A first observation is the sharp decrease in the number of variables between the two simplified models and the reference case (up to 90% for the complete power plant). As explained previously, the detailed model of the storage (TES_A) needs to solve the energy and the mass balances in the 200 discretized cells, whereas both simplified methods (TES_B and TES_C) only consider two sub-tanks of variable volume. The additional correlations implemented in the model TES_C increase slightly the number of variables but these remains largely fewer than for the detailed model TES_A. Regarding the solar field, the deterministic calculation of the radial heat balance in each cell requires almost 3000 variables whereas the simplified method reduces this number to 600. Besides the number of variables, it can be seen that simplified models are between 75 and 215 times faster than the detailed one. The tremendous gain in computational speed is extremely valuable when performing long-term simulations, or when using directly these dynamic modeling tools in iterative problems like optimizations.

Tab. 1 – Number of variables and simulation times for each model of the complete power plant (with the relative reduction compared to the reference case given in parenthesis)

	Detailed model (PTC_A - TES_A)	**Simplified model (PTC_B - TES_B)**	**Improved model (PTC_B - TES_C)**
No. of variables (TES)	4607	77 *(- 98%)*	442 *(- 90%)*
No. of variables (µCSP)	7602	735 *(- 90%)*	1100 *(- 85%)*
Simulation time (Day 1)	5680 sec	75 sec *(- 98%)*	66 sec *(- 99%)*
Simulation time (Day 2)	9960 sec	46 sec *(- 99%)*	43 sec *(- 99%)*

5. Conclusion and future work

Because of the intermittent nature of solar irradiances, μCSP systems almost never operate in nominal working conditions. They are characterized by strong transients and require powerful dynamic simulation tools to permit a proper evaluation of their performance. Model reduction, i.e. the simplification of detailed model, is an attractive method to improve the computational efficiency when simulating such systems. In this context, a μCSP plant consisting of a thermocline storage, a solar field of parabolic trough collectors and a 5kWe ORC is considered. Both complex and simplified models are developed for the solar field and the thermal energy storage.

In a previous work, an individual comparison applied to each component demonstrated the great potential of simplified methods to replicate predictions of the detailed models. In this contribution, it is proposed to further evaluate the validity of model reduction by simulating the whole μCSP plant under identical operating conditions by connecting together these detailed and simplified models. Results demonstrate good agreements for the solar collectors. However, the initial assumption of a constant thermocline thickness in the thermal storage leads to significant errors. Therefore, empirical correlations are identified and implemented in the model to simulate the dynamic evolution of the thermocline thickness within the tank as a function of real-time parameters. This new model of the storage is integrated in the μCSP plant and much better results are demonstrated. Regarding numerical aspects, the number of variables is drastically decreased by using the simplified models, e.g. 85% less when considering the complete power plant. Besides increasing the robustness, the reduced number of variables permits the simplified models to achieve much faster computational speed for a same simulation (up to 99% less time).

In conclusion, model reduction has demonstrated to be a convenient and powerful tool to permit a direct application of dynamic modeling in iterative problems (e.g. control optimization) or for long-term simulations. Really good agreements are found between simulation results of the simplified and the detailed models, but there is still room for improvements. As an example, future works include to change the shape of the transition profile implemented in the two-zone moving-boundary model of the TES. Indeed, better accordance with the complex model could be achieved by using a LCDF function (Bayón and Rojas, 2014).

Abstract

In this study, thermodynamic analysis of supercritical carbon dioxide (sCO_2) recompression Brayton cycles integrated with solar thermal tower systems was carried out. First part of the model deals with generating a surround heliostat field layout. This heliostat field is then optimized for optical performance on annual basis using an evolutionary algorithm called the differential evolution. The other part of the model deals with modeling a recompression Brayton cycle, which uses the heat collected at the central receiver through the heliostat field. The developed mathematical model was implemented for six different locations (cities) in Saudi Arabia for comparative analysis. The selected cities were Tabouk (North), Madinah (West), Dhahran (East), Riyadh (Central), Bishah (South), and Najran (South). In addition, an auxiliary heat exchanger was also added before the expansion turbine to keep the turbine inlet temperature constant and, thus, to keep the net power output uniform. The target net power output was set to be 40 MW. The findings reveal that the highest annual average heat collected was for Madinah, 938,400 kWh/day, and the second highest was for Tabouk, 933,100 kWh/day. Consequently, the least amount of annual average fuel hybridization required was 5.82% for Madinah and 6.34% for Tabouk during daytime hours.

Keywords: *Solar tower power plant, supercritical CO_2, recompression Brayton cycle, hybrid solar power plant, heliostat optimization, Saudi Arabia*

1. Introduction

Solar tower or central receiver system comprises of a field of mirrors on the ground, which directs the solar radiation to a receiver mounted at the top of on a central tower. The receiver converts the solar radiation into heat and drives a thermodynamic cycle, which is usually a Brayton or a Rankine cycle, to generate power. Each individual mirror in the field is called a heliostat and it is equipped with a two-axes tracking system. As compared to parabolic troughs, solar towers can achieve higher temperature as more sunlight can be concentrated on a single receiver and the loss of heat can be minimized. Moreover, solar towers provide an opportunity to increase the capacity factor by using a thermal storage system and to maximize the power generated by allowing flexible generation strategy along with higher efficiency levels. With these advantages, A solar tower can be a tough competitor to parabolic trough in the future market with gained operating experience and reduced cost (IRENA, 2012).

In a study conducted by (Noone et al., 2012), a biomimetic pattern was proposed for the heliostat field layout. The model was based on the discretization of the heliostat surface for the calculation of the optical performance parameters, specifically the shading and blocking factor and the intercept factor. In their approach, a heliostat surface was divided into cells, however, this approach can be time consuming. (Besarati and Yogi Goswami, 2014) performed an optimization of the same biomimetic heliostat field pattern. In their study, a method was proposed to identify the potential shadowing and blocking heliostats for the calculation of the shading and

Selection and/or peer review under responsibility of Scientific Committee

blocking factor. Using their approach, a case study was carried out for the design of 50 MWth solar tower plant for Dagget, California.

A code called HFLCAL (Schmitz et al., 2006) was developed by the German Aerospace Center to optimize a heliostat field on annual basis. The code calculates the intercept by describing an analytical function, which computes the reflected image of each heliostat as a circular normal distribution. Their analysis was carried out for two latitude locations, i.e. 20° N and 40° N.

In a different study conducted by (Pitz-Paal et al., 2011), annual optimization of a heliostat field for solar to chemical energy conversion efficiency was performed for solar fuels production. The optimization was carried out by coupling genetic algorithm and the Nelder-Mead algorithm. It was concluded that the chemical process selected has a high impact on the basic design parameters and the performance. Furthermore, their study was carried out for a latitude location of 36.12°.

(Collado and Guallar, 2012) developed a code named Campo which takes into account thousands of heliostat co-ordinates for the optimization process. The code was validated in a different study (Collado and Guallar, 2013) using the literature data collected from Gemasolar (a solar tower power plant). In their study, more than desired number of heliostats was generated. Then optimization of the generated heliostat field was carried out by applying radial increments in the heliostat rows manually. And finally, the heliostats which had lower annual optical performance were eliminated to acquire the desired number of heliostats. Their study was carried out for Seville, Spain (latitude 37.46° N)

The Chinese Academy of Science developed a code for the heliostat field layout optimization called HFLD (Wei et al., 2010a, 2010b). In their code, the optimization was based on the receiver geometrical aperture and an efficiency factor. However, the intercept factor was calculated using the Monte Carlo ray tracing method. As a result, the accuracy will depend upon the number of rays traced and, consequently, this will result in a high computation time. Using this code, a new layout was also proposed for the PS10 power plant. Furthermore, this study was conducted for a latitude location of 40.4° N.

In a study by (Yao et al., 2009), a power plant was modeled using TRNSYS and integrated with HFLD (Wei et al., 2010a, 2010b) developed by the Chinese Academy of Science for the demonstration of 1 MW central receiver plant in Dahan, China. The basic flow calculation in the solar central receiver system and their integration to a plant were described. On the other hand, (Le Moullec, 2013) performed a techno-economic study on a coal fired power plant with a supercritical CO_2 Brayton cycle and a post combustion CO_2 capture mechanism. It was observed that the reduction of cost avoided CO_2 was 45% and the reduction in the levelized cost of electricity (LCOE) was 15%, without storage and transport, when compared to a reference supercritical coal fired power plant equipped with a standard carbon capture process.

The effect of a transient solar heat input on a supercritical CO_2 split expansion Brayton cycle was studied by (Iverson et al., 2013). They studied the performance of the turbomachinery in response to a fluctuating solar heat source. It was observed that the thermal mass in the system effectively enables the Brayton cycle to continue to run for short periods until the thermal input can recover.

It can be observed from the literature review that no study has been conducted when integrating a sCO2 recompression Brayton cycle with a solar thermal tower system accounting for the actual optical losses of the heliostat field. Furthermore, no study considers DE optimization technique for the optimization of the heliostat field on annual basis. In this article, a heliostat field was first generated for six selected locations (cities) in Saudi Arabia; and then these generated heliostat fields were optimized on annual basis while calculating all the necessary optical performance parameters of all the heliostats at every step of the optimization. The selection of the locations takes into consideration different potential geographical locations of the proposed solar power system. The locations selected for the analysis were Tabouk (North), Madinah (West), Dhahran (East), Riyadh (Central), Bishah (South) and Najran (South). Then, after calculating the heat collected through the solar thermal system for the selected cities, comparative performance analysis was carried out for the aforementioned cities. The results of the current research will be a valuable reference for both researchers and engineers in the solar thermal power field.

2. Mathematical modeling

A mathematical model was developed to achieve the objectives of the present study. The first part of the mathematical model deals with generating a preliminary heliostat field in a radial staggered configuration. The generated heliostat field is then tested for its optical performance, and there are five parameters which constitute the optical performance of the heliostat field layout namely the shadowing and blocking factor, the intercept factor, the atmospheric attenuation factor, the cosine factor, and the actual mirror reflectivity. The generated heliostat field is then optimized on annual basis using an evolutionary algorithm called the differential evolution (HFLODE: Heliostat Field Layout Optimization using Differential Evolution). Finally, a recompression Brayton cycle using sCO_2 as a working fluid was integrated with the solar thermal tower system with a net power output of 40 MW. Comparative performance analysis was carried out for six different locations nin Saudi Arabia while taking into account the direct normal incident irradiation for all of these locations.

2.1 Generating a heliostat field

The characteristic diameter is the distance between the center of the adjacent heliostats and it is defined by

$$DM = DH + dsep + x_1 \quad \text{(eq. 1)}$$

where DM is the characteristic diameter, DH is the heliostat diagonal and $dsep$ is any additional security distance between the heliostats. Here, x_1 is one of the optimizing parameters. By varying the value of this paramter, we can control the azimuthal spacing between the adjacent heliostats.

The minimum radial distance between the heliostat rows is equal to the height of an equilateral triangle and it is defined as

$$\Delta R_i = x_{2,i} DM \cos 30° \quad \text{(eq. 2)}$$

where $x_{2,i}$ is the second optimizing parameter and i denotes the zone of the heliostats. Using the parameter $x_{2,i}$ the radial spacing between the rows of the heliostats can be controlled and in turn the optical performance of the heliostats.

2.2 Solar positioning model

In order to calculate the instantaneous optical efficiency of the heliostat field, it is necessary to include a solar positioning model which can be defined as (Duffie and Beckman, 2013)

$$\delta = \frac{23.45\pi}{180} \sin\left(2\pi \frac{284 + n_d}{365}\right) \quad \text{(eq. 3)}$$

$$\omega_{sunrise} = \cos^{-1}(\tan\phi \tan\delta) - \pi = -\omega_{sunset} \quad \text{(eq. 4)}$$

$$\alpha_s = \sin^{-1}(\cos\phi \cos\delta \cos\omega_s + \sin\phi \sin\delta) \quad \text{(eq. 5)}$$

$$\gamma_s = \mathrm{sgn}(\omega_s) \left| \cos^{-1} \frac{\sin\alpha_s \sin\phi - \sin\delta}{\cos\alpha_s \cos\phi} \right| \quad \text{(eq. 6)}$$

where δ is the solar declination angle, ω_s is the hour angle, n_d is the day of the year, ϕ is the latitude angle, α_s is the solar altitude, and γ_s is solar azimuth angle. Note that all angles are in radians.

2.3 Optical efficiency of the heliostat field

The total optical efficiency as defined by (Collado and Guallar, 2012) is

$$\eta_{opt}(x,y,t) = \rho \cos\omega(x,y,t) f_{at}(x,y) f_{sb}(x,y,t) f_{itc}(x,y,t) \quad \text{(eq. 7)}$$

where ρ is the reflectance of the heliostats, $\cos\omega$ is the incidence cosine between the incident sun ray and the normal to the heliostat surface, f_{sb} is the shadowing and blocking factor, f_{itc} is the intercept factor accounting for the fraction of the reflected rays intercepted by the receiver, and f_{at} is the atmospheric attenuation efficiency. Furthermore, x, y, and t represent the co-ordinates and time, respectively. The detail modeling of these five parameters was demonstrated in our previous study (Atif and Al-Sulaiman, 2015).

Standard deviation of tracking errors,	0.63 mrad
Standard deviation of beam quality errors	1.88 mrad
Emittance of the receiver surface, ε	0.85
Absorptance of the receiver surface, α_R	0.95

2.4 Optimization of the heliostat field

The differential evolution is a population based optimization technique, which is characterized by its simplicity, robustness, few control variables, and fast convergence (Abido and Al-Ali, 2009). Because the DE technique is an evolutionary algorithm, it is suited for non-linear and non-differentiable optimization problems as well.

The strategy applied in this technique is to use the difference between randomly selected vectors to generate a new solution. For each solution in the original population, a trial solution is generated by performing the process of mutation, recombination, and selection operations. The old and new solutions are compared and the best solutions emerge in the next generation.

Furthermore, the DE in most instances as compared to the annealed Nelder and Mead approach, adaptive simulating annealing and the breeder genetic algorithm outperformed all of the aforementioned optimization techniques in terms of the required number of function evaluations necessary to locate a global optimum of the test functions (Storn and Price, 1997). Therefore, the DE was selected in this study.

The following equation is used for calculating the monthly averaged annual optical efficiency of the heliostat field:

$$\eta_{maa} = \frac{\sum_{j=1}^{12} \int_{t=sunrise}^{t=sunset} \eta_{opt} dt}{\sum_{j=1}^{12} \int_{t=sunrise}^{t=sunset} dt} \qquad \text{(eq. 8)}$$

where η_{maa} is monthly averaged annual heliostat field efficiency, the subscript *maa* denotes monthly annual averaged, and *j* denotes the average day of each month from January to December for the whole year as given in (Duffie and Beckman, 2013; Klein, 1977). This equation was used as the objective function for optimization.

2.5 Central receiver

The radiation heat losses, the convection heat losses and the optical losses were considered for the modeling of the central receiver as discussed next. The modeling of the central receiver was performed in EES. The equation for the radiation heat losses was given by (Sheu and Mitsos, 2013) as

$$Q_{rad} = F_{view} A_R \varepsilon \sigma T_R^4 \qquad \text{(eq. 9)}$$

where F_{view} is the radiation shape factor, A_R is the radiative area of the central receiver, ε is emissivity of the receiver, σ is the Stefan Boltzmann constant, and T_R is the receiver temperature.

The equation for convective heat losses from the central receiver is given as

$$Q_{conv} = A_R h_{conv} (T_R - T_{amb}) \qquad \text{(eq. 10)}$$

where h_{conv} is calculated by Bejan correlation for vertical chamber with natural convection and is defined as (Segal and Epstein, 1999)

$$h_{conv} = 0.557 \times 10^{-6} \left(\frac{T_R - T_{amb}}{H_t}\right)^{0.25} [\text{kW/ m}^2 - \text{K}] \qquad \text{(eq. 11)}$$

where H_t is the total height of the solar tower and T_{amb} is the ambient temperature.

where

$$Q_u = Q_{net} = \alpha_R Q_{in} - (Q_{rad} + Q_{conv}) \qquad \text{(eq. 12)}$$

$$Q_{in} = \eta_{opt} Q_{solar} \qquad \text{(eq. 13)}$$

$$Q_{solar} = I A_h \qquad \text{(eq. 14)}$$

Here, α_R is the absorptance of the receiver, I is the direct normal incident radiation, A_h is the total area of the heliostats, Q_u (or Q_{net}) is the net useful energy gained at the receiver, Q_{solar} is the total incident energy on the heliostat field, and Q_{in} is the net energy gained at the receiver.

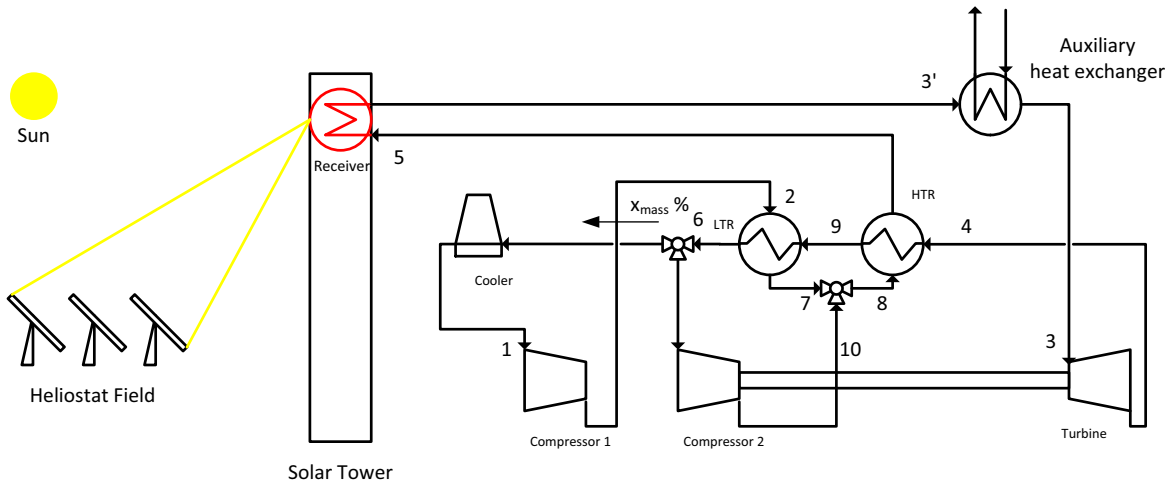

Fig. 1: Recompression closed loop supercritical carbon dioxide Brayton cycle with auxiliary heater

2.6 Closed loop sCO_2 recompression Brayton cycle

In a previous study by the authors (Al-Sulaiman and Atif, 2015), it was demonstrated that the recompression Brayton cycle demonstrated the highest thermal efficiency as compared to other Brayton cycles. Therefore, this cycle was selected for this study. In the recompression Brayton cycle (Figure 1), the flow is split into two streams after the low temperature regenerator and before passing through the cooler. These two streams are the one that flows to the main compressor through the cooler and the other one flows to the recompression compressor. Consequently, the system rejects less heat and the compressor work is reduced, which in turn causes the thermal efficiency to improve. The analysis of the Brayton cycle was also performed in EES and this code was integrated with the central receiver. The modeling of this cycle is presented as follows.

The power input of the first compressor is defined as

$$W_c = x_{mass}\dot{m}(h_2 - h_1) \quad \text{(eq. 15)}$$

where x_{mass} is the fraction of the mass flow rate through the first compressor, $\dot{m}$ is the mass flow rate of sCO_2, and h is the specific enthalpy.

The power input of the second compressor is defined as

$$W_{c2} = (1 - x_{mass})\dot{m}(h_{10} - h_6) \quad \text{(eq. 16)}$$

The useful energy gained at the receiver is defined as

$$Q_u = \dot{m}(h_3' - h_5) \quad \text{(eq. 17)}$$

The heat added by the auxiliary heater is defined as

$$Q_{aux} = \dot{m}(h_3 - h_3') \quad \text{(eq. 18)}$$

The turbine power can be defined as

$$W_T = \dot{m}(h_3 - h_4) \quad \text{(eq. 19)}$$

Tab. 3: Basic design and operating parameters used for the sCO_2 recompression Brayton cycle

Temperature at the inlet of compressor (first compressor)	31.25° C
Turbine inlet temperature T_3 (*TIT*)	570° C
Pressure at the inlet of the compressor (first compressor)	7.4 MPa
Pressure ratio	2.7
Mass flow rate $\dot{m}$	469.2 kg/s
High temperature regenerator effectiveness (Chacartegui et al., 2011)	0.85
Low temperature regenerator effectiveness	0.7
Isentropic efficiencies of the compressors (Chacartegui et al., 2011)	0.8
Isentropic efficiency of the turbine (Chacartegui et al., 2011)	0.9
Thermal efficiency of the cycle η_{th}	0.4517
Net power output by the cycle	40079 kW ≈ 40 MW

Applying the energy balance on the high temperature regenerator to obtain

$$h_4 - h_9 = h_5 - h_8 \quad \text{(eq. 20)}$$

Applying the energy balance on the low temperature regenerator to obtain

$$x_{mass}(h_7 - h_2) = h_9 - h_6 \quad \text{(eq. 21)}$$

The energy rejected at the cooler is defined as

$$Q_{out} = x_{mass}\dot{m}(h_6 - h_1) \quad \text{(eq. 22)}$$

The net power output of the cycle is defined as

$$W_{net} = W_T - W_C - W_{C2} \quad \text{(eq. 23)}$$

The thermal efficiency of the cycle is given by

$$\eta_{th} = \frac{W_{net}}{Q_u + Q_{aux}} \quad \text{(eq. 24)}$$

The fraction of fuel hybridization required to keep a constant power output is given by

$$f_{hybrid} = \frac{Q_{aux}}{Q_{solar} + Q_{aux}} \quad \text{(eq. 25)}$$

The input solar share is defined as

$$X_{solar} = \frac{Q_{solar}}{Q_{solar} + Q_{aux}} \quad \text{(eq. 26)}$$

3, Results and discussion

In this study, a complete thermodynamic analysis of the solar thermal tower system integrated with a closed loop sCO_2 recompression Brayton cycle was performed. This analysis was carried out for six different locations in Saudi Arabia taking into account each of the locations' direct normal irradiation. The target net power output was 40 MW and the analysis was carried out in accordance with this net power output. This net power output was made uniform and for this purpose an auxiliary heat source was added. This plant would be operational with the input solar energy and auxiliary heat source for daylight hours; nonetheless, for nighttime operation the plant would operate on auxiliary heat source. Detailed analysis of the input solar share and the auxiliary heat provided has also been performed. Table 1 lists the design parameters of the heliostat and the central receiver which were used in this study whereas the operating conditions of the recompression sCO_2 Brayton cycle are listed in Table 2. Finally, in Table 3 the details of the cities including the latitude and longitude with the annual heat collected at the central receiver is provided.

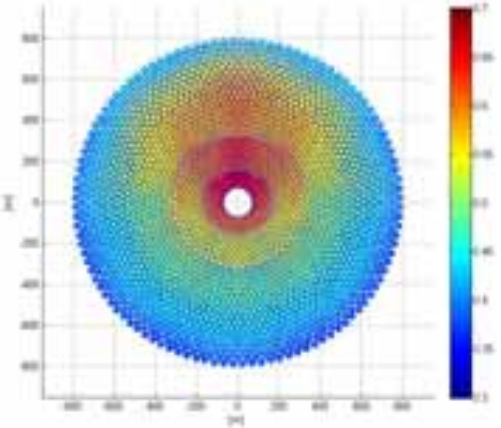

Fig. 2e: Contours of the optical efficiency of the optimized heliostat field on annual basis for Bishah, Saudi Arabia

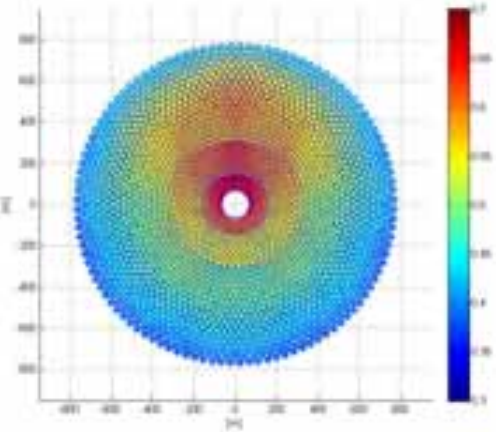

Fig. 2f: Contours of the optical efficiency of the optimized heliostat field on annual basis for Najran, Saudi Arabia

The solar resource data for each of the locations aforementioned was taken from a renewable energy resource website sponsored by NASA ("Surface meterology and Solar energy," n.d.). The data available on this website is averaged over a period of 22 years from 1983 until 2005. The averaged values over a month of direct normal irradiation are available there. A preliminary generated heliostat field was optimized on monthly averaged annual basis. Therefore, Equation 8 was used for the annual optimization for all the locations considered in this study. This code calculates all the necessary optical performance parameters of all the heliostats at every step of the optimization until the best layout of the generated heliostat field is found. The optimized heliostat fields for all of selected locations have been depicted in Figures 2a-2f.

As the data available on the aforementioned website was available on monthly basis, the average efficiencies of each month for all the locations were calculated after the heliostat fields were annually optimized. These efficiencies were used as an input to the EES code for the analysis of the receiver and recompression Brayton cycle. In this study; optical, convection heat, and radiation heat losses were taken into account, whereas the conduction heat losses were neglected from the receiver.

Figures 3a – 3f depicts bar graphs for the average heat collected for each month, for Tabouk, Madinah, Dhahran, Riyadh, Bishah, and Najran, respectively. Moreover, it can be observed that Madinah has the highest annual average heat collected in kWh/day (Table 3), whereas Tabouk has the second highest and Dhahran has the lowest. For Tabouk, Madinah, Dhahran, and Riyadh; the highest heat collected is in the month of June, whereas for Bishah and Najran it is not the case. Furthermore, it will be more preferable to install a plant where there are fewer fluctuations in the solar irradiation, such as Madinah (Figure 3b) and Bishah (Figure 3e). Such operating conditions will results in more stable operations. Therefore, the lifetime of the plant increases and its cost decreases.

A closed loop sCO_2 recompression Brayton cycle was integrated with the central receiver where the net heat collected was used as an input to the Brayton cycle. The modeling of the Brayton cycle was performed in such a way that heat gained at the receiver was used as an input value to the cycle rather than the turbine inlet temperature. Consequently, the temperature T_3' will not remain constant and will depend upon the irradiation of a particular location. Thus, the power output will not be uniform. To address this, an auxiliary heat exchanger was added before the turbine so that if the net heat gained at the receiver is low, extra heat will be added to keep the turbine inlet temperature constant and hence to keep the power output uniform. For this study, the turbine inlet temperature was fixed at 570° C and the net power output was fixed at 40MW. Figure 4 illustrate the percent hybridization required for all the cities during daylight hours. In other words, these bar graphs also show indirectly the amount of auxiliary heat required to keep a uniform power output in the daytime. From the figure, it can be observed that Madinah requires least amount of external fuel hybridization, i.e. only 5.82%, whereas Tabouk requires second least 6.34% and Najran requires third least i.e. 7.62%. During nighttime, the auxiliary boiler is working.

Tab. 3: Performance comparison of different locations of Saudi Arabia

City	Longitude	Latitude	Average annual heat collected at the central receiver (kWh/day)
Tabouk	36.5° E	28.5° N	933103
Madinah	39.5° E	24.5° N	938388
Dhahran	50.5° E	26.5° N	827420
Riyadh	46.5° E	24.5° N	855262
Bishah	42.5° E	20.5° N	882216
Najran	44.5° E	17.5° N	893359

4. Conclusions

A complete thermodynamic analysis of a solar thermal tower system when integrated with a sCO_2 recompression Brayton cycle was performed for six different locations in Saudi Arabia considering the local solar irradiation intensity for each location. The selected locations for the analysis were Tabouk (North), Madinah (West), Dhahran (East), Riyadh (Central), Bishah (South), and Najran (South). Heliostat fields were first generated and tested for their optical performance for these locations. The optical efficiencies of the generated heliostat fields were then optimized on annual basis considering all the optical performance parameters at every step of the optimization. A closed loop sCO_2 recompression Brayton cycle was then integrated with the central receiver where the heat is captured, which is reflected from the heliostat field. Furthermore, to keep the net power output uniform, an auxiliary heat exchanger was added before the expansion turbine. The findings indicated that the highest annual average heat collected was for Madinah (938,400 kWh/day) and the second highest was for Tabouk, (933,100 kWh/day). Similarly, the least amount of annual average fuel hybridization required was 5.82% for Madinah, and 6.34% for Tabouk during daytime.

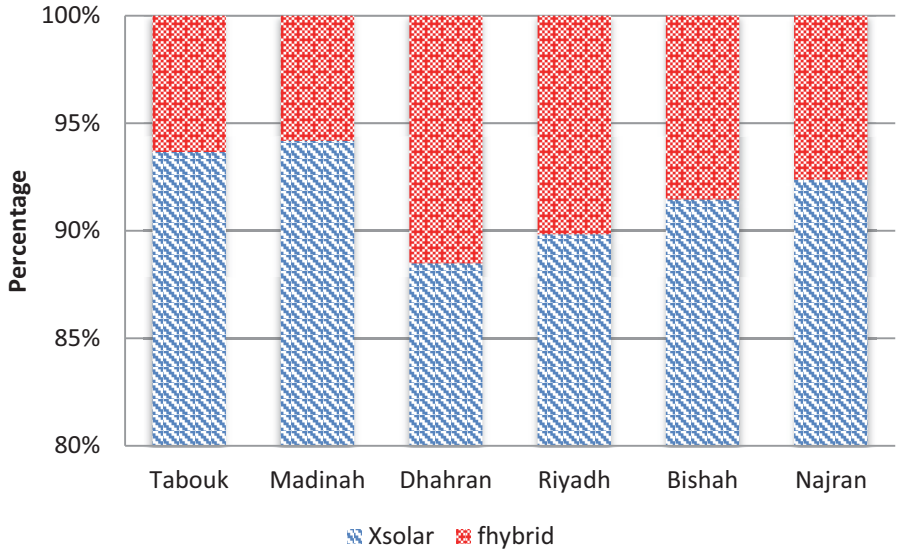

Fig. 4: Percentage of annual hybridization required for all of the locations considered.

The dynamic performance of different configurations of Solar Aided Power Generation (SAPG)

Jiyun Qin, Eric Hu, Graham J. Nathan

School of Mechanical Engineering, the University of Adelaide, Adelaide (Australia)

Abstract

Solar Aided Power Generation (SAPG) is defined as solar heat used to displace extraction steam to preheat the regenerative Rankine cycle (RRC) power plant's feedwater. In an SAPG plant, heat exchangers (termed as solar preheaters, SP) facilitate the heat exchange between solar heat and feedwater. Depending on the locations of the SPs in the power plant, an SAPG plant can have different configurations. In order to respond to solar variations, SAPG plants can be controlled using different approaches. The performance of SAPG plants with different configurations and controlled using a different approach has been compared by using real solar radiation data from Adelaide, Australia. Solar radiation data from two consecutive periods of five days during summer and winter were used for simulation. The results show that the performances of the SAPG plant with different configurations and approaches to control are different, and there is an optimum configuration and approach to control for the SAPG plant.

Keywords: *Solar Aided Power Generation, Plant configurations, Series configuration, Parallel configuration, Dynamic performance.*

1. Introduction

A Solar Aided Power Generation (SAPG) plant is a variant of the regenerative Rankine cycle (RRC) power plant. In an RRC power plant, steam is extracted from the steam turbine to preheat the feedwater in a feedwater heater (FWH). In an SAPG plant, solar thermal energy carried by the heat transfer fluid (HTF) is used to displace the heat of the extraction steam by preheating the feedwater. The displaced extraction steam can be expanded further to produce power. Compared with solar-only power plants, an SAPG plant has advantages of lower cost and higher solar to power efficiency (Hu et al., 2010).

In an SAPG plant, a heat exchanger (called a solar preheater, SP) is used to facilitate the heat exchange between the solar thermal energy and heat of the feedwater. The heat exchanger can be arranged in parallel or series with the FWHs. Most of previous studies about the SAPG plant are based on the configurations that the SP is in parallel with the FWHs of power plants (Yan et al., 2010; Yang et al., 2011; Peng et al., 2013, 2014a, 2014b; Hou et al., 2015). In contrast, some recent studies about the SAPG plant are based on the configuration that the SP is in series with the FWHs (Hou et al., 2013; Wu et al., 2015). Based on the steady state simulation, Yan et al. (2010) and Yang et al. (2011) found that more solar input leads to higher technical performance. Peng et al. (2013, 2014a, 2014b) assessed an SAPG plant by using daily solar radiation data from different seasons. It was found that the efficiency of the solar field is influenced by the variations in solar radiation. Hou et al. (2013, 2015) and Wu et al. (2015) evaluated SAPG plant performance by using annual solar radiation data. Hou et al. (2013) assessed an SAPG plant without any solar storage system while Wu et al. (2015) assessed an SAPG plant with a solar storage system. It is found that the performance of the SAPG plant is influenced by the solar radiation. However, these previous studies about the SAPG plant are based on the single configuration. The comparison between different configurations is

lack of study.

In order to respond to solar variability, the extraction steam of an SAPG plant can be controlled with different approaches. Hou et al. (2013, 2015) and Wu et al. (2015) evaluated the SAPG plant based on an assumption that feedwater outlet temperature of FWHs keeps unchanged. This means that all the extraction steam should be adjusted in response to solar resources. However, the SAPG plant can also be controlled with varying feedwater outlet temperature of FWHs. This means that the extraction steam can be adjusted in pre-set order to respond to solar resource variability. This may help to improve the performances of the SAPG plant.

Hou et al. (2013) evaluated SAPG performance by using real solar radiation data. The result showed that the performance of an SAPG plant is influenced by the solar radiation. However, the SAPG plant in the papers of Hou (2013) and Peng (2013, 2014a, 2014b) are based on the parallel configuration. It is necessary to compare the dynamic performance of four configurations controlled using different approaches under variations of solar radiation.

2. Concept description

Depending on the locations of Solar Preheaters, an SAPG plant can have four different configurations, termed as Parallel 1 (P1), Parallel 2 (P2), Series 1 (S1) and Series 2 (S2) configurations. Figures 1 to 4 shows the schematic diagram of P1, P2, S1 and S2 configurations, respectively. As shown in Fig. 1 and 2, in the P1 the P2 configurations the SP is parallel with the FWHs of the power plant. In the P1 configuration, each FWH has one parallel SP, while in the P2 configuration, all the high pressure FWHs or low pressure FWHs have one parallel SP. As shown in Fig. 3 and Fig. 4, in the S1 and the S2 configurations the SP is in series with the FWHs of the power plant. In the S1 configuration, the SP is located in series between FWH3 and DEA (deaerator) to displace the extraction steam before the extraction point at DEA (points A, B and C in Fig. 3), or is located in series between FWH8 and the condenser to displace the extraction steam after the extraction point at DEA (points D to H in Fig. 3). In the S2 configuration, the SP is located in series between the boiler and FWH1 to displace the extraction steam before the extraction point at DEA (points A, B and C in Fig. 4), or is located in series between DEA and FWH5 to displace the extraction steam after the extraction point at DEA (points D to H in Fig. 4). In the S1 configuration, the extraction steam is displaced from lower pressure extraction points to higher pressure extraction points; while in the S2 configuration, the extraction steam is displaced from higher pressure extraction points to lower pressure extraction points.

In order to respond to solar variability, the SAPG plant can be controlled with two typical approaches: (1) at a constant feedwater temperature exiting FWH (CT); or (2) at a varying feedwater temperature exiting FWH (VT). The CT approach means that the outlet temperature at each FWH is maintained as constant by adjusting the extraction steam flow rates at all designated displaced extraction points (i.e. points A to C or E to H in Figs. 1 to 4). The VT approach means that the extraction steam flow rate at the designated displaced extraction points (i.e. points A to C or E to H in Figs. 1 to 4) is displaced in pre-set order to respond to solar resource variability. In the VT approach, the two most typical pre-set orders are: (1) the extraction steam is displaced in order from higher pressure extraction point to lower pressure extraction point, which is termed as the HL-VT approach; or (2) the extraction steam is displaced in order from the lower pressure extraction point to the higher pressure extraction point, which is termed as the LH-VT approach. Different configurations can be controlled with different approaches in response to solar variability. Table 1 summarises the configurations and their possible control approaches.

3. Methodology

3.1. Pseudo-dynamic model

In order to evaluate the performance of an SAPG plant under variable solar radiation, a pseudo-dynamic model has been developed. The pseudo-dynamic simulation models of four configurations are based on steady state simulation. The steady state simulation model is developed by using the matrix method of an SAPG plant (Hou et al., 2013). The pseudo-dynamic models simulate the technical performance of an SAPG plant at a series of time intervals. At each time interval, the SAPG plant is assumed to be operated at a steady state. A stable mass flow rate of HTF at a constant temperature in each time interval is input into the model.

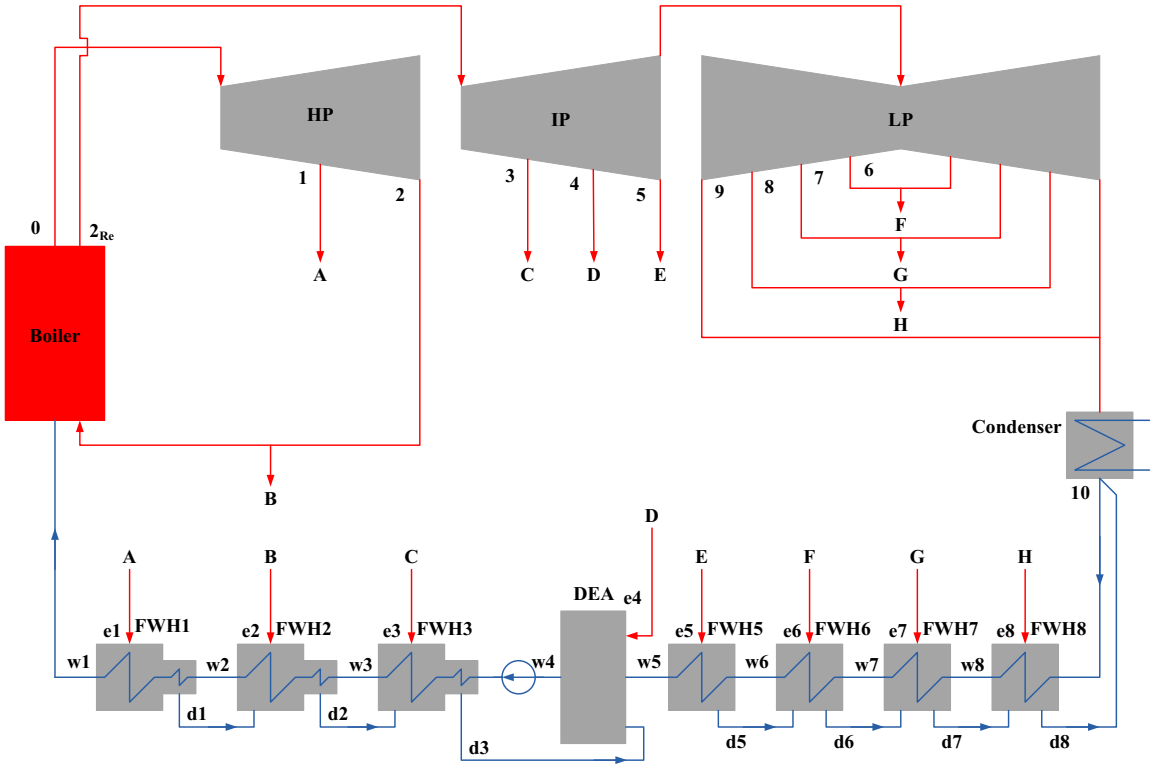

Fig. 5: Schematic diagram of a reference power plant used to demonstrate the matrix method; the power plant has seven closed FWHs and one deaerator (DEA).

Figure 5 shows a reference power plant used to demonstrate the matrix method. As shown, the reference power plant has seven closed FWHs and one deaerator which is an open FWH. In the matrix method, the

simulation is based on the heat and mass balance calculation of the FWH system. The heat and balance equation of the FWH system is given as,

$$\begin{pmatrix} q_1 & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & 0 \\ r_2 & q_2 & \ddots & \ddots & \ddots & \ddots & \ddots & \vdots \\ r_3 & r_3 & q_3 & \ddots & \ddots & \ddots & \ddots & \vdots \\ r_4 & r_4 & r_4 & q_4 & \ddots & \ddots & \ddots & \vdots \\ \tau_5 & \tau_5 & \tau_5 & \tau_5 & q_5 & \ddots & \ddots & \vdots \\ \tau_6 & \tau_6 & \tau_6 & \tau_6 & \tau_6 & q_6 & \ddots & \vdots \\ \tau_7 & \tau_7 & \tau_7 & \tau_7 & \tau_7 & \tau_7 & q_7 & \vdots \\ \tau_8 & \tau_8 & \tau_8 & \tau_8 & \tau_8 & \tau_8 & \tau_8 & q_8 \end{pmatrix} \cdot \begin{pmatrix} y_A \\ y_B \\ y_C \\ y_D \\ y_E \\ y_F \\ y_G \\ y_H \end{pmatrix} + \begin{pmatrix} \dot{Q}_{Solar,1}/\dot{m}_0 \\ \dot{Q}_{Solar,2}/\dot{m}_0 \\ \dot{Q}_{Solar,3}/\dot{m}_0 \\ 0 \\ \dot{Q}_{Solar,5}/\dot{m}_0 \\ \dot{Q}_{Solar,6}/\dot{m}_0 \\ \dot{Q}_{Solar,7}/\dot{m}_0 \\ \dot{Q}_{Solar,8}/\dot{m}_0 \end{pmatrix} = \begin{pmatrix} \tau_1 \\ \tau_2 \\ \tau_3 \\ \tau_4 \\ \tau_5 \\ \tau_6 \\ \tau_7 \\ \tau_8 \end{pmatrix} \quad \text{(eq.1)}$$

where q_i (kJ/kg) is the specific enthalpy decrease of extraction steam in the ith FWH; τ_i (kJ/kg) is the specific enthalpy increase of the feedwater in the ith FWH; and r_i (kJ/kg) is the specific enthalpy decrease of the drained steam from the (i-1)th FWH in the ith FWH. For the Closed FWHs (FWH 1 to 3 and 5 to 8 in Fig. 5) and the Open FWH (DEA in Fig. 5), the q_i, τ_i and r_i are described as follows:

Closed FWH: $q_i = h_{ei} - h_{di}; \tau_i = h_{fi} - h_{fi+1}; r_i = h_{di-1} - h_{di}$

Open FWH: $q_i = h_{e4} - h_{w5}; \tau_i = h_{w4} - h_{w5}; r_i = h_{d3} - h_{w5}$.

In Eq.1, $y_i (i = A\ to\ H)$ equals the $\dot{m}_i/\dot{m}_0$, and $\dot{m}_i$ (kg/s) is the mass flow rate of extraction steam at each extraction point, $\dot{m}_0$ (kg/s) is the mass flow rate of steam through the boiler (point 0 in Fig. 5).

In order to evaluate the performance of the four configurations of an SAPG plant, the solar power output, and solar power output per solar collector area are calculated.

- Solar power output (W_{Solar}, MW):

$$W_{Solar} = W_{Total} - W_{Ref}, \quad \text{(eq. 2)}$$

where W_{Total} (MW) is the total power output of the power plant after solar input (power boosting purpose), and W_{Ref} (MW) is the output of the power plant without solar input.

- Solar power output per solar collector area (kWh/m^2):

$$x_{Solar} = \frac{W_{Solar}\Delta t}{1000.\mathrm{A}_{Solar}}, \quad \text{(eq. 3)}$$

where W_{Solar} (MW) is the solar power output, A_{Solar} (m^2) is the solar collector area.

3.2. Solar resource

In the present paper, historical solar radiation data from 2010 for Adelaide (34ºS, 138ºC) were selected for the evaluation. The historical data were taken from the Australia Government Bureau of Meteorology (BOM, 2014). The solar radiation data for two consecutive five typical days in summer and winter were used for the simulation. Figure 6 and 7 show the hourly solar radiation of consecutive five typical days in summer and winter, respectively.

3.3. Case study

The power plant shown in Fig. 5 is used as case study for comparison. It is a 300MW sub-critical power plant and the solar heat is used to displace the extraction steam at points A to C. In order to displace the extraction steam, it is assumed there is a 10 ºC temperature difference between the feedwater temperature and HTF temperature, so the temperature of HTF from the solar field is at 280 ºC. The solar heat is assumed to be collected by the LS-2 parabolic trough solar collector. The area of each set of LS-2 solar collector is

235.5 m2 (Length 47.1 m, Width 5 m). It is assumed that 200, 300, 400 and 500 sets of LS-2 solar collectors are used to collect solar heat for feedwater preheating purposes. The simulation of the LS-2 solar field is based on the previous work of Zhou et al. (2015).

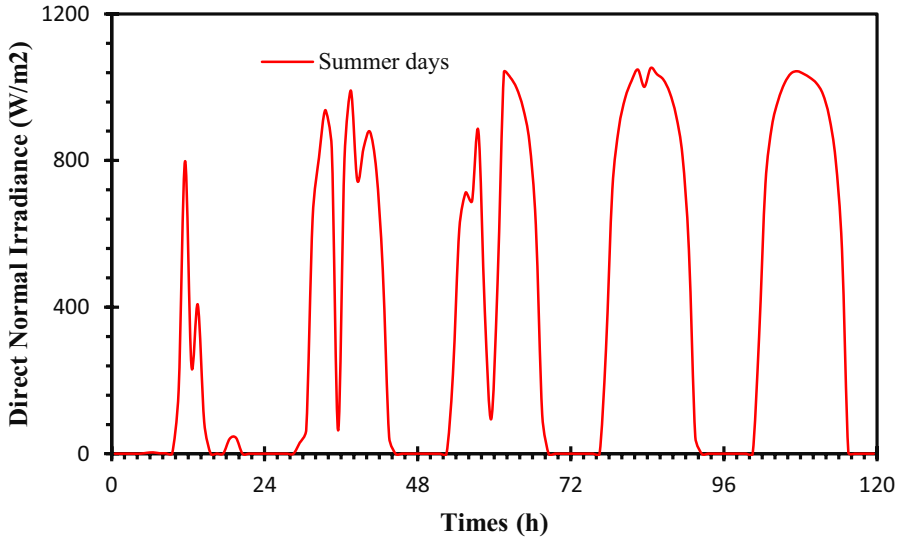

Fig. 6: Hourly Direct Normal Irradiance (W/m^2, DNI) on five consecutive typical days in summer for Adelaide.

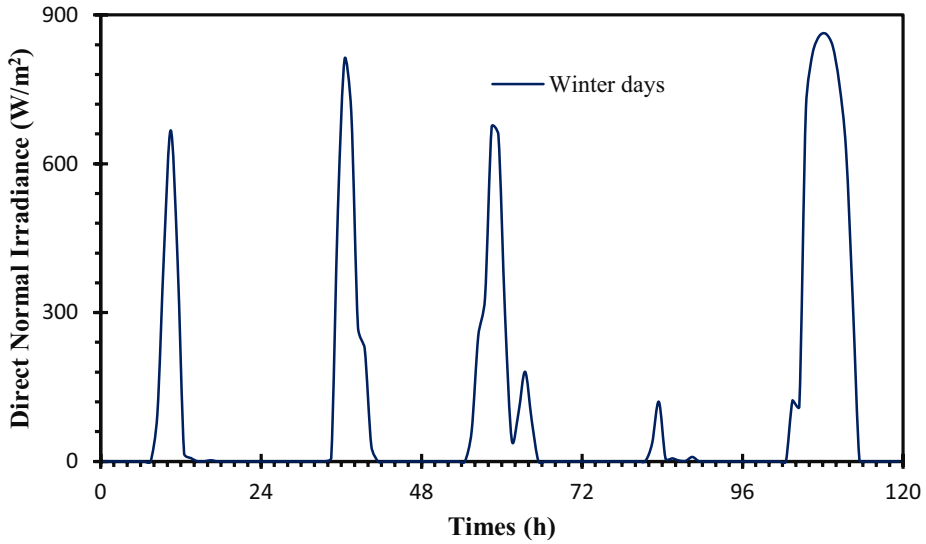

Fig. 7: Hourly Direct Normal Irradiance (W/m^2, DNI) on five consecutive typical days in winter for Adelaide.

4. Results

Figures 8 and 9 present the hourly solar power ouptut of SAPG plants with different configurations and controlled with different approaches on five consecutive typical days in summer and winter using 500 sets of parabolic trough solar collectors to produce the HTF. As shown in these figures, the P1 configuration and the P2 configuration both controlled in the CT approach have the same hourly solar power output. These two secnarios are the most common SAPG plants of previous works. It is also shown that the P1 configuration controlled in the LH-VT approach and the S1 configuration controlled in the CT approach also have the

same hourly solar power output. The results of Figures 8 to 9 also show that the P2 configuration controlled in the HL-VT approach has the highest hourly solar power output on the days both in summer and winter, and the P1 configuration controlled in the LH-VT approach and the S1 configuration controlled in the CT approach have the lowest hourly solar power output.

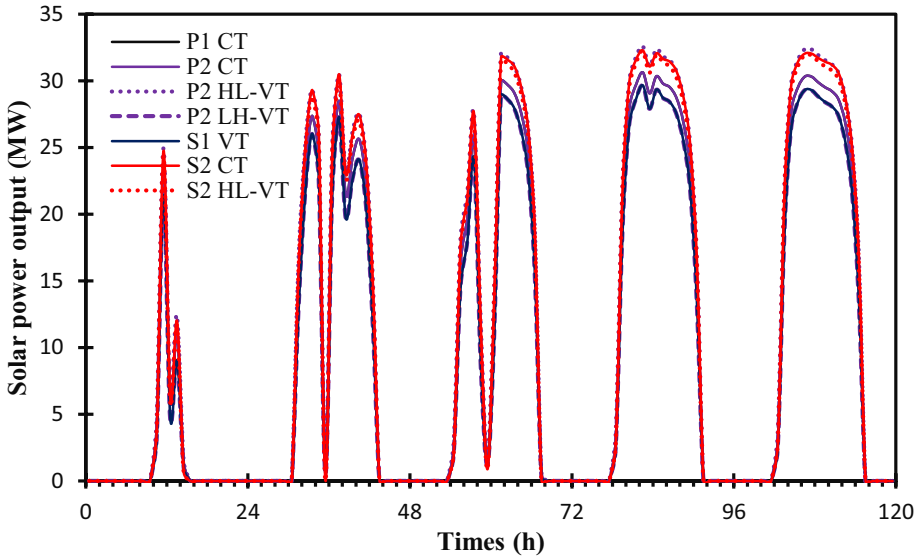

Fig. 8: Hourly solar power output of different configurations controlled with different approaches on five consecutive typical days in summer using 500 sets of parabolic trough solar collectors to produce HTF. P1 and P2 configurations both controlled in the CT approach is the most common SAPG plants of previous works.

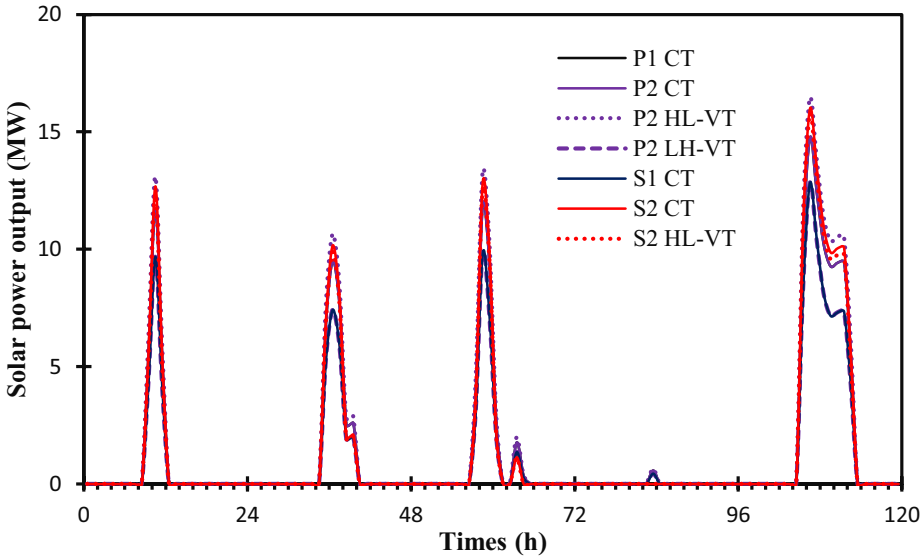

Fig. 9: Hourly solar power output of different configurations controlled with different approaches on five consecutive typical days in winter, using 500 sets of parabolic trough solar collectors to produce HTF. P1 and P2 configurations both controlled in the CT approach is the most common SAPG plants of previous works.

From Fig.8 to 9, it is also shown that the S2 configuration controlled in the CT and HL-VT approach have second and third best hourly solar power ouput. However, in the S2 configuration, the HTF temperature exiting the SP changes with variations in solar radiation. In other configurations, the HTF temperatures exiting the SPs remain constant at 180 ^{o}C, which is lower than in the S2 configuration. This means that the heat loss in the solar collectors of the S2 configuration is higher than the other configurations. Namely, the solar filed efficiency of the S2 configuration is lower than other configurations. Figure 10 and Figure 11

show the HTF temperature exiting the SP on five consecutive days in the summer and winter, respectively. It is shown that the S2 configuration controlled in the VT-HL appraoch have higher HTF temperature exiting SP than the S2 configuration controlled in the CT appraoch. This means that the heat loss in the solar collector of the S2 configuration controlled in the VT-HL appraoch is higher than the S2 configuration controlled in the CT appraoch.

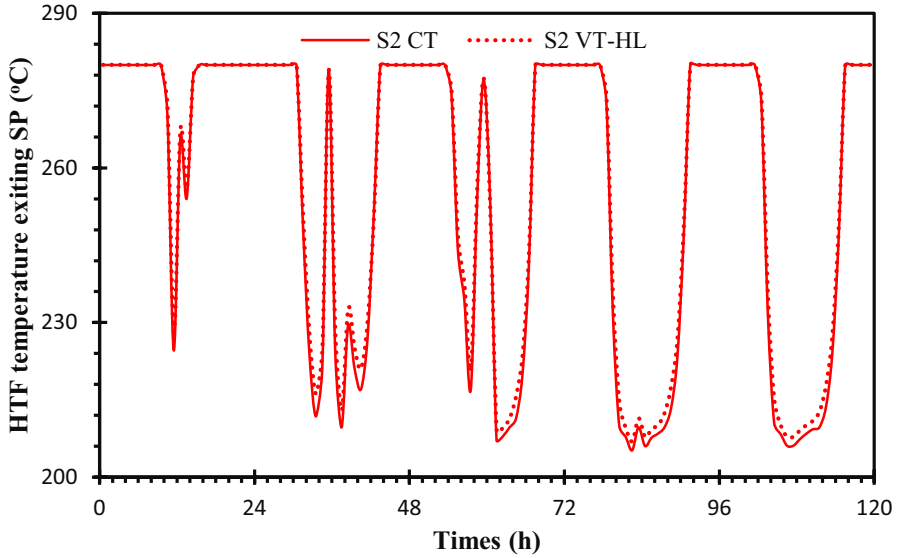

Fig. 10: HTF temperature exiting SP (ºC) for S2 configuration controlled in CT and HL-VT approach on five consecutive typical days in summer, using 500 sets of parabolic trough solar collectors to produce HTF.

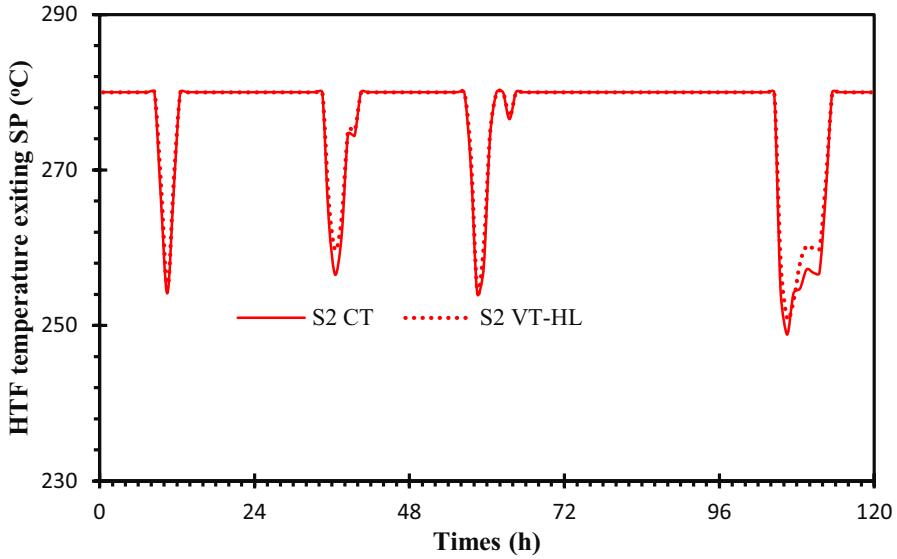

Fig. 11: HTF temperature exiting SP (ºC) for S2 configuration controlled in CT and HL-VT approach on five consecutive typical days in winter, using 500 sets of parabolic trough solar collectors to produce HTF.

Figures 12 to 13 present the daily solar power output per solar collector area (x_{Solar}) for the SAPG plant with different configurations on five consecutive typical days in summer and winter, respectively. It is shown in Figures 12 and 13 that the P2 configuration controlled in the HL-VT approach have the maximum x_{Solar} in both summer and winter days. This is caused by the highest hourly solar power output. From Figures 12 and 13, the results indicate that for the S1 consifugration controlled in the CT appraoch and P1 configuration controlled in the LH-VT approach, the x_{Solar} increases with the incremental solar collector area. The reason is thought to be cuased by the larger solar collector area means more solar thermal energy used for

displacement purpose, which means more high quality (higher pressure extraction steam) extraction steam is dispalced. In contrast, for the other cases, the x_{Solar} decreases with the incremental solar collector area.

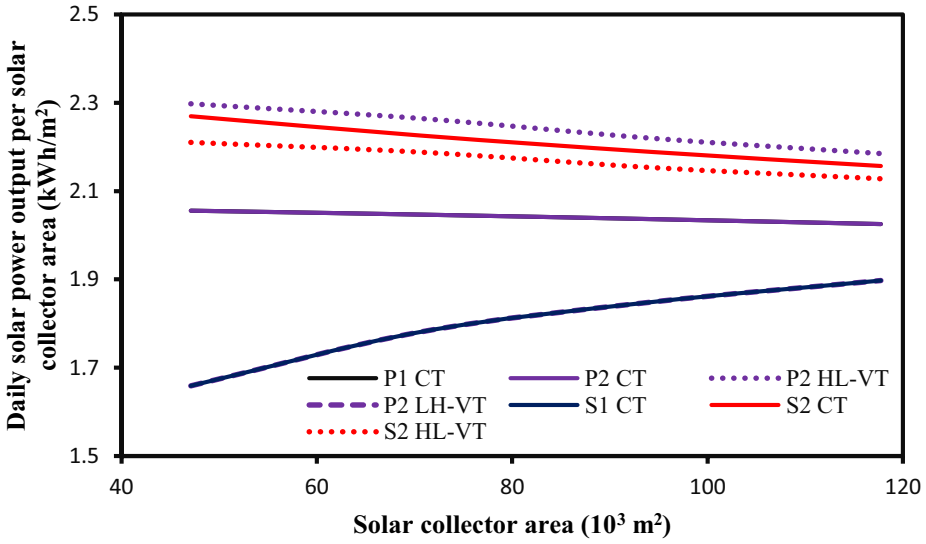

Fig. 12: Daily solar power output per solar collector area (x_{Solar}, kWh/m²) on five consecutive days in summer.

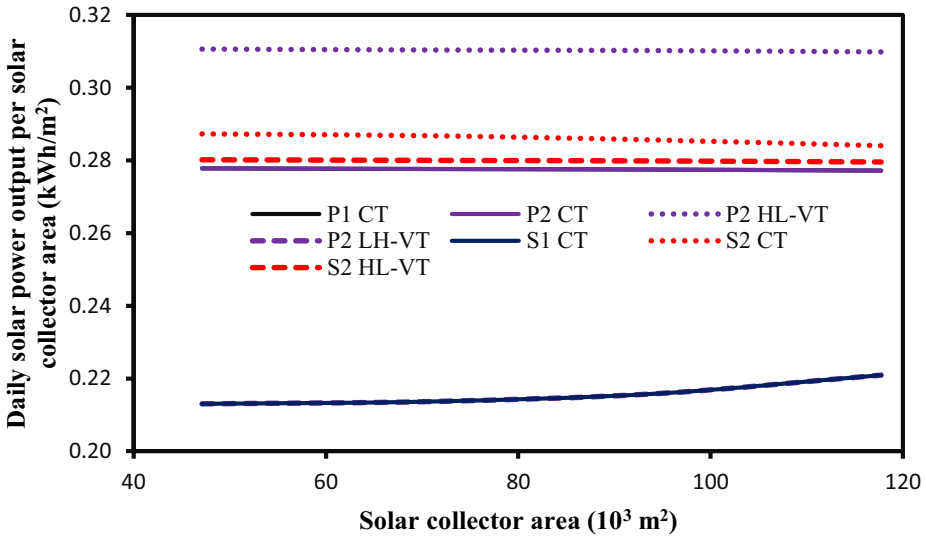

Fig. 13: Daily solar power output per solar collector area (x_{Solar}, kWh/m²) on five consecutive days in summer.

400	7.34	7.34	7.16	8.57	8.57	7.66	7.70
500	7.31	7.31	7.05	8.59	8.59	7.59	7.61

Table 4 presents the ratio of power output on five consecutive days in summer to that in winter ($W_{Solar}\Delta t_{Summer}/W_{Solar}\Delta t_{Winter}$). The higher $W_{Solar}\Delta t_{Summer}/W_{Solar}\Delta t_{Winter}$ means the higher impact of variations in solar radiation on SAPG's performance. It is shown that the P2 configuration controlled in the HL-VT appraoch has the lowest $W_{Solar}\Delta t_{Summer}/W_{Solar}\Delta t_{Winter}$. This means that variatios in solar radiation have the lowest impact on the performacne of P2 configuration controlled in the HL-VT approach. It is also shown that for the P2 configuration controlled in the LH-VT approach and S1 configuration, $W_{Solar}\Delta t_{Summer}/W_{Solar}\Delta t_{Winter}$ increases with the incremental solar collector area. In contrast, for other cases, $W_{Solar}\Delta t_{Summer}/W_{Solar}\Delta t_{Winter}$ decreases with the incremental solar collector area. This means that for the P2 configuration controlled in the LH-VT approach and S1 configuration, the impact of variatios in solar radiation on the SAPG's performance increases with the incremental solar collector area, while for other cases, the impact of variations in solar radiation decreases with the incremental solar collector area.

5. Conclusions

Pseudo-dynamic simulation models of four possible configurations of the SAPG plant, together with three alternative control strategies for the power boosting operation mode have been developed. The dynamic performances of different SAPG plants have been analysed using hourly solar radiation data in 5 consecutive summer and winter days in a location (Adelaide, Australia), respectively. The total solar power output of the SAPG plant and the daily solar power output per unit solar collector area ($\boldsymbol{x_{Solar}}$) were used as criteria to analyze the dynamic performance of SAPG plants with different configurations and control approaches. The results show that:

- the P2 configuration controlled in the HL-VT approach has the highest hourly solar power output, while the P2 configuration controlled in the LH-VT approach and the S1 configuration controlled in the CT approach have the lowest hourly solar power output in both winter and summer;
- For the S2 configuration, the HTF temperature exiting the SP is higher than other configurations. This indicates that the heat loss in the solar collectors of the S2 configuration is higher than the other configurations;
- The P2 configuration controlled in the HL-VT approach has the highest $\boldsymbol{x_{Solar}}$ in both summer and winter days;
- The variations in solar radiation have the lowest impact on the performance of P2 configuration controlled in the HL-VT approach while have the highest impact on the P1 configuration controlled in the LH-VT approach and the S1 configuration controlled in the CT approach;
- The P2 configuration controlled in the HL-VT approach is the best among the seven configurations and control approaches combinations in the selected location (Adelaide, Australia).

Concentrating or non-concentrating solar collectors for Solar Aided Power Generation?

Jiyun Qin, Eric Hu and Shengcao Yuan

School of Mechanical Engineering, the University of Adelaide, Adelaide (Australia)

Abstract

A hypothesis has been put forward that using non-concentrating solar collectors in a Solar Aided Power Generation (SAPG) plant might be a more efficient and economical option than using concentrating solar collectors. Few previous works on this topic have been carried out due to the perception that concentrating collectors produce higher temperature (solar) heat, thus higher solar thermal to power efficiency of the SAPG plant. However, other factors related to concentrating collectors, such as collecting only direct solar radiation, taking up more land area to install them, and higher capital and operation costs, have been overlooked. In this paper, a detailed comparison study between using concentrating or non-concentrating solar collectors in an SAPG plant have been undertaken. The results show that using non-concentrating solar collectors in an SAPG plant is superior in some cases.

Keywords: *Solar Aided Power Generation, Net solar efficiency, Concentrating solar collectors, non-concentrating solar collectors.*

1. Introduction

Due to the high capital costs of stand-alone solar power plants, integrating the solar thermal energy into a conventional fossil fired power plant attracts great interest nowadays. Solar Aided Power Generation (SAPG) is a method of integrating solar thermal energy carried by heat transfer fluid (HTF) into a conventional fossil fired power plant. In an SAPG plant, the HTF could be used to displace the extraction steam by preheating the feedwater to boiler at various temperature (and pressure) levels (Hu et al., 2010). The saved/displaced extraction steam by solar heat can expand further to generate power.

Generally, both concentrating solar collectors and non-concentrating solar collectors can be used in an SAPG plant. Since concentrating solar collectors can produce HTF at higher temperatures (200°C - 450°C), and non-concentrating solar collectors can produce HTF at lower temperatures (50°C - 200°C), concentrating solar collectors and non-concentrating solar collectors can be used to displace the extraction steam at different temperature levels. Yan et al. (2010) and Yang et al. (2011) found that displacing the extraction steam at higher temperature levels can produce more power output. Therefore, the previous works of Hou et al. (2013, 2015), Wu et al. (2015) and Peng (2013, 2014a, 2014b) evaluated the SAPG plant using concentrating solar collectors to displace the extraction steam at high temperature levels. However, the advantages of non-concentrating solar collectors could not be ignored. Concentrating solar collectors can only collect direct solar radiation (I_N). Nevertheless, non-concentrating solar collectors can absorb both direct solar radiation and diffuse solar radiation (I_D). Therefore, on a given piece of land, non-concentrating solar collectors may collect more solar heat than concentrating solar collectors. Zhou et al. (2015) compared using concentrating solar collectors and non-concentrating solar collectors in an SAPG plant by using the concept of Net Solar Efficiency. The net solar efficiency of an SAPG plant is defined as the power output from solar thermal energy in the SAPG plant divided by the total solar energy radiation falling on the land of the solar field. It was found that using non-

doi:10.18086/swc.2015.04.18 Available at http://proceedings.ises.org

concentrating solar collectors has advantages above using concentrating solar collectors from the net solar thermal point view. However, previous work of Zhou et al. (2015) has not considered the differences of capital and installation costs between concentrating and non-concentrating solar collectors. An economic comparison of using concentrating and non-concentrating solar collectors in an SAPG plant is needed.

2. Methodology

On a given piece of land, solar collectors with different layouts lead to different thermal outputs of the solar field. In this study, a solar field model has been developed that can calculate the solar annual useful heat output (from concentrating and non-concentrating fields) at different temperature levels under local weather conditions (for a given location). In the model, the annual output is the sum of annual hourly yields of the field and the layout of the solar fields including the shading factor between rows of the collectors has been considered. The outputs of the solar field model are fed into an SAPG plant simulation model developed in-house to calculate the solar power generation. In the study, a parabolic trough (PT) solar collector is used as the representative of concentrating solar collectors and the evacuated tube (ET) solar collector is used as the representative of non-concentrating solar collectors.

2.1. Parabolic trough solar collectors

The useful thermal energy produced by the PT solar collectors ($\dot{Q}_{useful,PT}$, kW) is calculated as:

$$\dot{Q}_{useful,PT} = \dot{Q}_{absorb,PT} - \dot{Q}_{loss,PT} \quad \text{(eq. 1)}$$

where $\dot{Q}_{absorb,PT}$ (W) is the solar energy absorbed by PT solar collectors and $\dot{Q}_{loss,PT}$ (W) is the heat loss of the solar field.

In Eq.1, the $\dot{Q}_{absorb,PT}$ is given as:

$$\dot{Q}_{absorb,PT} = \eta_{op,PT} I_N \cos\theta_{i,PT} K_{\theta,PT} \eta_{Row\ shading,PT} \eta_{end,loss} F_e A_{PT} \quad \text{(eq. 2)}$$

where $\eta_{op,PT}$ is the optical efficiency of the solar collector, I_N (W/m^2) is the Direct Normal Irradiance (DNI), $\theta_{i,PT}$ is the local solar radiation incidence angle, $K_{\theta,PT}$ is the incidence angle modifier of the solar collector, $\eta_{Row\ shading,PT}$ is the row shading of the solar collector, and $\eta_{end,loss}$ is the aperture area of the solar field. In Eq.2, each factor is calculated from previous work of Zhou et al. (2015).

The heat loss of the solar field in Eq. 1 can be divided into two parts. One is the heat loss of heat pipes $\dot{Q}_{loss,pipe,PT}$ (W) and the other is the heat loss of the PT solar collectors $\dot{Q}_{loss,collector,PT}$ (W). The heat loss is dependent on the solar collectors. In this study, LS-2 PT solar collectors are used as a case study. The $\dot{Q}_{loss,collector,PT}$ and $\dot{Q}_{loss,pipe,PT}$ of an LS-2 solar collector are given as:

$$\dot{Q}_{loss,collector,PT} = b_1 K_{\theta,PT} \dot{Q}_{absorb,PT} + (b_2 + b_3 \Delta T)\Delta T A_{PT}, \text{ (Dudley et al., 1994)} \quad \text{(eq. 3)}$$

where b_1 is 0.00007276, b_2 is 0.00496 (W/m^{2}K), b_3 is 0.00691 (W/m^{2}K^2) and ΔT is the temperature difference between the mean loop temperature of the solar collector and the ambient temperature.

$$\dot{Q}_{loss,pipe,PT} = (0.01693\Delta T - 0.0001683\Delta T^2 + 6.78 \times 10^{-7}\Delta T^3) A_{PT}. \text{ (Patnode, 2006)} \quad \text{(eq. 4)}$$

2.2. Evacuated tube solar collectors

The useful thermal energy produced by ET solar collectors is the product of the thermal efficiency of the ET solar collector and the solar radiation absorbed by the ET solar collector, which is given as:

$$\dot{Q}_{useful,ET} = \eta_{ET}\dot{Q}_{absorb,ET}, \quad \text{(eq. 5)}$$

where $\dot{Q}_{absorb,ET}$ (W) is the solar energy collected by the ET collectors and η_{ET} is the thermal efficiency of the ET solar collector.

Based on the experimental data, Budihardjo and Morrison (2009) found that the thermal efficiency of the ET solar collectors can be given as:

$$\eta_{ET} = 0.536 - 0.824\frac{\Delta T}{I_G} - 0.0069\frac{\Delta T^2}{I_G}, \quad \text{(eq. 6)}$$

where ΔT is the temperature difference between mean loop temperature and ambient temperature, and I_G (W/m2) is the global solar radiation.

In Eq. 5, the $\dot{Q}_{absorb,ET}$ is given as (Du et al., 2013):

$$\dot{Q}_{absorb,ET} = I_G\eta_{Row\ shading,ET}A_{ET}, \quad \text{(eq. 7)}$$

where $\eta_{Row\ shading,ET}$ is the row shading factor of the parallel row and A_{ET} is the area of the ET solar collectors.

For the ET solar collectors, global solar radiation falling on the collectors can be given as (Duffie et al., 2006),

$$I_G = I_D\frac{(1+\cos\beta)}{2} + I_N\cos\theta_{i,ET}, \quad \text{(eq. 8)}$$

where β is the tilt angle (the angle between the collector plane surface and the horizontal), $\theta_{i,ET}$ is the local solar radiation incidence angle, and I_D (W/m^2) and I_N (W/m^2) are solar diffuse radiation and direct radiation, respectively.

In Eq.8, the incidence angle of the ET solar collectors is given as (Duffie et al., 2006):

$$\cos\theta_{i,ET} = (\cos L\cos\beta + \sin L\sin\beta\cos A_{ZS})\cos\delta\cos\omega + \cos\delta\sin\omega\sin\beta\sin A_{ZS} + \sin\delta\,(\sin L\cos\beta - \cos L\sin\beta\cos A_{ZS}), \quad \text{(eq. 9)}$$

where Azs is Azimuth angle, L is the Latitude, ω is hour angle and σ is the solar declination angle.

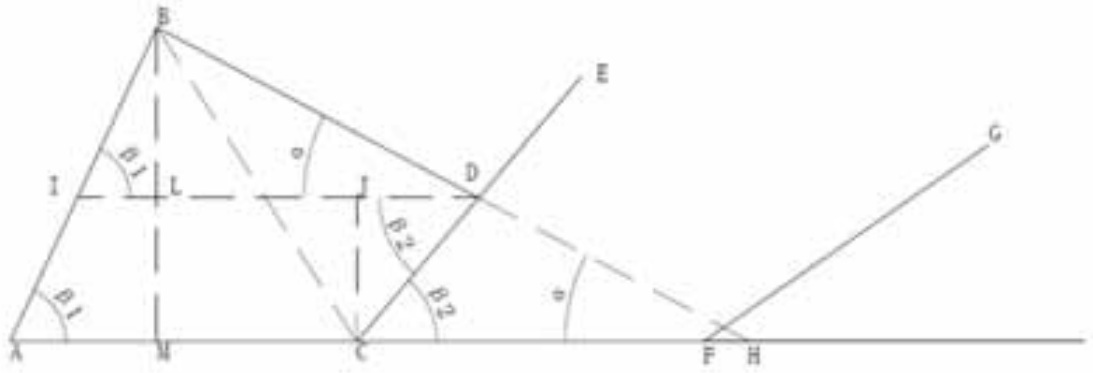

Fig. 1: Two dimensional drawing of the three rows' ET solar collectors.

In Eq.7, the row shading factor should be considered if ET solar collectors are installed in rows. Figure 1 presents a row shading analysis for three rows of ET collectors. For the first row of ET solar collectors, there

is no shading on the collectors. As a result, the shading factor for the first row of ET collectors can be ignored. For the second row of ET solar collectors, the shading factor can be given as:

$$\eta_{Row\ shading,ET,2} = 1 - \frac{CD}{CE}. \quad \text{(eq. 10)}$$

The CD can be given as:

$$CD = \frac{CJ}{\sin\beta_2} = \frac{ML}{\sin\beta_2} = \frac{BM-BL}{\sin\beta_2}. \quad \text{(eq. 11)}$$

In Eq.11,

$$BM = l\sin\beta_1. \quad \text{(eq. 12)}$$

$$BL = BD\sin\alpha. \quad \text{(eq. 13)}$$

where the length of the collector is l (m) and the altitude angle is α.

By using the trigonometric functions, Eq. 10 can be given as:

$$\eta_{Row\ shading,ET,2} = 1 - \frac{l\sin\beta_1 - \frac{\sqrt{l^2+d^2-2ld\cos\beta_1}.\sin\left(180^o - \cos^{-1}\frac{(\sqrt{l^2+d^2-2ld\cos\beta_1})^2+d^2-l^2}{2d\sqrt{l^2+d^2-2ld\cos\beta_1}} - \beta_2\right)}{\sin(\beta_2+\alpha)}\sin\alpha}{\frac{\sin\beta_2}{l}} \quad \text{(eq. 14)}$$

where the distance between two rows is d (m)

In the second row, for the N[th] row of ET solar collectors the shading factor can be given as:

$$\eta_{Row\ shading,ET,N} = 1 - \frac{l\sin\beta_{N-1} - \frac{\sqrt{l^2+d^2-2ld\cos\beta_{N-1}}.\sin\left(180^o - \cos^{-1}\frac{(\sqrt{l^2+d^2-2ld\cos\beta_{N-1}})^2+d^2-l^2}{2d\sqrt{l^2+d^2-2ld\cos\beta_{N-1}}} - \beta_N\right)}{\sin(\beta_N+\alpha)}\sin\alpha}{\frac{\sin\beta_N}{l}}$$

. (eq. 15)

As shown in Eq.14 and 15, the different tilt angle (β) of each row of ET solar collectors have different shading factors. By adjusting the tilt angel (β) of each row in Eq. 15, a minimum shading factor can be calculated. Then, by using the minimum shading factor of each row, the $\dot{Q}_{absorb,ET}$ is calculated by using the Eq. 7.

2.2. Net solar efficiency

On a given piece of land, solar collectors with different layouts lead to different thermal outputs of the solar field. Integration of different amounts of solar thermal energy with different temperature levels into an SAPG plant can also produce different power outputs. The net solar efficiency of an SAPG plant is defined as the power output produced by the solar energy divided by the total solar radiation falling on the given piece of land, which is given as (Zhou et al., 2015):

$$\eta_{Net} = \frac{W_{Solar}}{\dot{Q}_{Total,land}}. \quad \text{(eq. 16)}$$

where W_{Solar} (W) is the power output from the solar thermal energy in the SAPG plant and $\dot{Q}_{Total,land}$ (W) is the total solar radiation falling on the given piece of land.

3. Case study

In the present paper, both the ET and PT solar collectors were installed at three cities Quito (Ecuador, 0°N, 78°W), Reykjavik (Iceland, 64°N, 22°W) and Adelaide (Australia, 34°S, 138°E), respectively. On the given piece of land with same area, the solar thermal energy produced by the ET solar collectors are used to displace extraction steam with lower temperature levels (extraction steam to low pressure feedwater heater) and solar thermal energy produced by the PT solar collectors are used to displace extraction steam with higher temperature levels (extraction steam to high pressure feedwater heater), as shown in Fig.2 and Fig. 3.

In this study, it is assumed that the land area of 1,000 m^2 (length of 40 m, width of 25 m) is used to install the ET and PT solar collectors, respectively. For the ET solar collectors, the distance between each row of solar collectors is 8 m. For the PT solar collectors, the distance between each row of solar collectors is 10 m. Therefore, there are 8 rows ET solar collectors and 3 rows PT solar collectors installed in the land area. It is assumed that the size of each set of the ET solar collector is 10m×25m and the size of each set of the PT solar collector is 5m×40m (the width of the LS-2 PT solar collector is 5m). Therefore, on the given 1,000m^2 land, the area of the ET solar collector is 1,250 m^2 for the ET solar collector and 600m^2 for the PT solar collector. The parameters of ET and PT solar collectors on the given land are shown in Table 1.

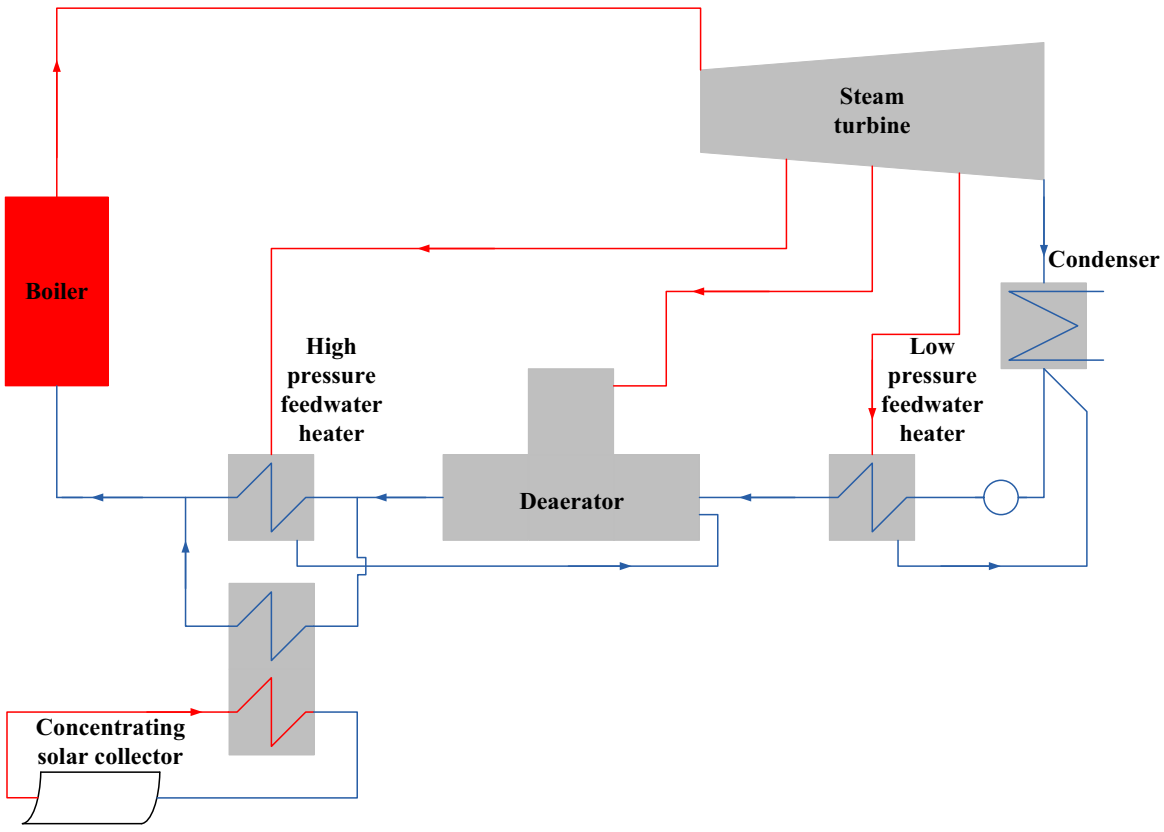

Fig. 2: Case studies of the concentrating solar collector (i.e. PT solar collector) integrated into an SAPG plant to displace the extraction steam to high pressure feedwater heater.

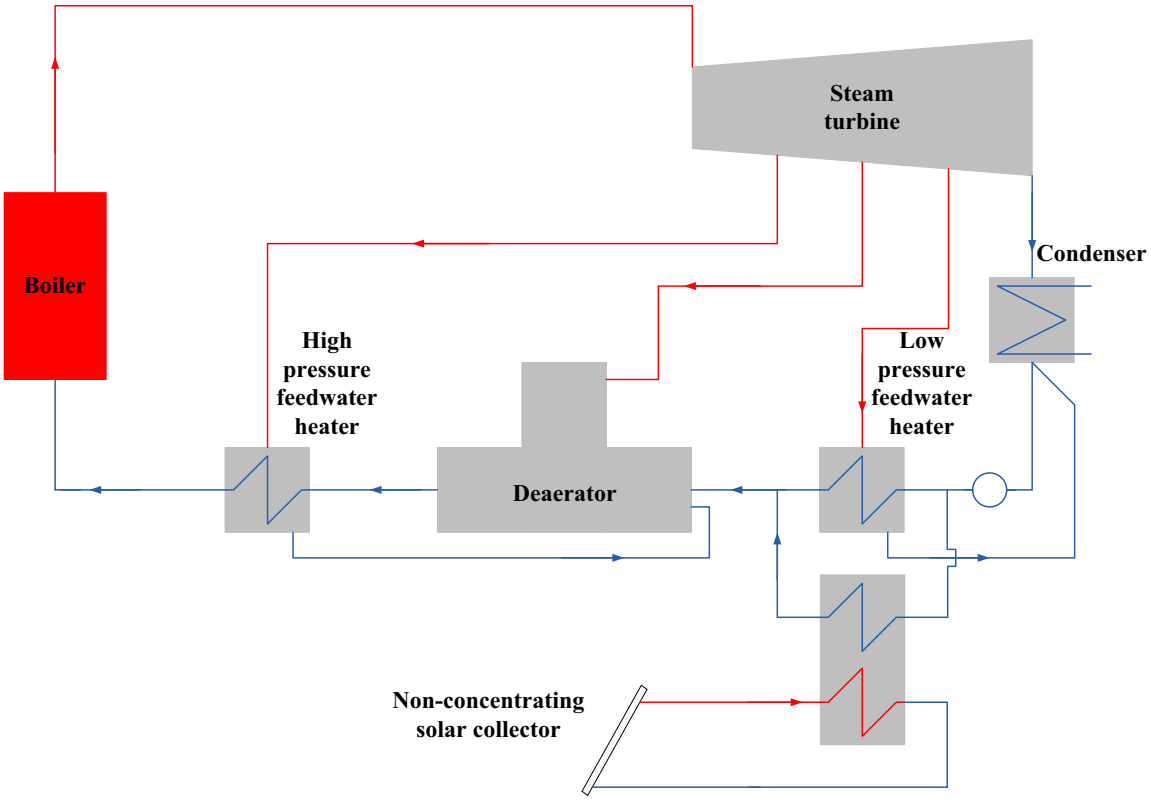

Fig. 2: Case studies of the non-concentrating solar collector (i.e. ET solar collector) integrated into an SAPG plant to displace the extraction steam to low pressure feedwater heater.

Tab. 1: Parameters of ET and PT solar collectors

Solar collector	Model	Total area (m^2)	Cost (AU$/$m^2$)
ET	VHP 30	1,250	255
PT	LS-2	600	651

It is also assumed that the solar thermal energy is integrated into 300 MW and 600 MW subcritical power plants based on the simulation results of Yan et al. (2011). Yan et al. (2011) pointed that the solar thermal to power efficiencies of displacement of high pressure extraction steam (Fig. 1) and low pressure extaction steam (Fig. 2) are 36% and 23% for a 300MW power plant and 41% and 24% for a 600 MW power plant. After the calculation of the useful thermal energy produced by the solar collectors, the solar power output can be calcualted by using the solar thermal to power efficiencies of the SAPG plant.

4. Results

Tab. 2: Annual useful thermal energy produced by evacuated tube (ET) and parabolic trough (PT) solar collectors

	Quito (Ecuador, 0°N, 78°W)	Adelaide (Australia, 34°S, 138°E)	Reykjavik (Iceland, 64°N, 22°W)
$Q_{Total,land}$ (MJ)	9,976,994	8,257,336	4,787,782
$Q_{useful,ET}$ (MJ)	4,963,798	4,012,944	2,530,093
$Q_{useful,PT}$ (MJ)	2,678,270	1,924,509	671,999

Table 2 presents the annual useful thermal energy produced by ET and PT solar collectors. $Q_{useful,ET}$ and

$Q_{useful,PT}$ are then can be integrated into the power plant for power generation purpose. The solar radiation is calculated based on the Bird Clean Sky Model (Bird et al., 1981).It was found that Quito has the highest annual solar radiation in three locations, and Reykjavik has the lowest annual solar radiation in three locations. It is also shown that annual useful thermal energy produced by the ET solar collectors is higher than that produced by the PT solar collectors in three locations. The reason is thought caused by the higher total solar collector area (Table 1) in the given land.

Tab. 3: Annual solar radiation in different locations calculated by the Bird Clean Sky Model

	Quito (Ecuador, 0°N, 78°W)	Adelaide (Australia, 34°S, 138°E)	Reykjavik (Iceland, 64°N, 22°W)
Annual DNI (kWh/m^2)	3451.4	3235.8	2520.2
Annual direct radiation (kWh/m^2)	2369.1	1921.7	1055.2
Annual diffuse radiation (kWh/m^2)	402.6	372.0	277.5

The results of Table 2 also show that for the ET solar collectors, the annual useful thermal energy produced in Quito is 1.24 times higher than in Adelaide and 1.96 times higher than in Reykjavik. However, for the PT solar collectors, the annual useful thermal energy produced in Quito is 1.39 times higher than in Adelaide and 3.98 times higher than in Reykjavik, which is higher than the ET solar collectors. The reason for this is thought to be that ET solar collectors can absorb both direct solar radiation and diffuse solar radiation, while PT solar collectors can only absorb direct solar radiation. The proportion of diffuse solar radiation in global solar radiation in Reykjavik and Adelaide are higher than Quito, which is shown in Table 3. Another reason is that the working area of ET solar collectors is higher than PT solar collectors on a given piece of land.

Tab. 4: Net solar efficiencies of evacuated tube (ET) and parabolic trough (PT) solar collectors

		Quito (Ecuador, 0°N, 78°W)	Adelaide (Australia, 34°S, 138°E)	Reykjavik (Iceland, 64°N, 22°W)
300MW	$\eta_{Net,ET}$	11.4%	11.2%	12.2%
	$\eta_{Net,PT}$	9.7%	8.4%	5.1%
600MW	$\eta_{Net,ET}$	11.9%	11.7%	12.7%
	$\eta_{Net,PT}$	11.0%	9.6%	5.8%

Table 4 shows the net solar efficiencies of ET and PT solar collectors in three locations. It is shown that the ET solar collector has higher net solar efficiencies than the PT solar collector. The reason for this is thought to be that on a given piece of land, the number of ET solar collectors can be arranged more than PT solar collectors. This means that the collector area of the ET solar collectors is higher than that of the PT solar collectors. It is also shown that the net solar efficiency of ET solar collector is highest in Reykjavik and the net solar efficiency of PT solar collector is highest in Quito. The reason is thought to be that Reykjavik is furthest from the equator in three locations and have highest proportion of diffuse radiation and Quito is closest to the equator in three locations and have highest proportion of direct radiation.

Tables 5 and 6 present the annual electricity production and cost of electricity (COE) of ET and PT solar collectors used in SAPG plants with 300MW and 600MW subcritical power plants, respectively. In present paper, the calculation of the COE only includes the cost of the solar collectors. The capital cost of the solar collectors is calculated by using the collector's cost in Table 1. From Tables 5 and 6, for both types of solar collectors, the COE increases with increasing the latitude of installed locations. When ET and PT solar collectors are installed on the same land area, the COE of ET solar collectors is lower than the COE of PT solar collectors, especially in places with higher latitude. Moreover, the advantage of ET solar collectors in cost is more obvious when the latitude is increasing. In other words, if the installed location of the solar collectors is further from the equator, the COE of ET solar collectors is cheaper than the COE of PT solar collectors. The reason for this is thought to be that when the latitude is increasing, the proportion of direct solar radiation is decreasing and the proportion of diffuse solar radiation is increasing.

Tab. 5: Annual electricity production ($Q_{electricity}$) and cost of electricity (COE) of evacuated tube (ET) and parabolic trough (PT) solar collectors used in an SAPG plant with a 300 MW subcritical power plant

	Quito (Ecuador, 0°N, 78°W)	Adelaide (Australia, 34°S, 138°E)	Reykjavik (Iceland, 64°N, 22°W)
$Q_{electricity,ET}$ (kWh)	317,312	256,383	161,645
COE_{ET} (AUD/kWh)	0.05	0.08	0.10
$Q_{electricity,PT}$ (kWh)	267,827	192,450	67,200
COE_{PT} (AUD/kWh)	0.09	0.25	0.34

Tab. 6: Annual electricity production ($Q_{electricity}$) and cost of electricity (COE) of evacuated tube (ET) and parabolic trough (PT) solar collectors used in an SAPG plant with a 600 MW subcritical power plant

	Quito (Ecuador, 0°N, 78°W)	Adelaide (Australia, 34°S, 138°E)	Reykjavik (Iceland, 64°N, 22°W)
$Q_{electricity,ET}$ (kWh)	330,920	267,530	168,673
COE_{ET} (AUD/kWh)	0.05	0.08	0.10
$Q_{electricity,PT}$ (kWh)	305,025	219,180	76,533
COE_{PT} (AUD/kWh)	0.08	0.22	0.30

5. Conclusions

The net solar efficiencies and cost-performance of using concentrating (e.g. Parabolic trough) and non-concentrating (e.g. Evacuated tube) solar collectors into an SAPG plant have been compared by using the solar radiation data in three cities Quito (Ecuador, 0°N, 78°W), Reykjavik (Iceland, 64°N, 22°W) and Adelaide (Australia, 34°S, 138°E), respectively. It is found that,

- Although the thermal efficiency of parabolic trough (PT) solar collectors is higher than the thermal efficiency of evacuated tube (ET) solar collectors, the net solar efficiency of ET solar collectors is higher than the net solar efficiency of PT solar collectors.
- The net solar efficiency of ET solar collectors in Reykjavik is hightest, and the net solar efficiency of PT solar collectors in Quito is hightest.
- The cost of electricity (COE) of using ET solar collectors is lower than the COE of using PT solar collectors.

In conclusion, on a given land with the same area, non-concentrating solar collectors (e.g. ET solar collectors) are superior to concentrating solar collectors (e.g. PT solar collectors) in both technical and economical terms.

Abstract

In a solar updraft tower plant (SUTP) system, heated air by solar heat under the transparent collector rises up through the updraft tower. When wind passes by, the turbine generator under the tower produces electricity. New mathematical analysis model was developed with considerations about realistic physical pressure drops through the whole SUTP system. The new analysis model was validated by the experimental data of prototype plant in Manzanares, Spain. The new model was well corresponded with the experimental data.

Keywords: *Solar chimney, Manzanares prototype, SUTP*

1. Introduction

The use of fossil fuel caused significant climate changes like global warming. This situation makes the melt of glacier, sea water level rise. To solve these problems, renewable energy sources are emphasized these days like wind energy and solar energy. The solar updraft tower plant (SUTP) is considered as a promising alternatives among various renewable energy sources. Solar updraft tower system is an electricity generating system using updraft air flow generated by solar energy. The SUTP is composed of three components such as solar collector, updraft tower and power generators. The schematic diagram of SUTP is shown in Fig. 1. In the SUTP system, heated air under the transparent collector induces updraft air flow to the tower due to density difference between inside and outside of the chimney. Air turbine is located at bottom of solar tower to generate electricity using this highly accelerated air. In this system, air under transparent collector is heated up and density difference of air induces updraft air flow in tower located at center of collector. When heated air flow by solar collector rise up through the solar chimney, the turbine generator produce the electricity in the bottom of chimney. The SUTP would be effective in the area of the large amount of solar energy and wide geographical areas for sufficient air flow like the desert regions. Compared to conventional solar power generation, this system has several advantages, such as very simple structure and low maintenance cost.

The first solar chimney design was developed by J. Schlaich, and a pilot plant prototype was built in Manzanares, Spain, in 1981. The 50-kW prototype operated and produced electricity for 8 years, showing the feasibility of a solar chimney power plant. An experimental evaluation of the protytype and

doi:10.18086/swc.2015.04.19 Available at http://proceedings.ises.org

the preliminary test results of the prototype plant were reported by Haff et al. [1, 2]. These authors presented the basic principles of solar chimney power plants, such as the construction cost and large-scale plants. Bernardes et al. [3] developed an analytical and numerical model for a solar chimney power plant, and heat transfer under the collector was investigated using thermal ananlysis. A water storage system was established under the collector. Additionally, simulation calculations were compared with experimental results from the pilot plant in Manzanares. Pretorius et al. [4, 5] evaluated a numerical model for the performance of a large-scale solar chimney power plant. A computer simulation program was used to solve the governing equation and heat transfer equation. A comprehensive analysis of the solar chimney was conducted under various situations. A preliminary study examining the influence of several factors was conducted using a mathematical model. Two comprehensive studies from the Pretorious and Bernardes papers on heat transfer in the collector were summarized by Bernardes et al. [6]. Their paper compared the comprehensive governing equation for the collector and chimney. Additionally, the assumptions pertaining to the governing equations were compared with respect to continuity, momentum and the energy equation. The convective heat transfer schemes in the collector were compared under several situations. Zhou et al. [7] conducted a comprehensive review of solar chimney power plants, providing information on the description, physical process, experimental and theoretical study status, among others. Koonsrisuk et al. [8] developed a mathematical model of a solar chimney power plant and validated the result with an actual physical plant. They predicted the performance of a large-scale commercial solar chimney and found the optimum design for high power output. Guo et al. [9] predicted the annual performance of an SCPP in Sinkiang, China. The effect of the collector and chimney radii on the power output was estimated, and the potential annual power requirement of SCPPs in the Hami region was presented.

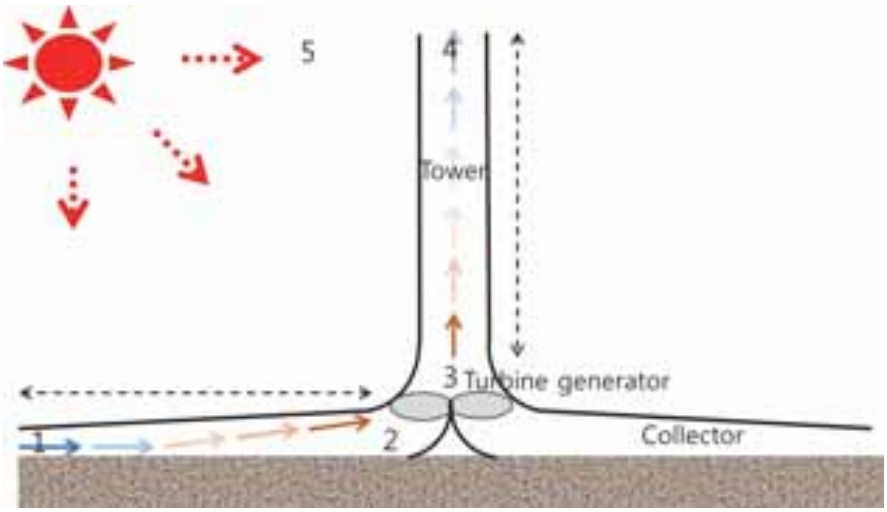

Fig. 1: Schematic diagram of SUTP

In this study, new mathematical analysis model was developed with considerations about realistic physical pressure drops through the whole SUTP system. The new analysis model was validated by the experimental data of prototype plant in Manzanares, Spain. Temperature rise of air through collector was calculated considering heat transfer of collector system, including absorption, reflection, and radiation. Pressure drop and mass flow rate was calculated through iteration process using MATLAB. The final output power can be predicted from pressure, density, temperate and pressure drop at each

point. All the essential parameters, such as temperature, pressure, density, and output power, were compared with the results of Manzanares pilot plant and were found to be in a good agreement.

2. Mathematical model development

2.1 Assumption

The new model is based on several assumptions: ideal gas law, steady state, radially one-dimensional flow under collector, the adiabatic tower wall. From these assumptions, the thermal analysis in the collector was conducted. The solar irradiation was the only heat source. The absorbed heat into the collector roof and the ground was assumed to transfer the heat into the air flow by convection heat transfer. The radiative heat emissions from the collector roof and the ground were also considered. The solar tower scale was selected to dimension of the pilot plant in Manzanares, Spain to validate the measured data with our developed mathematical model. But the roof height of collector was inclined to the tower center. Thus, inlet collector height is 1.2 m and height is increased linearly, so outlet collector height is 2.5 m.

Tab. 1: Dimensions of solar updraft tower plant

Tower height	194.6 m
Tower radius	5.08 m
Collector radius	122 m
Collector inlet height	1.2 m
Collector outlet height	2.5 m

In calculation of turbine pressure drop, the ratio of the pressure drop across the turbine to the total driving pressure was assumed to 2/3. Many researcher have assumed the optimum values of pressure ratio is 2/3. In this study, the pressure ratio across the turbine was optimized using our developed mathematical model.

2.2 Thermal analysis in the collector

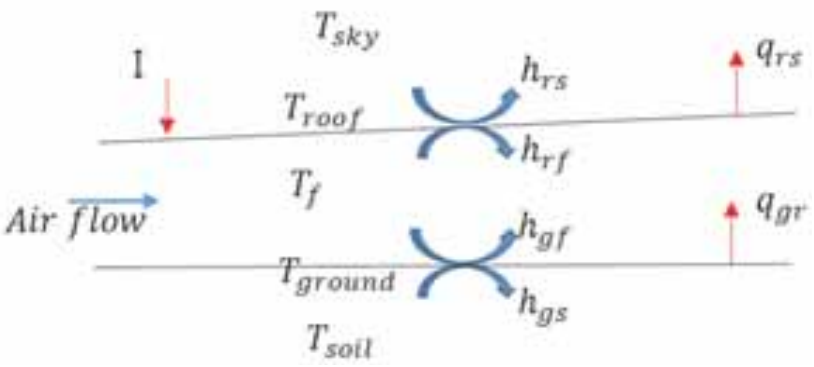

Fig. 2: Thermal analysis in the collector

The schematic diagram of heat transfer circuit in the collector is shown in Fig. 2. $\mathrm{h}_{rs}, \mathrm{h}_{rf}, \mathrm{h}_{gf}$ and h_{gs} is convective heat transfer coefficient and $\mathrm{q}_{rs}, \mathrm{q}_{gr}$ is radiative heat flux from roof to sky and from ground to roof. The solar irradiation heated the collector roof and ground, then the heated roof and ground transfer the heat the air flow in the collector. The heat transfer equation is following:

Roof: $\mathrm{I}\alpha_r + q_{gr} = h_{rs}(T_r - T_s) + h_{rf}(T_r - T_f) + q_{rs}$ (eq. 1)

Air: $h_{rf}(T_r - T_f) + h_{gf}(T_g - T_f) = \frac{\dot{m}C_p}{2\pi r}\frac{dT_f}{dr}$ (eq. 2)

Ground: $I\tau_r\alpha_g = h_{gf}(T_g - T_f) + h_{gs}(T_g - T_{soil}) + q_{gr}$ (eq. 3)

Left side of equation is incoming heat from the surrounding and right side of equation is output to surrounding. Equation (1),(2),(3) is thermal heat transfer equilibrium equation in roof, air and ground. I is the total solar irradiation on collector, τ_r is transmittance of roof and α_r and α_g are the absorption coefficient of the roof and ground. Temperature of sky is calculated by the ambient temperature. The temperature of soil was assumed constant at all area. The equation of radiative heat flux and heat transfer coefficient is following:

$q_{gr} = \frac{1}{\frac{1}{\varepsilon_g}+\frac{1}{\varepsilon_r}-1}\sigma(T_g^4 - T_r^4)$ (eq. 4)

$q_{rs} = \varepsilon_r\sigma(T_r^4 - T_{sky}^4)$ (eq. 5)

$h_{rs} = 3.87 + 0.0022\left(\frac{v_w\rho c_p}{\mathrm{Pr}^{\frac{2}{3}}}\right),\ (v_w: ambient\ air\ velocity)$ (eq. 6)

$h_{rf} = h_{gf} = 3.87 + 0.0022\left(\frac{v\rho c_p}{\mathrm{Pr}^{\frac{2}{3}}}\right),\ (v: collector\ air\ velocity)$ (eq. 7)

$h_{gs} = 2\sqrt{\frac{k\rho c_p}{\pi t}}$ (eq. 8)

When the collector roof temperature exceeds the ambient temperature and collector inside situation, equation (6) and (7) can be used. Equation (8) is ground heat transfer coefficient and t is second of time.

2.3 Pressure drop

The driving force for air flow in the SUTP system was designated by considering the density difference between inlet and outlet of the tower. It is described as (eq. 9). The pressure drops due to friction losses through the overall SUTP system would disturb the flow. Along the flow path of the SUTP system, friction losses and form losses on the tower were considered. The ratio of turbine pressure drop to total driving force was assumed to be 0.66. It is an optimized value for high power performance of turbine. Mass flow rate of the system was calculated by computing the iterative in-house MATLAB code.

Driving force=$\Delta P_{tot}=\int_0^{H_c}(\rho_{out}-\rho_{in})gdz$ (eq.9)

$\Delta P_{tur}=\Delta P_{tot}-\Delta P_{drop}$ (eq.10)

$\Delta P_{drop}=\Delta P_{tur.in}+\Delta P_{f,chim}+\Delta P_{k,out}$(eq.11)

$\Delta P_{tur.in}=K*\frac{\rho}{2}*V_2^2$: Turbine inlet form pressure drop

$\Delta P_{f,chim}=f*\frac{H}{D}*\frac{\rho}{2}*V^2$: Chimney frictional pressure drop

$\Delta P_{k,4}=K_{out}*\frac{\rho_4}{2}*V_4^2$: Chimney outlet form pressure drop

The pressure drop of turbine makes the wheel rotate, generating the electricity. It is the difference between the driving force and pressure drop over chimney as (eq.10). The pressure drop of system is the sum of the pressure drop over a form loss at turbine inlet, friction loss at chimney wall and chimney outlet form loss as (eq. 11). The ultimate goal of the draught equation is to determine the pressure drop across the turbine. Using this pressure drop, the power generated by the turbine may be calculated.

2.4 Power output

The flow of air through the tower of the solar tower power plant drives a turbine at the base of the tower. The turbine drives a generator which generates electricity. The power output of the system was calculated by the (eq. 12). η_{tg} is turbine efficiency and V_{avg} is volumetric flow rate of air. For the maximum of power on system, the pressure ratio across the turbine play an important role in calculating the performance. Many researcher have assumed the optimum values of pressure ratio is 2/3. In this study, the pressure ratio across the turbine was optimized using our developed mathematical model.

$P_{out}=\eta_{tg}\Delta P_{tur}V_{avg}=\eta_{tg}\Delta P_{tur}v_{tur}A_c$ (eq.12)

2.5 Calculation algorithm

The overall power performance of solar updraft tower plant was calculated following an algorithm using MATLAB. The procedure of calculation is following figure 3. The pressure, temperature and density in region of 2, 3 and 4 were obtained using the thermal analysis and several equation. Then, the mass flow rate of system was assumed to some values. The air velocity of each region can be calculated using mass conservation equation. Air flow pressure drop of system can be calculated at several regions. The form pressure drop at chimney inlet, friction pressure loss at chimney wall and outlet form pressure loss at chimney outlet were obtained, then the velocity can be calculated using the pressure drop conservation equation. Mass flow rate was recalculated from obtained velocity. Then, the calculation cycle was recurred until the small difference between the previous value and current value. After the iteration process, the power output of system can be calculated.

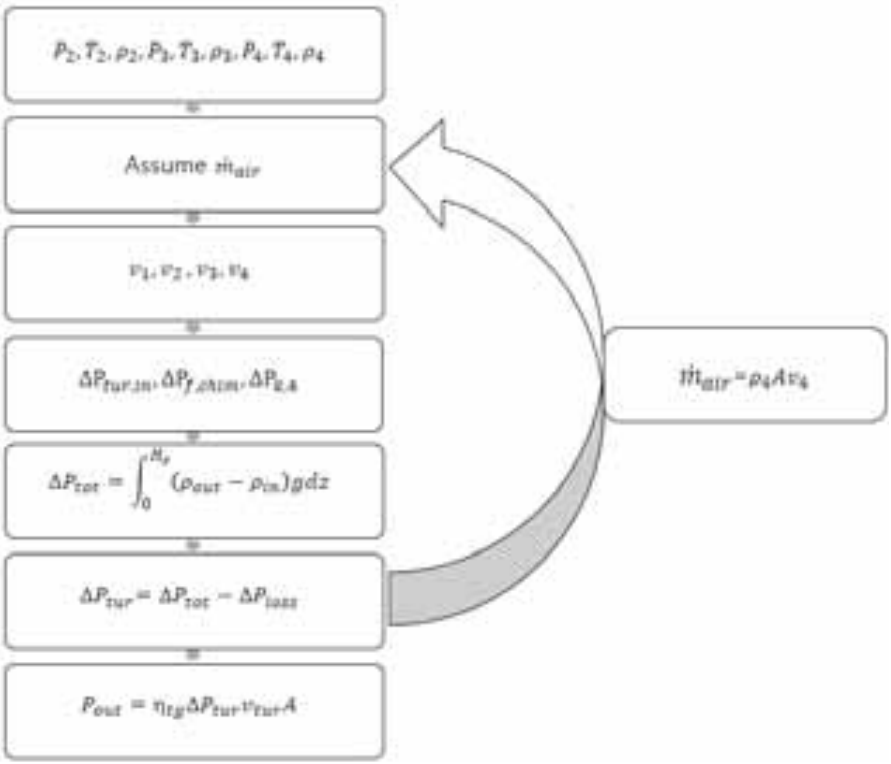

Fig. 3: Calculation algorithm of SUTP

3. Results and Discussion

3.1 Validation of developed model with manzanares experimental data

To validate the new mathematical model, information of the ambient temperature and solar irradiation data on 2nd of September in 1982 from the Haff's paper were utilized for the initial condition. The calculated result of the power output, pressure drop, velocity and temperature change in the collector were compared with the real data. In fig. 4, solar irradiation at Manzanares region was measured and the profile was obtained at all day long. Ambient temperature at Manzanares region was also figured in fig. 5.

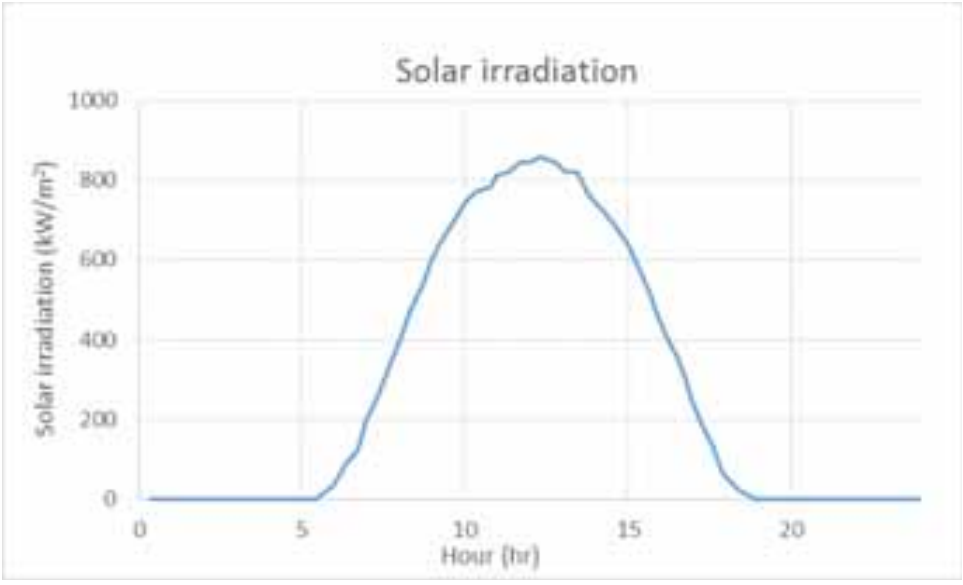

Fig. 4: Measured solar irradiation at Manzanares on 2 September 1982

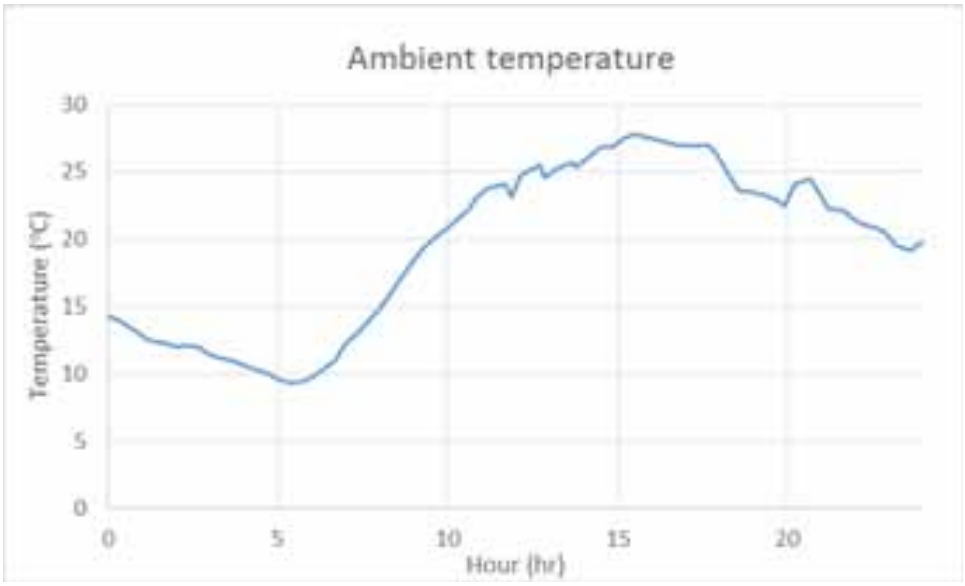

Fig. 5: Measured ambient temperature at Manzanares on 2 September 1982

In calculation of SUTP performance, ambient temperature and solar irradiation was used as initial conditions. Using this values, the calculated output power was compared with measured values at fig. 6. Overall trend of power is similar, but the calculated power is slightly higher at early morning. The maximum power is about 34 kWe at the 12 pm. The power at night is zero because there is no solar irradiation. At fig.7, temperature rise in collector was compared with measured data. The trend is similar, but the temperature rise until 8 am is quite different. But the temperature rise at daytime is similar from about 15 ^{o}C to 20 ^{o}C. At fig. 8, air velocity at chimney was compared with the measured data. Measured velocity profile is quite fluctuating, so it is difficult to compare each other. But, overall trend of velocity is similar, and the calculated velocity data is underestimated than measured one. At fig. 9 and 10, the calculated pressure difference at total system and turbine system were compared with measured one. The trends are also similar each other.

d

Fig. 10: Comparison of calculated turbine pressure difference with measured turbine pressure difference

3.2 Large scaled SUTP

Idea of solar updraft tower plant was suggested for the high electricity production at the dry area where the solar energy is abundant and water storage is deficient. For the high electricity production, scale of solar chimney should be expanded to obtain the high power. Many research evaluate performance of large scaled solar chimney. In this paper, the large scaled tower was assumed to operate ordinarily at same condition of Manzanares initial value like ambient and solar irradiation. At that conditions, the size of solar tower was changed like following table. 2. Slope of collector is linearly tilted from inlet to outlet of roof. Other basic values are same with values of the manzanares calculation. From the figure 11 to 15, the result of the large scale tower plant was obtained. The maximum power is about 130 MWe at 12 pm. The temperature rise in the collector is maximum 35 ^{o}C at 12 pm. The air flow velocity at chimney is highest value of 20 m/s at day time. The maximum pressure difference profile followed also similar trend. From the large scaled analysis, we could estimate the performance of system at the specific tower dimension.

Tab. 2: Dimensions of large scaled solar updraft tower plant

Tower height	1,000 m
Tower radius	100 m
Collector radius	3,000 m
Collector inlet height	5 m
Collector outlet height	10 m

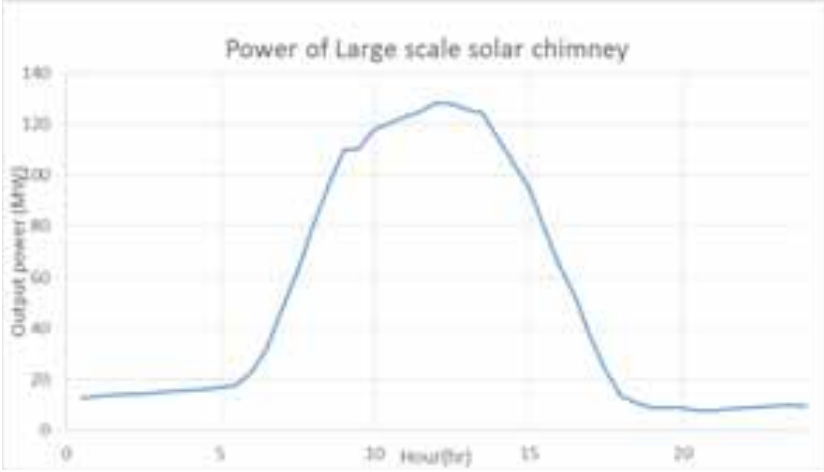

Fig. 11: Calculated output power of large scaled SUTP

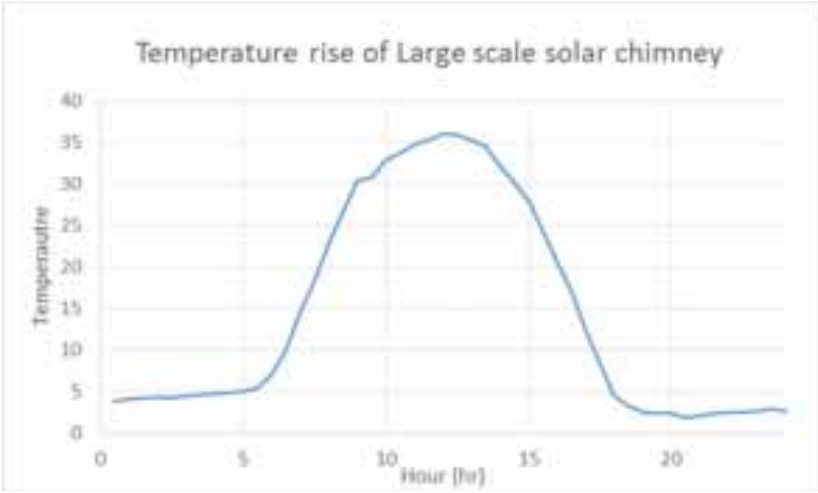

Fig. 12: Calculated temperature rise of large scaled SUTP

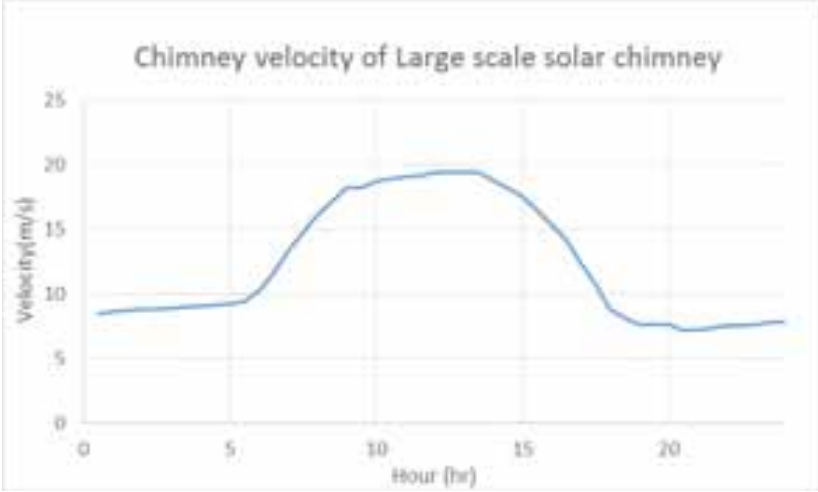

Fig. 13: Calculated chimney velocity of large scaled SUTP

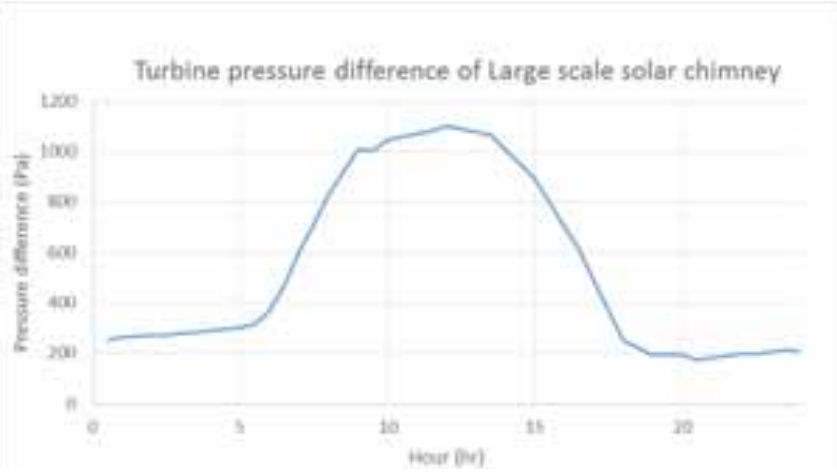

Fig. 15: Calculated turbine pressure difference of large scaled SUTP

4. Conclusions

A new mathematical analysis model was developed to evaluate the performance of SUTP system. The prediction of new model was compared with experimental data. The new model was validated with measured data, and the trends of overall data was considerably well-estimated. By using this mathematical method, large scaled SUTP system was also evaluated. The output power scale was about 100MWe. But there are many defect on our model development, so more comprehensive study for improving the model should be conducted.

Abstract

The authors present the integration of a solar thermal energy performance model in an already existing solar atlas infrastructure. With this tool, the user will be able to select the design parameters of a solar power plant and the key performance indicators will be delivered. In particular, this paper presents the two performance models proposed to assess the performance of utility-scale solar thermal power plants. The results of these models have been used for the evaluation of the potential of solar energy in the Arabian Peninsula.

Keywords: *solar thermal energy (STE), simulation, parabolic trough collector (PTC), central receiver systems (CRS).*

1. Introduction

Until now, countries like Saudi Arabia and UAE have based their energy consumption on its great resources of oil and gas. However, the Middle East is a region with high solar energy potential. The use of solar energy to produce electricity instead of burning fossil fuels would have several advantages, like avoiding consuming a well valued resource, and reducing the dependence of a finite resource.

To impulse the development of solar energy projects, KACARE proposed the development of a solar atlas, where the solar irradiance potential would be offered to the general public. The website is online and operational (KACARE, 2015). Moreover, a joint project between ReCREMA and KACARE aims to include a solar technology assessment layer into the atlas, where the performance of several solar technologies will be available. The technologies included in the solar simulator will be photovoltaic solar energy (PV) and solar thermal energy technologies, like parabolic trough collectors (PTC) and central receiver systems (CRS).

In this paper, the models used in the solar simulator for the solar thermal technologies are presented and compared. The spatial aspects of the simulation are analyzed to improve the speed and performance of the simulator. As an example of the capabilities of the model, two plants are designed and their annual performance is calculated.

2. General overview of the solar atlas operation

There are three kinds of inputs for the solar technology assessment atlas: the user defines the major characteristics of the plant (i.e. design net output power, solar multiple and hours of storage), the pixels on the map states the location-related information and the fixed inputs are logic design assumptions specified in the model to simplify it and avoid long computation times, benchmarked with industrial standards.

Once the inputs are defined, the model performs two calculations for each pixel of the map. First, the layout of the plant is determined. Then, the tool estimates the annual performance of the plant.

doi:10.18086/swc.2015.04.20 Available at http://proceedings.ises.org

3. Performance models

3.1. CRS Model

During the first step of the design point evaluation, a detailed power block model is used to calculate the required power at the steam generator. This power block model simulates a 50-100 MWe state of the art steam Rankine cycle. Bigger sizes would imply a significant drop of the optical efficiency due to the extreme atmospheric attenuation in the Arabian Peninsula.

Therefore, sizes bigger than 100 MWe are assumed as multiples of the power block model. The partial load behavior is also modeled assuming sliding pressure control, and performance maps are created to be implemented in the annual performance calculations. Knowing the power absorbed at the steam generator and the solar multiple (defined by the user), the power absorbed by the receiver can be estimated. Using this value and the information provided by each pixel (design direct normal irradiance and latitude), the height of the tower and the size of the receiver are optimized through pre-calculated DELSOL3 optimizations. The optimization has been done with the economic parameters incorporated, although the user will not be able to change the values. In this optimization, the pre-calculated data is limited to 105 possibilities for each variable and the rest of the possible combinations are interpolated from the data.

The layout of the solar field cannot be obtained by interpolation and therefore, it should be calculated for each case. For that purpose, a complete optical model in MATLAB has been developed. This optic model discretizes the field using a cell pattern similar to DELSOL3 approach, and takes into account the optical behavior of each cell. The shadowing and blocking (S&B) engine uses an intelligent neighbor selector and the classic approach of surface projection. Fig. 1 shows the validation results of the S&B engine proposed, against a ray-tracing code and its evolution along the year.

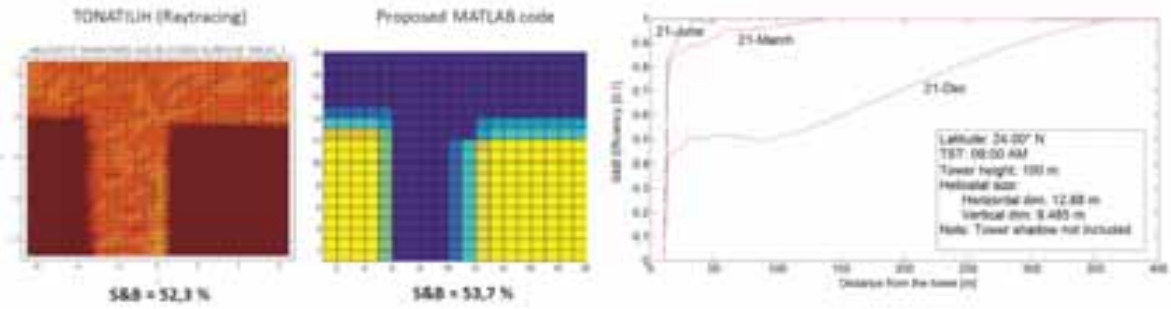

Fig. 1: S&B validation of the proposed code in MATLAB using Tonatiuh Raytracing

The evaluation of the flux at the receiver necessary to determine the spillage, is numerically calculated using a circular Gaussian approach similar to the one used in HFLCAL. The computer program HFLCAL was developed by Michael Kiera at the German company Interatom during the project GAST (GAS-cooled Solar Tower) in the early 1980's (Kiera, 1989). Once the optical efficiencies are calculated, the optical model re-arranges the cells and calculates the optimum field layout.

The size of the receiver is interpolated from the pre-calculated DELSOL3 optimization data and introduced into a thermodynamic receiver model. The receiver model calculates the thermal efficiency of the receiver as well as other outputs needed for the overall model e.g. molten salts mass flow rate, salts-pump consumption. The partial load behavior is also calculated and represented in a set of performance maps which will be used in the annual performance model.

The Fig. 2 shows an example of the solar field created by the model. The rather circular geometry agrees with the DELSOL3 optimizations and reflects the fact that in areas with a significant atmospheric attenuation, as the case of the Arabian Peninsula, circular fields are preferred against North/South fields. This field creation takes into account energy performance and economic parameters. If only the energy performance were taken into account, the resulted solar field will have very high tower with big receivers

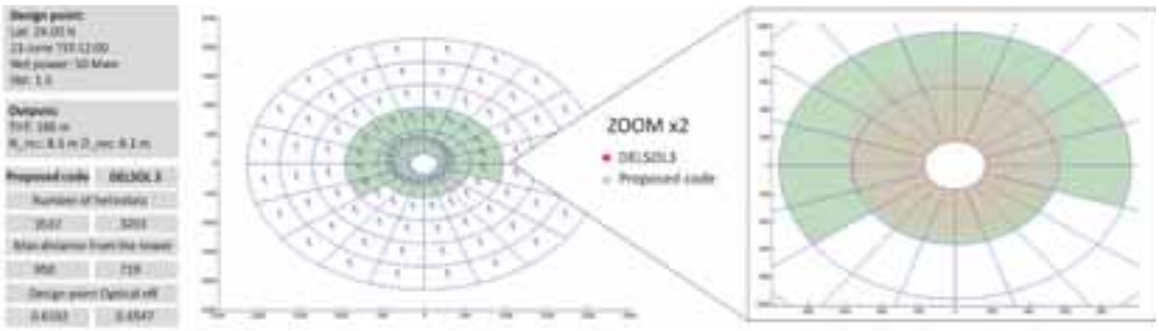

Fig. 2: Solar field layout created by the proposed model

3.2. PTC Model

The PTC plant design, which is defined by the spatial organization of the collectors, is easier to determine. The PTC collectors are arranged in loops of collectors in series. Ideally, every loop receives the same irradiance and heats a fraction of the thermal oil by the same temperature difference. Hence, the aperture area of a PTC solar field depends on the desired power, the available incident power (Q_{sun}) and the performance of one loop to transform this incident power in thermal energy.

Therefore, the calculation of the efficiency of one loop in design conditions is needed to design the power plant. To do so, first the amount of energy available for the loop and then the optical and thermal losses of the collector are calculated. Once the plant design is determined, the annual performance of the plant can be simulated. For every time step, the simulator uses the meteorological database associated to the pixel to follow the same step than for the design.

First, the available incident power (Q_{sun}) is defined by the following expression:

$$Q_{sun} = \mathrm{G_b} \cdot \cos\theta_i \cdot A_{apert} \qquad \text{(eq. 1)}$$

where G_b is the direct irradiance, θ_i is the incidence angle and A_{apert} is the aperture area of the solar field.

Then, the absorbed energy by the collector tube is calculated following the guidelines proposed by the GuiSMo project Eck et al. (2014) that recommends including accurate optical efficiency information of the collector, the incidence angle modifier (IAM), the end losses and the shading effects.

The optical efficiency is calculated by eq.2. It is assumed that the solar field is periodically cleaned and that the value of F_d (cleanliness factor) changes randomly among certain values that follow a normally distributed function, and so do the reflectivity of the mirrors, the transmissivity of the tube cover and the absorptivity of the tube. This method was proposed by Zaversky et al. (2012) and the values used are based on the SEGS experimental data.

$$\eta_{opt,0^\circ} = r_{0^\circ} \cdot \gamma_{0^\circ} \cdot \tau_{0^\circ} \cdot \alpha_{0^\circ} \cdot F_{d,0^\circ} \qquad \text{(eq. 2)}$$

where r_0 is the reflectivity of the parabolic mirrors, γ_0 is the geometric intercept factor of the collector, τ_0 is the transmissivity of the receiver's glass cover and α_0 is the absorbance of the selective coating on the metallic pipe, all at θ=0º.

The IAM is determined by:

$$\mathrm{K}(\theta) = 1 - \mathrm{a_0} \cdot \theta - \mathrm{a_1} \cdot \theta^2 + \mathrm{a_2} \cdot \theta^3 + \mathrm{a_3} \cdot \theta^4 \qquad \text{(eq. 3)}$$

where θ is the incidence angle and the coefficients used are a_0=2.2307·10^{-4}, a_1=1.1·10^{-4}, a_2=3.18596·10^{-6} and a_3=-4.85509·10^{-8}.

The end losses (f_{end}) and the shading effects ($f_{rowShadow}$) are calculated following the equations, from Eck et al. (2014):

$$f_{end} = 1 - f_m \cdot \tan\theta / l_{col} \qquad \text{(eq. 4)}$$

$$f_{rowShadow} = \max\left[0, \min\left[1, \frac{d_{row}}{w_{col}} \frac{\sin\alpha_s}{\cos\theta}\right]\right] \quad \text{(eq. 5)}$$

where l_{col} and w_{col} is the length and width of the collector, d_{row} is the distance between rows, f_m is the focal length of the parabola and α_s is the solar altitude.

The energy absorbed by the tube is defined as:

$$Q_{abs} = Q_{sun} \cdot IAM \cdot \eta_{\text{opt},0^\circ} \cdot f_{end} \cdot f_{shadow} \quad \text{(eq. 6)}$$

The receiver thermal losses are calculated following the regression lines obtained by Burkholder et al. (2008) for the Schott PRT70:

$$H_L = b_0 + b_1 \cdot (T_{HTF} - T_{amb}) + b_2 \cdot {T_{HTF}}^2 + b_3 \cdot {T_{HTF}}^3 + b_4 \cdot G_b \cdot \cos\theta \cdot {T_{HTF}}^2 + \\ + \sqrt{V_w} \cdot (b_5 + b_6 \cdot (T_{HTF} - T_{amb})) \quad \text{(eq. 7)}$$

where T_{HTF} is the temperature of the fluid, T_{amb} is the ambient temperature, V_w is the wind speed and the coefficients are shown in Tab. 1.

Tab. 1: Values of the coefficients for the heat losses calculations (Burkholder, 2008).

b_0	4.05
b_1	0.247
b_2	-0.00146
b_3	5.65E-6
b_4	7.62E-8
b_5	-1.70
b_6	0.0125

The thermal losses of the piping are calculated following the method proposed by Patnode (2006):

$$H_{L,Pip} = c_0 \cdot (T_{HTF} - T_{amb}) + c_2 \cdot (T_{HTF} - T_{amb})^2 + c_3 \cdot (T_{HTF} - T_{amb})^3 \quad \text{(eq. 8)}$$

where c_0=1.693·10^{-2}, c_1=1.683·10^{-4}, c_3=6.78·10^{-7}.

Once the amount of thermal energy provided by the solar field is calculated, the control algorithm determines the amount of energy sent to the power block and thermal storage.

For the determination of the efficiency and power production of the power block the model uses the equation proposed by Llorente et al. (2011).

$$\eta_{PB} = a_1 + a_2 \cdot \exp\left(-P_{in} / a_3\right) \quad \text{(eq. 9)}$$

where the P_{in} is the power delivered to the power block after the heat exchanger (η_{HEX}=0.95), a_1 = 0.397, a_2 = -0.243 and a_3 = 28.23 MWt

The model is compared with the performance of a solar plant located in similar desert conditions: the 100 MW Shams 1 solar plant, operated by Shams Power Company, owned by Masdar, Total and Abengoa, located in Madinat Zayed (UAE). The solar field has 627,840 m^2 of parabolic trough, divided in four section. The particularity of the design of this plant was the addition of a gas booster before the turbine, to increase the steam temperature the feeds it, which allows an increase of the efficiency of the turbine.

The data used, provided by Shams Power Company, has allowed the comparison of the power output from the solar field (before going to the power block) for the same conditions (DNI and ambient temperature) and compared with the actual values obtained in the field. Due to the particular configuration of the power block, the power production could not be included in the comparison. The scatter density plot of the measured

($P_{SF,meas}$) and predicted solar field power ($P_{SF,mod}$) is shown in Fig. 3, where the correspondence of the model values with the measured is good with a slight overestimation of the production in the model for lower values.

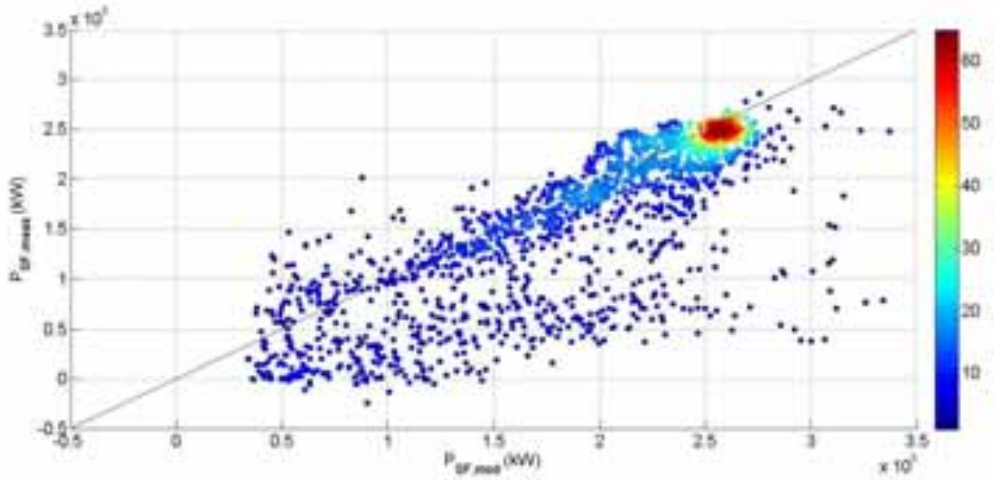

Fig. 3: Scatter density plot for power measured and power predicted by the model

4. Preliminary results

4.1. Geographic influence on the design of power plants

In this work, the presented models have been used to analyze the effect of the geography distribution of the input variables (G_b, solar angles) on the final design of the plants.

In Fig. 4 a map of the distributions of the direct solar irradiance G_b in 2013 of Saudi Arabia is shown. The country is located between the parallels 35 and 15 in the northern hemisphere, which means almost 15° of amplitude. This great extension affects the distribution of the DNI, with an increasing gradient that goes from north to south. However, the greater values are found at the west of the country, by the coast.

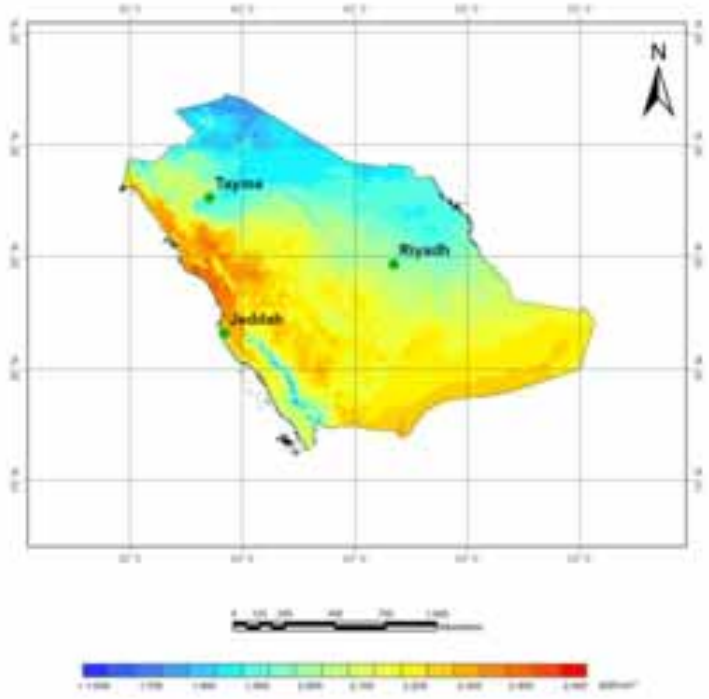

Fig. 4: Beam irradiance on Saudi Arabia on 2013

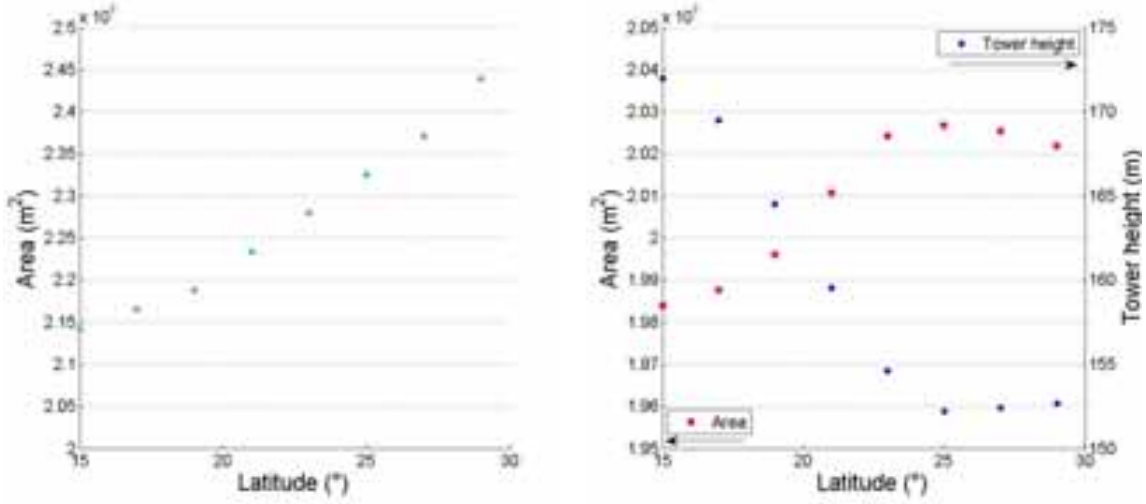
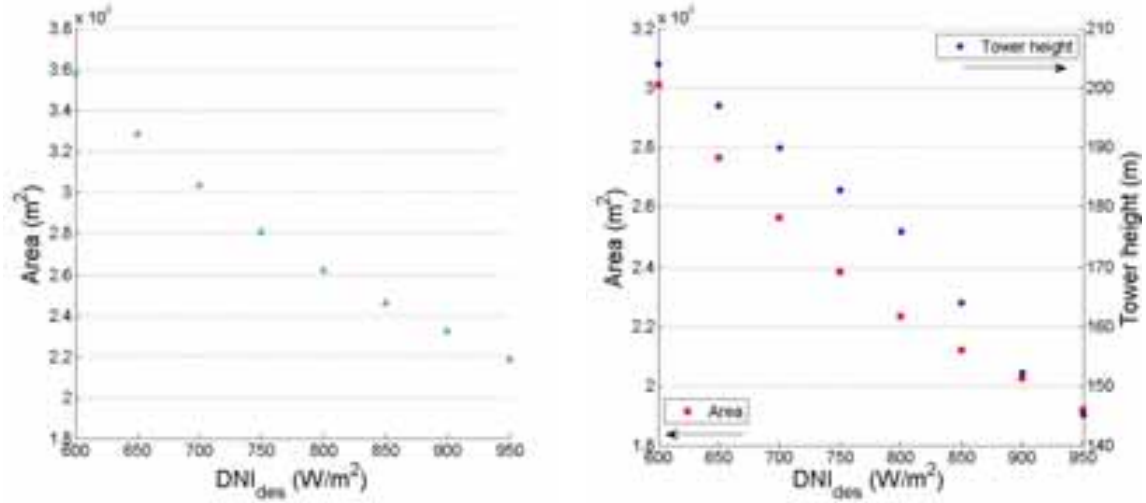
In Fig. 5 and 6 the effect of the design beam irradiance and the latitude on the design of the plants is shown. The latitude affects the position of the sun in relation to the the collectors or heliostats and it therefore has an impact on the incidence angle value. The southern the location, higher the sun will reach in the sky and smaller the incidence angle will be. As a consequence of this, the smaller the latitude (south), the smaller the area required to reach the desired power in the design conditions. Regarding the height of the tower, it gets taller when going south because the solar angles allow circle shaped heliostat field. This means that the heliostats are closer and the tower is higher.



(a) (b)

Fig. 5: Effect of the latitude on the design of the plant (a) PTC and (CRS)



(a) (b)

Fig. 6: Effect of the design beam irradiance on the design of the plant (a) PTC and (CRS)

Regarding the effect of the DNI (Fig) has on the design, the greater the DNI, smaller area will be needed to cover the desired power on the design conditions. Hence, the higher the DNI, the smaller the plant will be. Again, this means that as we go south in the country, the required area will be smaller.

As the DNI values and solar angles are no constant along the year, the choice of the design point (DNI and solar angles) will affect the performance of the plant. If a winter design date is chosen, the plant will be overdimensioned and most of the time the plants will be producing more energy that what they were designed for, having to dump most of this energy by defocusing. If a summer design date is chosen, the plant may be underdimensioned, producing under the desired power for most of the year.

4.2. Case study: design of a plant in Riyadh

The models presented in the previous section have been used to design two plants in Riyadh, which has a latitude of 24.53° and a beam irradiance on design of 843.9 W/m^2. The results of this exercise are shown in Tab.1.

Tab. 1: Comparison of the designed plants for Riyadh

Design point	Design CRS	Design PTC
Latitude: 24.53N	Tower Height: 186 m	Collectors per loop: 4
Longitude: 46.44E	Dimension receiver: 8.1 x 6.1 m^2	Number of loops: 151
21-June solar noon	Number heliostats: 3537	Total number SCA: 604
Design net power: 50MWe	Max distance of the tower: 950 m	Aperture area: 3.44 ·10^5 m^2
SM:1.5	Optical efficiency: 0.6102	

Fig. 7 and 8 show the summary of the simulation for the two solar fields of Tab. 1: each square represents the hourly average power delivered by the solar field of every month. The DNI resource is the same for both technologies, the months with less resource being March, April and May.

However, the production of the CRS solar field is more constant through the year than PTC solar field one. The reason of for this difference divergence discrepancy is the different in incidence angle between the two technologies. In winter, when the sun is lower, the PTC optical efficiency decreases more significantly due to single-axis tracking.

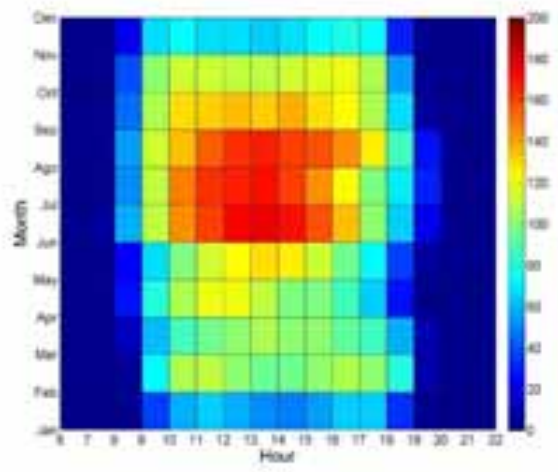


Fig. 7: Average power delivered to the power block by the parabolic trough collector solar field for every hour of every month

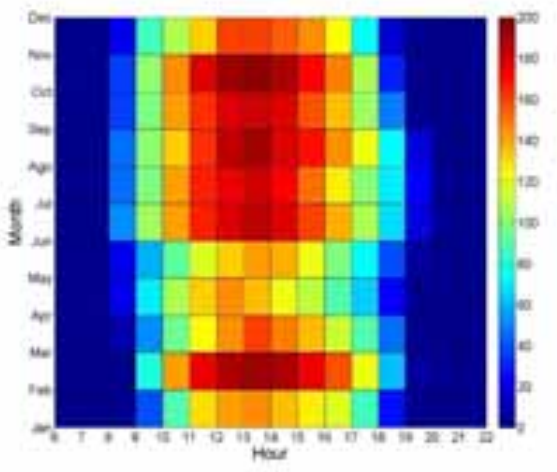

Fig. 8: Average power delivered to the power block by the central receiver system (heliostats and receiver) for every hour of every month

5. Conclusions

This paper presents the model used in a solar technology atlas for Saudi Arabia. The models for two technologies are presented: PTC and CRS. Both models are validated, either with real operational data or from widely accepted industry codes. In this work, a special focus has been given to the design step of the calculations.

Therefore, the presented models have been used to analyze the effect of the geography distribution of the input variables on the final design of the plants. The southern the location, both the beam irradiance and the solar angles values allow the reduction of the area of the solar field to reach the same power. Moreover, due to the

solar angles in low latitudes, in the case of the CRS the tower gets higher and the heliostat field design will be more compact.

As a final step, two plants have been designed in Riyadh and their annual performance has been calculated. A more stable thermal energy is delivered to the power block in the case of CRS, being the PTC more variable seasonably.

Abstract

This paper shows the results of an exergoeconomic assessment of a solar polygeneration plant. Solar polygeneration plant consists of a concentrated solar power (CSP) type parabolic trough, a multi-effect desalination MED module, a refrigeration absorption module, and process heat module, in order to produce electricity, desalinated water, cooling and process heat respectively.

A solar polygeneration plant is justified due to the high demand for the products produced, where a CSP plant produces high residual heat (waste heat) that is possible to leverage through polygeneration.

The methodology allows coupling thermodynamic equations and economic relations in order to solve complex systems. Polygeneration plant was evaluated to be installed in Crucero, in northern Chile where the direct normal irradiance reaches values of 3,389 kW h/m^2/year.

The results indicate that the polygeneration plant has an energy efficiency of 62.8%, an exergy efficiency of 24.5%, products cost rate of 10,713.2 USD / h and a net present value (NPV) of 4.3 MUSD.

Keywords: *CSP, MED, CHP, cooling, polygeneration, exergoecononomic, thermoeconomic.*

1. Introduction

Concentrated solar power (CSP) produces electricity, but it can also be coupled with other technologies in a polygeneration scheme to produce other products, such as desalination water, industrial cooling and process heat (Serra et al., 2009), especially where those products are in short supply and when there is high solar irradiation. The combined production of products by polygeneration scheme permits to increase the thermodynamic efficiency of the consumed resources. Polygeneration can transform waste heat into useful heat to drive other processes. Exergoeconomic analysis combines both economic and thermodynamic analysis (1st and 2nd law of thermodynamics) by applying the concept of cost that is an economic property, and the concept of exergy that is a thermodynamic property. The main objectives of exergoeconomic analysis are: to identify the location, magnitude and sources of exergy destruction and losses in an energy system; to calculate the cost associated with these losses; to assess the production costs of each product in the energy conversion system, which has more than one output; to facilitate feasibility and optimization studies for energy system; to assist in decision-making procedures concerning plant operation and maintenance; and to compare technical alternatives (Tsatsaronis, 1993).

Concentrated solar power (CSP) technologies can be parabolic trough collector (PTC), central receiver (CR), linear fresnel (LF) or dish-Stirling (DS). CSP-PTC has proven to be the most mature and lowest cost solar thermal technology (IRENA, 2012). Multi-effect distillation (MED), multi-stage flash (MSF) and reverse osmosis (RO) represent the most reliable, commercially proven and efficient methods to provide fresh water by desalination, and can be coupled with the CSP plant (Palenzuela et al, 2011; Cipollina et al, 2009). Absorption and vapor compression are the most important technologies to produce industrial cooling (Infante

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.04.21 Available at http://proceedings.ises.org

and Kim, 2013; Hassan et al, 2012). Solar absorption systems utilize the thermal energy from solar collector to separate a refrigerant from the refrigerant/absorbent mixture. Solar absorption systems have been published in some studies (Sarbu and Sebarchievici, 2013; Ullah et al., 2013). Industrial process heat is used in different industrial processes. The thermal energy demand is below 300 °C (Fernández-García et al., 2010).

Finally, exergoeconomic analysis of polygeneration systems with fossil fuel as main energy source has been published in some studies. A few studies have been made on exergoeconomic analysis of polygeneration systems with CSP plant but there is not study on exergoeconomic analysis with the current scheme polygeneration.

This work shows the results by using a model to simulate a polygeneration plant, which consists of a CSP-PTC, a MED desalination plant, a single effect LiBr/H2O absorption refrigeration plant, and a process heat plant for the production of four products: electricity, desalination water, industrial cooling and process heat.

2. Work description

2.1. Objectives and methodology

The objective of the present study is to evaluate exergoecomically a solar polygeneration plant producing power, desalinated water, industrial cooling and process heat. Figure 1 shows the polygeneration plant studied.

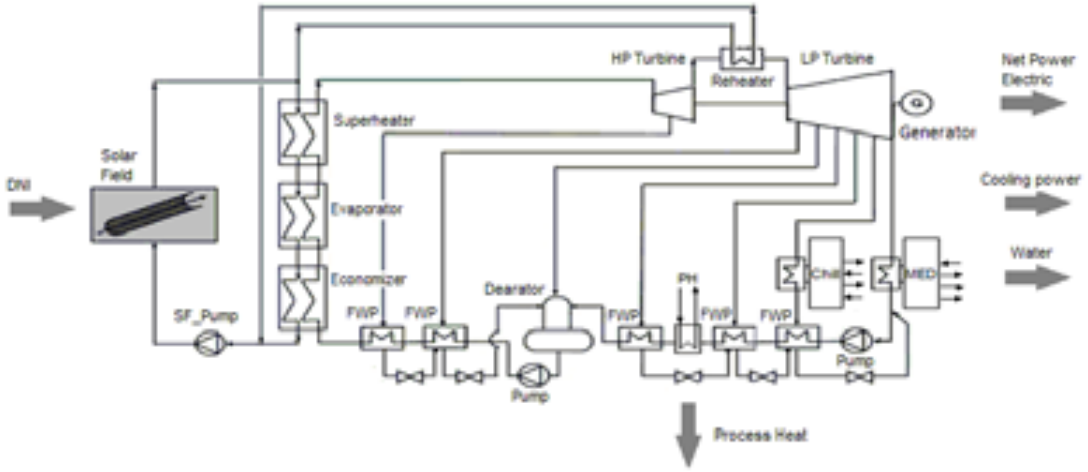

Fig. 1: Configuring solar polygeneration plant.

The methodology followed is presented in Figure 2. First, from preliminary design and modeling of CSP-PTC plant, multi-effect distillation (MED), absorption refrigeration plant, and a heat exchanger, different coupling points are evaluated to select the most appropriate in technical terms. After that, aggregation level is selected allowing the delimitation of the boundaries analysis (Figure 3). Then, a physical structure and productive structure is obtained and the fuels and products are determined. Subsequently, different models are defined: thermodynamic model (1st and 2nd law of thermodynamics), economic model (determination of investment costs, operation and maintenance), exergoeconomic model (Bejan et al, 1996) (determination exergetic unit cost USD/kWh, fuel cost rate, product cost rate, destruction cost rate, total cost rate USD/h, and exergoeconomic factors) and financial model. Finally, the system is solved.

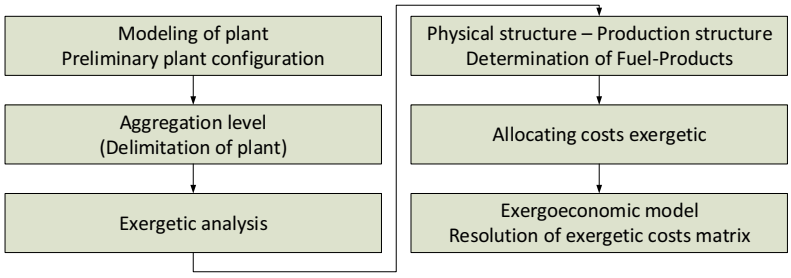

Fig. 2: Methodology.

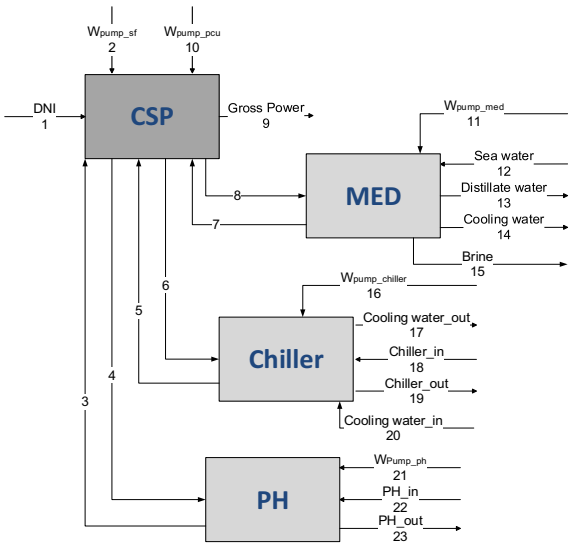

Fig. 3: Aggregation level for exergoeconomic assessment in polygeneration plant.

IPSEpro was used for the modeling and simulations of the system. This software allows to elaborate the flowsheet of a process using the components available in libraries or created by user. It then solves the flowsheet using Newton-Raphson method, linearizing the non-linear equations at starting value. Matlab and EES (equation engineering solver) were used to obtain characteristic parameters in each plant and to exergoeconomics assessment.

The polygeneration plant was evaluated to be installed in northern Chile, Crucero, latitude -22.14°, longitude -69.3°, DNI 3,389 kWh/m^2/year (Escobar et al, 2015).

2.2. Design problem.

Preliminary design and model plants were done separately and subsequently coupled so as to operate in a scheme polygeneration. The CSP-PTC plant is configured with a solar collector field with Skal-et, thermal fluid Dowtherm A and a power block of 55 MW of gross capacity. The power conversion unit consists of a regenerative Rankine cycle with reheat and five extractions. The CSP plant was modeled without thermal energy storage and without backup system. The desalination plant was modeled with 12 effects parallel-cross feed MED plant with 11 feed preheaters. The refrigeration plant was configured with a single-effect LiBr-H_2O absorption chiller with 5 MW of power cooling. As a final point, a heat exchanger was configured for the production of process heat, with 7 MW power heating.

Each plant was validated separately. There is no information about plants operating under this polygeneration scheme. The CSP-PTC plant was validated from Blanco et al. (2011), the MED plant was validated from Zak et al. (2012), and the refrigeration plant was validated from Herold et al. (1996).

2.2.1. Coupling of technologies.

Several coupling points were evaluated between CSP plant and other plants. The most appropriate point of coupling was selected (Figure 1) according to the technical constraints imposed by each system.

MED plant was coupled with CSP plant condenser. In the chosen configuration it was not possible to regulate the amount of water produced. Given that MED plant must operate within a temperature range of 64 to 74 °C (Al-Karaghouli et al, 2013), it was necessary to increase LP turbine backup pressure from 0.06 bar to 0.37 bar (see Table 1). Therefore, electric power was reduced to increase this pressure.

The solar field aperture area must increase to maintain electrical power, but it will increase investment cost and LEC. Polygeneration plant should increase solar field aperture area from 294.534 m^2 to 356,063.7 m^2 equivalent to increase aperture area in 20.9 %.

Desorber of the absorption refrigeration plant required operating temperature within 80 to 110°C (Srikhirin et al, 2001). Absorption refrigeration plant is coupled to the LP turbine 5th extraction where temperature is 108.3°C (see table 1).

Main parameters of polygeneration plant are presented in Table 1.

Tab.1: Polygeneration plant design.

Solar field	Value Unit
Irradiance at design day, SM=1.4	1010.0 W/m^2
Solar Field inlet/outlet temperature	293.0 °C / 393.0 °C
Collector efficiency	0.68
Aperture area	356,063.70 m^2
Power conversion unit	Value Unit
Gross power production	55.55 MW
HP turbine inlet pressure/temperature	103.57 bar / 373 °C
HP turbine extraction pressure/temperature	30.6 bar / 234.9 ºC
LP turbine 1st extraction pressure/temperature	12.77 bar / 341.6 ºC
LP turbine 2nd extraction pressure/temperature	6.18 bar / 259.6 ºC
LP turbine 3rd extraction pressure/temperature	5.99 bar / 256.2 ºC
LP turbine 4th extraction pressure/temperature	2.63 bar / 175.9 ºC
LP turbine 5th extraction pressure/temperature	1.17 bar / 108.3 ºC
LP turbine back pressure/temperature	0.37 bar / 73.9 ºC
HP turbine / LP turbine isentropic efficiency	85.2% / 85.0%
Generator and Motor mechanical and electrical efficiency	98.0 %
Pumps isentropic efficiency	70.0 %
Multi Effect Desalination	Value Unit
Feed seawater intake temperature	25.0 °C
Feed seawater intake salinity	0.042 kg/kg
Feed seawater after down condenser temperature	35.0 °C
Maximum salinity in each effect	0.072 kg/kg
Top Brine Temperature (TBT)	65.0 °C
GOR	9.07
Fresh water production	37,341 m^3/day
Concentration factor	1.71
Single stage absorption chiller	Value Unit
Cooling power	5.0 MW
Chilled water inlet / outlet temperature	10.0 °C / 6 °C
Cooling water inlet temperature (absorber)	25.0 °C
Cooling water outlet temperature (condenser)	35.0 °C
Inlet temperature desorber	108.5 °C
COP	0.70
Process Heat	Value Unit
Heating power	7.0 MW
Hex inlet / outlet temperature	63.0 °C / 90.0 °C

2.2.2. Decision variables.

Decision variables used are: LP turbine back pressure, LP turbine 5th extraction pressure, isentropic efficiency of turbine and of pump. LP turbine back pressure varies between 0.28 to 0.40 bar, it influences the inlet temperature to the first effect of the multi-effect desalination module. LP turbine 5th extraction pressure varies between 1.00 to 1.30 bar, it influences the desorber inlet temperature of the cooling system. Isentropic efficiency varies between 80% to 90% in turbine and between 65% to 75% in pump.

2.2.3. Exergoeconomic and economic parameters.

Exergetic analysis considered reference temperature 25°C, reference atmospheric pressure 1.013 bar, and reference mass fraction LiBr 0.5542 kg/kg.

Investment cost MUSD (CAPEX) and operating and maintenance cost MUSD/year (OPEX) considered are: 241.13 and 4.0580 in CSP (IRENA, 2012; NREL, 2013), 22.85 and 1.2587 in MED plant (Li et al., 2013; Verdier et al., 2011; Trieb eta al., 2009; Trieb et al., 2008; IEA-ETSAP and IRENA, 2012), 3.15 and 0.0069 in Refrigeration plant (Mokhtara et al., 2010; Lazzarin, 2013; Misra et al., 2003, Infante and Kim, 2013.), and finally 0.197 and 0.0004 in process heat plant (Turton, 2012). It has been considered a horizon of 25 years and a discount rate of 10%.

For financial evaluation, sales prices of each product were considered: electric energy 0.12 USD/kWh (CNE, 2015), electric power: 9.5 USD/kW/month (CNE, 2015), desalinated water: 3.5 USD/m^3 (Wood Mackenzi, 2014), cooling: 0.1 USD/kWh (CDEC-SING, 2014; Demir et al, 2008), process heat: 0.08 USD/kWh (CDEC-SING, 2014; Kecebas et al, 2013). Chile has an imposition rate on the utility of 21% (SII, 2015). A constant depreciation over the plant lifetime is chosen here.

In the model, variations of kinetic energy, potential energy, and pressure drops in the lines were disregarded.

