge with increasing observation time *T*.

Returning to eq. (3), we write:

$$S_{vv} = \frac{\int_{SR}^{SS} vv(t) \cdot dt}{T_d} \approx 1 - C_{vv} = \frac{\int_{SR}^{SS} (1 - cc(t)) \cdot dt}{T_d} \qquad \text{eq. (11)}$$

S_{vv} is the daily relative vertical visibility duration.[1]

vv(t) also corresponds to the reading of a ceilometer that indicates either 0 (covered) or 1 (clear). Thus, eq. (10) is the fundamental equation for the estimation of cloud cover by ceilometer readings.

Cloud cover by ceilometer readings is calculated as the complement to one of the moving average of the ceilometer readings over the period *T*. Thus, it is the moving average of *cc(t)* over *T*, and not *cc(t)*. The integration time – *T* of a ceilometer is small in comparison to the rate of change of cloud cover. Therefore, the difference between the two values is negligible.[2] Daily mean cloud cover derived from ceilometer readings – C_c is then the mean over T_d of the moving average of *cc(t)* over *T*. Note that this procedure, contrary to eq. (11), will deviate from reality, even under the ideal conditions of the theoretical model.

The automatic determination of cloud cover by ceilometer is established practice. In the USA, it has replaced cloud cover observations by ground-based human observers at the end of the twentieth century.

5. The non-linearity

The non-linearity under discussion is an upward bend of the straight line for *S=g(C)* in Fig. 1. See also the least square fits for $S_s=g(C_g)$ in Fig. 2.

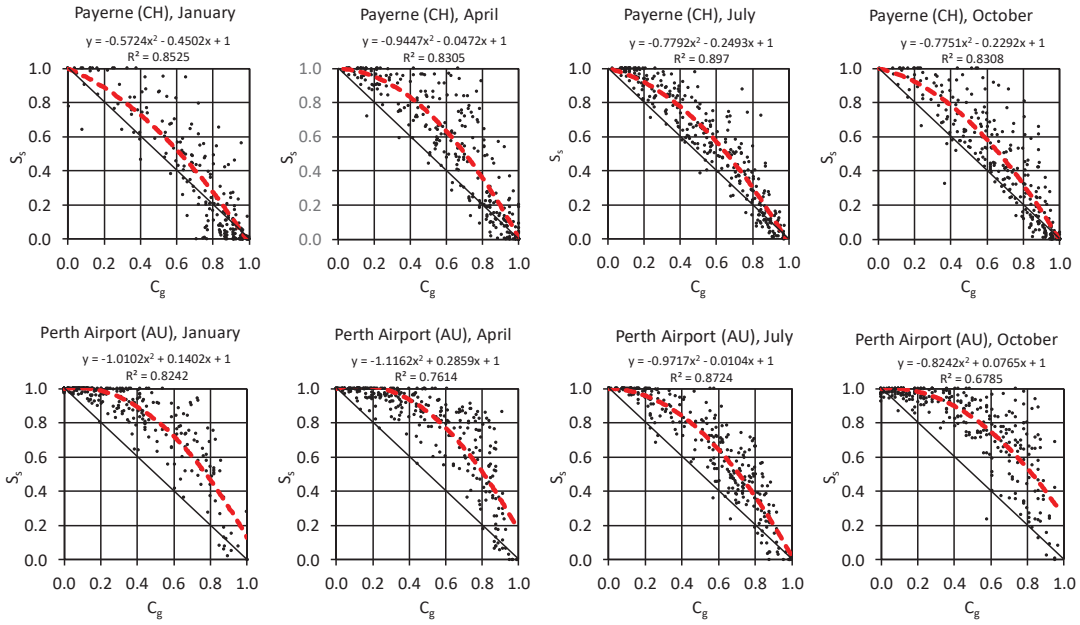

Fig. 2: Plots $S_s=g(C_g)$ of daily relative sunshine duration measured by sunshine recorder – S_s as a function of daily mean cloud cover reported by ground based human observers – C_g. Observe the slight upward bend of the least square fits.

Observe the subscripts introduced for *S* and *C* in Fig. 2. The subscript *s* indicates that a value was derived from sunshine recorder readings, and the subscript *g* indicates that it was derived from cloud cover observations by ground-based human observers.

[1] For the sake of compatibility with the theoretical model, we prefer to use the mnemonic S_{vv} (instead of, for example, *V*) for daily relative vertical visibility duration.
[2] For the determination of cloud cover, ceilometers use a sampling interval – Δt of about 30 seconds and an integration time *T* of about 30 minutes.

It is worth the while to have a closer look at the two variables S_s and C_g:

- Daily relative sunshine duration from the traces of sunshine recorders – S_s: This is the daily relative sunshine duration from sunrise to sunset, measured by a sunshine recorder at a single point on earth, in the line of sight to the sun. It is well known that the free line of sight to the sun depends on the elevation of the sun in the sky due to the vertical extent of clouds and the height of the cloud layers in the sky (Lund and Shanklin, 1971).
- Daily mean cloud cover from observations by ground-based human observers – C_g: The objective is to determine the proportion of the sky dome that is obstructed by clouds when seen from a single point on earth – $cc_g(t)$. Every single cloud cover observation – $cc_g(t)$ is an instant average of cloud cover over the entire sky dome. Daily mean cloud cover – C_g is then the mean of cloud cover – $cc_g(t)$ from sunrise to sunset.

These two variables are not related by the linear relation $S=1-C$, but by the slightly up bent curves of the least square fits depicted in Fig. 2. It is well known that for a function of two random variables $Y=g(X)$ – here $S_s=g(C_g)$ – the probability density functions (*pdfs*) – $f(x)$ and $f(y)$ are related by:

$$f(y)\cdot|dy| = f(x)\cdot|dx| \qquad \text{eq. (12)}$$

The vertical bars indicate absolute values.[3]

Thus, in consequence of the up-bent function $S_s=g(C_g)$, the pdf of S_s as well as of C_g will be skewed towards higher values than in the linear relationship $S=1-C$. Hence, the mean of S_s becomes greater than the mean of $1-C_g$.

Fig. 3 depicts probability bar charts of S_s and $1-C_g$ with the corresponding means for selected calendar months in Payerne, Switzerland and Perth Airport, Australia. It follows from the foregoing paragraph that the pdf of S_s is skewed to the right and the one of $1-C_g$ to the left. As to be expected, the mean of S_s is always greater than the mean of $1-C_g$. (Means are marked with overbars.)

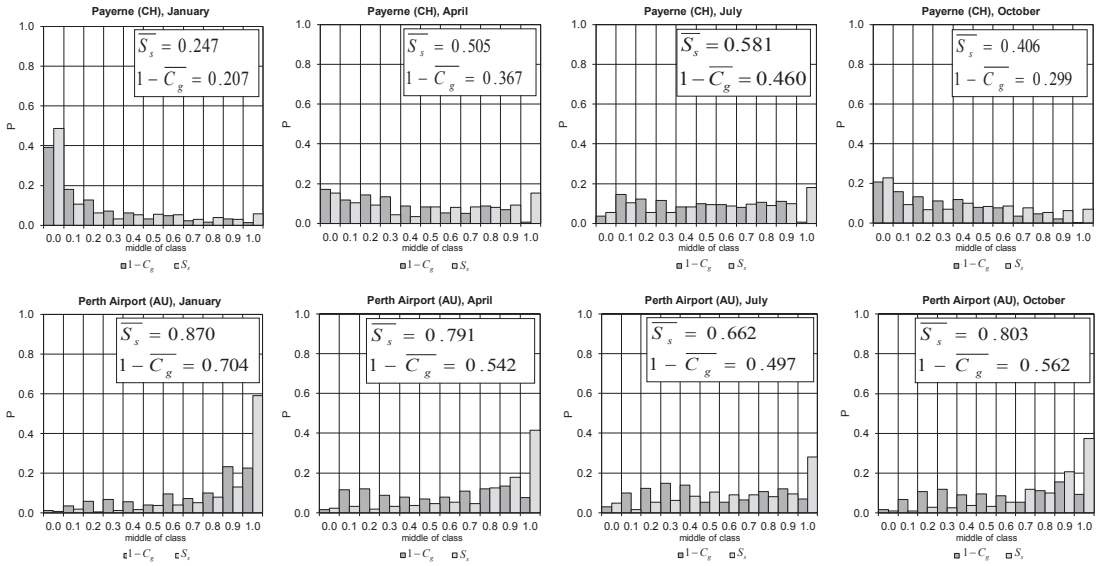

Fig. 3: Comparison of the probability bar charts of daily relative sunshine duration measured by sunshine recorder – S_s and the complement to one of mean daily cloud cover measured by ground based human observers – 1-C_g. Observe that the mean of S_s is higher than that of $1-C_g$. Overbars indicate means.

A concentration of readings of $1-C_g$ around *0.1 ... 0.4* keeps the mean of $1-C_g$ low. Cloud cover observations by ground-based human observers seem not to reflect properly the free line of sight to the sun through open cloud fields. A further disturbance that keeps the mean of $1-C_g$ low is caused by the reluctance of ground

[3] As an alternative, to the least square regressions for $Y=g(X)$ in Fig. 2, one may obtain a regression line for $Y=g(X)$ from $f(x)$ and $f(y)$, based on eq. (12). It brings $f(x)$ and $f(y)$ in proper relation. Although the objectives of the two regression methods are different, they lead to only slightly different results here.

based human observers to declare minimum cloud cover of 0 okta (tenth), because they are instructed to do so only when the sky is absolutely clear. On the other hand, excessive readings for $S_s=1$ keep the mean of S_s high. Hoyt (1977) attributes this effect to thin cirrus clouds: while a ground based human observer would see a covered sky, a sunshine recorder would still register sunshine.

6. Delimiting results

As for the relation $S=1-C$ of the theoretical model, imagine that corresponding to daily relative cloud cover from observations by ground based human observers – C_g, there is daily relative sunshine duration – $S_g=1-C_g$. Likewise, imagine that corresponding to daily relative sunshine duration from sunshine recordings – S_s, there is mean daily cloud cover – $C_s=1-S_s$. Consequently, for the case of the up bent relation $S_s=g(C_g)$ encountered in the real world, the following inequalities hold true: [4]

$$1-\overline{S_s} < \overline{C} < \overline{C_g} \;,\; 1-\overline{C_g} < \overline{S} < \overline{S_s} \;,\; \textit{whereby} \;\; \overline{C}=1-\overline{S} \qquad \text{eq. (13)}$$

The overbars indicate that the values are expectations. $\overline{C}$ and $\overline{S}$ correspond to the theoretical model; they might have been estimated from vertical visibility readings – *vv(t)* by ceilometer. Fig. 4 depicts the inequality for $\overline{C}$ at Payerne, Switzerland and Perth Airport, Australia.[5]

The inequalities may be helpful for data cross checks and to estimate a parameter when others are known. Each of the three results – $C_s=1-S_s$, $C=1-S$, and $C_g=1-S_g$ – is also correct in its own right. One might as well chose data of that observation method whose results fit best a specific problem at hand. For example, Morf (2011) suggests to use cloud cover observations by ground based human observers when the emphasis is on diffuse irradiation and data from traces of sunshine recorders when the interest concentrates on good results for direct irradiance. Climatologists might prefer data from zenithal views by ceilometer.

Hoyt (1977), analyzing data from 72 locations in the USA, concludes that $1-S_s$ is a better estimate for C than C_g. He reasons that $1-S_s$ comes closer to cloud cover estimates from satellite observations. This result must be viewed with caution, because the viewing angle of satellites down to earth is mostly not in strict nadir direction.

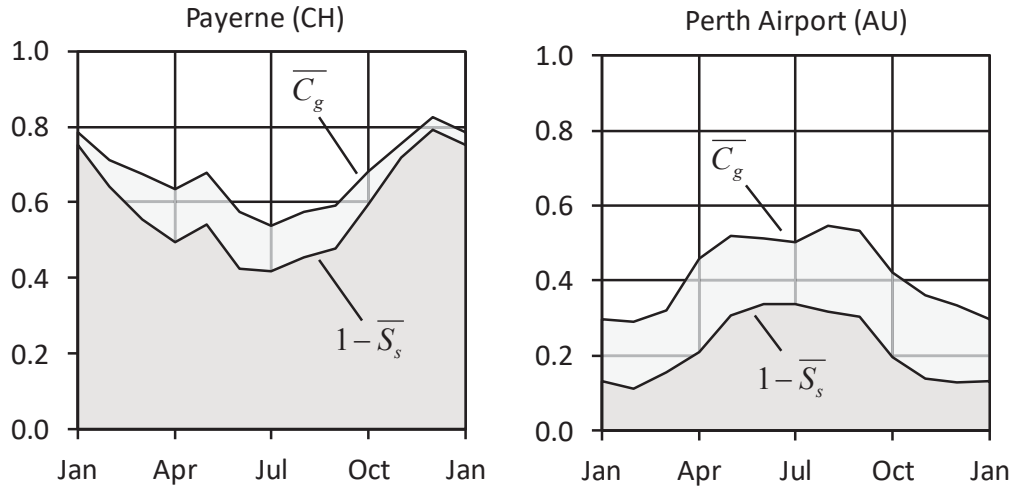

Fig. 4: Delimiting the expected daily mean cloud cover – $\overline{C}$.
The value of $\overline{C}$ must lie within the upper boundary $\overline{C_g}$ and the lower boundary $1-\overline{S_s}$.

[4] Moriarty (1991) predicts a down bent relationship for $S_s=g(C_g)$ at high latitudes. The inequalities would have to be modified to cover this case. So far, we have not encountered this effect in the real world.
[5] The irregularity in May for Payerne is a consequence of the outbreak of the volcano Eyjafjallajökull in April 2010.

7. Verification of the inequalities

So far, we could not thoroughly verify the inequalities of Section 6 in the real world, because there are few records of the three variables that have been taken at the same location, at the same time, and over a sufficiently long time-period. However, Neske (2014)[6] presents two data cloud diagrams of daily relative sunshine duration – S as a function of daily mean cloud cover – C that have been taken at two stations that are both representative for the area of Hamburg, Germany.

- One was taken from 2004 to 2011 at the NDR Transmitter Mast in Hamburg Billwerder by the Meteorological Institute of the University of Hamburg. S_s was calculated from pyranometer readings and C_c from ceilometer readings.
- The other was taken from 1996 to 2011 at Hamburg Airport by the German National Meteorological Service – DWD. S_s was derived from the recordings of an electronic SONI sunshine switch and C_g from observations by ground-based human observers.

The S_s values of the two stations are statistically undistinguishable, whereas the C values are different. For Hamburg Airport the function $S_s=g(C_g)$ has the characteristic upward bend as in Fig. 2. For Hamburg Billwerder the linear relation $S_s=1.088-0.9088 \cdot C_c$ is a good fit. As expected, the use of the ceilometer data at Hamburg Billwerder instead of the estimates by ground-based human observers has brought the relation more within reach of the relation $S=1-C$ of the theoretical model.

8. Concluding remarks and outlook

The findings in this work contribute to the understanding of the stochastic behavior of sunshine and cloud cover, and indirectly also of solar irradiance. We hope that they will facilitate the estimate of model parameters (Morf, 2011; Morf, 2013), and will give new impulses to the challenge of generating realistic two-dimensional cloud cover patterns as a function of time (Morf, 2011). As already brought to attention in Morf (2014), there seems to be one single Markov process that drives most cloud related dynamic processes. We hope this observation will give rise to interest for further investigations.

As a byproduct, this paper provides support for the approach by Morf (2011) of modeling cloud cover as a strictly stationary stochastic process that is invariant to the observation area. Otherwise, determining cloud cover from single point ceilometer readings would be impossible.

The relationship between the differing results given in form of inequalities in Section 6. might be helpful for a seamless transition from historical records of cloud cover estimates by ground based human observers to the automated cloud cover estimates based on ceilometer readings being introduced starting at the end of the last century.

Our proof that the mean of cloud cover converges to the mean of relative sunshine duration with increasing length of the observation period deserves further mathematical evaluation and exploration. It describes a transition of a random variable to a certainty.

In mathematical terms:

Given an indicator function $ind(t)$ with probability $P_{ind=1}(t)$, then

$$\frac{\int_0^T ind(t) \cdot dt}{T} \sim \frac{\int_0^T P_{ind=1}(t) \cdot dt}{T} \quad T \to \infty \qquad \text{eq. (14)}$$

The equation states that the two terms converge with increasing observation time – T.

As a simple example, consider the discrete case of tossing a coin. Then the probability of receiving *head* – $P_{ind=1}(t)$ will be 0.5, and with increasing number of tosses the probability to have a *head* in the tosses will

[6] Caution must be taken in Neske (2014): The paper uses an uncommon linear scale for daily mean cloud cover – C with a value of 0 for a totally cloud free sky and a value of 0.8 for a fully cloud covered sky.

turn into certainty. The consequences of this statement cannot be overestimated. The reasoning "if the probability for an event is infinitely small, then it will never happen" should rather be exchanged against the statement "even if the probability for an event is infinitely small, it will certainly happen".

9. Data

Publicly available data sets of the following locations are used in this paper:

- Payerne, Switzerland, 46.80 N / 6.93 E, for the years 2001-2010
- Perth Airport, Australia, 31.93°S / 115.98° E, for the years 1998-2007

From both stations, records of daily sunshine duration from sunshine recorders are used. The rare days with unreliable or missing data were removed. The time between sunrise and sunset was set to the duration of the period where the sun is more than 5° above the horizon.

From both stations, cloud cover data observed by ground-based human observers are used. At both stations, observations are taken every three hours starting at zero hours local time. The rare days with unreliable or missing data were removed. Cloud cover observations of 9 okta were changed to 8 okta. Daily mean cloud cover was calculated as the average of cloud cover from sunrise to sunset using linear interpolation; the result in *okta* was converted to *tenth*, dividing by 8. For every calendar month, local time for sunrise and sunset was determined based on the average maximum possible sunshine duration.

Conflict of Interests

The author declares that there is no conflict of interests regarding the publication of this paper.

Abstract

The dependencies of spectral regions of incident solar radiation in ultraviolet and visible spectra on concentrations of air pollutants were studied. We used two different approaches to conduct linear model analyses. First, linear models with different meteorological factors as explanatory variables were made for the entire data set without division according to solar elevation angle. These models showed no apparent influence of air pollutants on incident solar radiation but did reveal an effect of air pollutants on incident solar radiation in combination with relative air humidity. Secondly, after eliminating the major effect of solar elevation angle, linear models showed a spectrally dependent influence of dust particles PM_{10} and NO_x and increasing effects of the other air pollutants on at least one of the studied spectral regions. Dust particles PM_{10} caused a significant reduction in almost all spectral regions. We found that air pollutants affect the spectral composition of incident solar radiation, but it is difficult to identify the direct and indirect impacts of air pollutants on solar radiation in its different spectral regions.

Keywords: *linear regression, pollutants, solar elevation angle, solar radiation*

1. Introduction

Air pollutants created during anthropogenic activities are important compounds in the atmosphere's boundary layer. In addition to their impact on human health (e.g. Pedersen et al., 2006; Sram et al., 2013), they contribute to changes in incident solar radiation, particularly in its intensity, proportions of direct and diffuse radiation (Rooba, 2009), and spectral composition (Jacovides et al., 1997). The absorption and scattering caused by air pollutants are the main physical mechanisms which influence incident solar radiation (Charlson et al., 1992). Absorption of solar radiation is mainly by ozone, water vapour, and compounds of nitrogen and/or carbon (Thuillier et al., 2003). Black and brown carbon particles are the main effective absorbents of ultraviolet and visible solar radiation, and subsequent thermal radiation emission can induce cloud evaporation (Moosmüller et al., 2009) and thus increase the penetration of solar radiation to the Earth's surface. Radiation scattering, especially in the spectral range from 550 to 700 nm, causes an increase in diffuse radiation (Jacovides et al., 1997). These effects have a strongly regional character because of the prevailing influence of local sources of air pollution, pollutant properties, and removal mechanisms (Esteve et al., 2014). The spatial variability of air pollutants is the primary cause of different irradiances in urban versus rural areas when the sky is clear (Jacovides et al., 1997). Various air pollutants selectively affect different spectral regions of solar radiation. For example, UVB radiation is mainly absorbed by ozone (O_3) and sulphur dioxide (SO_2). UVA radiation is absorbed by nitrogen dioxide (NO_2), which has no influence on the transmission of UVB (World Meteorological Organization, 2011). Air pollution has been found to have a significant influence on both ultraviolet and visible regions of the solar spectrum, decreasing in longer wavelengths in urban areas (under cloudless conditions the attenuation of visible radiation reaches 18% in very polluted air; Jacovides et al., 1997). This effect is most important at low latitudes and during summer months (Zhou & Savijärvi, 2014.

doi:10.18086/eurosun.2016.09.06 Available at http://proceedings.ises.org

In this contribution, we used two different approaches to describe the influence of air pollution and other meteorological parameters on the intensity and spectral composition of incident ultraviolet (UV) and visible (VIS) solar radiation. The influence of particular air pollutants on individual spectral regions of UV and VIS spectra is not well known. We first analysed the influence of other meteorological factors, and secondly we studied the influence of individual air pollutants on particular spectral regions of incident solar radiation. We hypothesized that air pollutants significantly influence incident solar radiation and that air pollutants reduce short-wave spectral regions (UVB, UVA, blue radiation) more so than longer-wave spectral regions (green and red radiations) of incident solar radiation (according to Jacovides et al., 1997).

2. Material and methods

Two identical systems of sensors for solar radiation measurements were situated in the botanical gardens of the University of Ostrava (49°49.64873' N, 18°19.56197' E). Data from the first system were used for analysis. Data from the second system were used as a control of measurement reliability. Both systems consist of UVA and UVB sensors (Skye, UK), sensors measuring at wavelength intervals 400–700 nm (VIS), 510–700 nm, and 600–700 nm, and a sensor for global radiation (EMS Brno, Czech Republic). Spectral regions of VIS were calculated from the following interval measurements: blue (400–510 nm), green (510–600 nm), and red (600–700 nm). The systems also contain sensors for measuring air temperature and relative air humidity (EMS 33R, EMS Brno). Air pollution (hourly concentrations of PM_{10}, NO, NO_2, NO_x, SO_2, O_3, and CO) and hourly values for air pressure were taken from the website www.ims-msk.cz (provider: Public Health Institute Ostrava; their own data). Hourly values for visibility were taken from the website https://www.wunderground.com/history/airport/LKMT/2013/5/8/DailyHistory.html?req_city=NA&req_state=NA&req_statename=NA (meteorological data from airports). Data were divided according to weather into three categories – cloudy, partly cloudy, and sunny days. Only data for sunny days were used for analyses in order to eliminate the influence of clouds, which is difficult to define.

We used two different approaches to data analysis by linear regression. First, we analysed the influence of meteorological factors and air pollution on the spectral composition of incident solar radiation. We used solar elevation angle (SA), relative air humidity (Hum), air pressure (AirPress), and visibility (Vis) as meteorological factors and air pollutants (PCpol) as one variable using the first principal component equation $-0.33\ PM_{10} - 0.38\ NO - 0.41\ NO_2 - 0.44\ NO_x - 0.36\ SO_2 + 0.32\ O_3 - 0.39\ CO$ because of very high correlation among concentrations of individual air pollutants. We created a total of 15 linear models for each measured spectral region of incident solar radiation using different explanatory variables and their combinations (Tab. 1). We compared the coefficients of determination (R^2) for the final linear models. The main aim was to determine those factors which contributed significantly to improving the correspondence of the linear models with the measured data. We hypothesized a significant influence of air pollutants on incident solar radiation. These linear models were made for data in 2014, 2015, and the first half of 2016. In total, we used 615 hourly measurements from 179 days.

Secondly, we analysed the relationship between the intensity of incident solar radiation (UVA, UVB, blue, green, and red radiations) and concentrations of air pollutants (PM_{10}, NO, NO_2, NO_x, SO_2, tropospheric O_3, and CO). Each linear model had only two explanatory variables – solar elevation angle and one air pollutant (because of highly correlated concentrations of air pollutants; Tab. 2). In order to reduce the effect of varying solar elevation angle on solar irradiance, data obtained for the period when the solar elevation angle was within intervals 15–25° and 25–35° were analysed separately. These intervals were chosen according to the maximum solar elevation angle during winter months. If we were to use data with a greater solar elevation angle, we would lose winter data which are important because the highest concentrations of some air pollutants occur during winter. We compared the significances of each air pollutant's influence according to the p-values from the linear models. The main aim was to determine whether particular air pollutants influenced the spectral regions of incident solar radiation during different radiation conditions (given by two intervals of solar elevation angle). We hypothesized a significant reduction of incident solar radiation due to air pollutants. These linear models were made for data in 2014 and 2015. In total, we used 313 hourly measurements from 63 days.

The statistical analyses were performed in the R statistical environment version 3.3.0 (R Core Team, 2016).

3. Results and discussion

First, we studied linear models for spectral regions of incident solar radiation made using different combinations of explanatory variables. Solar elevation angle and relative air humidity were revealed as the most important explanatory variables (Tab. 1). The linear model with only solar elevation angle as the explanatory variable accounted for 62.53% of variability in UV radiation and 57.56% of variability in VIS radiation. Relative air humidity was the only explanatory variable to show an opposite effect – it explained variability in VIS radiation (36.55%) better than variability in UV radiation (29.33%; Fig. 1). The linear model with solar elevation angle and relative air humidity as explanatory variables exhibited the best explained variability among all models (71.72% for UV radiation, 72.00% for VIS radiation). The addition of other variables did not improve the linear models in a significant way. The addition of air pollutants to the linear model with solar elevation angle and relative air humidity as explanatory variables increased the explained variability of linear models by 0.74% for UV and by 1.04% for VIS radiation (Tab. 1, Fig. 1). However, the addition of air pollutants to the linear model with only solar elevation angle as the explanatory variable increased the explained variability of linear models imperceptibly (0.035% for UV and 0.057% for VIS radiation). These results demonstrate that the influence of air pollutants is important in combination with relative air humidity.

Tab. 1: Coefficients of determination (in %) for different types of linear models for measured spectral regions. SA = solar elevation angle, Hum = relative air humidity, Vis = visibility, AirPress = air pressure, PCpol = principal component of air pollutants. Bold values are displayed in Fig. 1.

These linear models were created from all data without division into intervals according to solar elevation angle, which is the main factor determining the intensity of incident solar radiation. This fact could be the reason why other meteorological factors showed only a small improvement in linear models and our hypothesis about the significant influence of air pollutants on incident solar radiation was not proven. From these results it is difficult to quantify the exact influence of meteorological factors and air pollutants on incident solar radiation.

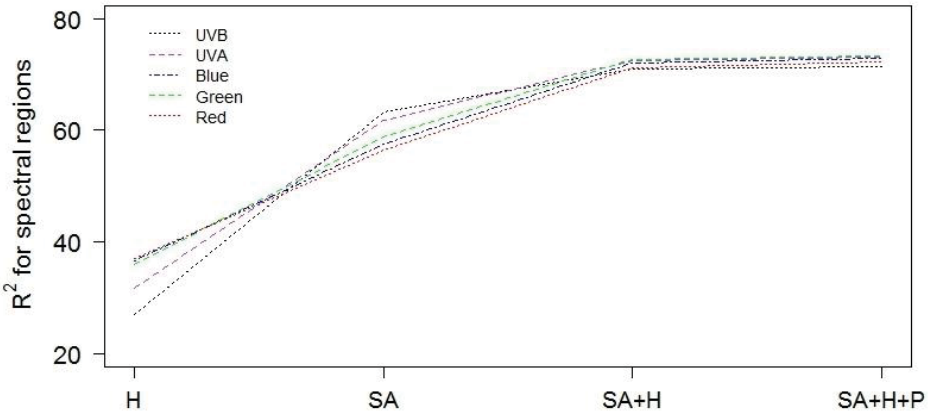

Fig. 1: Coefficients of determination (in %) for selected linear models for measured spectral regions. H = relative air humidity, SA = solar elevation angle, P = principal component of air pollutants. Only linear models with significant improvement of explained variability are shown.

Next, we studied the different influences of particular air pollutants on individual spectral regions of incident solar radiation during varying intervals of solar elevation angle. Each linear model had only two explanatory variables – solar elevation angle and one air pollutant (Tab. 2).

The air pollutant PM_{10} had the most significant reducing effect on all studied spectral bands except for the green band (Tab. 2). This effect was expected because dust particles cause a reduction of incident solar radiation (Rooba, 2009). However, the results surprisingly showed that the influence of PM_{10} on incident solar radiation was spectrally dependent insofar as PM_{10} had no significant influence on green radiation. Nitrogen oxides had a significant negative effect only on the intensities of some spectral bands, particularly blue radiation (Tab. 2). They showed surprisingly positive effects on green radiation at higher solar elevation angles. The effects of NO_x are more significant for visible than ultraviolet radiation. Palancar et al. (2013) reported that NO_2 significantly absorbs UV radiation, but our results did not confirm that.

Tab. 2: Statistical significances (p-values) of linear models of radiation dependencies on air pollutants. Bold number indicates significant dependence (i.e. p-value < 0.05). Grey colour denotes a positive effect.

Sulphur dioxide had a significant positive effect on UVB, UVA, green, and red radiation at lower solar elevation angles (Tab. 2). These results contradicted our expectations. Such positive effects might be caused by multi-scattering of radiation on these molecules or could be connected with other climatic factors which accompany higher SO_2 concentrations. The fact that this effect occurred only during low solar elevation angles can be connected with the higher SO_2 concentration during winter months (there are usually lower SO_2 concentrations when solar elevation angle is higher).

Tropospheric ozone had no significant effects on UV radiation but a significant positive effect on blue radiation and a significant negative effect on green radiation (Tab. 2). These results also contradicted our expectations, based on the general knowledge that ozone absorbs light with a wavelength shorter than 300 nm (e.g. Lu & Khalil, 1996). Although it had been thought that ozone does not absorb light with a wavelength longer than 350 nm (e.g. Kudish and Evseev, 2011), in reality it also absorbs visible light in the Chappius band with absorption peaks at 575 and 603 nm (e.g. Jodpimai et al., 2016). This fact could explain the significant reduction in green radiation, but the absence of effect on UV radiation was rather surprising. Carbon monoxide had a significant effect only in a single case – on green radiation in combination a lower solar elevation angle (Tab. 2). It seems that CO has no special influence on incident solar radiation.

Although studies about the general reduction of solar radiation by anthropogenic aerosol are quite common (e.g. Rooba, 2009; Esteve et al., 2014), detailed analyses are not available. To the best of our knowledge, there are no scientific reports regarding the influence of individual air pollutants on incident solar radiation in the spectral regions we have studied.

4. Conclusions

The results of this study were dependent upon the approach used. Linear models on data which were not divided according to solar elevation angle did not confirm our hypothesis about the significant influence of air pollutants on incident solar radiation. That was due to the dominant effect of solar elevation angle on incident solar radiation. The influence of air pollutants in combination with relative air humidity, however, was noticeable. After eliminating the major effect of solar elevation angle, linear models showed a significant influence of individual air pollutants on particular spectral regions of incident solar radiation. The spectrally dependent influence of PM_{10} and NO_x and positive influence of SO_2 on incident solar radiation were the main findings of this study. It is evident that air pollutants affect the spectral composition of incident solar radiation, but it is difficult to recognize the direct (especially absorption) and indirect impacts of air pollutants on absorption and scattering characteristics of the atmosphere for spectral regions of incident solar radiation with different wavelength ranges.

ANALYSIS OF MEASURED AND MODELED SOLAR RADIATION AT THE TÅRS SOLAR HEATING PLANT IN DENMARK

Zhiyong Tian, Bengt Perers, Simon Furbo and Jianhua Fan

Department of Civil Engineering,Technical University of Denmark, Kgs.Lyngby, Denmark

Abstract

A novel combined solar heating plant with tracking parabolic trough collectors (PTC) and flat plate collectors (FPC) has been constructed and put into operation in Tårs, 30 km north of Aalborg, Denmark in August 2015. To assess the operation performance of the plant, detailed parameters, such as solar radiation, inlet and outlet temperature for the solar collector field, flow rate and pressure, ambient temperature, wind speed and wind direction were measured. Global horizontal radiation, direct normal irradiation (DNI) and total radiation on the tilted collector plane of the flat plate collector field have been measured in Tårs solar heating plant. To determine the accuracy of modeled and measured solar radiation in Tårs solar heating plant, monthly comparisons of measured and calculated radiation using 6 empirical models have been carried out. Comparisons of measured and modeled total radiation on the tilted surface with different methods were also studied. The results have shown that the DTU model could be used to calculate the diffuse radiation on horizontal surface and the anisotropic models (Perez 1988 model and Perez 1999 model) with only 1% and 2% disagreement with measured data respectively were the most accurate to be used for the calculation of total radiation on the tilted collector surface under Danish climate conditions only based on global horizontal radiation.

Keywords: Tårs solar heating plant, solar radiation, diffuse radiation, total radiation on tilted surfaces, measurements, calculations

1. Introduction

Solar radiation data are the best source of information for estimating thermal performance of solar thermal systems and necessary for design and assessment of solar thermal systems. However, a drawback, common for solar energy systems is the unpredictable nature and variability of solar radiation. Solar heating systems are strongly dependent on weather conditions. The accuracy of the solar radiation is valuable for design and evaluation of the solar energy systems. In the past, in most cases cheap and low accurate solar radiation meters were used to measure solar radiation in solar heating plants. Acquiring information about correct and typical solar irradiation available at potential plant sites is of high importance for controlling and planning of the solar heating plants to improve the thermal performance of the solar thermal systems.

Generally, climate stations only measure global radiation and only in rare cases DNI or diffuse solar radiation. Therefore, total tilted surface irradiation in most cases is calculated by using measured global horizontal irradiation by means of empirical models for general use.

A novel combined solar heating plant with a 4039 m^2 parabolic trough collector field and a 5960 m^2 flat plate collector field in Tårs has been put into operation in August 2015 (Aalbog CSP.2016). To evaluate the thermal performance of the plant and the accuracy of modeled solar radiation, detailed solar radiation, such as, DNI, global (total) horizontal radiation and total titled solar radiation are measured. In addition, a weather station was also constructed nearby the solar heating plant to make sure that the pyranometers in the plant have correct values to reduce systemic errors and to measure the direct normal irradiance. South facing flat

doi:10.18086/eurosun.2016.09.12 Available at http://proceedings.ises.org

plate collectors were installed with 50° tilt in the solar heating plant. Pyranometers were adhered to the flat plate collector with the same tilt to measure the total radiation on the tilted surface. Calibrated high class solar sensors were used.

Previous empirical models for conversion of global solar radiation may not be applicative under Danish climate conditions with high accuracy. A DTU model has been developed to calculate the diffuse radiation on horizontal surface under Danish climate conditions based on the global radiation (J. Dragsted,et al. 2012). DTU model was used to calculate the diffuse radiation on horizontal surface and 5 empirical models were used to investigate the total radiation on the tilted surface in this paper. The difference between measured solar radiation and modeled total radiation on the tilted surface estimated by the empirical formulas under Danish climate conditions were shown. Calculated total tilted radiation only based on the global horizontal radiation and based on both the global horizontal radiation and beam radiation were discussed, which could provide a new method to calculate total tilted radiation with less measurements under Danish climate conditions and maybe the proposed method can be extended to other Nordic area with similar weather conditions.

2. Monitoring equipments

As is shown in the figure 1, Denmark has 6 climate zones. The Tårs plant is located in the first climate zone, in the northern part of Denmark. Figure 2 illustrates the locations of the weather station and the pyranometers in the flat plate collector field in Tårs solar heating plant. The weather station is next to the solar heating plant. There are several pyranometers to measure the global solar radiation on horizontal surface and the tilted plane of the flat plate collectors in the middle of the flat plate collector field to reduce systematic errors (figure 3). The latitude of the plant is 57.39 °N and the longtitude is 10.11°E respectively.

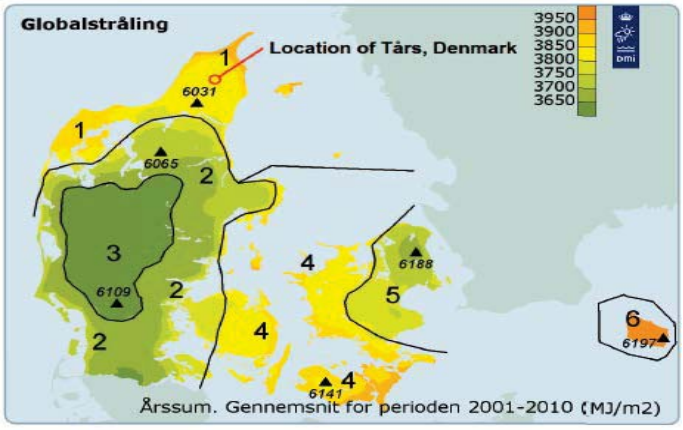

Fig.1. Location of Tårs in Denmark.

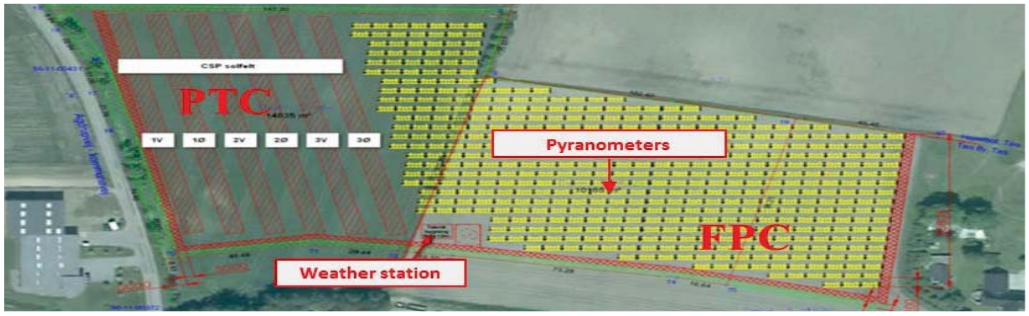

Fig.2. Location of the weather station and pyranometers

Fig.3. Pyranometers in the middle of flat plate collector field

As is shown in figure 2 and figure 3, five pyranometers with a tilt 50° were installed in the middle of the flat plate collector field. One is installed on a horizontal surface. Four pyranometers were installled on the tilted collector plate. Global solar radiation on the horizontal surface and solar radiation on the titled collector plane were measured with Kipp&Zonen SMP11. DNI was measured with a PMO6-CC pyrheliometer with the sun tracking platform Sunscanner SC1 in the weather station next to the solar heating plant, see Fig.2 and 4. Table 1 and 2 show the technical specifications of Kipp&Zonen SMP11 pyranometer and PMO6-CC pyrheliometer. It is estimated that that the uncertainty of the measured solar radiation is about 2%.

Fig.4. Weather station and pyrheliometer at Tårs solar heating plant

Table 1. Specifications of Kipp & Zonen SMP11 Pyranometer

Parameters	Values
Spectral range (50% points)	285 to 2800 nm
Response time (63%)	< 0.7 s
Response time (95%)	< 2 s
Zero offset A	< 7 W/m²
Zero offset B	< 2 W/m²
Directional response (up to 80° with 1000 W/m² beam)	< 10 W/m²
Temperature dependence of sensitivity (-20 ºC to +50 ºC)	< 1 %
Analogue output (-V version)	0 to 1 V
Analogue output (-A version)	4 to 20 mA

Table 2. Specifications of PMO6-CC pyrheliometer

Parameters	Values
Dimension	80 x 80 x 230 mm
Mass	2.15 kg
Field of view (full angle)	5°
Slope angle	1°
Range	up to 1400 W/m^2 (Or custom design available)
Traceability to WRR	< 0.1%
Operating temperature range	-25 °C to +50 °C

3. Models

Solar radiation, including DNI, global horizontal radiation and total solar radiation on a tilted south facing surface of 50° parallel to flat plate collectors have been measured with high time resolution: 2 minutes time steps. Hourly mean values are calculated based on the measurements. Six solar radiation models using the hourly mean data are used to calculate the diffuse radiation on horizontal surface and total solar radiation on the tilted surfaces. The DTU model was used to calculate diffuse radiation on the horizontal surface. And five empirical models for general use were used to calculate the total solar radiation on the tilted surface (Beckman W A.,et al. 1990-2012). Calculation methods of five empirical models were investigated (Beckman W A.,et al. 1990-2012). Ground reflectance was assumed to be 0 in the calculation of modeled solar radiation in the solar heating plant, which is the fair value when shadow between collectors is taken into consideration in the calculations.

4. Results and Discussions

Based on the measurements, total radiation on the tilted flat plate collectors has been investigated with different models. Further, accuracies of the different mentioned models on the calculation of total radiation on the tilted surface have been figured out. The TRNSYS platform was used to set up the mentioned models. Monthly comparisons of modeled and measured solar radiation on horizontal and tilted surface are presented.

4.1 Total radiation on 50° tilted surface facing south

To investigate the total radiation on the tiled surface and accuracy of the different empirical models, calculated total radiation on the tilted surface by the isotropic and anisotropic models based on measured total horizontal radiation and measured beam radiation are shown in figure 6. Because the tilt of the flat plate collectors is 50°, all the mentioned tilted surfaces are 50° tilt surfaces towards south.

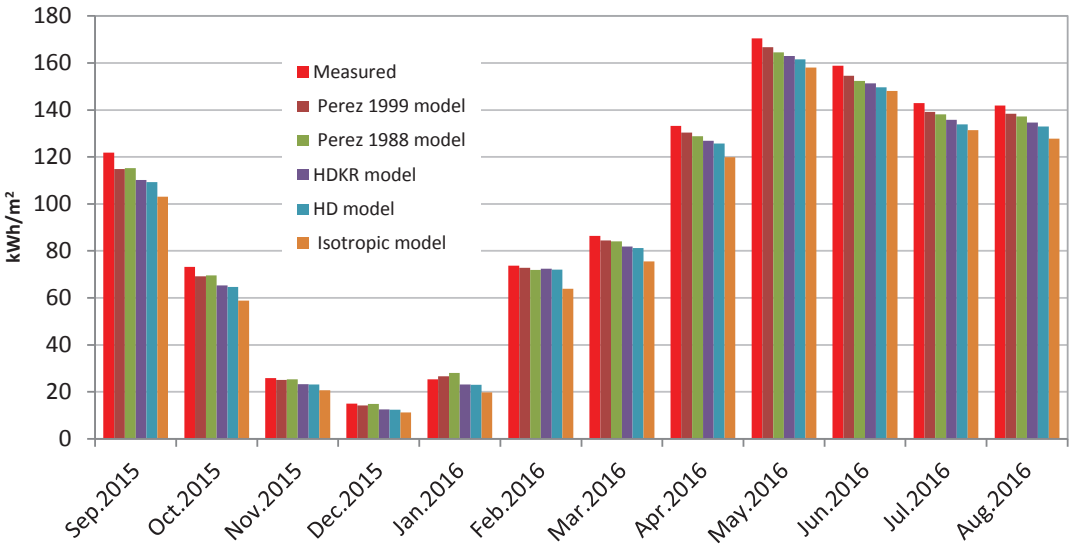

Fig.5. Modeled and measured monthly total radiations on 50° tilted surface facing south (Sep.2015 – Aug.2016)

Fig.5 illustrates measured and modeled total radiation on the tilted surface. The modeled total radiation by isotropic model is lower than the measured values obviously. For the four anisotropic models, the modeled total tilted radiations of the Perez 1999 model and Perez 1988 model are the closest to the measured values with only average -3% and -1% difference between the modeled and measured values, which is the same as reported by Andersen E., et al (Andersen E., et al,2004).