2.3. Models developed.

The exergoeconomic assessment involves applying a thermodynamic model where are made mass balances (eq. 1), energy balances (eq. 2) and exergy balances (eq. 3). For determining the exergy specified (eq. 4) the potential and kinetic exergy were disregarded. It is calculated the different kind rates of exergy, such as, exergy work rates (eq. 5), exergy process heat rates (eq. 6), exergy physical rates (eq. 7), exergy chemical rates (eq. 8), and exergy rates from sun (eq. 9). Thereby thermodynamic properties and rates of exergy in each stream are determined.

$$\sum(\dot{m}_{in} - \dot{m}_{out}) = 0 \quad \text{(eq. 1)}$$

$$\sum(\dot{m}_{in} h_{in}) - \sum(\dot{m}_{out} h_{out}) - \dot{W} + \dot{Q} = 0 \quad \text{(eq. 2)}$$

$$\sum(\dot{Q}\left(1 - \frac{T_0}{T}\right)) - \dot{W} + \sum(\dot{m}_{in} e_{in}) - \sum(\dot{m}_{out} e_{out}) - \dot{E}_D = 0 \quad \text{(eq. 3)}$$

$$e = e_{ph} + e_{ch} + e_p + e_k \quad \text{(eq. 4)}$$

$$\dot{E}_{work} = \dot{W} \quad \text{(eq. 5)}$$

$$\dot{E}_{heat} = \left(1 - \frac{T_0}{T}\right)\dot{Q} \quad \text{(eq. 6)}$$

$$\dot{E}_{ph} = \dot{m} e_{ph} = \dot{m}((h - h_0) - T_0(s - s_0)) \quad \text{(eq. 7)}$$

$$\dot{E}_{ch} = \dot{m} e_{ch} = \dot{m}\left(-\Delta G + \left(\sum_p n e_{ch} - \sum_R n e_{ch}\right)\right) \quad \text{(eq. 8)}$$

$$\dot{E}_{sun} = A \cdot DNI \cdot (1 + \frac{1}{3}\left(\frac{T_0}{T_{sun}}\right)^4 - \frac{4}{3}\left(\frac{T_0}{T_{sun}}\right)) \quad \text{(eq. 9)}$$

Additionally, It is calculated the energy efficiency in power plant (eq. 10), coefficient of performance (COP) in Single stage absorption chiller (eq. 11), energy efficiency in process heat (eq. 12), energy efficiency in MED (eq. 13), utilization factor of polygeneration plant (eq. 14), gained output ratio (GOR) in MED (eq. 15), exergy efficiency (eq. 16), and solar multiple (SM) (eq. 17).

$$\eta_{CSP} = \frac{\dot{W}_{net}}{\dot{Q}_{in}} \quad \text{(eq. 10)}$$

$$\eta_{PH} = \frac{\dot{Q}_{out}}{\dot{Q}_{in} + \dot{W}_{pump}} \quad \text{(eq. 11)}$$

$$COP_{abs} = \frac{\dot{Q}_{chiller}}{\dot{Q}_{desorb} + \dot{W}_{pumps}} \quad \text{(eq. 12)}$$

$$\eta_{MED} = \frac{\dot{m}_{distillate} h_{distillate}}{\dot{Q}_{in\_med} + \dot{W}_{pumps}} \quad \text{(eq. 13)}$$

$$\eta_{polygeneration} = \frac{\dot{W}_{net} + \dot{m}_{distillate} h_{distillate} + \dot{Q}_{chiller} + \dot{Q}_{out}}{\dot{Q}_{in}} \quad \text{(eq. 14)}$$

$$GOR = \frac{\dot{m}_{distillate}}{\dot{m}_{steam\ 1st\ effect}} \quad \text{(eq. 15)}$$

$$\varepsilon = \frac{\dot{E}_{out}}{\dot{E}_{in}} = 1 - \frac{\dot{E}_D}{\dot{E}_{in}} \quad \text{(eq. 16)}$$

$$SM = \frac{\dot{Q}_{th,solar\ field}}{Q_{th,power\ block}{}_{design\ point}} \quad \text{(eq. 17)}$$

The economic model is then applied. This is quantifying the capital investment cost rates (eq. 18), the operating and maintenance cost rates (eq. 19), and the total cost rates (eq. 20).

$$\dot{Z}_k^{CI} = \frac{CC_L}{\tau}\frac{PEC_k}{\sum_k PEC_k} \quad \text{(eq. 18)}$$

$$\dot{Z}_k^{OM} = \frac{OMC_L}{\tau}\frac{PEC_k}{\sum_k PEC_k} \quad \text{(eq. 19)}$$

$$\dot{Z} = \dot{Z}_k^{CI} + \dot{Z}_k^{OM} \quad \text{(eq. 20)}$$

Later it is developed the exergoeconomic model. By exergy balance costs (eq. 21) it is obtained exergy cost unitary c_j and exergy cost rate $\dot{C}_j$ (eq. 22) for each stream.

$$\sum_{j=1}^{n}(c_j\dot{E}_j)_{k,in} + \dot{Z}_k^{CI} + \dot{Z}_k^{OM} = \sum_{j=1}^{m}(c_j\dot{E}_j)_{k,out} \quad \text{(eq. 21)}$$

$$\dot{C}_j = c_j\dot{E}_j = c_j(\dot{m}_j e_j) \quad \text{(eq. 22)}$$

With these results it is calculated the exergy destruction cost rate (eq. 23), exergy destruction ratio (eq. 24), relative cost difference (eq. 25), and exergoeconomic factor (eq. 26).

$$\dot{C}_{D,k} = c_{F,k}\dot{E}_{D,k} \quad \text{(eq. 23)}$$

$$y_{D,k} = \frac{\dot{E}_{D,k}}{\dot{E}_{F,tot}} \quad \text{(eq. 24)}$$

$$r_k = \frac{c_{P,k} - c_{F,k}}{c_{F,k}} = \frac{c_{F,k}\left(\dot{E}_{D,k} + \dot{E}_{L,k}\right) + \left(\dot{Z}_k^{CI} + \dot{Z}_k^{OM}\right)}{c_{F,k}\dot{E}_{P,k}} \quad \text{(eq. 25)}$$

$$f_k = \frac{\dot{Z}_k}{\dot{Z}_k + c_{F,k}\left(\dot{E}_{D,k} + \dot{E}_{L,k}\right)} \quad \text{(eq. 26)}$$

For evaluating economic, it is calculated the levelized cost (eq. 27) of energy (LEC), of water (LWC), of cooling (LCC), and process heat (LHC). crf is the capital recovery factor (eq. 28).

$$LC = \sum_{j=0}^{n}\frac{capex_j crf + opex_j + Cf_j}{(1+i)^j}/(Annual\ Production_j) \quad \text{(eq. 27)}$$

$$crf = \frac{i(1+i)^n}{(1+i)^n - 1} \quad \text{(eq. 28)}$$

Finally, it is calculated the net present value (NPV) (eq. 29) and internal rate of return (IRR) (eq. 30).

$$NPV = \sum_{j=0}^{n}\frac{Cash\_in_j - Cash\_out_j}{(1+i)^j} \quad \text{(eq. 29)}$$

$$0 = \sum_{j=0}^{n}\frac{Cash\_in_j - Cash\_out_j}{(1+IRR)^j} \quad \text{(eq. 30)}$$

3. Results and discussion.

3.1. Monthly production, production in clear day and production in partial day.

Polygeneration plant receives 968.6 GWh/year from the sun, of which 666.03 GWh/year are transferred to the power conversion unit. Consequently, gross electric energy produced is 186.9 GWh/year, net electrical energy is 179.5 GWh/year, water produced is 5.32 Mm^3/year, power cooling is 16.9 GWh/year and power

heating is 23.7 GWh/year. Average monthly net electrical energy is 14.9 GWh/month, water is 0.44 Mm^3/month, power cooling is 1.41 GWh/month, and power heating is 1.97 GWh/month (Figure 4).

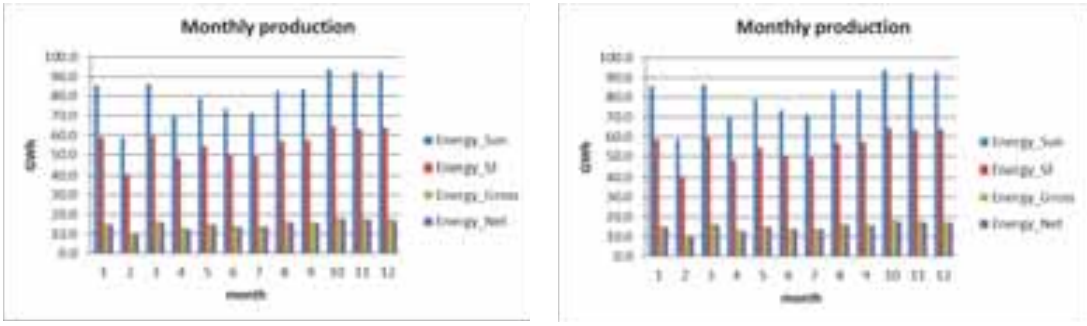

Fig. 4: Monthly production of: a- energy sun, energy solar field (SF), energy_gross (electricity), energy_net (electricity). b- energy_net (electricity), energy_ cooling, energy process heat (ph) and water volume.

In Figure 5 the monthly exergy destruction is presented. Average monthly exergy destruction is 50.7 GWh/month for polygeneration plant, 47.1 GWh/month in CSP plant, 3.2 GWh/month in MED plant, 0.3 GWh/month in cooling plan, and 0.1 GWh/month in heating plant.

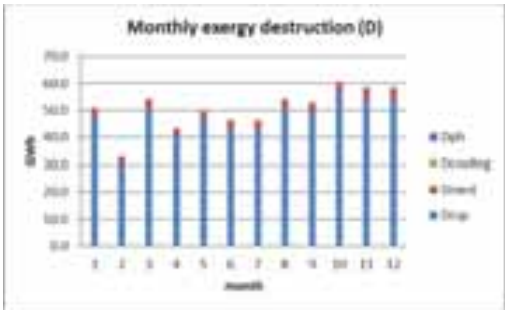

Fig. 5: Monthly exergy destruction in CSP plant, MED plant, Cooling plant and Process Heat plant (ph).

Production was analyzed on a clear day on December 21 (Figure 6a) and on a partial day on June 19 (Figure 6b). Some collectors in the solar field must be out of focus (partial defocusing) on clear day from 10:00 to 18:00 to maintain maximum production of plant design. Thermal energy storage could return this extra energy to power conversion unit.

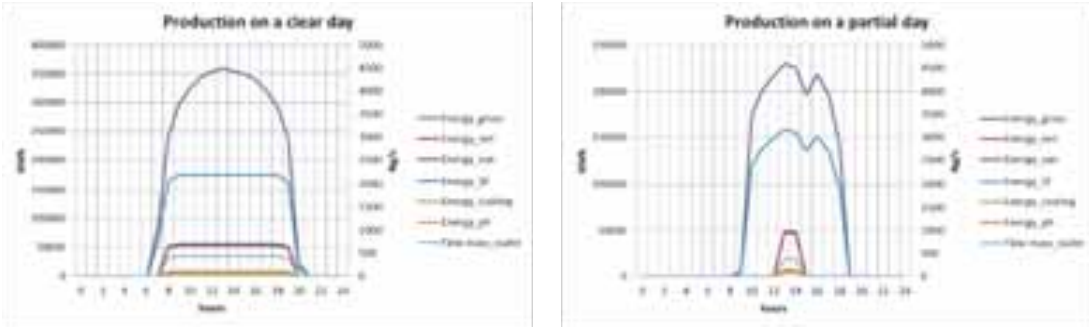

Fig. 6: Production on a: a- clear day, b- partial day.

In a partial day, such as in Figure 6b, energy collected by the solar collectors is insufficient to operate at full load and it must operate at partial loads. Consequently, polygeneration plant produces less energy. A backup system could improve polygeneration plant production.

3.2. Exergoeconomic assessment results.

In relation to the exergoeconomic assessment: exergy destruction cost rate plus total cost rates (capital investment plus operating and maintenance) are 9332.0, 1156.3, 123.9 and 32.8 USD/hour for CSP plant, MED plant, cooling plant and heating plant respectively. Relative cost differences are 99.0%, 99.0%, 92.8% and 46.5%. Exergoeconomic factors are 97.6%, 97.0%, 84.9% and 43.2 10% for CSP plant, MED plant, cooling plant and heating plant respectively. According to these indicators, it is recommended to optimize

CSP plant. This requires reducing total cost rates (capital investment plus operating and maintenance) in demerit of equipment efficiency. Effects of cooling plant and heating plant are marginal, although the location of these plants affects performance of CSP plant.

Operating on a clear day or partial day has a direct impact on exergetic unit cost and product cost rate, as shown in Figure 7.

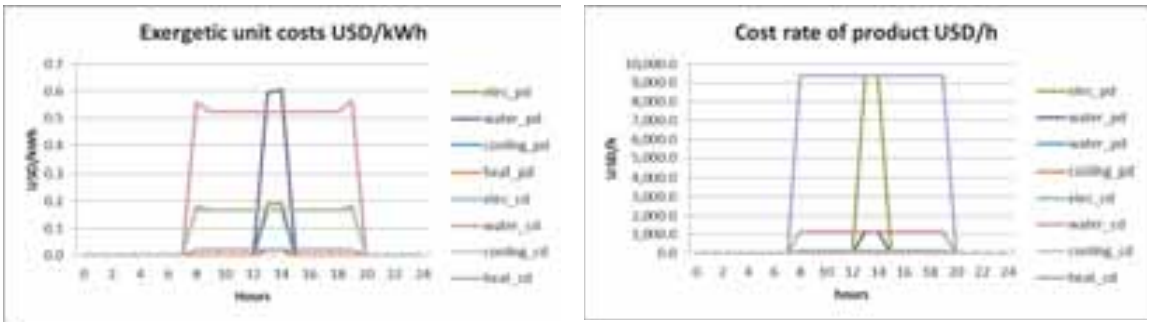

Fig.7: a- Exergetic unit costs USD/kWh. b- Total product cost rate of USD/h. (pd: partial day, cd: clear day)

3.3. Solar multiple results.

Minimum total cost rate of products (electricity + water + cooling + heat process) and minimum total levelized cost (LEC + LWC + LCC + LHC) is reached at solar multiple of 1.3 (see Figures 8 and 9). Minimum total product cost rate is 10713.3 USD/h, the minimum LEC is 0.168 USD/kWh and the minimum LWC is 0.734 USD/m^3 for annual production.

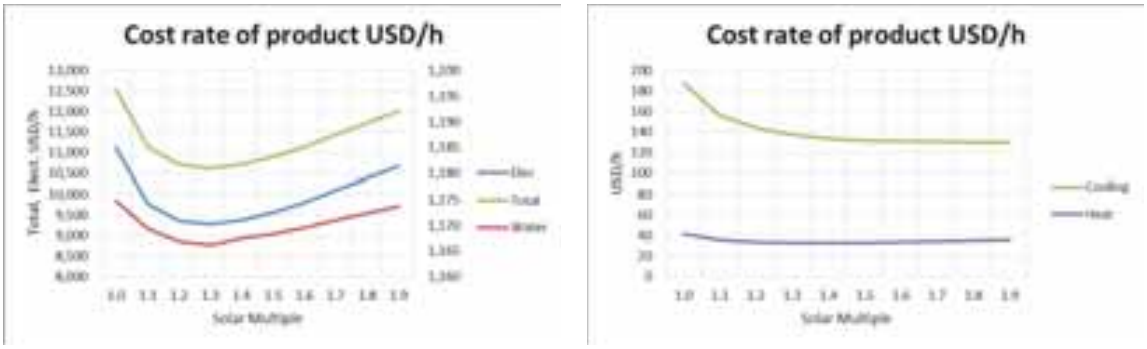

Fig.8: Product cost rate of: a- Total, electricity and water. b- Cooling and heat process.

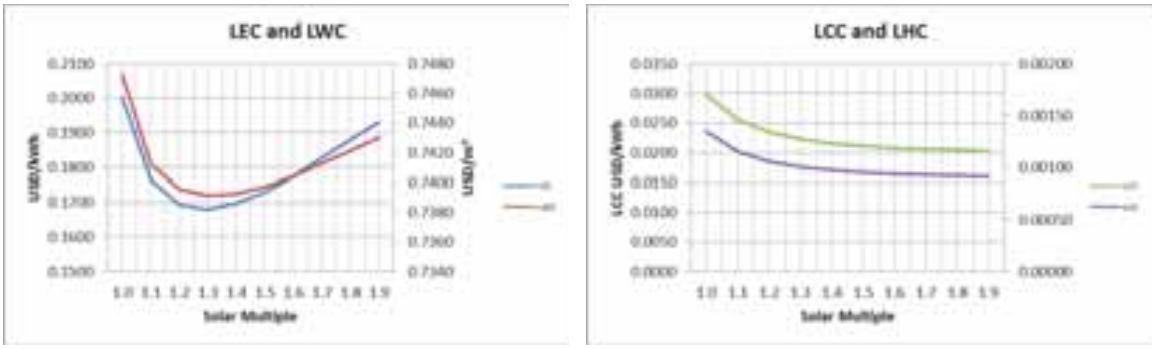

Fig. 9: a- Levelized energy cost (LEC) USD/kWh and Levelized water cost (LWC) USD/m3. b- Levelized cooling cost (LCC), Levelized heating cost (LCH) USD/kWh.

The production of each of the products is raised by increasing the solar multiple, see Figure 10, but also increases investment costs, operation and maintenance costs. Thus, the criterion for selecting the optimal size of the plant in CSP plant is where the minimum LEC is reached (Montes et al., 2009). In the case of polygeneration plant the criterion for selecting the optimal size of the plant is where the minimum total product cost rate is reached that matches with minimum LEC, minimum LWC and minimum total levelized cost.

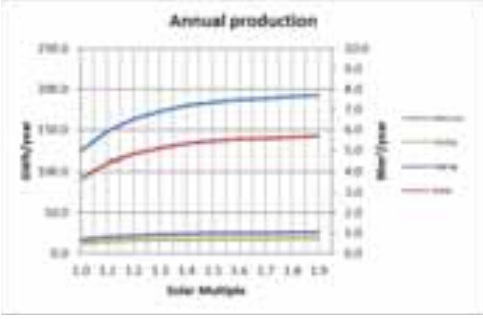

Fig.10: Polygeneration plant production.

3.4. Decision variables.

The results are presented in Figures 11 and 12. Minimum product cost rate is produced at a pressure of 0.28 bar but the maximum NPV occurs at 0.4 bar by varying LP turbine backup pressure. On the other hand, minimum cost rate of product is produced at the same pressure of maximum NPV by varying LP turbine 5th extraction pressure.

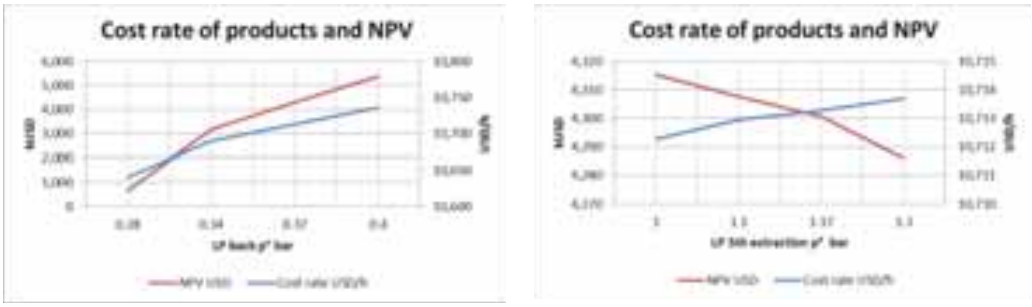

Fig.11: Effects of: a- LP turbine backup pressure, b- LP turbine 5th extraction pressure.

Fig.12: Effects of Isentropic efficiency in: a- turbine, b- pump.

3.5. Energy efficiency.

In Figure 13 Sankey diagram of polygeneration plant is presented. Utilization factor of polygeneration plant is 62.78%. The efficiencies are: 68.8% in solar field, 30.6% in the power conversion unit, 20.9% in CSP plant, 89.9% in MED plant, 99.98% in heating plant and a COP of 0.7 in cooling plant.

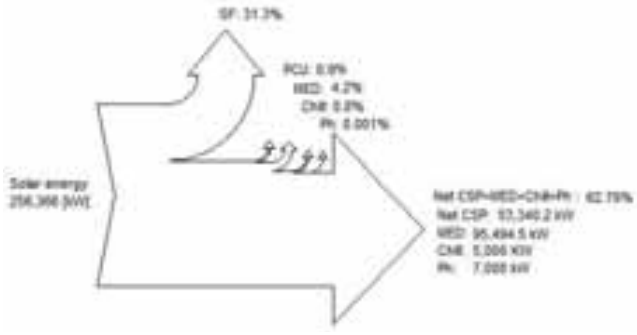

Fig. 13: Sankey diagram of polygeneration plant.

3.6. Exergetic efficiency and exergy destruction.

In Figure 14 Grassmann diagram of polygeneration plant is presented. The exergetic efficiencies are: 24.5% in polygeneration plant, 57.1% in solar field, 52.7% in power conversion unit, 24.7% in MED plant, 66.9% in heating plant, and 33.9% in cooling plant.

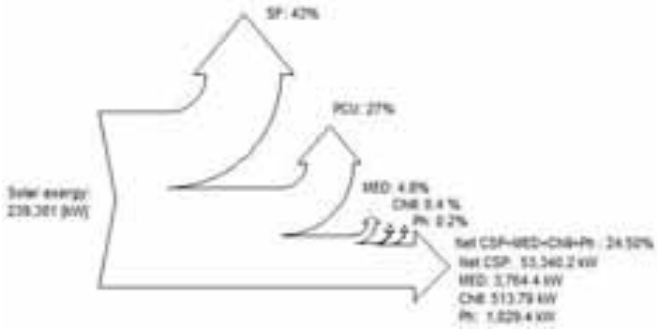

Fig. 14: Grassmann diagram of polygeneration plant.

In Figure 15 exergetic efficiency and exergy destruction in each subsystem are presented and evaluated. Exergy destruction are the following: 43.0% in solar field, 27.0% in power conversion unit, 77.6% in CSP plant, 4.8% in MED plant, 0.4% in cooling plant, 0.2% in heating plant, and 75.4% in polygeneration plant. Figure 14 shows that the effect on the destruction of exergy in cooling plant and heating plant is marginal.

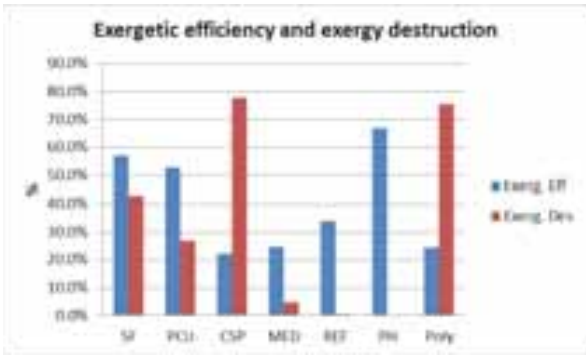

Fig.15: Exergetic efficiency and exergy destruction in polygeneration plant.

In Figure 16 exergetic efficiency is presented in each component of CSP plant. The main components where exergy destruction occurs are: solar collectors (43.0%), evaporator (11.4%), reheater (4.8%), economizer (3.8%), superheater (2.2%), LP turbine (1.8%), generator (1.0%), HP turbine (0.9%) and CFWP3 preheater (0.4%).

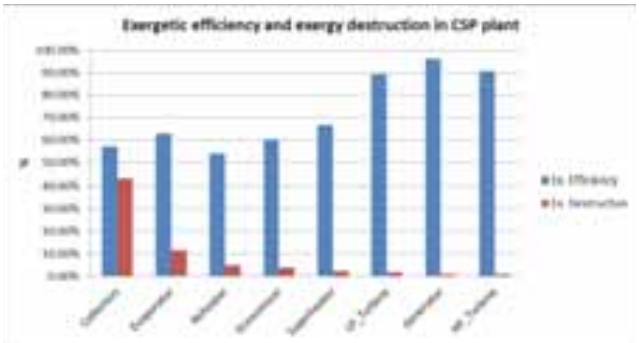

Fig. 16: Exergetic efficiency and exergy destruction in main components of CSP plant.

In Figure 17 exergetic efficiency in main components of MED plant is presented. The main components where exergy destruction occurs are: Effect 1 (1.11%), condenser (0.75%), and second to twelfth effects (from 0.24% to 0.16%).

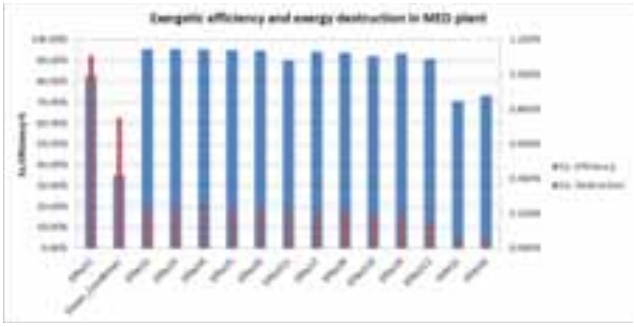

Fig. 17: Exergetic efficiency and exergy destruction in main components of MED plant.

In Figure 18a exergetic efficiency in main components of cooling plant is presented. Main components where exergy destruction occurs are: absorber (0.44%), desorber (0.06%), condenser (0.05%), and evaporator (0.05%).

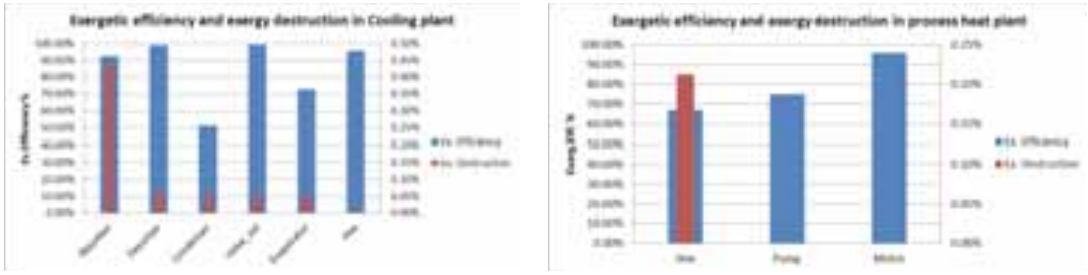

Fig. 18: Exergetic efficiency and exergy destruction of a- cooling plant. b- process heat plant

Finally, in Figure 18b exergetic efficiency in process heat plant is presented. The component where most exergy destruction occurs is the heat exchanger (0.21%).

4. Conclusions

The achievements of this work are the design and simulation of a solar polygeneration plant for the production of electricity, desalinated water, industrial cooling and process heat, using a CSP-PTC plant, a MED plant, a simple effect absorption cooling plant, and a heat exchanger for process heat, simulated hourly, and performing an exergoeconomic analysis.

In terms of energy efficiency, a polygeneration plant that operates individual plants has more efficiency. Polygeneration plant has a utilization factor of 62.7% (20.8% CSP, 89.9% MED, 0.701 refrigeration and 99.9% process heat) meanwhile CSP plant has an efficiency energy of 20.9%.

In terms of exergy efficiency and exergy destruction, polygeneration plant exergetic efficiency is 24.5%. In CSP plant the highest exergy destruction is produced in solar field and power conversion unit. The second highest is produced in MED plant. Destruction of exergy in cooling plant and heating plant is marginal. The main components where exergy destruction occurs in CSP plant are solar collectors (43.0%), evaporator (11.4%), reheater (4.8%), economizer (3.8%), and superheater (2.2%).

A production on clear day generates surplus energy, which can be stored in thermal energy storage. Thermal energy storage could return this extra energy to power conversion unit and raise the plant availability.

According to the exergoeconomic assessment, it is recommended to optimize CSP plant since CSP plant has the biggest total cost rate. This requires reducing total cost rates (capital investment plus operating and maintenance) in demerit of equipment efficiency.

Regarding solar multiple, the minimum LEC and LWC occurs with a solar multiple of 1.3. LEC varies from 0.17 to 0.20 USD/kWh, LWC ranges from 0.739-0.747 USD/m^3, LCC varies from 0.02 to 0.03 USD/kWh, and LHC varies from 0.001 to 0.0013 USD/kWh. The criterion for selecting the optimal size of the plant is where the minimum total cost (product cost rate) is reached.

When it comes to varying the decision variables, the main results in polygeneration plant are a product cost rate of 10,713.2 USD/h and NPV of 4.3 MUSD. LP turbine backup pressure, LP turbine 5th extraction pressure, temperature effects condenser outlet in MED plant, and temperature effects condenser in cooling plant are evaluated. Minimum product cost rate is produced at a pressure of 0.28 bar but the maximum NPV occurs at 0.4 bar by varying LP turbine backup pressure.

As future actions the study should incorporate a thermal energy storage (TES) and backup, as well as, apply optimization tools.

Hybrid Solar Tower Pilot Plants for Co-Generation of Heat and Power for Brazilian Agro-Industry

Gilles Maag[1], Kimberly Tolentino de Oliveira[1], and Celso Eduardo Lins de Oliveira[1]

[1] University of São Paulo, Faculty of Zootechny and Food Engineering, Pirassununga, SP (Brazil).

Abstract

A currently undergoing project of two 100 kW_{el} central tower receiver concentrating solar power pilot plants for co-generation of heat and electricity for agro-industrial consumers is being presented. A strong agro-industrial sector and high solar resource make Brazil an ideal candidate for such a system. Grid-independent energy availability is ensured by hybrid firing of the plants' micro-turbines with bio-diesel. A steady-state-based model using DNI (Direct Normal Irradiance) values calculated from measured GHI (Global Horizontal Irradiance), using the DISC model, is applied to predict the yearly production of electricity of one of the plants and its degree of coverage of the associated slaughterhouse's requirements. An optical efficiency matrix of the heliostat field was obtained through ray-tracing simulations using the dedicated software tool Tonatiuh. Calculated yearly solar electricity production is 137 MWh, 76.5% of which can be used by the slaughterhouse, covering 48.5% of its consumption, the remainder being covered by bio-diesel. 23.5% of the produced solar electricity can be supplied to the grid. The yearly solar-to-electricity efficiency of the plant is 11.3%.

Keywords: c*o-generation, concentrated solar power, distributed generation, hybrid, solar tower, agro-industry, pilot plant.*

1. Introduction

CSP (Concentrating Solar Power) technology has been deemed a promising route for heat and power supply of agro-industrial processes in regions benefiting from high solar resource (> 2,000 $kWh \cdot m^{-2} \cdot y^{-1}$) as is the case for wide areas of Brazil, especially the North-East and Center regions. In regions of poor grid reliability and high electricity prices, CSP can be advantageous compared to other new renewable sources such as photovoltaics and wind power, by ensuring grid-independent energy availability thanks to thermal energy storage and hybridization with biofuels, and the possibility of co-generation of process heat. Previous studies considering implementation of solar energy applications in industry or agro-industry were able to individuate a significant potential for energy, process heat and cooling supply (Fuller, 2011; Mekhilef et al., 2011; Quijera et al., 2011a, 2011b; Tora et al., 2010).

To promote the use of CSP and demonstrating the functioning of the technology, the construction of two pilot-scale central tower receiver co-generation plants and their integration with agro-industrial facilities is currently undergoing in Pirassununga, São Paulo (case #1) and Caiçara do Rio do Vento, Rio Grande do Norte (case #2). Both plants use solar/bio-diesel hybrid-powered Brayton cycles, with 390 and 250 kW_{th} cavity receivers, respectively, operating with air at 1,173 K and 4.5 bar, powering 100 kW_{el} micro-turbines, as have been successfully operated and tested in past (Amsbeck et al., 2010). The solar field consists of 75 (case #1) and 47 (case #2) heliostats, each having a paraboloid-shaped, rectangular reflective surface of 8 m^2 area. A focal length of 30 m was chosen, close to the average distance to the receiver aperture (whose diameter is 0.9 m), situated at 25 m height. A design of the solar field and a process schematic are shown in Fig. 1.

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.04.22 Available at http://proceedings.ises.org

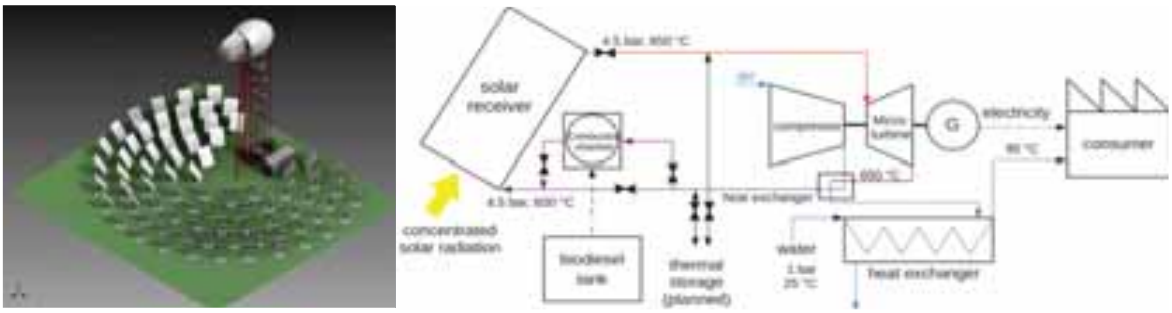

Fig. 1: Design of heliostat field for plant #1 (left), and process schematic of the two 100 kW_{el} hybrid solar tower plants (right).

Co-generation and tri-generation applications for microturbines (Buck and Friedmann, 2007; Ho et al., 2004; Kaikko and Backman, 2007), as well as solar turbine systems of various sizes and degrees of hybridization (Barigozzi et al., 2012; Le Roux et al., 2011; Schwarzbözl et al., 2006) have been proposed. The pilot plants are planned to provide energy and process heat supply to a school slaughterhouse (case #1) and a dairy factory (case #2). In this work, the performance of plant #1, in terms of electricity supply, is predicted using a numerical model based on 10 min steady-state intervals using DNI obtained from measured GHI data at the installation location.

2. Methodology

2.1. Solar resource

At the considered location (21°57' S, 47°26' W), only measured GHI data is available, in 10-min intervals, over a measurement period of 6 years. DNI values were estimated using the DISC model (Maxwell, 1987; Ineichen et al., 1992). From the individual data points, a probability distribution function f(DNI,m,h) is obtained for each discrete month m and hour h interval. Using a Monte Carlo numerical approach, the DNI at any time t is statistically determined using the following relationship:

$$\Re = \frac{\int_0^{\mathrm{DNI}(t)} F(\mathrm{DNI})|_{m,h}\, d\mathrm{DNI}}{\int_0^{\mathrm{DNI}_{\max}} F(\mathrm{DNI})|_{m,h}\, d\mathrm{DNI}} = \frac{\int_0^{\mathrm{DNI}(t)} F(\mathrm{DNI})|_{m,h}\, d\mathrm{DNI}}{1}, \quad \text{(eq. 1)}$$

with $F(\mathrm{DNI})|_{m,h}$ being the cumulative distribution function and$\Re$a random number [0;1[. The underlying assumption is that DNI values are statistically independent from those at previous times. This assumption, while differing from realistic conditions, is possible since steady-state conditions of the solar plant are assumed in each discretization interval (see Section 2.5.).

2.2. Solar resource

The radiative solar power incident on the heliostat field is then:

$$\dot{Q}_{\mathrm{field}}(t) = \mathrm{DNI}(t) A_{\mathrm{field}}, \quad \text{(eq. 2)}$$

with the reflective field area A_{field} = 602 m^2 and the radiative power entering the receiver cavity is:

$$\dot{Q}_{\mathrm{receiver,in}}(t) = \dot{Q}_{\mathrm{field}} \eta_{\mathrm{field}}\big(\alpha(t), \gamma(t)\big), \quad \text{(eq. 3)}$$

with $\alpha(t)$ and $\gamma(t)$ being the elevation and azimuth angle of the solar vector at time t, computed using the PSA Algorithm (Blanco-Muriel et al., 2001). A field efficiency matrix for 6 intervals $\Delta\alpha$ and 12 intervals $\Delta\gamma$ was computed using a collision-based Monte Carlo model of the heliostat field and the receiver aperture with the software Tonatiuh (Blanco et al., 2005). Linear interpolation was then used to determine $\eta_{\mathrm{field}}(\alpha,\gamma)$.

Net power absorbed by the receiver is:

$$\dot{Q}_{\mathrm{receiver,net}}(t) = \dot{Q}_{\mathrm{receiver,in}} - \dot{Q}_{\mathrm{reradiation}} - \dot{Q}_{\mathrm{conduction}}, \quad \text{(eq. 4)}$$

with

$$\dot{Q}_{\mathrm{reradiation}}(t) = \varepsilon \sigma T^4, \quad \text{(eq. 5)}$$

where T is the receiver temperature. Assuming the receiver efficiency

$$\eta_{\text{receiver}}(t) = \frac{\dot{Q}_{\text{receiver,net}}(t)}{\dot{Q}_{\text{receiver,in}}(t)}, \quad \text{(eq. 6)}$$

to be 90% at nominal operation point (21st December, solar noon, DNI = 1,000 W m^{-2}, denoted by subscript "N") allows to calculate $\dot{Q}_{\text{receiver,net,N}}$ at the same point using Eq. 6. If constant receiver temperature T = 1,173 K, and ambient temperature T_∞ = 298 K are assumed, $\dot{Q}_{\text{conduction}}$ and $\dot{Q}_{\text{reradiation}}$ are constant and can be determined using Eqs. 4 and 5 at nominal operation point. $\dot{Q}_{\text{receiver,net}}(t)$ can then be calculated at every time by Eq. 4. If the combined losses are higher than $\dot{Q}_{\text{receiver,in}}(t)$, receiver operation is stopped. Similarly, an upper threshold of $\dot{Q}_{\text{receiver,in,max}} = 1.05\dot{Q}_{\text{receiver,in,N}}$ is defined.

2.3. Consumer requirements

Based on their 2013 production and typical electricity consumption values per amount of produced meat, the consumer's yearly electricity consumption $W_{\text{consumer,}}$ is estimated to be 215 MWh$_{\text{el}}$. Assuming 30% of this value being for refrigeration (operated 24 hours-a-day) and 70% for plant operation during working hours (9 hours-a-day, 8am – 5pm), the following consumer power consumption is determined:

$$P_{\text{consumer}}(t) = \begin{Bmatrix} 54.4\ \text{kW}_{\text{el}}, \text{8am - 5pm} \\ 6.8\ \text{kW}_{\text{el}}, \text{5pm - 8am} \end{Bmatrix}. \quad \text{(eq. 7)}$$

2.4. Power block

No thermal losses are assumed between receiver and microturbine. The microturbine is assumed to have a constant thermal efficiency etaturbine = 0.28. Electrical power produced from solar source is then:

$$P_{\text{solar}}(t) = \dot{Q}_{\text{receiver,net}}\eta_{\text{turbine}}. \quad \text{(eq. 8)}$$

If the solar resource is insufficient to cover the consumer's requirement, the remainder is delivered by biofuel:

$$P_{\text{biofuel}}(t) = \begin{Bmatrix} P_{\text{consumer}}(t) - P_{\text{solar}}(t), \text{for: } P_{\text{consumer}}(t) \geq P_{\text{solar}}(t) \\ 0\ \text{kW}_{\text{el}}, \text{for: } P_{\text{consumer}}(t) < P_{\text{solar}}(t) \end{Bmatrix}. \quad \text{(eq. 9)}$$

On the other hand, if the solar resource exceeds the consumer's needs, and the legislative framework allows for it, solar electricity can be supplied to the grid:

$$P_{\text{grid}}(t) = \begin{Bmatrix} P_{\text{solar}}(t) - P_{\text{consumer}}(t), \text{for: } P_{\text{solar}}(t) \geq P_{\text{consumer}}(t) \\ 0\ \text{kW}_{\text{el}}, \text{for: } P_{\text{solar}}(t) < P_{\text{consumer}}(t) \end{Bmatrix}. \quad \text{(eq. 10)}$$

The field efficiency, reactor efficiency, and total plant efficiency are obtained as follows:

$$\eta_{\text{field}}(t) = \frac{\dot{Q}_{\text{receiver,in}}(t)}{\dot{Q}_{\text{field}}(t)}, \eta_{\text{receiver}}(t) = \frac{\dot{Q}_{\text{receiver,net}}(t)}{\dot{Q}_{\text{receiver,in}}(t)}, \eta_{\text{plant}}(t) = \frac{P_{\text{solar}}(t)}{\dot{Q}_{\text{field}}(t)}. \quad \text{(eq. 11)}$$

The solar fraction of total produced electrical energy, the solar fraction of the slaughterhouse's consumption, and the fraction of solar electricity delivered to the grid are defined as:

$$\varphi_{\text{solar}}(t) = \frac{W_{\text{solar}}(t)}{W_{\text{biofuel}}(t)+W_{\text{solar}}(t)}\ ,\ \varphi_{\text{consumer,solar}}(t) = \frac{W_{\text{solar}}(t)-W_{\text{grid}}(t)}{W_{\text{consumer}}(t)}\ ,\ \varphi_{\text{solar,grid}}(t) = \frac{W_{\text{grid}}(t)}{W_{\text{solar}}(t)}. \quad \text{(eq. 12)}$$

2.5. Yearly/monthly performance and discretization

Heat energy consumed Q or generated electrical work W over a given time lapse $t_0 \leq t \leq t_f$ – here: one month or one year - is obtained by integration. A numerical solution is obtained by discretization in time intervals Δt = 600 s, over which time-dependent variables are assumed to be constant.

$$\{Q, W\} = \int_{t_0}^{t_f}\{\dot{Q}(t), P(t)\}dt \approx \sum_{i=1}^{(t_f-t_0)/\Delta t}\{\dot{Q}_i, P_i\}\,\Delta t. \quad \text{(eq. 13)}$$

Finally, the capacity factors of the solar plant and of the power block are:

$$c_{\text{solar}} = \frac{W_{\text{solar}}}{P_{\text{solar,N}}(t_f-t_0)}\ ,\ c_{\text{power block}} = \frac{W_{\text{solar}}+W_{\text{biofuel}}}{(P_{\text{solar,N}}+P_{\text{biofuel,N}})(t_f-t_0)}. \quad \text{(eq. 14)}$$

3. Results

Figure 2 shows the electrical power generation from solar source and the consumer's consumptions for three different selected examples of day: (a) on 21st December, with DNI(t) > $DNI_{85\%}$, (b) on 21st March, with DNI(t) varying over the entire statistical distribution, and (c) on 21st June, with DNI(t) < $DNI_{30\%}$. In is shown that for days with very good solar resource, the entire daytime consumption of the slaughterhouse can be supplied by solar energy.

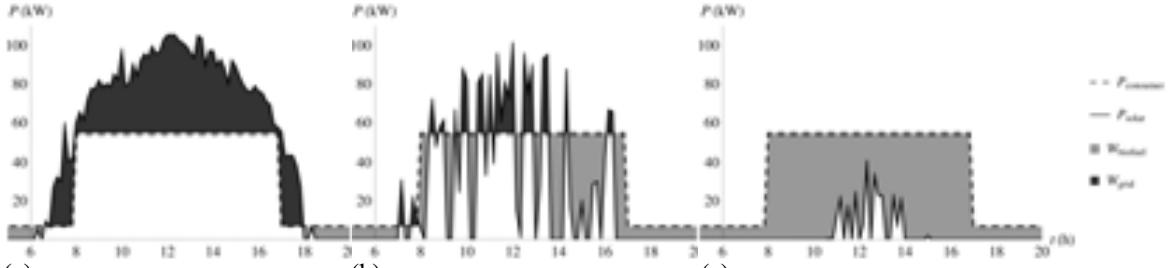

Fig. 2: Electricity generation from solar source and consumption by the slaughterhouse for: (a) Dec. 21st, DNI(t) > $DNI_{85\%}$; (b) Mar. 21st; (c) Jun. 21st, DNI(t) < $DNI_{30\%}$.

However, for less sunny days, such as case (b) or (c), significant amounts of biofuel are needed to supply the required electricity. Especially in case (b), the addition of TES (Thermal Energy Storage) could significantly decrease this amount.

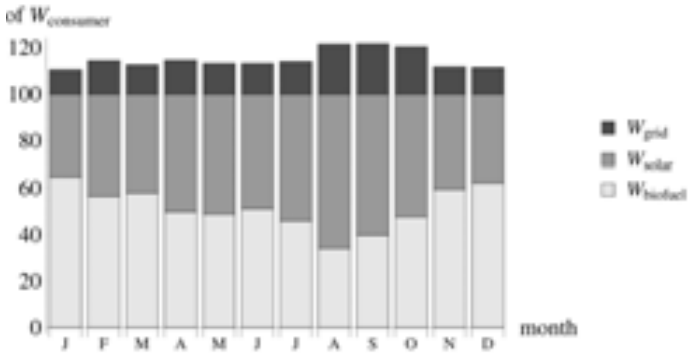

Fig. 3: Monthly source and utilization distribution of generated electricity in % of $W_{consumer}$.

This solar fraction is shown in Fig. 3 for each month, which shows the totally generated electrical energy per source and destination, as a percentage of total consumption by the slaughterhouse. The solar fraction of the slaughterhouse varies between 35.2% in January and 65.9% in August, with a yearly value of 48.5%. These relatively high solar fractions are favored by the hourly distribution of the consumer's consumption, which is significantly higher during daytime. The solar fraction of total electricity generated lies between January's 41.4% and August's 71.9%. The yearly average is 55.2%. These values are higher, since a yearly average of 23.5% of solar energy is supplied to the grid, since it exceeds the consumption. The addition of a TES system would allow to reduce the biofuel consumption, currently at 44,360 l y^{-1}, if bio-diesel (LHV = 32.3 MJ l^{-1}) were to be employed. The present analysis does not assume biofuel-generated electricity to be supplied to the grid. Depending on the biofuel type/cost and electricity market prices, this may however be the case.

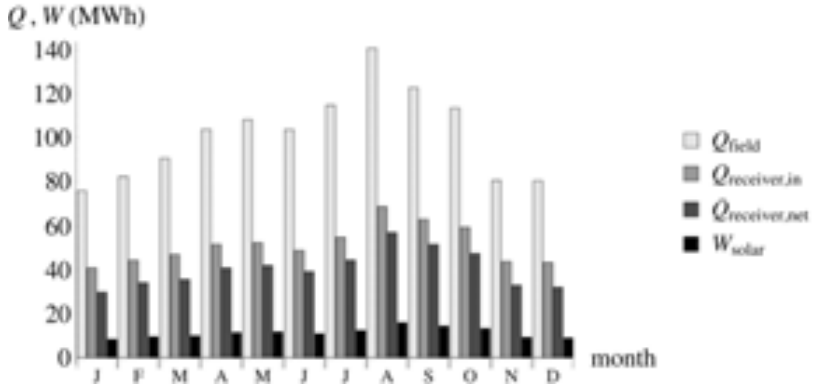

Fig. 4: Monthly energetic performance of solar plant.

Figure 4 shows the performance of the solar plant in terms of field, receiver, and power block energy losses. The solar-to-electrical energy efficiency of the plant is slightly varying seasonally (10.7% - 11.8%) due to differences in field efficiency. The yearly value is 11.3%. While this value is relatively low, also due to the small size and pilot nature of this plant, the total efficiency of the plant can be significantly improved by co-generation of power and heat, which will be done for this plant, but an analysis of which is out of the scope of this work. From both Fig. 3 and 4 it is observable that, due to the tropical location of the plant, the influence of astronomical factors (length of day, sun elevation) on plant performance is superseded by that of seasonal atmospheric phenomena (such as dry/wet period), resulting in poor summer performance, compared to late winter/early spring.

Tab. 1: Summary of nominal (on Dec. 21, solar noon, DNI_N = 1,000 W m^{-2}) and yearly plant parameters.

Nominal parameters			Yearly parameters		
$\dot{Q}_{field,N}$	kW	602.0	Q_{field}	MWh	1,216.5
$\dot{Q}_{receiver,in,N}$	kW	397.0	$Q_{receiver,in}$	MWh	621.0
$\dot{Q}_{receiver,net,N}$	kW	357.2	$Q_{receiver,net}$	MWh	489.9
$P_{solar,N}$	kW_{el}	100.0	W_{solar}	MWh_{el}	137.2
$P_{biofuel,N}$	kW_{el}	0.0	$W_{biofuel}$	MWh_{el}	111.3
$P_{grid,N}$	kW_{el}	45.6	W_{grid}	MWh_{el}	32.3
$\dot{V}_{biofuel}$	l/h	0.0	$V_{biofuel}$	l	44,360*
$\eta_{field,N}$		0.659	η_{field}		0.510
$\eta_{receiver,N}$		0.900	$\eta_{receiver}$		0.789
$\eta_{turbine,N}$		0.280	$\eta_{turbine}$		0.280
$\eta_{plant,N}$		0.166	η_{plant}		0.28
$\varphi_{solar,N}$		1.000	φ_{solar}		0.552
$\varphi_{consumer,solar,N}$		1.000	$\varphi_{consumer,solar}$		0.485
$\varphi_{solar,grid,N}$		0.456	$\varphi_{solar,grid}$		0.235
			c_{solar}		0.157
			$c_{power\ block}$		0.284
*if bio-diesel (LHV = 32.3 MJ l-1) is used.					

A summary of the nominal and principal yearly parameters of the plant can be found in Tab. 1.

4. Conclusions

A steady-state-based numerical model for the prediction of a solar/biofuel hybrid central tower receiver power plant was formulated and used to simulate the performance of a 100 kW_{el} pilot plant to be built in Pirassununga, São Paulo, Brazil, to deliver electricity and heat to a slaughterhouse. The results show a yearly generation potential of 137.1 MWh_{el} from solar energy. A yearly average of 76.5% of the produced solar electricity can be used by the slaughterhouse, covering 48.5% of its consumption. The remainder is covered by bio-diesel (44,360 l y^{-1}). The remaining 23.5% of the produced solar energy can be sold to the grid. Alternatively, TES would allow to postpone the generation of this energy fraction, allowing for a reduction in bio-fuel consumption. The energy balance of the solar plant shows a total plant efficiency of 11.3%. An influence of dry/wet season on the plant performance is observed, as opposed to the typical summer/winter effect generally observed at higher-latitude locations.

Solar Thermal Reduction of Metal Oxides as a Promising Way of Converting CSP into Clean Electricity on demand

I. Vishnevetsky*

Weizmann Institute of Science, Rehovot (Israel)

Abstract

Available main results of full endothermic reduction of different metal oxides with promising for solar thermochemical redox cycles for hydrogen production and electricity generation on demand are compared. New experimental results of preliminary non solar and solar tests related to an influence of such process parameters as the partial pressure of product gases, the rate of heating and cooling, temperature of metal vapours deposit sites on the morphology and purity of reduced metals, apparent kinetic parameters, undesired by-products formation and intensity of reoxidation are discussed. It is shown that pure reduced metals with strong metal-oxygen bond strength as aluminum and magnesium can be obtain in vacuum with fast preheating rate 150-200 degree per minute with temperatures and CO partial pressure at deposit sites no higher than 460-600°C and 0.07-0.1 mbar. Morphology of such reduced metals also strongly depends on deposit temperatures and can vary from conglomerates composed of submicron and nanocrystallines (50-60°C at water cooling deposit site), metallic flakes with spherical or flat micron and submicron particles (200°C about) to metallic plates (400-600°C). The main positive and negative results of different oxides reduction are described and promising ways of future desirable investigations are proposed.

Keywords: *metal oxides, reduction, solar thermal, clean electricity, CSP, accumulation of solar energy*

1. Introduction

The main challenge of solar energy industrial application is not stable DNI that strongly depends on time of day and year and whether conditions. So processes, which allow using on demand metals reduced periodically during sunny weather, are promising. Such metals accumulate significant amount of solar energy during the endothermic reduction step followed by the exothermic oxidation step of thermochemical redox cycle when this energy can be directly converted into electricity using the metal-air fuel cells or transferred to hydrogen fuel in the hydrolysis reaction. The main problems of hydrogen energetics are storage and transportation of hydrogen fuel. Here reduced metals can be transported to a place of electricity production on demand where hydrogen will be produced close to a fuel cell on a vehicle board or near other autonomous sources of heat and power.

Last 15-20 years R&D of solar redox cycles for hydrogen and electricity production attracts a considerable interest that reflects in a significant amount of publications Reviews of such investigations were presented by Fletcher (2001), Steinfeld and Palumbo (2001), Kodama (2003), Steinfeld (2005), Roeb M. et al. (2012) and Muhich C. et al. (2015). Features of solar thermochemical redox cycles for hydrogen production from water as a function of reactants' main characteristics were described by Vishnevetsky et al. (2011). Reduction step can be oriented to full or partial reduction especially for metals with higher valence. Partial reduction or splitting usually produces suboxides in a solid phase and need lower temperatures but demonstrates lower hydrogen productivity per unit mass of solid and usually suitable for continuous hydrogen production in a solar plant cyclically with reduction step (Hydrosol project; Konstandopoulos and Agrofiotis, 2006; Scheffe and Steinfeld, 2014), It does not solve the problems related to hydrogen storage and transportation especially at a solar plant area with concentrated optics. So only full reduction, that provides higher productiveness of redox cycle for hydrogen production and electricity on demand will be considerate here.

Before solar reactor design not solar tests help to realize preliminary investigation of forward, backward reactions and morphology of reduced metals at more stable than solar conditions. Not solar setups based on conventional electrical devices must be designed to simulate different heating and cooling facilities typical for solar reactors. Three possible options of preliminary not solar reactors were described by Vishnevetsky et al. (2005, 2010, 2011b).

First one provides one side heating usually typical for solar reactor. Thermal energy here spreads in the radial direction from the SiC tube, heated by an electric current till 400 A. Such reactor was used for forward reaction investigation when the main products are vapour of a reduced metal, CO and small amount of CO_2. Reaction progress leads to layerwise volatilization of reaction mixture described by Osinga et al.(2004) as shrinking packed bed.

doi:10.18086/swc.2015.04.23 Available at http://proceedings.ises.org

The second one imitates a solar tubular reactor (see Fig, 3d below) where a cylindrical electrical furnace simulates 2D-CPC. This reactor is used for reduction of metals with boiling point higher then reaction temperature when product appears in liquid phase and does not leave the reaction zone. Morphology of the reduced metal depends on the solidification conditions and will be discussed below.

The third one, presented in the experimental section (Fig.6), provides fast heating that especially important for reaction with complicated chemistry in order to avoid by-product formation during preheating. Wide range of temperature distribution on metal vapour deposit sites in IH reactor (Vishnevetsky et al., 2013) allows investigating not only forward but also backward reaction as function of temperature at deposit sites.

Solar thermal chemical reactors for full metal oxides reduction through thermal decomposition or carbothermic reduction are available today not only at laboratory but also at a pilot scale. They can be operated at atmospheric pressure and in vacuum condition. The progress achieved during last 15 years is widely presented in the literature.

Laboratory and pilot scales of a ‘‘rotating-cavity’’ solar reactors for the thermal dissociation of ZnO were developed in PSI and ETH, Switzerland. Continuously injected ZnO powder is distributed on the rotating inner cylindrical wall, accumulates solar flux and protects cavity wall from overheating. Such reactors can provide forward reaction temperature till 2300 K. The first 10 kW version was presented by Haueter et al. (1999) and the modernized version by Schunk et al. (2008). Dynamic modelling and 100 kW pilot scale demonstration were described by Villasmil et al. (2014a, 2014b) and by Meier, (www.stage-ste.eu). Smaller 1kW solar reactor with a rotating cavity, continuously injected ZnO particles and hemispherical glass window was developed in Processes, Materials, and Solar Energy Laboratory (PROMES-CNRS), France and described by Abanades et al. (2007).

One of the main technological challenges of window solar reactors is reliable protection of quartz window from reduced metal vapour deposition. One of such way to protect flat windows is creating vortex-type stable flow with significant flow rate of carrier gas which is induced toward the aperture, similar to a tornado flow configuration proposed by Kogan and Kogan (2002). Other way to protect window is two cavity reactor developed in PSI and ETH, Switzerland. 5 kW laboratory scale reactor was described in details by Wieckert et al. (2004) and Osinga et al. (2004a, 2004b). 300 kW pilot scale was presented by Wieckert et al. (2007). Its possible industrial futures proposed by Epstein et al. (2008). The main principle of two cavity reactor is heating of reaction mixture not by direct CSP but by secondary radiation from the solar absorber placed in the upper cavity which prevents the penetration of metal vapours to the quartz window from the lower cavity where reaction can be proceed at 1500 K. Such reactors can be used for batch tests and for continues feed operation. Testing of international SOLZINC 300 kW pilot scale batch reactor with packed bad mixture of ZnO with beech charcoal was tested in Solar Research Facility Unit of WIS, Israel, using beam down optic and biggest CPC in the Wold.

Presented ways of window protections do not solve this problem completely especially during a long continuous operation of a reactor. The other way is non-windowed solar reactors developed in WIS, Israel. Such reactors can be tubular (Adinberg and Epstein, 2004) or with ceramic crucible (Vishnevetsky et al., 2006). Here SiC ceramic parts (tubes or crucibles) are sealed and irradiated with indirect or direct CSP. Advanced SiC ceramics as Hexoloy SA, for example, must possess superior strength characteristics and high working temperature to withstand the high temperature gradient from the colder flange for safe sealing to the hot reaction zone. Such 30 kW laboratory scale reactors were tested in the WIS Solar Tower using parabolic mirror and CPC as second and third concentrators after heliostats.

Light elements with strong metal oxygen bond strength need very high temperature for carboreduction of their oxides at atmospheric pressure. As it is well known according Le Chatelier’s principle vacuum conditions can reduce significantly temperatures of such reactions but need additional energy consumption for pumping. Different energy and temperature estimations as function of pressure were presented by Vishnevetsky and Epstein (2015). This 10 kW vacuum solar reactor was developed and tested in WIS, Israel, and presented below in Fig.7. Stoichiometric reaction mixture (a few tens of grams) of oxides with beach charcoal was compressed to pellets 1 cm diameter using 10wt.% of sugar as a binder. The main test results obtained during magnesia, alumina and boria solar carboreduction in vacuum are presented by Vishnevetsky et al. (2012, 2013, 2014, 2015). According preliminary investigation a sharp temperature drop from the hot reaction zone to the deposit site is necessary in order to avoid the recombination during metal vapor deposotion. So design of this vacuum reactor with spherical quartz window was accompanied by numerical simulation of temperatures and stress distribution (Vishnevetsky et al., 2012, Ben-Zvi, 2013), that was confirmed by good resistance of the quartz window during tests and measuring temperature values which changed from 1900 K in the reaction zone till 320 K about at water cooling deposit site. This reactor was modified later by adding the second option as uncooled deposit area to study vapour deposition at higher temperature for getting liquid reduced metal.

Miniature (1g reactant) solar vacuum reactor was also developed and tested in CNRS-PROMES, France (Abanades et al., 2008 and Chambon et al., 2010).

New available solar and not solar test results are presented below. It includes effecting of such process parameters as the partial pressure of product gases, the rate of heating and cooling, temperature of metal vapours deposit sites on the

morphology of reduced metals, on apparent kinetic parameters, undesired by-products formation and intensity of reoxidation. The main challenges and possible ways to avoid these problems also will be discussed.

2. Thermodynamics

The main equations of thermochemical redox cycle for full oxides reduction are thermal carboreduction (Eq.1a) or thermolysis (Eq.1b) followed by hydrolysis (Eq.2) or oxidation in metal-air fuel cells (Eq.3) of fully reduced metals:

$$Me_xO_y + yC = xMe + yCO \quad \text{(eq.1a)}$$

$$Me_xO_y = xMe + \left(\frac{y}{2}\right)O_2 \quad \text{(eq.1b)}$$

$$xMe + yH_2O = Me_xO_y + yH_2 \quad \text{(eq.2)}$$

$$xMe + 0.5yO_2 = Me_xO_y \quad \text{(eq.3)}$$

Partial reduction of oxides can be realized for metals with higher valence at lower temperatures, but it is not considered here as hydrolysis/oxidation of suboxides have lower productiveness.

As it is well known the reaction summarized in Eq.1a is not solid-solid reaction (Berman amd Epstein, 1999; Byung-Su Kim et all., 2006) but gas-solid reaction (Me_xO_y+yCO=xMe+yCO_2) with intermediate gas product CO_2. Depending on the reaction temperature, CO_2 is fully or partially transformed to CO through the Boudouard reaction (C+CO_2=2CO). For carboreduction processing at atmospheric pressure Boudouard reaction usually is responsible for the reaction rate. Full conversion of CO_2 to CO occurs at 1100 -1200°C or lower temperatures when reduced metal has a catalytic effect as tin, e.g. (Epstein et al., 2010). In vacuum condition temperature of full conversion in Boudouard reaction is 600-700°C and CO_2 is usually fully transforms to CO at higher temperatures suitable for carboreduction of alumina and magnesia as an example. During carboreduction of light elements with complicated chemistry a series of more solid-gas reactions with intermediate suboxides and oxicarbides formation takes place.

All thermodynamic estimations were made using A. Roine HSC Chemistry Computer Code. According data presented in Fig.1 temperature of full conversion strongly increases with metal-oxygen bond strength as atom mass decreases and according Le Châtelier's principle can be reduced under vacuum conditions. In the other hand the lighter metals are more productive for hydrogen production per unit mass of a reduced metal. Also must be taken into account that despite the fact that thermolysis is free of CO, its reduction temperature is significantly higher than carboreduction temperature, and can be implement only at lower pressure of product gases that could be realized or at atmospheric pressure using significant amount of carrier gas, or at vacuum conditions. Figs.2b and 2c indicate that reaction temperature of ZnO carboreduction at atmospheric pressure is lower than ZnO thermolysis temperature at 1 mbar. Also it is usually impossible to prevent fully the reoxidation of reduced metals by pure oxygen. For today conversion achieved during ZnO thermal dissociation is 40% about (see section 4.1), whereas conversion of ZnO carbothermal reduction is 85-95% according XRD quantitative analysis (Wieckert et al. 2007; Vishnevetsky and Epstein, 2007). On the other hand, if carbon in Eq.1a was produced from bio source as charcoal, for example, its using can be considered as positive from economic and ecological point of view because product CO is an additional fuel and resulting CO2 will absorbed by plants, which will be used later for new charcoal production.

Besides advantages regarding high hydrolysis productivity of lighter elements with high metal-oxygen bond strength (Vishnevetsky et al. 2008, 2011a; Rosenband and Gany, 2010) their disadvantage is higher reduction temperature at atmospheric pressure that need vacuum conditions (compare ZnO and MgO carboreduction in Fig.2c, d) but also by-products formation during preheating of reactant mixture on the base of elements with higher valence, as shown in Fig.2e, f. Here it is possible to compare thermodynamics of carbothermic reduction of oxide with simple (ZnO, MgO) and complicated (Al2O3, B2O3) chemistry.

Another feature of carboreduction or splitting of oxides is output of CO or O_2 gases which usually contact with reduced deposited metals at the exit of the reactor that provokes reoxidation in backward reaction especially with oxygen. Possible way to avoid this future is the presence in the reaction zone of some amount of easily oxidizable element whose oxide is not gaseous but solid. Examples of equilibrium diagram for such reaction for Zn reduction, as an example, are presented in Fig.3

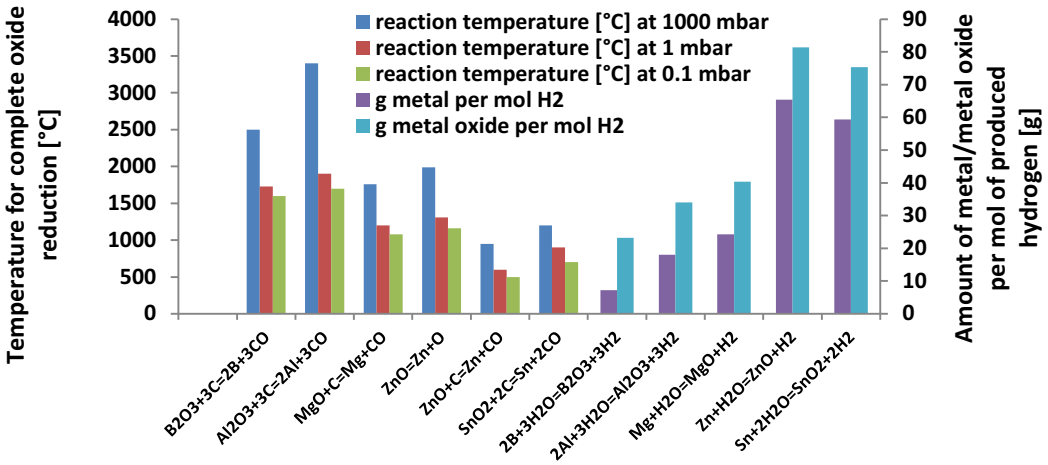

Fig.1: Thermodynamic estimation (Antti Roine HSC Chemistry Computer Code) of temperature for complete oxide reduction and productiveness of hydrolysis reaction

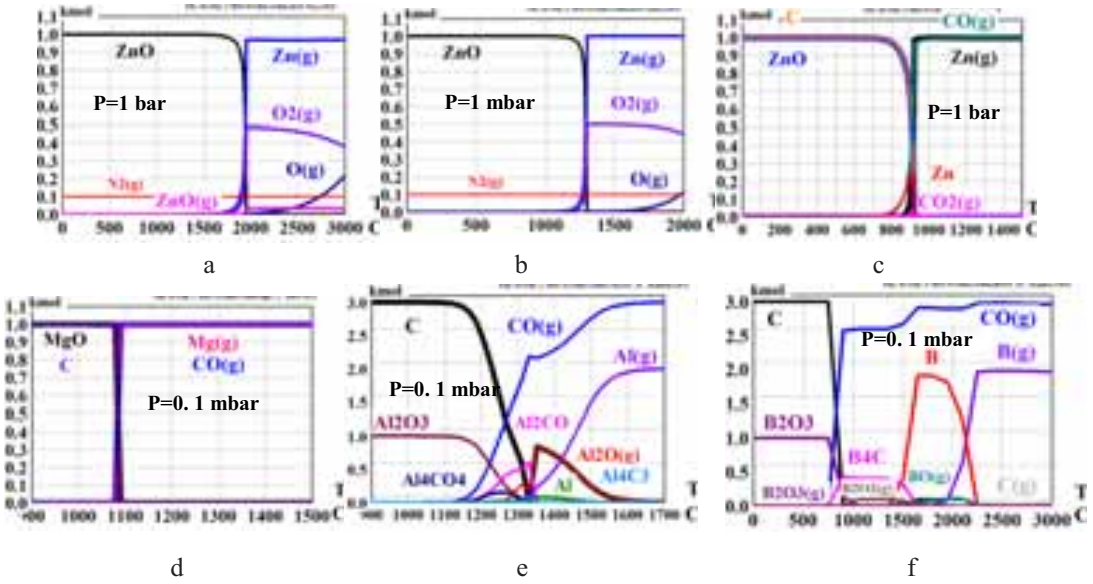

Fig.2: Equilibrium diagrams of (a) ZnO splitting at atmospheric pressure and (b) in vacuum; carboreduction of (c) ZnO at atmospheric pressure and (d) magnesia, (e) alumina, (f) boria in vacuum

As it is possible to conclude addition to the ZnO powder some amount of easily oxidizable element can significantly decrease reoxidation of reduced zinc. Of course, Molybdenum is not the best candidate for this but a small amount of light easily oxidizable element as boron, for example, can solve the problem catching the oxygen in the hot reaction zone made of a high temperature ceramic in a solar reactor. Equilibrium diagrams in Fig.3 (c, d) demonstrates that only 8.8 weight % of boron not only prevents Zn reoxidation but also significantly decreases temperature of zinc vapour production even at atmospheric pressure (compare Fig.3 c, d with thermal splitting in Fig.2 a, b). Bororeduction thermodynamically occurs at all temperatures and boron, unlike Mo, presents in the equilibrium diagram in oxidized form together with pure zinc also at low temperatures. In this case separation of reduced zinc from boron oxide can be realized during vaporization of Zn at temperatures higher than 900-1000°C at atmospheric pressure when boron oxide still liquid. If reaction proceeds at higher temperatures when Zn is in gas form, liquid B_2O_3 rests in a hot reaction zone. This process is free of CO_2 and could provide pure zinc solving the problem of Zn recombination because of instead gas product O_2 or CO there is liquid B_2O_3 which does not leave the hot reaction zone together with Zn. So following experiments of ZnO decomposition with small addition of pure boron powder could be very promising. Here it must be marked that such process is more suitable for recovering zinc oxidized in zinc-air fuel cells whereas for hydrogen production pure boron could be used itself. Boron oxide produced here can be used in different industries such as metallurgical, atomic energy, electronic and others or reduced to boron using solar energy.

Thermodynamic analysis indicates that bororeduction of magnesium oxide has no advantage over its carboreduction because of by-products as magnesium borides formation and a presence of boron oxides and suboxides in gaseous phase.

3. Experimental results and discussion

3.1. Morphology of carbo reduced metals depending on conditions of their vapors condensation or liquid product solidification

As it is possible to conclude from available results, metal hydrolysis can be realized using fine powder (Vishnevetsky et al. 2007, 2008, 2009, 2011a and Epstein et al, 2010) or liquid metal (Berman and Epstein, 2000). 10 μm conglomerates composed of micron and submicron particles have higher productivity compare with powder with larger particles or bubbling of liquid metal with water vapor.

Reduction of metals with boiling point higher than reaction temperatures provides product in a liquid phase which does not leave the reaction zone. Morphology of the reduced metal depends on the conditions of solidification (Vishnevetsky et al., 2010) and can present big conglomerates (Fig.4 a) or micron and submicron particles solidificated on the inert supports as 10 μm alumina particles, for example (Fig.4 b, c). Conversion of reduced tin was about 90%.

When reaction temperature is higher than boiling point of reduced metals in reaction conditions their morphology depends on quenching procedure. Quencher/cooler on the base of Cyclone with cold purge gas was used in SOLZINC pilot plant (Wieckert et al., 2007). It allows providing zinc powder with conglomerates till 10-20 μm composed of micron and submicron particles (Fig.5 a, b) and purity 85-95% as was mentioned above.

Morphology of metals deposited on surfaces of cold zone installed after hot reaction area (Figs.6, 7) strongly depends on temperature of a deposit site and on CO partial pressure at the deposit area. Deposits on water cooled surfaces usually represent powder with flakes deposited on sites with temperatures 50°C about or thin metallic films located on outer layers of a deposit or in a transition area from the hot to cold zone.

Fast cooling of Al vapors leads to formation of conglomerates composed of nanocrystallines, typical for flakes (Fig. 8 a, b) or composed of submicron spherical particles of Al (Fig. 8 c, d, e). Vacuum reactor (Fig. 7a) with water cooling deposit tube at 50-60°C was modified by adding the second option as uncooled deposit area to study vapour deposition at higher temperature for getting liquid reduced metal (Fig. 7b). Depending on insulation thickness and weather conditions temperature of the stainless steel tube can change from 340°C till 680°C. The best results with Al weight percent 97% according EDS were available in tests with hotter deposit site at temperature no higher than 460°C. Photo of metal plates (bright side contacting with the steel tube) collected from the lower cup and SEM image of outer matte side are presented in Fig. 8 f, g.

Maximal total weight conversion of reduced Al was 90% at avg./max. CO partial pressure 0.04/0.07 mbar and avg./max. reaction temperature 1525/1600°C. Increasing CO partial pressure till 0.2/0.4 mbar leads to conversion decreasing till 35-45%.

SEM images of magnesium deposited at sites with different temperatures are presented in Fig.9. Here also fast cooling of the magnesium vapor on the water cooled tube leads to formation of big conglomerates (Fig,9 a, b) composed by submicron crystals with 100% Mg contents (Fig.9 c). Deposit on transition area from hot to water cooled zone with temperature 200°C about composed by metallic flakes also arranged to spherical forms (Fig.9d). SEM image of inner layer with 100wt.% Mg contents deposited on place 6 in IH reactor (Fig.6b) with temperature 600°C about is presented in Fig.9e and the outer layer of the deposit from the same place with 70wt.% of Mg and 30% of MgO in Fig.9 f. Total conversion of Mg reduced in the solar vacuum reactor at avg./max P_{CO}=0.03/0.07 mbar and avg./max $t_{reaction}$=1535/1575°C was 90-95% related to reacted magnesia and 60-65% related to loaded magnesia because of significant amount of non-reacted sintered conglomerates (Fig. 10).

3.2. Apparent activation energy as a function of CO partial pressure.

Unlike true activation energy of the reacting molecules apparent activation energy does not have such physical meaning and can depend on many parameters of a specific setup, including the partial pressure of participating gases that can be found in the literature (Ruiz and Delmon, 1992, as an example).

According LeChatelie principle CO partial pressure is a main parameter responsible for a rate of carboreduction reaction at given temperature. As it was mentioned above in Thermodynamics section such reactions realized as gas solid reactions where CO_2 is the main intermediate gas product that is usually fully transforms to CO at high temperatures suitable for carboreduction of alumina and magnesia.

When one of the main reaction product is gas, the rate of reaction can be estimated through its initial flow rate (Vishnevetsky and Epstein, 2009) related to amount of suitable elements in loaded reactants. Reaction rate of alumina and magnesia carboreduction was estimated as initial conversion rate through the CO release. The main measured parameters that must be taken into account are CO flow rate, reaction temperature and CO partial pressure (Fig.11). As it is possible to see, CO release in vacuum conditions presents in two peaks: CO in first peak is related to carbon and oxygen in sugar as a binder and in charcoal impurities and CO in second peak is a product of the reaction under consideration. First peak usually accompanied by small amount of H_2, CH_4 and CO_2 (Vishnevetsky et al., 2014). When carboreduction is carried out at atmospheric pressure at lower temperatures (ZnO and SnO_2 as an example) significant amount of CO_2 presents also in the main peak (Wieckert et al., 2007; Epstein et al., 2010) that also must be taken into account for initial conversion rate estimation. Starting of the second peak developing in vacuum condition is presented in Fig.11c, where τ_0 is time of the second peak onset and other τ_i (i=0,1, 2…) is times when CO flow rate develops. Conversion during any initial time period related to loaded moles of oxides can be calculated through release of CO and CO_2 (if any) using Eq.4 and initial conversion rate according Eq. 5 where initial amount of released oxygen atoms is divided to total amount of oxygen atoms in loaded oxide. Taking into account the short time difference between τ_i and τ_{i+1} related temperature and pressure can be simply averaged between τ_i and τ_{i+1}.

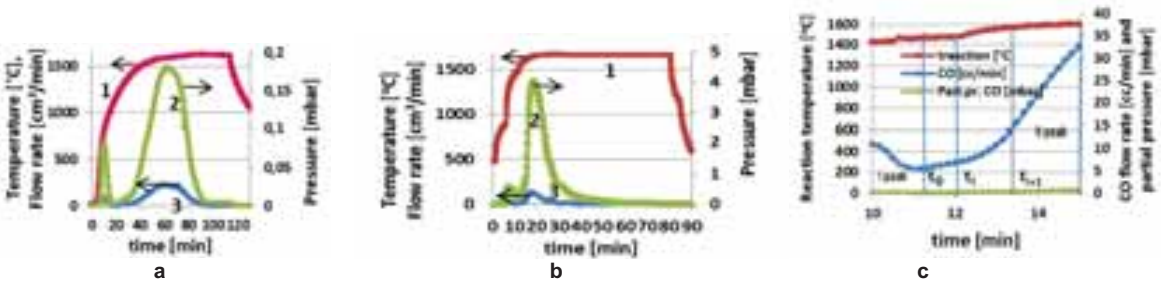

Fig.11: Main reaction parameters 1- Reaction temperature, 2 – CO partial pressure, 3 CO flow rate (alumina case): (a) batch solar reactor with slow preheating; (b) IH reactor with fast preheating; (c) second peak starting

$$Conversion = \frac{\text{mols CO} + 2*\text{mols}CO_2}{y*\text{loaded mols } Me_x O_y} \quad \text{(eq.4)}$$

$$\frac{dConv._{initial}}{d\tau} = \frac{\int_{\tau_i}^{\tau_{i+1}} \left(F_{CO}(\tau) + 2*F_{CO_2}(\tau)\right) d\tau}{22.4*10^3*y*\text{loaded mols}Me_xO_y*(\tau_{i+1} - \tau_i)} \quad \text{(eq.5)}$$

Examples of Arrhenius plots for different averaged CO partial pressure are presented in Fig.12a. As it is possible to conclude higher pressure leads to higher apparent activation energy and higher pre-exponential factor which is proportional to the total number of reactants collisions. The last one confirms once again that oxide reduction with carbon has solid gas character (oxide with CO which is generated in Boudouard reaction of product CO_2 with loaded C). Apparent activation energy of alumina and magnesia carboreduction as function of CO partial pressure is presented in Fig.12b. It is possible to conclude that E_a sharply decreases at pressure less than 0.1 mbar and smoothly increases with higher pressure.

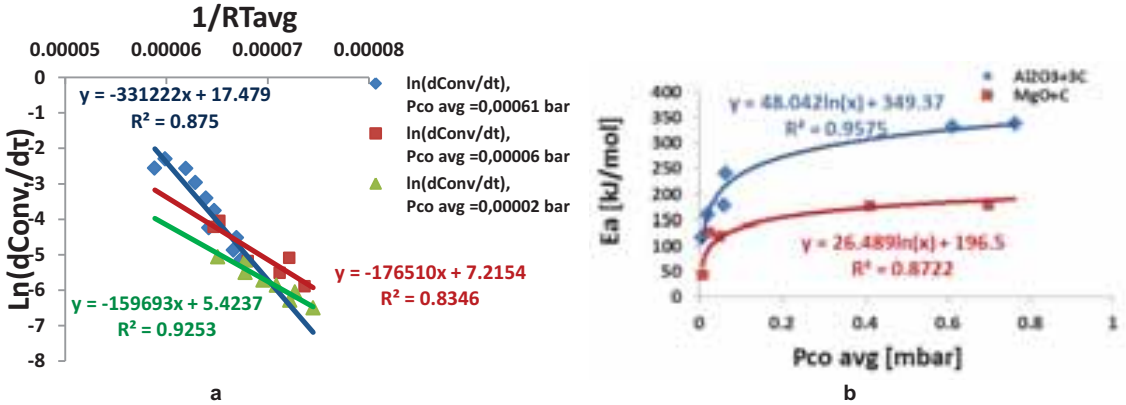

Fig.12: (a) Examples of Arrhenius plots for different averaged CO partial pressure (alumina case) and (b) apparent activation energy as function of averaged CO partial pressure (alumina and magnesia case)

4. Current challenges of metal oxides thermal reduction and possible ways to overcome them

4.1 Recombination of Zn produced by thermal dissociation

As it is mentioned in Thermodynamics section, one of the main challenges of thermal splitting is recombination of reduced metals in backward reaction. The results achieved using laboratory rotating cavity reactor (Schunk et al., 2008) was Zn content in filtered particles at the range from 18.7 to 41.7 mole% of pure Zn and tests results of pilot scale reactor (Villasmil et al., 2014b) also provide only12–49% depending on the flow rate of Ar injected to a quench area. CNRS-PROMES reactor (Abanades et al., 2007) provide 70% Zn yield but using small cavity with ID=20 mm, whereas no pure zinc was produced when cavity ID was 30 mm.

ZnO thermal dissociation also was tested in the vacuum solar reactor with water cooling deposit site presented in Fig.7a by replacing all graphite parts to the same size parts made of a high density zirconia without cover that allows reaching 1800°C in reaction zone with loaded 15-20g ZnO pellets. Total maximal pressure was about 1 mbar and O_2 partial pressure is about 0.1 mbar. Full Zn conversion was no higher than 46% whereas according XRD quantitative analysis in some samples Zn wt.% reached 58-73%.

It was also demonstrated by Chambon at al.(2010) that in CNRS-PROMES vacuum reactor where 1g sample pellet was placed close to the refrigerator (on the distance of 4 cm only) it was possible to increase the mole fraction of reduced zinc from 10% to 75% decreasing total pressure from 20 kPa to 5 kPa.

After ZnO thermal dissociation tests in IH vacuum setup (Fig.6) with molybdenum crucible it was possible to get from deposit place 7 (with not very low temperature, about 300°C) bluish deposit with 96-100 wt. % Zn content that was about 75% of all Zn in loaded ZnO (FIg.13). Tests were run with 10g ZnO pellets at temperatures 1400-1500°C and partial pressure of oxygen was negligible, less than 0.004 mbar.

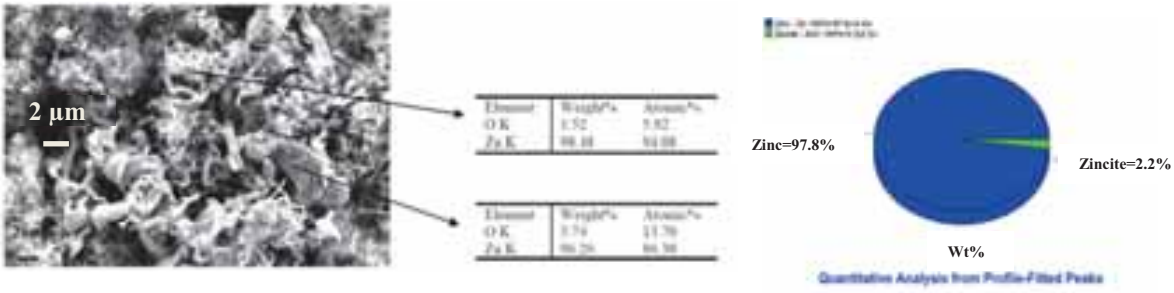

Fig.13: (a) SEM image with EDS analysis and (b) XRD quantitative analysis of the bluish deposit at the low part of zirconia tube with 97.8 wt.% of Zn

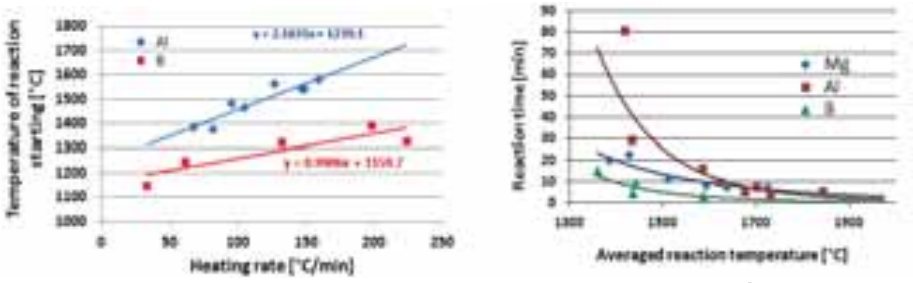
At the same time the surfaces of molybdenum crucible and support tube were covered by MoO_2 with small addition of $Zn_2Mo_3O_8$. Zn recombination was not happened because of Mo cached the most of oxygen already in hot zone that is confirmed by thermodynamics (Fig. 3a, b) where instead gases Zn and O_2 (Fig.2a, b) only Zn(g) and MoO_2 are presented as reaction products.

4.2 By-product formation and possible oxide sintering at slow heating rate in batch reactors

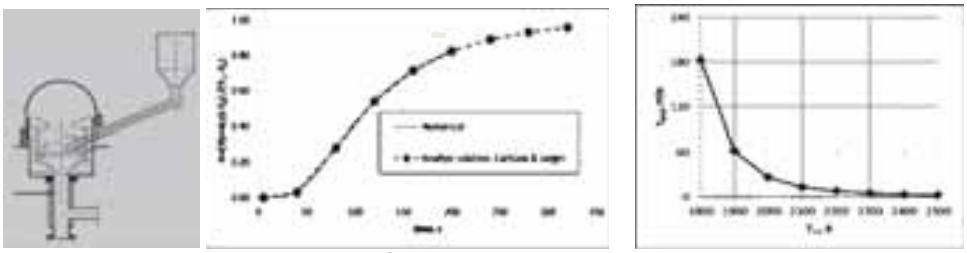
Thermochemical batch reactor is the most convenient and safe for using concentrated solar energy especially in vacuum conditions. But the main challenge of batch reactor is relatively slow heating rate of the reactant loaded into a cold reactor. As it is possible to conclude from data in Fig.14a (details are presented by Vishnevetsky and Epstein (2015)), slower heating rate leads to reaction starting at lower temperature that provokes by-product formation in processes with complicated chemistry (Fig.2 e, f). As a result the reaction occurs at lower average temperature. Reaction time is longer (Fig.14b) that also could provoke possible reactant sintering and a significant amount of unreacted residual (Fig.10).



a b

Fig.14: (a) Temperature of reaction starting as function of the preheating rate and (b) reaction time at half the height of the CO peak as a function of the averaged reaction temperature.

Possible way to circumvent these problems is using a feeder reactor when reaction pellets doses by a vibrating vacuum feeder to a preheated vacuum reactor (Fig.15 a). Preheating and consumption times of reaction pellet dosed to the preheated reactor were estimated by Ben-Zvi (2015).The main results are presented in Fig.15b, c.



a b c

Fig. 15: (a) Solar reactor with vibrating vacuum feeder; (b) preheating and (c) consumption time of reactant pellets as function of reaction temperature (alumina case, P_{COavg}=8.17E-4 bar Ea ~337 kJ/mol)

According numerical and analytical estimation for alumina case, as an example, (Ben-Zvi, 2015) preheating time (Fig.15b) of 10 mm diameter spherical pellets is 5-6 min in the reactor with a feeder (1D transient conduction with initial pellet temperature T_0 =300K and prescribed outer temperature, T∞.) whereas in the batch reactor it is need one hour to reach the desirable temperature in the reaction zone (Fig.11a). In contrast to the preheating rate, pellets consumption time in a feeder reactor (Fig.15c) depends on temperature in the reaction zone and can be comparable with the pellets consumption time in a batch reactor (1-1.5 hours at 1600°C).

5. Conclusions

- Solar and non-solar setups developed during last 10-15 years for investigation of full reduction of metal oxides promising for solar thermochemical redox cycles for hydrogen production on demand are briefly described.
- Morphologies of reduced metals with different metal oxygen bond strength and boiling points were presented for various quenching conditions.
- Analyses of the purity of reduced metals with strong metal-oxygen bond strength as aluminum and magnesium show that metals with 95-100% purity and total conversion of reacted oxides at the level of 90-95% is possible when avg./max. CO partial pressure and temperature at the cold deposit area no higher than 0.07/0.2 mbar and 460°C in the case of aluminum and 0.1/0.35 mbar and 600°C in the case of magnesium. Rising of temperature and/or pressure results in recombination of reduced metals.
- Morphology of deposited aluminum and magnesium also strongly depends on deposit temperatures and can vary from conglomerates composed of submicron and nanocrystallines (50-60°C at water cooling deposit site), metallic flakes with spherical or flat micron and submicron particles (200°C about) to metallic plates (400-600°C).

- Apparent activation energy of alumina and magnesia carboreduction was estimated through an initial conversion rate as function of CO partial pressure. It was shown that this energy sharply decreases at pressure less than 0.1 mbar and smoothly increases with higher pressure.
- It was shown that significant recombination by oxygen of thermal dissociated Zn can be prevented by presence of an easily oxidizable element. Deposits with 98-99% pure zinc were available after tests with Mo crucible as sample holder in the IH reactor. It was demonstrated thermodynamically that small amount of boron could serve as the best easily oxidizable agent. Further confirmation in future experiments is required.
- It was experimentally confirmed that slow preheating rate in the batch vacuum reactor leads to decreasing temperature of reaction starting and averaged reaction temperature, resulting in undesirable by-product formation in forward reactions with complicated chemistry and possible sintering of oxides during longer preheating and reaction time. The possible way to prevent such disadvantage is using the reactor with a vacuum feeder. Preheating and consumption time of reactant pellets dosed to the hot reactor are estimated by a numerical simulation.
- Desirable following investigation of bororeduction of oxides with relatively heavy metal atoms and R&D of a vacuum reactor with vibrating vacuum feeder are proposed.

Abstract

A windowed fluidized bed reactor prototype was studied and developed for solar thermochemical gasification of coal cokes with steam and CO_2. The windowed fluidized bed reactor is assumed to be combined with a newly developed beam-down optics. Recently, quartz sand was employed as a chemically-inert bed material for the fluidized bed and worked as a thermal transfer/storage medium inside the reactor for coke gasification under direct light irradiation. In order to design a laboratory-scale prototype windowed fluidized-bed containing of quartz sand and coke particles, the reactor model of fluidized bed was made from a transparent acrylic resin to allow us to observe a fluidizing particle through the sidewall of the reactor body; a branching tube is equipped with the sidewall of the reactor to continuously supply coal-coke particles from a screw feeder. In the present study, in order to evaluate fluidization performance of coal-cokes, the pressure loss between the inlet and outlet gases was examined, and descending coal-coke particles on the sidewall of the reactor was observed in the reactor model. The moving velocity and distance of descending particles from the top to bottom of fluidized bed were measured by the visual observation of the tracer particles on outside wall of reactor model.

1. Introduction

Coal gasification using CO_2 or steam as an oxidant is a highly endothermic process at high-temperature, and is used to produce solar-hybrid syngas (solar-fuel) composed of a mixture of hydrogen and carbon monoxide. Solar gasification is a promising key technology for thermochemical conversion, which can produce clean gaseous fuels from solid carbonous material by using high-temperature solar heat [1-6]. The greatest advantage of solar-driven gasification is the storage of a significant fraction of solar energy as the chemical energy of the synthesized fuel molecules, and the fuels can reduce the net CO_2 emissions to the environment and conserve fossil fuels.

$$CH_n(coal) + H_2O(l) = CO + (1+n/2)H_2 \qquad \Delta H_{298K} = 175\ kJ/mol \qquad (1)$$

$$CH_n(coal) + CO_2 = 2CO + n/2H_2 \qquad \Delta H_{298K} = 172 kJ/mol \qquad (2)$$

The calorific value of coal or carbon feed can theoretically be upgraded by about 45% when the process heat required to drive the reactions (1) and (2) is provided by concentrated solar radiation. Syngas derived from solar energy can be thermochemically converted to hydrogen via water–gas shift reaction; to liquid hydrocarbon fuels such as diesel, kerosene, and gasoline via Fischer–Tropsch synthesis; or directly used as a combustion fuel for power generation.

The present authors in Niigata University study a windowed reactor prototype using fluidized bed of coal cokes particles, and have proposed to combine the windowed solar chemical reactor, such as a solar gasifier, with a newly developed solar reflective tower or beam-down optics [7-10]. Recently, quartz sand was employed as a chemically-inert bed material for the fluidized bed and as a thermal transfer/storage medium inside the reactor for coke gasification under direct light irradiation. In order to design a laboratory-scale $30kW_{th}$ prototype windowed fluidized-bed containing of quartz sand and coke particles, the reactor model of fluidized bed was made from a transparent acrylic resin to allow us to observe a fluidizing particle through the sidewall of the reactor body; a branching tube was equipped with the sidewall of the reactor to continuously supply coal-coke particles from a screw feeder [11].

doi:10.18086/swc.2015.04.24 Available at http://proceedings.ises.org

In the present study, in order to evaluate fluidization performances of coal-cokes, the pressure loss between the inlet and outlet gases was examined, and descending coal-coke particles on the sidewall of the reactor was observed in the reactor model. The moving velocity and distance of descending particles from the top to bottom of fluidized bed were measured by the visual observation of the particles on outside wall of reactor model.

2. Experimental procedure

2.1. Preparation of quartz sand as a bed material

Quartz sand was purchased from Japan Pure Chemical Co., Ltd. The quartz sand was sieved using mesh screens into four particle size ranges: 100–200 μm, 200–300 μm, 300–500 μm, and 500–700 μm; the quartz sand of 300–500 μm size was used as the chemically inert bed material for investigation. Real and bulk densities of quartz sand at 25 °C are 2.6 g cm^{-3} and 1.3 g cm^{-3}, respectively. The loading amount of quartz sand was 2000 g. The layer height/layer diameter ratio (L/D ratio) was 1.17.

2.2. Fluidized-bed reactor cold model (FBCM)

Fig. 1 shows schematic view of a fluidized bed reactor cold model (FBCM) with a transparent quartz window at its top. The reactor model of laboratory-scale prototype windowed fluidized-bed containing of quartz sand and coke particles was fabricated. The FBCM was made from a transparent acrylic resin to allow us to observe a fluidizing particle through the sidewall of the reactor body; a branching tube was equipped with the sidewall of the reactor in order to continuously supply coal-coke particles from a screw feeder. In the present study, an orifice type distributor was newly designed in order to enhance an internal circulation of fluidizing particle; a number of pores were densely arranged in a center of the distributor, while pores were sparsely located in a circumference of the distributor [11].

Fig. 2 shows photographs of the FBCM. A windowed fluidized-bed reactor can prevent direct contact, ensuring an interspacing gap between the coal-coke particles and window. It assumed that concentrated solar radiation passes downward through the window and directly heats the FBCM of fluidizing particles. A draft tube is located at the center of the fluidized particle bed inside the reactor, and is possible to remove itself in order to evaluate the impact on internal circulation of quartz sand. For the internally-circulating fluidized bed (ICFB) with draft tube, inlet gas (air in this study) is allowed to flow into the draft tube and annulus region between the internal tube and reactor wall. In this reactor design, it is expected that the fluidizing particles are always transported upward in the draft tube and move downward in the annulus region. This forced circulation pattern will enable solar energy to be transferred from the top to the bottom of the fluidized particle bed; the bed temperature remains high and homogeneous, thus preventing localized overheating of some areas within the bed. Therefore, by directly heating the bed, the solar gasification will occur in the fluidized bed inside the reactor.

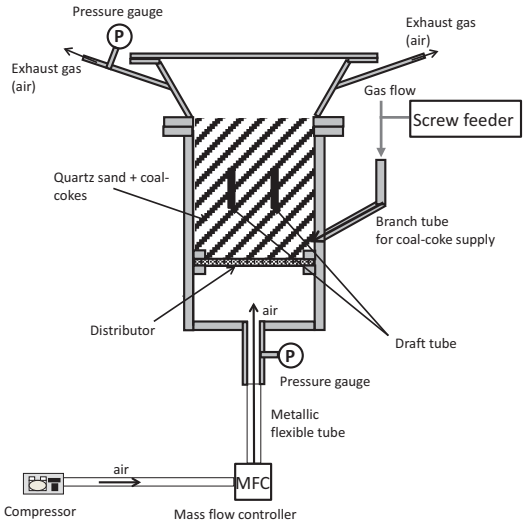

Figure 1 Experimental set-up for fluidization performances of mixture of the coal-coke and quartz sand using the reactor model of fluidized bed reactor.

Figure 2 Photograph of experimental system using fluifdized bed reactor conbined with screw feeder for coal-coke supply.

2.3. Fluidization performance testing using the designed reactor model of fluidized bed reactor

Fluidization performances of mixture of the coal-coke and quartz sand using the reactor model of fluidized bed reactor were examined in this study. The quartz sand of 300-500 μm size was selected and used for testing in the series of experiment. 40 g of coke particles were mixed with 2000 g of quartz sand, and the mixture was loaded in the fluidized bed region of the reactor tube. The static bed heights were 140 mm before fluidization. The air flow into the bottom of reactor was controlled by mass-flow controller; the gas stream was passed through the distributor; the internally circulating fluidized bed was formed inside the reactor resulting in the fluidization of mixture of coal-coke and quartz sand. The air could be flowed at volumetric gas velocities of 0-100 N $dm^3 \cdot min^{-1}$ (superficial gas velocities of 0-0.147 $m \cdot s^{-1}$) to examine the fluidization performances of mixture of the coal-coke and quartz sand. The gas pressures at gas inlet and outlet were measured by using pressure gauge, respectively. In addition, the descending cokes and sand particles on the sidewall of the reactor were observed in the reactor model. The moving velocity and distance of descending particles from the top to bottom of fluidized bed were measured by the visual observation of the particles on outside wall of reactor model. From the fluidization performances, the impacts of internal circulation of mixture of coal-coke particle and quartz sand on the fluidization state in the fluidized bed reactor are evaluated.

3. Results and Discussion

A windowed reactor model of fluidized bed reactor designed for solar coke gasification using quartz sand as a bed material was used in the series of experiments. The reactor model was used for the fluidization performance testing of mixture of coal-coke and quartz sand in this study. Figure 3 shows relationship between pressure loss of fluidized bed and gas velocity in the reactor model of fluidized bed reactor with/without draft tube. Figure 3 (a) is the results for use of internally circulating fluidized bed with draft tube, while Figure 3 (b) exhibits the results for use of fluidized bed without draft tube. As seen in Figure 3 (a), the values for U_{mf} and pressure loss for the fluidized bed reactor with the draft tube (U_{mf} = 0.071 m s^{-1}, and pressure loss of 1.67 kPa) were almost the same with those for that without draft tube (U_{mf} = 0.077 m s^{-1}, and pressure loss of 1.63 kPa) (Fig. 3 (b)). This result means that draft tube in the reactor did not impact on the gas velocity and pressure required for making fluidization. Namely, the draft tube did not facilitate a formation of fluidized bed at boundary region between fixed bed and fluidized bed. However, in a higher gas velocity region than the value for U_{mf}, a pressure loss for the fluidized bed with draft tube slightly decreased with increasing gas velocity; a pressure loss for that without draft tube is almost constant although increasing gas velocity. This result for lowering pressure loss indicates that the orifice type distributor enhances an internal circulation of mixture of coal-coke and quartz sand; in addition, the presence of draft tube embedded in the fluidized bed forms a coordinate internal circulation of bed particles in the reactor. This tendency appeared similarly at the previous results of the batch-type fluidization testing for use in a mixture of coal-coke and quartz sand without screw feeder [11]. This result for decreasing pressure loss indicates that a draft tube have a potential to enhances a fluidization of mixture of coal-coke and quartz sand in a reactor. The effectiveness of draft tube appears prominently in higher gas velocity than the U_{mf} value (U_{mf} = 0.071 $m \cdot s^{-1}$).

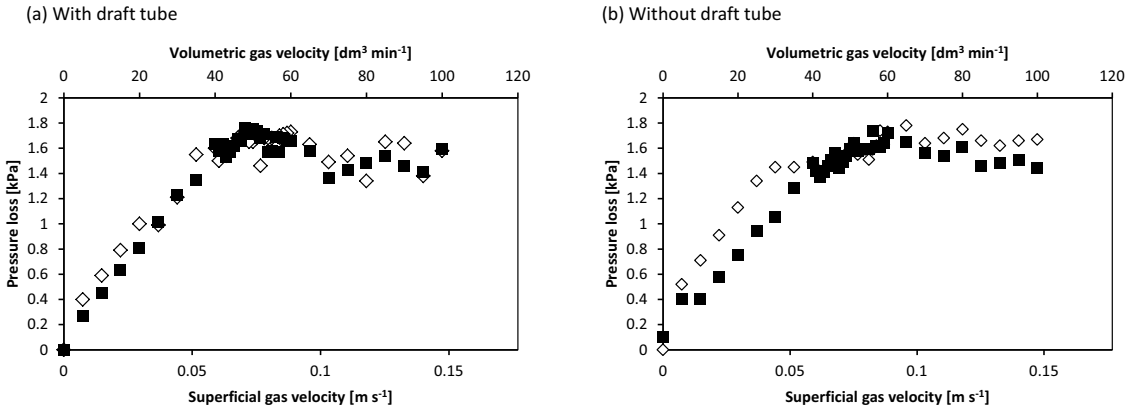

Figure 3 Relationship between pressure loss of fluidized bed and superficial gas velocity in the designed reactor model of fluidized bed (a) with or (b) without draft tube. A mixture of quartz sand and coal coke particles are used as a fluidization medium in the reactor model. The open plot is the results for increasing gas velocity, and the closed plot is the result for decreasing gas velocity in the figures.

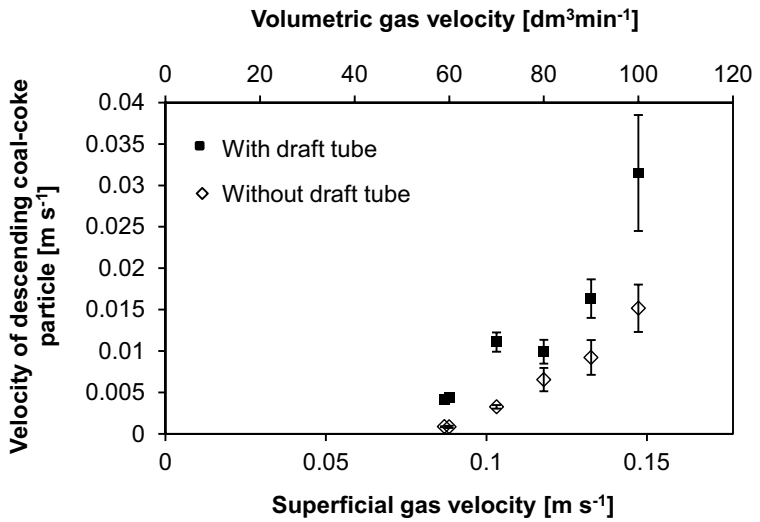

Figure 4 Relationship between descending coal-coke particle of fluidized bed and superficial gas velocity in the designed reactor model of fluidized bed reactor with/without draft tube. The descending particles were observed at a position of 35 mm below height from the bed surface.

A velocity of descending particle are measured at different bed height, the results are shown in Figure 4-6. The result observed at a position of 35 mm below height from the bed surface appears in Figure 4. The mixture of quartz sand and coal coke particles was fluidized in the reactor model, and coal-coke was observed as a descending particle. The open plot is the result for without draft tube, and the closed plot is the result for with draft tube in the figures. A velocity of descending particle increases with increasing gas velocity for fluidized bed reactor with and without draft tube. The velocity of coal-cokes at the bed layer (0.25H, H = bed height) is 1.5-5.1 times higher in the fluidized bed with draft tube than that without draft tube in a wide range of superficial gas velocity U = 0.088-0.147 m·s^{-1}. This means that the use of draft tube dominantly enhances the mobility of coal-cokes at higher gas velocities than U_{mf}. The tendency for increasing velocity of descending coal-coke particle was obviously observed in comparison to the only use of quartz sand [11]. These results shown in Figure 4 mean that coal-coke is descended at a fast velocity on the outer wall of the reactor tube in the fluidized bed in comparison to the quartz sand; the use of draft tube enhances the velocity of descending coal-coke in a mixture bed of coal-coke and quartz sand at a wide gas velocity range.

The results for velocity of descending particle at further deep depth of the fluidized bed are shown in Figure 5. The velocity of descending coal-coke particle was measured at a position of 55 mm below height from the bed surface. The velocity of coal-cokes is 1.9-7.5 times higher in the fluidized bed with draft tube than that without draft tube in a wide range of superficial gas velocity U = 0.088-0.147 m·s^{-1}. The result indicates that the velocity of descending coal-coke was decreased with the deep layer (0.4H) of the fluidized bed with and without draft tube, but coal-coke in the fluidized bed with draft tube could be moving down relatively faster than that without draft tube as the bed layer was increasing depth. On the other hand, the velocity of descending quartz sand was also decreased with the deep layer, but the velocity of quartz sand in the fluidized bed with draft tube was 2 times higher than that without draft tube in a range of U = 0.088-0.147 m·s^{-1}[11]. This means that coal-coke particle can be subject to influence by using draft tube.

Figure 6 show the results for the velocity of descending coal-coke particle at the middle layer (0.46H, H = bed height) of the fluidized bed. The velocity of descending particle was measured at the position of 65 mm below height from the bed surface. The velocity of coal-cokes is 2.4-7.5 times higher in the fluidized bed with draft tube than that without draft tube in a wide range of superficial gas velocity U = 0.088-0.147 m·s^{-1}. As seen in Figure 4-6, a difference of velocity of coal-coke particle between fluidized bed with and without draft tube remains at high gas velocity although the bed layer is deeper. The results for velocity of descending coal-coke particle means that an internally-circulating fluidized bed with draft tube enhances velocity of descending coal-coke particle at bed layer for the surface to middle depth (0.46H) in the velocity range of U = 0.088-0.147 m·s^{-1}.

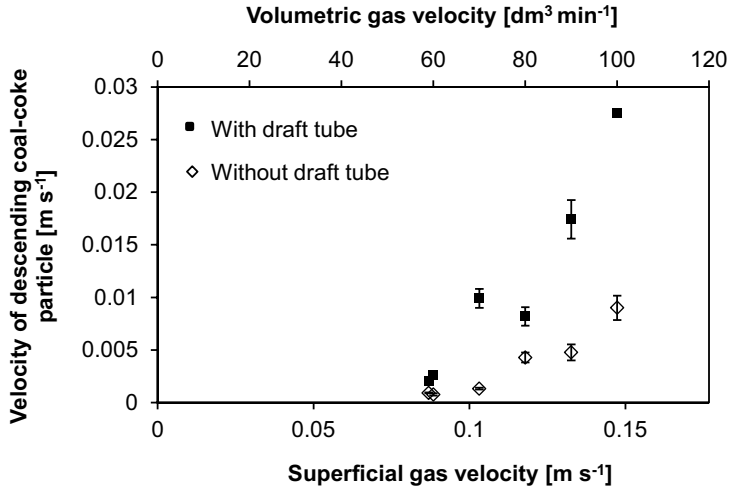

Figure 5 Relationship between descending coal-coke particle of fluidized bed and superficial gas velocity in the designed reactor model of fluidized bed reactor with/without draft tube. The descending particles were observed at a position of 55 mm below height from the bed surface.

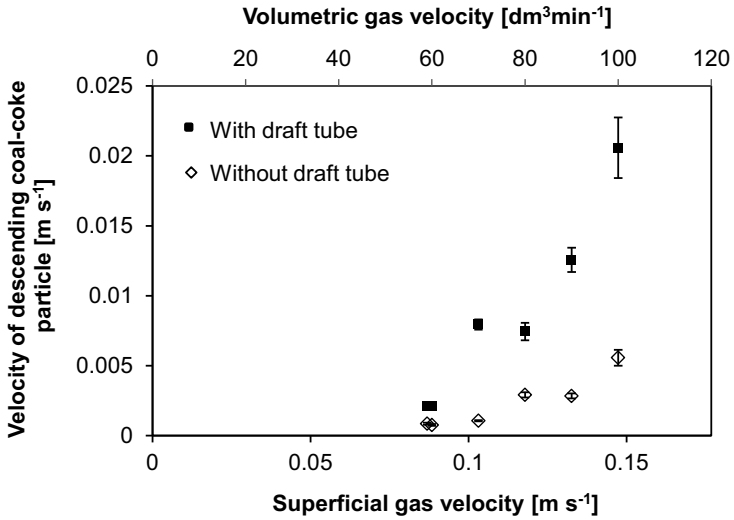

Figure 6 Relationship between descending coal-coke particle of fluidized bed and superficial gas velocity in the designed reactor model of fluidized bed reactor with/without draft tube. The descending particles were observed at a position of 65 mm below height from the bed surface.

* Moving distance : moving distance from fluidized surface to bottom

A moving depth of descending coal-coke particle on the sidewall of the reactor is observed in a range of U = 0.088-0.147 m·s^{-1}.The results are listed in Table 1. The moving depth of descending particle was measured from the surface of fluidized bed to the disappearance height (the particle is moving towards the center of fluidized bed) on the sidewall of reactor. The branch tube is used to feed coal-coke particle into the fluidized bed of quartz sand by gas passing, and the volumetric and superficial gas velocities for the branch tube are listed in Table 1. In the case of the fluidized bed with draft tube, coal-coke particle is moved down to 80 mm depth (0.57H) at U = 0.087 m·s^{-1}. The moving distance increases with increasing gas velocity. The muximum distance of 95 mm (0.68H) at U = 0.15 m·s^{-1} is almost corresponded to a lower surface of draft tube. The results indicate that draft tube has a functional role in conveying a descending particle at deeper layer along the sidewall of the reactor. On the other hand, in the case of the fluidized bed without draft tube, the moving distances are 70 mm (0.5H) and 88 mm (0.63H) at U = 0.087 and 0.15 m·s^{-1}, respectively. The moving distance increases with increasing with gas velocity, however, the moving distance in the fluidized bed with draft tube is superior to that without draft tube in a range of U = 0.087-0.15 m·s^{-1}. The results for the moving distance indicates that an internally-circulating fluidized bed with draft tube have a potential to move a fluidizing particle downward on sidewall of the reactor as well as upwards moving in the center region of the fluidized bed. Furthermore, as seen in Table 1, it is striking that the gas velocities passed through the branch tube are relatively lower for the internal-circulation with draft tube than the conventional fluidized bed without draft tube. The results for gas velocities in the branch tube means that coal-coke particles feeded through the branch tube can be easily to enter into an internally-circulating fluidized bed of quartz sand with draft tube in comparison to a fluidized bed without draft tube. One of the reasons will be due to high mobility (moving distance at deeper layer and moving velocity along the sidewall) of coal-coke particles in an internally-circulating fluidized bed with draft tube.

In the next step, based on the results in this study, a laboratory-scale prototype windowed fluidized-bed of quartz sand and coke particles feeded by screw-feeder will be fabricated and tested for coal-coke gasification under continuous supply of coal-coke conditions by concentrated Xe-beam or solar radiation.

4. Summary

A laboratory-scale prototype windowed fluidized-bed containing of quartz sand and coke particles was designed and, the reactor model of fluidized bed was made from a transparent acrylic resin to allow us to observe a fluidizing particle through the sidewall of the reactor body; a branching tube was equipped with the sidewall of the reactor to continuously supply coal-coke particles from a screw feeder. The fluidization performances of coal-cokes, the pressure loss between the inlet and outlet gases was examined, and descending coal-coke particles on the sidewall of the reactor was observed in the reactor model.

This result for decreasing pressure loss indicates that a draft tube have a potential to enhances a fluidization of mixture of coal-coke and quartz sand in a reactor. The effectiveness of draft tube appeared prominently in higher gas velocity than the U_{mf} value (U_{mf} = 0.071 m·s^{-1}). As seen in Figure 4-6, a difference of velocity of coal-coke particle between fluidized bed with and without draft tube remained at high gas velocity although the bed layer was deeper. The results for velocity of descending coal-coke particle means that an internally-circulating fluidized bed with draft tube enhances velocity of descending coal-coke particle at bed layer for the surface to middle depth (0.46H) in the velocity range of U = 0.088-0.147 m·s^{-1}. The results for the moving distance indicates that an internally-circulating fluidized bed with draft tube have a potential to move a fluidizing particle downward on sidewall of the reactor as well as upwards moving in the center region of the fluidized bed. Furthermore, as seen in Table 1, it is striking that the gas velocities passed through the branch tube are relatively lower for the internal-circulation with draft tube than the conventional fluidized bed without draft tube. The results for gas velocities in the branch tube means that coal-coke particles feeded through the branch tube can be easily to enter into an internally-circulating fluidized bed of quartz sand with draft tube in comparison to a fluidized bed without draft tube. If the behaviour of coal-coke particles is done at high-temperature, gasification performances of gasification rate will be expected under the continuous supply of coal-coke particles feeded through the branch tube.

Abstract

Thermochemical energy storage using redox pair of Co_3O_4/CoO powders was studied for thermal energy storage (TES) using concentrated solar radiation as the energy source. Reversible chemical reactions (reduction – oxidation redox cycles) of oxides under air atmosphere are used to storage significant thermal energy via the enthalpies of the chemical reactions at high-temperature. A promising concept for solar TES is proposed using fluidized bed with Co_3O_4/CoO redox pair. In the present study, the effects of particles size of Co_3O_4/CoO powders on thermochemical storage performances are investigated in order to explore the potential of the material for fluidized-particle bed reactor. The Co_3O_4 powders with particle sizes of 100-200, 200-300, 300-500 and 500-700 μm were used to test redox performances by thermo-gravimetric analysis. A flowability (fluidization state) of Co_3O_4 powders in a fluidized bed reactor for thermochemical energy storage is also examined in this study. A basic relationship between pressure drop of inlet gas and gas flow rate was experimentally examined using bed materials with different particle sizes by a small-scale quartz reactor at ambient pressure and temperature.

Keywords: *Solar thermochemical storage, redox material, Co_3O_4/CoO, Fluidized bed reactor*

1. Introduction

Concentrated solar radiation has some specific properties such as high density, heterogeneous distribution of thermal flux, and frequent thermal transients due to the fluctuating insolation resulting from cloud passage. Thus, concentrated solar power (CSP) system requires to effectively storage the high temperature heat in order to realize long-term operation of the system such as around-the clock operation. Also, solar chemical reactor for solar hydrogen production can convert the high-temperature solar heat into chemical fuels via endothermic thermochemical process, for example, two-step water-splitting cycle, methane reforming and gasification of carbonous materials.

Thermal energy can be stored as sensible, latent or thermochemical heat. Thermochemical heat storage (TCS) presents higher energy densities than sensible or latent heat, and it can be used at higher temperature ranges. The thermochemical heat storage consists of charge, storage and discharge steps. The high-temperature heat provided by concentrated solar radiation is used to proceed with an endothermic reaction of reversible chemical reaction during the charge step. Thus, the high-temperature heat can be chemically stored as reaction products. Finally, the reaction products are used in order to recover the high-temperature heat through an exothermic reaction of reversible chemical reaction during the discharge step. Redox pair operating at temperature range of 600-1000ºC, much higher than the operational limit of 600ºC for current state-of-the-art molten nitrate salt heat transfer fluid, is eligible for next–generation CSP plants (Agrafiotis et

doi:10.18086/swc.2015.04.25 Available at http://proceedings.ises.org

al., 2014a, Carrillo et al., 2014), while redox pair at temperature range of 800-1000ºC works for solar methane reforming and gasification of carbonous materials to produce hydrogen and synthetic gas.

The choice of the redox pair for TCS are important with regard to thermodynamics, energy storage capacity, material costs, reaction kinetics, toxicity and cyclic behavior (Worner et al., 2012). A redox cycle through a hercynite cycle ($FeAl_2O_4$) was studied for TCS by the University of Colorado (Ehrhart et al., 2014). A redox pair of CuO/Cu_2O was recently tested for TCS (Alonso et al., 2015). Wong evaluated various metal oxides as a TCS medium by thermodynamic calculation and experimental analysis (Wong, 2011). Among those which were suitable for TCS, a redox pair of Co_3O_4/CoO showed beat re-oxidation kinetics. Recently, Co_3O_4/CoO redox pair has been studied for some TCS performances from the viewpoints of thermodynamic analysis, material testing and reactor/heat exchanger developments (Schrader et al., 2015, Neises et al., 2012, Tescari et al, 2014, Carrillo et al., 2014, Pagkoura et al., 2014, Agrafiotis et al., 2014a and Agrafiotis et al., 2015b).

Co_3O_4/CoO redox pair store and release energy through the following redox reaction:

$$Co_3O_4 \rightarrow 3CoO + 1/2O_2 \qquad \Delta H = 196.5 \text{ kJ/mol-reactant at } 950\ ^{o}C \qquad (1)$$

Co_3O_4 presents a high potential for TCS and fits the operation temperature for CSP plants (Wong, 2011) and solar chemical reactor. A promising concept for CSP plants provided with a volumetric air central receiver using Co_3O_4/CoO redox pair is proposed and studied (Agrafiotis et al., 2014a).

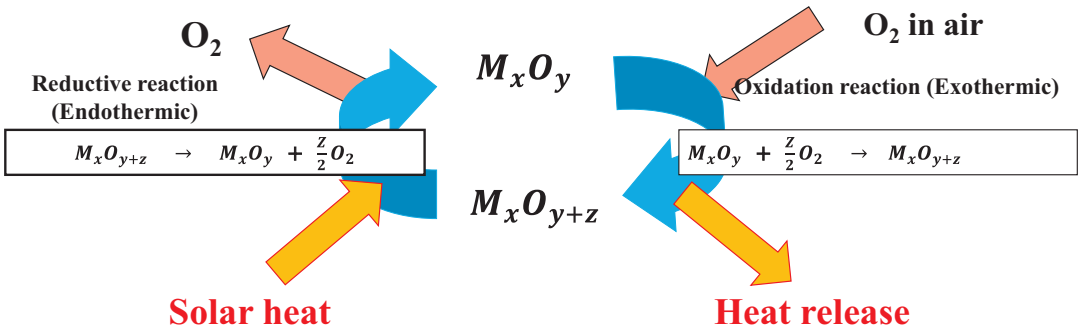

Figure 1. Schematic diagram of thermochemical energy storage by M_xO_{y+z}/M_xO_y redox pair.

The present authors in Niigata University have been developing windowed receivers/reactors prototype using fluidized bed of reacting (coal cokes, and metal oxides) or chemically-inert (quartz sand) particles, and have proposed to combine the windowed solar chemical reactor/receiver with a newly developed solar reflective tower or beam-down optics. In the present study, the effects of particles size of Co_3O_4/CoO powders on TCS performances are investigated in order to explore the potential of the material for fluidized-particle bed reactor. A flowability (fluidization state) of Co_3O_4 powders in a cold testing of fluidized bed reactor is also examined in this study.

2. Experimental procedure

2.1. Preparation of Co_3O_4 powders for fluidization testing and thermochemical storage testing

Co_3O_4 powders were purchased from Japan Pure Chemical Co., Ltd in Japan. The Co_3O_4 powders were divided into four particle size ranges: 30–100 μm, 100–300 μm, 300–500 μm, and 500–700 μm. The Co_3O_4 powders of all particle sizes were prepared for investigation of fluidization state in a cold testing of fluidized bed reactor and thermochemical storage testing by using thermogravimetry reactor (Thermo plus EVO 2/TG-DTA series manufactured by Rigaku Co. ltd.) and a differential scanning calorimeter (DSC). The Co_3O_4 powder of 30–100 μm and 500–700 μm size were used as the redox material for investigation on redox performances.

2.2. Fluidization testing of Co_3O_4 powders by a small-scale quartz reactor of fluidized bed

A basic relationship between pressure loss of inlet gas and outlet gas was experimentally examined using Co_3O_4 powders with different particle sizes by a small-scale quartz reactor at ambient temperature in order to examine a flowability (fluidization state) of Co_3O_4 powders in a fluidized bed reactor for thermochemical storage processes. Fig. 2 shows an experimental setup for flowability test of fluidizing particles by using a small-scale quartz reactor. The diameter of the quartz reactor tube was 25 mm with a thickness of 2 mm, and a length of 48 mm. A porous quartz frit (the hole diameter is 40 μm) was used as the distributor for the small-scale quartz reactor.

Each size of Co_3O_4 powders (21-28 gram) was tested as the fluidized bed of chemical storage material. The Co_3O_4 powder was put into the quartz reactor. The bed height of Co_3O_4 powder inside the reactor is 25 mm for all the particle size. Air was flowed upwards from the bottom of the reactor through the distributor to create the fluidization of Co_3O_4 powder under various air flow rates. A pressure difference for the inlet and outlet gas was measured under various gas flow rates by manometer. The relationship between pressure loss of fluidization gas and flow rate was experimentally examined using each size of Co_3O_4 powder.

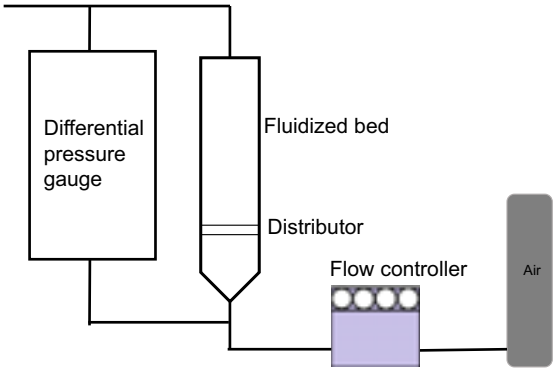

Figure 2. Flowability test of CeO_2 particles ranged in variety size by a small-scale quartz reactor.

2.3. Thermochemical storage testing by thermogravimetry reactor and DSC measurement

Approximately 100 mg of Co_3O_4 powder was packed into a platinum cup (5 mm in diameter and 5 mm deep), and mounted on the balance in a ceramic reaction chamber. Fig. 3 shows experimental set-up for thermogravimetry reactor used for endothermic thermal reduction (TR) step of Co_3O_4 powder and exothermic air oxidation (AO) step of CoO powder. The Co_3O_4 powder mounted in the thermogravimetry reactor were first heated to 1373K with different heating rates of 10 K/min and 30 K/min using an electric furnace, while passing air (purity 99.9%) through the reactor at a flow rate of 0.2 $dm^3 \bullet min^{-1}$(nor) controlled by mass flow controller (KOFLOC RK1700), in order to perform the TR step for heat charging. The temperature of the Co_3O_4 powder was controlled using an R-type thermocouple in contact with the platinum cup. The powder was heated at a constant temperature of 1373 K for 30 min. The weight change of the powder by O_2 release during AO step for heat discharging was measured against time in order to monitor a degree of reaction fraction of AO step.

A reaction conversion α for O_2 release and uptake during the TR and AO step was defined as follows:

$$\alpha = \frac{m - m_i}{m_f - m_i} \quad (2)$$

where m and m_i are weight of sample at time t and initial weight, respectively; m_f is final weight when an ideal reaction proceeds. In thermogravimetry, the reaction fraction α was calculated by the measured weight change of sample.

Subsequently, the powder subjected to the TR step was cooled to 1073 K in air stream at a flow rate of 0.2 $dm^3 \bullet min^{-1}$(nor) to perform the subsequent AO step in an electric furnace of thermogravimetry reactor, and the AO step was continued for 30 min. The temperature of the sample was too controlled using a R-type thermocouple in contact with the platinum cup. The weight change of the powder by O_2 uptake during AO

step was measured against time in order to monitor a degree of reaction fraction of AO step.

The TR and AO steps were alternately repeated three times.

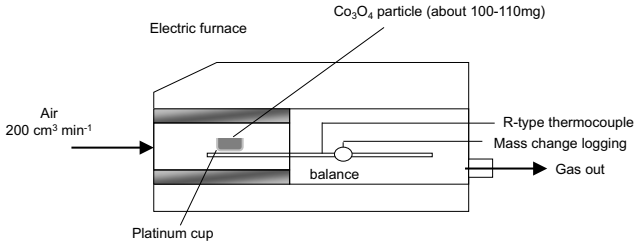

Figure 3. Schematic of the thermogravimetry reactor for thermochemical energy storage using Co_3O_4/CoO redox pair.

The chemical energy storage capacity at the redox temperature and sensible heat capacity arising from the Co_3O_4 and CoO powders were measured for the Co_3O_4/CoO redox pair using a differential scanning calorimeter (DSC). Also, the redox temperature of Co_3O_4/CoO redox pair was estimated from a measurement of endothermic and exothermic peaks by DSC. The specific heat C_p values of the Co_3O_4/CoO redox pair before and after the cyclic reaction were also measured to estimate the dependence of the sensible heat on the temperature using the DSC. The programmed heating and cooling rates for the DSC measurements were as follows: 1) a heating rate of 10 K/min between room temperature and 1000 °C, 2) 30 min at 1000 °C, 3) a cooling rate of 10 K /min down to 800 °C, and 4) 30 min at 800 °C. The heating/cooling cycle in the DSC was repeated three times in air stream.

3. Results and Discussion

3.1. Fluidization testing of Co_3O_4 powders by a small-scale quartz reactor of fluidized bed

Fig. 4 shows results for fluidization testing using a fluidized bed reactor. The Co_3O_4 powder with different particle sizes between 50 and 700 μm diameter was used and tested as a bed material for the fluidized bed reactor. For the particle size of 50-100 μm, a pressure loss initially increased with superficial gas velocity of inlet gas, and reached the small peak of 690 Pa at a velocity of 0.068 m·sec^{-1}. Subsequently, the pressure loss plateaued and then increased to about 1460 Pa. This behavior of pressure loss for the superficial gas velocity indicates that the velocity of 0.068 m·sec^{-1} corresponds to start a fluidization of Co_3O_4 powder; a minimum superficial gas velocity (U_{mf}) = 0.068 m·sec^{-1} for the particle size 50-100μm. Similarly, for the particle size of 100-300 μm, a peak value for pressure loss was reduced to about 510 Pa in comparison to that for the particle size 50-100 μm, while the value of U_{mf} slightly decreased to 0.054 m·sec^{-1}. In addition, the plateau region where the value for pressure loss is stable for increasing superficial gas velocity of inlet gas, was apparently expanded when the particle size was used.

According to the results in this figure, the fluidization state can be categorized into three regions: fixed layer, bubble fluidization and turbulent fluidization regions. Firstly, a pressure loss increases with increasing a superficial gas velocity. This region was called to fix bed layer, and U_{mf} was corresponded to the following value for the peak of the pressure loss. It was observed that hereafter, a particle started fluidizing. By further increasing a superficial gas velocity, the pressure loss plateaued. In this region, a particle bed made a bubbling fluidization. Beyond the bubbling fluidization, the pressure loss increased again, a particle bed formed a turbulent fluidization. The fluidization state aimed in this study is a lower superficial gas velocity and a mild fluidization of a particle bed in the reactor. Thus, a bubble fluidization was targeted in this study. Based on the experiments of fluidization testing of Co_3O_4 powder, the powder with a smaller size which enables it to make a bubbling fluidization under a lower passing air are favorable for the fluidized bed reactor operating a thermochemical energy storage.

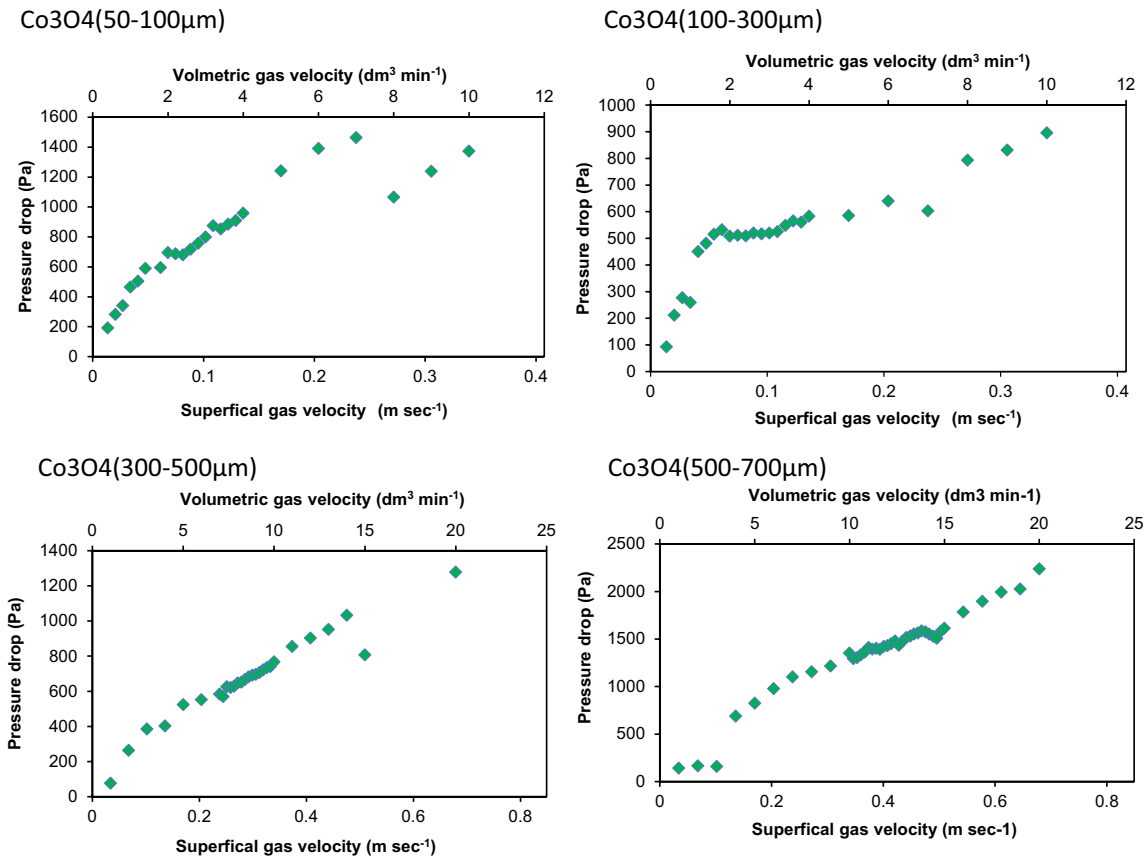

Figure 4. Pressure drop of fluidized bed using various Co_3O_4 powder size

3.2. Thermochemical storage testing by thermogravimetry and DSC measurements

Fig. 5 shows redox reactivity and cyclic performances of Co_3O_4 powder with different particle sizes by thermogravimetry analysis. The heating–cooling operation was performed by a trapezoid mode in order to drive each step as much as possible at temperature of 1100°C and 800°C. For the particle size of 30-100 μm, the weight of sample rapidly decreased with increasing temperature of the sample and reached almost stoichiometric weight change of the sample (Co_3O_4 = 3CoO + 1/2O_2) during TR step. The conversion α of HC step was 99.7, 99.4 and 99.5% for 1st, 2nd and 3rd cycles, respectively. Subsequently, when temperature of the sample decreased in the AO step, the sample returned back to almost initial weight (3CoO + 1/2O_2 = Co_3O_4). The conversion α of AO step was 99.1, 99.2 and 98.6% for 1st, 2nd and 3rd cycles, respectively. Similarly, the weight change of sample for the particle size of 500-700 μm presented superior reactivity and cyclic stability as well as that for particle size of 30-100 μm. Thus, the redox reactivity and cyclic reactivity was independent of the particle size of Co_3O_4 powder.

Fig. 6 shows reaction rate of the Co_3O_4/CoO redox during TR and AO steps for Co_3O_4 powder with the particle size of (a) 30-100 μm and (b) 500-700 μm. The heating–cooling operation was performed by a trapezoid mode. The reaction rate in each step was expressed by a time-derivative of reaction conversion $\frac{d\alpha}{dt}$ for O_2 release and uptake during the TR and AO step. For the particle size of 30-100 μm, the temperature that TR step starts was about 910°C at all cycles. The peak rate in the TR step was $\frac{d\alpha}{dt}$ = about 0.3 at temperature of 945°C. The profiles of reaction rate were reproducibly observed in the TR step at all cycles. On the other hand, for the particle size of 500-700 μm, the temperature that TR step starts was about 920°C at all cycles. The peak rate in the TR step was almost the same ($\frac{d\alpha}{dt}$ = about 0.3) at temperature of 945°C. This means that TR step can start with lower (10°C) temperature as a particle size of Co_3O_4 powder is smaller, but the peak rate in TR step is independent of the particle size. In the case of AO step, the

temperature that AO step starts was almost the same (800°C) with the particle size of 30-100 μm and 500-700 μm, thus was independent of particle size. The reaction rate at a maximum in AO step was 840-850°C, and lower than that for TR step. The results indicate that oxidation reaction of CoO is rate-determining step for thermochemical storage using Co_3O_4/CoO redox pair.

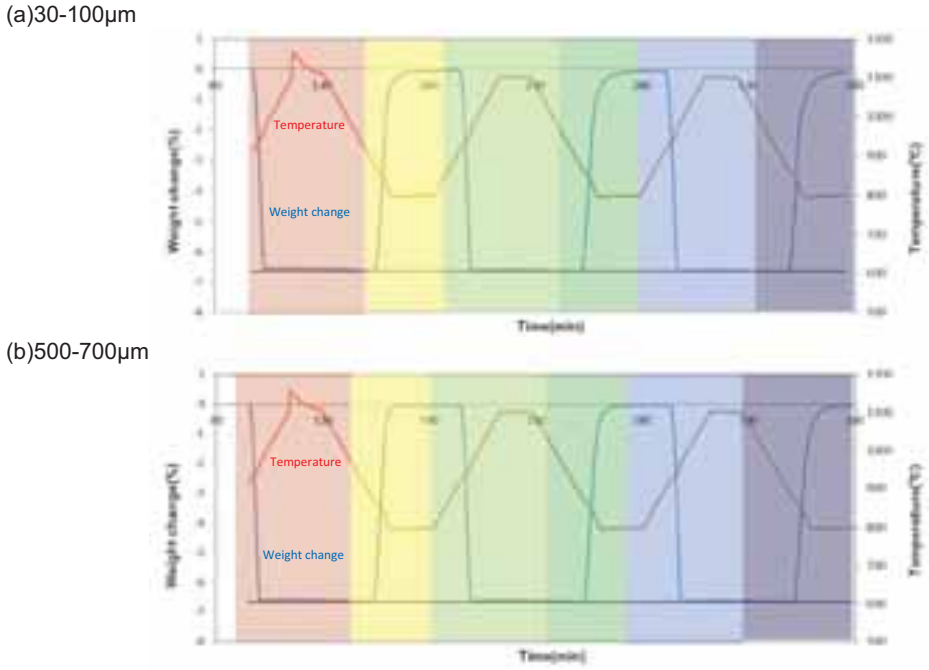

Figure 5. Redox reactivity and cyclic reactivity of Co_3O_4 powder with the particle sizes of (a) 30-100 μm and (b) 500-700 μm. Red and blue lines are temperature and weight change of the sample, respectively. The heating–cooling operation was performed by a trapezoid mode.

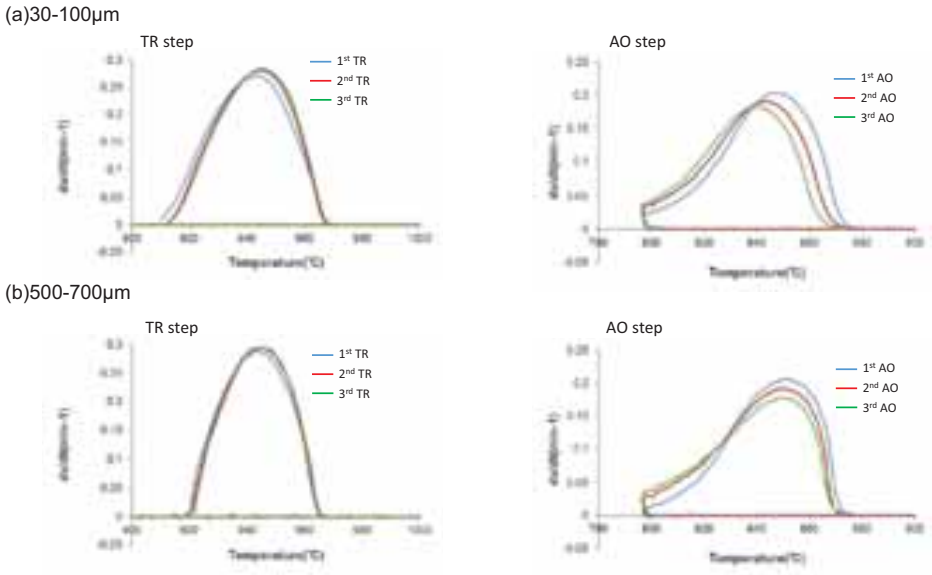

Figure 6. Reaction rate of the Co_3O_4/CoO redox during TR and AO steps for Co_3O_4 powder with the particle size of (a) 30-100 and (b) 500-700 μm. The heating–cooling operation was performed by a trapezoid mode.

Fig. 7 shows comparison for weight change of powder sample with the particle sizes of 30-100 μm and 500-700 μm during TR and AO steps. In the experiments, the samples were subjected to each step without keeping constant temperature of 1100°C for TR step and 800°C for AO step. Namely, the heating–cooling operation was performed by a rectangle mode in order to simulate a heat charging/discharging of Co_3O_4/CoO redox by using a fluidized bed reactor under a concentrated solar radiation. The thermal reduction of Co_3O_4 into CoO proceeded completely for both particle sizes. However, the air oxidation of CoO into Co_3O_4 was

apparently slower for the particle size of 30-100 μm than for that of 500-700 μm in the temperature range of 700-850°C. In order to compare the oxidation rate of CoO during AO step under the heating (charging)-cooling (discharging) operation, the reaction rate of the Co_3O_4/CoO redox during TR and AO steps was plotted against reaction temperature. The plot of reaction rate is shown in Fig. 8. The profiles of reaction rate were reproducibly observed in the TR and AO steps at all cycles. As seen in Fig. 8(a), the temperatures that TR step starts were 915°C for the particle size of 30-100 μm and 920°C for 500-700 μm. Also, the temperatures that TR step terminates were about 965°C for both particle sizes. Further, a peak rate in the TR step was $\frac{d\alpha}{dt}$ = about 0.3 at temperature of 945°C. The temperatures and peak rate for the TR step were almost the same with the results by the different operation mode. However, as seen in Fig. 8(b), for the AO step, the temperatures that AO step starts were 890°C for the particle size of 30-100 μm and 880 °C for 500-700 μm. Also, the temperatures that AO step terminates were 780°C for the particle size of 30-100 μm and 790°C for 500-700 μm. The results for reaction temperatures mean that a temperature region for the AO step expands further high- and low-temperature as a particle size of Co_3O_4 is smaller. The peak rare in the AO step was greater for the particle size of 500-700 μm than that for 30-100 μm. The peak rate in the AO step was $\frac{d\alpha}{dt}$ = about 0.20 at temperature of 865°C for the particle size of 30-100 μm, while that was $\frac{d\alpha}{dt}$ = about 0.22 at temperature of 855°C for 500-700 μm. The temperatures and peak rate for the AO step were different by the operation modes.

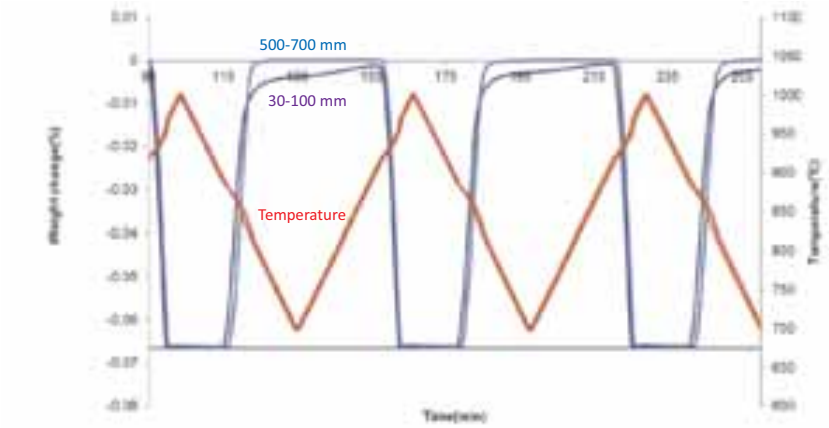

Figure 7. Redox reactivity and cyclic reactivity of Co_3O_4 powder with the particle sizes of 30-100 and 500-700 μm. Red and blue lines are temperature variation and weight change of the sample, respectively. The heating–cooling operation was performed by a rectangle mode.

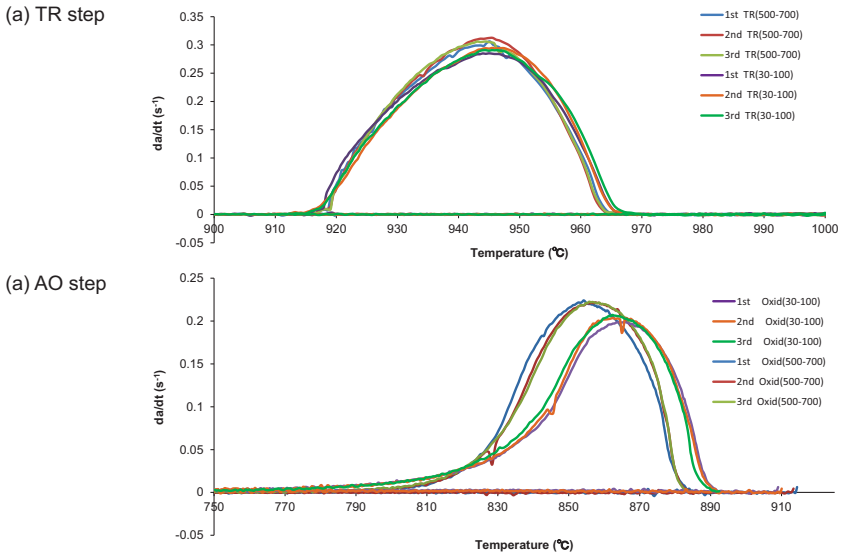

Figure 8. Reaction rate of the Co_3O_4/CoO redox during TR and AO steps for Co_3O_4 powder with the particle size of 30-100 and 500-700 μm at (a) TR and (b) AO steps. The heating–cooling operation was performed by rectangle mode.

Fig. 9 shows the DSC results for the thermal storage capacities of the Co_3O_4/CoO redox material with particle size of (a) 30-100 and (b) 500-700 μm in the charging and discharging modes. The amounts of thermochemical heat storage during the charging and discharging modes were measured at the peak area. For the results of the 30-100μm, as seen in Fig. 9(a), there was a major endothermic peak at temperatures of 949–951°C during the TR step, while a major exothermic peak was observed at temperatures of 853–866°C during the AO step in the 3 cycles. The endothermic and exothermic peak corresponded to the Co_3O_4/CoO redox reaction. The enthalpy changes, ΔH, (Co_3O_4 = 3CoO + 1/2O_2 for an endothermic TR step; 3CoO + 1/2O_2 = Co_3O_4 for an exothermic AO step) were estimated from an integration of the peak area. In addition, the reaction conversions, α, for each step were calculated from the theoretical enthalpy changes, $\Delta H_{theoretical}$. The values of $\Delta H_{theoretical}$ were calculated by thermodynamic software of Factsage. The values of ΔH and α were listed in Table 1. The values of ΔH and α for the 1st TR step were slightly less than those for the 2nd and 3rd TR steps, but each step could almost stoichiometrically charge and discharge. Thus, the values of ΔH and α indicate that the Co_3O_4/CoO redox reaction ideally proceeded in viewpoint of quantitative thermal charging/discharging. For the results of the 500-700 μm, as seen in Fig. 9(b), there was a major endothermic peak at temperatures of 950–954°C during the TR step, while a major exothermic peak was observed at temperatures of 854–862°C during the AO step in the 3 cycles. The endothermic and exothermic peak corresponded to the Co_3O_4/CoO redox reaction was observed at almost same temperature, respectively. The values of ΔH and α for the particle size were listed in Table 2. The results for ΔH and α indicate that the particle size did not impact on the values of ΔH and α in quantitative viewpoint (Fig. 5 and 7), but effect on a kinetic viewpoint (Fig. 6 and Fig 8(b)).

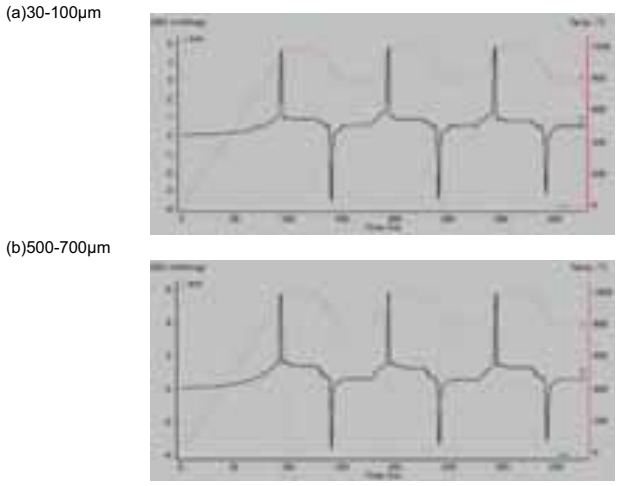

Figure 9. DSC analysis of Co_3O_4/CoO redox material with particle size of (a) 30-100 and (b) 500-700 μm. The heating–cooling operation was performed by a trapezoid mode.

In addition to the thermochemical heat storage based on the value of ΔH, the specific heat values C_p, depending on the temperature in the range of 800–1000°C, were experimentally measured for the Co_3O_4/CoO redox material, and the sensible heat was experimentally estimated to evaluate the thermal storage performances. As a reference, the values of the heat storage capacities for a molten carbonate salt (Na_2CO_3) were calculated using the thermodynamic equilibrium software FactSage ver 6.4. Fig. 10 shows the heat storage capacities per unit weight for the redox pair with the particle size of 30-100 and 500-700 μm. The values for the heat storage capacities were plotted as a standard based on a temperature of 800°C. As shown in Fig. 10, the discontinuous increments are equivalent to the amounts of thermochemical heat due to the Co_3O_4/CoO redox reaction at reaction temperatures of 930-975°C. A sensible heat from the oxidized solid phase of Co_3O_4 enhanced the heat storage capacities in the temperatures of 800-930°C. Beyond the reaction temperature over 975°C, sensible heat from the reduced solid phase of CoO contributed to the increase in the heat storage capacity. The heat storage capacity for the redox pair with the particle size of 30-100 μm was almost the same storage level in comparison to that with the particle size of 500-700 μm. Also, the heat storage capacities for the Na_2CO_3 molten salt discontinuously increase due to latent heat of solid-

liquid phase transition at a temperature of 858°C, and has a heat storage capacity of > 500 kg/kJ at temperatures in the range of 858-930°C, which is higher than that for the redox pair. However, the thermochemical heat strongly contributes to enhancing the thermal storage capacities of the redox pair. The thermal storage capacity for the redox pair is two times higher than that of the molten salt at 1000°C. These results indicate that the thermochemical heat storage for the redox pair is available to use in solar thermochemical processes and CSP, as well as that of the carbonate molten salts. From the viewpoint of the temperature range, using the redox pair for thermal storage may be appropriate for the solar tower/beam down receiver system using fluidized particle bed using high-temperature air as a heat transfer fluid.

Table 1 Enthalpy change and reaction conversion in each step for Co_3O_4/CoO redox material with the particles size of 30-100μm.

4. Summary

The present authors in Niigata University have been developing windowed receivers/reactors prototype using fluidized bed of reacting (coal cokes, and metal oxides) or chemically-inert (quartz sand) particles, and have proposed to combine the windowed solar chemical reactor/receiver with a newly developed solar reflective tower or beam-down optics. In the present study, the effects of particles size of Co_3O_4/CoO powders on TCS performances were investigated in order to explore the potential of the material for fluidized-particle bed reactor. A flowability (fluidization state) of Co_3O_4 powders in a cold testing of fluidized bed reactor was also examined in this study.

For the fluidization testing of Co_3O_4 powders by a small-scale quartz reactor of fluidized bed, the fluidization state aimed in this study was a lower superficial gas velocity and a mild fluidization of a particle bed in the

reactor. Thus, a bubble fluidization was targeted in this study. Based on the experiments of fluidization testing of Co_3O_4 powder, the powder with a smaller size which enabled it to make a bubbling fluidization under a lower passing air were favorable for the fluidized bed reactor operating a thermochemical energy storage. From the viewpoint of stability of fluidization, the particle size of 100-300 μm showed the minimum pressure loss at the value of U_{mf} among the all particle size tested.

For the thermochemical storage testing by thermogravimetry and DSC measurements, the heating–cooling operation was performed at 1100-800°C by a trapezoid and rectangle modes in order to evaluate a heat charging/discharging performances of Co_3O_4/CoO redox with different particle size. TR step could start with lower (10°C) temperature as a particle size of Co_3O_4 powder was smaller, but the peak rate in TR step was independent of the particle size. Oxidation reaction of CoO was rate-determining step for thermochemical storage using Co_3O_4/CoO redox pair. In DSC measurement, the endothermic and exothermic peak corresponded to the Co_3O_4/CoO redox reaction was observed at almost same temperature, respectively. The results for ΔH and α indicate that the particle size did not impact on the values of ΔH and α in quantitative viewpoint (Fig. 5 and 7), but effect on a kinetic viewpoint (Fig. 6 and Fig 8(b)).

The present work reports synthesis of highly photoactive silver-sensitized mixed phase ZnO nanoparticles. The structural, optical and chemical characterizations of the prepared materials were done using XRD, TEM, UV–DRS, PL and EPR. The photoactivity of the nanoparticles was assessed through photocatalytic degradation kinetics of methylene blue. The rate constant of the photocatalytic degradation of methylene blue using silver sensitized mixed phase ZnO was found to be 3.7 and 1.2 times higher than monophasic (wurtzite) ZnO without and with silver sensitization, respectively, under visible light. The increase in the activity is mainly attributed the synergy of the interacting phases at the homojunction and the surface plasmon resonance due to the metallic silver.

Keywords: Photocatalyst, surface plasmon resonanace, mixed phase

1. Introduction

Two of the most investigated semiconductor photocatalysts-TiO_2 and ZnO, have some inherent constraints in achieving high photocatalytic activity due to their large band gap, which restricts the photo-absorption only to the UV region of solar spectrum and low separation probability of photo-generated charge carriers leading to high recombination. To overcome these constraints different techniques such as doping [Vazquez et al. 2015, Kumar et al. 2015], formation of nanocomposite [Wenga et al. 2014], sensitization [Pawar and Sunyong, 2014] and mixed phase transformation [Nair et al.2011] had been implemented for such semiconductor photocatalysts. Recently, it has been reported that these problems can also be alleviated by plasmonic/ semiconductor photocatalyst [Chiu et al. 2015 and Rajbongshi et al. 2014a]. Surface plasmon resonance of metal at UV and visible region can extend photo activity in higher wavelength also. Further, noble metal Ag acts as electron scavenger which enhances the life time of energetic charge carriers by reducing their recombination probability. Also many researchers have reported that mixed phase TiO_2 shows photocatalytic activity under visible light. Recently Rajbongshi et al. reported that like TiO_2, mixed phase (wurtzite and zincblende) of ZnO also shows higher photocatalytic activity under visible light [Rajbongshi and Samdarshi, 2014b]. But the main challenge of synthesis of mixed phase ZnO is in ensuring the suitable synthesis conditions in addition to an appropriate matching substarte for the formation of metastable zincblende phase of ZnO [Ashrafi,2007]. The challenge of synthesis of metastable zincblende (ZB) phase with wurtzite (WZ) subdomian has been recently solved by a single-step and simple synthesis procedure using dopant as a substrate. But none of the dopants used were known to show plasmonic resonance under visible light. This encouraged the present work to study the photocatalytic activity of the mixed phase ZnO with Ag sensitization to take the advantage of surface plasmon resonance; and wurtzite and zincblende homojunction. The basic investigation suggest that Ag can act as a sensitizer and a substrate for the formation of mixed phase ZnO as reported earlier[Rajbongshi and Samdarshi, 2014b]. Some studies on the role of Ag in formation of mixed phase have been reported earlier in the case of ZnS [Synnott,2013; Tsuji,2006].

In this present study Ag sensitized mixed phase ZnO photocatalyst was synthesized by sol-gel co-precipitation method. The photocatalytic activity was studied under visible light for methylene blue degradation for the synthesized photocatalyst.

2. Material and Methods

2.1. Material synthesis

The chemicals used for synthesis of Ag doped ZnO were zinc acetate dihydrate $(CH3COO)_2$ Zn. $2H_2O$, silver nitrate, sodium hydroxide pellets (NaOH) and ethanol. Sol-gel co-precipitation method was used as reported earlier [Rajbonghi and Samdarshi 2014b] to synthesize the sample. The calcinations temperatures were 400 and 425^{o}C for Ag-senistized single phase (AZ(M)) and Ag-sensitized mixed phase ZnO (AZ(S)), respectively. For comparison single phase ZnO(without Ag sensitization)was also synthesized and calcined at a temperature of 400^{o}C.

2.2. Characterization

Structural and morphological analysis was done by XRD (Rigaku Miniflex, Japan) and TEM (model JEM-100CX II (JEOL Japan). The spectral response of the material was evaluated using a UV–DRS spectrophotometer (Shimadzu UV-2200, Japan) with diffuse reflectance attachment. The photoluminescence spectrum was recorded using a photoluminescence spectrometer (LS55, Perkin Elmer, USA) for studying the trap states. Further study on oxygen vacancy and defects on the material was done using ESR spectrometer (JEOL, Model: JES-FA200).

2.3. Photocatalytic activity test

The photocatalytic activity of the synthesized nano-material was studied using probe pollutant - methylene blue (MB) with visible irradiance at the reactor surface of 14.5 W/m^2 at 28^{o}C. The adsorption-desorption equilibrium was ensured by keeping the catalyst loaded MB in dark for one hour. The change in the concentration of the sample was recorded by correlating it with the absorbance of the sample, measured using UV-Vis spectrophotometer (Shimadzu 1700, Japan) at the wavelength of 650 nm for MB.

3. Result and discussions

XRD spectra of pristine ZnO and Ag doped ZnO are shown in Fig.1a,b. Pristine ZnO is monophasic wurtzite(Fig.1a). Among the Ag-sensitized samples, AZ(M) shows the mixed phase of wurtzite (JCPDF: 891397) and zincblende (JCPDF: 652880) phases of ZnO while AZ(S) is single phase of wurtzite (Fig.1b). The diffraction peak (111) at $\theta = 38^o$ is identified for metallic Ag which matches with the JCPDS file No: 893722. Another extra peak can be identified for AgO in Ag doped ZnO sample. The particle size that has been calculated using Scherrer formula [Zachariah et al.,2008] is given in Table 1. From the Table it can be seen that mixed phase sample AZ(M) posses higher particle size for zincblende ([111] plane) phase.

Table 1: Particle size and band gap of the synthesized sample

Sample	Particle size (nm)		Band gap (eV)
	WZ	ZB	
ZnO	14.2	-	3.12
AZ(M)	13.3	18.6	2.93
AZ(S)	12	-	3.03

Fig.1c shows the TEM image of the sample AZ (M) wherein the presence Ag of about 20nm in size is clearly visible. The particle size from TEM analysis accords well with XRD results. The formation of wurtzite (WZ) and zincblende (ZB) polymorph of ZnO with an additional phase for metallic silver is shown in Fig.1d. The d-spacing for wurtzite and zincblende is found to be 0.25 and 0.23nm, respectively, and that of Ag to be 0.21nm. So AZ (M) is a combination of homo- and heterojunction of wurtzite-zincblende ZnO and ZnO-Ag, respectively.

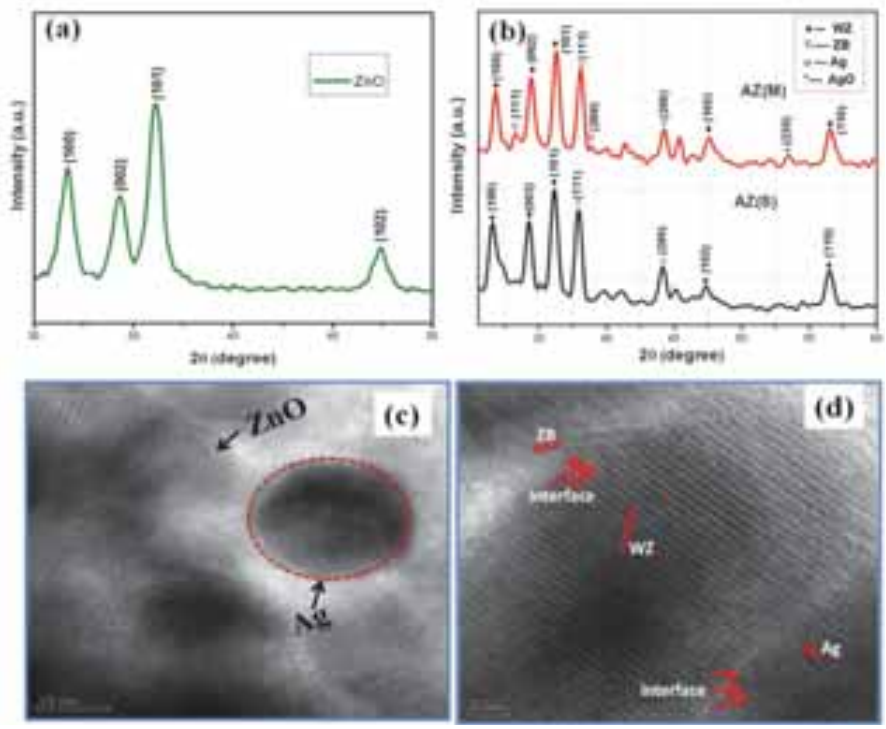

Fig.1: XRD spectrum of (a) Pristine ZnO (b) AZ(M), AZ(S); (c) and (d)TEM micrograph of AZ(M)

UV-DRS spectrum of pristine and Ag-ZnO sample is shown in Fig. 2a. All the Ag-sensitized samples show red-shift compared to the pristine ZnO. The band gap of the materials calculated using Tauc's equation [Xu, H., and Zhang, L., 2009.] is found to be 3.03 and 2.93 eV for AZ(S) and AZ(M), respectively while that of the pristine ZnO it is 3.12 eV (Table 1). In UV-DRS spectrum it can be observed that samples AZ(S) and AZ(M) show absorption peak near at 410 and 550nm, respectively. It has been reported that Ag shows a typical absorption peak in the range 400-550 nm due the surface plasmon resonance [Ansari et al., 2013; Logar et al., 2010]. So the peaks at 410 and 550nm are ascribable to the surface plasmon resonance of metallic silver. The emission centered at 370nm is due to the near band edge emission for ZnO. The PL spectra measured at excitation wavelength 325nm are shown in Fig.2b. The visible emission intensity of Ag doped ZnO sample was lower than the pristine ZnO ascribing the quenching of fluorescence due to the Ag, which increases the electron hole pair life time. The quenching of PL intensity (Fig.2b) is higher in AZ(M) which may due to synergistic effect of WZ-ZB homojunction and also Ag-ZnO heterojunction. PL spectra also reveal the increase of oxygen vacancies after Ag doping in ZnO.

Oxygen vacancy and the local environment of Ag are also investigated through EPR analysis (Fig.2c). Both pristine ZnO and AZ(S) show the EPR signal with g value 1.9 but AZ(M) shows a shift with g value at 1.8. These signals are ascribed to impurities or defects due to oxygen vacancies and broadening of the signal

for AZ(M) sample indicates increase in the oxygen vacancy. The g value 2.1 is assigned to zinc vacancy in the sample. The EPR signal at g value 2.35 in the sample AZ(M) is assigned to the Ag^{+} which indicates the presence of high amount of AgO in the sample [Deng et al.,2008]

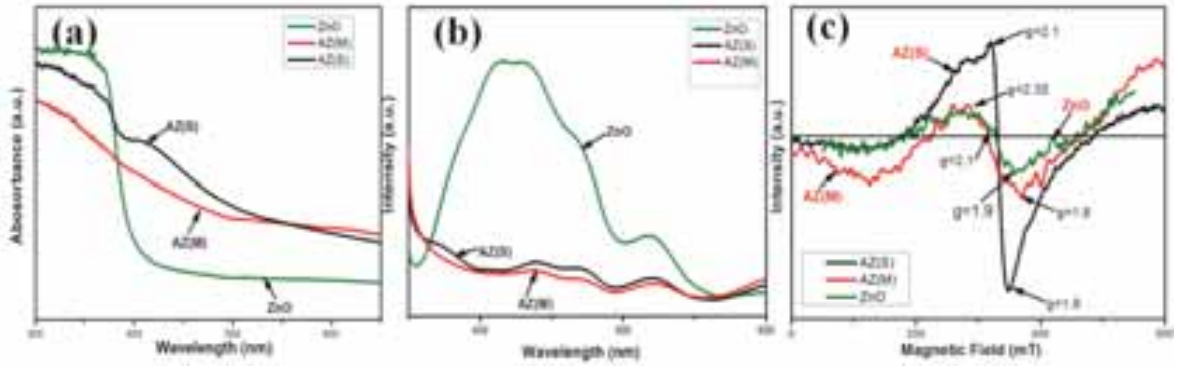

Fig. 2: (a) UV-DRS (b) PL and (c) EPR spectrum of the samples.

3.1. Photocatalytic activity test

To evaluate the photocatalytic activities of Ag-ZnO photocatalyst the degradation of methylene blue (MB) was investigated under visible light. Fig.3a shows the degradation kinetics of MB over Ag-sensitized ZnO samples. It is evident from the Fig.3 that the Ag-sensitized ZnO samples show excellent visible light activity compared to the pristine ZnO for methylene blue degradation. The degradation rate constant was calculated using $\ln(C/C_o)$ vs. time curve (Fig.3b) and it is found to be 0.007 and 0.006 min^{-1} for AZ(M) and AZ(S), respectively. But pristine ZnO shows a rate constant of 0.002 min^{-1}. So, AZ(M) shows 3.7 and 1.2 times higher photocatalytic activity under visible light compared to monophasic sensitized and unsensitized ZnO. The higher photocatalytic activity of AZ(M) compared to pristine ZnO and AZ(S) indicates the synergistic effect of mixed phase homojunction which increases the charge carrier migration and separation; and Ag nanoparticles anchored surface plasmon effect on ZnO nanoparticles. SPR of Ag enhances the photocatalytic activity by increasing electron concentration in ZnO. Besides these, increase in the life time of the photogenerated charge carrier also reduces due to the reduction in probability of the recombination of the charges which again helps in the enhancement of photocatalytic activity.

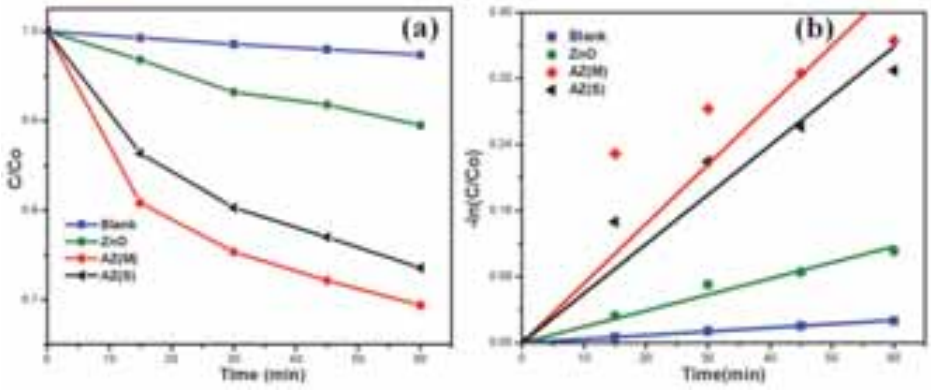

Fig. 3: (a) photocatalytic degradation of MB, (b) $\ln(C/C_o)$ vs. time curve for determination of rate constant

4. Conclusion

In conclusion, we have demonstrated synthesis of Ag-doped ZnO having mixed phase(wurtzite and zincblende) ZnO with an advantage of surface plasmon resonance of noble metal Ag. Surface plasmon resonance helps in extending the absorption spectrum of the photocatalyst in the visible region. Homo-junction interface of wurtzite-zincblende of ZnO helps in the separation and migration of the charge carrier to the surface. Photocatalytic activity study concludes that the mixed phase Ag-sensitized ZnO shows higher photocatalytic activity compared to pristine and single phase ZnO with and without sensitization due to the presence of homojunction of wurtzite-zincblende ZnO and heterojunction of Ag-ZnO on multiple aspects of the photocatalytic activity.

Thiolate Capped Noble Metal Particles as Novel Sensitizers for Solar Cells

Ziyu Cheng, Wenguang Fan and Michael K.H. Leung

Ability R&D Energy Research Centre, School of Energy and Environment, City University of Hong Kong, Hong Kong, China

Abstract

MPA (3-Mercaptopropionic acid) capped noble metal particles (Ag, Au) are studied in this project as sensitizers for solar cells. TiO_2 nanotube arrays were fabricated via etching anodization method. The MPA capped noble metal sensitizer was deposited onto the surface of the TNAs using in-situ hydrothermal method. Different initial molar ratios of Ag and Au were investigated. The specimens were characterized using FE-SEM, HRTEM, XRD, XPS and UV-vis spectroscopy. Photoelectrochemical measurements, including *J-V* curves, stability test and electron lifetime assessment, were conducted to examine the performance of the sensitized TiO_2 materials. It is found that the Ag (0) @ Ag (+) – MPA nanocluster showed the best performance in light energy conversion. Better stability was also achieved compared to previous works.

Keywords: *Nano-photocatalyst, visible-light activation, nano metal clusters, solar cell sensitization.*

1. Introduction

Metal-cluster-sensitized solar cell uses silver glutathione (Au-GSH) nanoclusters deposited on the mesoporous TiO_2 film as the photoanode (Kamat et al. 2014). The light-electricity conversion efficiency reached about 2.3% under AM 1.5 illumination. The mechanism of the excitation of the Au-GSH nanoclusters was characterized and reported in the literature (Linic et al. 2011). The excitation behavior of the Au-GSH nanoclusters is size-dependent and similar to that of dye molecules rather than plasmonic particles. The small nanoclusters composed of metal atoms behave as big molecules.

Recently, investigators studied the use of hybrid nanomaterials as sensitizers in liquid-junction solar cells illustrated in Fig. 1 (Chen et al. 2013, Fan et al. 2014). When there are incident photons with energy exceeding the semiconductor's bandgap energy, the electrons of the semiconductor can absorb the photon energy and be excited to the conduction band, leaving positively charged holes in the valence band. The excited free electrons will migrate through the circuit under the built-in potential difference. The holes capture electrons from the electrolyte so some species are oxidized. Meanwhile, when the free electrons reached the cathode, they reduce the oxidized species in the electrolyte. The chemical state of the electrolyte remains unchanged and the net effect of the cell is converting the photon energy to electricity. On the other hand, the excited free electrons may simply recombine with the holes without producing any useful electricity.

In liquid-junction solar cell, the hybrid nanomaterial consists of noble metal particles and organic compound. The metal-organic hybrid nanomaterials can absorb long-wavelength photons and inject charge carriers to the electrode, which is same as the roles played by traditional dye and quantum dots. The hybrid materials have shown some very intriguing and promising features and good chance to a step-forward in the field. The main objective of this research is to develop noble metal (silver and gold) based hybrid nanomaterials for enhancing solar photovoltaic performance.

2. Experimental

2.1. Sample fabrication

Etching anodization method is a commonly employed fabrication approach of self-ordered titanium nanotube arrays (TNAs) and has been a relatively mature means. Although the first nanotubes did not show very neat morphology, it demonstrated the effect of F^- ions on fabricating TNAs. A series of studies explored the impacts of pH value, the water content, the organic electrolyte system (such as ethylene glycol), constant voltage, duration and so on. Under the existence of anodic voltage and conductive electrolyte, the metallic titanium is firstly oxidized to TiO_2 and the H^+ in the electrolyte is reduced to H_2. If there was no etching ions (e.g. F^-) in the electrolyte, the reactions lead to formation of a compact oxide layer on the surface of Ti. Addition of F^- ions leads to formation of $[TiF_6]^{2-}$. The $[TiF_6]^{2-}$ species is water soluble, therefore reaction (eq. 1) represents an etching process of the as-formed TiO_2. During the anodization process, the F^- ions are driven to the anode under the electrical field, penetrate the as-formed amorphous TiO_2, and undergo reaction (eq. 1). If all the parameters are within a certain range, the combination of above mentioned processes lead to the formation of independent tube array (Roy et al. 2011). After anodization, a post-annealing treatment converts the amorphous TiO_2 into crystalline structures. The crystal phase can be determined by the annealing temperature.

$$TiO_2 + 4H^+ + 6F^- \rightarrow [TiF_6]^{2-} + 2H_2O \qquad \text{(eq. 1)}$$

The deposition of noble metal (Ag) onto the TiO_2 nanotube arrays occurs in dark condition. Silver nitrate (Strem, 99.9%) aqueous solution was mixed with 3-Mercaptopropionic acid in a glass vial. Then, 1 M NaOH (Sigma Aldrich, 97%) was added drop by drop into the vial till the mixture returned to clear and then the pH value was adjusted to 9.0. deionized (DI) water was added into the solution till the solution reached 15 mL. One piece of TNAs foil was placed into the vial with the TNA facet facing down. A dose of 5 mL ethylene glycol (Sigma Aldrich, 99%) was added into the vial. The solution was then purged with N_2 gas for 20 minutes. The vial was placed in a Teflon vessel with 25 ml DI water. The Teflon vessel was fixed and sealed into a stainless steel autoclave. The whole system was then heated in a 120 ^oC oven for 4 hours. The autoclave was then taken out of the oven and cooled down to room temperature. The sample was washed with DI water, and dried in nitrogen steam. We fabricated samples of different Ag:Au molar ratios: 3:1, 1:1 and 1:3 as shown in Fig. 2.

Au-GSH nanoclusters was deposited onto titanium dioxide fluorine-doped tin oxide (TiO_2-FTO) glass electrodes. The deposition followed a modified in-situ hydrothermal approach. Basically, 0.06g of gold (III) chloride trihydrate (Aldrich, ≥99% trace metal basis) and 0.07g of L-glutathione reduced, was mixed in 75 ml of DI water in a round bottom flask. TiO_2-FTO-glass electrodes were immersed into the solution and the solution was purged with N_2 gas. Then the flask was heated and refluxed at 70 ℃ for 24 hours. During the entire experiment, the solution kept being bubbled with N_2 gas.

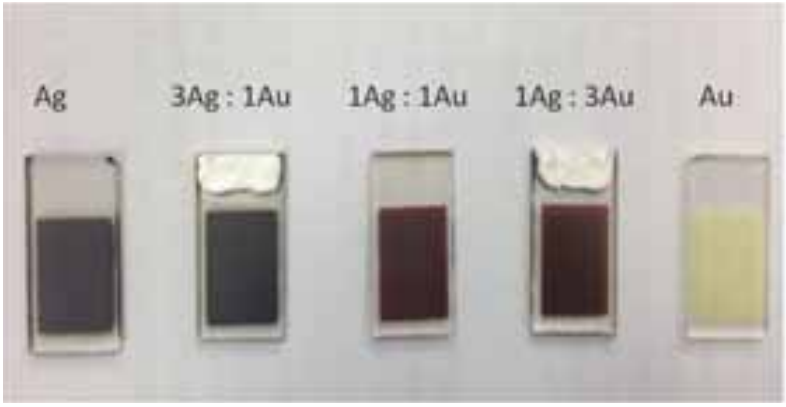

Fig. 2: TiO_2-nanoparticle-FTO samples

2.2. Material characterization

The light absorption ability of the sensitizers was examined using UV-Vis spectroscopy, where a small aliquot was taken from the remaining liquid after the in-situ hydrothermal deposition. Characterization of the morphology was carried out using field-emission scanning electron microscopy (FE-SEM) with acceleration voltage of 5.0 kV, and high-resolution transmission electron microscope (HRTEM) at 200 keV. For FE-SEM, the sample was cut into small pieces and attached to an aluminum plate with conductive silicon tapes and then subjected to observation. For HR-TEM, the sample was scratched off from the foil and dispersed onto a copper mesh with the help of ethanol. Elemental composition of the samples was analyzed using energy dispersive X-ray spectroscopy (EDX) equipped on the FE-SEM. The crystalline structure of the samples was scanned using X-ray diffraction (XRD), with Cu Kα radiation, from 2θ of 20° to 80° with steps of 0.02°. The surface energy state and chemical composition was analyzed with X-ray photoelectron spectroscopy (XPS) with Al Kα as the excitation source.

2.3. Photoelectrochemical performance

The photoelectrochemical (PEC) measurements were conducted using the three-electrode cell setup. The sample was assigned as the working electrode. The other two electrodes, the counter electrode and reference electrode, was a platinum plate and a saturated calomel electrode (SCE), respectively. A 2-cm diameter quartz window is located in one wall of the cell and its distance from the working electrode was kept at 2 mm to minimize the light absorption by the electrolyte in the spacing. A redox electrolyte was filled into the cell which was prepared through mixing 0.5M sulfur powders and 0.5 M sodium sulfide solution. The experiment was carried out under exposure to artificial sunlight obtained mounting a neutral density metallic filter and an AM 1.5G filter on a 300-W Xe lamp (Newport). The incident power density at the working electrode was adjusted to approximately 100 mW/cm^2 and was kept the same for every measurements. A potentiostat instrument (Solartron) was used to conduct the measurements and collect the data.

3. Results and discussion

3.1. Material properties

In the SEM and TEM images (Figs. 3 and 4) of samples fabricated show the deposition of nanoparticles onto the TiO_2 nanostructures. The EDX measurements (Table 1) indicate that the nanoparticles are Ag and Au.

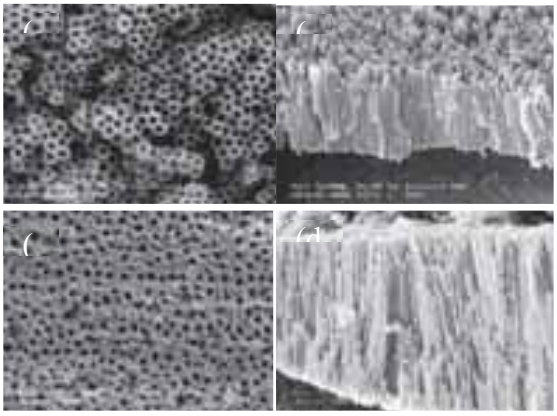

Fig. 3: SEM images of TNAs

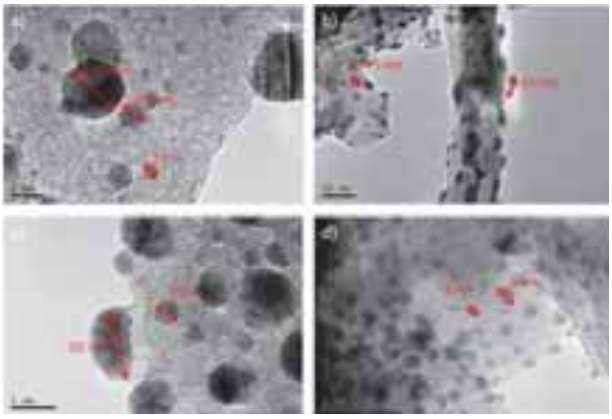

Fig. 4: TEM of TNAs with Ag and Au deposition

Table 1: Atom percentage from EDX analyses

Element	Sample 1 Ag	Sample 2 3Ag:1Au	Sample 3 1Ag:1Au	Sample 4 1Ag:3Au	Sample 5 Au
O	59.06	51.41	52.18	57.98	61.57
Ti	31.73	29.58	28.19	31.02	31.5
S	1.21	3.86	3.73	1.86	0.48
Ag	2.39	4.45	3.1	0.9	0
C	5.6	7.1	8.59	6.43	5.6
Au	0	1.31	1.13	1.81	0.85

3.2. PEC performance

Figure 5 shows the UV-Vis absorption of the five samples. The Au modification yields better visible-light absorption. The *J-V* curves of the samples are shown in Fig. 6. Ag-MPA sensitized TNAs exhibits the best performance. The short-circuit current density is 1.5 mA/cm^2, which is 38 times greater than that of bare TNAs electrode (0.04 A/cm^2).). On the other hand, the Au Sample 5 is not satisfactory. The sample sensitized by Au-MPA nanoclusters did not show much increase in performance compared to bare TNA. The overall trend shows that Ag-based sensitizers exhibit higher photo-activity than the Au-based counterpart.

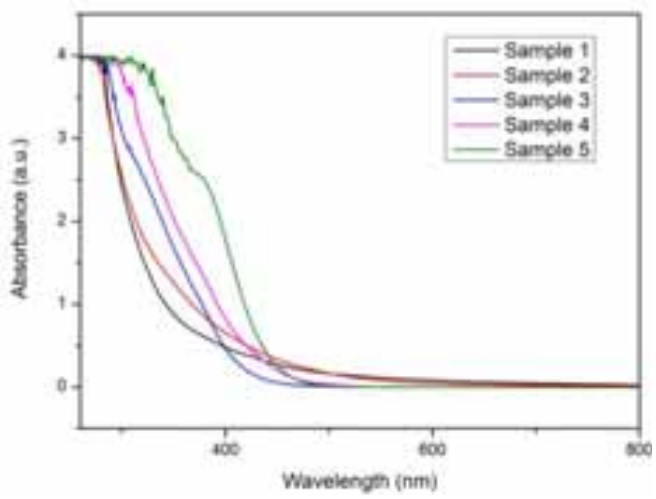

Fig 5: Ultraviolet-Visible spectral absorption

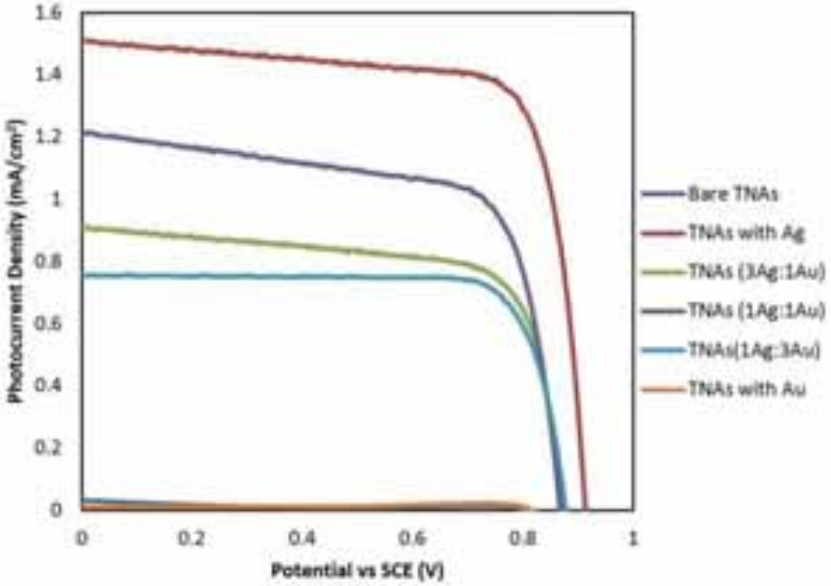

Fig. 6. PEC performance of samples fabricated

\

4. Conclusion

TiO_2 nanotube arrays fabricated by anodization have uniform morphology with pore diameter of ~100 nm and tube length of ~6 μm. After annealing, the TNAs are transformed into Anatase phase with a trace amount of Rutile. MPA capped Ag nanoparticles are deposited onto the surface of TNAs through the in situ-hydrothermal method. The nanoparticle diameter is 6~7 nm. The nanoparticles are classified as nano-clusters. The deposition of the Ag-MPA nanoclusters onto TNA can boost the PEC performance for significant increase in solar conversion efficiency.

Abstract

Photocatalytic active, well-ordered TiO_2 nanotubes (TNTs) were synthesized using electrochemical anodization of a Ti substrate. A third generation electrolyte comprising mixture of ethylene glycol and ammonium fluoride in water was used to grow the TNTs at 60 V and 2 h deposition time. The effect of post-annealing on the physical properties and the photocatalytic activity of the TNT samples at two different temperatures, 300°C and 400°C was investigated. Further, the effect of pre-annealing of Ti substrate foil before growth of TNTs between 250°C and 650°C was investigated. Calcining at 300°C and 400°C for 1 h transformed the TNTs from amorphous to anatase phase. SEM images reveal dense and self-organization of TNTS for Ti foils annealed at 350°C and 440°C. The photodegradation rate of MB was twice as high for samples annealed at 400°C compared to those annealed at 300°C. The length of the TNT reached a maximum of 8.85 μm on Ti foils pre-annealed to 440°C for 1 h, after which a drastic reduction to 4.87 μm and 4.24 μm was observed on Ti foils pre-annealed to 525°C and 625°C respectively. The wall thickness systematically decreased as 32 nm, 31 nm, 29 nm, 21 nm, and 20 nm, respectively, when TNTs were grown on Ti foils heated at 250°C, 350°C, 440°C, 525°C, and 625°C.

Keywords: *Anodic, Titanium dioxide, Nanotubes, Photocatalytic*

1. Introduction

Titanium dioxide nanotubes (TNTs) prepared by electrochemical anodization have a high surface to volume ratio with size dependent physicochemical properties (Rani, 2010). TNTs with controlled dimensions have shown promising properties in many applications such as dye sensitized solar cells, photocatalysis, gas sensing, biomedical and antimicrobial applications (Rani, 2010). Titanium dioxide (TiO_2) photocatalysts were first used for remediation of environmental pollutants in 1977, when Frank and Bard reported the reduction of CN^- in water (Frank and Bard, 1977), leading to a dramatic increase in research in this area (Fujishima, 1999). Other binary semiconductors that have been studied as photocatalysts include ZnO, WO_3, Fe_2O_3, CdS and ZnS but hitherto TiO_2 stands out as superior for most practical applications. TiO_2 photocatalysis works at room temperature with supply of low intensity UVA light (< 390 nm); practically of the order 1 mW/cm^2 or higher. Photo-generated electrons in the conduction band of TiO_2 are reducing enough to produce superoxide from dioxygen (Fujishima et al., 2000), and the holes in the valance band are sufficiently low (with respect to the vacuum level) for oxidation reactions. Moreover, TiO_2 is resistant towards photo-corrosion, it is chemically stable in aqueous solutions, and it is non-toxic (Hsien et al., 2000). However, the large band gap of TiO_2 limits its application for efficient solar energy utilization. The most commonly used crystalline structures of TiO_2 are anatase and rutile with energy band gaps of about 3.2 eV and 3.0 eV, respectively. This means that only about 4% of the entire solar spectrum can be utilized by TiO_2. Anatase TiO_2 films are reported to have higher conversion efficiency, photocurrent and electron diffusion length than rutile films of same thickness (Park et al., 2000; Tanaka et al., 1991). Preparation and post-treatment methods can further enhance the photocatalytic activity. For example TiO_2 nanotubes and

doi:10.18086/swc.2015.04.28 Available at http://proceedings.ises.org

nanowires are reported to have high photocatalytic activity because of a large surface area to volume ratio and efficient collection of charge carriers at their interfaces. The photocatalytic efficiency of TiO_2 films has been improved by pre-heat treatment, post-heat treatment and doping. For films made by electrochemical anodization, spray pyrolysis, hydrothermal, dip coating, impurities arising from chemical solutions used during deposition can be removed by heat treatment. TNTs made by anodic oxidation are generally amorphous with high recombination centers limiting their photocatalytic activity (Li et al., 2012; Ghicov et al., 2006), although ways to promote crystallization have been reported by (Grimes et al., 2009). TNTs can however readily be crystallized upon calcination. Anatase TiO_2 has previously be been prepared by calcining amorphous TNTs between 300^{o}C and 400°C (Regonini et al., 2010). Annealing amorphous TiO_2 nanotubes at temperatures between 450 °C and 750 °C was shown to yield mixtures of anatase and rutile phases (Li et al., 2012). The effect of substrate annealing on the TNT structure has also been studied and shown to influence the growth mode (Weizhen et al.2011; Zheng et al., 2015).

In this study, electrochemical anodization of Ti foils has been performed to fabricate TNTs using a so called third generation electrolyte with the purpose of investigating the effect post-annealing on the TNT structure and photocatalytic activity. Further, the effect of pre-annealing the Ti substrate foil on the TNT physical properties is also investigated.

2. Experimental

2.1. Preparation and electrodeposition of TNTs on non-annealed Ti foils

Ti foils with dimension 15mm×15mm×0.25 mm were used as anode materials (purity 99.7%, Sigma Aldrich) in a two electrode setup. A Pt foil with size 25mm×25mm×0.25 mm was used as counter electrode (purity 99.9%, Sigma Aldrich). Prior to use the electrode foils were cleaned by sonication in ethanol for 5 minutes, and then rinsed in distilled water and dried in a stream of nitrogen gas. Anodization was performed using a constant DC voltage of 60 V. All chemicals used in this work were purchased from VWR chemicals Sweden with stated purity 99.9 % or better. Electrolyte solutions with the following compositions were used to prepare TNTs on non-annealed Ti foils: (i) 95 vol% ethylene glycol, 5 vol% water, and 0.37 g ammonium fluoride (NH_4F) corresponding to 0.1 M, and (ii) 47.5 vol% ethylene glycol, 2.5 vol% water and 0.37g NH_4F corresponding to 0.2 M. Anodization was done for 2 h. The as prepared TNT samples were rinsed in distilled water and dried in a stream of nitrogen. The as prepared TNTs were subsequently annealed in air for 1 h. The morphology of as prepared samples was characterized by scanning electron microscopy (SEM; Zeiss 1550, Jena, Germany) employing 1 to 10 kV acceleration voltages with an in-lens secondary electron detector. The TNT length was measured by profilometry (DektakXT, Bruker, Germany). The crystallinity and phase composition was measured using X-ray diffraction (XRD) with 2θ between 20 and 80° using a Philips D5000 diffractometer employing averaged Cu $K_{\alpha 1}$ (λ = 1.5418 Å) radiation. The photocatalytic activity of the samples was measured using a homebuilt photocatalytic reactor, which continuously can measure the methylene blue (MB) concentration in the reactor as a function of UV illumination by recording the calibrated transmittance of the 670 nm absorption band due to MB in the well-stirred solution with a diode laser (Bozhidar, 2011). A concentration of 1 ppm MB in 100 mL water was used in the experiments.

2.2 Preparation and electrodeposition of TNTs on pre-annealed Ti foils

Prior to anodization the Ti foils were heated in an oven at varying temperatures between 250°C to 625°C in steps of about 100^{o}C in a stream of nitrogen for 1 h. After annealing, the Ti substrates were cleaned by sonication in ethanol for 5 minutes, rinsed in distilled water, and finally dried in a stream of nitrogen gas. The anodization electrolyte comprised of 93 vol% ethylene glycol, 7 vol% water and 0.15 M NH_4F. Anodisation was done in 100 mL Teflon beaker using electrode separation distance of 3 cm at 55VDC for 2 hours. Samples were prepared using an optimized electrolyte preparation procedure where ammonium fluoride was first mixed with water and magnetically stirred. The solution was then added to ethylene glycol and magnetically stirred. The TNTs were then calcined at 400^{o}C to obtain anatase crystalline structure after which characterization of the samples was done.

3. Results and discussion

3.1 Post-annealed TNTs on non-annealed Ti foils

Figure 1 shows SEM images of two samples, TNT07 and TNT08 measured at different magnification, but grown under the same electro-deposition conditions as described section in 2.1. Both TNT sample have tube diameters 120 nm and 10 nm wall thickness, and the TNTs are arranged in hexagonal structure.

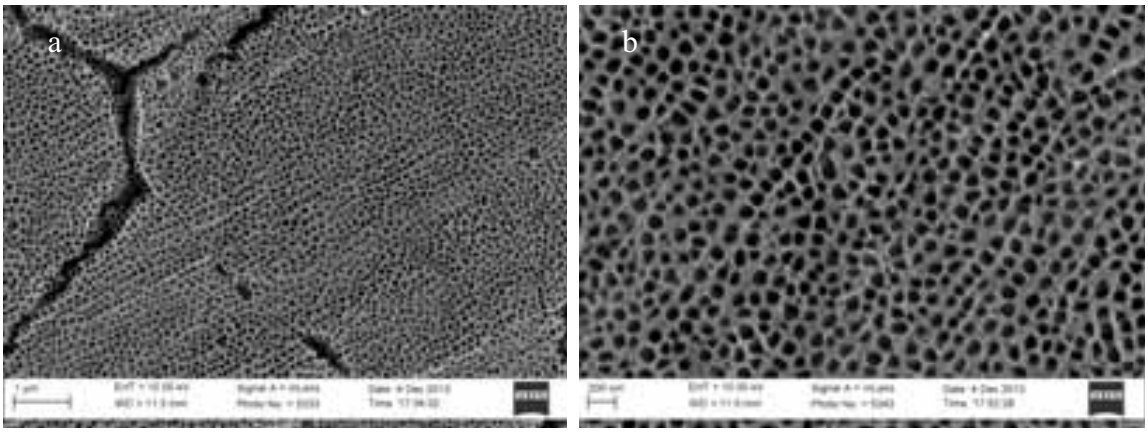

Fig. 1: SEM images for sample TNT 07 and TNT 08 with different magnifications prepared by anodisation for 2hours in 0.2 M NH_4F, 95% Ethylene glycol and 5% H_2O

The as-prepared TNTs were amorphous but on calcining samples TNT07 and TNT08 at 400°C and 300°C, respectively, for 1 h, the TNTs crystallized as shown Fig. 2 XRD diffractograms. It is seen that both samples exhibit predominately the anatase phase, with minor reflections form rutile crystals. The XRD diffractogram in Fig. 2 show that the intensity ratio of the <004> to the <001> reflection is higher for the sample annealed at 400°C than the sample annealed at 300°C. Rutile <111> and <211> reflection peaks are also observed which are more intense in the sample annealed at 400°C.

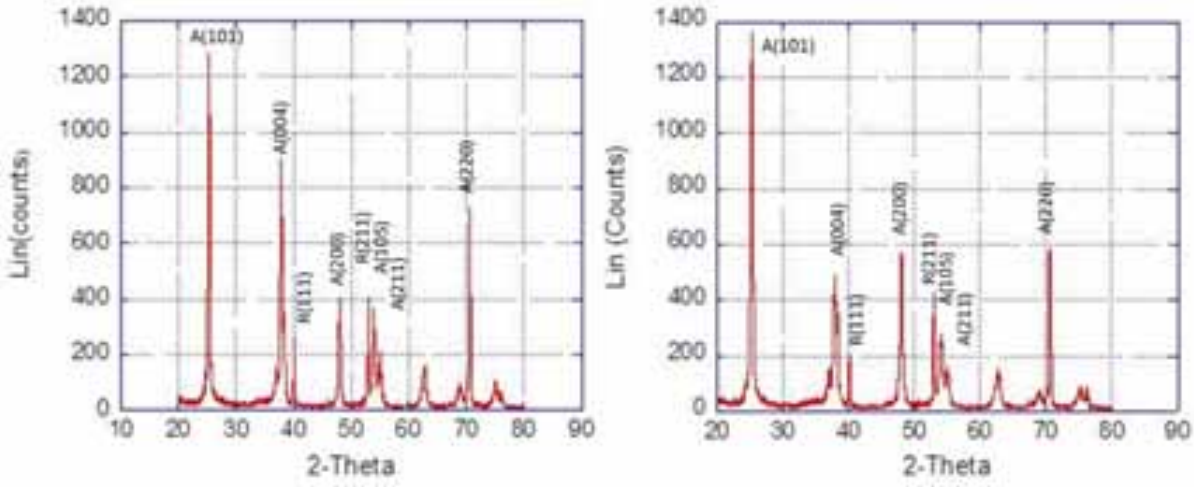

Fig. 2: XRD diffractograms of samples (a) TNT07 calcined at 400°C and (b) TNT08 calcined at 300°C.

Scherrer analysis of the <101> reflection peak was used to obtain a rough estimate of the crystallite size, *d*, viz.

$$d = \frac{0.94\lambda}{\beta cos\theta}$$

where 2θ = 25.27° and 2θ = 25.25° for the sample annealed at 400 °C and 300 °C, respectively, β is the FWHM corrected for the instrumental line broadening, yielding d = 37 nm and 32 nm, respectively, indicating a crystallite growth with increasing annealing temperature, as expected.

The photocatalytic properties of the samples, where measured in 1 ppm MB solutions. The calibrated MB concentration, as measured by the 670 nm laser intensity integrated in the reactor, is shown in figure 3a, and shows a linear decrease of transmittance in the solution as a function of increasing MB concentration, thus validating the performance of our experimental setup. The photocatalytic degradation rate of sample TNT08 post-annealed at 300°C (Fig. 1b) is k_{dec} = 0.0019 min^{-1}, while that of TNT07 post-annealed at 400°C (Fig. 1a) is k_{dec} = 0.0035 min^{-1}. We attribute this to a higher degree of crystallinity after post-annealing at 400°C, and possibly due to the increased rutile content which has been reported to enhance the photocatalytic activity due to synergetic bandgap matching of rutile and anatase particles that are in physical contact to each other (Su et al., 2011)

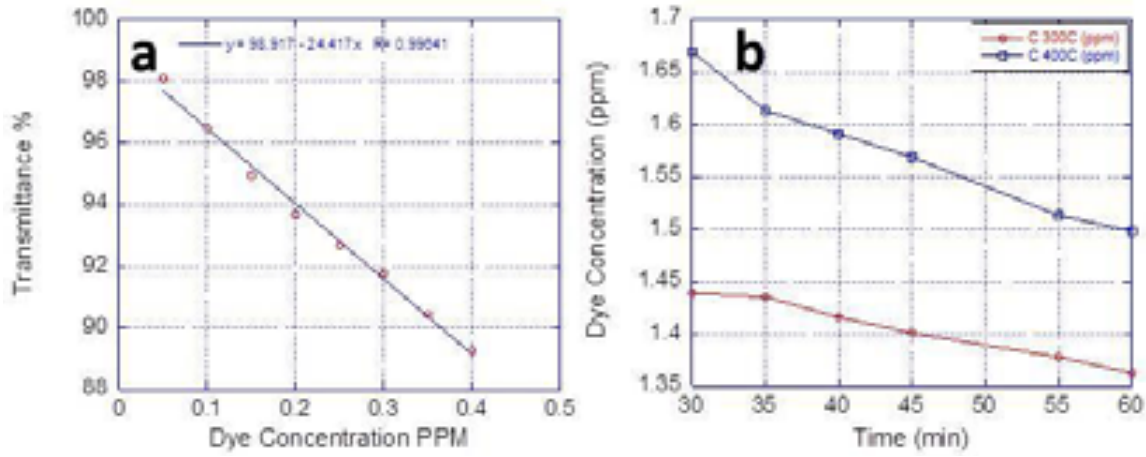

Fig: 3 (a) MB calibration curve for photocatalytic measurements (b) Methylene blue degradation for samples TNT 07 and TNT 08 calcined at 400°C and 300°C. The illumination time in (b) started at time = 30 min.

3.2 TNT on pre-annealed Ti foils

SEM images of a pristine non-annealed Ti foil and annealed Ti foil are shown in Fig. 4. It is seen that the micro-structure and surface morphology are changed upon annealing. Heating of Ti foils brings about rearrangement, crystal growth, as well as surface oxidation of the Ti foil that can facilitate TNT nucleation by providing new reactive sites. The pristine Ti metal foils are polycrystalline in nature and characterized by randomly distributed grain boundaries which act as defect sites for TNT nucleation (Grimes and Mor, 2009). Thus the defect sites act as templates for TNT growth. Substrate heating influences the crystal structure and mechanical behavior of the Ti foils which influences the TNT nucleation and growth. Annealing smoothens the Ti foil which and improves the order and arrangement of TNTs, as we now discuss.

SEM images of TNTs grown on annealed Ti foils pre-annealed between 250°C and 625°C are shown in figure 5 (a-e). SEM images taken from the bottom side of the TNTs are shown in figure 5f. For the non-annealed TNT bottoms, the TNTs have clear grain boundaries. The distribution and size of TNTs is irregular. Some are pentagonal, others are hexagonal, some are small others are large. This irregular distribution and size effects are inherent in the Ti foil and come about during processing of the Ti foils and are transferred to TNTs during the growth process in electrochemical anodization. Pre-heating treatment rearranges the atoms

within the Ti foil through diffusion and smoothen the surface. The inset in figure 5f shows TNTs grown on annealed Ti foils. Here the bottom parts of the TNTs are more densely packed and almost cylindrical

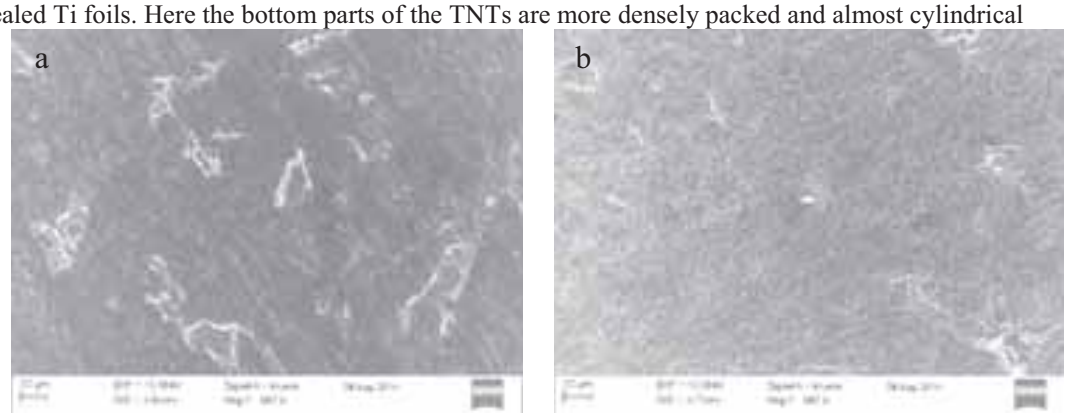

Fig. 4: SEM Images of (a) non annealed Ti foil, and (b) annealed Ti foil.

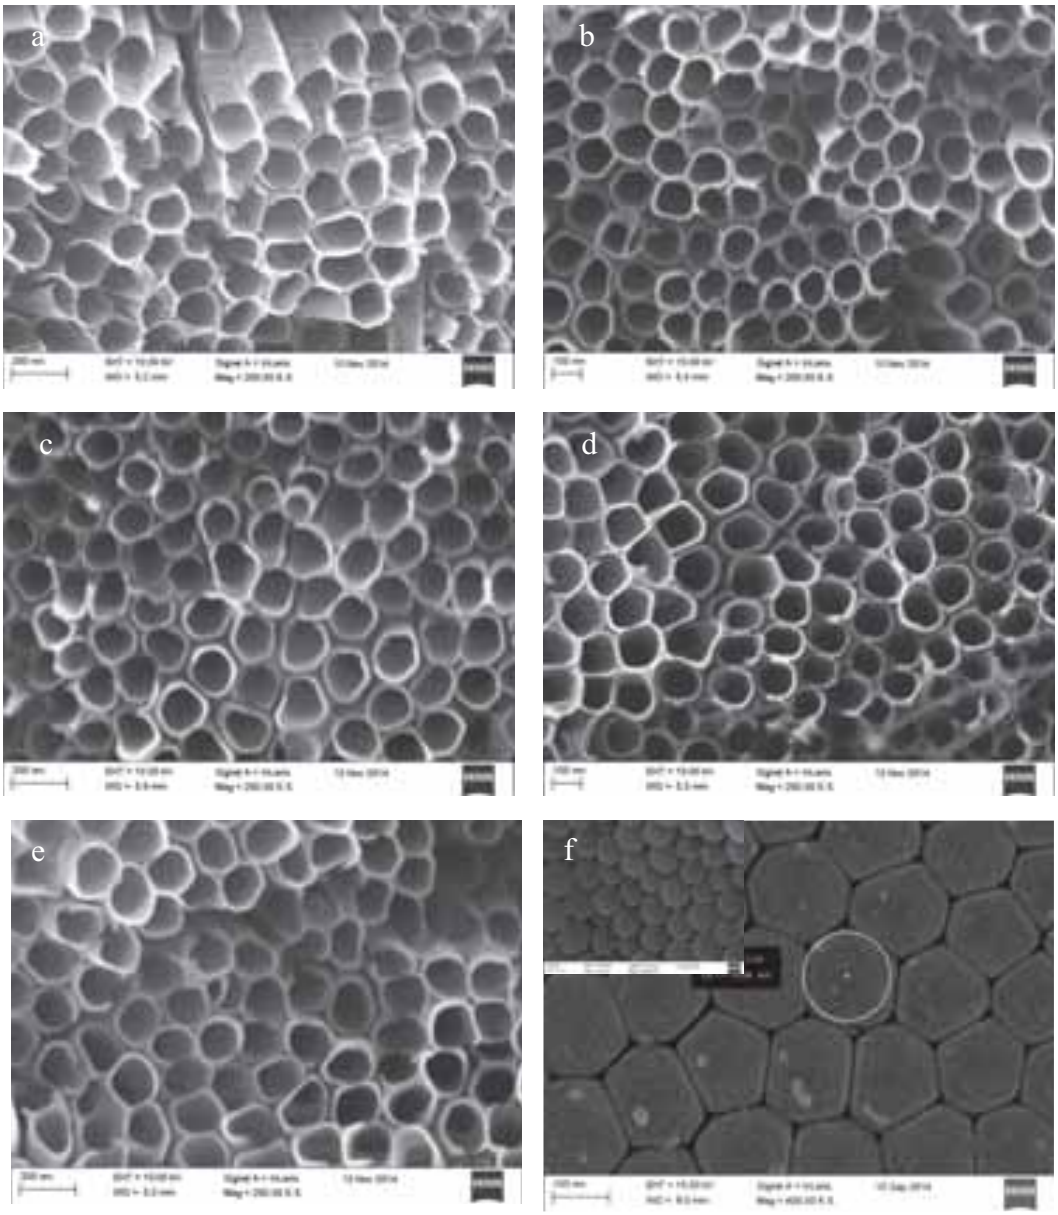

Fig. 5: SEM top-down images of TNTs grown on pre-annealed Ti foils at (a) 250°C (b) 350°C (c) 450°C, (d) 525°C (e) 625°C, and (f) SEM images from scraped off TNT bases grown on non-annealed, and in the inset, annealed Ti foils.

Annealing helps to reduce residual stresses developed during the process of fabricating the Ti foils (Zheng et al., 2015). Heat treatment changes the structure, mechanical properties of the Ti foils improving the structural and mechanical properties of the annealed of the Ti foil which affect the growth of TNTs during the process of anodization as reported by Xialong et al. (Xialong et al, 2010). In the latter study it was noticed a change in microstructure in Ti foil through the formation of V- like structures with ultrathin walls as a result of rearrangement of atoms within the Ti foil. Annealing causes atoms to migrate in a crystal lattice reducing defects and dislocations in the material which in turn changes hardness and ductility of material. While by preheating Ti foil we induce superior properties, it should be noted that from the findings of Zheng and colleagues (Zheng et al., 2015), Ti foil has been shown to exhibit different stages when heated in a so called microforming process. Temperatures below 300^{o}C brought about elastic and work hardening stages. At 450^{o}C the material exhibited elastic, work hardening and softening periods. Fracture strain set in at 450^{o}C and increased thereafter because of the occurrence of the softening behavior with deformation setting in when the temperature was increased (Zheng et al., 2015). With increasing annealing temperature stress on Ti foil is reduced and when the foil is used to grow TNTs, the initiation of TNT growth is affected. A compromise has to be attained where pre-annealing gives desirable TNT growth, structure and high-order with good characteristics.

Figure 6a shows the influence of physical properties of TNTS of Ti foils pre-heated at 250^{o}C, 350^{o}C, 440^{o}C, 525^{o}C, and 625^{o}C. Nanotube inner diameter significantly drops by 18 nm from 158 nm to 140 nm when Ti foils are heated to 350^{o}C. At higher annealing temperatures the inner diameter of the TNTs exhibits only a slight decrease of inner diameter. A similar trend is noticeable for the outer diameters of the TNTs. These results show that most of rearrangement of the crystal atoms within the Ti foil that act as nucleation sites for TNT takes place when the Ti foil is heated between 250^{o}C and 350^{o}C. Packing of the TNTs continues at higher annealing temperatures. This difference in packing of TNTs is seen in the SEM images in figure 5, and the dramatic change of TNT packing above 250^{o}C is clearly evident.

The wall thickness for Ti foils pre-heated at 250^{o}C, 350^{o}C, 440^{o}C, 525^{o}C, and 625^{o}C reduces as 32 nm, 31 nm, 29 nm, 21 nm, and 20 nm, respectively. In fluoride containing electrolytes, wall thickness is a function of electrolyte concentration, water content and anodizing voltage. At high fluoride contents, thin walls are produced because of effects of chemical etching. As seen in figure 6b only short nanotubes were grown on Ti foils annealed at 525 ^{o}C and 625 ^{o}C. This means with all other anodizing parameters kept constant in growing all the TNTs, the effect of etching of tube walls is most pronounced for the short nanotubes. Short TNTs means disorder, since the metal\oxide base interface is etched away in the fluoride containing electrolyte leaving spacing between growing TNTs. Longer TNTs protect the electrolyte from reaching the metal\oxide base interface. This explains why we have drastic reduction in wall thickness from 29 nm to 21 nm in TNTs grown on Ti foil heated at 440 ^{o}C and 525 ^{o}C, respectively, together with the use of already deformed electrode with reduced stress. As seen in figure 6b the TNT length drastically reduces by almost twice from about 8850 nm to 4870 nm.

When Ti foils were heated from 250°C to 625°C, the TNT length first increased as 7490 nm, 7970 nm, 8850 nm, for the pre-heat treatment at 250^{o}C, 350^{o}C and 440^{o}C, respectively, after which the length was observed to decrease at higher temperatures beyond 450^{o}C (Fig. 6b). At 525°C and 625^{o}C, the TNT length decreased as 4870 nm and 4240 nm, respectively. Several factors have been reported to influence the growth of TNT, among them being pH of electrolyte, diffusion, temperature of solution and stress induced effects. In ethylene glycol containing electrolytes, high ammonium fluoride content means high pH. This increases the rate of chemical dissolution hindering TNT growth. High temperatures of electrolyte in ethylene glycol containing electrolytes means reduced viscosity of the bulk ethylene glycol solution leading to fast migration of the fluoride ion which diffuses at twice the rate of oxygen ion thereby affecting growth of TNT. This explains why viscous electrolytes such as glycerol and ethylene glycol have been known to produce well-ordered and long nanotubes because the rate of diffusion of F^{-} is reduced enabling growth (Paulose et al., 2007). Aqueous electrolytes only produce TNTs only a few um long because of chemical dissolution\oxidation (Beranek et al. 2003). Stress builds up during oxidation of Ti foil in electrochemical anodization and is present in the growing nanotubes (Macak; 2008). Heating Ti foils at temperatures between 250-450^{o}C reduces stress on Ti foil (Zheng et al., 2015). In this work, the proposition is that the remaining

stress on Ti foil after annealing at this temperature coupled with stress induced effects during anodization can influence the oxidation\dissolution behavior in the anodization set up initiating growth, self-organization and cause an increase in nanotube growth length as shown in figure 6b for TNTs grown on Ti foil pre-annealed at 250°C, 350°C and 440°C. The reduction in nanotube length in figure 6b, when Ti foils are heated at 525 °C and 625 °C, can be explained by the fact that at temperatures above 450°C stress on Ti foil is minimal, fracture and deformation has set it on the Ti foil (Zeng et al., 2015. The formation of tube bottom (TiO_2) layer at the metal\oxide interface is permanently exposed to compressive stress (Macak; 2008). A reduction in nanotube length as shown in figure 6b means that the fluoride containing electrolyte easily penetrated to the lower part of the nanotube bottom base eroding the nanotube bottoms, and at the same time hinder oxidation\dissolution behavior at the metal\oxide layer. Eventually this leads to reduced growth. We conclude that a mechanically deformed Ti foil, when used as anode electrode in the electrochemical anodization, will perform poorer than a normal working anode which has not undergone deformation. Since the formation of TNTs takes place at the anode and it is the working electrode, care should be taken not to anneal Ti foils above 440°C.

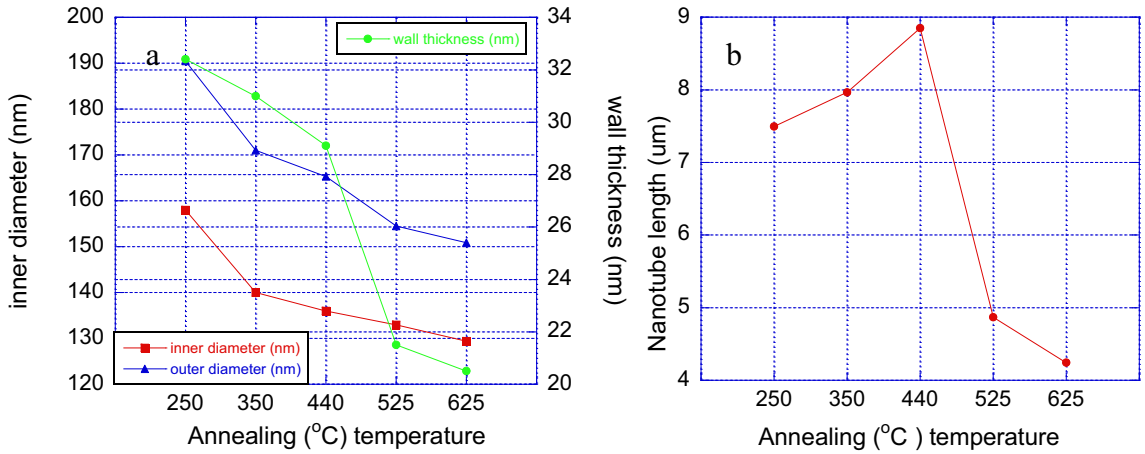

Fig. 6: (a) A graph of physical parameter (inner, outer and wall)dimension (b) Nanotube length of TNTs anodised on preheat treated Ti foils at different temperature in 93% ethylene glycol, 7% vol water and 0.15 M NH_4F for 2 hours in 55VDC

4. Conclusions

The effect of Ti annealing temperature on already grown amorphous titanium dioxide nanotubes has been explored. Heat treatment on the as-prepared amorphous TNTs at 300°C and 400°C gives predominantly TNTs with anatase phase, with minor reflections form rutile crystals. The grain sizes as deduced from Scherrer analysis of XRD diffractograms yield d = 37 nm and 32 nm for the TNT07 and TNT08 samples, respectively, demonstrating larger grain sizes with increasing calcination temperature of the amorphous TNTs, and a tendency for alignment along the <004> direction. The rate of photodegradation of methylene blue is higher for the sample annealed at 400°C than that annealed at 300°C which is attributed to increasing crystallinity, and possibly higher percentage of inter-mixed rutile phase. The effect of Ti foil annealing before growth of TNTs is further explored and found to influence nanotube growth, the nanotube structure, and optical properties of the nanotubes. Ti foils annealed between 250°C and 625°C gave an increase in nanotube length up to 440°C, beyond which there was a great reduction in nanotube length from about 8850 nm at 440°C to 4870 nm for Ti foil heated at 525 °C. Nanotubes wall thickness reduced systematically up to about 29 nm at 440°C after which the wall thickness reduced to 21 nm for nanotubes grown on Ti foil heated at 525°C. The outer diameter reduces from 165 nm at 440°C to 154 nm at 525°C. There is structural rearrangement of nanotube structure with better and closer hexagonal packing of the TNTs achieved at 440°C, but beyond this temperature, disorder sets in due to shortening of TNTs which are due to effects of chemical etching as a result of exposure to electrolytes. In this work we propose titanium foils for growing TNTs using electrochemical anodization in ethylene glycol and ammonium fluoride electrolytes should be heated in an atmosphere of nitrogen for one hour at 440°C. The as prepared amorphous nanotubes should

further be calcined at 400^{o}C to get pure anatase for photocatalytic applications since it is the best phase for photocatalytic applications.

Abstract

Highly- ordered and self-organized titanium dioxide nanotubes (TNT) for photocatalytic activity were fabricated by anodization method, and characterized using scanning electron microscopy, X-ray diffraction, UV-Vis spectrophotometry, and profilometry. Anodization electrolyte preparation and growth conditions were studied towards the growth of ordered TNTs by systematically varying electrolyte composition and mixing procedures. TNTs were grown by anodizing pure titanium foils in a third generation electrolyte consisting of 0.2 M ammonium fluoride and water. For optimization purposes, the samples were anodized at a constant DC voltage of 60 V for two hours while varying the electrolyte composition by employing different ways of mixing the electrolyte so as to achieve a homogeneous solution. The concentration of fluoride was varied between 0.005 M to 0.3 M, while the water content was varied between 3 and 50 vol %. Introducing a two-step anodization procedure, improved TNT structures were achieved. The as-prepared TNTs between 87 nm and 170 nm; and wall thickness between 20 nm to 40 nm depending on anodizing conditions were amorphous, and were found to transform into highly crystalline anatase structure upon calcination at 400^{o}C. The physical dimensions of the TNTs varied with length between about 7.2 nm to 46 nm; inner diameter. The TNTs were shown to be active for methylene blue photo-degradation, and that reaction rate was shown to be more than twice as high on the two-step anodized TNTs.

Keywords: *Anodization, TiO_2, nanotubes, photocatalysis.*

1. Introduction

Titanium dioxide nanotubes (TNT) have attracted considerable interest due to its wide applicability in a variety of fields such as gas sensing, photocatalytic pollutant degradation, dye sensitized solar cells, self-cleaning surfaces, antibacterial coatings and biomedical application (see Rani, 2010, and references therein). Various ways to prepare TNTs have been reviewed by Macak et al, (2007) and Rani et al (Rani, 2010). Anodic oxidation of Ti foils has been shown to yield high quality TNTs (Mizukoshi et al., 2013), by judicious control of parameters such as electrolyte concentration, applied voltage, pH and temperature. Several different types of electrolytes have been reported over the years to grow ordered TNTs. This includes the so-called first, second, third and fourth generation of electrolytes (Raja, 2010). The nature of electrolyte (aqueous or non- aqueous) plays a key role, and has been found to influence the TNT growth. In viscous organic electrolytes TNTs with smooth walls are obtained at low water concentrations (Macak et al, 2007). In such electrolytes high order is achieved because of reduced rate of dissolution. High water content favors transition to sponge like structures rather than nanotubular structure (Kiyoung et al., 2013). Aqueous electrolytes give rise to high chemical dissolution rates causing dissolution of the oxide, thus resulting in short TNTs of just a few micrometers. Nanotube dimensions have been tailored by controlling the concentration of electrolyte (Paulose et al., 2007), voltage (Regonin et al., 2013), water content (Macak et al., 2005), anodizing time (Choi et al., 2006; Crawford et al., 2007), and temperature (Prida et al., 2007;

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.04.29 Available at http://proceedings.ises.org

Varghese et al., 2005). In fluoride containing electrolytes the structure of TNT depends on the amount of the fluoride content. Increasing the fluoride content increases the pH, which in turn affects the oxidation/dissolution behavior due to fast etching of the Ti substrate. Low concentrations are required to obtain uniform nanotubular structures since they minimize oxide dissolution into the electrolyte.

In this work, TNTs were grown using electrochemical anodization employing a so called "third generation" electrolyte containing ammonium fluoride, ethylene glycol and water, and optimum processes parameters were established. A second anodization step was adopted and shown to result in TNTs with improved physical properties. Finally, the photocatalytic activity of the TNT s towards photo-degradation of methylene blue in water solution was demonstrated.

2. Experimental

2.1 Titanium dioxide nanotube preparation

2.1.1 Materials

Ti foil with dimensions 8 mm × 8 mm × 0.25 mm was employed as anode material (purity 99.7%, Sigma Aldrich). Prior to use the Ti foils were cleaned by sonication in ethanol for 5 min, and then rinsed in distilled water and dried in a stream of nitrogen gas. A Pt counter electrode with size 25 mm × 25 mm × 0.25 mm (Sigma Aldrich, purity > 99.7%) was used. The electrolyte mixing procedure was varied to see the effect on the TNT morphology and order of nanotubes. A mixture of ethylene glycol (Ethane-1, 2-diol, $C_2H_6O_2$, Sigma Aldrich, purity > 99.8%), ammonium fluoride (NH_4F, Sigma Aldrich, purity >99.99%), and distilled water was used for the reaction. The relative amounts of the chemicals were varied, as described below. All anodisation experiments were done with a two-electrode system a constant voltage of 60 V using 100mL Teflon reaction cell. The electrode separation was fixed at 30 mm.

2.1.2 Electrolyte mixing conditions

NH_4F is a white solid which is immiscible in ethylene glycol but very soluble in water. Proper mixing of the electrolyte solution is crucial to obtain homogenous mixtures with proper NH_4F concentration. Here three sets of mixing procedures were adopted, which differed in how NH_4F was mixed with ethylene glycol: (A) All chemicals were simultaneously mixed in a teflon reaction beaker with a magnetic stirrer for 30 min. (B) NH_4F was first dissolved in H_2O and vigorously hand shaken. The solution was then added to ethylene glycol to yield the desired composition, while constantly stirred with a magnetic stirrer. The solution was then ultrasonicated for 3 minutes. (C) NH_4F was first disolved in water and mixed with magnetic stirring. The solution was then transferred to the teflon reaction beaker containing ethylene glycol and magnetically stirred. In all three cases, the as prepared samples were cleaned by immersing them in deionized water for 3 min and dried in a stream of nitrogen gas. Anodization was done for 2 h.

2.1.3 Water concentration

TNT were grown using 3 vol%, 5 vol%, 7 vol%, 10 vol%, 15 vol%, 20 vol%, 30 vol% to 50 vol% in all set of experiments to investigate the effect of water content on TNT growth. The concentration of NH_4F was kept constant at 0.1 M. Anodization was done for 3 h using method (C) of electrolyte preparation.

2.1.4 Fluoride concentration

The NH_4F concentration was varied between 0.05 M to 0.3 M while keeping the ethylene glycol (95 vol%) and H_2O concentration (5 vol%) fixed. Anodization was done for 2 hours.

2.1.5 Two-step anodization

A two-step anodization was employed using an electrolyte consisting of 0.1 M NH_4F in 95 vol% ethylene glycol and 5 vol% H_2O. The electrolyte mixing procedures in (A), (B) and (C) were employed to study their effect on TNT Growth. In the first step of anodization, TNTs were grown in 0.1M NH_4F, 95 vol % Ethylene glycol and 5 vol % H_2O for 4 hours in 60V DC after which they were removed by ultra sonicating the samples in ethanol for 5 minutes , and rinsed in deionized water. The samples were finally dried in a stream of nitrogen prior to a second 1.5 h anodizing step at 60 V using the same electrode separation distance was

30 mm.

2.2 Characterization

The TNT were characterized by scanning electron microscopy (SEM) using a Zeiss microscope (Zeiss 1550, Jena, Germany). An acceleration voltage of 10 keV and an in-lens secondary electron detector were employed. X-ray diffraction (XRD) was performed with a Philips D5000 diffractometer employing averaged Cu $K_{\square}$ (λ = 1.541056 Å radiation. A profilometer (DektakXT, Bruker, Germany) was used to measure the thickness of the opal and inverse opal films. Reflectance measurements were performed in UV/Vis/NIR transmittance spectra taken in the 300–1000 nm range with a Perkin-Elmer Lambda 900 spectrophotometer. Photocatalytic measurements were performed in a reactor described in detail elsewhere (Stefanov, 2011) consisting of a continuously stirred reaction cell with a 670 nm laser to measure the absorbance of methylene blue (MB) in situ during UV illumination. A standard 4 W BLB tube lamp (4W F4T5/BLB, OSRAM, Germany) operated at λ = 365 nm) was used as a light source. The lamp intensity was measured with a calibrated thermopile detector (Ophir, North Andover, MA, USA) and was measured to be 2.44 mW cm^{-2} at the UV tube wall. The intensity distributions at the position of the film in the reactor was estimated to be 0.38 mW cm^{-2}. A concentration of 1 ppm methylene blue in 100 mL deionized water was employed in all experiments. The absorbance of MB at 670 nm was continuously monitored during UV illumination. The absorbance of the water solution without methylene blue was used as a reference for the absorbance measurements.

3. Results and discussion

3.1. Electrolyte preparation

Figure 1 shows top-view SEM images of TNTs obtained from a one-step anodization process employing different electrolyte mixing conditions. Figures 1a shows an image of TNTs grown using an electrolyte prepared by method A in Section 2.1.2, using 0.2 M NH_4F, 95 vol% ethylene glycol and 5 vol% H_2O, whereby all chemicals were simply mixed in the Teflon reaction beaker and mixed with a magnetic stirrer. Deposition of un-reacted NH_4F is visible as particles and non-porous layers on top of the TNTs. Figure 1b shows a SEM image of TNTs grown from electrolyte prepared by dissolving NH_4F in water, and shaking till it was fully dissolved in the water (method B). Adding NH_4F solution to the ethylene glycol results in less amounts of unreacted NH_4F which is visible as non-porous layer on top of the TNTs. Small amounts of NH_4F are however deposited on top of TNT layer, meaning that it was not fully mixed. In Figure 1c shows a SEM image from TNTs grown from uniformly mixed electrolyte where NH_4F was added in water and carefully mixed with a magnetic stirrer to ensure that all the fluoride ions fully dissolved (methods C). Only after complete pre-mixing, the NH_4F solution was added to bulk ethylene glycol solution under stirring to obtain a homogeneous solution. This procedure produced densely packed and well-ordered TNTs with 120 nm diameter, 20 nm wall thickness and length of about 23 μm. The as prepared TNTs were immersed in distilled water for 3 minutes and dried in a stream of oxygen, followed by ultrasonication in isopropyl alcohol to remove top non- porous yielding well organized nanotubes.

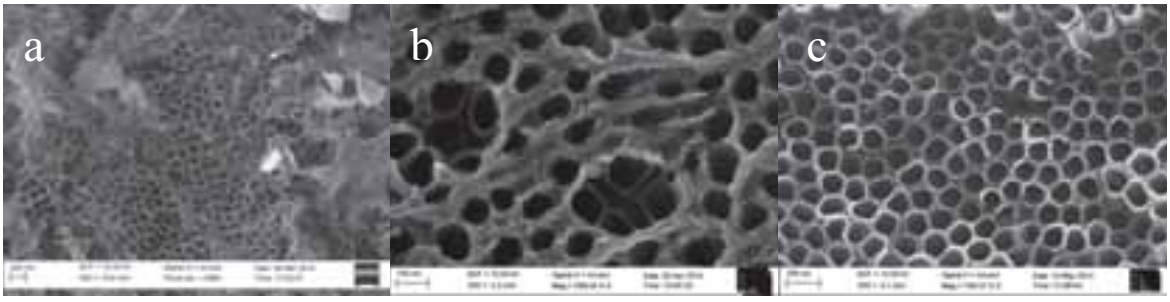

Fig. 1 Dependence of mixing condition: TNT prepared from anodization of Ti foil in a freshly prepared electrolyte consisting of 95% ethylene glycol, 5% H_2O and 0.2 M NH_4F at 60 V for 2 hours, according to mixing procedures (a) method A, (b) method B, and (c) method C (see Section 2.1.2).

Figure 2 shows SEM images from a batch of TNTs grown with different water concentrations between 3

vol% and 50 vol% at a fixed concentration of 0.1 M NH_4F. Compact and smooth nanotubes are grown at low water contents because of reduced chemical dissolution rates on the oxide layer. At high water content

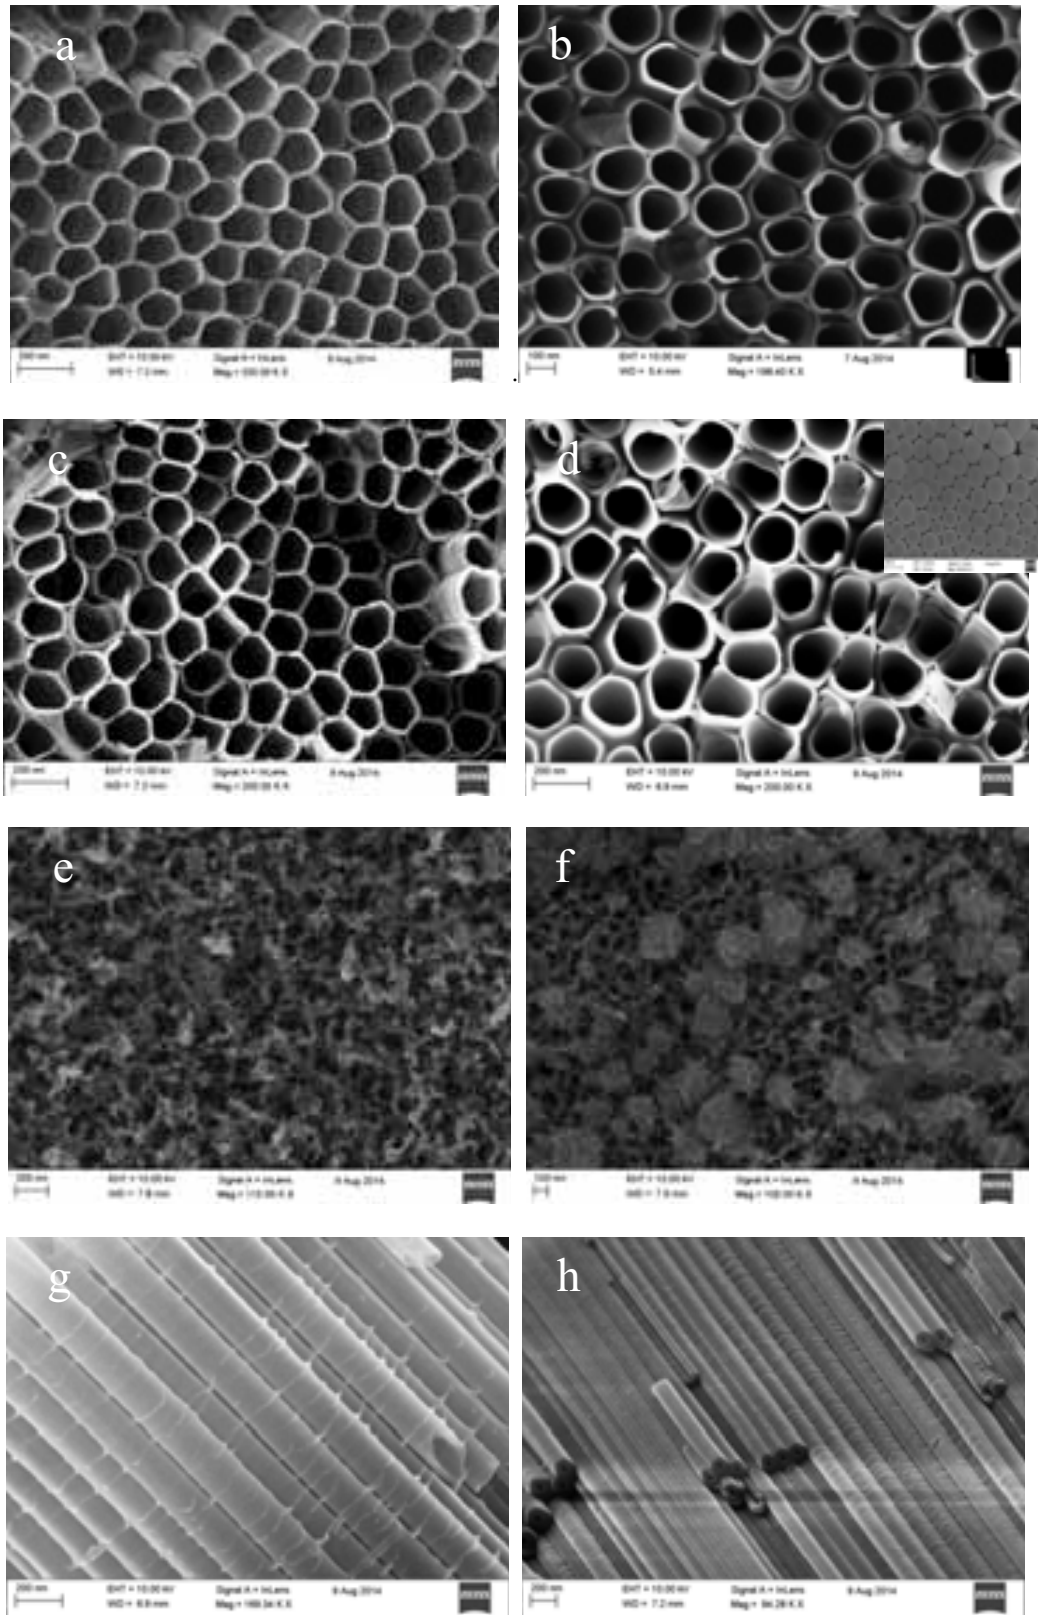

Fig. 2 SEM images showing TNTs prepared from an electrolyte in 0.1 M NH4F with varying H2O concentrations: (a) 3 vol%, (b) 10 vol%, (c) 7 vol% (d) 10 vol % (e) 15 vol% (f) 50 vol%. (g) and (h) show cross sections showing 10 % H2O and 3% H2O respectively. The anodization was carried out at 60 V for 3 hours.

(>10%), ripples are formed as seen in the cross-section image in Fig. 2g. due to etching of the nanotube walls by the F^- ions. The minimum water content for growth of well-ordered structure has been reported to be 0.18 vol% employing 20 V anodizing potential (Raja et al. 2007). When the water content is less than 1 vol%, the formation of long nanotubes (> 300 nm) is impossible no matter the applied voltage (Yin et al., 2010). In our case, well-ordered TNTs were grown at low water contents between 3% H_2O and 7 % H_2O. At higher concentration exceeding 10 vol % less ordered sponge-like structures were formed (Fig 2e and f). At high concentrations the viscocity of electrolytes is decreased leading to an increasing dissolution rate and disordered growth.

The water concentration affects the crystallinity of the nanotubes. Figure 3a shows XRD diffractogram from samples made with different water concentrations, which were post-annealed at 400°C in an oven for 1 h. All TNTs exhibit anatase stucture but the anatase peaks diminish with increasing water concentrations at 10%. The most developed crystalline TNTs are obtained at < 10 vol% H_2O.

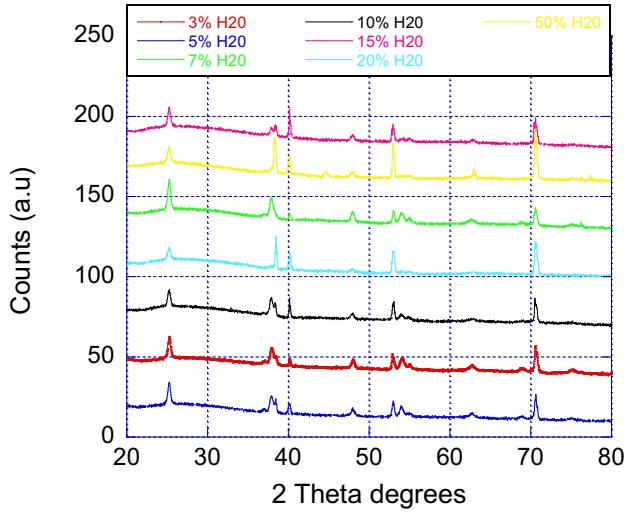

Fig. 3 XRD diffractograms of TNTs prepared with varying water concentrations in 0.1 M NH4F anodized at 60 V for 3 hours.

3.3 Fluoride concentration

Figure 4 shows top-view SEM images of TNTs obtained from a one-step anodization process with varying NH_4F concentration between 0.05 M and 0.3 M.

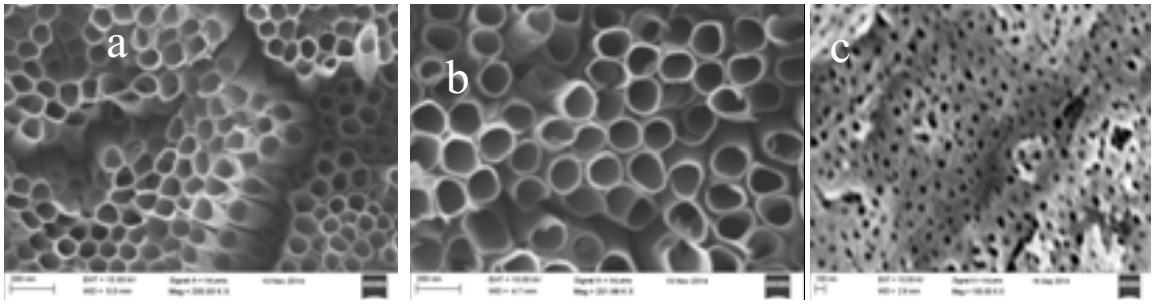

Fig. 4 Selected SEM images of TNTs obtained with varying NH_4F: (a) 0.3M, (b) 0.1M (c) 0.05M, respectively, in 95 vol% ethylene glycol and 5 vol% H_2O. (d) XRD diffractograms at varying NH_4F concentrations of 0.05M, 0.1M, 0.15M, 0.2M and 0.5M. Anodization was done at 60 V for 2 h using electrolyte preapartion method C.

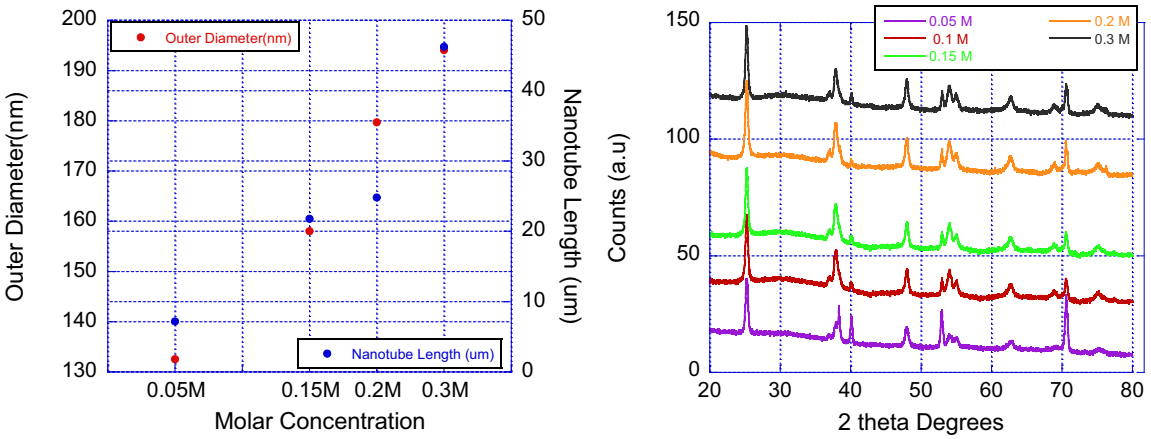

Fig. 5 Outer diameter and length of TNTs verses NH_4F molar concentration prepared by anodization at 60 V for 2 h in an electrolyte containing 95 vol% ethylene glycol and 5 vol% H_2O at varying molar concentrations using method C of electrolyte preparation.

The F^- ions act as powerful oxidants of the Ti plate leading to formation of TiO_2. The fluoride ions react to form Ti fluoride complexes as shown in reaction 3 from which TNTs are formed according to reaction 4 (Macak et al., 2007), viz.

$$4\ H_2O + 4\ e^- \rightarrow 2\ H_2 + 4\ OH^- \quad \text{(eq. 1)}$$

$$Ti \rightarrow Ti^{4+} + 4e^- \quad \text{(eq. 2)}$$

$$Ti^{4+} + 6F^- \rightarrow [TiF_6]^{2-} \quad \text{(eq. 3)}$$

$$[TiF_6]^{2-} + 2H_2O \rightarrow TiO_2 + 6F^- + 4H^+ \quad \text{(eq. 4)}$$

$$TiO_2 + 6F^- + 4H^+ \rightarrow [TiF_6]^{2-} + 2H_2O \quad \text{(eq. 5)}$$

Increasing the fluoride content in the electrolyte increases the rate of nanotube formation. For example the length of the nanotubes as measured by profilometry is increased as 7.2 µm, 22.6 µm, 24.8 µm and 46.2 µm for concentrations 0.05 M, 0.1 M, 0.2 M and 0.3 M, respectively. By increasing the amount of F^- ions, the rate of chemical etching on the nanotubes also increases causing thinner walls, as evident from fig.ure 4 (a) and (b). Fig. 4d shows XRD diffractograms for TNTs prepared at different NH4F concentrations between 0.05M and 0.3M. A well-developed anatase phase structure is obtained in all cases. The distribution of the reflections was however observed to change as a function of F^- concentration, with the <101> orientation slightly increasing with F^- concentration, which correlates with the decreasing wall thickness and suggests that (101) planes develop perpendicular to the growth direction. At 0.3 M the intensity of the <101> reflection is reduced. This may be explained due to the effect of increased etching rates on the surfaces of the TNTs. From these results, it appears that a NH_4F concentration around of 0.2 M in the 95 vol% ethylene glycol and 5 vol% water electrolyte yields optimum growth conditions for long, well-ordered TNTs.

3.4 Second step anodization

In Figure . 6 a-d SEM images of TNTs formed after the two-step anodization procedure described in Section 2.1.5. It is evident that the TNT array is more ordered and uniform than those formed in the corresponding one step anodization (Figure 1).

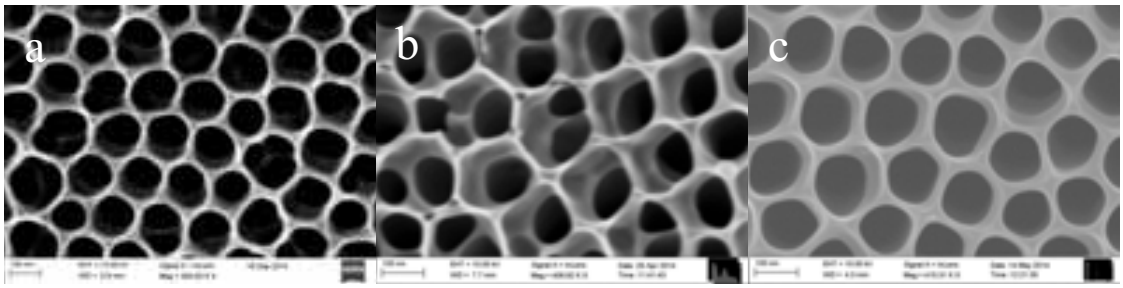

Fig. 6 SEM images of TNTs formed after two-step anodization procedure, employing (a) method A, (b) method B, and (c) method C, respectively, in the second anodization step. The electrolye compositon was 0.1 M NH_4F in 95 vol% ethylene glycol and 5 vol% H_2O.

Superior order and structure are obtained when the electrolyte is thoroughly mixed (method C), thus enhancing reaction between the participating species in anodization reactions. The crystallinity is poor as seen in XRD in Fig 7 (a) because TNTS were grown from un-optimized electrolyte conditions procedure (A) with impurities of unreacted species in electrolyte being trapped as nanotubes grow thus introducing defects and affecting crystallinity. Image (b) is from procedure (B). In the two-step anodization procedure, TNT grow from a pre-textured surface from the first anodization step, and this has been reported to cause fast initiation of pore nucleation and ordering (Zhao et al. 2007). The TNTs are seen to be arranged in a hexagonal super lattice.

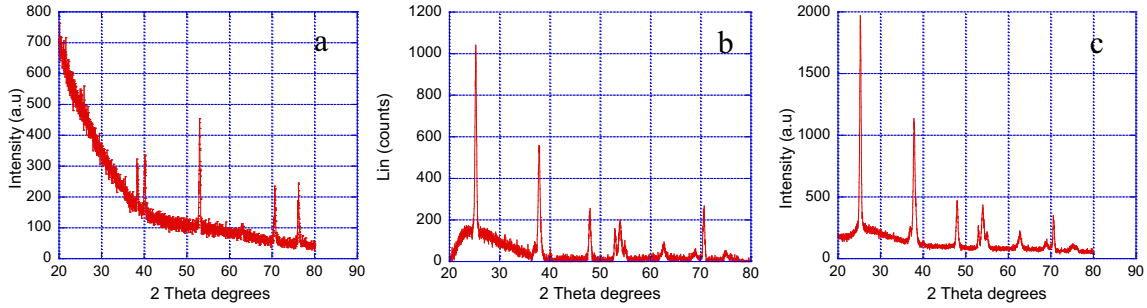

Fig. 7 XRD diffractograms TNTs formed after two-step anodixation obtained after different electrolyte mixing protocols to prepare the first anodization step. (a) Prepared according to method (A), (b) method (B), and (c) method (C) respectively.

It is evident that well-developed crystalline anatase TNT were obtained for samples which were prepared according to methods B and C in the first anodization step.

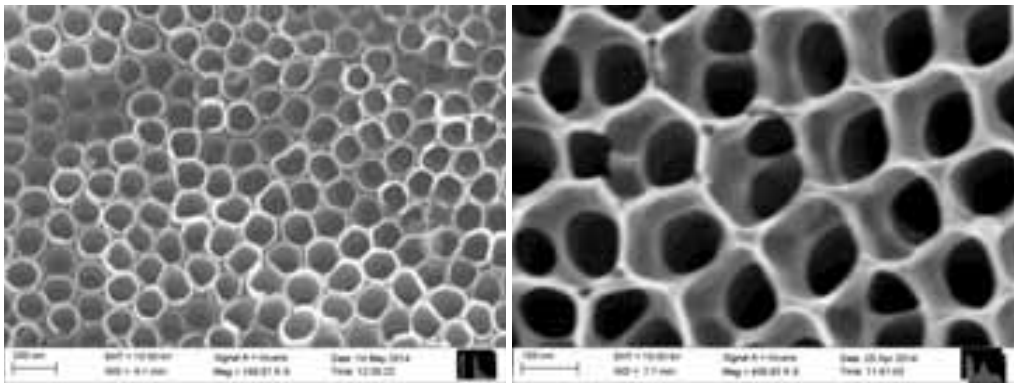

Fig. 8 SEM images of nanotubes anodized using different electrolyte mixing conditions. (a) Sample R21 from Optimized process in first step anodisation method (C) (b) SEM images of sample 14 after second step anodization using method (A).

When the optimized electrolyte preparation procedure (C) is applied to prepare electrolyte for growing TNTs in a second step anodization, a more crystalline well developed anatase phase is obtained (Figure) 7 c. The particle size of ammonium fluoride is reduced in every step of magnetic stirring exposing large area for the electrolyte to oxidize of the Ti plate during anodization. This leads to faster formation of the complex

$[TiF_6]^{2-}$ from which TiO_2 is formed. It also ensures that the concentration of ammonium fluoride participating in the reaction is as expected since all the fluoride particles take place in the chemical reaction due to reduced size. The crystallinity of the sample is dependent on the electrolyte preparation procedures. The presence of unreacted particles in the formation of any material in our case TiO_2 film will be an impurity and introduce defect sites on TiO_2 film reducing crystallinity.

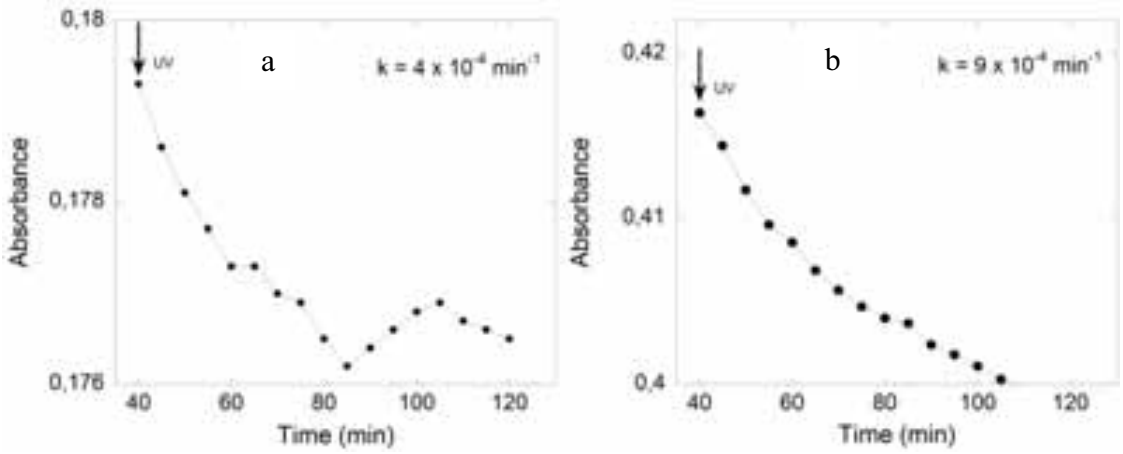

Fig .9: Photocatalytic degradation of methylene blue (1 ppm) in deionized water by TiO_2 nanotube samples (a) prepared according to the 1-step method C, and (b) two-step method A, respectively. Illuminations was done with a 370 nm BLB lamp with lamp power of about 0.4 m W cm^{-2} at the position of the sample surface. The pseudo-first order rate constants are shown as insets in the figures.

Figure 8 a shows top-view SEM images of Sample R 21 of TNTs obtained from optimized one-step anodization process described in section 3.1, while Figure 8 b show SEM image from a two-step anodization process. A well-ordered uniform nanotublar structure is obtained after the second step of anodisation. We attribute the improved nanotube properties to template assisted nucleation on top of the nanotube structures formed after the first anodization step. During a one-step anodization on a Ti foil, nucleation and nanotube growth takes place at random sites. By introducing a template through a first anodization step, a pre-defined pattern for nanotube nucleation is made. Nanotubes grow on already ordered imprints and retain the order as they grow. The intermittent cleaning and electrolyte exchange removes impurities and improves the quality of subsequent nanotube growth.

Finally, the photocatalytic activity of the porous TNT structures was determined by measuring the decomposition of MB. The photocatalytic degradation rates for one sample from the 1-step and one from the 2-step anodization procedure were measured and determined to be k = 4×10^{-4} min^{-1} and k = 9×10^{-4} min^{-1}, respectively, from a pseudo-first order kinetic analysis (Figure. 9). The rate constant for the (non-optimized electrolyte) TNTs from second step anodisation was found to be more than twice as large compared to the one from the 1-step anodization procedures, confirming the microscopy results that the 2-step process yields higher quality TNTs.

4. Conclusion

The preparation procedures of highly ordered and self-organized titanium dioxide nanotubes for photocatalytic application have been presented. Optimized growth conditions including electrolyte preparation, water content, ammonium fluoride concentration and second step anodization have been explored. Water content and ammonium fluoride concentrations are known to influence the order and self-organization through high chemical dissolution and fast etching rates. Here we show that although NH_4F is an essential component in the formation of TiO_2 by oxidation of Ti plate and formation of $[TiF_6]^{2-}$ complex. Increasing ammonium fluoride beyond 0.2 M in this work causes thinning of nanotube walls, and introduces disorder in the nanotube structure. Increasing the water content increases the rate of chemical dissolution causing ripples on the nanotubes. Beyond 10 vol% a sponge-like structure is obtained. An optimized

electrolyte preparation procedure where NH_4F is first dissolved in water followed by magnetic stirring to fully dissolve the NH_4F particles and subsequent transferring the NH_4F solution in ethylene glycol ensures that all participating species in the electrolyte are intimately mixed forming a homogeneous solution. Magnetic stirring in both stages of electrolyte mixing reduces the particle size; which is an important parameter in determining how fast the reaction will proceed. Furthermore, ensuring all particles are intimately mixed improves the crystallinity by reducing impurities and defects on the TiO_2 nanotube structure as nanotubes grow. A second step of anodization improves the order and self-organization of the nanotubes, and hence the photocatalytic activity. Growing nanotubes employing a second step anodization and using the optimized electrolyte preparation procedure is expected to further enhance the photocatalytic activity. We propose that the two-step anodization method, followed by use of optimized electrolyte procedure, a water content of 3 vol% and ammonium fluoride of between 0.1 M and 0.2 M can be used to fabricate well-ordered TiO_2nanotubes which are photocatalytic active.

Abstract

Chile is developing a national strategy to reduce the external dependence on energy supply sources, for which renewable resources must provide 20% of the electricity generation by 2025. As the northern part of the country exhibits a large arid desert area that has the highest radiation levels in the world and a considerable amount of active geothermal areas, proposing the hybridization of both renewable resources together is deemed advantageous considering the benefits that each resource presents and allows exploring potential synergies between both. A thermodynamic model is developed using the Engineering Equation Solver (EES) software in order to evaluate the performance of a single-flash power plant assisted by a parabolic trough collector system for four different geothermal reservoir conditions. The benefits of delivering the solar thermal energy to the superheating or evaporating processes are analyzed, in order to achieve the maximum 2nd law efficiency for the generation of additional power, or to reduce the geothermal fluid flow consumption. The results in the single-flash hybrid system show that the superheating process generates 0.23 kW of additional power per kW of thermal energy, while enhancing the brine evaporation produces only an additional 0.16 kW of power per kW of solar thermal energy. Hence, the single-flash hybrid power plant is able to produce at least 20% of additional power output and increase at least 3% the exergetic efficiency. This hybrid flash system presents a promising alternative towards the generation of additional power output and extending the lifetime of a geothermal well.

Keywords: *Solar Energy, Geothermal Energy, Hybrid scheme, Thermodynamic analysis*

1. Introduction

Chile is a relatively small country located along the west coast of the southern half of South America, which is endowed with a wide range of natural resources and through the production, addition of value and exportation of such resources it has emerged as a successful economy. However, the country has evinced over the last years several energy issues due to its high dependence on fossil fuels such as crude oil and natural gas, of which more than 90% are imported (CNE, 2013). Currently, the country's primary energy consumption is dominated by fossil fuels, which accounts for 66% of the energy consumed, while renewable energy sources comprising hydroelectricity, wood-based biomass and incipient solar and wind farms, are responsible for the remaining 34% mostly due to the large contribution of hydropower sources (CNE, 2013). This scenario indicates that Chile is a net energy importer and establishes a complex situation due to the difficulties in fulfilling the energy demand growth associated to additional economic and social development. Responding to this situation, the Chilean government has proposed a national strategy based on decreasing the external dependence of the energy supply focusing on promoting the so-called "*Non-Conventional Renewable Energy sources*" (NCRE), defined as small-scale hydro (under 20 MW), biomass, wind, solar, geothermal and tidal energy sources. Large-scale hydropower is considered a renewable source although its already large contribution to the Chile energy mix and its techno-economical maturity does not merit further government

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.04.30 Available at http://proceedings.ises.org

support for additional development. The government has defined that the existing NCRE quota should grow up to 20% of electricity injected to the interconnected systems by 2025. Currently, NCRE accounts for 9% of the total installed capacity (2,242 MW), whereas 40% corresponds to wind, 23% solar PV, 19% biomass, 16% small scale hydro and 2% biogas (CIFES, 2015). In addition, the government has recently proposed the "*Agenda Energía 2050*", which establishes a schedule to reach the aforementioned goal, along with measures to promote their development (Ministerio de Energía, 2014).

Chile presents a long and narrow territory that extends for 4,330 km, with a wide range of climates due to its vast extension. There is a huge potential for renewable energy, especially at the northern region, which exhibits the most arid desert in the world along with a low presence of clouds and high altitude over the sea level resulting in exceptionally clear skies with low aerosol contents. Recent investigations indicate the existence of a significant solar energy potential in the northern regions, where the annual average of daily global horizontal irradiation (GHI) reaches levels higher than 7.5 kWh/m^2, and whereas the daily average of direct normal irradiation (DNI) present values higher than 9 kWh/m^2 (Escobar et al, 2014, 2015). Furthermore, the Chilean territory is also located in the "*Pacific ring of fire*" accounting over 15% of the world's active volcanoes and more than 300 active geothermal areas through the country, with an estimated resource potential of 16,000 MWe (Hogson, 2013). There are currently more than 20 geothermal areas under exploration in Chile, where the geothermal reservoirs present temperatures over 150ºC and are located no deeper than 3,000 meters (Lahsen et al., 2010). According to this, the northern region of the country accounts for at least six already explored geothermal areas and more than 25 other sites with potential for geothermal generation. The present study proposes to assess the use of these two renewable resources combined in a hybrid scheme, configuring a power plant capable of take advantage of the benefits that each source presents. Solar energy is available during day hours according to the specific climate conditions in a given site; while geothermal energy does not present variations by season. Although, the installation of such systems requires a longer period for deployment than the time needed for solar systems. Considering the high potential of both sources in the northern region of Chile, the present study focuses on the optimization of hybrid schemes that enable the possibility of exploiting these two sources together efficiently.

Hybrid solar-geothermal schemes have been proposed in several previous studies that focused on different technologies for exploiting the geothermal resources, such as single-flash (Mir, 2011), double-flash (Lentz and Almarza, 2006, Mir et al., 2011) and binary plants (Greenhut et al., 2010, Astolfi et al., 2011, Zhou et al., 2013, Zhou, 2014, Ruzzenenti et al., 2014) which were commonly combined with parabolic trough system. Lentz and Almarza (2006) proposed a hybrid system to increase the steam quality by integrating a solar field to a geothermal flash plant located at Cerro Prieto, Mexico. This work also analyzed two different alignments for the solar collectors, N-S and E-W. Later, the authors also evaluated the increase on steam production associated with the liquid-steam mixture by increasing the enthalpy of the geothermal resource. One of the issues presented was the corrosion caused by the geothermal fluid, which limited the performance of the hybrid system. Considering this aspect, Greenhut et al. (2010) assessed the performance of a system by including a heat exchanger between the solar and geothermal fluid, in order to compare the thermodynamic and economic performance of a binary and single-flash system on a steady-state condition. Astolfi et al. (2011) presented a solar concentration plant and a binary geothermal plant based on an organic Rankine cycle (ORC). The study was based on hourly simulations, where the solar resource of two different sites in Italy and the United States were compared by means of the levelized cost of energy associated with the operation of these plants. The research evidenced the attractiveness of incorporating solar energy to low-enthalpy geothermal systems. Later, Mir et al. (2011) developed an evaluation of solar-geothermal systems in order to estimate the effect of increasing the fluid temperature and enhancing the steam generation process, thus achieving higher power production at the geothermal system by adding a solar field of parabolic trough collectors. This allowed quantifying a reduction of geothermal resource consumption up to 10%, considering the same power output than a stand-alone geothermal plant. Recently, Zhou et al. (2013) proposed a binary geothermal system with solar boosting to investigate the effects on the hybrid system performance of parameters such as ambient temperature, solar irradiance, geographical location and resource quality. The power output and the economic performance adjusting parameters were analyzed and compared with stand-alone solar and geothermal plants, showing an outstanding potential on these aspects. They also focused on the synergies of the hybrid system to determine the potential for improvement on efficiency and cost reduction. Another recent study evaluated a

hypothetical ORC plant employing different working fluids. The effect of the fluid used within the power block on the life cycle assessment and exergy utilization from the geothermal resource was estimated and established that the sustainability of the resource relates to the surface of the heat exchanger and the operating conditions of the solar field (Ruzzenenti, 2014).

The aforementioned studies show a growing interest in the efficiency and utilization of the hybrid solar-geothermal systems. However, there are several issues that have not yet been addressed, which are crucial to determine the real potential towards the hybridization of both resources. Most of the studies analyzed the potential for increasing the power output, determining the economic benefits and comparing between all the configurations proposed, taking advantage of the solar energy system for configuring a thermal booster to the geothermal power plant, thus achieving higher thermal efficiencies, energy production and a significant reduction in the cost of electricity. The results agree that there is an improvement opportunity as the hybrid schemes can reduce the high costs associated with the exploitation of renewable energy resources. Nevertheless, there are still some aspects yet to be investigated in order to quantify the real potential from these hybrid systems and benefits on operating the subsystems combined. In this context, the exergetic or 2nd law efficiency of the combined system can be maximized by a proper optimization of the size and the configuration of the hybrid scheme.

Here it is proposed to study the single-flash geothermal technology, with the objective to develop a thermodynamic model of a solar-geothermal hybrid system that can optimize its operation under several resource conditions, maximizing the 2nd law efficiency of using both energy sources with the intent to determine the most effective way to utilize the solar energy captured by the parabolic trough collectors and address the potential benefits such as the reduction on the geothermal fluid extraction rate. To this end, an hourly simulation of a full year of the hybrid solar-geothermal power plant operation was developed in order to evaluate the system performance at one location in the northern region of Chile.

2. System description

Geothermal plants are commonly classified by its capacity: small (under 5 MW), medium (over 5 and under 30 MW) and large scale (over 30 MW) (Bertani, 2010). The small scale plants consider binary and back pressure systems, whereas medium are often associated to flash plants, and finally large scale plants usually refer to dry steam units. In this study, the focus is on medium scale flash geothermal power plants whose hybridization has already been proposed (Lentz and Almarza, 2006a, 2006b, Greenhut, 2010, and Mir, 2011). Regarding the solar technologies, solar thermal energy at medium and high temperature can be supplied by concentration systems of which the parabolic trough collectors are most appropriate for combined use in a geothermal facility due to its modularity and flexibility of installation and operation (Peterseim, 2014).

The single-flash system is one of the most common schemes for geothermal power plants in the world, accounting for 41% of the installed capacity and energy produced (Bertani, 2010). This system is considered the simplest way to convert the geothermal energy into electricity when a steam-liquid mixture composes the geothermal fluid. Fig. 1 corresponds to a single-flash hybrid system integrated to parabolic trough collectors array. The proposed hybrid scheme aims to allow the evaluation of the solar resource impact for superheating and evaporating the geothermal brine. The solar superheating is used to superheat the steam obtained from the separation process in the geothermal flash plant while the solar evaporator is used to increase the evaporation rate.

3. Thermodynamic model

The simulation model for the solar-geothermal hybrid systems proposed was developed using the Engineering Solver Software (Klein, 2015), which is widely used by the scientific community dealing with thermodynamic-related simulations. It allows for the solution of algebraic equations governing the cycles and easily communicates with a thermodynamic properties database based on REFPROP-NIST (Lemmon, 2002).

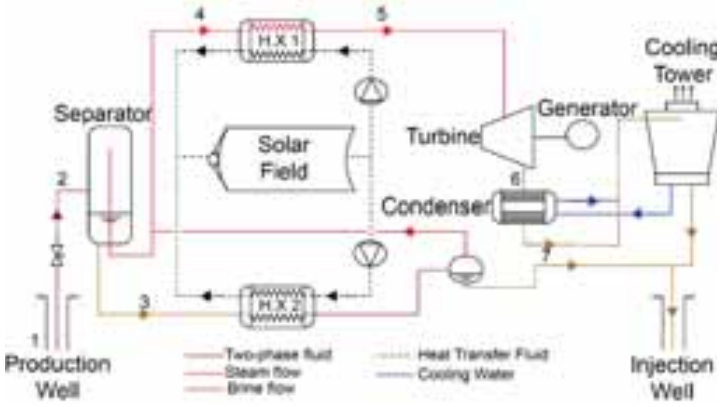

Fig. 1: Single-flash hybrid power plant scheme

The energy analysis is based on the 1st law of thermodynamics, neglecting kinetic and potential energy variations:

$$\dot{Q} - \dot{W} = \sum \dot{m}_{out} h_{out} - \sum \dot{m}_{in} h_{in} \quad \text{(eq. 1)}$$

where $\dot{Q}$ denotes the heat transfer rate, $\dot{W}$ the work transfer from the system, $\dot{m}$ the mass flow rate, h are the specific enthalpies and the subscripts in and out denote the inlet or outlet of the system, respectively.

The exergetic analysis is based on the 2nd law of thermodynamics, using the following exergy balance expression:

$$\dot{X}_{heat} - \dot{W} = \sum \dot{X}_{out} - \sum \dot{X}_{in} + \dot{X}_D \quad \text{(eq. 2)}$$

where $\dot{X}_{heat}$ is the exergy transfer by heat, $\dot{X}_{out}$ the exergy outlet, $\dot{X}_{in}$ the exergy inlet and $\dot{X}_D$ the exergy destruction.

The exergy transfer by heat ($\dot{X}_{heat}$) can be obtained using the following expression:

$$\dot{X}_{heat} = \left(1 - \frac{T_0}{T}\right) \dot{Q} \quad \text{(eq. 3)}$$

where T_0 is the environmental temperature, and T the temperature of the heat source.

The exergy flow in each component is expressed as follows:

$$\dot{X}_i = \dot{m}_\iota [(h_i - h_0) - T_0 (s_i - s_0)] \quad \text{(eq. 4)}$$

where $\dot{m}_\iota$, h_i and h_0 represents the flow rate, specific enthalpy at the state i and environmental state, respectively; s_i and s_0 the specific entropy at the same states. Hence, in order to evaluate the performance of the hybrid system, the 2nd law efficiency is used according to the following expression:

$$\eta_{II} = \frac{\dot{W}}{\dot{X}_{geo} + \dot{X}_{HTF}} \quad \text{(eq. 5)}$$

where $\dot{W}$ indicates the net power delivered by the hybrid system, $\dot{X}_{HTF}$ and $\dot{X}_{geo}$ are the exergies delivered by the heat transfer fluid from the solar field and geothermal field, respectively. The solar exergy is considered as the provided by the heat transfer fluid (HTF) and expressed as follows:

$$\dot{X}_{HTF} = \dot{m}_{HTF} \left[(h_{HTF,out} - h_{HTF,in}) - T_0 \left(s_{HTF,out} - s_{HTF,in} \right) \right] \quad \text{(eq. 6)}$$

where state HTF, out and HTF, in corresponds to the solar field outlet and inlet, respectively.

On the other hand, the exergy from the geothermal resource is defined as (Kanoglu, 2012):

$$\dot{X}_{geo} = \dot{m}_{geo} [(h_1 - h_0) - T_0 (s_1 - s_0)] \quad \text{(eq. 7)}$$

where the state 1 represents the geothermal reservoir. The exergy of the geothermal resource only considers the reservoir conditions, since the brine generated at the separation process is considered an exergy loss, according to the established technical literature (Agung, 2014, Jalilinasrabady 2012).

3.1 Geothermal resource

For the purpose of this study, four geothermal reservoir characteristics were examined: two considering compressed liquid (cases 1 and 3) and two considering saturated water-steam mixture (cases 2 and 4), as shown in Table 1 (Ocampo, 1998, Anderson, 2014). Therefore, the brine production on the geothermal field is assumed to follow the choked well flow proposed in DiPippo (2008), where the relation between the total mass flow of geothermal fluid is function of the wellhead pressure, as expressed by the following equation:

$$\dot{m}_{geo} = 99.663 - 2.6287P_2 + 0.5802{P_2}^2 - 0.04212{P_2}^3 \quad \text{(eq. 8)}$$

where $\dot{m}_{geo}$ is the mass flow rate extracted from the well and P_2 is the pressure at which the separator operates. The flashing process in the well between the states 1 and 2 is considered as isenthalpic, neglecting any change in the kinetic or potential energy according to previous studies (DiPippo 2008 and 2013). Other operating conditions for the system considered herein are summarized in Table 2.

Tab. 1: Geothermal reservoir characteristics

Resource	Temperature	Enthalpy	Pressure	References
Case 1	240 ºC	1038 kJ/kg	100 bar	(Ocampo, 1998)

Parameters	Value
Ambient temperature	15 ºC
Ambient pressure	0.8 bar
Heat exchanger effectiveness	70%
Solar irradiance	1000 W/m^2
Maximum solar HTF temperature	391 ºC
Condensing temperature	50 ºC

3.2 Solar field model

For the purpose of this study, the solar field is considered as an arrangement of parabolic trough collectors using Therminol VP-1 as heat transfer fluid. The performance of the system is determined by using the model developed by Duffie & Beckman (2006), later adapted by Wendel (2010). The amount of solar thermal energy output rate ($\dot{Q}_{solar}$) is calculated by accounting the relation between the collector performance and the loss factors related to the utilization of direct normal irradiation ($\dot{G}_{b,T}$), as follows:

$$\dot{Q}_{solar} = A\left[f_{shadow} f_{corner} \dot{G}_{b,T}(a_1 + a_2\Delta T) f_{dirt} IAM - b_1\Delta T - b_2\Delta T^2\right] \quad \text{(eq. 9)}$$

where the parameters included in this equation are: A the solar field collection area, ΔT the temperature difference between the average temperature of the HTF and ambient temperature, IAM the incident angle modifier, f_{shadow} the losses factor due to shadowing, and f_{corner} the loss factor due to the collectors corner. Finally, the optical coefficients a_1 and a_2, the thermal coefficients b_1 and b_2; and the dirtiness coefficient f_{dirt} in (eq. 9), are given by the collector properties according to the manufacturer data (Hublitz and Spinnler, 2003, Lüpfert et al., 2001). The EuroTrough collector is used for a variety of application such as industrial process heat and electricity generation, and it was selected for the solar-geothermal hybrid system because of the low specific investment cost.

3.3 Turbine model

Geothermal turbines generally operate at wet steam conditions and therefore its isentropic efficiency is affected by the amount of moisture present in the steam during the expansion process. As the moisture increases, the turbine reduces its efficiency. This effect can be quantified by using Baumann's rule (DiPippo, 2008), which proposes that a 1% average extra moisture causes roughly a 1% drop in the turbine efficiency.

Hence, the isentropic efficiency is defined as:

$$\eta_T = \eta_{TD}\left(\frac{x_{in}+x_{out}}{2}\right) \quad \text{(eq. 10)}$$

where η_{TD} represents the turbine efficiency at dry steam conditions, x_{in} is the inlet dryness fraction and x_{out} the outlet dryness fraction.

The variation in the inlet turbine temperature is given by the solar resource availability and the pressure drop at the inlet nozzle of the turbine, which limits the mass flow admitted by the device. Chaibakhsh (2008) developed a relationship between the mass flow, temperature and pressure drop over the steam turbine as follows:

$$\dot{m}_{in} = \frac{K}{\sqrt{T_{in}}}\sqrt{P_{in}^2 - P_{out}^2} \quad \text{(eq. 12)}$$

where $\dot{m}_{in}$ represents the inlet mass flow rate, K the mass flow coefficient, T_{in} the inlet temperature, P_{in} the inlet pressure and P_{out} the outlet pressure.

The heat exchanger considered in this work to deliver the solar thermal energy towards the steam was modeled using the effectiveness-NTU method (Nellis and Klein, 2009).

4. Results and discussion

4.1 Stand-alone power plant results

The optimization methodology for the single-flash plant and each geothermal reservoir was developed by varying the separation pressure in order to achieve the highest power output possible. The separation pressure optimizes the amount of geothermal fluid through the system and the steam generation at the separator. The maximum amount of power output possible as a function of the separation pressure is shown in Fig. 2. The amount of power output generated by each reservoir is highly related to the thermodynamic state of the geothermal fluid, where the two cases with higher power production correspond to those with higher enthalpy. Case 1 presents higher resource temperature, yet it is not enough to generate a similar power production as in cases 2 and 4.

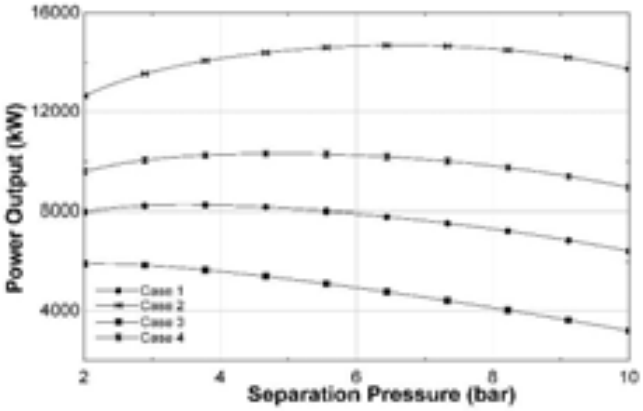

Fig. 2: Power output of the reservoir as function of separation pressure

4.2 Single-flash hybrid power plant

4.2.1 Additional power generation

The solar thermal energy in the single-flash hybrid scheme is added in two heat exchangers (HX) as shown in Fig. 1. The first HX is used for superheating the steam, while the second HX generates additional steam in the separator system. The additional power produced by both devices, when there is solar thermal energy available, was evaluated considering the reservoir case 2 as shown in Fig. 3. The HX 1 generates a higher amount of additional energy per kW of solar power delivered. For every kW of thermal energy the superheating process generates 0.23 kW of additional power output. Delivering the solar thermal power to the superheating process increases the steam quality at the turbine discharge, which improves the turbine efficiency. On the other hand, the HX 2 generates only 0.16 kW of additional power per kW of solar thermal power. Nevertheless, it has to be considered that the first HX can only superheat the steam flow until it reaches 320 ºC due to the HX effectiveness limitation.

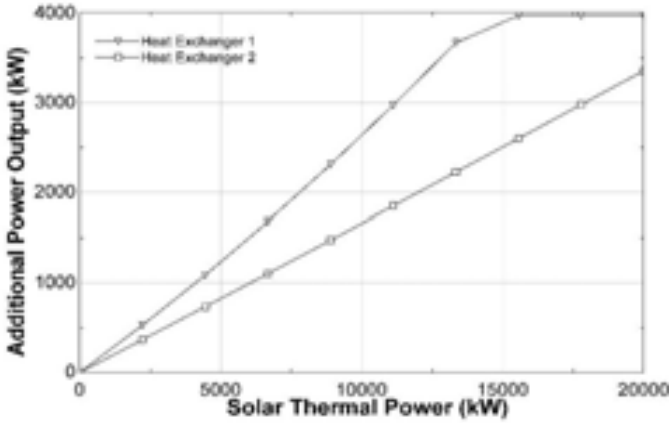

Fig. 3: Additional power output as function of solar thermal power

This situation is observed in Fig. 4, where the superheated steam temperature and additional steam generation as function of the solar thermal power is shown. Each additional kW of solar thermal power causes an increase of 0.012 ºC in the steam temperature and/or generates 0.00035 kg/s of additional steam. The optimization of the integration of both energy resources is developed by varying the separation pressure and solar thermal power in order to achieve the maximum 2nd law efficiency.

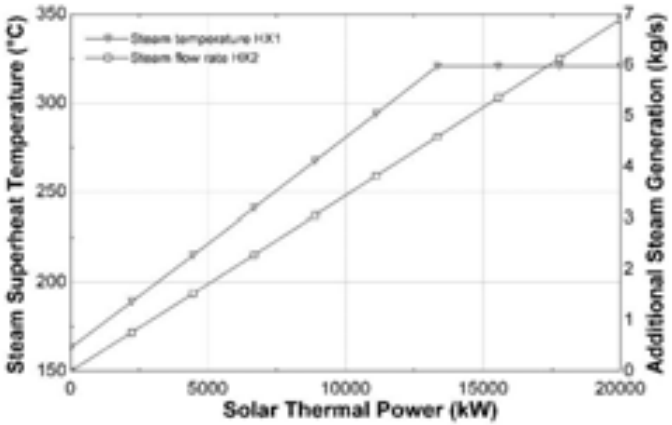

Fig. 4: Superheated steam temperature and additional steam generation as function of solar thermal power

The exergetic efficiency increases whenever solar thermal energy is supply to the superheating process. In contrast, using the solar energy to generate additional steam produces a lower rate of power, which is reflected in a reduction of the 2nd law efficiency. Fig. 5 shows the effect of the solar thermal power addition in the 2nd law efficiency for the four cases. The exergetic efficiency increases on the four cases proposed until it reaches a maximum and then it decreases. As the solar power is added, the amount required for each case is defined by the flow rate and temperature of the steam. The geothermal reservoirs with high enthalpy allow the separator to produce a higher amount of steam and at a higher pressure. This causes the hybrid single-flash plant to require a higher amount of thermal power as the enthalpy of the resource increases to achieve the maximum 2nd law efficiency. The maximum exergetic efficiency for the hybrid system proposed is achieved once the superheat steam reaches a temperature of approximately 320 ºC. Increasing the solar field aperture area to deliver additional thermal power to the HX 2 decreases the power production as shown in Fig. 3. This effect causes the reduction of the exergetic efficiency. The results of the geothermal only and single-flash hybrid power plants are shown in Table 3. The optimization routine indicates that the hybrid scheme increase slightly the separation pressure to achieve the maximum 2nd law efficiency. This benefits the system because a higher separation pressure reduces the flow rate and increases the steam temperature, which requires a lower amount of thermal power to achieve the maximum 2nd law efficiency. In the four cases analyzed for the single-flash power plant, the efficiency and power output increase as long as thermal power is delivered towards the superheating process. The power output for the single-flash hybrid presents at least 20% of additional power output and the 2nd law efficiency increase by more than 2.9%, for each reservoir case.

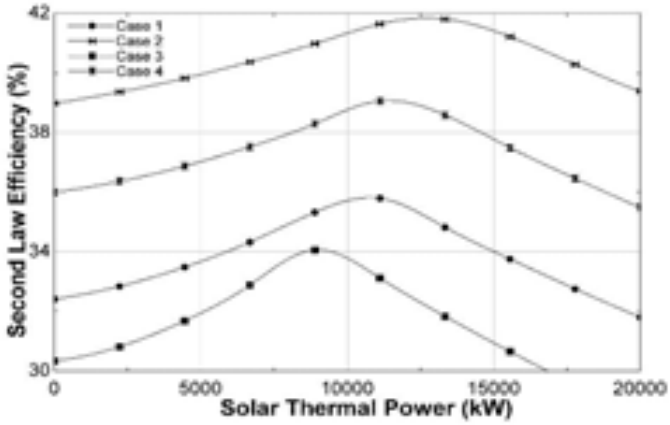

Fig. 5: 2nd law efficiency of the reservoir as function of solar thermal power

4.2.1 Geothermal flow rate reduction

The single-flash hybrid power plant can be used for a second purpose, which is reducing the geothermal fluid consumption thus allowing an extended geothermal well lifetime. This is carried out considering the power output of a single-flash only power plant fixed. Thereby, whenever there is solar energy available, the hybrid system is able to reduce the geothermal flow and compensates with the superheating of the steam or enhancing the steam generation until it reaches the fixed power output. The geothermal flow rate reduction is achieved by increasing the separation from the choked well flow considered in (eq. 8). The superheating process was used for this case due to the higher power production rate as it is integrated with the solar thermal energy. The effect of adding solar thermal power to the geothermal flow rate is studied for the proposed cases, as shown in Fig. 6. The higher enthalpy resources present a higher pressure, which enhances the reduction of the geothermal fluid given the geothermal well choked-flow conditions. The amount of geothermal flow reduction is directly related to the separation pressure and amount of steam that can be superheated. Cases 2 and 4 present higher steam rates, which is reflected in a considerable reduction of the geothermal fluid flow. This reduction achieves a stable point when the steam reaches it maximum superheat temperature given by the steam characteristics at the inlet of the HX.

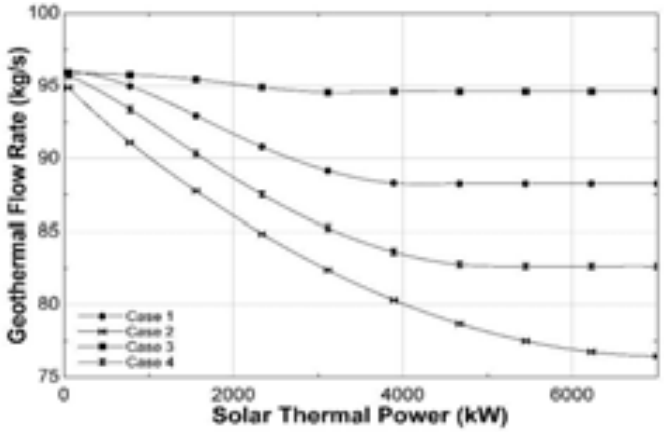

Fig. 6: Geothermal flow rate as function of the solar thermal power.

The high enthalpy resources present an increase of the 2nd law efficiency as long as the geothermal flow rate is reduced, as shown in Fig. 7. Cases 2 and 4 present a considerably increase in the 2nd law efficiency caused by the pressure and steam through the system. Once the superheat process reaches the maximum capacity the efficiency starts decreasing. Case 1 presents a geothermal flow reduction, which is still unable to produce a considerable increase in the 2nd law efficiency. As mentioned, the pressure at which each separator operates according to each reservoir conditions contributes to the reduction in the geothermal fluid flow. Case 3 presents no improvement in the 2nd law efficiency due to the low pressure at which the separator operates, which is determine by the lower enthalpy from the reservoir.

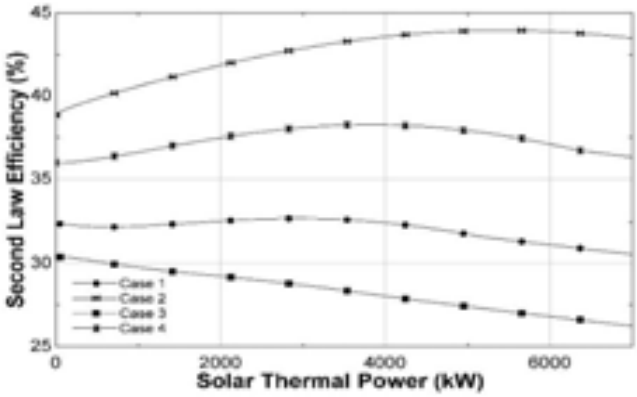

Fig. 7: 2nd law efficiency as function of solar thermal power for reducing the geothermal flow rate

The optimum results from the single-flash hybrid for geothermal flow reduction purpose are shown in Table 3. Case 3 does not present any difference because the integration presents a decrease in the 2nd law efficiency. As on the other cases, it can be seen how the geothermal flow is reduced while the 2nd law efficiency is increased. The geothermal flow rate can be reduced up to 16% depending on the reservoir conditions.

Tab. 3: Single-flash hybrid power plant results

	Single-flash power plant				Additional power generation				Geothermal flow rate reduction

5. Transient simulation of hybrid power plant

The transient simulations consider hourly meteorological data from a selected location in Chile, Crucero, which displays excellent solar resource while being relatively close to existing geothermal prospection sites (Escobar et al, 2015). This region is well known for the large number of clear days throughout the year, while a few cloudy periods are present during February due to the "altiplanic winter" effects and in proper wintertime, in this case during the months of June to August. Total direct normal irradiance (DNI) in Crucero amounts to over 3500 kWh/m^2-year, possibly the highest in the world. The geothermal flow presents a high thermal inertia because of minimum variation of the reservoir conditions throughout the year. There is no thermal energy storage considered partly due to the higher additional costs involved and partially since the power dispatchability (understood as power production able to supply expected electricity grid demand as requested with minimum variability) is achieved by the combination of the solar-geothermal hybrid system able to produce baseload conditions. The analysis presented in the previous sections evaluated the optimum conditions for the operation of the hybrid systems, in which the 2nd law efficiency is maximized. Case 2 was selected to evaluate the performance of the single-flash hybrid system under the design conditions considering the common variation of the solar resource along a year. The transient simulations for the single-flash hybrid system are developed with the objective to maximize the power output or minimize the geothermal flow consumption throughout the year by integrating the hourly simulation results.

5.1 Additional power generation

The performance of the hybrid single-flash for two representative days with clear and cloudy skies are shown in Fig. 8, for which as a reference the hybrid scheme generates 14.68 MW when there is no DNI available.

During a clear day, there are hours with DNI higher than the rating conditions, causing the system to reach its maximum capacity of 18.43 MW. The alternative of using HX 2 for periods with high DNI does not compensate the investment costs, due to the low additional power generated. As in the northern region of Chile there are only a small number of cloudy days, the hybrid scheme is still able to generate during low levels of DNI. For example, as observed in Fig. 8, at a DNI of 400 W/m^2 the hybrid scheme can produce 6.7% of additional power output.

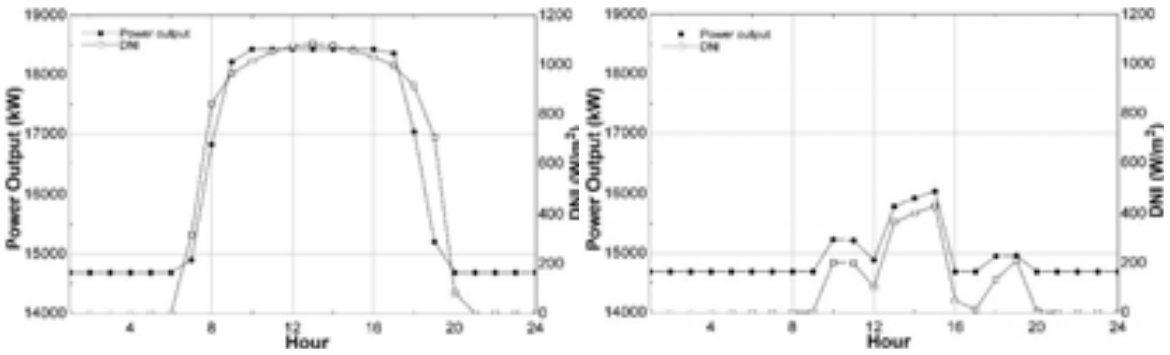

Fig. 8: Single-flash hybrid power plant daily performance

The results from the hourly simulations during a full year are shown in Fig. 9. The dark blue zones represent the base power production of the single-flash geothermal-only power plant, which corresponds to 14.68 MW, while the color code corresponds to the extra power derived by integrating the solar collector arrangement. As mentioned, the altiplanic winter effects during February reduce the production to the levels of the geothermal-only power plant. During spring, the higher average of power output is produced, reaching 17.53 MW when solar energy is available, while autumn presents a lower performance with an average power production of 16.71 MW. The performance of the hybrid single-flash system during the year presents an average power output 7% higher than the single-flash geothermal-only plant. Higher radiation values during summertime do not translate directly into additional power generation as the solar field is dimensioned with a design DNI of 1000 W/m^2, where higher DNI values only result in collector defocusing.

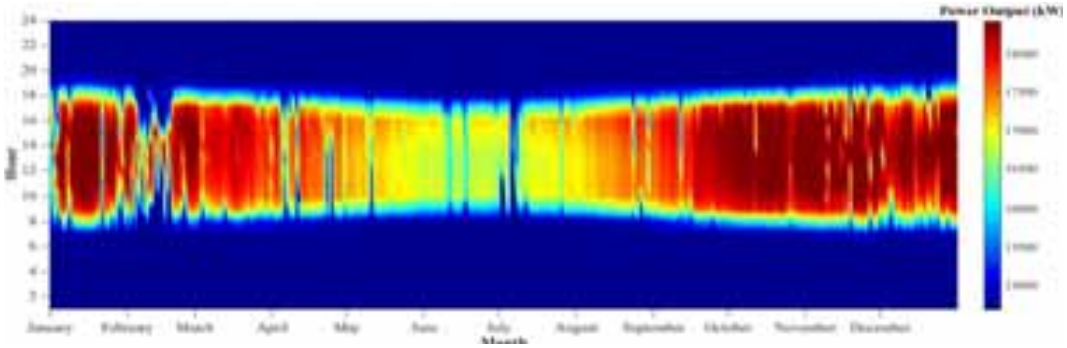

Fig. 9: Single-flash hybrid power plant year performance

5.2 Geothermal flow rate reduction

The hybrid single-flash power plant performance is able to reduce the geothermal fluid flow consumption during the year as shown in Fig. 10. The geothermal-only power plant operates with a geothermal flow rate of 95.43 kg/s, which is represented with the red layer. The lower amount of geothermal fluid flow that the hybrid system can achieve by integrating the solar thermal power is 76.84 kg/s considering the same base power output of 14.68 MW. The best performance in terms of geothermal fluid flow reduction is achieved during the spring with an average of 80.5 kg/s, while the worst operational results are observed during autumn where the solar system reduces the flow rate to only 82.9 kg/s. The average geothermal fluid flow is reduced during the year to 89.19 kg/s. Similar to what was presented in section 5.1, higher radiation values during summertime do not translate directly into additional geothermal fluid flow reductions, as the solar field is dimensioned with a design DNI of 1000 W/m^2, where higher DNI values only result in collector defocusing.

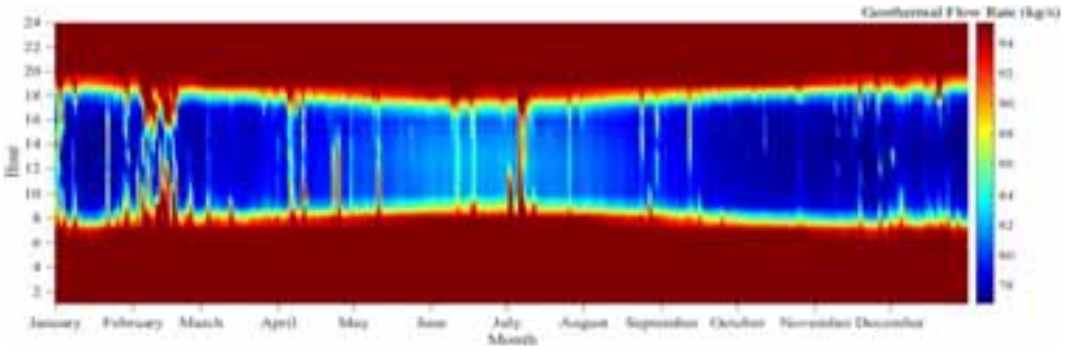

Fig. 10: Single-flash hybrid power plant year performance

6. Conclusions

An evaluation for a solar-geothermal hybrid power plant was developed in order to estimate their performance over a year. The optimization of the thermal power provided by the solar field showed that the superheating and evaporating process are able to increase the power generation, with the superheating process presenting higher rates (0.23 kW) of additional power output per kW of thermal power integrated to the single-flash hybrid plants. Delivering solar thermal energy in order to increase the steam temperature increases the 2nd law efficiency and allows the turbine to operate in a region of increased efficiency. Considering the hybridization of these two renewable resources, utilization of high-enthalpy geothermal resources shows greater promise given that the higher steam flow rates allow a better performance for the superheating process resulting in additional power generation and higher exergetic efficiencies. The solar field aperture area that maximizes the 2nd law efficiency of the flashing hybrid power plant is directly related to the steam flow conditions. The geothermal resources with higher enthalpy presented a larger reduction on the geothermal flow rate consumption due to the separation pressure at which they operate. Considering the reduction rate of the geothermal fluid produced by the solar energy, a 20-year useful life of a production well can be extended in at least 1 ½ years generating approximately 4.5 GWh of additional power output during. The benefits from the hybridization of these renewable sources are evident in terms of the power production increase during peak hours and the useful life extension for the production well. Furthermore, the hybrid scheme is a simple design considering the implementation of components that are common in a stand-alone geothermal power plants and concentrated solar power plants. For the Chilean energy market, the solar-geothermal power system presents an interesting yet still undeveloped alternative that can help fulfill the renewable energy utilization targets. These hybrid systems constitute an additional opportunity to diversify the energy resources utilization, with environmentally friendly base load energy using the large renewable potentials existing in the country.

Renewable Electricity Production Effect on the Energy Balance of Latvia

Peteris Shipkovs[1], Galina Kashkarova[1], Kristina Lebedeva[1], Janis Shipkovs[1], Lana Migla[1]

[1] Institute of Physical Energetics, Riga (Latvia)

Abstract

The paper presents current situation in the Latvian Energy sector, the place and the role of renewable energy resources in the Energy and Electricity production. The dynamics of the energy consumption and production is described along with evaluation of the environmental, legislative, and economic aspects of renewable energy use.

Keywords: *Renewable Energy Resources, Renewable Electricity, Energy Consumption, Energy Balance*

1. Introduction

The climate changes, pollutions, and energy insecurity are among the greatest problems of our time. According to the EU directives, the Energy sector is one of the areas in which the EU Member States have been sharing competence. The time span from 2014 to 2020 is a transitional phase for the EU's Energy policy, when the relevant objectives set for 2020 are to be achieved, with future objectives elaborated.

In particular, by 2020 the EU has to achieve the following climate and energy policy objectives set by the European Council of March 2007:

- to reduce greenhouse gas (GHG) emissions by 20% relative to the 1990 level;

- to increase the share of renewable energy resources (RES) in the energy consumption by 20%;

- to improve the energy efficiency by 20%.

In compliance with the EU legal acts on the climate and energy, the Latvian objective by 2020 is to ensure 40% of RES share in the final energy consumption.

Latvia has already made substantial improvements in the energy balance owing to the diversion from the use of fossil fuels (especially fuel oil or solid fuel) to that of wood biomass. In the time span from 1990 to 2013, the use of fossil fuels rapidly decreased – of liquid fuels by 59.7%, of solid fuels by 82.3%, and of natural gas by 49.6%, while the total wood biomass, biogas and biofuel use increased by 105%. According to the EuroStat, Latvia is currently holding the second place among the EU 28 Member States as to the RES share in the final energy consumption, and in 2013 reached 37.10% of the total gross final consumption.

2. Strategy and Policy Targets on Renewable Energy Use

The key directions of the efficient, well-balanced, market-oriented energy policy of Latvia set forth in the informative report "Long-Term Energy Strategy 2030 – Competitive Energy for Society" (Energy Strategy 2030, approved by the Cabinet of Ministers at the meeting of 28 May 2013) are aimed at the

doi:10.18086/swc.2015.04.31 Available at http://proceedings.ises.org

development of the state economy's competitiveness, promoting welfare of the society.

The main task of Energy Strategy 2030 is to ensure a positive impact of the energy sector on the national economy of Latvia, at the same time striving to achieve secure and sustainable energy supply, i.e.:

– secure energy supply – a stable energy supply and developed infrastructure provided for energy consumers;

– sustainable energy supply – reduced dependence on the imported energy resources; implementation of new and efficient technologies for the RES use and of the measures for improvement of energy efficiency.

The Energy Strategy 2030 envisages a 50% decrease in the energy import from non-EU suppliers, with a half of the total final energy consumption in the state ensured by RES, which is to be achieved by increasing the RES share in the heat, electricity and transport sectors.

Currently, in order to increase the energy production from domestic energy resources, to decrease the use of fossil fuels as well as to reduce the GHG emissions, different renewable energy sources (RES) are used for energy production. As shown in Table 1, the RES (the **bold text**) use has a stabile tendency for growth in general and, in particular, for electricity production.

Table 1: Dynamics of Primary Energy Resource Consumption (PJ).

	2010	2011	2012	2013	2014
Natural gas	61.3	54	50.8	50.3	45.4
Oil products	64.6	59.5	58.4	59.3	59.7
Coal and coke	4.5	4.6	3.8	3	2.5
Electricity (imported)	14.3	14.4	17.8	18	19.2
Hydro energy	**12.7**	**10.4**	**13.3**	**10.5**	**7.2**
Fuel wood	**45.6**	**46.9**	**52.5**	**53.1**	**55.9**
Wind energy	**0.18**	**0.26**	**0.4**	**0.43**	**0.5**
Biogas	**0.56**	**0.92**	**2.2**	**2.7**	**3.1**
Others	0.07	0,08	0.07	0.14	0.13
Total	203.81	191.06	199.27	197.47	193.63

The National strategy as well as plans and programs have been developed in view of reducing the negative environmental impacts of the energy sector, promoting the use of Renewable Energy Sources.

The RES segment in the electricity production comprise hydropower plants, wind power plants, biogas power plants and biomass power plants, as well as cogeneration stations utilizing RES (Table 1, Table 2).

Table 2 illustrates the share of RES in the total energy consumption and its share in the electricity production (Shipkovs *et al*., 2014).

Table 2: Share of RES.

	2000	2010	2013	2014
Share of RES in the total energy consumption, %	29.5	35	37.1	34.0
Share of RES in the electricity production, %	47.7	49.3	56.9	42.6

The main RES types in our country are the fuel wood and hydro resources, which in 2014 accounted for 34% of the total consumption of energy resources.

Over the last ten years (2004-2014) the total consumption of RES has increased by 12%.

Fuel wood is the most commonly used RES in Latvia, and its share in the total energy consumption in the time from 2010 to 2014 increased from 23.4% to 30.2%. In 2014, the share of fuel wood in RES consumption was 82.1%, which is 3.4 PJ or 4% more than in 2013 (Fig. 1).

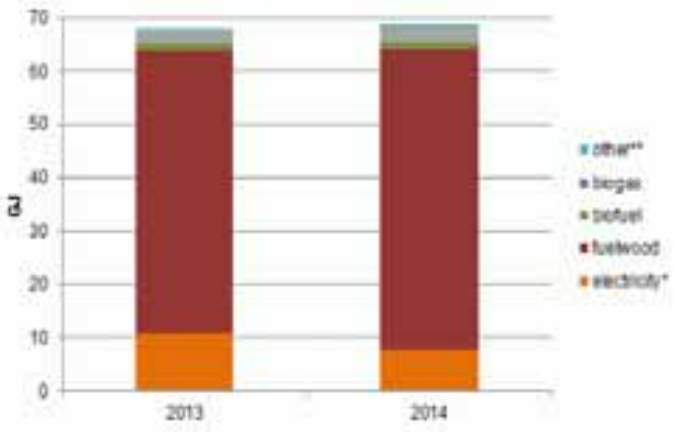

Fig. 1: Consumption of renewable energy resources in 2013 and 2014, GJ.

In 2014 the total consumption of fuel wood grew by 6% as compared with 2013 (see Fig. 1); consumption changes are also seen in the breakdown by sectors. The share of fuel wood increased both in households and in transformation sector for heat and electricity production. The main fuel wood consumers are households, which mostly use firewood (85%). In 2010, the share of consumed fuel wood in households was 42.9%, in 2013 – 45.4%, and in 2014 – 46.3%. The fuel wood consumption by sectors is shown in Fig. 2.

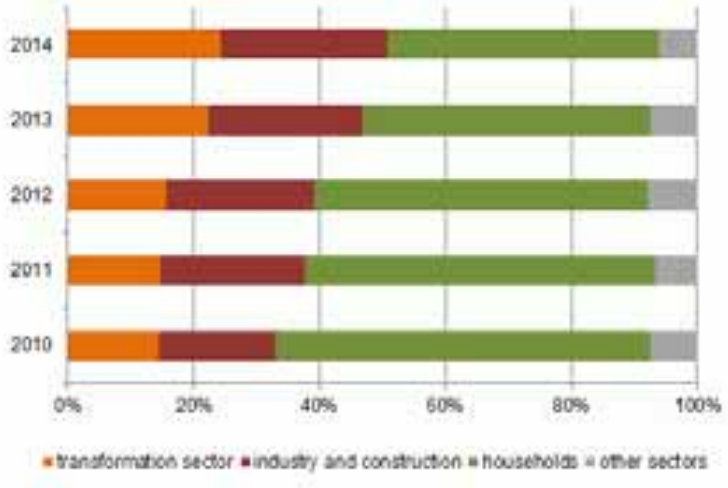

Fig. 2: Fuel wood consumption in Latvia, %.

Over the time span 2010-2014 the share of fuel wood in transformation sector increased by 9.8%, in 2014 reaching 24.3% of the total consumption in Latvia. In the transformation sector mainly wood chips are used (86.5%). The greatest growth in consumption of fuel wood in the transformation sector was recorded in 2014, when the share of wood chips grew by 25.1% as compared with 2013. This was due to the new CHP plants which started their operation in 2014, and to the annually increasing RES share along with reduced share of natural gas. Since 2007, the installed electrical capacity of RES CHP plants by 2014 had increased 12 times, reaching 121 MW; the electricity production increased 16 times, reaching 669 GWh, which accounts for 22% of the total electricity produced in CHP plants.

Directive 2009/28/EC of the European Parliament and of the Council on the promotion of the use of energy from renewable sources stipulates that the share of energy from RES by 2020 must account for at least 40% of the final energy consumption. In 2008, this share in Latvia was 29.81%, in 2010 – 35%, in 2013 – 37.1%, and also in 2014 this percentage slightly rose, reaching 34 %. Each Member State is obliged to ensure that by 2020 the share of electricity produced from RES (biofuel, biogas) and consumed in transport is at least 10% of the final consumption of energy in transport (in 2013 Latvia reached 3.08%).

In Latvia, current legislation foresees promotion of purchasing the energy produced from RES, namely, the electricity produced by the cogeneration plants using local energy sources.

The next planned steps in order to promote further use of RES in Latvia are as follows:

- Participation in the EU Emission trading.
- Introduction of energy tax (CO_2 tax).
- Setting the overall RES target in the primary energy supply, with sectoral and type breakdown.
- Implementation of pilot projects.
- Organization of public awareness campaigns about RES.

3. Electricity Market

The electric energy makes the basis for economic development of every country, and the global demand for this energy is constantly growing. As of now, the use of fossil or nuclear sources for energy production becomes problematic for many reasons. The only real environment-friendly way of producing electric power is the use of renewables, which are considered as the main energy source in the future.

In Latvia, the shortage of local energy creates dependence on electricity importers (see Table 3 for the electricity supply dynamics). Therefore, to reduce this dependence, it is necessary constantly to increase power generation capacity, which in turn contributes to an increase in hazardous emissions and greenhouse effects reinforcement.

Table 3: Electricity Supply in Latvia (GWh).

	2000	2005	2009	2010	2011	2012	2013	2014

One of the ways to reduce the electricity imports might become additional sources of energy, especially clean ones. Increase in the electricity production from different renewable sources is shown in Table 4.

The electricity market in Latvia has been open since 1 January 2015. Pursuant to the amendments to the Electricity Market Law of 18 September 2014, households have an opportunity to freely choose the provider and agree on the electricity price based on an agreement just like legal entities. The amendments to the Electricity Market Law of 18 September 2014 further envisage special tariffs for the protected consumers.

Along with complete opening of the electricity market as of 1 January 2015, a support instrument for protected consumers was introduced.

Table 4: Increase in the electricity production from different RES.

Energy sources	Installed capacity, MW		Electricity production, GWh		Electricity production increase from 1995 to 2013
	1995	2013	1995	2013	
Wind	1	67	0	120	× 120
Hydro (big)	1504	1560	2934	2912	× 0.99

Total	1 487	1 508	1 515	1 22	1 642	1 701	1 764	1780

Over the last years the capacity of hydropower plants did not change much; in turn, the electric capacity of other power and CHP plants grew significantly. For instance, capacity of wind power plants in 2014, as compared with 2013, rose by 3%, and compared with 2012 – by almost 17%. The electric capacity of biogas CHP plants in 2014 grew by 9.4% as compared with 2013, while this indicator for biomass power plants and CHP plants was 14.5% greater in 2014 than in 2013, and 174% greater as compared with 2012. One of the factors promoting RES development is the State support, which allows selling electricity within the mandatory procurement framework.

In 2014, the energy production from RES promoted the mandatory procurement of electricity and investment support from the EU Cohesion Fund, the Climate Change Financial Instrument, and the European Agricultural Fund for Rural Development. Renewable energy is closely linked to the country's energy independence, environmental protection and climate change, as well as to its impact on the competitiveness of the economy. Now it is vitally important to increase the independence of Latvian energy sector. For this purpose serves the use of RES which increases a positive impact on reducing the energy dependence on imported energy and the share of RES in final energy consumption.

As shown in Fig. 3, the greatest share (over 70%) of electricity from RES is produced by hydropower plants. In 2014, hydropower plants with the capacity >10 MW (Plavinas Hydropower Plant, Riga Hydropower Plant and Kegums Hydropower Plant) produced 1 925 GWh of electricity, or 68.7% of the total electricity produced from RES.

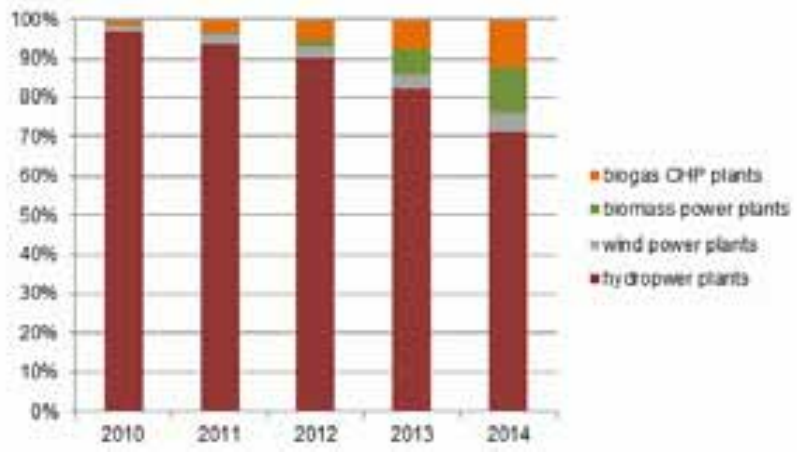

Fig. 3: Electricity produced from renewable energy resources, %.

Important contribution to the total renewable energy balance is being made by three large hydro stations: Kegums Hydroelectric Power Plant (HPP) – 264.1 MW, Plavinas HPP – 884 MW, Riga HPP – 402 MW. To increase the installed capacity of hydropower, reconstruction of the hydro generation units is underway (see Table 6).

Table 6: Planned reconstruction of Hydro Power Plants.

	Year	Number of turbines	Increase of utilization rate	Increase in generation
Plavinas HPP	2014-2016	2	5% ... 9%	+18 GWh
Kegums HPP	2014- 2017	3	5% ... 6%	+22 GWh
Riga HPP	2017- 2021	6	3.5%... 5%	+25 GWh

Small hydropower plants had played a special role at the beginning of Latvian electrification and local electricity grid development. This was worth expanding, so at the end of 1926 there were installed 26 HPPs with the total capacity of turbines 1.5 MW and of power generators 1.26 MW. The Latvian hydro resource potential was first analyzed in 1931. Small hydropower development continued until the beginning of 70-ies. At that time, construction of large power plants and transmission lines was developed. With time, the operation of small HPPs became unprofitable, and from 1963 to 1977 they were decommissioned. In turn, from 1992 to 2012 there were put into service 143 small HPPs, 91% of which were restored or reconstructed and only 9% rebuilt (Shipkovs *et al*. (2013)).

The theoretical potential of Latvian small and medium-sized rivers as energy sources is calculated to be ~ 900 million kWh. Technically achievable potential of hydro energy resources (taking into account mining and processing facilities and technological transformation capabilities) is 150-300 million kWh per year. Currently, only 20-40 % of the real small river resource potential is utilized. This potential can be increased by improving the existing HPP technologies and power generation efficiency.

With a greater than 40% share of cogeneration in the total gross electricity production, Latvia is among the top three member states in the EU, as all thermal electricity is produced by CHP plants (Shipkovs *et al*., 01.2013). The total installed CHP capacity more than doubled from 2006 and reached 1.252 MWe in 2013, with the number of CHP plants increased from 43 to 166 and the electricity generation increased by 60% reaching 3.2 TWh in 2013. The combined cycle turbine operating on natural gas is a prevailing technology at four largest public district heating CHP plants, with ~ 85% share in the total CHP capacity and > 60% – in the CHP electricity and heat generation in 2013. Gas engines are most often used at smaller CHP units (<20 MW) where among the 162 existing CHP plants there are only 46 autoproducers CHP plants. The CHP generation is concentrated in a small number of major CHP units, which is the main reason for rather big fluctuations in the CHP electricity and heat generation (see Fig. 4).

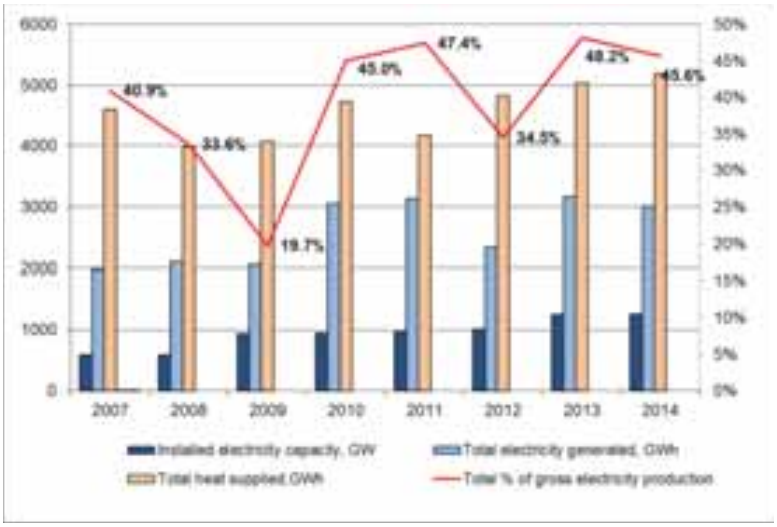

Fig.4: CPH installed capacity and generation.

With a greater than 78.9 % share, the natural gas is the major fuel used at CHP plants, followed by wood biomass and biogas (see Fig. 5) whose share is ever growing.

In 2014, CHP plants supplied almost 60% of the total produced heat to widespread district heating systems, covering ~ 70% of the households' heat demand and approx. 22% of the total heat demand in Latvia.

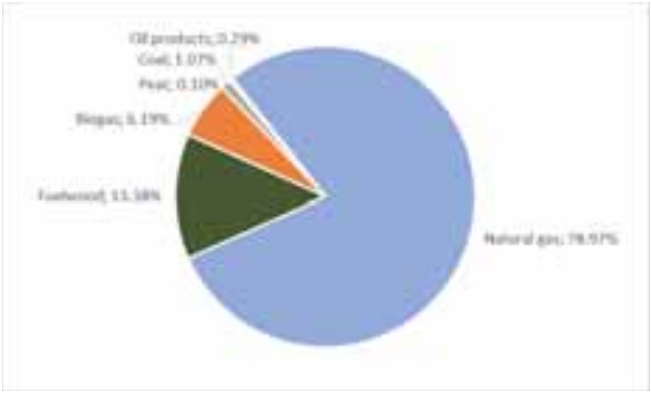

Fig.5: Structure of fuel consumption by CHP plants (2014).

Until the beginning of the year 2009, biogas was produced by "Riga Water Ltd." at its water purification plant (capacity of 2 MWe), with the resulting electricity spent for their production needs at Riga landfill "Getlini Eco" (installed capacity of 5 MWe), LAU Study and Research Farm "Vecauce" (total capacity 270 kWe, and two plants at Liepaja landfills (total capacity of 1 MWe) In 2009, Latvian entrepreneurs (58 in number) received a quota for biogas production with a total installed capacity of ~ 54 MWe. In the same year, one unit of the North landfill Daiba was put into operation with a capacity of 170 kWe, and a number of biogas plants (the total installed capacity of 10-12 MWe) was launched. In March, 2010, the "MC" Ltd. biogas plant was put into operation. In 2014, already 54 biogas plants were operating, of which: at domestic landfills – 7, operating with domestic waste water – 1, with food production residues or waste water – 2, in agricultural sector – 44 (the total installed capacity 58 MW, with 350 GWh of electricity produced).

The estimates obtained for the biogas potential are shown as related to agricultural and industrial branches (Fig. 6); also, the technically achievable potential of biogas that could be obtained from household waste was estimated to be 0.3 TWh.

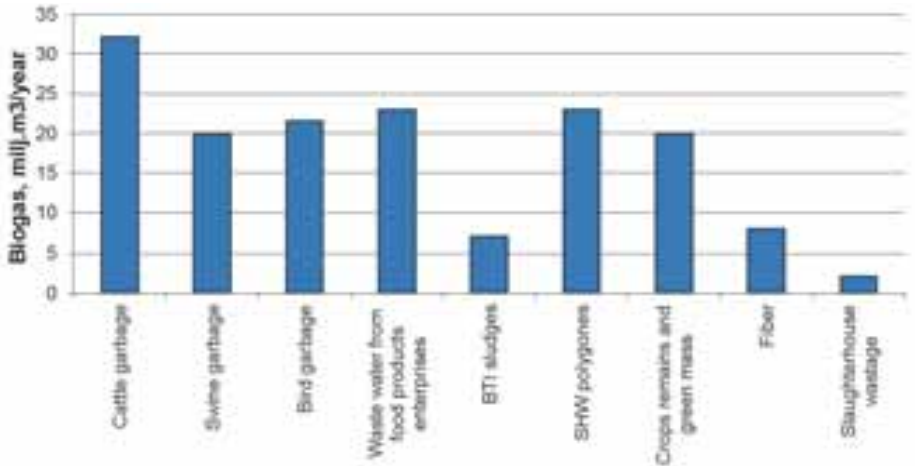

Fig.6: Biogas production potential.

As concerns wind energy, Latvia possesses a very good potential for its development along the Baltic Sea coastline, especially owing to a high voltage transmission line running there (see Fig. 7). Accordingly, the wind power plants are installed mostly in the seaside area, with totally produced electricity of 140 GWh.

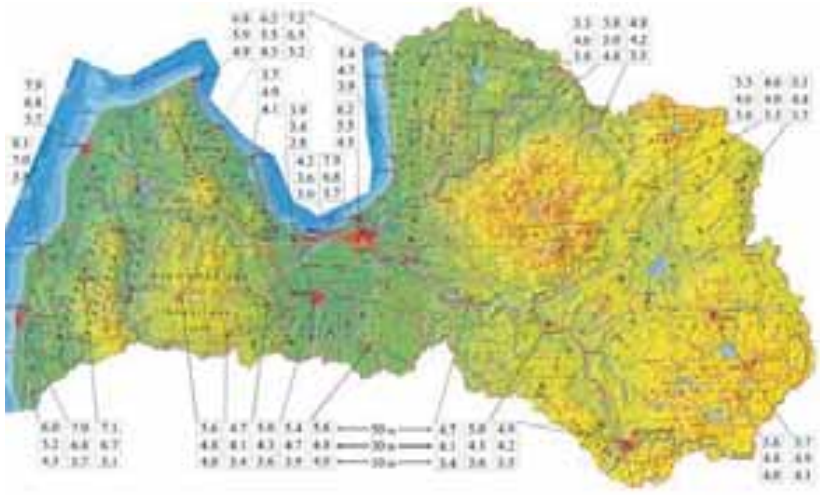

Fig.7: Wind map (on 10 m, 30 m, and 50 m heights).

Wind power output rose quickly, from 2 MW in 2000 to 69 MW in 2014; in particular, when the wind power farm "Pope" had been built in 2012, the country's installed wind power capacity was doubled (up to 68 MW). So far Latvia uses only 5 % of its wind power potential. The wind map in Fig. 7 made up for the whole country shows that wind farms could be constructed along practically all its coastlines. The related branch should continue the development at a steady pace, given the fact that the renewable energy action plan envisages increasing the wind turbine fleet's capacity to 416 MW by 2020 (180 MW offshore included).

Latvia is firmly embarked on the electricity supply source diversification process, which will enable our country to gradually wean itself off the electricity imports and even eliminate the impact of hydropower's up-and-down performance on the renewable energy share of its electricity mix.

Concerning the use of solar energy for electricity generation in Latvia, it is insignificant up to now; still, in 2013 solar energy (PV solar panels) came in sight, with the produced electricity of 0.2 TJ.

4. Conclusions

In Latvia, the potential for RES use development in high in terms of all factors: technical, social, and the market.

Firewood and wood waste will remain the most important source of bio-energy in the future. However, contribution of bio-energy is closely associated with possibility of using it not directly as fuel for electricity and heat generation but also for production of fuel for transport, with reducing the costs of RES use technologies.

Today, many problems in the RES use area exist – e.g. high costs of equipment, low interest among the policy makers, and, as a result, deficiency of national support; still, despite these problems, there are also opportunities for development, namely: liberalization of energy supply, focussing on the decentralized energy production, higher prices for fossil fuels, etc.

The progress in developing the energy production technologies using renewable energy resources has been made in many countries; however, there is a need to make the results widely known, to transfer and exchange technologies and practices. Recent development of different technologies for this purpose opens new possibilities for RES use also in small countries such as Latvia.

Availability of the economic instruments for promotion of RES in the electricity market and for heat generation would help Latvia in its search for the opportunities to encourage RES application through Kyoto mechanisms and building up the required legal and administrative framework. The combination of the mentioned measures should create necessary operating conditions for new RES power plants (especially for large-scale wind farms) and conversion of the existing power stations on biomass to cogeneration plants. In Latvia, economic stimuli have been established for construction and operation of small HPPs, WPPs and CHP plants. In particular, power plants using RES for electricity production have priority access to the transmission and distribution systems in Latvia.

In Latvia, renewable electricity generation is stimulated through a complex support system based on a feed-in tariff, which also includes elements of a quota system and tenders. The existing state support mechanisms for energy production from renewable energy resources are being assessed and revised by The Ministry of Economics. Stringent supervision of subsidized electricity producers, and stricter controls with limited timeframe for the implementation of RES projects have been introduced. In January 2014, a new tax for subsidized electricity producers was introduced, which should be paid by the companies receiving financial support for power generation from RES or from combined heat and power plants. Although the access of renewable energy plants to the grid is subject to the general legislation on energy, the electricity from renewable sources is not given priority. Also, devices for heat production from RES are not given priority connection, and there is no special legislation promoting the connection of RES heating devices to the heat transmission network at the national level.

Scanning of current energy strategies shows that Latvia has its energy strategy and plans while generally no specific strategies regarding solar power. Another major effort is to identify and analyze the supportive structures that exist for those who intend to invest in the solar power and to investigate it.

The structure of the modern energy supply systems in combination with renewable energy resources is promoted by new progressive technologies that increase the efficiency of renewable energy utilization and pledges support for a wider RES use.

The review of all renewable energy resources which could be more or less used for electricity production shows that Latvia has real possibilities for achieving its targets for the future. Latvia has already a 20-year experience of creating a viable energy policy to provide the State with stable energy supply and promote effective and rational energy utilization. Progressing in the relevant technologies and developing the State laws will lead to creation of a stable energy sector that in turn will promote rational and effective RES use.

Numerical model for pressure drop and flow distribution in a solar collector with horizontal U-connected pipes

Federico Bava[1] and Simon Furbo[1]

[1] DTU Civil Engineering, Technical University of Denmark, Brovej, Building 118, 2800 Kgs. Lyngby (Denmark)

Abstract

The development of a numerical model for calculating the pressure drop and flow distribution across a solar collector in isothermal conditions is described in this paper. More specifically, the considered collector layout is that of a harp collector with U-type configuration. The different hydraulic resistances causes unbalance of flow distribution in the absorber pipes, so this aspect had to be considered in order to correctly evaluate the pressure drop. The model was written in Matlab and makes use of pressure drop correlations found in literature for both friction losses and local losses. The model was compared in terms of overall pressure drop against measurements which were performed on an Arcon Sunmark HT 35/10 collector. Different flow rates, temperatures and fluid types were tested during this validation process. In case of pressure drops larger than 1 kPa, the relative error between model and measurements was no larger than 7%, while the absolute average value no larger than 3%. For smaller pressure drops the relative difference was usually larger, but still within the accuracy of the differential pressure sensor. Concerning the flow distribution, it was found that the flow regime was the main parameter affecting the results. Turbulent regime resulted in a much more uniform flow distribution across the absorber pipes compared to laminar regime.

Keywords: *solar collector, pressure drop, flow distribution, friction losses, propylene glycol, heat transfer fluid, temperature, flow rate.*

1. Introduction

The pressure drop over a solar collector is a parameter which must be known and taken into account, when connecting collectors in a solar collector field both in series and parallel. In fact, the pressure drop influences the flow distribution throughout the field, affecting its overall efficiency and energy output, and determines the requirements of the pumps which need to be installed to supply the field in the most efficient way.

The standard norm ISO 9806 does not provide strict guidelines on how to measure the pressure drop characteristic curve, as it states that "the fluid used in the collector for the test shall be water or a mixture water/glycol (60/40), or a mixture recommended by the manufacturer. The temperature of the fluid shall be (20±2) °C" (ISO 9806). Additionally, the conditions during the test may differ significantly from the actual operating conditions of the collector, both in terms of fluid type and temperature. For this reason, it could be useful to have a model able to derive the pressure drop of a collector for different temperatures and fluids, starting from a single test carried out in a specific operating condition.

The most common layout used when manufacturing large flat plate collectors is harp U-type layout, where a number of parallel pipes connecting two manifolds, which have inlet and outlet on the same side. Almost all solar collector field. On the other hand, the parallel pipe design has the disadvantage that perfectly uniform flow distribution cannot be achieved. The flow distribution in flat plate collectors with parallel pipes has been the topic of many investigations, as it may strongly affect the collector efficiency. In fact, several studies show that the efficiency diminishes for decreased uniformity of flow distribution, as a consequence of non-uniform outlet temperatures for the different collector pipes (Chiou, 1982). Wang and Wu (1990) proposed a discrete numerical model to predict the flow distribution in solar collector arrays with vertical

doi:10.18086/swc.2015.10.01 Available at http://proceedings.ises.org

pipes in U-type configuration, taking into account buoyancy force. The flow rate in the riser tubes decreases monotonically with the inlet manifold distance. The same trend was found by Jones and Lior (1994), who considered a single collector with vertical pipes and neglected buoyancy. Weitbrecht et al. (2002) carried out both an experimental and analytical study on the flow distribution in a Z-type collector, investigating the influence that the inset of a pipe into the manifold has on the pressure drop across the tee junction. However, only laminar flow and one specific tee geometry are considered.

Fan et al. (2007) studied the flow and temperature distribution in a large solar collector with 16 U-connected horizontal tubes. A numerical model, based on CFD calculations and taking into account buoyancy, and experimental measurements are compared. The results show that the flow distribution is dominated by friction (and hence buoyancy can be neglected), if the velocity in the collector pipes is high compared to the temperature rise across the collector. In large solar collector fields in Denmark each row usually consists of a number of collectors between 10 and 25 (Windeleff and Nielsen, 2014), so the temperature rise in each collector is relatively small, while the flow rate is relatively high. Consequently, it can be considered that buoyancy plays a minor role in the flow distribution in this kind of installations.

The aim of the study presented in this paper was to develop a numerical model for calculating the pressure drop over a U-type collector. Benchmark of the model was a solar collector for large collector fields, so the flow across the collector could be considered controlled by friction only and the model was developed accordingly.

2. Material and method

2.1. Solar collector design

The developed model was based on the design of U-type large scale collectors. These collectors usually have a number of horizontal pipes welded to absorber strips and connecting two vertical manifolds located along the sides of the collector with their outlet at the top corners of the external frame (Figure 1).

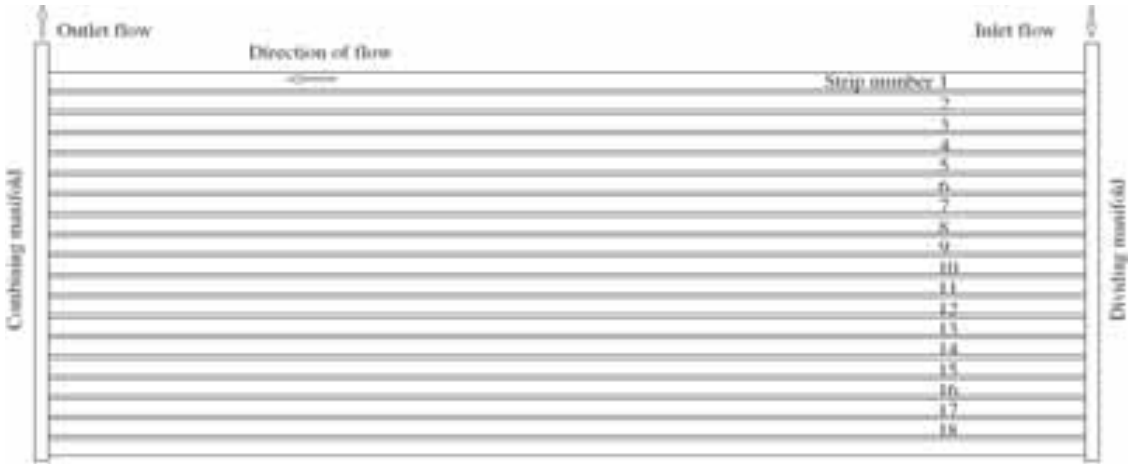

Figure 1: Sketch of a U-type absorber with horizontal pipes.

The choice of this design for the model was motivated by the fact that this is the most frequently adopted design when manufacturing large collectors for solar heating field applications. In fact, these collectors are easy to assemble and quick to connect to one another when they are installed side by side in a field.

The developed numerical model was validated in terms of pressure drop against measurements carried out on a collector of this type, more specifically an Arcon Sunmark HT-SA 35/10 collector, having an aperture area of 12.60 m^2. The collector piping was made of copper and had circular cross section. The 18 horizontal pipes were 5.80 m long, had an inner diameter of 9.1 mm and an intermediate spacing of 122 mm. The manifolds had an inner diameter of 32.9 mm.

Though, as long as the general collector design is preserved, the model can be easily modified to treat also collectors having for example a different number of horizontal pipes, various manifold and pipe diameters.

2.2. Pressure drop correlations

In a solar collector, as well as any other hydraulic circuit, the total pressure drop is given by the sum of two types of pressure losses: friction (or major) losses and local (or minor) losses. Friction losses occur in pipe flow because of viscous effects generated by the pipe surface. Local losses are due to variations of the velocity vector. Valves, bends, tees and abrupt changes in a pipe cross-sectional area are examples of components causing local pressure losses.

The friction loss along a straight pipe of constant cross section is a function of the flow velocity, pipe length, pipe diameter and a friction factor which strongly depends on whether the fluid flow is turbulent or laminar. This pressure loss is calculated by the Darcy-Weisbach equation:

$$\Delta p = \lambda \frac{l}{D_h} \frac{\rho w^2}{2} \qquad \text{(eq.1)}$$

where Δp is the pressure drop [Pa],

λ is the Darcy friction factor [-],

l is the pipe length [m],

D_h is the pipe hydraulic diameter, which equals the inner diameter for a full flow circular pipe [m],

ρ is the fluid density [kg m^{-3}],

w is the mean fluid velocity [m s^{-1}].

As mentioned above, the friction factor depends on the type of flow regime and, if this is turbulent, on the roughness of the pipe as well. The parameter indicating whether a flow is laminar or turbulent is the Reynolds number, defined as

$$Re = \frac{w \rho D_h}{\mu} \qquad \text{(eq.2)}$$

where Re is the Reynolds number [-],

μ is the fluid dynamic viscosity [Pa s].

Density and viscosity are properties characteristic of each fluid and are strongly dependent on the temperature. Water and propylene glycol/water mixtures are the most common fluids used in solar thermal applications. Water thermophysical properties are well known and are easily found in literature. For the density, (eq.3) was used, while the dynamic viscosity was evaluated through (eq.4).

$$\rho = 1000.6 - 0.0128\ T^{1.76} \qquad \text{(eq.3) (Furbo, 2015)}$$

$$\log_{10} \mu = \log_{10} (1.002 \cdot 10^{-3}) + (20 - T)/(T + 96) \cdot [1.2378 - 1.303 \cdot 10^{-3}\ (20 - T) + 3.06 \cdot 10^{-6}\ (20 - T)^2 + 2.55 \cdot 10^{-8}\ (20 - T)^3] \qquad \text{(eq.4) (Kestin, 1978)}$$

Given the large variability of the properties of propylene glycol/water mixtures found in literature and in product datasheets, these were experimentally investigated at the Department of Chemical Engineering of the Technical University of Denmark, making use of an Anton Paar DMA 4100 densimeter and an Anton Paar AMV 200 viscometer. Three samples with glycol concentration of 40%, 45% and 50% were tested at temperatures between 20 °C to 80 °C with an intermediate step of 10 °C. The experimental data points were then interpolated with the polynomial expressions (eq.5) and (eq.6).

$$\rho = 1013 - 0.2682\ T + 0.7225\ x - 1.94 \cdot 10^{-3}\ T^2 - 4.964 \cdot 10^{-3}\ x\ T \qquad \text{(eq.5)}$$

$$\mu = (-2.881 - 6.721 \cdot 10^{-3}\ T + 0.2839\ x + 1.959 \cdot 10^{-3}\ T^2 + -7.036 \cdot 10^{-3}\ x\ T - 1.883 \cdot 10^{-5}\ T^3 + 4.862 \cdot 10^{-5}\ x\ T^2) \cdot 10^{-3} \qquad \text{(eq.6)}$$

where T is the fluid temperature [°C],

x is the mass concentration of propylene glycol in the mixture [%].

Laminar flow regime is characterized by low values of Reynolds number, while turbulent flow occurs for higher values. In literature it is often stated that, for fully developed flow in a circular pipe, laminar flow occurs for Re<2300, and turbulent flow for Re>4000 (Holman, 2002). The flow regime between laminar and turbulent is referred to as transitional regime. In reality, the exact value at which change in flow regime occurs is extremely difficult to determine and depends on whether small disturbances are present. In the developed model, flow was assumed laminar for Re<2300, and turbulent for Re>3100, as a result of a series of tests carried out to evaluate transition in flow regime in the HT collector pipes.

In case of laminar flow, Darcy friction factor was calculated through Hagen-Poiseuille law:

$$\lambda = \frac{64}{Re} \qquad \text{(eq.7)}$$

For turbulent flow in smooth pipes, Blasius correlation (eq.8) was used, as the collector manifolds and pipes were made of commercial copper tubes, characterized by very small absolute roughness (Binder, 1973).

$$\lambda = \frac{0.3164}{Re^{0.25}} \qquad \text{(eq.8)}$$

Although not used in the present study, other friction factor correlations were implemented in the model, such as those proposed by Colebrook (1939) and Haaland (1983) for turbulent flow in pipes of known roughness, and by Joseph and Yang (2010) for any flow regime in smooth pipes.

Following the example of Jones and Lior (1994), the friction factor in the transition region (2300<Re<3100) was calculated by linear interpolation between the value obtained from (eq.7) for Re=2300 and that obtained from (eq.8) for Re=3100.

Regarding local losses, in the solar collector under investigation the only discontinuities were represented by the tees connecting the horizontal pipes to the manifolds. The correlations used to model the pressure losses in tees were mainly obtained by Idelchik (1994). Though, Idelchik's correlations refer to tees with sharp edges and without any inset, while the collectors under investigation presented 2-3 mm inset of the horizontal pipes into the manifold. As even short insets have been proven to be able to affect the pressure drop across tees (Ohnewein et al., 2015), Idelchik's correlations were corrected based on the results from Ohnewein et al. (2015).

2.3. Numerical model

Using the pressure drop correlations described in the previous section, a numerical model was developed in Matlab in order to compute the flow distribution and the resulting pressure drop across the collector. The input data to the model are design characteristics of the collector hydraulics and operating conditions of the heat transfer fluid (type of fluid, volume flow rate and temperature). The fluid temperature, which is assumed to be constant throughout the collector, is used to determine density and viscosity of the fluid.

Given an initial flow rate as input, the model assumes that this flow is uniformly distributed in all horizontal pipes and the resulting pressure drop for each of the possible fluid paths is calculated. Because a uniformly distributed flow is assumed, the pressure drop increases from one strip to the next (see strip numbering in Figure 1), as the fluid path becomes longer due to additional manifold segments. In reality, the pressure drop has to be the same, irrespective of the path the fluid follows, resulting in an adjustment of the flow rate in each strip.

2.4. Experimental setup for pressure drop measurements

To validate the model, the pressure drop across a large solar collector was measured in different operating conditions and compared to the value given by the model. The collector used for this purpose was a HT-SA 35/10 manufactured by the Danish company Arcon-Sunmark (see Section 2.1).

A differential pressure sensor TA-SCOPE from the company TA Hydronics, was used to measure the pressure drop across the collector. The instrument has a nominal accuracy which is given by the higher value between 0.1 kPa and 1% of the measured value.

The flow rate supplied to the collector was measured by a Kamstrup MP115 electromagnetic flow meter. Its accuracy is stated to be within ±0.5%. Additionally, the instrument was tested with different fluids,

temperatures and flow rates at the end of the pressure drop tests and its nameplate calibration factor was confirmed.

Transparent plastic pipes were connected to the inlet and outlet of the collector at one end and to the pressure sensor at the other end, as shown in

Figure 2. The transparent pipes made it easier to verify that no air was present in the circuit, which otherwise would alter both flow rate and differential pressure measurements.

Figure 2: Solar collector HT-SA 35/10 used for the validation and plastic pipes arrangement for pressure drop measurement.

Pressure drop measurements were carried out for different flow rates (between 0.08 and 0.72 liters s-1, corresponding to 0.3 and 2.6 m3 h-1) and at two temperature levels (approximately 25 °C and 70 °C), both using pure water and a 50% propylene glycol/water mixture as heat transfer fluid. The tests were performed in cloudy sky conditions, so that the temperature rise across the collector was negligible and the assumption of isothermal flow introduced in the model was fulfilled.

3. Results

3.*1. Validation of the model*

The comparison between measured and calculated pressure drops as function of the flow rate is shown in Figure 3 and Figure 4 for water and 50% propylene glycol/water mixture. Given the configuration of the hydraulic circuit, it was possible to test volume flow rates up to 2.6 m^3 h^{-1}, corresponding to pressure drops

of approximately 9-10 kPa. The lower boundary of the tested flow rate was determined by the error of the differential pressure sensor, which became increasingly predominant when measuring pressure drops lower than 1 kPa.

Note that the data points referred to as "25 °C" were actually characterized by mean fluid temperatures between 19 °C and 33 °C while those at "70 °C" between 67 °C and 77 °C.

In both diagrams, the typical quadratic relation between pressure drop and flow rate can be observed, as the different groups of points are approximately aligned along parabolic trajectories. Additionally, the influence of the fluid temperature on the pressure drop across the collector can be noted by comparing the different series of points within the same diagram. As expected, a fluid flow at lower temperature caused a higher pressure drop, provided that equal flow rates are compared.

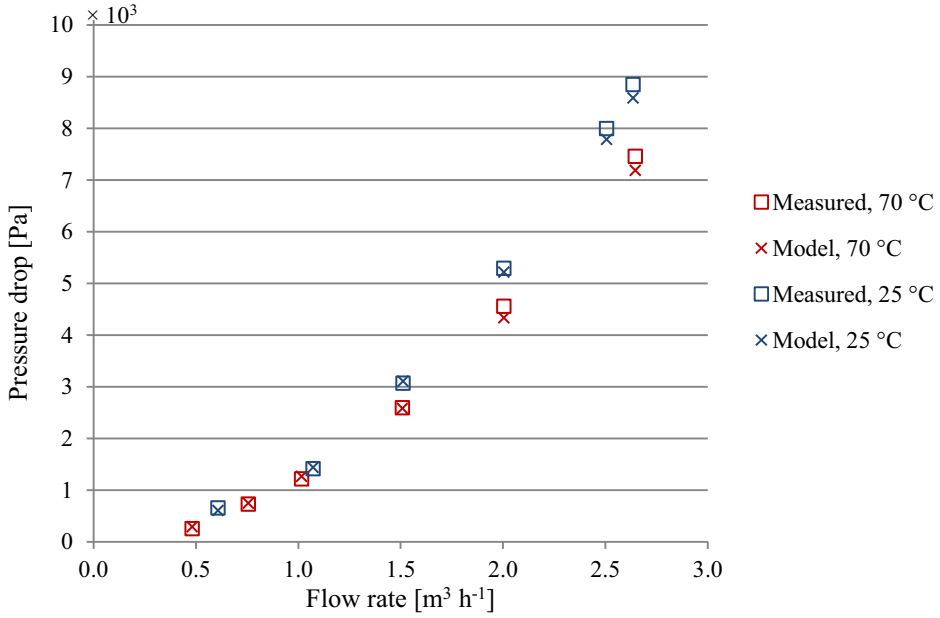

Figure 3: Comparison between measured and calculated pressure drops for water.