4.2 Measured and calculated total tilted radiation

Normally the total radiation on tilted surfaces is not measured in solar heating plants. Calculated total radiation on tilted surfaces only based on measured global radiation on horizontal surface is useful. By the DTU model, calculated diffuse radiation and beam radiation are obtained only based on measured global radiation on horizontal surface. Because the anisotropic models (Perez 1999 model and Perez 1988 model) are closest to measured value in section 4.1, the anisotropic models (Perez 1999 model and Perez 1988 model) were selected to calculate the total radiation on the tilted surface based on the calculated diffuse radiation and calculated beam radiation. The calculated total tilted radiation by the Perez 1988 model and Perez 1999 model are only 1% and 2% respectively larger than the measured one from Sep.2015 to Aug.2016, see figure 6. Calculated total tilted solar radiation by the Perez 1999 model mainly is a bit higher than measured values in the summer (Fig.6.b.). The Perez 1988 model has the best agreement with measurements of the investigated two empirical models. Compared to the calculated total tilted radiation based on the measured global radiation and measured beam radiation, the accuracy of calculated total tilted radiation only based on the measured global radiation also has high accuracy (the anisotropic model -Perez 1999 model and Perez 1988 model).

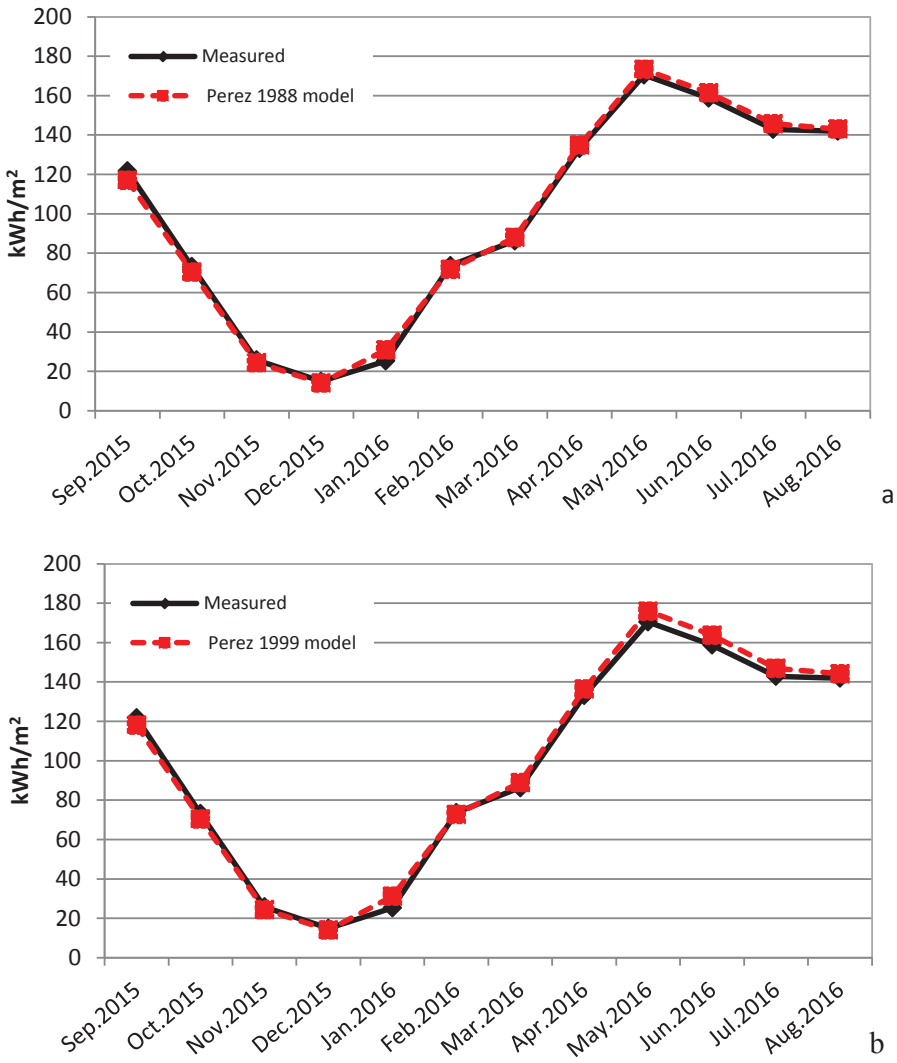

Fig.6. Measured and calculated monthly total radiation on 50° tilted south facing surface (Sep.2015 – Aug.2016: a-Perez 1988 model, b- Perez 1999 model.)

5. Conclusions

Measured and modeled solar radiation in a demonstration solar heating plant in Denmark were analyzed. The main purpose of this paper is to present a new calculation method to determine tilted total radiation on tilted flat plate collectors for large solar heating plants in Denmark. Calculated total tilted solar radiation only based on measured global horizontal radiation was investigated. Furthermore, an isotropic model and four anisotropic models for general use have been investigated for calculation of total radiation on tilted surfaces under Danish climate conditions.

It is suggested that the anisotropic model can be used to calculate total radiation on the tilted surface with better accuracy than the isotropic model under Danish climate conditions. The anisotropic models (Perez 1999 model and Perez 1988 model) are the most suitable empirical model for the calculation of total radiation on the tilted surface under Danish climate conditions. Calculated tilted solar radiation based on the anisotropic models and DTU model only based on the global horizontal radiation can be a new method to predict the total radiation on tilted surfaces accurately under Danish climate conditions.

Rear Wheel Steering System for Racing Solar Cars

Toru Fujisawa and Takashi Kawaguchi
Kanagawa Institute of Technology, Atsugi (Japan)

Abstract

Some of our students study energy by producing racing solar cars. Of course, they are concerned with solar energy and how to use it efficiently, however they must also study total energy system for making good solar cars. In solar education we try to provide them with an opportunity for learning engineering technologies around the solar energy to realize that solar power is related to other fields and branches. For example, it is important to reduce resistance to motion of a car to save the energy. So they designed a rear wheel steering system and a narrow spat in order to make the drag force be small. The spat is a kind of cover for a tire. They showed the rear wheel steering caused the width of the spat to be more narrow. The drag force, which is a part of the resistance to motion, on two front spat was estimated. From the result, they calculated the total energy saving over the route of the 2013 World Solar Challenge. It is recognized that adding the rear steering system to the car is useful for the race.

Keywords: *Solar Education, Energy Education, Mechanical Engineering, Racing Solar Car, Drag Force Coefficient, Rear Wheel Steering System, World Solar Challenge*

1. Introduction

Solar energy is origin of other forms or types of energy on the earth. When we teach energy to our students, we may have to make them consider that solar energy plays a significant role in many fields and understand that solar power is related to other fields and branches.

One of main purposes of solar education is getting and using solar energy effectively. In our racing solar car team, students have found out the power density of solar radiation is low. So they improve the car with various techniques. The work for their improvement suggests the using solar energy is related to other fields and many technological knowledge is needed for the using that energy effectively. Now teachers try to show the students recognizing that solar energy is included in total system and emphasizing that using energy in the system is related to many fields.

An example of the improvement of the solar car was introducing a rear wheel steering system to the car. This improvement was effective way for reducing the drag force to save the energy, because that force depends on a width of a vehicle spat covering a tire. The knowledge of other fields, example for vehicle dynamics and fluid dynamics, was used to utilize solar energy.

2. The racing solar cars

The racing solar car, which is shown in Fig.1, was designed by our students for the World Solar Challenge (WSC) and participated in the 2013 WSC adventure class. It has a 1.3 kW photovoltaic (PV) system, a 5.2 kWh rechargeable Lithium-ion (Li-ion) battery system, a carbon fiber monocoque, two front tires and one rear tire which contains an in-wheel motor. The motor is a 2.0 kW direct drive one.

After the 2013 WSC, the solar car team members tried to improve the car. For example, reducing resistance to motion of the car became their aim, because it is important for saving energy to reduce the resistance. The

doi:10.18086/eurosun.2016.10.04 Available at http://proceedings.ises.org

members thought that one of the solutions to the reducing is adding a rear wheel steering system to the solar car.

When a vehicle turns left or right, for a given turning radius, the larger the steer angle of a rear tire is, the smaller that of the front tires is. So steering a rear tire can make the width of a vehicle spat covering a front tire be more narrow. The fact suggests that the spat's drag force, which is included by the resistance to motion, may be small.

Fig. 1: KAIT (Kanagawa Institute of Technology) racing solar car participated in the 2013 WSC

3. Turning radius and steer angle

We consider the relation between turning radius and steer angle in this section. If a steady-state turning at very low speed is assumed, centrifugal force doesn't act on the car, lateral forces are not needed, and side-slip angle is 0 while front and rear wheels travel in the heading direction of the car and make a circular motion (Abe and Manning, 2009), as shown in Fig.2. α, γ, W and T are given.

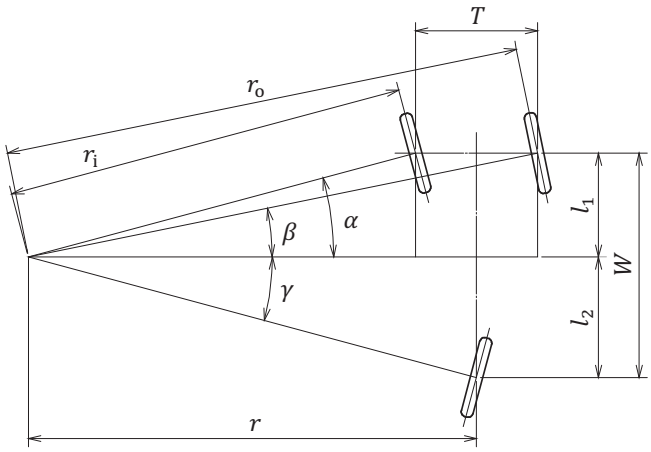

Fig. 2: Turning radius and steer angles (α, β : front; γ : rear) for steady–state turning at low speed

We start by

$$W = l_1 + l_2 = (r - T/2)\tan\alpha + r\tan\gamma = -T\tan\alpha/2 + r(\tan\alpha + \tan\gamma) \quad \text{(eq. 1)}$$

then

$$r = (W + T\tan\alpha/2)/(\tan\alpha + \tan\gamma)\ . \quad \text{(eq. 2)}$$

And from Fig. 2,

$$\tan\beta = l_1/(r+T/2) = (r-T/2)\tan\alpha/(r+T/2) = (1-1/(r/T+1/2))\tan\alpha\ , \qquad \text{(eq. 3)}$$

$$r_o/T = (r+T/2)/(T\cos\beta) = (r/T+1/2)/\cos\beta\ . \qquad \text{(eq. 4)}$$

Putting

$$p \equiv r/T + 1/2 = (W/T + \tan\alpha/2)/(\tan\alpha + \tan\gamma) + 1/2\ , \qquad \text{(eq. 5)}$$

we obtain

$$\tan\beta = (1-1/p)\tan\alpha\ , \qquad \text{(eq. 6)}$$

and a dimensionless radius :

$$r_o/T = p/\cos\beta = p/\cos\tan^{-1}\big((1-1/p)\tan\alpha\big)\ . \qquad \text{(eq. 7)}$$

For the racing solar car, $W = 2000$ mm, $T = 1300$ mm , so $W/T = 1.54$. Figure 3 presents the dimensionless radius : r_o/T for both the inside front steer angle α and the rear one γ at $W/T = 1.54$.

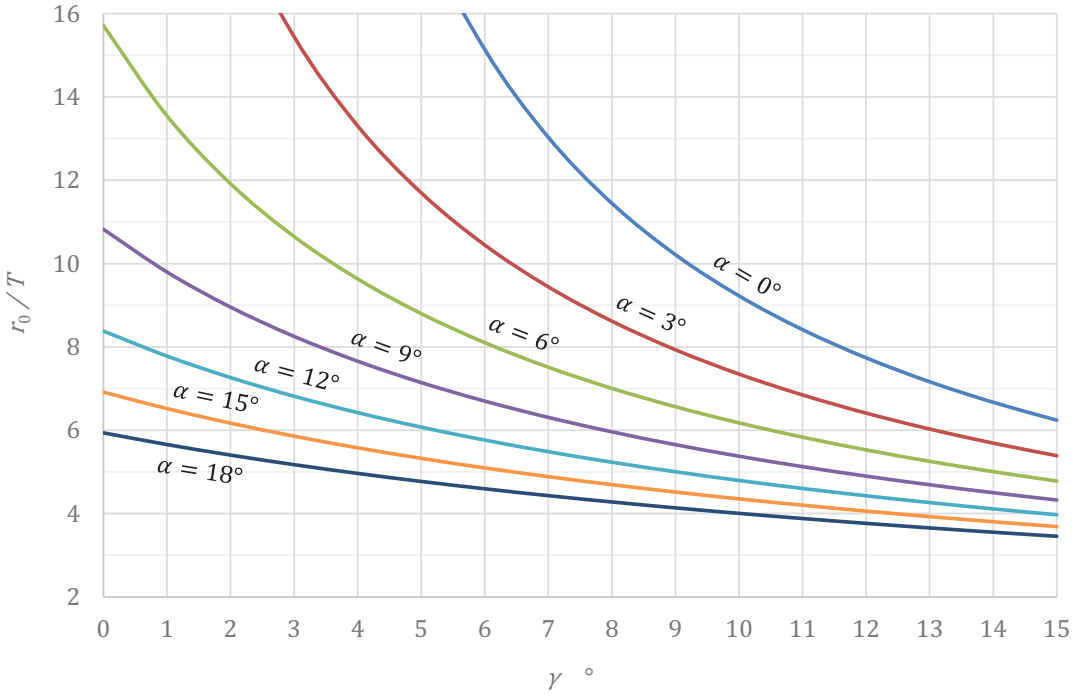

Fig. 3: Dimensionless turning radius r_o/T , inside front steer angle α and rear one γ for steady–state turning at low speed at *W/T* = 1.54

According to regulations for the 2013 WSC, the Solar car must be able to make a U-turn in either direction within a 16 m lane, kerb to kerb. If the car has no rear wheel steering system, the maximum value of inside front steer angle α must be 18° or more in order to observe the regulations, because of $r_o/T < (16/2)/1.3 = 6.15$ and Fig. 3. However we can satisfy the regulations at that angle $\alpha = 7.5°$, if the car has the rear steering system and rear steer angle γ is 9°.

4. Drag force on the front spat

In the previous section, we know that the rear wheel steering system is effective against the reducing the front steer angle. So the width of the spat, which covers a tire, may become narrow and the drag force on the narrow spat is smaller than that on the wide one. We assume that the shape of the spat is a streamlined two-dimensional cylinder, and we are going to guess the drag coefficient C_D by the procedure shown in Fig.4.

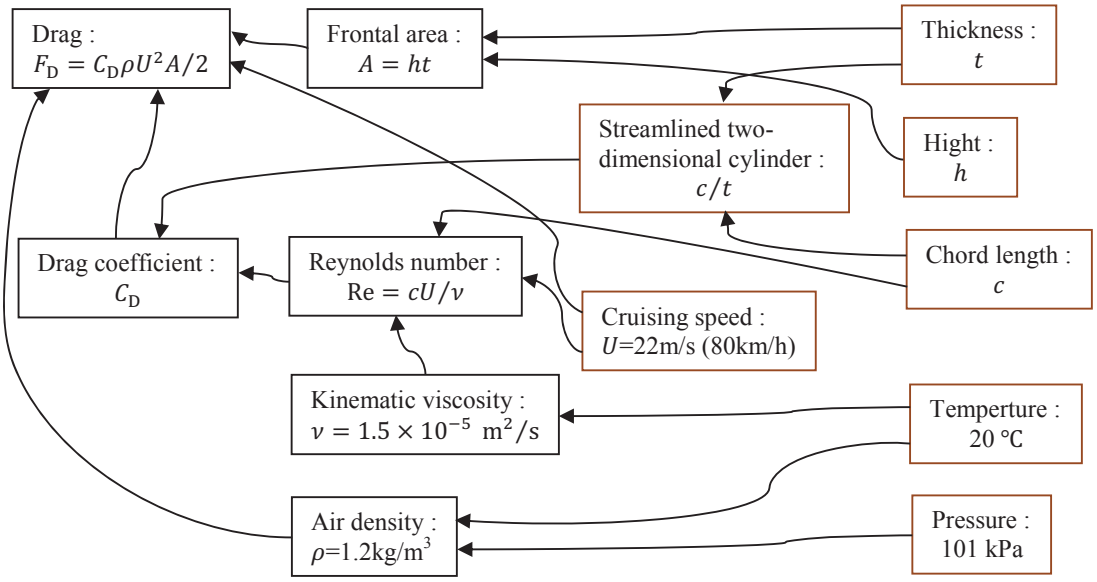

Fig. 4: Procedure for determining drag from the shape of the spat, the cruising speed, air temperature, atmospheric pressure

Reynolds number is defined here by

$$Re \equiv cU/\nu \qquad \text{(eq. 8)}$$

where c is the longitudinal length of the spat, U is the cruising speed of the car and ν is kinematic viscosity of air . The chord length c is approximately 1200 mm. Let the air temperature, atmospheric pressure, the cruising speed be 20℃ , 101 kPa and U =22 m/s (80km/h) respectively. So the kinematic viscosity $\nu = 1.5 \times 10^{-5}$ m^2/s, the air density ρ=1.2 kg/m^3. Then Reynolds number is

$$Re = 1.2 \times 22/(1.5 \times 10^{-5}) = 1.8 \times 10^6 \ . \qquad \text{(eq. 9)}$$

The diameter of the front tire of the solar car $D = 552$ mm and the width of it $B = 103$ mm, then

$$D \sin\alpha + B \cos\alpha = \begin{cases} 174 \text{ mm} & \text{for } \alpha = 7.5° \\ 269 \text{ mm} & \text{for } \alpha = 18° \end{cases} \qquad \text{(eq. 10)}$$

is needed for width of inside spat cavity. If there exists the rear wheel steering system, that is, $\alpha = 7.5°$, the outside width of spat is $t = 190$ mm. On the other hand no rear one, that is, $\alpha = 18°$, the outside width of spat is $t = 285$ mm. Then

$$t/c = \begin{cases} 0.16 & \text{for } \alpha = 7.5° \\ 0.24 & \text{for } \alpha = 18° \end{cases} . \qquad \text{(eq. 11)}$$

We obtain the drag coefficient

$$C_D = \begin{cases} 0.082 & \text{for } \alpha = 7.5° \\ 0.075 & \text{for } \alpha = 18° \end{cases} \qquad \text{(eq. 12)}$$

from Fig. 5 (Granger, 1995; Goldstein, 1965; Shames, 1992; White, 2011). Figure 5 gives drag coefficients for Reynolds number $= 10^6$, and our one : 1.8×10^6 is not that, however it is likely that the drag coefficient for Reynolds number $= 1.8 \times 10^6$ is nearly equal to that for $Re = 10^6$. Generally, the drag coefficient of bluff forms depends on the span, but on low-drag forms the effect of aspect ratio is considerably smaller than that on bluff forms (Goldstein, 1965). So the effect of the aspect ratio on the drag coefficient is negligible.

The drag force F_D is expressed by

$$F_D = \frac{1}{2} C_D \rho U^2 A \qquad \text{(eq. 13)}$$

where A is the frontal or projected area. Let the spat height be 308 mm, then

$$F_{\mathrm{D}} = \begin{cases} 0.082 \times 1.2 \times 22^2 \times 0.190 \times 0.308/2 = 1.4\mathrm{N} & \text{for } \alpha = 7.5° \\ 0.075 \times 1.2 \times 22^2 \times 0.285 \times 0.308/2 = 1.9\mathrm{N} & \text{for } \alpha = 18° \end{cases} \quad \text{(eq. 14)}$$

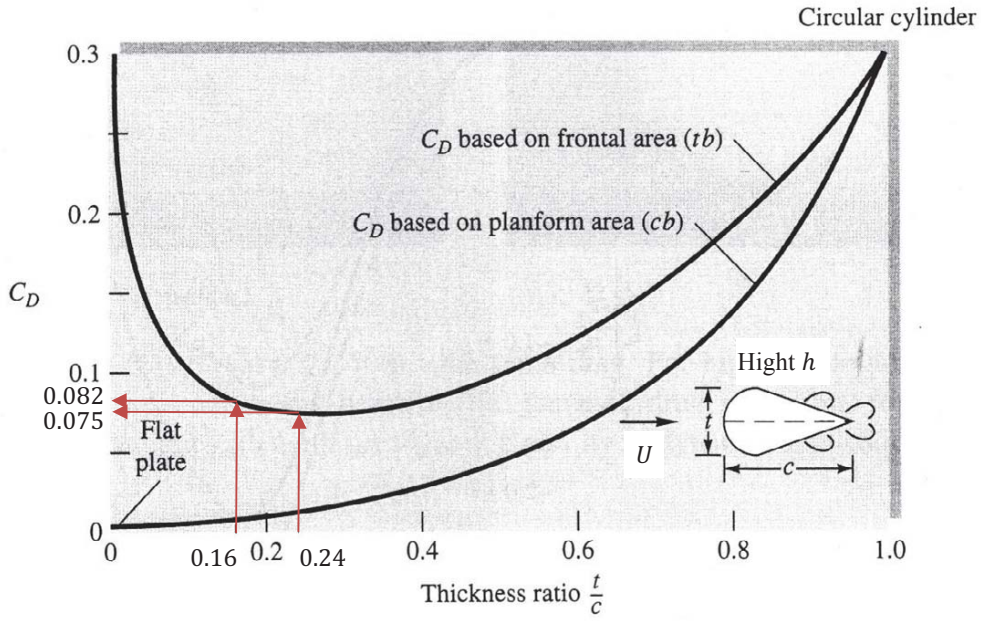

Fig. 5: Drag coefficients for a streamlined two-dimensional cylinder at *Re* = 10^6 (White, 2011)

5. Energy consumption of the rear wheel steering system

The rear wheel steering system consists of a DC 12V geared motor, a screw driven liner actuator, a stroke sensor, a microcontroller. The motor is controlled by feedback. The actuator can push or pull the swing arm of the rear wheel. A part of the system is shown in Fig. 6.

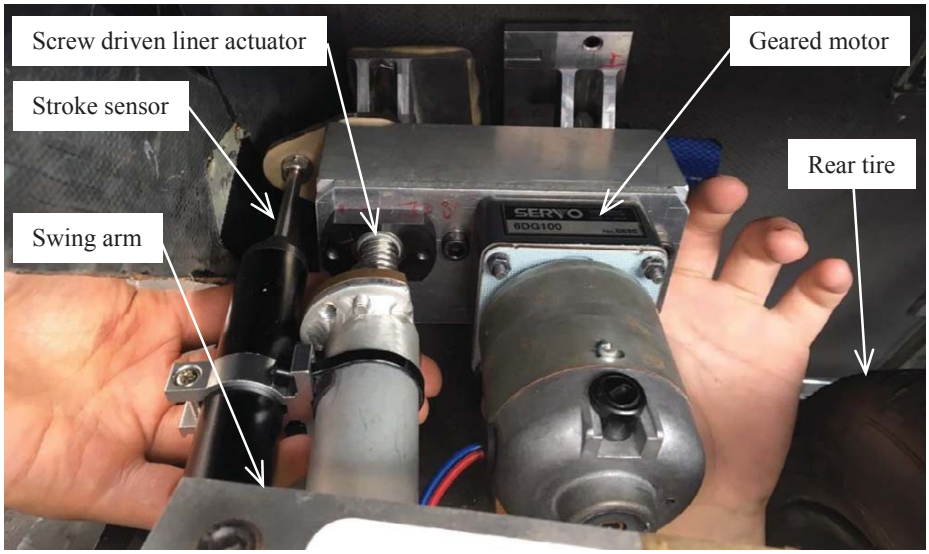

Fig. 6: Putting the rear wheel steering system to the solar car

The solar car team member measured the current of the steering system and Fig. 7 shows the result. The current was approximately 1A, so electric power was 12W and it took 2×6s=12s for one cornering operation.

Then 12×12s=144J is needed for one that operation. Since it is likely that the efficiency of the electric power is 70%, the energy consumption of the rear wheel steering system is $144/0.7 = 206$J. They also researched the number of turning that required the rear wheel steering on the 2013 WSC route. The turnings were 26, so the total energy consumption of the rear wheel steering system is $206 \times 26 = 5.36 \times 10^3$J throughout the race.

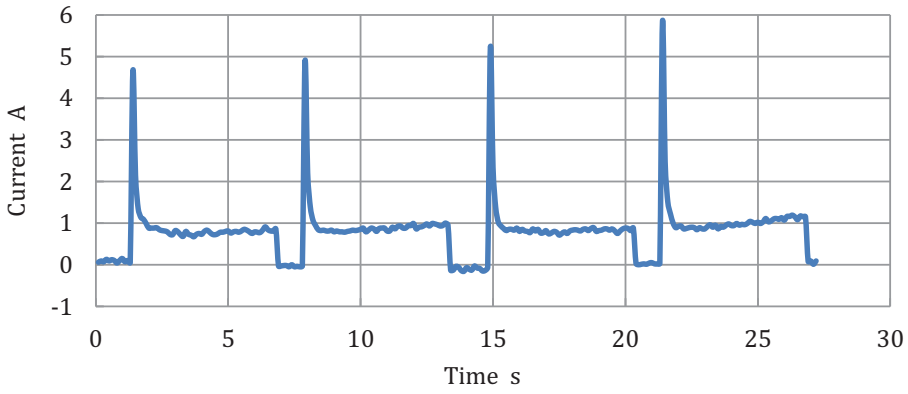

Fig. 7: Current consumed by the rear wheel steering system

6. Effect of the rear wheel steering

We consider the effect of rear wheel steering system here. The travelling distance by no rear steering operation in the WSC route is approximately 3008km. The merit in the rear wheel steering is reducing the resistance to motion. It saves the energy : $2 \times (1.9 - 1.4) \times 3008 \times 10^3 = 3 \times 10^6$J, because front spats are two. The demerit is the consumption of electric power of the rear steering system : 5.36×10^3J for the result of previous section. Now we can guess the effect. It is $3 \times 10^6 - 5.36 \times 10^3 \cong 3 \times 10^6$ J energy saving in the race.

7. Conclusions

The racing solar car has been improved. The rear wheel steering system added to the car may make the total driving energy consumption be reduced throughout the WSC. We obtained the following.

If the solar car has the rear wheel steering system and rear steer angle γ may be 9°, we can satisfy the 2013 WSC regulations at the inside front steer angle $\alpha = 7.5°$.

The drag force on the front spat with the rear wheel steering system may be 1.4 N at the cruising speed = 22 m/s (80 km/h). But with no that system the force is 1.9 N.

The effect of the rear wheel steering system throughout the WSC, we estimated, is 3×10^6 J energy saving. Effective solar energy usage induces our students to study many fields related to solar energy practically.

Using TRNSYS in a graduate course on solar energy engineering

Michaël Kummert

Polytechnique Montréal, Dept. of Mechanical Engineering, Montréal (Québec), Canada

Abstract

This paper presents a graduate solar energy engineering course which relies on the TRNSYS simulation tool to engage students in the learning process through design and analysis activities. The course learning objectives are discussed in relation to Bloom's revised taxonomy. The paper then presents an overview of the course contents, as well as teaching and assessment methods. Student feedback has been overwhelmingly positive on the use of TRNSYS, and on the combination of theoretical notions and practical, simulation-based design exercises. The students also pointed out the lack of software training material specific to the subject, which leads to difficulties in selecting and configuring the appropriate components.

Keywords: education; teaching; solar energy; simulation; modeling; TRNSYS

1. Introduction

Most university-level courses on renewable energy are taught at the graduate[1] level, either as part of a program focusing on that topic, or as elective courses in more general programs (Kandpal and Broman, 2014). Renewable energy education at Polytechnique Montréal followed the general trend in North America, where renewable energy education in universities took off in the late 20th century, in the wake of the oil crises. Solar energy was often among the first graduate courses created, with many instructors adopting the seminal "Solar Engineering of Thermal Processes" textbook currently available in its 4th edition (Duffie and Beckman, 2013). At the beginning of the 21st century, dwindling research and education funding had resulted in only about 10 US universities offering regular solar energy courses, down from around 150 in the early 1980s (Goswami, 2001). The solar energy course at Polytechnique again followed that trend; it was not taught for about 10 years before being reinstated in 2011.

The course described in this paper is known as MEC 6214 – "Énergie Solaire et Applications" (Solar energy and applications). It is taught once a year, during the winter term (January to May). The current course contents and teaching methods are the results of 6 years of trial and error by the author, although the basic structure and the learning objectives remained the same. As pointed out by Kandpal and Broman (2014), "*the scope and contents of a course essentially depend upon the expertise, interest(s) and biases of the course teacher*". The course described in this paper is no exception: both the theoretical aspects addressed in the first part of the course and the practical, simulation-based approach are a result of the author's experience and level of comfort with the selected topics and tools. As a consequence, this paper does not pretend to represent the best practice in teaching solar energy engineering. It represents the author's contribution to the sharing of teaching methods and materials, and an example of how a detailed simulation program as TRNSYS can enrich a solar energy course and help engage students in the learning process.

Note: The author has made some teaching material available on an open website accompanying this paper: https://moodle.polymtl.ca/course/view.php?name=mec6214p (most material is in French at this time)

[1] "graduate" in the paper title and in the text refers to the level of a student who has graduated from a university-level "undergraduate" program, often a Bachelor's degree (~4 years). The term is frequently used in the USA and in Canada, while "postgraduate" is often used with the same meaning in Europe and some other countries.

doi:10.18086/eurosun.2016.10.01 Available at http://proceedings.ises.org

2. Prerequisites

The general policy at Polytechnique Montréal is to have no prerequisites for graduate courses. While most students taking the course have completed or are about to complete a Bachelor's degree in mechanical engineering, students from other engineering branches and sometimes other backgrounds (architecture, economics, physics) have also taken the course. The required prior knowledge is limited to basic thermodynamics and heat transfer: energy balance of closed and open systems, conduction, convection and radiation heat transfer, heat exchangers. Reading material is provided to cover these topics, e.g. Chapter 3 in (Duffie and Beckman, 2013) or thermodynamics and heat transfer textbooks, but no special tutorial sessions are organized. No prior knowledge of the software tools (especially TRNSYS) is expected, but a small number of students have typically been exposed to them in other undergraduate or graduate courses. In particular, TRNSYS is used to some extent in many of the core courses given at the school on building physics, HVAC systems, building energy modeling, and other renewable energy systems (i.e. geothermal).

3. Learning objectives

After taking the course, the students should be able to:

- Describe the environmental and economic context relevant to solar energy engineering
- Assess the solar energy resource of a site
- Calculate the solar radiation incident on a surface (beam, diffuse and ground-reflected components)
- Explain the principles of solar collectors and solar energy systems
- Calculate the performance of solar collectors
- Analyze the economic and energy performance of solar energy systems*
- Design and simulate the performance of solar energy systems
- Justify the use of given renewable energy technologies (wind, solar thermal, solar photovoltaic) in particular applications

*It should be noted that, adopting the approach of Duffie and Beckman (2013), the course focuses on solar thermal systems but also covers more briefly solar photovoltaic (PV) systems and wind energy systems.

Using Bloom's revised taxonomy (Anderson and Krathwohl, 2001), some learning objectives listed above fall in the lowest 3 categories of educational objectives in Figure 1: remember, understand, and apply (where the "remember" objective is not mentioned explicitly but implied). These categories are more present in the first part of the course ("fundamentals" part, see below).

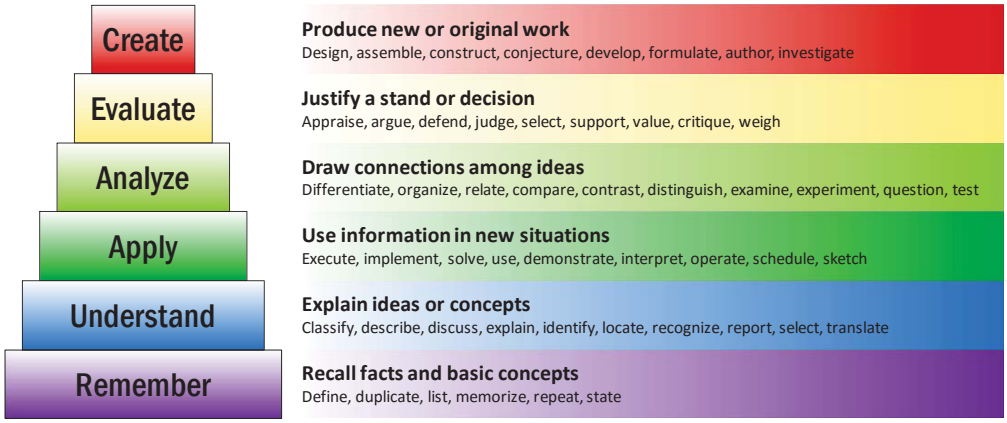

Figure 1: Bloom's revised taxonomy, adapted from (Armstrong, 2016)

The upper categories (Analyze, Evaluate and Create) rely on performance simulation with TRNSYS: students learn how to design solar energy systems first by analyzing the performance of pre-defined systems, by assessing the impact of design changes, and then by proposing and comparing different designs. In theory, it would be possible to perform these activities without relying on software tools, e.g. by using monthly

design methods such as F-Chart (Klein, Beckman and Duffie, 1976). However, using simulation programs such as TRNSYS allows to consider a much larger variety of systems combining different technologies (e.g. solar thermal, solar PV, and wind); it also allows investigating the dynamic behavior of complex systems and control strategies.

4. Teaching and assessment methods

The course follows the typical pattern for graduate courses at Polytechnique Montréal, which consists of a weekly 3-hour lecture (there are normally 13 lectures per term). There are no formal labs or tutorials, but the students are expected to dedicate time to the course at home for personal study, homework assignments and exam preparation, for a total of 96 hours. The total theoretical workload for students is 135 h over the teaching term, which corresponds to 3 credits at Polytechnique Montréal. It can be loosely translated to 5 or 6 ECTS (European Credit Transfer and Accumulation System).

The course is based on "Solar Engineering of Thermal Processes" (Duffie and Beckman, 2013), which has been one of the most popular textbooks to teach solar energy engineering since the 1970's, in North America and throughout the world. The course mainly relies on the first 6 chapters for the "fundamentals" part (see below), which is taught in conventional lectures with homework assignments.

Engaging students

There is increased evidence that traditional lectures are not the most efficient at maximizing learning and course performance in Science, Technology, Engineering and Mathematics (Freeman *et al.*, 2014). Students benefit from active learning, which is defined by the adoption of instructional practices that engage students in the learning process, such as collaborative, cooperative, and problem-based learning (Prince, 2004). While promoting student engagement is an unquestionable objective, it can be challenging to realize in a course with 39 hours of faculty-students contact and a relatively large number of students (the average course enrollment is above 30 students per term, with an upward trend).

The first approach taken to engage students in this course is to try and bring some collaborating learning in the biweekly homework assignments. Students solve the assignments and submit their results individually, but a significant part of the next lecture (roughly one hour) is taken to discuss the problem and the results. The students and instructor diagnose the errors in submitted results. In many cases, students work on different datasets, which was originally intended to prevent plagiarism, but has proven useful in transforming individual efforts into a form of teamwork, where all students contribute one part of a larger parametric analysis.

The second approach to engage students relies on simulation-based problems (assignments or intermediate steps of the final project). During the second half of the term, the time spent giving conventional lectures is considerably reduced, to approximately 1 teaching period (50 min). This leaves two periods for participative activities. Instead of the conventional classroom used for the first part of the term, the course takes place in a computer lab, which allows students to perform simulations during the class. They can analyze their results and diagnose their problems with the help of the instructor, within the constraints imposed by the number of students (i.e. each student gets relatively little time for individual assistance).

Assessment methods

The assessment relies on individual homework assignments (biweekly individual assignments, worth 1/3 of the final mark together), on a written exam (individual, 1/3 of the final mark), and the final project (groups of 2 or 3 students, 1/3 of the final mark). The weight of these different assessments have evolved over time, in response to student feedback that the initial weight for the exam (40 %) did not give a fair share to the other activities. The exam is organized as a mid-term assessment, which comes after the lecture-based "fundamentals" part of the course. It is a conventional written exam, during which students only have access to a 2-page document that they have created themselves and to a non-programmable calculator. In terms of Bloom's taxonomy, the learning objectives assessed in the exam mostly fall in the lower 3 categories (remember, understand, apply), with some attempts to reach levels 4 and 5 (analyze and justify), e.g. with questions asking to define a solar fraction that would apply to a particular system. The homework

assignments ask for numerical answers but also in many cases for a report with some analysis and critique of the results and assumptions, which can be seen as pertaining to categories 4 and 5: analyze, and evaluate. This is especially true for the assignments that use TRNSYS simulations. But to really attain the highest category of educational goals ("create", i.e. design, formulate and investigate), the course relies on simulation-based exercises, and this level is probably only reached during one or two assignments, and the final project, which is a group activity (2 or 3 students).

A practical exam using TRNSYS was introduced in 2012 and 2013. This 2-hour exam was taking place right after the conventional written exam, and was originally intended to test whether students had gained a sufficient understanding of how the program can be used to analyse solar systems, but it proved difficult to test more than basic TRNSYS skills, which was not in line with the learning objectives, so that exam was withdrawn in 2014 and for following years.

5. Use of TRNSYS and other software tools

Literature review: courses using TRNSYS

The literature on teaching solar energy with TRNSYS (or with other simulation tools) is scarce. A few papers report on successful attempts in universities across the world to use TRNSYS in teaching various subjects, from building energy systems to solar energy engineering.

TRNSYS is used in several courses at Polytechnique Montréal, from 4th year (BEng) courses in building heating and cooling mechanical systems to graduate courses on geothermal systems and solar energy (the course described in this paper). It is also used in a graduate course on building energy modeling (Bernier *et al.*, 2016). Students in graduate programs such as the recently created course-based Master in energy engineering are likely to take several of these courses (if not all), which offers synergies and reduces the student effort to learn the software.

Megri (2014) discusses the use of TRNSYS in the department of Architectural Engineering at North Carolina A&T State University. The paper presents a methodology for students to build their own model, perform numerical experiments, and analyze the results. The selected case study is a solar-assisted ground-source heat pump system coupled to a multizone building. According to the author, students prefer easier-to-use programs such as EQuest, but TRNSYS has the benefit of not restricting the type of systems which are analyzed. The instructor needs to master the TRNSYS program and the subject areas.

Charles and Thomas (2009) use TRNSYS in undergraduate courses for engineering and architecture students. The program is coupled with CONTAM for bulk airflow analysis, and other tools are used for climate analysis and Computational fluid Dynamics (CFD). The focus is on encouraging teamwork and benefitting from complementary experience, and simulation is not performed by all class students but rather by an external expert, the instructor, or a few volunteer students. The authors report that students find TRNSYS difficult and are more attracted towards the CFD software. The latter can produce visually attractive results and the authors express that using a little bit of "colorful fluid dynamics" is a necessary evil to generate interest. In spite of the difficulties, the authors conclude that simulation helps students understand the iterative nature of the design process and makes them aware of various physical phenomena. It is also a common platform to support collaboration.

Gómez-Moreno (2015) describes how TRNSYS is used in an undergraduate course on HVAC systems in Industrial Engineering at Universidad de Jaén. Transient simulations are used to help students understand the dynamic behavior of HVAC systems, enhancing the knowledge of steady-state performance that they have gained through more conventional teaching methods. The program is also used to introduce renewable energy in a course that otherwise focuses on air-conditioning systems. The authors state that a software program like TRNSYS is the ideal tool for the students to acquire new competencies and to understand the dynamic behavior of complex systems. It also has the benefits to promote student engagement and increase the motivation. They present the results of a student survey showing that 80 % or more of the students have found that the simulation tool is useful to complement the lectures, help understand the operation of HVAC and solar systems, increase their interest in the course, and improve the quality of teaching.

Gravagne *et al*. (2008) report on the use of TRNSYS in a graduate elective course on solar energy in the department of mechanical engineering at Baylor University. The authors mention the use of TRNSYS for LEED certifications of buildings and for SRCC certifications of solar thermal systems as key aspects in support of selecting the program, as well as a series of features introduced in version 16 that made the software more relevant to classroom use. TRNSYS was only used midway through the class, and it was used to revisit problems that had been solved by hand or with generic software such as Excel or Matlab. One benefit of this approach is that students had a deeper understanding of the software assumptions and results. They could identify spurious results more easily after developing intuition by obtaining results the "hard way". TRNSYS was then used as a design tool in the final project. This allowed students to perform activities (design) for complex systems that they would not have been capable of analyzing without the program. The "mixed quality" of the documentation required a careful preparation by the instructor, so that students are not frustrated by hard-to-find information. Cryptic error messages, and non-standard units, such as the use of kJ/h for energy rates, are also pointed out as weaknesses. But overall, TRNSYS improved the learning experience and most students expressed their wish to start using TRNSYS earlier in the course.

These examples show that TRNSYS can be used successfully for teaching solar energy engineering and other topics. But there is a need for a larger body of shared knowledge about how the tool can be used efficiently for teaching and learning, and there is also a need for publicly available material to support that objective. This paper and the accompanying website is the author's attempt to contribute to that material.

Why was TRNSYS selected?

Ideally, an engineering course should be tool-independent. However, the pursuit of this noble objective quickly faces practical problems: can the instructor master all the tools involved? is the time invested in software installation and basic learning justified? can all the licenses be obtained without investing too much time and money? As discussed below, the students taking this course sometimes felt that using different programs would have been beneficial, while attempts to be tool-independent (and therefore using several different tools) can lead to students being frustrated at the time and energy involved to install and master these software tools (Beausoleil-Morrison and Hopfe, 2016). In many cases – as well as in this course – students also express the need for more software training material adapted to the course (Gravagne and Van Treuren, 2008; Beausoleil-Morrison and Hopfe, 2016). Over the years, a course instructor can reasonably build specific training material adapted to a particular course for a software program, but creating and maintaining that material for several different tools seems impractical.

As indicated in the introduction, the choice of TRNSYS came naturally to the course instructor, as he was very familiar with the program and confident that he could not only use the program to obtain simulation results but also investigate its assumptions and algorithms. When teaching an engineering discipline, being able to examine the actual source code of the software is a great advantage that few commercial programs offer, and open-source alternatives are not always available. Numerous validation studies including TRNSYS have been published, such as the BESTEST inter-model comparison (ASHRAE, 2014). TRNSYS is also used as a reference tool in international standards (ISO, 2013) and certification programs (Burch *et al.*, 2012; SRCC, 2015), which is a testimony to the software relevance for solar energy systems.

TRNSYS' main advantage is probably its flexibility, which comes from its modular structure and from the well-developed libraries of component models. Components can be connected together to form a system, and then configured by modifying the relevant parameters. Assessing different system configurations only requires to add/remove components from the libraries and modify the connections, without modifying the equations and algorithms used in the model. The program flexibility is also expressed by the fact that many different *domains* (Clarke, 2001) can be analyzed together: thermal processes and electrical flows within buildings, HVAC systems and renewable energy systems can form one coupled system. This is a great advantage over some easier-to-use tools which are generally restricted to a single domain or technology (e.g. solar thermal systems for hot water production, or solar photovoltaic systems).

Flexibility has a cost: students can be overwhelmed by the numerous components and libraries, and they can define wrong connections that will result in meaningless results without being flagged as errors. If students do not know how a system operates, i.e. if they do not understand the physical processes involved and its

control strategies, they will not be able to create a TRNSYS model of that system. In that respect, it is the author's point of view that TRNSYS is fully aligned with the learning objectives of a graduate course on solar energy systems engineering.

How TRNSYS and other tools are used

During the first part of the course, students are encouraged to use generic software tools such as spreadsheets and EES (Klein, 2014) to solve sun-earth geometry and solar radiation calculation problems (e.g. anisotropic tilted radiation calculation) and radiative heat transfer problems (e.g. spectral transmittance and absorptance).