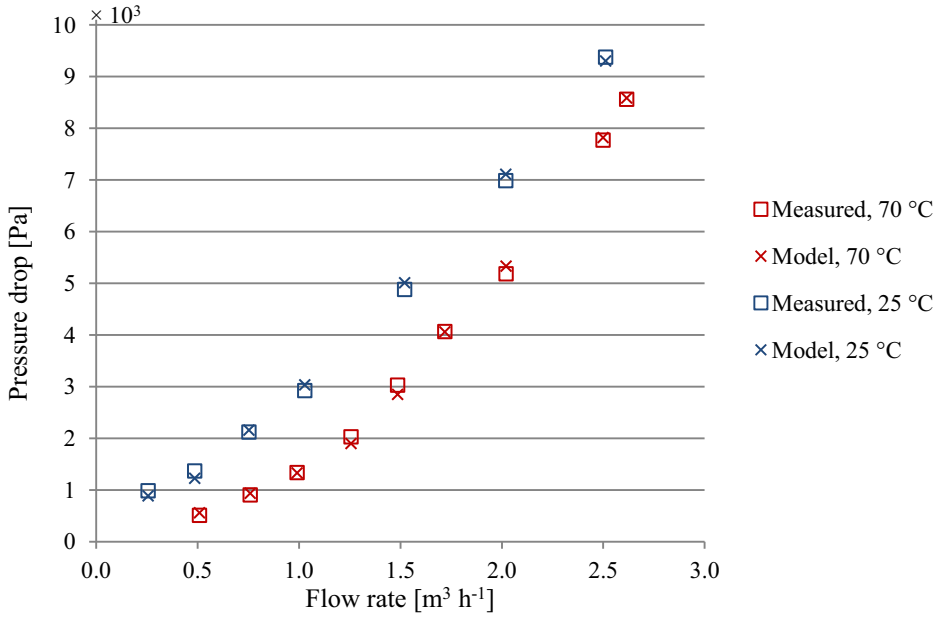

Figure 4: Comparison between measured and calculated pressure drops for 50% propylene glycol/water mixture.

3.2. Flow distribution

Using the developed model, it was possible to calculate the flow distribution inside the HT 35/10 collector at different flow rates and fluid types. The case with water at 20 °C was investigated. Water flow across the horizontal pipes of the collector was either laminar or turbulent at a temperature of 20 °C depending on the flow rate.

The flow distribution is shown Figure 5, where the flow distribution is expressed in terms of the parameter χ, defined by (eq.9) as:

$$\chi_i = \frac{V_i}{\sum_{i=1}^{18} V_i} \qquad \text{(eq.9)}$$

where χ_i is the fraction of the total collector flow rate flowing in the i-th horizontal pipe [-],

V_i is the volume flow rate in the i-th horizontal pipe [m^3 h^{-1}].

In case of a perfectly uniform flow distribution, the parameter χ would have a constant value of 5.56%, regardless of the horizontal pipe number.

The flow distributions shown in Figure 5 are decreasing, from the top to the bottom of the collector, with the only difference being the slope of the profiles.

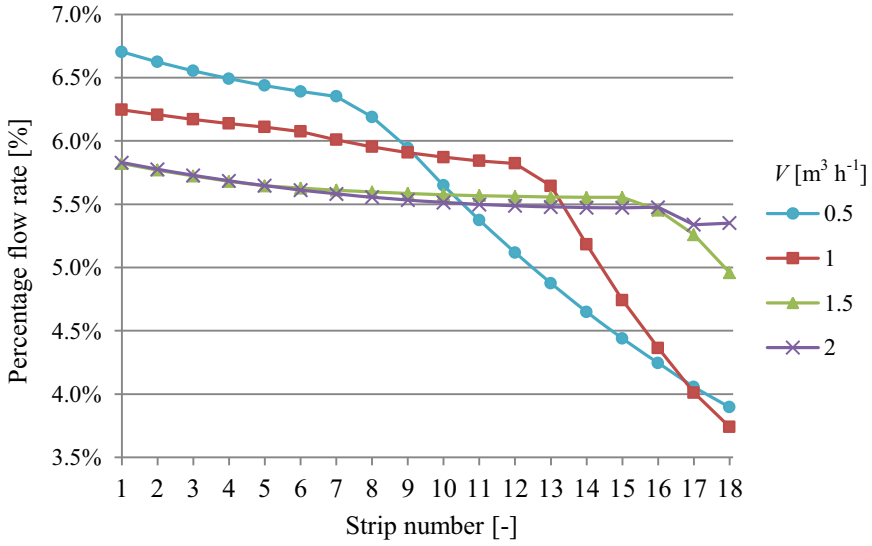

Figure 5: Flow distribution inside the collector at different flow rates for water at 20 °C.

As can be seen in Figure 5, in case of flow rates of 0.5 and 1 m^3 h^{-1}, laminar regime took place and a much less uniform distribution occurred. In these conditions χ varied between 3.7% and 6.7%. For higher flow rates the flow regime became turbulent and the flow distribution became more uniform and similar to that of water at 70 °C.

Although the pressure drop across the horizontal pipes played the most significant role in all cases, its importance for the different paths was quite different, depending on the flow regime. In case of turbulent regime in all horizontal pipes, the pressure drop along these represented 85%-89% of the total collector pressure drop for the top pipe, and 75%-77% for the bottom pipe. The remaining part was caused by forward and return manifolds as well as tee junctions. In case of laminar regime, the pressure drop in the horizontal pipe was 86%-92% of the total for the top pipe, and 48%-54% for the bottom pipe.

4. Discussion

The pressure drop values given by the model matched the measured values with a reasonable accuracy. If pressure drops higher than 1 kPa were considered, the average absolute value of the relative differences between model and measurements was lower than 3% for both tested fluids. All relative differences were within ±7%, with the only exception of a single point which had a 10% deviation.

For pressure drops lower than 1 kPa, the relative differences were slightly higher. In general, the lower pressure drop measured, the higher deviation was found: the highest deviation (15%) was found for a pressure drop of 0.2 kPa. Nevertheless, as the absolute difference between model and measurement in this case was equal to 0.04 kPa, this was well within the accuracy of the differential pressure sensor (0.1 kPa). Beside the accuracy of the instruments, other sources of error might be the assumptions made by the model, such as linear interpolation between laminar and turbulent conditions in case of transitional regime and fully developed flow throughout the pipes.

As expected, given the same temperature and flow rate, the pressure drop for the glycol/water mixture was larger than that of water, due to the much higher viscosity.

Additionally, the pressure drop for both fluids was higher at lower temperatures, due to the increased viscosity. Nevertheless, this effect was much more relevant for the 50% glycol/water mixture than for water. This was due to two main factors. Firstly, the kinematic viscosity of water decreases by a factor of 2.7 when the temperatures increases from 20 °C to 80 °C, while that of a 50% glycol/water mixture decreases by a factor of 5 for the same temperature variation. Secondly and more importantly, the higher viscosity characterizing the glycol/water mixture caused the Reynolds number in the horizontal pipes to be lower than 2300, meaning laminar flow regime. Even at the highest tested flow rate of 2.5 m^3 h^{-1}, the glycol/water mixture at 25 °C was still characterized by a completely laminar regime (Re<1500), entailing much higher friction factors compared to those at the higher temperatures.

Despite its secondary importance, also the higher density contributed in increasing the pressure drop at lower temperatures, and again the effect was more important for the glycol/water mixture, as its density varies by 3.8% in the range 20 °C-75 °C, compared to 2.3% for water.

Concerning the flow distribution, the results given by the model showed a decrease in flow rate from the top to the bottom pipes. This was the obvious consequence of the fact that only friction was considered as driving force for the flow distribution, so that the longer the hydraulic path, the higher the resistance.

A large difference appeared to exist when comparing flow distributions obtained for different flow regimes. Because of the weak dependence of the friction factor on the Reynolds number in the turbulent regime, the friction factor can been considered approximately constant in all horizontal pipes. Due to the geometry of the collector, the flow regime in most part of the manifold was turbulent, when it was turbulent in the horizontal pipes. This entailed that the pressure losses both in manifold segments and tees were relatively small compared to that occurring across the horizontal pipes, and it could be compensated by a slight unbalance in the collector flow distribution. As the pressure drop coefficients for tees in laminar regime are much higher than in turbulent regime and the laminar friction factor behaves similarly, the flow rate in the last tubes needed to diminish abruptly in order to cause the same pressure drop as the previous hydraulic paths.

When using water at 20 °C, the higher viscosity caused the flow regime inside the horizontal pipes to change from completely laminar to completely turbulent, depending on the flow rate (Figure 5). At 0.5 m^3 h^{-1}, the flow regime in all the horizontal pipes was laminar, while that in the manifold was initially turbulent and then, as more fluid was diverted to the horizontal pipes, laminar. The precise tee junction after which the change in flow regime occurred can be identified looking at the change in slope in the curves in Figure 5: a milder slope corresponds to turbulent flow in the manifold, while a steeper slope to laminar flow. The main reason for this behavior was that the local loss coefficients for tees in laminar regime are more sensitive to flow conditions than in turbulent regime, so they varied more significantly from one pipe to the next. As the hydraulic resistance between two consecutive pipes differed more significantly, this needed to be compensated by a larger difference in flow rates. A secondary reason is the linear dependence of the friction pressure drop on the flow rate in laminar conditions, which, compared to the quadratic dependence in turbulent conditions, required a larger variation in flow rate to compensate the varying pressure drop across the horizontal pipes.

Increasing the flow rate, the distribution became more uniform, as a longer part of the manifolds experienced turbulent conditions and the regime inside the horizontal pipes became transitional (V=1 m^3 h^{-1}) and then turbulent (V≥1.5 m^3 h^{-1}).

When using the presented model to evaluate the flow distribution in a solar collector, a user should keep in mind the assumptions and simplifications which were introduced, such as linear interpolation between laminar and turbulent friction factor for the transition region, fully developed flow along the horizontal pipes and manifold segments, and reliability of literature correlations when applied to the treated cases. The model was validated only in terms of overall pressure drop across the collector, and not in terms of flow distribution.

5. Conclusions

A model for estimating the pressure drop across a solar collector with U-type configuration in isothermal conditions was developed in Matlab. The model was validated against pressure drop measurements carried out on a HT-SA 35/10 collector in different conditions of flow rate, fluid type and temperature.

For pressure drops higher than 1 kPa, all relative differences between model and measurements were within ±7%, apart from one point. On average, the relative difference between model and measurements was within ±3%. For lower pressure drops the relative difference increased up to a maximum value of 15%, but always within the accuracy of the differential pressure sensor (0.1 kPa).

As expected, flow rate and viscosity were the main factors influencing the pressure drop, so different fluids having similar values for these two parameters gave almost identical pressure drops. This suggests a pressure drop curve for a glycol/water mixture at relatively high temperature can be evaluated using water at sufficiently low temperature, provided that in these conditions the two fluids have similar viscosity and density.

Regarding the flow distribution, it was found that this was mainly affected by the flow regime in the manifolds. Turbulent regime throughout the manifolds entailed a much more uniform flow distribution than laminar flow. This was mainly due to the strong dependence of the local losses for the tee junctions in laminar conditions, which caused relatively large difference in pressure drop even at small flow rate variation, as that occurring between two consecutive tees. If the presented model is used to evaluate the flow distribution in a solar collector, the introduced assumptions and simplifications must be taken carefully into account.

Abstract

This study examined the performance of a solar collector with a linear parabolic mirror mounted vertically on walls. In order to simplify the system, it does not have sun tracking function and focuses on hot water supply only during winter which dominates annual hot water demand. The objectives are to design optimal shape of the parabolic concentrator by simulations and to demonstrate the heat recovery by experiments. The inclined angle and the focal length of the paraboloid are the design parameters. Since the parabolic mirror does not truck the sun, there should be the optimal setting of the design parameters which maximize the thermal energy collection during winter season. The simulation results indicated that the inclined angle of 25 ° and the focal length of 95 mm would be optimal, based on which the proposed collector was made and tested outdoors. The experimental results showed that the temperature of the hot water actually gained 45.8 degC in February, 2015.

Keywords: *Solar Water Heater, Parabolic mirror, Solar concentration,*

1. Introduction

In energy use of residential sector in Japan, the share of hot water demand is about 30%. Therefore, solar water heaters are considered effective to save fuel consumption for hot water supply. While solar water heaters are set on the roof conventionally, vertically–installed type solar collectors are also available in the market recently, especially for apartment houses. They are placed on the fence of veranda. One drawback of vertical setting is that solar collecting performance is not high enough so that the temperature of hot water is relatively low. Therefore, this study proposes a vertical solar collector with a parabolic mirror to concentrate solar light to get higher temperature.

CPC (compound parabolic concentrator) is a well-known technique for solar collectors with concentration, which consists of two parabolic mirrors. Although CPC is capable to collect sun light within a certain range of incident angle without sun tracking, the structure is complicated. In contrast, the device proposed by this study simply consists of one parabolic mirror without sun tracking. The merits of the proposed device are the following. It can be mounted on building walls which are not used for solar collectors in Japan. The area of solar absorber is much smaller than flat type collectors, which leads to cost reduction because the absorbers are expensive component due to anti-reflective coating.

There are two design parameters for the parabolic mirror, that is, inclined angle and focal length. Tamata(1) investigated the effect of the inclined angle on the performance of the parabolic mirror when the

doi:10.18086/swc.2015.10.02 Available at http://proceedings.ises.org

focal length of the parabolic mirror was assumed constant. In this study, the focal length is also considered in addition to the inclined angle. Since the parabolic mirror does not truck the sun, there should be the optimal setting of the design parameters which maximize the thermal energy collection.

The objectives of this study are to find optimal design of the parabolic concentrator by ray-tracing simulations and to demonstrate the heat recovery by experiments. It should be noted that the performance of heat recovery in winter season is discussed in the study because hot water demand is much larger in winter than that in summer in Japan.

2. Solar thermal collector with a parabolic mirror

Figure 1 shows the cross-sectional view of the thermal collector. The thermal collector is assumed to be installed on vertical walls. It consists of a linear parabolic mirror for concentration and an absorber at the bottom. The focus of the parabolic mirror is designed to be located on the top surface of the absorber. In this study, the collector is assumed to be 100 mm wide as shown in Fig.1. The angle noted as φ is the inclined angle of the parabolic shape. P represents the focal length, and H indicates the aperture width of the collector. The absorber is divided into five segments to investigate the position that sun light is reflected by the mirror.

Sun light coming to the parabolic mirror is reflected to the focus when the angle φ is equal to the sun elevation. In the other cases, the reflected sun light is distributed on the absorber. The local energy flux changes time to time due to the sun movement.

Figure 2 shows the shape of paraboloid corresponding to various combinations of φ and P. The larger φ and P become, the longer the paraboloidal shape expands. It indicates that the aperture width H strongly depends on φ and P. Because the amount of sun light captured by the absorber is determined by the aperture size of H. It is necessary to find the optimal combination of φ and P in order to maximize the heat recovery.

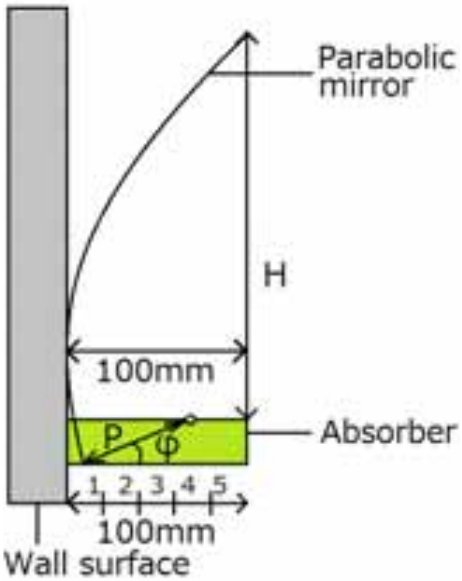

Fig.1 Cross-section of the proposed solar collector

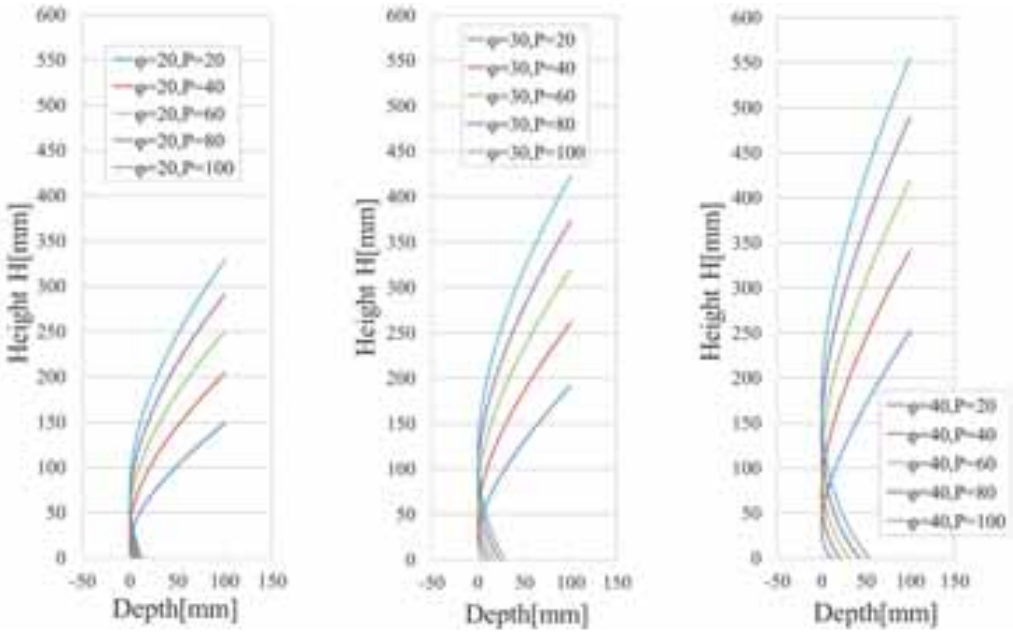

Fig2. Parabolic shape change by design parameter

3. Optimal design of the parabolic mirror

3.1 Simulation method and assumptions

This study investigates the influence of P change when φ is 15~40 degree. The ray tracing tool named Trace Pro was employed to calculate the sun light directly captured by the absorber and indirectly reflected by the mirror.

Simulation period is from November to February and location is Tokyo. Both Light reflectance rate of a parabolic mirror and heat absorption rate of the absorber are assumed 100 % to observe the maximal performance. The solar collecting device faces to the south and solar constant is 1067 W/m^2.

3.2 Thermal energy collection in winter season

Figure 3 shows the results for various combinations of P and φ. The graph indicates that there is a peak over P for a given φ. The reason why collected thermal energy increase is that H is extending as P is increasing. Larger H collects more sun light to the absorber. On the other hand, in the case where P becomes too large, thermal energy collection decreases because parabolic mirror cannot reflect sun light to the absorber enough when the sun elevation is low. Figure 4 shows example of the light collecting behavior when P is 30 mm or 90 mm and the sun elevation is 20 degree. Sun light is reflected to the absorber when P is 30 mm. In contrast, sun light is reflected out of the absorber when P is 90 mm.

Figure 3 also indicates that optimal P that obtains the peak of thermal energy collection becomes small when φ becomes large. The peaks of every φ settings seem to make a concave curve which has a peak at 95 mm of the focal length when φ is 25 degree. The peak is understood as the global maximum of the heat recovery by the proposed way.

According to this analysis, the optimal design is obtained with the parameters of φ=25 degree and P=95

mm. The aperture width H =321mm. The position of the focal length on the absorber is 86 mm from the wall surface. Therefore, sun light is reflected to the inside of the focal length on the absorber when the sun elevation is larger than 25 degree. Sun light is reflected to the outside of the focal length on the absorber or outside of the device when the sun elevation is lower than 25 degrees.

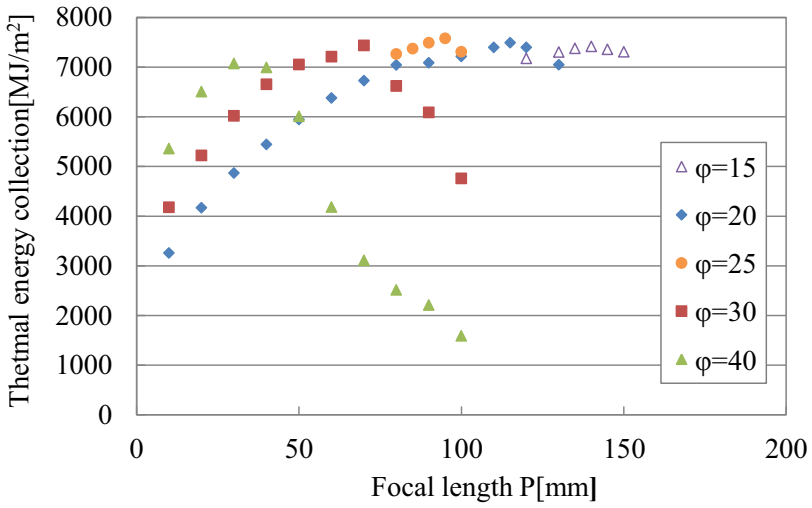

Fig.3 Thermal energy collection

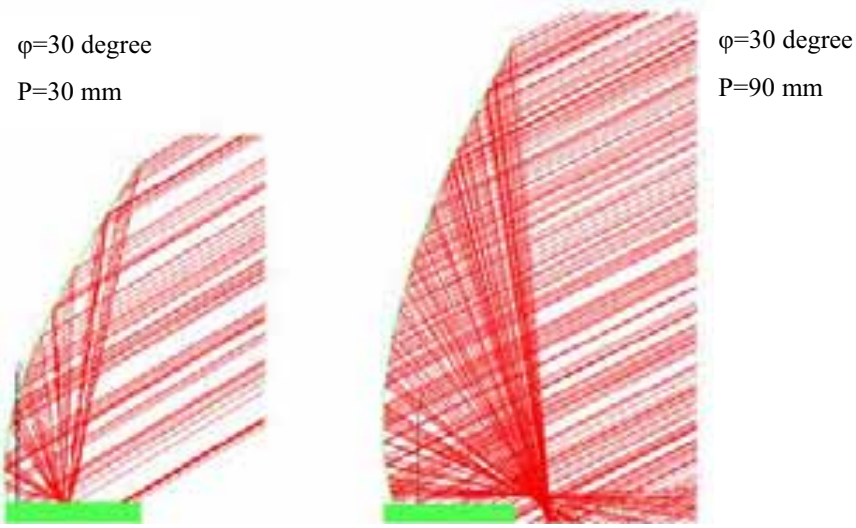

Fig.4 Light collecting behavior

(The φ is larger than the sun elevation)

4. Energy density distribution on the absorber

Figure 5 shows the energy recovery of the entire absorber in each month in the optimal design case with φ=25 degree and P=95 mm. The monthly performance is almost same approximately. It should be noted that the distribution of sun light changes because the reflection by the parabolic mirror depends on the sun elevation. The local heat recovery performance is evaluated in this section in order to understand the profile of the solar concentration on the absorber. The absorber is divided into five segments as shown Figure 1 to

investigate which part collects solar energy well. In this optimal design case, the focus is located in the part 5 of the absorber. Figure 6 shows the light collecting behavior when the sun elevation is 20, 25, 30, and 40 degree. It can be seen from the Figure that sun light is reflected to the part 5 or outside of the absorber when the sun elevation is lower than 25 degree while sun light is reflected to the part 4 and 5 when the sun elevation is higher than 25 degree. As the sun elevation becomes larger, the reflected rays shift inward on the absorber so that the part 1, 2, and 3 get heated when the sun elevation is considerably higher than 25 degree. Figure 7 indicates local heat recovery by the segments. The highest performance is observed at the part 5 in December. It is because the maximum sun elevation is 31 degree in December. The contribution of the part 5 is significantly large compared with that of the other parts. In November and January, the performance of the part 4 and 5 dominates the heat recovery. In contrast, the part 3 takes the maximum position in February where the performance of the part 5 is much reduced. In sum, the part 4 and 5 are recognized as important parts to recover solar thermal energy while the part 3 works well in February. It is also suggested that the contribution of the part 1 is insignificant.

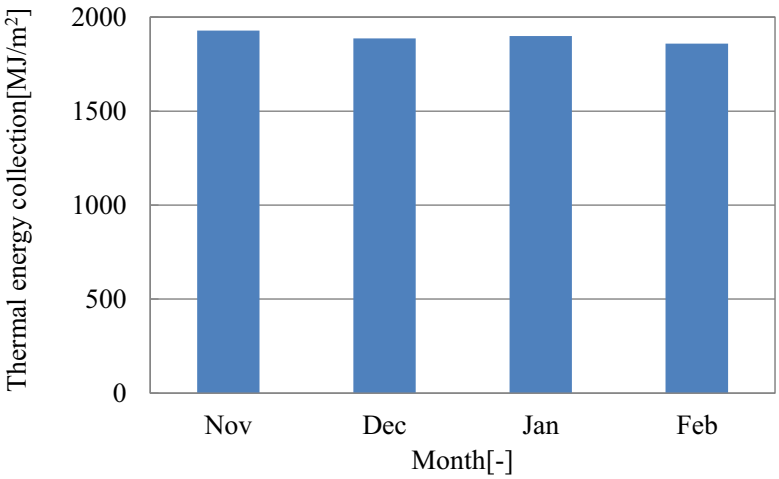

Fig.5 Thermal energy collection in each month

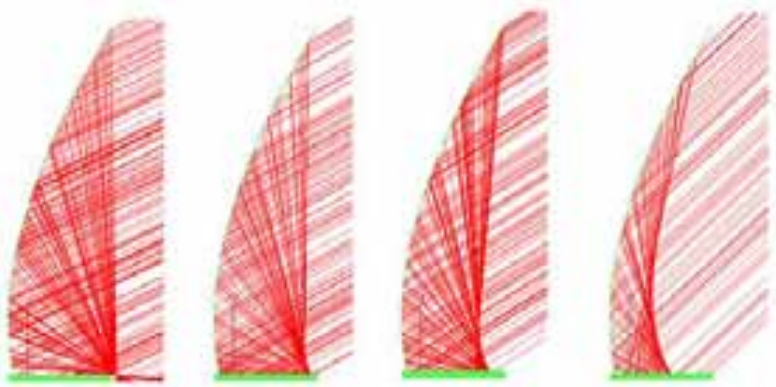

Fig.6 Light collecting behavior (φ=25°, P=95mm)

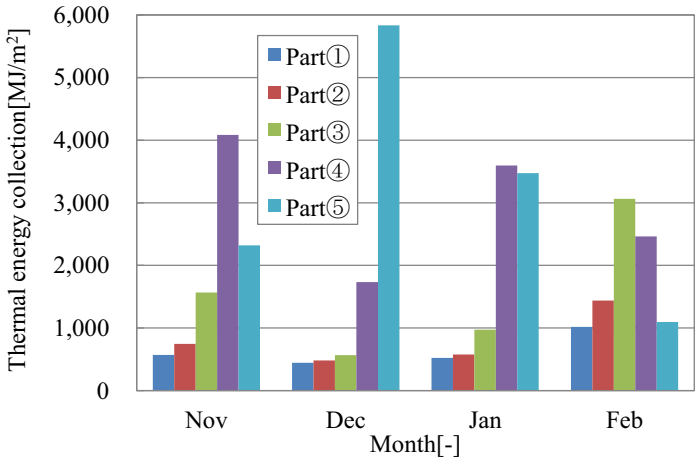

Fig.7 Thermal energy collection of each part

5. Monthly performance compared with conventional solar collectors

To demonstrate the usefulness of the proposed device, comparison of monthly performance was conducted among three collectors. One is the device proposed in this study, another is a flat plate collector of vertical type, and the other is a conventional flat plate collector inclined at 30 degree. The index is the average energy density on the absorber because higher temperature is beneficial for domestic hot water production. Figure 8 shows the results of monthly thermal energy density of above 3 collectors. It is seen that the proposed device and the vertical type flat collector have similar profile throughout a year while the conventional flat type collector holds almost stable energy density in any month. The proposed device collects solar energy significantly higher than the others, more than twice from October until March in terms of the density. On the other hand, the performance of the proposed device is less than the conventional collector from May until July. Heating load for hot water increases in winter, but reduces in summer. Because the pattern is in accordance with the profile of energy density of the proposed device, the proposed device is advantageous to produce hot water required in each month.

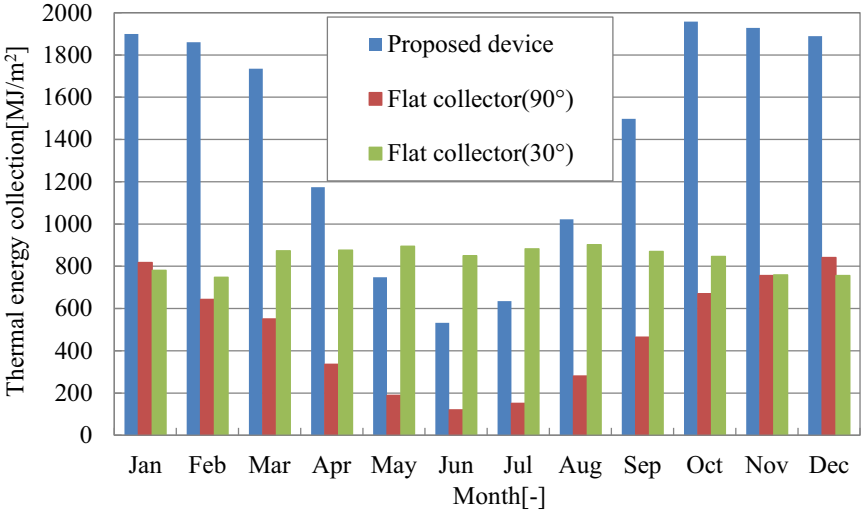

Fig.8 Monthly thermal energy collection

6. Heat collection experiments

6.1 Experimental setup and conditions

The experimental device was made based on the optimal design, which photo is shown in Figure 9. Five copper pipes with chrome plating were used as the absorber. The pipes were not thermally insulated just for preliminary experiments. The water in the tank was circulates through the device by a pump. Figure 10 illustrates the water flow in the absorber. In addition, Figure 10 shows temperature measurement points and corresponding thermocouple number. Thermocouple numbers from 1 to 6 were for water temperature measurement and numbers from 7 to 11 were for surface temperature measurement of the copper pipes.

The device was set up to face south at Tokyo University of Agriculture and Technology Koganei Campus in Tokyo. Measurement days were 29th January and 2nd February. Measurement time was from 9:00 to 16:00 in order to avoid the shade. The maximum temperature was 8.0 degC and the minimum temperature was 3.9 degC during the experiment on 29th January. On the other hand, the maximum temperature was 9.4 degC and the minimum temperature was 5.4 degC during the experiment on 2nd February. Thermocouples ware calibrated to have the accuracy of water temperature measurement to be ± 0.5 degC and the accuracy of surface temperature measurement of copper pipes to be ± 1.0 degC. Measurement interval of temperature was 10 s. The amount of water was 2 litters and the flow rate was controlled to be 0.2 l/s.

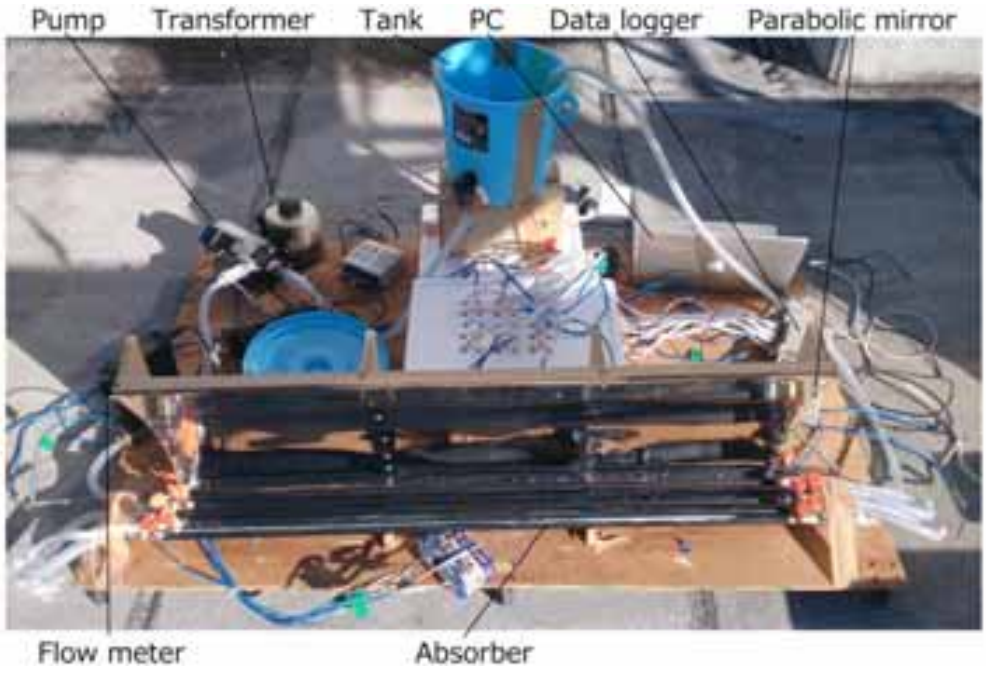

Fig.9 Experimental setup

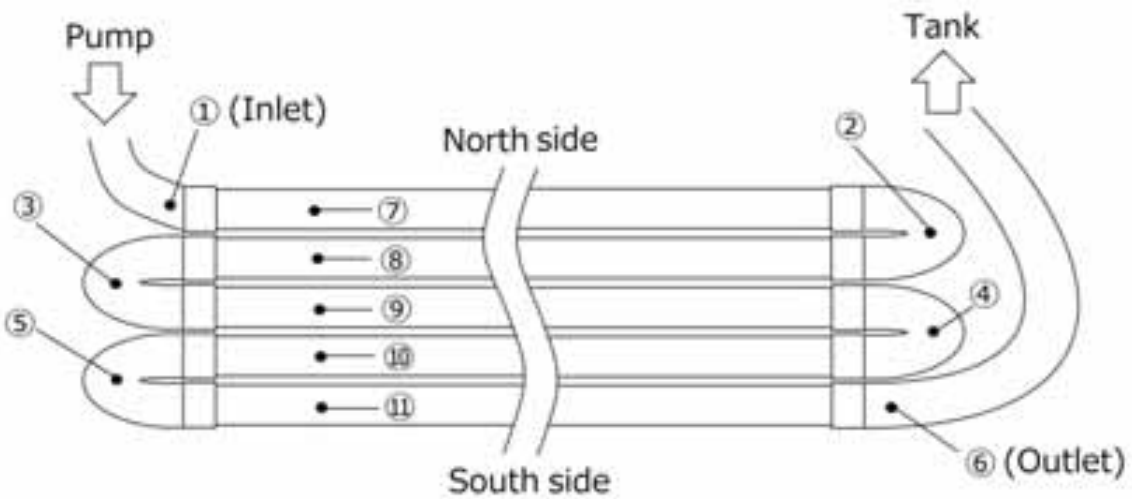

Fig.10 Schematic of the absorber

6.2 Water temperature behavior with / without parabolic mirror

Figure 11 shows the measurement results of the water temperature behavior with the parabolic mirror on 2nd February, which also shows the direct irradiance. The measurements of thermocouples from 2 to 4 were similar to that of number 1 and the measurement number 5 was similar to that of number 6. Therefore, the results of number 2, 3, 4, and 5 were not shown in Figure 11. As the graph shows the water temperature continued to rise over time, and rose up to 45.9 degC at around 12:00. Temperature difference of 5 degC was obtained from the inlet (Thermocouple number 1) to the outlet (Thermocouple number 6). Direct irradiance was 0 kW/m^2 after 15:30 due to the shade of other building. Therefore, the temperature of number 6 is lower than number 1 due to heat dissipation because the pipes have no insulation.

Figure 12 shows the results of the water temperature behavior without the parabolic mirror on 29th January. Although the water temperature rose to 30.9 degC at around 13:00, temperature difference between inlet and outlet of the absorber was very small. The water temperature was falling because the weather became cloudy after 13:30.

The experimental results with / without mirror clearly reveal that the concentration by the parabolic mirror is certainly effective to boost the temperature of hot water. It should be noted that the temperature could be higher than the experiment if the absorber is well insulated.

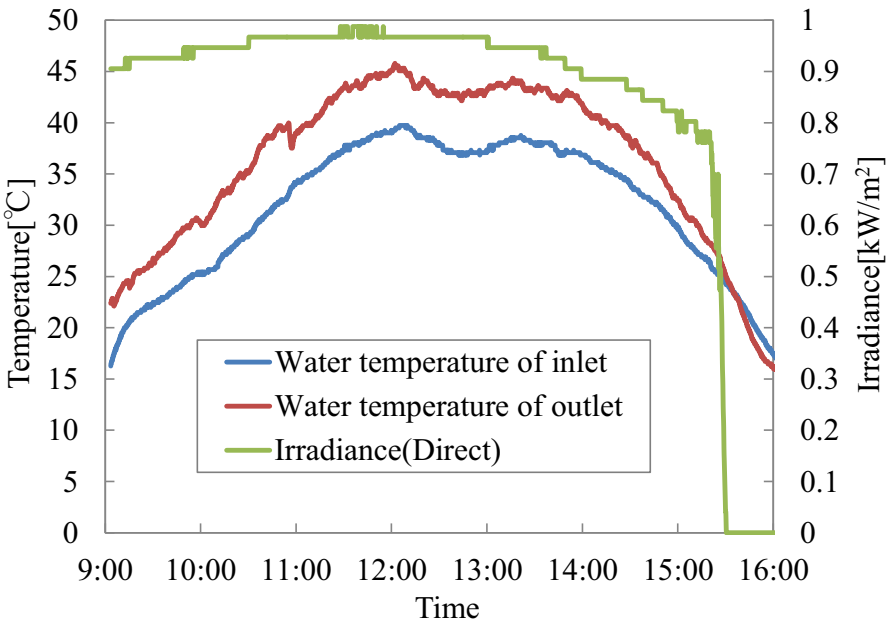

Fig.11 Behaviors of water temperature and irradiance

(With concentration)

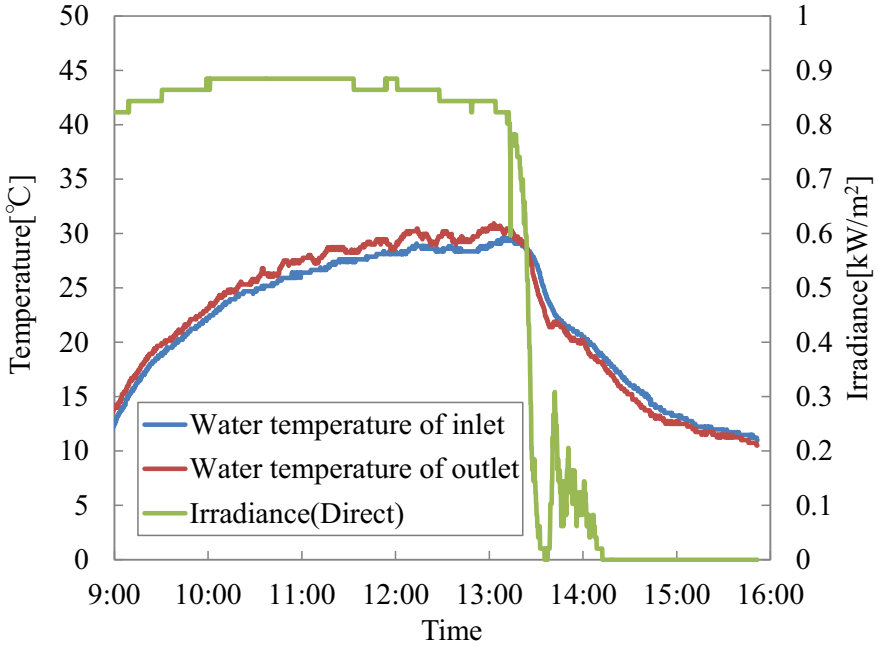

Fig.12 Behaviors of water temperature and irradiance

(Without concentration)

7. Conclusion

This study proposed a solar collector with concentration by a parabolic mirror which is assumed to be mounted on vertical walls. To be simplified, the mirror shape is just a parabola and no sun tracking is equipped. The optimal design of the parabolic mirror was derived from sensitivity analysis to maximize solar heat recovery in winter, which is achieved with the parameter settings of φ=25 degree and P=95 mm.

The simulation results suggest that the attained energy density by the proposed debice is more than twice as much as that of conventional inclined flat plate collectors in winter. It will be advantageous to get high temperature hot water.

The performance of the proposed device was also examined by experiments in winter. Even though they were considered preliminary, the concentration by the parabolic mirror was confirmed effective to produce higher temperature than that without mirror by 15 degC.

Abstract

In this work the numerical simulation and experimental validation of a Compound Parabolic Concentrator (CPC) are presented. The numerical model solve the governing equations of continuity, momentum and energy inside the CPC receiver tube, together with the energy equation in the receiver tube wall and the thermal analysis in the solar concentrator. The model can predict the increment of temperature between the inlet and outlet section of the CPC, the thermal efficiency and the pressure drop through the CPC together with the flow variables (mass flow rate, temperature and pressure) in each control volume in which the CPC is divided.

A prototype of a CPC has been designed and built using a cylindrical receiver with a real concentration rate of 1.8, acceptance angle of 30°, and aperture area of 0.17 m^2.

The protocol ANSI-ASHRAE 93-1986 standard was used with appropriate instrumentation for measuring the different variables in the CPC. For this prototype experimental tests were performed using water as working fluid for a wide range of inlet water temperatures and mass flow rates.

Statistical analysis was carried out in order to compare variations between the experimental results and numerical results. According to the results, the numerical model provides good tendencies for the design and optimization of CPCs.

key-words*: solar energy, CPC, numerical model, characterization curves, statistical analysis*.

$[X]_{j-1}^{j}$	Difference between the variable X at the outlet section and the inlet section.

1. Introduction

The alternative to reduce dependence on fossil fuels and the amount of CO2 emitted into the atmosphere is the use of renewable energies. Water is generally heated by commercial fuels (LP gas, natural gas, electricity) in urban areas to be used for space heating, domestic or industrial processes. The majority of commercial fuels are directly or indirectly produced by fossil fuels which have limited reserves and contribute greatly to the global warming. The integration of renewable energy systems will utilize clean and sustainable energy to reduce the dependence of fossil fuels and provide long term energy savings.

Solar energy collectors transform solar radiation into heat and then transfer this heat to a fluid. The compound parabolic concentrator (CPC) is a versatile solar collector due to the amount of applications and geometries that can be used. The CPC is a good choice for applications in direct evaporation or water heating near its boiling point, because these stationary collectors have a good quality rate between cost and performance at medium temperature levels [1]. The CPC could be used in a great variety of solar applications for low and medium temperature ranges; the most important is the heat production for industrial processes, such as sterilization, pasteurization, drying, distillation, adsorption and absorption cooling, etc.

CPCs consist basically of three elements: receiver, cover and reflector. In order to achieve good CPC performance, a numerical model is a useful tool in order to design it. In this work a numerical model of the CPC was carried out; then a CPC was designed and built selecting carefully the geometry and material of each component. Appropiate instrumentation was selected and used in order to compare the experimental data of the CPC under different working conditions with the model results in order to validate it.

2. CPC Design

The design of the reflector portion of a CPC tubular receiver (Figure 1) is determined by the diameter of the receiver and the desired concentration factor. The reflector geometry is given in two separate parts:

An involute section $|\theta| < \theta_c + \pi/2$ and a segment of a parabola $|\theta| > \theta_c + \pi/2$

$\gamma(\theta) = r\theta \quad \text{for} \quad |\theta| \leq \theta_c + \frac{\pi}{2}$ (Involute)

$\gamma(\theta) = \left[r \frac{\theta + \theta_c + \frac{\pi}{2} - \cos(\theta - \theta_c)}{1 + \sin(\theta - \theta_c)} \right] \quad \text{for} \quad \theta_c + \frac{\pi}{2} \leq |\theta| \leq \frac{3\pi}{2} - \theta_c$

The curve is generated by increasing θ in radians, calculating the length γ and the X,Y coordinates.

$$x = r \sin\theta - \gamma \cos\theta$$
$$y = -r \cos\theta - \gamma \sin\theta$$

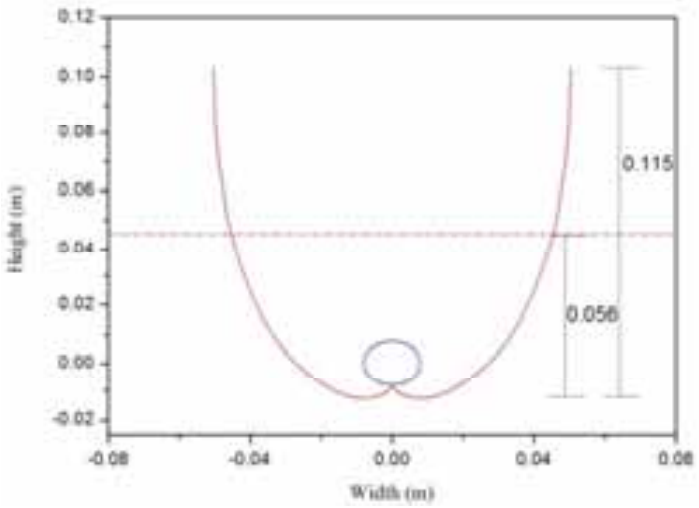

Figure 1. A CPC tubular receiver design.

In practical applications the upper part of the reflector are less efficient to reflect solar rays to the receiver. For this reason, it is truncated and the cost of reflective material is reduced. Table 1 shows the percentage of material saved when truncation is applied.

Table 1. Truncated and non-truncated final designs.

	Non-truncated (m)	Height truncated (m)	% Reduction
Height	0.115	0.056	51
Aperture	0.100	0.090	10
Reflector perimeter	0.281	0.163	42.1

3. Numerical model

The CPC was designed using a one-dimensional numerical model that solves the governing equations of continuity, momentum and energy. The fluid flow inside the receiver tube, the heat conduction in the receiver tube wall, and the heat transfer in the solar concentrator were solved in a segregated manner. For

more detailed of the numerical model see N. Ortega, et. al. [2] .

Figure 2 shows a control volume in CPC and the energy balances in each component (receiver tube, cover and reflector, Fig 2a) together with a control volume for the fluid flow (Fig 2b)

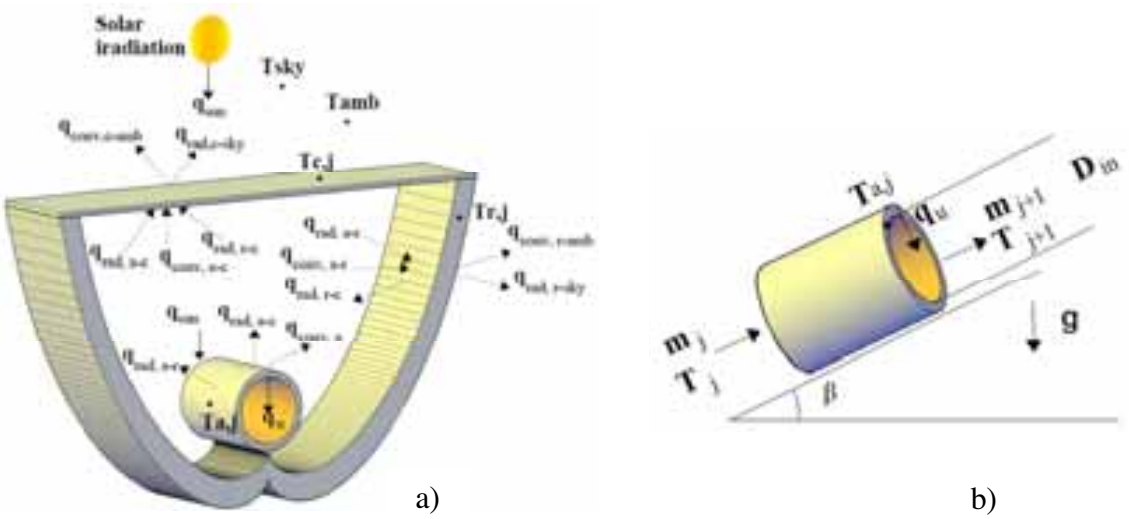

Figure 2. A CPC control volume. a) energy balance in each component; b) the fluid flow control volume.

For the fluid flow inside the receiver tube (see Fig 2b), the following governing equations have been integrated using a control volume analysis and a step by step method in the flow direction.

Continuity:

$$[\dot{m}]_{j-1}^{j} + \frac{\partial m}{\partial t} = 0 \tag{1}$$

The mass flow rate is obtained from the discretized continuity equation: $\dot{m}_j = \dot{m}_{j-1} - \frac{A_t \Delta x}{\Delta t}\left(\bar{\rho}_{tp} - \bar{\rho}_{tp}^{o}\right)$ (2)

Momentum:

$$\left[\dot{m}_g V_g + \dot{m}_l V_l\right]_{j-1}^{j} + \Delta x \frac{\partial \tilde{m}}{\partial t} = -[P]_{j-1}^{j} A_t - \tilde{\tau}_w p_{Ar.j} \Delta x - mgsin\beta \tag{3}$$

The discretized momentum equation is solved for the outlet pressure:

$$P_j = P_{j-1} - \frac{\Delta x}{A_t}\left\{\pi D_{in} \Phi \frac{\bar{f}}{4} \frac{\bar{m}^2}{2\rho_{tp} A_t^2} + \left[\frac{\dot{m}}{\Delta x}\left(x_g \vec{V}_g + \left(1 + x_g\right)\vec{V}_l\right)\right]_{j-1}^{j} + \frac{\bar{m} - \bar{m}^o}{\Delta t} + \rho_{tp} A_t g sin\beta\right\} \tag{4}$$

Energy:

$$\left[m_l e_l + m_g e_g\right]_{j-1}^{j} + \frac{\partial(\bar{m}_l \bar{e}_l + \bar{m}_g \bar{e}_g)}{\partial t} - A_t \Delta x \frac{\partial \tilde{P}}{\partial t} = \tilde{q}_u p \Delta x \tag{5}$$

From the energy equation and the continuity equation, the following is obtained for the outlet enthalpy:

$$\mathrm{h}_j = \frac{\left(2\pi D_{in} \Delta x\right) q_u - a\dot{m}_j + b\dot{m}_{j-1} + cA_t \Delta x / \Delta t}{\dot{m}_j + \dot{m}_{j-1} + \bar{\rho}_{tp}^{o} A_t \Delta x / \Delta t} \tag{6}$$

Where:

$$q_u = \mathrm{h_f}\left(T_{a,j} - (\bar{T}_j + \bar{T}_{j+1})/2\right) \tag{7}$$

$$a = \left[x_g \vec{V}_g + \left(1 - x_g\right)\vec{V}_l\right]_j^2 + gsin\beta\Delta x - h_{j-1} \tag{8}$$

$$b = \left[x_g \vec{V}_g + \left(1 - x_g\right)\vec{V}_l\right]_j^2 + gsin\beta\Delta x + h_{j-1} \tag{9}$$

$$c = 2\left(\overline{P}_{j-1} - \overline{P}^{o}_{j-1}\right) - \overline{\rho}^{o}_{tp}\left(\mathrm{h}_{j-1} - 2\overline{\mathrm{h}}^{o}_{j-1}\right) - \left(\overline{\rho}\overline{V}^{2}_{j-1} - \overline{\rho}^{o}\overline{V}^{o\,2}_{j-1}\right) \tag{10}$$

The discretized equations are coupled using a fully implicit step by step method in the flow direction. From the known values at the inlet section and the wall boundary conditions, the variable values at the outlet of each CV are iteratively obtained from the discretized governing equations. Outlet values are the inlet values for the next CV. The procedure is carried out until the end of the receiver tube is reached.

The heat conduction in the receiver tube wall has been written assuming one-dimensional transient temperature distribution. A characteristics CV is shown in Figure 3, where P represents the central node, E and W indicate its neighbors. The CV faces are indicated by e, w, n, and s. Integrating the energy equation over this CV, the following equation was obtained.

$$\left((\tilde{\mathrm{q}}_{\mathrm{sun}} - \tilde{q}_{rad,a-c} - \tilde{q}_{rad,a-r} - \tilde{q}_{conv,a})\mathrm{P_n} - \tilde{\mathrm{q}}_{\mathrm{u}}\mathrm{P_s}\right)\Delta\mathrm{x} + (\tilde{\mathrm{q}}_{\mathrm{w}} - \tilde{\mathrm{q}}_{\mathrm{e}})\mathrm{A}_t = \mathrm{m}\frac{\partial\tilde{\mathrm{h}}}{\partial\mathrm{t}} \tag{11}$$

here $\tilde{\mathrm{q}}_{\mathrm{u}}$ was evaluated using the convective heat transfer coefficient and temperature in the fluid flow and receiver wall temperature in each CV, and the conductive heat fluxes are evaluated from the Fourier law: $\tilde{\mathrm{q}}_{\mathrm{e}} = \mathrm{k}_{\mathrm{e}}(\partial\mathrm{T}/\,\partial\mathrm{x})_{\mathrm{e}}$ and $\tilde{\mathrm{q}}_{\mathrm{w}} = \mathrm{k}_{\mathrm{w}}(\partial\mathrm{T}/\,\partial\mathrm{x})_{\mathrm{w}}$

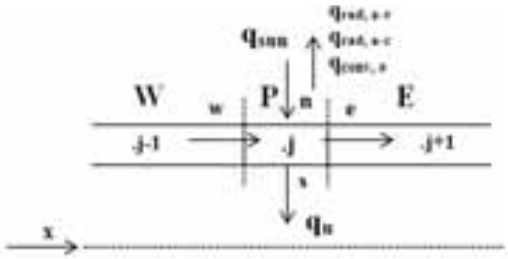

Figure 3. CV for the receiver tube wall.

The useful energy gain (q_u) is equal to the cover incident solar energy reduced by optical losses in the concentrator, the thermal losses in the cover, the reflector, and the receiver tube.

In order to calculate the receiver tube, cover and reflector temperatures in each CV; it is necessary to solve iteratively the following equations of energy balance of each component:

Receiver: $q_{sun,a} - q_{rad,a-c} - q_{rad,a-r} - q_{conv,a-c} - q_{conv,a-r} - q_u = 0$ (12)

Cover: $q_{abs,c} + q_{rad,a-c} + q_{conv,a-c} + q_{rad,r-c} - q_{conv,c-env} - q_{rad,c-sky} = 0$ (13)

Reflector: $q_{abs,r} + q_{rad,a-r} + q_{conv,a-r} - q_{rad,r-c} - q_{conv,r-env} - q_{rad,r-sky} = 0$ (14)

With equation (12, 13 and 14), the following equations are obtained:

$$T_r = \frac{(h_{rad,a-r}+h_{conv,a-r})T_a + h_{conv,r-amb}T_{amb} + h_{rad,r-sky}T_{sky} + (h_{conv,r-c}-h_{ra,r-c})T_c}{h_{rad,a-r}+h_{conv,a-r}+h_{conv,r-amb}+h_{rad,r-sky}+h_{conv,r-c}-h_{ra,r-c}} \tag{15}$$

$$T_c = \frac{(h_{rad,a-c}+h_{conv,a-c})T_a + h_{rad,c-sky}T_{sky} + h_{conv,c-amb}T_{amb} + (h_{conv,r-c}-h_{ra,r-c})T_r}{h_{rad,a-c}+h_{conv,a-r}+h_{rad,c-sky}+h_{conv,c-amb}+h_{conv,r-c}-h_{ra,r-c}} \tag{16}$$

$$T_a = \frac{(h_{rad,a-c}+h_{conv,a-c})T_c + (h_{conv,a-r}+h_{ra,a-r})T_r + q_{sun,a} - q_u}{h_{rad,a-c}+h_{conv,a-c}+h_{conv,a-r}} \tag{17}$$

The convective heat transfer coefficient between the receiver tube and the reflector and between the receiver tube and cover were expressed by [3]:

$$h_{conv,a-r} = 3.25 + 0.0085\frac{(Ta-Tr)}{2D_{out}} \quad (18)$$

$$h_{conv,a-c} = 3.25 + 0.0085\frac{(Ta-Tc)}{2D_{out}} \quad (19)$$

$$h_{rad,r-c} = \frac{\sigma(T_c^2+T_r^2)(T_c+T_r)}{(1-\varepsilon_c)/\varepsilon_c+((1-\varepsilon_r)/\varepsilon_r)(A_c/A_r)}\frac{A_r}{A_a} \quad (20)$$

$$h_{rad,c-sky} = \varepsilon_c\sigma(T_c^2 + T_{sky}^2)(T_c + T_{sky})\frac{A_c}{A_a} \quad (21)$$

$$h_{rad,r-sky} = \varepsilon_r\sigma(T_r^2 + T_{sky}^2)(T_r + T_{sky})\frac{A_r}{A_a} \quad (22)$$

$$h_{rad,a-c} = \frac{\sigma(T_a^2+T_c^2)(T_a+T_c)}{(1/\varepsilon_c)+(A_c/A_a)((1/\varepsilon_a)-1)} \quad (23)$$

$$h_{rad,a-r} = \frac{\sigma(T_a^2+T_r^2)(T_a+T_r)}{(1-\varepsilon_r)/\varepsilon_r+((1-\varepsilon_a)/\varepsilon_a)(A_r/A_a)} \quad (24)$$

The convective heat transfer coefficients between the cover and the ambient and between the reflector and the ambient are expressed by Duffie and Beckman [4]:

$$h_{conv,c-amb} = (5.7 + 3.8v)\frac{A_c}{A_a} \quad (25)$$

$$h_{conv,r-amb} = (5.7 + 3.8v)\frac{A_r}{A_a} \quad (26)$$

The numerical model can predict the increment of temperature between the inlet and outlet of the collector, the efficiency, the energy gain by the transport fluid and the pressure drop of the CPC together with the flow variables (mass flow rate, temperature and pressure) in each control volume in which the CPC is divided. The numerical model can be used with fluid mixtures and with or without phase change in the fluid flow.

4. Experimental setup

Figure 4 shows the CPC designed and built. The real concentration is 1.8, acceptance angle is 30° and aperture area of 0.17 m^2. Table 2 shows the characteristics of geometry and materials used in the construction of this CPC.

Figure 4: CPC designed and built.

Table 2: Geometrical characteristics and materials used for the CPC

Parameter	Characteristics
Cover	
Low-iron tempered glass	transmittance=0.91
Thickness (mm)	4
Reflector	
Anodized aluminum	reflectance=0.90
Thickness (mm)	0.35
Receiver	
Copper	½" nominal diameter
Internal/ external Diameter (mm)	14.5/15.9
Selective surface	absorptance=0.90
CPC	
Acceptance angle (°)	30
Maximum concentration	2.00
Real concentration ratio	1.80
Width (m)	0.090
Height (m)	0.057
Length (m)	1.95

An experimental setup was constructed (Figure 5). Proper instrumentation to control and register the different variables of the system together with a program to save the experimental data was developed. The following variables are register every 3 second in experimental tests: temperatures, global solar irradiance at the collector plane and mass flow rate. The instrumentation used and their uncertainties for the evaluation of CPC are shown in Table 3.

Figure 5. Experimental unit.

Table 3: Instrumentation

	Instrument	Operating range	Uncertainties
Temperature meter	Thermistor	-40 a 150°C	±0.1°C
	K-type thermocouple	-20 a 750°C	±1.1°C
Mass flow meter	Coriolis	0 a 20 kg/min	±0.1%
Radiation meter	Pyranometer-class II	285 a 2800 nm	±1%

5. Experimental tests

The tests were carried out in the Solar Platform of the Instituto de Energías Renovables of the Universidad Nacional Autónoma de México, located at Temixco, Morelos, México, at 18°50.36' N and at 99°14.07' W, with an altitude of 1219 m above sea level. In Temixco, the yearly average ambient temperature and solar irradiance on the horizontal plane are 23.1 °C and 20.05 MJ/m^2 day, respectively.

The collector is mounted on the support structure and the collector angle is set according to the day of the year of the test. CPC mass flow rate and inlet temperature were maintained constant with the recirculation loop, pump, and electrical heaters installed in the storage tank for cold water. The water coming from the CPC was stored in the hot water storage tank. The water in the hot water storage tank was returned with the recirculation pump to the cold water storage tank to fix a new temperature and mass flow rate to repeat the process.

The experimental tests were performed using water as working fluid at solar noon. The mass flow rate, inlet and outlet temperature at the collector, the ambient temperature and the irradiance at the collector plane were registered every 3 seconds.

6. Results

Figure 6 shows the thermal efficiency against the temperature difference between fluid inlet temperature and ambient temperature in relation with the solar irradiance at the CPC plane. The experimental and numerical results with a mass flow rate of 0.7 kg/min and 1.0 kg/min are shown. The errors bars in figures represent the uncertainty obtained in the experimental measurement.

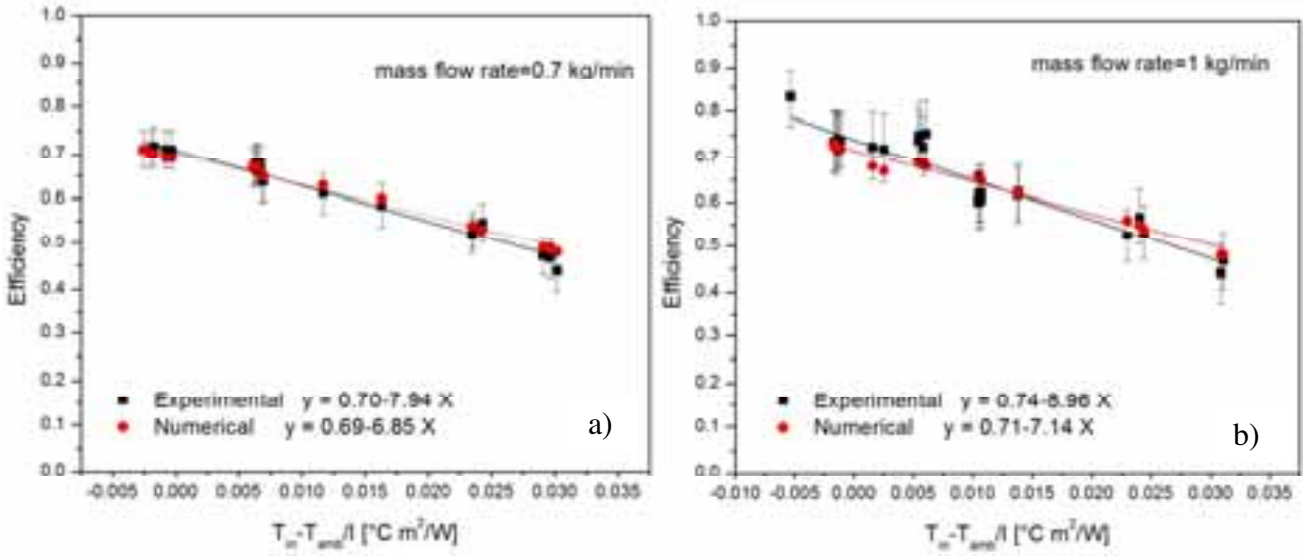

Figure 6. Numerical and experimental thermal efficiency results with a mass flow rate of: a) 0.7 kg/min and b) 1.0 kg/min.

The error and standard deviation between the experimental data and numerical results are shown in Table 4.

Table 4. Comparison between experimental and numerical results for the thermal efficiency.

Mass flow rate (kg/min)	Efficiency	
	Error (%)	Standard deviation (%)
0.7	±2.5	±1.9
1.0	±4.5	±3.2

Figure 7 shows the comparison of the increment of temperature through the CPC between the numerical results and experimental data for two different mass flow rate.

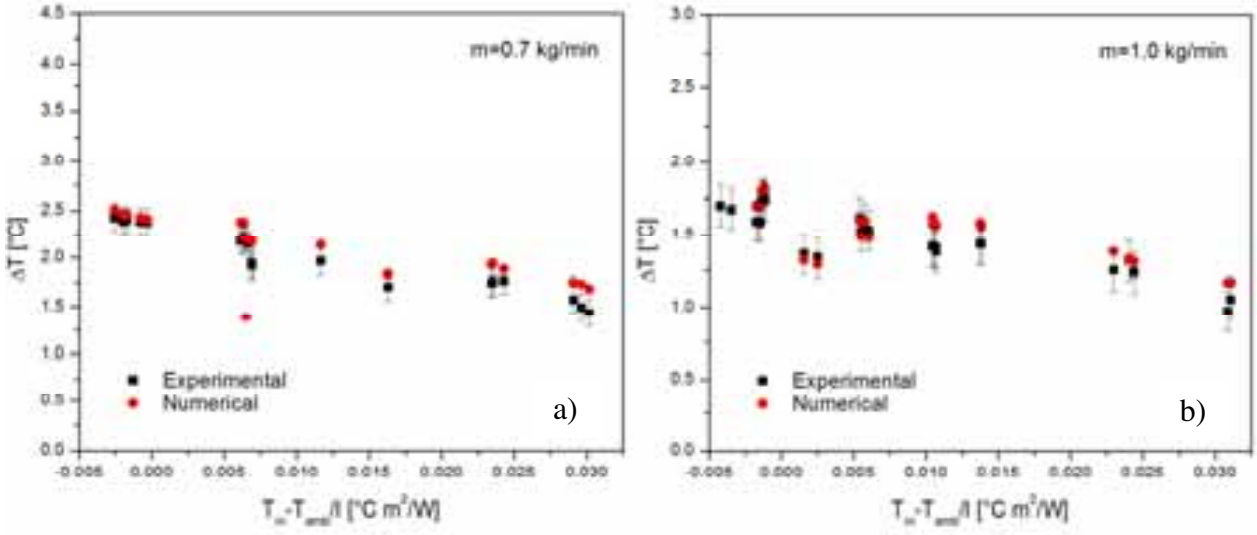

Figure 7. Comparison of the increment of temperature through the CPC between the experimental and numerical results for a mass flow rate of: a) 0.7 kg/min and b)1.0 kg/min.

The error and standard deviation between the experimental data and numerical results are shown in Table 5

Table 5. Comparison between experimental and numerical results for the increment of temperature.

Mass flow rate (kg/min)	ΔT	
	Absolute error (°C)	Standard deviation (°C)
0.7	±0.10	±0.06
1.0	±0.17	±0.17

7. CONCLUSIONS

The numerical model developed is based on the applications of governing equations and used empirical correlations. The numerical algorithm solves in a segregated manner the subroutines: heat conduction in the receiver tube wall, fluid flow inside the receiver tube and the useful energy gain in the solar concentrator.

A prototype of CPC with a real concentration of 1.8 and aperture area of 0.17 m^2 was designed and built. The experimental and numerical results were compared in order to validate the model.

Numerical model has proven to be reliable and was validated with experimental data of the CPC. The results have been satisfactory. The comparison between the experimental and numerical results shows that the numerical model provides good results and tendencies.

STUDY OF A THERMAL–PHOTOVOLTAIC SOLAR HYBRID SYSTEM

Haruhiko MIYANABE [1], and Keizo YOKOYAMA [1]

1 Kogakuin University, Japan

Abstract

The solar hybrid panel used in this research includes, besides a PV part, a heat acquisition part consisting of flat heat pipes and heat collection pipe on the back of the solar PV module. The system is capable of simultaneously converting solar energy into both electricity and heat. It has the potential to improve total solar energy conversion efficiency while reducing generation losses caused by rising temperature of the solar PV module. This study aims to achieve practical use of this solar hybrid panel. The report describes basic characteristic of the heat pipe used for the heat-collecting module. The energy balance of the system was simulated and compared against measurement data. Sensitivity analysis was also performed. As a result, the heat pipe was found to function normally when the angle of tilt is at least 10 degrees.

Keywords: *Photovoltaic, Solar thermal, Hybrid, Experiment, Simulation*

1. Introduction

Photovoltaics have become popular throughout the world. Their conversion efficiency is about 10–15%. The current efficiency is not very high. Utilization of solar heat, on the other hand, has a conversion efficiency of 40–50%. However applications of solar heat are limited. Therefore, various studies are being conducted to extend utilization technology (E. Yandri, 2011).

A thermal-solar hybrid system has characteristics of both photovoltaic power generation and solar heat collection. This report provides an overview of demonstration experiments on such a system, and the system's performance characteristics.

2. Composition of the thermal-solar hybrid panel

The solar hybrid panel used in this research includes, besides a PV part, a heat acquisition part consisting of flat heat pipes and heat collection pipe on the back of the solar PV module. The system is capable of simultaneously converting solar energy into both electricity and heat (see Fig. 1 and Fig. 2). It has the potential to improve total solar energy conversion efficiency while reducing generation losses caused by rising temperature of the solar PV module. Fig. 3 shows the installed condition and Fig. 4 shows a schematic diagram of the system.

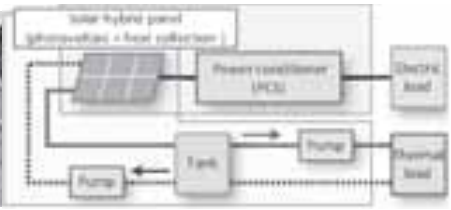

Fig. 4: Schematic of solar hybrid system

doi:10.18086/swc.2015.10.04 Available at http://proceedings.ises.org

3. Overview of research

Although the aim of this research is to achieve practical use to the solar hybrid panel, this report develops an understanding of the basic characteristics of the heat pipe used in the heat-collecting module. A simple simulation of the energy balance was conducted. Sensitivity analysis was also performed while varying a number of parameters.

4. Overview of micro flat heat pipe

Table 1 provides an overview of the heat-collecting module used in the solar hybrid panel. Fig. 3 shows a schematic diagram of heat transfer in the micro flat heat pipe.

The heat pipe has a capillary structure and has a working fluid sealed inside. The principle of heat transfer is as follows: When the heat pipe is heated, working fluid is vaporized, and it moves upward from the bottom of the heat pipe. At the top of the heat pipe, it is condensed by cooling, and when it becomes a liquid it returns again to the bottom of the pipe due to the capillary phenomenon. In this way, heat transfer is carried out continuously.

Table 1: Overview of heat pipe

Outer dimensions (height x width x thickness) [mm]	765×60×3
Material	Pure aluminum (extruded)
Working fluid	Acetone
Thermal conductivity [W/cm^2]	37.35
Isothermality	Less than 1 [K/m]
Max. heat flow density [W/cm^2]	100 to 200
Working temperature range [ºC]	-50 to 170
Internal withstand pressure [MPa]	5.07 or higher
External withstand pressure [MPa]	3.92

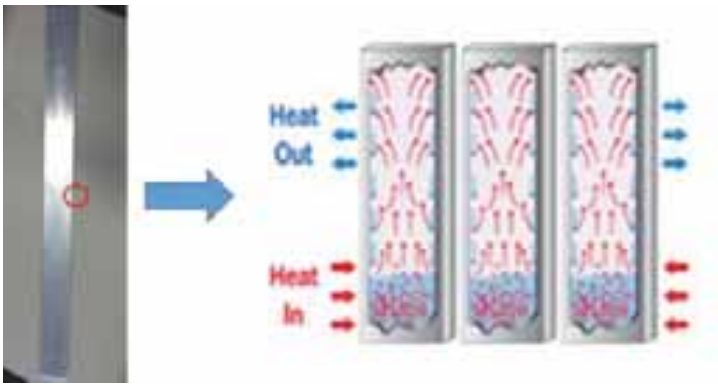

Fig. 5: Schematic diagram of heat transfer of heat pipe

5. Heat pipe characteristic test

Experiments were conducted to determine how heat transport conditions of the heat pipe changed due to angle of tilt, heat input, presence or lack of insulation on the back side, and differences in length.

5.1 Overview of experiment

The experiment used a mask-formed flat heating element to evenly heat the entire pipe. In a product, the added heat is collected by water at one end of the heat pipe, but in this experiment the heat is radiated to the outside via the air. Figure 3 is a schematic diagram of the solar hybrid panel, and the experimental equipment was built to simulate this, as shown in Fig. 4. Insulation (1 and 2) on the heating element side was used to reduce heat loss from the flat heating element.

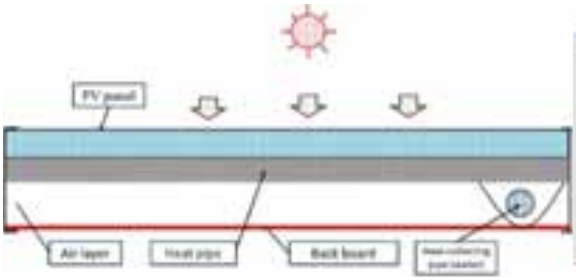

Fig. 6: Schematic diagram of solar hybrid panel

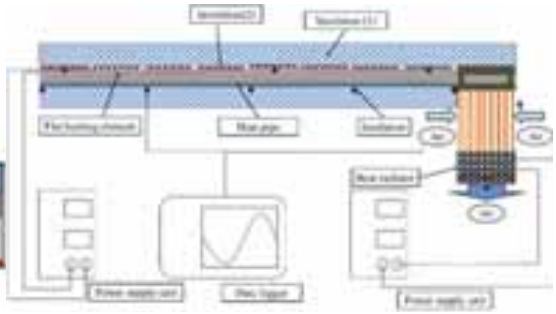

Fig. 7: Diagram of experiment

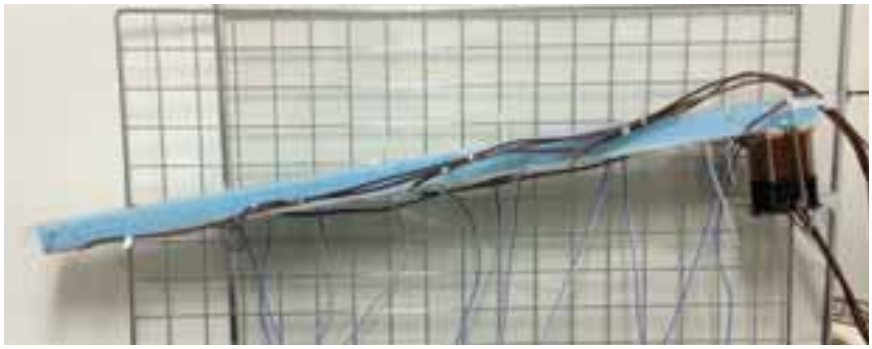

Fig. 8: Experiment equipment

5.2 Experiment cases

There were five experiment parameters: angle of tilt, heat input, presence or lack of insulation on the back side, heat radiation air flow, and differences in length. The experiment was carried out for 64 cases by combining the parameters from Table 2. Measurement points are indicated in Table 3 and Fig. 9.

Table 2: Experiment parameters

Parameter	Number of levels	Levels
Angle	6	0°,5°,10°,20°,45°,90°
Heat input*	5	217 W/m^2 (10 W) 435 W/m^2 (20 W) 651W/m^2 (30 W) 871 W/m^2 (40 W) 1085 W/m^2 (50 W) 1302W/m^2 (60 W)
Radiator air flow	3	Standard (0.033749 m^3/s) 50% 25%
Insulation	2	With insulation, without insulation
Heat pipe length	2	Type-M (60 mm × 765 mm), Type-L(60 mm × 955 mm)

*Corresponds to intensity of solar radiation passing through PV panel.

Table 3: Measurement points

Measurement points	Nounber oh points
Panel back side temperature	CH1, CH3, CH5, CH7, CH9
Flat heating element	CH15,CH17,CH19
Outside air temperature	CH11
Outlet temperature	CH19

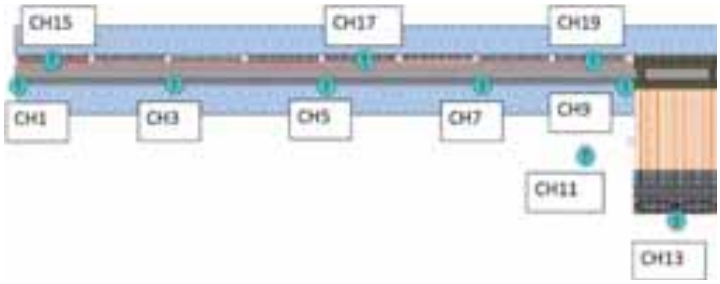

Fig. 9: Measurement points

5.3 Test results

(1) Angle of tilt and heat input (Fig. 10)

As the angle of tilt of the heat pipe increases, the average back side temperature decreases, and the heat pipe functions normally. With low heat input of 10 W or 20 W, the back side average temperature decreases by 5 degrees or more. When heat input is 30 W or higher, the back side average temperature decreases with an angle of inclination of 10 degrees or more and there is also equalization of the temperature distribution. Therefore, it can be said that heat transport of the heat pipe functions properly if the angle of inclination is10 degrees or more.

(2) Heat radiation air flow (Fig. 11)

When heat radiation decreases, average temperature of the heat pipe back side rises. This is because a larger amount of heat is radiated when the air flow of the radiator is high. If heat input is high, the difference in temperature due to the difference in heat radiation increases. In the case with heat radiation air flow of 50% and heat input of 60 W, the back side average temperature rose by approximately 3ºC. The heat radiation performance is not affected very much with low heat input of around 10 W.

(3) Effects of insulation (Fig. 12)

In the case with insulation, back side average temperature is about 1°C higher than with no insulation. This is because, when there is no insulation, heat is radiated from the surface of the uninsulated heat pipe.

(4) Comparison of heat pipe length (Fig. 13)

A comparison was performed based on differences in length. When heat radiation air flow is low, the temperature of a long heat pipe rises somewhat, but otherwise there is hardly any difference.

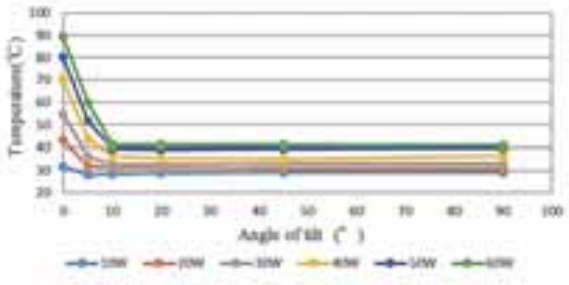

Fig. 10: Relationship of angle of tilt and heat input different

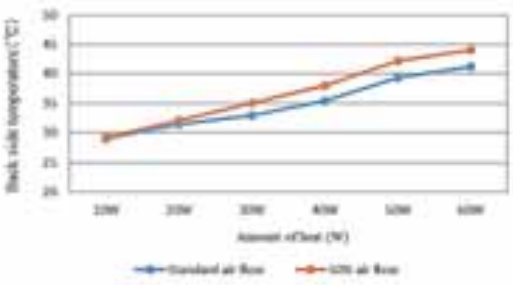

Fig. 11: Comparison of back side temperatures with radiation air flow rates

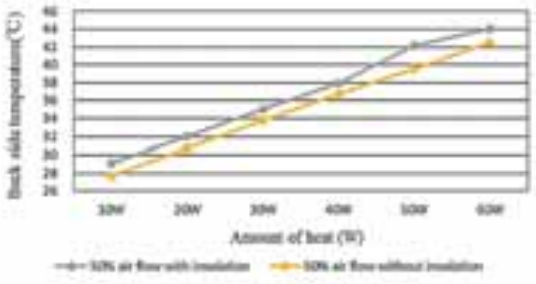

Fig. 12: Comparison of back side temperatures with difference in insulation

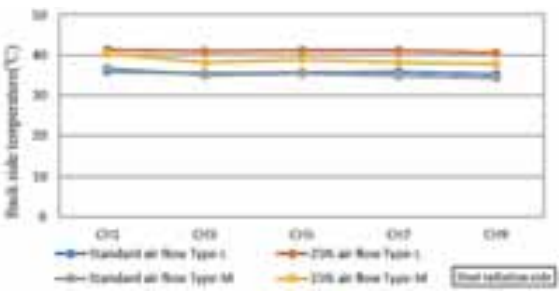

Fig. 13: Results of length comparison corresponding to 40W to 40W

6. Energy balance of the panel

A simulation model was created based on the schematic diagram (Fig. 14) of solar hybrid panel. The model was implemented in spreadsheet software using the heat balance equations given in Table 4. Table 6 shows the spreadsheet.

In the simulation, the heat-collecting pipe efficiency was defined by comprehensively taking into account factors such as the type of mounting of the heat-collection part and the water temperature. The PV panel was assumed to be integrated with glass (reflection and absorption only; thermal conductivity the same as glass), and surface reflectance was assumed to be 5%. The temperature difference at both sides of the heat pipe was assumed to be 1ºC. Thermal conductivity of the back side of the panel was assumed to be due to convection only and radiation was ignored because the surface is facing the rooftop. Thermal resistance of the acrylic panel on the back side was included in the thermal resistance of the air layer.

6.2 Energy balance sensitivity analysis

Variation in the amount of heat collected was analyzed while varying the wind speed and silicone grease conductivity in the heat balance spreadsheet for the solar hybrid panel (Table 6). Fig. 20 and 21 graph the amount of heat collected when the wind speed and silicone grease conductivity are varied. The following points are evident in the results.

(1) Sensitivity analysis of thermal conductivity of the silicone adhesive.

Heat conduction performance of the silicone adhesive was evaluated. Thermal conductivity of the currently used silicon adhesive is 0.8 W/mK. If the silicon adhesive is changed to one with higher or lower thermal conductivity, there is almost no change in the amount of heat collected at and above 0.2 W/mK. This calculation is carried out assuming that thickness of the silicon adhesive is 1 mm, and therefore in the actual equipment the thickness is will be less, and the effect is likely to be even smaller.

(2) Sensitivity analysis of the wind speed

The amount of heat collected was compared when wind speed is varied. With a high wind speed, the convection heat efficiency increases, and thus the amount of heat collected decreases. It is evident that the size of this decrease is about 2%/(m/s).

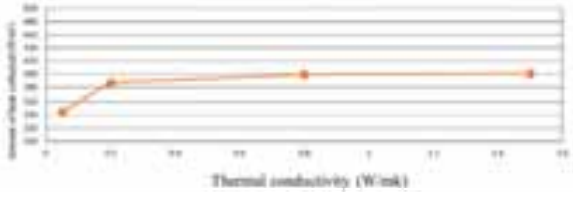

Fig. 20: Silicone adhesive conductivity sensitivity

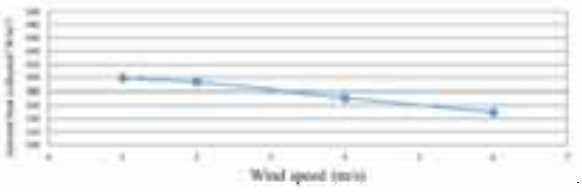

Fig. 21: Wind speed sensitivity

7. Conclusion

Basic experiments were carried out to develop an understanding of the characteristics of the heat pipe used in this solar hybrid panel. Also, a simulation model was created, and sensitivity was analyzed. The following findings were obtained as a result.

(1) Heat pipe properties

- Length of the heat pipe has little effect, and if the angle of tilt is at least 10 degrees, the system operates normally regardless of the intensity of solar radiation.

- If the heat radiation air flow rate is decreased, then temperature decreases when heat pipe temperature increases.

- When there is insulation, temperature of the heat pipe rises, and when there is no insulation, temperature of the heat pipe falls due to radiation of heat from the uninsulated surface.

(2) Energy balance simulation

- In sensitivity analysis of the energy balance, it was found that thermal conductivity of silicone adhesive does not have an effect on the amount of heat collected.

- In sensitivity analysis of wind speed, it was found that the amount of heat collected decreases as wind speed increases.

In the future, we plan to further evaluate performance of the solar hybrid system by measuring the amount of heat collected and the amount of power generated in the actual system.

Abstract

Aiming to get a precise understanding of wind pressure distribution on trough concentrator surface, wind tunnel experiments on trough concentrator model were carried out in HD-3 atmospheric boundary layer wind tunnel at Hunan University in this study. The length scale of the trough concentrator was 1:15, and 324 measuring taps were arranged symmetrically on both sides, with 162 taps on each. The distribution contours of mean wind pressure coefficient and fluctuating wind pressure coefficients on mirror surface under typical working conditions were obtained. The variation of mean wind pressure coefficient of some taps with yaw angles and pitch angles were provided. Extreme wind pressure was calculated by Hermite moment-based method, and the extreme wind distribution was also presented in this article.

Keywords: *Trough Concentrator, Wind Tunnel Experiments, Wind Pressure Distribution, Hermite moment-based method,*

1. Introduction

From the beginning of the 70's of the last century, a lot of various experimental solar thermal power stations were invested in developed countries. Solar thermal power is a widely discussed research topic in engineering field, and trough solar power generation (shown in Fig.1) is an internationally dominating technique with a good commercialization prospect. Since solar thermal power stations are usually located in the open, flat areas, wind load has to be properly estimated. By studying wind pressure distribution on mirror surface of heliostat and parabolic dish collectors through boundary layer wind tunnel experiment, Peterka and Derickson put forward the algorithm of wind load design on heliostat and parabolic dish collectors. Hosoya and Peterka have conducted a series of wind tunnel tests. Their tests presented the peak load and the distribution of local pressure across the face of the solar collector.The research of wind load on heliostat surface with different Reynolds numbers was done by Pfahl. Naeenia and Yaghoubi studied trough solar concentrator by conducting numerical simulation and wind tunnel experiments, and different wind loads on mirror surface with different pitch angles. Gong introduced an algorithm for wind-induced response calculation. He also studied the wind load characteristics on mirror surface as well as the characteristics of wind field around a trough concentrator through on-site measurement.

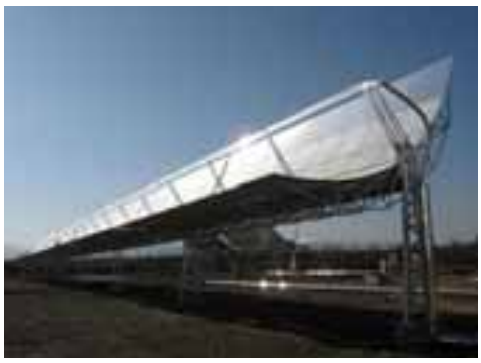

Fig. 1: Trough concentrator (The picture is from National solar thermal Union)

The trough concentrator surface is in an arch shape, thus it can be known that the wind pressure distribution on it is complex. However, there are quite a few researches have been done for the wind pressure distribution on such structures in China. And the wind resistance design of trough concentrator in China is thus in accordance with the existing specifications or technical standard of other countries. However, due to different geographical features and climate condition, the requirements on the strength and rigidity of the concentrator group cannot be met while designed in accordance with such codes. Although there have been some advances for trough collectors in wind tunnel testing and in field measurement, there are still some limiting aspects of the measurement. Compared with previous wind tunnel test, in this paper, in order to obtain more accurate experimental data, the number of wind pressure measuring taps has been increased to 324. In addition, this paper presented the distribution of mean and fluctuating wind pressure on mirror surface. Aiming to get a precise understanding of wind load distribution on trough concentrator surface, wind tunnel experiments on trough concentrator model were carried out in HD-3 atmospheric boundary layer wind tunnel at Hunan University in this study.

2. General information of the experiment

2.1. Experimental apparatus

The experiment was carried out in HD-3 atmospheric boundary layer wind tunnel in Wind Tunnel Laboratory of Hunan University. The wind tunnel was a straight type boundary-layer wind tunnel with low speed. The cross section of the experiment area had a width of 3 meters and a height of 2.5 meters, while the wind speed in the experimental segment was continuously tunable in the range of 0.5~20m·s-1. Cobra probe system could be applied to measure the mean wind speed, turbulence intensity and fluctuating wind power spectrum of flow fields. The pressure measuring apparatus was a DTCnet System made by PSI Corporation. The DTCnet System has 8 modules, and each module has 64 channels, the measuring range is 0.36PSI, with accuracy± 0.05%.

2.2. Experimental model

The trough concentrator prototype consisted of mirror surface, a supporting girder, left and right fin plates, a heat collecting pipe bracket, a transmission system and pillars on both sides. The horizontal projection of mirror surface was 12.2×6.75m, as shown in Fig.2. The mirror surface consisted of 96 small mirrors with a gap of 0.02~0.05m between them. The length scale of the trough concentrator was 1:15 (Fig.3). In order to measure the wind pressure on front and back mirror surface simultaneously in the pressure measuring experiment on mirror surface, 324 measuring taps were arranged symmetrically on both sides, with 162 taps on each. The measuring taps on front surface were arranged in a sequence from A~T, while the measuring taps on back side were arranged in the sequence of AX~TX corresponding to the taps on front surface, as shown in Fig.4. Since the length scale was small, the gaps between small mirrors in the prototype were ignored in experimental the model, the mirror surface in the experimental modal only consisted of two parts.

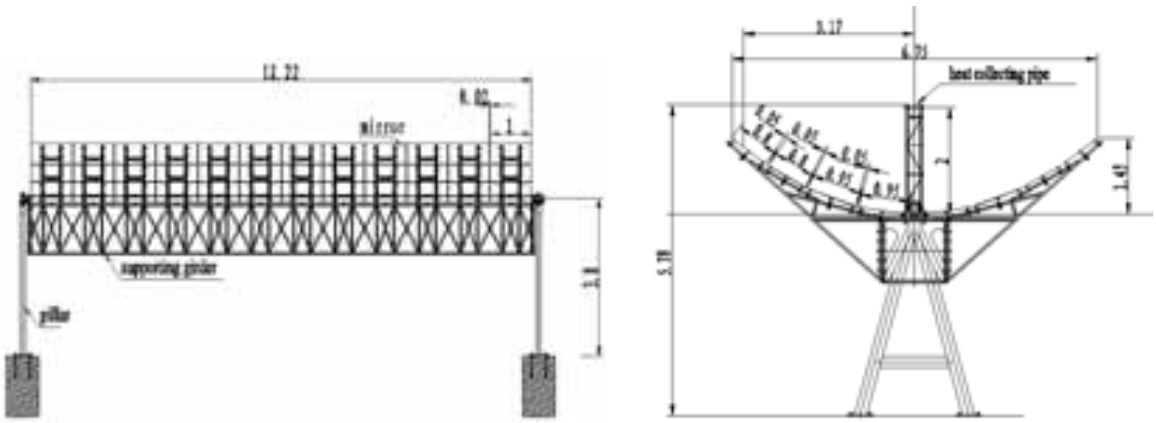

Fig.2: Structure of a trough concentrator

Fig.3: Model of a trough concentrator (1:15)

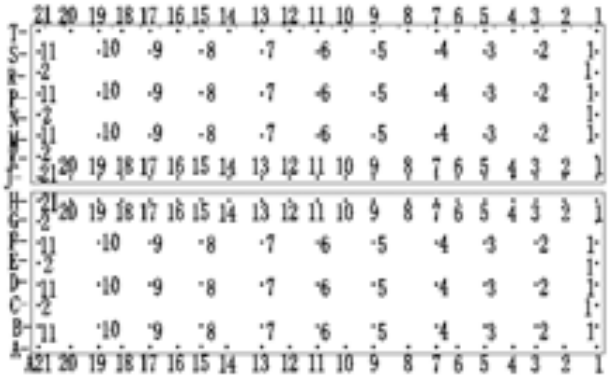

Fig.4: Layout of pressure measuring taps

2.3. Experimental conditions

In the wind tunnel experiment, the horizontal angle of concentrator θ increases from 0° to 180° in increments of 5 clockwise. The vertical elevation angle β of mirror surface increases from 0° to 90° in increments of 10 clock wise, totally 10 different angles. Consequently, 37*10=370 operating conditions are included. The sketch map of the angle of mirror is shown in Fig.5. Because the trough concentrator is a symmetric structure along X axis and Y axis, when the pitch angle is greater than 90°, for example, the pitch angle is 150°, and the yaw angle is 0°(150-000), the wind load of the trough solar collector of 150-000 condition is analogous to that of 30-180 condition. Therefore, we only measured the wind loads for the pitch angle in the range of 0°~90° in wind tunnel test. (Operating condition is expressed in the form of "pitch angle of mirror surface -yaw angle", for instance, 30-000 indicates an operating condition with pitch angle of 30 ^{o} and yaw angle of 0 ^{o}).

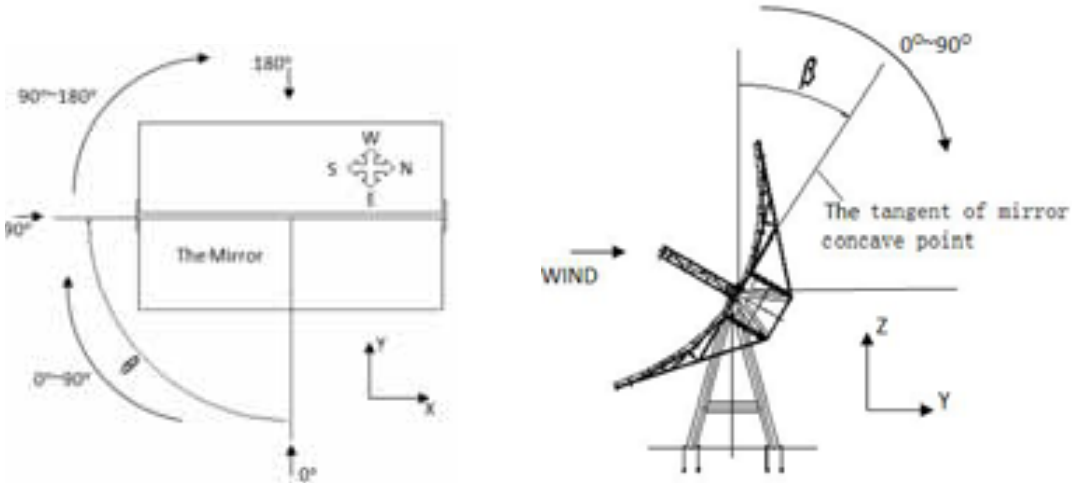

Fig.5: Horizontal wind angle of concentrator in wind tunnel

2.4. Wind field simulation

The comprehensive comparison for the near-ground wind field of wind load codes between China and Europe and America were made, including the mean velocity profile and turbulence intensity profile, fluctuating wind spectrum, etc. The mean velocity profiles of Chinese and Euro codes have a faster increase than other countries, but the mean velocity profile has little difference in the codes of different countries. Compared with other countries, the turbulence intensities in Chinese code are relatively small. For example, with terrain category B (such as the building sparse open country, suburb, forests) and at the height of 10m, the turbulence intensity value of Chinese code is 0.12, the minimum value of the other countries is 0.19, and the maximum value is 0.26.

Based on the terrain roughness characteristics of the site where the trough concentrator is located, the spire-roughness technique was used to simulate the atmospheric boundary layer wind field in wind tunnel according to international experiment method and current Chinese Code on terrain category B. Wind velocity profile is expressed by Equation (1):

$$V_z = V_b \left(\frac{Z}{Z_b} \right)^{\alpha} \qquad \text{(eq. 1)}$$

Where Z_b is the standard reference height; V_b is the mean wind speed at the standard reference height; Z is the height above ground; V_z is the wind speed at the height Z; α is the surface roughness index. The experiment in this study is to simulated terrain category B, so the value α was set to be 0.15 accordingly.

The turbulence intensity profile is calculated according to Equation (2) and (3):

$$I_z(z) = I_{10} \bar{I}_z(z) \qquad \text{(eq. 2)}$$

$$\bar{I}_z(z) = \left(\frac{Z}{10} \right)^{-d} \qquad \text{(eq. 3)}$$

where the turbulence intensity at the height of Z is $I_z(z)$; I_{10} is the nominal turbulence intensity at the height of 10m; the surface roughness index is set as 0.14; Z is the height above ground; d is 0.15. The wind velocity profile and turbulence intensity profile are shown in Fig. 6. The power spectrum of longitudinal fluctuating wind speed is compared with power spectrum by ESDU in Fig. 7.

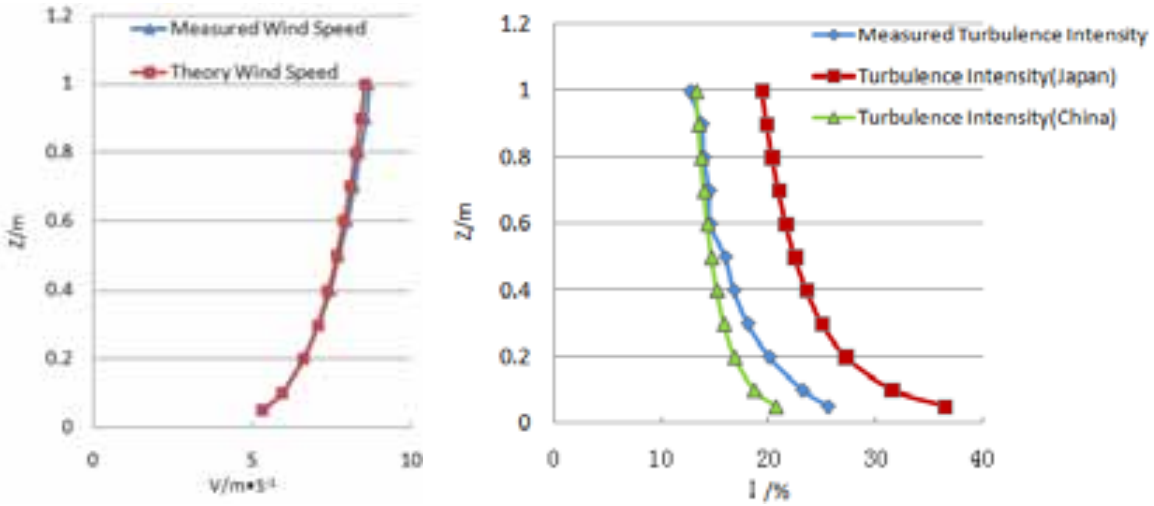

Fig. 6: Mean wind speed profile and the turbulence intensity profile

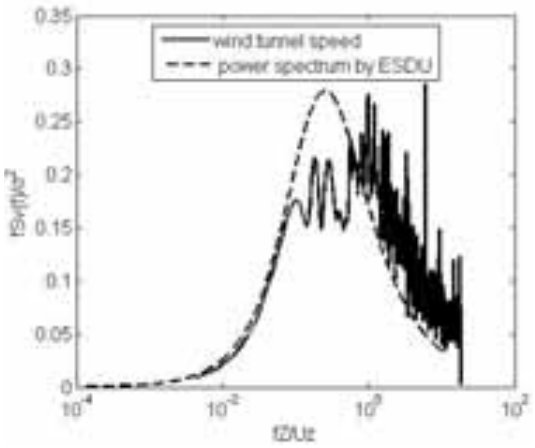

Fig. 7: Wind speed power spectrum of along wind fluctuating wind

3. Processing of experiment data

The measuring taps were arranged symmetrically at the same location on the front side and back side of mirror surface in wind tunnel experiment, respectively. Equation (4) is the calculation equation of net wind pressure coefficient for each measuring position on mirror surface:

$$C_{Pi}(t)=\frac{P_i^f(t)-P_i^b(t)}{\frac{1}{2}\rho V_H{}^2} \qquad \text{(eq. 4)}$$

where $C_{Pi}(t)$ is wind pressure coefficient; i is the serial number of measuring tap; $P_i^f(t)$ and $P_i^b(t)$ are the wind pressures of measuring taps on front side and backside (the leeward side when pitch angle and yaw angle are 0°). With a sampling frequency of 312.5 Hz, 10000 P_i data were recorded for each measuring taps. ρ is the air density in experiment; V_H is the wind speed of the reference tap, and the height of the reference velocity is 0.67m which corresponds to a prototype height of 10m, which is in accordance with Chinese code[10]. By analyzing $C_{Pi}(t)$, the mean wind pressure coefficient, fluctuating wind pressure coefficient could be calculated according to Equation (5) ~(6).

$$C_{Pi,mean}=\frac{1}{N}\sum_{i=1}^{N}C_{Pi}(t) \qquad \text{(eq. 5)}$$

$$C_{Pi,rms}=\sqrt{\frac{1}{N-1}\sum_{i=1}^{N}\left(C_{Pi}(t)-C_{Pi,mean}\right)^2} \qquad \text{(eq. 6)}$$

where $C_{Pi,mean}$ is the mean wind pressure coefficient of the measuring tap i; $C_{Pi,rms}$ is the fluctuating wind pressure coefficient of the measuring tap i; $C_{pi}(t)$ is the time history value of the wind pressure coefficient of a certain measuring tap; i =1, 2, ..., N , N is the number of samples.

4. Distribution of wind pressure

4.1. Distribution of mean wind pressure

The contour map of mean wind pressure coefficient on mirror surface in typical operating condition is shown in Fig. 8.

As shown in Fig. 8, when yaw angle and pitch angle are 0°, the wind pressure coefficients on mirror surface are all positive values. The maximum value is located in the region a little above the middle part of mirror surface. As pitch angle increases, the position of the maximum wind pressure moves toward the edge of mirror surface in the windward. The maximum wind pressure appears at the edge as well as near the concave tap of the mirror surface because of its arch shape when pitch angle reaches 60°. This is different from the wind pressure distribution on heliostat surface. Wind pressure coefficient on the lower part of mirror surface becomes negative when pitch angle reaches 90°. When yaw angle increases to 45°, wind pressure coefficient starts to decrease from the edge of mirror in the windward to the leeward along with the increase of pitch angle. When yaw angle is 90°, pitch angle variation has little influence on wind pressure coefficient distribution because wind direction is parallel with mirror surface. Furthermore, the wind pressure coefficient on the whole mirror surface is small, varying from 0.04 to 0.67. When yaw angle is 135°, wind pressure coefficients on mirror surface are generally negative because the back side of mirror surface is windward, and maximum value appears at the edge of mirror surface in the windward, and the wind pressure distribution pattern is similar to that when yaw angle is 45°. When yaw angle is 180°, wind pressure coefficients are all negative, and the maximum value appears at the central part of mirror surface, the wind pressure distribution pattern is similar to that when the yaw angle is 0°.

Fig. 8: Contour map of mean wind pressure coefficient at the measuring taps on concentrator surface

4.2. Distribution of fluctuating wind pressure

The contour of fluctuating wind pressure coefficient on mirror surface under typical operating condition is shown in Fig. 9. When yaw angle is 0^o, the maximum fluctuating wind pressure coefficient moves toward the edge of mirror surface in the windward as pitch angle increases. This is because cylindrical vortex forms at the edge of mirror surface when air flow reattaches to mirror surface as soon as it is separated by the thin mirror in the windward. Consequently, the maximum fluctuating wind pressure coefficient appears at the edge of mirror surface. When pitch angle increases to 90^o, besides the maximum fluctuating wind pressure at the edge of mirror surface, another two maximum wind pressure coefficients appear symmetrically in the central part of mirror surface in leeward. This is resulted from two symmetrical vortices formed in the leeward after the separation of air flow separated at the edge of mirror surface. When yaw angle increases to 45^o, fluctuating wind pressure distribution shows a similar pattern despite pitch angle changes. It decreases from the edge of mirror surface in windward to leeward. When yaw angle is 90^o, fluctuating wind pressure distribution changes in a gradient pattern because strong air flow separation happens at the edge of mirror surface. When yaw angle is 135^o, the fluctuating wind pressure distribution at different pitch angle is similar to the distribution of mean wind pressure. When yaw angle is 180^o, the fluctuating wind pressure distributions at pitch angle of 0^o, 30^o and 60^o are similar to the distribution of mean wind pressure. In general, fluctuating wind pressure distribution on mirror surface is similar to the distribution pattern of mean wind pressure.

Fig. 9: Contour map of fluctuating wind pressure coefficient distribution on concentrator surface

5. Variation of mean wind pressure coefficient with the yaw angles on mirror surface

The variation of mean wind pressure coefficient of some measuring tap on mirror surface with yaw angles are shown in Figure 10. A11, A20 and D6 are measuring taps located near the edge, corner and central part of the same mirror surface (marked as surface A), respectively. The mean wind pressure variation curve of these taps shows the same trend under four pitch angles. When yaw angle is 90^o, the mean wind pressure coefficient value changes from positive to negative or vice versa. This is a favorable condition for wind resistance because the wind pressure coefficient value is relatively low. At the pitch angle of 90^o, the wind pressure coefficient values of measuring taps A11 and D6 are smaller than that at other three pitch angles. However, a large negative wind pressure coefficient, roughly 2.76, appears at measuring tap A20 at pitch angle of 90^o and at yaw angle of 35^o. This is quite different from that of heliostat and deserves attention in the process of wind resistant design. T11, T20 and P6 are measuring taps located on the same mirror surface (marked as surface B), and the mean wind pressure coefficient variation curves of these taps are consistent despite the change of pitch angle. With the exception of the measuring tap T20 located at the corner, the solar collector has fortunate condition when the yaw angle and pitch angle are both 90^o.

(d) Measuring tap T11 (e) Measuring tap T20 (f) Measuring tap P6

Fig. 10: Mean wind pressure coefficient variation curves at typical measuring taps

6. Extreme wind pressure

Zou Q and Li Z have proved that when pitch angle of mirror surface is large, the wind pressure distribution on mirror surface shows non-Gaussian characteristics. When we calculate the extreme wind pressure coefficients of the non-Gaussian regions on mirror surface by Peak-Factor, the Peak-Factor method is defective for calculating extreme pressure coefficients. Because the peak factor method is based on the assumption that the wind pressure distribution is Gauss distribution. Therefore, in this article we use Hermite moment-based method to calculate the extreme wind pressure coefficients.

Kwon and Kareem (2009) revisit the non-Gaussian peak factor for univariate stationary non-Gaussian processes and clarify the expression of the Hermite moment-based non-Guassian peak factor as (Kareem and Zhao,1994; Kwon and Kareem, 2009):

$$\overline{x}_{ng} = \partial\left\{\left(\beta+\frac{\gamma}{\beta}\right)+h_3\left(\beta^2+2\gamma-1+\frac{1.98}{\beta^2}\right)+h_4\left[\beta^3+3\beta\left(\gamma-1\right)+\frac{3}{\beta}\left(\frac{\pi^2}{6}-\gamma+\gamma^2\right)+\frac{5.44}{\beta^3}\right]\right\} \quad \text{(eq. 7)}$$

where γ is Euler's constant (≈ 0.5772); $\beta=\sqrt{2\ln(v_0T)}$; v_0 is the mean zero upcrossing rate of a standardized non-Guassian process $x(t)$, which is obtaind from a general non-Guassian process $X(t)$ as $x(t)=\left[X(t)-\mu_X\right]/\sigma_X$; μ_X is mean value of $X(t)$; σ_X is the standard deviation of $X(t)$; T is time duration; ∂, h_3, h_4 are parameters of moment -based Hermite modle, which gives a transformation from a standard Guassian process $y(t)$ to the standardized ono-Guassian process $x(t)$ as :

$$x(t)=\partial\left\{y+h_3\left(y^2-1\right)+h_4\left(y^3-3y\right)\right\} \quad \text{(eq. 8)}$$

where the parameters h_3, h_4 control the shape of the distribution, ∂ is the scaling factor.

$$\partial=\left(1+2h_3^2+6h_4^2\right)^{-\frac{1}{2}},\quad h_4=\frac{\sqrt{1+1.5(\gamma_4-3)}-1}{18}.\quad h_3=\frac{\gamma_3}{4+2\sqrt{1+1.5(\gamma_4-3)}} \quad \text{(eq. 9)}$$

where γ_3 is skewness of a process $x(t)$; γ_4 is kurtosis of a process $x(t)$.

Extreme wind pressure distribution could be derived from equation (7)~(9). Because article length is limited, the maximum and minimum wind pressure coefficient distribution maps on mirror surface under some operating condition are shown in Fig. 11 and Fig. 12, respectively. As shown in the contour, the maximum and minimum values move to the edge of mirror surface with the increase of yaw angle and pitch angle; High pressures are typically concentrated around the edges of the collector because of flow separation or vortex formation from the corner where the most wind damage, such as breakage of the mirror is expected to occur.

7. Conclusion

- As the pitch angle and the yaw angle increase, wind pressure distribution on mirror surface changes obviously, and the maximum wind pressure coefficient moves toward the edge of mirror surface close to wind.
- High pressures are typically concentrated around the edges of the collector, and the breakage of the reflector panels at the edge is expected to occur. Therefore, the mirror panels should be improved in stiffness of the edge parts to resist wind-induced vibration.
- Peak factor method is not suitable for the calculation of the extreme wind pressure of trough condenser. Because the wind pressure distribution on mirror surface shows non-Gaussian characteristics. In this article , we use Hermite moment-based method to calculate the extreme wind pressure coefficients.
- The wind pressure distribution pattern on mirror surface and wind pressure coefficient value derived from the analysis in the article can be used as reference for the optimization design of concentrator group and the research on mirror surface deformation control.
- Some limiting aspects of the measurement are figured out. Firstly, pitch angle of solar collector could vary from 0^o~360^o. In this study, pitch angles measured are in the range of 0^o~90^o, and these information about wind loads at these pitch angles will be studied in the future. Secondly, this study is research the isolated collector. Actually, in practical engineering solar collectors are work in groups, thus the interference effects of neighboring collector need to be studied in the future.
- All conclusions drawn in the article can be applied to trough concentrator with plane size and height

similar to that of the concentrator in the article. For concentrators whose height and size are quite different from that of the prototype in the article, the wind pressure distribution may deviate from the findings in this article and more research needs to be carried out.

GEOMETRICAL PARAMETRIC ANALYSIS TO FIND OPTIMUM CONFIGURATION OF A SOLAR CONCENTRATOR WORKBENCH USING LINEAR FRESNEL TECHNOLOGY

Alexandre Bittencourt[1], Victor C. Pigozzo F.[1], Júlio César Passos[1], Gabriel Mendes Cascaes[1], André Burigo[1]

[1]Universidade Federal de Santa Catarina, Florianópolis (Brasil)

Abstract

In this study, a numerical model was developed in order to obtain the optical efficiency of a solar collector with a linear Fresnel concentrator. This model was build based on the ray-tracing and Monte Carlo methods. The goal was to use this model to obtain the parameters required to build a linear Fresnel workbench in our laboratory. With this model it was possible to obtain the optimum configuration of a linear Fresnel workbench taking into account physical and financial constraints.

Keywords: *Renewable Energy, Solar Energy, Numerical Model, Linear Fresnel, Concentrated Solar Power*

1. Introduction

Linear Fresnel solar concentration technology is associated with lower costs and greater simplicity of manufacture when compared to other solar concentration technologies available in the market (Muñoz-Antón et al, 2014). However, this technology is relatively new and more studies on this subject need to be carried out. In this regard, the implementation of a linear Fresnel solar collector workbench on the roof of one of our facilities is being investigated in our laboratory. In order to obtain the most promising configuration for this workbench, in terms of fulfilling our objectives, taking into account the physical and technical constraints of the laboratory, a series of algorithms was developed to evaluate the influence of the geometric parameters on the performance. In these algorithms parameters such as the number of mirrors, mirror spacing, mirror curvature, height of the absorber element and the aperture area of the absorber element are varied. With the model developed the geometric efficiency of the collector was evaluated with the position of the sun varying during the day. This model was validated using the software SolTrace, developed by the National Renewable Energy Laboratory (NREL, 2015). The linear Fresnel workbench will be used to study direct steam generation (DSG) and the associated technical thermal issues. The profile of the distribution of the solar radiation flux on the absorber element was determined since this parameter is of great importance regarding DSG technologies.

2. Linear Fresnel Solar Concentrators

The linear Fresnel collector is a type of concentrated solar power (CSP) technology. There are four main types of CSP technologies in the market: the solar tower and the parabolic dish (which involve punctual concentration), and the linear Fresnel and the parabolic trough (which involve linear concentration). Each technology has its particular characteristics, with advantages and disadvantages. Currently, the use of linear Fresnel technology for direct steam generation seems to be favored (Muñoz-Anton et al., 2014). In 2012 there were 29 CSP plants installed around the world and 31 plants under construction (Pavlovic et al., 2012). In most of these the parabolic trough concentration technology is used. Despite the increasing number of plants being installed, the viability of this technology still relies heavily on government incentives and an increase in production levels, which would result in a cost reduction (Wagner, 2008).

The linear Fresnel collector is composed of several elements. One of these is the absorber assembly, which is composed of an absorber element and often a cavity in which the absorber element is mounted. The absorber element usually consists of a single metal tube or a bundle of tubes with a spectrally selective coating to absorb

doi:10.18086/swc.2015.10.06 Available at http://proceedings.ises.org

as much of the concentrated radiation as possible and minimize the emission in the infrared spectrum (Duffie and Beckman, 2006). These tubes are generally made of stainless steel and the working thermal fluid flows inside. The cavity serves to promote the greenhouse effect and thus reduce thermal losses. It can work with a secondary reflector (Zhu et al., 2013).

Next to the ground are the rows of mirrors that reflect radiation to the absorber assembly. These may be flat or have a slight concavity to improve the concentration rate (Abbas et al., 2013). The rows of mirrors are generally orientated in a north-south axis, and they follow the sun's movement during the day, from east to west. The influence of the mirror curvature on the profile of the concentrated radiation was studied in this paper.

3. Geometric Model Using Monte Carlo Ray-Tracing

In order to evaluate the Fresnel configuration a routine was implemented in Matlab. In this routine the Monte Carlo Ray-Tracing (MCRT) method was used, in which the trajectory and energetic weight of each ray are defined using probabilistic functions. The MCRT method is a powerful tool for analyzing the optical characteristics of solar concentrators (Cheng et al., 2014).

The interactions of each ray with the collector elements have been analyzed, and the optical proprieties of these elements, such as reflection, absorption and transmission, can be taken into account (Delatorre et al, 2014). The optical efficiency of the collector is obtained when these parameter are included in the simulation (Zhu, 2013).

However, since this paper focuses on the analysis of the geometric efficiency, parameters such as the mirror reflectivity, the glazing transmissivity and the selective coating of the absorber element are not considered in the primary analysis. This simplification does not represent the real absorber, but it provides the distribution of the radiation concentration in the aperture plane, which will be useful later for thermal evaluations (Facão and Oliveira, 2011). To determine the geometric efficiency of the collector, aimed at obtaining the best configuration for the workbench, this approximation provides good results with great simplicity.

Another simplification is made by considering the absorber assemble as a flat surface which represents its aperture area. The objective is to obtain the concentrated radiation profile in this aperture area and the total concentrated radiation.

This model is equipped to analyze both plane and curved mirrors and its validation was carried out applying two different approaches. First, a plane mirror model was obtained and validated using the software SolTrace of the NREL (National Renewable Energy Laboratory). SolTrace is a highly rated software program designed for this purpose and it has been validated in several experimental studies (SolTrace, 2015), (Wendelin, 2003), (Wendelin et al. 2013), (Maliage and Roos, 2012). However, SolTrace is not an optimization tool and it is not suitable for analyzing several conditions in a row.

Later a model of an existing collector, the FRESDEMO, was developed and the concentrated radiation profile in the absorber was compared with that obtained by Abbas et al. (2013). In this case, the mirrors were slightly curved.

Figure 1 shows several of the dimensions of the collector: the width of the receiver (Wr), the width of each mirror (Wm), the width of the collector (Wcol), the receiver height (hr), the spacing between adjacent mirror lines (Sm), the number of mirror lines (n) and the mirror curvature (Cm).

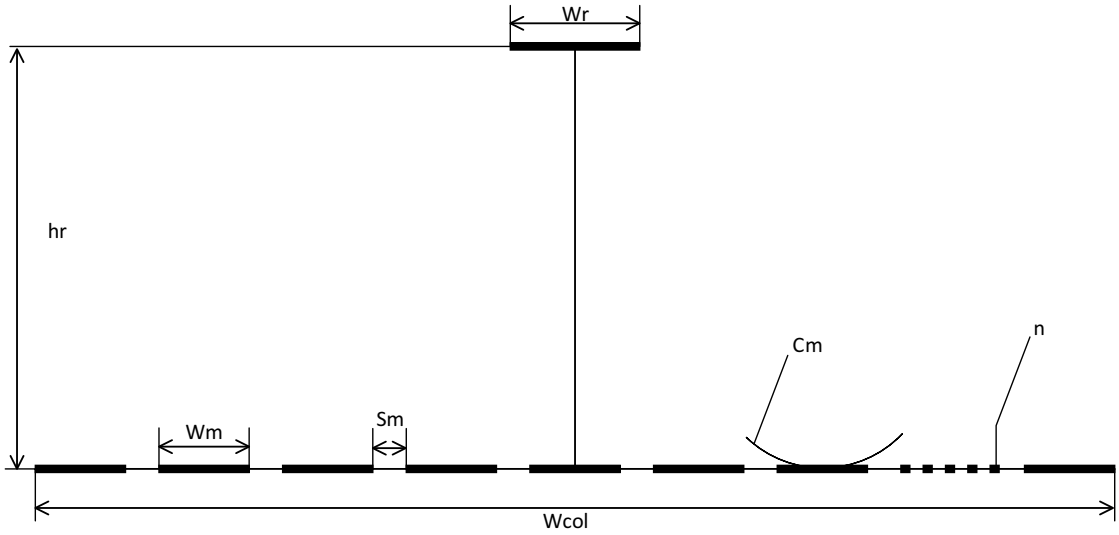

Figure 1: Dimensions of the collector.

4. Results

Since the experimental Fresnel collector is to be installed on the roof of one of the LEPTEN laboratory facilities, spatial and financial constraints must be taken into account. The first constraints are the total width and length of the collector. The area were the Fresnel will be installed is 6m wide and 12m long and thus it is limited to a width of 5m (W_{col} = 5m) to allow easy access for installation and maintenance. The length of the collector was similarly limited to 12m. Considering the collector width limit the other variables can be changed in order to analyze the geometric efficiency.

The geometric efficiency is defined as the ratio between the amount of rays (or energy) that impinge on the width of the receiver aperture and the rays reaching the entire collector width, as shown in equation 1, where η_g stands for the geometric efficiency while n_{r_abs} and n_{r_coll} are the number of rays produced by the MCRT that hit the absorber and the collector aperture, respectively. A useful relation to characterize the Fresnel collector is the filling factor defined in equation 2. This is the relation between the mirror field area and the total area of the collector.

$$\eta_g = n_{r\_abs}/n_{r\_coll} \quad \text{(eq. 1)}$$

$$ff = W_m * n/W_{col} \quad \text{(eq. 2)}$$

The first simulations showed that some of the variables can be kept constant without significantly influencing the final geometric efficiency. This initial analysis is of qualitative rather than quantitative importance. The influence of the spacing between mirrors on the efficiency was the first factor analyzed. In this analysis the mirror width and height were fixed at 300mm and 3500mm, respectively, and the receiver width was defined as 10% greater than the width of the mirrors. The number of mirror rows varied between 10 and 16, and the spacing between mirror lines varied from zero to the maximum allowed respecting the collector width. As shown in Figure 2, for most of the numbers of mirror rows analyzed the maximum efficiency was reached with the largest mirror spacing possible. The only case where the maximum efficiency was not observed at the maximum spacing was 10 rows of mirrors. This is because greater spacing between the mirrors reduced the losses due to shading and blocking, but a limit was reached when significant shadowing and blocking were no longer present. On the other hand, greater mirror spacing means that the mirrors at the extremities will be even farther from the absorber assembly, increasing the loss due to its increased inclination.

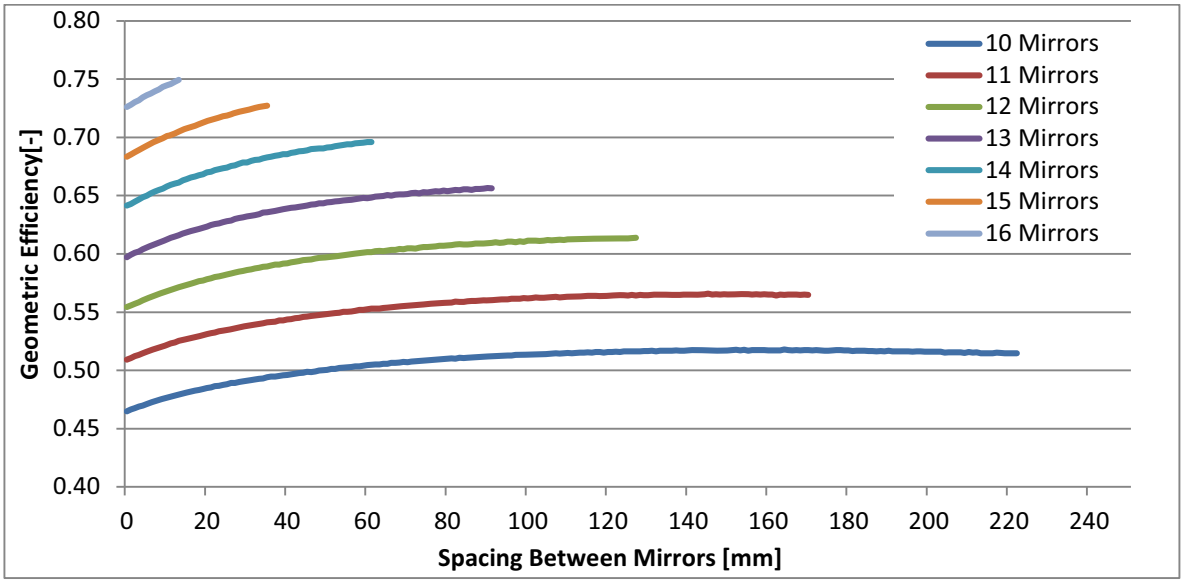

Figure 2: Influence of the number of mirror lines and the spacing on the geometric efficiency.

Therefore, it can be concluded that for all of the cases to be analyzed the maximum spacing between mirror lines will give the best results.

The next step was to determine the influence of the receiver width to mirror width ratio on the efficiency and the results are shown in Figure 3. The efficiency increases with the receiver width as the receiver can intercept more rays reflected from the mirrors. However, the larger the receiver is the larger the shadow it produces on the mirror field will be. For this reason, there comes a point where the efficiency begins to decrease with an increase in the area of the receiver aperture. The curve reaches a maximum at approximately$W_r = 1.1 * W_m$. In this analysis the receiver height is fixed at 3.5m and the spacing between mirrors is set as larger as possible. The same analysis was carried out for different mirror widths and for all cases the same result was achieved. Thus, the relation $W_r = 1.1 * W_m$ was maintained constant in all other analyses. All of these studies were carried out considering plane mirrors. Later, it is shown that for curved mirrors this ratio is far lower, and the receiver width is smaller than the mirror width.

The influence of the receiver height on the geometric efficiency was analyzed by fixing the mirror width at 300mm and using the largest possible spacing between rows. It was observed that on increasing the receiver height the efficiency also increased. It was also concluded that the receiver height has a very weak relation with the other variables.

The analysis is bi-dimensional, which means that the geometrical efficiency obtained is in fact a transversal geometric efficiency. In a three dimensional case, taking into account the collector length, there is another type of loss called end losses. A real-scale Fresnel collector must be sufficiently long to ensure that these end losses are minimal. Because the collector analyzed is short (length = 12m) these losses are large when the sun is low in the sky, for instance, during winter. For flat mirrors, for receiver heights larger than 3500mm the increase in the efficiency is minimal.

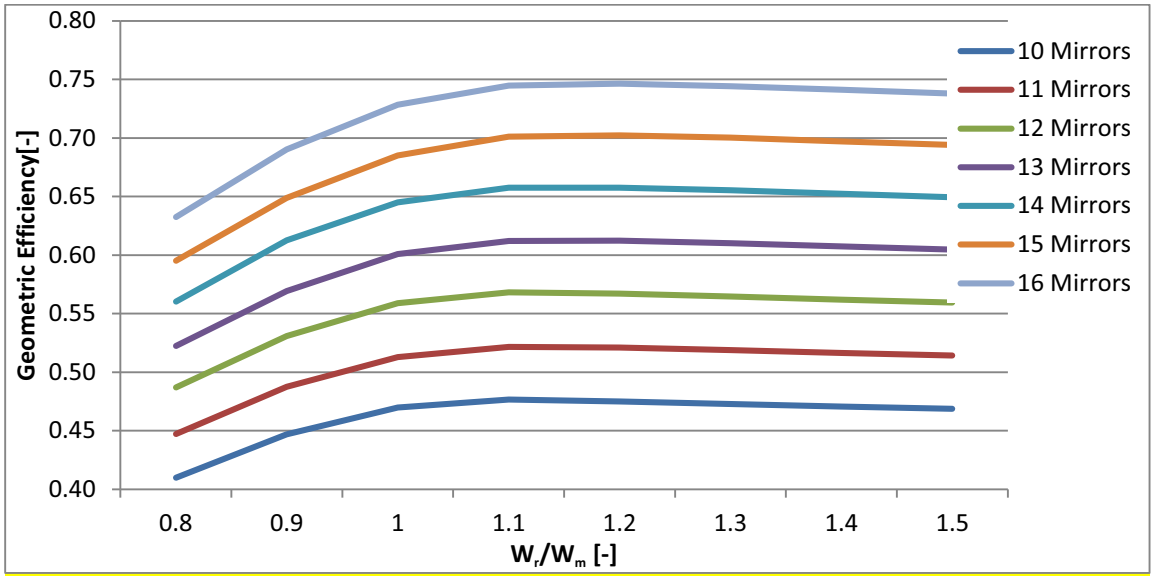

Figure 3: Relation between receiver width and mirror width.

This increase in the efficiency with the receiver height is even more difficult to observe for curved mirrors, as shown in Figure 4. This figure is for the specific case of a collector with 10-mirror rows, each mirror with a length of 450mm each, curved, with an average focus of 1.1 times the absorber height, and using the maximum spacing between mirrors. Other cases were studied and presented similar results.

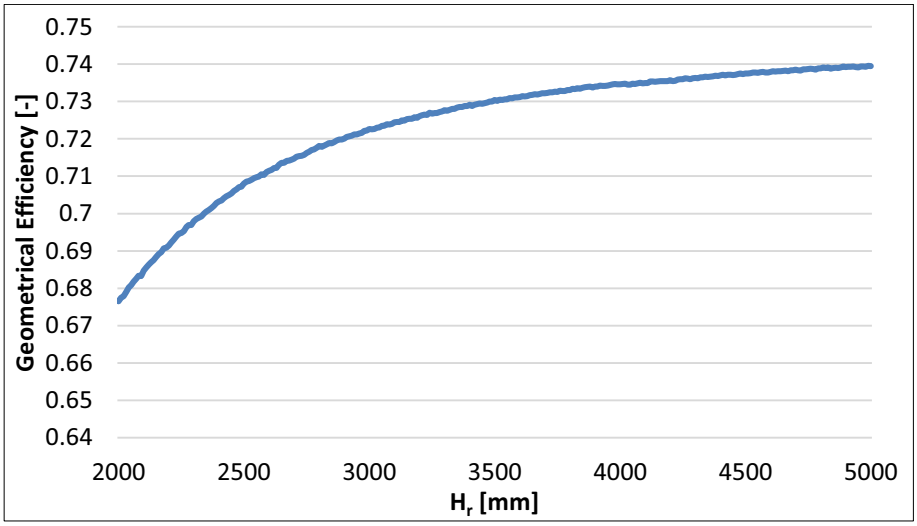

Figure 4: Influence of the receiver height on the geometric efficiency.

The relation between the number of mirror rows and different mirror sizes in the form of a filling factor was analyzed. Figure 5 shows the results for plane mirrors and $W_r = 1.1 * W_m$ using the largest possible spacing and a receiver height of 3500mm. The same analysis was performed for curved mirrors for different focus distances; however, by analyzing these results the conclusions were the same as in the case of flat mirrors.

The filling factor defines a relation between the number of mirror lines and the mirror width, as defined in equation 2. Thus, obtaining the curves for different numbers of mirror lines, varying the filling factor is sufficient to characterize the collector geometry.

As expected, the larger the filling factor the better the efficiency will be and the same is true for a greater number of lines. However, despite the higher efficiency, these cases are not always practical or economically feasible since a greater number of lines requires more components like tracking devices, axes, mirrors and control devices.

Another important observation in relation to Figure 5 is that for low filling factors the efficiency rises considerably with the filling factor, and for filling factors close to unity the increase in the efficiency is not as great. This analysis shows that one can operate with filling factors between 0.9 and 0.95 with an efficiency only 3% lower than the maximum efficiency. This allows some flexibility to deal with costs and building issues associated with the project.

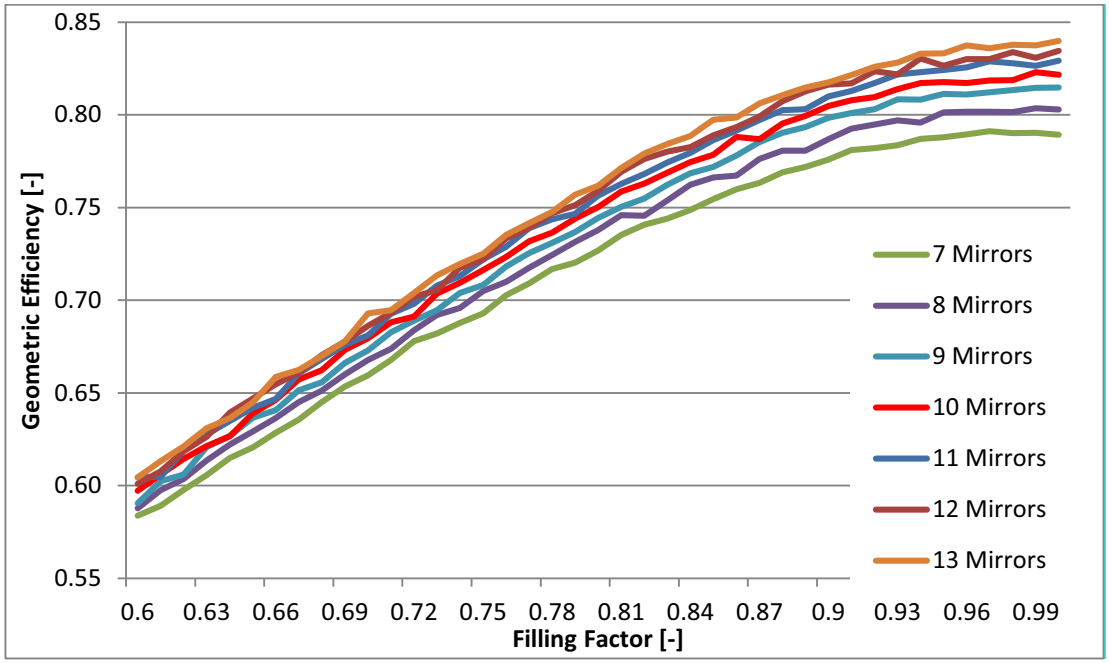

Figure 5: Influence of filling factor and number of mirror lines on efficiency.

The influence of the mirror curvature on the concentrated radiation which is focused on the absorber aperture was analyzed. The distribution of the concentrated radiation over the absorber aperture throughout the day, for different focal lengths, is shown in the Figures 6, 7 and 8. The focal length reported herein is the mean distance between the mirrors and the middle of the absorber aperture area. These figures relate to a collector with 10 mirror rows of 450mm, the absorber height is 3000mm and the maximum spacing between mirrors is applied. Three focal lengths were analyzed: 1.0, 1.1 and 1.2 times the receiver height.

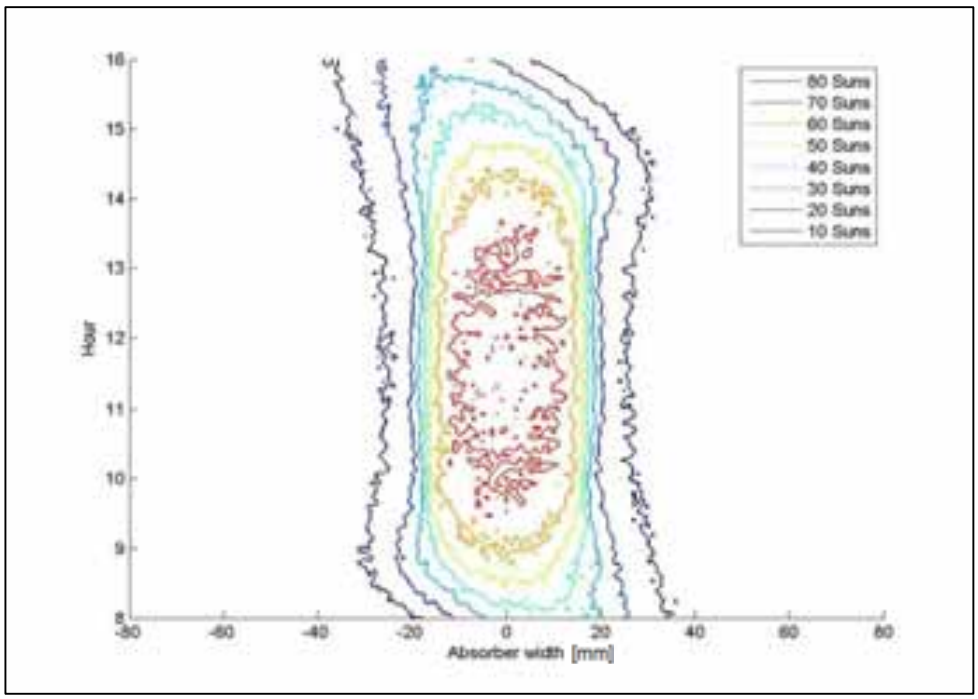

Figure 6: Profile of the concentrated radiation for a focal length 1.0 times the receiver height.

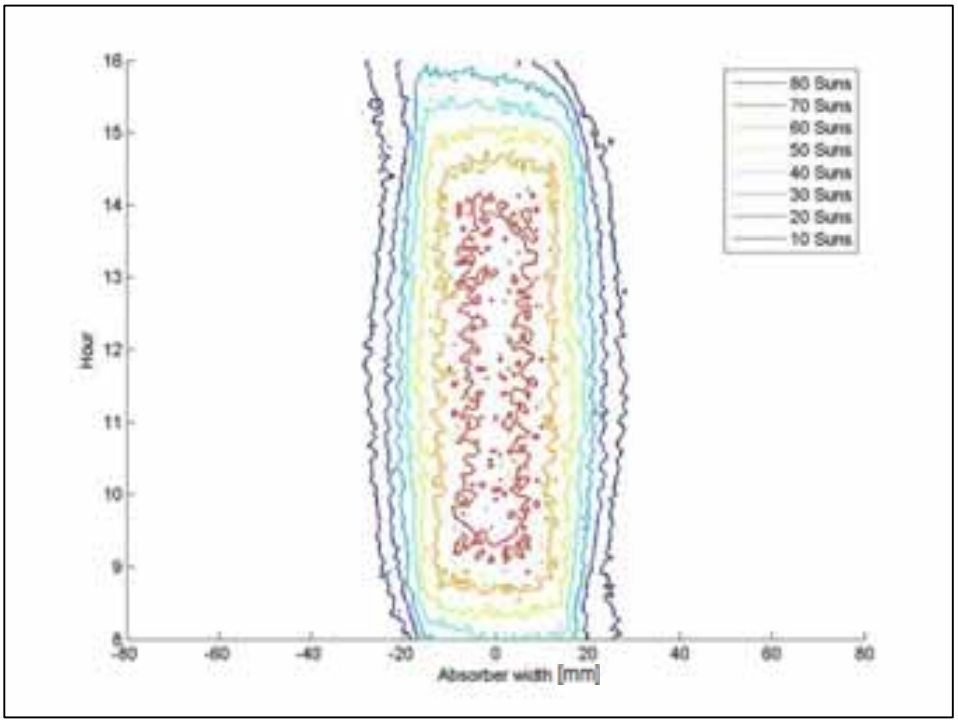

Figure 7: Profile of the concentrated radiation for focal length 1.1 times the receiver height.

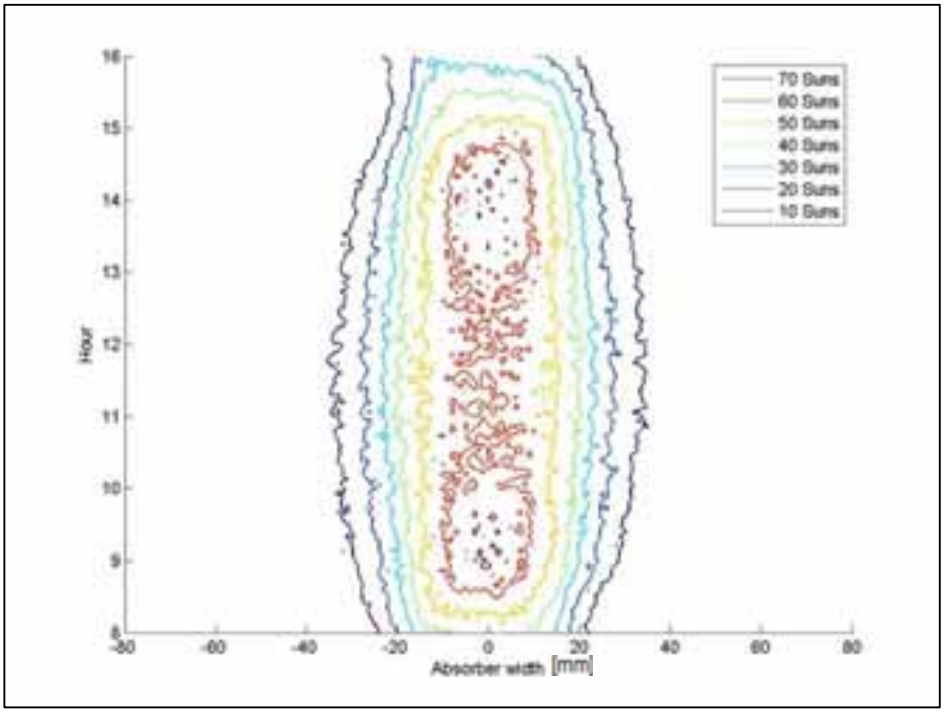

Figure 8: Profile of the concentrated radiation for focal length 1.2 times the receiver height.

It can be seen that for a focal length 1.0 times the receiver height the profile for the concentrated radiation on the absorber aperture area is more homogeneous during the day. This is of interest, since the collector operation will be steadier during the main solar hours of the day. These concentrated radiation profiles favor the use of a set of tubes in the absorber assembly, because this configuration provides good operational flexibility. Muñoz-Anton et al. 2014 demonstrated that in this configuration, for a set of four tubes in a DSG operation, one can set the flow to pass first through the outermost tubes to allow preheating and then through the inner tubes for the phase change. Other numbers of tubes and flow configurations can be used in order to obtain better use of the concentrated profile. The higher the number of tubes for the same flow the lower the diameters can be and, therefore, the heat exchange coefficient will be improved. However, lower diameters also lead to higher pressure losses (Abas et al., 2013).

Focal lengths of shorter than 1.0 and greater than 1.2 times the receiver height were also studied, but they

produced a much more disperse profile than those shown in Figures 6, 7 and 8.

5. Model Validation

This model was validated using the SolTrace software, available from the National Renewable Energy Laboratories. The reliability of SolTrace has been validated via several experimental studies. However, this software does not allow the plant parameters to be changed automatically according to the time of day, making it difficult to generate an optimization routine.

To validate the model, several Fresnel configurations were simulated under the same radiation conditions using both software programs. The results obtained with the model developed in this study were very close to those provided by SolTrace.

A commercial collector FRESDEMO was then modeled, considering curved mirrors, and the results compared with data available in the literature.

Initially, a collector configuration was implemented in SolTrace and compared with the Matlab results for an entire day, as shown in Figure 9. The validation was carried out in both the transversal and longitudinal directions. The longitudinal direction represents the end losses.

For all cases the collector was oriented along the north-south axis and it tracked the sun in the east-west direction during the day. The maximum difference in the values for the concentrated radiation heat flux obtained using the model developed in this study and SolTrace was 1.1%. Considering the end losses (the longitudinal case) this maximum difference was 18.5%. This large difference is observed for high incidence angles which will almost never occur in real applications.

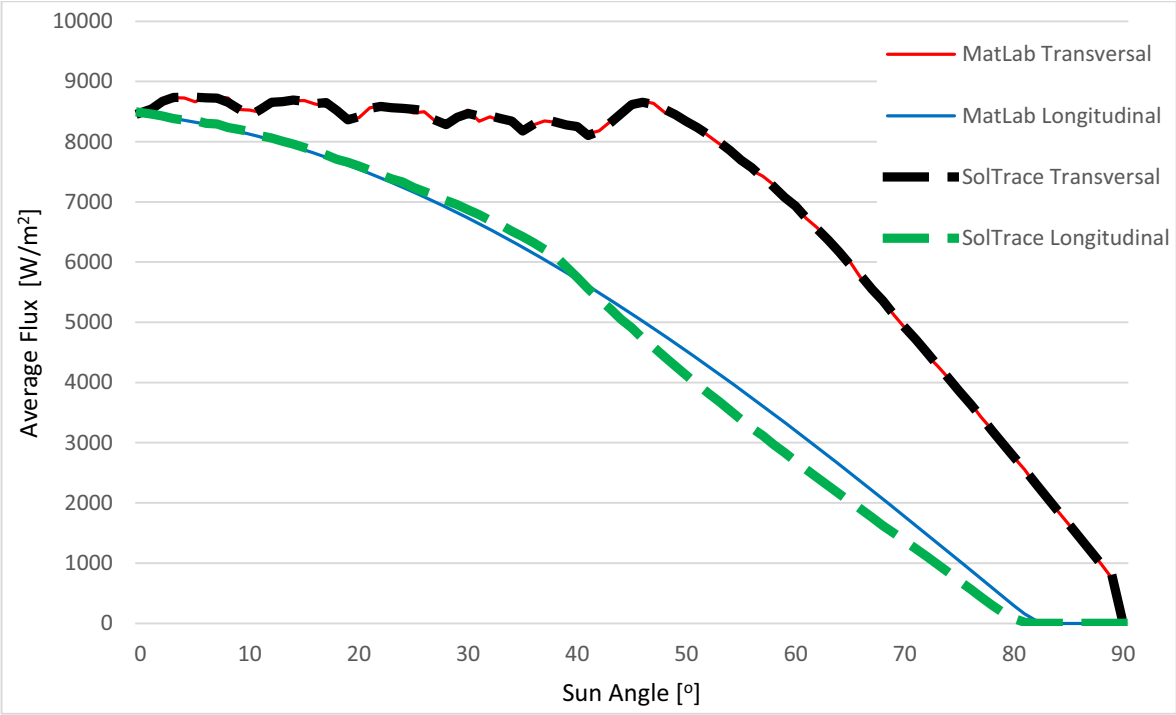

Figure 9: Comparison between the model and SolTrace results.

Figures 10 and 11 show a comparison between the results for the concentrated radiation in the absorber aperture plane for the FRESDEMO collector obtained by Abbas et al. (2013) and with the model presented herein. The focal length used by Abbas et al. (2013) was not reported and thus the focal length used in the model was 1.1 times the mean distance between the mirrors and the absorber. Our model showed good agreement with the radiation profile presented by Abbas et al. (2013). This simulation was carried out using the collector parameters reported by Abbas et al. (2013).

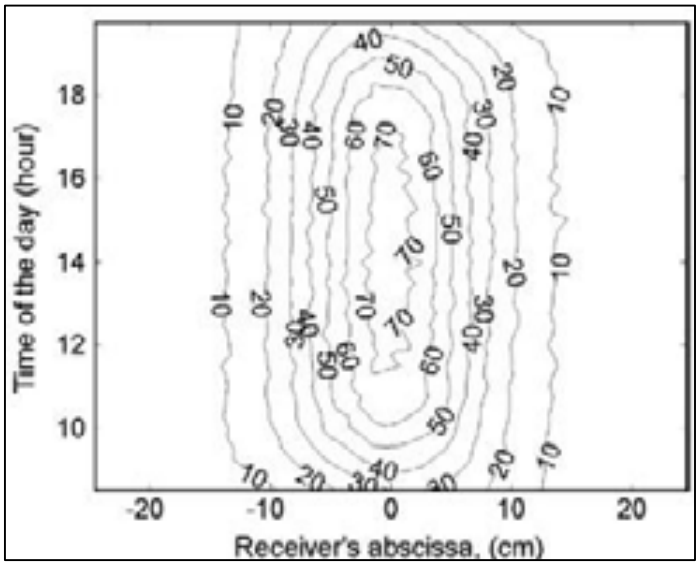

Figure 10: FRESDEMO concentrated radiation profile for the receiver (source Abbas et al., 2013).

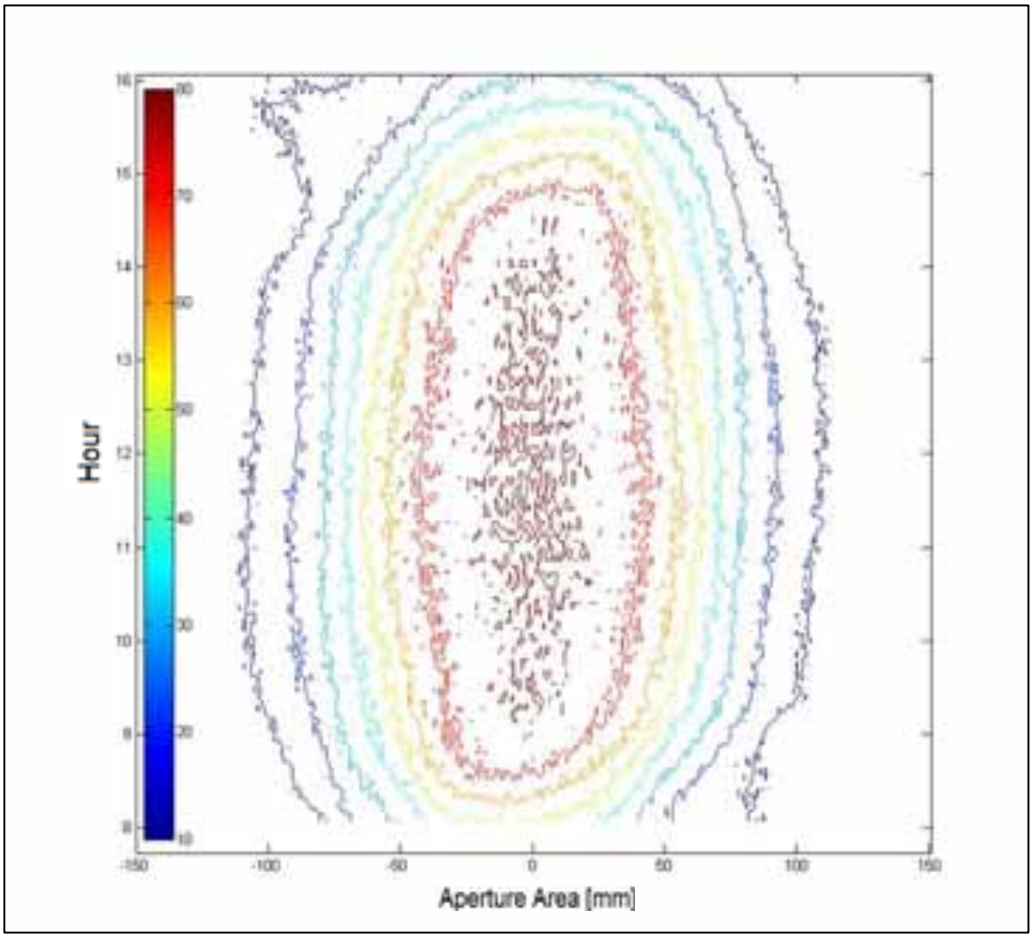

Figure 11: Concentrated radiation profile for the receiver obtained with our model.

6. Conclusions

The model described herein showed good agreement with SolTrace. With this new model it was possible to simulate several aspects of the collector geometry, to make comparisons and to achieve the best configuration for the proposed application. To simplify the work, sensitivity analysis was initially carried out and it was found that some variables do not have a strong relation with others. These variables were then maintained fixed in the subsequent optimization analysis.

An important conclusion is that the mirror row spacing should be the maximum allowed respecting the total

collector width, in order to achieve the best geometric efficiency. The receiver height was also analyzed and 3.5m was selected as an appropriate value in terms of efficiency and operational aspects. For this receiver height and using flat mirrors the best value for the receiver width to mirror width ratio was 1.1.

Considering the constraints identified using the model developed it was possible to evaluate the influence of the geometric configuration of the Fresnel on its efficiency. This study allowed the final configuration of the workbench to be installed in the laboratory to be defined, that is, 10 rows of mirrors with a width of 450mm, with the absorbing assemble placed at a height of 3m. The absorber assembly adopted is the trapezoidal cavity, using a set of four parallel absorber tubes. The trapezoidal cavity was selected due to its technical and constructive advantages and the multitube absorber provides some flexibility in relation to the operational strategies.

The total width of the four tubes is 140mm. The reflective mirrors have a slight curvature which allows the absorber element width to be smaller than that of the mirrors. This bending increases the rate of concentration in the central area of the absorber element, as shown in Figures 6, 7 and 8.

STRUCTURAL AND OPTICAL PROPERTIES OF SEVERAL IRON-MANGANESE OXIDES TO PREPARE THIN FILMS AS SOLAR SELECTIVE ABSORBERS

Elisa Sánchez[1], Enrique Barrera[1], Federico González[1], Ricardo Rosas[1], Eduardo Ríos[2]
[1] Universidad Autónoma Metropolitana, Distrito Federal, México
[2] Universidad Autónoma Chapingo

Abstract

In this work, the behavior of the mixture to form manganese iron oxides used as pigments for application in solar absorbers is investigated. Polished aluminum as substrate was covered with mixed Fe:Mn oxide by the impregnation method. After drying the thin films, the samples were submitted to different heat treatment temperatures. Chemical structure and optical properties were respectively evaluated using XRD and UV-Vis-IR spectrophotometry technique. The evolution of different structural phases during the addition of manganese ions process is discussed with Rietveld refinement of the X-ray diffraction. The results indicated a phase mixture of the two oxides for concentrations x = 0.87, 0.5 and a solid solution x = 0.93, 0.35, however the best selectivity values were obtained in the sample x = 0.35, indicating the addition of manganese is crucial for the pigment applied to solar applications substrate.The thin film profilometry let us to evaluate thin film thickness and the surface roughness. Finally, the effects of mixed oxides chemical composition on the solar selectivity (α / ε), will be discussed.

Keyword; *Selective coatings, hematite, absorptance*, *emittance, Rietveld method.*

1. Introduction

Domestic water heating systems with solar energy technologies, are still at the date, a subject of study because the conversion of thermal solar energy in these systems depends largely on the materials used as absorbers, specially in their optical properties[Kenenndy 2002]. Selective surfaces of high solar absorptance (α) and low thermal emittance (ε) are used as the solar absorber [Duffie, 199, Zhang 2000]. The selectivity values (α/ε) depend on the precursors, the deposition method and also of the substrate used.
The most significant methods are chemical electrodeposition [Reza et al, 2015], sputtering [Barshilia, 2008], vacuum evaporation, spray pirolysis [Avila et al, 2004], sol gel [Tulchinsky et al, 2014, Vince et al 2003], painting technique [Orel, 2005] and electroplating[Driver 1977] have commercial application for large-scale production. Today, the problem of the available selective surfaces is that they are not only rather expensive but also appropriate for large scale production. The solution lies in the selective properties paints applied with a method easy and inexpensive: painting method.

The types of paint can be categorized as Thickness Insensitive Spectrally Selective (TISS) or Thickness Sensitive Spectrally Selective (TSSS) [Orel, 2005, 2007]. It is possible to obtain a high solar absorptance (> 0.95) but the thermal emittance should be about 0.5 for TISS paints [Orel et al., 2007]. Several studies have shown that using paints based on metal oxides [Geng, 2012] as $FeMnCuO_x$ transition can achieve acceptable selectivity values. The solar selective coating is one of the most important components of the solar collectors. Their optical properties must influence favorable both the efficient absorption of sunlight and low heat energy losses through the solar collector [1]. Some preparation methods for these coatings are spray pyrolysis, [2] and by the impregnation of FeCuMnOx and Fe_3O_4 pigments [3], [4]. In this work, it is

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.10.07 Available at http://proceedings.ises.org

investigated the behavior of the mixture to form manganese iron oxides used as pigments for application in solar absorbers. Polished aluminum as substrate was covered with several mixed ratios Fe:Mn oxide by the impregnation method. After drying the thin films, the samples were submitted to different heat treatment temperatures. Chemical structure and optical properties, using XRD and UV-Vis-IR spectrophotometry technique, were respectively evaluated. The thin film profilometry let us to evaluate thin film thickness and the surface roughness. Finally, the effects of mixed oxides chemical composition on the solar selectivity (α / ε), is discussed.

The hematite (α-Fe_2O_3) [Hosseini, 2008] and α-Mn_2O_3 in bixbite phase were used as red and black pigments since ancient times. Now they are used in various industrial applications for paints, enamels and plastics thanks to its low price, low toxicity and high thermal and chemical stability. In phase α-Mn_2O_3 the Mn 3+ ions are coordinated octhaedrically, while ions O are 4 Mn ions, so close. The $(Fe1\text{-}xMnx)_2O_3$ [Saha, 2002] system is interesting because the extreme phases crystallize in different space groups. The phase with x = 0 (Fe_2O_3) does in the rhombohedra system with space group R-3c (Fig 1a) while the phase with x = 1 (Mn_2O_3) crystallizes in the cubic system (Fig 1b), with space group Ia3. The crystal structure of the pigment has an influence on its optical properties. The objective of this work is to study the optical characterization of selective surfaces containing different amounts of Fe-Mn ions for use as pigments for solar absorbers. The crystal structure of the pigment has been studied by XRD [Rietveld, 1969, Lutterotti, 1992], the optical surface characterization was performed by uV-VIS-infrared spectrometry and the details of the surface morphology were conducted with profilometry.

Theoretically solar absorptance is defined as the fraction between absorbed radiation and solar radiation. It was calculated according to equation 1. where λ is wavelength, R(λ) reflectance and Is (λ) normal irradiance.

$$\alpha_s = \frac{\int_{0.3}^{2.5} I_s(\lambda)\big(1 - R(\lambda)\big)d\lambda}{\int_{2.5}^{20} I_s(\lambda)d\lambda} \qquad (eq\ 1)$$

The thermal emittance is a ratio between a radiation emitted by the surface and the radiation that a black body at the same temperature emmit , which is presented as:

$$\varepsilon_s = \frac{\int_{2.5}^{25} E(\lambda,T)\big(1 - R(\lambda)\big)d\lambda}{\int_{2.5}^{25} E(\lambda,T)d\lambda} \qquad (eq\ 2)$$

Where E (λ, T) is the spectrum of the radiation of a black body at temperature T.
The objective of this work is to obtain the chemical, surface and optical characterization of solar selective thin films containing different quantities of Fe-Mn ions, used as pigments, for solar absorbers applied with a method type painting.

2. Experimental

2.1 Preparation of $(Fe_xMn_{1-x})_2O_3$

Mixed Fe:Mn and single oxide powder by the co-precipitation method were prepared, under the following procedure: Iron (III) chloride hexahydrate ($FeCl_3$ $6H_2O$) and manganese (II) chloride ($MnCl_2$ $4H_2O$) were mixed while maintaining a molar ratio 2: 1. This mixture was added to a 1M solution of NH_4OH, where a chemical precipitate occurred, that after washed with distilled water, let's to obtain our powder to prepare the solar selective thin film on Al substrate. Other compositions of mixed oxides prepared were in the proportions: Fe: Mn (2.2: 0.8, 2.8: 0.2)

2.2 Paint coatings

The Aluminum substrate were immersed in the different suspension containing various Fe:Mn, molar ratios. The thin film were submitted at different thermal treatments: 100, 150, 200 and 300° C, in order to observe

the thermal stability of the films.

2.3 Instrumental

The phase identification of the synthesized powders was performed using a Bruker-D8 Advance X-ray diffractometer with Cu Kα radiation (1.5406 A°) in a Bragg Brentano geometry and a one-dimensional position-sensitive silicon strip detector (Bruker, Lynxeye) operating in the 0-D mode. The 2θ step size used in the registered data is equal to 0.02^0. The patterns have been analyzed by the Rietveld method of the Fullprof program [Rodriguez, 2001]. The Rietveld method consists of simulating a diffraction pattern and refining a proposed structural model until a satisfactory match is found between the experimental and simulated patterns, the method is a full-profile approach that was initially introduced for the refinement of crystal- structure parameters but has been expanded for application in quantitative phase-analysis. The simulated XRD pattern is calculated from a large number of parameters, including crystal-structure parameters of each component phase, a scale factor for each constituent phase to adjust the relative intensities of the reflections, parameters describing the peak profile and the background, and other parameters in the simulation.
Reflectance spectral of the spectrally selective paint coatings were measured in the wavelength interval 0.3-20 μm. A Varian UV/ Vis/NIR spectrophotometer equipped with an integrating sphere was used to record reflectance spectra in the wavelength interval 0.3-2.5 mm. The infrared wavelength interval, 2.5-20 mm, was covered with an Infrared spectra are recorded on a Thermo Scientific Nicolet IS50 FTIR equipped with a gold-coated integrating sphere

With the total spectral reflectance, measured into two wavelength range is it easy build a reflectance spectra both in the uV.Vi and NIR in a Medium IR Those measurements can be used to determine the optical properties of the solar selective thin films.
The average thickness and surface morphology of the coatings were measured by means of a profilometer Bruker DektakXT.

3. **Results and discussion**

3.1 XRD patterns and Rietveld Method

Results are shown in Fig. 1 and reflection lines at 2θ = 24.18°, 33.20°, 35.67°, 40.91°, 49.5°, 54.11°, 62.49° and 64.05° indicate pure Fe_2O_3 structure, relative to (0 1 2 1), (1 0 40), (1 1 0), (1 1 3), (0 2 4), (1 1 6), (2 1 4) and (3 0 0) planes,. The diffraction lines at 2θ = 23.27°, 33.14°, 38.45° assigned to (2 1 1), (2 2 2), (4 0 0) planes correspond to the pure oxide Mn_2O_3, indicate the diffraction pattern of a solid solution. The absence of Manganese oxide in the samples x=0.93 in the diffraction pattern indicate that Mn^{3+} cations are introduced in the Fe_2O_3 lattice structure and confirms the formation of a solid solution, as identified by the displacement of the diffraction line. The sample x=0.87 to x=0.5 present phase segregation.
Rietveld Refinement graphs (experimental data and difference theoretical data) of the materials after the heat treatments are presented in Fig. 2. The parameters such as refined cell parameters, atomic positions and percentage of phases present in the mixtures are presented in Table 1.

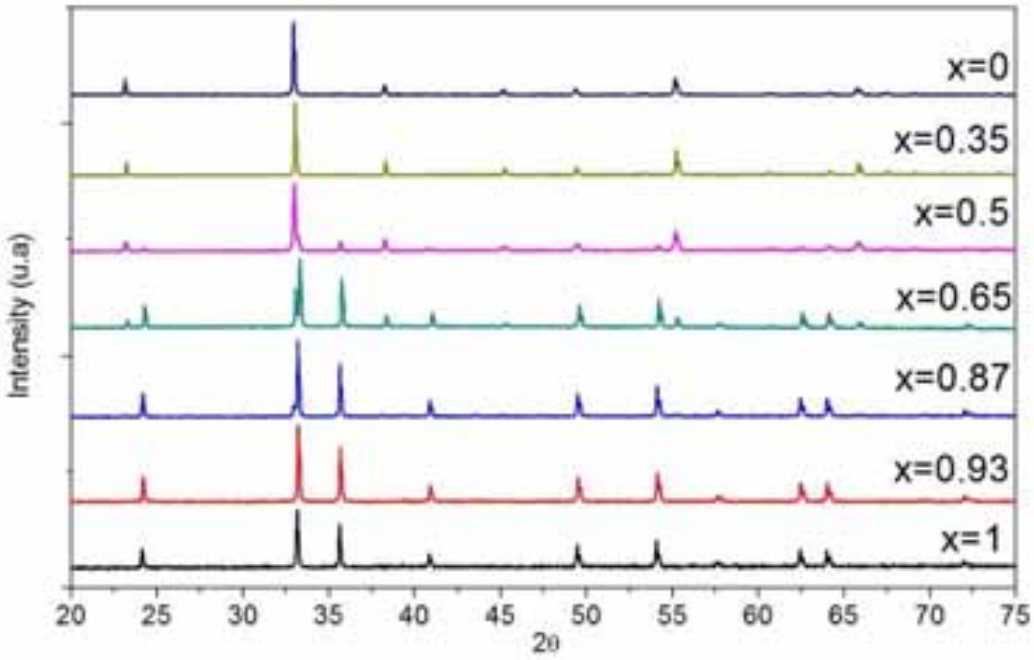

Fig. 1 XRD patterns of oxides prepared at different molar concentration at 800 °C.

The structural parameters of each sample were evaluated by the XRD study. A Corundum and a bixbyite structural phase for Fe_2O_3 and Mn_2O_3 pure compound was obtained respectively. Also both phases in the samples with mixtures of ions, are observed. A Rietveld Refinement graph (experimental data and theoretical data difference) of a representative material after heat treatments is presented in Fig. 2. The parameters such as refined cell parameters, atomic positions and percentage of phases present in the mixtures, are summarized in Table 1.

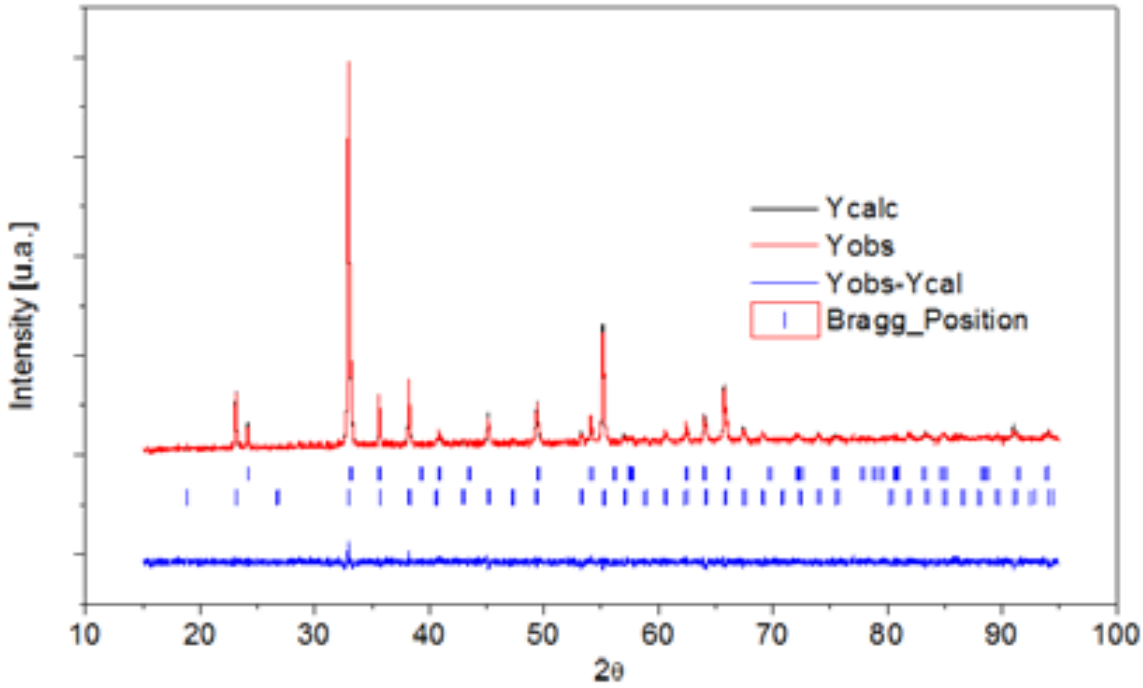

Fig. 2 XRD patterns of oxides prepared at different molar concentration at 800 °C.