TRNSYS (Klein *et al.*, 2014) is used from the beginning for homework assignments, in parallel with hand calculations or generic tools. This is intended to familiarize students with the program and to provide practical examples of the notions defined during the lectures. Examples of assignments include assessing the incident radiation incident for different slope and azimuth angles in TRNSYS using different tilted radiation models (isotropic vs. Perez), comparing the sun position, extraterrestrial, terrestrial and tilted radiation values calculated by TRNSYS to hand-calculated values. Other authors use this two-step approach to help the students develop an understanding of underlying assumptions and algorithms, and intuition (or skepticism) when analyzing simulation results (Gravagne and Van Treuren, 2008; Bernier *et al.*, 2016). Simple solar thermal systems are also introduced (without requiring students to actually build them in TRNSYS) so that students can study the "instantaneous" (i.e. time-step) efficiency of solar collectors, and compare these values to the efficiency curve provided by manufacturers or certified performance tests. Later homework assignments include simple design exercises, mostly involving changing component sizes and control parameters. During the final project, the design exercise can be related to the "create" level in Bloom's taxonomy, as the students start with a clean sheet and a realistic set of constraints and objectives (e.g. reach a given solar fraction, attain the net-zero objective, or design a stand-alone system). In most cases the load (thermal and/or electrical) that the system must meet is provided to the students in data files or calculated using simple methods, so that the students can focus on the solar system itself.

Over the years, specific assignments were introduced which relied on other tools dedicated to PV systems and solar thermal systems, but this led to mixed feedback by students (it is good to experience different tools, but students need more time to learn how to use each of them), and to some uncomfortable situations for the instructors involving crippling software bugs and licensing problems. These problems can happen with any program, including TRNSYS, but it is obviously less demanding to deal with the peculiarities and limitations of one program than to do it for several tools, especially when the instructor and his/her team are using that one program for research on a regular basis.

Teaching how to use a program vs. using a program to teach

As shown in section 3, the course learning objectives are related to understanding and applying solar engineering principles, as well as simulating, analyzing and designing solar systems. "Mastering TRNSYS" (or any other tool) is not one of the learning objectives. Other university-level courses using simulation generally share that approach (Gravagne and Van Treuren, 2008; Megri, 2014; Beausoleil-Morrison and Hopfe, 2016; Bernier *et al.*, 2016). The emphasis should be on underlying assumptions and algorithms, and results analysis, rather than expertise with a particular tool. The key to applying simulation effectively for design and analysis is to develop confidence in the simulation while keeping a critical mind.

One approach to avoid the difficulties of using the software is to employ "simulation specialists" who do the modelling work while students focus on proposing design alternatives. Successful applications of this approach for teaching to engineering and architecture undergraduate students have been reported by Charles and Thomas (2009), who compare cases where the simulation specialist is an external expert, the instructor, or a subset of volunteer students. Reinhart *et al.* (2012) also relied on a pool of "simulation experts" to perform the simulation in a design exercise that they transformed into a game where students compete to obtain the lowest energy use intensity within predefined cost limits. The game was useful in teaching how to interpret simulation results and use them in an iterative design process, and also served as a teaser.

In a later paper, Reinhart *et al*. (2015) describe how the same "learning by playing" approach was applied to a group of 18 undergraduate and graduate students who performed the simulations themselves. The course

included a series of simulation exercises culminating in a game where the students competed to design the building with the lowest greenhouse gas emissions. The authors report overwhelmingly positive student feedback, but insist on the need to keep the complexity of input files provided to the students at a reasonable level. They insist that instructors must be intimately familiar with the strengths and weaknesses of the programs used, so that they can detect and explain wrong results caused by user errors or software limitations. They mention that for larger classes, the teaching staff (one instructor and a teaching assistant) will need to increase and the use of online tutorials may be required to complement lectures and lab sessions.

The approach taken by the author in the course described in this paper is to have students use TRNSYS themselves, individually (for homework assignments) and in groups of 2 or 3 (for the final project). The software is introduced right from the first assignment, and the emphasis is placed on obtaining and analysing results during the first weeks. Later assignments and the final project are actual design exercises of increasing complexity.

6. Course structure

An example of course schedule is provided on the accompanying website (see first page).

Part 1: fundamentals

After the introduction lecture, the first part of the teaching term (approximately six 3-hour lectures over 6 weeks) follows the topics presented in (Duffie and Beckman, 2013). Table 1 shows the topics and examples of assignments.

Table 1: Topics covered in lectures and examples of assignments for course part 1 (Fundamentals)

Topics covered in lectures	Examples of homework assignments
Course objectives, context, introduction to TRNSYS Examples of successful solar energy systems Worldwide context : energy and environment, solar (thermal and photovoltaic) resource and markets	**First contact with TRNSYS** Run existing solar thermal project Configure an output component (printer) Examine the impact of collector slope and azimuth Obtain and analyze results
Extraterrestrial solar radiation Solar geometry, sun position angles, equation of time	
Available solar radiation Measurement of solar radiation, clear sky radiation, beam and diffuse radiation, isotropic and anisotropic models for incident radiation on tilted surfaces	**Tilted radiation, SDHW system balance** Calculate incident radiation on a tilted surface Compare results with TRNSYS for different anisotropic models Perform an energy balance of a Solar Domestic Hot Water (SDHW) system using TRNSYS
Radiation characteristics of opaque materials Kirchhoff's law, spectral distribution of solar and long-wave radiation, absorptance, reflectance and emittance	**Collector absorptance and emittance, collector shading** Calculate α and ε from spectral properties and solar spectrum In TRNSYS, optimize collector rows (azimuth, slope, spacing).
Radiation transmission through transparent surfaces Reflection, absorption, and transmission, spectral and angular dependence of properties, transmittance-absorptance product ($\tau\alpha$)	**Collector stagnation temperature and efficiency** Calculate (by hand) the stagnation temperature of a collector In TRNSYS, examine the dynamic collector efficiency and compare to the performance curve. Students must use certified performance (ISO or SRCC) to configure the TRNSYS components.
Flat-plate solar collectors Collector energy balance, overall heat loss coefficient, collector heat removal factor and flow factor, Hottel-Willier equation, collector testing and performance data.	

Example of collaborative learning through individual assignments

In some of the assignments, students are given different conditions, which are then combined by the instructor during the feedback session to provide a complete picture. One simple example is the slope and azimuth of solar thermal collectors in an SDHW system. Students are provided the TRNSYS project shown in Figure 2 and are asked to assess its performance for a given slope and azimuth angle. All student answers are then combined and used to draw plots of the collector useful energy (Figure 2, top right) and collector efficiency (Figure 2, bottom right) for all slopes and azimuth angles. This is used to discuss the fact that the collector output is not necessarily maximum at the maximum of incident radiation (not shown in the figure) and that the collector efficiency does not really show where the system output will be maximum.

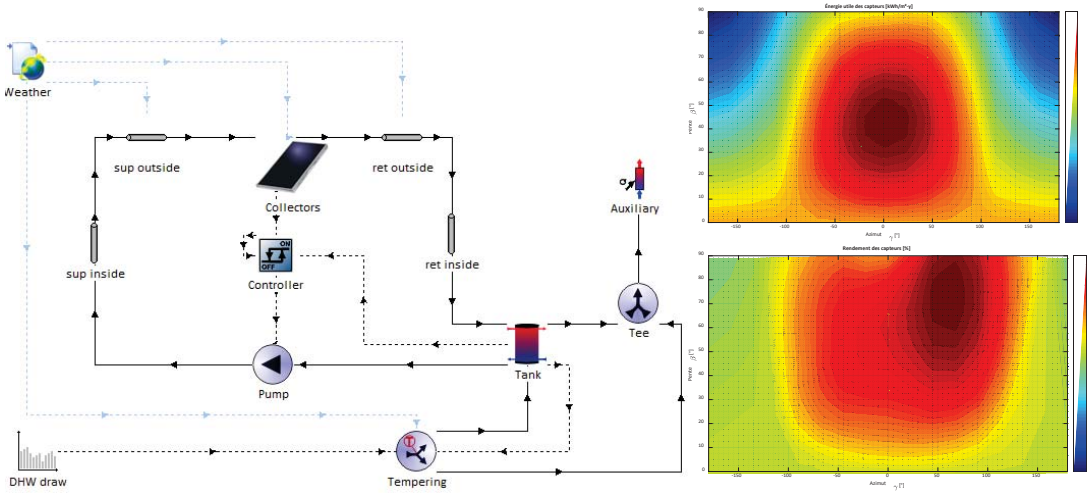

Figure 2: TRNSYS model of an SDHW system and example of results for different orientations and slopes

Part 2: applications

The second part of the teaching term (approximatively six 3-hour sessions) combines short lectures with practical design exercises. The course focuses on solar thermal applications for domestic hot water and space heating, but concentrating solar power generation and solar cooling are also covered. Photovoltaic systems are considered from a design perspective in combination with solar thermal systems, e.g. to design net-zero buildings. Occasionally wind energy is also introduced in the design of stand-alone systems. The subjects covered are sometimes adapted to make room for a graduate student who presents his/her work. Past examples include solar thermal/photovoltaic collectors, and control / fault detection of solar thermal systems.

This part of the course strongly relies on a series of homework assignments and on the final project, which all use TRNSYS. Examples of assignments and projects are again available on the accompanying website (see first page). The following paragraph briefly describe a few examples.

Design of solar thermal systems: thermal load, collectors, thermal storage

Generally, the load is provided for assignments and for the project, but for one assignment students are asked to use 2 weeks of measurements from a real site to extrapolate the design load used in a simulation. The importance of sizing the thermal storage in a solar system is shown by various examples. One assignment asks the students to compare the system performance for various collector areas and thermal storage capacities. This is also used to introduced parametric studies in TRNSYS, and student are developing the classical solar fraction vs. collector area and storage volume curves.

Photovoltaic and PV-T systems

The theory of photovoltaic system is covered briefly, the focus being on system-level design and on the interaction with other renewable energy technologies.

Examples of assignments are to design a stand-alone PV-powered system for a bike-sharing company (inspired by the actual systems in Montréal), and to design an off-grid house powered by wind and PV (optimization between the two renewable energy sources and the battery capacity).

Economic Analysis for renewable energy systems

Basics of engineering economic analysis (cash-flow, discounted payback time, internal return rate, etc.) are briefly covered. The concept of levelized life cycle cost is introduced to compare different renewable and non-renewable energy technologies. Economic analysis is typically integrated into the last two homework assignments, while the first ones focus on energy performance only. This is generally combined with exercises asking the students to perform and present energy balances, e.g. through Sankey diagrams.

Concentrating Solar Power and solar cooling

Due to time constraints, these applications, which are less relevant for the Montréal context, are typically covered in a descriptive manner through a lecture presenting the principles and successful applications. These topics generate a significant interest among the students so the possibility of offering optional final project topics is being considered.

Putting it all together: the final project

The final project is intended to be a comprehensive design exercise where students must optimize the performance of their proposed configuration through an economic analysis. The energy performance is defined by the levelized life cycle cost of energy, or specified through targets such reaching a given solar fraction, net-zero energy, or stand-alone operation. Examples of final projects are:

- Design of an SDHW system for a building serving food to homeless people (this project used data from a real project including on-site DHW draw measurements, mechanical room and roof space constraints and local shading). Students were using different weather data, transposing the real site into different contexts.
- Design of a solar combisystem with a 75 % solar fraction for a residential building (students were allowed to select any city and exact location, including local shading).
- Design of a stand-alone polar research station (latitude higher than 75°) powered by solar thermal, PV and wind with a 90 % renewable energy fraction.

One difficulty of the final project is providing detailed feedback to the students, as it is typically due at the end of the exam session. Oral presentations were used during some years but the number of students make it difficult to organize during the last weeks of the term. The project start has been moved earlier in the term (typically before the mid-term exam), and intermediate deliverables are used to provide some feedback.

7. Student feedback and lessons learned

Formal independent surveys (2011 – 2016)

Polytechnique Montréal has a formal assessment program where students fill out anonymous evaluation forms which are collected by an independent school department (“bureau d’appui pédagogique”, teaching support group). Professors then receive the compiled evaluation results in the form of percentages of agreement to some 20 questions. Two questions are related to the use of TRNSYS: one on the clarity of homework instructions (it was noticed that complaints were mostly related to difficulties with the TRNSYS files), and one on “equipment, materials, and software”. Table 2 shows responses to both questions.

Table 2: Answers to independent student surveys (in % over the 6 years, total number of respondents = 150 over 180 students)

Question	Strongly disagree	Disagree	Agree	Strongly agree
Instructions for homework assignments are clear	0.5 %	4.5 %	45 %	55 %
Equipment, materials, and software used are useful	0 %	0 %	14 %	86 %

In addition to these questions, students are asked to comment on the course in a dedicated space. All answers are again collected by the independent department and then communicated to the instructor. The question is formulated to ask students if they have suggestions to improve the course, but some students use the space to identify the parts that they especially like. The most frequent or relevant comments are summarized below:

- An overwhelming number of students write positive statements on the course as a whole and the fact that it mixes theoretical aspects (the “fundamentals” part) with practical design applications. The fact that these

practical applications are simulation-based design exercises is very often mentioned as a positive point.

- The use of TRNSYS is appreciated, and a few students have suggested also using other programs that would be more likely to be used by consultants.
- Some students have complained that the gap between homework (where "ready-made" TRNSYS projects are provided most often) and the final project (for which students start from a clean sheet) was too large.
- Some students have suggested to spend more time on how to use TRNSYS, or to organize a specific course on the program at the beginning of the term. They have also mentioned that it would help to have more online tutorials available.
- A few students have also suggested increasing the time spent in class using the software (i.e. reducing the lectures). In one extreme case, a student complained about the "fundamentals" part with "equations that we will probably never use in our engineering career", and he/she suggested replacing it with more simulation-based case studies with economic analysis.
- During the years when other programs were used, some students appreciated the mix of programs but many complained that there was not enough time to learn how to use the different programs.
- Over the years, a few students also complained specifically about the place of TRNSYS in the course, and that the course was on simulation rather than on solar energy (2 students over 6 years). One specific comment was that TRNSYS was "irrelevant in the real world", being "much too complicated".

In-class specific survey in 2016

In addition to the formal surveys, the instructor asked some specific questions at the end of the course in 2016. The written survey was anonymous, but answers were collected and processed directly by the instructor. 30 students (over 35) responded to the survey, which had 3 closed questions and was also asking for any other suggestion to improve the course. Table 3 presents the results of the closed questions.

Table 3: Answers to specific student survey in 2016 (in %, total number of respondents = 30 over 35 students)

Question	Strongly disagree	Disagree	Agree	Strongly agree
Simulation-based applications are an important part of the course	0 %	0 %	3 %	97 %
It is a good idea to use TRNSYS, which is flexible and forces users to understand how systems operate, instead of other programs that would be easier to use	0 %	0 %	37 %	63 %
Even if the course is mostly about solar thermal systems, it is a good idea to also cover solar photovoltaic systems and wind energy conversion, even briefly, and to use PV and/or wind in the final project.	0 %	0 %	4 %	96 %

The suggestions to improve the course are summarized below (the numbers in bracket indicate the number of students who made the suggestion). There were 24 comments in total for 30 respondents, and 4 of these comments repeated that TRNSYS was a good tool to understand how systems operate, which was already covered by the second question:

- (5) There should be a separate course (or some periods in the solar class) dedicated to TRNSYS.
- (3) The instructor should provide more explanations on specific TRNSYS components before they are used for the first time in homework or in the project.
- (3) More practical sessions should be devoted to TRNSYS during the course.
- (3) Other easier-to-use programs should be presented as well.
- (3) TRNSYS homework should insist more on creating systems (not just using "pre-canned" systems).
- (2) More TRNSYS tutorials and exercises should be available online.
- (1) TRNSYS documentation should be available in French

Lessons learned

Student feedback has been overwhelmingly positive on the use of TRNSYS, and most students seem satisfied that the course combines theoretical notions (through hand-written exercises and exam) with practical, simulation-based design exercises. The choice of TRNSYS is approved by the vast majority of students, even though they realize that other programs exist which would be easier to use. The second question of the 2016 survey was especially formulated to validate that hypothesis. Some students would like to be exposed to other programs, but they do see value in using a more flexible program even if it is more complicated.

The students generally suggest to spend more time teaching how to use TRNSYS, either in the solar course or in a dedicated training course. They also point at the lack of suitable online examples and tutorials. This illustrates the challenge of teaching solar energy engineering with TRNSYS rather than teaching how to use TRNSYS – it does not seem possible to avoid "software training courses" completely, whether they happen during the class or they are provided elsewhere. The students also indicated a need to evolve more progressively from the first homework assignments, which are very simple and rely on using ready-made projects, to the final project where students must create their system model from scratch. In particular, the difficulty of knowing which components to use and how each component should be used is insufficiently addressed in the present course structure. Again, training material specifically adapted to the course should be developed and provided, either as part of the course material or as online tutorials.

Although not directly indicated by survey answers, anecdotal evidence gained during the attempts to use other programs suggests that the level of comfort and expertise of the instructor with the software is critical to its successful use in teaching. If the instructor uses the program on a regular basis for teaching and research, he/she will know the software limitations and quirks. Even if the problems cannot be fixed, students can be warned about misleading indications, bugs and other problems before they get frustrated with them, which will completely change the dynamics of the exercise. In the author's experience, just quickly trying a few examples before an assignment using a program that is only used once a year for teaching is asking for trouble, even with commercial programs.

8. Conclusions

This paper presents a graduate solar energy engineering course which relies on the TRNSYS simulation tool to engage students in the learning process through design and analysis activities. The course learning objectives are discussed in relation to Bloom's revised taxonomy, showing the role of simulation in reaching the higher levels of objectives. The paper then presents an overview of the course contents, as well as teaching and assessment methods. TRNSYS is used for assignments during the entire teaching term, in order to help students gain confidence in the program and in their skills using it. Some assignments compare hand-calculated values to simulation results to encourage the developments of intuition and skepticism toward simulation results. Student feedback has been overwhelmingly positive on the use of TRNSYS, and on the fact that the course combines theoretical notions (through hand-written exercises and exam) with practical, simulation-based design exercises. Students appreciate the fact that TRNSYS encourages them to think about the design and operation of solar systems before being able to model them, even if they realize that other tools might be easier to use and deliver results faster. Students also point out the lack of training material specific to the subject, which leads to difficulties in selecting and configuring the appropriate TRNSYS components. An accompanying website provides examples of course schedule, assignments and projects.

9. Acknowledgement

I wish to thank Sandy Klein and Bill Beckman from the University of Wisconsin-Madison Solar Energy Lab, who provided material that was very helpful when I started teaching this course – and more importantly inspired me with their passion for teaching and research in solar energy.

Solar house prototypes as *living labs in architecture* for holistic sustainability education

Torsten Masseck

Universitat Politècnica de Catalunya (UPC), Sant Cugat del Vallès (Spain)

Abstract

The LOW3 prototype solar house of UPC has been designed and built between 2008 and 2010 and converted and operated as a *Living Lab for sustainable architecture and lifestyle* since 2011 at the ETSAV campus at Sant Cugat del Vallés (Barcelona) under the responsibility of the author (www.livinglab-low3.blogspot.com)

This paper highlights the importance of *Living Labs* as innovation infrastructures in Higher Education and presents the specific educational experience of LOW3 within the institutional framework of UPC, drawing from 5 years of action research regarding pluridisciplinary, experience based sustainability education.

Keywords: *Living Labs, Education for Sustainable Development, Sustainable Lifestyle, Sustainable Architecture, Solar Architecture*

1. Background

Education at schools of architecture must attend the demand for a new profile for architects, integrating and fostering corresponding SD competences through new learning methodologies, tools and concepts (EDUCATE Project Partners 2012). A series of recent developments give relevance to the research on *Living Labs in Architecture* as new tools for a holistic Education for Sustainable Development (ESD) with a specific focus on renewable energies in housing and our daily lives:

- A new educational reality, with redefined objectives in higher education based on competence-based learning and a more transdisciplinary approach
- A new knowledge reality, with an urgent need for acquisition of new knowledge regarding specific subjects like low energy buildings, low-impact building materials and energy efficient technologies
- A new social reality, shifting towards participation, constant social innovations and a higher demand for environmental standards
- A new professional reality, requiring more interdisciplinarity, the ability to deal with complexity and uncertainty and new forms of project development processes based on collaboration

Important considerations regarding the essence of ESD are furthermore the understanding of sustainability as a (socially constructed) reality, "*... as a dynamic and/or evolving concept, as controversial and the source of conflict*", and as a "*catalyst for change*" (Wals & Jickling 2002), which in consequence needs places for its collective negotiation and definition. This might require a new form of collaborative and empathic learning in order to develop a new collective "*biospheric consciousness"* (Rifkin 2011). Finally ESD seems to require so-called "*transformative learning"* based on psychological, convictional and finally behavioral transformation (Wiek et al. 2011, Boehnert 2012). On the other hand a newly strengthened social responsibility of university towards society in the development of innovative solutions for our environmental, social and economic conflicts must lead towards new processes in teaching, research and technology transfer based on a strong interaction with their local and regional communities and society in general (Cortese 2003). Living Labs seem to play here an interesting role as collaborative multi-stakeholder platforms.

doi:10.18086/eurosun.2016.10.06 Available at http://proceedings.ises.org

2. Introduction

In the area of architecture, the ETSAV School of Architecture at Sant Cugat del Vallés can be considered a pioneering institution in understanding its campus and buildings as a laboratory to learn about energy efficiency in buildings, but also its community as an important stakeholder for a broader approach to sustainability regarding its socio-economic environment.

Solar Decathlon is an international competition for 20 selected universities to plan and build prototypes of energy self-sufficient solar houses. In 2008 a first ETSAV team under the lead of the author started the development of the first prototype solar house LOW3 at the campus in order to participate in the Solar Decathlon Europe 2010 competition in Madrid (Masseck 2011).

The LOW3 project (2008-2010) demonstrated over a 2 year period the importance and impact of a new way of education in architecture, based on the development and construction of a prototype house at the campus with a high degree of team self-organization, individual responsibility, and a strong link between teaching and research.

LOW3 has been reconstructed in 2011 and renamed *Living Lab LOW3 – Laboratory for sustainable architecture and lifestyle* at the ETSAV Campus at Sant Cugat del Vallès (Barcelona) with the objective of establishing an open platform for collaboration with companies, and an exploration of experience-based concepts for teaching, research and innovation activities.

Living Lab LOW3 adds since then value to the academic offer at UPC-Barcelona Tech through its innovative transdisciplinary educational programs, transmitting experience-based knowledge about integrated energy design in architecture and a holistic approach to sustainability. This paper argues that Architecture Living Labs like Living Lab LOW3 make a positive contribution to architectural education in its approach to sustainability including the holistic paradigm shift towards solar architecture, renewable energies and standards like Nearly Zero Energy Buildings.

3. Methodology

The concept of Living Lab LOW3 is influenced by the concept of user involvement in research and innovation, derived from the definition of Living Labs, as well as the co-creation and open innovation in real-life settings through a multi stakeholder approach (academia, companies and research entities but also local administration), understanding both students, researchers as well as citizens as the "users" of this newly generated platform. (Masseck 2013)

The concept of Living Lab LOW3 is that of an activities platform with a participatory approach to teaching and learning based on a prototype solar house, offering its spaces, its equipment and its infrastructure to diverse user groups from both inside and outside the UPC.
Teaching and learning activities take place in parallel with research projects and outreach activities in order to create synergies between sectors, people and disciplines. Finally, Living Lab LOW3 is also a place for the networking of people in order to engage in new sustainability projects and initiatives, fostering the human factor behind these activities.

Living Lab LOW3 is an educational research project under continuous development since January 2011. During almost 5 years of its existence, new teaching formats, methods and tools have been tested regarding the link between formal and non-formal learning, the exploration of the personal learning environments of participants and the synergies between teaching, research and innovation.

Living Lab LOW3 applies a mixed-methods approach with quantitative and qualitative research methods. Phenomenological research has been used in the Live-at-LOW3 experiment, evaluating the experience of students living a sustainable lifestyle in the LOW3 solar house. The tools used are surveys, questionnaires, semi-structured interviews, amongst other formats like video documentaries and participant's videos.

4. Results

Results of this innovative educational project can be described in the following areas:

- *General educational and research activities* referring to a huge amount of diverse activities regarding teaching and learning as well as research and innovation at an university campus
- *Specific Living Lab teaching formats* regarding innovative approaches to sustainability education applying a user-centered living lab approach, and
- *Activities as a higher education transition platform,* which contributes to a holistic sustainability transition of university and the society it is embedded.

4.1 Activities at Living Lab LOW3

Since 2011 3 regular Living Lab LOW3 courses, 6 innovation seminars, 2 international sustainability seminars, 1 house occupation experiment, 5 open doors days and around 25 educational visits have taken place at Living Lab LOW3, with links to different Master and PhD Programs both inside and outside the UPC and the ETSAV undergraduate program. Additionally more than 30 specific events opened up the house to user groups to disseminate knowledge to the academic community and beyond.

Fig.1 shows an educational activities map of the project, resuming the areas of knowledge; disciplinary, transdisciplinary and ESD related initiatives, as well as the corresponding formats, methods, and outcomes:

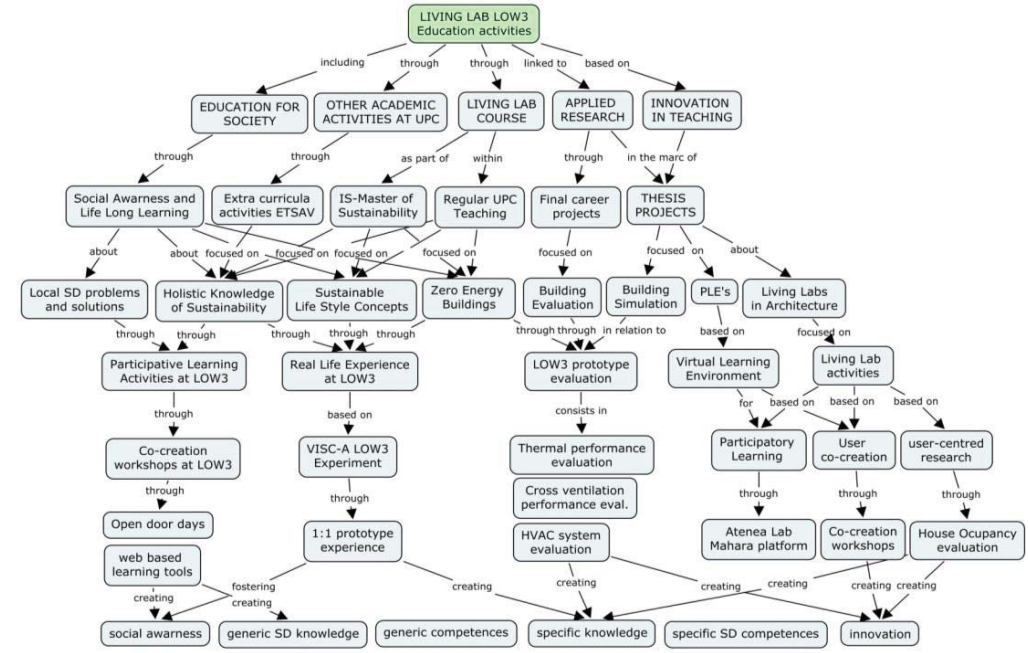

Fig. 1: Educational activities map Living Lab LOW3

4.2 Live-at-LOW3 Experiment

One of the most intensive, experience-based, transformative teaching and learning activities has been the 'Live-at-LOW3' experiment, a house occupation experiment in 2012.
The 'Live-at-LOW3' experiment was carried out within the elective course "Living Lab LOW3", linked to the Master Program Sustainability (IS.UPC) and the ETSAV undergraduate program.

This teaching and learning concept needed special commitment by the participating students. No regular timetable could be guaranteed during the course. The house-occupation experiment has been a holistic approach to user-centered research.
Two selected students evaluated and tested the prototype solar house during 14 days with the participating course students preparing, accompanying and evaluating the experiment through the monitoring and evaluation of the inhabitant's lifestyle with a holistic view on housing, consumption, food and mobility.
This course had a transformative effect on its participants, as in parallel to the generated theoretical knowledge about sustainable lifestyles, the related experience-based learning showed to be highly effective.

The experiment included:

- Monitoring energy consumption (daily consumption, relation to daily activities, comparison with solar production)
- Assessing water consumption (grey water recycling, dry toilet, water saving measures)
- Measuring waste production (daily production, type and weight)
- Assessing indoor comfort (day and night comfort in the house, privacy, air quality, noise)
- Reporting about food habits (local market, own vegetable garden and even 2 hens at the campus)
- Calculating the overall ecological footprint of the inhabitants

Results were published in course reports[1], the experiment was filmed and published through a documentary as well as local newspapers, and television showed interest in the experiment and its outcomes[2].
A holistic learning and user-centered research process was conducted in order to evaluate the LOW3 solar house, its concept, its technologies, and the resulting comfort for inhabitants. A wider engagement of the academic community, as well as society in general, could be achieved through open door days, media interest (national and local TV and radio emissions, digital newspapers) and the use of social networks and ICT (YouTube channel for video diary, documentary, live webcam).

The educational experiment was very successful, with students evaluating their participation and related learning as very positive. Nevertheless the educational format had to overcome administrative and legal issues, was time consuming for all participants, depending on a special personal commitment of all participants, and needed a certain amount of economic resources, which is the reason why this format could not be repeated since then.

4.3 The role of Living Lab LOW3 as multi-stakeholder platform

Living Lab LOW3 has shown to function as a multi-stakeholder platform for the following activities:

- Interchange between the professional and the academic world of architecture, bringing together professional associations interested in life-long learning and additional professional qualification programs, and the university (students, teachers, research groups), creating synergies between the academic and the professional world of architecture and building construction.

- Link to the productive sector of the building industry, allowing synergies in the knowledge dissemination about materials, products or services, within an environment which allows critical reflection, in-situ evaluation and as a consequence, a creative approach to innovations.

- Link to public administration, allowing collaboration between municipalities and academia regarding knowledge generation and dissemination, consultancy services, formative activities as well as specific project developments.

[1] http://www.low3.upc.edu/eng/plataforma_eng.html
[2] http://www.livinglab-low3.blogspot.com.es/2012/10/fin-del-primer-experimento-visc-low3.html#more

- Link to society, offering a place for knowledge dissemination and critical reflection, learning and experiencing different aspects related to a more sustainable lifestyle like the resource consumption in buildings, the environmental impact of materials, alternative forms of living such as co-housing, or the amount and impact of food and water consumption in private households.

- Transition Platform for the academic community, serving as a place for meeting, working and innovating for all kind of groups of the academic community (and beyond), generating synergies and allow the creation of new initiatives e.g. for HE transition projects towards SD, or community outreach projects, organized by student teams or even administrative staff. This approach reflects the idea of Living Labs as *Transition Arenas* e.g. for SD transition of HEIs. (Masseck 2016)

Figure 2 shows the diversity of uses of Living Lab LOW3 for research, teaching and outreach.

Fig. 2: Diversity of uses of Living Lab LOW3 for research, teaching and university outreach

Living Lab LOW3 today forms part of a new, emerging educational ecosystem at ETSAV, which links formal teaching with informal learning and established educational courses to a whole series of outreach initiatives supported by non-formal learning environments at the campus.

5. Conclusions

Architecture Living Labs can serve as multi-stakeholder platforms, which connect the academic world with its surrounding - the professional world of architecture and building construction, the productive sector, public administration, and last but not least, society as a whole. Through its experimental character, Living Labs can offer a place to meet, reflect, discuss, learn, explore and develop ideas, concepts and strategies with regard to sustainability in a most holistic way, not only limited to architecture but also considering the lifestyles adopted by society which include existing consumption and production models, political and economic issues, as well as social processes and innovations.

The diversity of activities related to one single platform like Living Lab LOW3, allowed the creation of many synergies among actors, programs and projects. Stakeholders have the opportunity to participate in a community of users beyond established academic structures, with transversality from high school students up to senior researchers.

In this sense Living Labs can be seen as social ecosystems within the specific context of university and with a strong link to the surrounding socio-economic context, fostering the creation of transversal educational communities.

SHWwin: freeware (beta stadium) for Universities and schools for the simulation of solar thermal plants

Wolfgang Streicher[1] (Author), Dietmar Siegele[1]

[1] University of Innsbruck, Unit for Energy Efficient Buildings, Innsbruck (Austria)

Abstract

The simulation software SHWwin is being developed since 1993, first at the Institute of Thermal Engineering at Graz University of Technology, Austria and since 2009 at the Unit for Energy Efficient Buildings at the University of Innsbruck, Austria. In 2015 a new Version compatible with 64bit Operating Systems (Windows 7© and higher) was relaunched. Several new features like swimming pool, second domestic hot water store, English language, statistics on temperatures and pressure distribution, thermotrophic or back cooled collectors and others were implemented and a new layout of the graphical user interface was developed.

Like the old Version also the new Version is available for free from the author to be used for education and research. SHWwin has a large number of sets of hydraulic layouts. As all parameters of e.g. heat stores (position of in/outlets, sensors) and control can be chosen freely, it is a nice tool to show students dependencies and relevance of the parameters and allows optimizing plants. Climate data can be taken from e.g. Meteonorm (2015) or any other source.

Keywords: *Simulation Tool, Solar Thermal Systems, Freeware, Education,*

1. Introduction (SWC_Heading1)

Several tools for the simulation of solar thermal plants are on the market. Besides tools with predefined hydraulics like TSOL (2015) or Getsolar (2015) there are tools with free definable hydraulics like Polysun (2015) or TRNSYS (2015) available. SHWwin is closest to TSOL-professional but is available for free for educational and research purposes. It is being developed since 20 years and the recent update has a new GUI and several new features like swimming pool, Tank-in-Tank storage, 2nd DHW store, thermotrophic layers as collector cover, maximum allowed temperature at stagnation for the collector pump to switch on, statistics about temperatures and pressures in the system with expansion device layout, and can be run under Windows 7© or higher. There is no online help desk available, but reports on bugs are always welcome and will be repaired as fast as possible with updates to all users. Translation of the GUI in other languages or the translation of the help file from German to English (and other languages) would be welcome.

2. Functions of SHWwin

SHWwin runs on all windows platforms starting with windows 7©. Additionally the kernel (an .exe) file can run standalone using the ASCII input files normally generated by the GUI. All input and output files including weather data can be edited also manually as ASCII files. So a coupling to other tools like e.g. MatLab or GenOpt is possible. SHWwin simulates dynamically solar thermal systems. Time steps can be chosen freely, but 3 or 6 minute time step is recommended.

Climate data on a hourly base can be used either from climate date generators (e.g. Meteonorm (2015)) or from other measured or produced hourly data.

doi:10.18086/eurosun.2016.10.05 Available at http://proceedings.ises.org

The following solar thermal plant designs can be simulated:

- Domestic hot water plants
- Combined domestic hot water and space heating plants (two store systems, one store system and DHW once through heat exchanger or Tank-in-Tank)
- Both of the above can be coupled with an indoor or outdoor swimming pool
- Solar assisted district heating networks

Each plant design allows several variations e.g. the choice of:

- Internal or external heat exchangers
- Fixed pipe positions or stratifying units or two inlets/outlets at the tank.
- All positions of heat exchangers, in/outlet pairs and temperature sensors can be freely chosen
- How the auxiliary heat is delivered (immersed electric rods or external boiler). The boiler can deliver only in the buffer (space heating) store or in both stores (SH and DHW)
- Auxiliary heat to DHW store (if chosen) can be either delivered directly from boiler or via the buffer store. Additionally an electric direct heating rod is available.
- Priority for solar heat input on space heating, domestic hot water, swimming pool or to the currently lowest temperature is available

Several collector volume flow strategies are available (see Figure 7, left column bottom)

- Fixed mass flow (can be freely chosen).
- Variable mass flow with either fixed collector outlet temperature or fixed ΔT between collector outlet and highest heat sink (e.g. for district heating systems)

Figures 1 – 3 show examples for hydraulic layouts.

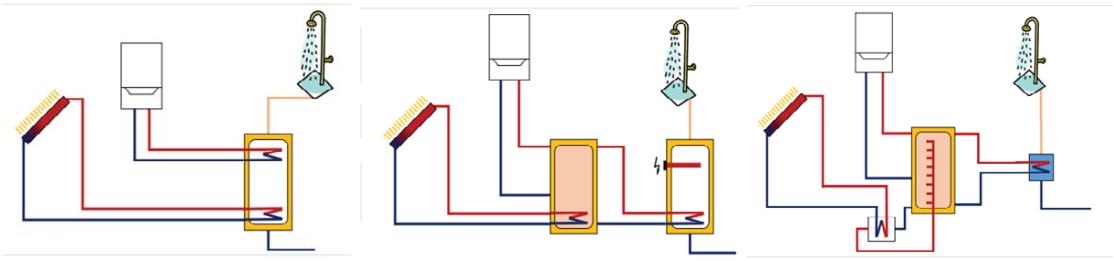

Fig. 1: Examples for hydraulics for domestic hot water (DHW) systems

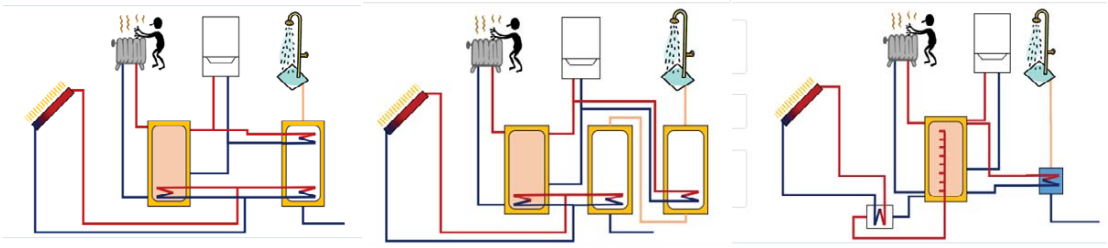

Fig. 2: Examples for hydraulics for domestic hot water and space heating systems (Combisystems)

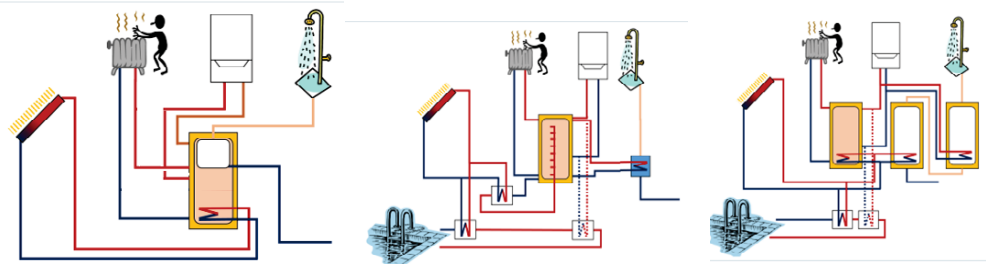

Fig. 3: Examples for hydraulics for domestic hot water, space heating and swimming pool systems

Plant Control settings

- On/Off temperature difference for the collector loop
- Blocking of state of collector loop for a specific time.
- Setting of a maximum temperature above which the collector pump cannot start to prevent the start of the collector pump during a stagnation period with steam in the collectors.
- Temperature settings of solar, boiler and electric rod input (maximum temperature, hysteresis)
- Temperature difference to load DHW store from space heating store to the domestic hot water store (if this plant design is chosen)

Additional available functions are

- Generation of statistics of temperatures and pressure in the collector loop. For this function the expansion vessel is either designed automatically or can be chosen. The volumes of each part of the solar loop have to be given by the user. For this function a coupling to Excel© is made. Results are tables and graphs, the latter are shown in Figure 4.

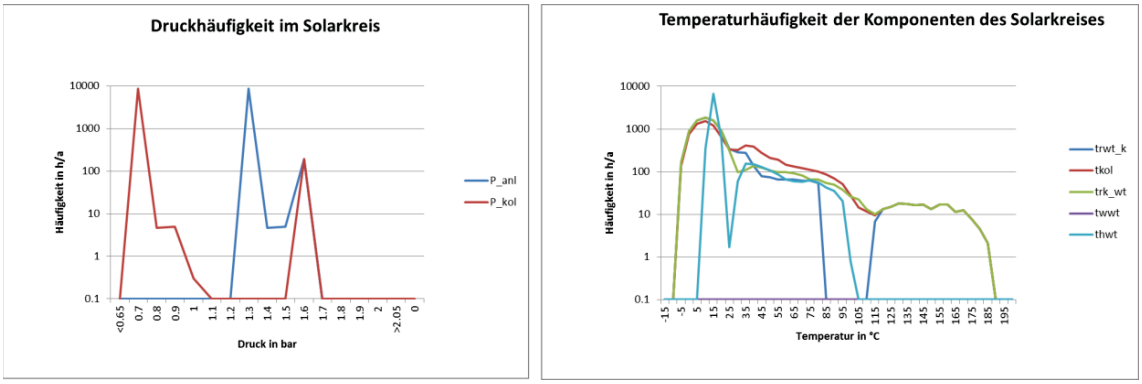

Fig. 4: Collector loop statistics of pressure and temperature in SHWwin

- If measured data of auxiliary heat input into the buffer store or the heating system, the domestic hot water demand or the space heat demand was measured in a real plant, this data can be used as input and overrules the respective simulation data.

3. Description of the SHWwin GUI

Currently the GUI is available in German and English language. To change between the languages the option button has to be clicked. When the language is changed, the program has to be shut down and restarted. The F1 online help is currently only available, if the German language is chosen.

When starting, first of all, a weather data file has to be chosen. All relevant main project data including a picture of the plant can be given (see Figure 5). Here also some general simulation values (start, end, number

of time steps per hour ...) and the specific general functions stated above can be chosen. In the standard data set of SHWwin there are already some weather files available.

The next step is to choose the hydraulic system (Figure 6). Figures 1 to 3 show examples for systems available. Then, details for all components have to be defined. First the general system can be chosen in the above part and then hydraulic details can be added in the lower klick box area. The graph on the lower right side is changing accordingly, so that the user can directly see, which configuration is chosen.

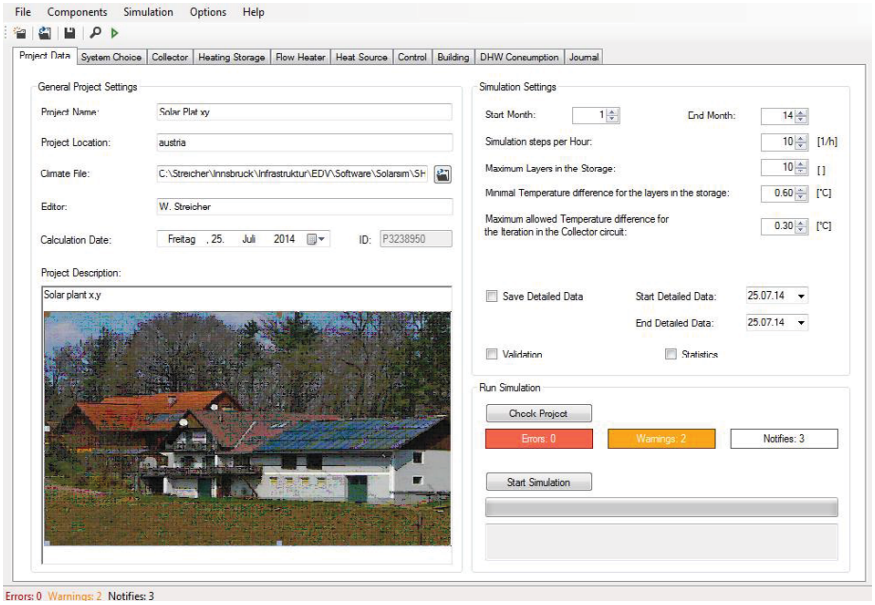

Fig. 5: System choice and visualization in SHWwin

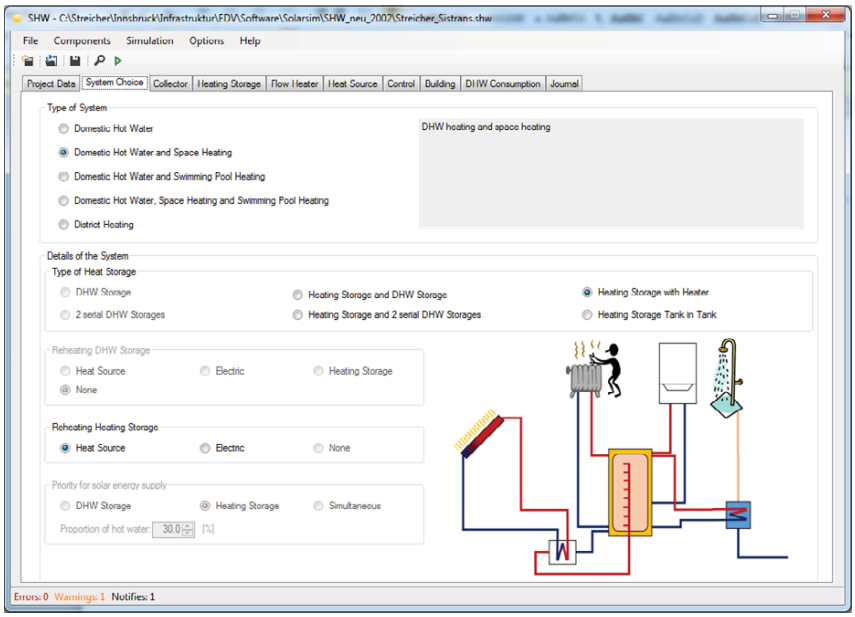

Fig. 6: System choice and visualization in SHWwin

After this, the input data of the different components have to be filled in. All fields are already prefilled with default values that allow immediately a simulation run. For many components databases are available, which are partly filled and can be edited and expanded by the user.