Table 1: Result of the Rietveld refinement for the several pigments prepared.

Experimental Composition	%wt Phase	Space group	Lattice parameters (°A)			
			a=b=c	a=b	c	$\chi 2$
0	(100) Mn_2O_3	Ia-3	9.4173	-	-	1.36
0.35	(100) Mn_2O_3	Ia-3	9.4174	-	-	1.39
0.5	(58.9)Mn_2O_3	Ia-3	9.414	-	-	1.38
	(41.1) 2.70	R-3c	-	5.037	13.737	
0.87	(97.30) Fe_2O_3	Ia-3	9.414	-	-	1.39
	(2.70)Mn_2O_3	R-3c		5.036	13.738	
0.93	(100) Fe_2O_3	R-3c	--	5.036	13.738	1.36
1	(100) Fe_2O_3	R-3c	--	5.037	13.734	1.38

Quality refinement setting for the samples studied has a satisfactory value. No traces of hydroxyl groups into the structures are observed. The concentration of the two phases for the Fe: Mn samples, 1: 1, 2.2: 0.8, 2: 1, were obtained. Different concentrations result in a change in the percentages of each phase present in the solution, i.e., a greater amount of Mn in the solution, increased the cubic phase (Mn_2O_3), these results are summarized in Table 1.

3.2 Spectral selectivity

Considering the reflectance spectra of some representative samples, figure 3, using the two equations, 1 and 2, it was easy evaluate the solar absorptance and thermal emittance of the films, respectively, with the procedure described by Duffie and Beckman, in the regions of UV / Vis / NIR wavelength, see table 2. Also in this table it is represented some other properties of the prepared thin films, like the thin film thickness and surface roughness.

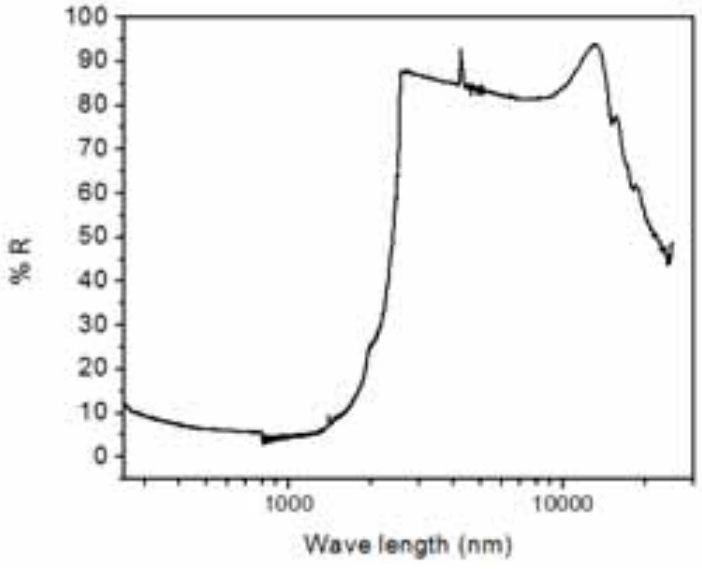

Fig. 3 Direct-hemispherical reflectance of a representative sample $(Fe_xMn_{x-1})_2\ O_3$; x=0.35 at 800°C

3.3 Perfilometry

In addition, 3D roughness parameters based on the value of Ra, were obtained in this work; where Ra is defined as the roughness average. Table 2 includes the results in this parameter and Fig. 4 shows 3D surface images employed to obtain this parameter for the thin films onto Al substrate. The strong increase in roughness with paint technique is clear

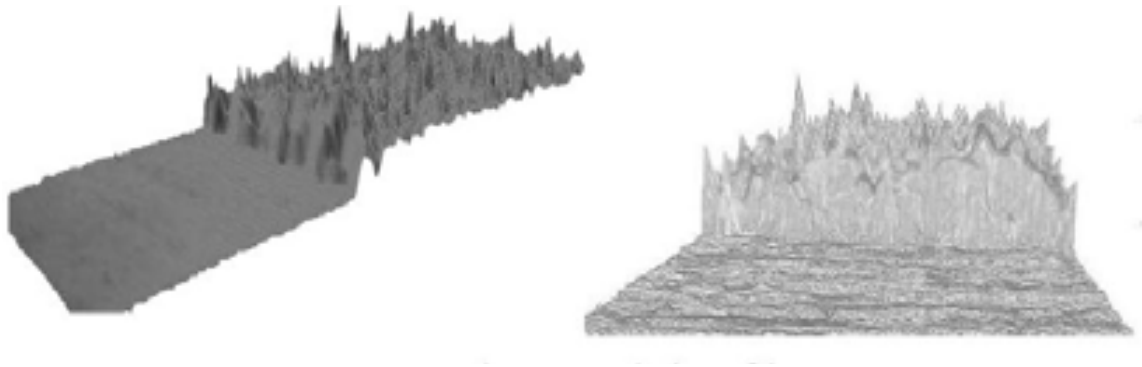

Fig. 3. Surface morphology representation 3D of representative *(*$(Fe_xMn_{1-x})_2O_3$ thin films on Al substrate.

Table 2 The optical properties, surface roughness and thin film thickness as a function of the chemical composition of the thin films.

Sample x=	Property			
	Optical		Morphology	
	absortance	emittance	Surface Roughness(µm)	Film thickness(µm)
0	0.918	0.31	0.55	15
0.35	0.931	0.29	0.45	20
0.5	0.899	0.38	0.41	18
0.87	0.894	0.30	0.5	16
0.93	0.897	0.38	0.6	14
1	0.695	0.49	0.75	18

4. Conclusions

Solar selective thin films of iron oxides and mixed oxides of Fe:Mn were prepared and characterized by several chemical and spectrophotometric technique like XRD (Rietvelt method), surface profilometry and UV-Vis-NIR. This way, it was possible to evaluate the photothermal optical properties of several thin film coatings. The mixed oxides prepared, show better optical properties for the photothermal conversion of solar energy, having a great thermal stability, that could be used for solar colector working even at mid temperature. At the date we are optimizing the main experimental parameters in order to optimize the optical properties of the solar films.

Abstract

In this investigation, a revised photovoltaic/thermal collector model based on TRNSYS TESS type 560 was developed to do the year-round performance prediction of both glazed and unglazed PV/T system. Simultaneously, a photovoltaic/thermal collector with the designed parameters was fabricated and tested to validate the model. Results showed that the simulation has a good agreement with experiment results. The mean error of both thermal and electrical efficiency is less than 15%. Furthermore, four domestic systems, including glazed and unglazed photovoltaic/thermal, photovoltaic and solar thermal systems, were built in TRNSYS. Annual performance of the four systems was obtained and analyzed. Compared with PV，glazed PV/T can supply extra 3850.4 MJ heat, but the power generation decreases by 24.1%. The glazed PV/T SDHW system shows a similar trend of SF and auxiliary heat with the flat plate SDHW system. The variation of SF is between 19.2% and 80.5% with an annual average value of 45.9%. The unglazed PV/T system can supply 339.5 kWh electricity and offer 806.3 MJ heat for preheating, which result in a low SF of 12.9%. Based on the view of comprehensive utilization of solar energy, the glazed PV/T system seems to be a more promising solution in SDHW system.

Keywords: *photovoltaic/thermal collector; TRNSYS simulation; performance comparison*

1. Introduction

Solar photovoltaic (PV) modules are now widely used for power generation to lead a sustainable and low-carbon economy. However, the temperature of PV modules is increased by the absorbed solar radiation that is not converted into electricity, causing a decrease in conversion efficiency. Increasing the temperature of the PV module by 1 °C will lead to a decrease of the solar electrical efficiency of crystalline and amorphous silicon cells by 0.5% and 0.25%, respectively(Skoplaki and Palyvos 2009). Thus, a variety of researches have been done to decrease the temperature of PV panels in order to increase their conversion efficiency. The very first attempt to explore the possibility of using the heat generated on PV panels as usable thermal energy was conducted in the late 70s(Kern Jr and Russell 1978), while the experimental studies utilizing proprietary devices showed up in the mid 90s(Bhargava, Garg et al. 1991, Garg, Agarwal et al. 1994, Bergene and Løvvik 1995).

Although the idea of combining the PV panel and solar thermal collector has shown a lot of advantages, the development and research on commercial PV/T system is slow. The early experimental studies involving PV/T systems were performed by modifying a commercial PV panel with a heat exchanger installed at the back of it(Huang, Lin et al. 2001). During the past few years there have been significant technological advancements concerning all types of PV/T collectors (Daghigh, Ruslan et al. 2011, Ibrahim, Othman et al. 2011, Tyagi, Kaushik et al. 2012) and some commercial products start to show up in the market. At present, four types of PV/T collectors that focus on working media: air(Joshi and Tiwari 2007, Kumar and Rosen

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.10.08 Available at http://proceedings.ises.org

2011), water(Dubey and Tiwari 2008, Chow, Pei et al. 2009), refrigerant(Chow, Pei et al. 2010) (Omojaro and Breitkopf 2013)and heat pipe(Wu, Zhang et al. 2011), are available.

With the low price of PV modules and the high government subsidies, many families in China now choose to install household photovoltaic systems. Meanwhile, most of them have already installed the solar thermal collector systems for domestic hot water (DHW) supply. As the demand for electricity and thermal energy shows up in the same time, in this way, the PV/T system seems to be the most promising renewable energy solution without extending the installation area.

In this paper, A system model is built in TRNSYS and the year-round performance comparison of PV/T (glazed and unglazed), solar thermal and PV system is conducted. The performance characteristics of the four different systems are analyzed to supply the basis for selection of different domestic solar systems.

2. PV/T component model and validation

2.1. Unglazed PV/T component

Type 560 in TRNSYS Electrical Library (TESS) is intended to model an unglazed solar collector which has the dual purpose of creating power from embedded photovoltaic (PV) cells and providing heat to a fluid stream passing through tubes bonded to an absorber plate located beneath the PV cells. It relies on linear factors relating the efficiency of the PV cells to the cell temperature and also the incident solar radiation. The cells are assumed to be operating at their maximum power point condition. Fig.1 shows the heat transfer model of this type and the thermal model of this collector is based on algorithms presented in Chapter 6 of the classic “Solar Engineering of Thermal Processes” textbook by Duffie and Beckman(Duffie and Beckman 1980).

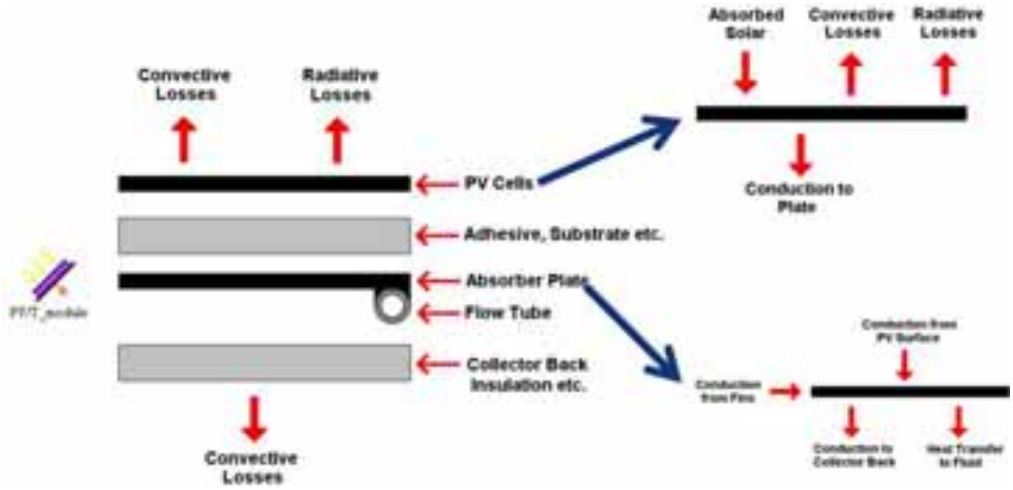

Fig. 1: Heat transfer model of unglazed PV/T component

2.2. Glazed PV/T component

In order to model a glazed PV/T module, a single glaze cover model is appended to the existing model of type 560. The glaze cover heat transfer and solar transmission model is based on the Chapter 6 of the classic “Solar Engineering of Thermal Processes” textbook by Duffie and Beckman(Duffie and Beckman 1980). The new model is complied in Fortran and name type 560b in order to call it from TRNSYS.

2.3. Component validation

In order to validate the two PV/T components in TRNSYS, two PV/T solar collectors were fabricated and tested. The main parameters of the two components are listed in Tab. 1. The experiment system schematic diagram is shown in Fig.2 and the experiment system picture is displayed in Fig.3. The temperatures of the system are measured by a group of PT1000 sensors (A class, error: 0.1 ºC). The water flow rate is measured by an integrating flow meter with an accuracy of ±5% （of reading）. The ambient condition is monitored by a micro weather station (Davis 6152c) and Kipp & Zone CM22 pyranometer , and the accuracies of the

radiation and temperature are ±5%（of reading） and ±0.5 °C, respectively. The power generation of the PV module is monitored by a DC voltage and current sensor with a accuracy of ±5%（of reading）. All the data is captured and handled by a Graphtec GL800 acquision system.

Tab. 1: Main parameters of PV/T components

Collector area (m^2)	2
Nominal efficiency of PV panel (%)	15
Tube spacing(m)	0.125
Tube diameter(m)	0.01
Absorber thickness	0.0003
Glass cover transmittance	0.9
Number of glass cover	0/1
Glass cover spacing (m)	0.03
Temperature coefficient of PV cell efficiency(1/°C)	-0.005
Radiation coefficient of PV cell efficiency($h.m^2/kJ$)	0.000025
Storage tank volume (m^3)	0.15

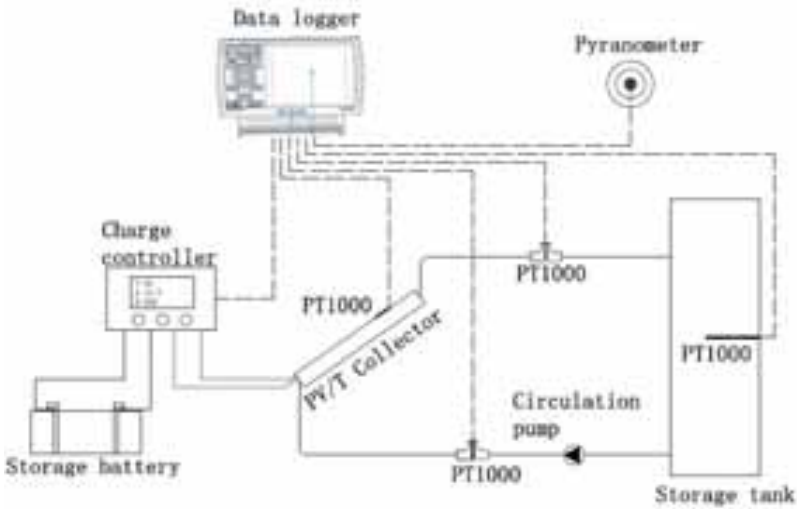

Fig. 2: Schematic diagram of experiment system

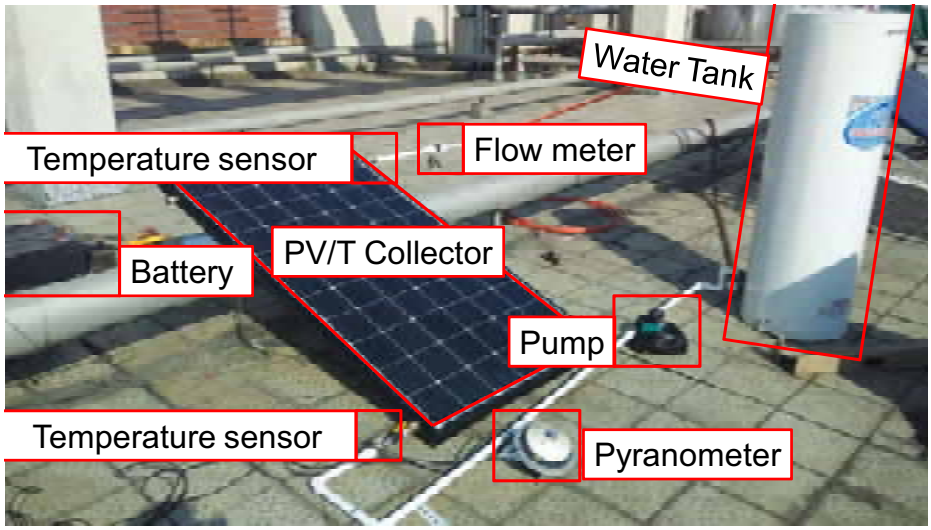

Fig. 3: Picture of experiment system

The experiment was done on June 13th and the ambient conditions including solar radiation intensity and ambient temperature are shown in Fig. 4. The average solar radiation intensity on the titled surface and ambient temperature during the test are 767 W/m^2 and 22.1 ^{o}C, respectively. The initial water temperature in the tank is 20 ^{o}C.

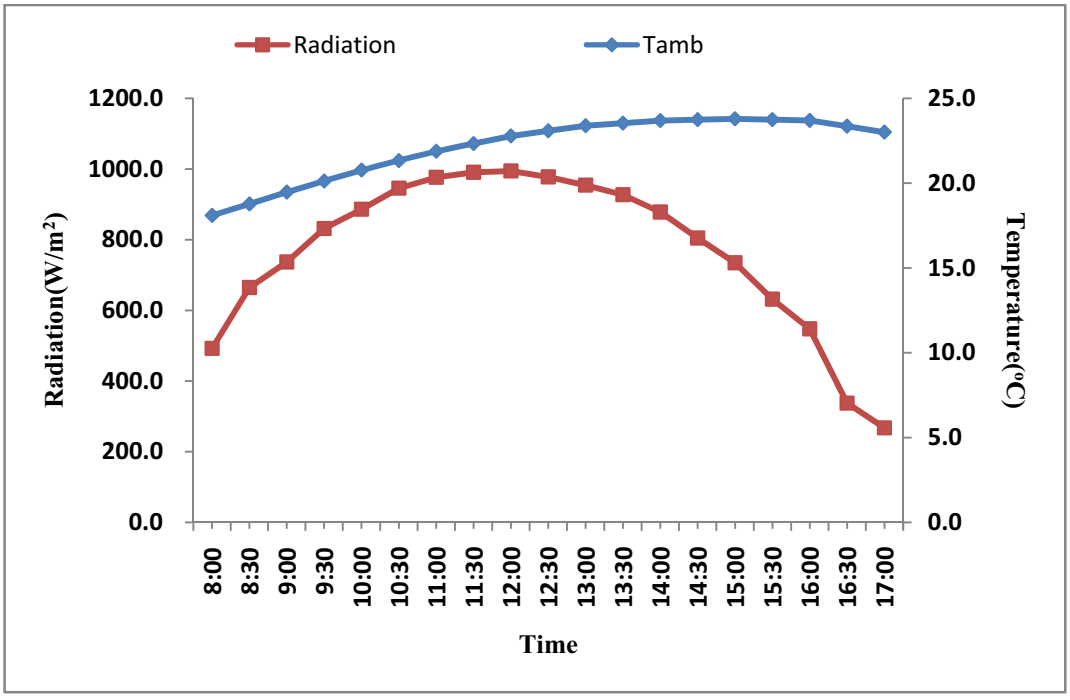

Fig. 4: Ambient condition of experiment

The comparison of electrical efficiency of both systems is shown in Fig. 5. The simulated result shows nearly the same trend with the experiment value. The maximum relative error (RE) of the electrical efficiency is about 8.5% due to the loss of efficiency in MPPT controller.

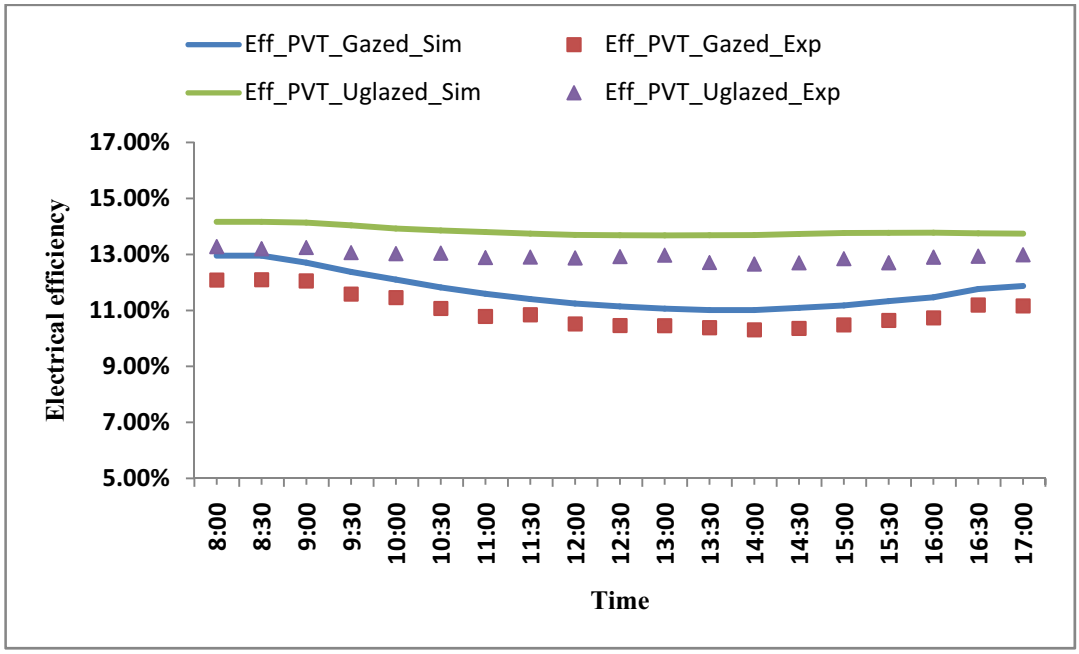

Fig. 5: Comparison of Electrical efficiency between experiment and simulation

Fig. 6 shows the tank temperature between experiment and simulation. The tank temperature started at 20 ^{o}C and rised to 50.1 ^{o}C and 30.3 ^{o}C for the glazed PV/T and unglazed PV/T system respectively. The simulated tank temperature is nearly consistent with the experimental value with a maximum RE of about 12.9 %. The tank loss coefficient is set as a constant in the simulation model but in the experiment, it is influenced by the ambient conditions, such as the wind speed. Furthermore, the loss of pipes and pump is neglected in the simulation model.

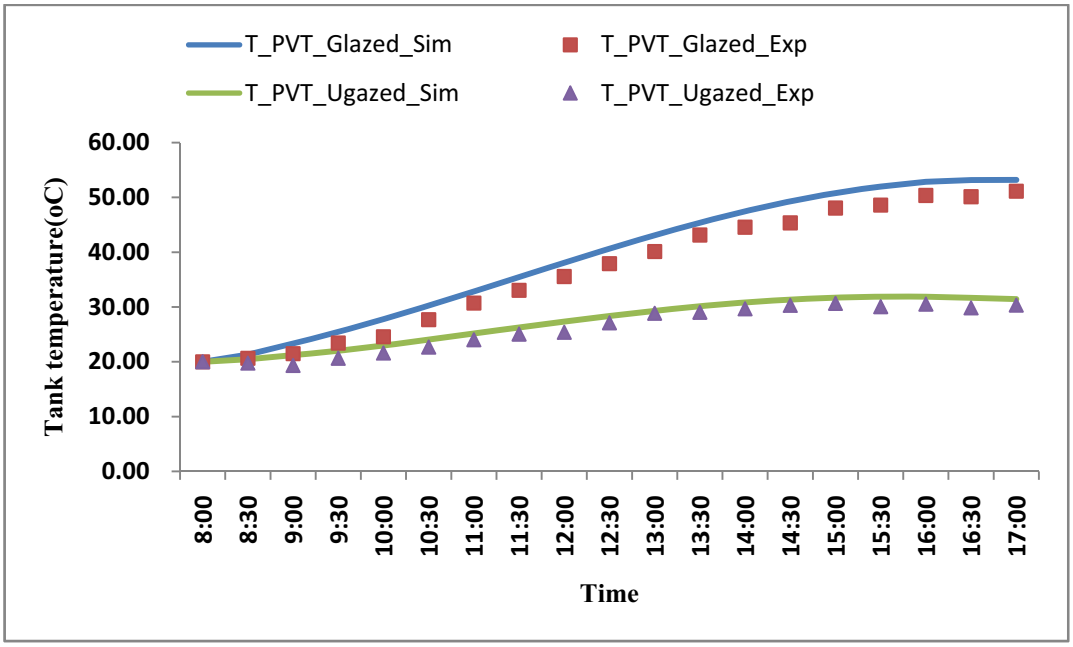

Fig. 6: Comparison of tank temperature between experiment and simulation

3. TRNSYS model description

3.1. System description

In order to make a comparison of the PV/T system performance with the traditional flat plate solar collector

on solar domestic hot water (SDHW) system, three system models with different solar collectors are built in TRNSYS. The schematic diagram of SDHW system is shown in Fig. 7. A diverter and a mixer is set to maintain the hot water supply temperature as 45 °C. An auxiliary heater is applied to provide auxiliary heat when the outlet temperature is lower than 45 °C . The DHW demand displayed in Fig. 8 is a real test schedule of a Shanghai family of 3 people. The peak of DHW load appears in the morning, noon and evening. Furthermore, a traditional PV panel is studied to analyze the difference of electrical performance between PV/T and PV. The main type numbers and parameters of the components in the model are listed in Tab. 2.

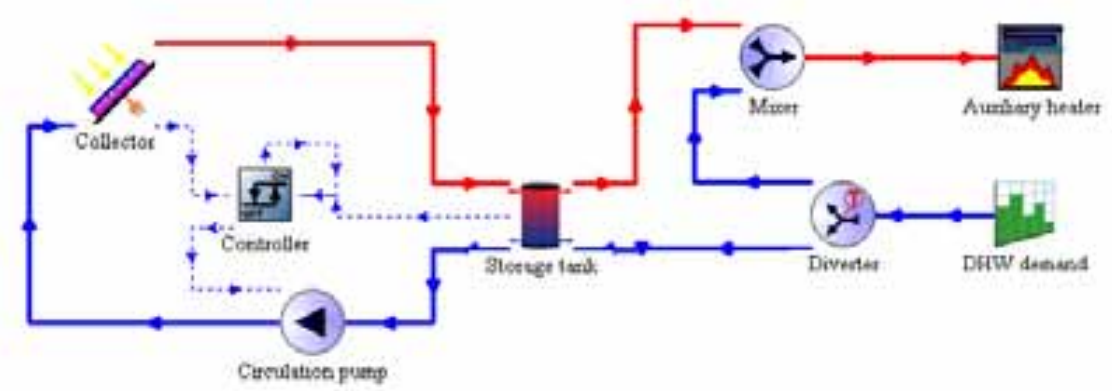

Fig. 7: Schematic diagram of SDHW system

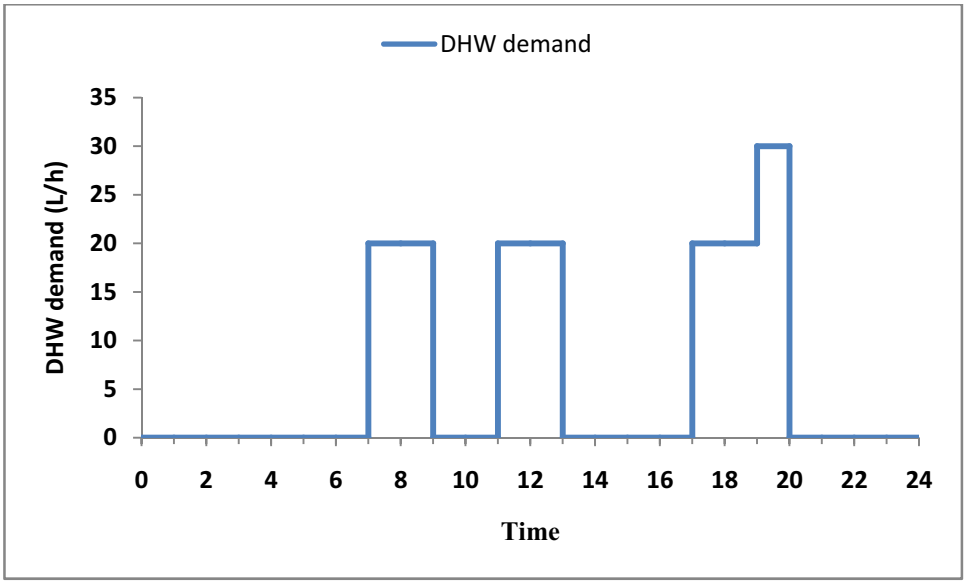

Fig. 8: Schedule of DHW demand

Tab. 2: Main type numbers and parameters of the components

Component name	TRNSYS type number	Main parameters
PV/T (glazed/unglazed)	Type 560b/560	area: $2m^2$ rated electrical power: 300W inclination angle: 30^o
Flat plate solar collector	Type 1	area: $2m^2$ efficiency curve: $\eta = 0.749 - 5.6 * (T_{in} - T_{amb})/G$ inclination angle: 30^o
PV panel	Type 562	rated electrical power: 300W inclination angle: 30^o
Tank	Type 4e	volume: 150L
Circulation pump	Type 3d	rated power: 45 W rated flow rate: 140kg/h
Controller	Type 2b	temperature difference: 8(on)/4(off)
DHW demand	Type 14h	shown in Fig.8
Diverter	Type 11b	
Mixer	Type 11d	
Auxiliary heater	Type 700	

A CN-Shanghai-583670. tm2 (Typical Meteorological Year Version 2) format weather data file is read as the boundary conditions of the simulation model. The replenishment water temperature of the storage tank is set as the mains water temperature, which changes with the ambient conditions seasonally.

3.2 Performance index

For purpose of evaluating the performance of the four different systems, the following performance index is calculated based on the simulated results:

(1) Average thermal efficiency

$$\eta_{th} = \frac{Q_{tank}}{\int A * G_{solar}} \qquad \text{(eq. 1)}$$

(2) Average electrical efficiency

$$\eta_{ele} = \frac{E_{PV}}{\int A * G_{solar}} \qquad \text{(eq. 2)}$$

(3)Solar fraction

$$SF = \frac{Q_{total} - Q_{aux}}{Q_{total}} \qquad \text{(eq. 3)}$$

4. Results and discussion

4.1 Electrical performance

The annual electrical performance of PV/T and PV system is displayed in Fig. 9. Compared with pure PV system, the unglazed PV/T system shows a slight enhancement on the electricity generation and electrical efficiency. The annual electricity output of the unglazed PV/T and PV system are 339.5 kWh and 335.2 kWh, respectively. However, the glazed PV/T system shows a significant decrease in electricity generation due to the high temperature of the PV panel. The annual electricity output of the glazed PV/T is 254.6 kWh, which is 80.6 kWh lower than the PV system. The average electrical efficiency of unglazed PV/T, glazed PV/T and PV system are 12.5%, 9.4% and 12.3%.

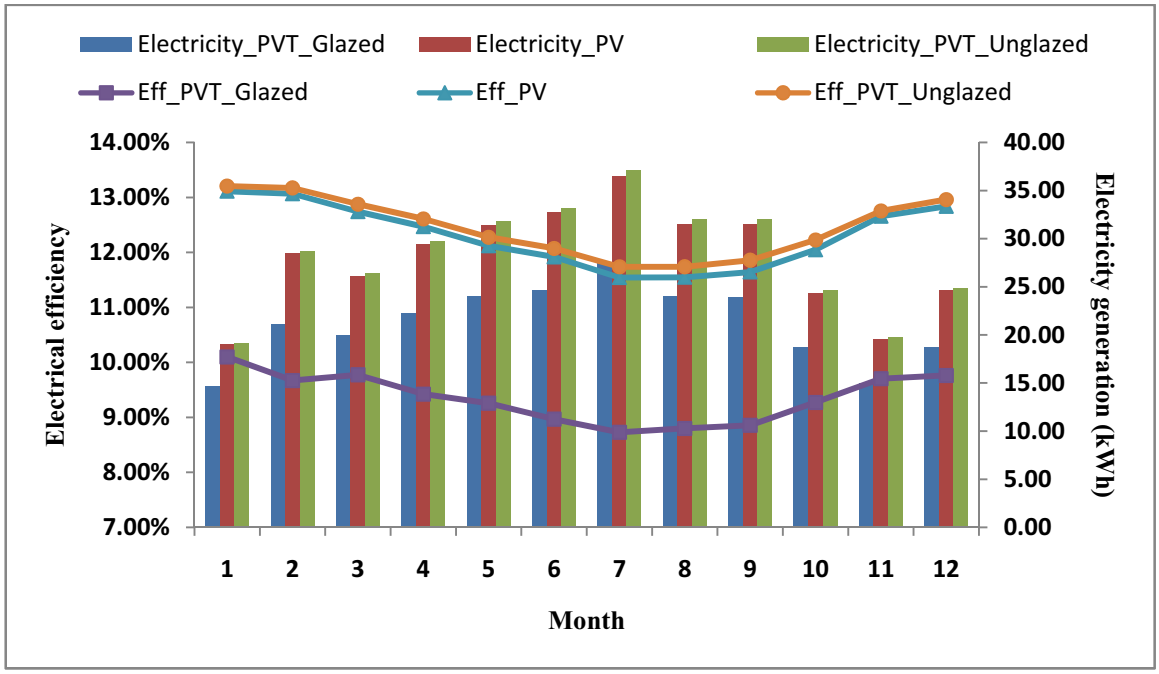

Fig. 9: Annual electrical performance of PV/T and PV system

4.2 Thermal performance

The annual thermal performance of PV/T and flat plate solar collector system is shown in Fig. 10. Because the emissivity of PV surface in the glazed PV/T is much higher than the absorber in flat plate solar collector, the heat collected by glazed PV/T system is 24.2% lower than the flat plate solar collector. The average thermal efficiency of glazed PV/T and flat plate solar collector are 29.3% and 40.0%, respectively. Nevertheless, the heat loss coefficient of unglazed PV/T system is dramatically higher than glazed PV/T system due to lack of glass cover. The PV panel in unglazed PV/T system is exposed to the ambient, so both convection and radiation heat transfer coefficient is significantly higher than the glazed system. As a consequence, the unglazed PV/T system can only supply 806.3 MJ heat for preheating of the SDHW system.

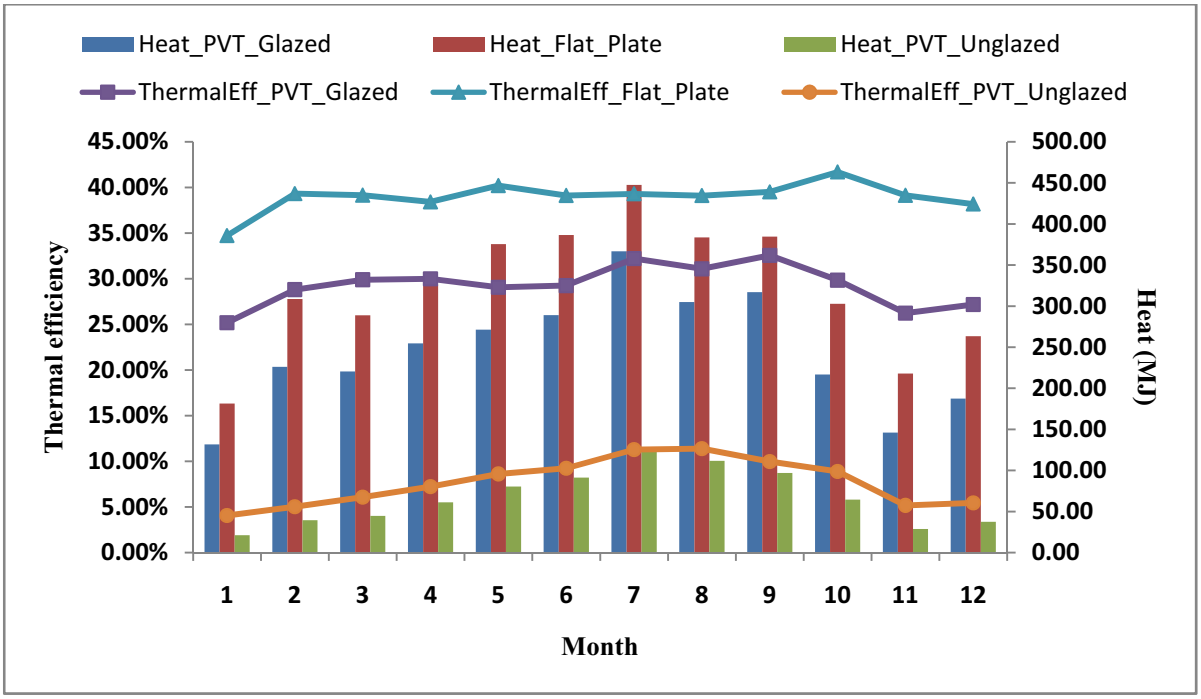

Fig. 10: Annual Thermal performance of PV/T and flat plate solar collector system

4.3 Solar fraction and auxiliary heat

Fig.11 shows the solar fraction as well as the auxiliary heat of PV/T and flat plate SDHW system. For the flat plate SDHW system, the solar fraction (SF) ranges from 26.4% to 95.9% and the annual average solar fraction reaches 60.1%. The required auxiliary heat is about 2907.5 MJ. The glazed PV/T SDHW system shows a similar trend of SF and auxiliary heat with the flat plate SDHW system. The variation of SF is between 19.2% and 80.5% with an annual average value of 45.9%. According to the analysis above, the heat collected in the unglazed PV/T SDHW system can only serve as a preheating, which result in a low average SF of 12.9%.

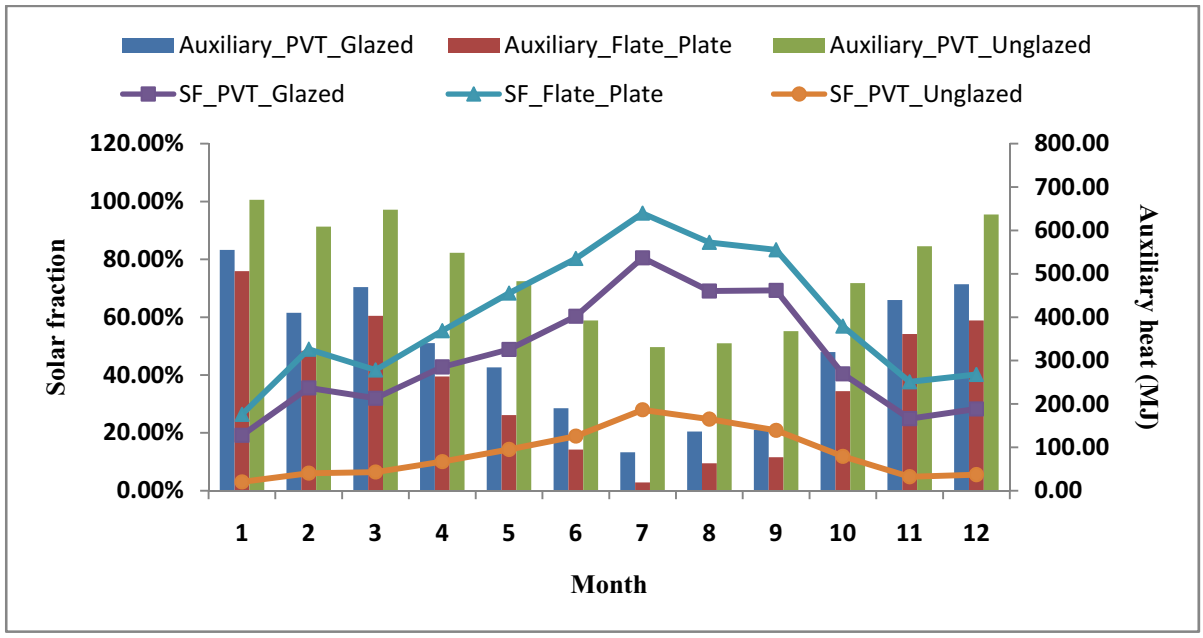

Fig. 11: Solar fraction and auxiliary heat of PV/T and flat plate solar collector system

5. Conclusion

In this investigation, a revised photovoltaic/thermal collector model based on TRNSYS TESS type 560 was developed and validated to do the year-round performance prediction. Three SDHW system as well as a PV models are built in TRNSYS to analyze the electrical and thermal performance of PV/T components applied in SDHW system. The following conclusion can be drawn from the investigation:

(1) According to the validation, the revised model based on TRNSYS TESS type 560 is accurate enough to do the performance prediction of PV/T SDHW system.

(2) Compared with pure PV system, the unglazed PV/T system shows a slight enhancement on the electricity generation and electrical efficiency. The glazed PV/T system shows a significant decrease in electricity generation due to the high temperature of the PV panel. The average electrical efficiency of unglazed PV/T, glazed PV/T and PV system are 12.5%, 9.4% and 12.3%.

(3) The heat collected by glazed PV/T system is 24.2% lower than the flat plate solar collector because of the high emissivity. The average thermal efficiency of glazed PV/T and flat plate solar collector are 29.3% and 40.0%, respectively. As a consequence of high heat loss coefficient, the unglazed PV/T system can only supply 806.3 MJ heat for preheating of the SDHW system.

(4) For the flat plate SDHW system, the annual average solar fraction reaches 60.1%, resulting in an auxiliary heat of 2907.5 MJ. The glazed PV/T SDHW system shows a similar trend of SF and auxiliary heat with the flat plate SDHW system. The variation of SF is between 19.2% and 80.5% with an annual average value of 45.9%. The SF of unglazed PV/T SDHW system is 12.9%.

(5) Based on the view of comprehensive utilization of solar energy, the glazed PV/T system seems to be a more promising solution in SDHW system.

Abstract

Many developing countries use biomass as their primary energy supply. Unwise utilization of biomass affects the environment, health and safety of women and children in particular. In addition, it causes indoor air pollution, which is a reason to the deaths of millions. This paper demonstrates solar cooker with an integrated PCM thermal storage and heat transportation loop suitable for high temperature applications. The system is designed to particularly suite *Injera* baking application. *Injera*, a yeast-risen flat bread type is the most common staple food type served three to four times a day in Ethiopia. A similar food type is also eaten in, Eritrea, Somalia, Sudan and Yemen. The system storage has a capacity of about 250ºC and retains the heat for about two days. The storage is coupled polar mounted concentrator with fixed receiver and steam heat transfer fluid. The steam circulates naturally between the evaporator and condenser in a closed loop. The study has demonstrated indirect charging, simultaneous charging-discharging and discharging of the stored heat. The frying pan is a custom-made aluminum plate casted by embedding a 10mm coiled stainless steel steam pipe as heating element. The pan is 500mm in diameter and 30mm thick, and the fins are 20mm in diameter and 140mm long. The fins are immersed into a 20kg PCM, which is coupled to a 1.8m diameter parabolic dish collector. The solar fryer demonstrates Injera baking for average family size on top of a heat storage charged by a solar energy. This baked Injera able to cover three to four days food consumption of the family.

Keywords: *solar energy, solar cooker, solar Injera baking, parabolic dish cooker,*

1. Introduction

1.1. Background on solar cooker and thermal storage

Many developing countries use biomass as primary energy supply for their household's energy consumption. This energy in return affects the environment, health and the livelihood development of the people. In these countries women and children are often in charge of fetching firewood and cooking, in which they spent most of their valuable energy and time traveling long distance in search of this fuel. In addition, they are also the most affected from indoor air pollution from this energy and traditional cookstoves.

On the other hand, the progress of solar cookers technology is very slow in spite of their benefits. One reason for this can be lack of integration between social and technology researches. Secondly, the outreaches of these cookers often do not consider the active participation of end users. Moreover, many studies of solar cooker focus on direct cooking and with low temperature heat storage for low temperature applications.

Many developing countries, which are dependent on biomass, have huge potentials of solar energy that can potentially substitute the role of biomass. However, solar energy technologies have rarely introduced in these places. Moreover, solar thermal technologies in general have not reached a robust stage of mass production and distribution. Although some countries have introduced solar box cookers, their success has been limited due to technological and social factors in which none of the cookers enabled night cooking and indoor use. Such technical limitations also affect users' norm of cooking, which may cause a social ban on the adoption

doi:10.18086/swc.2015.10.09 Available at http://proceedings.ises.org

of new technology.

To improve acceptance of solar cookers and assure their widespread use, a continuous improvement in technical development, social awareness and thermal storage is required. Thermal energy storage helps to store the surplus energy during the day and keep it for late evening use. In addition, it helps to supply nearly uniform heat during the process of cooking. Some solar cooker design features allow charging and discharging simultaneously. For example, A. Lecuona et al.'s solar cooker could cook family lunch while charging the storage simultaneously [1]. The stored heat of this cooker allows dinner cooking and breakfast heating for the following day. Such design features help to expand the acceptance of solar cooking. Another solar cooker design, which used heat pipes, flat-plate collector and integrated indoor phase change material (PCM) storage, was able to cook food at noon, evening and keep the food warm at night and the following morning [2]. The solar fryer in this paper will solve these barriers and enable users to perform any time indoor cooking practice. The use of PCM storage for cooking is increasing and diversifying with time. For example, H.M.S. Hussein et al. [2] have tested a PCM storage coupled to flat plate collectors for indoor cooking and heating of food during the evening. In addition, A. Lecuona et al.'s [1] portable solar cooker with PCM storage enables day and nighttime cooking.The purpose of this paper is therefore to design an indirect solar cooker with latent heat storage, which is dedicated for baking the Ethiopian food called Injera.

Injera is yeast-risen flat bread with slightly spongy texture. It is the most common food type, which is served three to four times a day. Similar food type is also eaten in, Eritrea (Injera), Somalia (Canjeero), Sudan and Yemen (Lahoh) [3]. Injera is used to bake on a clay stove called "Mitad". The baking process demands a significant amount of energy, which mainly comes from biomass as most of the populations live without access to electricity. The biomass based Injera kitchen is full of smoke and soot that affects the health of millions. The solar stove designed in this study has tried to give a solution for this acute problem.

2. Materials and Methodology

2.1. Heat storage

The heat storage in this paper is designed to accommodate 20 kg of solar salt (nitrate salt mixture of 40% KNO_3 and 60% $NaKO_3$), which is sufficient to supply heat for an average household size. This PCM is selected based on the baking temperature requirement of Injera. The storage configuration contains a baking plate with embedded stainless steel steam pipe and down going aluminum fins. These fins are design to transport optimal conduction heat to the PCM. This design halts any direct contact of the steam and the PCM. More over the storage has a 10% vacant space to avoid any pressure development and volume variation during phase transition of the PCM. The schematic of the whole system is given in Fig.1. The thermosyphon loop is designed to simplify the heat transfer mechanisms over long distances.

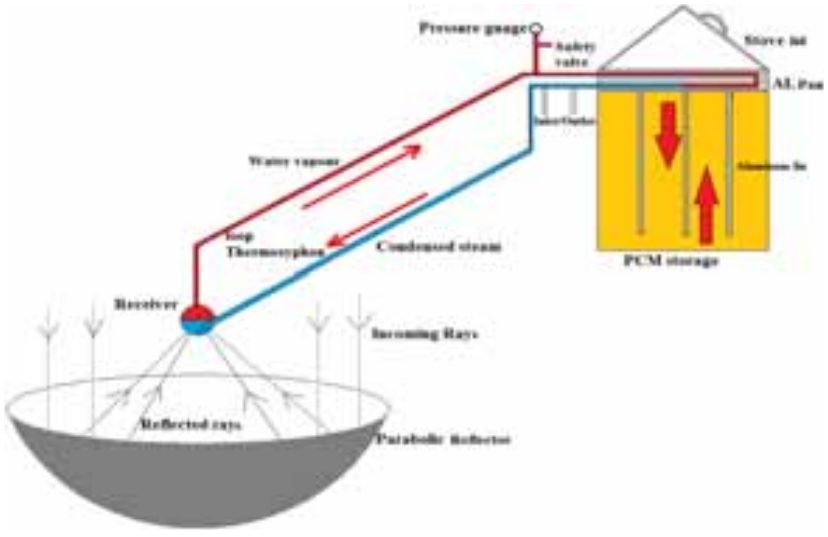

Fig.1: Schematic of the developed system

The frying pan has an embedded stainless steel (SS) steam pipe, which is the heating element of the system and it resembles a heating element of modern electric stoves. The system was coupled to 1.8m parabolic dish collector filmed with alando solar reflector. This system was tested at Mekelle, Ethiopia (13°28'48.30"N latitude). The concentrator design used polar mounted reflectors with fixed receiver philosophy. The list of sensors and equipments used during the experiment this research is given in Table 1.

Table 1: system components

Label	Description	Label	Description
A	Pressure relief valve	F	Inlet, out let and directional control valves
B	Pressure gauge	G	Parabolic dish reflector
C	Tracking sensor	H	Data logger
D	DC motor	I	K-Type Thermocouples
E	Solar PV source	J	Receiver

2.2. Parabolic dish concentrator design

In solar power generation, the use of pressurized steam is a common practice. However, its use for small-scale application such as cooking is rare. In fact there exists some large-scale steam solar cookers; however, they use low-pressure steam. For example, Scheffler steam rice cooker uses steam in the range of 3bar. On the other hand, high-pressure steam solar cookers are not commonly used due to their technical and safety concerns while generating the steam.

a) Collector design

The fixed receiver of this concentrator was used to generate steam and in return this steam was used to charge the heat storage. Parabolic dishes can be manufactured from optimized petal shaped sheets with due attention on precision design and manufacturing as studied by Lifang and Steven [4]. The other and easier way to get parabolic dish for solar concentration purpose is to customize existing satellite dishes by filming them with appropriate reflector materials. The parabolic dish used in this paper is a six petal satellite dishes. The dish is filmed with a self-adhesive aluminum reflector, Miro high reflective 95 and thicknesses of 0.5mm.

b) Receiver design

The receiver used in this research is developed by welding of two cylindrical cups of black steel. The cups have 100mm diameter, 5mm thickness and 40mm height. Figure 2 shows the actual pictures of the receiver during experiment. Random temperature measurements in the illuminated area of the receiver lie between 300 to 1150°C. However, larger part of the receiver is exposed to radiation loss.

Figure 2 Receiver of a parabolic dish collector

c) Thermal performance

The thermal efficiency of the system is given by the ratio of the useful energy stored to the energy incident at the concentrator's aperture. The storage energy is the sum of the energy stored in the PCM and in the aluminum fins. Hence, the thermal efficiency of the system is computed by:

$$\eta_{th} = \frac{c_{Al} m_{Al} (T_f - T_i) + m \int_{T_i}^{T_f} c_p dT}{A_a I_B} \quad (1)$$

Where cp is the effective heat capacity of the PCM

Both normal and diffuse radiation enters the aperture area of any solar collectors. However, in concentrating collectors only the direct radiation can be focused on the receiver.

The thermal analysis of the system was performed only for its solid phase sensible heat-storing ability as it was not fully charged. The systems reached 187°C as maximum temperature of the storage during the experiments of this paper. Therefore, the thermal performance for this test was found 23%. The performance of the systems was affected by non-smooth manual tracking, dust on the reflector and some damages on the collector as shown in Fig. 3, which affect its focusing. In addition, this system was exposed to higher wind speed, which resulted in higher convective heat loss from its receiver and the system as whole.

d) Tracking mechanism

The system used a gear mechanism auto tracker to track the sun in the east-west direction. The tracker has 50kg carrying capacity and use 9V DC motor driver. The motor gets its power from a 10W PV source. The gear ratio of the motor is 1:600 and its shaft runs at 9 rpm. This speed is further reduced in to a 1:10 gear ratio to transfer the required torque to track the collector. This speed of the motor allows the mechanism to catch up the position of the sun in case the sun comes out of longer time stay in clouds. A light diode and a shading device control the motor. The reflector starts to track the sun automatically until the sensor becomes perpendicular to the sun radiation. Tracking happens when the sun shines and if there is no sun, there is no tracking.

e) Insulation

Aerogel and Rockwool insulations were used to insulate the storage and the steam pipelines respectively. The insulations maximum working temperature is about 650°C and the maximum working temperature of the system was set to 250°C (by adjusting the pressure relief valve) and the design thickness of the insulation is 25mm for the heat storage and 50mm for the steam pipeline. The insulations thermal conductivity is 0.03W/Km and 0.07 W/Km respectively and they have the same surface emissivity of 0.05.

f) Pipe lines

The steam pipeline is 10mm in diameter and 1mm thickness. This pipe is used as a pipeline of the thermosyphon loop and as a heating element for the frying pan. The pipe has 100bar design pressure and is used for 40bar working pressure. The pipeline used Swagelok connectors and valves. A pressure gage is used to measure the pressure of the steam and regulated with the help of a safety valve that reliefs the pressure when it passed the pre-set value (40bar). The pipeline was used to flash before the beginning of every experiment to avoid air inclusion.

3. Results and discussion

The storage integrated solar fryer developed in this research is shown in Fig. 3 and 7. The polar mounted concept eases the demand of tracking mechanism in the secondary axis. The fixed receiver was found suitable for steam generation. The steam circulates between the evaporator (receiver) and frying pan (condenser) in a closed loop naturally. The steam carries the heat from the receiver and drops it on the frying pan (casted aluminum plate). The fins attached to this plate in return carries this heat to the PCM by conduction. The unit was tested for simultaneous charging-discharging, discharging of a fully charged storage and discharging of

partially charged storage (cloudy day). The solar radiation used when analyzing the system thermal efficiency is shown in Fig. 3(b).

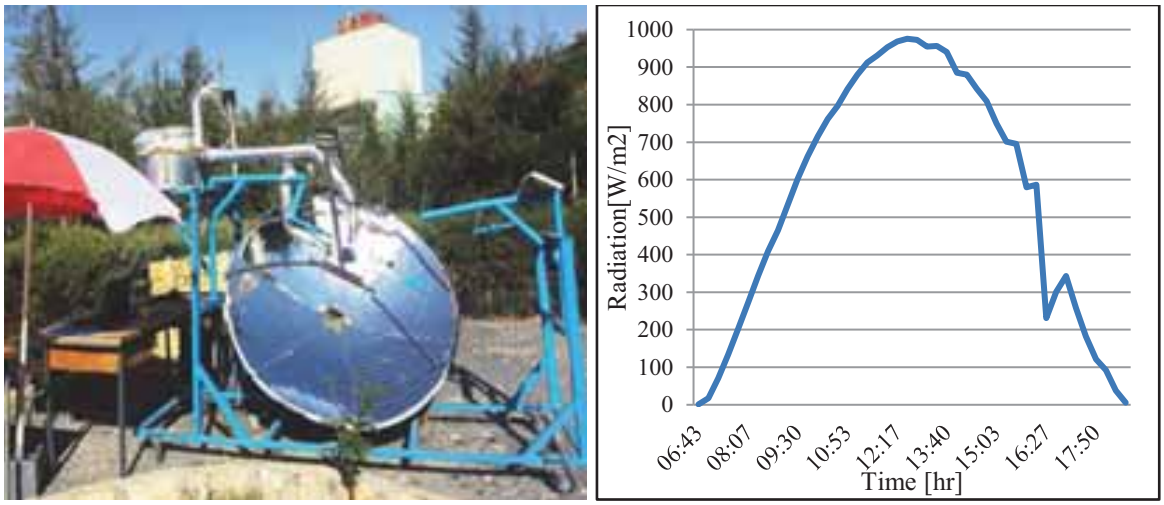

Figure 3: 1.8m parabolic dish collector with PCM storage (Mekelle Unit) Figure 1: Global solar radiation of Mekelle on 27-02-2014, when the stove reach 187°C

The storage charging process has simulated using COMSOL multiphysics 4.3. In this simulation a 20kg of solar salt with circularly rolled plate fins instead of many cylindrical fins. The 2D and 3D simulation results show the 20kg solar salt storage is fully charged in about seven hours, when a 250°C continuously circulating steam is used to charge. The simulation considers a constant loss of 15°C from the storage. The fins assumption has reduced the overall charging time of the storage. The simulation has shown the charging of the PCM found between two fins is very quick; however, the PCM adjacent to the storage wall and bottom changes its phase very slowly. This simulation result suggests to half the dimension of the gap between the fin and the storage wall (side and bottom). Therefore, the PCM thickness between the fin and the wall should be 20mm. Moreover, it was found rolled plate fins charge the PCM faster than rod fins. In addition to the PCM charging development, the simulation has also run to show the thermal resistance effect of the SS pipe wall on the frying pan as shown in Fig. 4(b).

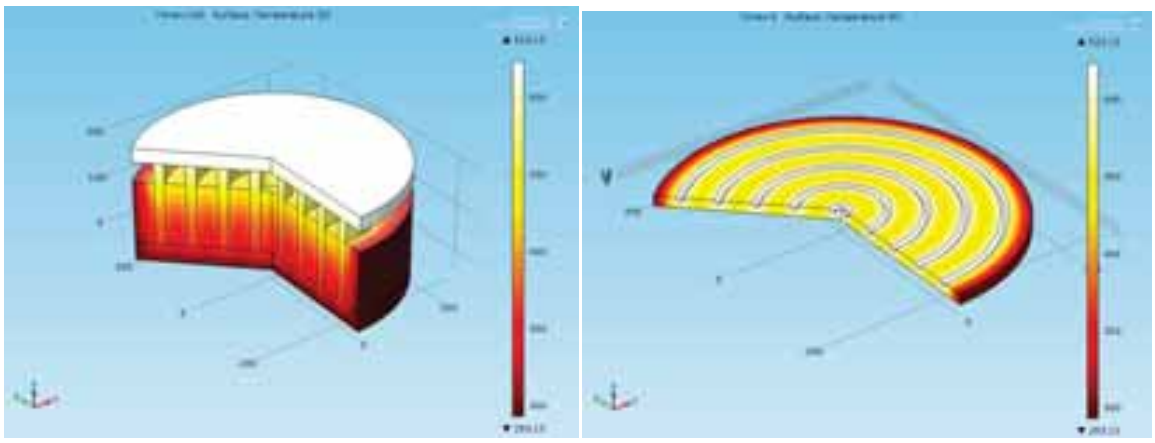

Figure 4: COMSOL simulation of a) PCM charging and heat transfer between SS and aluminum wall, b) frying pan with embedded SS steam pipe

3.1. Simultaneous charging-discharging

In this system, when the collector starts focusing the radiation on the receiver, the regulated water inside the receiver starts boiling and a vapor at low temperature starts circulating in the closed loop of the thermosyphon loop. In the first day of the test, the stagnation temperature of the system was not reached the melting point of the PCM. Though, the storage was tried to be charged in successive days using the advantage of the PCM's heat retention ability this did not help to charge the storage fully, this was probably mainly due to the huge

heat losses from the receiver.

The test was then preceded to a simultaneous charging-discharging during the peak hours of solar radiation. When simultaneous charging-discharging test was started, the circulating steam and temperature was 160°C and 150°C respectively. During this test the intended application, Injera and bread baking, was perfect regardless of literature values. When baking was started, the circulating steam and the storage have experienced a sudden drop of temperature. However, the temperature has slowly recouped during the baking period. Figure 5 shows the baking and charging behavior of the system during simultaneous charging-discharging.

In the first cycles, the progress of the storage temperature was very slow, because it took extended time to took the food from the frying plate. And this was accompanied by large losses from the baking surface. However, when this time was reduced by improving the baking surface interaction baking surface as shown in the last two cycles of Fig 5, the baking speed and storage temperatures have improved.

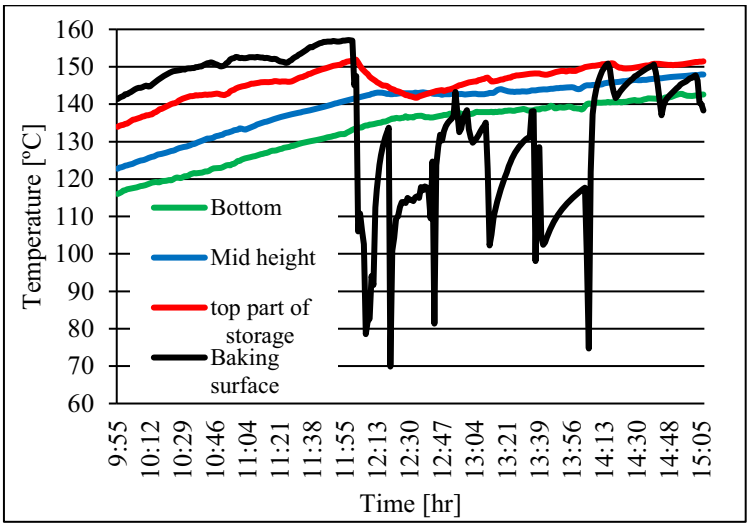

Figure 5: PCM charging and baking practice simultaneously from the sun

In the beginning of Injera baking on this stove, the surface texture of the frying pan was rough and it stacked the Injeras. Taking out the baked Injera from the surface of the frying pan was a big challenge. In addition, the quality of the Injera was not attractive. To avoid the sticking impact of the aluminum-baking surface, a borosilicate glass has been placed on top of it, but the Injera quality remained unattractive. However, the frying pan was suitable for bread baking. Simultaneous changing-discharging process helps to utilize more energy during the day. However, the storage charging process took more time as the inlet heat splits in to charging and baking.

a. Discharging of a fully charged PCM storage

In this study, an artificial resistor heating element was coiled around the receiver in order to melt the salt fully. The heating element has been delivering a uniform and regulated heat. The heating element was set to a maximum temperature of 450°C, at which it was delivering an average power of about 700W to the receiver. This power was equivalent to the solar power supply obtained from a 1.2m parabolic dish concentrator with 80% optical efficiency and $800 w/m^2$ average beam radiation. The storage took about eight hours of phase change duration.

The stored heat was tested to bake Injera and bread needs of average household size, i.e. 19 Injeras and six breads. The stored heat was run for about four hours of intensive baking and the remaining heat was left to discharge naturally while it was still capable of performing another cooking. The Injera baking speed of this test was faster compared to ordinary electric and biomass stove baking speed. In the baking process, the Injera consumes the phase transition heat. And the bread baking process consumes sensible heat of the solid PCM. The nearly uniform temperature drop with short baking cycle during Injera baking cycles shows the role of the heat buffer/storage to perform isothermal practice. The sticking problem of the baking surface has been improved with continuous heating and polishing with oil. Consequently, the baking process and the quality of

the Injera's were improved.

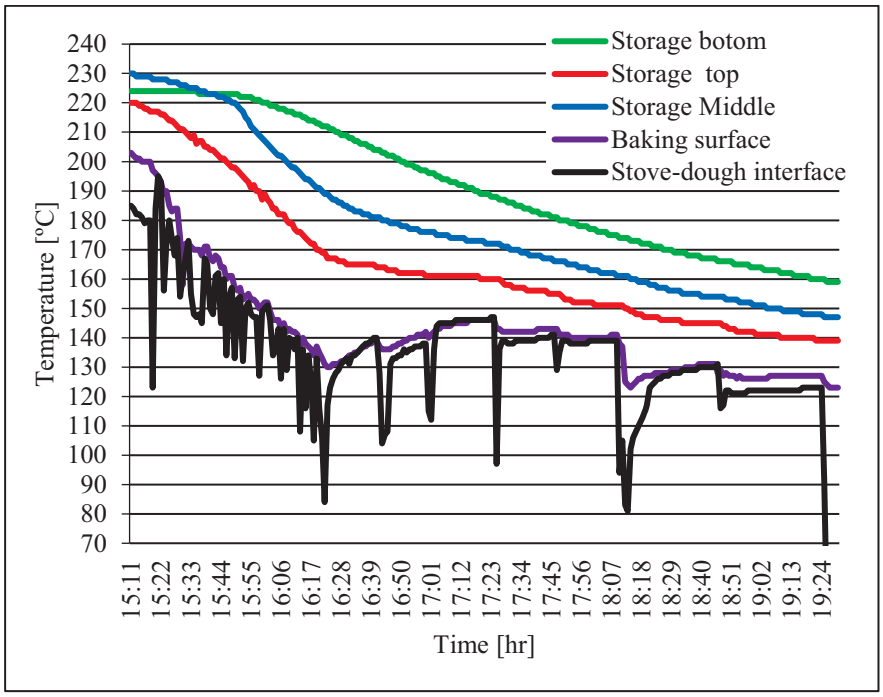

Figure.6: PCM discharging through backing

b. Discharging of partially charged storage

The third practical test for this system is to prove if it works for cloudy seasons; when the available radiation is not capable to melt the salt. Successive Injera baking tests were performed from a partially charged storage. The baking tests show smooth baking process with very good Injera quality, which is the same as the quality of Injera baked on customary Injera stove as shown in Fig. 7. This system has smooth baking surface texture similar to the ordinary stove and it used oil seeds to polish it. Unlike oil, oil seeds have the ability to give smooth baking surfaces by filling its irregularities.

Figure 7: Injera baking process and the final Injera quality

This system has been giving demonstration of solar Injera baking to local media, Mekelle University communities, and external guests. The demonstration has impressed many students, internal and invited

professors from six universities, media and to the university community at large. In addition to the routine solar Injera baking on test demonstration, one planed demonstration was arranged. The aim of this demonstration was to create awareness how solar energy was able to bake Injera and cook the different common Ethiopian dishes. The university community has appreciated the innovation of the research's role in mitigating climatic and health problems caused from extensive use of biomass fuel during Injera baking and cooking processes. Figure 17 shows the Injera baking process, which includes polishing, pouring, and taking off and the final Injera.

The Injera baking cycles plotted in Fig. 8 shows the Injera baking process was taking on average three minutes per cycle. This graph indicates another important point, i.e. during Injera baking; it is not the surface temperature that matters most but also the heat transfer. In many of the experiments, the baking surface temperature was unbelievably abled to bake Injera as low as at 60 and 80ºC. For instance, nearly all of the Injera baking cycles shown in Fig. 18 are below 110°C. This result is very attractive compared to literature values (180-220°C), which can possibility revolutionized the stove technology.

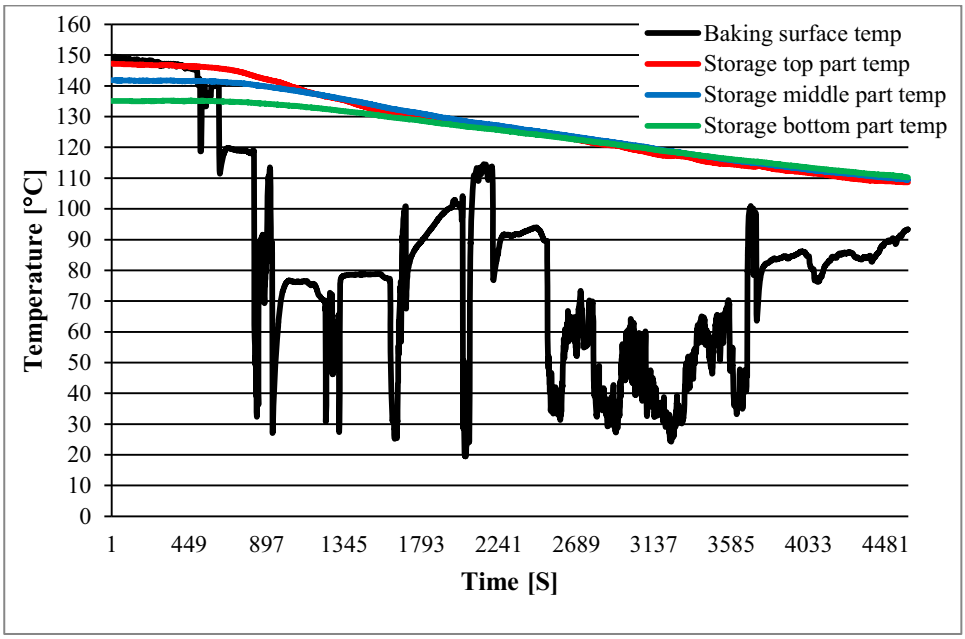

Figure 8: Injera baking from a partially charged PCM storage

Figure 9: serving solar prepared meal

Conclusion

A concept for Injera baking (Ethiopian bread) on top of a heat storage charged from a solar concentrator has been developed and demonstrated. Heat transfer by a thermosyphon principle, with water as the working fluid at about 40-bar pressure. Vapor is generated at the heat absorber in the focus point of the parabolic concentrator and condenses in coiled tube, which is casted into an aluminum baking plate. The baking plate has heat-conducting rods extending into a latent heat storage ("solar salt", Nitrate mixture). The following conclusions can be noted: Injera can be baked on an aluminum surface, provided the surface is sufficiently smooth and otherwise prepared similarly as for the traditional clay based pan during the frying process. Injera can be baked at lower temperatures (110-150°C) than previously assumed (180-220°C), as long as sufficient heat transfer can be maintained during the baking process. The required temperature will then depend on the material of the baking plate. A boiling/condensing natural circulation loop (thermosyphon) is feasible with water as the heat transfer fluid. As the water volume is small, the high pressure is manageable but requires high quality pipe and valve components. A boil-off startup procedure is operationally easy. The system can be optimized with respect to losses in the heat transfer loop, in particular at the absorber. The absorber is a spherical boiler in a fixed position, with the solar illuminated area moving from one side to the other during the daily sun tracking.

Night Radiative Cooling With Unglazed PVT-Water Collectors: Experimental Results and Estimation of Cooling Potential

Jose I. Bilbao[1] and Alistair B. Sproul[1]

[1] University of New South Wales, Sydney (Australia)

Abstract

A PVT-Water collector was built and tested 24 hours per day during a period of six months in Sydney, Australia. The results provided enough experimental data to accurately build and tune a PVT model of the system in TRNSYS. The experimental setup included a pyrgeometer used for the calculation of the radiation losses to the sky. This article presents the experimental results obtained during the night radiative cooling periods and results from simulations carried out with the tuned TRNSYS model for the estimation of the sky cooling potential for this application. The results show that the unglazed PVT water system can achieve good levels of night cooling (around 750 Wh/m^2 of cooling per night during summer months) with radiation losses accounting for circa of 60% of the total cooling achieved and convection losses for 40%. Simulations show that similar night radiative cooling levels are obtained for other climates with minimum of 400 Wh/m^2 per night in Singapore to around 900 Wh/m^2 in Tucson, Arizona.

Keywords: *Sky Cooling, Night Radiative Cooling, PVT-Water*

1. Introduction

The use of night radiative cooling has been explored (Robinson and Sharp, 2012) and tested (Hamza et al., 1995) in several systems and applications, particularly in the cooling of buildings using PVT systems (Fiorentini et al., 2015; Yong et al., 2015). However, most of the examples found in the literature are carried out without accurate measurements of the sky temperature (except for Eicker and Dalibard, 2011), so estimations of the effective sky temperature are used instead. Unglazed PVT systems, either using air or water as the working fluid, are particularly well suited to provide radiative cooling due to the non-selective nature of the absorber (solar cells). However, limited information can be found in the literature regarding the portion of cooling provided by convection losses and by radiation losses. In the case of PVT air systems, the total cooling obtained can sometimes be mixed with the effects of ventilating a building using cooler ambient air, also known as night purging. On the other hand, in PVT water systems the portion of cooling done by convection and radiation losses of the absorber can be calculated directly.

This study uses high resolution experimental data (one minute) to tune and validate a TRNSYS model that has shown to produce very good levels of accuracy (Bilbao and Sproul, 2012), which in turn is used to simulate the potential of radiative cooling in different climates. The aim of the study is to provide a first comparison between experimental and simulation results and a detailed analysis of the night radiative cooling potential of unglazed PVT-water modules using a validated model. The measured data and simulations show promising results for night radiative cooling. However, further work is required and more and better sky temperature measurements are required across the world to properly assess radiative cooling.

2. Method

An experimental setup was built at the University of New South Wales (UNSW), Sydney, Australia. The setup involved a PVT water system, a weather station and a 24/7 data logging system. The weather station included a pyranometer for measuring solar irradiance and a pyrgeometer for the calculation of the sky

doi:10.18086/swc.2015.10.10 Available at http://proceedings.ises.org

temperature, both installed on the plane of the PVT system (34° tilt and 7° azimuth). The experimental data was used to tune and validate a steady state PVT model developed in TRNSYS by the authors (Bilbao and Sproul, 2012), called Type850. The model is capable of taking into account the sky temperature for the accurate calculation of radiative thermal losses to the sky.

The validated model was then used to estimate the night radiative cooling potential on different climates for rooftop PVT installations in TRNSYS. A detailed description of the experimental setup and the validation process is presented below.

2.1 Experimental Setup and Data Quality

The experimental setup uses a closed circuit water system connecting the PVT water module with a 100 liters storage tank. A frameless Siemens PV module (SM110) was used to build the PVT-water module using a fully wetted collector. The system is completed by a pump which maintains the water circulating between the PVT module and the tank 24 hours a day, unless a stagnation experiments is being carried out. This setup provides a natural way of 'resetting' the system each day, by releasing to the environment the thermal energy stored in the tank during the day, via night radiative cooling using the PVT module.

Table 1 shows all the sensor and logging equipment used for the experiment. Uncertainty calculations for the measurements and a more detailed description of the experimental setup can be found in Bilbao and Sproul (2015).

Table 1 – Measurement Equipment used in the Testing Rig

Type and Model	Measurement
Thermocouple 1	Inlet temperature (°C)
Thermocouple 2	Outlet temperature (°C)
Thermocouple 3	Lower end of PVT module, between PV module and collector (°C)
Thermocouple 4	Top end of PVT module, between PV module and collector (°C)
UCC Flow Meter DFC9000	Flow rate (pulses)
Hukseflux Pyranometer SR12	Global irradiance at module plane (W/m^2)
Hukseflux Pyrgeometer IR02	Far infrared radiation at module plane (W/m^2)
Vaisala Weather Transmitter WXT520	Ambient Temp (°C), Wind Speed (m/s), Relative Humidity (%), measured two meters above PVT module
dataTaker DT505	Log PVT data (currents, voltages, temperatures, and flow rate)
dataTaker DT80	Log weather data

Much care was taken in designing and building the experimental setup in order to collect as much data as possible. However, there were small problems during the six months the system was collecting data, from sensors, to the PVT module, to the pump, that impeded the logging of good quality data during the whole period. Thus, only days with a full data set were used for this publication, as shown in Table 2, which are equivalent to four months of full data.

Table 2 - Number of days with good quality experimental data

Data	Jan 12	Feb 12	Mar 12	Apr 12	May 12	Jun 12	Total days
PVT – PV	30	29	23	3	22	30	137
Irradiance	31	29	31	22	26	30	169
Sky Temp	13	29	31	19	24	30	146
Total days	**13**	**29**	**23**	**3**	**22**	**30**	**120**

A summary of the weather data (POA solar irradiance, daily average dry bulb temperature, and daily average sky temperature) obtained during the months of the experiment is shown in Fig. .

Fig. 1: Summary of Weather Data

2.2 Tuning of the model and experimental validation

The tuning and validation method consisted in an iterative process using theoretical values as a starting point for each parameter in the model. Selected parameters of the model were varied on each iteration and the residuals against the experimental results calculated. The electric parameters were fitted first (efficiency and temperature coefficient of the PV cell) followed by thermal parameters (heat loss coefficients and total heat transfer coefficient between the absorber and the fluid, $U_{pv\text{-}f}$).

The theoretical values used for the parameters provided acceptable results in thermal and electrical outputs with mean bias errors (MBE) below 2%. Hence, only few parameters were fine-tuned resulting in a MBE of -0.4% and a coefficient of variation for the root mean square error (CVRMSE) of 9.8% for the electrical output, while for the thermal output the best result obtained was an MBE of 0.1% and a CVRMSE of 16.3%. However, for this study the thermal output and thermal losses of the PVT system are most relevant for evaluating the night radiative potential. A linear regression (see Figure 1) for the thermal losses shows good agreement between the experimental data and the model with an R^2 of 0.96 for hourly data, which confirms the good performance of the model.

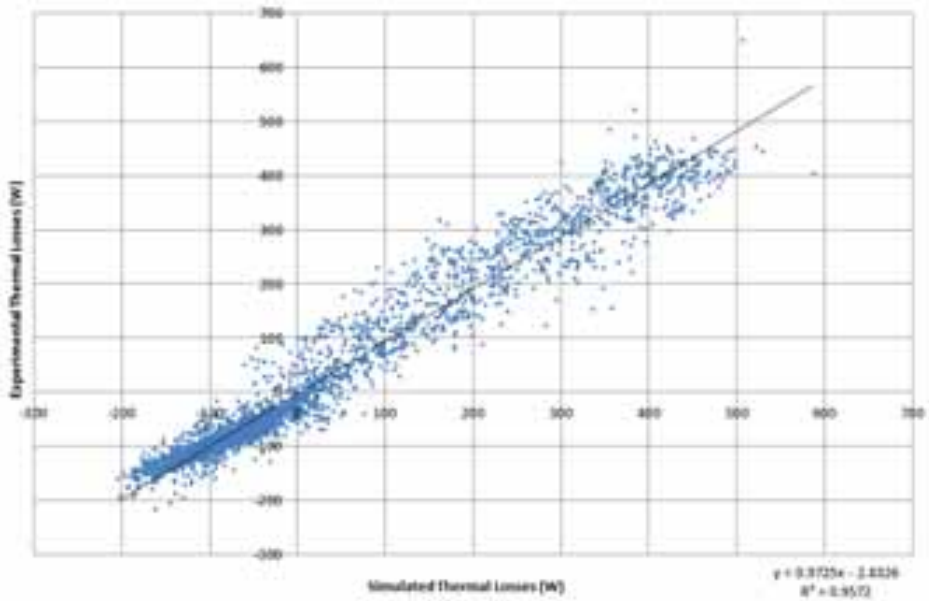

Fig. 2: Comparison of Simulated Thermal Losses (TRNSYS Model) and Experimental Thermal Losses

2.3 Annual Simulations for Different Climates

Simulations were carried out using TRNSYS 16. The tuned model Type 850 was selected for the PVT-water module (of 1 m^2) in conjunction with standard TRNSYS types for pump (Type3b), pipes (Type709), weather engine (Type15), and water tank (Type4c). The water tank was used as a thermal mass reservoir in order to imitate the scenario of providing night radiative cooling to a building. The tank starts ends the day warm and then is progressively cooled during the night by the PVT system. This resembles the experimental setup described above and provides a more realistic simulation than assuming a constant inlet temperature for the PVT system.

Other important assumptions are described below:

- Meteonorm TMY2 weather files were used for all locations.

- PVT modules on all locations were assumed to be installed flat on a 10 degrees tilt roof facing south or north, depending on the hemisphere. Given the high levels of insulation at the back of the PVT modules this could be considered equivalent to a BIPVT roof installation.

- Potential effects of the surroundings were not taken into account. However, the effects of potential heat islands (within the urban landscape) are minimized by choosing a rooftop installation with 10 degrees tilt which ensures a good sky view factor.

- A constant flow rate of 0.02 kg/s.m^2 was used.

- The cities of Singapore, Tucson (Arizona), Sydney (Australia), and Hamburg (Germany) were selected for this study given their diverse climate classifications (Af, BSh, Cfa, and Dfb respectively).

3. Results and Discussion

The analysis of the experimental data showed that, on average, the PVT-water system can provide, on average, circa of 750 Wh/m^2 of cooling per day on Sydney climate during summer months (Jan-Mar). The cooling potential increases, as expected, during autumn and winter months to 1,000 Wh/m^2, as shown in Figure 3. However, building cooling is usually not required during these months, at least on the Sydney climate, except for very specific building loads like data centers.

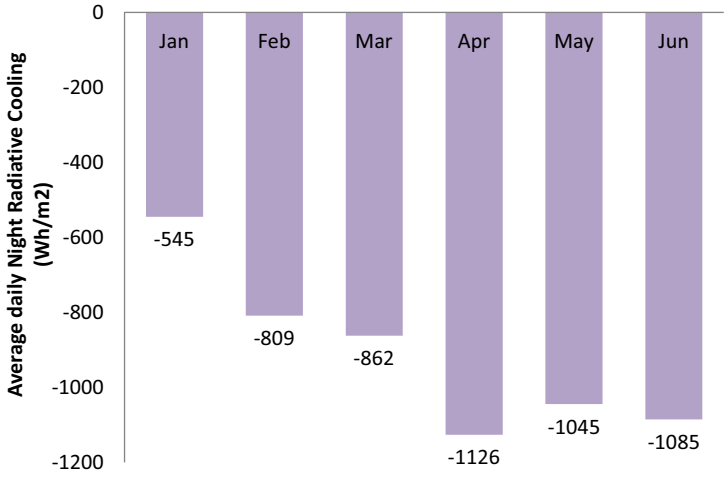

Fig. 3: Average Daily Night Radiative Cooling by a PVT-water module in Sydney from measured data

The results on show good potential for using PVT water systems for night cooling in Sydney climate. However, in order to design systems and really assess the cooling potential it is important to understand how this cooling is achieved, i.e., the portion of radiative and convective heat losses at night as part of the total cooling. The model developed in TRNSYS (Type850) was hence used to calculate the heat losses of the PVT-water module (top radiation, top convection, and back and edges) during night time using the same weather data obtained from the experiment. The results (Figure 4) show that radiation losses (Q_{rad}) account on average for 57% of the total heat losses, while convective losses (Q_{conv}) from the top surface of the

module are responsible for the 40% of the heat loss and the back and edge losses (Q_{be}) for only the 3%. Figure 4b also shows that the radiative cooling portion is slightly larger during winter months (mostly due to the increase of clear nights in Sydney when compared to summer) but is still relevant during summer. This ratio however is not fixed and depends greatly on the inlet water temperature and wind speed. For example, the closer the inlet water temperature is to ambient, the less important will be the convective heat loss to ambient and the more relevant will be the portion of radiative heat losses. This effect can be clearly observed in the simulation results for a clear summer night shown in Figure 5. In the simulation (from 8pm to 5am) the sky radiative cooling increases during the night as the sky temperature drops (effectively increasing the gap with the ambient temperature) while the convective losses drop as the temperature of the inlet water becomes closer to ambient temperatures.

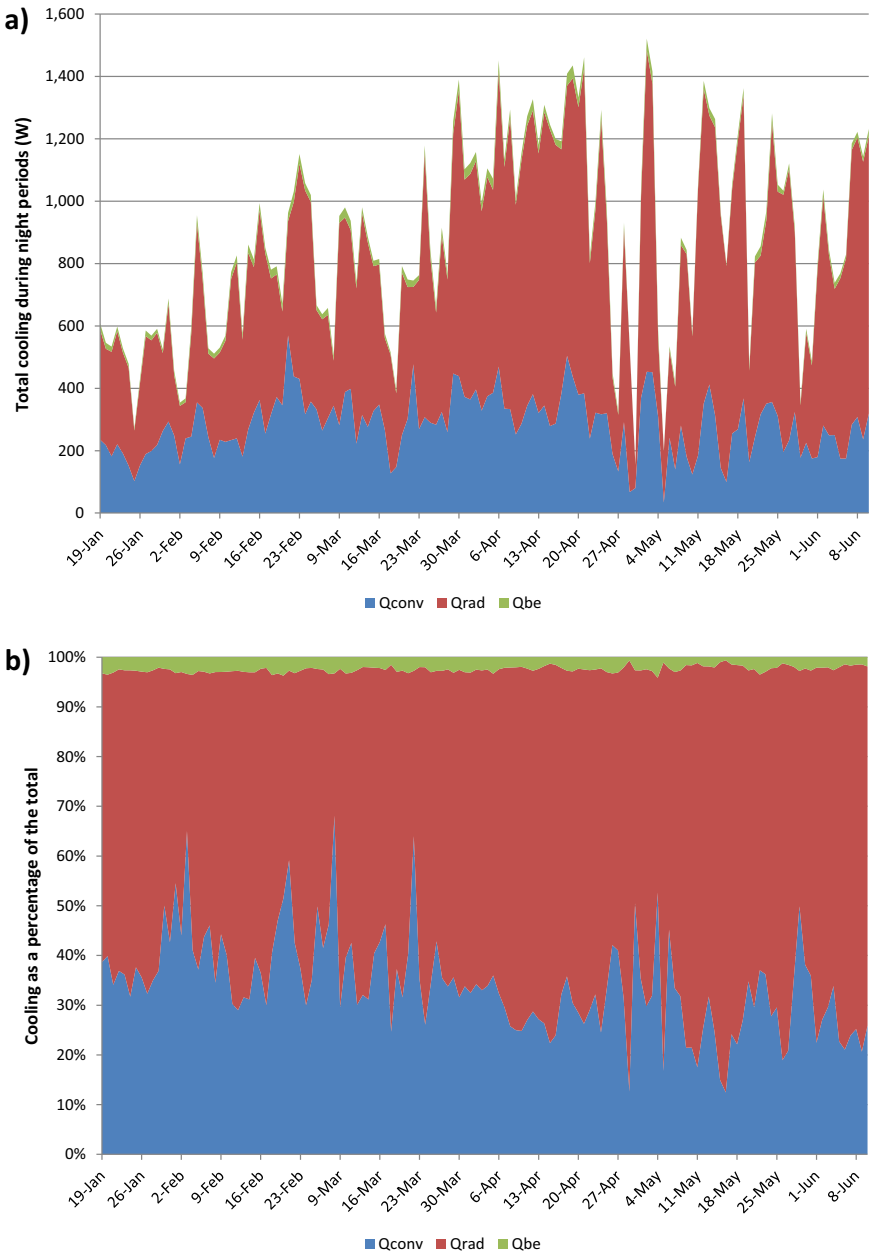

Fig. 4: Estimated daily heat losses or 'cooling' (top convection, top radiation, and back and edge) for the experimental PVT water system during night periods, in a) Wh and b) as a percentage of the total

These results have important ramifications and present interesting options for unglazed PVT modules, as they could be used for combined cooling/heating cycles, providing electricity, space heating during day winter months and cooling during clear summer nights, effectively a trigeneration system. An efficient hydraulic design for the PVT system is of paramount importance, as the benefits of providing space cooling/heating and the potential efficiency gains by cooling the PV cells can be outweighed by an inefficient water and air moving system (Farshchimonfared et al., 2015).

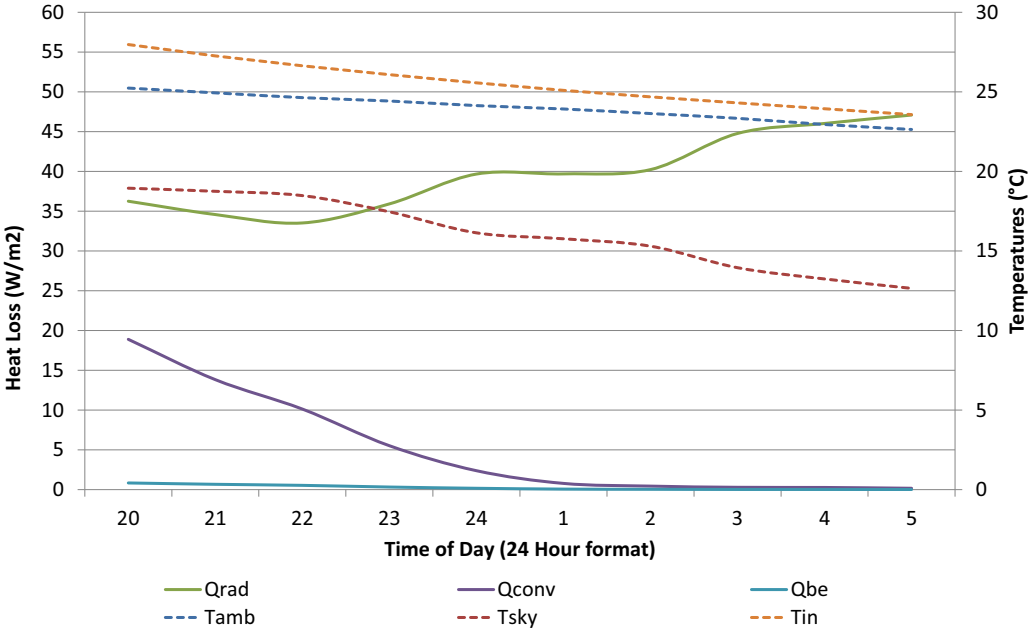

Fig. 5: Convective and radiative losses during a night

Of course, the cooling (and heating) capacity will depend on the weather conditions of the specific site and the type of installation along with tilt, orientation, and surroundings. This type of night radiative cooling might not be suitable for tropical zones, with high humidity and overcast days, but it might prove successful for temperate climates. Therefore, a set of simulations were carried out for four different climates (cities of Singapore, Tucson, Sydney, and Hamburg) in order to assess the potential of night radiative cooling under different conditions. A summary of the results for the year-long simulations are presented in Figure 6.

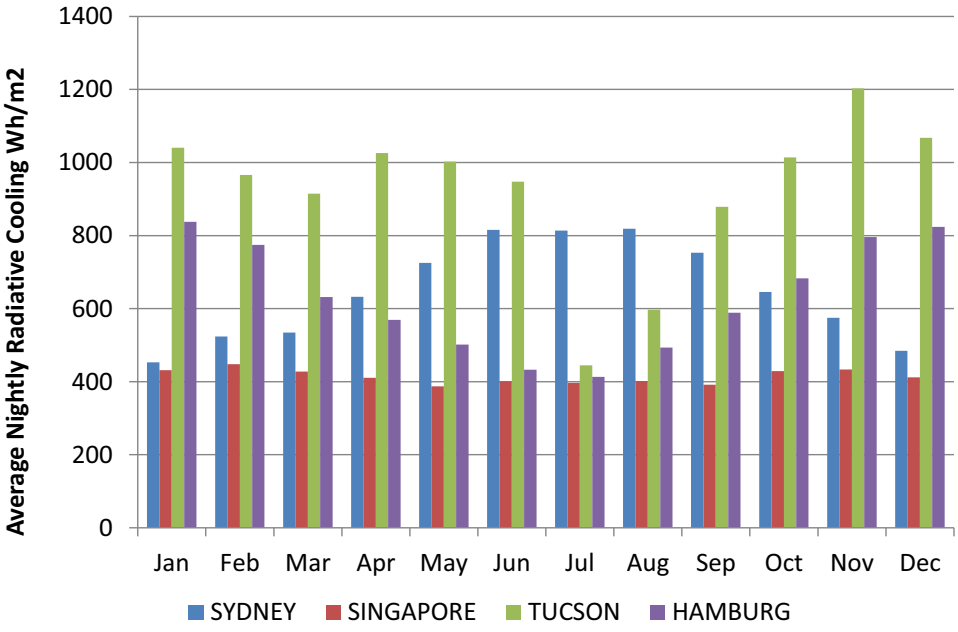

Fig. 6: Average PVT nightly radiative cooling during the year for different locations

As expected, the climate of Singapore produced limited night cooling potential around the year, with the average hovering around 400 Wh/m^2 per night. The drier climate of Tucson provided more than double of the cooling capacity with an average of 925 Wh/m^2 per night during the year. The night radiative cooling potential in Tucson is relatively constant during the year except for the months of July and August corresponding to the monsoon season in Arizona. On the other hand, Sydney offers similar night radiative cooling as Singapore during the (Sydney) summer months, with an increase cooling potential in winter (notice that Figure 3 shows measured data for Sydney and Figure 6 shows simulated data for Sydney with TMY2 data files, hence the discrepancy in values). A similar result is obtained for Hamburg, but with the corresponding seasons for the north hemisphere, with around 450 Wh/m^2 of cooling per night during summer and more cooling potential during winter (when the additional cooling potential is probably not needed). However, autumn and spring seasons (when present) seem to offer the best balance between night radiative cooling potential and cooling need.

Despite the difference in climates the model showed that on average it is always possible to obtain some level of night radiative cooling (see Figure 7). When compared to the output of convective cooling during night time, the results from the model and TMY2 weather files show a predominance of the radiative heat loss portion of at least 80% of the total. This differs from the measured results from the test rig built at UNSW in Sydney where the convective portion was closer to 40%. Given the fact that Type850 model shown good agreement to the measured data when using the logged weather data for the site, the difference can only be attributed to the weather file and difference in location. Furthermore, when running a simulation for Sydney with TMY2 data and the PVT module tilted at 30 degrees instead of 10 degrees, the model does show an increase in convective cooling and reduction in radiative cooling (Figure 7).

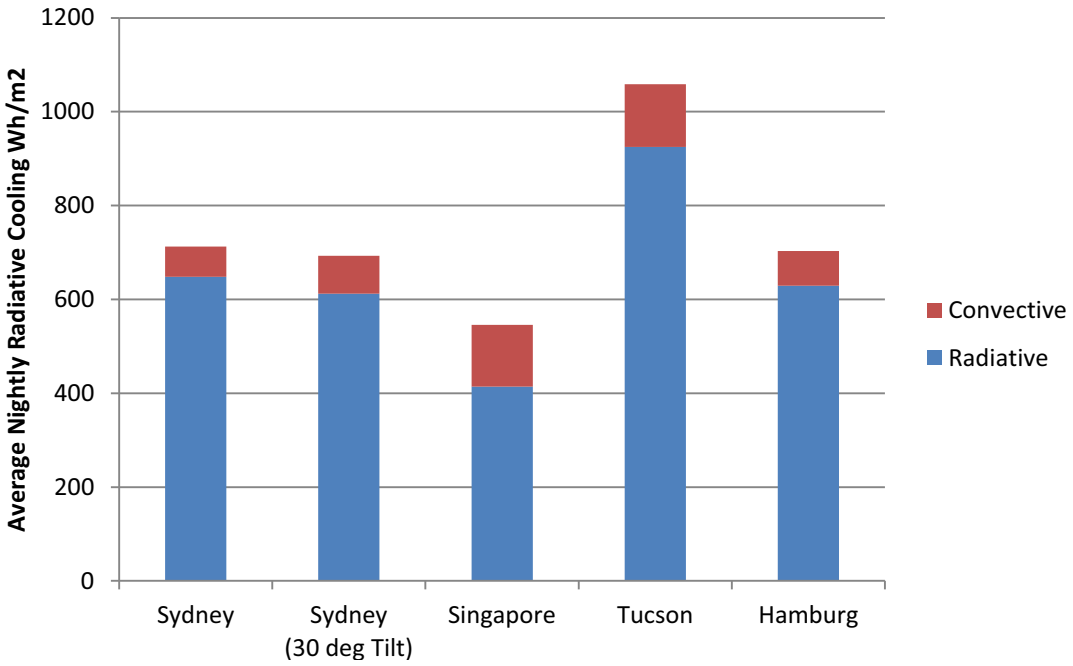

Fig. 7: Average PVT nightly radiative and convective cooling for different locations

If night radiative cooling is a better option than night purge or normal air conditioning for providing space cooling to buildings will depend on many factors including HVAC design and climate, as mentioned above. However, night radiative cooling using PVT water systems (using unglazed PVT modules) could be used as a complement for those technologies.

Further work and a more extensive analysis are required in order to explore and optimize the use of PVT water systems as a real trigeneration option. Moreover, with research already underway to assess the solar potential of all surfaces in the built environment (Redweik et al., 2013) it could be possible to use a similar approach to assess the night radiative cooling potential by including a sky view factor analysis.

4. Conclusions

PVT systems can offer important levels of night radiative cooling, which depends on the climate. From Singapore to Tucson (Arizona), the results of the simulations showed radiative cooling potential of the unglazed PVT system from 400 Wh/m^2 to 900 Wh/m^2 per night and that it is possible to provide cooling through the whole year, which might be beneficial for some applications like data centers. An additional 10% to 20% cooling can be obtained from convective cooling, although the portion of radiative and convective cooling depends on many variables including weather and system design and operation. More importantly, results seem to indicate that night radiative cooling is a real possibility for complementing night purge and other low energy cooling options. Consequently, it makes sense to use unglazed PVT systems already integrated into buildings as tri-generation systems, in order to use the full potential of the technology.

Performance Analysis of Concave Cavity Surface Receiver for a Non – imaging Solar Concentrator

K. S. Reddy and T. Srihari Vikram

Heat Transfer and Thermal Power Laboratory, Department of Mechanical Engineering,

Indian Institute of Technology Madras, Chennai – 600 036, INDIA

Abstract

In the present study, a numerical investigation of concave surface cavity receiver of non-imaging solar concentrator is carried out considering various operating and geometrical parameters such as mass flow rate of the fluid, solar radiation and receiver configuration. The fluid outlet temperature, pressure drop across the coil for different receiver configurations are studied along with the heat loss estimation of concave cavity surface receiver for non-imaging concentrating collector. The convective and radiative heat loss from the receiver surface is calculated based on 3-D numerical simulations. For helical receiver, the temperature rise is found to be 30°C (0.5kg/min) and 17°C (1kg/min) respectively; whereas for helical-spiral receiver, the temperature rise is found to be 27°C (0.5 kg/min) and 15°C (1 kg/min). The pressure drop across the coil ranges between 1kPa to 14kPa for different mass flow rate and solar radiation for two configurations of the receiver. The present model can be used for estimating the heat transfer and fluid flow characteristics of helical receiver for EHC.

Keywords: Solar energy, Non-imaging collectors, concave cavity surface receiver, Process heat

1. Introduction

The use of conventional fuels such as oil for process heat applications is slowly finding their way to the renewable energy means. One of the most promising renewable energy sources is solar thermal which can be widely used for variety of applications ranging from process heating to power generation. IRENA (2015) briefs that solar thermal can fulfill the process heat demands irrespective of its geographic location. It discusses the technical highlights, process and technology status detailing about the various options for process heat applications. It also presents a brief insight of various process heat systems installed all around the world. Lauterbach et al., (2010) reports that industrial sector is one of the most promising application for solar process heat application. Solar thermal heat is used for the following broad categories of industrial applications such as “heating of fluid streams”, “heating of baths/vessels” and “drying” and studied the feasibility of solar collectors for the industrial applications (Lauterbach et al., 2011). The development of new collectors provides scope for its use in industrial process heat applications. The emergence of new medium temperature collectors provides opportunities for the use of solar thermal energy because they can supply higher temperature demands and can co-exist with the installed high temperature heat networks (Martinez et al, 2012).

Non-imaging optics involves the design of optical components for solar concentrating systems. For given concentration ratio, non-imaging optics provides wide acceptance angles for solar applications. A non-tracking, non-imaging solar concentrator with low heat loss has been proposed and its optical and thermal performance has been investigated by Ustaoglu et al., (2015). It was found that the absorber temperature is uniform and with a concentration ratio of 2.51, the concentrator, even at an absorber temperature of 373 K, operates with an average efficiency of 47.8%, although the absorber is assumed to have a gray surface. The concentrator’s thermal efficiency has been compared with that of other solar collectors, and found to be higher than that of conventional solar collectors. Kaiyan et al., (2011) presented a novel multiple curved

doi:10.18086/swc.2015.10.11 Available at http://proceedings.ises.org

surfaces compound concentrator. It consists of a parabolic and a flat contour. It consists of focus at the backside which is extremely useful and convenient for some applications. The comparison with traditional paraboloid and CPC has been carried out. Garcia-Botella et al., (2006) presented an analysis of elliptical concentrators studying on concentration ratio and analysed for some applications such as concentrators and illuminators. A new 3-D asymmetric concentrator (hyperbolic concentrator) is studied based on different theories. Based on ray tracing analysis, it has been shown that 3-D concentrator in the shape of hyperbola intercepts maximum incident rays can be used for non-tracking solar application (Garcia-Botella et al., 2009).

Ali et al. (2010) compared the optical performance of 2-D and 3-D elliptical hyperbolic concentrator (EHC) and found that the optical efficiency of 2D and 3D system are 63% and 78% respectively. Ali et al., (2011) presented optical performance of 3D static circular and elliptical hyperboloids. Four different configurations of hyperboloids are studied based on the ray tracing techniques and flux distribution at the receiver aperture has been presented. The parametric studies have been carried out and the optical efficiency of the systems have been compared and have been compared and evaluated. It has been found that elliptical hyperboloid performs better than other three configurations. A detailed parametric study on the elliptical hyperbolic concentrator has been performed by Ali et al., (2013). The overall performance of the concentrator was assessed based on the acceptance angle, effective concentration ratio and optical efficiency. Optimization of the concentrator profile and geometry has also carried out to improve the overall performance and flux distribution at receiver aperture for different geometric parameters have also been presented. The optical efficiency of the system has been estimated to be 27% with concentration ratio of 20x and wide range of incidence angles (±30°).

Helical coil receiver was proposed for solar desalination applications using elliptical hyperboloid concentrators (Reddy et al., 2014). 2-D ray tracing has been carried out to study the optical performance of the proposed system and a parametric study has been carried out for fluid flow and heat transfer in helical coil and the system has been optimized for higher performance. The experimental performance investigation of EHC for process heat applications has been carried out by Ali et al., (2014). The maximum stagnation temperature and outlet fluid temperature was found to be 150°C and 90°C at flow rate of 0.5 kg/min. Ray tracing analysis has been carried out to estimate the flux at receiver plane and compared with that of the IR images. Experiments have been carried out for two different flow rates and the outlet temperature of the fluid has been determined.

In the present study, a numerical investigation of concave cavity surface receiver with helical and spiral coils used in elliptical hyperbolic concentrator (EHC) is carried out considering various operating and geometrical parameters such as mass flow rate, solar radiation, receiver configuration etc. and the outlet temperature of the fluid and the pressure drop across the receiver coil has been estimated. The heat loss analysis from the concave cavity surface receiver has also been carried out to study the performance of the concave cavity surface receiver by varying the incident solar radiation and emissivity of the surface.

2. Modelling of Helical – Spiral coil for Elliptical Hyperbolic Concentrator

2.1 Elliptical Hyperbolic Concentrator

Elliptical Hyperbolic Concentrator (EHC) consists of a hyperbolic concentrator with elliptical aperture both at top and bottom and a receiver placed at the bottom to collect the incident solar energy and convert to useful thermal energy. The receiver consists of helical coil which is wound in a elliptical shape to capture the incident concentrated solar radiation. The schematic of side view of the elliptical hyperbolic concentrator system is shown in Fig.1. The working fluid flows through the bottom of the receiver and gets heated due to

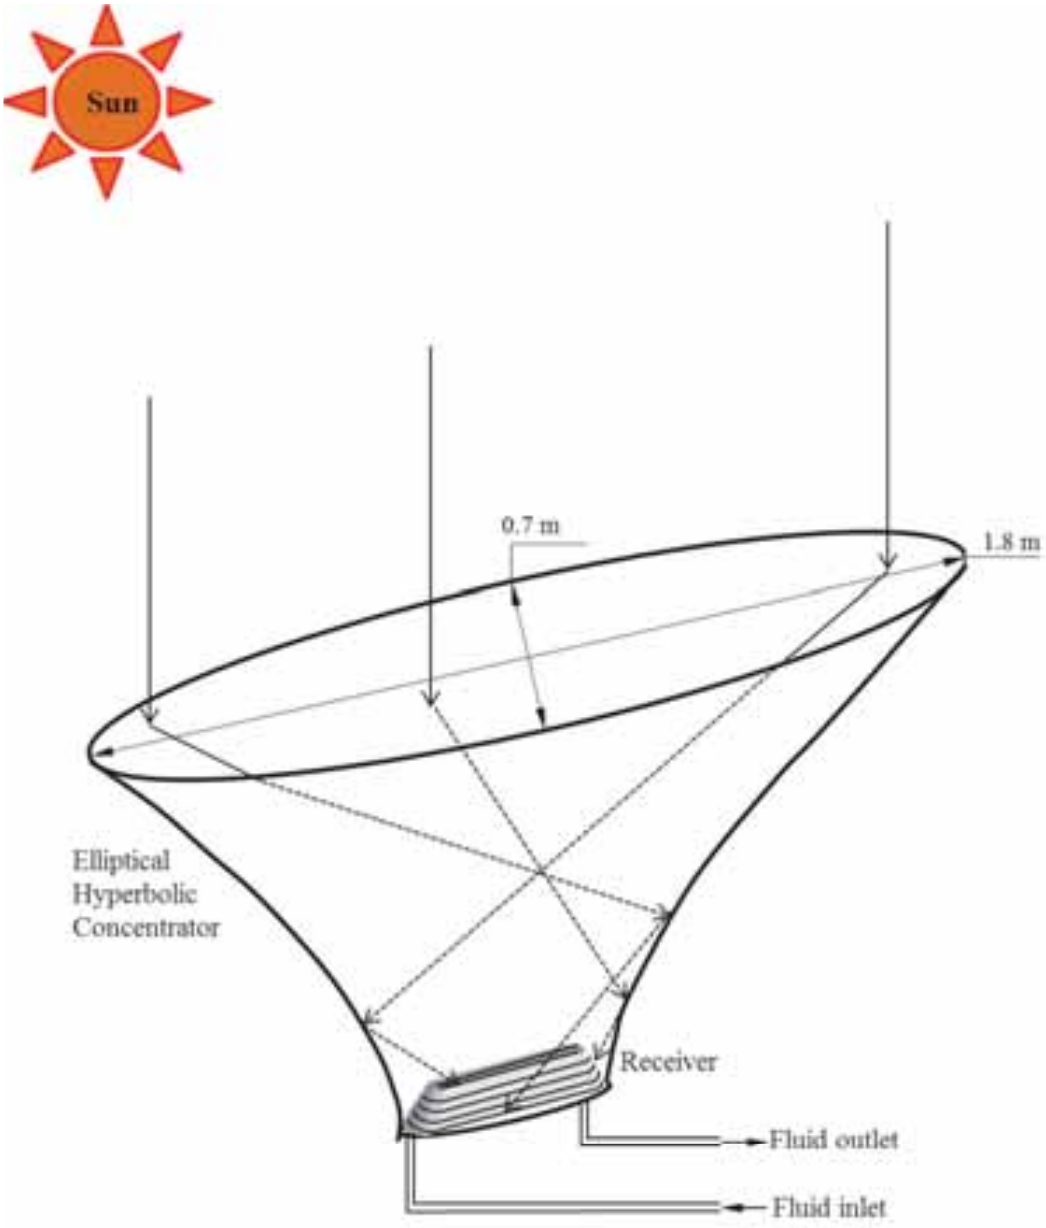

Fig. 1: Elliptical Hyperbolic Concentrator system (side view)

the incident solar energy and leaves at the top. EHC is a non-imaging concentrating collector having wide acceptance angle and does not require tracking.

2.2 Modelling of Helical-Spiral Coil

The helical receiver is a concave cavity surface receiver consisting of copper tube (Diameter: 6mm, No. of helical turns: 7; spiral turns: 5) wound in the elliptical shape (Fig. 2) is placed in the bottom aperture of EHC. The receiver coil is wound over a trapezoidal metal plate to hold in proper position. The trapezoidal metal plate forms a concave cavity. The working fluid (water) enters the receiver coil at the bottom and leaves at the top. The front view and bottom view of the concave cavity surface is shown in Fig. 2 and the helical coil receiver with and without spiral coil is shown in Fig. 3

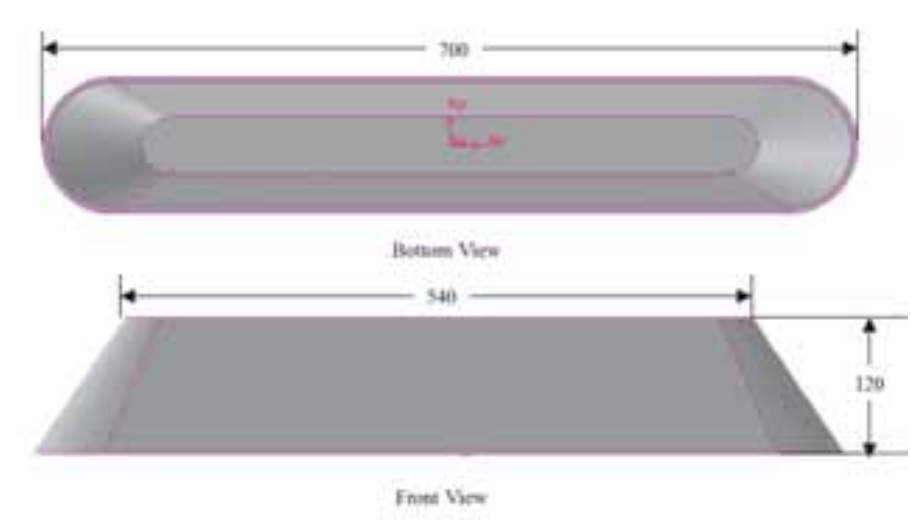

Fig. 2: Concave cavity surface receiver

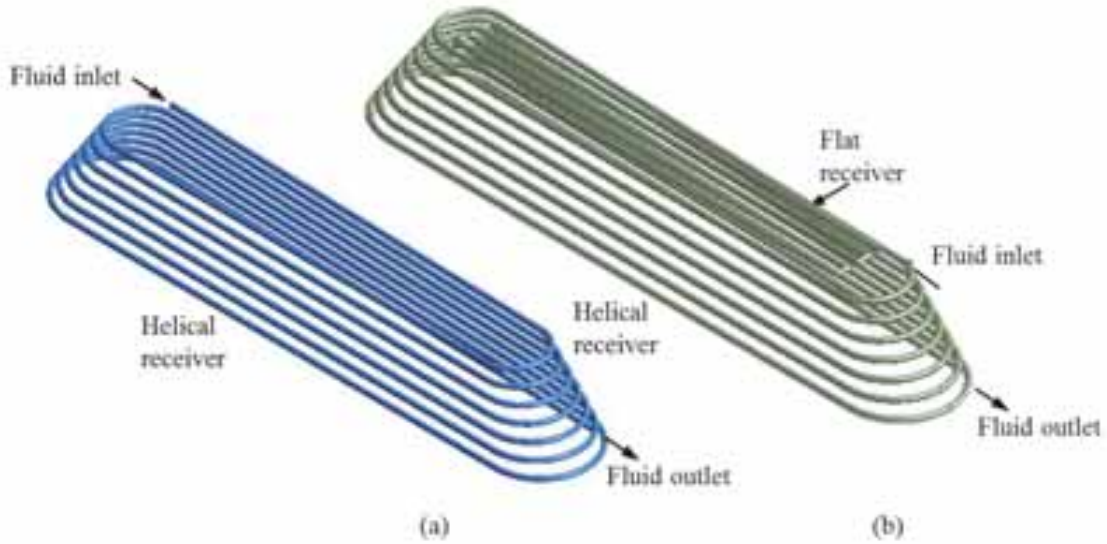

Fig. 3: Helical coil receiver (a) without spiral (b) with spiral

The geometry of the concave cavity surface receiver has been modelled using modelling software, GAMBIT 2.4.6. The helical coil receiver has been modelled using ANSYS Workbench V14.5.

2.3 Mathematical model

The flow and heat transfer simulations are carried out by solving the system of governing equations simultaneously:

Continuity equation is given by:

$$\nabla \cdot \vec{V} = 0 \qquad \text{(eq.1)}$$

Momentum equation is given by:

$$\vec{V} \cdot \nabla(\rho \vec{V}) = -\nabla p + \mu . \nabla^2 \vec{V} + \rho \vec{g} + \vec{F}_c \qquad \text{(eq.2)}$$

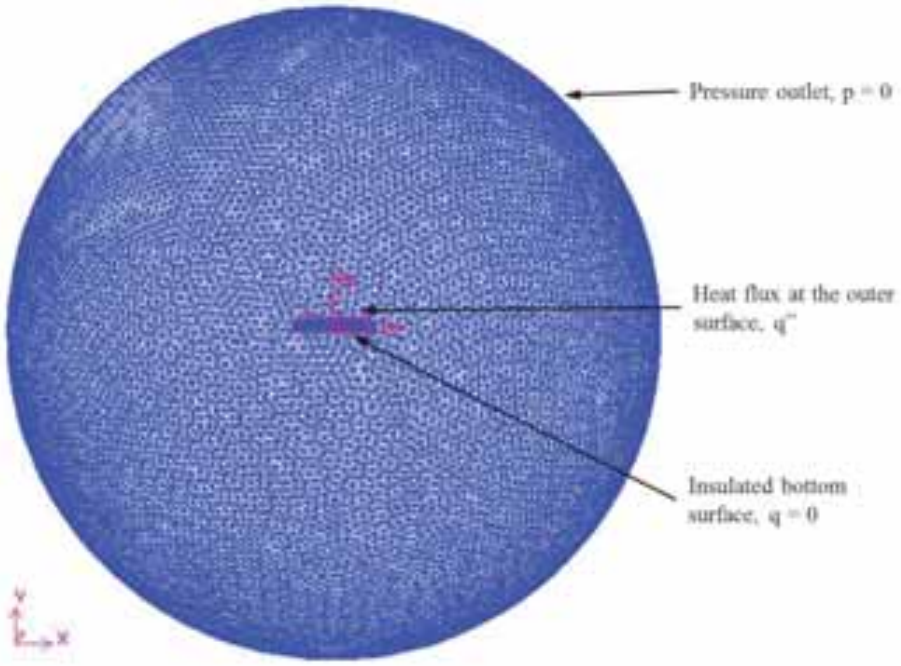
Energy equation is given by:

$$\vec{V} \cdot \nabla(\rho C_p T) = k \nabla^2 T \qquad \text{(eq. 3)}$$

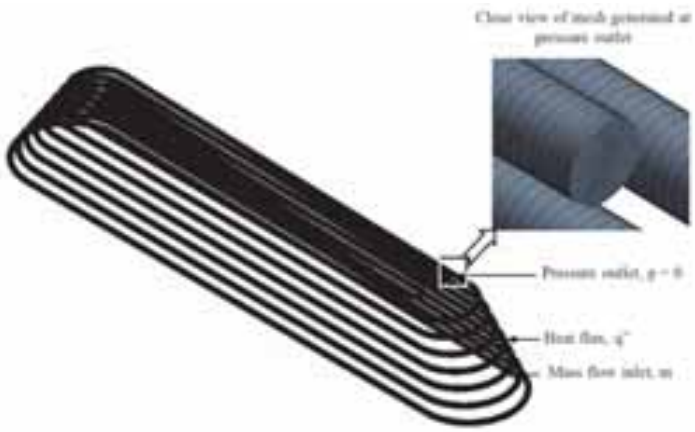
The laminar, steady state and 3-D governing equations are solved in ANSYS FLUENT V14.5 using an implicit solver. Along with the above-mentioned conditions, surface-to-surface radiation model is also incorporated to account for the radiation exchange between the surfaces of the concave cavity surface receiver.

2.4 Boundary Conditions

The concentrated solar radiation falls on the concave cavity surface receiver placed at the bottom aperture of EHC. Hence the outer surface of the trapezoidal cavity is subjected to heat flux and the bottom surface of the cavity surface is insulated to minimize the heat loss from the receiver. To account for the effect of atmosphere, a spherical domain is considered which is 5 m in radius. This model has been used to estimate the heat losses from the receiver. Similarly to account for fluid flow and heat transfer analysis, the receiver coil is subjected to various boundary conditions. As the receiver coil is wound around the trapezoidal (concave cavity) surface, the concentrated solar flux is applied on the outer walls of the receiver coil. The mass flow rate is specified at the inlet of the receiver at the bottom and the pressure outlet is set at the outlet of the receiver at the top. The computational domain and boundary conditions of the concave cavity surface receiver and receiver coil are shown in Fig. 4.



(a)



(b)

Fig. 4 : Computational domain and boundary conditions (a) Concave cavity surface receiver (b) Helical – Spiral receiver coil

2.5 Numerical Procedure

The computational domain of the concave cavity surface is created using GAMBIT 2.4.6. The atmosphere surrounding the concave cavity surface receiver is modelled such that the cavity receiver is placed inside large spherical domain. The size of the external domain is increased until it had an insignificant effect on the working fluid and heat flows from the receiver. In the present analysis, external domain is considered as 5 m diameter based on the numerical simulations. The fine mesh is considered for the receiver and coarse mesh is considered for outer atmosphere/domain. The computational domain of concave cavity surface considered in the present study is shown in Fig. 4. For pressure velocity coupling, SIMPLE algorithm has been used, with body force weighted algorithm for discretization of pressure with first order upwinding scheme for the discretization of equations. For the fluid flow simulations, A convergence criterion of 10^{-3} was imposed on the residuals of the continuity equation, momentum equation. A convergence criterion of 10^{-6} is considered for energy equation. The present numerical procedure for heat loss from concave cavity surface receiver is validated with Reddy and Kumar model (2009) and found to vary within acceptable limits. The present numerical procedure is validated with two different models (i) conical tube bundle and (ii) spiral coil. The fluid flow and heat transfer characteristics of conical tube bundle has been studied by Ke et al, 2011. The heat transfer and heat transfer coefficient obtained by Ke et al (2011) for the inlet flow velocity of 0.1 m/s has been compared with the present numerical procedure and the results are tabulated (Table 1) and shows good agreement. The heat transfer and flow characteristics of spiral coil carried out by Naphon (2011) is compared at flow rate of 0.05 kg/s. Table 1 shows the comparison of experimental and numerical results for heat transfer rate and outlet temperature of the spiral coil.

Tab. 1: Validation of numerical procedure

Parameter	Ke et al, 2011	Present numerical procedure	Naphon, 2011	Present numerical procedure
Heat transfer coefficient (W/m^2K)	150	152.46	-	-
Heat transfer (W)	307.45	310.35	2785.25	3031.72
Outlet fluid temperature (°C)	-	-	34.65	35

3. Performance analysis of concave cavity surface receiver

3.1 Heat loss analysisfrom concave cavity surface receiver

The 3-D numerical simulations have been carried out to estimate the heat losses from the concave cavity surface receiver. The effect of the parameters like DNI and emissivity of the receiver are varied to study the heat losses from the concave cavity receiver.

The heat losses from the receiver are estimated based on the following equations:

$$Q_{total} = h_{total} A_s (T_w - T_a) \quad \text{(eq.4)}$$

$$Q_{rad} = h_{rad} A_s (T_w - T_a) \quad \text{(eq.5)}$$

$$Q_{conv} = Q_{total} - Q_{rad} \quad \text{(eq.6)}$$

3.1.1 Effect of solar radiation

The effect of solar radiation on the heat loss from the concave cavity receiver is studied by varying the incident solar flux on the surface of the concave cavity surface receiver. Fig. 5 shows the temperature contours of the concave cavity surface receiver for solar radiation of $250 W/m^2$ at theoretical maximum heat flux of 10150 W/m^2. The maximum surface temperature at the receiver is about 470 K. Fig. 6 shows the temperature contours of the concave cavity surface receiver for solar radiation of 1000 W/m^2 at maximum heat flux of $40607 W/m^2$ incident on the receiver. The maximum surface temperature on the receiver is about 933K.

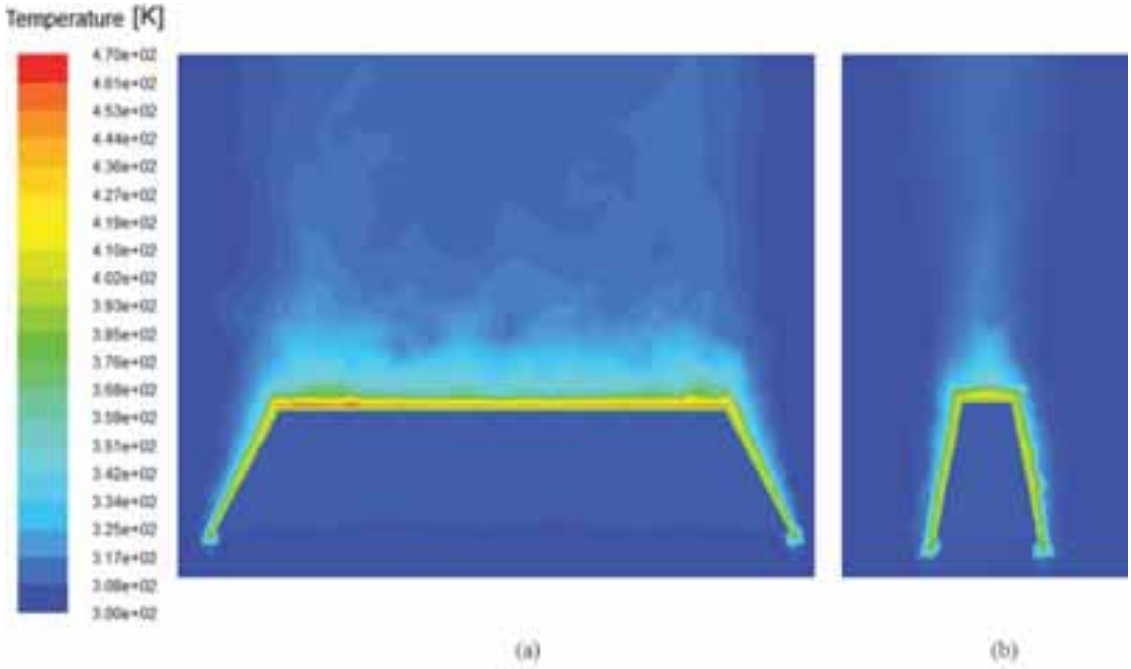


Fig. 5: Temperature contours of concave cavity surface receiver at different planes for DNI = 250W/m^2 (a) Z = 0 (b) X = 0

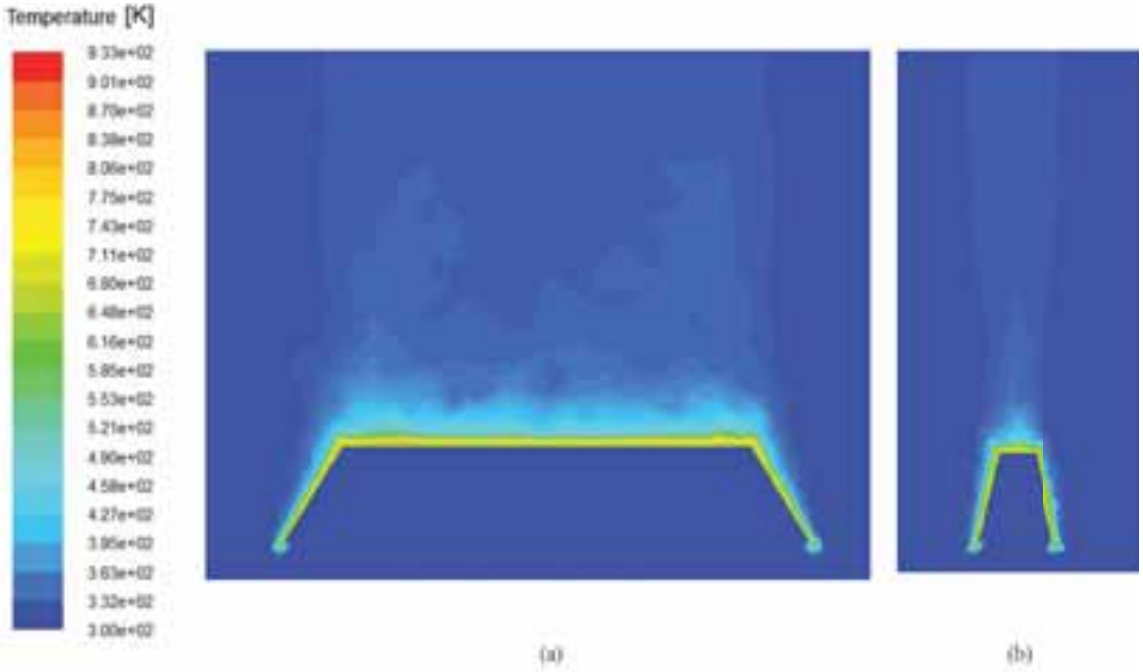

Fig. 6: Temperature contours of concave cavity surface receiver at different planes for DNI = 1000W/m^2 (a) Z = 0 (b) X = 0

3.1.2 Effect of emissivity of receiver surface

The emissivity of the receiver surface is varied to study the effect on heat loss from the receiver surface. The emissivity of the receiver surface is set to 1 as it is coated with black matt paint. The temperature contours for receiver at an emissivity of 1 for average heat flux value is shown in Fig. 7

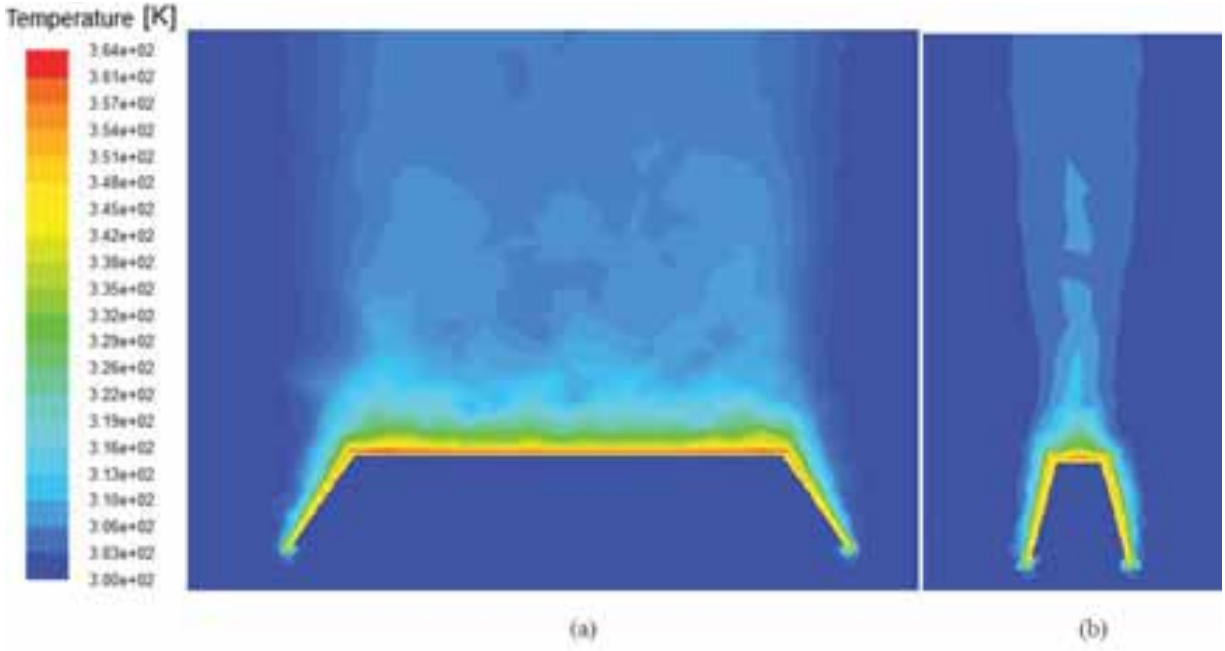

Fig. 7: Temperature contours of receiver (ε =1) at different planes for DNI = 1000W/m^2 (a) Z = 0 (b) X = 0

The comparison of heat losses and the maximum temperature in the receiver surface is calculated and tabulated in Table 2. The values correspond to the average heat flux incident on the receiver surface.

Tab. 2: Comparison of parameters for different DNI and emissivity

Parameter	DNI = 250 W/m^2		DNI = 1000 W/m^2	
	ε = 0	ε = 1	ε = 0	ε = 1
Maximum Temperature (°C)	70	44	123	112
Convective Heat loss (W)	28	28	111	111
Radiative Heat loss (W)	-	17	-	65
Surface temperature of receiver (°C)	47	44	113	91

3.2 Fluid flow and heat transfer analysis of helical-spiral coil receiver

The fluid flow and heat transfer analysis have been carried out to estimate the outlet temperature of the fluid and the pressure drop across the coil. The two types of coil configuration are studied to study the performance of the system.

3.2.1 Effect of solar radiation

The incident solar radiation on the receiver surface is varied to study the effect on the receiver performance. The solar radiation values of 250 W/m^2 and 1000 W/m^2 are considered in the present study. The outlet temperatures are calculated for two different configurations are estimated. For helical receiver, the temperature rise of 57°C (0.5kg/min) and 38°C (1kg/min) is observed for 1000W/m^2. At solar radiation of 500 W/m^2, the temperature rise is found to be 30°C (0.5kg/min) and 17°C (1kg/min) respectively. The effect of solar radiation incident on the receiver is studied and found that there is temperature difference of 27°C for twice increase in solar radiation.

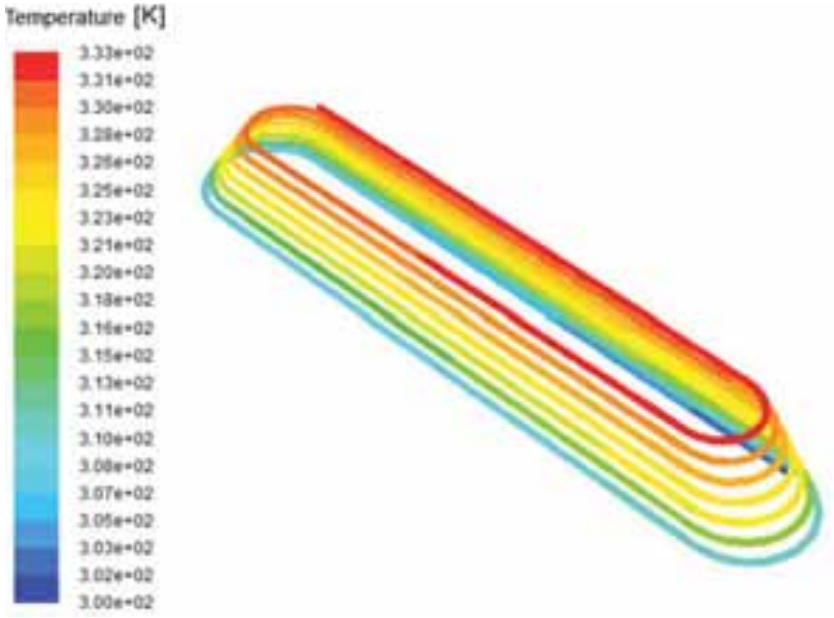

Fig. 8: Temperature contours of helical receiver for DNI of 500W/m^2

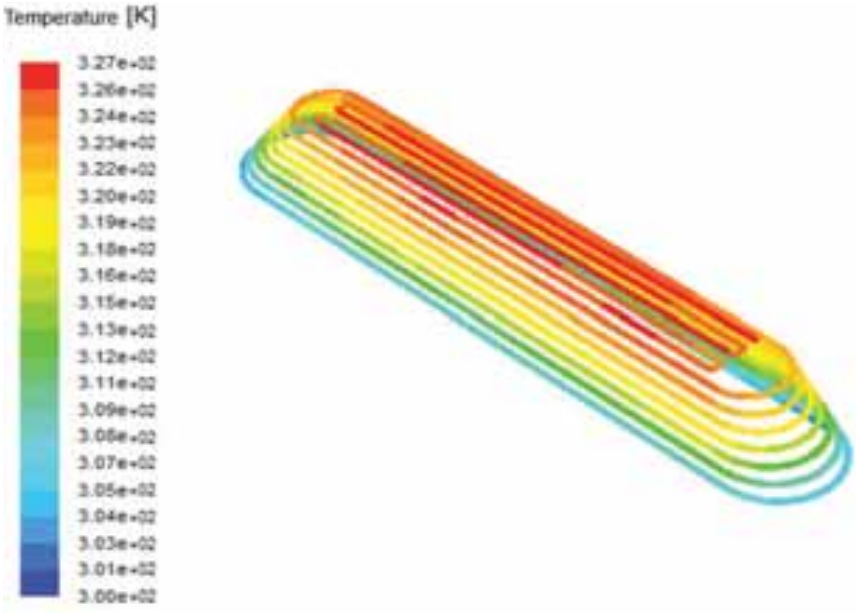
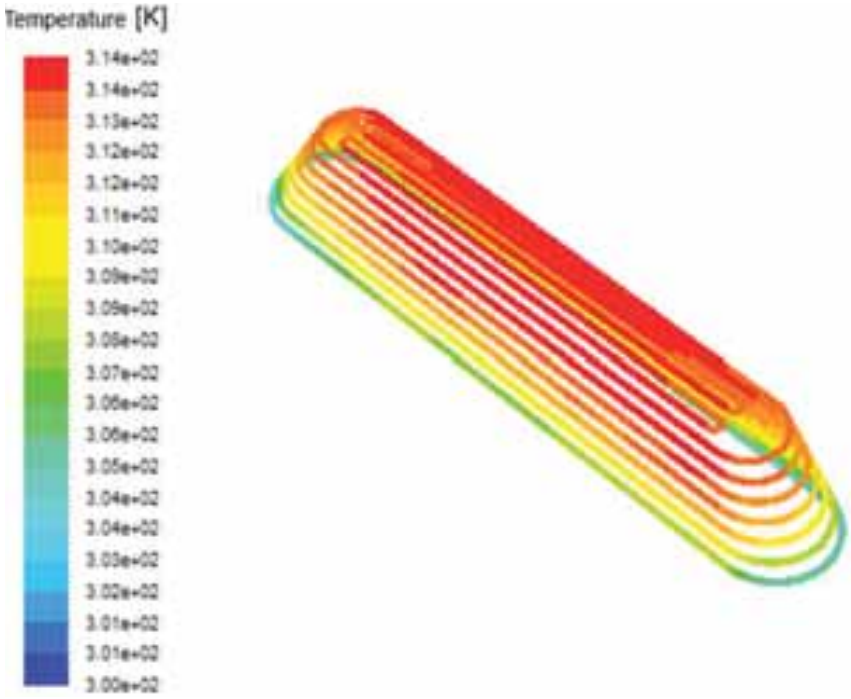
3.2.2 Effect of flow rate

The effect of flow rate on the receiver performance has been carried out. The flow rate values of 0.5 and 1 kg/min have been considered for the present analysis. Based on the flow rate, it is observed that at solar radiation of 250W/m^2, the temperature rise was found to be about 27°C and a pressure drop of 13023 Pa for 0.5 kg/min and temperature rise of 17°C and pressure drop of 14062 Pa was observed for 1 kg/min. For twice the mass flow rate, the variation of average fluid temperature is about 20°C for helical receiver.



(a)



(b)

Fig. 8: Temperature contours of helical - spiral receiver surface for different flow rates and DNI = 250W/m^2

(a) 0.5 kg/min (b) 1 kg/min

The variation of the temperature of the fluid along the coil length for the helical receiver is shown in Fig. 7. It is observed that, for the flow rate of 0.5 kg/min, the outlet fluid temperature is 87°C and for 1 kg/min, it is about 65°C.

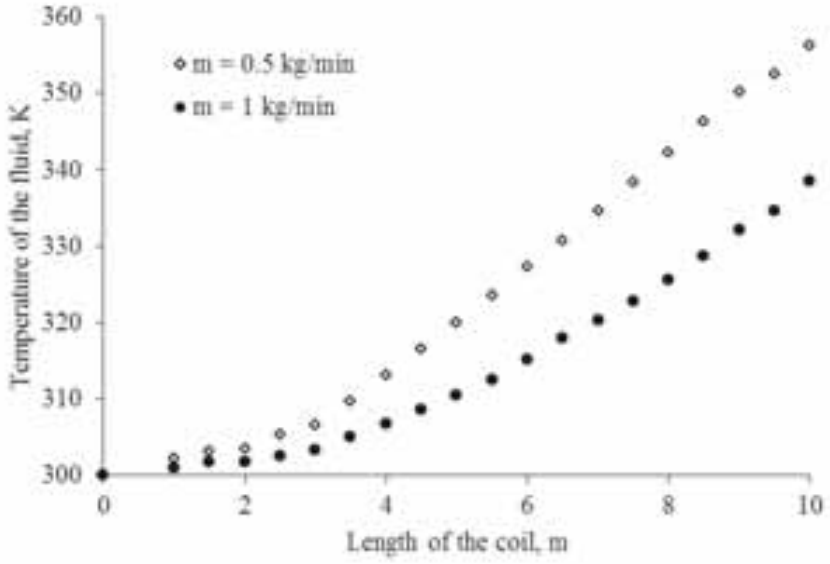


Fig. 9: Variation of average fluid temperature along coil for helical receiver

3.3 Performance investigation of helical-spiral coil receiver

The performance investigation of the helical-spiral receiver is carried out considering the useful heat transfer to the fluid and the heat loss from receiver comprising of the conductive, convective and radiative heat losses from the system. The heat collection efficiency of the receiver is given by (Reddy at al., 2014):

$$\text{Heat collection efficiency} = \frac{\text{Energy absorbed by the fluid}}{\text{Energy incident on the receiver}} \qquad \text{(eq. 7)}$$

Based on the analysis, it is found that receiver heat collection efficiency is about 84%.

4. Conclusion

In the present study, 3-D numerical investigations have been performed to study the heat loss from the concave cavity receiver surface and the fluid outlet temperature and the pressure drop across the helical coil. The heat loss analysis from the concave cavity surface receiver has been carried out by varying the incident solar radiation and emissivity of the surface. The study has been carried out for different parameters such as different solar insolation values, emissivity of the receiver surface and flow rates. Based on the analysis, For helical receiver, the temperature rise is found to be 30°C (0.5kg/min) and 17°C (1kg/min) respectively; whereas for helical-spiral receiver, the temperature rise is found to be 27°C (0.5 kg/min) and 15°C (1 kg/min). The pressure drop for helical receiver varies between 1kPa to 8kPa and 3kPa to 14 kPa for helical-spiral receiver. The present 3-D model can be used to study the performance of the helical coil receiver for elliptical hyperbolic concentrator.

Nomenclature:

Abstract

Based on the linear Fresnel concentration technology, a hybrid solar thermal power and cooling cogeneration system has been developed aiming for the solar thermal utilization in hot climate regions. The thermal from the solar Fresnel collectors can be used for air condition with high efficiency solar absorption cooling, and can also be used for power generation with Organic Rankine's cycle (ORC) cycle. It mainly consists of linear Fresnel solar collector, molten salt thermal storage tank, steam drum, ORC power generation equipment and absorption chiller. And this paper introduces the running modes under different kinds of solar radiation conditions. The system will turn on the heat storage mode when the incident solar rays are strong, and will switch to the heat release mode under poor insolation. Actually, we can choose to run the hybrid system in the mode of cooling or electricity generation in response to our needs. The Fresnel solar collector acts a crucial role in different running mode. Therefore, simulations on the mirror field and the absorber of the collector are operated respectively. On the basis of the results, we make the optimal operation strategies for the hybrid system. According to the analysis above, we can draw the conclusions. The hybrid solar thermal power and cooling cogeneration system is designed with several running modes, which guarantees the system runs stably and reliably.

Keywords: *solar thermal utilization, solar Fresnel collector, ORC cycle, absorption cooling, power generation*

1. Introduction

Solar energy is certainly the most considerable renewable and clean energy with the reserves of fossil energy decreasing, while the consumption increasing. Solar thermal utilization is quite an important way to use the generous energy from the sun. However, the traditional solar utilization manners in low temperature level area cannot meet the demand of industrial production. Various concentration technologies are needed to gather solar energy of high quality. The linear Fresnel solar collector with cavity receiver is an economical manner in middle temperature level area, compared with the trough solar collector which is relatively more mature. It concentrates sunlight with a series of discrete mirrors to heat the working fluid flowing through the cavity receiver up to about 300℃. The collected energy can be used to various processes, such as cooling, electricity generation, industrial heating and seawater desalinization.

Absorption refrigeration circulates with water or ammonia as the refrigerant are harmless to the environment and the ozone layer; And the cycle is driven by heat energy, which includes, in addition to the use of boiler's steam, fuel's combustion heat, waste heat, exhaust heat, solar energy and other low grade heat. The working medium mostly used in the absorption chiller is lithium bromide solution which performs well in operation.

doi:10.18086/swc.2015.10.12 Available at http://proceedings.ises.org

The entire device, except the pumps and valves, mainly consists of the heat exchangers, so that the machine works smoothly and noiselessly. Meanwhile, the refrigerator is running in a vacuum condition, and the structure is simple, safe, reliable and easy to install. The downside is that the solution of lithium bromide in the atmosphere has a very corrosive harm to metals, thus resulting in a higher requirement for the pipes of the equipment, and additional larger cooling load. 1.n lift cycle for Li-Br absorption chiller is an improved cycle based on single effect cycle and two stage cycle. In the cycle, the flow process of Li-Br solution is improved, making one part of the fluid circulate in the way of single effect cycle and the other part in the way of two stage cycle.

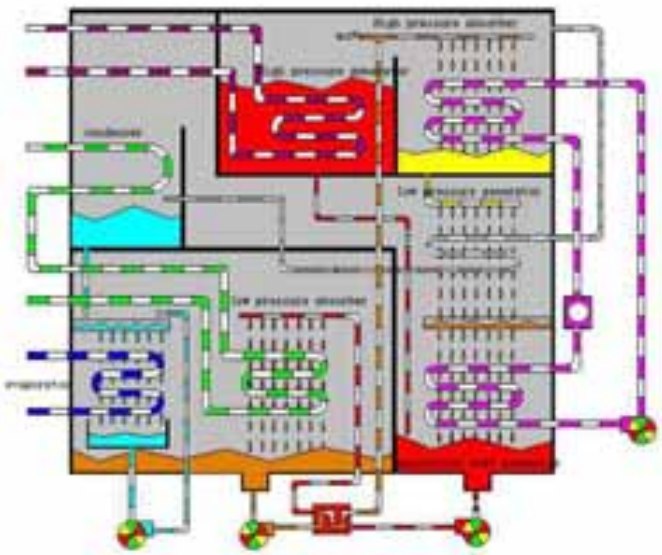

Fig. 1 Flow diagram of the 1.n lift cycle

The organic Rankine's cycle (ORC) is similar to the ordinary Rankine's cycle except that it uses the organic fluid not water as the working medium whose boiling temperature is low and the vapor pressure is high. The ORC may utilize the heat resource of low grade in power generation. The working medium absorbs heat from the heat resource and vaporizes quickly which is to drive the turbine.

In the solar thermal power generation field, heat storage is quite important to ensure the whole system operate continuously and effectively. The material storing the heat is more likely to be the phase change material (PCM) and nitrate is the common choice. Most nitrate's melting point is about 300℃ and the outstanding advantage of the salt is the low price, and low corrosivity and stable physical performance below 500 ℃. The disadvantage is that the heat of solution is small (only 20-30 kcal / kg), and the thermal conductivity is low[only 0.7 kcal / (m • h • ℃)], so that it would be overheated partially. However, compared with other molten salts, nitrates are still in the ascendant.

Solar salt is a kind of composite of nitrates which is the best choice in solar thermal molten salt power generation. Because it has the highest upper limit temperature (600 ℃), so it can keep the steam turbine operating at peak efficiency. In addition, it is one of the cheapest nitrate molten salt. But the Solar salt's freezing point is too high (220 ℃), comparing with the synthetic oil whose freezing point is only about 10 ℃ (Therminol VP-1,13 ℃). Therefore, some protective measures aiming at the high freezing point need to be taken to increase the strength of pipes, valves and other facilities, which would increase the operational and management costs. Given this, ternary molten salt Hitec (142 ℃), Hitec XL (120 ℃) are compounded, the freezing points of which are reduced a lot, and the upper limit temperature is decreased little. Thus, the synthetic molten salt has a broad application prospects in solar thermal power generation.

2. Hybrid system

2.1 Components

This solar thermal system is to achieve the functions including cooling, power generation, heat storage, domestic hot water preparation and many other features. Four linear Fresnel solar collectors in series are applied in the system, the absorber of which has a half cylinder trough cavity. The refrigerator is 1.n lift Li-Br absorption chiller, with a cooling capacity of 50kW. Organic Rankine's cycle power generator is used and the organic working fluid is R11, and generating power is 5kW. The refrigerator and power generator are designed and positioned in parallel and sharing one cooling tower, not working at the same time due to the limited collector area. The thermal storage use the hitec molten salt as the medium, storing heat according to the phase change latent heat. In addition, the system incorporates a drum for generating stable and high quality steam, equipped with an electric heater as an auxiliary heat source. Furthermore, a plate heat exchangers is assembled to produce domestic hot water through heat exchange with the steam drum.

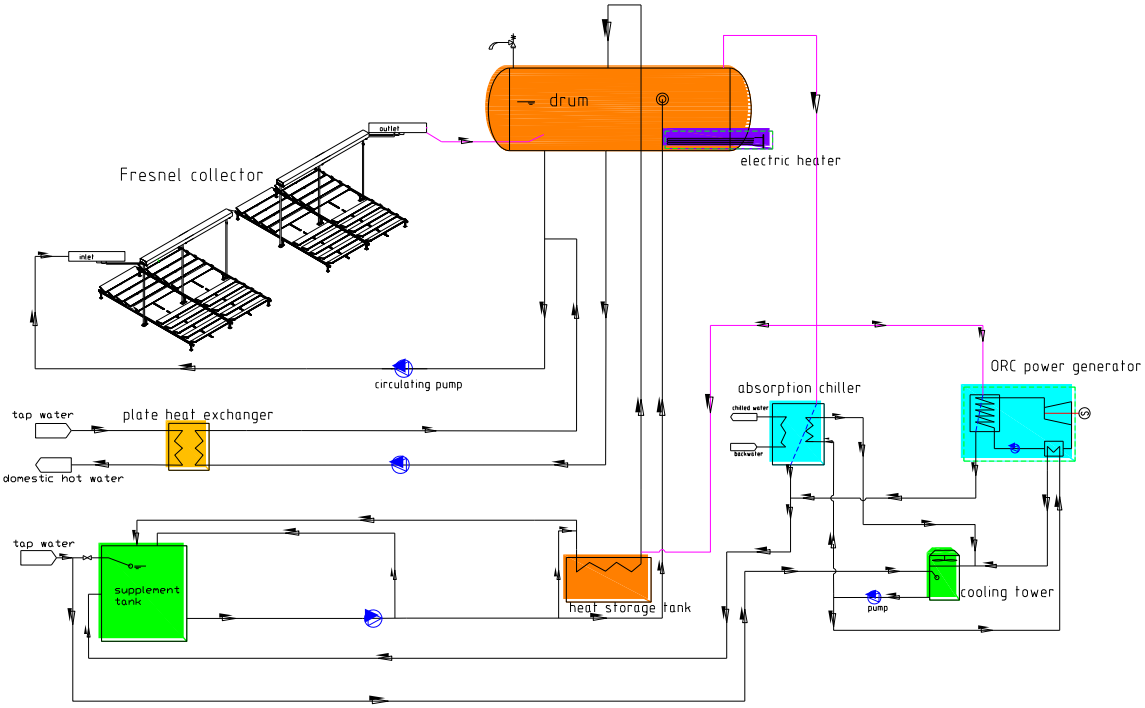

Fig. 2 schematic diagram of the hybrid system

2.2 System process

This system is a direct steam generation system (DSG), and the cycle working fluid is water. In the absorber of the collector, the water is heated to steam or mixture of water and vapor and flows into the drum where the vapor and the water are separated. The liquid water returns to the absorber through the drop tube. Meanwhile, the steam, heated by the electrical heater if necessary, runs out of the drum directly and entrances the terminal equipment, the refrigerator or the power generator. After driving the terminal equipment, the steam becomes liquid water and flows into the supplement tank. A circulating pump is there to deliver the water from the tank to the drum, where the steam and the water mix together to generate the steam that meets the demand. When the collector can't provide sufficient heat to produce steam, the electrical heater is enabled for additional heating.

When the solar radiation is intense, the steam generated in the drum is of high quality and surplus to drive the terminals. The heat that is spare from the steam would be stored in the heat storage tank. The water coming out of the tank returns to the supplement tank, mixing with the backwater from the terminals, and

returns to the drum. When the solar radiation is weak, the heat storage tank, probably in combination with the collectors, could heat the water into steam for driving the terminals. If the terminals and the heat storage tank are not in use, the high temperature steam or water is switched into the plate heat exchanger to produce domestic hot water.

2.3 Running modes

The system is endowed with great flexibility to achieve variable functions and is able to runs in several operation modes which are switched through controlling the valves. Table 1 is a scan of all running modes.

Table 1 Seven running modes of the hybrid system

[1]	C-T	Collector mode	Collectors provide the complete production needs of steam.
[2]	C⊕E-T	Auxiliary heating mode	Collectors, joint with electric heater, provide heat for the steam generation
[3]	C-T // S	Heat storage mode 1	The steam provides heat for the terminal and heat storage tank in parallel.
[4]	C-S	Heat storage mode 2	The steam provides heat only for the heat storage tank.
[5]	C⊕S-T	Exothermal mode 1	Collectors and the heat storage tank in series provide heat for steam generation.
[6]	S-T	Exothermal mode 2	Only the heat storage tank provides heat for steam generation.
[7]	C-D	DHW mode	The steam heated by the collectors is used to produce domestic hot water.

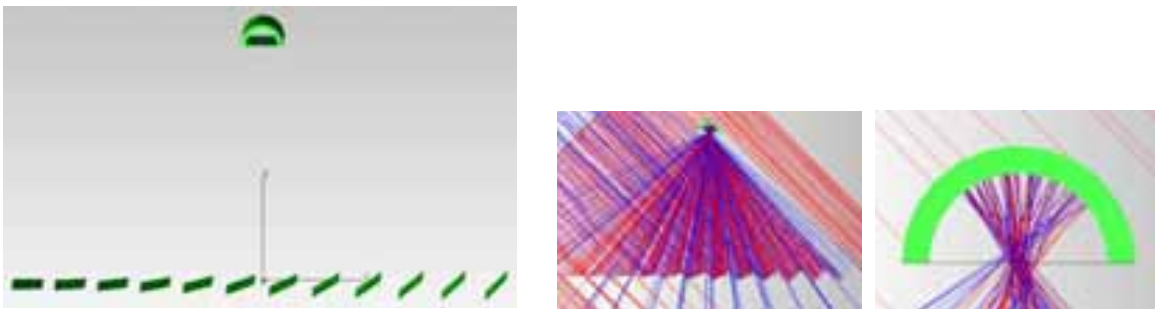
Note: The symbol ⊕ means the two equipment are in series while // in parallel.

3. Simulation

In the hybrid system, the solar collector plays a pivotal role in operation modes. And the performance of it has an essential effect on the refrigerator and power generator. Therefore, it is necessary to figure out the characteristics of the linear Fresnel collector. Simulation software TracePro and Fluent are used to establish the optical model and the heat transfer model of the collector respectively.

3.1 Optical simulation

First, according to the design parameters of the reflective mirrors and the cavity absorber, as well as the mirrors' slant angles in different incident angle of light, establish the mirror field and absorber model in TracePro's workspace (see Figure 3 (a)), and define the surface properties and light source. Then ray tracing simulation is carried on(see Figure 3 (b)) and the radiation energy distribution on the glass cover and the inner wall of the cavity is obtained.



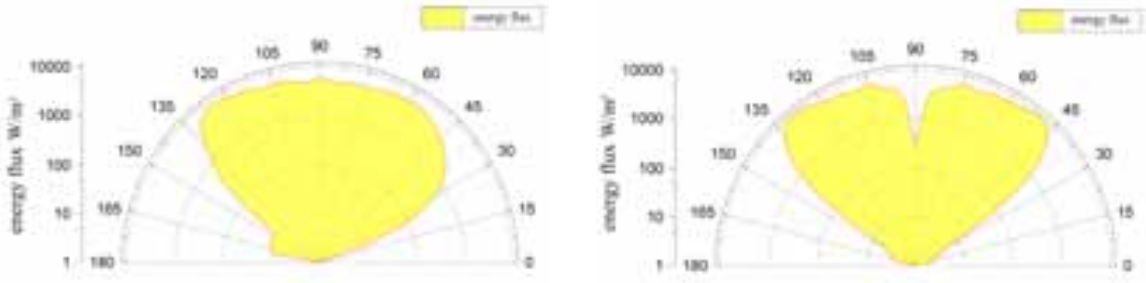
(a) (b)

Fig. 3 Geometry model of the collector and the ray tracing（$\alpha = 45°$）

The lights reflected by the mirror field converge onto the absorber, forming a facula of high energy density along the glass cover. Part of the lights reflected by the glass cover, most lights transmit through and disperse on the semi-circular inner wall of the absorber uniformly.

3.1.1 Energy flux density distribution

In the middle of the cavity absorber, take a cross section perpendicular to the longitudinal direction of the cavity, and the energy flux density distribution in polar coordinates is presented in Figure 4 and Figure 5(a). The incident angles are 45°and 90° respectively.



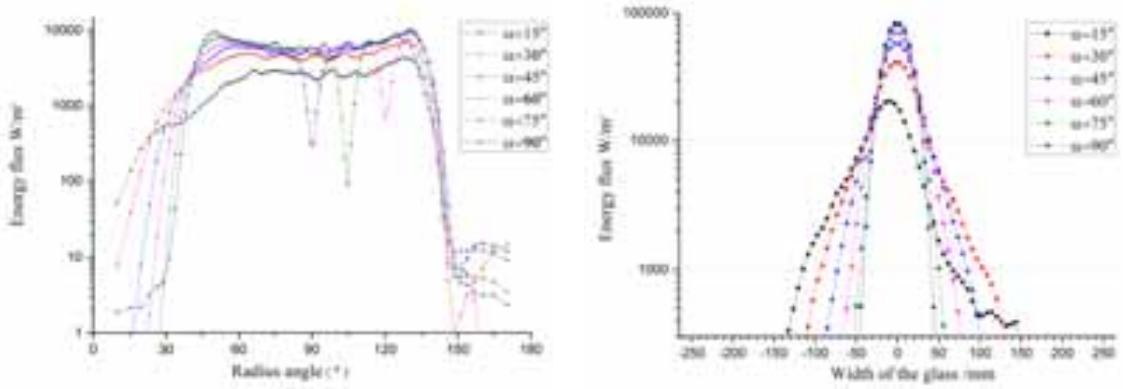
(a) $\alpha = 45°$ (b) $\alpha = 90°$

Fig. 4 Polar diagrams of the energy flux density on the inwall of the cavity

From Fig. 4 and Fig. 5(a) the characteristics of the energy flux density distribution on the cavity wall appear as follows: (a) with the rise of the incident angle, the energy density increases on the whole; (b) when the incident angle is 90° , there is a low ebb in the distribution of the energy flux density at the radius angle; The cause is the shadow the absorber project on the mirror field; (c) no matter how much the incident angle is, the energy falling on the cavity concentrate within the radius angle range of 30°-150°. Thus, the absorber's heat pipes should be arranged within the angular range.

3.1.2 Width of the facula

The width of the facula on the glass cover tells the concentration performance of the collector. Figure 5(b) shows the incident energy flux on the glass cover. As is seen, the width, the energy flux on the edge of which is 300W/m^2, decreases with the incident angle rising from 0° to 90°. According to the width of the facula, the geometric concentration ratio of the collector can be calculated (Table 2).



(a) on the inner wall of the cavity (b) on the glass cover

Fig. 5 Rectangular diagrams of the energy flux density on the absorber

Table 2 The facula width of the glass cover and the geometric concentrating ratio

Incident inclination angle	15°	30°	45°	60°	75°	90°
Facula's width/mm	285	240	190	145	110	95
concentration ratio	21.1	25.0	31.6	41.4	54.5	63.2

3.2 Heat transfer simulation

On the basis of the optical simulation's results, the appropriate distribution of the tubes in the cavity of the absorber is determined (see Fig. 6). There are five tubes that distributed within 30° ~150° where the heat flux energy is high and uniform. The boundary condition on the inner wall of the cavity is the energy flux distribution that is calculated in the optical simulation. Figure 7 shows the temperature contour on the cross section of the absorber. The aluminum fins between adjacent tubes transfer heat from the concentrated radiation to the tubes, however, is not able to deliver heat fleetly for the medium on both side of them perform weak in heat conduction.

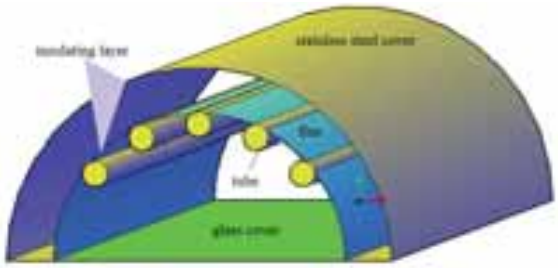


Fig.6 structure of the absorber

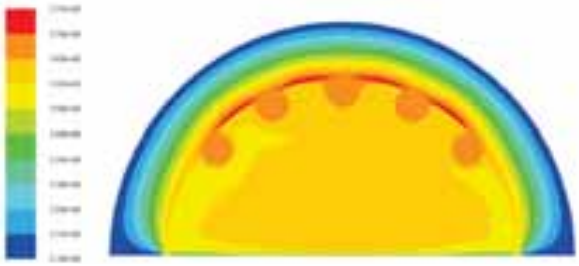

Fig.7 temperature contour of the absorber

The air's temperature is high and near to the water flowing through the tube, therefore the heat loss occurring on the glass cover is mainly in form of convection and radiation. Fig.8 shows the thermal efficiency and the heat loss ratio of the radiation of the absorber. The efficiency decreases with the rise of temperature of the water entering the tubes, and is about 54% when the water is 100℃. The pressure in the tube is high enough to ensure the water wouldn't vaporize. The radiation heat loss of the absorber maintains a steady level, about 1/3, which will rises slowly when the water's temperature is higher than 80℃. The convection heat transfer through the glass cover still dominates the whole heat loss of the absorber.

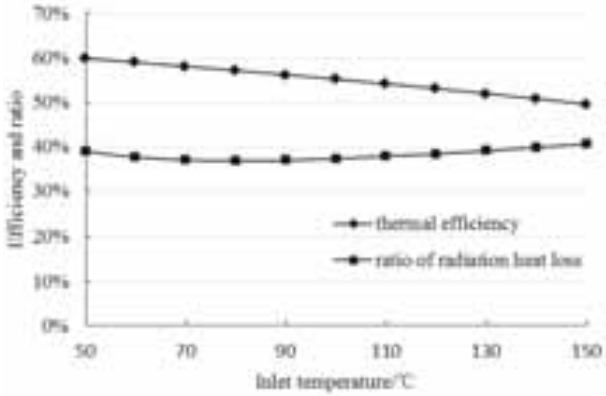

Fig.8 thermal efficiency and the heat loss ratio of the radiation of the absorber

The steam used in the terminals is about 120℃ where the efficiency of the collector is about 50%, so the heat collecting capacity of the collector is at least 2 times the steam heat consumption of the refrigerator and power generator. Considering the extra factors the simulation ignores, the practical efficiency is definitely lower than 50%, the mirrors' area of the collector is a key to guarantee the system performs well.

4. Conclusion

According to the introduction and simulation of the components and system, we could draw the conclusion as follows. The hybrid solar thermal power and cooling cogeneration system is designed with several running modes, which guarantees the system runs stably and reliably. In good weather condition, the system can meet the demand of cooling or electricity continuously. In poor condition, the storage unit works and can supply

supplementary heat for at least one hour. The Fresnel collector performs well in light concentration. The light incident into the cavity is focused on the angular range 30°~150°, and the facula formed on the glass cover is 9.5mm at minimum. As to the heat transfer property, the temperature of the tubes and fins in the cavity distributes even and uniform. The thermal efficiency of the collector is about 55% when the inlet temperature of water is 100℃ more or less. When matching the collector with the refrigerator or power generator, the heat collecting capacity should be considered carefully. The flexibility and reliability are reflected mostly by using the heat storage tank.

Abstract

This paper studies the effect of an absorber tube with and without an extended surface of a solar flat plate water heater. The investigation of this system is carried out using with data acquisition system. Here, a tube and rod are used as an extended surface inside an absorber tube. The extended surfaces are frictionally engaged with the inner side of the tube wall, and it is kept in the axial flow direction of the fluid flow path. The various performance factors such as friction factor and non-dimensional numbers are analyzed. The results show that the outlet temperature of the extended surface absorber tube collector is 8 °C higher when compared to the plain tube collector. Also, it was found that the rod extended surface gives a higher outlet temperature when compared to the tube extended surface. While there was low friction loss, no impact on the pressure drop was found using extended surface inside the absorbing tube.

.

Keywords: Solar flat plate water heater, extended surface absorber tube, non-dimensional number

1. Introduction

Solar flat plate water heating system plays a dynamic role in using solar energy. Active and passive techniques are used for enhancing the heat transfer rate in this system. Nowadays researchers are trying to modify the system and heat transfer fluid (passive), both of which play a vital role in enhancing the efficiency of the collector. The passive technique involves using helical, spiral and curved shaped tubes, twisted tape, micro and longitudinal fins apart from nanofluids. The performances of the systems are analyzed based on the flow type, non-dimensional number, thermal performance, the effect of friction and so on.

[1] This review paper highlights the work done using helical, spiral and curved shaped tubes for both single-phase and two-phase fluids. As much as single-phase heat transfer studies have been reported for the above-mentioned passive types; two-phase heat transfer characteristics have rarely been reported. Most of the work has been done for flow characteristics and pressure drop. [2-7] Different types of twisted tape inside an absorber tube have been worked for achieving better heat transfer rate. Several performance factors like friction factor, pressure drop and heat transfer have been analyzed experimentally and computationally. The effect of natural and forced circulation of heat transfer fluid has been reported using single-phase flow. Here, there are two types of twisted tapes used inside an absorber tube with different configurations namely - trailing edge and helical, which are subjected to comparison. In the helical twisted tape, for various twist angles of **3 to 7**, the heat transfer and the pressure drop were found to be increased.

The Nusselt number correlation was analyzed for the trailing edge twisted tape (comprising of full-length twist, twist with rod and spacer fitted at the trailing edge for lengths of 100, 200 and 300mm for twist angles of **3 – 5**). It was reported that the spacer fitted was better than all other configurations. The author also developed a new correlations for various twisted absorber tubes. The trail edge twisted tape was found to give better results than that of the helical twisted tape. Compared to the plain tube, the overall thermal efficiency enhancement lied from 38.7% to 53.3% at an increased pressure drop of 8.9%. [8, 9] The twisted tape attached with a wire nail and V-cut and their performance factors were evaluated and reported. While the heat transfer in these configurations was higher than the normal twisted tape, both these configurations have not been compared amongst themselves. In the above research works, the performance factors have been analyzed, and it has been reported that there was an enhancement of heat transfer while using twisted tapes. The ratio of pitch to diameter is an important parameter for twisted tapes, and it decreases with increasing pressure drop and heat transfer rate.

doi:10.18086/swc.2015.10.13 Available at http://proceedings.ises.org

[10] The simulation on the circular tube edge fold twisted tape was done, from which the thermal and hydraulic behavior were studied. The increase in the heat transfer in this case was accounted because of the tangential velocity and asymmetrical velocity profile. [11, 12] Thermal performance and friction factor have been analyzed using nanofluids with different twisted tapes and micro fins. Micro finned tube with double twisted tapes gave much higher heat transfer rate than all other types using nanofluids. This paper does not focus on the effect of pressure drop. [13] The experimental investigation on air gap for solar water heater using honeycomb structure with different bottom arrangement has been done. The results indicated that a 3mm gap from the bottom for a single honeycomb unit gave optimum results. Heat removal factor and collector efficiency factors were defined using uncertainty analysis and were compared with experimental data. [14] Theoretical analysis was performed to study the entropy generation and pressure drop for the solar collector with passive technique. The heat transfer fluid was used with metal oxides of nanoparticle at various volume fractions. The exergy destruction has been analyzed based on entropy generation for CuO nanoparticle. The entropy generation is less for CuO than that of other nanoparticle metal oxides. [15] Circular tube with longitudinal fins has been analyzed experimentally. It has been reported, that higher pressure drop occurs in staggered arrangement compared to continuous fin. [16, 17] The efficiency of the collector was theoretically and experimentally reported for sheet and tube solar water heater using rectangular duct and fin. The above analysis states that there is an enhancement of heat transfer when using staggered arrangement on absorber tube for various profiles. The objective of the present work is to design the solar water heater with low heat transfer resistance between the absorbent and absorber tube in order to increase the convective heat transfer coefficient without affecting the flow of an absorbent.