Figure 7 shows the inputs for the solar collector. The grey values on the left column are taken from database values (accessible by clicking on the first input box on the left column below collector). An old database from SPF Rapperswil, Switzerland is available for collectors which can be expanded by the user. Of course all values can be changed by the user clicking on "Edit Free". The input is related to key values of collector tests (parameters for the characteristic curves for efficiency and incident angle modifier and the thermal active mass of the collector).

The right column shows the volume flows through the collector to different stores. The input is given as relative value [kg/m$^2_{collector_area}$, h] grey values give the absolute resulting volume flow. Also some fixed fluid properties and the connecting tube characteristics have to be given.

On the very low right side collectors with thermotrophic layer or backside cooler for maximum temperature control during stagnation of the collector can be defined by putting in parameters for the change of the collector efficiency curve depending on the mean collector temperature. For thermotrophic layers the conversion factor c0 and for the backside cooler the heat transfer coefficient c1 are altered by an additional temperature dependent factor fc0 or fc1. Figure 7 right shows a sample dependency.

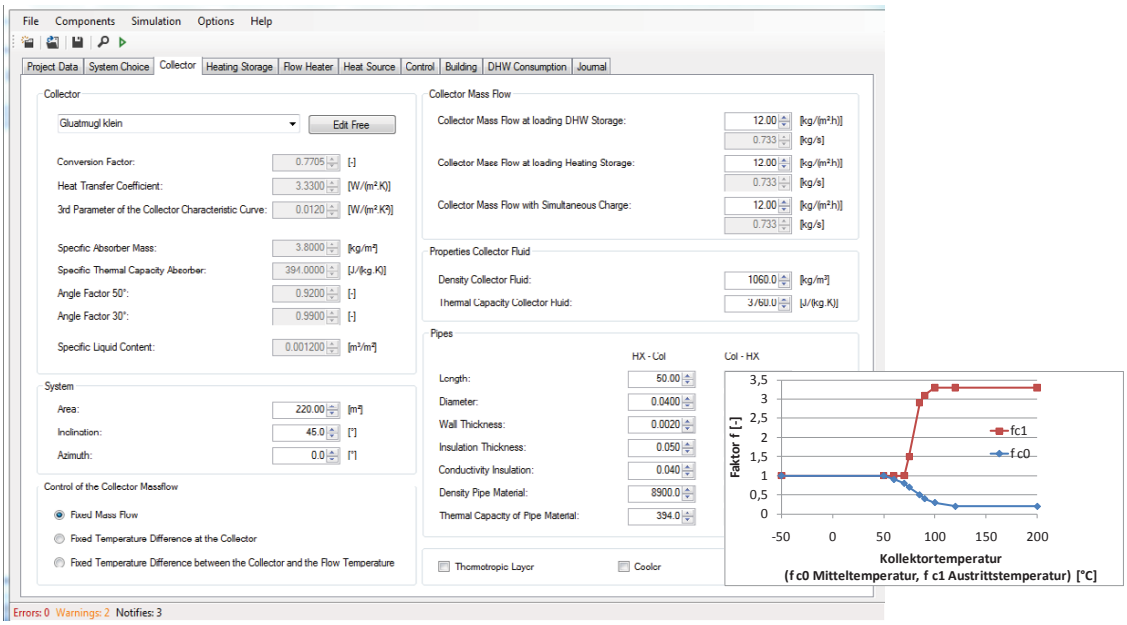

Fig. 7: Input for solar collectors and solar loop in SHWwin

Figure 8 shows the input data for domestic hot water store. All volumes, heights, insulation thickness and properties etc. can be freely chosen. The graph in the lower right is changing accordingly, thus the visual control of the store design is given. Additionally key values like volume for backup heating and solar are calculated simultaneously and shown to check the input data.

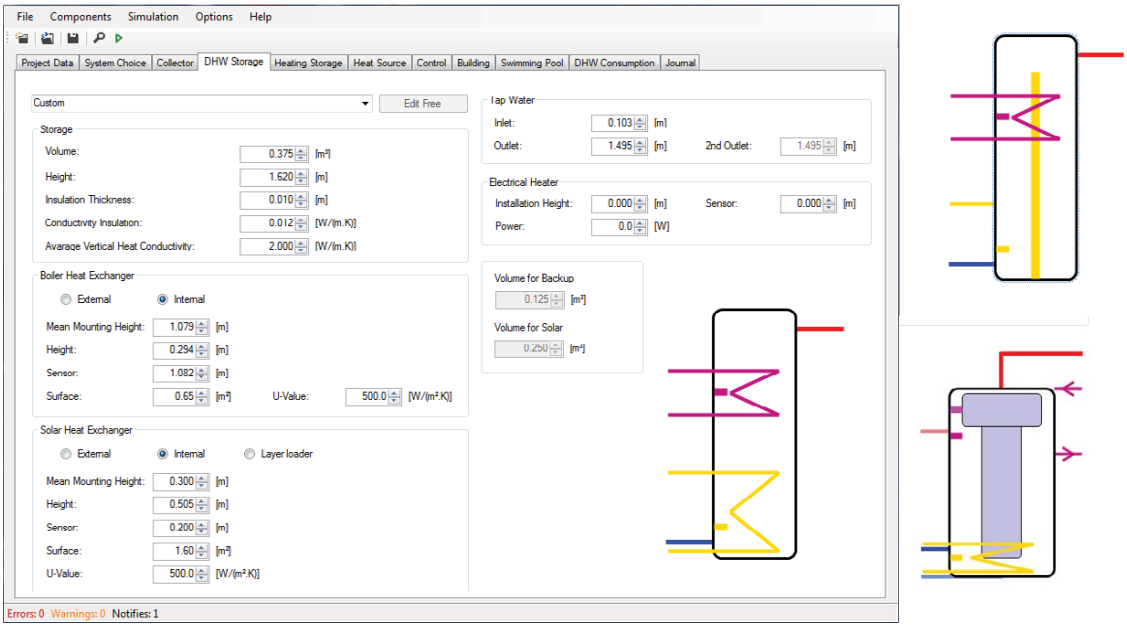

Fig. 8: Input and visualization of water stores for different types of heat input and output in SHWwin

The domestic hot water demand (Figure 9) can be given in terms of standard daily use with daily, weekly and monthly distribution. The cold water temperature can be varied via sinus curve variation over the year with the lowest temperature in February. Additionally a domestic hot water circulation can be defined.

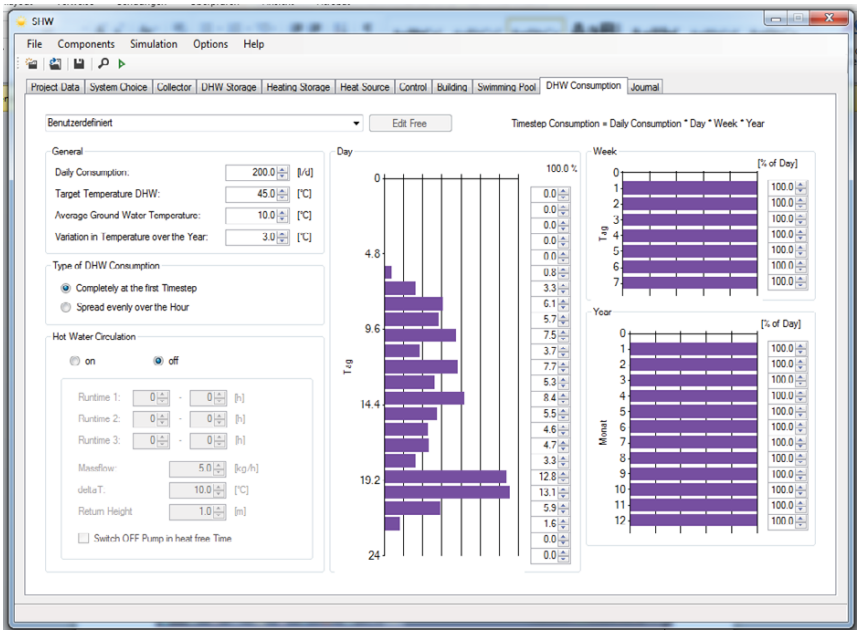

Fig. 9: Input and visualization of the domestic hot water demand in SHWwin

The space heating demand (see Figure 10) can be defined by the heat load reduced by internal gains and unheated parts as well as by the solar radiation passing up to 6 defined window areas. The flow/return temperature to the heating system is given as heating curve over the ambient temperature including a radiator exponent. The resulting curve is visualized for understanding and control purpose.

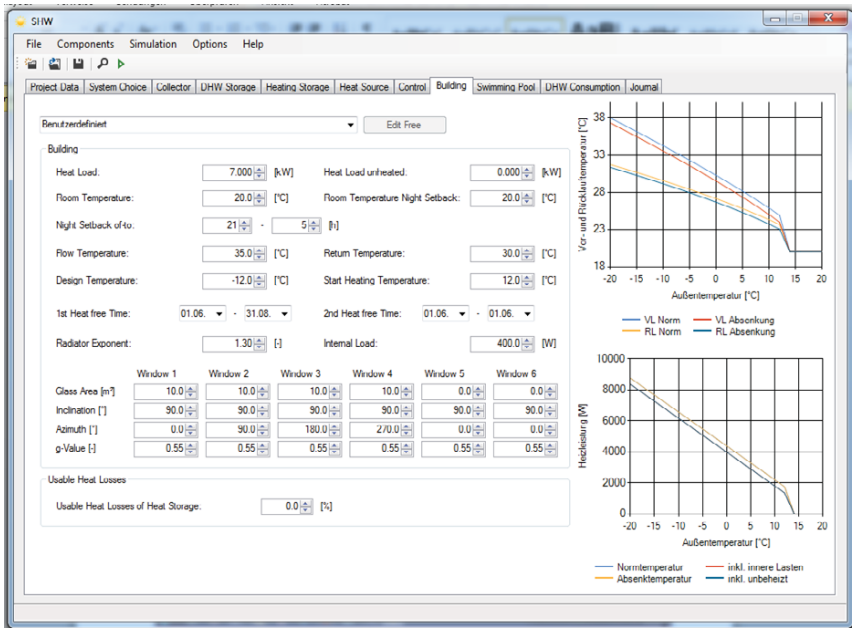

Fig. 10: Input and visualization of space heating demand in SHWwin

If a solar assisted district heating system is chosen the heat demand is defined by a space hating load and temperature curve over the ambient temperature (Figure 11). The domestic hot water demand is added to the given heat load.

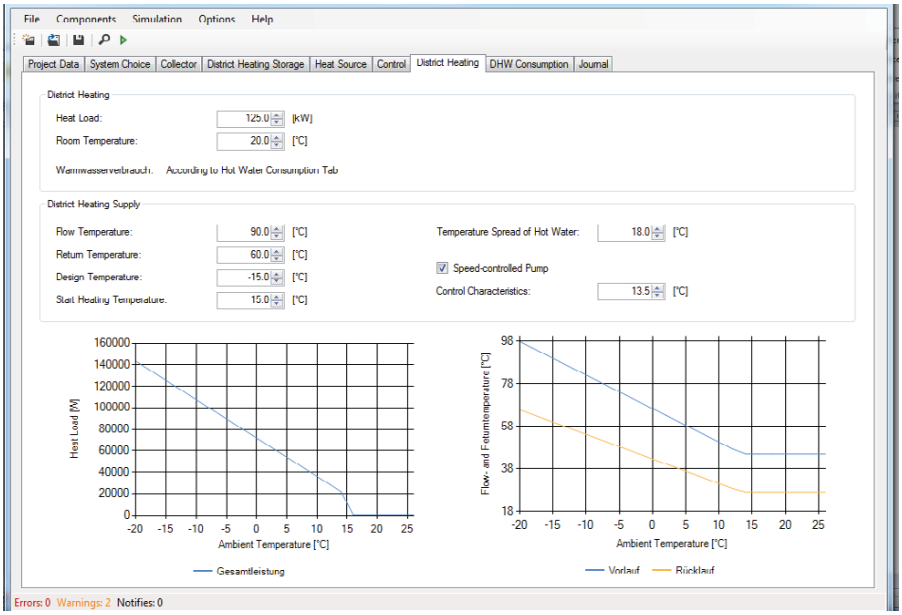

Fig. 11: Input and visualization of district heating network demand in SHWwin

An Online Help via the F1 button is available, if the German language is chosen. For every input value the online help can be invoked by clicking on the respective input button and then pressing F1. A help message with description of the value and some additional information will pop up (see Figure 12).

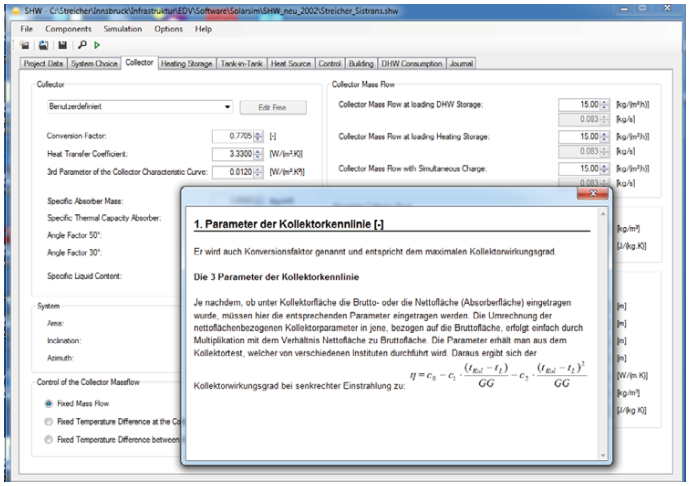

Fig. 12: Online Help via F1 in SHWwin (only if German language is chosen)

Before starting the simulation a check of the input data is performed and Errors, Warnings and Infos are delivered. This check can be invoked manually by pressing the magnifying glass. Also in the lower left edge of the window the actual number of Errors, Warnings and Infos is shown. By clicking on it, clear text messages about the nature of Error/Warning/Info (in German) show up and hints how to correct the input data are given. This is very important, as the input data can be freely chosen and e.g. heat exchangers or sensors could be placed above or below the storage. Additionally stability values are checked (e.g. if the volume turned around between an inlet/outlet pair in one time step is bigger than the volume available). The input boxes that induce the error are marked red. Figure 13 gives an example for errors occurring at a tank-in-tank buffer store inputs. As long as there are Errors in the input file (e.g. the heat exchanger is below or above the store) the simulation does not start.

Warnings give the user information about control settings that are not matching to the temperatures of the demand or too low auxiliary power. The simulation can be started despite the existence of Warnings. The respective input boxes are marked orange. Info's just give some hints on detailed system layout.

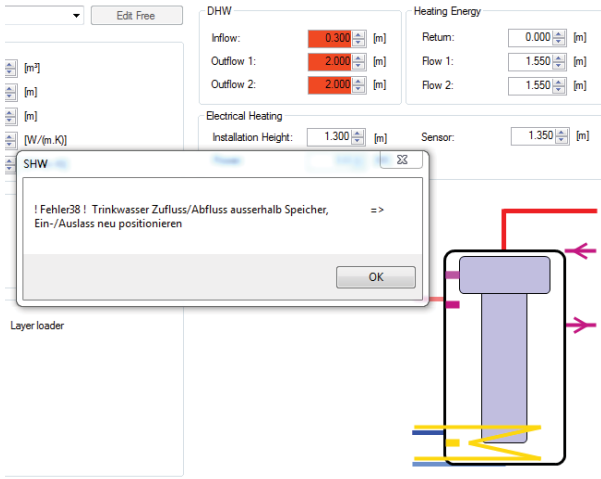

Fig. 13: Inherent input data check and display of input mistakes including suggestions for improvement

After the simulation is finished a summary with monthly and seasonal data and KPI's (key performance indicators) and some graphical and ASCII-data output is available. Additional this output includes all input data in (German) text including the units and can be seen as simulation protocol. Figure 14 shows the respective window with the first part of the output data.

Fig. 14 Output from for monthly and seasonal energy balance

Additionally the values can be shown as graphs on monthly or daily bases (Figure 15) as well on a time step bases for a selected time period (one file per day). To select the time step based output, the respective values have to be set in the project register card (see Fig. 5) in the middle right. The values to be shown can be chosen, the nomenclature can be found in the (German) handbook.

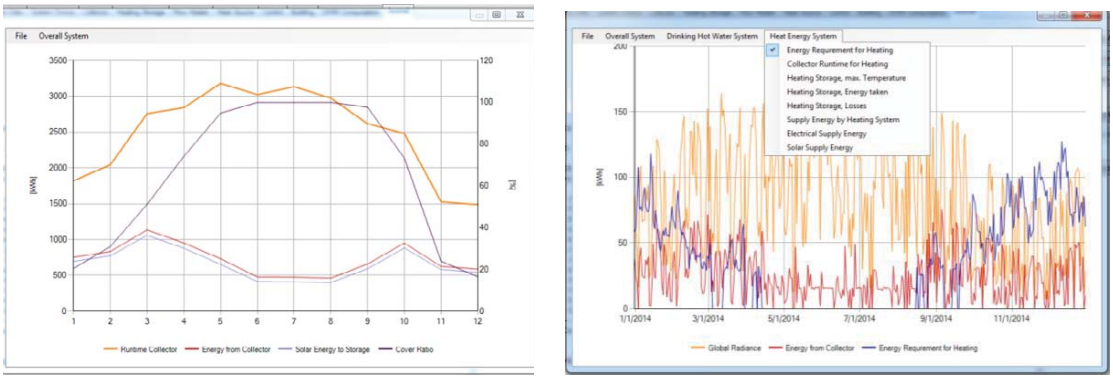

Fig. 15 Graphical output for selected values on monthly and daily bases

Input files or project files can be shared. Each project gets a number and one can save the project file at any place of your computer. This file is very small and can be sent to colleagues that can open it again with their SHWwin Version.

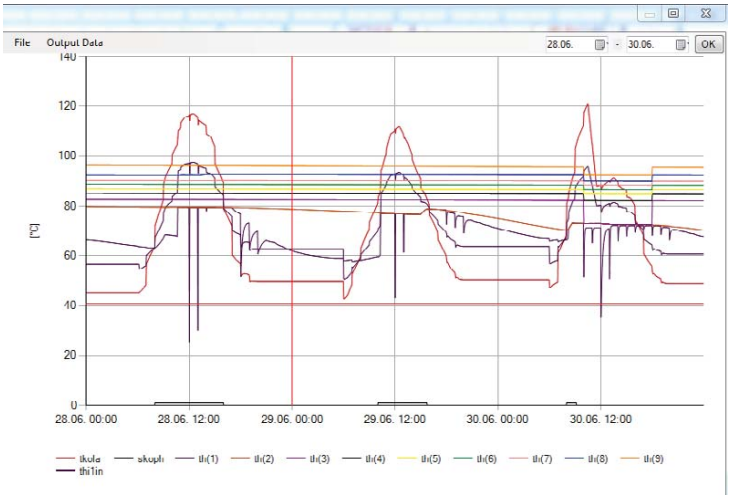

Fig. 16 Graphical output for selected values on time step bases (store temperatures, collector outlet temperature, store inlet temperature, running time collector)

The whole program is available for free for educational or research purpose at Innsbruck University. Just send an E-Mail to wolfgang.streicher@uibk.ac.at. A ZIP file will be delivered with the installation files, some weather data and a full German manual. As it is freeware, there is NO online support available. Of course, there may be some bugs in the program. The author would be happy, if you can send him a description of the bug and the respective input and weather data file.

As the full program is only available in German language and the GUI also in English language, the Authors are looking for helping hands to translate the GUI and the HELP files into other languages. As .xml structures are used for all text inputs this can be quite simply integrated. Volunteers can contact the author for more details.

No liability is taken by the authors for any results of simulations with the SHWwin program.

Methodology in the teaching solar energy, IDEA

Torres Montealban Jonas

Universidad Autónoma Chapingo, Km 38.5 Carretera México-Texcoco, MEXICO

Abstract

The aim of this paper was design, apply and evaluate a teaching-learning experience in physics, by means of implementation of a methodology: integration didactic with exploration applied (IDEA), with students of precollege level. We considered for this study, solar energy applications and we worked in four stages, each one of which represents the elements of methodology: the integration of learning theories, the teaching of discipline, the exploration with worksheets and the application in prototypes. Participated in this study 47 students and we review the topic of transfer of thermal energy. Therefore, through exploring with PreTest and PostTest, during and after the intervention methodology; we get an integrating conceptual in the topics studied. Finally, was possible to achieve a significant conceptual gain in both the acquisition of cognitive and procedural elements. Accordingly, the methodology can be an alternative in the teaching-learning process of physics.

Keywords: *Physics education, worksheets, didactic integration and solar energy.*

1. Introduction

We can apply different strategies for understanding physical situations, this depend of historical moment or and theory teaching learning that is fashionable. However, there is no recipe that can be applied in solving contextual problems, or a general theory of education that give respond to different aspects of thinking of students in the classroom and their relationship in everyday life. In this sense, behavioral learning theories; Humanistic, Cognitive and Information Processing, to mention some; which develop activities that fail to be consistent with the results obtained by educational researchers in the classroom. However, they try to give an order to guide students in solving science problems (Hardin, 2013).

Based on the above, it is to reflect on: the what, the how and, what for, the problems are solved in physical situations into the classroom and these can be transferred to situations of human activity. Move from something memoristic to the critical thinking; from to simple association, to the understanding of problems in the classroom; from lab, to the problems in everyday life. We have implemented in the topic of transfer of thermal energy, for the course of pre-university physics: the IDEA methodology (by its acronym), based on the following four processes concatenated.

Integration of learning theories

In a classic sense, and with proven qualities in the teaching-learning process, we know that students can be involved them with many differences styles of strategies, as shown in Figure 1; collaborative work, the problem solving, (Mendez, 2014), active learning (Sokoloff and Thornton, 1997). Lab activities (Gros, 1990). Thus, develop of attitudes and critical point of view, about the phenomenology. With this, it was possible the achieve objectives, as: developing of skills cognitive, metacognitive and instrumentals, (Segura, 1984).

doi:10.18086/eurosun.2016.10.02 Available at http://proceedings.ises.org

Didactic of Physics

In the case of thermal energy, in which we pretend to analyze and describe the ideas that students have about the transfer of thermal energy: conduction, convection and radiation; in order to generalize the transformation and conservation of energy. The information with we begin the study, we obtained from data collection instruments, questionnaires, which is designed through reliability and validity a analysis process (Sampieri, et al., 2006). These instruments are referred to previous teaching experiences on the same theme and with discussions in academic meetings with physics teachers. With these criteria, we approach reliably to an appropriate instrument where we could observe the representation the concepts and variables that they were taken into account for the measurements, (Sampieri, et al., 2006).

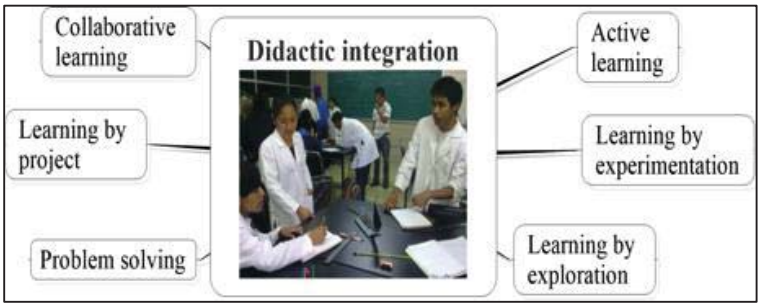

Fig. 1. Didactic integration, theoretical-experimental.

Furthermore, we also consider the concepts that students have in everyday language about the "heat" (Lara and James, 2013). And there are two points of view on how to introduce the concepts of thermal energy transfer. The first one, has to do with the systematization of the concept of energy conservation. The second one, has to see with a gradual process of knowledge nucleus, which are incorporated into the new attributes, to complete the meaning of the mechanisms of thermal energy transfers; conduction, convection and radiation, (Solbes and Tarin, 2004). The two aspects were part of the design of data collection instruments and the IDEA learning activities, It was with the aim of introducing the concept of "heat" as a measure of thermal energy transferred in a particular type of process; for our study is the use of solar thermal energy, (Sandino and Lilia, 2012).

Exploration with worksheets

Through explorations with sheets, a path didactic methodology IDEA of teaching learning is obtained in the classroom-laboratory, by way of elucidate the problems to be explored, and the analyzing the possible resolution and their documentation. With these data collection instruments, learning is monitored, the difficulties to be addressed are identified and also we make emphasized on developing thinking skills and characteristic procedure of sciences like physics, (Michelini and Stefanel, 2012).

On the other hand, for us like teachers, they became design tools and reflection, on the learning processes of students. And with that obtain instruments work and data collection, with the possibility of transforming teaching practice in a research on action. It is so, as were designed, they implemented and analyzed four PretTest and their posttest. The worksheet were designed between peers academics and open discussions. As result we have eight elements to highlight in each of these worksheets, as show on Figure 2.

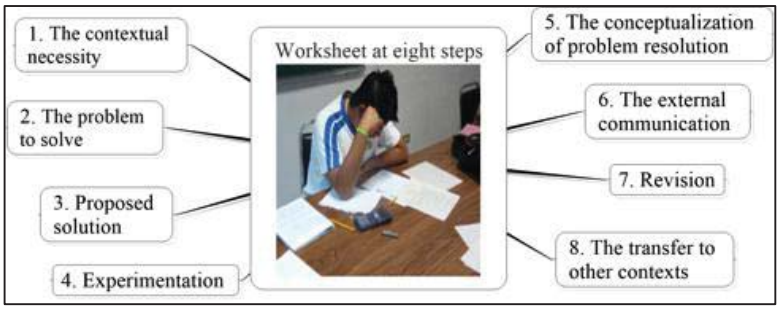

Fig. 2. Eight elements of worksheet.

The surveys features are listed below and are part of the integrated assessment through of methodology implementation. Survey I, questionnaire that provides conceptual information before methodological intervention. Survey II, questionnaire that provides information on previous experimental work on admission from course and before the methodological intervention. Survey III. Questionnaire that provides introductory information on concepts like temperature, thermal equilibrium and system, (Solbes and Tarín, 1998). Survey IV. Questionnaire that provides information on the theme of this study, which has to do with concepts the transfer of thermal energy, (conduction, convection and radiation). With this information, we have been able to document and to contrast the conceptual gain, through to the four Pre/Post Tests, before and after the methodological intervention, (Benitez, et al., 2010).

Application with an integrator project

This implies leave sideways the mechanical and memoristic learning, to focus on a job more challenging and complex; using a multicultural approach that encourages collaborative work; from the manufacture of a prototype solar energy (Rincón, 1999). By engaging of students in developing educational experiences in the classroom-laboratory, forming teams with different students and promoting research methods in order to solve real problems, (Eggen and Kauchack , 2005).

It is not the purpose to solve exercises of the final chapter, which only require a predetermined sequence and automated actions, with the possibility of obtaining a unique solution. Rather, the problem must be contextualized, open to the possibility of thinking different routes and other solution ways, (Pozo, 2002). This allows deploy collaborative dynamics between students and mediation by the teacher, with spaces for reflection and review. Thus preparing students in the constant participation: collectively, with the solar heater water, individually, with the solar stove and a team work, with the photovoltaic panel (Ramirez and Santana, 2014).

2. Objetive

To design, to implement and to evaluate the effect of integration didactic with exploration applied (IDEA), proposed methodology to develop learning on the subject of transfer of thermal energy, with college-level students, correlating conceptual and procedural aspects of physics, obtained through an integrative project on solar and with in worksheets exploration.

3. Methodology

We work with 47 students from precollege level. Students involved in the study are those who completed the four questionnaires after the intervention methodology. They have between 17 to 20 years old and 50% are women. Students are studying a year before to entrance to careers offered UACh. The specialties are around the agricultural studies, most are scholarship students and live within University or around in; are students from different Mexican states and therefore, they are of differences high schools, mostly public and many of them had not worked in the physics lab, (Barrera, 2009).

The IDEA methodology as a model of integration, It not only seeks the integration of organized bodies of knowledge, but also, the integration of educational proposals that are incorporated from the possibilities and

experience of teachers. Also it depends on the knowledge and skills developed by students at diagnosis, Figure 3.

The IDEA methodology are based on four stages; integration, teaching discipline, exploration and application. Indeed, we taken as base, the essential elements to attack of a problem situation, (Gansoso, 1999), which are: An initial state, determined by the situation in which the student is at the moment to address the problem; that is, knowledge of the problem, the attitudes on problem, motivations to find a solution, and the skills theoretical and experimental. A final state, characterized by the objective or goal that is required to achieve and that meets a need contextualized. And a problem space, consisting of all possible educational strategies to reach the final state, as active learning, problem-based learning and projects, the leaves of exploratory work, collaborative work, representational changes; and all that teachers consider, (Hillside, 2009).

The integration of different teaching methods of physics extensively tested, as well as, the contributions that the proposal adjusted IDEA to our study, are part of this alternative methodology, which aims to help students in the study of physics and you find it useful to meet problematic situations outside the classroom-laboratory.

Based on the above, we should start our study with real needs, to identify and analyze everyday problems and possible solutions (McDermott, 1996). Therefore, IDEA activities were designed to support students into cognitive construction, learning and understanding of the phenomena involved, as shown in Figure 4. All these related to the topic of study as: temperature, thermal equilibrium, heat, thermal energy transfer (conduction convection and radiation) and energy conservation.

As consequence of this were interpreted other phenomena as: the thermo syphon principle, the greenhouse, the concentration optics and the photoelectric effect. The teaching of physics helps us understand the functioning of systems that involve concepts around energy and its transformation such as solar thermal energy at a level of compression on subsystems, for instance, a solar water heater (Milena, 2013). Any photothermal prototype contains several subsystems that require physical concepts and his understanding; in order to give accurate explanations, such as solar concentration, insulating materials and heat conductors, the convective effects and interaction of electromagnetic waves, (Perrotta et al., 2013). It is clear that we need to compare studies related to alternative energies, as consequence of interest in clean energy, to help mitigate pollution and help with the family finances, considering that in Mexico every day gas prices and gasoline increase.

Learning activities IDEA

Methodology, integration didactic with exploration applied (IDEA) recovered what in recent years has been called the cognitive revolution, which are considered aspects such as: the impact of context on the thought processes of students, integration of bodies organized knowledge, the social nature of learning, the need to understand specific knowledge of the discipline (physics), problem solving developed by novice and experts; all this with the conviction that students construct their own understanding of the issues studied, (Eggen and Kauchack, 2004).

In our approach, we give opportunity to students to weave mental networks, by incorporating all types of experiential activities and information analyzed; in order to support their learning. And with this have deep understanding; and in context outside of the classroom-lab (teaching for understanding) with the integrator project, (Blythe, 1999). By working with nucleus of organized knowledge. The 47 students have already revised the mechanic topics; it corresponds to the unit previous to our study. We recover these prerequisites and prepare students so that after the methodological intervention. With this, they are getting ready to study electromagnetism, the last unit of the course.

This meant act accordingly, taking up what the student knows, and preparing them to the topic that they studied at the end of physics course, and immediately following the methodological intervention. Using a continuos knowledge spiral construction and with feedback, this is the basics for the begin of the application of the methodology. The evidences suggest that start with the students know about the issue and their misconceptions of it, (Quesada, 2005). Thus, it is about building and "genuine learning"; which involve

performing a wide and variety of activities of all kinds of experiences, not only to achieve the concept understanding, if not, at the same time, increase the understanding topic, (Perkins and Blyte, 2006). Based on information obtained in the 10 activities "IDEA", Figure 5. We implemented and applied the concepts studied in the integrator project.

In the analysis of the first survey (pretest-posttest), Showed an average rating of 3.8 out of 10, based on the exploration at entrance. Thus, we decided to choose, design and implement experiences and exteriorizations on the integrator project, as a result for the cultural differences by provenance (characteristic in Mexico). This have an effect on the goal of achieving a deeper understanding of the contents studied (declarative, procedural and attitudinal). Further, It is also of great importance to our proposal, the continuous assessment all process, (Diaz-Barriga, 2002).

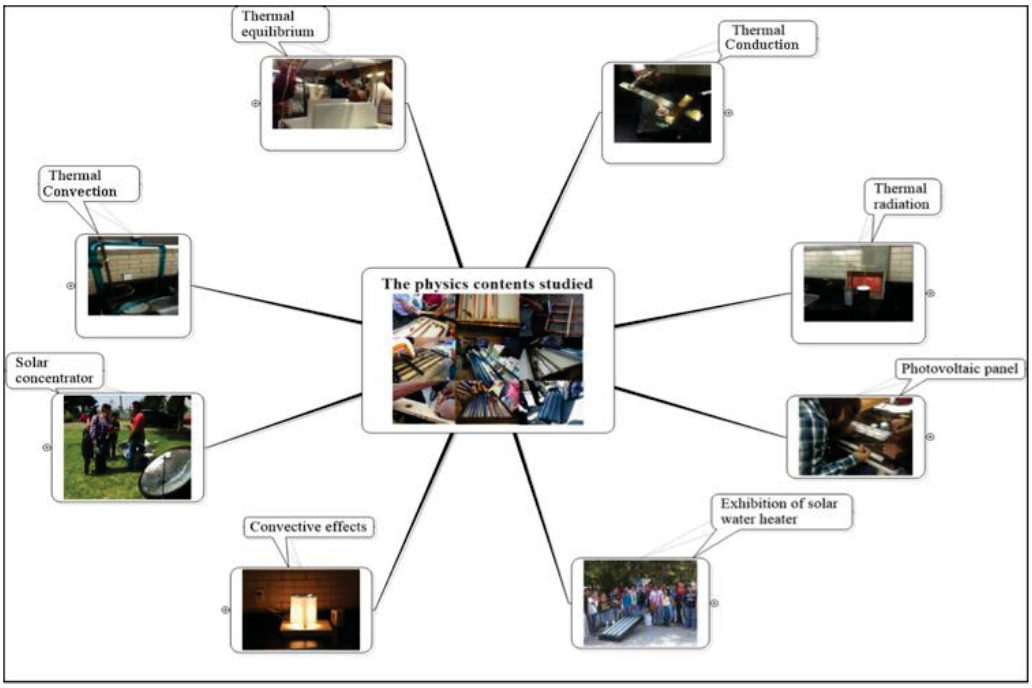

Fig. 3. Contents studied around thermal solar energy.

The entrance exploration, we reviewed general aspects of experimental work and the introductory concepts of thermodynamics at the precollege level. The experimental exploration, is central to our methodology propose, we emphasized lab job and the methodological of the sciences. In this questionnaire, students showed many shortcomings, mainly due to the few experience in a physics lab. This questionnaire has a result of 3.6 out of 10. So, emphasis on interpretation of the information obtained in learning activities. Referred to conceptual exploration (I). It gives us the opportunity on the previous ideas that the students have and the misconceptions that should be attacked with activities proposals "IDEA" .

Hence, the rate of 6.1 out of 10 that was obtained in this survey, gave us the guidelines to establish that phenomenology on temperature and thermic equilibrium, are very close to the daily life of students, and they can do inferences about the laws governing such thermodynamic phenomena to cognitive level they have in the this study, (Hierrezuelo and Molina, 1990). The conceptual exploration (II), is an accentuated exploration. It studies aspects on transfer of thermal energy; it gave us the challenge to increase the conceptual gain in this part. According, to the result obtained in the PreTest, it was 3.2 on 10. Therefore, by introducing the integrator project as a motivation means, we seek to strengthen the active participation, the collaborative job among students, and weave conceptual networks between what is known and what we are studying.

Worksheets explorative for students

For our research, the worksheets elaborated for students have been developed according to the teaching physics by inquiry. With this has been learned, how the worksheets can provide, "what ideas and what categories" were related each other, and "when and in what" context are used. Also, what alternatives and what meaning, were given during experience realized. The evidence suggests that the learning improve, when students work actively involved with worksheets guided activities in. It is clear that refers to the declarative, procedural and attitudinal content.

The IDEA learning activities are worksheets explorative for students, It enabling them to face the challenges in a flexible manner, to follow different learning issues, for instance: more directed to conceptual, formal, procedural aspects, and / or attitudinal. It is noteworthy that the worksheets explorative are own materials, these were reviewed among academic peers, and have characteristics as: phenomenological, experimental, formal and application. However, the worksheets can be combined depending on the objectives of the activity, (Michelini, et al., 2008).

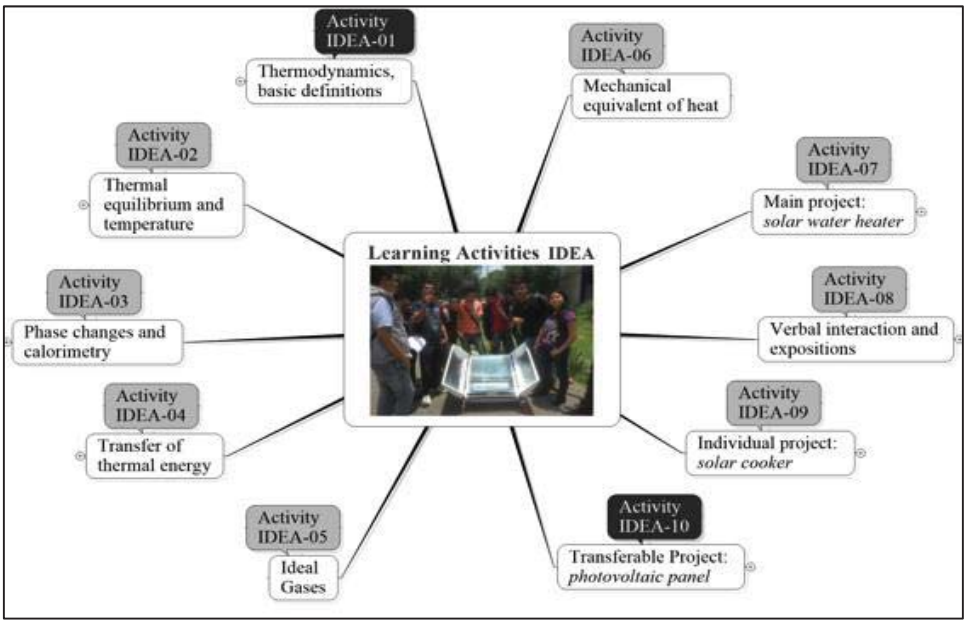

Fig. 4. Learning Activities IDEA.

Methodology implementation

After the results obtained on diagnosing, the Learning Activity IDEA-01. It has been called "Thermodynamics basic definitions" this implemented activity. It is phenomenological-experimental type. In this activity we should explain thermodynamic physical situations, ensuring that students decipher the meaning of the experience, so that the effect of the experience manages to be reflexive and with appropriation of something significant for them. Described below are the 8 steps integrated into each IDEA activity. These are listed as:

Step 1. *Contextual necessity*. With a sequence of concepts, these is presented to explore the characteristics and meaning, providing the formalism of the thermodynamic definitions.

Step 2. *Problem to solve*. In the beginning, the questions are presented based in to the concepts previously studied.

Step 3. *Proposed solution*. The students are prepared in the experimental part and they should have conceptual elements in order to start the possible solutions.

Step 4. *Experimentation*. Students carry out the experiments and make a description of each of the cases illustrated; putting attention on observation and in some specific aspects, describing the main features of processes.

Step 5. *Conceptualization of problem resolution*. The ability to solve problems successfully depends on a

number of factors related to the information processing, thus writing a solution of the problem, means to communicate and interpret the reasoning process leading to the solution.

Step 6. *External communication*. The strategy being employed is a verbal interpretation as: lab notebook, group expositions, science fairs, and another academics events.

Step 7. Revision. All the previous steps are considered again and we find a route that allowed us to study situations in the phenomenological and experimental plane in order to detect possible conceptual errors, false or unnecessary assumptions, wrong calculations, and confrontation with predicted answers.

Step 8. Transfer to other contexts. Finally, How to integrate the situations of Physics that have been learned to another context? That means, give continuity to the methodology; beginning with new questions and to transfer new goals to another project, in which concepts new can be learned, according to next unit. By way to get a virtuoso spiral of knowledge.

Integrator project

The aim of an integrator project is the application of concepts physics, through to manufacture three solar prototypes: a solar water heater, a solar oven and a solar panel. All of them are part of the integration project. The first one, a main project that involved 47 students in manufacturing solar water heater. The second one, an individual project, solar stove with readily available materials. The third one, a transferable project, a photovoltaic panel, (Chavez, 2008), which opens the possibility of transferring the methodology to another context, Figure 5. Thus, we can give continuity to the methodological, without give opportunity to traditional learning, (Harper, 2009).

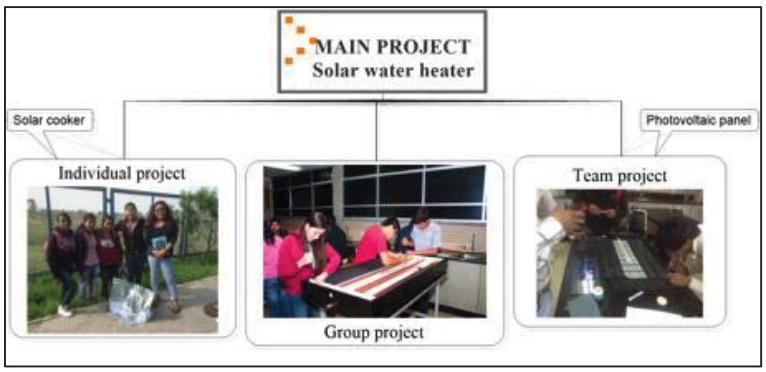

Fig. 5. Projects that are part of the proposal.

Therefore, we believe that it is necessary to provide a minimum of concepts to students not just to build their projects but also to have elements of communication in their expositions and consider physics as an important discipline for their professional development, (Parisoto, et al., 2014)

Integral evaluation

Our methodological approach does not consider the assessment as a synonym for test, exam or control; whose purpose is to qualify the student performance by a “foreground". For our proposal, evaluation is an important part of the teaching-learning process; serves as a starting point for further reflection to help us continuously improve the work of teachers, (Perez and Moreno, 1998).

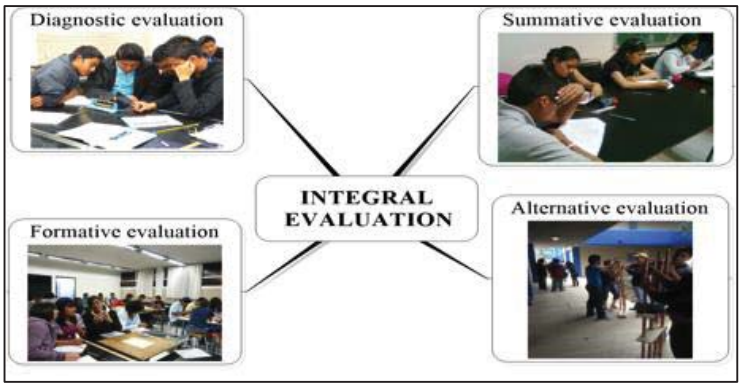

Fig. 6. Methodological assessment during intervention.