2. Experimental setup and data acquisition

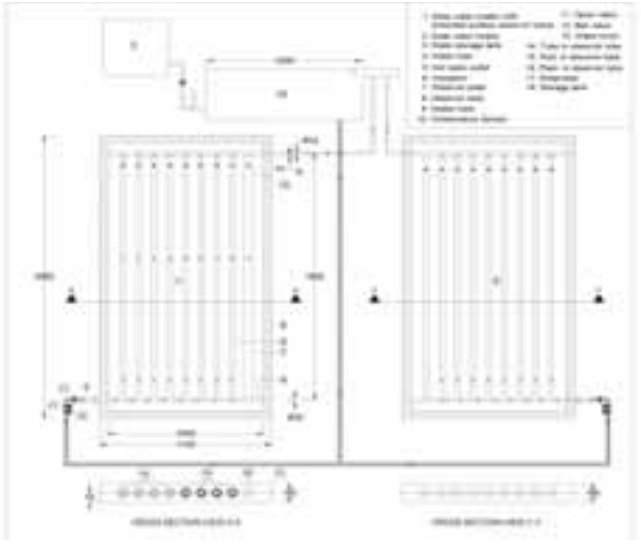

Fig: 1 Top view of solar water heater with and without modification

The study was carried out at the Institute for Energy Studies, Anna University, Chennai. The solar water heater collector was designed for 2 m^2 as per the dimensions are shown in Table.1.

a. Fig.1 shows two water heaters - one with (1) and one without modification (2). Open loop system was used.
b. Both flat plate solar collectors were placed in outdoor condition and oriented towards South with a tilt angle of 13º according to the topographical conditions.
c. The level of the tank was checked every 15 min. The system accelerated the driving force till there was no density difference in the absorbing fluid. The absorber plate absorbed the radiation emitted from the sun, which was transferred through the glass cover.
d. The insulations were provided for minimizing heat loss from the system to the surrounding. The selection of diameter for the extended surface rod and tubes were based on circumference and contact surface.

e. The experiment started at 9.00 am and readings was taken from 10.00 am. Before recording the data, primary work steps were taken like cleaning the glass, removing of residual water from the collectors, and inspecting the collector. The storage tank was filled with clean water every morning at 8.30 am and completely drained in the evening at 5.00 pm.

f. The setup ran from March 28th to May 9th and the following data were recorded at every 5-minute intervals. Measurements were taken multiple times and averaged to reduce experimental error. Solar radiation, ambient temperature, riser tube inlet and outlet temperatures were recorded continuously and averaged for every 30 min interval. On the final day, it was wound that there were a clear peak and deviation in radiation because of which that day was chosen for this study.

g. Thermocouple T – type was used for measuring the temperature with an error of 0.4% to its base value. The thermocouple was placed at each end of the riser tube at a 5mm distance of separation. The intensity of radiation was measured with the help of a pyranometer with an error of ±5% to its base value.

Table.1 Collector parameters

Collector Parameter	**Standards**
Type	Flat plate, 2 m^2, black paint, Single glass, tilt angle 13º.
Heat absorbent fluid	Water
Absorber plate area	1.62 m^2
Sun temperature	4350 K
Optical efficiency of the glass	0.82
Glass thickness	4 mm
Diameter of absorber tube	I.D = 13.8 mm, thickness of 1 mm
Lower and upper header	I.D = 22.3 mm, thickness of 1.5 mm
Insulation width	70 mm
Number of riser tube	9
Connecting pipe	I.D = 25.4 mm
Bottom insulation	Glass wool
Sidewall insulation	Thickness of 5 mm, wood
Absorber plate	Thickness of 4 mm, copper
Tube in tube	O.D = 2.5 mm, t = 0.5 mm, N= 8, L = 1500 mm, Copper
Rod in tube	D = 2.5 mm, N = 8, L = 1500 mm, Copper

3. Data reduction

Thermodynamic and Hydraulic analysis

Assumptions:

- At all the points in the system, the properties of the absorbent remain constant.
- All the processes are in steady state.
- Potential and kinetic energies are neglected.
- There is no soot formation and chemical reaction taking place inside the system.
- There is no mass loss in the absorbent fluid inside the system.

3.1. Energy and Mass balance

$$\sum \dot{E}_{in} = \sum \dot{E}_{out} \quad \text{(eq.1)}$$

$$\sum \dot{m}_{in} = \sum \dot{m}_{out} \quad \text{(eq.2)}$$

Energy balance equation can be expressed as

$$\dot{Q} + \sum \dot{m}_{in}\, \dot{h}_{in} = \dot{W} + \sum \dot{m}_{out}\, \dot{h}_{out} \quad \text{(eq.3)}$$

Whereas, $\dot{Q}_s$ is Available solar energy, expressed by the following equation [7]

$$\dot{Q}_s = I\ A_c \quad \text{(eq.4)}$$

Heat absorbed by the water (absorbing fluid) is

$$Q_{ab} = m\, C_p\, (T_{out} - T_{in}) \quad \text{(eq.5)}$$

3.2. Pressure Drop Analysis

$$\Delta P = f\, \frac{\rho V^2}{2}\, \frac{\Delta l}{d} \quad \text{(eq.6)}$$

$f = \frac{64}{Re}$ For laminar flow

$f = \frac{0.079}{(Re)^{\frac{1}{4}}}$ For turbulent flow

$$V = \frac{\dot{m}}{\rho \frac{\pi}{4} (D_H)^2}$$

Here K is loss coefficient, and D_H is hydraulic diameter

3.3 *Non-Dimensional number*

Nusselt number

$$Nu = \frac{h_i\, D}{K} \quad \text{(eq.7)}$$

$$\frac{1}{U_0 A_0} = \frac{1}{h_i A_i} + \frac{\ln \frac{D_0}{D}}{2\pi\, L\, K_w}$$

Prandtl number

$$Pr = \frac{C_p\, \mu}{K} \quad \text{(eq.8)}$$

Reynolds number

$$Re = \frac{D_i\, \rho\, V}{\mu} \quad \text{(eq.9)}$$

4. Result and discussion

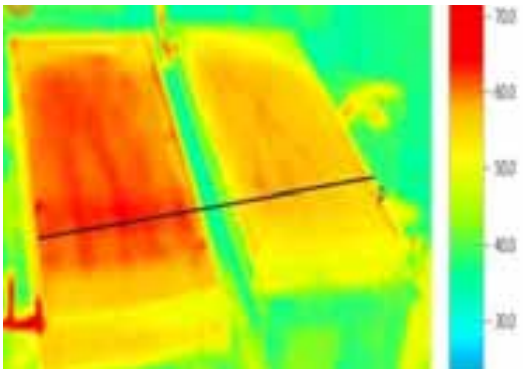

Fig: 2 (a) Thermal image

Fig.2 (b) Profile view

Fig.2 a and b shows that the temperature of the collector 1 is higher than that of collector 2. In Fig. 2 (b) Profile view, the cross section clearly shows that the peak temperature difference achieved by 8 °C. Testo 875-2 instrument was used for the thermal image. Fig. 2 (a) taken at a reflection temperature of 20 °C. The temperature range was given at the right side of the Fig. 2 (a). The average temperature of the collector 1 and 2 is 62 °C and 54 °C respectively. There is a gap between collector 1 and 2 and it impact on profile view curve. In the profile view, the gap is shown as slag in temperature. The cross section line is drawn at 0.675m from the bottom of the collector. The increase in temperature is due to increase in contact surface area with the axial flow to the water, and the extended surface reduces the thermal and viscous boundary layer. Only at maximum radiation, the maximum temperature difference is achieved. There is no temperature difference between rod and tube extended surface during acceleration and deceleration of radiation. The friction factor is increased for extended surface due to increase in the contact surface with the water. The rod extended surface has higher efficiency than the tube and plain tube configuration in all operating condition because of the thermal mass of the extended surface and friction factor.

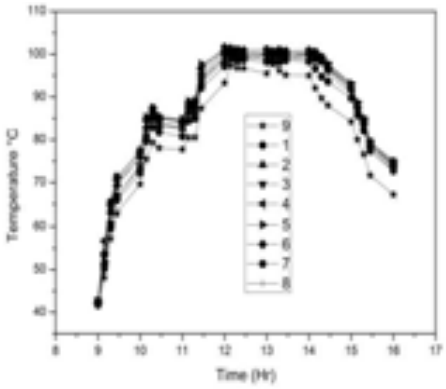

Fig.3: Time Vs Tubes outlet temperature

The arrangement of tubes shown in fig. 1. In Fig.3 first four tubes contain tube extended surface and are compared with a plain tube. Whenever the retardation takes place in radiation, there is a major peak in temperature differences has been achieved. In a constant peak radiation, there are no changes in outlet temperature of the tube. The heat absorbing fluid absorbed the heat, and it changed the phase so the maximum heat capacity achieved by the heat absorbing fluid in a peak radiation. While compared with plain tube there is an average difference in temperature around 8 °C achieved. The result shows that 4^{th} tube gives much better heat transfer compared with other tube because of its focus point. The extended surface increases the wetted surface area which in turn increases the heat extraction from the tube wall to the fluid.

Radiation which fell on earth surface on 9/5/14 is shown in fig 4. There is an unsteady radiation for up to 11.45 am and thereafter gradual retardation took place. Maximum peak achieved at the time of 11.45 am. The collector performance was analyzed for this day because of its unsteady radiation. This graph showed the average temperature of each tube outlet and compared with each other. The tube and rod in extended tube surface show clear performance ranges for different radiations. There was no major deviation in outlet temperature. Whenever the mass flow rate is higher, it affects 1 to 2 °C in each tube. Rod in the tube will result in better performance compared to the tube in tube extended surface. The intensity of solar radiation decreases from 01.00 pm. Hence the heat input to the collector is decreasing. The temperature difference between inlet and outlet decreases gradually which decreases the driving the force. Hence it reduces the instantaneous efficiency of the collector. The instantaneous efficiency is poor in morning and evening may be due to the higher reflection of solar radiation by the glazing which reduces the heat transfer.

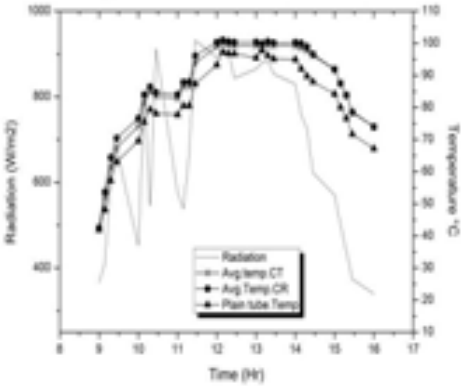

Fig.4 Time Vs Temperature difference with and without extended surface

Fig.5 shows the analysis of the outlet temperatures of both the collector. Collector 1 gives maximum output temperature in a peak radiation. During acceleration and retardation, there are no temperature changes in outlet because of the velocity of the heat absorbing fluid. In a thermosyphon process, the heat absorbing fluid leaves the system only when density difference is high. The velocity of the absorbing fluid is the determining factor for the outlet temperature of the collector. The temperature difference between inlet and outlet temperature is high. The extended surface increases the contact surface area which in turn increases the heat removal from the tube wall to the fluid. Hence there is a gradual increase in the Reynolds number for extended surface which in turn increases the instantaneous efficiency of the collector.

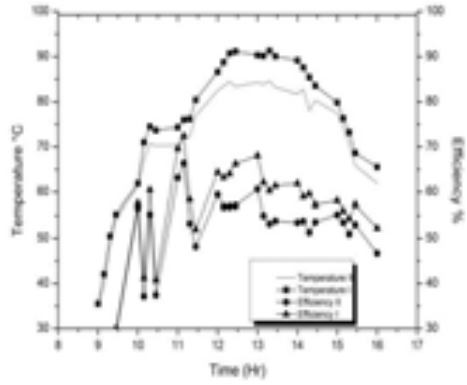

Fig.5: Time Vs Efficiency, Outlet temperature

Fig.6 explain that extended surface at leading edges will enhance the inertia forces of the heat absorbing fluid, so it reduces the viscous boundary layer. The extended surface absorber tube of the rod has maximum velocity than the tube in tube extended surface and plain tube. A thin boundary layer forms nearer to the wall surfaces, and it is stationary with respect to the surface. The thickness of the layer will be reduced when enhancing the velocity of the absorbing fluid till the free stream velocity is reached. There is no boundary layer at free stream velocity.

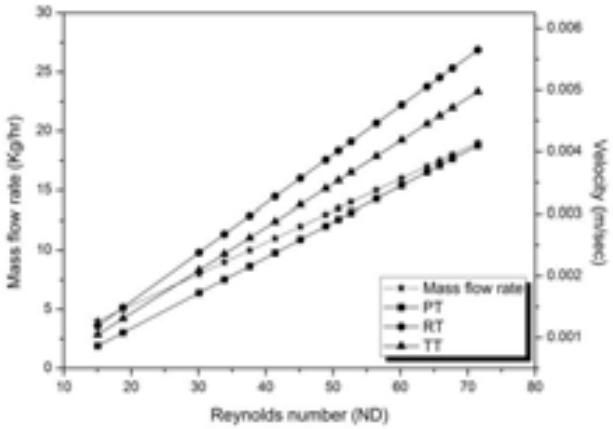

Fig.6: Effect of Reynolds number at different mass flow rate.

Fig.7 gives a clear picture about the relationship between Nusselts number and Reynolds number. When mass flow rate increases, inertia force also increased and reduced the thickness of the viscous boundary layer. It enhances the heat transfer coefficient. The Nusselts number rises with increasing Reynolds number if the mass flow rate is increased. The extended surfaces are frictionally contact with the inner side of the tube wall, and it extends the contact surface of the water flowing through it, so it reduces the plate temperature. The heat removal rate from the absorber plate of the extended surface collector is higher than that of the plain tube collector, and it has the minimum plate temperature. The rate of heat transfer from the absorber tube to water is high for the extended surfaces. The rod extended surface collector has very less absorber plate temperature than the plain tube and tube extended surface collector at same intensity of radiation due to the mass of the rod extended surface. A stably stratified layer of light and warm water is sustained near the top of the extended surface which absorbs the heat. The warmer water near the bottom of the absorber tube induces the convective motion, and it increases the velocity. A thin boundary layer forms near the wall, and it is stationary with respect to the surface. Buoyance force removes the energy from the fluid, higher than shear force. The turbulence is damped against the buoyancy force, and the heat transfer is entirely due to laminar flow in flat plate collector. Free convection increases with increase in the Nusselt number, and it is dominating the performance of the collector. Free convection is stronger when the Reynolds number is low. Due to increase in contact surface, the extended surface has higher Nusselt number.

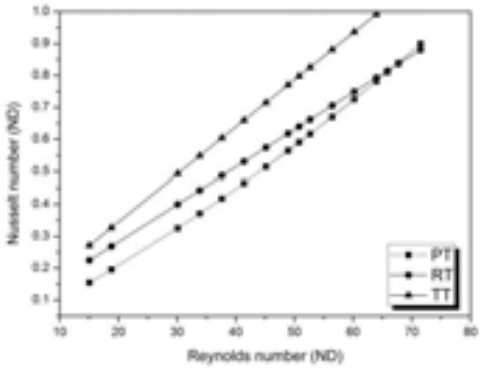

Fig. 7: Effect of Reynolds number on heat transfer

Fig. 8 shows the variation of friction factor with respective to the Reynolds number. Darcy friction factor is derived with the help of velocity of the flowing fluid inside the tube. Darcy friction only for tubes inside the collector. The viscous boundary layer is hampering the absorbing fluid velocity, and it will reduce Reynolds number. The pressure drop is measured for entire collector using head losses, and it is used for measuring the fanning friction factor. The extended surfaces have very less enhancement in friction factor compared to other types of heat transfer enhancement devices like twisted tape and grooved tube. Because of this extended surfaces are frictionally engaged with the inner wall, and it is fixed with the axial flow direction of the water. These heat transfer enhancement devices are highly suitable for the passive technique. As it is evident from the figure, the higher pressure drop is obtained for higher Reynolds number, and it decreases with a decrease in the flow rate.

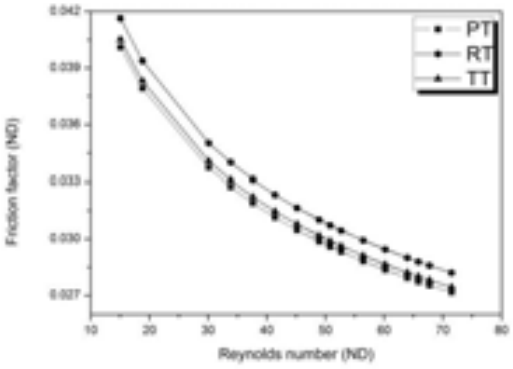

Fig.8: Effect of Reynolds number on viscous of the absorbing fluid

Fig.9 clearly shows the deviation of theoretical outlet temperature with experimental. Maximum deviation between the experimental and theoretical data was 10%. The theoretical outlet temperature of the collector does not consider the thermal loss inside the collector, so the value is higher than experimental.

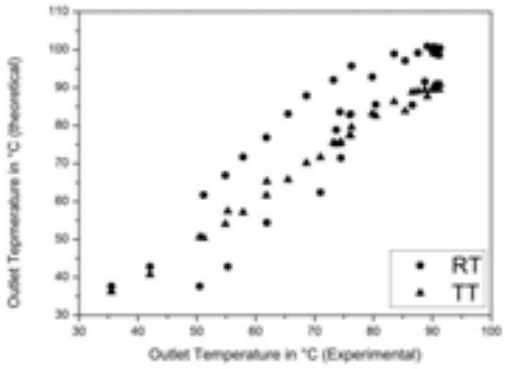

Fig.9: Comparison of experimental and theoretical outlet temperature data of the collector

5. Conclusion.

The experimental study of solar water heater with extended surface absorber tube was performed, and the Rod extended surface provides higher heat transfer rate compared to Tube extended surface because of the mass flux of the extended surface. Extended surface reduces the thermal and viscous boundary layer, so it increases the convective heat transfer rate. The velocity is increased by means of increasing the shear production, and the extended surfaces have been found to be effective in augmenting the heat transfer. The efficiency of the modified collector is increased by 22%. Extended surface also increases the non-dimensional numbers and friction factor.

Nomenclature

A_c	Collector area, m^2
C_p	Specific heat, $Jkg^{-1}K^{-1}$
D_h	Hydraulic diameter, m
f	Friction factor, Non dimension
I	Intensity of radiation, Wm^{-2}
k	Thermal conductivity, $W\ m^{-1}K^{-1}$
k_i	Thermal conductivity of insulation material $W\ m^{-1}K^{-1}$
k_w	Thermal conductivity of the tube wall, $W\ m^{-1}K^{-1}$
L	Length of the tube, m
m	mass flow rate, kgs^{-1}
N	Number of tubes, Nondimension
Nu	Nusselt number, Nondimension
Pr	Prandtl number, Nondimension
Re	Reynolds number, Nondimension
Q_{ab}	Heat absorbed, W
T_{Out}	Outlet temperature of the collector, K
T_{in}	Inlet temperature of the collector, K
T_a	Atmospheric temperature, K
V	Velocity, ms^{-1}

Greek Symbol

ρ	Density, kgm^{-3}
μ	Dynamic viscosity, Nsm^{-2}
μ_w	Dynamic viscosity of tube wall, Nsm^{-2}
η	Efficiency, %

Suffix

PT	Plain tube
RT	Rod as extended surface
TT	Tube as extended surface

Abstract

Photovoltaic thermal (PVT) solar panels produce both thermal and electric power from the some area. This paper concerns a PVT design where the series connected strings of cells are laminated using silicone to an aluminium receiver where the heat transfer fluid flows.

An evaluation of the impact of reaching high temperatures in the cell structural integrity and performance is presented. Eight small test receivers were made in which the following properties were varied: Size of the PV cells, type of silicone used to encapsulate the PV cells, existence of a strain relief between the cells, size of the gap between cells and type of cell soldering (line or point soldering).

These test receivers were placed in an oven for one hour, under eight different monitored temperatures. The temperature of the last round was set at 220°C which well exceeds the highest temperature the panel design can reach. Before and after each round in the oven, the following tests were conducted to the receivers: Electroluminescence (EL) test, IV-curve, diode function, and visual inspection.

The test results showed that the receivers made with the transparent silicone and strain relief between cells experienced less micro-cracks and lower degradation in maximum power. No prototype test receiver lost more than 30% of its initial power, despite the large cell breakage shown in some receivers. Prototype receivers with transparent (softer) silicone showed much far less cracks and power decrease when compared to red (harder) silicone receivers. As expected, larger cells are more prone to develop micro-cracks after exposure to thermal stress. Additionally, existing micro-cracks tend to grow in size into larger micro-cracks relatively fast with thermal stress. The EL imaging taken during our experiment leads us to observe that it seems far easier for existing cracks to expand than for new cracks to appear.

Keywords: *Stagnation Temperature, Electroluminescence test, IV-Curve, Concentration, PVT*

1. Introduction

Photovoltaic thermal (PVT) solar panels produce both thermal and electric power from the same area. Combining solar thermal and photovoltaic can be a way to increase the efficiency of the silicone cells by reducing the working temperature through active cooling (Giovinazzo et al. 2014).

Concentration allows a cost reduction by decreasing the receiver size in the panel. As per Giovinazzo et al. (2014), the biggest advantage of this type of collector design is to decrease material cost by reducing the amount of expensive components utilized (solar cell, receiver and/or selective surface).

Combining concentration with PVT (C-PVT) can also prove to be advantageous. However, concentrating does not bring only advantages. For non-concentrating collectors PVT, one disadvantage is

doi:10.18086/swc.2015.10.14 Available at http://proceedings.ises.org

the longitudinal shading caused by the frame or the absence of reflector on some solar incidence angles. This can have a very large impact on the electrical performance, if measures such as placing extra diodes are not taken (Gomes et al, 2013).

Stagnation temperature is reached when the heat losses of the panel are equal to the energy received from the sun. Another particularly important disadvantage of concentration is the increase of the stagnation temperature which can cause damage to the materials of the collector, in particular to the solar cells. This issue will be covered in detail in this paper.

A C-PVT collector was designed to produce 240W (electricity) and 1250W (thermal). An installation with 8 prototype C-PVT collectors has been made in a warm country and was found to produce only 1200 W (el). After one day, during which the stagnation temperature was reached, the production was found to have degraded significantly to 200W (el).

The most critical part in the manufacture of the PVT collector is the receiver, including all processes from the soldering of the cells to the choice of the materials (Khatri et al. 2011). Problems with the manufacturing process of the prototypes, in particular with the cell soldering, account for the difference between expected 1920W (el) and the initially obtained electrical output of 1200W. Such issues can easily be eliminated by process automation with an automatic tabbing stringer machine.

However, a more important issue that was discovered in this prototype C-PVT installation was the post-stagnation electrical power reduction to 200W. A number of hypotheses on the possible reasons for this decrease have been identified and a set of tests were designed to with the goal of gathering data to evaluate each hypothesis.

The Electroluminescence test (EL) is a powerful tool used to control the quality of the PV cell strings. Using this technique it is possible to identify defects that are not visible to the naked eye such as micro-cracks and black (or "dead") areas. These two defects are the principal cause of power losses in the cell strings, a fact which can be confirmed in the IV-Curve test (Chaturvedi et al. 2012).

2. Description of the collector and its components

Fig. 1 shows a schematic of the collector viewed from the top while fig. 2 shows a picture of the actual collector. The total size of the collector is 2.31 x 0.955 m. The length of the thermal receiver is 2.290 m and the height is 0.158 m (Bernardo et al. 2011).

The efficiency for direct (or "beam") light η_{direct} of the collector 70%, while the efficiency for diffuse light $\eta_{diffuse}$ is 50,8% (Gomes et al. 2014). Furthermore, the linear loss coefficient a_1 is 4,484 W/(m^{2}K) and the secondary loss coefficient a_2 is 0,0034 W/(m^{2}K).

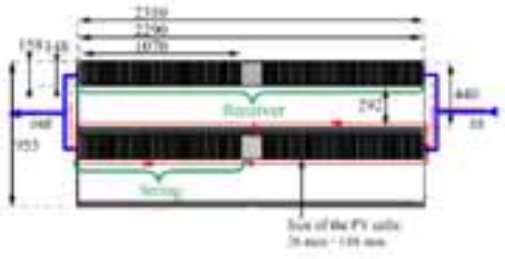

Fig. 1 - Top view of the PVT hybrid collector. The water connections are in blue and the electrical connections in red (Gomes et al. 2014)

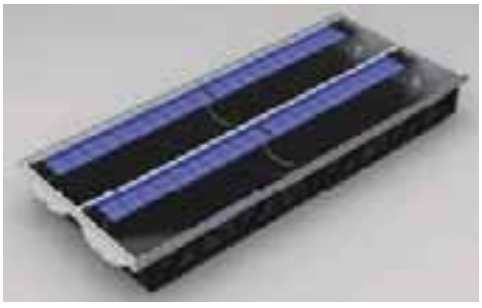

Fig. 2 - Solarus PVT hybrid collector

Reflector: The reflector geometry of the studied collector was initially developed by Vattenfall and the design is called Maximum Reflector Concentration (MaReCo) which belongs to a family of stationary reflectors patented by the Swedish company Solarus Sweden Sunpower AB. The reflector is composed of

a compound parabolic and circular reflective material used to concentrate the solar radiation which is made of anodized aluminum with a total solar reflectance ρ_{total} of 95%.

Receiver: The receiver is made of a 2.29m alumunium extrusion with a maximum expansion of 8 milimeters. The cells and silicone are laminated on both sides of the receiver.

Cell encapsulation: Cell encapsulation is done with two layers of silicone. The bottom layer: between the receiver aluminium core and the cells. The top layer: between the cells and the air.

In the prototypes created for the tests, two types of silicone gels are used: A highly transparent and electrically insulating silicone is used in the top layer but it could also be used in the bottom layer. A reddish brown silicon that is equally electrically insulating but has better thermal conductivity can only be used in the bottom layer since it is not transparent and if used on the top layer would block the sunlight from reaching the cells. The red silicone is considerably stiffer than the transparent silicone and thus transmits more stress to the cells when the receiver experiences thermal expansion.

Silicone Solar Cell: There are several cell string designs but the standard consists of 2 strings of 38 PV cells connected in parallel for each receiver side. Both the front side and the back side of the receiver consist of two PV strings each. The measured prototypes have two different cell sizes: a) 28mm*148mm or b) 52mm*148mm. This way, total number of PV cells per collector can be 152 or 304 cells, depending on the prototype design.

Glass: The module contains a glazed protection which is made of low iron glass with a solar weighted transmittance τ_{glas} of 95% (Gomes et al. 2014).

3. Description of the stagnation temperature issue

Eight C-PVT collectors and six concentrating thermal (T) collectors were installed in a warm country as show in figure 3. The eight C-PVT collectors were connected to eight micro-inverters. Four thermal loops were connected to a central tank. Three loops contained two PVT and two T while one loop had only two PVT collectors.

Fig. 3 -Test installation at latitude 30^0

The water outlet was not connected in the first day which was a very sunny and warm summer day. This implies that the collector has reached stagnation temperature which is around 175 ^{o}C.

One hour after installation, the combined output of the eight PVT was measured and found to be only 1200 W (el) instead of the expected 1920W (el). It should also be noted that the eight PVT collectors may also have been exposed to sunlight without cooling, prior to the installation. In the morning of the following day, the electrical production of the installation was again measured and it had been greatly reduced to only 200W.

The first measured electrical output of 1200W is well below the theoretical value expected of 1920W. This decrease is clearly a manufacturing problem which the company that produced the prototypes is aware that it is caused by the manual hand soldering process and that the company will solve this matter with the purchase of an automatic tabbing stringer machine during Q3 of 2015.

However, a more important issue that was discovered in this prototype C-PVT installation was the electrical power reduction to 200W that the installation showed in the second day, after prolonged stagnation. Four hypotheses on the possible reasons for this large decrease have been identified and are described below:

- The diodes broke down due to the high temperature
- The thermal expansion of the copper cell ribbon has damaged the cells
- The thermal expansion of the aluminium receiver has damaged the cells
- Unsoldering of the copper ribbon from the cells caused by the stagnation

The thermal part of the C-PVT installation was not affected in any way by stagnation. No leaks were found as well as no reduction in thermal power output. In fact, a slight thermal output increase has been reported since the solar cells are not converting the solar irradiation into electricity.

The thermal part of the C-PVT installation was not affected in any way by stagnation. No leaks were found nor any reduction in thermal power output. In fact, a slight thermal output increase has been reported, and is understandable as the solar cells are no longer capturing a portion of the energy and converting it to electricity.

4. Method

The prototype receivers:

In order to discover the cause of the electrical performance reduction, eight prototype small receivers were manufactured at the company that made the prototypes C-PVT in the installation: Solarus Sunpower Sweden AB. Table 1 details the characteristics of each small receiver:

Table 1 - Characteristics of the eight small receivers

Receiver	Cell size	Cells number	Cell Gap	Soldering	Silicone layers	Tabbing Strip
Receiver 1	1/6	7	No	Line soldering	Red-Transparent	Straight
Receiver 2	1/6	6	No	Line soldering	Transparent-Transparent	Straight
Receiver 3	1/6	6	Yes	Line soldering	Red-Transparent	Strain relief
Receiver 4	1/6	6	Yes	Line soldering	Transparent-Transparent	Strain relief
Receiver 5	1/6	6	Yes	Two points soldering	Transparent-Transparent	Strain relief
Receiver 6	1/6	7	No	One point soldering	Transparent-Transparent	Straight
Receiver 7	1/3	4	Yes	Line soldering	Transparent-Transparent	Strain relief
Receiver 8	1/3	4	No	One point soldering	Transparent-Transparent	Straight

The 8 receivers were identical with the exception of 6 parameters that were varied: Cell size, cell gap, cell number, soldering type, type of silicon used, existence of the strain relief. Four parameters are further explained below:

- Two cell sizes were used: 1/3 (52*148mm) and 1/6 (28*148mm)
- The cell gap is the space between the cells. *"No"* means the small standard gap while *"Yes"* means a longer gap (approximately triple of the standard gap)
- The strain relief is simply a bump in a long copper busbar that is designed to cope with the thermal expansion and prevent cell damage.
- The strain relief is simply an exaggerated "s" shape bent in the tabbing strip between each cell, designed to absorb thermally-induced mechanical stress without passing it on to the cells.
- The silicone is applied in two layers. A bottom layer placed on the aluminium receiver before the

cells. And a top layer placed after the bottom layer has totally solidified and at the same time as the solar cells. Two types of silicone were used. A soft transparent silicone with a high transparence and high dielectric resistance and a harder red silicone with no transparence, similar dielectric properties and a lower heat resistance.

Test method:

The test consists in placing the receiver 8 times inside an oven for one hour each time with a gradual increase of the oven temperature. In the first round the receiver temperature will be raised from 0°C to 60°C and in the next rounds 80°C, 100°C, 130°C, 150°C, 180°C, 200°C, 220°C.

It is important to point out that the collectors stagnation temperature is 175°C. Nevertheless, the tests at 200°C and 220°C give interesting results in order to determine a safety margin.

After each thermal cycle, the following parameters are recorded:

- Electroluminescence (EL) Test: IR photograph of the cells on the receiver was made using a Digital Rebel XTi Black Canon Camera without an IR filter. The system features an image size of (3,888 x 2,592) in RAW format with 10 megapixels. The test was done in a completely dark chamber. Cells were in forward bias with a current close to 4A. This test allowed the team to spot microcracks which are not visible to the naked eye.
- IV Curve test in a solar simulator: Pmax, Imax, Vmp, Isc, Voc, FF
- Diode Function test
- Visual Inspection: note the condition of the cells, any discoloration, etc.

An important note is that the cells in the prototype receivers are soldered manually which means that some micro-cracks arise from prototype production issues that will not occur in automatic cell soldering production. For this and other reasons, a baseline scenario was also tested recording all the above shown parameters. Additionally, the cells in the prototype installation displayed in figure 3 are also manually soldered.

5. Results and Discussion

The first small receiver to be tested had very similar characteristics to the collectors of the installation shown in figure 3.

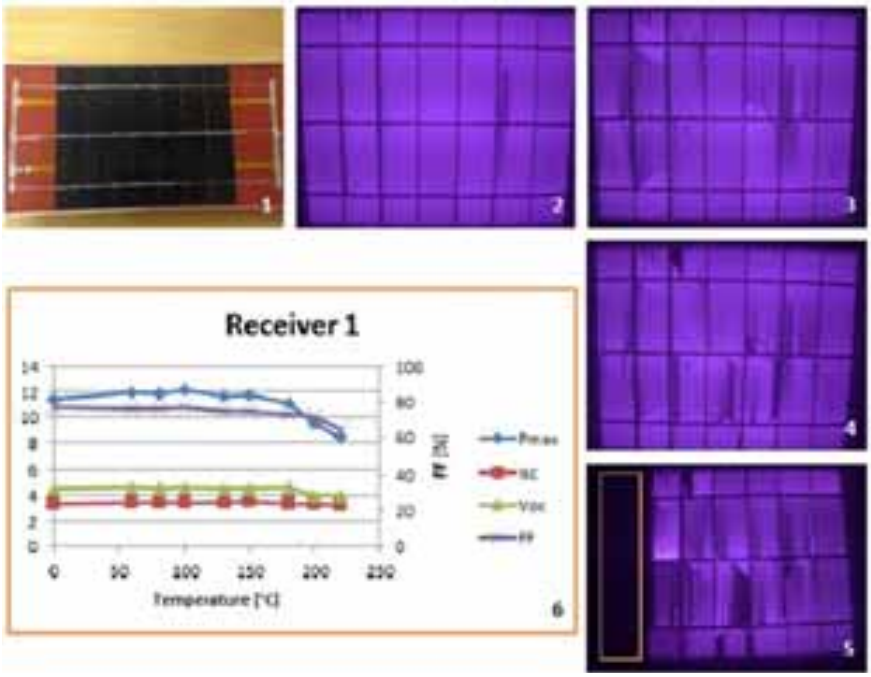

Fig. 4 – 1) Receiver 1; 2) Baseline; 3) Round 5 (150°C); 4) Round 6 (180°C); 5) Round 8 (220°C); 6) Parameters of the IV curve at different temperatures (Isc shown in the left Y axis).

As expected, after round 3 (exposure to 150°C), the EL test showed that the string has dark areas and a large number of micro-cracks which lead to a power decreases shown in figure 4 below. Raising the temperature in following heating rounds has significantly increased the amount of dark areas and micro-cracks. In the last round one cell became completely black caused by a short circuit between the top and bottom of the cell. The reason for the short circuit has not been determined but a likely explanation is that the solder on the top ribbon melted (or simply got contact) through a crack and reached the bottom ribbon.

The only difference between the first receiver and the second is the bottom silicone layer. In receiver 2, transparent silicone was used on both layers. From the 5 rounds of EL tests shown in figure 5, it is possible to see a large increase in microcracks after round 4 (180°C). Despite this, the IV curve basic parameters remain more or less constant throughout the 8 rounds with only a minor power decrease.

The number of micro-cracks in receiver 1 is higher than in receiver 2 for all temperatures, despite the baseline test (image 2) showing similar numbers.

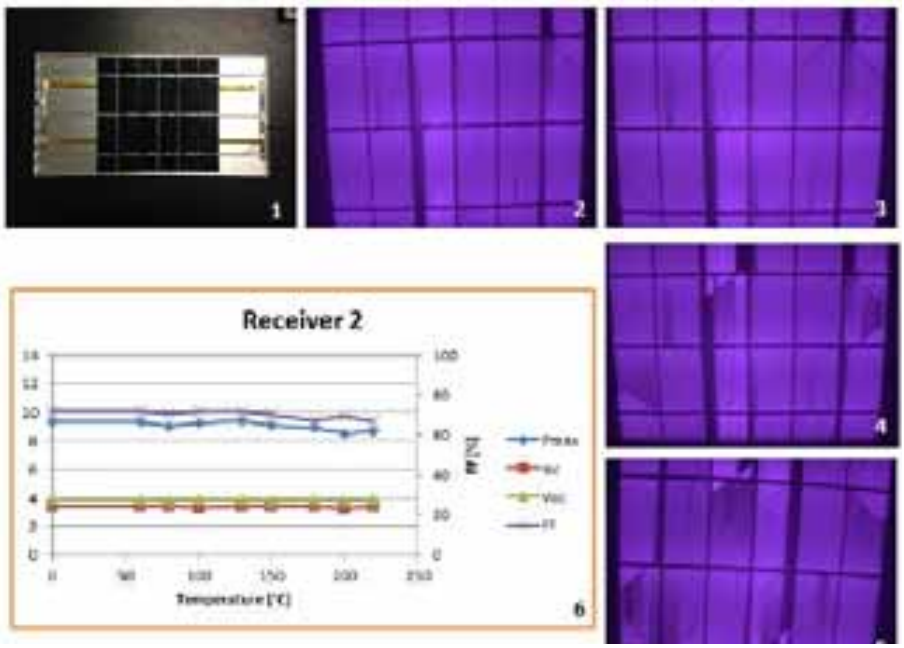

Fig. 5 – 1) Receiver 1; 2) Baseline; 3) Round 5 (150°C); 4) Round 6 (180°C); 5) Round 8 (220°C); 6) Parameters of the IV curve at different temperatures (Only Isc on the left axis).

The main goal of building receiver 3 and 4 was to test the impact of reducing the stress on the cell caused by the thermal expansion of the ribbon. This way, a strain relief bend was inserted before and after each cell. In order to isolate the impact of the different types of silicones two receivers were made: One with red silicone (receiver 3) and another with transparent silicone (receiver 4). The results from receiver 3 can be seen in Fig. 6 and from receiver 4 in Fig. 7.

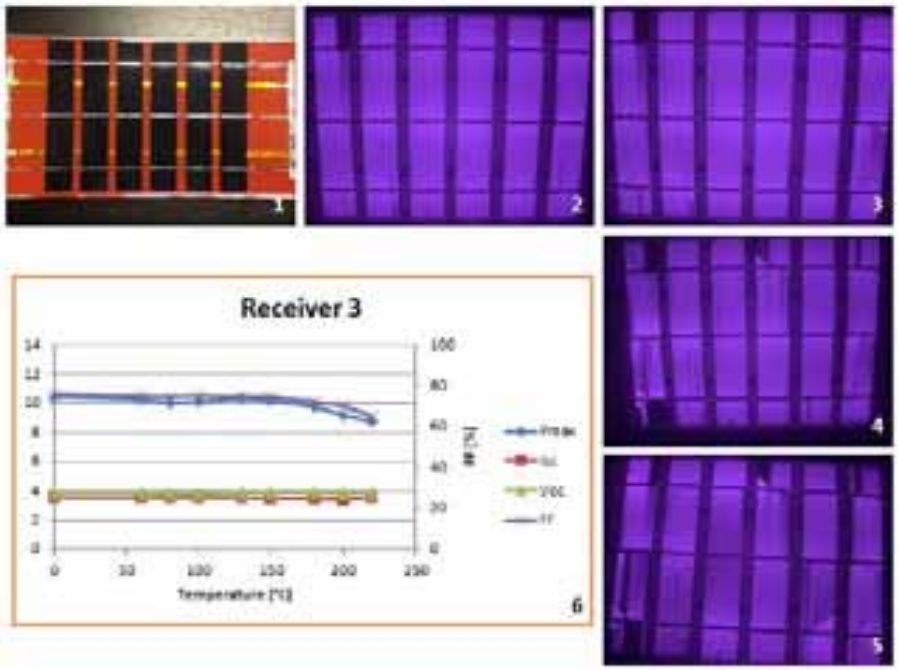

Fig. 6 – 1) Receiver 1; 2) Baseline; 3) Round 5 (150°C); 4) Round 6 (180°C); 5) Round 8 (220°C); 6) Parameters of the IV curve at different temperatures (Isc shown in the left Y axis).

The EL tests in Figure 6 show that in a receiver with red silicone, even with the strain relief between the cells, a large number of micro-cracks appear when exposed to higher temperature (180°C). Compared with receiver 1, receiver 3 exhibits a smaller power drop, albeit still displaying a significant power drop in the last 2 rounds.

In Fig. 7, the cells of receiver 4 have no significant damage along the 8 rounds, representing an improvement from the results obtained with receiver 2. However, receiver 4 showed one black cell in the last round likely caused by the same reason as in the receiver 1. The same black cell that appeared at round 7 (200°C) is also responsible for the sharp 15% drop. Excluding that effect, the power remains considerably constant.

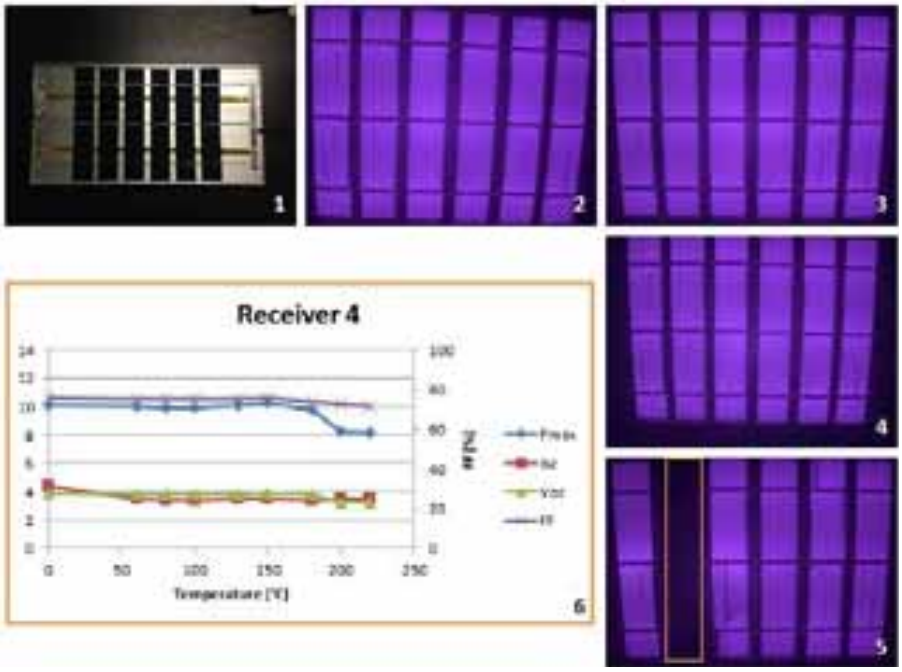

Fig. 7 – 1) Receiver 1; 2) Baseline; 3) Round 5 (150°C); 4) Round 6 (180°C); 5) Round 8 (220°C); 6) Parameters of the IV curve at different temperatures (Isc shown in the left Y axis).

Since our research group did not have, at the time of these tests, access to an expensive automatic cell soldering machine, it was also important that the group investigated the impact of different manual soldering techniques. This was accomplished with receivers 5 and 6 that have been made with point soldering instead of continuous soldering, like all previous receivers. Receiver 5 was done with two point soldering and strain relief, while receiver 6 had no strain relief and only one point soldering.

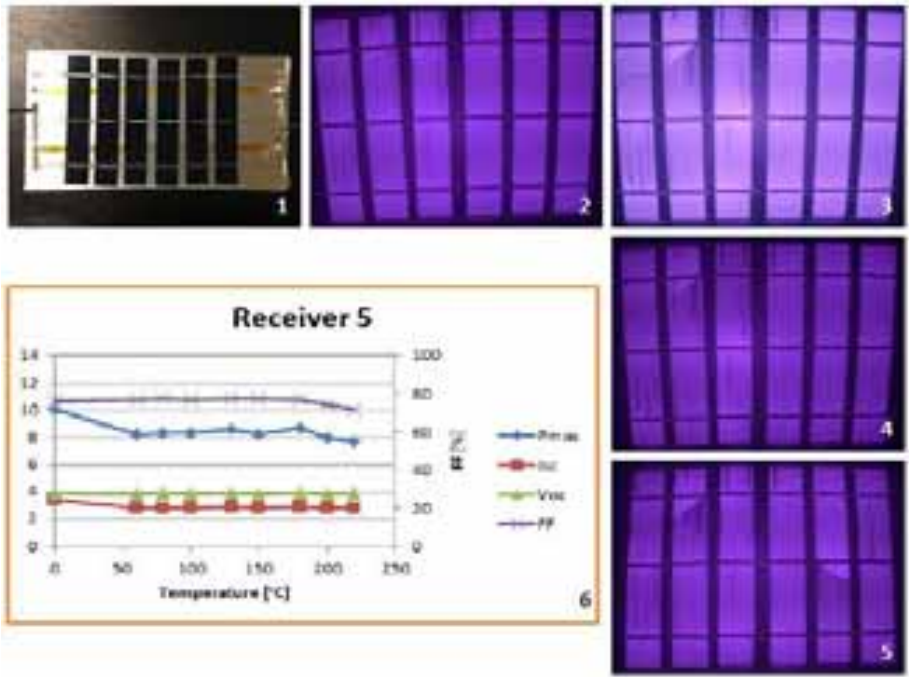

Fig. 8 – 1) Receiver 1; 2) Baseline; 3) Round 5 (150°C); 4) Round 6 (180°C); 5) Round 8 (220°C); 6) Parameters of the IV curve at different temperatures (Isc shown in the left Y axis).

In the graph of figure 8, it is visible that the Pmax of receiver 5 has one initial decrease at 50°C . This is due to the two broken cells shown in image three and it is likely to have been cause by our cell handling. If this effect is excluded, the Pmax remains relatively stable. It is interesting to note that only at 220°C one extra microcrack appears. The one point point soldering has much smaller electrical contact between the busbar and the cell than the line soldering but this shows no consequences in our measurements.

In figure 9, the Pmax of receiver 6 also remains fairly stable until one the cell becomes dark at 200°C (round 7) which seems to indicate that there are no large differences between one and two point soldering as well as with the existence of strain relief. One microcrack appears at 180°C and another appears 220°C.

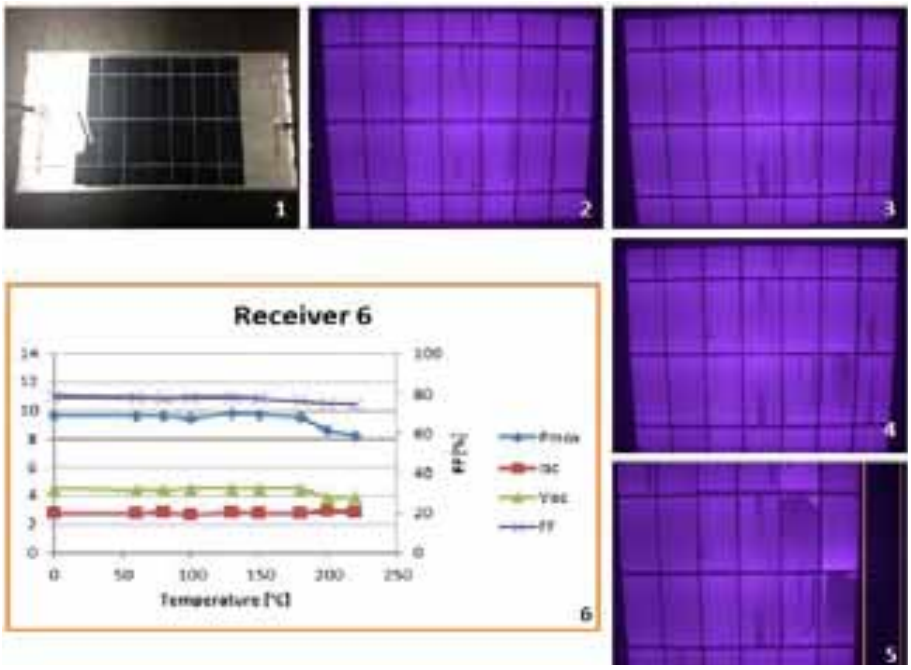

Fig. 9 - 1) Receiver 1; 2) Baseline; 3) Round 5 (150°C); 4) Round 6 (180°C); 5) Round 8 (220°C); 6) Parameters of the IV curve at different temperatures (Isc shown in the left Y axis).

Receivers 7 and 8 were made to evaluate the impact of temperature in larger cells (148mm*52mm). Receiver 7 was made with a much larger gap than usual between the cells, with line soldering and with strain relief between all cells while receiver 8 was made without strain relief, with point soldering and with a standard gap between cells.

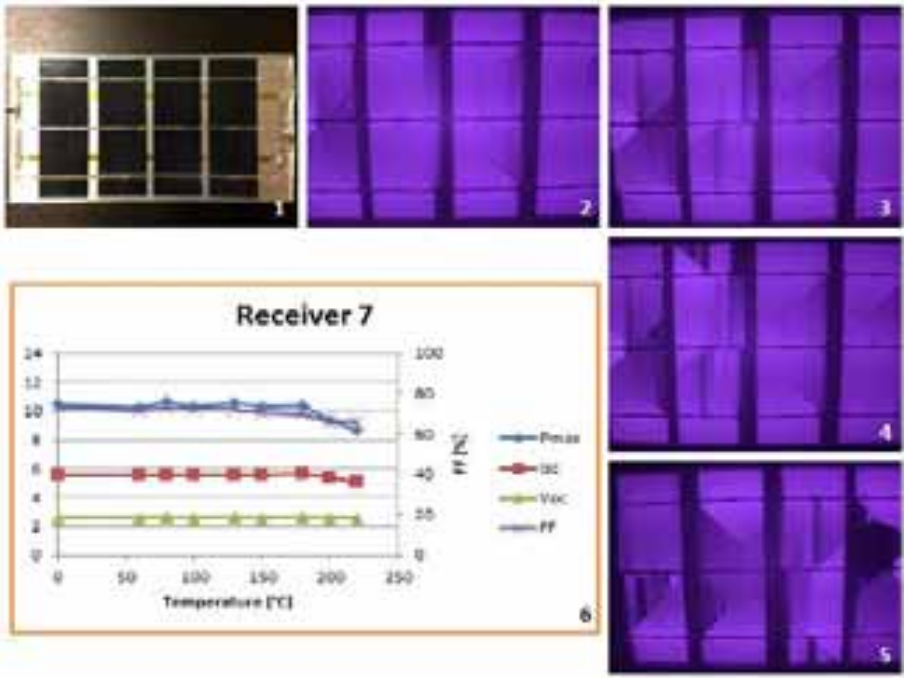

Fig. 10 - 1) Receiver 1; 2) Baseline; 3) Round 5 (150°C); 4) Round 6 (180°C); 5) Round 8 (220°C); 6) Parameters of the IV curve at different temperatures (Isc shown in the left Y axis)

Despite having more precautions against stagnation, receiver 7 shows more cell breakage then receiver 8 at any temperature. This seems to point that on large cells the effect of having large gaps with strain relief is less important than the type of soldering.

Strangely, the decrease in power is more pronounced in receiver 8 than in receiver 7. However, it must

be noted that receiver 2 starts off from a much worst baseline scenario since it shows some microcracks from start. From all the testing accomplished, it also seems safe to state that existing microcracks expand at fast rate than new microcracks are created.

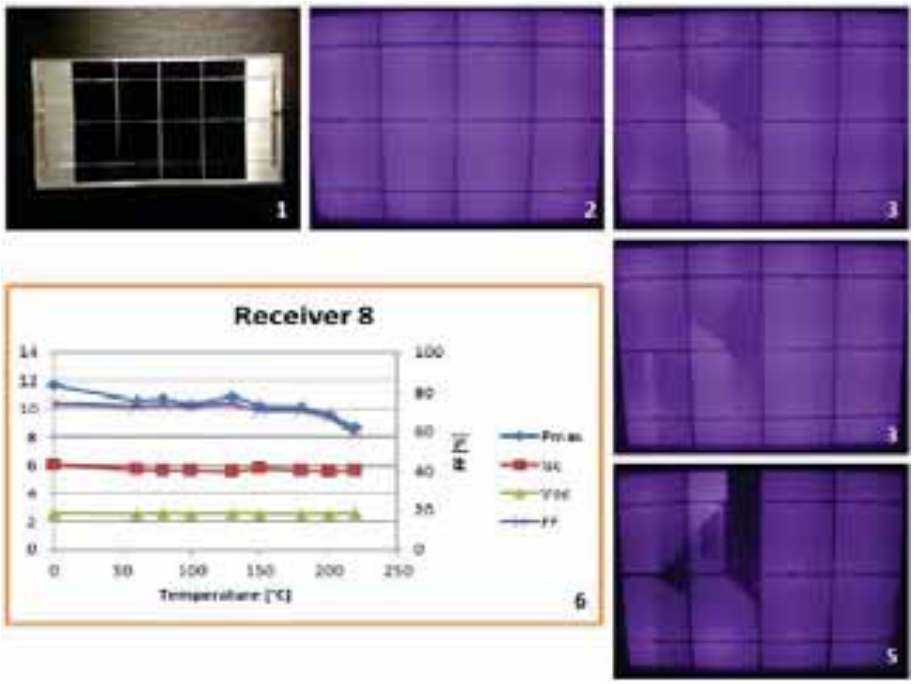

Fig. 11 - 1) Receiver 8; 2) Baseline; 3) Round 5 (150°C); 4) Round 6 (180°C); 5) Round 8 (220°C); 6) Parameters of the IV curve at different temperatures (Isc shown in the left Y axis)

Figure 12 and 13 compare the decrease in Pmax of the different receivers at different temperatures rounds. Receiver 2 shows the most steady Pmax across all temperatures Receiver 5 is also fairly stable is one excludes the handling problem on round 1. Receiver 1 shows an increase of power that is difficult to explain and is assumed to have been a human error. Overall, receivers with red silicone have the highest power decrease, if external factors are excluded. The existence of gaps seems to reduce the number of microcracks. No prototype test receiver losses more than 30% of its initial power, despite the large cell breakage shown in some receivers by the EL testing.

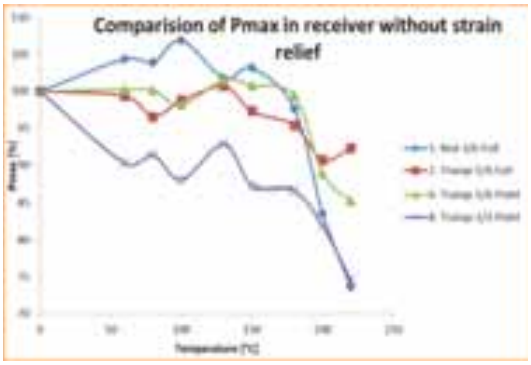

Fig. 13 - Comparison of Pmax decrease in receivers without strain relief

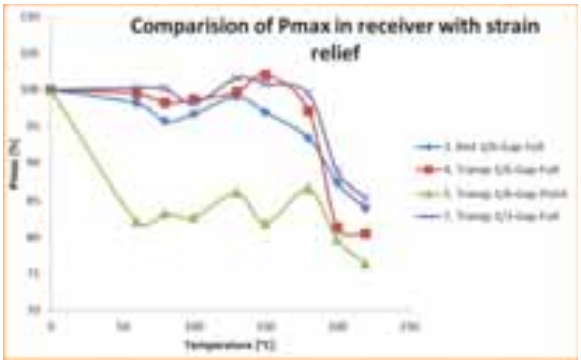

Fig. 12 - Comparison of Pmax decrease in receivers with strain relief

6. Conclusion

Eight different receivers have been built and were successfully tested to assess the impact of temperature variations in performance and cell structural integrity.

Two types of black areas in the cells were identified from the tests. They are namely irregularly shaped areas which are due to micro-cracks and regular rectangular areas which are due to broken finger contacts on the front of the cell. It was also noted that the majority of the micro-cracks were initiated at the soldering points, which is understood to be because of the different expansion coefficients.

From the previous figures, it is clear that receivers built with transparent silicone show far less cracks and power degradation after being exposed to the stagnation temperatures. This is understood to be due to two main reasons: 1) the transparent silicone is less rigid than the red silicone and thus further absorbs the mechanical stress of thermal expansion in the aluminium receiver; 2) the red silicone due to its lower viscosity is normally made in a thinner layer which further penalizes its ability to absorb mechanical stress.

No prototype test receiver lost more than 30% of its initial power, despite the large cell breakage shown in some receivers. After 8 rounds of testing, it was possible to conclude that the diodes were working perfectly at all temperatures, although the diode specifications stated a maximum junction temperature of only 200°C.

Larger cells are more prone to develop micro-cracks due to thermally induced stresses. From the tests that have been made, point soldering seems to lead to a reduction in the number of micro-cracks and black areas, especially in receivers with larger cells (148*52mm instead of 148*26mm). However, the impact of micro-cracks in the Pmax of receivers with point soldering is also larger because the smaller contact area between the ribbon and the cell.

From the electroluminescence images, the receiver presenting the lowest amount of micro cracks after round 8 (at 220°C) is receiver 5. This receiver has point soldering and strain relief between each cell. Receiver 4 and receiver 6 also exhibit low amounts of micro-cracks but both have a full black cell, possibly due to a contact between the top and bottom ribbon through the cell. Receiver 2 shows the most steady Pmax across all temperatures. Receiver 5 is also fairly stable if one excludes the handling problem on round 1.

Existing micro-cracks tend to grow in size into larger micro-cracks relatively fast. The EL imaging taken during our experiment leads us to conclude that it is far easier for existing cracks to expand than for new cracks to appear.

A limitation of this work was the absence of a fully automatic tabbing machine. Since this is expensive equipment, our team had to use manual soldering. However, by setting a baseline scenario for comparison, this limitation was addressed.

It is important to point out that the thickness of the bottom silicone layer is of the upmost importance in reducing the transference of thermally induced stress to the cells. The impact of the variations in the thickness of silicone in the thermal stress suffered by the cells has not evaluated in this paper and should be address in a future study.

Abstract

PBE (Brazilian Labeling Program) is a national program in Brazil that aims to establish standard criteria to compare the energetic efficiency and quality of several devices, such as refrigerators, vehicles, and flat plate solar collectors. The vast majority of solar collectors tested by PBE fail in the topic of infiltration of water condensation. Arguably, the presence of water inside the collector decreases its efficiency, since part of the solar radiation is lost to heat the infiltrated water. However, the determination of the heat losses due to infiltration has not yet been proven in actual flat plate solar collectors, since it has not yet been properly measured. The aim of this study was to evaluate the influence of water infiltration in the efficiency of flat plate solar collectors, evaluating devices from three classes of energetic efficiency: A, B, and C. For the samples evaluated, it was observed that the influence of the amount of water infiltrated on the efficiency is not significant. Therefore, this criterion should not be used to promote the rejection of the collector.

Keywords: *Efficiency, Solar collector, Infiltration*.

1. Introduction

A significant part of the energy consumption in residential segment is attributed to water heating (Prado and Gonçalves, 1998). According to Ghisi et al. (2007), it is estimated that refrigerators, freezer, air conditioners and electric showers account for nearly 60% to 70% of the Brazilian´s residential energy consumption. Also, except for the northeast of Brazil (the hottest region of the country), 81-92% of the Brazilian population use electric showers. Since electric showers consist of an electric-resistance water heater, they require very high electrical power (Oliveira and Rebelatoo, 2015). Flat plate solar collectors use the incident solar radiation to heat the water. Since Brazil has high levels of solar radiation and the solar collectors are able to operate with direct and diffuse components of solar radiation, these devices can successfully replacing electric showers. The basic parameter to consider in an analysis of a solar collector is its thermal efficiency, which depends on the collector parameters and thermal losses.

The efficiency of a solar collector depends upon how much a working fluid carries away the heat from the collector. Techniques are used to enhance the performance of solar collectors, mainly divided in increasing the heat transfer coefficient between the absorber plate/tube and the working fluid, using special type of coatings on the absorber (i.e, solar selective coatings), and increasing the thermal conductivity of the working fluid using nanoparticles (Suman, Khan and Pathak, 2015). Nanofluids are a mixture of liquid (base fluid) and nano sized particles (1-100 nm) suspended (Ferrouillat et al., 2013) that can be used instead of conventional heat transfer fluids (Al-Shamani et al., 2014).

Different countries have different standards to characterize and evaluate the efficiency of solar collectors. The most important standard for collector testing in Europe establishes a steady-state method and allows the application of a quasi-dynamic method performed outdoors. Osório and Carvalho evaluated and compared

doi:10.18086/swc.2015.10.15 Available at http://proceedings.ises.org

both the steady-state and the quasi-dynamic methods, showing similar results. The advantage of the quasi-dynamic tests was in terms of the time required to perform the analysis. Cruz-Peragon et al. (2012) proposed a 2D finite difference method to validate a characterization of a solar collector. Steady and transient states were analyzed under different operating conditions and results depicted the robustness of the method.

Sözen, Menlik and Ünvar (2008) developed a new formula based on artificial neural network to determine the efficiency of flat-plate solar collectors, for different conditions of ambient temperature, date, time, solar radiation, declination and azimuth angles.

In Brazil, there is a national program to evaluate and classify the solar collectors based on their energetic efficiency, named PBE – Programa Brasileiro de Etiquetagem (Brazilian Labeling Program). The efficiency is evaluated through a series of standard tests performed in laboratories, taking account several parameters, such as hydrostatic pressure, sealing, and water infiltration. According to the results, the collectors receive a grade from A to E, depending on the specific monthly energy production - PEME, according to the values shown in Table 1. One of the tests performed is the thermal shock, in which the device is exposed to water, and the maximum amount of infiltrated water is 5 g/m^2 of area. If the amount of infiltrated water exceeds this value, the solar collector is rejected.

It is well known that the infiltrated water reduces the efficiency of a solar collector, but the influence of the amount of water on the thermal efficiency has not been properly measured. The objective of this paper is to evaluate the thermal efficiency of solar collectors subjected to different levels of water infiltration. The tests were performed in devices evaluated as A, B, and C according to PBE Brazilian Program.

Tab. 1: Classification of the solar collector according to the energy production

Grade	Range of PEME (kWh/month-m^2)
A	PEME > 77
B	71 < PEME < 77
C	61 < PEME < 71
D	51 < PEME < 61
E	41< PEME < 51

2. Experimental setup

Experimental tests for the determination of the thermal efficiency of flat-plate solar collectors were performed in a closed location, using a Solar Simulator. This device consists of a eight special lamp system, with total power of 40kW, and the radiation spectrum similar to the sun. The artificial sky is composed of two tempered glass plates; between them, cool air flows, in order to simulate the radiation heat losses between the solar collector, sky and the wind generator system (Fig. 1).

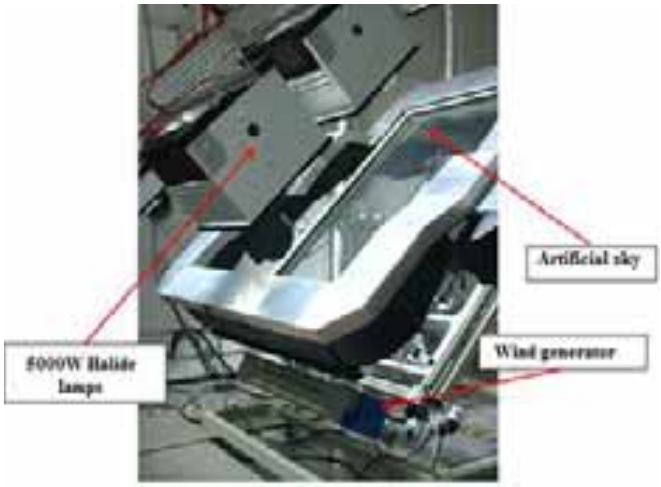

Figure 1 – Solar simulator, front view

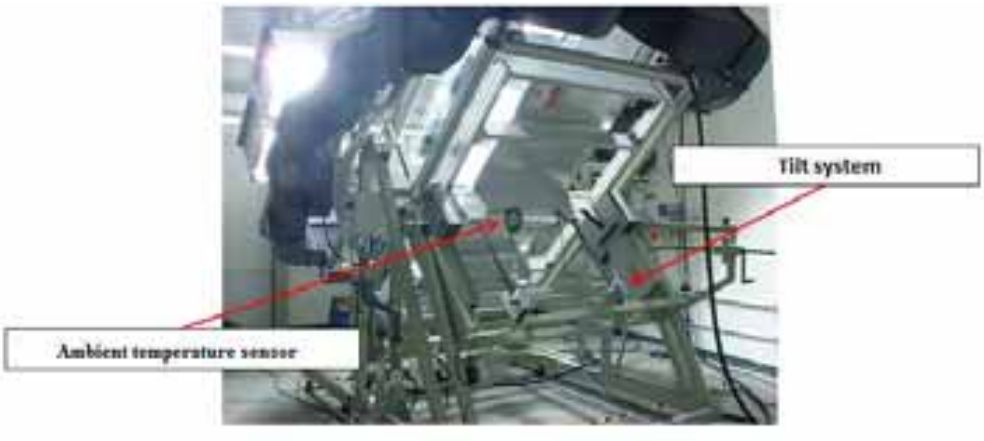

Figure 2 – Solar simulator, rear view

Figure 3 – Solar simulator and pyranometer

The tests followed Brazilian Standards NBR 15747-1 and NBR 15747-2. NBR 15747-1 specifies the reliability and durability requirements, safety and thermal performance of solar collectors for heating liquids. NBR 15747-2 specifies test methods for validating the durability requirements, reliability, safety and thermal performance of solar collectors for heating liquids presented in the previous standard.

In order to determine the efficiency, measurements of incident radiation on the solar collector plane, inlet and outlet water temperatures, volume flow rate and ambient temperature were performed, with the sensors indicated in Figures 2 and 3. A Precision Spectral Pyranometer (PSP) is used to determine the solar radiation, as indicated in Fig. 3. Platine resistance thermometer (PT100) are used to determine the inlet and outlet water temperatures and the ambient temperature (Fig. 2). The volume flow rate is measured with a volume flow meter. The wind velocity is controlled to be within the range specified by the Standards.

Based on the Quality Technical Regulations for Solar Water Heating Systems and Equipment, elaborated by the Brazilian National Institute of Metrology, Quality and Technology (INMETRO), the proof of non-compliance of the solar collector due to the infiltration and condensation must be performed through the thermal shock and rain penetration tests. The amount of infiltrated water is measured by the comparison of the

weight of the solar collector before and after the exposure of the device to water for a pre-determined time interval. In order to be approved on the certification test of water penetration, the maximum acceptable amount of infiltrated water is 5 g/m^2. The ambient temperature inside the Solar Simulator was kept between 15°C and 30°C.

A, B and C collectors were tested, in order to evaluate how the class influenced the results.

Water was inserted into the collectors, in pre-established quantities, using a syringe. The range of leakage was determined from the maximum allowed quantity of 5g/m². The standard states that the solar collectors when subjected to rain penetration test must present a maximum infiltration of 5 g / m². The infiltrated water withdraw collector heat to warm itself, which could reduce its efficiency. It is not defined in the standard reason for the threshold value of 5 g / m² have been adopted. For each collector, four tests were performed, in quantities equal to 10 g/m^2, 20 g/m^2, and 30 g/m^2, named, respectively, Test 1, Test 2, Test 3 and Test 4. The dimensions and quantities of infiltrated water are presented in Table 2.

Tab. 2: Dimensions and amount of infiltrated water

Collector	Area (m^2)	Amount of water (g)			
		Test 1	Test 2	Test 3	Test 4
A	1.7068	0	17	34	51
B	1.0060	0	10.06	20.1	30.2
C	1.0171	0	10.17	20.35	30.5

3. Analysis

The collector efficiency is defined as the ratio of the useful gain over some specified time period to the incident solar energy over the same time period (Duffie and Beckman, 2006)

$$\eta = \frac{\int Q_u dt}{A_c \times \int G dt} \quad \text{(eq.1)}$$

In eq. 1, G is the instantaneous solar radiation on the collector plane (W/m^2), A_c is the collector area (m^2) and Q_u is the useful energy gain.

The solar radiation is measured on the collector plane, as indicated in Fig. 3. The collector area is determined by the product of the width and length. The useful energy gain is determined by a energy balance between the outlet and inlet fluid.

$$Q_u = \dot{m}(h_o - h_i) \quad \text{(eq.2)}$$

Where $\dot{m}$ represents the mass flow rate of the water inside the collector, h represents the specific enthalpy and the subscripts *o* and *i* refer to the outlet and inlet. The enthalpy change is determined by:

$$h_o - h_i = c_p(T_o - T_i) \quad \text{(eq.3)}$$

The mass flow rate and the outlet and inlet temperatures are measured during the tests.

4. Results and discussion

In order to evaluate the influence of the infiltrated water in several kinds of solar collectors, type A, B, and C collectors were chosen. Table 3 shows the PEME and the uncertainties of the collectors, based on the tests performed without infiltration of water. It is important to mention that the PEME did not considerably change with the infiltrated water, with maximum variation of 4.3%, relative to type A collector.

Tab. 3: PEME and uncertainties collectors us without water infiltration tests

Collector	PEME (kWh/month-m^2)	Uncertainty (kWh/month-m^2)
A	84.87	0.32
B	83.90	0.34
C	75.66	0.37

The classification follows the range of values specified in Table 1.

Solar collector efficiency is expressed in the form of either a linear or a quadratic equation (Duffie and Beckman, 2006). The equations can be used to estimate the energy performance of a solar heating system. Based on the measurements the efficiency expressions were found for the collectors, for the tests performed. The expressions are given in Table 4. The average efficiency is defined as the efficiency for an abscissa of 0.02, which corresponds to the average value for a bath. The uncertainty is shown in the last column.

Tab. 4: Efficiencies of the solar collectors

	Expression	Efficiency with 0.02	Uncertainty
Collector A – Test 1	$\eta = 70.22 - 466.32\left(\frac{T_m - T_a}{G}\right)$	60.89%	0.32%
Collector A – Test 2	$\eta = 70.81 - 496.84\left(\frac{T_m - T_a}{G}\right)$	60.87%	0.33%
Collector A – Test 3	$\eta = 71.19 - 618.26\left(\frac{T_m - T_a}{G}\right)$	58.83%	0.41%
Collector A – Test 4	$\eta = 70.93 - 526.00\left(\frac{T_m - T_a}{G}\right)$	60.41%	0.37%
Collector B – Test 1	$\eta = 63.68 - 452.72\left(\frac{T_m - T_a}{G}\right)$	54.62%	0.34%
Collector B – Test 2	$\eta = 66.05 - 556.52\left(\frac{T_m - T_a}{G}\right)$	54.92%	0.38%
Collector B – Test 3	$\eta = 66.30 - 587.38\left(\frac{T_m - T_a}{G}\right)$	54.55%	0.40%
Collector B – Test 4	$\eta = 66.48 - 582.33\left(\frac{T_m - T_a}{G}\right)$	54.84%	0.41%
Collector C – Test 1	$\eta = 62.16 - 541.53\left(\frac{T_m - T_a}{G}\right)$	51.33%	0.37%
Collector C – Test 2	$\eta = 62.53 - 494.04\left(\frac{T_m - T_a}{G}\right)$	52.65%	0.34%
Collector C – Test 3	$\eta = 62.48 - 511.62\left(\frac{T_m - T_a}{G}\right)$	52.25%	0.36%
Collector C – Test 4	$\eta = 62.58 - 578.14\left(\frac{T_m - T_a}{G}\right)$	51.02%	0.41%

Figures 4 to 6 show the efficiency curves for collectors A, B, and C, respectively.

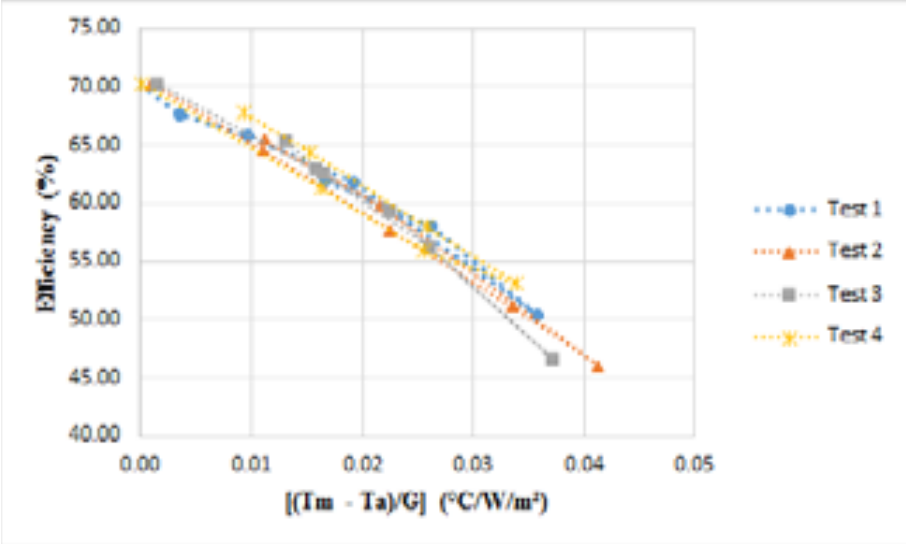

Figure 4 – Experimental collector efficiency for type A collector

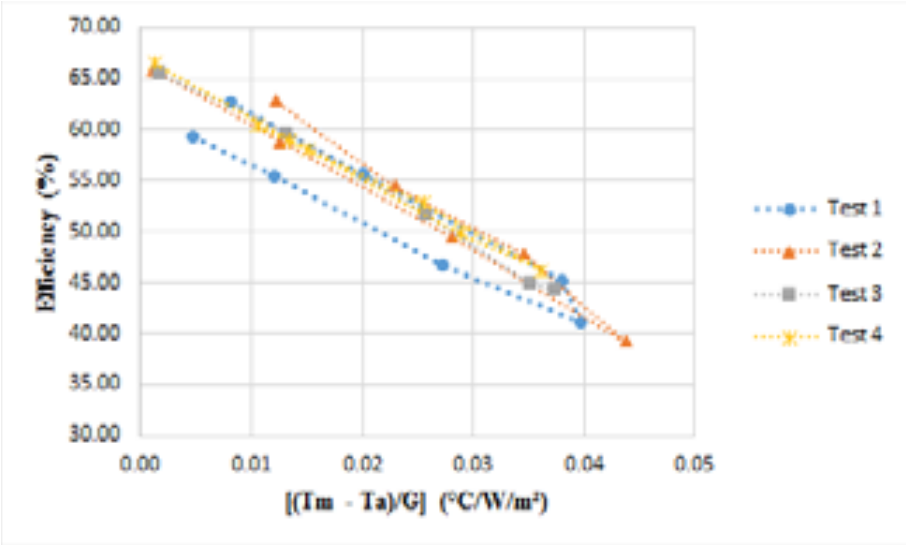

Figure 5 – Experimental collector efficiency for type B collector

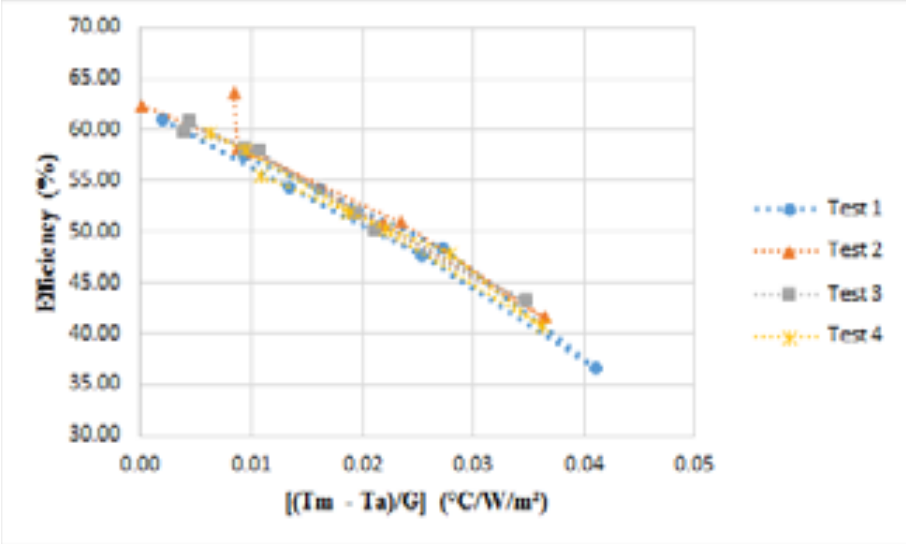

Figure 6 – Experimental collector efficiency for type C collector

It can be seen that the infiltration of water did not provide significant variations on the collector efficiency. The maximum variations of the average efficiency were 2.06%, 0.37% and 1.63%, for collectors A, B, and C, respectively. It is worth noting that, for type B collector, the efficiencies were within the uncertainty range, meaning that, for this collector, the water did not cause any effect on the average efficiency. It was not possible to determine a relationship between the amount of infiltrated water and the efficiency.

The Brazilian Standard specifies that, when the amount of infiltrated water in a solar collector exceeds 5 g/m^2 of area in the thermal shock test, it is rejected. The analysis performed showed that it was not possible to determine a decrease of the efficiency when values of 10, 20 and 30 g/m^2 of water are infiltrated. Therefore, the amount of 5 g/m^2 should not be considered to reject the new solar collector.

5. Conclusions

In this paper, it was evaluated the influence of water infiltration in a solar collector. There is not relationship between the infiltration and the classification of the collector A, B or C. Solar collectors of different specific monthly energy production were chosen to the analysis. The efficiency curve was obtained for the collectors without water and, subsequently, 10, 20 and 30 g/m^2 of water were infiltrated in the collector and the test was repeated.

The analysis showed that no significant variations of the efficiency or specific monthly energy production were observed with the infiltrated water for any type of collector, and that it could not be identified a relationship between the amount of water and the efficiency. Therefore, it can be concluded that the acceptable limits of the Brazilian Standard are too strict and should be rectified. The Standard is now in a revision process, in which the new limit is 30 g/m^2 to a higher period of sun exposure. Nevertheless, the analysis showed that, even this value is too strict.

A STUDY ON RELATIONSHIP BETWEEN THE ENERGY BALANCING AND THE REAL EXPERIMENT IN A HYBRID SOLAR HEATING SYSTEM

H.W. Choi[1], C.H. Son[2], J.I. Yoon[2] and K.H. Choi[2]

[1] Graduate school of Refrigeration and Air-Conditioning, Pukyong National University, Busan(Republic of Korea)

[2] Dept. of Refrigeration and Air-Conditioning, Pukyong National University, Busan(Republic of Korea)

Abstract

Research of the hybrid solar collector that can heat air and liquid simultaneously has been conducted for enhancement of the usage of solar energy. Thermal efficiency of this solar collector was investigated ranging from various operating conditions. This efficiency of the collector, however, was hard to generalize because of many factors that effect on the efficiency more than the traditional solar collector. Thus, in this study, the efficiency of hybrid collector was expressed by the energy balance and the efficiency of the collector was also investigated according to operating and external conditions. As a result, efficiency of the air side was increased with the increment of the inlet liquid temperature when the other conditions were constant different with traditional solar air heater. In case of liquid heating performance, efficiency was decreased with increment of inlet liquid temperature and decrement of solar radiation same as the traditional solar collector for hot water. Total thermal efficiency expressed as the ratio of the useful energy gain of heating mediums(air and liquid) to the incident of solar radiation was decreased with increment of inlet heating temperature and decrement of solar radiation similar with the traditional solar collector. Those tendencies are similar with the results of previous study, thus it can be regarded that the efficiency expressed from the energy balance as in appropriate. Furthermore, from these results it is expected to generalize the evaluation method of the hybrid solar collector and contributing for practical use if additional experiment with more various conditions are conducted.

Keywords: *Solar thermal system, Hybrid solar collector, Air-conditioning, Hot-water supply, Energy saving*

1. Introduction

In the use of solar energy, flat plate solar collector usually has been used for making hot water or heated air. In case of solar water heater, many research was conducted for enhancing the thermal efficiency(S. Sadhishkumar and T. Balusamy, 2014) and these heated water can be used for hot-water supply system in building, heat source for regenerating of liquid desiccant in liquid desiccant dehumidifier system(K. Gommed and G. Grossman, 2007; Mahmut et al, 2015) and so on. In case of solar air heater, it can be used in many field like drying application(M.A. Karim and M.N.A. Hawlader, 2004), air conditioning system(Ali Al-Alili et al., 2004; Zhi Yu et al., 2014) and so on.

But, different with this, study about hybrid solar collector heater that can make both hot water and heated air have been conducted(K.H. Choi et al., 2014; H.W. Choi et al., 2014; H.W. Choi et al., 2015). This collector can be applied for air conditioning system as well as hot water supply system. So, the usage of hybrid solar collector per unit area is being a more than traditional flat plate solar collector. But, efficiency of hybrid solar collector was hard to generalize because of the many factors that effect on the efficiency.

Thus, in this study, the efficiency of hybrid collector was expressed by the energy balance. And the efficiency of the collector was also investigated according to operating and external conditions by using the heat removal factor and the heat loss coefficient calculated from measured values when the air and liquid were heated simultaneously in flat plate solar collector. Furthermore, this paper put the purpose on the confirming of performance of hybrid solar collector when it was heating both air and.

doi:10.18086/swc.2015.10.16 Available at http://proceedings.ises.org

2. Experimental apparatus and method

Hybrid solar collector was made by installing air channel beneath the absorb plate of flat plate solar collector for hot water, so it can make hot water and heated air. Actual feature of hybrid solar collector is shown in Fig. 1. Fins were installed in air chnnel for enhancing the heat transfer rate from absorber to flow air. It has a $2m^2$ absorbing area and installed 33° angle from horizontal and azimuth 171° in Busan, South Korea. Fig. 2 shows the schematics of hybrid solar collector system.

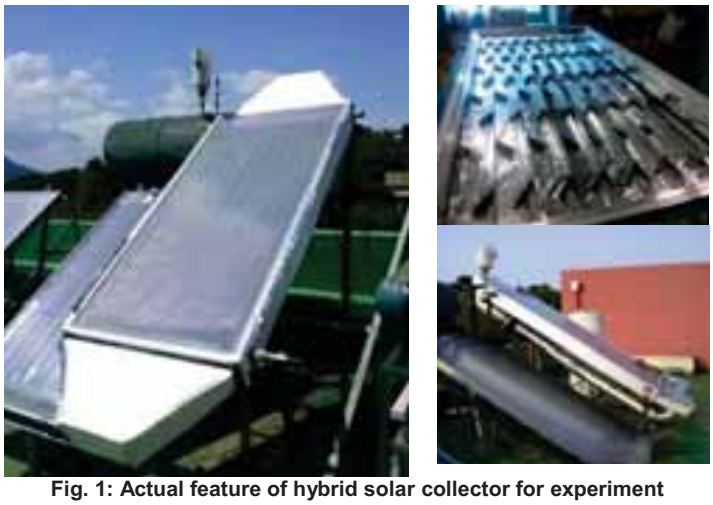

Fig. 1: Actual feature of hybrid solar collector for experiment

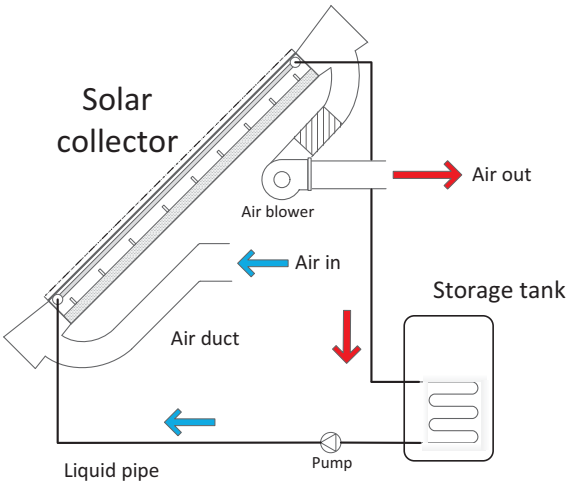

Fig. 2: Schematics of hybrid solar air-water heater system

Experiment was conducted at clear day. Air mass flow rate was changed from 0.02 kg/s to 0.10 kg/s on constant liquid mass flow rate 4 l/min and both air and liquid was heated simultaneously. Outdoor air was used directly as inlet air and T-type thermocouple was installed at lower side, center, upper side, left side and right side of absorbing plate for measuring mean temperature of absorber plate. Temperatures of inlet and outlet air were also measured by T-type thermocouple and liquid temperatures at inlet and outlet were measured by PT-100.

3. Data analysis

In this study, thermal efficiency of collector was defined using energy balance when the air and liquid were heated simultaneously. Useful thermal energy is defined as the heat gain of heating mediums and it also can be expressed by energy input and output as

$$\dot{Q}_u = \dot{Q}_{air} + \dot{Q}_L = \dot{Q}_i - \dot{Q}_o \qquad \text{(eq. 1)}$$

At this time, Q_i and Q_o can be written as equation (2), (3)

$$\dot{Q}_i = G\tau\alpha A_c \quad \text{(eq.2)}$$

$$\dot{Q}_o = U_{L,t}A_c(T_c - T_a) \quad \text{(eq.3)}$$

So, equation (1) can be rewritten as equation (4).

$$\dot{Q}_{air} + \dot{Q}_L = \dot{Q}_i - \dot{Q}_o = G\tau\alpha A_c - U_{L,t}A_c(T_c - T_a) \quad \text{(eq.4)}$$

Overall heat loss coefficient of collector can be written as equation (5) from equation (4).

$$U_{L,t} = \frac{G\tau\alpha A_c - (\dot{Q}_{air} + \dot{Q}_L)}{A_c(T_c - T_a)} = \frac{G\tau\alpha - (q_{air} + q_L)}{T_c - T_a} \quad \text{(eq.5)}$$

Heat gain of liquid can be written as equation (6) from "Hottel-Whillier-Bliss equation"(Duffie and Beckman, 1991).

$$\dot{Q}_L = \dot{m}_L C_{p,L}\left(T_{o,L} - T_{i,L}\right) = F_{R,L}A_c[G\tau\alpha - U_{L,L}\left(T_{i,L} - T_a\right)] \quad \text{(eq.6)}$$

At equation (6), $U_{L,L}$ is defined as heat loss coefficient of liquid side and the heat gain of air is condidered as heat loss of liquid side. This value can be assumed as constant value on the constant air and liquid mass flow rate and temperature difference between inlet air and outdoor air. it can be written as equation (8) from equation (7) if outoor air used as inlet air.

$$\dot{Q}_L = G\tau\alpha A_c - U_{L,L}A_c(T_c - T_a) \quad \text{(eq.7)}$$

$$U_{L,L} = \frac{G\tau\alpha A_c - \dot{Q}_L}{A_c(T_c - T_a)} = \frac{G\tau\alpha - q_L}{T_c - T_a} = f(\dot{m}_{air}) \quad \text{(eq.8)}$$

$U_{L,L}$ is changed by inlet air temperature, air and liquid mass flow rate. But in this experiment, $U_{L,L}$ is considered as a function of air mass flow rate as shown in equation (8) because only outdoor air used for inlet air directly and experiment was conducted on constant liquid mass flow rate. Heat gain of air side can be written as equation (9)

$$\dot{Q}_{air} = \dot{m}_{air}C_{p,air}\left(T_{o,air} - T_{i,air}\right) = \dot{Q}_i - \dot{Q}_o - \dot{Q}_L \quad \text{(eq.9)}$$

Heat gain of air side can be rewritten as equation (10) by substituting the equation (2), (3), and (6) to equation (9).

$$\dot{Q}_{air} = \dot{Q}_i - \dot{Q}_L - \dot{Q}_o = G\tau\alpha A_c - F_{R,L}A_c\left[G\tau\alpha - U_{L,L}\left(T_{i,L} - T_a\right)\right] - U_{L,t}A_c(T_c - T_a) \quad \text{(eq.10)}$$

The maximum heat gain of air side can be obtained when the whole collector surface is at the inlet air temperature. Then, heat removal factor of air side that represent the ratio of heat gain to maximum heat gain can be written as equation (11).

$$F_{R,air} = \frac{\dot{m}_{air} C_{p,air}(T_{o,air} - T_{i,air})}{G\tau\alpha A_c - F_{R,L} A_c [G\tau\alpha - U_{L,L}(T_{i,L} - T_a)] - U_{L,t} A_c (T_{i,air} - T_a)} \quad \text{(eq.11)}$$

So, heat gain of air side can be rewritten as equation (12).

$$\dot{Q}_{air} = F_{R,air} A_c \{G\tau\alpha - F_{R,L}[G\tau\alpha - U_{L,L}(T_{i,L} - T_a)] - U_{L,t}(T_{i,air} - T_a)\} \quad \text{(eq.12)}$$

The thermal efficiency of a collector is defined as ratio of the useful thermal energy to the total incident solar radiation. So, thermal efficiency of liquid side is expressed as equation (13) from equation (6).

$$O_L = \frac{\dot{Q}_L}{G A_c} = \frac{F_{R,L} A_c [G\tau\alpha - U_{L,L}(T_{i,L} - T_a)]}{G A_c} = F_{R,L}\tau\alpha - F_{R,L} U_{L,L} \frac{(T_{i,L} - T_a)}{G} \quad \text{(eq.13)}$$

Thermal efficiency of air side can be written as equation (14) from equation (12).

$$O_{air} = \frac{\dot{Q}_{air}}{G A_c} = \frac{F_{R,air} A_c \{G\tau\alpha - F_{R,L}[G\tau\alpha - U_{L,L}(T_{i,L} - T_a)] - U_{L,t}(T_{i,air} - T_a)\}}{G A_c} \quad \text{(eq.14)}$$

It can be rewritten as equation (15).

$$O_{air} = F_{R,air} \left\{ \tau\alpha (1 - F_{R,L}) + \frac{[F_{R,L} U_{L,L}(T_{i,L} - T_a) - U_{L,t}(T_{i,air} - T_a)]}{G} \right\} \quad \text{(eq.15)}$$

In the equation (15), relation of inlet heating medium temperature, ambient temperature, solar radiation and thermal efficiency of air side is derived. In this equation, η_{air} will be increased if inlet liquid temperature is increased or solar radiation is decreased If the inlet liquid temeprature is larger than ambient temperature. And if inelt air and ambient temperature is same, η_{air} will be change with $(T_{i,L} - T_a)/G$ to linear on the constant air and liquid mass flow rate. Total thermal efficiency of collector can be written as the sum of the thermal efficiency of air and liquid side. It can be expressed as follows:

$$O_t = \frac{\dot{Q}_L + \dot{Q}_{air}}{G A_c} = O_L + O_{air} = A - B\left(\frac{T_{i,L} - T_a}{G}\right) - C\left(\frac{T_{i,air} - T_a}{G}\right) \quad \text{(eq.16)}$$

Where,

$A = (F_{R,air} + F_{R,L} - F_{R,air} F_{R,L})\tau\alpha$

$B = F_{R,L}(1 - F_{R,air}) U_{L,L}$

$C = F_{R,air} U_{L,t}$

Therefore, total thermal efficiency of collector is written as heat removal factor and heat loss coefficient of two heating medium with operating conditions. Then if the heat removal factor and heat loss coefficient of each heating mediums can be obtained from experiment, total thermal efficiency or thermal efficiency of each heating medium is expected to predict. And also, A, B and C can be assumed as constant value on the constant temperature difference between inlet air and outdoor air, air and liquid mass flow rate.

4. Results and discussion

In this experiment, temperatures of two heating mediums and collector was measured with change of air mass flow rate on the constant liquid mass flow rate at noon that was shown similar solar radiation. Fig. 3 shows the measured temperatures of air, liquid and absorbing plate with air mass flow rate.

Outlet air temperature was decreased with increment of air mass flow rate and also temperature difference between inlet and outlet liquid was decreased with increment of air mass flow rate. It was considered as a result of the increment of heat transfer from liquid pipe to flow air with incremnet of air mass flow rate.

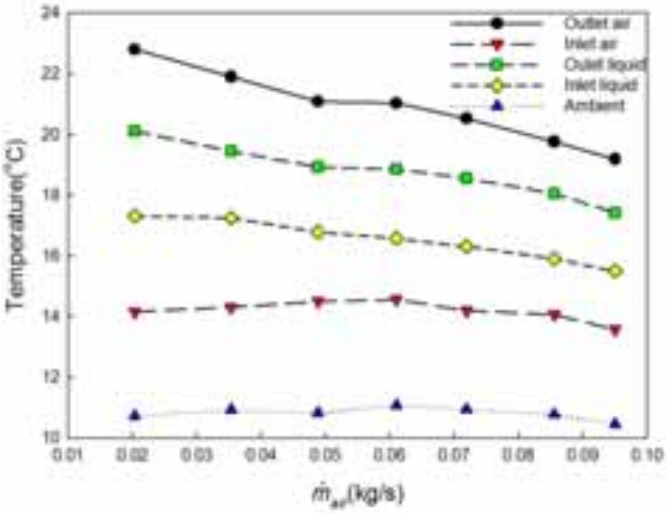

Fig. 3: Temperature profile when the air and liquid were heated simultaneously

Heat gain of each heating medium with solar intensity was shown in Fig. 4. Heat gain of liquid was higher than air on the low air mass flow rate. But it was decreased and the heat gain of air was increased with increment of air mass flow rate due to the increment of heat transfer from liquid pipe to flow air. Total heat gain in hybrid solar collector was increased with increment of air mass flow rate and it means extra heat gain was occured in addition to heat transfer from liquid to air with increment of air mass flow rate. it considered as a result of the heat transfer enhancement from absorbing plate to flow air with increment of air mass flow rate as well as from liquid pipe.

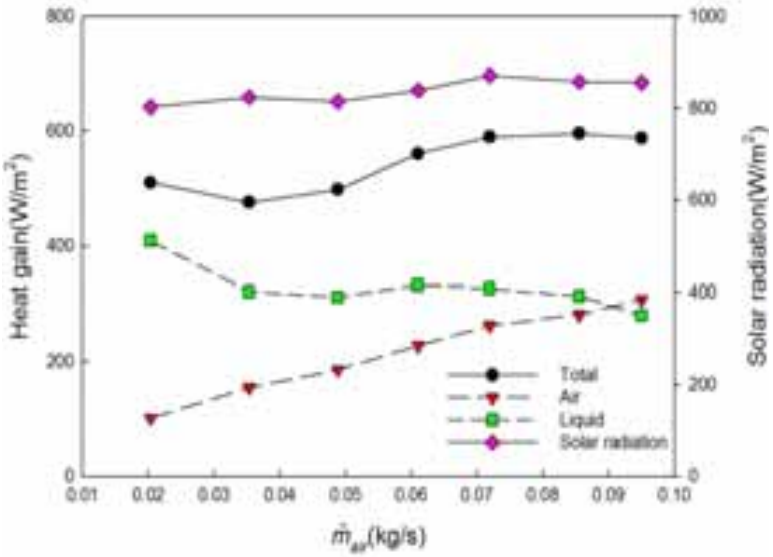

Fig. 4: Useful energy of collector and solar radiation

Heat loss coefficient of collector calculated from equation (5), (8) using measured value was shown in Fig. 5. Heat loss coefficient of liquid side was increased with increment of air mass flow rate. This result signifies that the heat transfer from liquid pipe to flow air was enhanced with increment of air mass flow rate. Whereas, total heat loss coefficient of collector was slightly decreased with increment of air mass flow rate because of the increment of heat transfer from liquid pipe and absorbing plate to flow air as previously stated.

Fig. 6 shows heat removal factors of air and liquid side. Heat removal factor of air side was increased with increment of air mass flow rate. As previously shown, this tendency is considered as a result of heat transfer increment from absorbing plate and liquid pipe to flow air with increment of air mass flow rate and by this, heat removal factor of liquid side was decreased with increment of air mass flow rate.

At this time, heat removal factor and heat loss coefficient can be expressed as a function of air mass flow rate from the experiment result as shown in Fig. 5, 6. In other words, heat removal factor and heat loss coefficient of

collector at specific air mass flow rate can be predicted when the outdoor air was used as inlet air on constan liquid mass flow rate. Therefore, total thermal efficiency of hybrid solar collector can be expressed as a function of air mass flow rate, inlet temperature of liquid, ambient temperature and solar radiation.

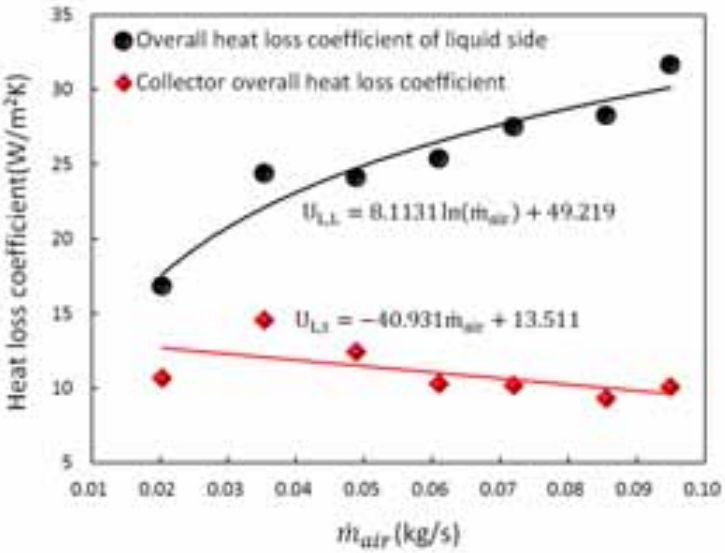

Fig. 5: Overall heat loss coefficient of collector and liquid side

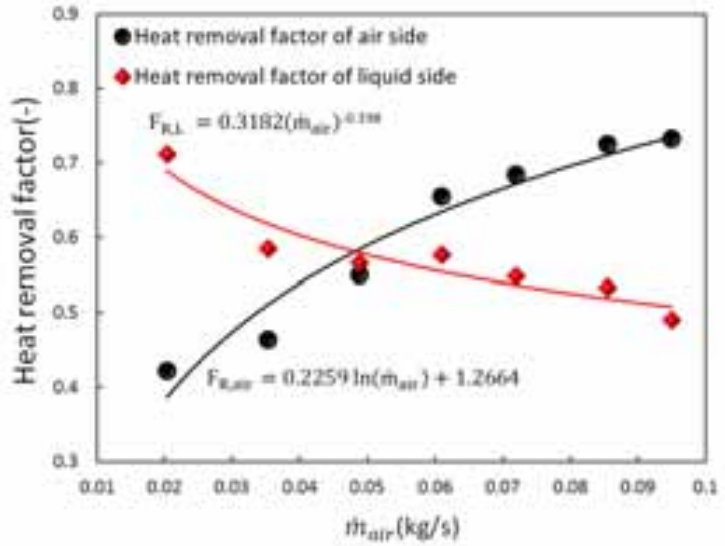

Fig. 6: Heat removal factor of air and liquid side

Namely, thermal efficiency can be predicted with respect to each operation and external condition using heat removal factor and heat loss coefficient obtained from experiment. Fig. 7 shows the thermal efficiency of air and liquid side with $(T_{i,L} - T_a)/\mathrm{G}$. using equation (13), (15). The efficiency of air was changed to linear because the temperature difference between inlet air and ambient was as small as ignored. These tendency was included in equation (15). The higher slope angle of air efficiency curve means that the higher efficiency increase of air side when the inlet liquid temperature was increased when the other conditions are same and it was increased with increment of air mass flow rate.

In case of the thermal efficiency of liquid, it was shown the maximum thermal efficiency about 0.6 while the air was also heated and it was decreased with increment of inlet air temperature, air mass flow rate and decrement of solar radiation. It is similar with tranditional flat plate solar collector for hot water but, decline of efficiency was higher than traditional flat-plate solar collector for hot water because heat gain of flow air was also considered as a heat loss of liquid.

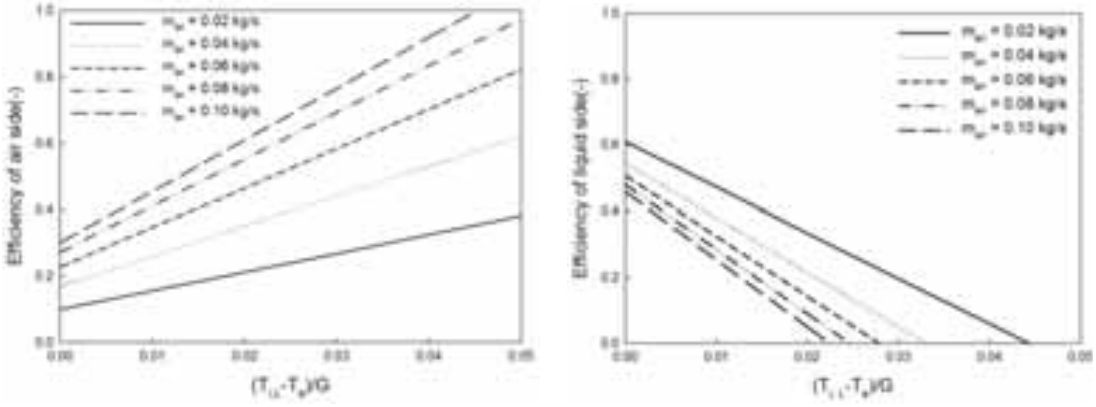

Fig. 7: Prediction of the thermal efficiency of hybrid solar collector; (a) air side (b) liquid side

Fig. 8 shows total thermal efficiency of hybrid solar collector including heat gain of air and liquid. Total thermal efficiency was increased with increment of air mass flow rate, solar radiation and decrement of temperature different between inlet liquid and ambient. Maximum total thermal efficiency of collector expressed as A in equation (16) was shown from 0.710 to 0.759 with air mass flow rate. And also, heat loss coefficient of liquid side expressed as B in equation (16) shown from 4.974 to 8.151 and it is decreased with increment of air mass flow rate.

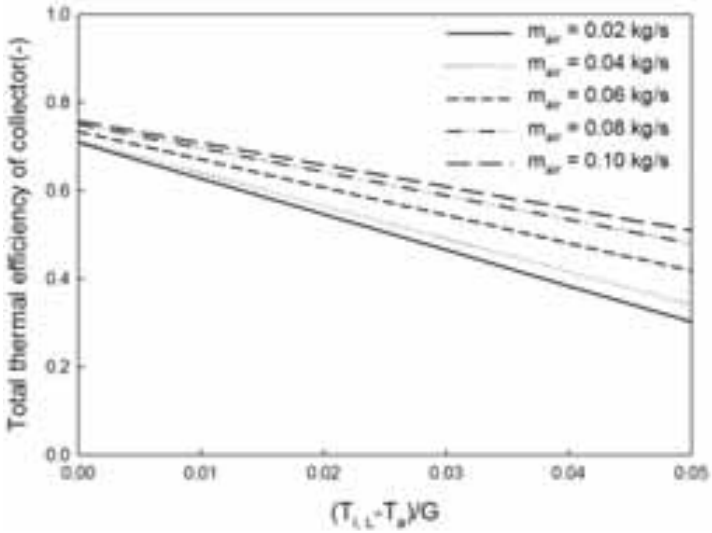

Fig. 8: Prediction of total thermal efficiency of collector

5. Conclusions

This study conducted a performance evaluation when the air and liquid were heated simultaneously in flat plate solar collector and the efficiency of hybrid solar collector influced by many factors was confirmed using the equation expressed by energy balance.

As a result, efficiency of the air side was increased with the increment of the inlet liquid temperature when the other conditions were constant and the efficiency of liquid side was decreased with increment of inlet liquid temperature and decrement of solar radiation. Total thermal efficiency of collector was decreased with increment of inlet air and liquid temperature and decrement of solar radiation similar with the traditional solar collector. From these results, the tendency of efficiency change confirmed using expressed equationit considered as an appropriate and it is expected to generalize the evaluation method of the flat plat solar collector that heating air and liquid simultaneously if additional experiment with more various conditions are conducted.

Abstract

Russia has a few renewable energy facilities in the buildings. In the buildings, the main source of the energy is provided by Russian fossil fuel resources. Based on the EU experience, Russia has started own research activity in the field of renewable energies in order to reduce the energy consumption. The combination of solar thermal with heat pump systems (SHP) is one of the promising systems that can provide the renewable energy in extreme weather conditions. Solar heating with a heat pump system for buildings has been designed to achieve different values of the fraction of a primary energy saving using the Flat Plate Collectors (FPC) for Solar Thermal (ST) and other supply energies like solar photovoltaic (PV) or wind technology, and having the higher efficiency of the system with net zero energy in thermal production.

Keywords: *Solar Thermal, Heat Pump, Photovoltaic, geothermal, combisystems*

1. Introduction

The combination of solar-thermal collectors and heat pumps provides interesting possibilities for innovative and energy efficient heating systems, with a high fraction of solar energy. Despite its high cost, these systems are gaining more and more importance due to the rising cost of the limited fossil resources. The Task 44 concluded in 2012 that it is possible: i) make up 87% of renewable energy share combining solar thermal and photovoltaic energy supply; ii) or to reach about 90% of renewable energies with geothermal resources.

This study analyzes one configuration of solar systems with a new water-to-water heat pump, in different cities of the Russian Federation, meant to cover all space heating and domestic hot water demand with renewable energy, solar and wind according to the weather conditions. PV has been a very interesting way to produce electricity and thermal energy if we combine this with heat pumps(vapor compression cycle). The final price for households in Russia varies from night tariff 3 c€/kWh to day tariff 9,6 c€/kWh in 2014 (without taxes), and the PV cost between 5 to 10 c€/kWh according to the Russian average radiation and supposing 20 years of duration. PV has not arrived to grid parity in Russia like in other northern countries of the EU. Counting that a modern compression machine has a 3-5 Coefficient of Performances (COP), and according to the Directive 2010/31/EU it's considered like another kind of renewable energy, the actual cost of thermal production with heat pumps is 1-4 c€/kWh depending on the working temperatures, refrigerant and quality of the machine (ASHRAE).

The resulting thermal energy costs obtained for FPC for DHW, simplified cost are from 3 to 7 c€/kWh depending on the collector type and the working temperature in Russia and solar radiation, in Russia ranges from 700-1500 kWh/m^2. The cost of the natural gas in Russia (it's one of the largest producers in the World) it's between 1,2-1,4 c€/kWh, very low compared with the ST and even with the Heat Pump. For the areas where there is gas pipe the solar thermal is only competitive for DHW not for heating, in this case it is not competitive yet, so we have to add the environment cost or the increasing of the gas prices. The fossil fuels are growing more than 0% annually, and the gas for households has grown more than 16% the last years (Gazprom), it's quite sure they won't reduce the price in the future.

Recently, reductions in electric PV costs and mature technology of air-to-water and water-to-water heat pump have provided a new model: solar-electric assisted heat pump. This system comes with fewer drawbacks than solar thermal energy, a smaller price tag for residential applications. Nevertheless, the best system will be a combination of both. The development of modern net zero-energy buildings (NZEB) became possible not only through the progress made in new renewable energy and construction technologies and techniques, but it has also been significantly improved by the combination of all the techniques and advanced combisystems.

The Geothermal heat pump systems have only just begun to penetrate the Russian market in the opposite of countries with similar weather conditions (Sweden, Denmark, Germany,..). Until now there the conventional sources where most known. The maximum values of COP are 4.24 in the southern regions of Russia, and the minimum values of, correspondingly, 2.73 in the north.(Vassiliev and Gornov 2010). For this system they need a vertical borehole at least 40 meters deep and horizontal of 400 m. of length, and not always there are the correct conditions, space or environment to do it, with a big initial investment. From previous studies it has been studied that geothermal can have a similar efficiency like the combisystem with solar thermal and heat pumps.

2. Description of the system

The auxiliary energy is coming from a heat pump (water-to-water system with inverter control) usually used for geothermal systems that can work with electricity from the grid or the PV system. A high efficiency heat pump in the range of 5 to 20 kW has been used to cover the energy needs of households with low energy demand occupied all the year.

Simulating the whole year system we reach different solar fractions depending on the efficiency of the system, the working temperature of the storage system, and the different COP of the heat pump. This system can operate with outside temperatures from -20ºC to 20ºC, with a high solar fraction and with a high efficiency of the solar collector. The storage operating temperature has to change during the year according to the external temperature and the solar radiation, in order to obtain a higher efficiency from the collector, and to work with the maximum efficiency of the heat pump. Only in summer or spring the solar energy can be used directly for thermal production. The FPC works in serial with the heat pump during the cold days and parallel during hot days, usually it will be in the spring and summer. Finally we will use the cooling of the evaporator to increase the PV efficiency. This system can have a very high performance coefficient and adapt its efficiency for whichever conditions. It is ideal for both cold and mild climates.

The typical configuration of the solar thermal systems is with a fixed working temperature, near to 60ºC. But in the task 44 a lot of cases have been studied with a heat pump working temperature lower than 60ºC, due to the fact that this high efficiency system can supply the rest of the energy with electricity. Most of the geothermal heat pumps are working with a maximum temperature of 20ºC in the evaporator, and they can arrive to 60ºC in the condensator to cover all the thermal energy demand. The southern countries we could use unglazed collectors and air-water systems(Moià-Pol et Alt 2012) but in the northern countries, where there are some months with a lot of hours below 0ºC, we need to work at temperatures below 25ºC (Moià-Pol

et Alt 2014) and work with high efficient FPC, specially designed for extreme conditions. There are some manufactures that providea good quality water-to-water heat pump, with high efficiency, working with an inverter compressor. The studied one has a maximum heating power of 13 kW and a nominal COP of 3,56 for heating temperatures of 35ºC-45ºC, and evaporating from -5ºC to 10ºC, with a refrigerant R-410A.

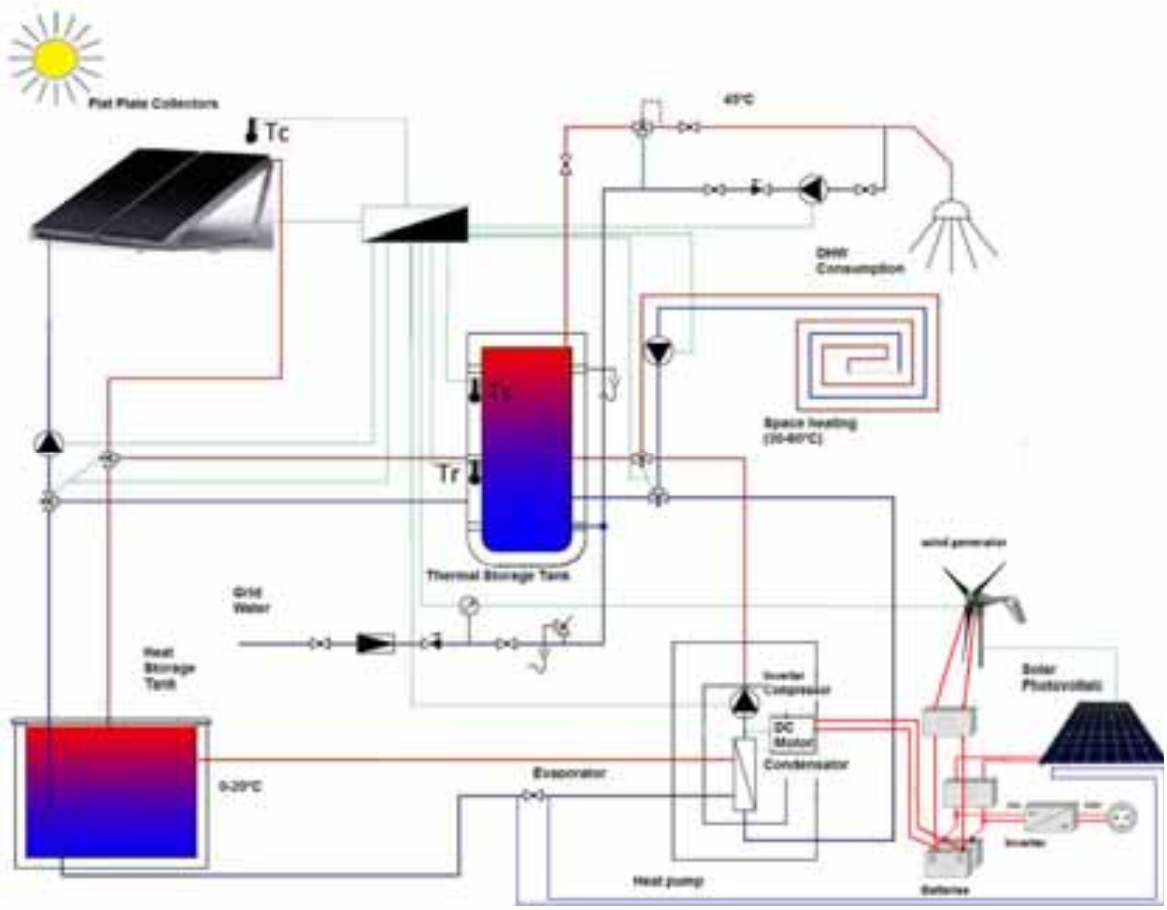

Fig. 1: Figure of the Solar Thermal and PV Heat Pump system for DHW and Space Heating

The Photovoltaic system has been a standard one, the panels with polycrystalline silicon 260Wp, and the inverter with an nominal efficiency of 95,5%, with a 95% of cleanliness and 2% of losses in the cables.

3. Simulation and Results

We have studied different houses within the Moscow region, and developed a simulation program from the conclusions and detailed analysis from other studies (c) using the typical meteorological year (TMY). In this second study, we have considered the PV for self-consumption, with small electrical storage with batteries; because the net metering contract with the electrical company doesn't exist yet in Russia nor in most of the EU countries.

ST Collector Efficiency $\eta = 0{,}807 - 3{,}075(T_m-T_a)/G - 0{,}022((T_m-T_a)/G)^2$ (eq. 1)(e)

Unitary Energy Consumption Heat Pump $kWe = 1{,}20122-0{,}0400633Ta+0{,}0010877Ta^2$ (eq. 2)(d)

PV Efficiency $\eta = Ta - 0{,}036G$ (eq. 3)

For the considered model mentioned above, the solar thermal energy has priority in front of other renewable energy sources, and reduces the overheating in the solar panels.

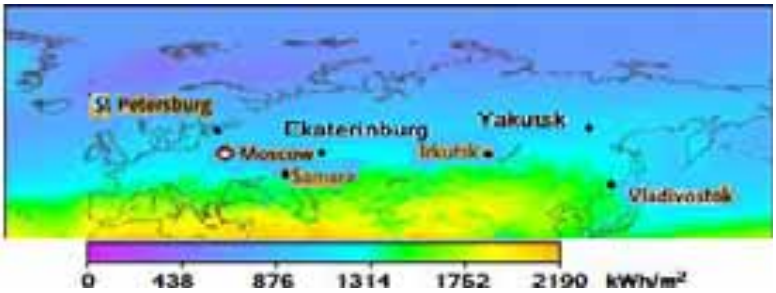

Fig. 2: Annual Solar Radiation per sqm in Russia. Source; Mattihas Loster 2006

Eight locations have been studied consisting of a constant hot water demand for 4 people during all the year. The typical residence considered is a cottage of 160 m² heating space for the eastern regions and a house with 80 m^2 heating space for the western regions, for the new emerging upper middle class. The studied houses have two floors, according to that the residence has been modeled into two zones: a conditioned zone representing a 50% of the total floor area during the day and another conditioned zone during the night. It has been supposed that it's a good quality house, according to sustainability criteria (insulation, orientation,..), when we are using renewable energies we need a low demand to make the system cheaper, with an efficient ventilation system. It has been considered the Russian law 2003 for the insulation (according to building regulations and rules 23-02-2003).

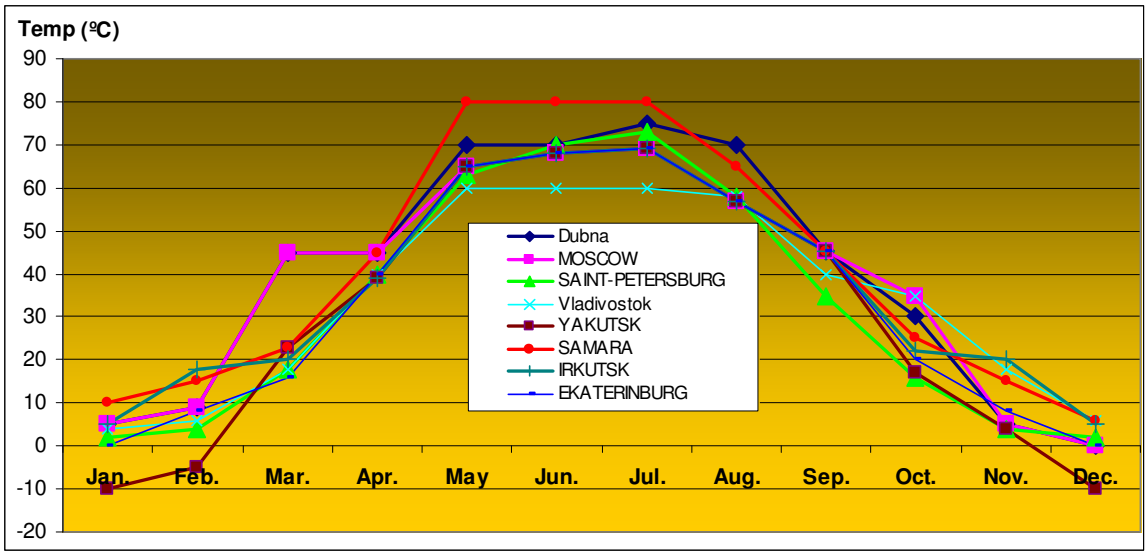

Fig. 3: Figure of the averaged solar monthly working temperature (ºC) for Russian Cities during a typical year

In the northern locations the annual maximum solar energy with the medium temperature of the solar collector between 25 and 30ºC (Moià-Pol et Alt 2014). In figure 3 we can see the considered working temperatures, in order to have a minimum efficiency of the 60% for each month, except for Yakutsk where we have -40ºC during December and January, and in this case we have taken the minimum temperature that can work the heat pump, -10ºC with an efficiency of the FPC of a 40%. For temperatures lower than 25ºC the efficiency of the FPC is higher but the energy requirements are lower and, therefore there are many hours with excess energy for a given storage volume. Each location has a different surface, according to the annual thermal necessities as to achieve a similar solar fraction. When the outside temperatures are rising the thermal energy demand is decreasing and during several months there is enough energy to cover the thermal energy demand so it's not necessary to work at the maximum efficiency point. We can work at higher temperatures to avoid overheating and stagnation problems. The system can only be solar thermal between 40 to 70ºC.

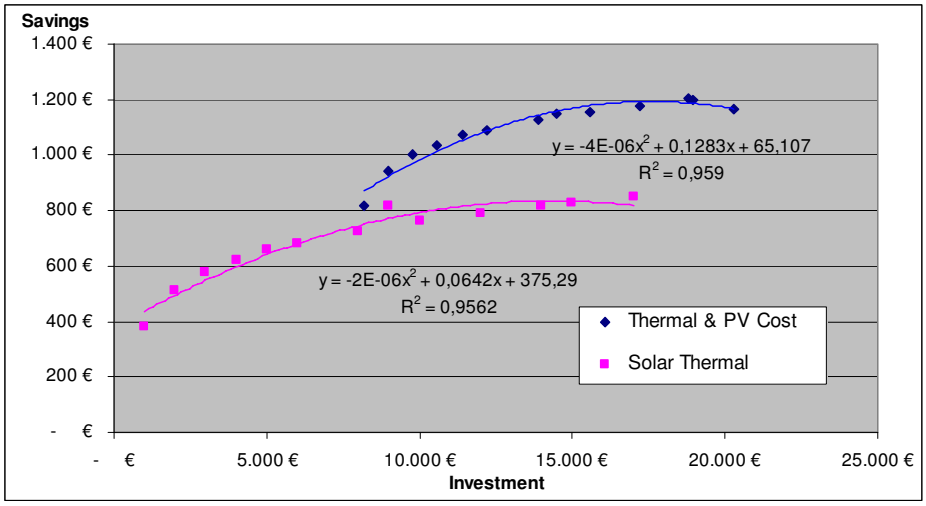

Fig. 4: Figure of the savings vs. investment with PV and ST for Moscow Region.

In order to avoid having a low averaged efficiency we should look for the optimal point of solar panels to accomplish the maximum solar energy gains without overheating. The medium temperature will be usually in winter lower than 20 ºC and in spring and autumn lower than 50ºC, in summer the FPC are working with more than 60 ºC in all the locations. When the medium temperature of the collectors would be higher than 45ºC we will make a direct heat transfer to the DHW or heating system, in parallel with the heat pump. The system according to have a high solar thermal fraction will have high temperatures at summer, with some overheating and stagnation problems.

According to the energy cost-efficiency of the PV and the FPC, we have studied different scenarios to find the optimal point of the system, without taking into account the heat pump and the storage of the buffer tank. The lower prices of the PV could imply to use 100% of this technology instead of using solar thermal, but with a detailed analysis of all the system, according to the COP, and thermal demand every month we can see the optimal point is between 12 and 30 m^2 in Moscow's region, depending on the electric tariffs, thermal demand and climate conditions.

a. Resume of the results.

Comparing all the locations, we could arrive to a similar efficiency for the solar thermal panels, with high renewable thermal fraction (heat pump + solar thermal), combined with PV, this can be a solution for supplying the 100% of the thermal energy demand.

Increasing the PV system we could cover the rest of the energy demand of the household, but this isn't the aim of this study. Combining with wind power, we can optimize the system in some locations with extreme conditions. The heat pump manufactures have made a big effort the last years in order to arrive to high efficiency systems, and the market of geothermal systems has increased. The heat pump with solar panels working in low temperatures could open a big market in locations with low radiation; even if they have cheap energy prices, like Russia.

Tab. 2: Results of one year simulation in four locations for DHW and Heating demand for a house of 160 m^2.

Location	Thermal Demand(kWh)	Solar Energy kWh/m^2	Electric Energy kWhe	ST m^2	Solar Thermal Fraction	Average FPC Efficiency	Power of the PV (Wp)
VLADIVOSTOK (L43)	13900	86,9	4614	13	83%	71%	3,3
MOSCOW (L55)	14690	91,8	5185	20	65%	64%	5,2
DUBNA (L57)	11875	148,4	3406	18	68%	64%	3,0
SAINT-PETERSBURG(L59)	11548	72,2	4100	24	69%	67%	4,9

We can see at the table that the size of the system depends on the solar radiation and the weather conditions. At continental climates with latitudes lower 55º, it gives us systems bigger than the conclusions of the Task

44, with 12 m^2 and storage of minimum of 1 m^3, in our case it's 13-18 m^2 with an storage minimum of 1,25 m^3.

Tab. 3: Results of one year simulation in five locations for DHW and Heating demand for a house of 80 m^2.

Location	Thermal Demand(kW)	Solar Energy kWh/m^2	Electric Energy kWhe	ST m^2	Solar Thermal Fraction	Average FPC Efficiency	Power of the PV (Wp)
IRKUTSK (L52)	8706	108,8	2579	17	78%	65%	2,6
SAMARA (L53)	10017	125,2	3221	18	74%	65%	2,9
MOSCOW(L55)	6449	40,3	1600	14	73%	66%	2,1
EKATERINBURG(L56)	10170	127,1	4562	18	73%	66%	4,3
KRASNOYARSK (L56)	10164	127,1	3090	15	75%	64%	3,0
YAKUTSK (L62)	23587	294,8	5863	24	60%	55%	5,5

At Boreal or Polar Climates or latitudes higher than 55º, the initial dimension of the system is very big, we will need a big investment for houses of 160 m^2, at this latitudes for smaller houses we can compare with the results of the Task 44. Other systems could be studied with seasonal storage, with water or chemical storage, and other technologies like wind turbines or hybrid geothermal heat pumps. Other scenarios with cooling demand will have to be studied in order to improve the system, and increase the PV system. Absorption machines with new refrigerants could be developed in order to be able to have solar cooling systems with competitive prices, but at this moment it's cheaper to use compression machines.

Actually in the market there are good geothermal heat pumps, and combisystems with air-to-water systems, but not yet a combination of all of them. This study only wants to make a first approach of these systems in Russia, it will be needed to analyze more in detail for each location, developing new algorithms to study the seasonal storage and make a test laboratory of this new system in a Russian research Institute. The results will change every year according to the prices of the devices and the energy cost.

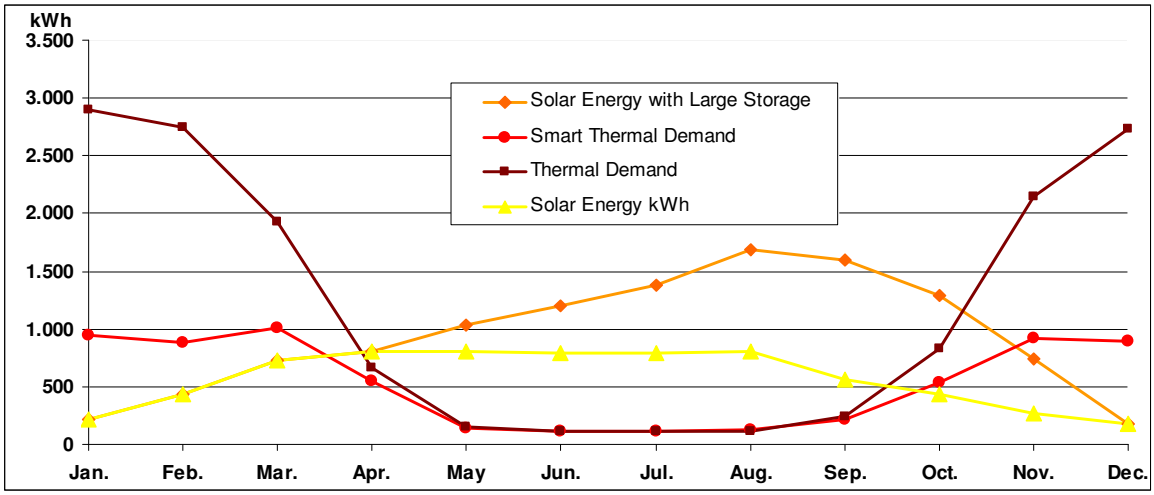

Fig. 5: Figure annual Thermal Demand and Solar Thermal production in Moscow Region

From figure 5, we see a normal thermal demand, an intelligent demand, with control temperatures and with timetable. We can see also with a solar thermal fraction of the 73% there are 5 months with overheating, that we can have stagnation problems. There are some parameters to be optimized for arrive to a high ST fraction, like the available volume in order to have a big buffer tank and arrive to have a seasonal storage, or share the solar thermal energy the months that we don't use to district heating systems, very common in the Russian cities.

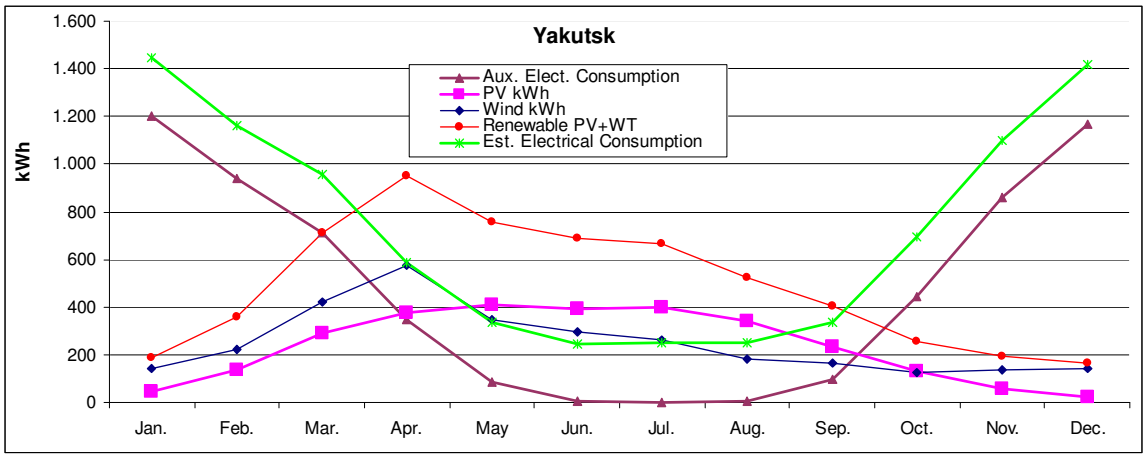

Fig. 5: Figure annual Electric production vs. demand, using PV and Wind Turbine in Yakutsk

In some cities with low solar radiation in winter, where they have some months with an average speed of wind up to 3 m/s. We have studied Yakutsk, Ikurtsk and Ekaterinburg where the wind energy has been simulated that could provide a wind turbine, working with 10% of the equivalent time. This could reduce the surface of the PV system and make more constant the renewable fraction every month, but actually the price of the wind power energy it's more expensive than the PV systems, when we have less than 20% of the equivalent hours working, and we have to add other problems, like noise and structure cost. The PV and the wind market for households also have to be analyzed for the government authorities, in order to allow net metering to avoid usage of batteries in this system, as we get closer to grid parity in Russia every year.

When we are working to NZEB we will need a big surface for the solar thermal and photovoltaic panels that some constructions, due to urban models, don't have at hand. In these study no one of the cases the surface of these systems it's more than the house surface. These parameters have to be included in future studies, in order to have the best solution for each case, when we have vertical constructions. Actually some of these systems have already been studied in the Task 53 - New Generation Solar Cooling and Heating Systems (PV or Solar Thermally Driven Systems).

Tab. 4: Comparing cost of the system vs. Geothermal in Moscow Region

	Estimated cost		**Estimated cost**
Heat Pump	6.000 €	Heat Pump	6.000 €
Solar Thermal + Pipes	8.500 €	Borehole	12.000 €
Thermal Storage Tanks	5.000 €	Pipes	7.400 €
PV System	3.600 €	PV System	6.000 €
Total	**23.100€**		**31.400 €**

There are some heat pump manufacturers that sell hybrid systems, geothermal and air for heating applications, in order to reduce the initial cost of the borehole and piping system. This could also be analyzed in future studies, adding solar thermal fraction, and finding the optimal point. In table 3 we can see that the estimated cost of the proposed system can be 30% cheaper than a conventional geothermal with close loop, but in the second case we can have excess of electricity production. Both systems, if they are designed during the construction project, could be cheaper and have fewer cost, the piping and thermal storage tank could be at the basement of the building with small over cost.

The savings of these systems are about 100% of the thermal energy demand. That means pay-back between 10-20 years, depending on the energy cost. If we compare this with other systems, like hydrogen fuel-cells, there are two times more expensive (40.000 €-60.000 €) and they need electricity for work, with efficiency lower than 50%.

Another advantage of these systems is that they can provide also cooling for the house during the summer, and saving investments of another system.

This system will be installed in Palma and in Dubna, to have real testing results, improve the simulation program, algorithms and find new technologies, materials and systems to have the optimal system for the cold countries will be able to have the same possibilities to arrive to Net Zero Energy Buildings.

4. Conclusions

FPC and PV with heat pump systems are a good solution for family households in Russia, both technologies are necessary in order to arrive to the future scenarios of zero emissions and net-zero energy building, and cover all the thermal demand. The combination FPC and PV in one planar construction is possible. Using in this case a semi-transparent PV not only reduces the overall cost of FPC and PV, but ensure the optimal ratio of generated heat and electrical energy. In the future, as a semi-transparent PV can be used hybrid organic-inorganic solar cells. Net Zero thermal Energy Building are in Europe a technical and economic reality, with the expected future increase of the fossil fuel price and the reduction of the alternative technology costs. This new combisystems opens new options to cover all the energy demand of the houses with an optimized mix, which benefits from the synergies of the different technologies.

Other combinations, like geothermal with solar thermal or seasonal storage could be analyzed in future studies, according to the results of the real test.

THE LIFE CYCLE COST OF STANDALONE SOLAR AIR-WATER HEAT PUMPS FOR AUSTRALIAN HOMES

Gazinga Abdullah[1], Wasim Saman[2], Martin Belusko[3], David Whaley[4]

School of Engineering, University of South Australia, 5095, Mawson Lakes, Australia

Abstract:

To combat increasing electricity prices due to the high operating costs of conventional reverse cycle air-air-heat pumps (RC-AA-HP), they can be powered by standalone PV systems as a radical demand side energy management solution. However, the heavy power consumption of their compressors necessitates very large and expensive standalone photovoltaic (PV) systems. Alternatively, reversible air-water heat pumps (RC-AW-HP) are integrated with thermal storage units, hence with downsized capacity RC-AW-HP but large thermal storage, the building thermal load can be handled equally. The resultant benefits of standalone PV powered RC-AW-HP, is the potential to need smaller, hence, less costly battery storage. One issue associated with using a standalone PV system is the excess power generated. However, the excess power can be utilized to power domestic heat pump water heater (D-HP-WH) which has a different load profile. Previous researches have not focused on such a system configuration, this study focuses on the techno-economic feasibility of a highly optimized component configuration for such a system to meet the entire all-year round space conditioning and domestic hot water demands of a typical Australian house in three vastly different Australian climatic conditions. The entire system is modelled and simulated in TRNSYS and coupled with GenOpt to carry out the optimization. The lifecycle cost assessment on the most optimized component configuration for 0.2% annual hours loss of load probability in generated electricity, reveal that the twenty years life cycle cost is AU$ 76,917 in Brisbane, AU$ 88,539 in Adelaide and AU$ 120,454 in Melbourne. These life cycle costs are higher than case of conventional RC-AA-HP and D-HP-WH run by grid electricity, consequently, powering RC-AW-HPs with standalone PV system is currently not cost competitive with powering them with grid electricity.

Keywords: *solar air-conditioning systems, heat pumps, photovoltaic, standalone*

1. Introduction

An increase in the market-penetration of RC-AA-HP is the main cause behind the rise not only in total usage of, but also in peak electricity demand. In Australia, peak air-conditioning (AC) demand occurs for short periods of time, i.e. only around 40 hours every year (Productivity commission, 2013). However, the entire electricity infrastructure should have sufficient capacity to handle any peak demand. Handling growing residential AC peak electricity demands requires ongoing upgrades in electricity infrastructure (Johnston, 2006). This has resulted in a rapid increase in electricity prices in several countries. In the case of Australia, prices have increased rapidly since 2007 (Carbon and Energy Market, 2012), and almost 50% of the rise was attributed to recouped investments in network infrastructure upgrades. To reduce such ongoing costly investment, a residential demand side energy management solution is necessary. Residential grid-connected photovoltaic (PV) systems lack potential for reducing peak air conditioning demands due to a time mismatch between midday peak PV generated power and residential evening air-conditioning peak demands. Utilizing standalone PV systems to power AC may offer radical demand side solutions. However, a large capacity battery is needed to buffer sufficient energy required to support the operation of large capacity of RC-AA-HP compressors during non-sunshine hours. As per current market status, battery banks, despite dramatic cost reduction are still prohibitively expensive, standalone PV to power RC-AA-HP is deemed economically unfeasible (Dan, et al. 2013; Gupta, 2011). Alternatively, RC-AW-HP is integrated with thermal storage, which allow meeting building peak demand with a downsized compressor capacity (Ehyaei et al., 2010; International Energy Agency and Energy Technology Systems Analysis Programme, 2013; Rismanchi et al., 2013). Trade-offs between the capacity of the PV array size, the battery bank, the heat pump and the thermal storage volume facilitate configurations that reduce the system life cycle cost. A drawback of standalone PV systems is what to do with excess power (Walid et al., 2011), practically, with the poor load factor of residential AC in Australia. But, that excess power can be utilised to operate doemstic heat pump water

doi:10.18086/swc.2015.10.18 Available at http://proceedings.ises.org

heater (D-HP-WH). A resultant benefit is that little oversizing is required, but the system still meets the entire 12 month thermal demand of the building. Previous studies have mostly focused on solar assisted AC, i.e.; less attention has been given to the economics of standalone AC, particularly in such configurations for combined space conditioning and domestic water heating. This study focus on optimizing the size of such system component configuration, with the aim of minimizing the system life cycle cost. The system will be sized for the thermal demands of typical Australian houses in, three vastly differnt Australian climate zones.

2. Building and system specifications

Since space conditioning, domestic hot water demand, and availability of solar radiation are all influenced by the climatic conditions of the site, the size and cost of the system will be site dependent. Thus, the system will be sized for the three different Australian climatic conditions selected: Brisbane, Adelaide, and Melbourne. To make research findings applicable to typical Australian homes, the space conditioning demand for a typical, detached, two story single family houses with 180 m^2 conditioned area was determined (Wong, 2013). In regard to the thermal fabric of the house, it was constructed of brick-veneer and insulated to meet the minimum Australian mandatory building thermal energy efficiency requirement of 6 stars energy rating criteria. According to that rating, the minimum annual thermal energy required to maintain the house thermally comfortable should not exceeds 43 MJ/m^2 in Brisbane, 96 in Adelaide, and 114 in Melbourne (Nation Wide house energy rating scheme, 2012). The domestic hot water demand is taken from the demand pattern provided in Australian standard AS/NZS 4234:2008 for evaluating energy consumption of hot water systems (Australian/New Zealand Standard, 2008).

The standalone heat pump is constructed from a PV and thermal subsystem, see figure (1). The PV subsystem, which includes the PV panels, lithium ion battery bank, and the DC-AC inverter, provides all the power required to run the thermal subsystem. The PV is monocrystalline with a conversion efficiency of 16%; the battery is lithium ion allowing a discharge depth limited to 80% of its available capacity. The inverter is sized according to the peak-power required by the load. The charge controller logic is set to prioritizing meeting the demand, then charging the battery. The PV panel is oriented due north and tilted with angle equal to the local latitude.

The thermal subsystem includes two sub-subsystems. One sub-subsystem is a RC-AW-HP which maintains the temperature of the water inside a stratified water storage tank below 10^oC in summer and above 45^oC in winter. The RC-AW-HP has nominal coefficient of performance of 3.2 in cooling mode and 4 in heating mode. But the performance at part load condition adjusted by with the normalized performance data for one of market available RC-AW-HP brand using its online published technical data. Two pumps are used to circulate the water; one in the heat pump-thermal storage loop activated with RC-AW-HP, one in the thermal storage-air handler unit loop activated with the air handler unit fan whenever there is a space conditioning demanded. A variable speed fan is used to control the flow of air supplied to the house through a ducted system set to control and maintain zones at setting temperatures suggested by (Nationwide house energy rating scheme, 2012). The maximum flow of the supplied air is limited to 8 air-changes per hour, and the parasitic power of the fan and pumps is scaled with the RC-AW-HP capacity. The thermal storage unit is assumed to be sensible stratified water tank that heats/cools the air when water circulates through the air-handler unit. The tank is simulated with 20 nodes, and the insulation level around the storage tank set to R2.7 (0.37 $W/m^2.k$) (AIRAH, 2013). The storage function changes from chilled buffer storage in summer to hot buffer storage in winter and the inlet and outlet ports location was optimized concurrently with the season.

The other sub-subsystem is a heat pump water heater, used to maintain the temperature of the water inside an insulated tank at 60^oC to prepare sanitary hot water sufficient for four persons in a house. The heat pump performance data is normalised from the manufacturer's published catalogue data for four heat pump capacities.

Figure (1) shows the components and configuration of the system

3. Methodology

3.1 Evaluation criteria

Technical criteria was used to correctly size the system component to adequately meet the three building thermal loads; space heating in winter, space cooling in summer, and water heating all year around. For standalone systems, matching energy demand and available energy capacity should be viewed not only in terms of the daily or yearly energy required but also in terms of demand time. Hence, the annual hour's loss of load probability is used for sizing both the thermal and the electrical subsystems. The criteria are based on the number of hours throughout the year when the demand exceeded the system's available capacity. The current system is sized for the following annual hours loss of load probability targets: the RC-AW-HP is sized for 5% of the space thermal conditioning demand, the D-HP-WH for no more than 1% of the domestic hot water demand, and standalone photovoltaic subsystem for 0.2% of the electricity demand of both heat pumps.
The optimization was performed using component sizes as design variables, life cycle cost as objective and standalone as constraints. For speed and accuracy, Hybrid algorithm is chosen for finding the optimal component size.
The economic criterion used is a life cycle cost for twenty years. All cash flow related to the system is discounted back using real discount rates. The life of components is adjusted to the study period by replacing or reselling at salvage value equal to the remaining life of the component.

3.2 TRNSYS project model:

TRNSYS 17 (TRaNsient SYstem Simulation Program) (Klein, 2012) is used to build a complete project model that represents the standalone solar PV subsystem, RC-AW-HP, and D-HP-WH in separated subproject models. Project components include those from the TRNSYS standard library, TESS (Thermal Energy System Specialists) library and three more components developed by the researcher. The project model is coupled with GenOpt optimization (Wetter, 2011) developed at Lawrence Berkeley National Laboratory for minimization of a cost function.

3.3 Economic parameters

Table (1) below lists parameters that feed into the economic model, all of which are gathered by the researchers from online retail price lists and suppliers based mainly in Australia.

Table (1) details related to price of components that feed to the economic model (C refer to component specific capaicty).

Component	Initial cost	Installation	Cost reduction	Maintenance	Life years
Photovoltaic panel (kW)	1900/C (C in kW)	1200/kW	0	0.03% of purchase cost	25
Battery bank (kWh)	1100/C (C in kWh)	6% of purchase cost	50% by 2035	0	10
Inverter, charger, and maximum power point tracker	(508.9*C+ 885.76)+925 (C in kW)	0	0	0	10
Reverse cycle air-water heat pump	581.6+447.6*C (C in kW)	$AU 2500	16% by 2035	5% of purchase cost	15
Heat pump water heater	5.3538*C+ 819.9 (C in m^3)	$AU 500	16% by 2035	5% of purchase cost	15
Pump	269+239.6 *C (C in kg/s)	$AU100 per pump	0	0	15
Storage tank	680*C + 720 (C in m^3)	$AU100	0	0	15
Air-handler unit	35.95*C+680.69 (C in kW)	0	0	0	20

The financial parameters used in the economic model are a 2.2% inflation rate and a 7% nominal discount rate. Also, the Australian government subsidies installing PV and D-HP-WH under a Small-scale Renewable Energy Scheme, offering a rebate called the small scale renewable energy technology certificate (STC)

(Clean Energy Regulator). With this rebate, householders can receive a discount based on the number of STCs that the system is eligible for. Market prices for STCs fluctuate, but currently stand at around AU$ 35 per STC. The number of STCs that a system may attract depends on its size and the geographical location where it is to be installed. For PV systems, each 1 kW is eligible for a cash- back equal to AU$ 622 in Brisbane, and AU$ 725 in both Adelaide and Melbourne. For the D-HP-WH, the number of STCs depends on both the manufacturer and size of the tank. But D-HP-WH which can displace highest energy should be eligible for AU$ 1484 (i.e. 42.2 STC) in both Adelaide and Brisbane, and AU$ 1621 (i.e. 46.3 STC) in Melbourne. These rebates are deduced from the life cycle cost after the optimization.

4. Results and discussion:

6.1 Technical optimization:

System optimization was carried out to reduce the system life cycle cost by varying components sizes but maintaining the above mentioned targeted reliability in annual hours loss of load probability constraints. To guarantee the accuracy of optimal results, each optimization was repeated six times with a different preliminary component size estimated for each of the above stated climate zones. Each optimized configuration was obtained after more than 500 year rounds simulations with 7.5 minute time step. Table (2) lists the components size yields from an optimization which configured the most minimized life cycle cost system. The discrepancy between different component sizes appropriate for each climate is strongly linked with the amount of highest thermal load, the amount of highest heat pumps electrical energy demand, the season when these demands occur, and at what time of day, and how long it continued. For the current research targeted reliability, if the system's available capacity fits the building yearly load profile and the climatic pattern of the site, then it should be practically applicable when it is sized to operate as a standalone system.

Table (2) shows the optimal size of each RC-AW-HP, for each climate zone. In Brisbane, despite the minor space conditioning demand for sensible cooling and heating, compared to Adelaide, a relatively very large thermal storage, i.e. 7.4 m^3, and a large capacity RC-AW-HP, i.e. 3 kW, was needed compared to that anticipated. For Brisbane, this is due to the need to remove the high humidity which dictates maintaining a larger quantity of water chilled at and below 10^oC. Apparently, during the night, less electrical energy is consumed by the RC-AW-HP when using large chilled water storage; instead, the second pump operates more in circulating the vast ready chilled water. This expains why a smaller battery (20 kWh) is needed in Brisbane, compared to those required in both Adelaide and Melbourne. In Brisbane, concurrency of summer high solar intensity with a high cooling load enables the PV system to amply generate the required power to run the heat pumps and recharge the battery.

Table (2) optimized size of components forming the minimized life cycle cost of the standalone system.

	Battery (kWh)	RC-AW_HP (kW)	Photovolatic (kW_p)	Thermal storage (m^3)	D_HP_WH (m^3)
Brsibane	20	3	9	7.4	0.27
Adelaide	28	2	9	7.8	0.34
Melbourne	44.5	5	12	3	0.34

Contrary to Brisbane, in Melbourne the peak space conditioning demand occurs in winter, and lasts for several successive days, the significant part of it occurring at night. When compared to Adelaide, relatively larger capacity RC-AW-HP, i.e. 5 kW, was needed to charge heat in a smaller volume thermal storage, i.e. 3 m^3. Obviously, maintaining a smaller volume of heated water and using a more powerful RC-AW-HP demands less electrical energy than in the case of using downsized RC-AW-HP and a large volume hot storage. Also, when compared to Adelaide and Brisbane, the capacity of the PV panel is larger, i.e. 12 kW_p, since it generates less electrical energy under days with overcast skies. Inevitably, a considerably larger battery bank capacity, i.e. 44.5 kWh, was also required to avoid power interruption during the day and guarantee continuous night operation.

Table (2) shows that for Adelaide, the optimized configuration requires smaller RC-AW-HP, i.e. 2kW, and large thermal storage, i.e. 8 m^3, than the other two climates. This is due to a high peak sensible cooling demand and significant heating load. On account of the noticeable variation between electrical and thermal storage sizes in hot and cold climates; it can be concluded that using large chilled water storages for space cooling in summer considerably reduces the required battery capacity for the same annual loss of load

probability. Unlikely, using hot storage for space heating not have that considerable potential to reduce the minimum required battery capacity.
The capacity of the configured PV panel, i.e. 9-12 kW_p, may look a little large for residential buildings, but the system configuration is standalone with a superior degree of reliability, less than 5 hours per year the electricity demand is not met. Should more annual hour's electrical loss of load portability be tolerated, the size and cost of the electrical parts of the system will reduce substantially, but then the system need to be assisted by mains-grid electricity.
In terms of sizing the D-HP-WH, the size that was found to be suitable for Brisbane was a 270 litre tank and heating rate of 75 litres per hour, while those suitable for Adelaide and Melbourne were 340 litre tanks and heating rates of 75 litres per hour. The power that was needed to operate the heat pump was added to the power required to run the RC-AW-HP during the optimization. The daily D-HP-WH power pattern is similar throughout the year, but higher in winter than in summer. Adding the D-HP-WH power profile caused the PV subsystem to be a slightly oversized, but significant amount of the PV dumped power was usefully utilized by the D-HP-WH.
It is important to emphasize that these configurations do not represent those with the best fit technical configuration for the building load, nor for the selected climate zones. They represent configurations that with a given component cost and target constraints, lead to obtaining the component configurations that have minimized life cycle cost systems. Should the system to be sized for other climates, by loading the applicable load profile, or other cost or constraints targets, the project model can be used to determine the optimized standalone system's components configuration.

6.2 Economic evaluation:

The twenty years life cycle cost of the most optimized component size configuration presented in table (2) was found to be AU$ 83,907 in Brisbane, AU$ 96,814 in Adelaide and AU$ 130,782 in Melbourne. Depending on the size of the PV panel and the climate, when government rebates in the form of STCs are added to both the PV panel and the D-HP-WH, the life cycle cost reduces in Brisbane to AU$ 76,917 , in Adelaide to AU$ 88,539 and in Melbourne to AU$ 120,454. If the system life cycle cost break down to the life cycle cost of main forming components then it becomes obvious which component costs dictate the cost of the system.
Figure (2) shows in each of the three climate zones, the greatest cost is associated with the battery, followed by the PV panels, followed by the thermal storage unit. If the percentage of investment attributed to the battery and the thermal storage are cross-correlated and compared for the three climate zones, it becomes evident that, when the percentage cost of thermal storage is higher, the percentage cost attributed to the battery is less. Since the price of the cubic meter of thermal storage is less than the price of each kWh battery capacity it replaces, with larger thermal storage the life cycle cost of the system must in all probability decrease correspondingly. To be more specific, in space cooling dominated climates, large chilled water storage can reduce the minimum capacity of a battery required for settling standalone solar PV powered RC-AW-HP.

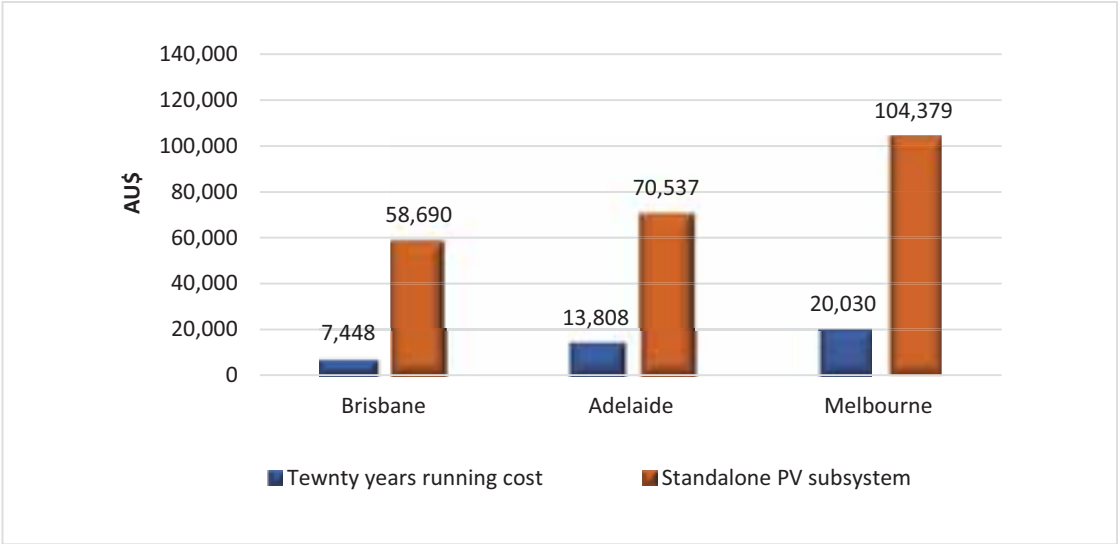
Figure (2) the life cycle cost break down to main forming components in the three climates

6.3 Competitiveness with conventional system:

To investigate how such standalone PV powered RC-AW-HP and D-HP-WH is cost competitive in comparsion with powering them by grid electricity, the life cycle cost of the PV subsystem is compared with the twenty years running cost of the conventional RC-AA-HP and D-HP-WH if electricity is purchase from the grid. The comparison is shown in figure (3). Clearly, the investment required in the reliable standalone PV system is enormously higher than purchasing the power from the grid for running the conventional systems in the three climate zones. Hence, the economic potential of space conditioning houses with RC-

AW-HP off-grid is weak in comparsion with current component costs and electricity charges. Unless in case of remote dwellings where costly investment in constructing new or extending electricity network infrastructure is needed to sustain powering conventional AC. Adding these infrastructure costs to the running cost can influenec individual householders to select the presented standalone PV powered heat pumps instead of paying for infrastucture network extensions.

Figure (3) comparing the twenty years running cost and standalone PV subsystem life cycle cost in the three climates



5. Conclusion:

In this study, a TRNSYS 17 project model is used to optimize the configuration of components forming the standalone PV subsystem powering RC-AW-HP and D-HP-WH for the thermal demand of typical Australian house in three vastly different Australian climatic zones. The life cycle cost of most optimized configuration of these systems with rebate was found to be AU$ 76,917 in Brisbane, AU$ 88,539 in Adelaide and in Melbourne AU$ 120,454. It has been found that chilled water storage can contribute to reducing the capacity of the battery, consequently, the overall standalone system cost. Whether investment in such a system is cost competitive with purchasing electricity from the grid to power conventional RC-AA-HP and D-HP-WH in residences; the life cycle cost of the standalone PV subsystem is compared with a 20 year discounted electricity cost needed to power conventional RC-AA-HP and D-HP-WH. The results demonstrate that purchasing electricity from the grid to run these conventional options costs much less than investing in a standalone PV subsystem. Indeed, unless the tariff increase considerably, or, the cost of batteries decrease significantly, or the householder is faced with heavy investment in electricity infrastructure charges, it is currently uneconomic to invest in a standalone PV driven air to water heat pump systems.

THE EXPERIMENT OF A NEW TYPE OF BUILDING INTEGRATED SOLAR RADIANT HEATING SYSTEM

Yu Yingying[1], Niu Baolian[1] and Shi Liangyan[1]

[1] School of Energy and Mechanical Engineering, Nanjing Normal University, Nanjing (China)

Abstract

A heat pipe radiant heating system is discussed, combined with the building and solar energy by heat pipe. The system is composed with solar collector, heat pipe and radiant heating terminal. The heat pipe delivered the heat of solar absorbed by itself from outdoors to indoor and then heating the room by radiant. This paper adopts a combination of experimental and simulation to test and analysis the system. The results showed that the indoor average temperature can reach above 16℃ during the daytime in winter, and the temperature distribution is uniform. The system is an energy-saving and practical building integrated solar radiant heating system.

Keywords: *solar building, radiant heating, gravity heat pipe, zero-energy consumption*

1. Introduction

In the hot summer and cold winter areas without central heating in China, most buildings use small separated heating equipment such as air conditioning, heaters and electric blankets. However, low operating efficiency and high energy consumption can lead to energy waste and environmental pollution when widely-ranging. Thus, it is essential to find an energy-efficient and comfortable way of heating.

Solar energy is clean and efficient and non-polluting, and the solar thermal technology in buildings has been have a certain development in many countries.

Susheela and Sharp (2001) designed and tested a heat pipe system that could be installed on existing homes without demolishing the wall of the building. The absorber portion was mounted on the outside of a south-facing wall, with water contained in tanks as the thermal mass on the inside of the wall. Experiments were performed outdoors, and system efficiencies (defined as the ratio of power delivered to the room over incident insolation) reached as high as 60% during sunny days. Computer simulations were also performed to model the performance of the unit.

Primarily based on design improvements recommended by Susheela and Sharp, Albanese et al. (2012) tested a bench-scale experimental model. Experimental variations included fluid fill levels, addition of insulation on the adiabatic section of the heat pipe, and fins on the outside of the condenser section. Filling the heat pipe to 120% of the volume of the evaporator section and insulating the adiabatic section achieved a system efficiency of 85%. Addition of fins on the condenser of the heat pipe did not significantly enhance overall performance. The heat pipe system provided substantial gains in performance relative to conventional direct and indirect gain passive solar systems and, thus, presents a promising alternative for reducing building energy use.

To better understand system performance in realistic weather conditions, in particular, the relatively cloudy and cool conditions, Robinson et al. (2013) designed, built and installed a full-scale prototype of the heat pipe system in a classroom on the University of Louisville campus in Louisville, KY. During the spring heating season of 2010 (January–April), maximum daily peak thermal efficiency was 83.7% and average daily peak thermal efficiency was 61.4%. The maximum hourly average room gain achieved during the season was 163 W/m^2. On days with good solar insolation, the thermal storage was heated to temperatures

doi:10.18086/swc.2015.10.19 Available at http://proceedings.ises.org

sufficient to provide significant energy to the classroom – even during the coldest days of the season. During the longest period (4 days) of low insolation during the season, average hourly heat delivery to the room from storage remained positive, and was never less than 16.6 W/m^2.

Operation temperature of solar heating systems makes the use of a radiant floor to transfer heat into the conditioned spaces suitable. Compared with thermal storage wall, temperature radiant floor heating system has more advantages in terms of indoor thermal comfort. In recent years, the application of heat pipe in solar radiant heating becomes more and more.

Manillez et al. (2005) studied and tested the solar floor radiant heating system that 15.36m^2 collector to meet the heating and hot water load of 172m^2 room. The solar fraction recorded this day was of 0.468, that is, solar energy supplied 46.8% of the combined heating and hot water loads, one of the highest solar fractions of the season.

Zhang Yufeng et al. (2006) studied the performance of a carbon-steel/water thermosyphon and applied it to low-temperature under-floor heating system. Experimental investigation has been done to find out the effect of inclination angle (-4°~90°), evaporative length (30~180mm), temperature (40~60 ℃), flow rate (0.1~0.3m^3/h) and flow direction (forward flow, counter flow) of hot water on thermosyphon performance. The evaporator section of the carbon-steel tube is heated by hot water while its condenser section is cooled by air. Experimental results indicate that the thermosyphon performance with counter flow is much better than that with forward flow. The heat transfer rate and surface temperature of condenser section increase with the rise of hot water temperature and flow rate. With increasing inclination angle and evaporative length, heat transfer rate and surface temperature increase at first, and then start to decline after attaining their maxima. This thermosyphon works well in all experimental conditions, and it yields the highest thermal performance with the evaporative length of 120mm, inclination angle of 38°, flow rate of 0.3m^3/h, temperature of 60℃, and counter flow of heating water.

The existing experimental studies about heat pipe radiant heating systems with water, the heat transfer loss is inevitable between the water and heat pipe. Besides, the pump needs energy consumption. The building integrated solar radiant heating system can reduce the irreversible loss and improve energy efficiency. The system absorbs solar thermal by heat pipe and heating the room directly by radiant without any power consumption when the solar radiation is enough. This paper will analyse the indoor temperature distribution of the system, and the influence of evaporative length and quantity of working fluid on the performance of heat pipe to further explore the method of improving the syetem efficiency and indoor thermal comfort.

2. Experimental study

2.1. System introduction

The building integrated solar radiant heating system is composed of an outdoor heat collector, an indoor heat release module and heat pipes as Fig. 1 shows. The system uses heat pipes as heat transfer component. The evaporator section is placed in the solar collector. While the temperature rose, the working fluid inside the evaporator section absorbs the heat and evaporates to gas and run into the condenser section. When the gas enters into the condenser of heat pipe, it will sent heat into the indoor air and then turn into liquid, finally it will return back to the evaporator of the heat pipe. Then the new cycle will carry on and solar energy will be transferred into the room. In order to prevent heat transfer from indoor to outside, we use the gravity heat pipe with a thermal diode effect.

Compared with the traditional solar hot water floor radiant heating system, the heat pipe radiant heating system directly transmitted the solar thermal energy for indoor radiant heating without the middle transfer medium, which will reduce the irreversible loss of heat transfer between water and working fluid and improve the utilization rate of solar energy. The system is suitable for office buildings, kindergartens and secondary school classrooms and other daytime office spaces, and it can provide the basis for residential heating temperature, reduce fuel consumption.

The gravity heat pipe used in the system is 3.12m in total length, and the evaporator section is about 1.8m

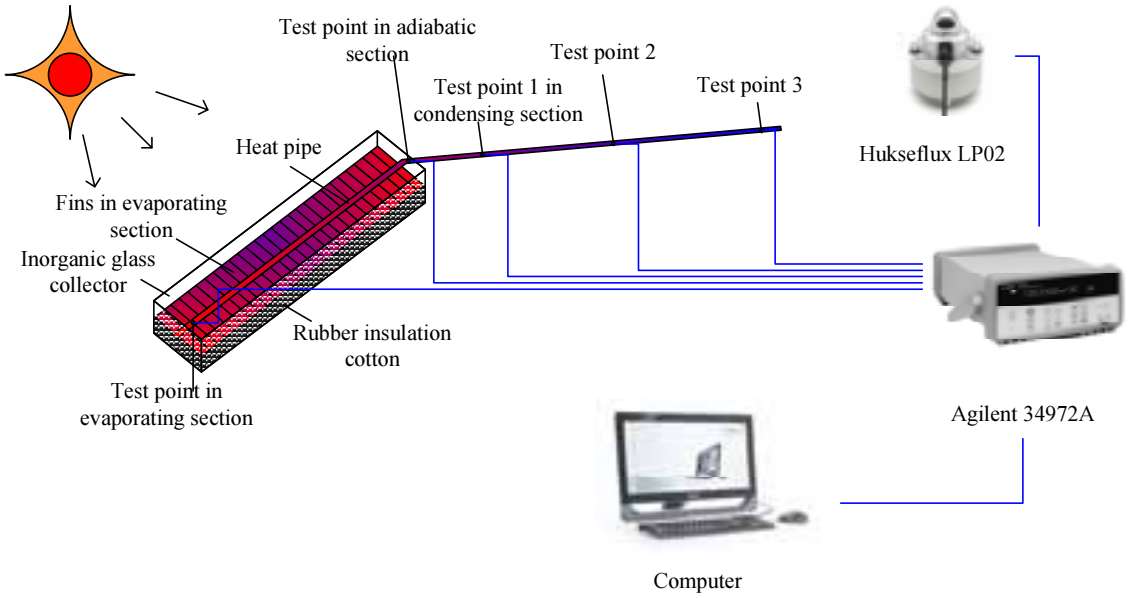
with 8mm outer diameter, the condenser section is 1.2m with 12mm outer diameter, the insulation section is 120mm with 12mm outer diameter. The working fluid of the gravity heat pipe is R600a and the tube of heat pipe is made of cooper with 1mm thickness of pipe wall. The collector part is basically the same as the ordinary plate type solar collector, that mainly consisted by the collector body, heat insulation material, heat absorbing layer and the transparent glass cover. The heat absorbing layer is the core design of the system, which is borne by the evaporator section of heat pipe with fins. The surface of fins is planted with a blue film, and it wrap up the heat pipe in 360° to absorb the maximum possible radiation and to raise the working fluid temperature. Between the heat pipe and the frame, 60mm thickness insulation cotton is used to keep the heat, and on the top of the collector, the organic transparent glass is used to transfer solar sunshine.

2.2. Test method

The experimental testing system is composed of two parts:

(1) Tests of heat transfer performance of single heat pipe

The experimental test system is shown as Fig.1. a HukseflUxLP02 short wave radiation sensor is used to measure insolation values with and the sensitivity of 12.13μV/(w•m^{-2}). Fluke hot wire anemometer is used to measure the wind speed with the sensitivity of 0.01m/s, twenty J-type thermocouples were placed in the evaporator and condenser respectively, to assess temperature difference between of them at the same time. Another one J-type thermocouples was placed outside to measure ambient air temperature. All data was collected using Agilent 34972 a.