Diagnostic evaluation, the PreTest applied is compared with the PostTest, in order to know what the students have studied and act accordingly. Formative evaluation, the worksheets exploratory are analyzed with the performance rubrics, these give us guideline to attack difficulties or conceptual knots, (Michelini and Stefanel, 2012). Summative evaluation, the lab notebook, the teamwork, the PostTest result, and all kind of participation are part of this assessment. Alternative evaluation, not just the exhibitions but also the creativity in designing prototypes and application of learning in context, show us another possibility to motivate students in the physics study.

Gain Hake

It allows measuring and comparing the conceptual gain during the methodological intervention. It should be noted that students arrive at precollege level from different schools from various states of the republic, and therefore they have heterogeneous knowledge levels about physics.

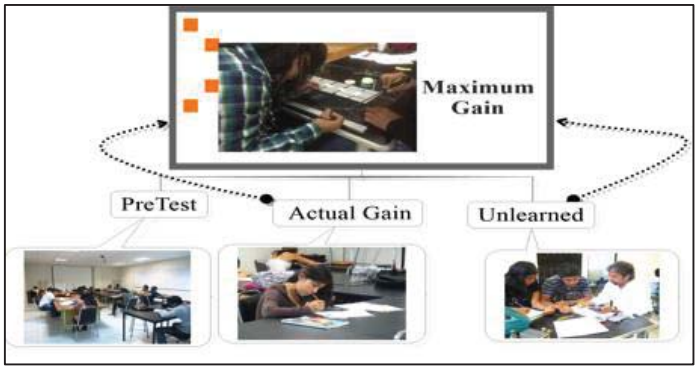

Fig. 7. Maximum gain estimation (g_max).

$$\text{PreTest effective\%} = \text{PreTest} - 20\% \quad \text{(eq. 1)}$$

$$g_{corr} = \frac{(\text{PostTest\%}) - (\text{PreTest effective\%})}{100\% - (\text{PreTest effective\%})} \quad \text{(eq. 2)}$$

where:

g_{corr} = average normalized gain

PreTest effective% = correct results in the survey

abefore methodological intervention.

PosTest % = Correct results in the survey

after methodological intervention.
Maximum gain is calculated by the follow expression:

$$g_{max} = 100 - \text{PreTest effective\%} \quad \text{(eq. 3)}$$

Average normalized gaing$_{ave}$; for group, It is calculated through determining the gain for each student and average evaluating:

$$g_{ave} = \frac{1}{n}\sum_{i=1}^{n} g_i \quad \text{(eq. 4)}$$

$$\mathbf{g}_{ave} = \frac{1}{n}\sum_{i=1}^{n} \mathbf{g_i}\left[\frac{Post_i - Pre_i}{100 - Pre_i}\right] \quad \text{(eq. 5)}$$

Where $n = 47$, are students who answered no just PretTest but also Posttest, and the sum was made with the n students of the study; obteniendo a real increase called: average normalized gain for the group, (Benitez and Mora, 2010).

Based on the above, we obtained value of ($\mathbf{g}_{corr}$); which quantifies the effectiveness of methodological intervention, shown in Table I. The Hake Gain (g), has values which cover the range [0,1]. Consequently, average differences between Pre/Post Test data give us the different ranges of the Hake Gain, and It interprets the effectiveness of methodological intervention, then: a high gain is ($g \geq 0.7$); an intermediate gain is ($0.3 \leq g < 0.7$); and a low gain is ($g < 0.3$). The results were not compared with a group traditional, considering that the results obtained by Hake for a traditional group (exhibition-conference) have an average gain of 0.2; so it was not necessary to make a comparison of student achievement between the two methods, (Seyed-Fadaei, 2014). However, we took 20% of average, according Hake traditional groups, which we was subtracted and represented the PreTest effective = PreTest-20%. Based on the above, the data allow us to project similar results for the other topics that the precollege level physics course contains, which is a general physics course. Other contents from the physics course are, mechanics and electromagnetism.

4. Results

Students involved in the study have between ages 17-20 years old, 50% are women. 47 students participated in the manufacturing of three prototypes: a solar heater (Group), a solar oven (single) and a photovoltaic panel (computer). The surveys were designed, were applied and analyzed before and after methodological intervention. During the development of the proposed 10 learning activities were implemented, and the concepts revised were: temperature, thermal effects, transfer thermal energy; we emphasized the concept of conservation and transformation of energy.

The activities called IDEA learning activities, covering three aspects: 1) the contents studied to give an overview of the subject studied; 2) The integration project, around the solar energy; and, 3) manufacturing of prototypes: a) solar water heater (collaboration skills); b) solar stoves (reflection skills); c) the photovoltaic panel (transfer skills), in order to move the proposal to other topics. Hence, there is a methodology continuing in entire course. We can see that there is no fragmentation the IDEA methodology, dismissing the possibility to apply a traditional methodology. Table 1, shows the four results of the surveys throughout the study process and the average normalized Hake gain ($\mathbf{g}_{corr}$)

By applying PreTest/Intervention/PostTest, the methodological proposals (Hake, 1998). The learning externalizations or realizations have shown from the results in the instruments applied to students before and after the proposed methodology, improves not just procedural and conceptual, but also attitudinal and application. The IDEA methodology and their tools, the worksheet, showed significantly high and positive achievement in promoting integrative theoretical learning and experimentation.

Tab. 1. Summary of survey and gain Hake.			
Type exploration	PreTest (%)	PostTest (%)	g_{corr}
Exploration income	18.00	71.65	0.6400
Experimental exploration	16.59	59.36	0.5100
Conceptual exploration (I)	41.50	83.60	0.8100
Conceptual exploration (II)	12.98	69.57	0.6600
Average	22.27	71.05	0.6550

The focus was on the different stages of development of the proposal, the consolidation of a group of teachers , which supports the development of prototypes for teaching physics. Result from the interest among teachers to give the course of precollege level with concept of energy and its conservation; and this is a reason for to use the methodology IDEA proposal. Similarly by comparing the final grade of physics course, progress is observed with respect to information of the scores at ingress/egress of intervention methodological, from 42.27% to 71.05%.

5. Conclusions

With the development of a planned and comprehensive proposal; It was possible to design, implement and analyze the methodological effect in teaching physics concepts with prototypes of solar and an evaluation along to the methodological intervention. The results were compared by analysis of the information collected, which were results the surveys and worksheets applied; in order to evaluate the proposal.

This research favor the development of a collaborative learning environment and with based on the factor of Hake, we get a conceptual Hake gain entry 0.6400. It is considered intermediate to high according to Hake rate. The evidence suggests significant progress, despite the student diversity.

For experimentation, we get a conceptual gain of 0.5100, a value low to intermediate according to Hake rate. The conceptual stage of introduction was the most effective with high gain of 0.8100, favoring the methodology in the first level of conceptual approach. The conceptual stage on accentuation; the gain is intermediate-high between 0.6600, which requires a higher abstraction level and a deep reflection on the last stage.

We can see there is an average gain of 0.6550 conceptual, which means a significant advance in understanding the concepts, involved. Also, the integration project at three levels (group, individual and team), enriches the study on organized bodies of knowledge, considering the daily needs, motivation and resolving a problematic situation.

The fundamental elements of the proposal methodological are the integration with different educational proposals interactive and the issues of transfer of thermal energy to be studied in context; achieving the effect of moving from the phenomenological (lived experience) to a thoughtful and appropriate description of the students at this university level.

It is about developing a critical thinking when transferring the information in context and a continuous assessment: diagnostic, formative, summative and alternative (exhibitions, solving everyday problems and creativity). Research supports the development of a collaborative learning environment the study of physics and with reflexive analysis and also retrieval of information is encouraged to make decisions that improve IDEA methodology and strengthen its structuration in next implementations.

Finally, the different ways to communicate information such as worksheets, all kind of information in the lab notebook, mathematical models in solving exercises, school exhibitions in scientific events, discussion between peers, the reconceptualization of problems, creativity and the use of solar energy. They are the basis of the didactic integration with applied exploration (IDEA), an alternative methodological to support students

in the study of physics.

Teaching Renewable Energy Systems by Use of Simulation Software: Experience at Universities of Applied Sciences, in In-Service Training, and from International Know-How Transfer

Andreas Witzig[1], Markus Prandini[2], Andreas Wolf[3], Lars Kunath[3]

[1] ICP Institute of Computational Physics, and [2] Competence Center Asia Business, both at the Zurich University of Applied Sciences, Winterthur, Switzerland

[3] Vela Solaris AG, Stadthausstrasse 125, CH-8400 Winterthur, Switzerland

Abstract

Experience in using simulation software for teaching solar energy and heat pump applications are presented and discussed in this publication. The authors present suitable didactic concepts specifically developed for teaching renewable energy and energy efficiency topics.

Two main advantages of applying simulation software in solar education are identified:

1. simulation can provide an understanding of data that is otherwise not accessible (e.g. cumulated operating hours and number of starts of a heat pump depending on control strategy);
2. use of simulation software in teaching have a positive influence on the motivation and attitude of the students.

These benefits typically come with costs of some additional effort in lecture preparation.

Finally, different international teaching programs are discussed, in which simulation software currently plays a major role. It is analyzed how education programs might have to be adjusted for different cultures and industries.

Keywords: *Renewable energy education, teaching solar systems, seamless learning, simulation software*

1. Scope and Introduction

The scope of this work is professional education in renewable energy from in-service training to the technical-university level. It does not cover solar education to children or to the common public. Furthermore, this work has a special focus on the use of simulation software in teaching and is an update to previously described experiences (Witzig 2009). In all the described courses, the curriculum focusses on the renewable energy topics and the skills required by engineers, planners and consultants involved in solar energy system analysis and design. Reflections about teaching experience do not cover courses specifically on the usage of software or on software programming aspects.

It has been recognized early that computer simulation has a high potential to influence learning in science (e.g. Feurzeig 1999, Rutten 2012), many articles and books have been published about it and there was a controversial discussion about the effect of the use of simulation tools in education. Specific overview articles also summarize the use of simulation software in specialized fields of technology. Examples are health care (Cook 2011), chemical and process engineering (Edgar 2006) and unequivocal results exist for many other field.

doi:10.18086/eurosun.2016.10.03 Available at http://proceedings.ises.org

2. General Observations

Three main prerequisites strongly influence learning achievements:

3. The choice of the simulation software has to closely match the interests and abilities of the students. General purpose mathematical tools like Matlab/Simulink or Mathematica are only helpful in engineering courses at university level when separate courses on how to use the tools are offered in the curriculum.

4. Simulation tools have to be user-friendly. On the one hand, the "fun" factor is not to be underestimated: if students *like* to play around with the tool, they also learn more. On the other hand, user-friendliness is required in order that students are efficient in their assignment work.

5. Personal laptops have to be available to all students. Computer laboratories have been an option at times when students have not had their own laptops. However, the advantage of bringing the exercises into the student's work environment allows a new dimension of involvement and reduces the cost of providing access to simulation tools.

These necessary conditions may vary depending on application field and teaching institution.

The authors think that temporal change of these boundary conditions are sometimes underestimated in the above cited review articles. While institutions and topics are relatively stable, simulation software improves steadily in its user-friendliness. In comparison to the first two points, the availability of laptops as a third requirement has changed dramatically in recent years. Students carry a large amount of computing power with them and have the ability to install and use standard software without any support from the teacher or the IT department.

3. Use of Simulation Software in Solar Education

Historically, the first software used in university-level solar education was TRNSYS (Kandpal 2015, Bronman 1991). The usage of TRNSYS in solar education was limited to a small group of people in the beginning due to the lack of computers. The user experience was impaired by the text based scripting interface but improved with the introduction of the TRNSYS simulation studio.

A number of software packages have been established later on in parallel to TRNSYS, most of them with a simpler user interface and somewhat reduced functionality. Some of them have successfully been applied in teaching solar energy (e.g. free: RETscren, PVGIS; commercial: T*Sol, Polysun, PVSyst, Insel).

Simulation software programs used in general physics education (e.g. Stella, Berkley Madonna, EES, Matlab) are less suitable for solar energy teaching since they are more complex and have no built-in references to renewable energy systems. It has been found that the tools have to use the specific nomenclature of the solar business and as to offer special functionality imposed by industry standards. Recent didactic concepts confirm that the "seamless" integration into the well-known environment of the student strongly increases the learning success (Milrad 2013).

The authors have been active for many years with the Polysun simulation tool and used it in the first place in solar and renewable energy teaching Swiss Universities of applied sciences, secondly in non-academic in-service training and thirdly for courses related to big companies in conjunction to commercial projects. All the above mentioned software tools have primarily been developed for professional users and not for the classroom, except some minor adaptation for educational usage is in the licensing scheme. Therefore, the graphical user interfaces are optimized to be useful for the customer target group. For Polysun these are the planners and engineers in consulting companies. Both in-service training and undergraduate courses profit from this because it makes the courses more application oriented.

In the use for undergraduate or in-service teaching courses it has been proven to be particularly useful to visualize relationships that are not accessible to measurement or analytical calculations, as discussed in the following three examples:

- While the characteristics of isolated components can be presented in lectures, it is a challenge to discuss the dynamic behavior of the hydraulic system. While governed by simple physical laws, the system performance is much more complex. Simulation software helps to let students investigate the operation of controllers and the placement of sensors. As shown in Figure 1, the Polysun simulation tool reveals the relevant details. Using trial and error or more systematic design methodology close to real planner's work, students use the software to "play around", investigate and optimize renewable energy systems.
- Yearly calculation results such as system efficiency, heat pump seasonal performance factors or cumulated operating hours and number of starts of a heat pump all strongly depend on the control strategy. With the use of a dynamic system simulation, these relationships become accessible for the teaching process and for exercises.
- Parametric studies with varying component characteristics and control strategies are another application area. Students have to learn to define an optimization target function and ask precise questions for optimization. Furthermore, the methodologies taught in renewable energy courses include the use of Excel as an analysis tool.

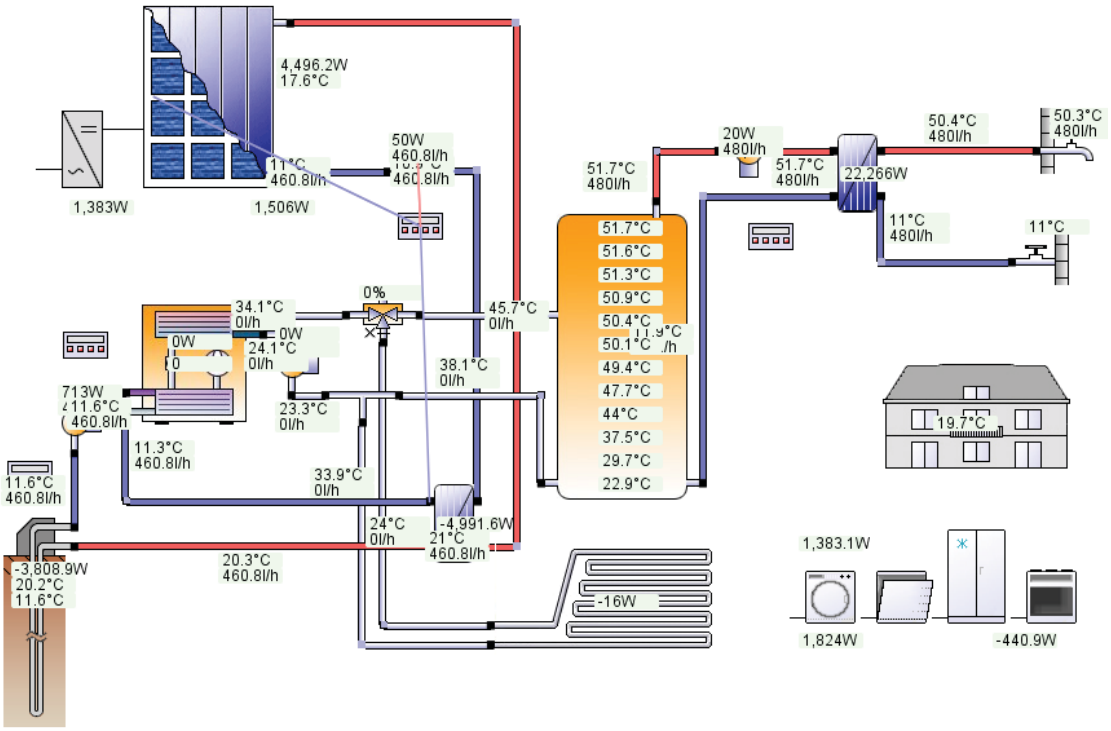

Figure 1: Polysun dynamic simulation allows to step into a certain time on a specific day of the year and follow the system behavior step by step on a short time scale. It allows students to recognize the details of the controllers, as for example in this application the controller (blue lines show connection to sensors, red lines show connection to the pump as an actuator).

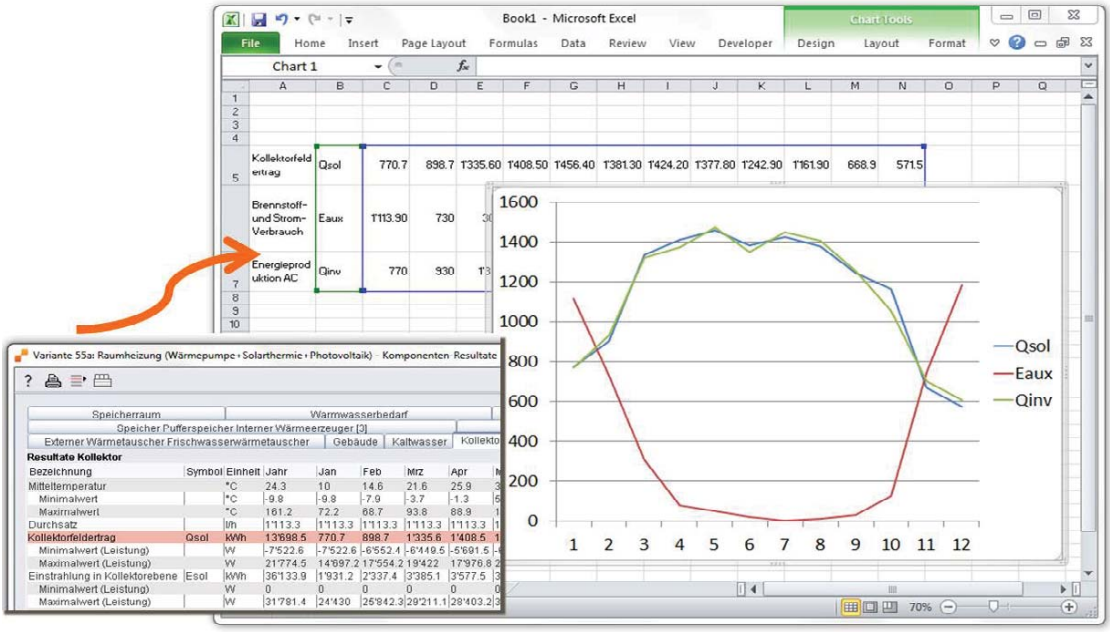

Figure 2: Simulation results can be manually or automatically transferred to other tools for advanced analysis and optimization. In this example it is shown how to transfer data to Excel.

Not least, the use of simulation software makes the renewable energy courses more attractive and increases the motivation and attitude of the students. It helps to position energy planners as high-tech consultants. Using a real-world planning tool provides a direct link to the work environment the students are likely to work in after graduation and allows showing how much impact good planning has on realistic projects and how much sense the future work will make.

While some bigger projects involve the creation of a curriculum (such as the examples reported in Section 6), the contents are typically encapsulated in smaller entities. The resulting teaching material can be used to enrich traditional solar energy or renewable energy courses in a similar manner as laboratory exercises as presented in Figure 3. It is important to convince teachers of traditional engineering topics to use examples from renewable energy systems to visualize general energy related topics. If material is provided in well-portioned entities and offered in a similar manner as experiments are in traditional engineering schools, the value of the teaching material increases and renewable energy topics have a higher chance to enter the general engineering curriculum.

Figure 3: Example for a hardware exercise from the experiment collection at Zurich University of Applied Sciences. Teachers can choose from a large collection of hardware experiments with well-prepared exercises to enrich classroom work. The authors propose to offer renewable energy topics using simulation software in a similar manner like physics experiments.

4. Recent Changes in the Solar Industry and in Solar Education

Renewable energy engineering has become more comprehensive in the last few years. In modern decentralized energy systems it is common to combine different renewable energy sources such as solar collectors and ground source loops. Some time ago, solar thermal engineering has been a self-contained topic, mostly situated in the mechanical engineering curriculum at universities of applied sciences. Now the interaction between the different disciplines (photovoltaics – energy storage – solar thermal – heat pump – ventilation and air conditioning) is addressed and in many engineering schools there are specific degree programs on energy and environment.

With the advance of the renewable energy industry, solar components have become more plug-and-play on the one hand, but renewable energy systems on the other hand have become more complex. The main expertise is therefore no longer in sizing and configuring solar components but in integrating the components into a system. Solar systems are often no longer strictly separated into solar thermal and photovoltaic systems. Hybrid systems and combination with heat pump and energy optimization controllers such as load shifting require new skills from planners and engineers. In consequence, it is required that students spend more time on understanding system dynamics and the proper functioning of controllers.

5. Learning Success and Secondary Effects of Simulation Software in Solar Education

Teaching courses using simulation software have to be supported by suitable didactic concepts, which need to cover classroom activities as well as computer homework (e.g. Rumsey 2000). In contrast to using video material in teaching, the application of simulation tools is very close to real “hands-on” activities. In so-called *seamless learning*, trainees study across boundaries such as location, time, analog/digital, and classroom/at home (Milrad 2013). Often, modern ICT technology is required to achieve a seamless learning

context (Pillay 2006). We often teach expert technicians in a 1:1 screen sharing setting, which allows immerging into the work context of the trainees and using their everyday examples. Alternatively, we use traditional classroom teaching enriched with exercises using simulation tools. During simulation sessions, the teacher acts in the role of a coach and students are actively pursuing their design projects. Interpretation of simulation results and double-checking results with simple back-of-the-envelope calculations are typically pursued with rigor and an excellent mental awareness when the example is chosen from the trainee's everyday scope of duty.

Advantages when using simulation software and modern ICT technology for teaching:

- Students are activated. They have to take responsibility, make decisions and organize their work.
- Trainees can pick the topic that is relevant for them.
- Collaboration between students: they share their findings, help each other, and discuss their results.
- Progress in the exercise is visible to the teacher during class and easily measurable after class.
- Exceptionally high motivation, in particular for in-service and screen sharing training.

Challenges and risks:

- Preparation is key for teaching with simulation software. Exercises have to be formulated in detail and test runs are indispensable.
- The teacher has to be a proficient user of the software as well as have the essential skills in the area of expertise of the course participants.

Not least, there are excellent and important practical experiments in solar education. As much as the authors believe that computer simulation has a positive learning effect, they are convinced that laboratory exercises are also a necessary requirement for solar engineers and do not consider computer simulation as a substitute for them.

Simulation makes the system aspect accessible. It has been shown in the literature that effect size of use of simulation software in teaching is especially high if it is used for phenomena that are unobservable (Trey 2008). In the case of hybrid solar system simulation there is no alternative to numerical simulation for the analysis of the dynamic system behavior. Experience shows that students get puzzled by the large number of unknowns in hybrid systems and, in particular, that rules of thumbs do only apply to limited parameter ranges. Simulation software helps to reduce the number of unknowns by the definition of adequate default values. These simplifications are necessary for good didactical best practice. The authors have experienced that it is only at the very top of University-level engineering courses, one should confront students with the large uncertainty that lies behind every system simulation. Otherwise, the learning effect regarding renewable energy topics is compromised. At any time, one has to be aware that solar simulation is only a tool used in solar education. In other courses at the MSc or postgraduate level (that go beyond the scope of this article), it is good to go into detail on computational algorithms and discuss the influence of each default parameter.

6. Teaching Experience Abroad

Solar energy is a world-wide topic and solar engineering education is in many regions of the world a limiting factor in the energy transition. The authors have been involved in renewable energy teaching in Switzerland and the neighboring countries, mostly in conjunction with the simulation software Polysun. Some specific activities also cover the Scandinavian countries (Bales 2016, Andersen 2016), the Mediterranean area and specific projects in Egypt (Khayet 2014), China (Wolf 2016, Prandini 2016) and Kuwait (Al-Yaseen 2016). In many activities, the simulation software Polysun played a major role in overcoming translation challenges and to measure and ensure the proficiency level.

Market development is very different in various regions. While in Germany, there was a strong growth in photovoltaics until 2013 with the installed photovoltaic area almost doubling several years in a row, there was a shortage of planners and installers. Teaching has been done on the job and especially the bigger institutions have been too late with offering appropriate programs and courses. On the technical side, systems have become standardized and simplified, and the required knowledge shifted from electrical engineering topics to the awareness of regulatory requirements and standards.

In many regions, certificates for students and teachers are important to award the successfully passed exams and to prove the technical and didactic skills of the local teachers. Concluding from all training activities abroad, it is essential to cope with cultural differences, to be ready to learn from one another and recognize technical discussions always as bi-directional know-how transfer.

6.1 China

The authors of this article have been involved in an exchange program funded by a Swiss platform REPIC (Renewable Energy & Efficiency Promotion in International Cooperation) and the activities included introducing software-based teaching methodology in a teach-the-teacher scheme. Close and intensive collaboration has been established prior to the project start and was a pre-requisite for a successful project.

- First, it has to be recognized that the Chinese solar market is mature and – in particular in the solar thermal field – technical solutions as well as the value chain differ significantly from European standards. The software had to be extended to cover the systems typically installed in China.

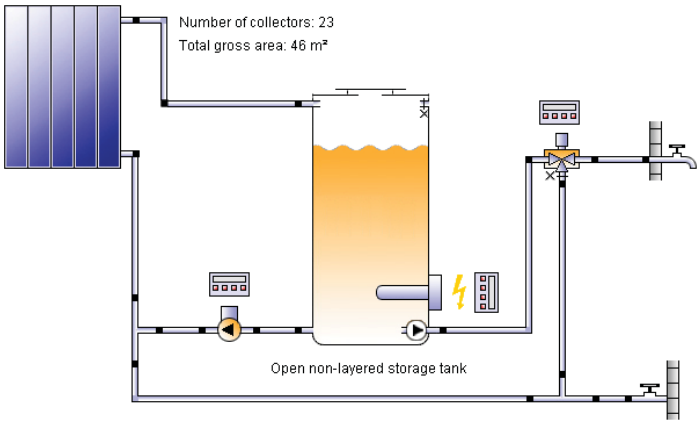

Figure 4: Typical Chinese system with open freshwater storage tank. Due to the strong circulation through the solar collector field, thermal stratification is destroyed deliberately. The tank is partially filled in times with low solar radiation, first fills up to 100% when more solar energy is available and heats up well above the required hot water temperature to increase energy storage capacity.

- Secondly, language was a major challenge since English has not been a common language between the European and the Chinese solar experts. Consecutive translation has been established for the know-how exchange and the simulation software graphical user interface has been translated into Chinese.
- Teaching methods have been adapted. As an example, the jigsaw exercise has proven to be very effective since it activated participants and trained technical expertise at the same time as teaching skills. Furthermore, it lowers language challenges when teachers and participants do not speak a common language since in jigsaw groups, Chinese-speaking participants teach their colleagues.

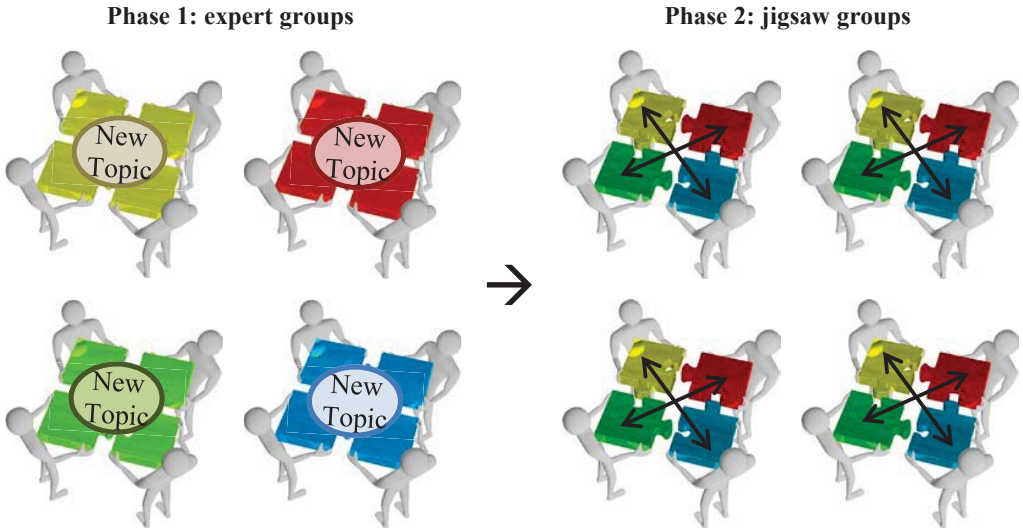

Figure 5: Jigsaw exercise. In a first round, small groups receive a new topic either by written or oral explanation. In a second round, groups are reorganized in order that participants teach each other. The jigsaw exercise proved to be a valuable didactic concept as an ice-breaker and to activate participants in teach-the-teacher courses.

6.2 Egypt

The teaching project in Egypt was supported by the EU Tempus Project SOLEDA and carried out by a large partner consortium of experts across the European Union (Khayet 2014). Simulation software only used a minor part of the budget but still played a significant role. To fulfil one of the requirements stated by the SOLEDA project plan, the Polysun graphical user interface has been translated into the Arab language, as shown in Figure 6. Furthermore, as a major contribution to the SOLEDA project, some general course content has been provided by the authors and extensive teach-the-teacher activities have been carried out at in different places in Egypt and Europe.

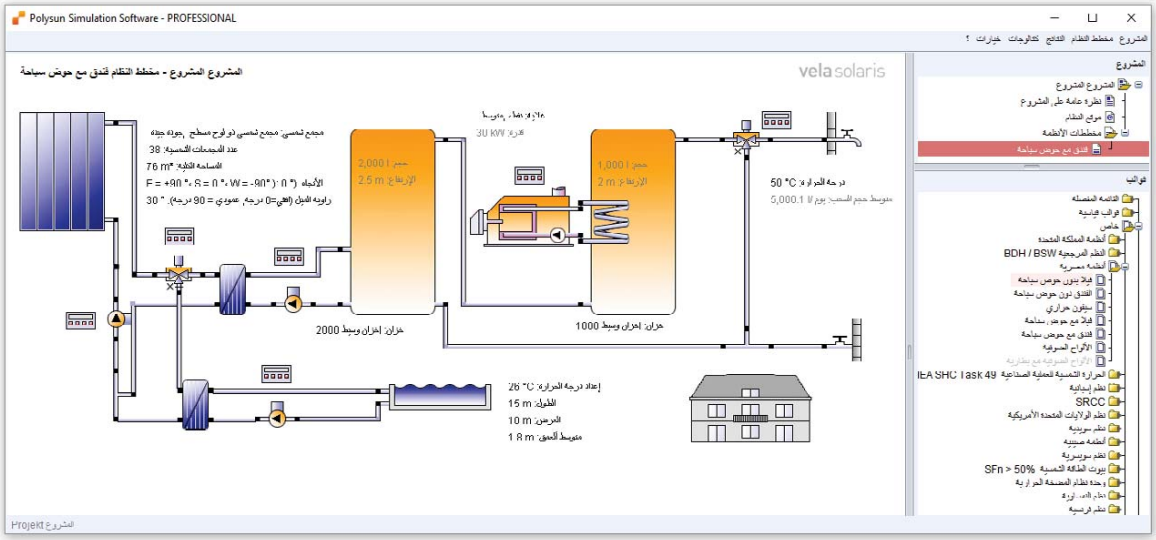

Figure 6: Polysun graphical user interface in the Arab language.

The project was running during a time of political change in Egypt. The positive attitude towards solar energy has been a constant source of motivation for all participants and also for the public (Soleda-Video 2016). Independent of political and economic boundary conditions, solar energy is a meaningful and high potential technology for Egypt and there is a shortage of skilled young professionals in this field.

6.3 Kuwait

A long collaboration with the Kuwait Solar Energy for Private Training Institute (Al-Yaseen 2016) is worth mentioning because it shows how different various regions have to be treated in regards to solar education. Even though the simulation software is available in the Arab language, it is used in English. Furthermore, high quality training material is provided by the Institute, all with animated explanations and impressively rendered. The teacher is an accredited instructor and exams for participants are carried out in Kuwait. Quality assurance is partly supported by Vela Solaris in Switzerland and the certificates are in integral part of the training courses and represent a high value for participants.

Figure 7: All teaching material is animated in high quality rendering.

7. Conclusion and Outlook

The authors have reported about experience with employing the simulation software Polysun in the educational context. The work spanned from supporting the curriculum of a new bachelor program to providing small learn objects that can be dealt with within a few lecture hours and can easily be shared between teachers. It has been found that simulation is useful to provide an understanding of data that is otherwise not accessible such as cumulated operating hours and number of starts of a heat pump depending on the control strategy. Consequently, students learn more and the solar and renewable energy topic becomes more tangible. Furthermore, the use of simulation software in teaching has a positive influence on the motivation and attitude of the students and the attractiveness of the courses. These benefits typically come with the costs of some additional effort in lecture preparation. Relieve from that additional burden could be found in building up a good system of sharing exercise material.

It is proposed to spend future work on studying the learning process when using simulation software in solar education and in measuring the effect size of these modern teaching methods. In particular, a measure should be found to estimate the attractiveness of solar education and the experience of a positive effect of using simulation software in renewable energy teaching should be quantified.

Abstract

This study aims to explore various energy conservation opportunities in the residential sector of Saudi Arabia when available standards are employed as compared to the typical local design practices. Based on the information collected from literature, the local design practices including physical, thermal, and operational characteristics are defined and simulated as a base case scenario for a typical single family residential building in Dhahran. A proposed case study is performed according to the benchmark design considerations of International Energy Conservation Code (IECC) 2012 and the simulation results are compared with the base case scenario in order to evaluate the energy saving potential. The proposed building is integrated with solar energy to meet the part load of the building. The credibility of solar energy integrated building is justified in terms of its economic as well as eco-environmental benefits.

Keywords: *Residential buildings; Energy conservation; Solar energy integration; GHG emissions*

1. Introduction

The buildings consume about 80% of the total electricity generated in KSA, a figure well above the average electricity consumption for the buildings in all over the world. A breakdown advocates that the residential sector accounts for the major part of the consumed electricity in buildings with a very high value of 51.2 %, followed by the commercial and government buildings that stand for 13.6 % and 13.4 % consumption, respectively (Asif, 2016). Therefore, energy conservation measures in the residential buildings is an important study that needs to be examined carefully to strengthen the energy security situation in KSA. The use of computer simulations to evaluate the performance of a building is a common practice now-a-days. Several comprehensive simulation tools are available to assist designers to implement innovative ideas and evaluate the energy savings potential in their proposed designs (Hong, Chou, & Bong, 2000). In most of the published literature related to energy performance of the residential buildings in KSA, the main focus of the researches is on the design optimization of the buildings to reduce the energy consumption (Alaidroos & Krarti, 2015; Almutairi et al., 2015; Budaiwi & Abdou, 2013; Taleb & Sharples, 2011). Although generous guidelines are available to reduce the energy consumption in a typical residential building in KSA but few studies have been conducted that implemented energy conservation measures and then integrated the renewable energy sources to meet the energy requirements of these buildings. Some studies specified the prospects of integrating the renewable energy sources in residential buildings to motivate the zero energy buildings concepts in the residential sector of KSA (Alrashed & Asif, 2012; Atieh & Shariff, 2015; Banani, Vahdati, Shahrestani, & Clements-Croome, 2016; Charfi, Atieh, & Chaabene, 2015). In zero energy buildings, the complete load of a building is shifted from conventional energy sources to renewable energy sources that is currently not practical in KSA due to technical, financial, and social barriers. However, the shift of the minor load (water heating load, lighting load, etc.) of a residential building to the renewable energy sources is possible and also helpful in providing the stability during summer peak load in KSA.

This study specified the energy conservation measures and solar energy integration to meet part of the energy requirements

doi:10.18086/eurosun.2016.11.01 Available at http://proceedings.ises.org

of a residential building in KSA. A single family residential building was selected in Dhahran. A literature review was conducted on energy conservation studies related to the residential buildings in Dhahran. The architectural features were defined for a typical residential building based on the local design practices that includes physical, thermal, and operational characteristics. The building was modeled using Visual DOE 4.0 software and considered as the base case scenario. Parametric analysis was carried out for different envelope design considerations to improve the thermal performance of the building. A proposed case study was examined according to the benchmark design considerations of International Energy Conservation Code (IECC), 2012 and the simulation results were compared to the base case scenario in order to evaluate the energy saving potential. The proposed building is integrated with grid connected solar PV system to meet the lighting load. The credibility of solar energy integrated building is justified in terms of its economic as well as eco-environmental benefits.

2. Base Case for Residential Building

Significant research has been carried out to evaluate the design parameters adopted in different climates of KSA. (Al-Haddad, 1988) conducted a field survey on more than 300 houses in major cities of KSA to develop a typical villa for energy simulation studies. (A. Ahmad, 2004) stated the features of a typical residential building for single family in Dhahran. He collected the data from surveys, building plan reviews that are filled by municipal authorities, and interviews conducted with building owners. (Al-saadi & Budaiwi, 2007) also conducted a survey to summarize the characteristics of a typical residential building for a single family in Riyadh and Dhahran. Based on the data obtained from literature, the base case scenario is simulated using RETScreen software that imports authentic climatic data from its database recorded by the National Aeronautics and Space Administration (NASA). The initial base case is modelled based on the input data summarized in Table1.

The simulations were performed first for a typical residential building of Dhahran as a base case scenario. The annual energy consumption for the base case scenario is presented in Fig. 1. Fig. 1 shows that the space cooling load is the highest among all the loads and responsible for 71 % of the overall annual energy consumed in a typical residential building of Dhahran. Lighting load is the second major contributor in total annual energy consumption followed by space heating load, equipment's load, and water heating load.

Table 1. Typical architectural features of a single family residential building in Dhahran (A. Ahmad, 2004; Al-saadi & Budaiwi, 2007).

Location	Dhahran
Direction	Front elevation facing East
Shape	Rectangular
Number of floors	2
Height between floors	3.5 m
Dimensions of floor	15 x 20 m
The area of floor	300 m^2
The area of walls	490 m^2
The area of windows	20% of the total area of walls
Type of glass	Single glazed (6 mm)
The volume of house	2100 m^3
Infiltration	0.5 ACH (Airtight)
Walls construction	15 mm outside plaster (Stucco) + 200 mm CMU Hollow + 15 mm inside plaster (Stucco)
Roof construction	15 mm Cement plaster + 200 mm CMU Hourdi Slab + 100 mm Foam + 4 mm water proof membrane + 25 mm Sand Fill + 50 mm Mortar + Terrazzo
Floor construction	100 mm slab on grade
Number of occupant	6
Occupancy rate	50 % during weekdays and 75 % on weekends

Type of lights	30 % Incandescent lamps and 70 % fluorescent lamps
Lighting load	10 W/m^2 for 1st floor and 8 W/m^2 for 2nd floor
Equipment load	12 W/m^2 for 1st floor and 5 W/m^2 for 2st floor
Air conditioning system	Constant volume residential system with electric heating
Thermostat	Two position thermostat with 25ºC cooling set point and 21ºC heating set point
Coefficient of performance	2.87

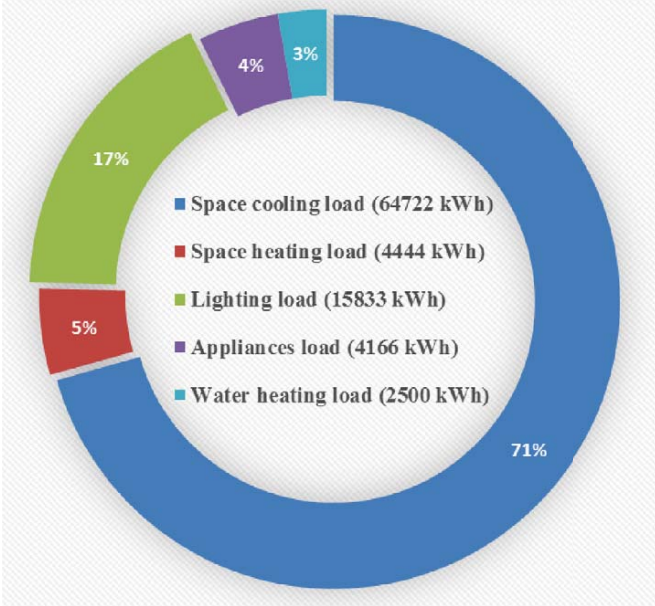

Fig.1. Annual energy consumption in a typical residential building of Dhahran (base case scenario).

2.1 Parametric analysis

Parametric analysis was performed to understand the effect of different design parameters on the energy consumption. Three different construction combinations were analyzed by varying the wall construction while keeping the roof construction same. These three combinations along with their properties are summarized in Table. 2.

Simulation results of different wall constructions were compared to the base case construction and presented in Fig. 2. Fig. 2 shows the decrease in energy consumption with the increase in thermal resistance of the walls. Construction 1 and 2 consist of a wall with higher thermal resistance and indicates a substantial decrease in the energy consumption for space cooling and heating when compared to the base construction. Although the wall in construction 3 has the highest thermal resistance, the decrease in energy consumption for Construction 3 is less as compared to construction 2.

Table 2. Different construction combinations by varying the wall construction while keeping the roof construction same.

Roof Construction	**R-value (m^2.°C/W)**	**Heat capacity (KJ/m^2.°C)**
15 mm Cement plaster + 200 mm CMU Hourdi Slab + 100 mm Foam Conc. + 4mm water proof membrane + 25 mm Sand Fill + 50mm Mortar +Terrazzo	1.69	629.8
Wall Construction	**R-value (m^2.°C/W)**	**Heat capacity (KJ/m^2.°C)**

Wall 1	15 mm cement plaster + 50 mm Precast Concrete Panel + 50 mm Polyurethane + 50 mm Precast Concrete Panel + 15 mm cement plaster	2.4	237.8
Wall 2	15 mm cement plaster + Hollow CMU Block + 50 mm Air Space + 100 mm Polyurethane + 15 mm Cement plaster	5	442.1
Wall 3	15 mm Cement plaster + 75 mm Polyurethane + 50 mm Precast Concrete + 75 mm Polyurethane + 15 mm Cement plaster	6.67	148.5

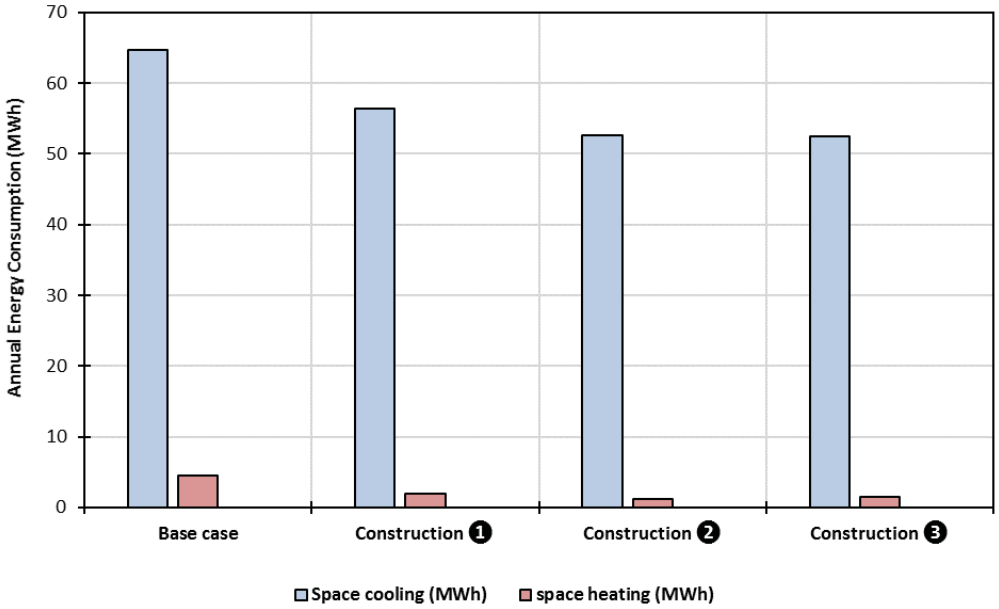

Fig.2. Annual energy consumption under different wall combinations.