(2) Tests of building integrated solar radiant heating system

The installation of gravity heat pipe of the system is shown as Fig.2. The GHPRHS prototype was fabricated, which used a plate solar collector as evaporator. The collector was consisted of nine copper tubes (10mm diameter) wrapped with fins soldered on the rubber insulation cotton (40mm thick). The dimension of the fins was 138mm×180mm×1mm. The total length of the each heat pipe was 3 m. and the diameter of the condenser was 12mm. The total surface area of the collector was 2.2 m^2. The fin surface was a selective black coating surface. The 2m×1.4m glazing consisted of 3.18 mm thick glass with an anti-reflective coating. At the indoor section, the copper pipe was fixed on the groove of the insulating material with the distance of 200mm between of them, which was covered with aluminum sheet with high thermal conductivity. In addition, 40mm thick insulation layer was put on the floor to avoid the heat loss from the floor. Above these heat pipes, laminate flooring was put on in order to simulate the real floor. The whole indoor surface area was 2.4m^2. All the condenser of the heat pipes were mounted at 5° from the horizontal.

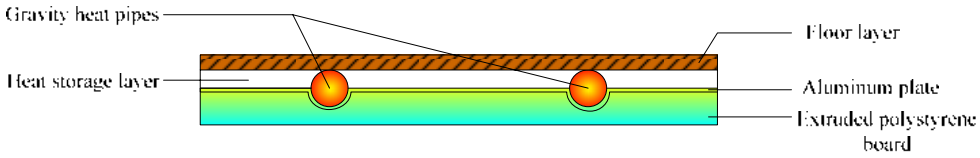

Fig. 3: The structure of indoor radiant heating model

3. Results and discussion

3.1. Theoretical model

Traditional evaluation method of heat pipe heat transfer performance is to compare the equivalent heat conduction coefficient, its mathematical expression is:

$$\lambda_{eff} = \frac{4L^2}{{d_0}^2} \cdot \left[\frac{1}{\left(\frac{\ln(d_0/d_i)}{2e}\right)+\frac{\lambda}{\alpha_e d_f e}+\frac{\lambda}{\alpha_c d_f c}+\frac{\ln(d_0/d_i)}{2c}}\right] \cdot \lambda \qquad \text{(eq. 1)}$$

The equivalent heat conduction coefficient is directly evaluated, and the parameters are easy to be measured. However, it still has shortcomings. By the formula, the longer the heat pipe is and the smaller the diameter is, the equivalent heat condunction coefficient will be high even if the heat transfer coefficient of the evaporating and condensating section are not high, especially for heat pipe with long length. This is exactly the deficiency of the equivalent heat conduction coefficient. The equivalent convection heat transfer coefficient is introduced to the model by Yu Tao(2008) and establish the formula as follow:

$$\alpha_{eff} = \frac{2\lambda Q(L_c+L_e)}{2\pi\lambda d_i(T_e-T_c)L_c L_e - Q d_i(L_c+L_e)\ln(d_0/d_i)} \qquad \text{(eq. 2)}$$

Here, α_{eff} is a weighted average of the boiling heat transfer coefficient and the condensation heat transfer coefficient, which is a comprehensive reflection of boiling and condensation heat transfer processes in the heat pipe. Besides, the right parameters of eq.2 can be obtained by measurement. Therefore, it is objective to evaluate the heat transfer performance, especially the gravity heat pipe by the equivalent convection heat transfer coefficient.

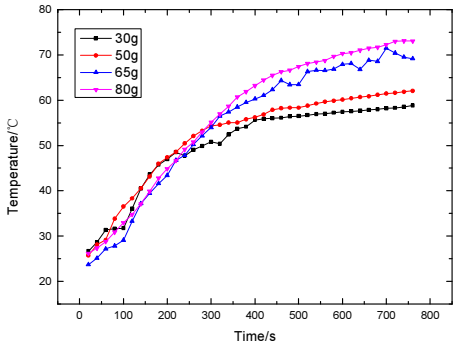
3.2. Heat transfer analysis of heat pipe with different charging ratio

Fluid charging rate is an important parameter to study the heat transfer performance of gravity heat pipe. When charging rate is too low, heat pipe will appear dry phenomenon; and when it is too high, heat pipe will appear boiling limit. The existing researches showed that the appropriate charging rate for heat pipe is between 30%~ 80%. Therefore, this experimental study on the filling rate in this range to observe the variation of heat transfer performance with the charging rate of two phase flow heat pipe, and provide a theoretical and experimental basis for the heat pipe radiant heating system.

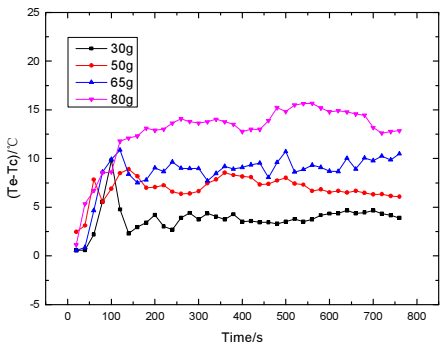
A series of daily outdoor tests have been performed, the amount of working fluid was varied in the range of 30g-80g corresponding to a ratio of fill charge volume to inner volume of the evaporator zone range of 30%-80%. The variation are given in Fig.5 including temperature in the condensing section, temperature difference of evaporating and condensing section and the equivalent convection heat transfer coefficient, the variation of temperature difference of evaporating and condensing section, the variation of the equivalent convection heat transfer coefficient with time in the same solar irradiance. It can be seen in Fig. (a) that the higher the charging ratio, the higher the temperature of condensing section after the start-up process. It's because the condensate film is the main factor to affect the heat resistance in condensing section in the same solar irradiance. The steam quantity follows the same trend as the charging ratio increasing, more steam generated in the evaporating section, the more steam be condensed in the condensing section, which will increase the thickness of condensate film and heat transfer thermal resistance. In addition, higher charging ratio made the steam flow faster and the friction between the steam and liquid film increasing, which will also increase the thickness of condensate film and is unfavourable to the heat transfer in the condensing section. While the condensation heat transfer coefficient decreases, the amount of steam generated by the evaporation section increases, leading to the rise of tube wall temperature of condensing section.

Fig.(b) shows that the temperature difference between the evaporating and condensing section are all increased first and then decreased and tend to be stable with different charging ratio. This is because the heat pipe needs time to start-up, and the evaporating temperature rise sharply in start-up time while the condensing temperature rise gradually after the steam reached a certain value in evaporating section. Higher charging ratio needs more time to start-up. Therefore, the time of temperature difference tends to be stable is shortest when the fluid amount is 30g in Fig.(b). It also can be seen from Fig.(b) that the temperature difference between the evaporating and condensing section is bigger with more charging ratio. This is because high charging ratio will lead more steam generated in the evaporating section and the condensing liquid in the condensing section increased, and the temperature of condensing liquid is always lower than that of the boiling liquid in evaporating liquid pool, which will reduce the temperature of tube wall of condensing section.

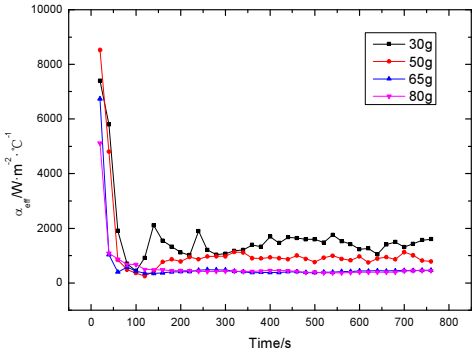
Fig.(c) shows that the equivalent heat transfer coefficient decreased with the increase of charging ratio. This is because when the charging ratio is low, the liquid level of liquid pool in the evaporating section is low and the heat transfer resistance is small which is beneficial to the liquid boiling in the liquid pool and the heat transfer coefficient of evaporating section is relatively large. However, when the charging ratio is higher, the liquid level of liquid pool increased and the heat transfer thermal resistance is larger, which decrease the velocity of bubble movement in the evaporating section and reduce the boiling heat transfer in the liquid pool, so that the heat transfer coefficient of evaporating section is reduced. Besides, the condensation heat transfer coefficient is also decreased with the increase of liquid charging ratio, and the equivalent convective heat transfer coefficient is the comprehensive reflection of the evaporating and condensing section, so the equivalent convection heat transfer coefficient decreased with the increase of liquid charging ratio.



(a)Variation of temperature in the condensing section



(b) Variation of temperature difference of evaporating and condensing section



(c) Variation of the equivalent convection heat transfer coefficient with time

Fig.5 The curve of heat transfer performance of heat pipe with different charging ratio

Table 1 is the calculated data of heat pipe heat transfer performance in different charging ratio. According to the data, the higher the charging ratio is, the smaller the heat transfer coefficient of condensing section, which is consistent with the analysis in Figure 5. However, the higher the working quality of the evaporation section, the more quantity of condensing heat release and the higher the solar thermal utilization rate of the heat pipe. This is because the temperature of tube wall of condensing section increases with the increase of working fluid, which lead to the temperature difference between the tube wall and the steam inside larger. Compared with the heat transfer coefficient, the temperature difference has a greater impact on the condensing heat release. Therefore, the higher charging ratio can lead to more quantity of condensing heat release, as a result, the solar thermal utilization rate of heat pipe can be higher with the high charging ratio.

Although the higher charging ratio brings the more heat energy from the condensing section, and will probably lead to the overheating of the condensing section. It can be seen from Fig.2 that the temperature of tube wall of condensing section can be up to 70℃ when the charging ratio is 60% and 80%. However, the tube wall temperature of indoor heating pipe should not be higher than 60℃ according to relevant regulations (2008). Indoor heating temperature is too high to get human thermal comfort with the local overheating. Comprehensively considering the heat pipe condensing temperature and heat release, the best liquid charging ratio is about 45%~50% in the system, with highest pipe wall temperature about 60℃ and the heat quantity about 70W highest pipe wall temperature is about 60℃ and the heat quantity is about 70W.

Tab. 1: Table of heat transfer performance in different charging ratio

Quantity of working fluid	Filling radio	t_v/℃	t_w/℃	h_c/W·(m^{-2}K^{-1})	Q′	η
30g	30%	59.5	57.2	565.53	58.8	0.341
50g	45%	63.1	59.7	426.78	66.8	0.402
65g	60%	72.3	66.1	325.24	98.7	0.473
80g	75%	78.1	69.2	259.08	178.1	0.823

3.3. Heat transfer and indoor thermal environment analysis of the radiant heating system

The experimental data were collected continuously under the condition of sunny days in winter in Nanjing.

Figure 6 shows the variation of indoor and outdoor parameters with time. It can be seen from the figure that the variation trends of the evaporating and condensing temperature are consistent, which increase and decrease with the solar irradiance. When the solar irradiance is about 100W/m^2, the heat pipes began to start-up and the evaporating and condensing temperature gradually increased, and it reached a maximum at 12:00 and then decrease. After about 16:00, the condensing and the indoor temperature tend to be equal and the heating collect is ineffective. In winter, the effective heating time is about 6 hours from 10:00 to 16:00. During 11:30 to 12:30, the solar irradiation has high intensity, and the temperature of condensing section is so high that leading the indoor temperature above 35℃. This is due to the non-thermal storage wall and

without heat storage material in the experimental room, and the heat storage material will be added to reduce the indoor temperature and maintain the human comfortable temperature.

Comparing the indoor air temperature and outdoor air temperature variation curves in figure 6, the outdoor air temperature is in range of 3.5~9.2℃ with the average temperature 6.9℃, while the indoor average temperature is 22.5℃, the average temperature difference can reach about 15℃. The results show that the indoor air temperature is greatly improved under the building integrated solar radiant heating system.

Figure 7 shows the curve of indoor temperature during the effective heating time, the two curves are respectively gained by the average value at the height of 1.0m and 1.7m in the room. The results show that the temperature difference is relatively small, which is very small with the variation range from 0.01℃ to 0.77℃. Therefore, the air temperature distribution in the room is relatively uniform and no obvious temperature stratification appears. Compared with the system proposed by Ji Jie(2011), the floor radiant heating system has a more uniform temperature field distribution and the indoor thermal comfort is higher.

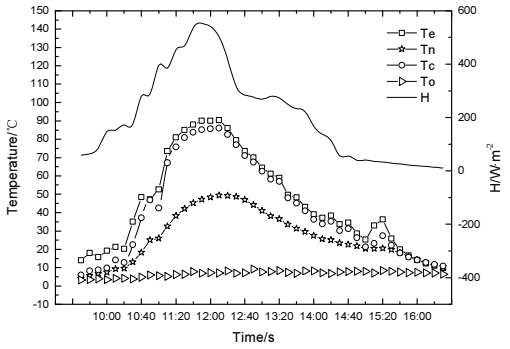


Fig.6 Variation of parameters versus time of indoor and outdoor

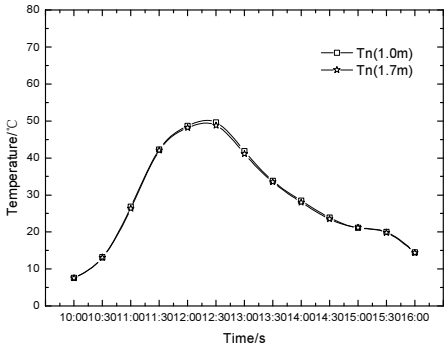

Fig.7 Variation of temperatures of air in the room versus time

From the analysis above, it shows that the system can run normally in sunny days and is an economic, environmentally friendly, and effective passive solar heating system. The indoor temperature can reach up to 20℃ in 30 minutes under the irradiance of 400W/m^2, while the outside temperature is around 5~6℃. Therefore, in the regions with abundant light supply, even if the outdoor temperature is very low, the system is still able to meet the needs of winter indoor heating with good heat-preservation wall.

Nomenclature

α_{eff}	equivalent convection heat transfer coefficient	d_0	outer diameter of heat pipe
λ	heat transfer coefficient of pipe shell	d_i	internal diameter of heat pipe
Q	heat flux of heat pipe	t_v	steam temperature in heat pipe
L_c	length of condensing section	t_w	tube wall temperature of heat pipe
L_e	length of evaporating section	h_c	heat transfer coefficient
T_e	temperature of evaporating section	Q'	heat release of condensing section
T_c	temperature of condensing section	η	solar thermal utilization

4. Conclusion

This work focuses on the testing of the performance of gravity assisted heat pipe and the radiant heating system, and gets the following conclusions:

(1) Charging ratio has a great impact on the performance of gravity heat pipe. The equivalent heat transfer coefficient decreased with the increase of charging ratio, while the quantity of heat release rose with charging ratio. Comprehensively considering the heat pipe condensing temperature and heat release, the best liquid charging ratio is about 45%~50% in the system, with highest pipe wall temperature about 60℃ and the

heat quantity about 70W highest pipe wall temperature is about 60℃ and the heat quantity is about 70W.

(2) The system is currently only used for indoor heating in winter, and in order to prevent the overheating in summer, installing globe valve on every heat pipe. Latter, the separated heat pipe will be taken to paralleling connect with hot water system in the heating system, which can produce hot water in summer when the heating system stop by the switch of the control valve. In non-heating period, the valve between the heat pipe radiant heating system and the collector will be closed, and the valve between hot water system and the collector will be open. It can also realize the energy saving in summer, using solar collector to heat the water and provide the hot water for life.

WATER QUALITY ON SOLAR WATER HEATERS IN REMOTE ISLANDS

Kai-Chun Fan[1], Keh-Chin Chang[1] and Kung-Ming Chung[1]

[1] Energy Research Center, National Cheng Kung University, Tainan, Taiwan

Abstract

The use of solar water heaters (SWHs) in Taiwan's remote islands has encountered scaling and corrosion problems attributed to sources of water. In this study, the Langelier Saturation Index (LSI), Ryznar Stability Index (RSI), Puckorius Scaling Index (PSI) and Larson-Skold Corrosive Index (LSCI) were employed to assess scaling and corrosion caused by tap-water and groundwater used for SWHs in Penghu, Kinmen, and Lienchiang Counties. The LSI, RSI and PSI results show a slight scaling tendency in Penghu County, but there is a corrosion tendency in Kinmen and Lienchiang Counties. Nevertheless, all LSCI values show a serious corrosion tendency. In addition, chloride ion (Cl^-) concentration levels are all higher than 35 mg/L, resulting in corrosion found in absorbing plates of SWHs using 304 stainless steel. Therefore, more corrosion-resistant metals are required for SWHs.

Keywords: *solar water heater; remote islands; water quality; scaling; corrosion*

1. Introduction

Solar thermal energy is widely used in many countries (Weiss et al., 2014). SWHs are mainly composed of four parts: solar collector, water storage tank, piping, and control systems. The absorbing plate is generally made of copper, aluminum, stainless steel or flexible polymer. Packing material between inside and outside barrels for a stainless-steel water storage tank is for thermal insulation. In Taiwan, the climatic conditions are predominantly sunny. The solar radiation ranges from 1,200 to 1,700 kWh/m^2/year. To disseminate SWHs, the Bureau of Energy, Ministry of Economic Affairs (BEMOEA, 1986–1991 and 2000–present) and some regional governments have established subsidy programs (Chang et al. 2013). The Energy Research Center at National Cheng Kung University (ER/NCKU) has been authorized by the BEMOEA to organize an operation unit for the second subsidy program since 2000. The accumulated area of solar collectors installed in 2012 reached 2.25 million m^2 (Lin et al. 2013). Note that the Low Carbon Island Project, including Penghu, Kinmen and Lienchiang Counties, was also launched in 2012 and promotion of SWHs was part of the project.

Service period of SWHs is of great concern for end users. In 2013, telephone interviews were conducted by the ER/NCKU for 6,482 SWHs installed in 2000, in which 3,379 end users (52.1%) were reached. The survey showed that there were 95.3% systems in operation, indicating the service period of SWHs more than 12 years at least. Further, malfunction of SWHs has been reported from time to time. In the period of 2000-2012, 942 cases were documented by the ER/NCKU, in which 555 of them (58.9%) were associated with leakage (corrosion or pitting) in absorbing plates, gate valves, storage tanks or pipe joints, resulting a reduction in service period (1-5 years).

In Taiwan, water resources are rich. Tap-water is the principal domestic water supply and the water quality is stable. In contrast, the principal domestic water sources in remote islands are tap-water from desalination and re-treatment groundwater. To assess water quality on SWHs in remote islands, this study sampled tap-water and groundwater from households with SWHs. Analyses of water quality were conducted, including pH, total alkalinity, total hardness, chloride, and sulfate. The water quality assessment methods including LSI, RSI, PSI and LSCI, were employed to estimate the tendency of scaling and corrosion (Langelier 1936;

doi:10.18086/swc.2015.10.20 Available at http://proceedings.ises.org

Ryznar 1944; Larson and Skold 1958; Carrier 1965; Puckorius 1983; Degremont 1991; Seneviratne 2007; Prisyazhniuk 2007; Gacem et al 2012). The values of LSI, RSI, and PSI are primarily used to estimate the scaling potential of calcium carbonate ($CaCO_3$) in water. It is also known that LSI is the oldest and most commonly used. However, Seneviratne (2007) thought LSI does not estimate the corrosivity of water because corrosion may still occur due to dissolved oxygen and solids, such as chlorides or sulfates which increase the conductivity of water and corrosion rates. Nevertheless, the LSCI proposed by Larson and Skold (1958) can be employed to estimate the corrosiveness of water on low-carbon steel and steel samples. In this study, the water quality survey aimed to address the corrosion problem on the service life of SWHs.

2. SWHs in remote islands

As shown in Fig. 1, Penghu County (119°19' to 119°43' E, 23°12' to 23°47' N) with 37,151 households lies approximately on the Tropic of Cancer. There are five townships (Husi, Baisha, Siyu, Wang-An and Cimei township) and one city (Magong city). Kinmen County (118°24' E, 24°27' N) with 36,558 households, made up of 12 jurisdictional islands, is located in the subtropical oceanic climate zone. There are six townships (Jincheng, Jingsha, Jinhu, Jinning, Lieyu and Wuqiu). Lienchiang County (119°51' to 120°31' E, 25°55' to 26°44' N) with 2,423 households, which also lies within the subtropical oceanic climate zone, is the smallest county in Taiwan. There are four townships (Nangan, Beigan, Jyuguang and Dongyin). Juguang Township includes two major islands: Dongju Island and Xiju Island.

As previously mentioned, scaling and corrosion are of great concerns for SWHs in remote islands. As shown in Fig. 2a, there is pipe blockage caused by scaling (calcium carbonate analyzed by X-ray diffraction). Figure 2b shows pitting near the weld on a storage tank, made of 304 stainless steel. The maximum diameter of pitting hole was larger than 1 mm. Figure 2c shows absorption tube and pipe welding (304 stainless steel) leaks due to corrosion and subsequent scaling. It is considered that the pitting problem was caused by poor welding, high chloride concentration in the water, and high temperature accelerated corrosion.

Fig. 1: Remote islands location map.

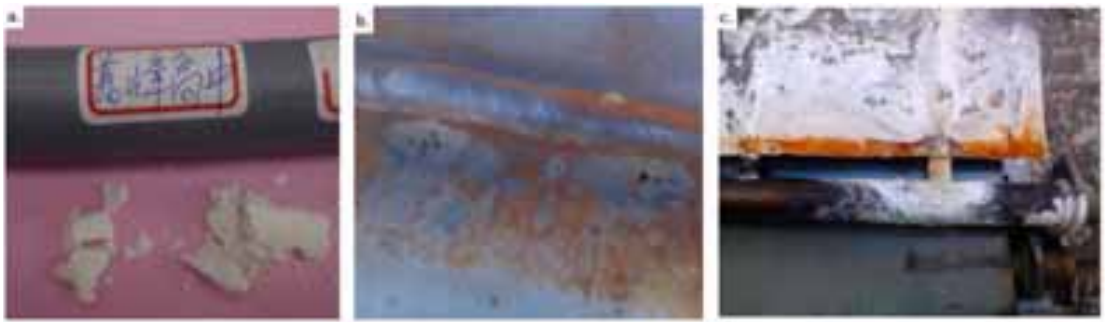

Fig. 2: (a) scaling of the connecting pipe; (b) pitting near the weld on storage tank; and (c) corrosion and scaling on solar collector plate.

In Taiwan, most tubes of collector plate and water storage tanks are made of 304 stainless steel, which is an alloy with higher levels of chromium (Cr) and nickel (Ni). It is known that the corrosion resistance of stainless steel is due to a sufficient amount of chromium to form a thin layer of a passivation film (chromium oxide). When the passive film is damaged by corrosion, uniform or localized corrosion will occur on the surface. According to the study by Parrott and Pitts (2011), when welding stainless steel, the high temperatures in the slow cooling process make the chromium and carbon form chromium carbide near the weld, causing the chromium to deplete. This makes the chromium passivation film easily damaged by corrosion, forming a significant local corrosion. Kopeliovich (2012) showed that electrochemical corrosion (oxidation-reduction reaction) by the chloride ions breaks down the passivation film on a stainless steel surface, and then causing pitting. Thus, presence of chloride ions (Cl^-) accelerates the corrosion rate. Figure 3 shows the concentration limits of 304 and 316 stainless steel at pH = 7 by chloride ions (Huang and Huang 2006). As the temperature reaches 80 ˚C, pitting occurred in 304 stainless steel, when the chloride ion concentration is higher than 35 mg/L. For 316 stainless steel, pitting occurred when the chloride ion concentration is higher than 130 mg/L.

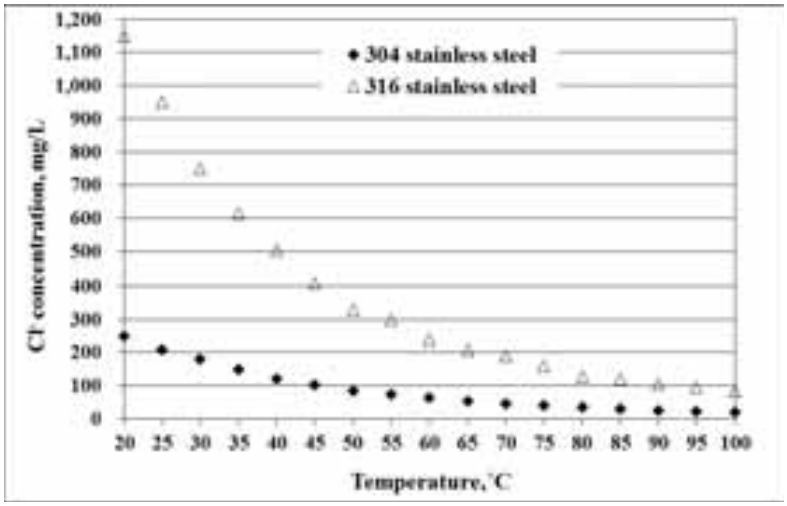

Fig. 3: Concentration limits of stainless steel corroded by chloride ions. (Huang and Huang, 2006).

3. Water quality Index-Assessment Methods

Water quality data for tap-water and groundwater were obtained from households with SWHs installed in 2013 and 2014. LSI, RSI, PSI, and LSCI were employed to assess scaling and corrosion in SWHs. The water qualities were analyzed by the Sustainable Environment Research Center/NCKU. In the remote islands, the temperature of SWHs can reach 70~80 ˚C in summer. Therefore, the designed water temperature was at 80 ˚C in this study.

3.1. LSI Assessment Method

Langelier (1936) first proposed a procedure for calculating the degree of saturation of water with respect to calcium carbonate, known as Langelier Saturation Index (LSI). Prisyazhniuk (2007) pointed out that LSI makes it possible to estimate the ability of water to corrode steel, or the tendency of water to form scaling.

Interpretation of LSI was given by Carrier Air Conditioning Company (U.S.), as shown in Table 1 (Carrier 1965). In the "Handbook of Drinking Water Quality" (DeZuane, 1997), LSI is given as follow.

$$LSI = pH - pH_S \quad (1)$$

where pH is measured in a solution of hydrogen ion activity; pH_S is a saturated sodium carbonate solution of hydrogen ion activity, as shown in Equation 2.

$$pH_S = (9.3+A+B)-(C+D) \quad (2)$$

where:

$A = (\log_{10}(TDS) -1)/10$; TDS: total dissolved solids, mg/L

$B = -13.12 \log_{10} (T + 273) + 34.55$; T : temperature, ˚C.

$C = \log_{10}$ (Hardness) - 0.4; Hardness, mg/L

$D = \log_{10}$ (Alkalinity); Alkalinity concentration, mg/L

Tab. 1: Interpretation of LSI (Carrier 1965)

LSI Value	Indication
2.0	Scale forming but non corrosive
0.5	Slightly scale forming and corrosive
0.0	Balanced but pitting corrosion possible
-0.5	Slightly corrosive but non-scale forming
-2.0	Serious corrosion

3.2. RSI Assessment Method

Ryznar Stability Index (RSI) was proposed by Ryznar (1944). The index is based on the calcium carbonate saturation index in water and can estimate the ability of scaling or corrosion, where $RSI = 2pH_S - pH$. Further, Table 2 shows the interpretation of RSI (Carrier 1965).

Tab. 2: Interpretation of RSI (Carrier 1965)

RSI Value	Indication
4.0 – 5.0	Heavy scale
5.0 – 6.0	Light scale
6.0 – 7.0	Little scale or corrosion
7.0 – 7.5	Corrosion significant
7.5 – 9.0	Heavy corrosion
> 9.0	Corrosion intolerable

3.3 *PSI Assessment Method*

The Puckorius Scaling Index (PSI) was proposed by Puckorius (1983). PSI is a modification of RSI with similar interpretations as shown in Table 2. When estimating the scaling and corrosion tendency of the solution, PSI addressed the buffering capacity in water and the maximum quantity of precipitate that can form when bringing water to equilibrium (Puckorius 1983). Therefore, the equilibrium pH (pH_{eq}) is adopted rather than pH, in which $PSI = 2pH_S - pH_{eq}$, where $pH_{eq} = 1.465 \times \log_{10}(\text{Alkalinity}) + 4.54$. The scaling was more serious with a smaller value of PSI, while a tendency of corrosion is observed for PSI > 6.0. It is also noted that the pH value for PSI is calculated according to the balanced hydrogen-ion activity in a solution, rather than measuring the pH with relevant apparatus. Therefore, the resulting PSI value is considered to be more accurate, comparing to both LSI and RSI values.

3.4 LSCI Assessment Method

The Larson–Skold Index (LSCI) describes the corrosivity of water toward mild steel (Larson and Skold 1958). The index is based on an evaluation of in-situ corrosion of mild steel lines transporting Great Lakes water. The index is the ratio of equivalents parts per million (ppm) of sulfate (SO_4^{2-}) and chloride (Cl^-) to the ppm of alkalinity in the form of bicarbonate plus carbonate ($HCO_3^- + CO_3^{2-}$), as given in Equation 3.

$$LSCI = \frac{C_{Cl^-} + C_{SO_4^{2-}}}{C_{HCO_3^-} + C_{CO_3^{2-}}} \quad (3)$$

where C was the concentration of mg/L (ppm); SO_4^{2-} was sulfate; Cl^- was chloride; HCO_3^- was bicarbonate; and CO_3^{2-} was carbonate.

LSCI does not considered temperature or pH buffering capacity as factors affecting corrosion behavior. However, previous studies indicated that stainless steel, copper, and aluminum can demonstrate pitting corrosion in environments that contain chlorine ions (Gallegos et al. 2005; Liang and Zhang 2006; Ghali 2010; Parrott and Pitts 2011; Kopeliovich 2012). Further, LSCI was interpreted as follows (Prisyazhniuk 2007):

LSCI < 0.8 — chlorides and sulfates did not influence the natural formation of the protective film;
0.8 < LSCI < 1.2 — chlorides and sulfates would hinder the formation of a protective film. A higher, as compared with normal, rate of steel corrosion was observed;
LSCI > 1.2 — as the value of the index grew, an increasingly higher rate of localized corrosion was observed.

4. Results and Discussion

Seneviratne (2007) demonstrated that scale formation and corrosion become more significant, as the temperature of a system increases. In this study, a hypothetical temperature of 80 °C was employed to estimate the indicators for assessing scaling and corrosion. Corrosion of metal components in SWHs is expected to be more significant when LSI value is less than zero, RSI value is greater than 7.0, PSI value is greater than 6.0, and LSCI value is greater than 0.8.

4.1 *Penghu County*

The results for SWHs using tap-water in Penghu County are shown in Table 3. Based on the analyses, the values of LSI, RSI and PSI showed a slight scaling tendency when SWHs using tap-water have, except for Siyu Township with a slight corrosion tendency due to a lower pH value. In addition, The LSCI is the ratio of ppm (mg/L) of SO_4^{2-} and Cl^- to the ppm of alkalinity. For the tap-water from desalination or groundwater re-treatment, it contains higher salts. The values of LSCI values for SWHs using tap-water are greater than 1.2, indicating a serious corrosion problem. Thus, although the values of LSI, RSI and PSI showed tap-water show a slight scaling tendency, a higher value Cl^- will result in corrosion of the passivation film on stainless steel surface. For SWHs using groundwater, the results are shown in Table 4. The values of LSI, RSI and PSI values show a serious scaling tendency for SWHs using groundwater, while the values of LSCI indicate a serious corrosion problem.

Also as shown in Tables 3 and 4, the levels of Cl^- concentration are greater than 127.3 and 203.0 mg/L for tap-water and groundwater, respectively. According to the study by Huang and Huang (2006), when the water temperature of SWHs reaches 80 ˚C and the Cl^- concentration level was higher than 35 mg/L, pitting would occur for SWHs using 304 stainless steel. Thus, the use of tap-water or groundwater for SWHs in Penghu County encounters a high risk of corrosion. Thus, 316 stainless steel or another corrosion-resistant material is required for extension of service period of SWHs.

4.2 *Kinmen County*

For SWHs using tap-water in Kinmen County, the data are shown in Table 5. The values of LSI, RSI, and PSI show a slight to serious corrosion tendency for SWHs using tap-water, corresponding to a lower value in the pH value. The LSCI analysis also indicates a serious corrosion problem ($2.8 \geq LSCI \geq 1.7$), except for the Lieyu Township. Note that tap-water in Lieyu Township is mainly from the rain-water in a reservoir. Therefore, the corrosion problems should be less significant. Further, the results for SWHs using groundwater are listed in Table 6. The values of LSI, RSI, and PSI show a slight to serious corrosion tendency. In addition, the values of LSCI are higher than those of tap water ($9.1 \geq LSCI \geq 1.2$). Higher LSCI value of groundwater in Jinning is due to low alkalinity concentration but not high Cl^- concentration. Except for the Lieyu Township, the levels of Cl^- concentration are 45.2-104.5 and 69.0-167.0 mg/L for tap-water and groundwater, respectively. Although the effect of Cl^- concentration level on corrosion problem for SWHs is less significant those systems installed in Penghu County, better corrosion-resistant materials are also required.

4.3 *Lienchiang County*

The results for SWHs using tap-water in Lienchiang County are listed in Table 7. The values of LSI, RSI and PSI also indicate a slight to serious corrosion tendency, except for Dongju Island, which shows a slight scaling tendency. The values of LSCI range from 1.2 to 24.1. A higher rate of steel corrosion can be expected. For SWHs using groundwater, the data are shown in Table 8. In Beigan and Dongju Islands, the values of LSI, RSI, and PSI show a slight scaling tendency, while there is a slight to heavy corrosion tendency in other townships. From the analysis of LSCI, ranging from 1.4 to 4.1, the rate of steel corrosion for SWHs using groundwater is less significant than that using tap-water. Further, the levels of Cl^- concentration are also shown in Tables 7 and 8. The values are 80.9-162.5 and 121.5-199.7 mg/L for tap-water and groundwater, respectively. Thus, the level of Cl^- concentration is also a critical issue for SWHs installed in Lienchiang County.

5. Conclusions

In Taiwan, long-term groundwater pumping has caused serious seawater intrusion in remote islands. Tap-water from desalination or groundwater re-treatment results in higher Cl^- concentration level. Therefore, water quality is a critical issue to disseminate SWHs. In this study, the samples of tap-water and groundwater in remote islands were collected and analyzed. In Penghu County, the values of LSI, RSI, and PSI for SWHs using tap-water and groundwater showed a slight scaling tendency, but all LSCI values indicated a serious corrosion tendency. In Kinmen and Lienchiang Counties, all index showed a corrosion tendency for both tap-water and groundwater. In addition, the issue of higher Cl^- concentration level in Penghu County should be addressed. Therefore, the commonly 304 stainless steel used should be replaced in order to delay pitting for SWHs and extend its service life.

Abstract

The objective of this research is the development, evaluation and analyzation of a new test method, called “rapid test method”, for fast and inexpensive assessment of concentrating collectors. The rapid test method aims to derive the instantaneous efficiency curve of a parabolic trough collector. Therefore, a new reference parabolic trough collector was designed and installed at a test rig in accordance with ISO 9806. The determination of the instantaneous efficiency curve according to the rapid test method was compared to the efficiency curve based on ISO 9806. The comparison shows that the rapid test method delivers reproducible and reliable values for the characteristic curve of linear concentrating collectors. The obtained results are within the limits of the measurement uncertainty of a characteristic curve based on ISO 9806. Therefore, the method can be regarded as reliable, inexpensive and easy to use alternative to the conventional measuring method.

Keywords: Rapid test method, ISO 9806, instantaneous efficiency curve, concentrating solar collector, parabolic trough collector, process heat, receiver testing

1. Introduction

The project "Development and testing of a novel method for determining the efficiency of concentrating solar thermal collectors" aims to examine, analyze and optimize the novel test method, called “rapid test method”, for small size parabolic trough collectors.

The conventional test method to evaluate the efficiency of solar thermal collectors requires high cost for the testing equipment, material and sensors. In addition, the test method requires a large number of sunny days that comply with the criteria of the standard. With the novel rapid test method the determination of performance data in the development phase of parabolic trough collectors can be conducted in a rapid, smart and inexpensive manner. Compared to the conventional measurement method in accordance to the ISO 9806:2013 standard, the application of the rapid test method can help to accelerate development steps, reduce cost and encourage small and medium-sized enterprises to tap the market segment of concentrating solar thermal collectors.

The theoretical and practical testing of the rapid test procedure is performed on a newly established test rig. Among others the test rig is equipped with a reference parabolic trough collector in order to ensure a high degree of comparability of the measurements.

2. The rapid test method

The rapid test method uses the results of two independent measurements - the stagnation temperature and the heat losses - to calculate the instantaneous efficiency curve of a parabolic trough collector. With the results of these measurements the efficiency curve can be numerically derived. Figure 1 illustrates the sequence of this approach.

The first set of measurements comprises the measurement of the stagnation temperature of a parabolic concentrator and the ambient air temperature at different levels of irradiation. The stagnation temperature is

doi:10.18086/swc.2015.10.21 Available at http://proceedings.ises.org

defined as the temperature where the system is at a steady state and in the thermal equilibrium with the environment. The irradiated energy from the sun on the collector is equal to the thermal losses, resulting in a collector efficiency of zero. The determination of the stagnation curve is carried out without water or oil as a heat transfer medium, but with air. In the absorber tube of the collector to be tested, solely air at atmospheric pressure is used, which highly reduces the complexity of test equipment. The general form of the equation for the stagnation curve is considered as: $f(G_u) = -a\ G_u^2 + b \cdot G_u$ and an example is presented in figure 2.

Secondly, the heat losses of the receiver as a function of the receiver temperature have to be determined. In this measurement a defined heat flow is transferred to the receiver pipe from the inside and the resulting wall temperature is measured. The heat can either be transferred by an electrical heating element or by a heat transfer medium that was heated up by an external heater. The application with an electrical heating element has the advantage that no closed loop for the heat transfer is required. Moreover, the application is regarded as cost effective and accurate. The general form of the equation for the heat loss curve is considered as: $f(\Delta T) = a \cdot \Delta T + b \cdot \Delta T^4$ An example for a typical heat loss curve is given in figure 3.

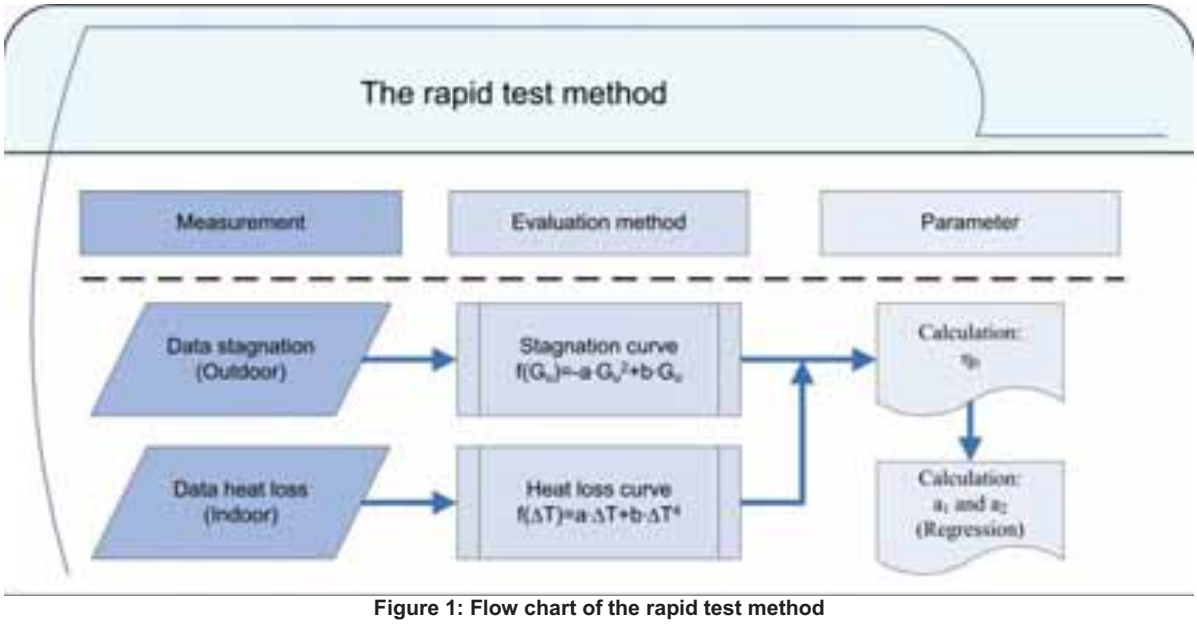

Figure 1: Flow chart of the rapid test method

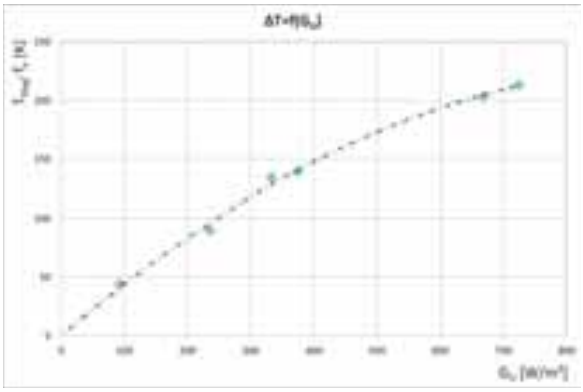

Figure 2: Example for the stagnation curve of a collector at different levels of irradiations

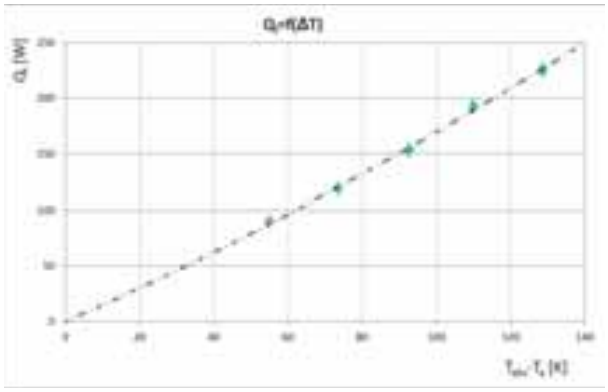

Figure 3: Example of a heat loss curve as a function of ΔT

Table 1: Nomenclature of the used indices and its description

Indices	Description	Unit	Indices	Description	Unit
η_0	Optical efficiency	[-]	G	Hemispherical solar irradiance	[W/m²]
η	Instantaneous efficiency	[-]	G_d	Diffuse solar irradiance	[W/m²]
a_1	Heat transfer coefficient	[W/(m²K)]	G_u	Usable solar irradiance	[W/m²]
a_2	Temperature dependence of the heat transfer coefficient	[W/(m²K²)]	G_b	Direct solar irradiance [DNI]	[W/m²]
ΔT	Temperature difference	[K]	Q_y	Thermal yield	[W]
$T_{fl;m}$	Mean fluid temperature	[°C]	Q_l	Thermal losses	[W]
T_a	Ambient temperature (ventilated)	[°C]	T^*_m	Reduced temperature difference	[(m²K)/W]
$T_{fl;Outlet}$	Collector outlet temperature	[°C]	T_{Stag}	Stagnation temperature	[°C]
$T_{fl;Inlet}$	Collector inlet temperature	[°C]	C	Concentration ratio	[-]
T_{Abs}	Absorber temperature	[°C]	A_p	Aperture area	[m²]
T_{corr}	Correction factor	[K]	F'	Collector efficiency factor	[-]

The way how the efficiency curve is derived from these two curves is explained below. Parameters and indices used are given in table 1.

The basic equation for the instantaneous efficiency curve is:

$$\eta = \eta_0 - \left(a_1 \cdot \frac{\Delta T}{G_u} + a_2 \cdot \frac{\Delta T^2}{G_u} \right) \qquad \text{eq.1}$$

Whereas the usable solar energy is defined as / 4 /:

$$G_u = G - G_d + \left(\frac{1}{C} \cdot G_d \right) \qquad \text{eq.2}$$

By introducing eq. 2 for G_u, the diffuse radiation that strikes the receiver's upper surface is also included in the examination. Up to a concentration ratio of approximately 50, the non-observance produces a non-negligible error. Moreover this approach allows the definition of the exact ratio between diffuse and hemispherical irradiation for different values of irradiance. For the rapid test method the temperature difference between stagnation temperature and ambient temperature is considered as ΔT:

$$\Delta T = T_{Stag} - T_a \qquad \text{eq.3a}$$

Whereas at the ISO based method the temperature difference is stated as:

$$\Delta T = \left(\frac{T_{fl;Outlet} + T_{fl;Intlet}}{2} \right) - T_a \qquad \text{eq.3b}$$

The reduced temperature difference is given by:

$$T^*_m = \frac{\Delta T}{G_u} \qquad \text{eq.3c}$$

To calculation the thermal yield of a collector at a certain irradiation and temperature level the following equation is valid:

$$Q_y = A_p \cdot G_u \cdot \eta \qquad \text{eq.4}$$

Consequently the thermal losses at an optional point can be expressed as:

$$Q_l = A_p \cdot G_u \cdot (\eta_0 - \eta) \qquad \text{eq.5a}$$

Hence, for the optical efficiency of a collector the following equation is valid:

$$\eta_0 = \eta + \frac{Q_l}{A_p \cdot G_u} \qquad \text{eq.5b}$$

For the stagnation temperatures measured during the rapid test method, the thermal losses are equal to the energy input into the system and the instantaneous efficiency is equal to zero. $\eta = 0$

From this consideration results the following formula:

$$\eta_0 = \frac{Q_l}{A_p \cdot G_u} \qquad \text{eq.6}$$

The heat loss at various radiation levels can be calculated using a combination of the stagnation curve and the heat loss curve. First, with the determined stagnation curve the temperature difference ΔT can be calculated for the corresponding irradiation. Second, the obtained temperature difference ΔT can be used in the formula of the heat loss curve to calculate the corresponding values. The numerical solution of the thermal loss at various radiation levels is then given by $Q_l = f(G_u)$. With the results obtained the optical efficiency can be calculated for each point i within the interval of the expected solar radiation G_u (0 W/m² ≤ G_u < 1000 W/m²). Resulting values for the optical efficiency at different radiation levels are presented in figure 4.

$$\eta_{0,i} = \frac{Q_{l,i}}{A_p \cdot G_{u,i}} \qquad \text{eq.7}$$

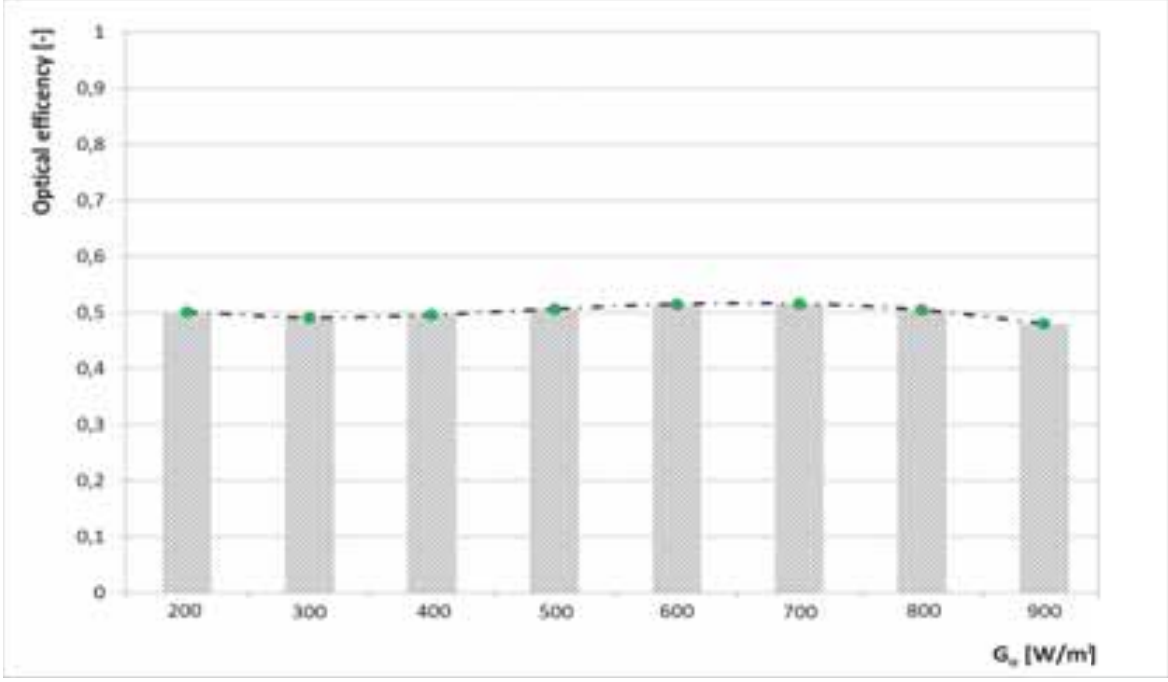

Figure 4: Example for the calculated optical efficiency at different supporting values between the lower and upper limit of the measurements

Uncertainties of measurements occur during the determination of the stagnation curve and the heat loss curve and have an effect on the value of the optical efficiency. The calculated optical efficiency varies slightly for different values of G_u, as shown in figure 4. This variation is based on the combination of two equations,

resulting in a higher-order function with a discontinuity at the saddle point of the equation. The mean value of the function of the results obtained for the optical efficiency will give a good approximation for a value η_0 for the further evaluation of the rapid test method. The limits for the integration will be set between the lowest $G_{u,low}$ and highest $G_{u,high}$ measuring point of the stagnation curve.

$$\eta_{0,mean} = \frac{1}{G_{u,high} - G_{u,low}} \cdot \int_{G_{u,low}}^{G_{u,high}} f(G_u) \cdot dG_u \qquad \text{eq.8}$$

When the optical efficiency is determined, the values for the heat loss coefficient a_1 and a_2 can be derived. The heat loss coefficient a_1 and the temperature-dependent heat transfer coefficient a_2 will be calculated by means of a regression in accordance to the least-square method. Since the instantaneous efficiency is set to zero at the stagnation point eq. 1 can be rewritten as:

$$\eta_{0,i} = \left(a_1 \cdot \frac{\Delta T_{,i}}{G_{u,i}} + a_2 \cdot \frac{\Delta T_{,i}^{\,2}}{G_{u,i}} \right) \qquad \text{eq.9}$$

To transfer the measured results of the rapid test method to real operation, the following three assumptions have to be made:

- A flow of a heat transfer medium through the absorber takes place.
- The operating point is in a steady state at a certain irradiance level and can be standardized to any irradiance level.
- The mean inner absorber tube temperature, which is measured at the rapid test method, is equal to the mean fluid temperature during a test in accordance with the standard. Otherwise a correction factor has to be determined.

$$T_{Abs} = T_{fl,m} + T_{Corr} \qquad \text{eq.10}$$

3. Test setup

At the Solar-Institut Jülich, a test bench infrastructure is operated, which allows to measure individual receiver and small parabolic trough collectors on a biaxial tracking test rig. Measurements of the solar thermal collectors are carried out based on the ISO 9806. The test rig operates with a pressurized water circuit / 1 / at temperatures up to 200 °C and at mass flows up to 200 g/s. The verification of the rapid test method was conducted with a direct comparison to the steady-state measurement method based on ISO 9806:2013. All tests were performed at the same collector with an identical receiver and insulation. The receiver openings shall be sealed to prevent free convection. Furthermore, a suitable number of measurement points in the absorber tube have to be chosen in order to determine a meaningful reference temperature. Figure 5 shows the test rig for the operation of the parabolic trough collector, which is in accordance with ISO 9806:2013. In figure 6 a reference parabolic trough collector is presented. The examined collector can biaxial tracked towards the sun during the tests and the incident angle can be checked and documented automatically by a heliosensor.

4. Results

In July 2014 the first measurements following the rapid test method and the conventional measurements according to ISO 9806 were taken at the SIJ. Both measurements were done at the same collector prototype in order to compare the results of the rapid test method with the ISO based method.

The concentration factor of $C \sim 25$ of the tested collector refers to an absorber tube diameter $\varnothing_a$ of 35 mm. The aperture dimension is 966 mm x 1688 mm. A reflective aluminum sheet was used as reflector. The receiver of this PTC consists of a black chrome coated absorber tube and a glass envelope tube without vacuum insulation. Over the period of the measurement time a reproducible efficiency curve was determined. Efficiency curves were developed with both methods, with the rapid test and the ISO 9806 method. With both curves yearly yield calculation were performed exemplarily for a biaxial tracking collector in Würzburg / Germany using the Energy Output Calculator ScenoCalc / 10 /.The deviation between both results was below 4.0%, based on an operating temperature at 50 °C, 75 °C and 100 °C.

For the rapid test method various criteria were defined, in order to evaluate measurement points during a steady-state phase. First measurements of the collector time constant returned values up to 3 min. This means that the temperature compensation of the receiver and its components requires a comparatively long time until it is in a thermal equilibrium with the environment. In the beginning the criteria as shown below in Table 2 derived from the ISO 9806 were applied. However, this resulted in occasional deviations in the evaluation. The results are distributed over a larger interval of measurement uncertainty. Since the stability of the measured stagnation temperature over time is the most important parameter for the evaluation, a more stringent criterion for the stability of the measured temperature was introduced for further measurements. The tolerable deviation of T_{Stag} was reduced to ± 0,5 °C/min**,** in return 1 min of stable conditions is enough to get one measurement point. An analysis of the available data with the criteria of the approach 2 gave a better approximation of the characteristic curve from the rapid test method towards the characteristic curve in accordance to ISO 9806.

Table 2: Criteria for the evaluation of measurements points according to the rapid test method

Criteria	Limit value approach 1	Limit value approach 2	Comment
T_a	± 0,5 °C of mean value	± 0,5 °C of mean value	Derived from measurements
G	$G_d/G_U \leq 30\%$	$G_U \geq 100$ W/m²	Derived from measurements
T_{Stag} Stability	± 1 °C / min	± 0,5 °C / min	Derived from measurements
time mean values	4 min after stability	1 min after stability	Derived from measurements
Wind *	3 m/s ± 1 m/s	3 m/s ± 1 m/s	On the basis of ISO 9806
G_u	± 50 W/m² of mean value	± 50 W/m² of mean value	On the basis of ISO 9806

*) The dependency of the wind is in accordance with ISO 9806 only relevant, if the receiver is constructed without a glass envelope tube or if a concentration ratio <3 exists.

It is recommended to determine the time constant before applying the rapid test method in order to obtain a statement about the heating behavior and thus to identify associated conditioning times of the receiver.

In figure 7, the characteristic curve based on ISO 9806 and the curve according to the rapid test method are shown. The calculated stagnation temperature of both methods differs by 4.2 °C at G_u = 1000 W/m² and T_a = 20 °C. The determined measurement points based on the ISO procedure are set in a lower range of the reduced temperature difference, since the corresponding measurements currently limited to an outlet temperature of 200 °C. The measuring points of the rapid test method are in the higher range of the reduced temperature difference, due to the obtained stagnation temperature. For additional information the measurement uncertainty at the respective measuring points are entered. The values are calculated by the Guide of Measurement Uncertainty (GUM). The expanded uncertainty is calculated by multiplying the coverage factor k = 2 with the standard uncertainty of the particular measurement method. The measurement uncertainty is traceable to the specifications and the results from the calibration of the used sensors. The calculated measurement uncertainties are given in the table 3 below.

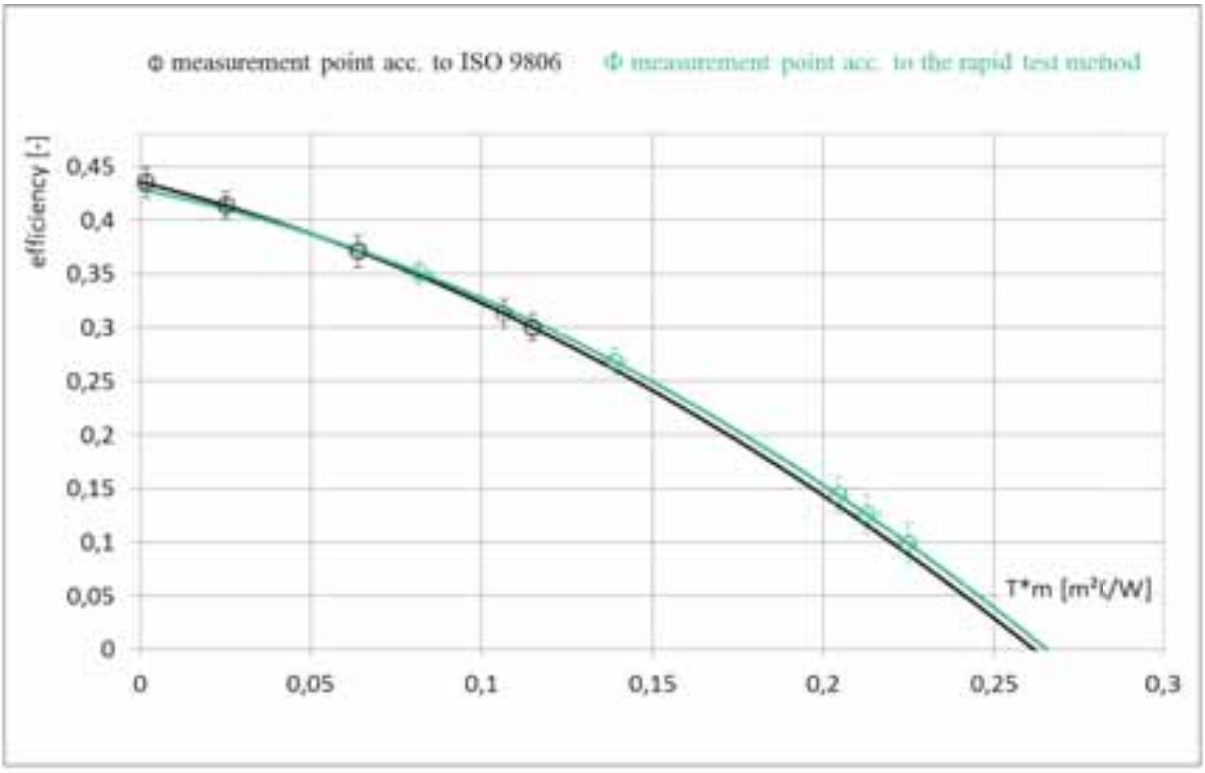

Figure 7: Diagram of the characteristic efficiency curve according to the steady state ISO 9806 method and the rapid test method at G_U of 1000 W/m²

Table 3: Values of the reduced temperature difference, the instantaneous efficiency and the values of the expanded measurement uncertainty displayed as absolute error for the selected operating points

Based on ISO 9806	T^*m [(m²K)/W]	0,00178	0,02506	0,06380	0,10651	0,11490
Absolute error		± 0,0002	± 0,0005	± 0,0014	± 0,0022	± 0,0023
	η [-]	0,435	0,414	0,371	0,313	0,300
		± 0,014	± 0,012	± 0,015	± 0,014	± 0,012
Rapid test method	T^*m [(m²K)/W]	0,08178	0,13884	0,20436	0,21263	0,22477
Absolute error		± 0,0018	± 0,0026	± 0,0037	± 0,0038	± 0,0040
	η [-]	0,351	0,268	0,144	0,126	0,099
		± 0,011	± 0,013	± 0,017	± 0,018	± 0,019

Furthermore, theoretical calculations and simulations are carried out to determine a correction factor for the rapid test method. Those calculations and simulations are necessary because of the physical conditions during the rapid test, which tend to have a higher mean temperature than the standard procedure. At the rapid test method, the mean temperature of the inner absorber tube is taken as a reference (eq.3a) whereas the ISO 9806 method considers the mean water temperature as a reference (eq.3b). By applying formula eq.10 the transformation towards the ISO curve can be conducted. In chapter 5 the determination of the correction factor is described.

5. Limitations of the rapid test method

Due to the different approach of the rapid test method and the test method based on ISO 9806, a different reference temperature for the calculation is taken into account as a basis for determining the instantaneous efficiency curve. In the rapid test method, the mean temperature inside the absorber pipe is measured during stagnation as a parameter and simultaneously treated as the average collector temperature. However, in the measuring method according to ISO 9806 the useful energy obtained from the collector is calculated by using the average fluid temperature. Owing to the differences in approach, the efficiency curve of the rapid test method is theoretically always higher than the method according to ISO 9806. To evaluate this bias theoretical calculations are performed using a receiver model with a given geometry. Further, FEM simulations to determine a correction factor for the rapid test method are carried out with COMSOL Multiphysics® Modeling Software. Moreover measurements to verify the results of the correction factor were conducted. In applying the rapid test method for absorber tubes of concentrating parabolic trough collectors there is only a slight variation of the considered average collector temperature, depending on the operation point and the mass flow rate. For the results given in figure 7 and table 3 the correction factor was determined for a mass flow of ~75 g/s, which is the mean mass flow during the measurements based on ISO 9806. The values for the correction factor at the figure 7 are between 1,5 °C to 6,5 °C, depending on the reduced temperature difference T^*m.

$$T_{Corr} = f(\dot{m}; T^*m) \qquad \text{eq.11}$$

Since the temperature correction factor is depending on the mass flow, the operating temperature, the ambient temperature and the specific receiver geometry, it must be determined for each receiver individually.

However, collector designs with low collector efficiency factor F' lead to a greater difference between the characteristics of the ISO 9806 and the rapid test. Consequently, a non-negligible error without the use of adapted correction factors will occur.

Since stagnation temperatures are measured in accordance to the rapid test method, very high thermal loads are applied on the coating of the receivers. Most absorber coatings available on the market are only stable below temperatures that are typically reached in the stagnation point at high irradiation values. The resulting thermal stress can lead to new order processes in the layers, increase reaction rates and may cause temperature-dependent diffusion processes within the layer /5/. These processes can lead to destruction, partial degradation by blistering or a change in the optical properties of the absorber coating. Table 4 gives an initial, non-exhaustive overview of different absorber coatings, which are available on the market or are currently in the research stage.

Table 4: Overview of absorber coatings and their temperature stability /3/,/5/,/9/ & /11/

) PVD: Physical Vapour Deposition* *) CVD Chemical Vapour Deposition*

Because of this limitation, concentrating collectors are measured during the course of the rapid test method just below the limit of their temperature stability. Measurements of stagnation temperatures takes place at lower irradiation levels in the morning or in the evening. Knowledge of the substrate layer and the functional layer with its technical specifications are thus preconditional for a careful implementation of the rapid test method. For safety reasons the receiver can be instrumented with a temperature sensor and the tracking control unit at the SIJ test rig will drive the parabolic trough out of the focus, if the temperature stability of the absorber is reached.

6. Outlook

The rapid test method delivers reproducible and reliable values for the characteristic curve of linear concentrating collectors. The obtained results are within the limits of the measurement uncertainty of a characteristic curve based on ISO 9806.

Therefore, the method can be regarded as reliable, inexpensive and easy to use alternative to the conventional measuring methods. For the testing season 2015, further comparative measurements are planned at different types of receivers and parabolic trough collectors in order to gather further experience in the implementation of the rapid test method and to check the procedure with different PTC designs.

Moreover the determination of the stagnation curve and the heating curve will be optimized in order to reduce the measurement uncertainties of the methods. Further optimization will be carried out by analyzing different regression approaches to reduce the statistical spread of the calculated optical efficiency.

Abstract

In this work, the optical performance of an asymmetrical small parabolic trough solar concentrator is experimentally characterized by adopting a direct method to define the solar flux map on the focal region. Due to the particular geometry of the optical system, the optimal plane of concentration is 45° tilted with respect to the plane containing the focal line and the vertex line. A water cooled heat flux microsensor installed on a two-axes linear handling system is used to measure the concentrated solar flux along the optimal concentration plane of the present optical system. The collected data are interpolated to obtain the flux distribution and to determine the width of the solar image over the focal line. These results together with the values of the direct normal irradiance collected during the tests and the nominal reflectance of the parabolic mirrors allow the evaluation of the intercept factor for different areas included in the concentration region.

Keywords: *solar flux mapping; heat flux microsensor; optical performance; parabolic trough, intercept factor*

1. Introduction

A parabolic trough solar collector consists of an optical system, named concentrator, that reflects the beam radiation onto a focal region, where a receiver is installed to convert the solar radiation into heat or electric energy. In order to work efficiently throughout the day, the system must be equipped with a tracking system to maintain the sun vector on the plane normal to the aperture area and containing the focal line. The ratio between the aperture area of the concentrator and the receiver area is defined as the geometrical concentration ratio and it qualitatively provides the operating temperature range of a concentrating collector. In ideal optics, parallel rays normally incident on the aperture area of a parabolic trough are concentrated along a focal line. In real applications, there is a concentration region around the focal line, whose width depends on the sunshape and on the total optical error. The sunshape represents the brightness intensity distribution across the finite angular size of the sun disc and the circumsolar aureole. The total optical error includes the shape and specular reflectance errors of the parabolic mirrors, the tracking error and the imperfect positioning and alignment of the receiver.

Experimental measurements and the development of reliable models implemented in Monte Carlo ray tracing tools become pivotal for the design and improvement of concentrating solar collectors. In the case of a parabolic trough collector, periodical monitoring the concentrated solar flux and its distribution is recommended to assess the accuracy of the tracking system, the durability of the mirror reflectance and the stiffness of the structure over time. Furthermore, the geometry and the configuration of the receiver should be designed according to the width of the concentration region and the solar flux distribution in order to optimize the performance. Once the solar map has been measured, given the aperture width of the receiver, one can calculate the intercept factor, that is the fraction of the beam radiation reflected by the mirrors and

doi:10.18086/swc.2015.10.22 Available at http://proceedings.ises.org

reaching the receiver. To ensure acceptable performance of the solar concentrating collector, the intercept factor should be higher than 90%.

The arrangement of the solar cells in a photovoltaic receiver and, if necessary, a secondary optics must be design considering that the non uniformity of the incident flux is expected to cause hot spots, current mismatch and to penalize the efficiency (Baig et al., 2013). On the other hand, in solar thermal collectors, the non uniform distribution of the concentrated solar flux on the external surface of the absorber can lead to perimetral temperature gradients. This is associated to differential thermal expansions that cause thermal stresses, whose effect can be very serious in some working conditions (Khanna et al., 2013, 2014, 2015, Eck et al., 2007). In common practice, a high mass flow rate is pumped in order to achieve a turbulent flow condition inside the tubular absorber- This approach is generally adopted in solar power plants but cannot be applied in small medium temperature concentrating collectors, especially for direct steam generation, where a certain flexibility of operation is required to maximize the working hours per day under stable conditions. The solar flux mapping is of great importance in the design of receiver with enhancement heat transfer.

In general, the measurement of the concentrated solar flux on the focal region can be performed through different techniques that can be classified as direct, indirect and measurement-supported simulation methods.

Direct methods refer to the use of a flux sensor, whose response can be directly associated with the concentrated flux. In order to get a fine spatial resolution of the measured concentrated solar flux, these sensors should have a small aperture and should be either distributed in the focal region or installed in handling systems (Röger et al., 2014). Both the techniques require the interpolation of the experimental data collected in specific points of the concentration region to get the solar flux map. In the former, several sensors are needed to obtain results with low uncertainty, but this entails that the measurement system has a very high investment cost. Furthermore, the spatial resolution may only be modest. In the latter solution, a handling system should be designed according to the geometry of the investigated concentrator; this solution allows to scan quickly the focal region and to collect much more experimental points as compared to the case of stationary and distributed sensors, thus increasing the accuracy of the results. The most common sensors employed in concentrating collectors analysis are radiometers and calorimeters (Ballestrín et al., 2012).

Radiometers deliver an electrical response that may be a voltage coming from a differential temperature sensor such as a thermocouple for the Gardon radiometer or a thermopile for the more recent heat flux microsensors (HFMs) or a current generated by a photodetector. Heat flux microsensors have been used by Ballestrin (2002) to investigate the concentrated solar flux distribution on a central volumetric receiver of a heliostat field at the Plataforma Solar de Almeria. Ferriere and Rivoire (2002) and Parretta et al. (2007) designed and realized two different radiometers arranging a photodetector respectively inside a single integrating sphere and two integrating spheres optically interconnected. Fernández-Reche et al. (2008) presented a comparative test performed in a solar furnace measuring concentrated solar flux using both a Gardon radiometer and a GaAs photovoltaic cell as photodetector. Riffelmann et al. (2006) developed the parabolic trough flux scanner (PARASCAN) to detect the solar flux on the tubular receiver of parabolic trough collectors having an aperture width of 5.76 m. The measurement system consists of two arrays of 96 photodiodes each, placed behind translucent Lambertian targets. The first array is arranged in front of the receiver tube, to detect the beam irradiance reflected by the mirrors towards the concentration region, while the second array is located behind the receiver, to measure the optical losses. The two arrays are fixed on a sliding carriage moved by a remote control. From the integrated values collected by the first and the second array, the intercept factor of the parabolic concentrator can be calculated.

When using a calorimeter mounted in the focal region of a concentrator, the solar flux can be derived from a thermal balance between the radiant power incident on the device aperture and the heat flow rate transmitted to a cooling fluid flowing through the sensor. Pérez-Rábago et al. (2006) and Estrada et al. (2007) employed calorimeters to measure the solar flux in point focus concentrators.

In indirect methods, digital cameras (CMOS cameras or, more often, CCD cameras) equipped with appropriate filters and zoom lenses are used to capture one or more images that can be related to the solar flux distribution after processing. The captured images are in gray-scale map, so they can only give qualitative information. In order to correlate the gray-scale value of each pixel to a physical irradiant flux

value, the system must be calibrated in situ. If accurately implemented and calibrated, indirect methods provide very high spatial resolution , high reliability and short measurement time.

In most cases, the digital cameras register the solar radiation reflected off a target which exhibits a diffuse reflectance very close to ideal Lambertian reflectance (camera-target method). This means that, whatever the angle of observation, the target surface appears equally bright. Ballestrín and Monterreal (2004) evaluated the concentrated solar flux on a central receiver of a heliostat fields by capturing images with a CCD camera on a moving uncooled Lambertian target. This target swings in front of the receiver aperture area and intercepts the reflected solar beam radiation in a measurement plane. Moving the target is necessary in high concentration ratio systems, where the concentrated flux may overheat and damage it. Two water-cooled Gardon radiometers placed very close to the receiver aperture are used to calibrate the CCD camera. Riffelmann et al. (2006) implemented the calibrated CCD camera-target method for flux mapping on the focal region of a parabolic trough concentrating solar collector. The Lambertian target has a notch which allows to enclose the tubular receiver and it can be moved through a telescopic arms along the focal region. On the target, higher and lower concentration areas as well as solar rays missing the absorber tube can be observed. After image processing, an approximate value of the local intercept factor can be calculated.

A new method, that has been applied to few receivers so far (Ho and Khalsa, 2012, Röger et al., 2014), regards the use of a digital camera only, without target, applied to external receivers. It is related to many sources of error that should be carefully taken into account. First, as the assumption of a perfectly diffusing material of the receiver is definitely not exact, its real reflectance should be characterized using a gonioreflectometer. Secondly, the receiver is provided with a selective coating with a high absorbance in the wavelength range of the solar spectrum and has a surface temperature much higher than the ambient air temperature. Hence, a special filter that can cut off thermal radiation emitted by the receiver in the infrared range should be adopted. Finally, the use of different filters during calibration procedure and during tests may entails error due to the difference between the actual attenuation factors and the manufacturers' specifications. Total errors associated to this method can be up to 20% - 40%, mainly because of large uncertainty in receiver reflectance and in filters' attenuation factors.

Lüpfert et al. (2008) presented a second version of PARASCAN to evaluate the flux distribution on the focal region of a parabolic trough with great accuracy. Fiber optics are arranged instead of photodiodes, behind the translucent Lambertian targets of the two parts of the moving measurement system. Each sensor part is composed by 12 segments where 16 optical fibers are mounted at distances of 2.5 mm., giving a very high spatial resolution. The optical fibers transmit the beam radiation concentrated on the focal region to a CCD camera equipped with neutral density filters, out of the hot region. A direct calibration of the system under natural sunlight is possible. From the measured flux maps, intercept factor have been calculated with an experimental uncertainty of ± 1%.

The last class of methods involves the use of ray tracing codes, which have proved to be powerful tools to model many types of solar concentrating collector and to obtain prediction of the solar flux on any surface. Nevertheless, the accuracy of the results depends on the quality of the input parameters: shape, tracking and receiver positioning errors, optical defects, optical properties of the materials and atmospheric conditions. Furthermore, the results should be validated against merely experimental measurements, in which, in this case, a high resolution and an extreme complexity is not required. Schiricke et al. (2009) developed an optical model of a parabolic trough solar concentrator by implementing in a Monte Carlo ray tracing software the photogrammetrically measured geometry of the collector, the nominal optical properties of the materials, the incidence angle of the solar rays on the aperture area, the measured values of direct normal irradiance and assuming a typical clear-sky sunshape. The model has been validated by comparing the simulated intercept factors and the flux map to those measured with an indirect method. It proved to be very accurate and reliable, hence it can be use to study the effect of different combinations of parameters on the collector performance.

In this work, a direct method based on the use of a radiometer mounted on a handling system is used to measure the solar flux map on the concentration region of an asymmetrical parabolic trough concentrator that has been designed for installing receivers with flat absorbers.

2. Experimental apparatus

The small parabolic trough concentrator considered in this work is asymmetrical since the reflective optics extends from the vertex line to the mirror rim (Fig. 1). It has been installed at the Solar Energy Conversion Lab of the Industrial Engineering Department, University of Padova. The present concentrator exhibits an aperture width of 2.9 m, a rim angle of 78°, a focal length of 1.81 m and a trough length of 2.4 m, resulting in an aperture area equal to 6.857 m^2. The reflecting optical system is made up by four back silvered glass facets arranged in two rows, which have a nominal reflectance of 96%, as provided by the manufacturer. Due to the small dimensions of the prototype, it is equipped with a two-axes solar tracking system to have the beam radiation normal to the aperture area without any cosine loss. The motion is governed by a solar algorithm when approaching the sun and by a sun sensor to achieve the best alignment. The particular geometry of the present parabolic trough concentrator is suitable to be coupled with a receiver provided with a flat geometry absorber. As an example, the receiver may be similar to some trapezoidal cavity receivers generally mounted on linear Fresnel solar collectors. In order to minimize the incidence angle of the concentrated beams on a flat receiver, the optimal concentration plane of this system is 45° tilted with respect to the plane containing the focal line and the vertex line.

Fig. 1: Prototype of the asymmetrical parabolic trough linear solar concentrator and solar flux map measuring system installed at the Solar Energy Conversion Lab of the University of Padova.

The solar flux mapping system has been designed so that the measuring plane corresponds to the optimal concentration plane. A water-cooled heat flux microsensor is mounted on a two axes (x, z) semi-automatic linear handling system. The horizontal axis (x-axis) is parallel to the trough length and the second axis (z-axis) lies on the width of the concentration region on the measuring plane. As declared by the manufacturer, heat flux microsensors have a very fast response time of 300 μs when the face is provided with a high absorptance black coating, as usual for radiant flux measurement in concentrating solar collectors. Water cooling of the sensor is necessary for applications requiring a continuous monitoring of the concentrated flux and to reduce the influence of the ambient conditions on the measurement accuracy. In fact, if the average temperature of the cooling fluid (distilled water) passing through the sensor is maintained close to the ambient air temperature, the effect of convective heat losses on the measurement of the concentrated flux can be neglected.

The horizontal x-axis is provided with a sliding carriage that can be fixed at several repeatable position along the trough length by appropriate blocking elements. On the sliding carriage, an electrical linear actuator is mounted and it allows the movement of the sensor along the z-axis to scan the concentration region. the

actuator has a stroke of 150 mm, a variable speed from 0.001 m s^{-1} to 2 m s^{-1} and a maximum positioning repeatability of 0.1 mm. On the top of the actuator, an aluminum structure supports the sensor and allows fine adjustments to make the optimal concentration plane and the measuring plane match (Fig. 2). The handling system has been mounted so that the heat flux microsensor moves on the optimal concentrating plane (Fig. 3).

Fig. 2: Electric linear actuator mounted on the sliding carriage of the x-axis and water-cooled heat flux microsensor arranged on a supporting structure.

Fig. 3: Position of the heat flux microsensor when the electric linear actuator is completely down (position 0).

The laboratory includes a first class pyrheliometer mounted on a high precision solar tracker that is used to measure the direct normal irradiance (DNI). A datalogger registers the electrical signals associated to the position of the actuator, the measured solar flux, the temperature of the heat flux microsensor's face and the direct normal irradiance with a sampling rate of 0.2 s and the collected data are reduced in Matlab® environment.

3. Experimental technique and data reduction

Before every experimental test, the reflecting facets of the parabolic trough concentrator, the sun sensor and the pyrheliometer have been cleaned. The solar flux map has been experimentally characterized on a trough length of 1200 mm along the x-axis, corresponding to a single row of parabolic mirrors. Along the investigated trough length, ten blocking elements have been arranged at a distance of 120 mm. Concentrated solar flux measurements have been performed according to the following procedure. The electrical linear actuator is brought at the first station in its zero position, in which the heat flux microsensor is 65 mm under the ideal focal line of the concentrator. The zero position of the actuator corresponds to the origin of the z-axis. Then, the working cycle of the actuator is started. It consists of a slow rise for collecting the experimental data and a quick descent to return in the zero position before being moved to the next position along the x-axis. At the end of the slow rise phase, the sensor is 65 mm above the ideal focal line, thus the investigated width on the concentration region is of 130 mm, centered on the ideal focal line. During each test, four values are registered by the data acquisition system: the position of the sensor, given by the electrical output signal of the actuator's encoder, the heat flux and the temperature signal from the heat flux microsensor and the direct normal irradiance measured by the pyrheliometer. The series of data collected during a tests are considered for data reduction in a Matlab® environment if the variations of the direct normal irradiance is within the experimental uncertainty of the pyrheliometer (± 2.5 % of the average value, with a level of confidence of 95.45 %). The number of collected data for concentrated solar flux depends on the number of measuring position along the x-axis, the actuator's speed along the z-axis and the sampling rate allowable by the data acquisition system: the higher the number of experimental data the more accurate the

resulting solar flux map. The heat flux microsensor is cooled by a flow of 0.017 kg s^{-1} of distilled water. The temperature of the cooling fluid at the inlet of the sensor is kept constant by dissipating the heat flow rate coming from the concentrated solar radiation to the ground water. Several tests have been conducted consecutively, in order to assess the repeatability of the proposed measuring technique under very similar test conditions.

The face of the sensor is coated with Pyromark 1200, a high temperature paint which has an emittance of 95 % as declared by the calibration report. According to the study by (Song et al., 2014), the total infrared spectral emittance of this coating is higher than 93% in the wavelength range between 3 μm and 14 μm. Therefore, unlike other coatings (Ballestrín et al., 2003), there is no need to introduce corrective dimensionless factors to account for the differences between the solar irradiance spectrum and the irradiance spectrum of the black body employed for the calibration of heat flux microsensors.

The procedure described in the work by Ballestrin (2002) has been adopted to evaluate the optical performance of the present asymmetrical concentrator. In order to define accurately the solar flux map and to calculate the incident power on an area of the concentration region, an interpolation of the experimental data has been performed. The interpolant should be able to predict well local trends, therefore the spline interpolants have been considered. Differently from the study by Ballestrin (2002), where an aiming strategy of 25 heliostats was set up to obtain a uniform flux distribution on the central receiver, in the present parabolic trough concentrator, a strongly non uniform flux distribution is expected. As a consequence, the spatial resolution to interpolate should be quite small to get a more accurate estimation of the incident power on an area of interest included in the focal region. In fact, the incident power is calculated by a numerical integration of the solar flux distribution, dividing the area of interest into *n* equal rectangular elements and using the tiled method, according to eq.1:

$$P_{inc} = \frac{A_{cr}}{n} \sum_{i=1}^{n} q_i'' \qquad \text{(eq. 1)}$$

where *n* is the number of data in the area of interest, A_{rc} is the surface of the area of interest and $q"_i$ is the i-th value of solar flux. Unfortunately, the spline interpolants do not allow the estimation of the uncertainty on predicted concentrated solar flux values. Therefore, in order to assess if the number of collected data is sufficient for a good definition of the solar flux map, different interpolants (linear, cubic and biharmonic) have been considered and the results of the numerical integration have been compared. If the obtained value of the power incident on an area of the concentration region does not change significantly when varying the interpolant, the accuracy in the solar flux map definition can be considered satisfactory. Once the incident power onto an area of interest has been calculated, the associated intercept factor γ can be determined as follows (eq. 2):

$$\gamma = \frac{P_{inc}}{\mathrm{DNI}\, A_{ap}\, \rho_{mir}} \qquad \text{(eq. 2)}$$

where DNI is the average value of the direct normal irradiance during the considered test run, A_{ap} is the aperture area of the row of mirrors and ρ_{mir} is the nominal reflectance of the mirrors, provided by the manufacturer.

The experimental uncertainty of the calculated power P_{inc} is derived from the combination of the integration uncertainty, the interpolation uncertainty and the uncertainties related to the handling system positioning and movement. The interpolation uncertainty has been computed as in the work by Ballestrin (2002). The interpolation uncertainty can be neglected because the chosen interpolant shall not affect the results. Furthermore, the geometry of the present asymmetrical parabolic trough concentrator allows to check that the measuring plane matches the optimal concentration plane. Finally, the uncertainty of the intercept factor has been calculated applying the law of propagation of uncertainty for uncorrelated inputs (Joint Committee

for Guides in Metrology, 2008) and neglecting the uncertainty of the nominal reflectance of the parabolic mirrors.

4. Results and discussion

Experimental measurements of the solar flux distribution on the concentration region of the asymmetrical parabolic trough concentrator have been performed consecutively during a clear sky day. The dimensions of the measuring area, which is the area scanned by the heat flux microsensor, are given by the actual stroke of the electrical linear actuator along the z-axis (130 ± 1 mm) and by the distance between the first and the last of the blocking elements along the x-axis (1082 ± 1 mm). During the presented test runs, the direct normal irradiance was around 890 W m^{-2} and the ambient air temperature was around 23°C. The water cooling of the microsensors allow to keep the temperature of its face between 19°C and 23°C during each scan of the concentration region. The speed of the electric linear actuator was set equal to 0.005 m s^{-1} in the rise phase and equal to 0.1 m s^{-1} in the descent phase. Measured data were sampled with a scan interval of 0.2 s. The resulting spatial resolution along the width of the concentration region is 1 mm and 1300 concentrated solar flux data were collected during each test. The spline interpolation has been executed over a grid with a spatial resolution of 1 mm x 1 mm, giving a set of 141873 data on the whole measuring area. A finer spacing does not entail significant variations in the calculation of the incident power on an area included in the measuring area, whatever its width.

Fig. 4 reports the 3D solar flux distribution obtained after interpolating the experimental data (blue dots) collected in a single test run through the biharmonic spline method. The origin of the z-axis corresponds to the zero position of the encoder integrated in the electrical linear actuator, while the origin of the x-axis corresponds to the projection of the external rim of the mirrors on the ideal focal line. The equation of the ideal focal line is z = 65 mm. For the sake of clarity, the solar map has been presented with a spatial resolution lower than that adopted for the calculation of the concentrated power on an area of interest included in the measuring area.

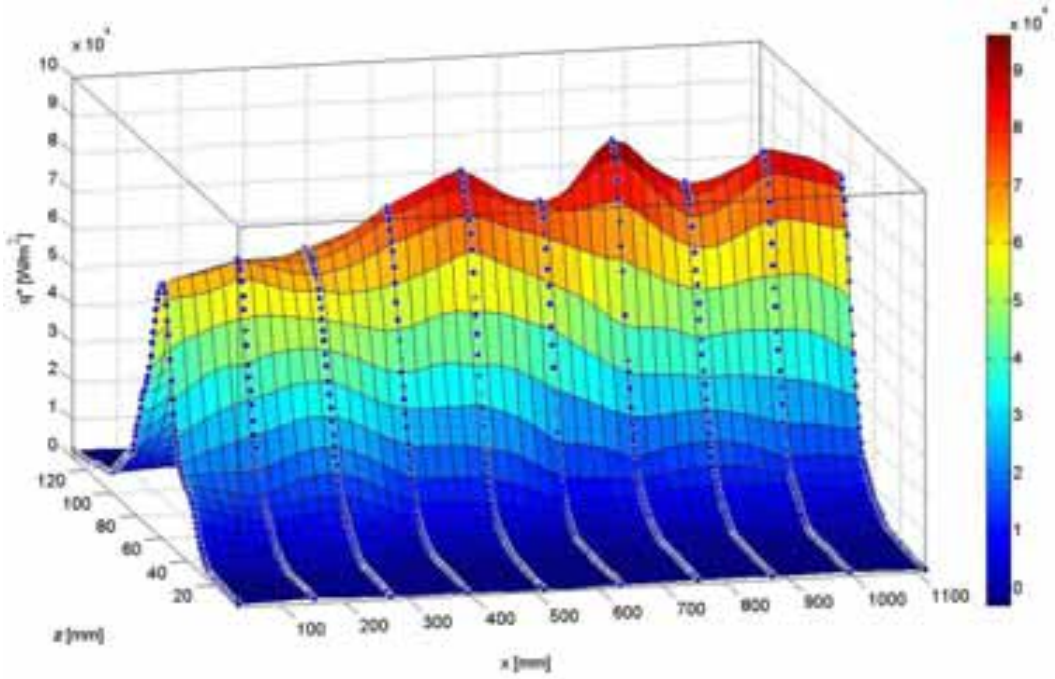

Fig. 4: Three-dimensional solar map on the measuring area defined during the experimental study of the optical performance of the asymmetrical parabolic trough installed at the University of Padova. The reported surface has been obtained after interpolating the experimental data through the biharmonic spline method.

As expected, the solar flux distribution is strongly non uniform along the width of the concentration region (z-axis). Nevertheless, there are significant variations of the solar flux even along the x-axis: the external rim of the mirrors in the considered row appears to be less efficient in concentrating the solar beam. In fact,

differently from the rest of the measuring area, the solar flux is below 80 kW m^{-2} on the first 300 mm of the investigated trough length. The maximum peak value of the measured concentrated solar flux is 96250 W m^{-2} at x = 750 mm, while the minimum peak value of 66900 W m^{-2} has been detected at the very beginning of the trough length (x = 33 mm). The isoflux contour plot related to the same test run is reported in Fig. 5: one can notice that the maximum width of the concentration region is of 100 mm and it centered on the focal line. On the central part of the mirrors composing the investigated row, the concentration of the solar beams is performed on a tighter width. According to the previous considerations, the calculation of the concentrated power and the determination of the intercept factor has been performed considering a trough length equal to the measuring area length (1082 mm) and two different widths: 100 mm and 70 mm.

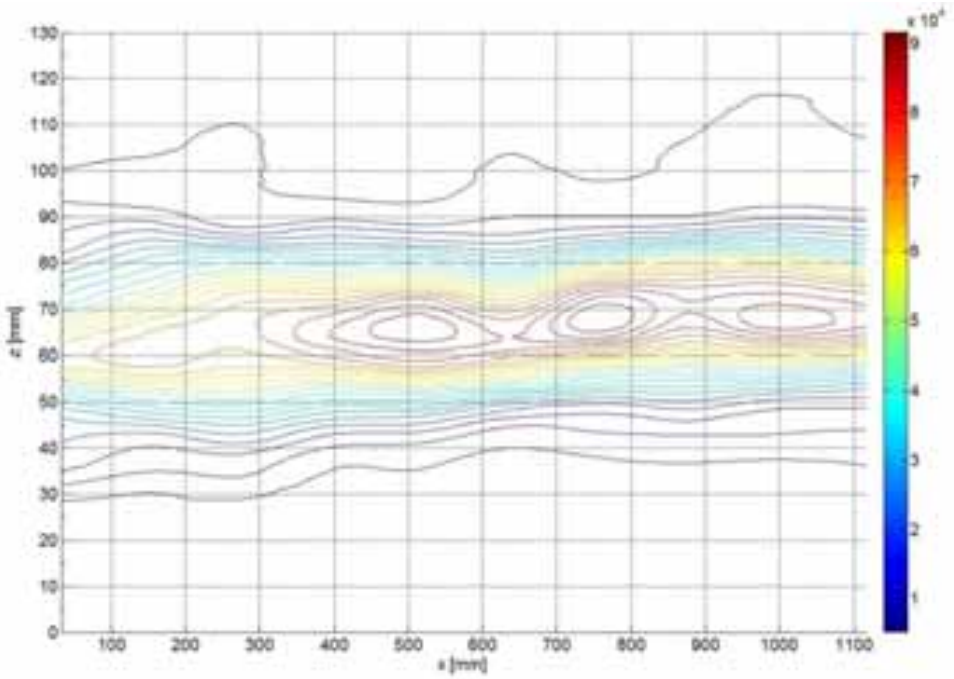

Fig. 5: Concentrated solar isoflux contour plot on the measuring area defined during the experimental study of the optical performance of the asymmetrical parabolic trough installed at the University of Padova.

Considering the solar flux map on the measuring area of Fig. 4, which has been obtained under a direct normal irradiance of 887 W m^{-2}, the concentrated power incident on an area of interest having a width of 100 mm is equal to 2705 W, while it results equal to 2604 W when the width is 70 mm. The variation of the concentrated power values is within ± 0.2 % when different spline interpolants are employed, which demonstrates that the number of experimental data collected during a single test run is high enough to get an accurate definition of the concentrated solar flux distribution on the measuring area. The experimental uncertainty of the concentrated power is between 4% and 5 % and it slightly increases when the width of the area of interest decreases. Considering these results and the nominal reflectance of the mirrors, the intercept factor is of 100% for a 100 mm width, which is consistent with the contour plot of Fig. 5, and it is of 97 % for a width of 70 mm. The shapes of the 3D surface resulting from the different test runs as well as the concentrated powers and the intercept factors on an area of interest do not vary significantly. This proves the repeatability and the reliability of the proposed experimental technique.

5. Conclusions

The solar flux map on the focal region of a prototype of an asymmetrical parabolic trough concentrator has been experimentally determined at the Solar Energy Conversion Laboratory, at the University of Padova. The solar mapping system is composed by a two-axes semi-automatic linear handling system and by a heat flux microsensor. The actual measuring area is 1082 mm x 130 mm, thus it includes a single row of mirrors of the present concentrator. During a single test run, data of the sensor position, concentrated solar flux, temperature of the sensor face and direct normal irradiance are acquired at scan interval with 0.2 s. To define

the solar flux map, the collected data have been interpolated by a spline interpolant over a grid with a spatial resolution of 1 mm x 1 mm. The obtained 3D surface for the concentrated solar flux distribution has been numerically integrated to calculate the concentrated power as a function of the width taken in the measuring area. Considering the nominal reflectance of the mirrors and the measured values of the direct normal irradiance, the intercept factor can be calculated for a certain area included in the concentration region.

According to the results, the solar flux distribution is strongly non uniform along the width of the concentration region and there are significant variations of the concentrated solar flux even along the trough length. In particular, the external part of the mirrors provide lower peak flux values near the focal line. The maximum width of the concentration region is 100 mm, whose corresponds a intercept factor of 100%. When considering a width of 70 mm, the intercept factors decreases to 97 %. The calculated value of the intercept factor varies within ± 0.2 % when different spline interpolants are considered and this entails that the number of collected data is high enough to get an accurate definition of the solar flux map. Several tests have been performed consecutively under the same test conditions and the variation of the results is negligible, proving the reliability and the repeatability of the proposed technique.

THE SEPARATED HEAT PIPE SOLAR HEATING SYSTEM

Shi liang yan [1], Niu Baolian[1] and Yu Yingying[1]

[1] School of energy and mechanical engineering, Nanjing Normal University, Nanjing(China)

Abstract

It is established a separated heat pipe solar indoor heating system .The system is divided into three parts: solar collector, separated heat pipe and indoor heating terminal. The system uses separated heat pipe as heat transfer component. It transfers solar energy from solar collector into the indoor heating terminals. So by the separated heat pipe the system will heat the indoor air with solar energy. The related experiments were carried out. The results showed that the solar thermal utilization efficiency can reach 56% when the solar radiation is at 725W/ ㎡, the evaporation and condensation temperature of heat pipe kept constant at 44.8 ℃ and 40.2℃ respectively. When the system started to run, it took three or more hours to make the indoor air temperature reach 22℃-24℃ at sunny or cloudy days. By the experimental data, it is proved that the system is a promising and feasible heating mode in the spacing heating.

Keywords: Separated heat pipe; Solar energy; Indoor air heating

1. Introduction

Solar energy is one of the renewable energy resources that hold a great potential for developed and developing countries in the future. Solar energy resources are very rich in China. Nowadays, it is being widely used for both heating and electricity generation, and has no restrictions as to the uneven distribution and the shortage of conventional resources. With the development of solar heating, the traditional heating mode has some disadvantages such as complex structure and low efficiency. It can’t keep up with the development of housing construction.

Heat pipe has been used in plenty of solar hot water system for its special thermal performance and even in the space heating system. Susheela and Sharp (2001) designed and tested a heat pipe system that could be installed on existing homes without demolishing the wall of the building. The absorber portion was mounted on the outside of a south-facing wall, with water contained in tanks as the thermal mass on the inside of the wall. Experiments were performed outdoors, and system efficiencies (defined as the ratio of power delivered to the room over incident insolation) reached as high as 60% during sunny days. Computer simulations were also performed to model the performance of the unit. Primarily based on design improvements recommended by Susheela and Sharp, Albanese et al. (2012) tested a bench-scale experimental model. Experimental variations included fluid fill levels, addition of insulation on the adiabatic section of the heat pipe, and fins on the outside of the condenser section. Filling the heat pipe to 120% of the volume of the evaporator section and insulating the adiabatic section achieved a system efficiency of 85%. Addition of fins on the condenser of the heat pipe did not significantly enhance overall performance. The heat pipe system provided substantial gains in performance relative to conventional direct and indirect gain passive solar systems and, thus,

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.10.23 Available at http://proceedings.ises.org

presents a promising alternative for reducing building energy use. To better understand system performance in realistic weather conditions, in particular, the relatively cloudy and cool conditions, Robinson et al. (2013) designed, built and installed a full-scale prototype of the heat pipe system in a classroom on the University of Louisville campus in Louisville, KY. During the spring heating season of 2010 (January–April), maximum daily peak thermal efficiency was 83.7% and average daily peak thermal efficiency was 61.4%. The maximum hourly average room gain achieved during the season was 163 W/m2. On days with good solar insolation, the thermal storage was heated to temperatures sufficient to provide significant energy to the classroom – even during the coldest days of the season. During the longest period (4 days) of low insolation during the season, average hourly heat delivery to the room from storage remained positive, and was never less than 16.6 W/m2.

In these system heat pipe had shown its great heat transfer ability. In order to develop much more heat pipe solar heating system, the separated heat pipe would be introduced into the solar space heating system in this paper. Separated heat pipe solar heating system is a promising technology which has simple structure and high efficiency. It can be divided into three parts: solar collector, separated heat pipe and heating terminal. Separated heat pipe can transfer solar energy from outside to inside of the room. Solar collectors receive energy and transfer heat to the heat pipe, and heat pipe delivers heat to the indoor heating terminals. There is no other transfer medium in the system. Compared with the traditional solar heating system, it has not second heat transfer with water and reduce irreversible loss at the process of heat transfer. As separated heat pipe can extend the length of the pipe, the system has some flexible when it is designed and mounted.

Especially in rural areas and cold in northern China, the distance between buildings is far and the rainy season is short. The surrounding residential buildings have no space restricted and can get sufficient sunlight. It can provide basis for residential heating temperature and reduce fuel consumption. So separated heat pipe solar heating system has broad application prospects in these districts. In this paper, some theory analysis and experiments about the new system were carried out and the performance of the separated heat pipe solar heating system was analyzed.

2. Experimental study

2.1. System introduction

Separated heat pipe solar heating system is composed of solar collector, separated heat pipe and heating terminal as Fig. 1 shows. The evaporation section is placed in the solar collectors. When it is received the solar energy, the working fluid in the evaporator will absorb the heat and evaporate to gas, and then enters into the condensation section. The working fluid in the condensing section sends heat to the indoor air and turns into liquid, finally it returns back into the evaporator by gravity. Then the new cycle will carry on and then the solar energy was transferred from outside to inside.

In the test of separated heat pipe solar heating system, it used separated heat pipe as heat transferring component, this system is mainly composed of solar collector, the separated heat pipe evaporation section 1, the separated type heat pipe condensing section 2, the adjustment of valve 3. The solar collector is basically the same as the ordinary plate type solar collector, which mainly consisted of the solar collector, heat insulation material the separated heat pipe evaporation section, heat absorbing layer and the transparent glass cover. The evaporator section was placed in the flat panel solar collectors with 2m x 1m.The separated heat

pipe condenser is composed of copper aluminum fin tube. The condensation section of the separated heat pipe is placed in the room as the indoor terminals providing heat into the room with 0.952 ㎡. Valve 3 is designed to close the circulation channel when the system doesn't work in summer. To avoid affect the indoor lighting, the solar collector is placed on the outside wall with inclined or vertically installation. The working fluid of the separated heat pipe is R600a which is the environmental friendly. The limit on the system installation is that the height of the evaporator must be lower than that of the indoor condenser to ensure the working fluid can flow back to the evaporator. The heating room is in the fourth floor of the office building with the area 40m^2.

Compared with the traditional solar heating system, the separated heat pipe solar indoor heating system works with gravity separated heat pipe to transfer solar energy into the room without any energy consumption. It belongs to distributed system like air-conditioner installed outside wall in every room. So it is easy installation and has no effect on daylight.

2.2. Test method

The experimental apparatus was set up in the campus of Nanjing Normal University, China. Twenty J-type thermocouples were placed in the evaporator and condenser respectively, to assess temperature difference between of them at the same time. Another two J-type thermocouples were placed in the inside and outside of the room to monitor the indoor air and outside air temperature. One Hukseflux LP02 solar pyranometers was used to measure insolation values with the sensitivity is 12.13μV/(w•m^{-2}). All data was collected using Agilent 34972 a.

3. Results and discussion

3.1. *Effect of solar radiation intensity on the surface temperature of indoor heating terminal and indoor air temperature at different weather conditions*

The experimental system was tested under different weather conditions including sunny and cloudy days, in the winter of 2014, in China. We counted the experimental data and chose the cloudy and sunny day as sample to analyze the performance of the system. It is the experimental data of solar radiation and surface temperature of heating terminal in the cloudy days as fig.(a) shown. When the solar radiation intensity exceeds 190W/m2 in the morning, the system starts to run. After four hours, solar radiation intensity reaches about 462W / ㎡ at noon and the system reaches stable conditions, the surface temperature of the condenser (indoor heating terminal) almost remains 29℃; the sunny day's experimental data is shown in fig.(b). When the solar radiation intensity exceeds 150W/m2 in the morning, the system starts to run. After three hours, solar radiation intensity reaches about 800W / ㎡ and the system is in the stable conditions, the surface temperature of the condenser almost remains 41℃, which is much higher than that of cloudy days. The indoor air temperature is shown in fig.(c) and fig.(d) respectively. It takes three or more hours to make the indoor air temperature reach 22--24℃ at sunny or cloudy days after the system starts to work respectively. And there is 5℃ and 9℃ temperature difference in the cloudy and sunny days respectively. So the solar radiation has great effect on the indoor air temperature. In the sunny days, according to six hours sunlight, the room temperature rising will attain 18℃, which will meet the demand of thermal comfortable temperature even the starting indoor temperature is 0℃. The better the thermal insulation of the room is, the higher the heating performance of the system is. Even in the cloudy days, the system has good thermal performance at the maximum solar radiation 462W / ㎡ and the room temperature rising 5℃ in four hours. It will be good auxiliary heating style to the electricity heating in the room, which will save much energy consumption in the south of china where is no centralized heating.

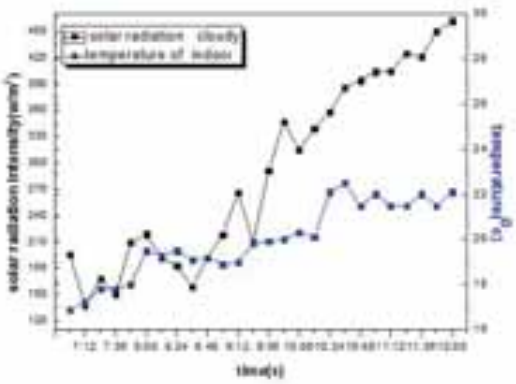
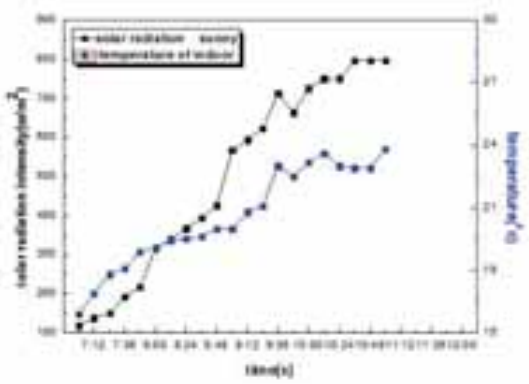
(b) Solar radiation intensity and the surface temperature of indoor heating terminal with time (sunny)

•

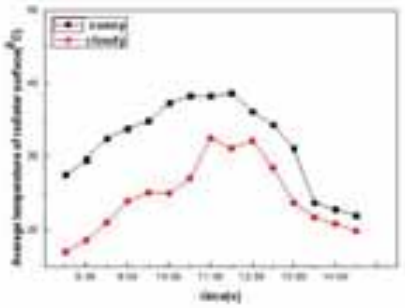


(c) Solar radiation intensity and the room temperature with time

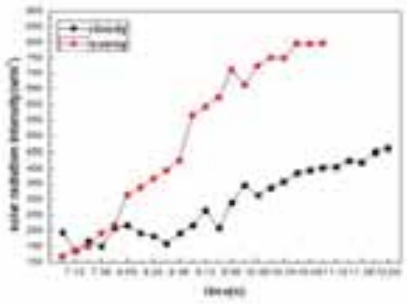


(d) Solar radiation intensity and the room temperature with time

Fig.(e) and (f) shows that solar radiation and climatic conditions have a great impact on the utilization of system thermal. It can be seen that there is 10℃ temperature difference from 8:00 to 11:00 with the large solar radiation difference. The main reason is that the amount of the working fluid at different weather days. In the sunny days, more working fluid absorbs solar energy and starts to work and transfers more heat energy to the condenser. On the other way, less working fluid transfer heat energy to the condenser and cause to the less working pressure and low working temperature in the cloudy days.

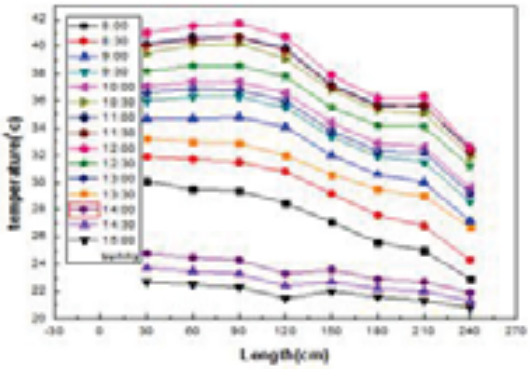


(e) Radiator surface average temperature variation at different solar radiation

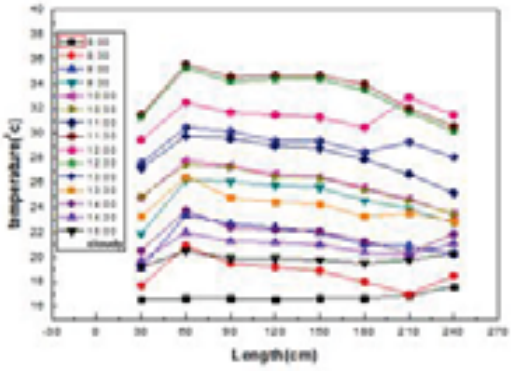


(f) Solar radiation variation at different weather condition

3.2. The profile of the radiator surface temperature at different length



(g) The radiator surface temperature distribution at different length (sunny)



(h) The radiator surface temperature distribution at different length (cloudy)

Fig.(g).(h) shows that the radiator surface temperature distribution at different the length. 0cm represents the terminal of the radiator the nearest distance to the solar collector. And the 240cm is the length of the radiator and also the longest distance to the solar collector. In the sunny days, the surface temperature of the radiator changes from 27.5 to 41.7℃ at 8:00~12:00, and the temperature changes from 41.7 to 20.8℃ at 12.30~15:00. In the cloudy days, the surface temperature of the radiator changes from16.6 to 34.7℃ at 8:00~12:00, and the temperature changes from 34.7 to 20.2℃at 12.30~15:00. The main reason that causes the surface temperature variation is the change of the solar radiation intensity. At the same time, the surface temperature of the radiator decreases with the increase of the radiator length. This director cause is the flow resistance. The more the length of the radiator is, the more the flow resistance of the working fluid is. Then the surface temperature is the lowest at 240cm with different solar radiation.

Tab. 1: Table of heat transfer performance at different weather conditions

Weather	Solar thermal efficiency	Evaporating temperature (℃)	Condensing temperature (℃)	Solar radiation intensity (w/m^2)	Heat flow (w)
cloudy	46.5%	30.2	25.2	358	333
sunny	56%	44.8	40.2	725	820
sunny	54%	40.1	36	672	727

The table 1 shows that the solar thermal utilization efficiency can reach 56% when the solar radiation is at 725W/ ㎡ and heat flow is at 820W, and the evaporation and condensation temperature of heat pipe keep constant at 44.8 ℃ and 40.2℃ respectively. The evaporator and condenser surface temperature difference can keep 4~5℃。

4. Conclusion

This work focuses on the testing of the performance of separated heat pipe solar indoor heating system and gets the following conclusions:

(1) Compared with the traditional solar heating system, the separated heat pipe solar indoor heating system works with gravity separated heat pipe to transfer solar energy into the room without any energy consumption. With the experimental investigation, it takes three or more hours to make the indoor air temperature reach 22--24℃ at sunny or cloudy days after the system starts to work. And there is 5℃ and 9℃ temperature difference in the cloudy and sunny days respectively in four hours.

(2) The solar thermal utilization efficiency can reach 56% when the solar radiation is at 725W/ ㎡ and heat flow is at 820W, and the evaporation and condensation temperature of heat pipe keep constant at 44.8 ℃ and 40.2℃ respectively

(3) The room temperature rising can attain 9℃ in three hours in the sunny days at the solar collector only 2m2 and the room area 40m2 in Nanjing , China.

Abstract

Well-designed liquid heating Flat Plate Collectors (FPC) or Evacuated Tube Collectors (ETC) could be used to provide heat at medium temperature levels for industrial processes. According to the most recent ISO 9806:2013 testing standard, the efficiency curve of a collector is constructed by a weighted least square fitting (WLS) based on at least four observations at temperatures spaced over the operating temperature range of the collector. This could lead to poor efficiency predictions at higher operating temperatures, since in this region the fit is not backed up by experimental data. To improve results in the extrapolated area without any additional experimental effort an extended observation fitting could be used, including the collector's stagnation temperature as an additional node point.

Two databases have been evaluated. One database was provided by the National Renewable Energy Centre in Spain (CENER), the other one by the Institute for Solar Technologies (SPF) in Switzerland. It has been shown that in the case of conventional FPCs the extrapolated stagnation temperature from the conventional 8-point fitting constantly underestimates the measured stagnation temperature. In the case of ETCs, on the other hand, the conventional approach leads to an overestimation.

Keywords: *IAM, Factorization, Collector testing, Medium temperature collectors, Industrial heat*

1. Introduction

The industry sector with its high and constant energy demand shows a remarkable potential for the integration of solar thermal technologies. However, beside this potential, current industrial processes still rely on conventional energy supply. Even though, in most cases, the exploitation of available solar resources is economically feasible and profitable, the unreliability and unpredictability often associated with solar energy restrict the companies from investing in new supplementary facilities. Nevertheless solar heat for industrial processes is on the rise.

The IEA task 49 created a database of operating plants to track the development of this sector. Apart from the numerous undocumented examples, the database currently counts 155 commissioned solar plants with a total capacity around 100 MW and 143,000 m^2 in size (Task 49, 2015). Projects are reported all over the world, increasing every year. Most of these plants rely on conventional flat plate and evacuated tube technology at moderate temperature levels below 100 ºC.

The temperature requirements of most industrial processes range from 60 to 260 ºC (Kalogirou, 2003). A significant share of such medium temperature processes could in theory be provided by well-insulated flat plate collectors (FPC) and evacuated vacuum tube collectors (ETC), that so far have mostly been deployed for domestic applications. Both collector types withstand operating conditions far beyond atmospheric pressure and are therefore capable of providing process heat at temperature levels above 100 ºC. Stagnation

doi:10.18086/swc.2015.10.24 Available at http://proceedings.ises.org

temperatures of conventional FPCs are around 200 ºC; those of ETC can reach even higher values, depending on the design (SPF, 2015).

According to the ISO 9806:2013 standard, the efficiency curve of the collector is based on observations at temperature levels evenly spaced over the operating temperature range of the collector. This operating range is usually below 100 ºC when operating at non-pressurized conditions. As a consequence, this approach could lead to an extrapolated area of the efficiency curve which shows larger uncertainties (see Fig. 1~~Fig. 1~~).

Con form
de fuente:

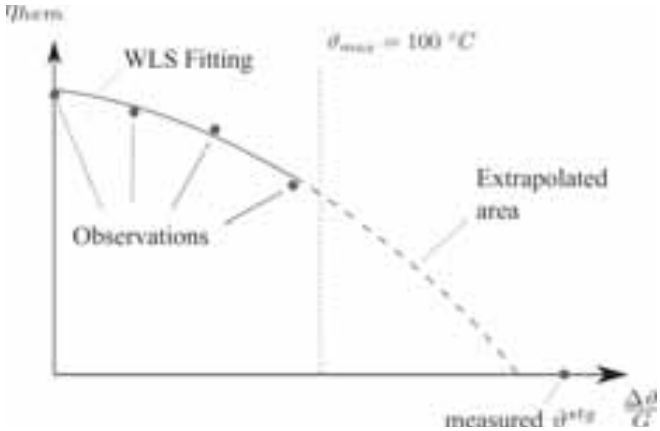

Fig. 1: Standard test procedure: At least four different experimental observations are needed to obtain the collector parameters from a WLS fitting.

One possibility to improve the accuracy of the high temperature part of a collector's efficiency curve could be to include the stagnation temperature in the fitting. The determination of the stagnation temperature forms also part of the standardized test procedure. This way, the methodology could allow improving results without any additional experimental effort.

This is meant to be a preliminary study. The feasibility of this study has been assessed by comparing both the extrapolated (not taking into account the stagnation temperature) and interpolated (taking into account the stagnation temperature) efficiency curve. To do so, three different datasets of FPCs and ETCs from two different databases have been considered. One FPC database was provided by CENER (CENER, 2015), the other two datasets consisting of FPC and ETC collectors were taken from the publicly available database of the Institute for Solar Technology (SPF, 2015). In a second step, the extrapolated stagnation temperature has been compared with the experimentally measured stagnation temperature.

Interestingly results showed a technology specific trend. It could be observed that the difference between measured and extrapolated stagnation temperature is constantly positive in the case of FPC collectors and constantly negative in the case of ETC collectors. To judge the accuracy of the new interpolated efficiency curve, experimental data is essential, which at this point is not available.

2. Collector model and standard testing regulations

In this section the collector model, the collector efficiency curve and the stagnation temperature assessment procedure are described the same way as they are defined in the standard.

2.1. Collector Efficiency Curve

The ISO 9806:2013 (ISO, 2013) is the international and currently most recent version of solar collector testing standard that includes most parts of the former European (CEN, 2006) and American standard (ANSI/ASHRAE, 2003). According to the ISO 9806:2013 standard, the performance of a collector can be characterized by its efficiency curve derived either under steady state or quasi-dynamic conditions. In the case of non-concentrating collectors that are not sensible to direct solar irradiation only, it is common practice to apply the steady state approach according to Eq. (1) (ISO, 2013).

$$\eta_{hem} = \eta_{0,hem} - a_1 \frac{\Delta\vartheta}{G} - a_2 G \left(\frac{\Delta\vartheta}{G}\right)^2 \quad (1)$$

with $\Delta\vartheta$ the temperature difference $\vartheta_m - \vartheta_a$. Where ϑ_m is the mean temperature of the heat transfer fluid (HTF) and ϑ_a is the ambient temperature. $\Delta\vartheta/G$ and $\Delta\vartheta^2/G$ are the explanatory variables of the collector efficiency curve, with G as the hemispherical solar irradiance.

Now, to characterize the collector's efficiency behavior, η_{hem} needs to be measured at least four times, each time at a different quantity $\Delta\vartheta/G$. An analytical expression according to equation (1) is then obtained by determining the characteristic constants $\eta_{0,hem}$, a_1 and a_2 applying a weighted least square fitting (WLS).

The ratio $\Delta\vartheta/G$ for different observations during the test is usually kept small to guarantee accurate fit in temperature regions the collector will most likely be operating on. This means, however, that for collectors that would possibly operate on higher $\Delta\vartheta/G$ -ratios, the fitted efficiency curve is not backed up by experimental data. Output predictions at this region could therefore be inaccurate.

Eq. (1)~~(1)~~ can be restructured to an energy output per collector area equation, when multiplying by the reference irradiance G. This form of the equation is discussed in Fig. 4~~Fig. 4~~.

$$\frac{\dot{Q}}{A} = \eta_{0,hem} G - a_1 \Delta\vartheta - a_2 \Delta\vartheta^2 \quad (2)$$

2.2. Stagnation Temperature Measurement Procedure

To overcome the problem of a lack of observations for higher temperatures without additional experimental effort, it may be useful to include the stagnation temperature as an additional node point in the fitting. For safety reasons (danger of collector over-heating), the stagnation temperature (ϑ_{stg}) is always provided alongside other collector data.

According to the ISO 9806:2013 standard, the stagnation temperature is defined as the highest temperature ϑ_{sm} that can be found on the absorber surface, while the collector is exposed to the available solar irradiance G_m and ambient temperature ϑ_{am} (outdoors, or in a solar irradiance simulator) under steady-state conditions without heat extraction from the collector (stagnation condition). To achieve these conditions with liquid heating collectors, it is recommended to drain the collector completely from all remaining heat transfer fluid and to seal all fluid pipes except for one to prevent cooling by natural circulation.

There is a standardized form of the stagnation temperature which is obtained by assuming a constant proportion of $\vartheta_s - \vartheta_a/G$. With the standard reference values $\vartheta_{as} = 30\,ºC$ and $G_s = 1000\,W/m^2$ according to Eq. (3), the standard stagnation temperature results in:

$$\vartheta_{stg} = \vartheta_{as} + \frac{G_s}{G_m}(\vartheta_{sm} - \vartheta_{am}) \quad (3)$$

Following these guidelines, the test demands that for FPCs the temperature sensor shall be positioned at two-thirds of the absorber height and half the absorber width (see Fig. 2), as it is supposed to be the point on the absorber surface where the temperature is highest during stagnation (ISO, 2013).

For ETCs the specifications are less strict. The ISO 9806:2013 states that in this case the temperature sensor should be placed at a suitable location in the collector, i.e. where the highest temperature relevant to the heat transfer fluid is to be found. Since, in the case of ETCs the absorber surface is not easily accessed, it is common practice to measure the stagnation temperature for a single tube at the tip of the pipe or copper tube respectively (see Fig. 2).

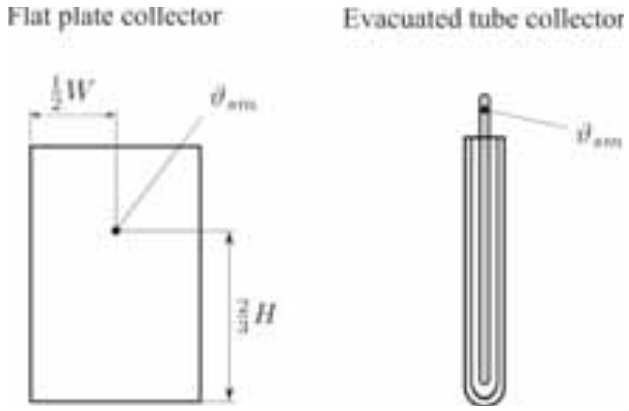

Fig. 2: Stagnation temperature measurement points according to the ISO 9806:2013, with W and H the width and the height of the flat plate collector respectively.

2.3. Collector model

When talking about using the stagnation point as an additional observation for the WLS fitting, attention should be paid to the mathematical model the efficiency curve is based on. Basically, the collector efficiency curve describes the heat transfer mechanisms within the system resulting in a fraction of useful heat and a fraction of heat losses. Fig. 3 illustrates this energy flow with the help of a resistance scheme as an analogy of an electric circuit. The scheme represents a collector with tube absorber. Q^{opt} is the energy flux in form of irradiation as it passes through the optical device. Q^{th} summarizes the heat losses consisting of radiation and convectional losses. The heat removal factor F' plays an important role in this study, as it represents the capacity of the system to transport heat from the absorber surface to the HTF. It takes into account the flow regime and absorber geometries. During stagnation the temperature ϑ_m of the absorber and ϑ_s on the absorber surface are supposed to be equal, since no heat is removed and enough time was given to reach an equilibrium of temperatures.

It is not trivial to say to what extent it is valid to assume that the stagnation point should form part of the efficiency curve. Even though heat transfer mechanisms for a drained collector differ significantly from those of an operating one with constant flow rate, the stagnation temperature measured in both cases should be the same. As Fig. 3 suggests, it is assumed that in case of stagnation there is no heat transport from the collector surface to the HTF. The absorbed energy Q^{opt} is lost completely in form of radiation and convection to the environment. It may therefore be assumed that the stagnation point should form a valid observation for the efficiency curve fitting.

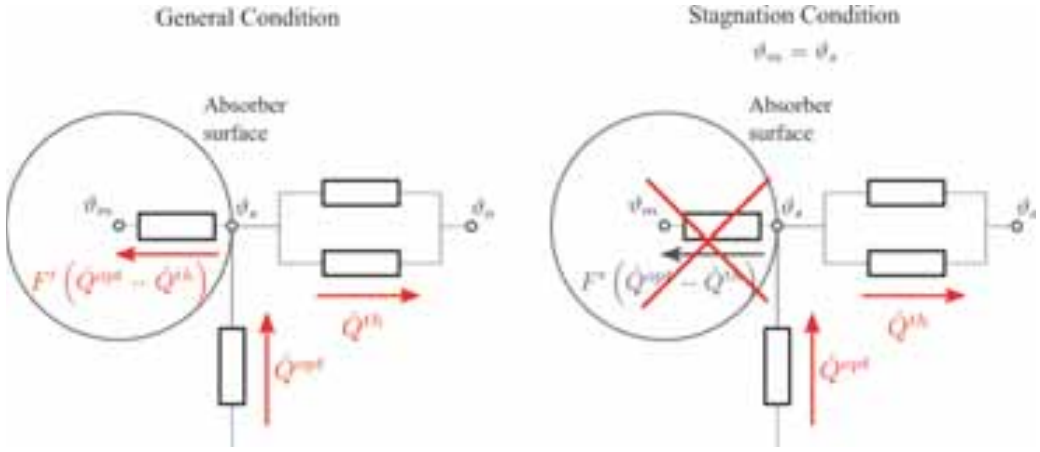

Fig. 3: General heat transfer mechanisms of a solar thermal collector during general operation and stagnation.

3. Method

Three datasets from two different databases have been evaluated. One database was provided by CENER. The database comprises 81 FPCs of different designs. Two more datasets were taken from the database of the Institute of Solar Technology in Switzerland (SPF) consisting of 24 FPCs and 23 ETCs respectively.

As for data provided by CENER, every collector was certified according to the standard regulations with eight data points at four different inlet temperatures. Apart from fitting the collector efficiency curve only to test results for the eight operational modes ($\Delta\vartheta/G$), the stagnation temperature with its typical efficiency of zero has been included as an additional observation as well.

The ISO 9806:2013 standard suggests a WLS fitting. Since uncertainty values of the temperature sensors were not available, it was applied a common multiple linear regression (MLR) fitting instead of the suggested WLS method. This will not make any difference to the outcome of the study.

The collector efficiency equation of Eq. ~~(2)(2)~~ can be converted into a multidimensional linear equation, such that it takes the form of the following general expression:

Con form
1, No revis
gramática

$$y_i = \beta_0 + \beta_1 x_{i,2} + \beta_2 x_{i,2} + \ldots + \beta_{p-1} x_{i,p-1} + \varepsilon_i \tag{4}$$

with y and x as the experimental parameters or observations, β as the regression coefficients and ε as the error. According to the MLR approach there exists a set of regression coefficients which minimizes the overall error $\sum_{i=1}^{n} \varepsilon_i$. This optimal coefficient vector is given by:

$$\widehat{\boldsymbol{b}} = (\boldsymbol{X}^T \boldsymbol{X})^{-1} \boldsymbol{X}^T \boldsymbol{Y} \tag{5}$$

where $\boldsymbol{b}$ is the vector of the regression coefficients.

$$\boldsymbol{b} = \begin{bmatrix} \beta_0 \\ \vdots \\ \beta_p \end{bmatrix} = \begin{bmatrix} \eta_0 \\ a_1 \\ a_2 \end{bmatrix} \tag{6}$$

applying this Eq. (1), the design parameters which need to be determined are the optical efficiency η_0 and the thermal coefficients $a$and a. **X** is a n × p -matrix that contains the n observations for each parameter p.

$$\boldsymbol{X} = \begin{bmatrix} 1 & x_{1,1} & \cdots & x_{1,p-1} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_{i,1} & \cdots & x_{i,p-1} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_{n,1} & \cdots & x_{n,p-1} \end{bmatrix} = \begin{bmatrix} 1 & \frac{\Delta\vartheta_1}{G} & \frac{{\Delta\vartheta_1}^2}{G} \\ \vdots & \vdots & \vdots \\ 1 & \frac{\Delta\vartheta_i}{G} & \frac{{\Delta\vartheta_i}^2}{G} \\ \vdots & \vdots & \vdots \\ 1 & \frac{\Delta\vartheta_n}{G} & \frac{{\Delta\vartheta_n}^2}{G} \end{bmatrix} \tag{7}$$

In the case of Eq. (1) these parameters are the constant 1 and the experimental results for $\Delta\vartheta_1/G$ and ${\Delta\vartheta_1}^2/G$. $\boldsymbol{Y}$ is also a vector of observations containing the experimental results of the collector efficiency η.

$$\boldsymbol{Y} = \begin{bmatrix} y_1 \\ \vdots \\ y_i \\ \vdots \\ y_n \end{bmatrix} = \begin{bmatrix} \eta_1 \\ \vdots \\ \eta_i \\ \vdots \\ \eta_n \end{bmatrix} \tag{8}$$

Apart from the regular fit, the 95%-confidence region has been calculated in order to analyze the accuracy of the fit and see how far the 8-point and 9-point fit are statistically apart. The 95%-confidence margin of a regression parameter is defined as

$$\beta_i^{conf} = \beta_i \pm t^*_{n-p,1-\alpha/2} \sqrt{\widehat{\boldsymbol{V}}(\boldsymbol{b})_{ii}} \tag{9}$$

with α as the confidence parameter; $\alpha = 0.05$. $t^*_{n-p,1-\alpha/2}$ is the t-value of the Student's *t*-distribution and $\widehat{\boldsymbol{V}}(\boldsymbol{b})_{ii}$ are the diagonal elements of the estimated variance-covariance matrix. The variance-covariance matrix is defined as

$$\widehat{\boldsymbol{V}}(\boldsymbol{b}) = MSE(\boldsymbol{X}^T \boldsymbol{X})^{-1} \tag{10}$$

where MSE is the mean square error of the error ε_i:

$$MSE = \sum_{i=1}^{n} (\boldsymbol{Y} - \boldsymbol{Xb})^2 \tag{11}$$

For the discussion in section 4 both efficiency curves, the 8-point fit and 9-point fit, have been plotted together with the 95%-confidence interval of the regression coefficient vector $\boldsymbol{b}$.

The SPF database already provides all efficiency curve parameters as well as the measured stagnation temperature. It was therefore not necessary to apply a MLR fitting and it was not possible to analyze the 95% confidence interval of the curve. Instead, only the difference between the measured stagnation temperature and the stagnation temperature suggested by the efficiency curve were compared with each other. This comparison also forms part of the discussion of the results obtained by the CENER data evaluation.

4. Results

4.1. CENER Database

The database comprises 81 FPCs of different design. The collectors were tested according to the ISO 9806:2013 standard regulations. Data therefore includes eight observations at four different temperature levels as well as the stagnation temperature. Based on this information one representative example has been chosen to compare two different efficiency curve fits with each other. One efficiency curve is based on the eight regular observations, while the other one also includes the stagnation point as an additional node point.

Fig. 4 shows the results for the 8-point (not including the stagnation point) and 9-point fit (including the stagnation point) of the selected collector. Beside the efficiency curves, the 95%-confidence region is indicated by dashed lines. The confidence range was determined according to Eq. (9)~~(9)~~. Interestingly, the extrapolated stagnation temperature ϑ_{fit} differs significantly from the measured stagnation temperature ϑ_{stg}. In this specific example the difference $\vartheta_{stg} - \vartheta_{fit}$ is 48.5 °C.

The 95%-confidence margin also indicates that the difference between both values is too large as to be explained by statistical accuracy of the fit. ϑ_{stg} lies far outside the 95%-confidence region. In some parts an overlap can be observed between the 95%-confidence uncertainty margins of both curves.

At this stage of research it is not possible to say which of the two curves represents the real collector behavior better. What should be noted regarding the 9-point fit is a less-realistic shape of the curve. Its curvature is opposed to the one obtained by the regular collector efficiency behavior.

The most probable solution to the real collector efficiency curve is somewhere in-between the two presented curves. In order to validate the suggested 9-point fit it is essential to obtain observations for the medium and high temperature range.

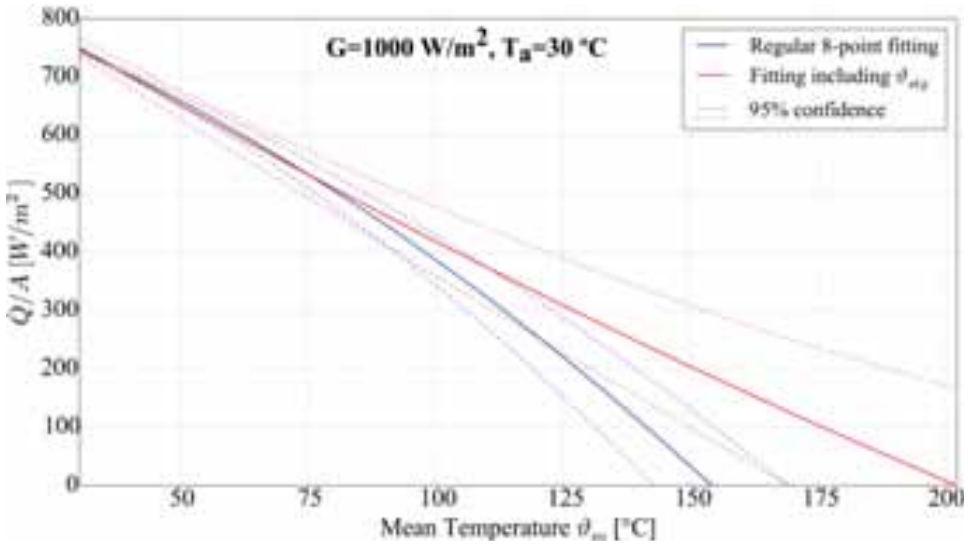

Fig. 4: Comparison of a regular 8-point fit with a 9-point fit that includes the stagnation temperature. A multiple linear regression fit (MLR) was applied to a flat plate collector with solar glass cover, aluminum plate absorber, and isolated with rock wool.

Fig 5 shows the distribution of temperature differences $\vartheta_{stg} - \vartheta_{fit}$ as they were found for all collectors of the database. Extrapolated stagnation temperature ϑ_{fit} from the 8-point fit is constantly underestimating the measured one. While the average gap is 39.47 ºC in one case it even reaches 83 ºC.

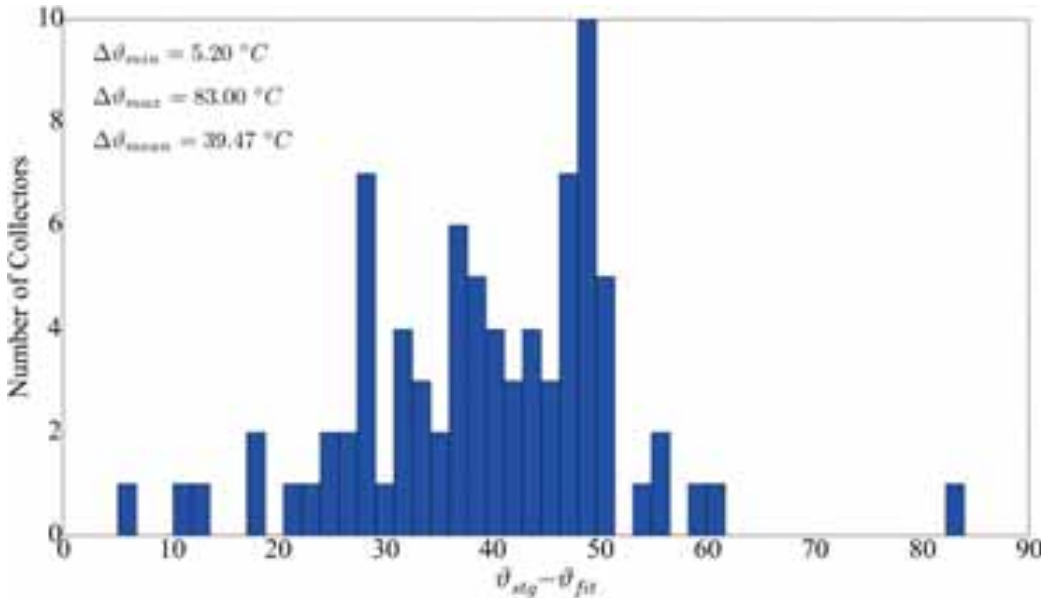

Fig. 5: Distribution of the difference between the actually measured stagnation temperature ϑ_{stg} and the estimated stagnation temperature ϑ_{fit}. The distribution represents results for 81 flat plate collectors certified by CENER.

4.2. SPF Database

SPF provides an extensive database of test results of FPCs and ETCs that is publicly available. Two datasets based on this database have been evaluated in this study. The datasets consist of 24 FPCs and 23 ETCs respectively.

As can be seen in Fig 6, results for FPCs show almost constantly positive temperature differences $\vartheta_{stg} - \vartheta_{fit}$ same as was reported for the CENER database. The maximum temperature difference found was 26.30 ºC. However, in three cases the measured stagnation temperature seems to be well represented by the extrapolated one.

As an interesting fact, it could be shown that in the case of ETCs the gap $\vartheta_{stg} - \vartheta_{fit}$ is negative in most of the cases. The extrapolated value is consequently overestimating the measured stagnation temperature. Especially in two cases a very large difference of -159.74 ºC could be found. It should be noted that one of the reasons for this negative temperature difference could be the way in which the stagnation temperature is measured for ETCs. Since it is often complicated to attach temperature sensors to the absorber surface inside the evacuated tube, the sensor is placed at the heat of the tube. Taking into consideration the temperature gradient along the tube as a result of heat transport mechanisms, a lower temperature can be expected at the tip of the tube than further down at towards the bottom.

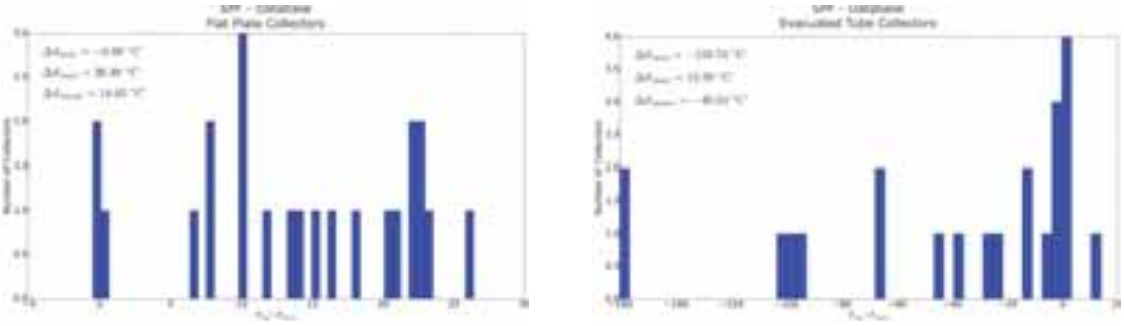

Fig. 6: Absolute distribution of the difference between the actually measured stagnation temperature ϑ_{stg} and the estimated stagnation temperature ϑ_{fit}. The distribution represents results for 24 FPCs and 23 ETCs from the SPF database.

5. Conclusion and Outlook

The conventional data fitting approach according to the ISO 9806:2013 standard constantly underestimates the actual stagnation temperature in the case of FPCs and overestimates it in the case of ETCs. The reason for these differences is most likely due to the way the stagnation temperature is measured. Stagnation temperature assessment methods differ for every type of technology. In addition, the accuracy of the measured stagnation temperature might depend on a couple of other effects such as the temperature dependency of optical properties and non-linear effects of convectional heat transfer.

An exemplary sample from the CENER database showed that since ϑ_{stg} was found outside the fit's 95-confidence interval; in this case statistical errors of the prediction could be excluded. In some parts an overlap was observed between the 95%-confidence uncertainty margins of both curves.

Whether a 9-point fit could yield more accurate results within the high temperature range of the efficiency curve is not straight forward to say. It will be necessary to validate this approach with experimental data at higher operating temperatures. This will be done in a further study. An evaluation of the results will show, whether the integration of ϑ_{stg} into WLS fitting is physically reasonable.

A NEW TYPE OF SIMULATION SOFTWARE FOR DETAILED COMPONENT-BASED SYSTEM ANALYSIS

Reza Shahbazfar

rs@3optim.com

Abstract

A new type of simulation software is introduced which performs sophisticated simulations on the transient thermal, and electrical and hydraulic system behaviour. In comparison to other available software, it can simulate the sensor and controller properties, and also enables hydraulic analysis. It is possible to set or influence the component parameters throughout a simulation. In addition, several open interfaces allow the use of the software in numerous fields of application, such as in particular its implementation in other software. The software core facilitates both a fixed and a variable simulation time step.

Individual system configurations can be designed by connecting single components such as in other component-based simulation tools. The program's component library contains 15 validated components. Further components can be modelled or imported by the user if required. The software was validated using TRNSYS 17 as well as analytical considerations, and very good results have been obtained.

Keywords: *Simulation software, component based, sensor and controller properties, variable time step, hydraulic circuit analysis*

1. Introduction

The demand for renewable energy sources and their availability fluctuate over time. These variations lead to a dynamic response of the respective systems. Common dynamic system simulations can be used to analyse or predict the system's behaviour, and several simulation tools have been developed in the past Connolly, D. et al. (2009). From a technical point of view, they can be divided into system-oriented and component-based tools. Component-based simulation tools are usually used in science and for sophisticated technical applications. Depending on the desired application, the potential of commercial software tools is restricted due to a number of missing functionalities or drawbacks. This motivated the development of the new component-based and detailed simulation software (MITHRA). The aim of the new software is to integrate and combine the following (partially new) features in a single program:

- Detailed modelling of sensor, controller and data logging properties
- Detailed analysis of hydraulic circuits
- Accessibility to automatically performed simulations
- Flexibility in usage: possibility to be implemented in another software, as a stand-alone or a server-based application
- Variation of component parameters during the simulation: e.g. the variation of solar thermal collector efficiency curve parameters or the heat transfer coefficient of hot water storages U = f(…)
- A variable time step
- Fast and simple modelling of new components and features
- The flexible and combined simulation of thermal, hydraulic, electrical and if required further system behaviour in one tool

In the following sections, the software structure will be introduced briefly, and the main parts "Simulation Core" as well as the "Component Liberty" will be described more specifically with a focus on the advanced methods of MITHRA.

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.10.25 Available at http://proceedings.ises.org

2. Software structure

The MITHRA software structure is shown in Fig1. It consists of a simulation core (a) and a component library (b). The simulation core processes the system information and its control strategy which are provided in two files (c). User-modelled components (d) can be simulated if necessary. The results of the simulations are dynamically written on an output file (e). Both the system file and the control file use a very simple and user-friendly syntax. However, visual interfaces like desktop or mobile apps can be applied to prepare these two files (f). The software is very well documented.

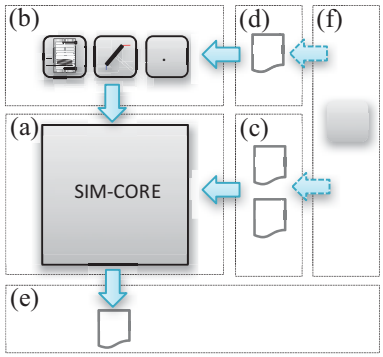

Fig. 1: Schematic structure of the software: (a) simulation core, (b) component library, (c) system file and control file, (d) user-defined components, (e) output file, (f) optional visual interfaces

Fig. 2 portrays an example of a solar thermal system which was investigated in MITHRA. It consists of a collector field with an area of 10 m^2 connected by an insulated pipe to a hot water storage with a volume of approximately 450 litre. The hot water storage has a direct temperature controlled electrical heater which is installed in the upper part. The major component details are shown in Table 1 and the measurement details are shown in Table 2. This system was modelled in MITHRA using the standard components.

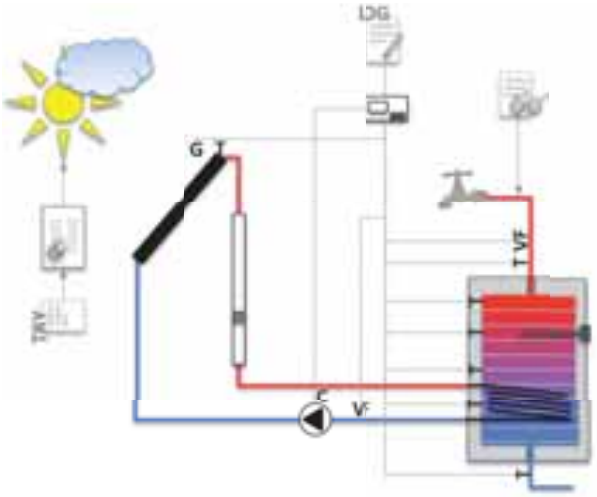

Fig. 2: Schematic structure of the exemplary solar thermal system simulated in MITHRA. The components are described in Table 1 and the sensors in Table 2

Tab. 1: Components' main information of the simulated example System shown in Fig. 2

Component	Important Parameters / Values
Test Reference Years Data , TRY-Processor, Weather data in simulation environment	Time Step = 1 min
Flat Plate Collector	Collector aperture Area = 10 m^2 η_0 = 0.8 a_1 = 3.24 $Wm^{-2}K^{-1}$ a_2 = 0.011 $Wm^{-2}K^{-2}$

Pipe	Internal Diameter (Pipe Wall) D_{in}= 0.03 m External Diameter (Insulation) D_{out}= 0.04 m Length L = 10.0 m
Pump	Set Volume Flow $\dot{V}$= 0.0001 m^3s^{-1}
Hot Water Storage	Internal Diameter (Tank) D_{in}= 0.6164 m External Diameter (Insulation) D_{out}= 1.0 m Height h = 1,5 m Number of Segments = 20 Electrical Heater Position = 70 % Electrical Heater Power P_{el}= 2 kW

Tab. 2: Sensors and control signal of the simulated solar thermal system shown in Fig. 2 from left to right and top to bottom

Abbreviations	Component	Unit
G	Solar Irradiance Sensor 1. in collector plane (G Collector)	W/m^2
T	Temperature Sensor 1. collector outlet (T Collector) 2. hot water storage internal - 99% height (T Storage 99%) 3. hot water storage internal - 70% height (T Storage 70%) 4. hot water storage internal - 50% height (T Storage 50%) 5. hot water storage internal - 30% height (T Storage 30%) 6. mains water(T Cold Water 99%)	° C
VF	Volume Flow Sensor 1. hot water withdraw (VF Hot Water) 2. solar primary loop (VF Solar Primary Loop)	m^3/s
C	Control Signal 1. solar primary loop pump (C Pump Solar Primary Loop)	1

The results obtained during a ten-day simulation, beginning on January 1 are shown in Fig. 3 and in Fig. 4 with more detailed measurement results for the exemplary day January 6. The components as well as the overall system show the expected qualitative behaviour. The quantitative evaluation is described in section 4 with the component validation with TRNSYS 17 standard library. For example, it can be observed that the upper set temperature of the electrical heater is 60 °C and the lower one is 55 °C, corresponding to the temperatures in the position of the electrical heater in 70% of the storage height (Fig. 3 and Fig.4). This is visualised in the temperature curve “T Storage 70%”. Due to stratification, mixing and several other modelled heat transfer phenomena, the upper storage temperature “T Storage 99%” is continuously influenced by the electrical heater but it remains in the desired temperature range. The system controller continuously compares the collector temperature “T Collector” with the temperature in the lower part of the storage “T Storage 30%”. In case of a (rather low) positive temperature difference of 5 K and more, the solar primary loop pump is turned on by setting the control signal “C Pump Primary Solar Loop” to “1”. The energy transport from the collector to the storage causes a temperature increase in the lower parts of the storage, as demonstrated by the temperature sensor T” Storage 50%” installed in the middle of the storage. In the weather dataset, January 5 is a sunny day with rather low hot water consumption. Thus, the solar thermal part of the system can fully heat up the water.

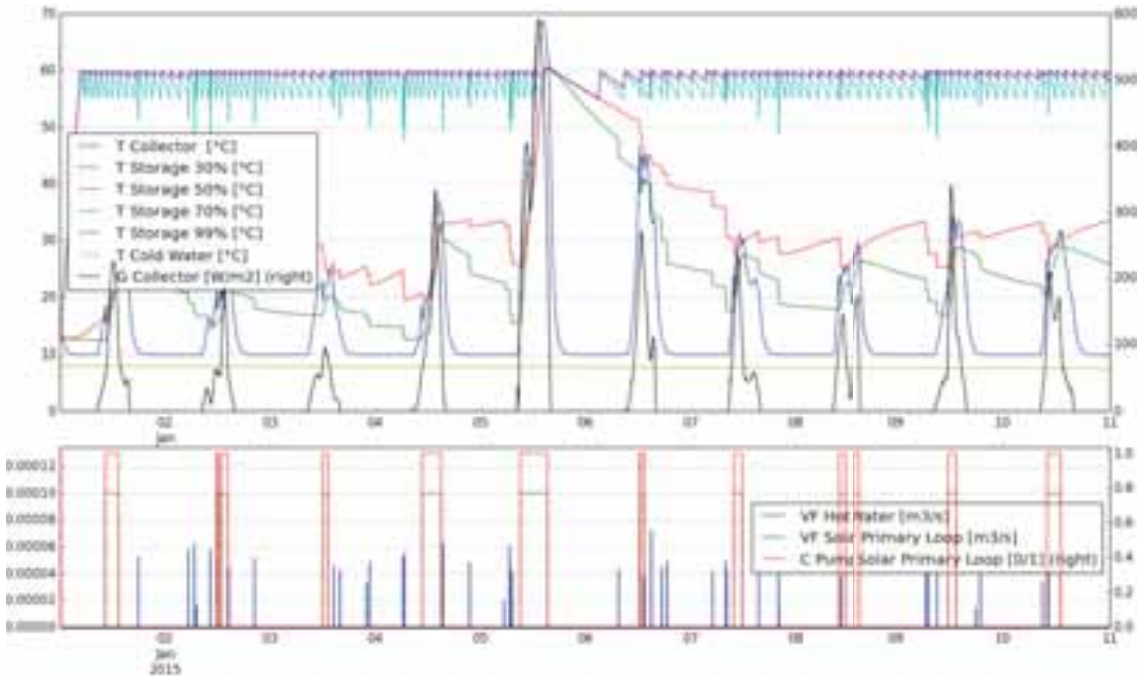

Fig. 3: Measurement results of the simulated solar thermal system shown in Fig. 2 using MITHRA. The 10 day simulation starts on January 1. The components and the sensors are described in Table 1 and Table 2.

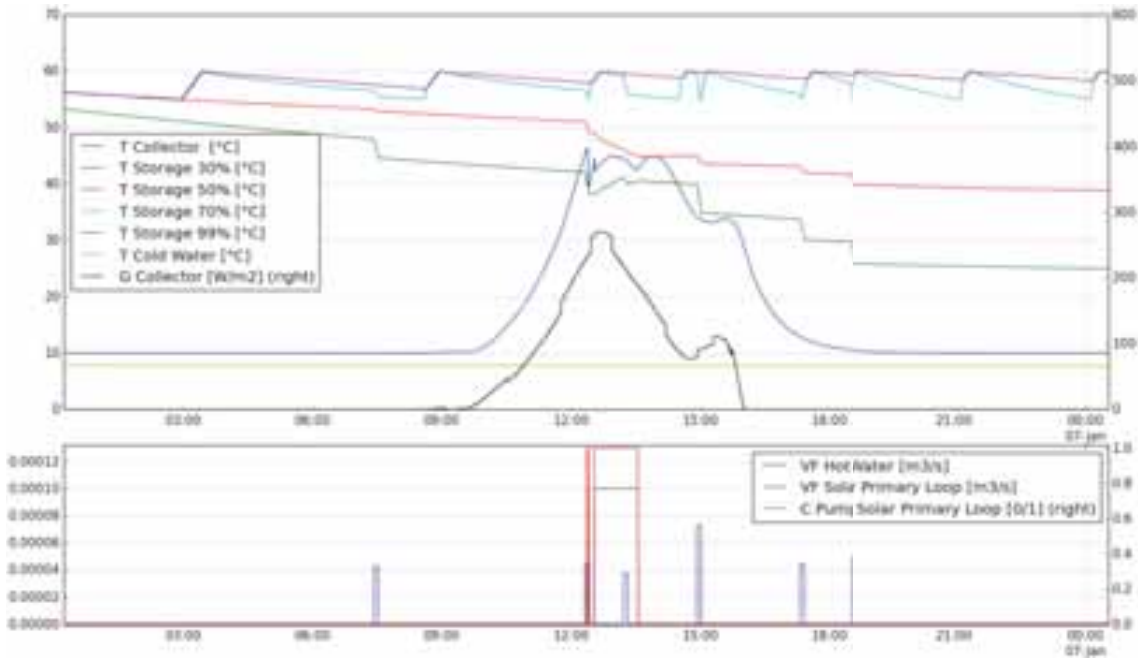

Fig. 4: Measurement results in detail for January 6 shown in Fig. 3.

3. Simulation Core

The simulation core is the most essential element of the software. In the very first step, it parses the input file, which contains the component and system description. Subsequently, a software environment is accessible where a simulation can be started manually as well as automatically by separate or wrapping software. After the simulation, an output file is generated containing the simulation results. Additionally, different implemented post processing methods for advanced plotting or data import and export are provided. In the following, the input and output files will be described before presenting the different features of the simulation core.

3.1 Input and Output Files

Figure 4 shows an example input file. The components are defined in the top of the file, and connected with each other using arrows in the bottom of the file. When defining the components, many component specific parameters can be set according to the requirements of the user. For example, to define a hot water storage tank it is possible to adjust 41 parameters, if necessary. In case the component parameters are not further defined in the input file, the component's default values will be used according to the program's manual.

An important feature is that hydraulic loops are defined (e.g. "CollectorLoop" in Fig. 5) and the components are assigned to a loop. Thereby, hydraulic circuit analysis can be performed. While some simple hydraulic analysis features are already implemented, more sophisticated features are in development.

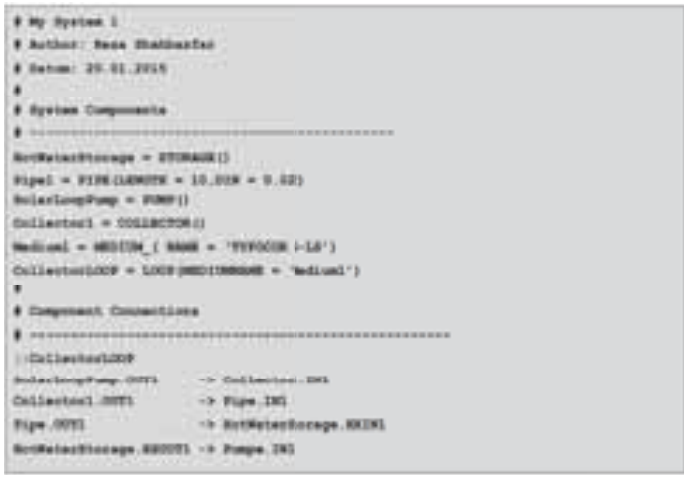

Fig. 5: Schematic structure of the simulated exemplary system in MITHRA. The components are described in Table 1 and the sensors in Table 2

The output file is generated by a data logger (see 4.9) and structured as a common csv file containing the sensor names in the first row and the time stamp in the first column (see Fig. 8). Therefore, it is easy to further process the simulation results in other programs, such as spreadsheet programs.

3.2 Port Concept

In each simulation time step, component states are linked to each other according to the system description in the input file. A port concept has been developed to enable the components to not only generate a value but also to interact with each other. Different type of ports can be distinguished:

1. Hydraulic Port
2. Energetic Port
3. Sensor Port
4. Free Port

Through a hydraulic port, energy and mass exchange including pressure is performed. The energetic port enables a non-mass-linked energetic exchange. The sensor port plays a special role since it only has a one-way interaction mode. The last category of ports is the free port, which is automatically defined by the simulation core according to the user's specific requirements; for example, when using a file reader to import different kinds of values.

3.3 Variable Simulation Time Step

Throughout system operation and respectively during simulation, there are times of high process dynamics causing highly fluctuating state values, but there are also less dynamic conditions with rather stationary conditions. In the solar thermal system (Fig. 2), one can observe typical dynamic system conditions. For example, they are caused by variations in solar radiation caused by clouds passing by, after a power-on of the solar primary pump or after a hot water withdraw. On the other hand, in the night and in the absence of a hot water withdraw the system temperatures are less dynamic.

The simulation core was designed in order to facilitate a variable simulation time step to enable the simulation to speed up under less dynamic conditions. Therefore, three different speed levels with different speedup factors can be defined at the beginning of a simulation. A suitable simulation time step is automatically chosen depending on the automatically reported component states and the required tolerance accuracy. In Fig. 6, the collector temperature and the control signal of the solar primary pump of the solar thermal system (Fig.2) are shown. The simulation was performed using a variable time step. Two short time ranges of the diagram (left dotted rectangle) are shown in Fig. 7. (left) The calculated points of the collector temperature are marked by a "+". It can be noted that the activation of the solar primary loop pump leads to more dynamic system conditions slowing down the simulation speed. Shortly after the disconnection of the solar primary loop pump, the system is less dynamic and the simulation speeds up once again (right dotted rectangle, see Fig. 7 right).

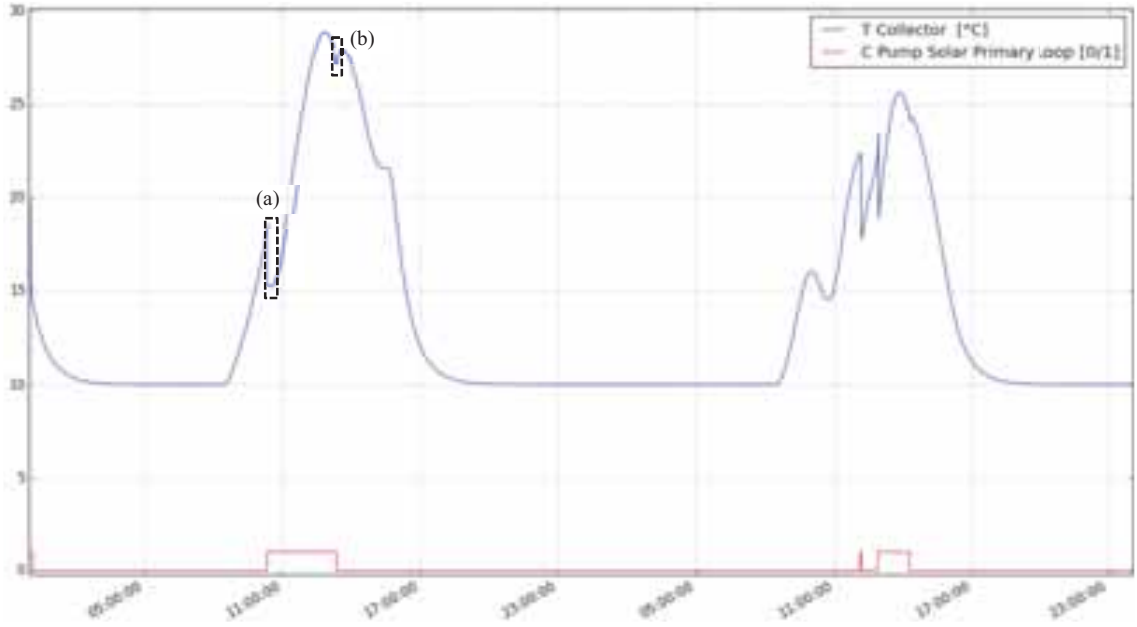

Fig. 6: Two days simulated in MITHRA using variable time steps. Two exemplary positions showing the automatic simulation speed change have been chosen (dotted rectangles) and are shown in Fig. 7 (left dotted rectangle) and Fig. 7 (right dotted rectangle).

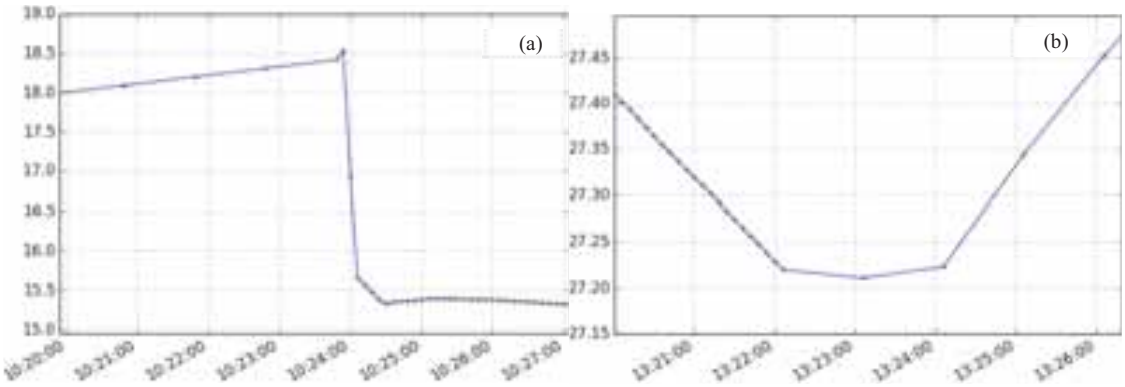

Fig. 7: X-zoom on left (a) and right (b) dotted rectangle displayed in Fig. 6. After the activation and disconnection of the primary solar loop pump the simulation time step (marked by "+") is reduced and increased, respectively.

3.4 Numerical Solver

In MITHRA, there is no global numerical solver. The numerical process is executed in the components. An explicit numerical solver has been developed to enable a fast modelling of new components. It is an automatically self-controlled solver, which reduces the simulation time on the one hand, and achieves the expected simulation accuracy on the other. This is achieved by an algorithmic manipulation of the calculated control points. It is possible to implement implicit numerical methods or to combine them.

3.6 Process Analyser

A process analyser to detect the simulation time (complexity) of each component and to plot the results if required has been developed. It detects malfunctioning components or other problems of the simulation. Additionally, warnings and errors are displayed and can be written to a file.

3.7 Hydraulic Circuit Analyser

Throughout a simulation, the hydraulic circuit analyser automatically investigates the hydraulic system behaviour. It can analyse the components of each loop and pre-calculate the pressure and the pressure drop due to a fictive volume flow. This makes it possible to automatically iterate the expected volume flow and flow direction in distribution manifolds. Therefore, the loops and the fluid within the loops are separately declared in the input file (see Fig. 5). Some components are modelled slightly different: For example, a pump can provide a pressure difference instead of a constant volume flow (see. 4.4), or new components like a safety valve and expansion vessel are modelled and can be used in loops. The hydraulic analyser works in a simple mode and its further development is possible.

4. Components

For a simulation, the system has to be described by its single components according to the input file shown in Fig. 5. While it is possible to create new components, a number of ready-to-use components are contained in the program's component library. Table 3 provides an overview of the available components. These components are quite flexible: By setting a parameter (usually called MODE), a wide range of different component constructions can be reproduced. Thus, the number of the components is not directly comparable with some existing programs. All components are validated using analytical methods or numerical methods with TRNSYS 17. A detailed mathematical and syntactical description of the components, including the validation results, is provided in the program's documentation with more than 100 pages.

Tab. 3: Component Library Overview – Ready-to-use components

Components	
Pipe	Sensor
Medium (e.g. Heat Transfer)	Equation Processor
Hot Water Storage	Numeric Function Generator
Pump	File Reader
Solar Thermal Collector	Safety Valve
Boiler	Expansion Tank
Distribution Manifold & Flow Mixer	Multi Zone Building Modell (in process)
Weather Processor / TRY	Heat Pump (in process)
Controller with Data Logger	Photovoltaic (in process)

The components are briefly described in the following sections with a focus on their advanced features.

4.*1 Pipe*

The component pipe is realized as a plug-flow-model. Additionally to the common features (for example, the calculation of the thermal losses to the environment), this component determines the hydraulic losses as well as the internal heat transfer between the single segments at different temperatures. The inlet and outlet heights can be defined. Thus, a thermal stratification in the pipe can be simulated if required. As an additional special feature, any pipe bends and a number of different hydronic components like elbows and ball or block valves can be defined and will be taken into account when the hydraulic losses are calculated.

4.2 Medium

In MITHRA, the heat transfer medium within the system hydraulics itself is considered to be a component. Therefore, the relevant required hydraulic and thermodynamic features like fluid density, viscosity, specific heat or aggregate state can be calculated dynamically with respect to the current individual system conditions. Different common mediums are already modelled, and the user can create new fluids if necessary.

4.3 Hot Water Storage

Heating applications often use hot water storage to ensure the user's thermal energy demand and to enable the system to bypass the time between energy availability on the one side and energy demand on the other. The system behaviour implies many different overlapping heat and mass transfer phenomena, which makes it rather complex to model. In MITHRA, detailed and very flexible hot water storage was modelled. In simulations, the storage medium is divided into nodes. For every node, a complex mass and energy balance is calculated. Besides the energy and mass calculations, the stratification of the storage medium including mixing effects is also considered.

It has to be underlined that in this model the number and positions of internal heat exchangers, electrical heating elements, inlets and outlets as well as the number of the nodes are not limited or restricted. The internal heat exchanger and the storage body can be described analytically by typing in the single parameters, or they can be described using overall values like U or U*A. The shape of the storage can be switched from cylindrical to cuboid.

4.4 Pump

The component pump converts electrical power into a pressure difference or to a pre-defined volume flow depending on the simulation mode and the fact whether the hydraulic circuit needs to be analysed or not. In the latter case, the pump characteristics dp = f(Vd, Pumplevel) can be defined. The pump is switched on by a control signal that is continuously variable or digital in the rage of 0…1.

The efficiency behaviour of the pump is described by two parameters: A first parameter describes the efficiency of the electromotor in terms of converting electrical energy into rotatory mechanical energy, and the latter factor describes the efficiency of the mechanical components of the pump in terms of converting the rotatory mechanical energy into a hydraulic pressure difference. Alternatively, it is possible to describe the pump's overall behaviour with a single parameter. Furthermore, the temperature increase of the fluid due to the pump inefficiency is also modelled.

4.5 Solar Thermal Collector

Several different approaches exist on how a solar thermal collector can be modelled. When performing a simulation and setting up these models, it is often problematic to get all the required parameters. Thus, many parameters need to be assumed which leads to an increase of the model uncertainty. To avoid this, a converse approach has been chosen in DSMIN for the development of the solar thermal collector model. Firstly, the data sheets of different available collectors on the market were analysed. The collector model was developed according to the identified and easily obtainable parameters. It primarily depends on the efficiency curve parameters, but also on the collector heat capacity and the incident angle of the solar irradiation. Moreover, the hydraulic collector behaviour was also taken into account. It is described by one or multiple parameters available in the collector datasheet or in the collector testing report.

4.6 Boiler

A boiler ensures that the thermal energy demand is met. Oil-fired or gas-fired boilers are two common types. Their system integration can vary as well. Usually, they are separate external devices heating up a medium in a closed loop and pumping the heated medium to the load.

In MITHRA, a flexible component model of a boiler was developed. It can convert an external energy source into thermal energy and supply it to the load using a pump. The temperature behaviour is regulated by setting an upper and lower temperature. The heat capacity, a constant or a variable efficiency function depending on the boiler's return temperature can also be taken into account in the simulation process.

4.7 Distribution Manifold / Flow Mixer

To split one inlet volume flow into multiple outlet flow rates a distribution manifold can be used. The outlet flow rates can be adjusted individually using valves. In MITHRA, a distribution manifold was modelled where the flow rate factors can dynamically be controlled by an external function during the simulation. A flow mixer is also available enabling the reverse process: Multiple inlet volume flows are mixed and provided as a single flow at the outlet.

4.8 Weather Processor

The climatic conditions play a key role for thermal or energy simulations. Thus, several methods and different sources have been developed in the past providing weather data especially for simulation purposes. Typically, solar diffuse and beam irradiance in the horizontal plane, ambient temperature, wind speed and air humidity are part of the weather information. In MITHRA, a weather processor was created as a component. It reads the weather data and is able to calculate the irradiance on the surface at any desired orientation. Therefor a complex calculation of the sun's position in the sky is internally performed and isotropic or non-isotropic sky models are utilised.

For Germany the "test reference years" (TRY) DWD (2014) is one of the most popular and free available sources for weather data used in simulations. A special "TRY mode" has been programmed in the component that enables the direct use of the TRY data without any intermediate step.

4.9 Controller and Data Logger

Energy and hydronic systems usually have a controller to ensure an appropriate operation. Usually the controller utilizes sensors, actuators and a control strategy. Common controllers provide the opportunity to log and transfer the current sensor an actuator values in a file or they analyse the data just in time. The controller in MITHRA was programmed to have these functionalities and be freely programmable.

The number of sensor inputs and actuator outputs can be chosen freely. For each input and output, the sensor type (e.g. temperature or flow sensor etc. or control signal) needs to be defined. Different simple and predefined control strategies are available, or user may define their own control strategy. An example of a control file is shown in Fig. 8. At the beginning of the file, the controller inputs are assigned to a local variable in order to be handled more easily. The solar primary loop pump is then controlled with four different if-statements using a delta-T switch-on (8 K) and switch off (4 K) including the protection of the solar loop components (100 °C) and of the storage protection at 95 °C. An example of a controller's logging file is provided in Fig. 9.