The energy consumption of a typical residential building in Dhahran was also analyzed under different roof combinations. Three different construction combinations are analyzed by varying the roof construction while keeping the wall construction same. These three combinations along with their properties are given in Table. 3.

Simulation results of different roof constructions are compared to the base case and presented in Fig. 3. Fig. 3 shows the decrease in the energy consumption with the increase in thermal resistance of the roof. The impact of different roof combinations on energy consumption is not as much significant as in the case of different wall combinations. The reason of lower reduction in the energy consumption with different roof combinations is due to lower floor area as compared to gross wall area and two floors of the building. As only the second roof is directly exposed to solar radiations, the impact of different roof combinations majorly influenced the second floor energy consumption. Therefore, the impact of different roof combinations on energy reduction is not as much significant as in the case of different wall combinations.

Fig. 3 also indicates that the energy consumption for space heating is higher for construction 1 and construction 2 as compared to base case construction. These results can be justified from the heat capacity values and the location of thermal mass. For construction 1, the thermal insulation is placed on the interior side that does not allow the indoor generated heat to be stored in the construction material. In construction 2, the heat capacity value of the roof is very low as compared to the base case construction, therefore the potential to store indoor generated heat is reduced.

Table 3. Different construction combinations by varying the roof construction while keeping the wall construction same.

Wall Construction		R-value (m^2.°C/W)	Heat capacity (KJ/m^2.°C)
Single 200 mm Hollow CMU Wall + 15 mm Stucco finishes on both sides (without insulation)		0.34	380
Roof Construction		**R-value (m^2.°C/W)**	**Heat capacity (KJ/m^2.°C)**
Roof 1	15 mm Cement plaster + 50 mm Ext Polystyrene + 200 mm Clay Brick Hourdi + 100 mm Plain Concrete + 4 mm water proof membrane + 25 mm Sand + 50 mm Mortar + Tiles	2.56	567.1
Roof 2	15 mm Cement plaster + 200 mm Siporex Hourdi + 100 mm Foam Concrete + 50 mm Exp Polystyrene + 4 mm water proof membrane + 25mm Sand + 50 mm Mortar + Tiles	4.35	337
Roof 3	15 mm Cement plaster + 200 mm CMU Hourdi Slab + 100 mm Foam Concrete + 100 mm Polyurethane + 4 mm water proof membrane + 25 mm Sand + 50 mm Mortar + Tiles	5.88	638

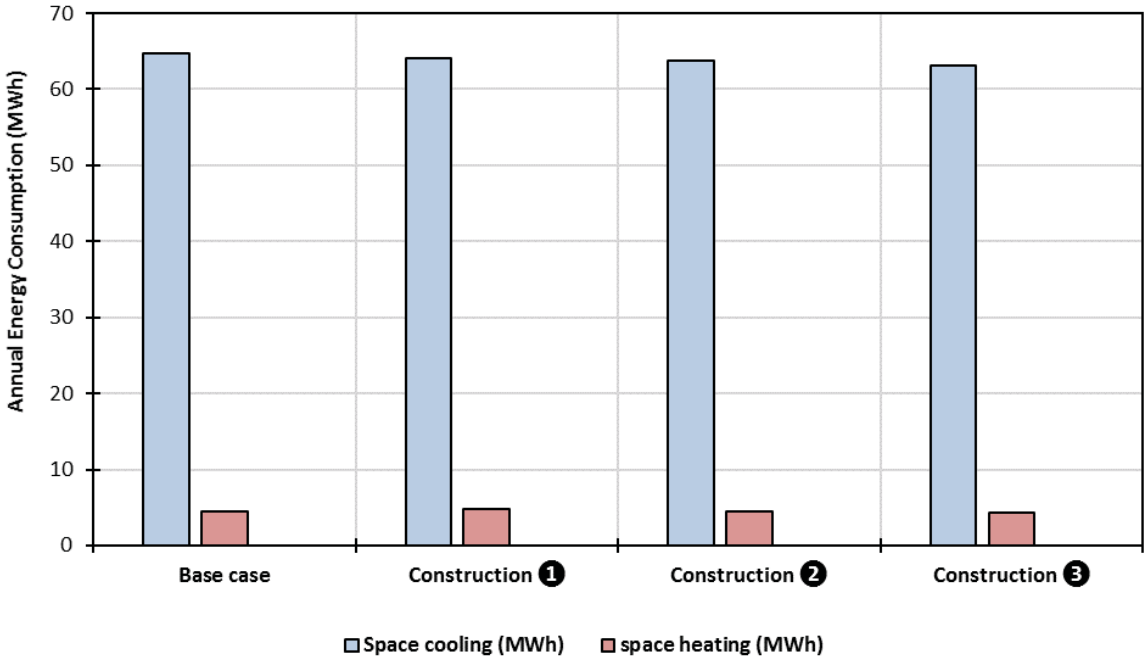

Fig.3. Annual energy Performance of Residential Building under different roof combinations.

The influence of different glazing on the energy performance of the building was also analyzed by using different glazing. Simulations were performed for double glazed, argon gas filled double glazed with low emissivity (low-e), and argon gas filled triple glazed with low-e. The characteristics of these glazing's are summarized in Table 4.

Simulation results of different glazing were compared to the base case and presented in Fig. 4 which clearly shows that the selection of glazing type plays a vital role in in the reduction of cooling and heating load. Fig. 4 shows that the energy consumption for space cooling is higher and energy consumption for space heating is lower for argon filled triple glazing when compared to argon filled double glazing. These results can be justified by the higher solar heat gain coefficient of argon filled triple glazing that allows more solar radiations to the space. Therefore, argon filled triple glazing performs

better in winter for heating purpose but it increase the cooling energy requirements in summer. The appropriate selection of the glazing U-factor (1/R-value) and the SHGC are required to balance the heating and cooling energy requirements.

Table 4. The characteristics of different types of glazing

Description	U-factor (1/R value) ($W/m^2.K$)	Solar heat gain coefficient (SHGC)
Double glazed	2.788	0.613
Double glazed, low-e, gas filled	1.317	0.278
Triple glazed,low-e, gas filled	0.772	0.471

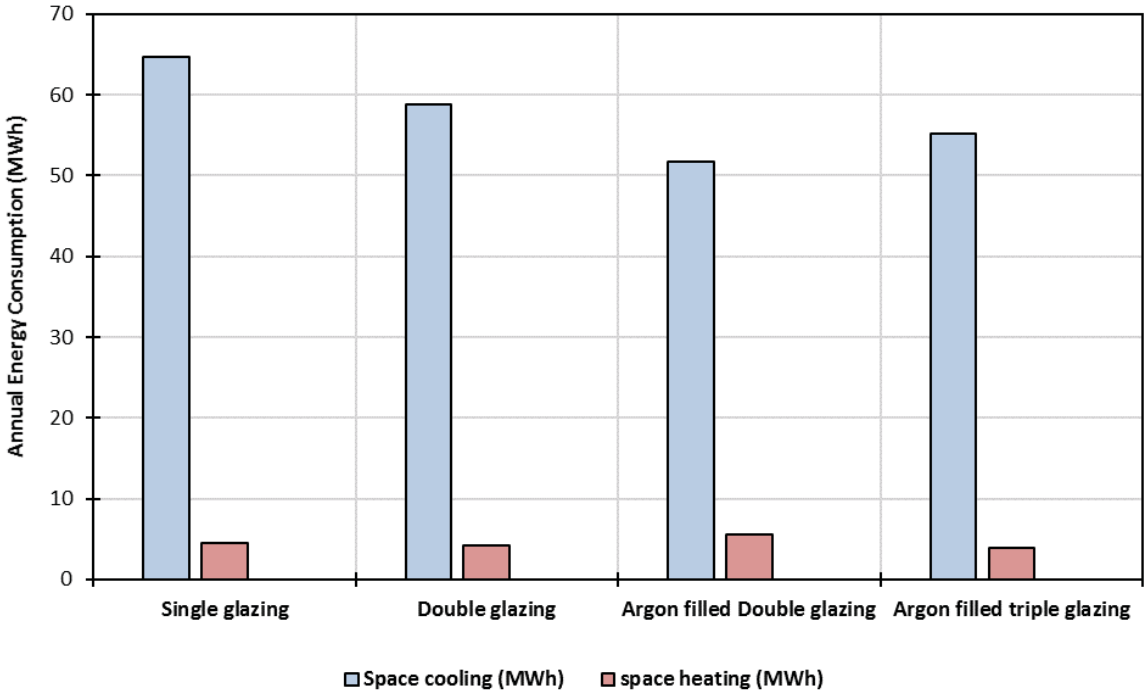

Fig.4. Annual energy Performance of Residential Building under different glazing types.

3. Proposed Case for Residential Building

A proposed case study was performed according to the benchmark design considerations of International Energy Conservation Code (IECC, 2012). IECC is intended to deliver state-of-the-art energy conservation practices for energy efficient building through model code regulations. The physical characteristics of the proposed case residential building are the same as in the base case. The minimum IECC requirements for envelope design in hot climates for residential buildings with less than or equal to 20 % windows area is as follow:

- The wall thermal resistance should be more than R-3/4.
- The roof thermal resistance (R-value) should be more than 5.28 m^2. ºC/W (R-30).
- The floor thermal resistance (R-value) should be more than 2.28 m^2. ºC/W (R-13).
- The U-value of glazing should be less than 2.27 $W/m^2.K$ with SHGC < 0.25.
- At least 75 % of the permanently installed lighting fixtures should be high efficacy lamps.
- All the appliances should be Energy Star certified.

Simulations were performed for the proposed case scenario according to the IECC standards and the results were compared

to the base case scenario to check the energy saving potential in the residential building, as shown in Table 5. It shows that there is 56 %, 37 %, 46 %, and 27 % less energy consumption for space cooling, space heating, lighting, and appliances, respectively.

Table 5. Comparison of annual energy consumption in base case and proposed case.

Type of load	Space cooling	Space heating	Lighting	Appliances
Annual energy consumption (kWh) - Base case	64722	4439	15833	4163
Annual energy consumption (kWh) - Proposed case	28611	2772	8550	3055
Annual energy savings (kWh)	36111	1667	7283	1108
Annual energy savings - %	56 %	37 %	46 %	27 %
Annual fuel consumption (GJ) - Base case	233	16	57	15
Annual fuel consumption (GJ) - Proposed case	103	10	31	11
Annual fuel savings (GJ)	130	6	26	4

4. Solar energy integration in Residential Buildings

The Kingdom of Saudi Arabia (KSA) is blessed with abundant solar radiations throughout the year. The vast open land of KSA receives high intensities of solar radiation for long periods that makes it an ideal region for solar energy conversion and its applications (Abd-Ur-Rehman & Al-Sulaiman, 2014). Irrespective of the enormous prospective of solar energy, KSA utilizes only a small portion of it and nearly all its energy requirements are met by fossil fuels. In this study an effort is being made to meet the part load of a residential building by using solar energy. Although, meeting the space cooling load by solar energy is not practical due to very high initial investment but lighting load can easily be met by using solar water heater.

Lighting load is the 2nd highest among all the loads and responsible for 17 % of the overall annual energy consumption in a typical residential building of Dhahran (as shown in figure 1). This load is satisfied by using conventional grid electric power that is generated by burning fossil fuels. The shifting of lighting load dependence from the conventional grid electric power to solar PV system could be a milestone towards improving energy savings and security in future concerns. For this purpose, grid connected PV system is simulated to fulfill the lighting load demand of a typical single family residential building in Dhahran. There are different technologies like mono-Si, poly-Si, a-Si, CIS, CdTe, and spherical-Si, that can be used for a grid connected PV system. Selection of certain PV technology type is directly related to the ambient temperature, optimum efficiency, nominal output temperature, and solar collector area (Natural Resources Canada, 1997). For the current study, year round working grid connected PV system was simulated using poly-Si technology. The implication of grid connected PV system is beneficial in two perspective: one is replacement of fossil fuels with renewable energy and second is the supply of surplus electric power to the grid system. The features of the designed grid connected poly-Si PV model are listed in Table 6.

Table 6. Characteristic features of modelled grid connected PV system (Abd-ur-Rehman & Al-Sulaiman, 2016; Natural Resources Canada, 1997).

Property/ Factor	Value
PV technology type	Poly-Si
Efficiency	16.4%
Nominal operating temperature	45 °C
Frame area / PV module	1.94 m^2
Control method	Clamped
Collector slope	Latitude of location
Solar tracking mode	Fixed
PV panel cost	2.7 $/watt
Electricity export rate	2.5 cents/KWh
Fuel cost escalation rate	4.0%
Inflation rate	2.5%
Discount rate	2.0%

Modelled grid connected PV system was analyzed in terms of its technical and main economic determinants (i.e. NPV, IRR, payback period and benefit-cost ratio). GHG emissions analysis was also carried out to visualize the environmental effects of energy transition. The economic determinants of the modelled grid connected PV system are summarized in

Table 7. The electricity export rate is assumed to be 2.5 cents/KWh that is equal to the electricity cost in the residential sector. Assuming the life time of the modelled grid connected PV system to be 25 years, the payback period is 13.3 years that is more than the half of PV system projected life. The long payback period is due to the highly subsidized cost of electricity in KSA. The high initial cost and absence of government incentive are the major restrictive factors in establishing the solar PV system. To encourage the practice of installing solar PV systems, the government should start incentive programs and should provide subsidy to substantiate the initial cost of establishing solar PV system.

Fig. 5 illustrates the effect of subsidy on the economic determinants of the modelled grid connected PV system. Results shows that the economic viability of the modelled grid connected PV system is directly influenced by the percentage of subsidy provided by the government. The incentive program that provides 50 % subsidy on the establishment of proposed grid connected PV system, the payback period could be reduced from 13.3 years to 6.6 years. Therefore, government should develop such incentives program that favors the establishment of clean energy projects to strengthen the energy security condition of KSA.

Table 7. Economic determinants of modelled grid connected PV system.

Factor	Value
Annual Electricity exported to grid	3.247 MWh
Net Present Value (NPV)	10,175 $
Internal Rate of Return (IRR)	9.8 %
Simple payback period	13.3 years
Benefit to cost ratio	2.45

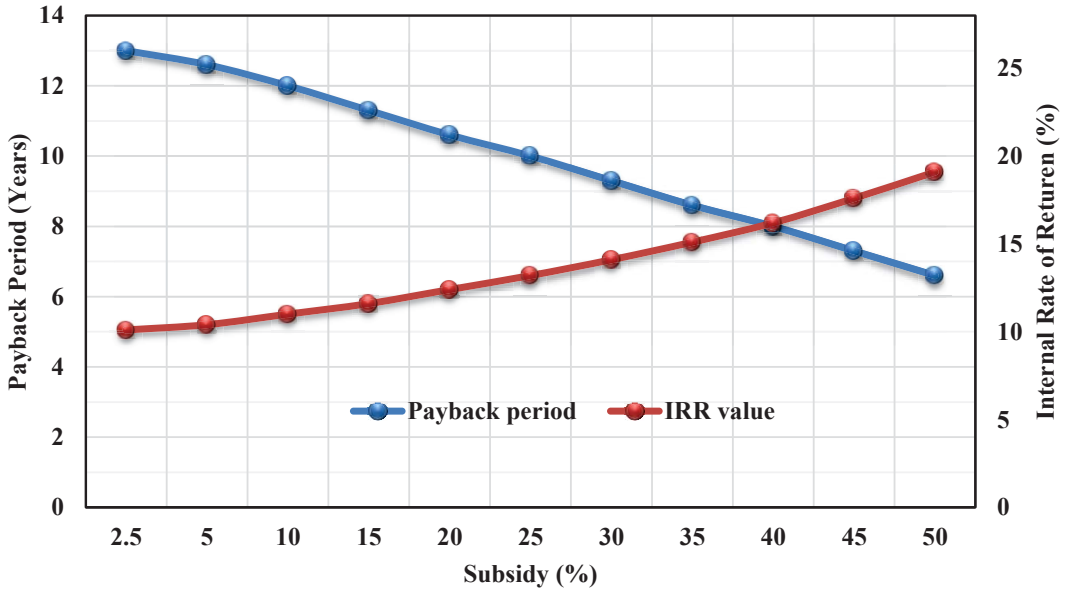

Figure 1. Effect of Subsidy on economic determinants of modelled grid connected solar PV system.

5. Conclusions

Residential buildings consume major part of the primary energy production and there is a huge energy saving potential in these buildings. Energy conservation measures in residential buildings is an important study and needs to be examined carefully to improve the energy security situation in KSA. The prevailing local design and construction practices in the residential buildings of KSA are energy inefficient. The buildings are poorly insulated, use inefficient appliances and lighting systems, and without the implementation of available standards. The implementation of IECC standards signpost the significant energy saving potential in the residential sector of KSA when compared to the typical local design practices. The simulation results for IECC standardized buildings shows 56 %, 37 %, 46 %, and 27 % less energy consumption for space cooling, space heating, lighting, and appliances, respectively.

Solar energy integration to meet the partial energy requirements in the residential buildings of KSA is technically and financially more viable as compared to zero energy building concept. The use of solar energy to meet the partial energy requirements of a residential building also provides the summer peak load energy stability in KSA. The implication of using grid connected PV system to meet the lighting load is economically justified in terms of subsidy provided by the government. Results indicate that the 50 % subsidy on the establishment of proposed grid connected PV system favors all economic determinants and results in reducing the payback period from 13.3 years to 6.6 years. Therefore, the government should start incentive programs and should provide subsidy to encourage the use of solar PV systems in residential buildings.

Renewable energy in Croatia: a review of present state and future development

Paolo Blecich, Marko Petrić and Bernard Franković

Faculty of Engineering, University of Rijeka (Croatia)

Abstract

Renewable energy has recently experienced a rapid expansion in Croatia. The improved feed-in tariff system attracted substantial investments and boosted the electricity generated from renewable energy systems. The installed renewable energy capacity rose rapidly from 100 MW in 2011 to more than 500 MW in 2016. In 2014 alone, 200 MW of new wind power plants were added. The total installed capacity in renewable power plants is capable of generating around 1250 GWh of renewable electricity per year. Renewable electricity represents a share of around 7% in the annual electricity consumption of Croatia. Wind energy is by far the most significant renewable energy source in Croatia, generating more than 85% of the renewable electricity. By installed capacity, the 455 MW in wind power plants is followed by 25 MW in biomass and biogas power plants, 12 MW in cogeneration and 8 MW in solar PV power plants. In order to keep up with the running expenditures within the feed-in tariff system, the incentive fee for renewable electricity support was increased fivefold by the end of 2013. At present, end consumers support renewable electricity generation with 5% of the cost of electricity. This incentive fee is expected to rise with newly added renewable power plants, aiming to double the share of renewable electricity from the present 7% up 13.6% by 2020.

Keywords: *Renewable energy, Croatia, feed-in tariff system, solar PV, solar thermal, wind energy*

1. Introduction

This paper gives an overview of the present state and future development of renewable energy in Croatia. Wind and solar PV energy are the most rapidly expanding renewable energy markets in Croatia. On the other hand, solar thermal and hydropower have slower growth rates. The substantial renewable energy growth is fueled by increasing energy demand, fossil fuel price and energy supply insecurity. Furthermore, improved policies and incentive programs as well as enhanced renewable energy components and systems have also contributed the renewable energy growth both in Croatia and worldwide [1-3]. The improved Croatian feed-in tariff system made investing in renewable energy more attractive to entrepreneurs and boosted the installed capacities of wind power in the first place. However, the feed-in tariff system collecting incentive fees presents an increasing financial burden to electricity customers since the agreed renewable electricity share targets are still far away.

2. Global renewable energy overview

The solar PV global installed capacity rose from 16 GW in 2008 to 232 GW while the wind global installed capacity rose from 121 GW in 2008 to 433 GW at the end of 2015 [1], as shown in figs. 1 and 2. The leading countries for installed solar PV capacities are China (44 GW), Germany (40 GW), Japan (36 GW), USA (27 GW) and Italy (20 GW). The country with the largest newly added solar PV capacity in 2015 was China with 15 GW, overtaking long-time leader Germany. The solar water heating collector capacity is estimated at 435 GWth (621 million m^2) in 2015, with China at the first place reaching a share of 73%, and followed by USA, Germany, Turkey and Brazil, whose combined share is 12% [4-6]. The solar water heating sector

doi:10.18086/eurosun.2016.11.02 Available at http://proceedings.ises.org

slowed down in 2014 and 2015, mainly due to shrinking markets in Europe and China. The concentrating solar thermal power (CSP) market has a global installed capacity of 4.8 GW with Spain and USA holding about 90% of the world total capacity.

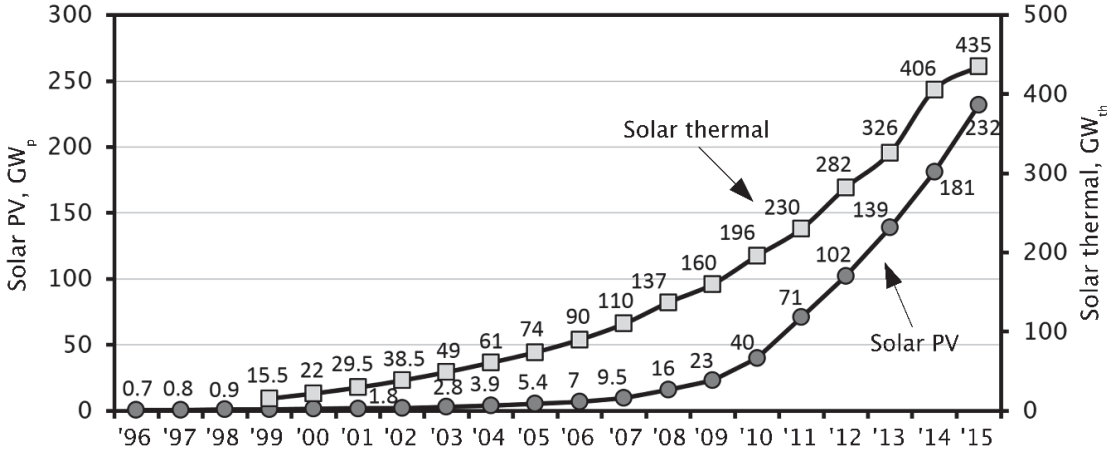

Fig. 1: Solar PV and solar thermal global installed capacity, 1996-2013, [1-6]

The leading countries for installed wind power capacities are China (145 GW), USA (74 GW), Germany (45 GW), India (25 GW) and Spain (23 GW), fig. 2. Again, China is the leading country for newly added wind power capacities with 32 GW in 2015 alone. The hydropower global capacity surpassed 1000 GW in 2013 and it was 1069 GW at the end of 2015. The leading countries for installed hydropower are China (296 GW), Brazil (92 GW), USA (80 GW), Canada (79 GW), Russia (48 GW) and India (47 GW). China added 16 GW of new hydropower plants in 2015 [1].

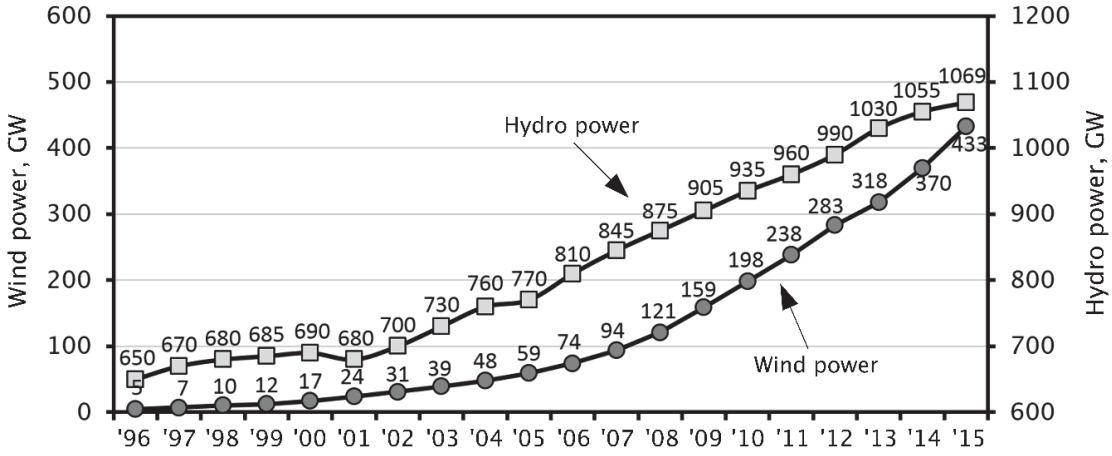

Fig. 2: Hydro and wind power global installed capacity, 1996-2013, [1-3]

Wind, hydro, biomass and geothermal energy are the most financially viable renewable energy sources on the market. The cost of electricity generation from hydro power plants is in the range of 0.02 to 0.09 €/kWh with a levelized cost (LCOE) of 0.045 €/kWh. Onshore wind power plants have costs of electricity generation in the range of 0.03 to 0.09 €/kWh with a LCOE of 0.054 €/kWh. Biomass energy, including solid, liquid and gaseous fuels, has a cost of electricity generation between 0.03 and 0.09 €/kWh with a LCOE of 0.06 €/kWh. The costs of electricity generation from geothermal sources is in the range of 0.05 to

0.11 €/kWh with a LCOE of 0.07 €/kWh. Nowadays, wind, hydro, biomass and geothermal energy provide electricity at a competitive cost, compared to the conventional fossil fuels. Electricity generation in fossil fuel power plants come at costs between 0.04 and 0.12 €/kWh and a LCOE of 0.055 €/kWh, all excluding health, environment and carbon emission costs.

Electricity generation in offshore wind power plants have significantly higher costs than those of the onshore wind power plants. The levelized cost of electricity generation (LCOE) in offshore wind power plants is almost three times the cost of electricity in onshore wind power plants: 0.15 €/kWh against 0.054 €/kWh. The cost of electricity generation from solar energy is still the highest among renewable energy sources. The cost of electricity is in the range of 0.07 to 0.20 €/kWh for utility PV power plants, 0.15 to 0.25 €/kWh for small-scale rooftop PV systems and 0.20 to 0.30 €/kWh for CSP thermal power plants. The levelized costs are 0.14 €/kWh for utility PV, 0.19 €/kWh for rooftop PV and 0.23 €/kWh for CSP. The efficiency of solar PV modules is still a major drawback, yet improvement is being made in this field as well. The efficiency of crystalline silicon PV modules is 10-20% while the efficiency of thin-film technology is only 5-12%. Nevertheless, the efficiency of concentrating PV modules (CPV) is 25% on average. The most-efficient existing PV module is a four-junction CPV which peaked a world record of 46% solar-to-grid efficiency. Hybrid photovoltaic thermal solar collectors (PVT) and concentrating PVT (CPVT) modules are capable of producing electricity and heat at efficiencies significantly higher than those of electricity-only CPV modules, with manufacturers claiming efficiencies of up to 75%. Solar thermal water heating systems reach 30-50% efficiency at an average cost between 0.05 and 0.15 €/kWh. Large-scale solar thermal systems, for multi-family houses and district heating have costs of energy generation between 0.03 and 0.10 €/kWh.

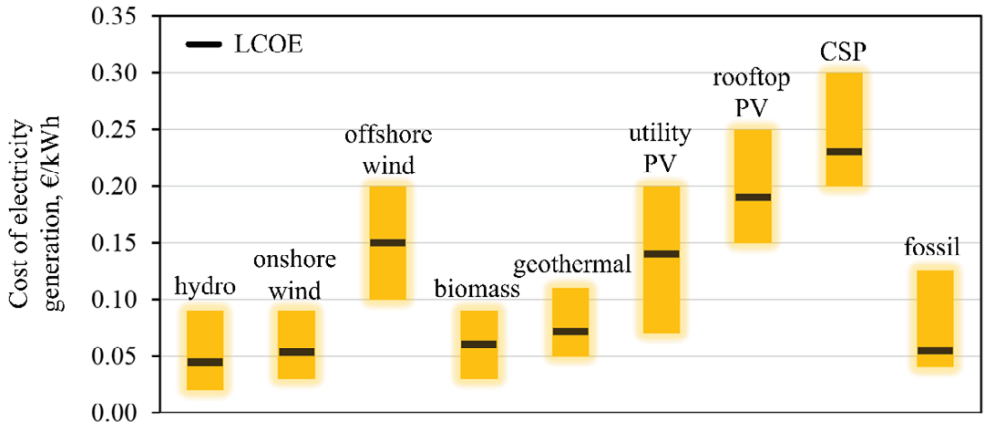

Fig. 3: Range of cost and levelized cost (LCOE) for electricity generation from renewable energy sources [1-3]

3. Renewable energy in Croatia

3.1. Present state

Under the Croatian feed-in tariff system, the currently installed renewable energy capacity of around 530 MW is capable of producing around 1250 GWh of electricity per year [7]. Ranked by installed capacity, wind energy dominates overwhelmingly with 455 MW and is followed by biomass and biogas installations, each having a total capacity of 25 MW, cogeneration with 12 MW, solar PV with 8 MW, small hydro with 3 MW and waste energy with 2 MW. Ranked by the number of operating power plants, the leading is solar PV with 155 power plants and is followed by 21 biogas installations, 17 wind power plants, 10 biomass installations, 7 small hydro power plants, 4 cogenerations and 1 waste energy power plant.

The nature of wind energy in Croatia is highly intermittent, whereas frequent and abrupt oscillations in the electricity output are expected over short periods of time, usually between morning and evening hours. In 2015, during 10% of the time the wind electricity output was negligible, usually less than 1% of the nominal capacity. On the other hand, the maximum instantaneous wind electricity output was 370 MW, which

corresponds to a maximum capacity factor of 84%. The average capacity factor for Croatian wind power plants is 25%, which corresponds to 2200 working hours at nominal capacity over a period of one year. For comparison, Danish wind power plant are able to achieve annual capacity factors between 50 and 60%.

The generated renewable electricity of 1250 GWh represents around 7% of the gross electricity generation which amounts to 17500 GWh in Croatia [7-10]. If large hydro power plants (> 10 MW) are accounted for in the renewable electricity mix of Croatia, the renewable electricity share varies significantly, depending on the quantity and distribution of rainfall throughout the year. For example, the share of renewable electricity was only 28% in 2012 but reached 58% in 2014. Likewise, the renewable energy share in the total primary energy consumption of Croatia is also variable: from 14% in 2012 up to 28% in 2014.

Under the European energy and climate plan, Croatia agreed that the share of renewable energy in the final energy consumption should reach 20% by the end of 2020. Furthermore, Croatia decided for two sub-targets: increase the renewable electricity share to 13.6% and increase the cogeneration electricity share to 4%, both with respect to the final electricity consumption. Unlike renewable electricity, the Croatian solar thermal sector is having a slower progress, because of smaller subsidies. The total installed solar thermal surface was around 200.000 m^2 by the end of 2015 in Croatia. This gives a specific solar thermal surface of only 47 m^2 per 1000 inhabitants in Croatia, whereas the EU-28 average is 85 m^2 per 1000 inhabitants [4-6].

3.2. Future development

Renewable energy has seen a fivefold increase of installed capacities in the last four years: from 100 MW in 2011 to more than 500 MW as of September 2016, as shown in Fig. 4. Wind power plants are usually installed along the coastal region of the Adriatic Sea, because of favourable wind conditions. On the contrary, solar PV systems are more frequently installed in West and North Croatia, despite lower annual solar irradiation but more attractive support schemes.

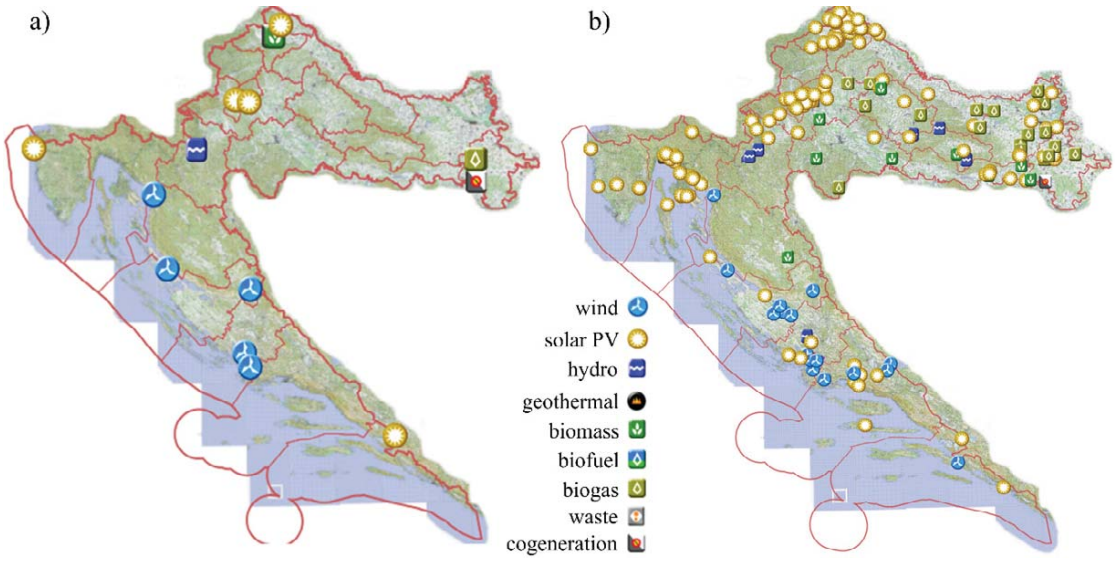

Fig. 4: Renewable energy installations in Croatia: a) 100 MW in 17 power plants in 2011; b) 530 MW in 215 power plants as of September 2016 [6]

At present, the 530 MW of installed renewable energy capacities supply around 7% of the electricity demand in Croatia. On the other hand the share of electricity from cogeneration systems is still negligible, less than 1% in the annual electricity consumption. In order to meet the agreed targets of 13.6% in renewable electricity share and 4% in cogeneration electricity share, a substantial increase in total capacity and number of installations in renewable electricity and cogeneration is necessary. It is estimated that an additional 500 MW in renewable electricity and 140 MW in cogeneration are required to meet the agreed share targets.

Wind energy will continue to dominate the renewable electricity mix in Croatia. According to the Croatian action [11] plan for renewable energy, the present wind energy capacity of 455 MW will reach 750 MW by 2020, as shown in fig. 5. Solar PV, from the present 8 MW is expected to reach 55 MW by 2020. Hydro energy (including large hydro) will be upgraded from the present 2100 MW up to 2500 MW by 2020, of which small hydro power plants will represent 100 MW. Biomass and biogas power plants have a combined total capacity of 50 MW, which is expected to increase up to 125 MW by 2020. Geothermal installations for electricity generation are at test phase at the moment and will reach 10 MW by 2020. The annual generated electricity can be estimated from the number of working hours at nominal capacity: 3000 hours for hydro, 2200 hours or wind, 1150 hours for solar PV, 6500 hours for biomass and biogas, 7200 hours for geothermal energy. Thus, the generated renewable electricity (excluding large hydro) will increase to 3200 GWh by 2020, from the present 1250 GWh. This returns a predicted renewable electricity share of around 18%, which is even more than the agreed target share of 13.6%. At present, wind power plants generate more than 85% of the renewable electricity in Croatia. However, this wind share is expected to decline to around 50% as new hydro, biomass and cogeneration capacities enter the renewable electricity mix of Croatia.

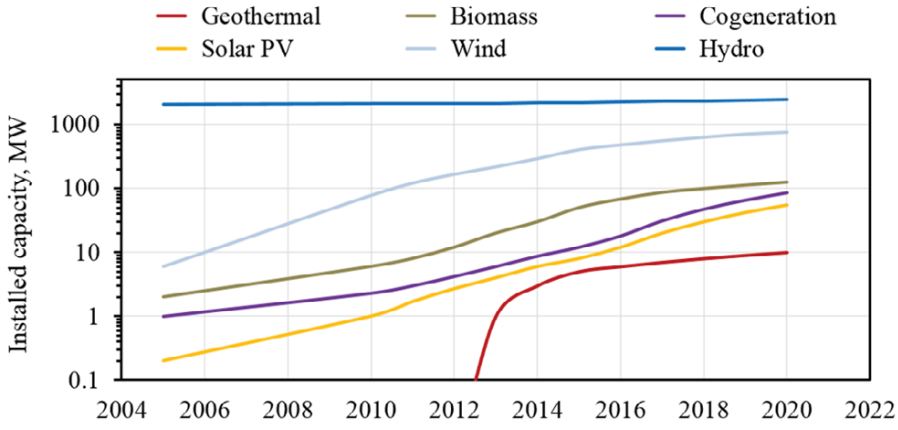

Fig. 5: Predicted renewable energy capacities in Croatia till 2020

The Croatian action plan [11] for renewable energy is a roadmap for increasing the use of renewable energy in the three major sectors of energy consumption: electricity, heating & cooling and transport, as shown in fig. 6. The overall combined share of renewable energy in the final energy consumption should be 20% or more by the end of 2020 in Croatia. The target share for renewable energy in electricity consumption of 39% by 2020, including large hydro power plants, will be achieved by upgrading hydro and wind capacities as well as installing new capacities of solar PV, biomass and cogeneration power plants.

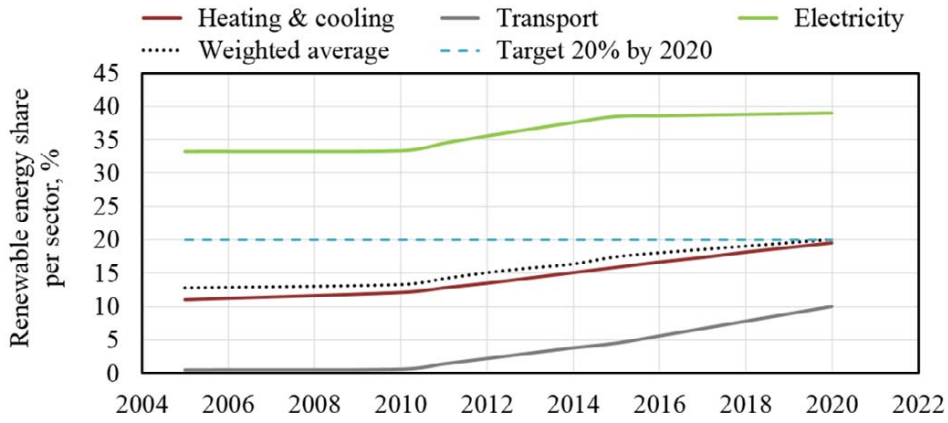

Fig. 6: Planned renewable energy share by consumption sector till 2020 in Croatia

The share of renewable energy in heating & cooling energy consumption is expected to grow from the present 15% up to 20% by 2020. This goal will be achieved with nationwide support programs for the energy retrofit of existing buildings, installation of solar collectors for space and water heating and replacement of fuel oil boilers with biomass and biogas boilers. The share of renewable energy in transport is expected to reach 10% by 2020. At the moment this goal seems hardly achievable, and attractive support programs will be necessary for the introduction of biofuel, hybrid and electric vehicles.

3.3. Economic aspects

To keep up with the running expenditures within the Croatian feed-in tariff system, domestic consumers had their taxes for renewable electricity generation increased in 2013. This increase was driven by the discrepancy between collected and distributed funds, which occurred in 2012 and 2013 [12], as shown in Fig. 7. Taking into account that the present renewable electricity tax is 5.8 €/MWh and that the price of electricity is 120 €/MWh for domestic consumers, nearly 5% of the price of electricity goes to renewable electricity support in Croatia. The renewable electricity taxes are going to rise since new renewable energy capacities are planned. The share of renewable electricity will be doubled by 2020, from the present 7% up to 13.6%. Recently, the Ministry of Economy of Croatia announced that the renewable electricity tax for domestic consumers will be raised to 20 €/MWh in 2017, and further to 23.3 €/MWh in 2018 and 25 €/MWh in 2019.

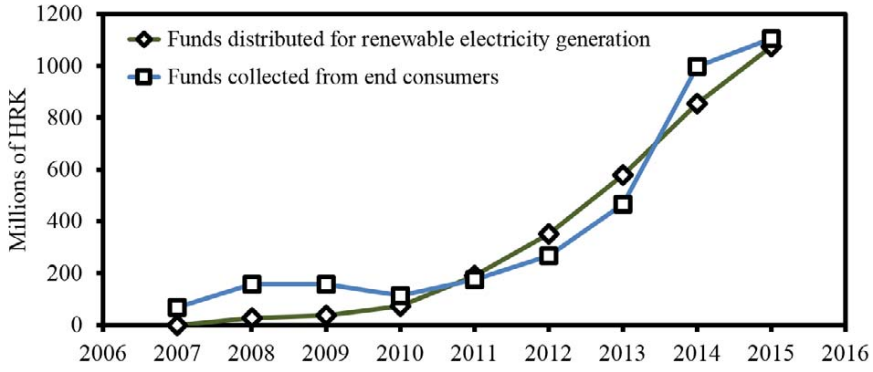

Fig. 7: Distributed and collected funds within the Croatian feed-in tariff system (1 EUR = 7.5 HRK)

The financial support for renewable electricity generation inside the Croatian feed-in tariff system was around 150€ million, or 1125 million HRK, in 2015. For a total amount of generated renewable electricity of 1250 GWh under the feed-in tariff system, the specific support for renewable electricity generation was equal to 120 €/MWh. For comparison, the European weighted average support for renewable electricity generation was 110 €/MWh in 2013 [13], as shown in figure 8.

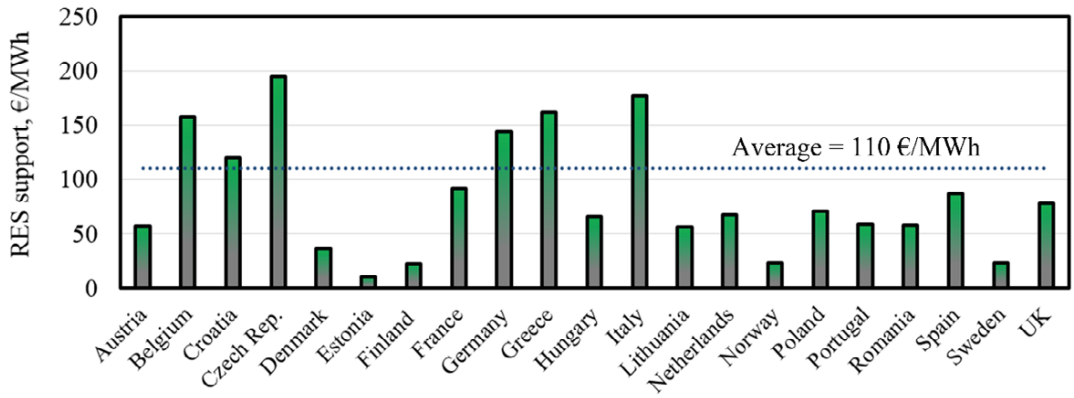

Fig. 8: Renewable energy support under the feed-in tariff system per unit of generated renewable electricity

The support for renewable electricity generation per unit of generated renewable electricity ranged between 11 €/MWh (Estonia) and 195 €/MWh (Czech Republic) in 2013. In Croatia, the specific support for renewable electricity generation was 120 €/MWh in 2015. However, this value does not take into account the penetration of renewable energy into the grid. Since the share of renewable electricity in the generated gross (renewable and conventional) electricity is 7% at the moment, the specific renewable electricity support per unit of generated gross electricity is 8.4 €/MWh in Croatia. The support for renewable electricity generation is collected from renewable electricity taxes for domestic and industrial consumers, carbon and environment taxes, grid fees, and other. At the moment, domestic consumers in Croatia have a renewable electricity tax of 5.8 €/MWh, which will be raised to 20 €/MWh in 2017 and further to 25 €/MWh in 2019. The annual electricity consumption of the average household in Croatia is 3500 kWh. Therefore, per year the average Croatian household supports renewable electricity generation with an amount of 20.3 €, which will become 87.5 € in the close future. In Europe, the specific support with respect to the gross electricity generation is up to 32 €/MWh (Italy), whereas the weighted average support is 13.7 €/MWh [13], as shown in fig. 9. Generally, countries with higher RES support in gross generated electricity have also higher shares of renewable electricity in their electricity markets.

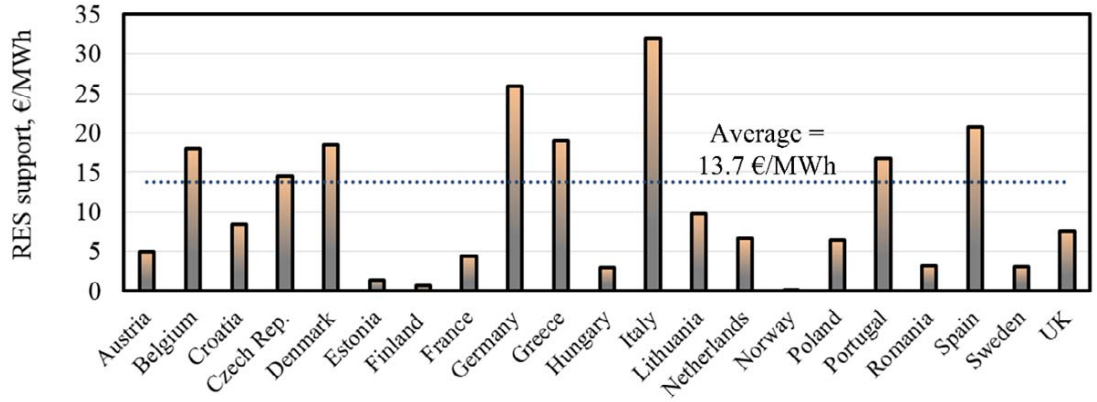

Fig. 9: Renewable energy support under the feed-in tariff system per unit of generated gross electricity

The renewable electricity support is somewhat correlated to a country's energy import dependency, as shown in fig. 10. Generally, countries with high dependency on imported energy tend to support more renewable electricity generation. For example, countries having high energy import dependency and large RES supports are: Italy with 79% and 32 €/MWh, Belgium with 77% and 18 €/MWh, Portugal with 75% and 17 €/MWh, Spain with 74% and 20 €/MWh, Greece with 66% and 19 €/MWh and Germany with 62% and 26 €/MWh. On the other hand, several countries have high energy import dependency, near or above 50%, but support renewable electricity generation to a lesser extent, such as Lithuania, Hungary, Finland, France and Croatia.

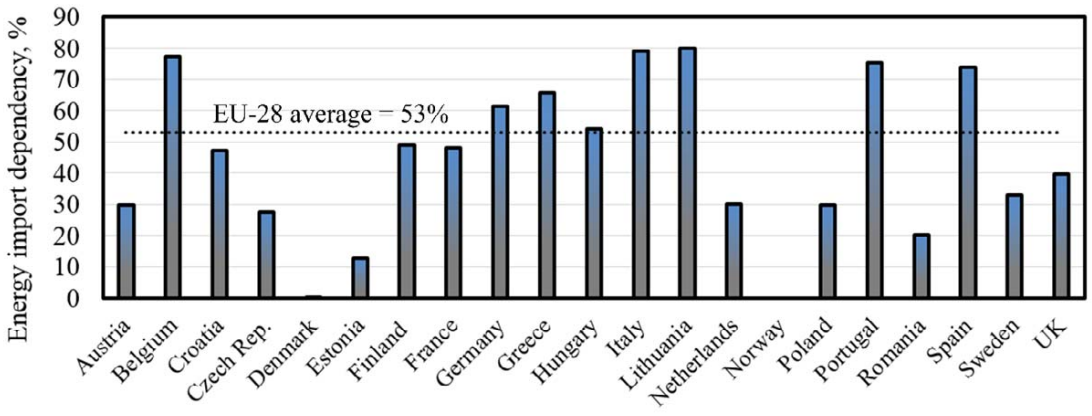

Fig. 10: Energy import dependency by country. Note: Norway is a net exporter, its energy dependency is set to 0.

4. Conclusion

Under the European energy and climate plan, Croatia agreed that the share of renewable energy in the final energy consumption should reach 20% by the end of 2020. Specific target shares have been decided for the three major energy consuming sectors: electricity, heating & cooling and transport. The target shares for renewable energy in electricity generation is 13.6% excluding large hydro or 39% including large hydro power plants. Today, excluding large hydro power plants, renewable electricity supplies 7% of the electricity consumption. If large hydro is included, the renewable electricity share is between 30 and 50%, depending on the available water resources during the year. The target shares for heating & cooling energy consumption and transport are set to 20% and 10%, respectively. At present, renewable energy represents 15% of the heating & cooling consumption and the 20% target will be most likely achieved. However, the renewable energy share in the transport sector is still negligible and the 10% target seem unreachable at the moment.

Renewable electricity is a fast growing market in Croatia. The support for renewable electricity generation will most likely continue to grow in the next 10 - 15 years. Today, the installed renewable electricity capacity is capable of supplying 7% of the electricity consumption in Croatia. The target share for renewable electricity has been set to 13.6% and the achievement of this target will require improved policy and stronger financial supports. The drawback of the fast growing renewable energy market are the increasing electricity prices in Croatia. The price of electricity is being pushed by the growing taxes for renewable electricity generation, which end consumers pay at a present rate of 5.8 €/MWh and will be paying at a rate of 20 €/MWh in 2017 and 25 €/MWh further in 2019. Inevitably, the price of electricity, which is 120 €/MWh at the moment, will grow alike. The collected funds from renewable electricity taxes are being converted into financial supports aiming to pull in new investments in the renewable sector. This renewable energy financial support, expressed in units of generated gross electricity, will grow from the present value of 8 €/MWh to around 20 or even 30 €/MWh in the next few years, whereas the EU average is 13.7 €/MWh. New renewable energy installations, especially wind farms, will need even more land to be converted to this purpose. However, the present expansion in the tourism sector opposes the expansion of renewable energy into islands and offshore areas, near seaside resorts and touristic centers.

On the other hand the solar thermal is having a slower progress. The total installed solar collector surface for water and space heating purposes was around 200.000 m^2 (140 MW_{th}) in Croatia by the end of 2015. It can be calculated that the per capita solar collector surface is 47 m^2 per 1000 inhabitants in Croatia which is only half of the EU-28 average with 85 m^2 per 1000 inhabitants. The slower progress of the solar thermal market in Croatia is mainly caused by less financial supports.

PV SITUATION IN PORTUGAL

L. Gil, G. Torres, I. Cabrita, L. Basílio, R. Costa

Direção Geral de Energia e Geologia

Summary

The situation of PV in Portugal is presented in this work, as well as statistics on the evolution of renewable energy (RE) and photovoltaic energy (PV) in Portugal in the last years. Data is also shown on the forecast of these energies for the coming years. In addition, policy measures for the use of PV are addressed, which have an impact on the larger use of PV for power generation.

Keywords: PV, Portugal, energy statistics, energy forecast, energy policy

1. Introduction

Between 2010 and 2014 the electricity consumption changed from about 24% to 25,6% of the total final energy, showing the importance of this energy resource in Portugal. So, having in mind the environmental and territorial sustainability, besides energy efficiency it is important to simultaneously increase the contribution of endogenous renewable energy sources in order to decrease Portugal's energy dependency and contribute for a competitive and low carbon economy. The NATIONAL RENEWABLE ENERGY ACTION PLAN **(**NREAP), based on the European objectives, states a target of 31% of renewable energy sources in the total energy consumption by 2020. In 2014 about 61% of the electricity generated in Portugal was based on renewable energy sources and about 27% of the gross final energy consumption was based on these resources. Solar energy is practically inexhaustible and constant, easily available in Portugal, mainly in the south, where the potential is quite considerable. Portugal is one of the European countries with better conditions for exploitation of this resource (see Fig. 1), featuring an average annual number of hours of sunshine, variable between 2200 and 3000, on the mainland (www.dgeg.pt), with an yearly global radiation from 1600 to >2100 kWh/m^2 (http://re.jrc.ec.europa.eu/pvgis/cmaps/eu_cmsaf_opt/G_opt_PT.png).

doi:10.18086/eurosun.2016.11.03 Available at http://proceedings.ises.org

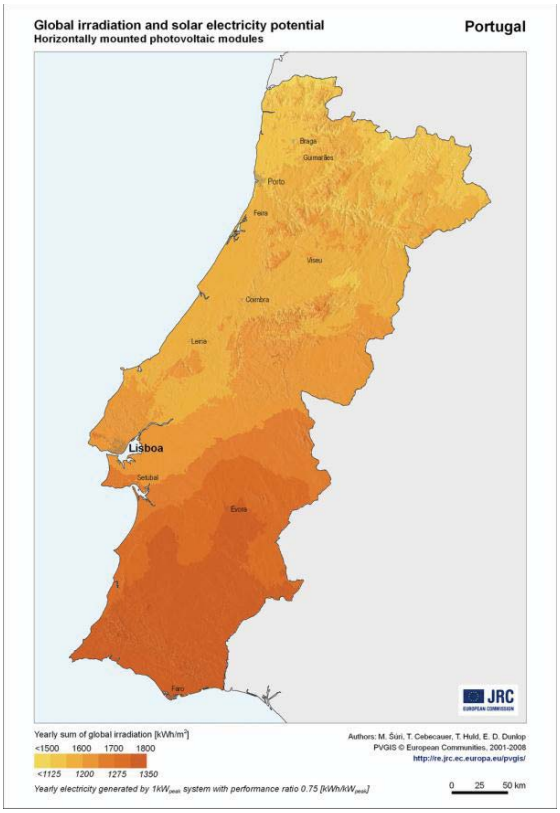

Fig. 1 – Global irradiation and solar electricity potential (re.jrc.ec.europa.eu/pvgis/cmaps/eu_cmsaf_opt/G_opt_PT.png).

2. Statistics on RE in Portugal and Europe

Data is shown (Tables 1-10, Figures 2-7) on the situation of RE in 2015 or the evolution in the last years namely: a) 2006-2015 total energy production for the different RE types; b) 2006-2015 installed capacity for the different RE types; c) distribution of installed capacity by type of RE by country region in 2014; d) 2008-2015 micro and mini-production installed capacity for the different RE types; e) 2008-2015 micro and mini-production for the different RE types; f) situation in 2005 and 2014 of total electric energy production and % of RE source in several European countries; g) situation in 2014 in several European countries of the RE production by type of RE source; h) situation in 2005 and 2014 of total electric energy production and % of RE source in several OECD countries.

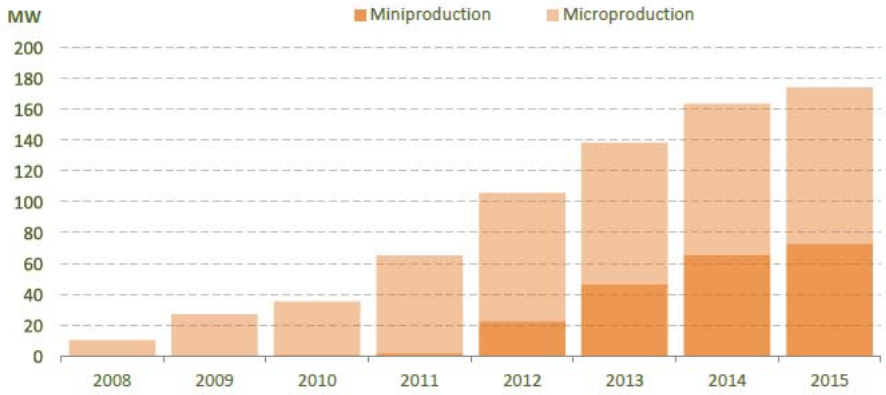

Fig. 5 - 2008-2015 micro and mini-production installed capacity (MW) for the different RE types (Portugal) (www.dgeg.pt).

Microproduction Law (Decree-Law 363/2007, of 2 November, revised by the Decree-Law 118-A/2010, of 8 October and by the Decree-Law 25/2013, of 8 March) regulates the small generation production of electricity (up to 5,75 kW) from RES. It provides for simplified licensing procedures for local grid-connected, low voltage, small/residential energy producers. The licensing of solar, wind, hydro, biomass and non-renewable CHP is conduced on-line via internet, using the System of Registration of Microgenerators (SRM). The connection capacity of a microproduction can only be up to 50% of the contracted power.

Miniproduction Law (Decree-Law 34/2011, of 8 March, revised by the Decree-Law 25/2013, of 19 February) regulates the small generation production of electricity (from 5,75 kW to 250 kW) from RES. It also provides for the same simplified licensing procedures for local grid-connected, low or medium voltage, small/commercial/industrial energy producers. The licensing of solar, wind, hydro, biomass and biomass is conduced on-line via internet, using the System of Registration of Miniproducers (SRMini). The connection capacity of a miniproduction can only be up to 50% of the contracted power and the annual consumption value of the user installation has to be at least 50% of the annual value of the generated electricity.

Table 7 - Situation in 2005 and 2014 of total electric energy production (TWh) and % of RE source in several OECD countries (www.dgeg.pt).

	Electricity producion in other OECD countries (TWh)							
	2005			2014			Δ% 14/05	
	Total	RES	%RES	Total	RES	%RES	Total	RES
Total OECD	10.461,0	1.670,3	16,0%	10.770,3	2.354,6	21,9%	3,0%	41%
New Zealand	42,0	27,5	65,5%	43,5	34,4	79,2%	3,6%	25%
Canada	628,2	379,0	60,3%	593,0	395,8	66,7%	-5,6%	4%
Turquey	162,0	39,9	24,6%	255,5	52,0	20,4%	57,7%	30%
Mexico	233,7	37,5	16,0%	300,1	52,3	17,4%	28,4%	40%
USA	4.258,3	356,4	8,4%	4.379,1	556,6	12,7%	2,8%	56%
Japan	1.049,1	92,8	8,8%	1.025,1	148,8	14,5%	-2,3%	60%
Australia	248,2	17,3	7,0%	248,2	36,9	14,9%	0,0%	113%
Norway	126,0	136,5	108,3%	126,7	138,3	109,2%	0,6%	1%

From all this data it can be seen that in 2014 Portugal was the third European country (Sweden, Austria better) with the largest share of electricity production by RE source and that when comparing to OECD countries Portugal was only outpaced by Norway, Canada and New Zealand. In 2015, from the total electricity production in Portugal (25.355 GWh), PV (797 GWh) contributed with 3,1%.

3. Statistics on PV in Portugal

Data is shown (tables, graphics) on the situation of PV in 2015 or the evolution in the last years namely: a) number and characterization of existing PV installations; b) 2006-2015 PV total energy production by country region; c) 2006-2015 PV installed capacity by country region; d) gross PV electricity generation in several (38) European countries.

In Portugal (including Madeira and Azores), the list of photovoltaic parks account for 129, in which 63 use polycrystalline silicon technology, 19 monocrystalline silicon technology, 7 thin films, 4 amorphous silicon and 4 multi-junction (see Table 9). Besides this there exists also aggregate data in micro-production (<5.75 KW) and mini-production (5.75 kW – 250 kW). So, provisional data for 2015 are an installed capacity of about 460 MW and a produced energy of about 797 GWh, overcoming the values foreseen in NREAP which were respectively of 383 MW and 593 GWh (NREAP, Table 3, p. 2077).

From the previous data it can be seen that solar photovoltaic installed capacity has grown from very small numbers to 460 MW, registering the largest relative low rate, comparing to other renewable energy sources. In the 10 year period of 2006-2015, PV energy production grew from 5 GWh to 797 Gwh, with an average growth near to 80 GWh/year. In the period of 2008-2015 micro PV installed capacity raised from 10.390 kW to 100904 kW (about 10 times more), a value over the foreseen for 2020 (see next item) and only in 6 years (2010-2015) mini PV installed capacity raised from 647kW to 72529 kW (about 112 times more), a value representing 29% of what is foreseen for 2020 (see next item).The micro/mini production represents about 34% of the total PV production. Only in 2015 ten new solar parks went into production. In this year Alentejo (south of Portugal) accounted for 38% of the total solar photovoltaic production. Comparing with other 38 European countries Portugal is the 13th PV electricity producer.

4. RE/PV Programmes/Policies

The NREAP is defined by the Council of Ministers' Resolution nº 20/2013, published in the Republic Diary, 1st Series, Nº70 from 10th of April 2013. This official document foresees, that the contribution of PV for 2020

is 670 MW of installed capacity and 1039 GWh of produced energy, respectively. Solar energy is expected to have an important role in the increase of decentralized power production; the production cycle is adequate to the consumption peaks, and also because has great resources availability and also R&D capacity.

The Decree-Law 363/2007 of November 2nd and the Decree-Law 34/2011 of March 8th regulate the production and selling of electricity by micro and mini power plants, respectively. Another Decree-Law (nº153/2014 of October 20th) is also related with this. So, besides the micro-production program continuation, in 2011 a mini-production was set having as aim the installation of 250 MW until 2020, mainly for services and industry. The enlargement of mini-production to larger capacities in face of demand and technology evolution can be considered. Aiming also at more 80 MW of installation capacity by 2020 in micro-production the two support programs may be fused.

5. Conclusion

In the last 10 years PV power production per year grew from only 5 GWh to about 800 GWh with the installed capacity in the same period changing from 3 MW to about 460 MW. From 2010 to 2015, PV mini and micro-production raised from only 35 MW to more than 173 MW, almost five times more. PV infrastructures are mainly placed in the south of the country where the solar potential is greater. The provisional data for 2015 for PV show that the installed capacity was about 20% higher (achieving 69% of 2020 value) ant the produced energy was about 34% higher (achieving 77% of 2020 value) than what was foreseen in the NREAP, demonstrating that national policies in this field are correct.

The Forecast of the World Renewable Energy Development till 2020

Sergey M. Karabanov[1], Pavel P. Bezrukikh[2] and Pavel P. Bezrukikh (Jr.)[3]

[1] Ryazan State Radio Engineering University, Ryazan (Russia)

[2] G.M. Krzhizhanovsky Power Engineering Institute JSC, Moscow (Russia)

[3] LUCOIL JSC, Moscow (Russia)

Abstract

There are quite a lot of forecasts of renewable energy development in whole and its different kinds. The principal forecasts are developed by IEA, BP, IRENA, EWEA, WWEA, ISEA and some other institutions. Many of forecasts prefer a remote prospect – years 2030, 2035, and 2050. Probably it is assumed that the forecast for 2020 will be achievable with great probability. However, famous programs experience of "Wind Force-10" and "Wind Force-12" in which the problem of achieving a wind power share in the world overall electricity production by 2020, respectively 10% and 12%, was set, means that such forecast is too optimistic as already now it is clear that these results are unachievable. On the other hand, IEA forecasts concerning renewable energy share in 2020 in world electricity production are considered to be too pessimistic. The realization of the forecast offered by the authors seems to be the most probable.

Keywords: *forecast, program, renewable energy sources, electricity production*

1. Introduction

The main goal of the paper is to define the share of renewable energy sources in the world overall electricity production in 2020. For this purpose it is necessary to define the following by the end of 2020: the general electricity production in the world; the installed capacity of power plants on the basis of different kinds of renewable energy sources and the produced electric power; growth rates of installed capacity of various renewable energy plants. The forecasting procedure combines the analysis of the growth rates of capacity and energy for the previous period with the research of installed capacity utilization factor of power plants based on different kinds, taking into account forecasts of growth of use of different kinds of renewable energy sources.

2. Analysis of forecasts for renewable energy utilization

According to REN-21 data concerning the installed capacity of wind, PV, biomass and geothermal power plants during the period of 2004-2014 the average annual growth rate is calculated for the whole period and in 2014 in relation to 2013 [1].

According to IEA statistics on electricity production by renewable energy power plants and data of REN-21 on installed capacity the installed capacity utilization factors for the above power plants are calculated.

Ehe installed capacity utilization factors aor wind power for 24 countries for the period of 2000-2013 were determined. On the basis of the obtained data analysis the growth rates of installed capacity and electricity production for 2015-2020 according to three scenarios of overall electricity production were justified.

According to scenarios offered by the authors the share of renewable energy by 2020 will be: minimum – 9.3%; average – 11.2%; maximum – 13.4%.

doi:10.18086/eurosun.2016.11.06 Available at http://proceedings.ises.org

According to IEA (2011) the share of renewable energy will be: "New Policies Scenario" – 8.4%; "Current Policies Scenario" – 7.2%; "450 Scenario" – 10.1%.

The forecasts discrepancy is quite considerable. Below are the reasons for the optimistic forecast.

According to the optimistic forecast of wind power development made in 1997 by "Wind Force-10" program the purpose was to achieve a share of 10% of wind energy of general electricity production by 2020 (Table 1). We monitored the forecast realization within more than 10 years and the obtained result is contradictory. Until 2010 the forecast of the wind energy installed capacity was overfulfilled. But as for the energy share produced at these stations significant underrun was observed. Obviously, the installed capacity utilization factor (ICUF) was taken into account not exactly. The forecast did not indicate the data for 2011 – 2014, but the ICUF in 2015 (433 GW) shows that in 2015 the forecast indicator for the capacity (573 GW) was not fulfilled. It can be stated that the forecast of annual rate and capacity utilization factor was unnecessarily optimistic.

In 2011 the International Energy Agency released the forecast for electrical energy production in the world, including renewable energy, until 2030 according to 3 scenarios. Table 2 shows the forecast data for 2020.

"New Policies Scenario" – is the central scenario combining a wide range of political obligations and plans of countries all over the world in the field of energy security, climate changes, environmental conservation, etc.

"Current Policies Scenario" – development with conservation, without changing the existing policy including obligations and plans.

"450 Scenario" provides aggressive schedule of actions necessary for limiting long-term increase of greenhouse gases concentration in the earth atmosphere up to 450 ppm of CO_2 equivalent.

Tab. 2: International Energy Agency scenarios, 2011

	Actual data				"New Policies Scenario"		"Current Policies Scenario"		"450 Scenario"	
	1990		2009		2020		2020		2020	
	bln. kWh	%	bln. kWh	%	bln. kWh	%	bln. kWh	%	bln. kWh	%
Fossil fuels	7490	63.4	13445	67.1	17593	63.1	18757	65.7	15835	59.0
Nuclear power	2013	17.0	2697	13.5	3576	12.8	3495	12.2	3741	13.9
Hydropower	2144	18.1	3252	16.2	4380	15.7	4254	14.9	4547	16.9
Renewable energy	173	1.5	650	3.2	2332	8.4	2063	7.2	2712	10.1
Renewable energy, including hydropower	2317	19.6	3902	19.5	6712	24.1	6317	22.1	7259	27.1
Whole world	11819	100.0	20043	100.0	27881	100.0	28569	100.0	26835	100.0

According to the scenarios the electric energy production in 2020 is to be 27881 – 28569 – 26835 bln. kWh, the share of renewable energy: 8.4 – 7.2 – 10.1%, accordingly.

This forecast is unduly pessimistic as it contradicts the actual status of the world energy balance. According to REN 21.2016 the share of organic fuel in the energy balance for electric energy production is 59.3%, nuclear power stations - 17% (total – 76.3%), renewables – 23.7%. The share of hydropower plants is 16.4%, "new" renewable energy power stations – 7.3%, including wind power stations - – 3.7%, biofuel power plants – 2.0%, PV power plants – 1.2%, the rest renewables – 0.4%.

The question is: what renewable energy share in the electric energy production is the most obvious?

To answer this question it is necessary to give proof of the electric energy production forecast in the world and also the forecast of growth of capacity utilization factor and electric energy production on the basis of some renewable energy sources.

3. Main results

The forecast of the word electric energy production for 2020 was made on the basis of the analysis of growth rates of electric energy production for the period of 1995 – 2014 (Table 3) taking into account a general slowdown in global economic growth. The average annual growth rate for the period of 1995 – 2014 was 3.07%; for the period of 2004-2014 – 3.0%; 2012-2014 – 2.0%, 2014 in relation to 2013 – 1.52%.

Taking into account the above data three scenarios have been accepted:

a) "Hardly probable" with the growth rate of 3.0%;

b) "Possible" with the growth rate of 2.6%;

c) "Probable" with the growth rate of 2.0%.

The comparison of the forecasts of the International Energy Agency (IEA) and Power Engineering Institute (PEI), Russia, shows high matching degree of the data for electric energy production for 2020 with the only difference that the "Probable scenario" (c) of PEI coincides with the least probable "450 Scenario" of IEA (Table 4).

To estimate the growth rate of the electric energy production on the basis of some renewable energy sources the data of REN21 (Renewable Energy Policy Network for the 21st Century) for 2016, 2015 and 2014 was used. Table 5 shows the growth rate of the installed capacity for the period 2004 – 2014, (2004 ÷ 2015) and in 2014 in relation to 2013, in 2015 in relation to 2014 for all renewable energy sources [1].

Ethanol annual production, bln. l	28.5	94.5	98.3	12.67/11.91	7.06/4.02
Biodiesel annual production, bln. l	2,4	30.4	30.1	28.6/24.85	12.93/-1.0
Number of countries with specified goals for renewables	48	164	173	13.07/12.52	13.89/5.49

Taking into account that with the increase of installed capacity the annual average growth rate inevitably slows down and considering the growth rates slowing down in 2014, for the forecasts for 2015 and 2020 quite moderate growth rates have been accepted.

To determine the electric energy production it was necessary to define the installed capacity utilization factor (ICUF) for all renewable energy sources.

According to the analysis the most complicated thing is to determine the ICUF for wind power stations. The calculations of ICUF of wind power stations on installed capacity of first 24 countries for the period of 2000-2013 (2012) according to World Wind Energy Association (WWEA) data on installed capacity of IEA have

been made. On the basis of this data the ICUF of a wind power station was accepted to be equal to 0.25; for a PV station – 0.12-0.13; for a geothermal station – 0.75.

Table 6 shows the forecast of ICUF and electric energy produced by renewable energy sources by 2015. This forecast was made in 2013 and the degree of its matching with the reality turned out to be quite high (In brackets the actual capacity in 2015 is indicated.)

Tab. 6: Forecast for renewable energy sources development for 2015

Power station type	2010 (actual)			2015 (forecast)		
	Capacity, GW	ICUF	Electric energy production, TWh	Capacity, GW	ICUF	Electric energy production, TWh
Wind power stations	198	0.197	341	429 (433)	0.25	939
PV stations	40	0.12	42	230 (227)	0.12	242
Solar thermal power stations	1.1	0.15	1,4	5 (4.8)	0.15	6.5
Biomass power stations	64.9	0.55	313	98 (106)	0.53	456

	12	8,8		11,5
	15	10		13
Biomass power stations	3	113	0.53	524
	5	125		580
	10	158		733
Geothermal stations	3	16	0.75	105
	5	17		112
	10	22		144
Total		1289		2676
		1513		3084
		1755		3579

The forecast for electric energy production on the basis of renewable energy sources is shown for three values of annual average growth rate. For each renewable energy source the accepted growth rates were considerably lower than in 2014 (Table 7).

The estimation of renewable energy share with three options of development forecasts of electric energy production by all power stations and three options of electric energy production by renewable energy stations becomes a multiple-option task.

The estimation of renewable energy share according to the average values has been made. The average value of the world energy production according to three options is equal to 27768 TWh. The average value of the renewable energy production according to three options is equal to 3113 TWh. Therefore, the renewable energy share in the total electric energy production (without hydropower stations) will be 11.2 %.

Maximum renewable energy share corresponds to the largest value of renewable energy production (3579 TWh) and to the minimum value of the total electric energy production (26764 TWh) and is equal to 13.4%.

The minimum renewable energy value corresponds to the inverse ratio, 2676 TWh and 28656 TWh, respectively, and is equal to 9.3%.

The wind energy share in the total electric energy production is: 5.3 % (minimum), 6.1 % (average) and 7% (maximum). Table 8 provides the comparison with the IEA forecast.

Tab.8: Renewable energy share in the world total electric energy production in 2020 (in brackets – the wind share forecast)

	Minimum, %	Average, %	Maximum, %
PEI	9.3 (5.3)	11.2 (6.1)	13.4 (7.0)
IEA	7.2	8.4	10.1

4. Discussion

The present paper considers the renewable energy development in the near future. This process is affected by many different factors. The research confirms that in spite of obstacles the renewable energy will develop with the rates exceeding the growth rates of the world economy and traditional energy.

The significance of the performed investigation is determined by the role the renewable energy will play in the world policy and economy. This role is defined by the following factors:

- possibility to provide energy independence or considerable decrease of fuel import dependence;
- possibility (for developed countries) to win the market of high-technology equipment, to provide the diversification activity of a country industrial complex;
- inexhaustibility of renewable energy sources and impossibility of their privatization or capture by other countries (unlike oil or gas fields);
- ecological cleanness.

5. Conclusion

The average annual growth rate of installed capacity of wind, PV and other renewable energy power stations as compared with the previous year is determined. For the period of 2015-2020 the growth rates will be: for wind power stations – 13-15%, PV stations – 15-25 %, biofuel power stations – 3-10%, geothermal power stations – 3-10 %.

For all types of renewable energy power plants the installed capacity utilization factors are defined. The coefficient for the weighted average value of wind power stations will amount to 0.25, PV stations – 0.13, biofuel power stations – 0.53, geothermal power stations – 0.75.

The forecast of installed capacity and produced electricity for 2015 and 2020 for all main renewable energy power stations is made.

It is shown that overall installed capacity of renewable energy power stations in the world will be about 1500 GW, including wind, PV and biomass power stations, respectively, 800 GW, 570 GW and 125 GW.

By 2020 the electricity production at renewable energy power stations will be approximately 3000 TWh.

Roadmaps for Energy (R4E): How to foster the sustainable energy transition of communities

Torsten Masseck[1], Elke den Ouden[2] and Rianne Valkenburg[2]

[1] Universitat Politècnica de Catalunya (UPC), Sant Cugat del Vallès (Spain)

[2] TU/e Lighthouse, Eindhoven (Netherlands)

Abstract

The sustainable energy transition of communities is one of the main targets within the European energy policies. Consistent energy planning is needed but conditioned by difficulties of city administrations to meet the necessary skills and have the necessary knowledge in order to lead the corresponding transition processes. R4E develops roadmapping capacities of 8 European partner cities (Eindhoven, Forlì, Istanbul, Newcastle upon Tyne, Murcia, Palermo, Sant Cugat de Vallès and Tallinn) together with their local stakeholders, and provides them with the necessary knowledge about innovative energy solutions in the fields of smart buildings, smart mobility and smart urban spaces.

A specific systemic approach to these future energy solutions has been developed, based on so-called Systemic Solutions Maps and Technology Outlooks, in order to strengthen the capacities of the participating stakeholders in designing detailed roadmaps and developing together with the city authorities specific project portfolios.

Keywords: *Sustainable energy transition, Roadmapping, renewable energies, Systemic Solution Maps, participatory processes*

1. Background

Sustainable Energy Transition of society refers to long-term process which transforms radically the exiting energetic reality of a society, mobilizing diverse groups of stakeholders. (Verbong & Rotmans 2012)

Transition management has evolved during the last years offering a structured approach to the complex societal problems and difficult governance related to transition processes. (Loorbach & Rotmans 2010) These processes include generating a long term orientation where to head to as society, for instance through the use of scenarios or roadmaps, but also include leaving options open, dealing with uncertainties.

Transition processes can be organized best in so-called transition management cycles. (Loorbach & Rotmans 2010) and renewable energy communities (RECs) can be drivers of these energy transitions as communities which invest in the production of renewable energy with the aim to cover their own energy needs. (Dóci et al. 2015)

The R4E project (www.roadmapsforenergy.eu) responds to the EE-07-2014 call entitled "Enhancing the capacity of public authorities to plan and implement sustainable energy policies and measures" within the Secure, Clean and Efficient Energy Work Program of HORIZON 2020 of the European Commission. The main challenge of the partners within R4E is to develop visioning and roadmapping capacities within municipalities to initiate joint activities to spur development and implementation of innovative energy solutions in cities.

The implementation of strategies and plans on municipal level suffers from the effects of the recent global economic and financial crisis, the shifting of competences and responsibilities between government levels, difficulties within organizations to meet the necessary, and changing, skills and capacities; and a lack of

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/eurosun.2016.11.07 Available at http://proceedings.ises.org

knowledge on the state of the art concerning technological and organizational innovation. This leads to imperfect implementation processes and loss of faith in the usefulness of strategies and action plans.

In order to overcome these barriers, R4E established the following objectives:

- Creating high quality visions and roadmaps that drive collaboration between municipalities, entrepreneurs, knowledge institutes and citizens to achieve longer term ambitious goals through short term decisions and actions
- Implementing with all partners a similar participative process for vision and roadmap development that enables continuous cross-city learning exchange of experiences, challenges and best practices.
- Building an ecosystem of relevant local parties in each city, laying the foundation for extended collaboration between partners to drive innovation for sustainability purposes, through joint projects, e.g. joint pre-commercial procurement projects.

This ambitious approach requires new processes and tools in order to foster understanding, communication and informed, shared decision-making among stakeholders.

2. Introduction

Our western societies are recently experiencing a strong shift towards participation of citizens and all type of interest groups in participatory, multi stakeholder processes, with the aim to find consensus among individual interests regarding societal changes and challenges, especially in the field of transition towards sustainability.

In the technological field so-called user-centered research has been developed in order to capture user insights or user behavior regarding innovations with the aim of shortening product-to-market periods and gaining higher security regarding user adoption and market success of a product or service. New infrastructures and processes have been developed like e.g. Living Labs and Open Innovation strategies.

Similar processes are increasingly taking place in the area of governance and decision making within municipalities, where citizens, entrepreneurs, academics and local entities as “users”, are expected to contribute to collective innovation and decision making processes.

Similar to the questionable role of users as actors in the field of innovation (lack of experts knowledge, lack of motivation for continuity, IP rights and exploitation of results) the capacity of individual stakeholders has to be questioned in overviewing the whole process e.g. of the current transformation processes of cities towards more sustainable energy models. These processes are highly complex and open ended, including technological developments and changes, legislation, governance, societal changes and social innovations, linked to individual as well as collective value discussions and behavior changes regarding our lifestyle.

The R4E project therefor takes a different approach to current energy strategies and plans, developing so-called “Energy Roadmaps”. The unique feature of the Roadmaps approach is that the process of development takes successful implementation through partnership and through an in-depth knowledge of the state of the art, now and in the near future, as a starting point. This approach is based on:

- An ongoing learning process among all stakeholders, acquiring the necessary technical and systemic knowledge of complex transition processes.
- Better communication among all participants, experts, politicians, researchers, entrepreneurs and citizens through a common language and trust building collective processes.
- More consistent and consented outcomes, which increase decisively the possibilities for a successful implementation of resulting action plans.

R4E offers a new strategy for complex transition processes of society towards a sustainable energy future, fostering within participatory processes the knowledge generation and improvement of the diverse stakeholder groups regarding renewable energy technologies, and a systemic view of energy in buildings and the urban context in general.

3. Methodology

R4E applies a specific 4-step process for the project itself, a specific 4-step structure for its desk studies as supporting documents for participatory stakeholder processes, and a specific approach for the learning and communication process of stakeholders through *Systemic Solution Maps* within the desk studies, in order to graphically represent the complexity of any energy-related transition process.

3.1 The 4-step R4E process

The R4E partner cities run through a 4-step R4E process (Figure 1), starting with the *Ambition setting* (step 1), and a *Vision development* and scenario building process (step 2) in order to discuss, define and describe a common desired future for their city with the participation of all type of local stakeholders such as citizens as well as relevant research and industry partners. In a third step partners develop *Energy Roadmaps* as the result of a cooperative process engaging, as in all previous steps, key stakeholders within the region from the business and knowledge sectors.

This results finally in the development of a specific *Project portfolio* (step 4) and well-developed implementation plans supported through a strong commitment of all participants. Figure 2 shows the general R4E approach in four steps.

Fig. 1: 4-step R4E process

The R4E process allows ideally engaging partners and stakeholder groups in a continuous process over 3 years and beyond, creating a strong collaboration based on trust and integration among all participants.

3.2 Desk Study structure

In order to support the participatory processes of the R4E project in generating consistent roadmaps for energy and solid implementation plans, desk studies about the state of the art of energy technologies and related sustainability concepts and solutions are facilitated to the participant cities.

These desk studies include the following 4-step approach in order to structure knowledge and give consistent future outlooks on technologies related to smart energy strategies of cities (Figure 2).

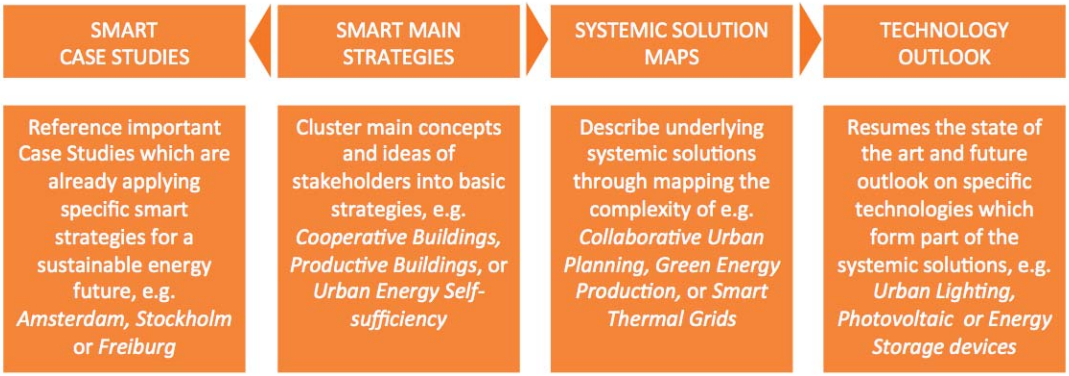

Fig. 2: R4E Desk study structure

After describing and further defining the *Smart Main Strategies* of the partner cities, based on the developed visions and scenarios for their energy future with horizon 2050, so called *Systemic Solutions Maps* are developed in order to represent graphically the complexity of each strategy and its interrelation with diverse concepts and technologies.

A third step consist in specific *Technology Outlooks* about technologies that have been mapped within the *Systemic Solutions Maps,* documenting their current state of the art, their specific challenges and their future perspectives.

In a fourth step *Case Studies* are referenced to the different Systemic Solutions in order to showcase light house projects of urban energy transition, which already apply specific smart strategies or smart technologies for a sustainable energy future.

This desk study structure allows all partners to generate and improve their knowledge in fields like e.g. the energetic refurbishment of existing buildings, or the establishment of smart energy grids with a high amount of distributed renewable energy sources, among many others, gaining a holistic and systemic vision of each strategy. The specific feature of *Systemic Solutions Maps* furthermore allows to be used as individual or collective tool for understanding complexity and interrelations among different strategies and technologies.

3.3 Systemic Solution Maps

Systemic Solution Maps are introduced as comprehensive representation of the inherent complexity of almost any strategy towards a reduced energy demand and a higher degree of sustainability on building level as well as on urban scale.

Systemic Solution Maps (Figure 3) are the connecting elements, which allow setting into the right relation the basic *Smart Main Strategies* for a sustainable energy future and the existing and developing energy technologies as well as related technological solutions described through the *Technology Outlook* section.

The systemic approach allows to map visually the interrelation of different parameters for a specific approach, e.g, in the field of material flows, water consumption or renewable energy generation, facilitating the understanding of the complexity of each specific field of action, the interrelation of technical, organizational and social aspects, as well as the corresponding developing technological solutions, which allow to transport this current representation of complexity into a vision of a possible future.

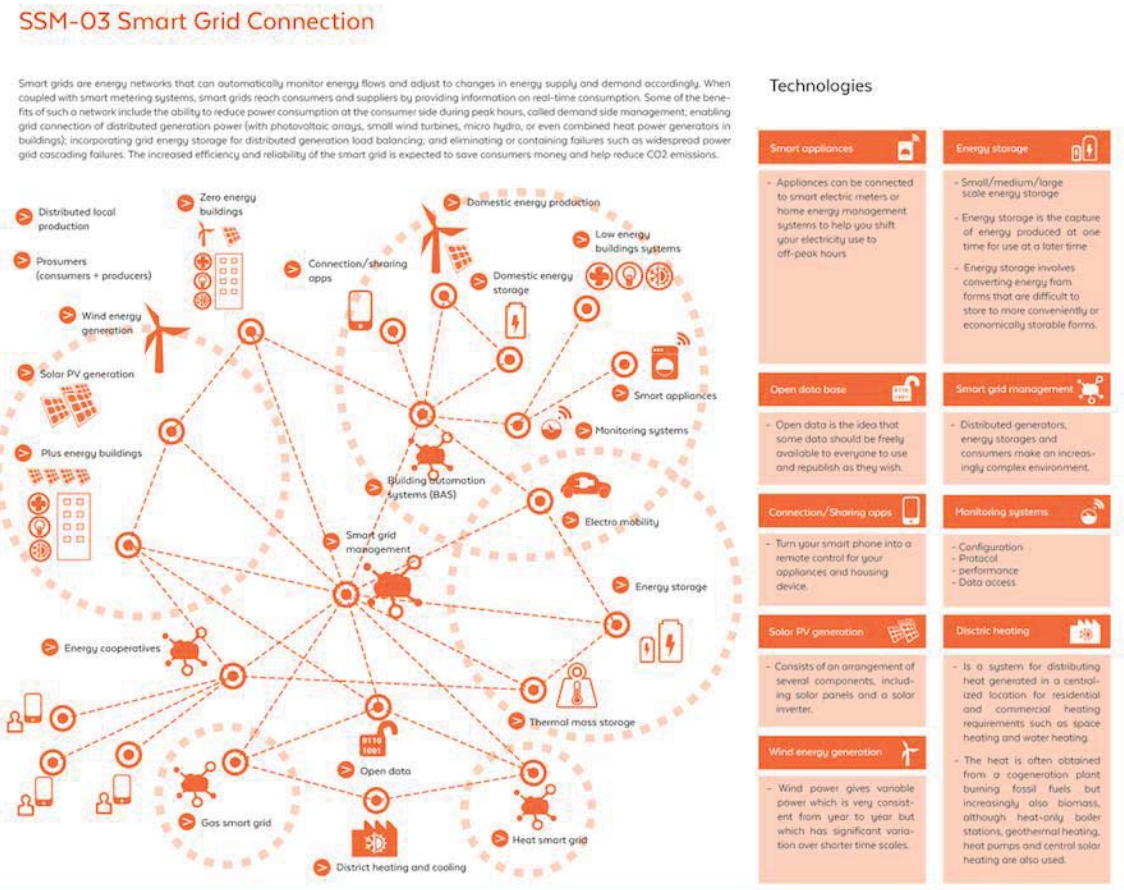

Fig. 3: General Structure of *Systemic Solution Maps*

Stakeholders may read and reflect individually on these *System Solution Maps*, may use them in their discussions and participatory processes as a tool, or even might adapt or further develop them according to their city specific social-economical, climatic, cultural and environmental background.

4. Results

The R4E project has just concluded its second step, *Vision development*, within the overall 4-step process. Desk studies have been almost terminated and will be handed out to partners during October 2016.

A total of 18 *Systemic Solutions Maps* have been developed in the fields of *Smart Buildings* and *Smart Urban Spaces* in order to map the complexity of different and diverse approaches like *Interactive Flexible Space Use, Collaborative Urban Planning*, *Communal Urban Farming, Thermal Smart Grids, Material Accounting Systems*, or *Health and Home Services* in the field or *Smart Urban Spaces*, and concepts like *Shared Use Management, Green Energy production, Smart Retrofitting Solutions, Waste Management, Building Water Management* or *Low Embodied Energy* among others in the field of *Smart Buildings*. Furthermore 50 *Technology Outlooks* have been elaborated resuming the state-of-the art and future potential of mapped technologies.

First *System Solution Maps* and *Technology Outlooks* have been presented to the city partners at the joint *Vision Building Workshop* in Istanbul in May 2016, obtaining valuable input from city representatives regarding the readability of the maps, their usefulness as tools in participatory processes, and most specially about missing or under represented issues, which should be included within the maps, e.g. stronger references to urban resilience strategies or a stronger focus on the complexity of historic buildings within the city context.

This stakeholder feedback has allowed to introduce changes and to improve the documents for their use as supporting tools in the following third step of the R4E process, the city specific *Roadmapping Workshops* from November 2016 on.

Desk studies and the applied methodology of *Systemic Solution Maps* and *Technology Outlooks* will than have to proof that they are useful tools for multi stakeholder processes, and that the applied mapping of complexities and relationships will result in a useful identification of potential synergies and even innovations.

This might contribute to the overall results to be expected of the R4E project after its successful conclusion:

- The empowerment of public authorities to develop, finance and implement ambitious sustainable energy policies and plans in order to implement efficiently recent and future European Energy Directives
- The introduction of a significant number of public officers and stakeholders in a new way of working, necessary for successful development and implementation of such plans
- The development of ambitious but effective and realistic policies and plans with an important impact on the behavior of final consumers

5. Conclusions

The sustainable energy transition of communities requires multi-stakeholder processes, which should be based on a high level of shared knowledge about related concepts, energy technologies and developments in the present and the near future in order to allow the successful collaboration of all important members of a community. The presented overall R4E process, with its desk studies as supporting documents and the specifically developed concept of *Systemic Solutions Maps* and related *Technology Outlooks* may contribute to this important knowledge generation and show their usefulness as tools for multi stakeholder processes towards a sustainable energy transition of cities.

Acknowledgements

The R4E project received funding from the European Union's Horizon 2020 research and innovation program under grant agreement Nº 649397. A special recognition must be given to Alfonso Godoy, Mariana Palumbo and Laia Nuñez Pinart for their collaboration in the project and the development of the corresponding methodologies and contents.

Abstract

With increasing solar PV installed capacity in India, forecasting of its generation is gaining importance. In India forecasting for renewable energy has been recently operationalized. Two kinds of forecasting needs to be done, one for the individual plants for scheduling and accounting actions and the other for entire grid control area for grid operation. Day ahead forecasting with 15 minute resolution, 16 times intra-day revision, was made mandatory as a consequence along with several sets of rules and mechanisms introduced by the Central as well as State level authorities. One innovative development is the concept of Renewable Energy Management Centers which would be co-located with existing load dispatch centers and take care about forecasting along with a few other activities. After establishment of REMC it is assumed that environment for improved grid integration of renewables would be created.

Key Words: *Forecasting of solar power; Grid integration of solar energy; Renewable Energy Management Centre.*

1. Introduction

1.1. Need for solar power forecasting in India

As of August 2016, the total installed generation capacity is India is 304.76 GW (CEA, 2016). The RES contributes to 14 % of the total installed capacity (shown in Fig 1). The Wind energy installed capacity is 27.15 GW. The contributions of different renewable energy sources are shown in Fig 2.

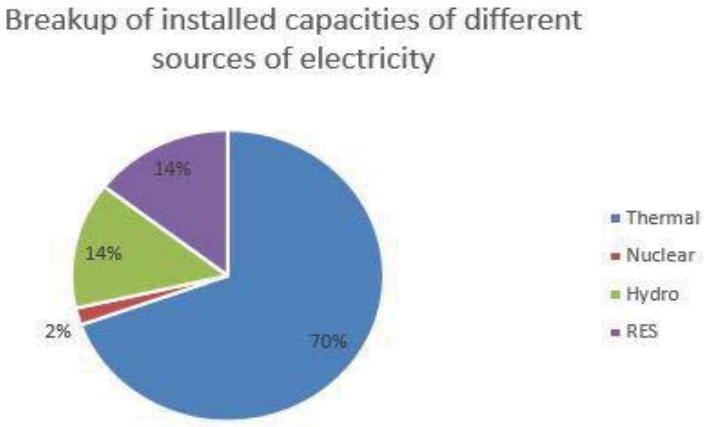

Fig. 1: The breakup of installed capacities of different electricity sources (CEA, 2016)

doi:10.18086/eurosun.2016.11.05 Available at http://proceedings.ises.org

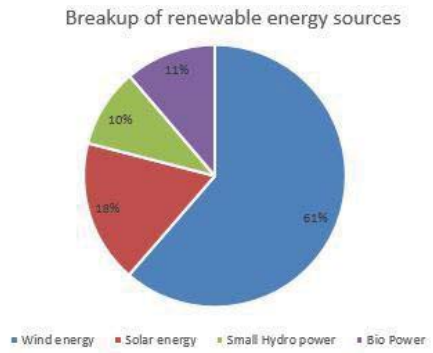

Fig.2: The breakup of installed capacities of different renewable energy sources (CEA, 2016)

In the recent years, there has been a steep increase in the solar power installations in India. Solar PV installed capacity is 8.1 GW as of August 2016. There has been an 80 % increase in the installed capacity of solar PV generations sources over the past 12 months (Economic Times, 2016). Govt. of India of also has a renewable energy installation target of 175 GW until 2022. This includes a target of installed capacity of 100 GW for solar energy, 60 GW for wind energy, 10 GW of bio energy and 5 GW for small hydro. There is a 40 GW target in roof top solar segment among the overall solar energy target (NITI Aayog, 2015). The state wise target of solar PV and wind generation installed capacities of the different states in India as per Ministry of New and Renewable Energy (MNRE) is given in Table 1 (MNRE, 2015).

The grid operators in many renewable energy rich states of India are finding it difficult to manage the grid. The absence of forecasting is hindering their operations. In year 2013, two to three billion units generated from wind were curtailed, mainly due to absence of forecasting (IWTMA, 2015). In India, primary and secondary controls are not fully operational. Therefore accurate control area wide renewable energy forecasting would go a long way for grid operators to effectively manage the grid. Accurate Forecasting by the grid operators would mitigate the actual requirement of primary, secondary and tertiary reserves.

It is also important that individual RE power plants forecasts the generation output of their power plants. This would enable them to provide accurate schedules to system operators. They can also earn better revenue by trading their electricity effectively in power exchanges.

Because of the reasons stated above, there has been a lot of developments in regulatory and institutional framework in the concept of solar power forecasting. Different important govt. institutions namely Central Electricity Regulatory Commission (CERC), State Electricity Regulatory Commission, Power System Operation Corporation (POSOCO), Load Dispatch Centres (LDC), etc. have actively worked to evolve solutions in the in the recent past. This paper has details regarding the different interesting developments in this regard.

2. Discussion

2.1. Structure of Load Dispatch Centers

India's power grid is synchronously connected and the operating frequency is 50 Hz. India's electrical grid is divided into five regions, in each where there is a Regional Load Dispatch Centre (RLDC) located. Each state in India constitutes a control area, where there is a State load dispatch centre (SLDC) located. SLDC is responsible for real time operations for grid control and does optimum scheduling and dispatch of electricity within the state (CERC, 2010). The RLDC exercises supervision over SLDCs in its region and is responsible for maintaining stability of grid operations, economy and efficiency of operation in the electrical region (CERC, 2010). The National load dispatch centre (NLDC) is hierarchal above RLDC. It is responsible for monitoring operations and security of national grid. NLDC is also responsible for supervision and control over inter-regional links (CERC, 2010).

2.2. Regulatory Interventions in RE Forecasting

As indicated in section 1.1, forecasting of generation is important in the perspective of grid operators and individual RE generators. Therefore CERC, SERC and FOR have taken this into cognizance and number of regulations have been drafted. Forecasting by SLDC have been suggested to be mandatory in order to maintain the grid security (APERC, 2016; FOR, 2015; JSERC, 2016; KERC, 2015; RERC, 2016; TNERC 2016). IEGC 3rd amendment mandates RLDCs to perform forecasting (CERC, 2015b). There is a huge motivation for grid operators to perform forecasting taking into consideration its importance in grid operations. Control area wide forecasting of the cumulative RE generation would be important functionality

through the establishment of REMC's. Other kind of usages of forecasting for grid operators are congestion forecast, ramp forecast, reactive power forecast, etc.

There has been a lot of developments with respect to regulatory interventions in generation forecasting for individual wind and solar PV power plants. This has been detailed in the following section.

2.2.1 Regulatory interventions in RE forecasting for individual solar PV power plants

In India, forecasting of RE generation was conceptualised in Indian Electricity Grid Code, 2010 through the Renewable Regulatory Fund (RRF) mechanism. Forecasting was made mandatory for wind energy projects greater than 10 MW and solar energy projects greater than 5 MW (CERC, 2010). There were not any commercial implications related to accuracy of forecasting produced by solar energy projects. Owing to implementation issues, RRF mechanism was not operationalised. Central Electricity Regulator Commission (CERC) released draft regulations regarding forecasting on 31st March 2015 (CERC, 2015a) as well as corresponding draft amendments to grid code and deviation settlement mechanism. After taking public opinion into considerations, amendments to grid code and Deviation Settlement Mechanism, 2015 was finalised (CERC, 2015b, 2015c). In November 2015, Forum of Regulators (FOR) announced model regulations on RE forecasting and scheduling applicable to projects feeding power within the state boundaries (FOR, 2015). Following similar lines, states of Karnataka, Tamil Nadu, Orissa, Rajasthan, Jharkhand and Andhra Pradesh came up with their draft regulations for RE generation forecasting and scheduling applicable at intra-state level (APERC, 2016; JSERC, 2016; KERC, 2015; RERC, 2016; TNERC, 2016). After receiving public comments, Karnataka Electricity Regulatory Commission (KERC) notified the regulation on forecasting. In different regulations, 16 revisions in the schedule are allowed for RE projects on intra-day basis. The above clause encourages RE power projects to perform intra-day forecasting of generation. The regulations related to forecasting are compared in Tab 2.

Tab. 2. Detailed inter comparison of different regulations related to forecasting in India (APERC 2016; CERC, 2010, 2014, 2015b, 2015c; FOR, 2015; JSERC, 2016; KERC, 2016; RERC, 2016; TNERC, 2016)

2.3. Infrastructure to support the activity of solar power forecasting

2.3.1. Solar Radiation Resource Assessment (SRRA) stations

As an intermediate step in the prediction of solar PV power output, Global Horizontal Irradiance (GHI) is predicted through the run of Numerical Weather Prediction (NWP) models. Ground measured value of GHI is really important to fine tune the predicted output. This step is called post-processing. It would help in eliminating the statistical bias.

Solar Radiation Resource Assessment (SRRA) project of MNRE is an important initiative that has a huge relevance in solar PV power forecasting as explained above. MNRE initiated the SRRA project and implemented it through National Institute of Wind Energy in 2010. GIZ provided technical assistance to the project. SRRA stations were setup in 121 locations across India. It is world's largest network of solar radiation resource assessment stations setup all over the country. It measures GHI, DHI, DNI along with other environmental parameters like ambient temperature, relative humidity, atmospheric pressure, wind speed and wind direction. The different parameters are measured every second and averaged over one minute interval. Secondary standard pyrheliometers are employed for measuring DNI. First class pyranometers are employed for measuring GHI and DHI. In every station, there are two pyranometers and one pyrheliometer. The measured data is stored in the Central Receiving System (CRS) established at NIWE. Four of the measurement stations are certified by Baseline Surface Radiation Network (BSRN).

2.4 Proposed infrastructure for aggregated Solar PV power forecasting

On advice of MNRE, Forum of Regulators (FOR) and CERC, Power Grid Corporation of India Limited (PGCIL) initiated a study to identify the transmission and control infrastructure up-gradation required for integrating renewables in the 12th five year plan of government of India. The Capital expenditure requirements and strategy framework for funding the same was analysed as well. Concept of Renewable Energy Management Centres (REMC) to effectively manage the intermittency and variability of resources was proposed (PGCIL, 2012). Total cost of six billion Euros was identified as the requirement to enhance the transmission and control infrastructure. The transmission lines that is being constructed under this project would evacuate power from renewable rich states to load centres. In India, this is the first project, in which transmission lines are being built on the basis of available renewable energy resource potential. Government

[1] AvC = Available Capacity for wind or solar generators means the cumulative capacity rating of the wind turbines or solar inverters that are capable of generating power in a given time-block;
AG = Actual Generation
SG = Scheduled Generation
Time–block; means a time block of 15 minutes, for which specified electrical parameters and quantities are recorded by special energy meter, with first time block starting at 00.00 hrs

of Germany through Kreditanstalt für Wiederaufbau (KfW Bank) had sanctioned concessional loans upto 1 billion Euros. The technical assistance is provided through Deutsche Gesellschaft für Internationale Zusammenarbeit (GIZ) GmbH. GIZ did studies in the areas of forecasting of renewable energy, balancing, improved market mechanisms, ancillary services, grid code, automatic generation control, etc that would help Indian govt achieve the huge targets for renewable energy. GIZ worked with the consortium of Ernst & Young, University of Oldenburg, Fraunhofer IWES, Ficthner to perform the different studies. Detailed Project Reports (DPR) were submitted for REMCs to be established in India. By September 2016, applications for tender for the REMCs to be established at Tamil Nadu, Andhra Pradesh, Karnataka and Southern Regional Load Dispatch Centre (SRLDC) were released by PGCIL (PGCIL, 2016). Tender applications for REMCs to be established at other SLDCs and RLDCs are expected to follow soon.

Indian Meteorological Department (IMD) and National Centre for Medium Range Weather Forecasting (NCMRWF) are the govt. owned weather services of the country. They have capabilities in running numerical weather prediction models and have shown interest in supporting the initiative of renewable energy forecasting in India.

2.4.1 Renewable Energy Management Centres

The REMCs are envisaged to be co-located with the already existing load dispatch centres at seven renewable rich states. They would also be co-located with RLDCs at southern, western, northern region and NLDC. Ministry of Power will bear the cost of 11 REMC control centre development (SCADA System including maintenance, Forecasting & Scheduling Tool / Software, Wind and Solar generation forecasting services for first 4 years, Servers, other control centre equipment). The location of 11 upcoming REMCs are shown in the Fig 5.

Fig 5: The locations of envisaged REMCs.

From the tender specifications released for REMC for southern region, certain features are explained in this paper. The schematic of REMC architecture is shown in Fig 6.

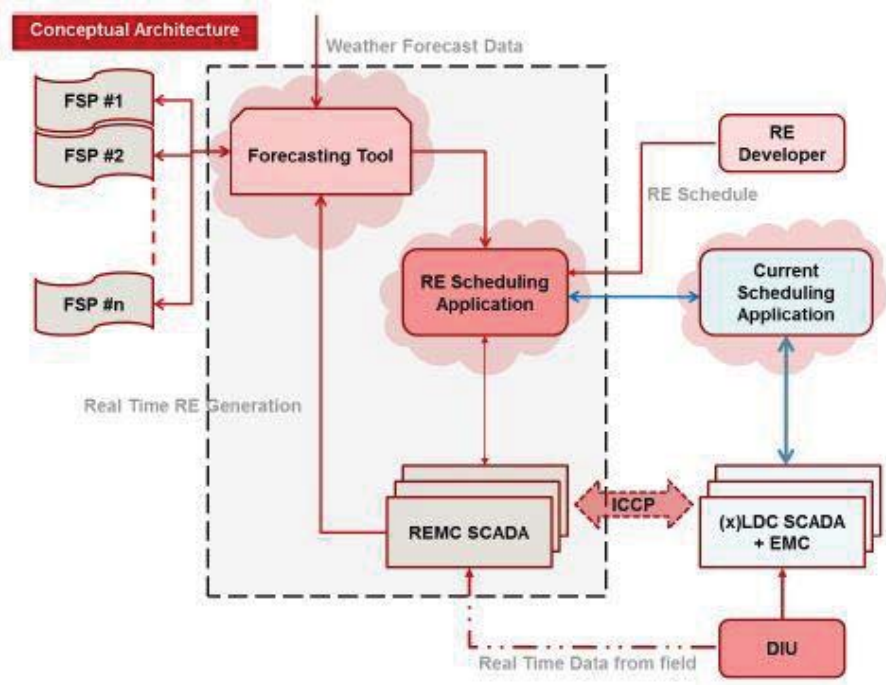

Fig.6: Schematic architecture of REMC (PGCIL, 2016)

The major functionalities of REMCs are the following:

- Real time RE generation Data Acquisition and Monitoring.
- Provide RE data to its partner xLDC, forecasting and scheduling applications.
- Forecasting of RE generation.
- Data Archiving and Retrieval.
- Providing RE information to its concerned xLDC for dispatching and balancing RE power.
- Central Repository for RE generation data that will be used by the concerned xLDC for Management Information System (MIS) and commercial settlement purposes.
- Coordination agency on behalf of xLDC for interacting with RE Developers.
- Developing future readiness for advanced functions such as Virtual Power Plants, Storage etc.

2.4.1.1. Forecasting tool

The schematic of the forecasting tool is depicted in Fig 7. The external Forecast Service Providers (FSPs) provide week ahead, day ahead and intra-day forecasts for wind and solar PV generation at pooling sub-station level as well as aggregated forecasts at state level. The forecasts are provided for intra-day, day ahead and upto week ahead time resolution. It would provide forecasts in 15 mins resolution for day ahead and intra-day forecasts and hourly resolution for week ahead forecasts. The forecast provided by the tool would assist SLDC personnel in scheduling the conventional generation, estimation of control reserves and load flow calculation. Historical SCADA data from STU pooling stations, available real time RE generation data from STU pooling station and static information about wind and solar power projects would be shared with the FSPs by the REMCs (PGCIL, 2016). It is crucial information for performing RE generation forecast.

The forecast combination and aggregation tool combines the external and internal forecasts in an optimal fashion using auto adaptive algorithms. The different FSPs and internal forecasting tool is expected to have strengths and weaknesses according to different weather situations. Therefore historical performance of the forecasts for the different weather conditions would be taken into account while arriving at combined forecasts. Through suitable upscaling technique, aggregated forecasts for the pooling stations and whole state are derived.

Internal forecasting tool produces forecasts for the different time resolutions in parallel to external FSPs. It is fully automatic and runs on an auto adaptive algorithm. It does not require operator's interaction. Static data,

historic SCADA data, real time generation data are to be provided to the internal forecasting tool. The algorithms would be tuned based on the forecasts and real time generation data. A service provider who provides weather forecast data is contracted for a period of four years to provide input to this tool.

Three external FSPs are contracted for the first two years to provide wind and solar generation forecasts. The two best performing FSPs would be retained for the subsequent two years. The contract for FSPs could be extended for further two years (beyond the serviced four years) at the same terms and conditions as per mutual agreement. The FSPs performance is continuously monitored. Normalised Root Mean Squared Error (NRMSE) is the metric according to which FSPs performance is monitored. RMSE is normalised with available generation capacity in each time block (PGCIL, 2016). The financial reward to FSPs would depend on the accuracy of the forecasts provided by them. During first year of operation, there is no financial implication as it is considered as the stabilisation period. From the second year, payment to the FSPs would be based on the following:

- Provide 100 % of payment if error (NRMSE) of the control area wide RE generation forecast is less than 7 %.
- Provide 90 % of payment if error (NRMSE) of the control area wide RE generation forecast is between 7 % and 9 %.
- Provide 80 % of payment if error (NRMSE) of the control area wide RE generation forecast is between 9 % and 11 %.
- Provide 70 % of payment if error (NRMSE) of the control area wide RE generation forecast is greater than 11 %.

If there is a slump in performance of WSP impacting the power forecast of the internal forecasting tool, then it could potentially be replaced without any additional financial implications.

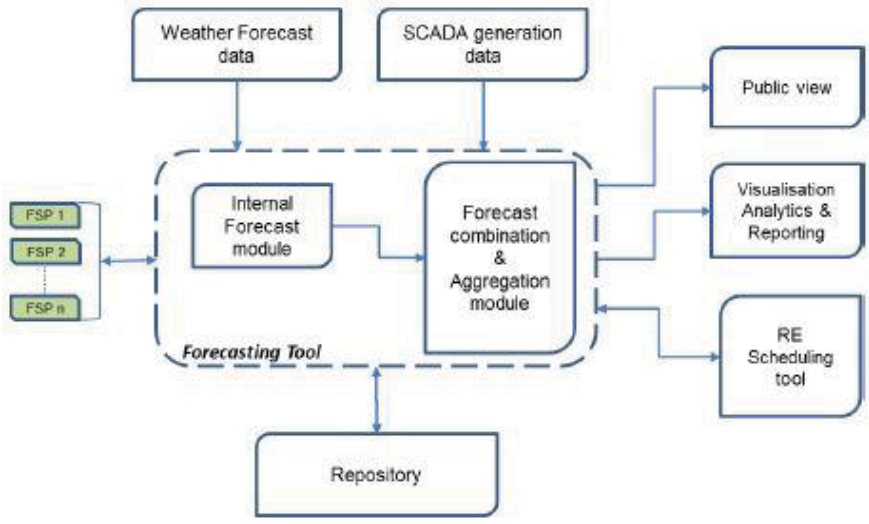

Fig.7: The schematic architecture of forecasting tool (PGCIL, 2016)

2.4.1.2. Scheduling Tool

The main functionality of the tool is collection of the proposed schedules from the RE generators. The individual RE power projects could upload the schedules into the system using web based system. The tool has the ability for bidirectional data exchange with forecasting tool and SLDC's main scheduling tool. The tool is configured for entering schedules for each time block (15 mins) on a day ahead basis. Individual RE generators must be able to provide revisions for 16 times in a day. The revised schedules are applicable from the fourth time block from which it is issued. Taking information from this tool, SLDC's main scheduling tool manages the schedule for conventional generation. Available capacity is submitted by individual

generator in every 15 min time block. This tool must have the capability to calculate the error in every time block. Therefore, real time generation through SCADA data is made available to the scheduling tool. This tool must be capable of producing alarms/ alerts for non-publishing of schedules by individual RE generators.

Due to congestion and other operational issues, there is a curtailment module that could issue instructions for reduction of power output from the RE power projects. Instructions could be given in terms of percentage reduction in generation or specifying the absolute power to be curtailed (in MW).

3. Conclusion

There has been a lot of developments in regulatory and institutional framework in the sector of wind and solar power forecasting. This is indeed very urgently required to satisfy govt. of India's huge renewable energy target. The REMCs once they are fully operational and functional, would go a long way to assuage the apprehensions of RE power projects owners. This would help in ensuring uninterrupted offtake of their generated power. REMCs could trigger more potential investments into this sector.

The potential of massive PV installation in Serbia

Dejan Doljak[1] and Djordje Samardzija[2]

[1] Faculty of Geography, University of Belgrade, Belgrade; Serbia, e-mail:, dejan.doljak@gmail.com

[2] One Degree Serbia, Belgrade, Serbia, e-mail: djordje.samardzija@1c.org.rs

Abstract

Paris climate agreement, adopted in December 2015, recognizes the need to revise voluntary submitted Intended National Determined Contribution (INDC) in order to limit global warming to 2°C.

With the objective to propose the improvement of Serbian INDC we investigate the technical potential of massive installation of residential solar PV roof top systems and utility scale solar PV power plants. Our research shows that solar may substitute around 81% of all electricity produced from coal and hydro. Thus, solar should be considered as a significant source of energy in future Serbian energy mix.

Keywords: *Serbia, low carbon economy, long term transition, solar, photovoltaic, technical potential, financial aspects*

1. Introduction

More than 180 states submitted their INDCs so far. However, estimated aggregate greenhouse gas emission levels in 2025 and 2030 resulting from existing INDCs do not fall within least-cost 2˚C scenarios but rather lead to a projected level of 55 gigatonnes in 2030. In order to hold the increase in the global average temperature to below 2˚C above pre-industrial levels States shall reduce emissions to 40 gigatonnes (UNFCCC, 2015).

Although adopted at the time of the 21st session of the Conference of the Parties (COP-21) the latest Serbian energy strategy (Republic of Serbia, 2015) suggests the continuation of usage of fossil fuels with focus on dirty lignite coal. No matter that the availability of some types of renewable energy resources (like solar) is much greater than in the Central Europe, the strategy underestimates the share of renewables in the future energy mix. Serbia and Serbian citizens already pays for their ignorance of renewables technologies. With only 6.2 $ per kilogram of oil equivalent (The World Bank, 2016a) and the high dependence on fossil fuels Serbian economy is one of the most energy and emissions intensive in the world. The increase of annual public health costs due the toxic emissions from burning lignite is estimated to 4 billion EUR (HEAL, 2016).

This paper presents new approach in the estimation of potential of solar energy in Serbia. The scope of our research includes the estimation of technical potential of massive installation of residential solar photovoltaic (PV) roof top systems and utility scale solar PV power plants. Solar thermal is out of scope. It will be addressed in the continuation of the research.

2. Solar energy potential – existing estimations for Serbia

Official data about the potential of various energy sources has been published in the national energy strategy that was adopted by the Parliament and the Government (Republic of Serbia, 2015). According to the authors of the strategy, total technically usable potential of solar power in Serbia is estimated to 0.24 million tons of oil equivalent (2.79 TWh per year). This figure includes electric and thermal potentials – 0.53 TWh and 2.26 TWh, respectively. The most important assumption in this official document that influenced entire estimation of potential of renewables was the consideration that the existing electric grid cannot handle more energy from intermittent sources than that presented in the strategy.

doi:10.18086/eurosun.2016.11.04 Available at http://proceedings.ises.org

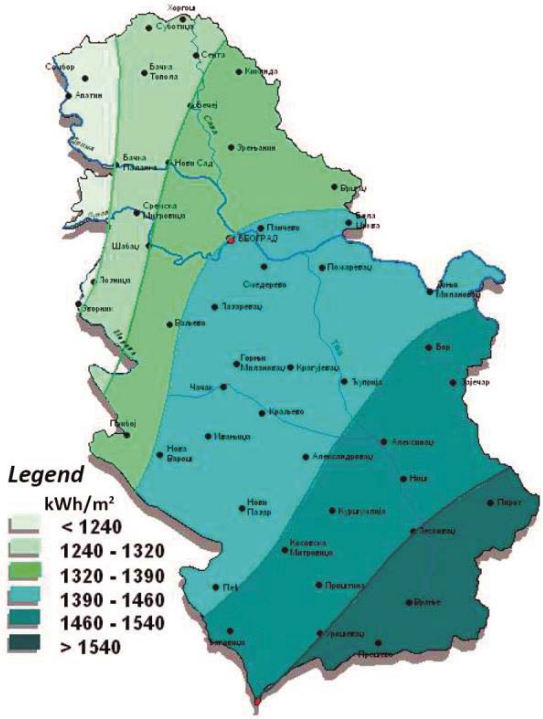

Fig. 1 Annual energy of global radiation on a horizontal surface (kWh/m^2). Source: (IMSI, 2004)

Fig. 1 shows that in Serbia, Sun energy has the tendency of increasing with decreasing latitude. The southern parts gain energy up to 1550 kWh/m^2 per year. However, solar energy is an intermittent source, which means that values vary on daily and seasonal levels. During the hot July days, square meter of horizontal surface receives an average of 5.9 to 6.6 kWh per day, but during January the radiation is reduced to only 1.1 to 1.7 kWh.

Radičević et al. (2009) claims that solar PV will represent only negligent share of energy mix in near future due to high costs of technology. Other academic and expert researchers like (IMSI, 2004) limited their exercises to the estimation of annual insolation without clear scenarios how to proceed with the installation of solar systems in Serbia.

The major obstacles of presented approaches can be summarized as:

- Existing electrical grid is considered as incapable to accept large amounts of variable power produced by renewable sources; and
- The renewables are presented and considered as very expensive.

Our opinion is that the establishment of estimations of renewables technical potential on these assumptions is entirely wrong since it is clear that the transition to renewable energy system cannot and will not happen overnight. Many publicly available researches, global policies and scenarios identify 2050 as a target year to develop sustainable and clean energy system worldwide in order to prevent catastrophic consequences of climate change. Until that time, countries should work on the improvement of electric grids and the implementation of smart grids, as well as, energy storages, in order to accommodate energy produced by intermittent sources and manage demand.

In the meantime, further researches and the economy of scale will lead to the reduction of technology costs well below current levels making renewables more efficient, more environment friendly and cheaper than today. In addition to the fact that the reduction of prices of solar PV panels is already underway it is worth to compare true costs of production of conventional energy with those produced by solar. The high air pollution and carbon costs of burning fossil fuels make conventional energy much more expensive than solar or wind.

Fortunately, other more optimistic renewables potential estimations have appeared recently. A professor from the Stanford University Mark Z. Jacobson and his team work on 100% Clean and Renewable Wind,

Water, and Sunlight (WWS) All Sector Energy Roadmaps for 139 Countries of the World. They estimate total potential capacity for solar energy in Serbia to 15.441 GW (Jacobson et al., 2016). Only 45% of this potential capacity will be enough to support country's transition to cleaner energy system entirely run on wind, water, and sunlight (WWS).

The group of independent think-tanks from South Eastern Europe has developed the SEE 2050 Carbon Calculator – regional renewable energy model and tool for the creation of individual energy transition scenarios. According to this group, the solar PV technology may provide around 24.45 TWh annually in Serbia (SEE Change Net, 2016), almost 10 times more than official estimations.

3. Massive installation of solar PV systems and power plants in Serbia

"Solar energy is the most abundant of all energy resources. Indeed, the rate at which solar energy is intercepted by the Earth is about 10,000 times greater than the rate at which humankind consumes energy. Solar technologies can deliver heat, cooling, natural lighting, electricity, and fuels. Solar technologies offer opportunities for positive social impacts, and their environmental burden is small." (Arvizu et al, 2011)

Having in mind small environmental footprint of solar, plummeting costs of solar PV technology and great natural solar resources that Serbia has (average annual insolation is around 40% higher than in Germany) our research team has developed the alternative scenario of development of Serbian energy system. The alternative scenario includes massive installation of solar PV roof-top systems and utility scale solar PV power plants.

Massive installation of solar PV roof-top systems

Solar PV technology allows residents, and public and private entities to join transition to low-carbon economy. By applying solar PV panels each of these categories can contribute to the mitigation of climate change on individual level. In addition to being energy consumers, owners of PV systems become energy producers making new class of actors in energy markets – "prosumers". Massive installation of solar power plants owned by citizens and legal entities will enable the decentralization and democratization of energy production. Such diversification of energy sources will improve energy security on individual and national level, reduce the power of monopoly of traditional state-owned fossil fuel companies, as well as, to reduce dependence on fossil fuel imports.

The researched scenario includes the installation of 6 kWp solar systems on the residential house and building roofs in Serbia. The roof area under solar panels is estimated to 40 m^2. It is assumed that commercial, utility and administration buildings with larger roofs could house larger systems – up to 15 kWp (around 100 m^2 of panels). Solar thermal collectors were out of scope of this part of the research and will be addressed in later stages.

The estimation was performed using the on-line *PVWatts* calculator (NREL, 2016). In order to validate *PVWatts* results, its estimations were compared to the output of another on-line calculator – *PV*SOL Online Calculation* (Valentin Software, 2016). No significant deviation in final results between these two on-line tools has been identified.

Having in mind that the roof orientation and tilt are uncertain categories, the estimated potential of a PV system is an average result calculated by variation of the following performance parameters:

- PV panel type (Standard, Premium);
- tilt (30° and 45°); and
- azimuth (East, South and West).

The assumed location of a solar PV system in this exercise is Belgrade, capital of the Republic of Serbia.

The exercise showed that azimuth has the greatest impact on the amount of generated electricity. The best results are obtained if solar panels are oriented to South (azimuth 180°).

Average annual amount of electricity generated by small-scale solar PV system with the capacity of 6 kWp mounted on the roof of the object in Belgrade is estimated to 6,269 kWh. The amount of generated electricity

varies during the year picking in July (Fig. 2) – 823.45 kWh, i.e. 2.5 times greater than average monthly electricity consumption of household in Serbia.

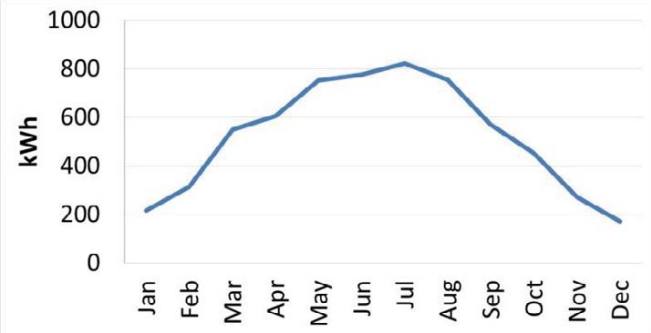

Fig. 2 Variation of production of 6kWp solar PV system located in Belgrade

The amount of electricity generated by 15 kWp solar PV system mounted on public and commercial buildings is obtained by the extrapolation of modeled small-scale solar PV system electricity production and amounts 15,671 kWh.

The total number of family houses in Serbia that can be used as locations for 6 kWp solar PV systems is estimated to 2,186,000 (Jovanović-Popović et al, 2013). The number of buildings that can house larger systems (15 kWp) is estimated to 42,389 (Statistical Office of the Republic of Serbia, 2016).

Tab. 1 Massive installation of small scale PV systems in Serbia: Estimated capacity and annual generation

Type of object	Number of objects	Capacity of installed system (kW)	Annual production of single system (kWh)	Total installed capacity (GW)	Annual generation of electricity (TWh)
Family houses	2,186,000	6	6,269	13.116	13.704
Residential buildings	9,556	15	15,671	0.143	0.150
Other buildings (commercial, admin.)	32,833	15	15,671	0.492	0.515
			Total	**13.751**	**14.369**

The amount of electricity generated by these 2.2 million solar systems mounted on rooftops is estimated to 14.369 TWh per annum (Tab. 1). The installation of these 13.751 GW of solar PV panels could cost somewhere between 30.252 and 71.505 billion USD. The costs are calculated according to the lowest and highest price of the installation of residential solar PV systems in the world published in (IRENA, 2015).

Massive installation of utility-scale PV power plants

In addition to the roof-top PV solar systems the research included the estimation of the installation of utility-scale PV power plants.

There are currently only a few major photovoltaic plants installed on the ground In Serbia. The most famous are “Solaris 1” (1 MW) and “Solaris 2” (675 kW) near Kladovo (Eastern Serbia), “Matarov” (2 MW) in Merdare (Southern Serbia) and solar power plant of capacity of 1 MW in Tancoš near Beočin (Vojvodina). According to the data provided by Serbian Ministry of Mining and Energy (MME), 17 solar PV power plants have status of privileged or temporarily privileged producers of electricity with total installed capacity of 6 MW (MME Serbia, 2016). These producers have right to receive feed-in tariffs.

Although, solar energy is considered as a clean, free and practically limitless energy source, systems for the exploitation of solar energy, such as photovoltaic plants, have certain restrictions, which depend on the type and size of projects. These restrictions primarily relate to the occupation of land which is limited and precious natural resource in today’s conditions.

In order to develop resource efficient scenario the research includes only the usage of degraded land as a location of potential big PV power plants. Degraded land is an area where the natural conditions are altered by human activity, and envisaged for rehabilitation after the exploitation. In accordance with the aim of the gradual replacement of conventional energy sources with renewable energy sources, the sites of the surface exploitation of the energy minerals (coal, lignite, bituminous rocks, oil and gas) are selected as potential

locations of solar power plant. These sites are defined and presented as a shape files. The assumption to use sites of the surface exploitation of the energy minerals as potential solar power plant locations is in line with the obligation of the Electric Power Industry of Serbia (EPS) to initiate the closure of coal power plants that do not meet requirements of the European Large Combustion Plants Directive after 2023.

In addition, the study includes areas for the exploitation of metallic and industrial raw materials, dumps of tailings and ashes, landfills, sites of conventional coal power plants, thermal power plants, brick plants etc.

For the purposes of this research, 2447 locations were identified and assessed. The total area covers 238.75 km^2 or 0.27% of the territory of Serbia.

The data on the overall installed capacity and annual production of energy have been obtained by the online software *Energy Capacity Assessment Tool* (First Solar, 2015) that uses GIS shape files as a source data about the form and size of power plant.

The total installed capacity of photovoltaic power plants on degraded land amounted to 15,531.93 MWdc for photovoltaic power plants that are built from cadmium-telluride solar cells, or to 16,178.12 MWdc power plant based on multi-crystalline solar cells. The results show, that the installation of photovoltaic power plants at all 2447 degraded locations under consideration would lead to the generation of 18.02 TWh electricity per year. This is around 33 times higher than the technically usable potential published in national energy strategy.

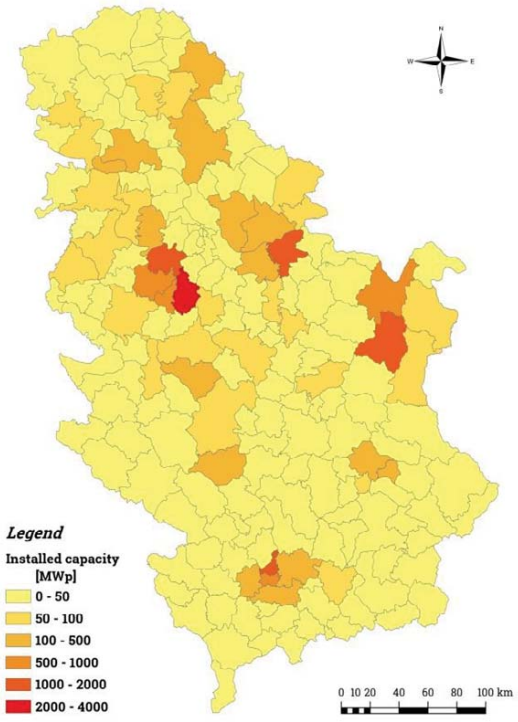

Fig. 3 Estimated total installed PV capacity per municipalities in Serbia

Fig. 3 presents the estimated capacity of installed solar PV power plants per municipality. The largest percentage of the production of solar energy (38%) would be accomplished by installing photovoltaic panels on existing mines of energy producing materials like open coal pits located in the following municipalities Obrenovac, Lazarevac and Kostolac (the darkest color on the map).

The Republic of Serbia has submitted the National Emission Reduction Plan (NERP) to the Secretariat of the Energy Community (Energy Community, 2016). Although the document is not publicly available there are indications that Serbia selected opt-out option for several operational coal power plants. This is expected to lead to the significant reduction of electricity generation capacity, by some 10% in year 2023, according to our assumptions. We recommend that Serbia prepare its energy system for this shock and make use of available renewables technology to cover the gap that will emerge after the closure of outdated coal power

plants.

The state-owned energy company EPS produced 37.433 TWh of electricity in 2013 (EPS, 2014). The implementation of utility-scale photovoltaic plants in the territory of the Republic of Serbia as presented in this article can substitute around 48% of the current production of the EPS.

Construction costs of photovoltaic systems at these locations are projected to 25 to 70 billion USD according to the lowest and highest installation costs in the world published in (IRENA, 2015).

Since the Spatial Plan of the Republic of Serbia 2010-2020 (RASP, 2010) envisions the establishment of a system of regional waste management centers, the surface of existing landfills, could be significant resource for the construction of a photovoltaic power plants, too.

4. Summary

Our research provides new outlook of solar prospective in Serbia. Unlike national energy strategy our scenario involves massive installation of solar PV systems and power plants that results in significantly greater estimations than official figures.

Tab. 2: Estimated potential for roof-top solar PV systems and utility-scale PV solar power plants in Serbia

Type of object	Number of objects/ locations	Capacity of installed system (kW)	Total installed capacity (GW)	Annual generation of electricity (TWh)
Family houses	2,186,000	6	13.116	13.704
Residential buildings	9,556	15	0.143	0.150
Other buildings (commercial, administrative)	32,833	15	0.492	0.515
Utility scale solar PV power plants	2,447	from 280 to 3,563,220	16.178	18.02
		Total	**29.929**	**32.389**

The summarized data are presented in Tab. 2 Estimated solar generated 32.389 TWh per annum can substitute around 81% of current total electric energy production in Serbia, i.e. the whole electricity produced by lignite power plants. Such huge estimated potential should make solar PV a critical element of the future country energy mix.

Initial capital installations costs have been estimated on the basis of average costs in countries across the world identified by (IRENA, 2015). The initial costs are presented in Tab. 3.

Tab. 3: Estimated total investment for the transition to solar PV-based electrical system in Serbia

Type of object	Total installed capacity (GW)	Installation costs (2014 USD/kW) (IRENA, 2015)	Initial capital installations costs (billion USD)	Estimated costs per year 2020-2050 (billion USD)
Family, residential, commercial small-scale solar PV systems (6 or 15 kW)	13.751	2,200 - 5,200	30.252-71.505	1.008-2.384
Utility scale solar PV power plants	16.178	1,570 – 4,340	25.399-70.212	0.847-2.340
Total	**29.929**		**55.651-141.717**	**1.855-4.724**

Total investment in the development of solar PV-based electrical system in Serbia by 2050 is estimated to 55 to 142 billion USD. This investment corresponds to 1.5 to 3.9 yearly gross domestic products (GDP) of Serbia (based on GDP value of 36.513 billion USD in 2015 (The World Bank, 2016b)).

Certainly these, at first glance, large figures may discourage decision makers to consider planned and persistent installation of renewable systems necessary for transition to low-carbon economy and the mitigation of climate change. Yet this total investment should not be considered as “pay at once costs” but

rather as a long-term investment up to 2050. In this case the highest amount of investment is leveled to 4.724 billion USD per annum or 13% of current GDP. In order to get clearer picture about this investment it could be compared to the economic cost of deaths from outdoor and indoor air pollution that are estimated to 33.5% of Serbian GDP (WHO, 2015).

The absence of environmental costs of solar PV energy production should be major driver to initiate and the transition to clean energy. (HEAL, 2016) claims that outdated Serbian coal power plants are responsible for 4 billion EUR (around 4.44 billion USD) of increased public health costs associated with air pollution.

The research presented in this article busts three renewable energy related myths in Serbia:

- It proves that natural resources for the transition to the low-carbon economy exist in Serbia;
- It proves that such transition can be undertaken using existing technology for the energy production; and
- Financial resources for such transition already exist in Serbian society, too. However, they are used to cover consequences of electricity generation by old technology.

The need for the transition to renewable energy sources has never been questioned from ecological and social perspectives. Our research shows that there are economic reasons for such a transition. Cost effectiveness in economic terms is added to the existing ethical reasons for the transition to renewable energy.

It is clear that the transition cannot be executed all in once and that coal will stay around for a while. The aim of this research is to stimulate national discussion and to show that alternative, clean future is possible. Our recommendation to national decision makers is to investigate possibilities of renewable energy and gradually divert capital flow from fossil fuels to renewables, particularly solar. Such strategy will ensure clean, cheap, abundant and decentralized energy available to all, while it pays for itself by reducing public health costs.

We recommend the following policy measures that can support the transition to low carbon economy:

- Incorporation of true costs of burning fossil fuels into price of energy by the implementation of carbon fee and dividend; and
- Improvement of country's capacity to effectively and efficiently perform the transition by including climate change and renewables topics/trainings in school and university education.

The presented research is the first step in the broader investigation of potential of solar energy in Serbia. Future research will include the estimation of potential of solar thermal in residential and commercial use. The presented investment includes the installation costs only. Our intention is to address operation and maintenance costs of running the electric generation system comprised of more than 2.2 million production units, as well as, to estimate the electricity costs to end-users. Envisioned transition from centralised electricity production to decentralised production based on solar technology offers new jobs. We will end research activities on this topic with the analysis of impact of transition on job market and estimate the number of lost and produced jobs.

Acknowledgments

This research was a part of project titled *Alternative INDC – Zero Carbon Serbia by 2050* executed by non-governmental organization and independent think tank One Degree Serbia (www.jedanstepen.org).