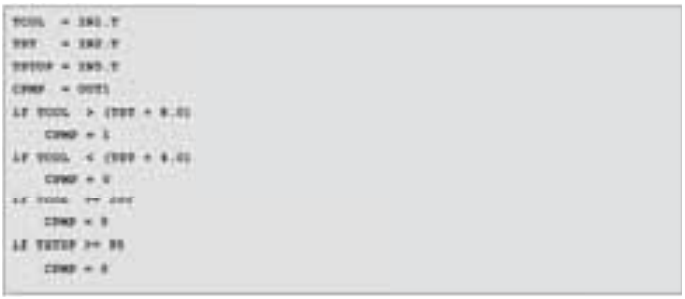

Fig. 8: Example of a simple control strategy for the controller.

Fig. 9: Example of a logging file generated by the controller. In the first column, the time stamp and the column names are provided in the first row

4.10 Sensors

As a special feature, the sensors are considered to be stand-alone components in MITHRA. Thus, it becomes easily possible to describe and numerically investigate their temporal response and measurement uncertainty in interaction with the rest of the system. In MITHRA, the measurement uncertainty is distinguished in systematic and random errors. Systematic deviation can be modelled as constant offset or can be function of the measured value or a function of simulation time. The random errors are defined by a maximum and

minimum limiting function that may also vary depending on the measured value and the simulation time. In between these two limits, a probability distribution function like a rectangular or a normal distribution function can be selected. The influence of the sensor's behaviour in terms of the logging file depends on the controller's data fetching mode (sampling or averaging and thresholding) and logging speed.

When performing detailed simulations, sometimes it can be necessary to take the sensors response behaviour into account. Hence, in MITHRA the physical sensor behaviour is provided. In Fig. 10, the overall behaviour of a simulated exemplary temperature sensor in different configurations is shown. Sensor "T_IDEAL" shows the values of the simulated system, assuming an ideal sensor. The thermal response behaviour of the sensor is modelled for the second sensor "T_SEN1". In the case of the third sensor "T_SEN2", random errors of the sensor are modelled additionally.

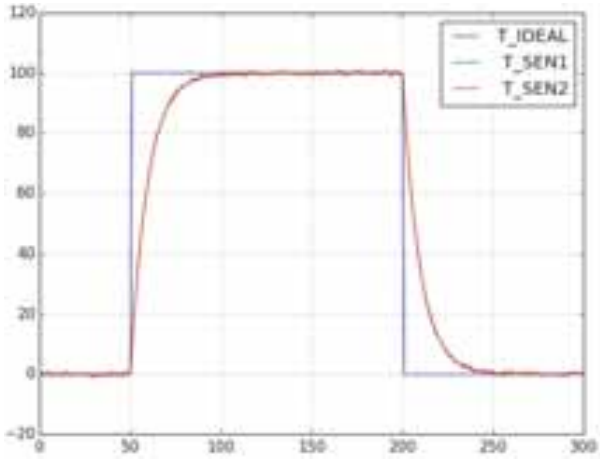

Fig. 10: Simulated temperature sensor in three different configurations: 1. Ideal ("T_IDEAL") 2. With a thermal response time (T_SEN1) 3. With thermal response time and random errors (T_SEN2)

4.11 Equation Processor

User-defined calculation can be performed using the equation processor component. The results are available at the output of the component. The number of used inputs has to be defined and the respective values must be connected in advance. It uses a similar syntax to the control file shown in Fig. 9.

4.12 Numeric Function Generator

For testing purposes or for basic control functions, it is sometimes necessary to quickly generate a value during the simulation. Thus, a value generator was modelled in MITHRA. It provides the opportunity to generate constant values, step functions or interpolations between given points and given time steps.

4.13 File Reader

The file reader makes it possible to read in external data into the simulation. The external file can contain a single value, multiple values or multiple time series provided in columns like in a csv format. In the latter case, the column separator can be defined manually. The file reader provides several mathematical and numerical functions like looping the file or using a simulation time depended or independent transfer function.

4.14 Safety Valve

A safety valve can be built into each loop to keep a maximum set pressure. In MITHRA it can be used for more sophisticated simulations including hydraulic circuit analysis. The component distinguishes an upper and a lower response pressure of the valve.

4.15 Expansion Vessels

Expansion vessels compensate the thermally caused volume variations of the fluid within the system. As expansions vessels typically have their pressure – volume characteristics, the volume compensation leads to a pressure variation in the system. To be able to simulate this behaviour, an expansion vessel has been modelled. Two different modes exist: In the first mode, a simple parametric approach is used that interpolates the "delta pressure" as a function of the "delta volume" with a predefined lookup table. The

second mode is for gas-filled membrane expansion vessels where the “delta pressure” can be calculated as a function of the “delta volume” using the ideal gas law of thermodynamics.

4.16 Component Validation

The component validation was performed by using analytical or numerical methods. For the latter, TRNSYS 17 standard library (see UW–Madison, 2009) was used to validate the component’s pipe, collector, hot water storage and weather processor. Different tests have been chosen that can isolate the component’s elementary behaviour as good as possible. For the variations within the test, a normal operation range was chosen. Additionally, two points (one extremely low and on extremely high) were considered. The component tests are described in Tab. 4.

Tab. 4: The components‘ main information of the simulated exemplary system shown in Fig. 2

Component	Variations
Pipe	Test 1: ambient temperature, Test 2: thickness of insulation , Test 3: thermal conductivity of insulation material, Test 4: inner diameter
Collector	Test 1: ambient temperature, Tests 2: irradiance, Test 3: flow rate, Test 4: collector return temperature, Test 5:incident angle, Test 6: maximum stagnation temperature (3 % max, not typical operation condition)
Hot Water Storage	Test 1: electrical heating in the upper of the storage, the vertical thermal conductivity over the time is compared, Tests 2: variations in the insulation U-Value, temperature of each node over time is compared , Test3: variation of the power of electrical heater in the bottom of the storage tank, the stratification over time is compared, Test 4: Variation of the volume flow in the internal heat exchanger, temperature over time of all nodes is compared, Test 5: hot water withdraw in the top of the tank is simulated and varied, the temperature over time of all nodes is compared
Weather Processor	Multiple test and the comparison of direct and diffuse radiation, variation of plans orientations and models anisotropic diffuse radiation calculation

In Fig. 11, an overview of the numerical validation results for typical operation ranges is shown. There are only small deviations in the range less than 0.5 percent. In very extreme situations, like a collector stagnation temperature, deviations up to 3,0 percent may occur. However, they are not of importance and the question which of the models is closer to the realty remains unanswered.

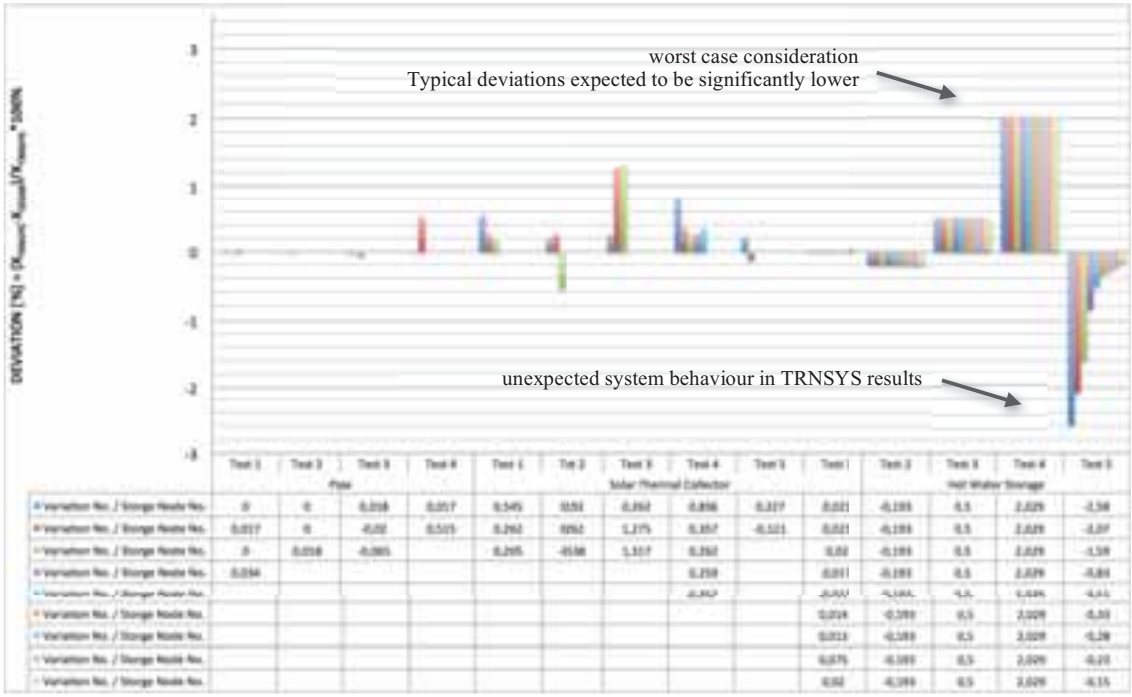

Fig. 11: Overview of the deviation in results for typical operation conditions. Tests according to Tab. 4.

5. Summary and conclusion

In this paper, a new type of flexible component-based simulation software for thermal, hydraulic and electric system simulations is introduced with many advanced methods from today's point of view. Among them, the measurement uncertainty of sensors and the controller can be modelled and investigated in interaction with the system in detail. The controller is freely programmable. Additionally, the basis for an automatic hydraulic circuit investigation is provided and can be further developed. The software can be used as stand-alone application, server-based or can even be implemented in other software. During a simulation, the component parameters can be changed. The simulation time step is variable. This tool enables a fast component or system modelling. In the software, a component library containing 15 flexible components is introduced. The components are analytically or numerically validated using TRNSYS 17 standard components. A detailed software manual containing detailed mathematical description and validation results of the components in more than 100 pages is available.

The development of this software took approximately one year of intensive programming. The experience shows that it is possible to further develop simulation tools with respect to the above named features, when considering these features from the first development steps of the simulation core and of the components. It is planned to use this software for some stand-alone and server based software applications. Three more sophisticated components will be finished by the end of spring 2016. The commercial use of MITHRA is possible but not available yet.

Complex Modeling of Solar Water Heating Systems

Ilia V. Slesarenko[1]

[1] Far Eastern Federal University, Vladivostok (Russia)

Abstract

The energy balance equations describe each part of the observed solar water heating system (SWHS) with the differential equation method. The theoretical model consists of a number of such equations and compile into a system. Because all parts of the system interact, the Runge-Kutta method helps to solve it and obtain the close-to-real output parameters. Any kind of embedded modifications cause the reaction of the rest of the parameters, and can also be modeled with the referred method. Experimental data verified the reliability of the represented method, enabling modeled system optimization.

Keywords: *differential equation, heat transfer, modeling, solar collector*

1. Introduction

Experimental data verifies the average monthly production of about 0.8 kWh / m^2 in winter and about 1.85 kWh / m^2 in summer by solar water heating systems (SWHS) on territory of Far East of Russia. The experimental SWHS shown on Figure 1 gained the peak generation of about 2.8 kWh / m^2.

Fig. 1 - General view of the experimental SWHS, its solar collectors (roof of the Far Eastern Federal University, campus building)

This solar water heater is an experimental installation with medium thermal power output, up to 70 kW. It is also equipped with the remote trackable solar activity sensors, thermometers and transducers (Table 1).

Tab. 1: Main specifications of the experienced SWHS

Parameter	Value
The area of solar collectors	150 m^2
Type of solar collectors	vacuum with heat pipes
Total volume of heat storage tanks	10 m^3
Type of coolant circulation	forced

Initially, the system had a number of specific drawbacks: limited average thermal power of about 35 kW per day, insufficiently small storage tank, highly uneven supply of heat to the hot water system of the building.

doi:10.18086/swc.2015.10.26 Available at http://proceedings.ises.org

Further optimizations were considered for the initial SWHS design to make it more energy efficient and gain the best performance:

- Increase in the number of installed solar collectors to enlarge the capacity of SWHS;
- Increase the storage tank to increase the duration of the hot water supply during the peak loads;
- Apply the heat pump (HP) that takes energy from a low temperature source and supplies additional heat to the main storage tank within the period of maximum load.

The developed mathematical model enables optimization of technical characteristics of the given system taking into account all methods of improvement.

The represented model shows reliable accuracy due to the matching of transient processes curves with the obtained from the experienced SWHS curves. The model can identify the types of transition functions for the main circulation circuits required to configure the control loops of the experimental SWHS.

2. Schematic diagram of the modeled SWHS

The considered peak heating load for the designed SWHS (Figure 2) was set at 150 kW. The project of the model implies an addition of the vapor compression heat pump (VCHP) with maximum generation capacity of 55 kW and 15 kW electric drive compressor load. The temperature of filtered showers dump water is about 25°C and therefore it is acceptable to use it as the source of heat.

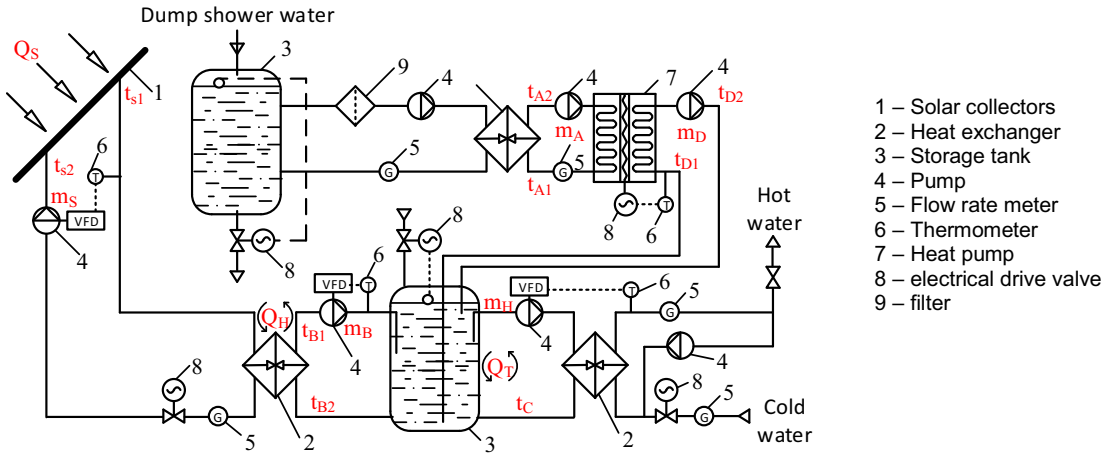

Fig. 2 – Schematic diagram of the modeled SWHS, with VCHP and dumb water heat source

Such complex solution gives the best cost effectiveness within the system lifetime. In addition, it is rather ecologically friendly because the backup source of heat is non-generated wasted energy, which supports the solar system. In addition, the proposed scheme allows the application of ventilation system in order to regenerate even more heat for the storage tank. Both the down hot water and the ventilation emissions from the facility can be the low-temperature heat sources for the HP. Inclusion of an additional buffer storage tank is highly recommended to redistribute load between SWHS and HP.

Selection of the most optimal version of scheme for the heat generating complex with reversible HP is the key issue of the described analysis. Several designs of the combined SWHS were carried out and compared with the practically modeled data. Analytical approach to the dynamic SWHS model has a number of practical advantages. The described further steps explain the performed elements analysis and ensure the necessary links between the basic units. Reflected communication between the physical parameters of different contours describe the potential problems for practical implementation. An absence of such problems in any analyzed model would therefore mean the most optimal performance within the modeled parameters.

3. System modeling

3.1 Solar collector

Solar heat absorption Q_S is changing during daylight hours, and also depending on the time of year. The equation $Q_S = f(\tau)$ represents an integral function varies with the special characteristic of the area, taking into account the specification and location of the solar collectors. The energy balance equation for the solar collector is:

$$Q_S + \dot{m}_S \cdot C_{pW} \cdot (t_S - t_S) = \dot{m}_S \cdot C_{pW} \frac{dt_{S_2}}{d\tau}, \qquad \text{(eq. 1)}$$

where $\dot{m}_1$ is the mass flow rate over the solar collectors circuit.

3.2 Recuperative heat exchanger

The following equations represent the changing of temperature of the heat transfer agent, neglecting the heat loss from the surface of the heat exchanger into the environment:

$$\dot{m}_S C_{pW}(t_{S1} - t_{S2}) - Q_H = \dot{m}_S \cdot C_{pW} \cdot \frac{dt_{A2}}{d\tau} \; ; \qquad \text{(eq. 2)}$$

$$\dot{m}_B C_{pW}(t_{B1} - t_{B2}) + Q_H = m_B \cdot C_{pW} \cdot \frac{dt_{B2}}{d\tau}, \qquad \text{(eq. 3)}$$

where Q_H is the heat transfer coefficient of the heat exchanger.

3.3 Storage tank

Water-filled tank is the heat storage system. The cold medium draws in at the bottom and accumulated in the upper zone hot water supplies the domestic demand. Overall, the model of the tank consists of two or more containers that exchange the heat through conventional stepped septum membrane.

The following energy balance equations represent the top and the bottom of the tank respectively:

$$\dot{m}_{T01} t_{T01} C_{pW} + \dot{m}_B t_{B1} C_{pW} - \dot{m}_H \cdot t_H C_{pW} - Q_T = \dot{m}_{TH} C_{pW} \frac{dt_{TH}}{d\tau}; \quad \text{(eq. 4)}$$

$$\dot{m}_{T02} t_{T02} C_{pW} - \dot{m}_B t_{B2} C_{pW} + \dot{m}_C \cdot t_C C_{pW} + Q_T = \dot{m}_{TC} C_{pW} \frac{dt_{TC}}{d\tau}. \quad \text{(eq. 5)}$$

Heat transfer within the water volume is fixed by $Q_T = V_T \cdot K_{HM}(t_{TH} - t_{TC})$, where V_T- volume of the tank, K_{HM} – heat and mass transfer coefficient. The coefficient depends on the temperature range and on the geometric characteristics of the tank.

3.4 Heat pump

The HP is the plate heat exchanger with two sections separated by an intermediate wall with simultaneous heating and cooling inside. The heat transferred from the cold section Q_C and heat transferred to the heated agent Q_{HP} is the function of the power drive of the compressor P_{HP} : $Q_{HP} = Q_C + P_{HP}$. The energy balance equations for the heat transfer inside of the HP are:

$$\dot{m}_A \cdot C_{pW}(t_{A2} - t_{A1}) - Q_{HP} = \dot{m}_A \cdot C_{pW} \cdot \frac{dt_{A1}}{d\tau}; \qquad \text{(eq. 6)}$$

$$Q_{HP} - \dot{m}_D C_{pW}(t_{D2} - t_{D1}) = \dot{m}_D \cdot C_{pW} \cdot \frac{dt_{D2}}{d\tau} \qquad \text{(eq. 7)}$$

Power to drive of the compressor is the variable parameter. The COP of the HP therefore varies due to changes in temperature of the condenser and evaporator.

3.5 Important notice for the system of equations

The simplified model can consist of only main equations mentioned above, interacting with each other. For the additional analysis, further input elements must have sufficient number of known parameters to satisfy both mathematical solution logics and thermodynamics laws.

The unified Runge-Kutta method was applied in MathLab software to conduct the approximated modeling of the observed system of equations.

4. Verification of the results

The modeled parameters were confirmed by comparison with the experimental data. The gathered data were obtained from the field tests of the combined SWHS, installed on the roof of campus building of the Far Eastern Federal University, Far East of Russia. The variation of main parameters of the observed SWHS with the given thermal generation is represented on Figure 3.

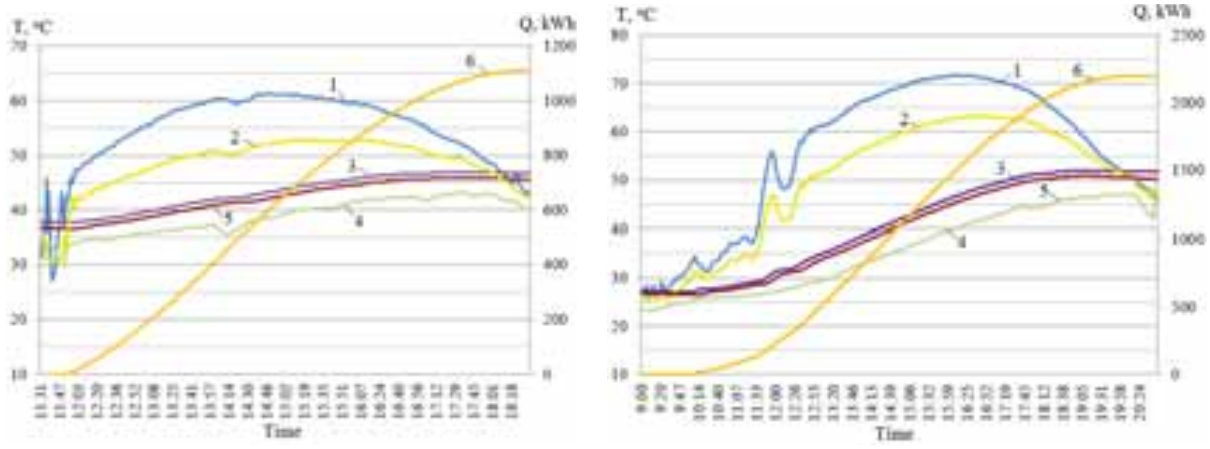

Fig. 3 - Experimental curves of the experienced SWHS from data gathered in January(a) and in July (b): 1 - temperature of the collector; 2 – temperatures of the first heat exchanger, collector agent circuit; 3 - average temperature of the tank; 4 – temperatures of the supply hot water; 5 – temperature at the bottom of the tank; 6 – cumulative solar heat gain.

The shown graphs describe the typical operaton cycle of the practical SWHS in cloudy day of summer (07/05/2012) and in snowy day of winter (01/17/2013).

In simplified view, the daily solar radiation function is an approximated sinusoidal dependence: $Q_S = Q_{S\,max} \cdot \sin(\tau)$. Also, it might be set by the parabolic function $Q_S = Q_{S\,max} \cdot (a\tau 2 + b\tau)$, where $Q_{S\,max}$ is the maximum density of solar radiation during the day.

Comparing with the modeled case, Figure 4 shows the output curves for the simulated 70 kW system with the same input data, and for the optimized system with the increased number o fsolar collectors, doubled volume of storage tank, and implemented 40 kW HP.

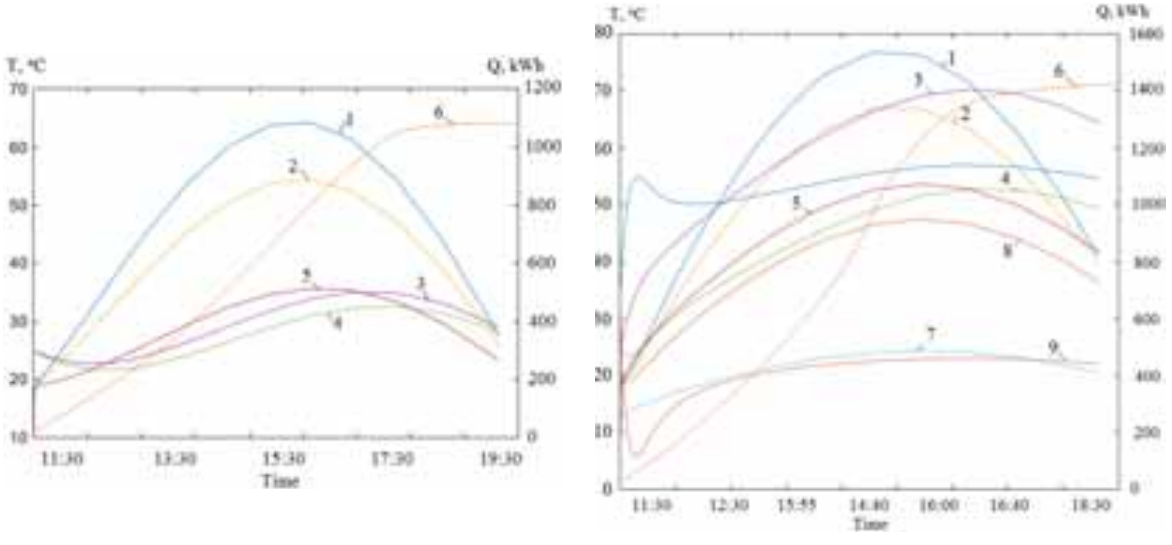

Fig. 4 - Transition functions of temperature changes in the solar collectors, heat exchangers and in main storage tank of the modeled SWHS (a – without HP, b – with the HP): 1 - the temperature of the collector; 2 – temperatures of the first heat exchanger, collector agent circuit; 3 - average temperature of the tank; 4 – temperatures of the supply hot water; 5 – temperature at the bottom of the tank; 6 – cumulative solar heat gain.

The represented model shows reliable accuracy due to the matching of transient processes curves with the obtained from the experienced SWHS curves. The model can identify the types of transition functions for the main circulation circuits required to configure the control loops of the experimental SWHS.

5. Description of the automatic control system

The modeled parameters of management actions are:

- mass flow rate regulation of the liquid in the solar circuit,
- HP power control,
- supply water flow rate control,
- water level control at the storage tank.

The operational disturbing influencers are:

- solar radiation changes at the collector surface,
- hot water demand changes,
- temperature changes of showers dumb water.

Figure 5 shows the block diagram of the control and measuring complex, which carried out the registration and recorded parameters on the main computer and automatically controlled the experimental SWHS during the tests.

Monitoring and recording environmental parameters and capacity of solar radiation incident on a horizontal and inclined surfaces produces automatic weather station Weather Station. In addition, accurate recording of direct solar radiation was carried out digital display solar radiation SOLRAD.

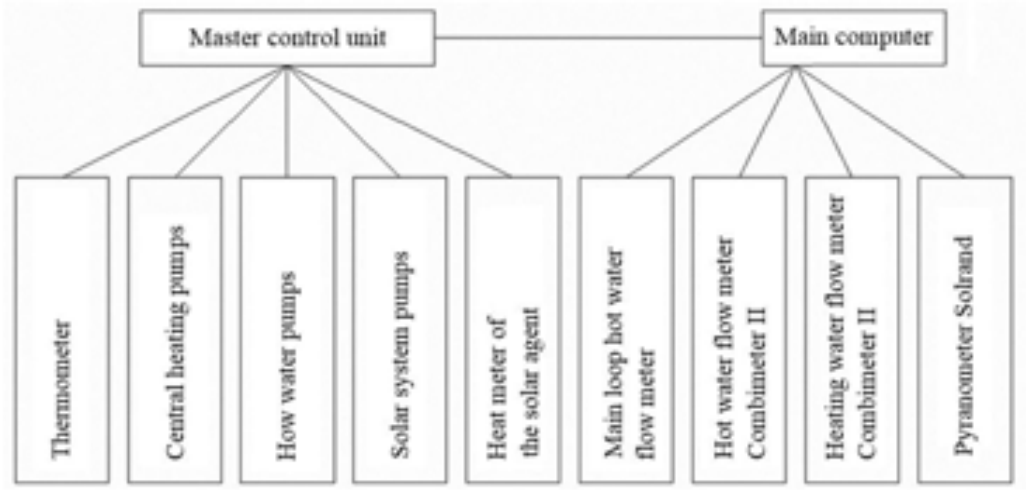

Fig. 5 - Measuring complex of the experimental SWHS

All electrical equipment for the experimental SWHS was tested and processed into the MS Excel spreadsheets.

6. Findings

1. One of the most effective and optimal scheme of SWHS is the combined solar thermal system with vapor compression heat pump (connected to two different low-temperature heat source).

2. Mathematical model improves the practical research findings. The tested method describes thermal processes of production, storage and transport of heat in the system, which can involve both series and parallel connection types, various sources of heat, and fluctuations of solar radiation intensity during the day. The model can also take into account the daily and seasonal changes in the thermal load of the consumer.

3. Comparative analysis of the experimental and calculated output characteristics data has shown the accuracy of the developed method.

Abstract

Solar Domestic Hot-Water Systems can be a useful tool to reduce the energy consumption and on-peak power demand. This is particularly important in the case of Brazil where water heating in most cases is done using electrical showerheads with high installed power and low load factor. Consumers and utility companies have conflicting interests: reducing the electricity bill and shave the on-peak consumption. In the present work, these two interests were weighted and put together in the same objective function in order to find the trade-off curve with the optimized design parameters (collector area, storage volume and set point temperature) of the solar system. The analysis is carry out by considering two different policies: rebate program and time-of-use tariff (TOU). The results of the first policy show the existence of a trade-off curve between the initial investment and the yearly electricity consumption, which can be used to size the monetary incentive used for rebating the initial cost of the SDHW system. On the other hand, the results of the second policy shows a trade-off curve between the annualized life cycle cost of the system and the yearly on-peak electricity consumption, which can be used to size the TOU tariff as a function of the commitment of the utility company on reducing the on-peak electricity consumption.

1. Introduction

Brazil owns one of the largest hydropower potential in the world (IEA, 2012a, 2010), because of that it currently represents the largest share on country´s electricity matrix. In fact, electricity from renewable sources currently holds a share of about 80% (70.6% hydropower, 7.6% Biomass and 1.1% wind) (EPE, 2014). This scenario of strong dependence of the hydropower makes the grid very sensitive to the seasonal rain cycles. Long periods of drought have depleted water reservoirs in 2013 and 2014, reducing the security of the system and increasing the electricity costs.

In addition, 73% of the dwellings use electric showerheads for bathing (EPE, 2012). Because of the high consumption rate, this device represents about 24% of the residential electricity consumption. As a result, roughly 5.5% (33.7 TWh/year including losses) of the electricity consumption is due to the electric showerheads (ELETROBRAS, 2007). Averaging this value on a daily basis, a daily electricity consumption of about 92.4 GWh/day is accounted. Setting this result to the statistical load profile of the residential sector (ELETROBRAS, 2007), a power load curve for this device can be estimated, as shown in Figure 1a. As depicted by this figure, electric showerheads are indicated as responsible for the two peaks on the residential electric demand profile, between 5-9 AM and 5-9 PM, with values around 11 and 14 GW, respectively. It is

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.10.27 Available at http://proceedings.ises.org

worth noting that on-peak consumption to supply the electric showerheads use in Brazil is an amount equivalent to the installed capacity of Itaipu, the second largest power plant in the world. Therefore, the electricity grid must be designed for supplying this peak, implying in high transmission and distribution costs for the system operator and utility companies.

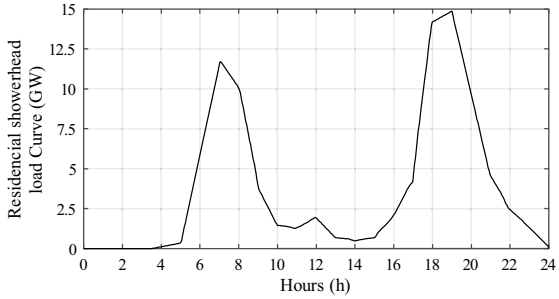

Fig. 1: Estimated showerhead load curve for Brazil.

The solar heating and cooling technologies can have an important role to play in realizing targets in energy security and economic development, especially the solar domestic hot water system, which is the most mature technology being used in a large scale since the 1960s (IEA, 2012b). This is not different for Brazil, the large-scale deployment of solar hot water system, could not only reduce the energy consumption that electric showerheads represents, but also reduce around 35 % of the on-peak power demand over the grid.

Currently, Brazil is the sixth country in total installed capacity of solar thermal collectors (IEA, 2012b). In fact, the energy supplied by solar thermal collectors currently operating in Brazil is around 4.3 GW_{th} per year, which accounts for only 3.6% of the dwellings in Brazil (EPE, 2012). As observed in other countries, a strong increase in the deployment of solar hot water heating could be achieved by introducing long-term subsidy schemes or solar obligations. According to (IEA, 2011), Brazil has a solar thermal target of 15 million m² installed in 2015, from about 7 million m² in 2011, however financial support and public policies are restricted or inexistent. In this context, this paper assesses the feasibility of thermosyphon and forced-circulation solar domestic hot-water systems (SDHWs) submitted to two different policies: a rebate program and time-based tariff. For each policy, the systems are designed in terms of the solar collector area, the thermal storage volume and the set point temperature for the in-tank heater

The main goal of these policies is to promote the use of SDHWS, considering the interest of both, consumer and energy supplier. Therefore, the system needs to be cost-effective in the point of view of the consumer (i.e. reduce the energy consumption) and for the system operator and utility companies (i.e. reduce the peak consumption).

The first policy consists of a rebate program, aiming to assist low-income consumers to acquire proper SDHWs by means of rebating or partial financing the initial cost. This will be led by the electric utilities, since they have interest in reducing on-peak consumption (Borges et al., 2005). Therefore, this case presents the optimization regarding the on-peak consumption and the acquisition cost of SDHW. This yields a Pareto frontier that is used as a tool for sizing financial incentives to acquire a solar energy system (Liu et al., 2010).

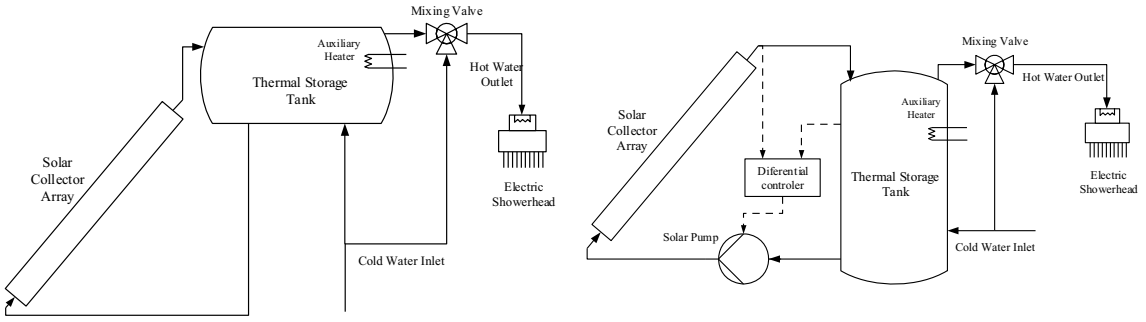
In the second policy, a time-of-use tariff for the electricity is established to discourage the consumption on-peak hours (Borges et al., 2004; Borges, 2000). Thus, the on-peak consumption and Annualized Life Cycle Costs (ALCC) are optimized to find the trade-off between paying for the electricity at on-peak hours and the increase in the ALCC due a large investing in a SDHWs. In addition, an ideal value for the time-of-use tariff can be established based on how much the distributor is committed on reducing the peak consumption (Salazar, 2004).

The proposed methods are assessed through a multi-objective optimization that considers the relevant figures in both cases, which are evaluated by a long-term transient simulation routine. A case study is presented, regarding thermosyphon and forced-circulation SDHWs for Florianopolis – Brazil, considering the two policies under different scenarios. Moreover, two levels of daily hot water consumptions were considered, 0.2 and 0.4 m^3 at 40 ºC, in order to analyze the sensitivity of the results for different hot-water demands.

2. System description

Two types of SDHWs are considered: thermosyphon and active (forced-circulation), as depicted in Figure 2. Thermosyphon systems, which work by natural circulation, are common in warm climates due the low probability of freezing, operational reliability and lower costs. This system avoids the use of pumps and dedicated control systems, however, the thermal storage needs to be placed at a higher position than the collector, and therefore is common to place it on the roof, limiting its size because of its weight and piping pressure drops.

Forced-circulation systems on the other hand, use a pump to circulate the water from the storage through the collector, allowing more flexibility on the installation of thermal storage, e.g it could be installed inside the house. Nevertheless, these systems are more complex, since they require a water pump and a differential temperature controller to ensure the proper operation of the system.



(a) (b)

Fig. 2: Schematic diagram of the solar domestic hot water; (a) thermosyphon, and (b) forced-circulation.

The solar collector and thermal storage tank considered are identical for both systems, which specifications are presented in Table 1. The specifications of the solar collector were taken from (INMETRO, 2015), considering a class A solar collector randomly chosen. Meanwhile, the configuration of the thermosyphon system are shown in Table 2, and the main features of the forced-circulation system are shown in Table 3. It is worth to mention that in both systems water is used as heat transfer fluid and no heat exchanger is considered.

Tab. 1: Specification common to both system considered.

Parameter	Values
Collector slope, β, (°)	37.6
Intercept efficiency, a_o, (-)	0.728
Efficiency slope, a_1, (W/m^2K)	6.18
Incidence angle modifier coefficient, b_0, (-)	0.1065
Tested flow rate, F_{test}, (kg/m^2h)	60
Thermal storage shape factor, S, (-)	0.5
Thermal storage insulation thickness, e_i, (m)	0.05
Thermal storage insulation conductivity, k_i, (W/mK)	0.126
Thermal storage maximum auxiliary heating rate, P_{tank}, (kW)	3

Parameter	Value
Ration between utilized and test flow rate, R_{ca}, [-]	0.5
Upper temperature difference to trigger the solar pump, T_{on}, (°C)	6
Lower temperature difference to trigger the solar pump, T_{off}, (°C)	0.4

Some of the simulation parameters used in the systems are function of the design parameters (i.e. solar collector area and thermal storage volume), and need to be calculated in each iteration of the optimization process. These parameters are, thermal storage overall heat loss coefficient, thermal storage diameter and height, positions of the thermal storage thermostat and heating element, length of the solar collector and inlet piping length, number of parallel solar collector risers and maximum flow rate for the solar pump. The equations used to calculate these parameters were described in detail by Borges, (2000); Salazar, (2004)

It is worth noting that two auxiliary energy heaters were considered for both system, one inside the thermal storage and other in line to the load. The second one works as an electric showerhead and was considered in the simulation model just to ensure a comfortable water temperature for the users, in the case of the solar energy and the auxiliary heater of the tank were not able to supply the load.

The thermal performance of the SDHWs depends significantly on the domestic hot water load profile. In addition, it is impractical consider the daily and consumer variation, thus the suitable solution is to use a repetitive load profile (Kalogirou and Tripanagnostopoulos, 2006). In this paper, a statistically representative load profile was used, as depicted in Figure 3 in terms of a normalized figure. This profile was experimentally determined in a previous study (Salazar, 2004), where a group of ninety families were studied, by monitoring their electrical consumption of showerheads in one year period.

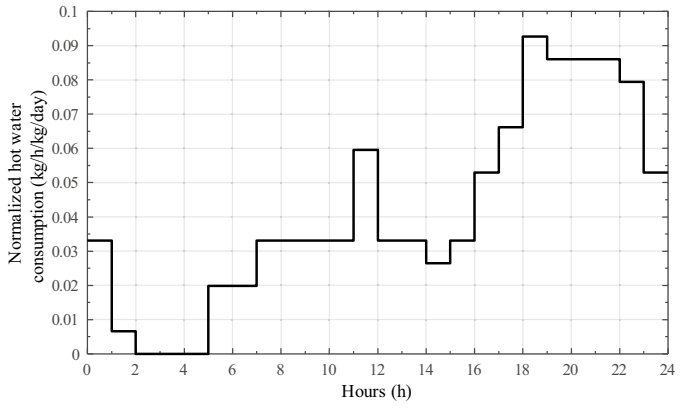

Fig. 3: Hot water daily consumption profile.

3. Methodology

The annual thermal performance and economic assessment, of both systems types, are determined by a transient simulation model. For that purpose, the Transient System Simulation Program (TRNSYS) (Klein, 2010) was used. Predicting the performance of solar systems by using simulation methods requires weather data input from the location where the system was installed. Therefore, the TMY file available from SWERA database (SWERA, 2013) for Florianopolis (27.6°S/48.5°W) was employed in this study.

The performance of the thermosyphon system was calculated through the (Morrison and Braun, 1985) model, whereas the one-tank forced-circulation system was considered as a stratified thermal storage with fixed inlet (Cooper et al., 1975). In addition, the auxiliary energy supply were simulated as electric heaters with a fixed thermal efficiency and with a maximum power (Table 1). Therefore, the actual power is modulated to meet the specified set point temperature.

Each system needs to be proper sized when submitted to two different policies that can be expressed as objective functions. Thus, an optimization routine was applied to the systems considering three design parameters as independent variables: the solar collector area, the thermal storage volume and the set point temperature for the in-tank heater. The combination of an optimization routine with a life-cycle simulation of a solar system was extensively explained by Borges et al., (2005).

Since the two used policies consider conflicting objectives between the consumer and the energy supplier, a weighted global criterion method was employed to accurately represent the behavior of these objectives in the optimization problems. With the weighted global criterion method, it is possible to solve a single objective by assigning relative weights (φ) to the conflicting ones (Borges et al., 2004, 2005; Marler and Arora, 2004)

The Generic Optimization Program (GENOPT) was used for the multi-objective and multi-parameter optimization, since it can be easily coupled with TRNSYS. This software has a large optimization algorithm library from which the hybrid algorithm of the Particle Swarm Optimization algorithm and the Generalized Pattern Search implementation of the Hooke-Jeeves algorithm (GPSPSOCCHJ) were selected. This decision is adequate for specific features of problems in which the objective function is not continuously differentiable, or it must be approximated, which is the case of the thermal simulation routines analyzed. Therefore, the design parameters can be only solved heuristically (Wetter, 2008).

3.1. Rebate program

The rebate program considers that the two conflicting objectives are the on-peak yearly energy consumption $\left(E_{peak}\right)$ and the initial investment of the solar system (IC), where the on-peak period is from 5 to 9 PM. Therefore, the optimization problem can be defined as follows,

$$\min_{\vec{x}} \left\{ f(\vec{x}) = (1 - \varphi)\frac{\mathrm{E_{peak}}(\vec{x})}{E_{peak,max}} + \varphi\frac{\mathrm{IC}(\vec{x})}{\mathrm{IC_{max}}} + \mathrm{C_1P_1}(\vec{x}) + \mathrm{C_2P_2}(\vec{x}) \right\}$$

$$\begin{aligned} &Subject\ to: \\ &\vec{x} \in S \\ &\mathrm{P_1}(\vec{x}) = \begin{cases} 0, & if\ ALCC \le ALCC_{limit} \\ \left(ALCC_{limit} - ALCC(\vec{x})\right)^2, & otherwise \end{cases} \\ &\mathrm{P_2}(\vec{x}) = \sum_t \begin{cases} 1, & if\ T_{cons}(\vec{x}) < T_{ideal} \\ 0, & otherwise \end{cases} \end{aligned} \qquad \text{(eq. 1)}$$

where S is the feasible region defined by the solar collector area (A_c), thermal storage volume (V_{tes}) and set point temperature for the in-tank heater. $E_{peak,max}$ and IC_{max} are the maximum values of the on-peak yearly energy consumption and initial cost possible on the feasible region, which were used to rewrite the two

conflicting objectives in a non-dimensional form. To do so, the optimization software was employed to find the maximum feasible values for each of the objectives, before the objective function were implemented in the simulation environment.

Two constrains were considered in this optimization problems, the first is used to guarantee that the annualize life cycle cost of the system $(ALCC)$ will be less than a specified value $(ALCC_{limit})$, and the second is used to guarantee that the system supplies water at the desired temperature (T_{ideal}). This constrained optimization problem was solved using a penalty method. (i.e. a constant value is added in the objective function when the constrained event is triggered), which are the two last terms on the right of the equation 1 ($C_1P_1(\vec{x})$ and $C_2P_2(\vec{x})$).

Since the relative importance of each conflicting function is not known, the domain of φ is divided in a series of discreet values and single objective optimizations were run for each value of φ. The results of this analysis can be presented by a curve (Pareto frontier) representing the initial cost versus on-peak yearly energy consumption. This curve is used as a tool for sizing financial incentives to acquire a system, as a solution for decreasing the on-peak power consumption. The methodology and the economic assumptions used for calculating the $ALCC$ and IC are described in the section 3.3.

3.2. Time-of-use tariff

For this policy, the two conflicting objectives considered are the on-peak yearly energy consumption and *ALCC* of the system. The period between 5 and 9 PM was considered as on-peak for applying the higher electricity tariff. In addition, the constraint used to guarantee that the system supply water is in the desired temperature to the consumers (T_{ideal}) is also considered. Therefore, the optimization problem can be defined as follows,

$$\min_{\vec{x}} \left\{ f(\vec{x}) = (1-\varphi)\frac{E_{peak}(\vec{x})}{E_{peak,max}} + \varphi\frac{ALCC_0(\vec{x})}{ALCC_{0_{max}}} + C_2P_2(\vec{x}) \right\}$$

$$Subject\ to: \quad \vec{x} \in S \qquad \text{(eq. 2)}$$

$$P_2(\vec{x}) = \sum_t \begin{cases} 1, & if\ T_{cons}(\vec{x}) < T_{ideal} \\ 0, & otherwise \end{cases}$$

where $ALCC_0$ is the annualized life cycle cost considering only the nominal value of the electricity tariff (C_e) and $ALCC_{0_{max}}$ is the maximum annualized life cycle cost possible on the feasible region. The equation 2 considers only the nominal tariff, in order to minimize the number of optimization runs. Different values of the tariff were considered in a post-processing procedure, in which the following equation was used,

$$ALCC(\vec{x}) = ALCC_0(\vec{x}) + E_{peak}(\vec{x})C_{e,TOU} \qquad \text{(eq. 3)}$$

where $ALCC$ is the total annualized life cycle cost, considering the time-of-use tariff - $C_{e,TOU}$, defined as the surcharge value added to the nominal electric tariff (C_e) during the on-peak hours. This approach removes the need of run the optimization routine for each time-of-use tariff. It is worth mention that in the case of a null value for the time-of-use tariff, the expression is reduced to $ALCC(\vec{x}) = ALCC_0(\vec{x})$.

Hence, the results of this analysis can be presented by a curve of $ALCC$ versus E_{peak}, for different values of the time-of-use tariff, showing the trade-off between paying for the electricity at on-peak hours and the increase in the $ALCC$ due a large investment on a SDHW.

3.3. Economic Figures

In order to determine the economic figures derived from the optimization processes, the life-cycle cost analysis

was considered according to (Duffie and Beckman, 2013),

$$LCC(\vec{x}) = (1 + C_{inst})IC(\vec{x})[1 + C_m PWF(N, i_m, d)] + PWF(N, 0, d)E_{aux}(\vec{x})C_e \quad \text{(eq. 4)}$$

where C_{inst} is the installation cost as a percentage of the initial cost, C_m is the annual maintenance cost as a percentage of the installed cost of the system, E_{aux} is the total auxiliary yearly energy consumption, PWF is the present-worth factor, N is the lifetime of the system, i_m is the maintenance inflation rate and d is the discount rate. In order to analyze the system on a yearly basis, the life-cycle cost can be annualized by the following equation,

$$ALCC(\vec{x}) = \frac{LCC(\vec{x})}{PWF(N, 0, d)} \quad \text{(eq. 5)}$$

Finally, the initial cost can be calculated as follows,

$$IC(\vec{x}) = (C_c A_c + C_{tes}(V_{tes}) + C_a P_{tank}) \quad \text{(eq. 6)}$$

where C_c is the solar collector cost per area, A_c is the solar collector area, C_{tes} is the thermal storage cost as a function of the storage tank volume (V_{tes}), C_a is the cost of the heating element per power and P_{tank} is the electric power of the auxiliary heater in the thermal storage.

The economic parameters considered herein are representative of the Brazilian market at the time of the study and listed in Table 4.

Tab. 4: Economic and cost considerations.

Parameter	Value
Solar system life cycle, N, $(years)$	20
Discount rate, d (%)	8
Maintenance inflation rate, i_m (%)	6.4
Solar collector cost, C_c $(€/m^2)$	119.25
Heating element cost, C_a $(€/kW)$	6.9
Annual maintenance cost, C_m $(\%\ of\ installed\ cost)$	1
Installation cost, C_{inst} $(\%\ of\ initial\ cost)$	15
Nominal value of the electric tariff, C_e $(€/kWh)$	0.1385
Exchange rates for Euro at March, 2014 , u $(BR\$/€)$	3.48

The cost, in euros, of the thermal storage (C_{tes}) was considered in the analysis by a regression model based on the prices of tanks with different volumes obtained of the main suppliers in the Brazilian market, as follows,

$$C_{tes}(V_{tes}) = \frac{1}{u}(4798.8V_{tes} - 2889.8V_{tes}^2 + 1196V_{tes}^3 - 216.9V_{tes}^4 + 14.911V_{tes}^5) \quad \text{(eq. 7)}$$

4. Results

The results of the case study are presented for Florianopolis – Brazil (27.6°S/48.5°W), considering the thermosyphon and forced-circulation SDHWs, where two levels of daily hot water consumptions were considered, 0.2 m^3 and 0.4 m^3, both at 40 ºC. These values were chosen because they can represent low-income consumers and standard consumers, respectively.

Regarding the rebate program, eight values of the $ALCC_{limit}$ were considered 130, 185, 200 and 215 €/year for low-income scenario, and 260, 370, 400 and 430 €/year for the standard consumer scenario. On the other hand, four values of the time-of-use tariff were considered in the time-based program: 0, 0.5, 1 and 2 €/kWh. Where these values are added to the nominal value of the electricity tariff in the period between 5 and 9 PM.

4.1. Rebate program

The trade-off between initial cost and yearly on-peak electricity consumption for an $ALCC_{limit}$ of 215 and 430

€/year, for the scenarios of 0.2 m³ and 0.4 m³ respectively, is depicted in Figure 4. Each point of these curves represent a result of the optimization process, with different design values that simultaneously minimize the weighted combination of the yearly on-peak electricity consumption and initial cost.

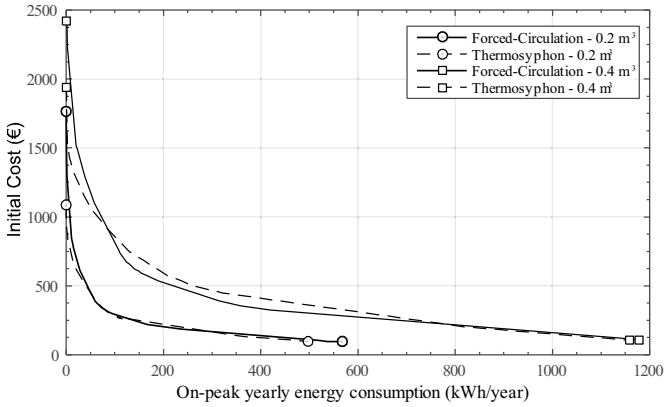

Fig. 4: Trade-off curves between initial cost and yearly on-peak electricity consumption obtained by the rebate program for an $ALCC_{limit}$ of 215 and 430 €/year for the scenarios of 0.2 m³ and 0.4 m³, respectively.

Three regions can be identified in figure 4, on the left, with high initial cost and low yearly on-peak electricity consumption there is the adverse region for the consumer, where a decrease in the on-peak electricity consumption represents a large increase on the initial cost. In contrast, on the right is observed the adverse region for the utility companies, characterized by low initial cost and high yearly on-peak electricity consumption, in this region a decrease on the initial cost represents a large increase on the on-peak electricity consumption. Finally, between these two regions, the negotiation region is observed, depicted by a small increase on the initial cost which represents a large reduction on the on-peak electricity consumption.

Within the negotiation region, systems with 0.2 m³ of daily consumption, show an increase from 150 to 250 € on the initial cost, providing a reduction from 325 to 125 kWh/year on the yearly on-peak consumption. It means that rebating 40% on the initial cost (100 € of 250 €) will provide a reduction of 62 % in the on-peak consumption, a result highly interesting for the utility companies.

Regarding the systems with 0.4 m³ of daily consumption, an increase from 300 to 400 € in the initial cost, gives a reduction between 500 to 300 kWh/year on the yearly on-peak electricity consumption. Meaning that rebating 25% on the initial cost (100 € of 400 €) will provide a reduction of 40 % on the on-peak consumption.

Finally, it is worth noting that for 0.2 m³ of daily consumption of hot water, both thermosyphon and forced-circulation systems present similar results. Moreover, for 0.4 m³, the forced-circulation system present lower values of on-peak yearly electricity consumption for the same initial cost. That result indicates that the forced-circulation system could be more effective in reducing the on-peak consumption, however, these are minor differences.

Figure 5, shows the effect of the $ALCC_{limit}$ in the trade-off curves for both the thermosyphon and forced-circulation systems, for the case of 0.2 m³ of daily consumption. It can be noticed that the limitation on the $ALCC$, reduces the domain of solutions that met the objective function, therefore, reduces the size of the trade-off curves and the negotiation region.

The proposed methodology helps defining the monetary incentive used for rebating the initial cost of the SDHWs, however, the proper size of this incentive can be only defined by the utility company and with its commitment in reducing the on-peak consumption.

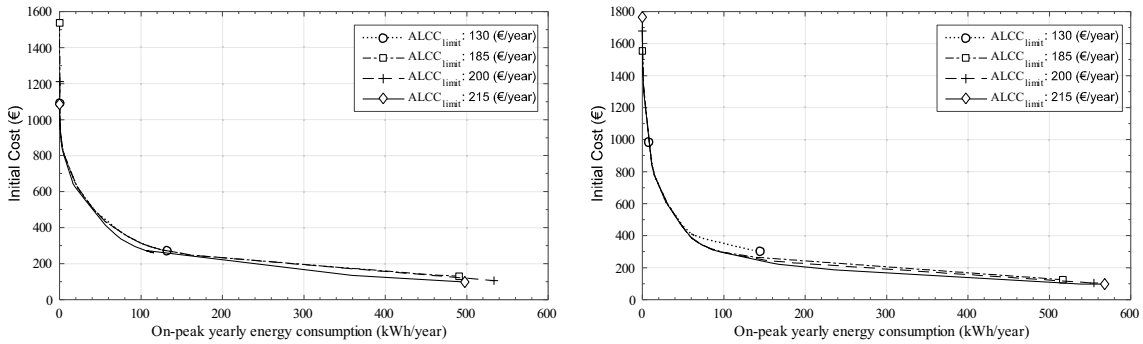

Fig. 5: Effect of the $ALCC_{limit}$ in the trade-off curves of the rebate program for thermosyphon (a), and forced-circulation (b) systems for a 0.2 m³ of hot water consumption.

4.2. Time-of-use tariff

The trade-off between the annualized life cycle cost of the system and the on-peak yearly electricity consumption are shown in Figure 6, where curves for the thermosyphon and forced-circulation are observed. The curves represented by a null value of time-of-use tariff (TOU tariff) were obtained by the optimization process using equation 2. On the other hand, the other curves were calculated as a post-processing procedure using equation 3, which allows consider different values for time-of-use tariff.

It can be seen that the results are very similar for 0.2 m³ and 0.4 m³ of hot water consumption, where the difference is due to a matter of scale. Moreover, under this policy the thermosyphon system shows better performance, being more effective on reducing the on-peak yearly electricity consumption.

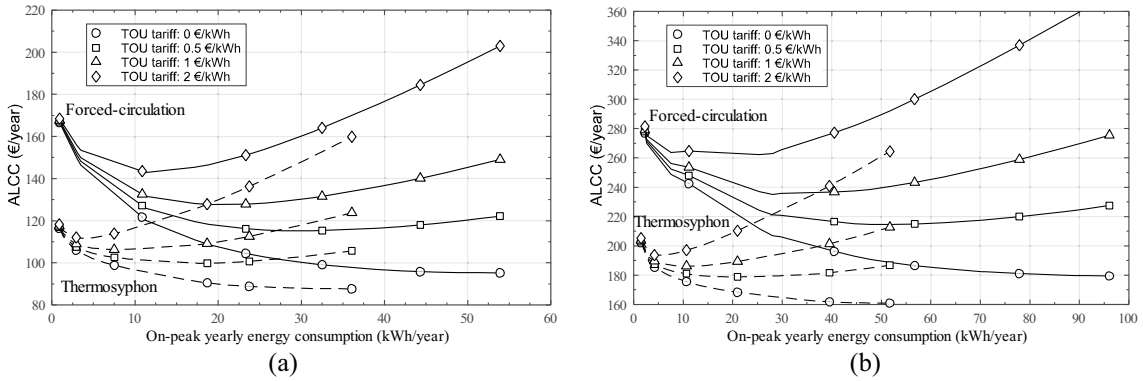

Fig. 6: The trade-off between the annualized life cycle cost of the system and the on-peak yearly electricity consumption for the thermosyphon and for-circulation system for 0.2 m³ (a), and 0.4 m₃ (b) of hot water consumption.

Regarding the different values of the TOU tariff, it can be noted that for each tariff exists a minimal value of the ALCC, indicating the optimal design for the consumer. Therefore, each minimal ALCC and its respective on-peak yearly electricity consumption can be calculated for each value of the time-of-use tariff. This is achieved by deriving the equation 3 with respect of the yearly on-peak consumption and equating to zero (minimal ALCC), as follows,

$$\frac{dALCC(\vec{x})}{dE_{peak}} = \frac{dALCC_0(\vec{x})}{dE_{peak}} + C_{e,TOU} = 0 \qquad \text{(eq. 8)}$$

where the $dALCC_0(\vec{x})/dE_{peak}$ can be calculated numerically or analytically if a regression model is applied in the $ALCC_0$ versus E_{peak} curve. Rearranging the equation 8, the intended time-of-use tariff $C^*_{e,TOU}$ can be calculated as follows,

$$C^*_{e,TOU} = -\frac{dALCC_0(\vec{x})}{dE_{peak}} \qquad \text{(eq. 9)}$$

This quantity can be plotted as a function of the on-peak yearly electricity consumption, as depicted in Figure

7. This methodology provides a tool for sizing the values of the time-of-use tariff in function of the commitment for reducing the on-peak consumption. Moreover, it is clear the existence of a negotiation region, where a small value for the TOU tariff can reduce in more than half the on-peak consumption.

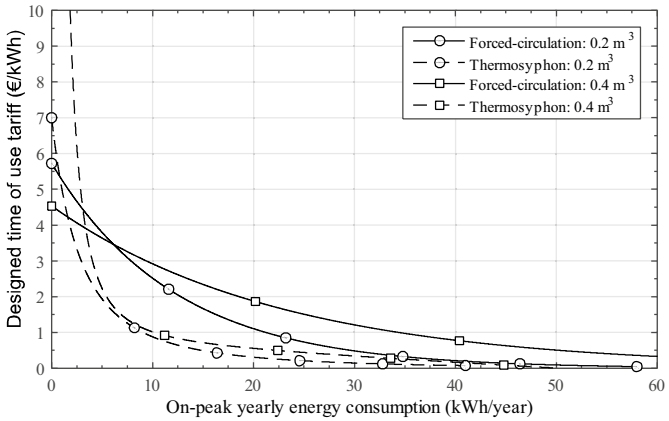

Fig. 7: Designed time-of-use tariff for the forced-circulation and thermosyphon system, considering both 0.2 m^3 and 0.4 $m^3$of hot water consumption.

Figure 7 shows that the designed values of the TOU tariff are similar for the thermosyphon system, regardless the level of hot water consumption. However, this trend is not observed for the forced-circulation system. When the system faces higher consumption, a higher TOU tariff is required to archive the same degree of reduction on the on-peak electricity consumption.

5. Conclusions

This work presented two methodologies for sizing financial policies for SDHWs, and measure its effectiveness on the reduction of on-peak electricity consumption. The approach analyzed herein considered the interest of both, consumer and energy supplier.

The first policy, rebate program, uses a trade-off curve between initial cost and yearly on-peak electricity consumption, where a clear negotiation region is identified. Therefore, it could be used as a design tool for defining the monetary incentive used for rebating the initial cost of the SDHW system, as a function of the commitment on reducing the on-peak consumption by the utility company

The second policy, time-of-use tariff, uses a trade-off curve between the annualized life cycle cost of the system and the yearly on-peak electricity consumption, for different time-of-use tariffs. This procedure shows the existence of a minimal value of the ALCC for each TOU tariff, indicating the optimal design for the consumer. Consequently, it is possible to determine the value of the on-peak yearly electricity consumption respective to the minimal ALCC, for each TOU tariff adopted. This yields a trade-off curve between the designed time-of-use tariff and the on-peak yearly electricity consumption, which helps to size the TOU tariff as a function of the commitment of the utility company on reducing the on-peak electricity consumption.

Abstract

This paper presents initial result of measurement and experimental work in smoky and dusty location of Ger district, Ulaanbaatar Mongolia, as well as some problems while using the solar water heating system for residential heating in Mongolian harsh and cold climate condition. By this research, the measurement devices were placed on the forced circulation evacuated tube solar collector system installed on the top of the residential house then the measurement had been done from December to April for last two years. As a result of this study, the average collector efficiency was 65.7 % and the system efficiency was 31.5 % in real condition during for the four months of measurements.

Keywords: *Mongolian harsh and cold climate, electric heater, evacuated tube solar collector, residential house, Ger district.*

Explanation: Ger district where more than half of the capital's residents live without access to basic public services like water, sewage systems and central heating.

1. Introduction

Converting solar energy into thermal energy is useful in Mongolia where lots of thermal utilizations are. Because, thermal energy is indispensible to all residential houses due to the average ambient temperature during the most months is below +2 ^{0}C in Mongolia. On the other hand, Mongolia has much solar resource for example the annual sunshine duration is about 2900 to 3300 hours [1] and yearly solar radiation is about 1450 to 1840 kWh m^{-2} year $^{-1}$ [2].

Type of equipments that converts solar energy into thermal energy such as flat plate and evacuated tube solar collector is rarely used in Mongolia. The reasons are up to now the capacity of recent solar collectors for the whole year has not been estimated accurately in Mongolian actual condition, also high initial investment of it is not attracting consumer's interest.

In recent years, the air pollution has been evidently increasing in populated Ulaanbaatar city, because of the number of households in Ger district who burn raw coal to heat their house have been growing. It is confirmed by several studies such as The World Bank Studies [3]. This is a sign of expressing that it is time to refuse raw coal application and to use new resources of thermal energy which is harmless to the environment and productive for household's economics.

Another big concern for Ger district of Ulaanbaatar city is the deficit and improper infrastructure of electric power. As a result of it, to use an electric heater has difficulties in residential houses. But the main reason of coal burning still in use for heating in Ger district is because of expensive electric bill for long heating season. Therefore we began to seek most convenient and harmless heating system and started setting up some evacuated tube solar collector on a few objects for undergoing the operation in the winter time.

doi:10.18086/swc.2015.10.28 Available at http://proceedings.ises.org

Ultimate goals of this research work contain to research hybrid heating systems with solar water heating device in Mongolian harsh and cold climate condition for a long time, and to estimate efficiency of evacuated tube solar collector in the actual usage as well as to modify it for Mongolian climate condition and application feature. In this paper, we present a preliminary outlook of measurement and experiment that includes collector efficiency, system efficiency and some problems encountered in the real operation.

2. Methodology

2.1 System description

The measurement was done in the residential house with area of 54 square meter located in Chingeltei Ger district of Ulaanbaatar city (see **Fig. 1**). The solar water heating system combined with electric heater was installed on it in 2013. Since the end of 2013 the sytem has been used for house heating. The hybrid heating system consists of evacuated tube collector which contains four sections that have 120 pieces of heat pipe, heat storage tank that has capacity of 500 liter (see **Fig. 2**), auxiliary electric heater of 3 kW located in the heat storage tank, radiator system for heating the house, and the solar circuit pipes. The length of solar circuit pipes to supply is 11 meters (5 meters inside of the house and 6 meters outside) and the return pipe length is 12 meters (5 meters inside of the house and 7 meters outside) (see **Fig. 3**).

Fig.1: Overview of the experimental system

Fig. 2: The tank and controller of system

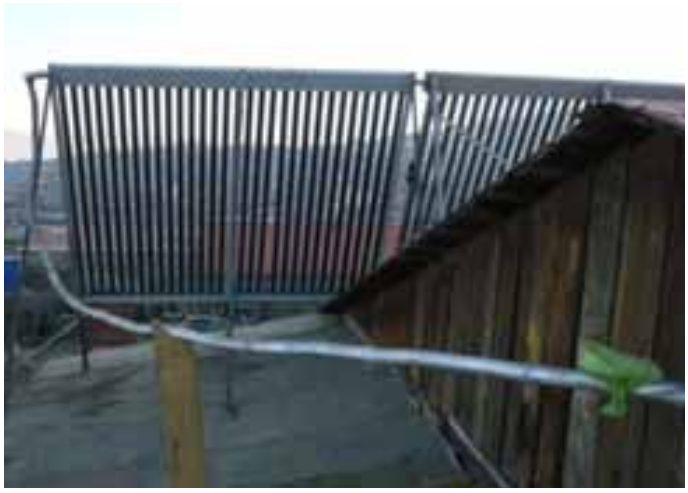

Fig. 3: Solar circuit pipe to return

2.2 Measurement and devices

Measurement was done twice in between from 2013.12.05 to 2014.04.11 and from 2014.12.03 to 2015.04.13. The following devices was used: flow meter (Ultrasonic-TDS-100), solar meter (Pyranometer-Ms-802), temperature sensors (Pt-100), power meter for measuring electrical consumption (Kyoritsu-Model-6300), data logger that stores and collects the data every 2 minute (Datamark-Ls-3000Ptv). The following temperatures such as ambient temperature (T_1), inside temperature of the house (T_2), solar fluid temperature at the collector outlet (T_3), solar fluid temperature at the collector inlet (T_4), solar fluid temperature at the tank outlet (T_5) and solar fluid temperature at the tank inlet (T_6) were measured (see **Fig. 4**).

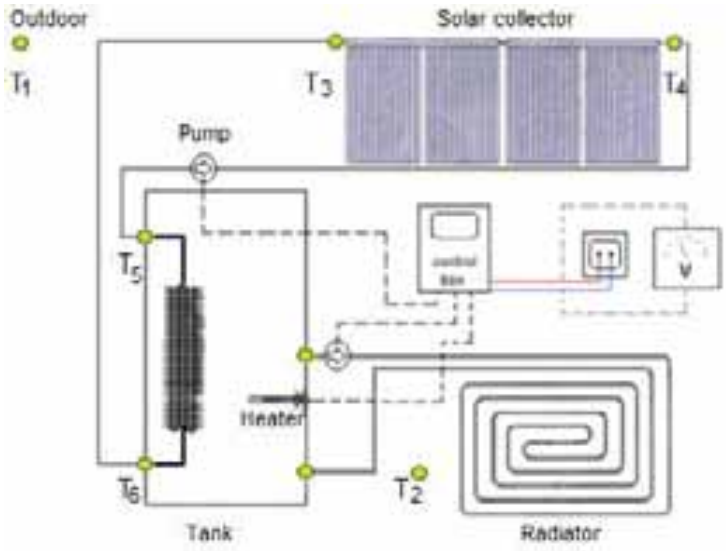

Fig. 4: The scheme of solar water heating system for house heating, and the green points indicate the temperature measurements

2.3 Calculation

Useful energy collected by the solar collector was calculated as:

$$Q_K = \dot{m}\, Cp\, (T_3 - T_4) \qquad \text{(eq. 1)}$$

To calculate the heat delivered in the tank, the solar fluid temperature data at the tank outlet and inlet was used:

$$Q_T = \dot{m}\, Cp\, (T_6 - T_5) \qquad \text{(eq. 2)}$$

The collector efficiency was calculated as:

$$\eta_K = \frac{Q_k}{A_c G} \qquad \text{(eq. 3)}$$

The system efficiency was calculated as:

$$\eta_S = \frac{Q_T}{A_c G} \qquad \text{(eq. 4)}$$

By these calculation methods above [4-6], the measurement data was processed on a specific day when the sky is more clearly. From every measured month the clearest sky day was selected. Then total daily energy collected by the solar collector and delivered to the tank was calculated on those days. As well as daily and monthly average collected and delivered energy was computed and compared. The measurement data from 2014.12.03 to 2015.04.13 used in the calculation.

3. Results and discussion

3.1 Performance of clear sky days

The days of 2014.12.13, 2015.01.21, 2015.02.15 and 2015.03.09 from every month measured were picked to compare daily energy performance. The daily global solar radiation on the collector's surface was 89 MJ day^{-1} on 2014.12.13, 110 MJ day^{-1} on 2015.01.21, 176 MJ day^{-1} on 2015.02.15 and 212 MJ day^{-1} on 2015.03.09. Daily useful energy collected by the solar collector was 64 MJ day^{-1}, 80 MJ day^{-1}, 128 MJ day^{-1} and 154 MJ day^{-1} respectively above. Daily heat energy delivered in the tank was 44 MJ day^{-1}, 43 MJ day^{-1}, 66 MJ day^{-1} and 73 MJ day^{-1}. Comparative estimate of daily energy was shown with **Fig. 5**.

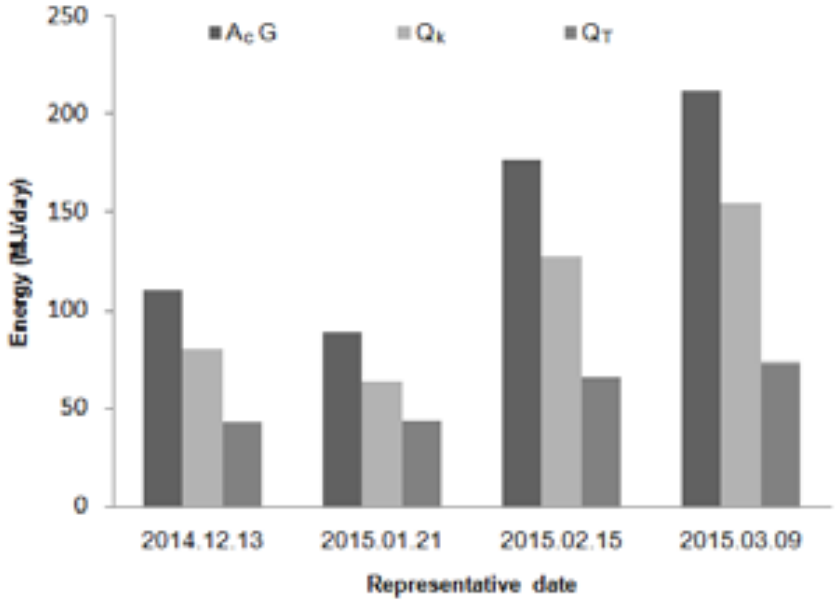

Fig. 5: Daily solar radiation on collector's total surface (Ac G), daily energy collected by solar evacuated tube collector (Q_k), daily energy delivered to the tank (Q_T)

3.2 Comparisons of the months

In this part of calculation, monthly total energy collected by the solar collector and total energy delivered to the tank wasn't computed, as we had lost some days' measurement data in February and March a few times because of capacity of data logger. In order to compare the performance of each month measured, the monthly average numbers were shown by percentage. Monthly average collector efficiencies were 64.9 % in December, 65.3 % in January, 66.1 % in February and 67.3 % in March. The reason why the collector efficiency about 65 % in December and January was, while the efficiency increased to about 67 % in February and March was connected with glass cleaning of the collector. The first half of the collector glass tube was wiped on February 11 and the rest of the part was cleaned on March 14.

Also monthly average system efficiencies were 38.5 %, 32.7 %, 27.9 %, and 26.8 % respectively. The process that collector system efficiency improves when the ambient temperature decreases during the coldest time of a year and the system efficiency reduces when the ambient temperature gets warmer was observed. It depends on water temperature in the tank. The water in the tank chills while circulating through the house heating radiator. Chilled water absorbs heat well from the solar fluid that was heated by solar collector. Thus the system efficiency in the winter time, when heat load is highest in December and January, is higher than that of the others. **Fig. 6** shows monthly average system efficiency and collector efficiency.

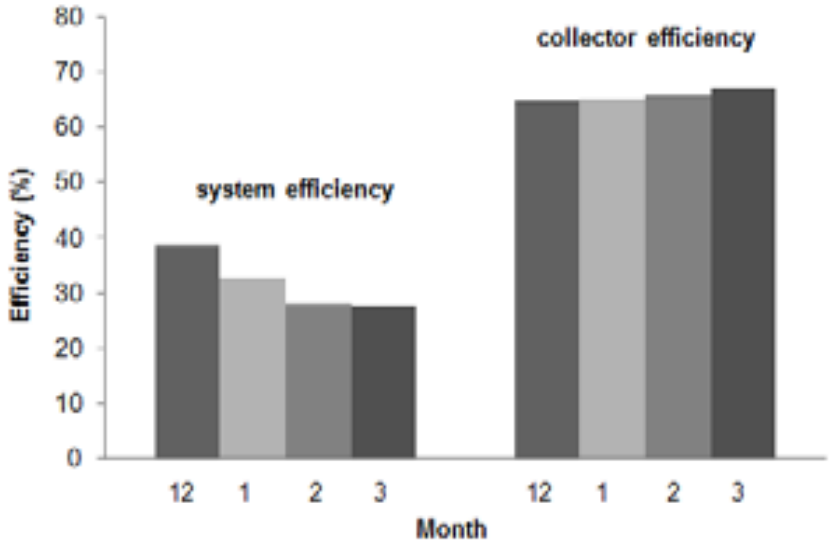

Fig. 6: Monthly average system efficiency and collector efficiency

From here, 59.3 % in December, 50.0 % in January, 42.2 % in February and 40.5 % in March of total energy collected by the solar collector were transferred into the tank, and the rest of the collected energy was lost when the energy was passing through the solar circuit pipes from the solar collector to the tank and from the tank to the solar collector.

3.3 Problems encountered

The surface of the collector glass tubes which transmits solar radiation were quite contaminated by soot and dust during the duration of experimental work (see **Fig. 7**).

Fig. 7: The glass tube contamination during the measurement (2014.01.10)

The main reason of decreasing the system efficiency is heat loss in the solar circuit pipes. During the measurement the heat insulators of the solar circuit pipes were renovated twice, but heat loss of pipes was not kept decreasing for a long time. Because material structure of the heat insulators deformed and material's body decayed and became thin due to temperature up and down during the operation time (-40 ^{0}C to +150 ^{0}C) and environmental various effects (see **Fig. 8**)

Fig. 8: Three months after heat insulator of solar circuit pipe changed (2014.01.10)

4. Conclusions

In order to estimate collector system efficiency in Mongolian actual smoky and dusty condition, the solar water heating system combined with an electric heater for heating the residential house was experimented and measured. As the result, the system efficiency was 31.5 % and the collector efficiency indicated 65.7 % averaged during the four months' measurement. Also 52 % of total energy collected by solar collector during

the four months measured was lost through the solar circuit pipes. After full cleaning of collector's glass tube, the collector efficiency increased by over 2 %.

The solar fluid was overheated by the collector during the power outage in several times, because of a solar water heating system with an evacuated tube collector uses an electrical circulation pump. Therefore, to operate the circulation pump continuously during the daytime, a small alternative resource of electric power should be used in the Ger district with electrical deficiency.

To decrease the air pollution level of Ulaanbaatar city, coal usage has to be eliminated in Ger district by finding new, convenient and harmless heating system. One of the reasonable heating systems is solar water heating systems combined with an electric heater. It is important to develop appropriate systems suitable for Mongolian climate condition and heat demand.

Nomenclature

T_i	temperature	(K)
$\dot{m}$	solar fluid mass flow rate	(kg s^{-1})
C_p	specific heat capacity	(J kg^{-1} K^{-1})
A_c	collector area	(m^2)
G	total global solar radiation at the collector's surface	(W m^{-2})

Experimental Investigation of the Filling and Draining processes of drainback systems (part 3)

Ruslan Botpaev, Yoann Louvet and Klaus Vajen

Kassel University, Institute of Thermal Engineering, Kassel (Germany)

Abstract

An experimental setup was constructed for the investigation of the filling and draining processes of a drainback system. Corrugated stainless steel (CSS) pipes in combination with transparent plastic hydraulic components (collector, heat storage) were applied in this study. CSS pipes are flexible, economically feasible and easy to install. However, sagging and the corrugated shape might be obstacles for a complete filling and proper draining. Therefore, several experiments with different diameters of CSS pipes (DN 12, DN 16, DN 20, DN 32) were performed. The recommended lower threshold of the flow rate for siphon establishment in hydraulics with CSS pipes has been experimentally obtained. Regarding the draining process a typical profile comprising of the emptying time and maximal draining flow rate is summarized. It is showed that the draining proceeds always in the same way (profile, emptying time) for the same hydraulics regardless of the adjusted flow rate during operation. The impact of the pumps on the draining process is also demonstrated. Finally a burst test was conducted, that proved a safe operation even by phase change of the remaining water. Conclusions are presented in details in this paper.

Keywords: *Drainback, drain-back, drain back, filling, siphon*

1. Introduction

Drainback solar thermal systems (DBS) offer failsafe freeze and overheating protections. High reliability of DBS is achieved due to three alternating stages: filling, operation and draining of the solar fluid. Each stage has its own functional purposes and requires a deep understanding of their specific peculiarities. Insignificant mistakes during design and installation might cause a fatal damage of the drainback system. Despite presence of some general recommendations towards optimal design and construction of DBS, there is a lack of publications concerning the filling and draining issues. Therefore an experimental setup was constructed for investigation of the existing knowledge gap. Different experiments were conducted and presented in the previous papers (parts 1, 2). Former both publications focused on experimental investigation of the drainback hydraulics, where smooth pipes were applied. In particular polyvinyl chloride (PVC) pipes were installed due to their transparency, which allowed the observation of the filling and draining processes. It has been shown that a siphon effect is essential for the filling process, which compensates the lift head to be overcome by the pump. The presence of an air vent at the top of the hydraulics modifies the filling and consequently the draining processes. A hydrostatic pressure difference between flow and return side is the driving force and of vital importance for a failsafe draining. In the scope of the present paper further findings on filling and draining behaviors are summarized. It is to emphasize that this paper is clearly understandable without familiarization with previous parts, despite their identical heading. The aim of the present investigation is to evaluate both operation stages (filling and draining) for the DBS with corrugated stainless steel (CSS) pipes. CSS pipes are flexible, economically feasible, compact for transportation and easy to install. However, sagging and the corrugated shape might be obstacles for a complete filling and proper draining. There are drainback systems which can be found on the market with CSS pipes, whereas some manufactures

doi:10.18086/swc.2015.10.29 Available at http://proceedings.ises.org

recommend restricting the solar piping to conventional copper pipes (Botpaev and Vajen, 2014a).

A schematic representation of both types of pipes is shown in Fig. 1, whereas the main dimensions are summarized in Tab. 1. The wave-shape of the CSS pipe is clearly visible in the longitudinal cross section of this pipe. Concerning other parameters it can be emphasized that the specific weight of CSS pipes is significantly lower, due to at least five times thinner pipe walls. Simultaneously, CSS pipes have a slightly larger top surface area and volume in comparison with copper pipes of identical sizes. It is not less important to notice, that CSS pipes obtain much higher pressure losses than copper pipes, but their cost on the market is slightly cheaper than conventional "red" pipes.

2. Description of experiments

The main advantage of CSS pipes is their flexibility, which allows flexible arrangement of the pipes without additional fittings and bending machine. Their competitive cost and compactness for transportation increased popularity among solar thermal system's plumbers; therefore CSS pipes have become a standard piping solution in solar thermal systems. Drainback systems however, require additional attention during design and installation due to the unique three stage operation modes. The complete hydraulics of the solar collector loop, including piping, should be completely filled after each pump activation; on the other hand the upper part of the hydraulics should be failsafe emptied when the pump is turned off. The latter is of vital importance in summer to avoid possible stagnation in collectors as well as in winter to prevent pipe failure. Can CSS pipes fulfill these specific drainback requirements?

The wave-shape profile of CSS pipes seems to be an obstacle for DBS, as the grooves inside retain water. Additionally these grooves can be a barrier for the air replacement from the hydraulics during the filling. Therefore the filling and draining properties of single samples of CSS and copper pipes were evaluated in a first step. The applied table experimental setup is shown in Fig.2. This setup consists of the following instruments and measuring devices: a "Sartorius" terminal connected to a weighing platform (accuracy ±0.1 g), a "Laserliner" digital spirit level (accuracy ±0.1° at 0° and 90°, and ±0.2° between 1° to 89°) for measurements of the tilt angle and a standard camera (not presented) to record the dynamic of the draining process. Six pipe samples: CSS pipes DN 12, DN 16, DN 20, DN 32 and copper pipes DN 6 and DN 20 of one meter each were tested. Each sample was fixed on a straight metal profile in

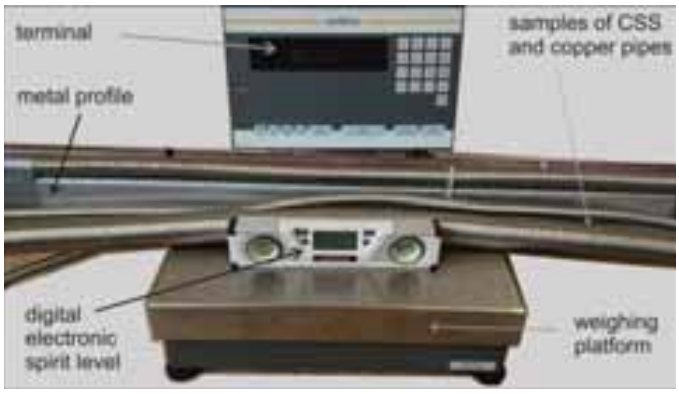

Fig. 2: Experimental setup for the filling and draining tests of CSS and copper pipes

order to maintain their linearity avoiding pipe sagging. Samples were weighed, then filled completely with water and drained at different tilt angles: 0° (horizontal), 2°, 5°, 10° and 90° (vertical). These slopes have been chosen based on a previous study summarizing the minimal recommended tilt angles for the piping in DBS (Botpaev and Vajen, 2014a). The pipes were differently filled: in vertical position from the top and from the upper edge of slightly sloped pipes. Afterward the pipes were shaken in order to test if air was still remaining in the tubes. The dynamics of the draining process was analyzed as well, through continuous weighing of the samples. Reduction of the sample's weight was recorded with a standard camera for an hour. Based on the results of this first set of experiments, quantitative draining features of CSS pipes in comparison with copper pipes were elucidated.

In a second stage the CSS pipes were integrated into an existing drainback experimental setup (Fig. 3). CSS pipes were installed in the flow side, whereas transparent PVC pipes were chosen for the return pipes. Two types of drainback systems were considered: one with heat storage as drainback reservoir and one with an additional drainback tank. Some hydraulic components were transparent for visual assesments of the processes. Pure water was colored red and used as the circulating fluid in the loop. The measuring equipment comprised magnetic-inductive flow meters, manometers and an Agilent data acquisition system. The system operated at ambient temperature during all conducted experiments.

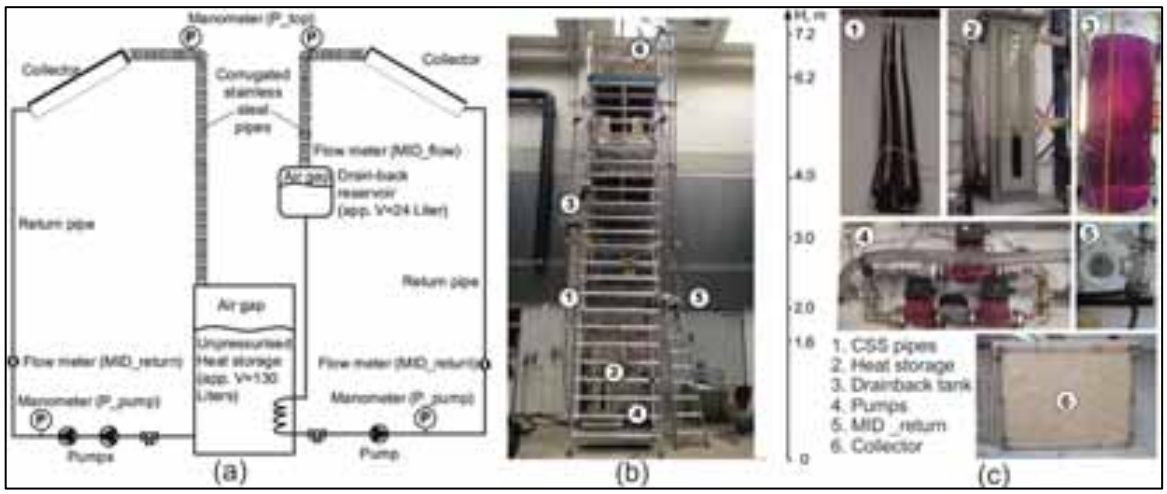

Fig. 3: Hydraulic scheme (a) of the experimental setup (b) and hydraulic components (c)

The experimental setup with a total height of 7.2 m (Fig.3, in the middle) consists of the following components:

- *Solar collector and piping.* Two parallel-connected heat-pipe collectors were hydraulically reproduced with vertical PVC (Ø38mm inside) pipes, which were mounted on a wooden board (1.7 m x 1.4 m). The tilt angle of the collector was 60° during the experiments. The piping to the collector (return side) was constructed with PVC (Ø19 mm inside) pipes, whereas CSS pipes (DN 12, DN 16, DN 20 and DN 32) were applied for the flow side. CSS pipes with a length of approx.

8.2 m were mounted in the flow side as a single piece, connected with fittings to the collector outlet and the heat storage inlet.

- *Heat storage.* Both types of drainback systems were connected to the same heat storage. The unpressurised storage was made from PP-H plastic in a cubic form. The inside dimensions are 320 mm x 320 mm x 1300 mm (LxBxH) with a total volume of about 130 litres. One centimetre of water column in the heat storage corresponds to one litre of water. On the front side of the heat storage a sight glass made of a polycarbonate plate was mounted. The heat storage has five connections - two of them connected to a heat exchanger coil located inside the tank, two others for the direct integration of the solar loop, and the last one is an air vent.
- *Drainback tank.* A drainback tank with a cylindrical form was bonded from a transparent Plexiglas pipe (Ø OD/ID 300/292 mm) and plates with an adhesive. The dimensions of this tank are 300 mm x 650 mm (BXH), which corresponds to a volume of 43 litres.
- *Pumps*. There are two possibilities to force the circulation in the solar loop of the experimental setup: either with one pump or with two pumps connected in series. Connection in series of two identical pumps doubles the head, allowing overcoming of the vertical lift head. A set of valves allows operating the solar loop either with a single pump Grundfos 25-120 or two small Grundfos Solar 15-80 pumps. The latter has two adjustable speed levels: min and max.
- *Measurements acquisition.* The data acquisition system Agilent 34970A was used for monitoring, gathering and evaluation of the measured data. Manometers and flow meters were the main sensors of the experimental setup. Muntwyler (2005) reported that some flow meters can cancel the draining proccesses, therefore magnetic-inductive flow meters (MID) were applied. The chosen MIDs - ABB Process Master 311 (accuracy ±0.4 %) are capable of measuring the flow rate in both directions. An additional advantage of MID flow meters is their ability to determine the presence of air bubbles in the flow. As long as air entrainment occurs in the stream, the sensor delivers fluctuating values of the flow rate. One flow meter was mounted in the return pipe directly above the heat storage at a height of 2 m, the second one in the flow pipe above the drainback tank at 4 m. Two digital manometers from JUMO GmbH & COKG were placed at the highest point of the hydraulics (accuracy ±0.8 kPa) and after the pumps (accuracy ±1.3 kPa). Some simple manometers were also applied for controlling purposes.

Several tests concerning the filling and draining processes were conducted and evaluated. The filling process was performed under different variations of the pump speed. The process of air replacement by water during the filling was analyzed by integrating the flow rate curve over the duration of the filling process. This test was conducted for two different hydraulic configurations, which were completely identical besides the arrangement of the CSS pipes in the flow side. The flow side piping of the first hydraulics was arranged vertically with one horizontal part at the level of the heat storage, whereas the second hydraulics had an additional horizontal part at the level between the collector and the heat storage. The length of the CSS pipes, however, was the same in both hydraulics. The course of the draining process under different operation strategies (high flow or low flow) was also analyzed. The impact of pump configuration (e.g. one pump vs. two), which are responsible for an additional pressure drop during the draining.

Finally some burst tests have been presented in order to estimate the freezing threat in CSS and copper pipes. A conventional freezing unit was applied for these experiments. In Fig. 4 is presented the interior of the

Fig. 4: The inner part of the freezer with the samples inside

mentioned freezer with the samples inside. Cables of installed NiCr-Ni thermoelements and isolating material are also shown; however they were used for other experiments which are beyond the scope of this paper. The pipe samples (CSS and copper) were filled with water and frozen, afterwards simply observed. The filling inclination was varied in accordance with obtained results from the first experiment, in order to find out its impact on the pipes while freezing.

3. Measurements and analyses

The results of the experiments are summarized in the present chapter, in the same order as they were described above. At the beginning the results of the filling and draining tests of the samples are analyzed, afterward the filling and draining processes of the setup are explained and finally the burst test is briefly described.

Experiment 1 – filling and draining properties of the CSS and copper pipe samples. Several simple experiments were performed to determine the filling and draining properties of the CSS in comparison to copper pipes. The samples were fixed on a straight metal profile to keep the linearity avoiding pipe sagging. Then the samples were filled, at the beginning in vertical position from the top, while the bottom was closed with a cap. Once the water level was close to the top, the samples were gently shaken, in order to remove the remaining air in the pipes. Observation, however, showed a full filling of the pipes without "shaking". Only copper pipes DN 6, had some difficulties by the filling due to prevailing surface tension. When the samples were filled in near horizontal position, some air was captured in the grooves, and could only be removed by placing the samples vertically. Further the filled pipe samples were adjusted to the desirable tilt angle, weighed, afterward the caps on both ends were removed, and the draining process launched. The draining profiles of the smooth copper DN 20 (Fig. 5, left) and CSS pipes DN 16 (Fig. 5, right) are presented in the Fig.5. Both graphs are scaled identically for better visual comparison of the draining dynamics of the smooth and "wave-shape" pipes. As expected the copper pipes drained completely by tilt angles steeper than 2°, whereas at a slope of 2° a small amount of water remained due to surface tension. For the same reason the copper pipe placed in horizontal position captures a considerably larger amount of water about 54 g, that represent 18 % of the water mass of the completely filled pipe sample. In CSS pipes as proposed a small amount of water always remains at all slopes range due to its special shape with grooves. It has to be emphasized that a comparable water mass remains both in horizontal as well as in vertical pipes. Moreover in vertical pipes after draining remains significantly larger amount of water than at flat slopes. This is a distinguished feature of CSS pipes, which retain water after the draining even in vertical position. Considering the dynamic of the draining for CSS and copper pipes at 0°, it can be noticed that the main volume of water flows out within 30 seconds from copper pipes, whereas about 3 minutes are required for CSS pipes.

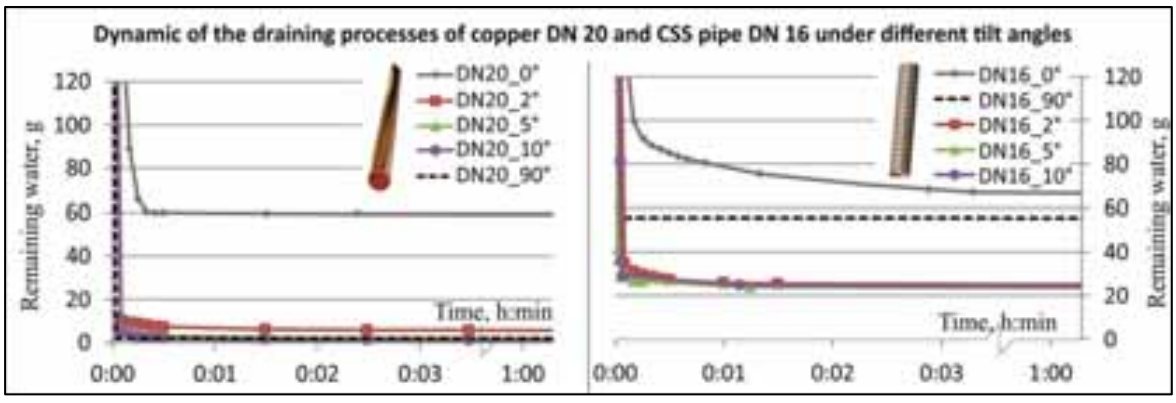

Fig. 5: Draining processes of a copper DN 20 (left) and CSS DN 16 pipe (right)

The draining processes of other samples show almost similar courses over the time, therefore only the measurements of remaining water after one hour are summarized in Tab. 2. The first columns in the table provide general information on the samples and the weighed water mass required to fill the pipes completely. This weight was considered in the next column as 100 %, in order to calculate the relative amount of remaining water after draining. The following columns present the remaining water mass after 1 hour of

draining in absolute values (gram) and in percent.

Tab. 2: Remaining water mass in copper and CSS pipes after 1 hour of draining

DN		Water content in the fully filled pipe		Remaining water mass in the pipe after 1 hour					
				0°		2°	5°	10°	90°
		g	%	g	%		g	g	g
Cu	6	33.0·(1±1%)	100	13.1±0.3	40	4.7±0.1	1.9±0.1	0.7±0.1	0±0.1
	20	310.5·(1±1%)	100	54.4±1.1	18	5.3±0.1	1.7±0.1	0.2±0.1	0±0.1
CSS	12	156.8·(1±1%)	100	90.3±1.8	58	27.5±0.6	21.9±0.4	20.5±0.4	41.4±0.8
	16	265.4·(1±1%)	100	64.5±1.3	24	24.0±0.5	23.0±0.5	22.0±0.4	55.6±1.1
	20	412.7·(1±1%)	100	53.7±1.1	13	31.7±0.6	30.4±0.6	29.6±0.6	88.9±1.8
	32	1086.6·(1±1%)	100	50.5±1.0	5	49.2±1.1	45.8±0.9	45.3±0.9	168.0±3.4

The percentage values of the remaining water, as presented in Tab.2, are illustrated in Fig.6. The graph shows the relative amount of remaining water one hour after the start of the draining process. Referring to Fig.6, it can be seen that the smaller the diameter, the more water (percentage values) remains inside. Moreover, a comparable water amount remains in the pipe regardless of the tilt angle for corrugated stainless steel pipes diameter larger than DN 16 (≥ DN 16). The latter statement is true, except in the case of a vertically positioned CSS pipe. When perpendicular to the horizontal, 15-26% of the water content remains in CSS pipes after the draining process, which should be considered during installation. On the contrary, smooth copper pipes empty completely as expected in a vertical arrangement. The "poor" emptying properties of the smooth horizontal pipes might be caused due to an insufficient initial hydrostatic pressure, which is the driving force of the draining. It is to emphasize that the draining of horizontal pipes in a real system proceeds in another way, where inertia of the flowing water and significantly larger hydrostatic pressure difference is present. Therefore, the emptying test of the presented experiment with 0° tilt angle should be considered as the worst draining case, as demonstrated in Botpaev et al. (2014) a horizontal arrangement of the smooth pipes does not affect the draining process of DBS. Similarly, better draining properties under the influence of inertia and hydrostatic pressure might be assumed for CSS pipes; however it is not possible in reality to arrange CSS pipes in such a lineal way, as it was done here by fixing them to a metal profile. Summarizing this first set of experiments, it has to be repeated that water always remains in the CSS pipes regardless of the slope. Furthermore, it should be noted that in vertical CSS pipes remains a significantly larger amount of water than in sloped one.

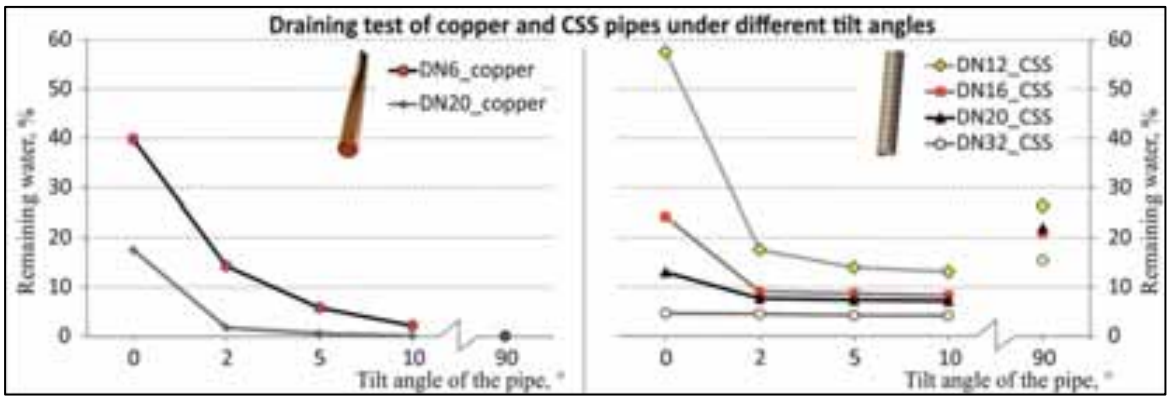

Fig. 6: Remaining water in copper and CSS pipes after one hour of draining process

Experiment 2 – filling and draining processes of a DBS with corrugated stainless steel pipes. The second set of experiments was performed with a second experimental setup, which was introduced above in Fig. 3. CSS pipes were integrated into an existing experimental setup, replacing PVC pipes in the flow side. The filling process of the system is presented in the Fig. 7, which similarly proceeds as the filling process of the same system with smooth pipes. The flow rate curve is drawn in black color, whereas the pressure is depicted in blue. The X-axis, which reflects the time in seconds was additionally split into several stages and designated with capital letters (A-C). The time interval between B and C represents the duration of the filling process with a typical spike of the flow rate at the beginning (red point). At the end of the filling process at time C all parameters such as the flow rate, the pressure after the pump and at the top are stabilized, indicating

complete air replacement by water in the hydraulics. The underpressure at the top (blue curve) shows a siphon establishment in the loop. The area under the MID_return curve over the length of the filling process, colored grey, is used to characterize the air replacement process in the solar loop (Botpaev and Vajen, 2014b). The speed of the installed pumps was varied and for each pump configuration the filling process was evaluated. Two identical but slightly modified hydraulics, the first one with one horizontal pipe arrangement of the flow side piping and the second with two (as described above) were applied.

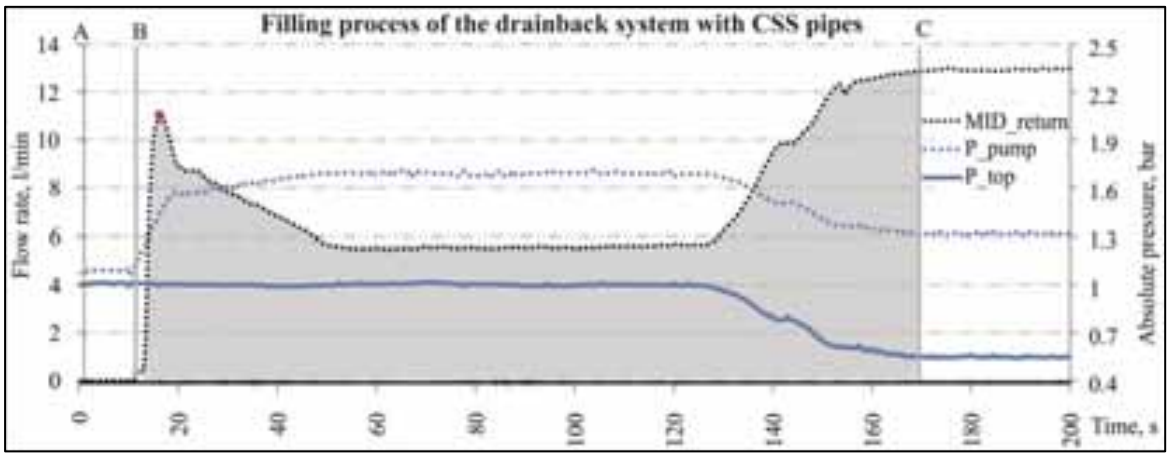

Fig. 7: The filling process of the drainback system with CSS pipes

In Fig.8 is presented the evaluation of the filling process with the above described integral method. The red point in the graph corresponds to the filling case depicted in Fig. 7, where the minimal flow rate after the spike is 5.4 l/min and the grey area under MID_return amounts to 19 l. Based on the rules for error propagation, the uncertainty of the integral is estimated and presented in the graph for two flow rates (9.7 and 25.1 l/min). The absolute uncertainties are increasing at higher flow rates, due to the impact of the uncertainty on the filling time. In spite of relatively good repeatability conditions of the experiments, there is obviously no reproducibility of the results for experiments with adjusted pump speed at minimal flow rate below 6 l/min for both hydraulic configurations (1- with one, 2- with two horizontal pipe arrangements). The filling time for these flow rates is not predictable, as the amount of water required for the filling (integral) varies significantly. The experiments with a minimal flow rate above 6 l/min show a good reproducibility of the results. It appears that a comparable amount of water should flow through the loop in order to completely remove the air in the upper part of the hydraulics independently of the flow rate. This means that the intensity of the air transport process remains identical in CSS pipe, although the filling flow rate increases. The bend of the curve (near 6 l/min) can be considered as a tipping point, a recommended lower threshold of the flow rate for a proper filling process of DBS with CSS DN 20 pipes. Above this threshold, a good reproducibility of the filling time is guaranted; the control unit of the solar thermal system can therefore be precisely adjusted. A further rise of velocity causes an increase of pressure losses in the pipes (Fig.8, right Y-axis), without intensification of the air transport process; therefore the filling around the threshold minimizes the pump energy consumption without hampering the filling process.

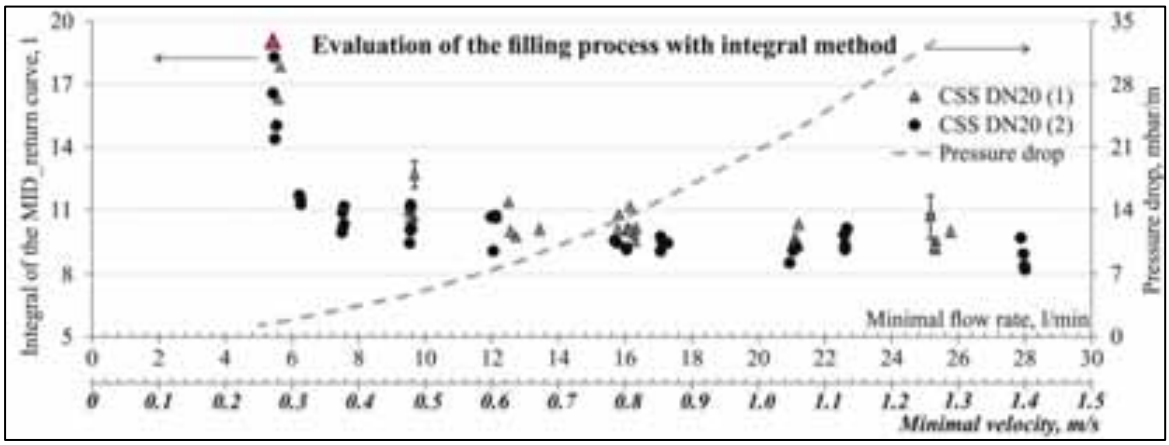

Fig. 8: Evaluation of the filling process with integral method

In Tab. 3 are summarized the values of the threshold flow rate for other CSS pipe diameters. These values were obtained based on the evaluation of two slightly modified hydraulics, as in the previous case. It is to be emphasized that the threshold for the CSS pipe DN 32 was indistinct due to lack of measurements data.

Tab. 3: Recommended lower threshold values for the filling process

CSS Pipe	DN 12	DN 16	DN 20	DN 32
Diameter of the CSS pipe, mm	12.6	16.5	20.5	34.6
Recommended lower flow rate threshold, l/min	0.85±0.01	4.00±0.04	6.00±0.06	35±2
Recommended minimum flow velocity, m/s	0.1·(1±1%)	0.3·(1±1%)	0.3·(1±1%)	0.6·(1±6%)

The minimum flow velocities in Tab.3 are calculated considering the minimal diameter (d on Fig. 1) of the CSS pipes. It should be noted that these values besides for DN 32 are smaller than the recommended minimum flow velocities in VDI 6002 (2014). This standard issued by the Association of German Engineers suggests to keep the minimum flow velocity at 0.4 m/s in order to transport the air from the hydraulics. However, this velocity is not sufficient for the filling of drainback systems with CSS pipes DN 32.

Some additional remarks about observations and calculations during the filling tests:

- There is a recommended lower flow rate threshold, which guarantees a full filling of the hydraulics. At this value occurs a predictable air replacement processes. Further growth of the flow rate lead to an increase of the pressure losses and a decrease of the filling time, but the intensity of the air transport process remains the same.
- Flow rates above 5 l/min cause vibrations in CSS pipe DN 12 followed by a strong rumble. The vibrations were observed also for other CSS pipe diameters, however without noise. It means that the distance between the bindings should be optimised also for vertical CSS pipes, in order to minimize the vibrations. In particular a transition zone vertical to horizontal and inverse have been carefully considered.
- The pressure losses in CSS pipes are approximately three times (depending on flow rate) higher than in smooth pipes.

In Fig. 9 is shown the dynamic of the flow rate during the draining process. Five experiments were carried out for the same hydraulics with different pump configurations as schematically shown at the top of the graph. For instance in experiment 1010 the draining occurred through both parallel lines, whereas in 1016 only through the large single pump, and during experiments 1102, 1006 and 1013 through the two serially connected pumps. The X-axis is a timeline of the process in seconds. The Y-axis is a flow rate measured by MID_return. Positive values correspond to the direction of the circulation during operation mode, whereas the draining process occurs in the opposite way therefore depicted in a negative range. Capital letters (C-F) at the bottom of the graph highlight the transitions between some characteristic operating stages of drainback systems. The time interval between C and D is the operating mode, at time D the pump is turned off, however due to inertia the circulation continues with a decreasing flow rate during a couple of seconds, at time E the circulation ceases, afterwards starts the draining process in opposite direction.

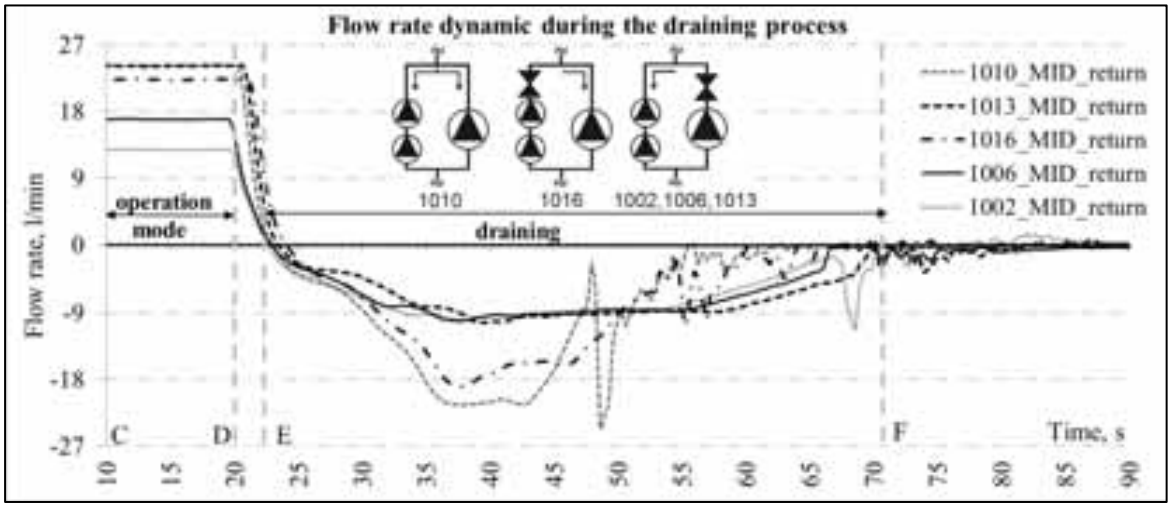

Fig. 9: Flow rate dynamic during the draining process

Pump represents a local pressure loss during the draining process. The value of the pressure loss depends on the pump(s) type and their hydraulic connection (serial or parallel). Obviously two parallel lines of pumps obtained the minimal pressure drop, whereas two pumps connected in series the maximal pressure drop. The pressure drop impacts the draining profile significantly. As presented in Fig. 9 the maximal amplitude of the flow rate during the draining process is twice larger in experiment 1010 (21.5 l/min) than for pump configuration adjusted in experiments 1002, 1006 and 1013 (9.3 l/min). Beside the maximal amplitude of the flow rate, this configuration ensures a minimal draining time which is also important. Furthermore it has to be emphasized that the draining process occurs in the same way for the same hydraulics regardless of the previous operation conditions (high flow, low flow or matched flow). It is visible that the profile of the flow rate curve (duration, amplitude) during the draining is identical for experiments 1002, 1006 and 1013, despite different flow rates during the operating mode. The flow rate during the draining even exceeded the flow rate during operation mode, as presented in the case of experiment 1016.

Some remarks about observations and calculations during the draining tests:

- The draining process proceeds always in the same profile, with identical amplitude and duration, for a certain DB hydraulics regardless of the flow rate during operation.
- The pump(s) represent(s) a relative significant pressure drop for the draining process, which impact the profile, duration of the draining process and its maximal amplitude.
- Small volumes of water always remain in CSS pipes after the draining process regardless of the tilt angle of the pipes. Furthermore in vertical pipes with large diameters more water remains than in sloped CSS pipes.
- The smaller the diameter of CSS pipes, the more water (in percentages to the full pipe) remains inside
- Vibration can occur during the draining for significantly high flow rates.

Experiment 3- burst test. In this last test, samples of different CSS pipes have been frozen in a freezing unit. Several tens of freezing and defrosting cycles have been carried out with CSS and copper pipes in horizontal position with different filling levels up to 50 %. They did not reveal any burst or visual damage of the samples. Fully filled copper pipes burst after the first freezing cycle, whereas CSS are elongated after the first freezing but are not burst. It can be concluded that remaining water in CSS pipes (partly filled) after draining does not present any danger for the pipes even after phase change of the heat transfer fluid. The only negative aspect is an energetic issue as the remaining water which transforms into ice needs to be melted at the start of the system.

4. Summary and conclusions

Experimental investigations of the filling and draining processes of drainback systems have been undertaken. The behaviour of these processes was evaluated for DBS with corrugated stainless pipes as solar collector loop piping. CSS pipes are widely used by assemblers of solar thermal systems as they are flexible, economically feasible, compact for transportation and easy to install. Because of specific design and installation requirements, the use of CSS pipe in combination with DBS was investigated in this study. In a first step, the filling and draining properties of several CSS and copper samples were investigated. The results show that CSS pipes are suited for the filling process, despite their distinguished shape with grooves. These grooves retain some fluid after the draining process, therefore water always remains in CSS pipes regardless of their tilt angle. Moreover, CSS pipes vertically positioned hold more water than identical samples with 2°, 5° or 10° slope, which is not the case for copper pipes. Indeed, Smooth pipes empty completely at angles steeper than 2°. Further experiments were conducted with a complete drainback setup. The suggested integral method was used to evaluate the filling process. The recommended lower value of the flow rate for CSS pipes with different diameters was obtained. This value is a threshold, above which a repeatable filling process with a predictable filling time is ensured. Further rise of the flow rate above this threshold during the filling is however not desirable as it causes additional pressure losses, without improvement of the air transport mechanism. Besides for DN 32 pipes, the obtained thresholds are in line with the minimum flow velocity recommended in VDI 6002. The draining experiments confirmed that the draining profile including amplitude and the draining time proceed always in the same way for a given hydraulics regardless of the flow rate during operation. The pressure drop through the pump(s) impacts the

draining profile, so it is desirable to install pump(s) allowing back flow, but also with a minimal pressure drop. Finally burst tests approved the applicability of CSS pipes for DBS, however a sufficient number of fastening points for both vertical and horizontal pipes is required, in order to avoid sagging and vibration of the pipes.

Abstract

Electricity plays an important role in the contemporary life, and it has become indispensible nowadays. Reducing the peak electricity load and increasing the load factor have been considered as one of the main tasks that have to be accomplished by both electricity generation-side and demand-side managements. The residential sector of Libya consumes over 31% of the total sold electricity, and 29.8% of that is delivered to the electric water heating load. This is inefficient way of electricity utilization. Usually, the electricity supplier in Libya increases the local generation capacity or import electricity from neighboring countries. Both solutions do not resolve the problem. This work attempts to investigate the effect of replacing electric water heaters in the residential sector of Libya by solar water heaters on reducing the electricity peak load and increasing the load factor. Our results show that on average 3% of the peak load demand can be saved. This is equivalent to 149.5 MW of reduced power. The study also revealed that an annual energy savings up to 2.55 TWh, and the load factor is improved by 2% (i.e. from 65% to 67%). This saved energy is equivalent to a power plant with a nominal capacity of 448 MW considering load factor of 0.65.

Keywords: *solar water heaters, electricity peak load, hot water load pattern, Energy saving,*

1. Introduction

Libya witnessed a rapid and significant development in various sectors and economic activities during the last quarter of the previous century. This development led to the growth in electricity demand. It is reported that the energy consumption per dwelling in Libya is over five times the consumption in Morocco. This could be attributed to the fact that electricity prices in Morocco is six times electricity prices in Libya (Missaoui, 2012). The consumption per capita of energy has been multiplied more than 13 times from 1970 to 2010, where consumption per capita increased from 338 kWh in 1970 to 4651 kWh in 2010. Therefore, meeting this demand has become a significant problem of concern, and it will impact the economy of the country. Thus, it is clear that Libya will face serious challenges as it attempts to meet the apparent rising demand of energy. At the same time, it seeks to decrease the dependence on the short-lived and potentially volatile oil and natural gas to reduce the negative environmental impacts.

Although Libya possesses high installed capacity per capita compared to other developing countries, Libya has suffered severe electricity shortages. The shortages have become worse in the past few years due to the loose of a part of the generated capacity as a consequence of the turbulence in the country and the continued increased electricity demand. In the past, this shortage was reduced by importing electricity from neighboring countries. However, this is no longer the case due to the experienced shortage of the electricity in these countries as well. Many solutions have been suggested and implemented to resolve this problem. Quick solutions such as installing new gas turbine power plants and renting diesel generators did not solve the problem.

From the aforementioned high electricity consumption per capita, it is obvious that it is not an electricity generation problem, but it is a demand side management problem. It is believed that implementing energy efficiency and energy saving strategies will alleviate this issue to high extent. In Libya, almost 100% of the domestic water heaters are electric, and they consume approximately 9.3% (3028 GWh) of the total electricity generated in the country in the year 2010 (Report 2010).

doi:10.18086/swc.2015.10.30 Available at http://proceedings.ises.org

This is equivalent to a power plant with a capacity of 532 MW considering load factor of 65%. There are many studies that deal with the demand side management including domestic water heating in the literature. Moreau (2010) conducted a study to see the effect of domestic water heaters during peak periods and its impact on the demand for electricity. He suggested a shifted load control strategy to minimize such effect. The study is conducted on the province of Quebec, Canada that has a high penetration rate of water heaters, approximately 1.7GW. It is based on an experimentally validated simulation model of water heaters, and the population diversity of hot water load profile. Three scenarios of controlling the number of deactivated water heaters during the peak demand are considered. In scenario 2 the results show that the peak reduction potential is approximately 595 MW at which the pick-up is controlled according to a prioritized random function spread over a range of two hours of the peak period. However, in scenario 0, controlled reactivation case, the peak demand is 225MW.

To alleviate the effect of the domestic water heating on peak demand and energy consumption, this article attempts to investigate the influence of replacing all expected electric water heaters with solar water heaters on the Libyan grid. The investigation includes an analysis of peak load in the Libyan electricity supply, hot water load pattern of the residential sector, complete replacement scenario of electrical water heaters with solar ones, and, eventually, perform estimation of the amount of saved energy, reduced peak power, and load factor improvement.

2. Electricity Sector in Libya

Libya is a country with a large area and relatively small population spread all over the place. The state owned General Electric Company of Libya (GECOL) is solely responsible for the generation and distribution of electricity for the whole country. By law, it has the responsibility of providing electricity to every household in the nation. Libya is a rapidly developing country, and the electrical demand is expected to grow at an annual rate of 6-8 % for the next 10 years due to the economic development and increase in people level of standard 0Report, 2008). Currently, approximately 37 % of the generated electricity is using natural gas, 18% heavy oil, 34% light oil, and the rest 11% is obtained from cogeneration (Report, 2010). Apparently, all used energy resources are from fossil fuels, and there is no contribution to new and renewable energy sources.

In Libya, the generated electric energy in 2010 is 32,558 GWh, and the total installed power capacity was 8,347 MW with an available power of 6,357 MW (Report, 2010). The calculated load factor of this year is 65%. Figure 1 illustrates the average hourly power for the four seasons of the year 2010.

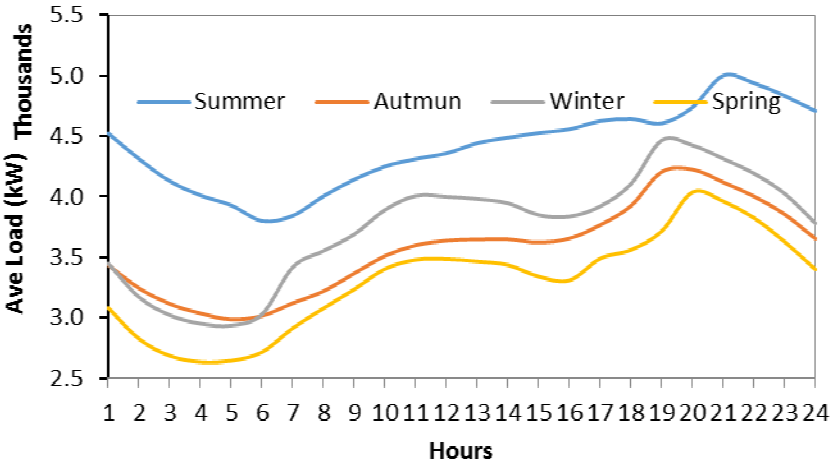

Figure 1. The average load of electricity during the four seasons of the year 2010.

It is clear that the peak power is almost after the sun set time, and, therefore, using solar energy without storage will not alleviate the peak power demand issue. However, solar water heating technology can store energy for later use, and, therefore, it can be a solution to this dilemma. Figure 2 shows the hourly maximum electricity peak during the year 2010, and it reveals that the global maximum is 5,759 MW in August month.

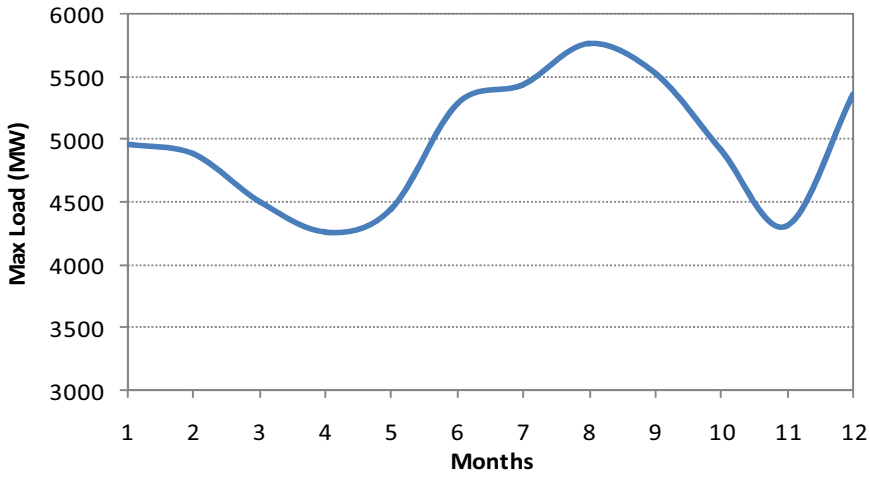

Figure 2. Monthly maximum electricity load for the year 2010

The reported incremental annual average change of the electricity peak load during the past few years is over 8% as shown in Figure 3. The year 2011 is the year of the revolution in Libya, and the supply of electricity was highly intermittent. Therefore, the years 2011 and beyond are not considered in this study.

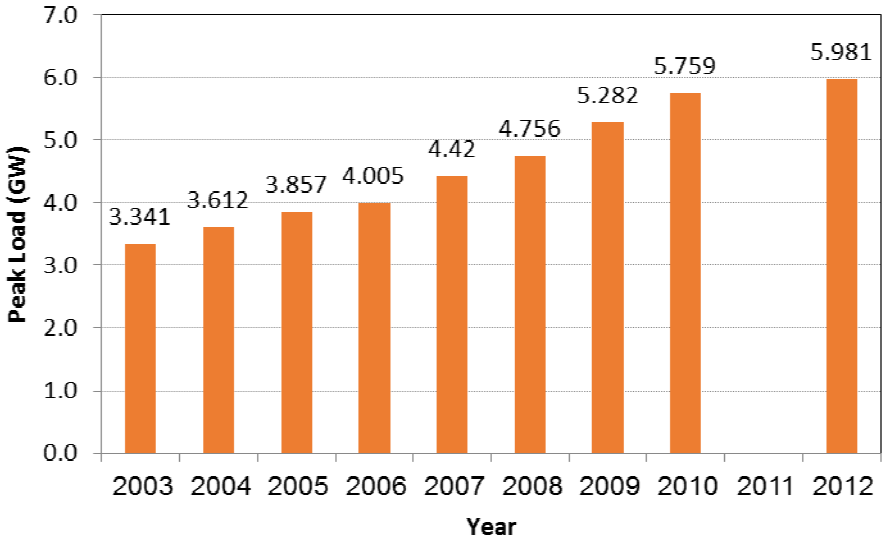

Figure 3: development of electricity load peak of Libya

Figure 4 shows the daily maximum electricity load for the year 2010. It is clear that the global peak is in the summer season with 5759 MW, and the average maximum power during the same season is 5060 MW. The second maximum occurs in the winter season with 5360 MW with the daily average maximum power of 4545 MW. The lowest maximum season power is the spring season with 4505 MW and the daily average maximum load of 4111 MW. In the autumn season, the maximum peak power is 5523 MW and the daily average maximum peak power during this season is 4333 MW. The drop in power between the summer and spring season is over 1000 MW in the maximum peak and in the daily average maximum peak. This huge difference could be attributed to the increased demand in buildings to meet the cooling load in the summer season.

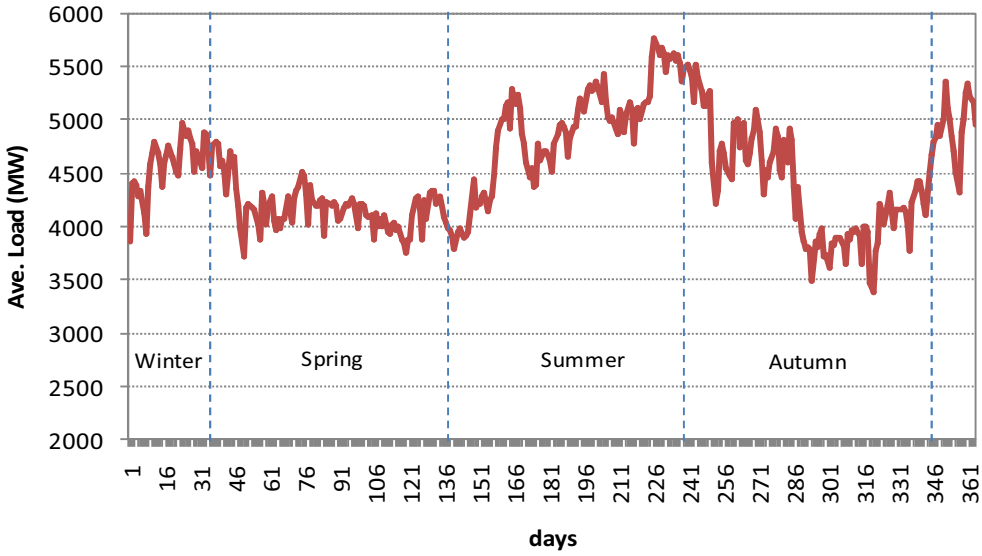

Figure 4. Daily maximum load for the year 2010

Studies made by CADMUS group (Khawaja, 2010a,b) show that the biggest demand at peak hours in the winter season is acquired by the residential sector with 34%. In the summer season the same sector demands 20% of the consumed peak energy, which comes the second after the public lighting demand as shown in Figures 5 and 6.

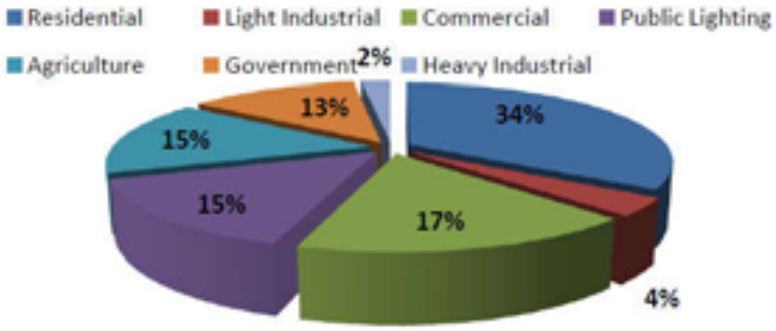

Figure 5: Winter demand at peak hours by sectors

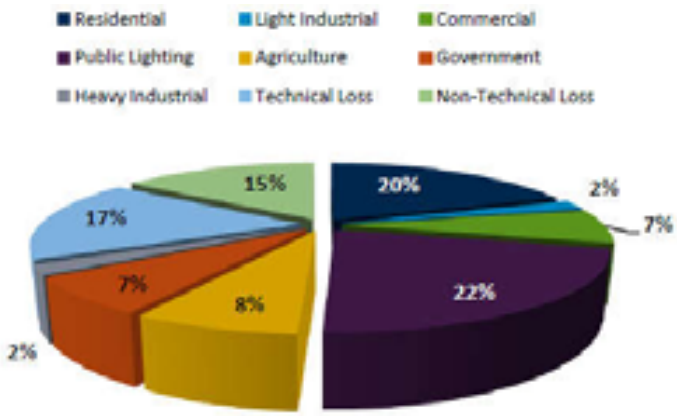

Figure 6: Summer demand at peak hours by sectors

Therefore, implementing energy conservation measures in the residential sector will highly alleviate the peak demand issue in the electricity system of Libya. Also the commercial sector composes a great share of power demand (17%) than energy consumption (13.06%). This is expected because these sectors have demand associated more with evening than daytime hours.

3. Residential Sector

According to the annual report of GECOL of the year 2010, domestic sector consumes 31.18% of the total electricity sold to different sectors of Libya as shown in Figure 7. In the meantime, a study conducted by (Ekhlat et al. 2009) shows that water heating in the domestic sector is the biggest consumer and represents about 30% as shown in Figure 8. Thus, around 9.3% of the national electricity consumption in the country is consumed by water heating for domestic purposes. In the year 2010 the total production of electric energy was about 32,558 GWh, and the amount of electricity sold was about 20,602 GWh. Therefore, the annual electricity used for domestic hot water based on generated electricity is around 3028 GWh.

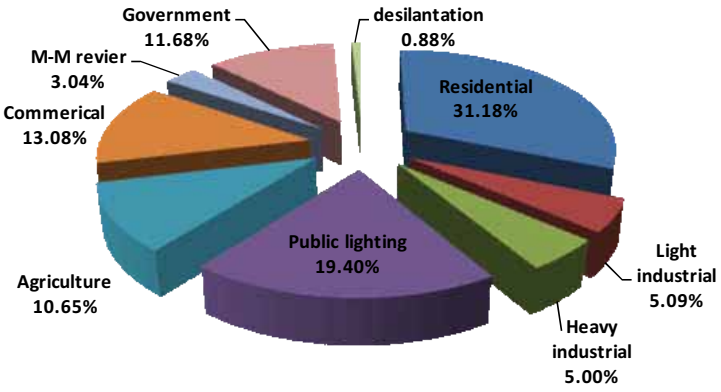

Figure 7. Sectarian distribution of electricity in Libya, 2010

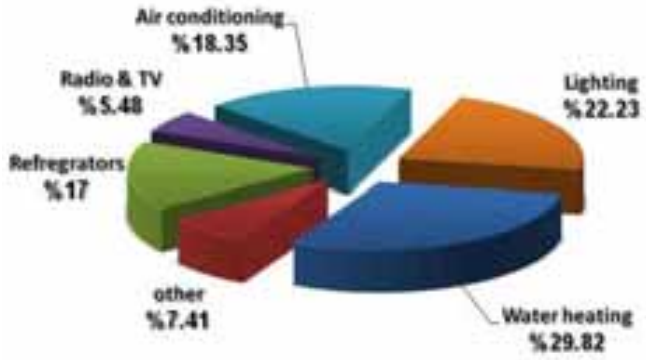

Figure 8. Electricity distribution in the Libyan houses

4. Hot water load in the Residential sector

More than a year of in-situ measurements of five solar water heaters installed in residential buildings are used to predict the average hot-water-load (HWL) pattern and quantity. The measurements were taken every 10 seconds and recorded every 30 minutes for more than a year. In this study, longer periods of measured data are used compared to the previously published data (Abdunnabi, 2005, Abdunnabi, 2012). The summary of the main results is presented in Table 1. The collected data is analyzed, and the hot water patterns for each season are obtained for the average Libyan family of 6 people. Figure 9 shows the typical seasonal hot water load pattern for the average Libyan family.

The methodology used to calculate the HWL pattern and quantity from the measured data is by unifying the different water quantities from five systems as energy, and the quantity of water is calculated at withdrawal temperature of 45°C. The results of all five systems were included in calculations as shown in Table 1. However, the summer results of the 240 liters system is excluded because the owner of this system declares that he purposely discharging large quantity of hot water daily during the summer season to protect the system from high temperature.

The study reveals that the daily quantity of hot water withdrawn at 45°C per person is about 60 litters. The estimated annual amount of energy consumed for water heating per person is about 510 kWh. For an average

Libyan family of six people, the annual amount of energy consumed per family is about 3060 kWh, which is slightly different from the previously obtained results of 2731 kWh/year/family (Abdunnabi, 2005). The study shows also that the average annual solar fraction is 70%.

Table 1: solar water heaters field study average data

Tank volume (L)	Collector area m^2	Persons/family	Ave consump. (Lit)	Ave. inlet Temp (°C)	Ave. outlet Temp (°C)	Annual energy kWh	Solar Fraction (%)
240	3.54	6	353	26.3	49.6	3450	75.2
280	4.4	4	274	24.36	47.3	2037	83.6
210	3.4	5	158	20.55	46.4	1698	57.7
240	3.54	4	319	21.82	44.44	2925	66.1
170	3	3	131	21.91	44.2	1190	58.7

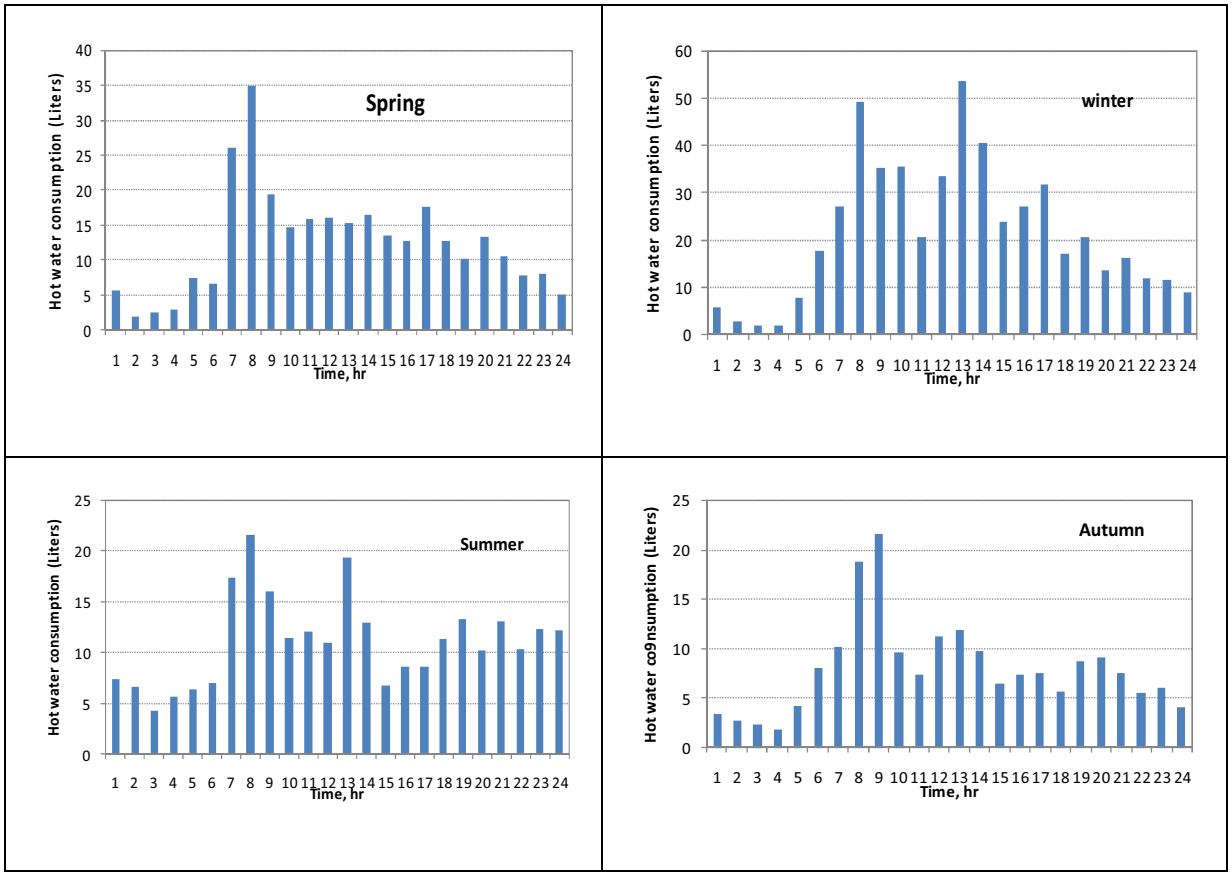

Figure 9: Typical seasonal hot water load pattern of Libyan families

To estimate the energy used for water heating in residential sector, two approaches are used: The first approach is based on the data obtained from GECOL (Report, 2010) and General Authority for information (GAI) (Report, 2007). The second approach is based on data collected from SWH field tests. The following sections will go through these two approaches in details.

First Approach

This approach will give the possible energy consumed for domestic water heating per family according to data obtained from GECOL and GAI. These data are listed in Table 2.

Table 2: Various data from GECOL and GAI

No	Category	Value	Remarks
1-	Electric Energy Sold	20,602GWh	GECOL (2010)
2-	Electric Energy Generated	32,558 GWh	GECOL (2010)
3-	Percentage of water heating in the residential sector	29.82%	Khlat, 2009
4-	Electricity consumption in the residential sector	31.18%	GECOL (Report,2010)
5-	Percentage of electricity used for water heating in domestic sector	9.3%	31.18% × 29.82%
6-	Number of Clients	889,447	GECOL (Report, 2010)
7-	Number of Houses, 2010	921,642	GAI, (Report, 2007)

From Table 2 we can calculate the maximum possible hot water energy consumption (HWEC) per family based on the generated electricity:

$$HWEC_{max} = \frac{Electric\ Energy\ Generated \times \%\ of\ water\ heating}{Number\ of\ Clients} \quad \text{(eq. 1)}$$

$$= \frac{32,558,000,000 \times 0.298}{889,447} = 3403\ kWh$$

The minimum possible HWEC per family based on electricity sold can be obtained using the same formula:

$$HWEC_{min} = 2153\ kWh \quad \text{(eq. 2)}$$

Second approach

This approach is based on the SWH field test data of HWEC and the data from GAI as given in section 4.

$$HWEC_{measured} = 3060\ kWh \quad \text{(eq. 3)}$$

Fortunately, this measured value lies between the minimum and maximum values obtained using the first approach, which makes this quantity acceptable although the number of measured samples is very small. Therefore, it is chosen to represent the typical value of HWEC for domestic sector of an average Libyan family of six people. This value is representing the useful energy of the hot water and does not represent the energy provided by the electric element in the water tank. The heat loss to the environment is not included, and it will be calculated in next section.

5. TRNSYS Simulation of EWH Performance

Commonly used electric water heaters are simulated using TRNSYS simulation program to calculate the heat loss to the environment. It is also used to assess the electric energy required to compensate the energy due to heat loss and useful energy consumed (i.e. for typical Libyan house consumption of 3060 kWh/year). Figure 10 shows the implementation of eclectic water heater in TRNSYS using a simplified electric heater model (Type 60).

The results of a single year simulation of a typical hot water load pattern of a typical Libyan house show that the consumed electric energy is increased by 8% due to the consideration of energy loss to the environment as shown in Figure 11. The calculations are made at a set point temperature of 45°C. The figure also shows the effect of increasing the set point temperature of the electric heater assuming a consumption of the same amount of useful energy (Q_useful). It is clear from the figure that increasing set point temperature from 45°C to 60°C is accompanied with an increase in the energy supplied by 4% to reach to 12%. Whereas, the heat loss to the environment is increased above 50%. In all calculations of different set point temperatures, the user temperature is maintained at 45°C.

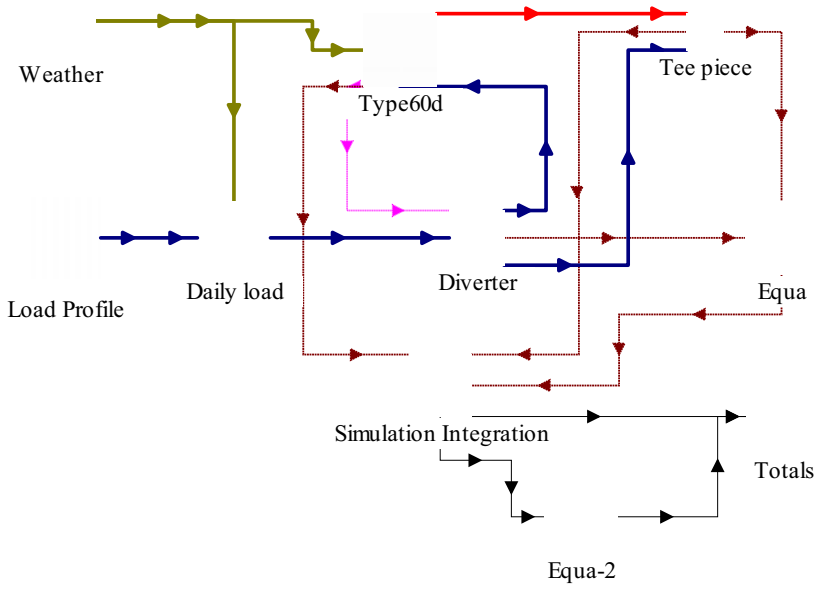

Figure 10: simulation of EWH in TRNSYS program

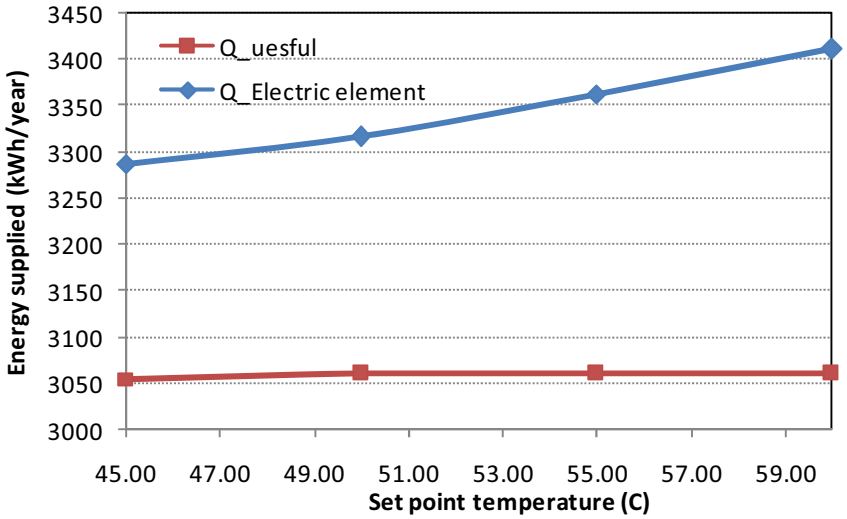

Figure 11: Effect of set point temperature on the energy supply and consumption

In This study, it is considered that the common set point temperature is 55 °C. The accompanied heat loss is about 10%. Therefore, the annual energy supplied by the electric heater per family is increased from 3060 kWh to 3364 kWh.

6. The Replacement scenario

The primarily results show that the effect of the electricity load of water heating in the residential sector on the electricity peak demand is very small. Therefore, in this study, we will investigate the maximum possible impact of a replacement scenario on the electricity peak demand without going in details of a gradual replacement. The replacement scenario is to replace the electric water heaters of the whole residential buildings by solar water heaters with an average annual solar fraction of 70%. This means that still there is 30% of the load energy demand that has to be covered by electricity.

7. Results and Discussion

The implementation of the results obtained on the residential water heating energy consumption on the electricity load for the four seasons are shown in Figures 11 to 14.

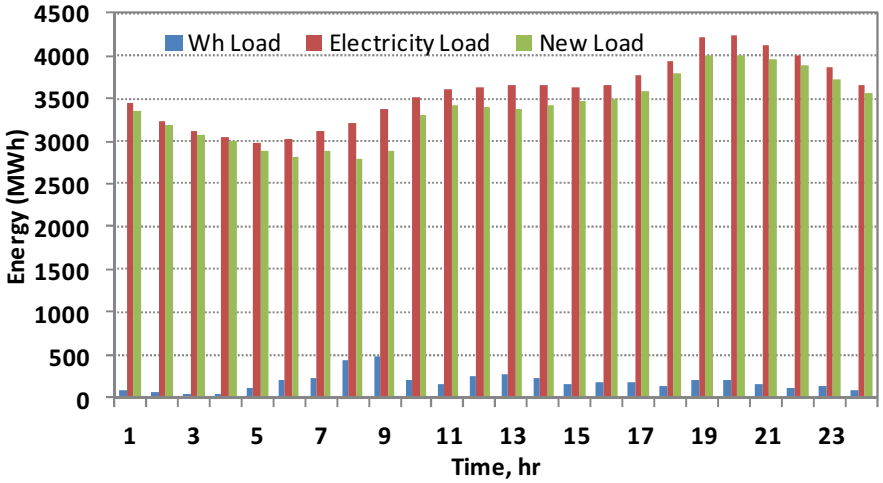

Figure 11: Energy load for autumn season

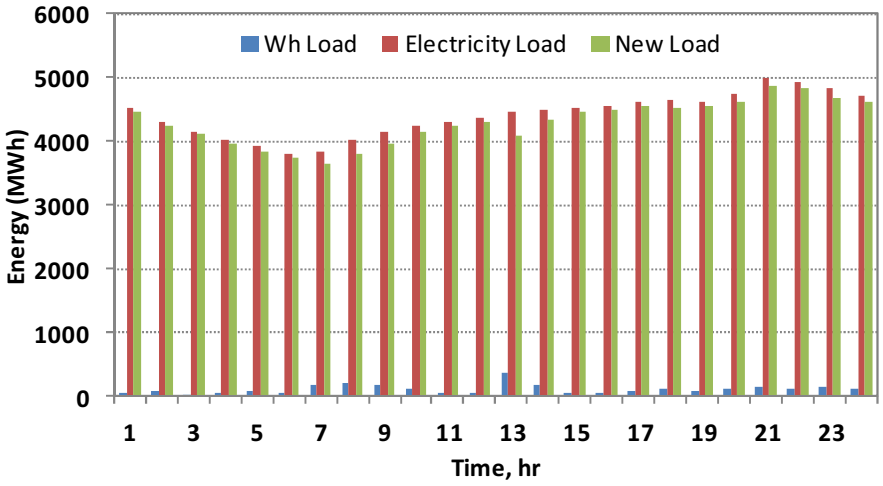

Figure 12: Energy load for summer season

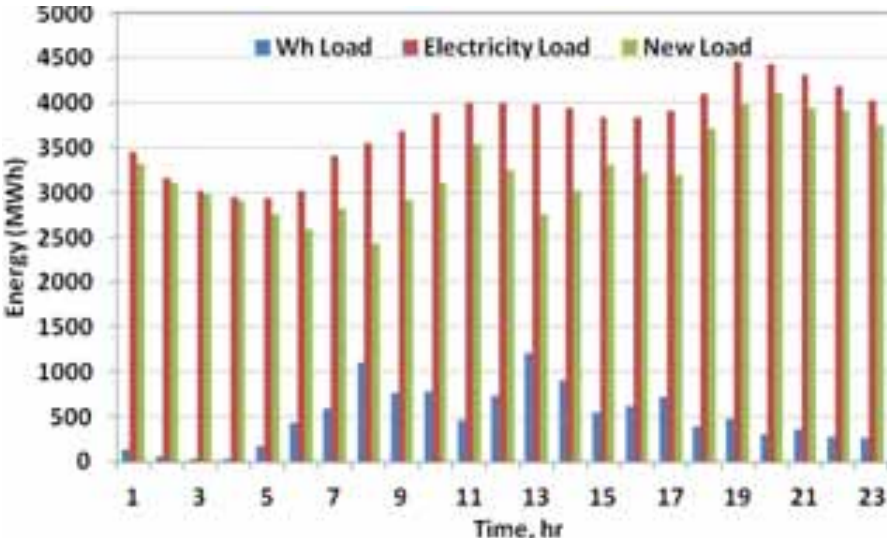

Figure 13: Energy load for winter season

In general, the obvious effect of the replacement scenario is in the winter season, so the peak load drops from 4465 MW to about 4085 MW with maximum saving in the peak load about 381 MW. Thus, the peak load is shifted one hour from 7:00 pm to 8:00 pm. Unfortunately, the maximum power capacity is needed in the

summer season where the lowest savings due to the replacement is achieved. The maximum peak load is nearly 5 GW at 9:00 pm, and the new peak load is 4.85 GW with maximum peak load savings of 149.5 MW.

In other mild seasons, autumn and spring, the maximum peak load savings are 237 and 329 MW, respectively. The peak times are at 8:00 pm for both seasons, and the new peak is shifted in spring to 9:00 pm, and in autumn it remains at the same time 8:00 pm.

The maximum peak load savings during summer, winter, autumn, and spring are 3%, 8.5%, 5.6%, and 8.1%, respectively. The average daily energy savings due to the replacement scenario in the summer, winter, autumn, and spring are 2.96 GWh, 12.8 GWh, 4.88 GWh, and 7.22 GWh, respectively. This is a considerable amount of energy that can be saved due to the suggested replacement scenario. When it comes to the reduction in the maximum capacity power installed due to the replacement scenario, it is only 149.5 MW that can be reduced. The maximum peak load of 5760 MW occurs in the summer (August) at night nearly 9:00 pm. Figure 15 shows the electricity load at the day of maximum peak load. The total energy consumption during this day is 122.45 GWh.

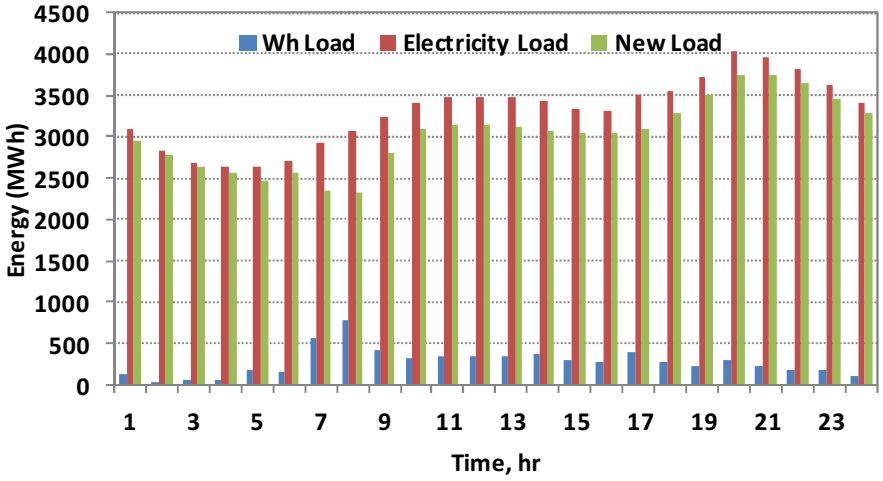

Figure 14: Energy load for spring season

The total annual saved energy using the replacement scenario of EWH with SWH is 2.55 TWh, and the load factor is improved from 65% to 67%. This saved energy is equivalent to a power plant with a capacity of 291 MW considering a load factor of 0.65, The nominal capacity will be 448 MW. This will be added to the fuel savings and huge environmental benefits due to avoiding burning fossil fuel that release harmful gaseous.

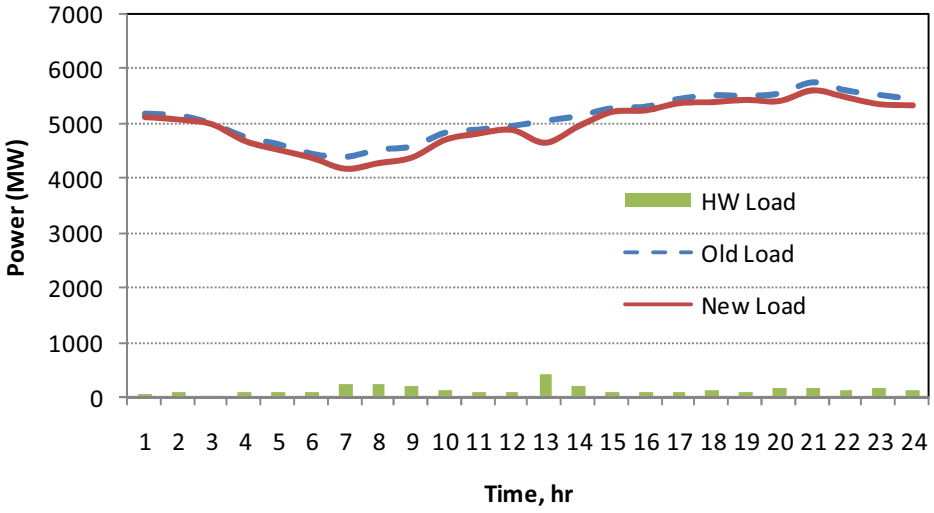

Figure 15: Effect of water heating load on summer peak load (15 August)

8. Conclusion

The Libyan electricity sector suffers from long terms intermittent for many years due to many reasons among of which bad of billing system and the high technical and non-technical losses. The total installed capacity is over 8 GW and the available operating capacity in 2010 is about 6.36 GW. The variation of the peak load among the four seasons of the year is over 1.5GW between summer and spring; this variation could be attributed to the energy consumption in buildings. On a daily basis, the maximum variation in the maximum peak load along the year is over 2.3 GW which is a very huge difference and has to be studied. Space heating/cooling, domestic water heating, and lighting are among the highest energy consumers in buildings.

Water heating for domestic purposes constitutes over 9.3% of the national electricity consumption in the country, which is equivalent to 3028GWh in 2010. The commonly utilized technology for water heating in the residential sector is the electric water heaters. This means that the most expensive along the expected life-long and the most pollutant technology used for domestic water heaters. Field study information about the hot water usage (profile and quantity) is used, and the annual hot water consumption for typical Libyan house is found 3060 kWh. The typical seasonal hot water load patterns are also obtained.

The study concluded that complete replacing of electric water heaters with solar water heaters in the residential sector will alleviate the electricity peak by 3% (149.5 MW) and improve the load factor by 2% (i.e. from 65% to 67%). However, the annual energy savings reach to 2.55TWh, and this is equivalent to a power plant with nominal capacity of 448 MW considering a load factor of 0.65. This will be added to the fuel savings and huge environmental benefits due to avoiding burning fossil fuel that release harmful gaseous.

NUMERICAL SIMULATION AND EXPERIMENTAL VALIDATION OF A SOLAR COOLING SYSTEM IN MEXICO

S. Lugo [1], O. García-Valladares [2]

[1] Posgrado en Ingeniería-Energía, UNAM, Temixco (México), sulu@ier.unam.mx
[2] Instituto de Energías Renovables, UNAM, Temixco (México), ogv@ier.unam.mx

Abstract

In this work the numerical simulation and experimental validation of a solar air conditioning to condition a 124 m^2 offices located in Jiutepec, Morelos, Mexico is presented. The model was developed and reported in a previous work, in which, using the software TRNSYS, the system is modeled for the design and sizing in order to reach the demand for air conditioning in comfort conditions for these offices. The system consists in a 8 kW adsorption air conditioning system, a thermal storage tank of 2m^3 and an area of 55.8m^2 of flat solar collectors of high efficiency, which is estimated to reach a solar fraction around 80%. The purpose of a validated model is produce a numerical tool in order to find the best operating conditions of the system and allow the study to any location where the solar cooling system can be implemented.

Keywords: *Solar cooling, TRNSYS, experimental validation, experimental analysis.*

1. Introduction

Mexico is in a privileged position to have high levels of solar radiation throughout most of the year; however this causes high temperatures in several states of Mexico and it is necessary to use cooling systems and air conditioning to have comfortable conditions. Nowadays, there are devices that can generate cold using solar energy, this is very attractive in places where cooling is required due to high ambient temperatures together with high solar radiation.

The advantages of solar cooling systems over conventional systems are mainly in the low electrical power requirement thus contributing to environmental protection, savings in energy costs and can be more easily used in remote locations away from the mains. Within the solar cooling exist two types of applications: absorption and adsorption cooling. For small capacity (<20kW) commercial absorption equipment are the following trademark: AOSOL, Pink GmbH, Robur, Sonnenklima GmbH, EAW, Yazaki, Rotartica and Climatewell. While in adsorption are: SorTech AG, InvenSor GmbH and ECN (IEA SHC-Task 38, 2010).

Among the many technologies for heat with the solar radiation, flat plate solar collectors is an option, they can reached temperatures close to 80°C with good efficiency. This range of temperature and the energy produce can be used in refrigeration equipment operating between 55°C to 95°C, the percentage of energy provided by the solar systems can be calculated (solar fraction).

The simulation program TRNSYS offers the versatility of coupling different independent models to form a solar cooling system under study. It also allows evaluate the system proposed in order to design and dimension its different components (TRNSYS, 2005).

2. Methodology

Through the program TRNSYS, the thermal behavior of offices of 124 m^2 located in Jiutepec, Morelos, Mexico has been simulated in order to show the current comfort conditions and to calculate the capacity of the refrigeration equipment necessary to achieve comfortable conditions inside the offices throughout the year (Lugo et. al., 2014).

doi:10.18086/swc.2015.10.31 Available at http://proceedings.ises.org

According to the cooling capacity required by the building, it was determined that the most appropriate system was an adsorption system trademark SORTECH model ACS 08 which has a nominal cooling capacity of 8 kW operating under the following conditions: inlet hot water temperature and flow 72°C and 1.6m^3/h, cooling water temperature and flow of 18°C and 2.0m^3/h, and an electric power required of 7W.

With SORTECH operating characteristics curves, this equipment was simulated using the TRNSYS Type 107; in this way, the interaction of this model with other components of the solar cooling system at different operating conditions was modeled.

In a second stage, the solar system was sized to provide at least 80% of the thermal energy required by the adsorption solar cooling equipment. The number and arrangement of solar collectors, size of the thermal storage tank and operating characteristics using a parametric study was obtained.

Solar technology used was flat plate solar collectors manufactured in Mexico by Modulo Solar SA de C.V. The solar collector used for this analysis is the model MS2.5 that has the following characteristics: 2.326 m^2 aperture area, mass flow rate of 3 l/min and efficiency curve according to Ec. 1 (Módulo Solar, 2013).

$$\eta = 0.7535 - 2.9132\frac{(T_{in}-T_a)}{H} - 0.0099\frac{(T_{in}-T_a)^2}{H} \quad (1)$$

The model validation is performed by comparing the results obtained using the TRNSYS simulation and experimental data collected for several days. The comparative error is expressed by the percentage mean absolute error (see Ec. 2) between the simulated and experimental data in the following form (Ayompe et. al., 2011):

$$PMAE = \frac{100}{N}\sum_{i=1}^{N}\frac{|C_i-M_i|}{M_i} \quad (2)$$

Where: *C* is the result of the value in each interval of TRNSYS

M is the result of experimentally measurement values in each interval

N is the number of data points used

In order to determine the thermal comfort in the space under study, the thermal sensation scale established by Fanger was taking account; it is based on the PMV and PPD indices divided into the levels shown in Table 1 (Fanger, 1972).

Table 1. Thermal sensation scale proposed by Fanger (Fanger, 1972)

PMV	PPD	Sensation
+3	99%	Hot
+2	77%	Warm
+1	26%	Slightly warm
0	5%	Confort (neutral)
-1	26%	Slightly cool
-2	77%	Cool
-3	99%	Cold

3. Numerical and experimental results

Daily monthly average weather conditions (Table 2) were obtained from the database generated by the UNAM, it contains meteorological information for populations in Mexico of more than 10,000 inhabitants (UNAM, 2013). These data were introduced to METEONORM software to generate a TMY format file that allows read the data in TRNSYS for short time intervals, in this case each hour (METEONORM, 2009).

Table 2. Weather conditions to Jiutepec, Morelos

Month	H MJ/m^2 day	Ht (20°) MJ/m^2 day	Ta °C	Ta_min °C	Ta_max °C	RH %
Jan	16.5	20.2	20.2	11.9	28.6	52.9

Average	**19.0**	**19.9**	**22.6**	**15.2**	**30.1**	**59.7**

Parametric study of solar thermal energy system was performed to obtain the area of solar collectors, the operating angle and the size of the thermal storage tank more appropriate for this case. The following conditions were considered for TRNSYS simulation: set point temperature (Tset = 72°C), difference for starting hydraulic pump (ΔT_on = 8°C) and difference to stop hydraulic pump (ΔT_off = 4°C).

Figure 1 shows the behavior of the solar fraction is shown against the area of solar collectors, with this results an area of 55.8m^2 (24 collector in an array of 4 series and 6 parallel 4Sx6P) was found in order to reach a solar fraction of around 80%.

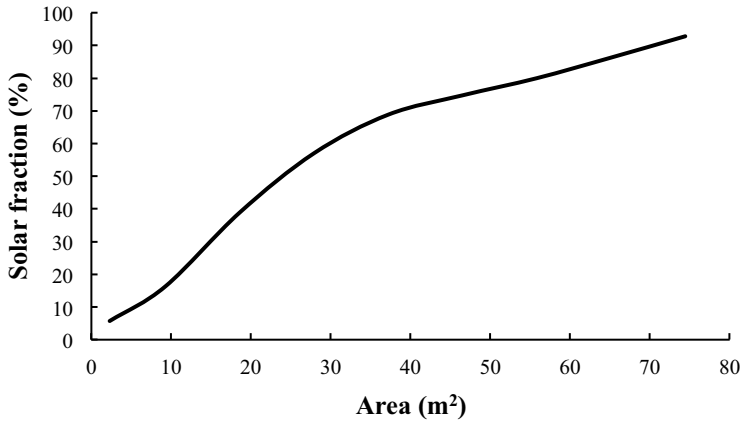

Figure 1. Sizing of flat plate solar collector arrangement

With the above arrangement (4SX6P), the solar fraction at different solar collector angles in order to find the optimum slope angle was simulated. It was obtained that 20° to the South was the best option (see Figure 2).

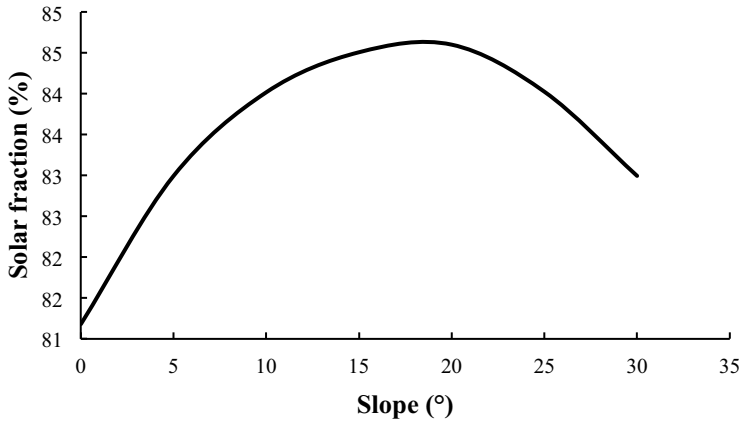

Figure 2. Slope of flat plate solar collectors

Taking into account the values found in the previous figures, the volume of the thermal storage tank was analyzed to find the better option (see Figure 3). The optimal volume of the tank found was 5 m^3, however considering the costs of it and that using a tank of 2 m^3 decreases only 1.8% the solar fraction, it was decided to use the latter one in the system installation.

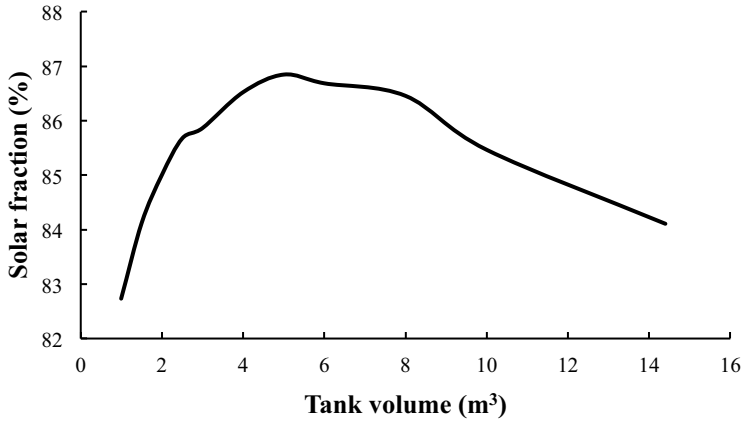

Figure 3. Volume of the thermal storage tank

According to the values obtained by the TRNSYS simulation, the final solar cooling system was designed and the selecting components are shown in Table 3 and Figure 4 shows the real components installed in the place of study in Jiutepec, Morelos.

Table 3. Components of solar cooling system

System	Trademark	Model	Quantity	Capacity
Solar cooling equipment	SORTECH	ACS08	1	8 kW
Solar collectors	Módulo Solar	MS2.5	24 (4Sx6P)	55.8 m^2
Thermal storage tank	MASS	THN-2	1	2 m^3

Figure 4. Installing components of solar cooling system

With the TRNSYS simulation of the solar cooling system, average monthly values of PMV and PPD were obtained throughout the typical year inside the offices, these range are from -0.6 to 0.07 and a maximum of 20%, respectively (see Figure 5). Therefore, according to the thermal sensation scale developed by Fanger (see Table 1), the offices under study will be in thermal comfort throughout the year.

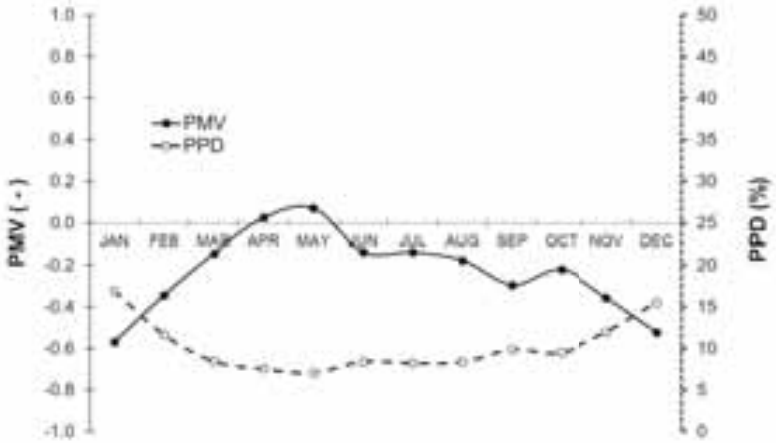

Figure 5. Comfort indices inside offices

Monthly theoretical results of this system (Figure 6) show that an annual average solar fraction of 85% is reached, surpassing the initial request. In addition, the proper functioning of equipment and comfort conditions in the offices are reached with this configuration according to the TRNSYS simulated data.

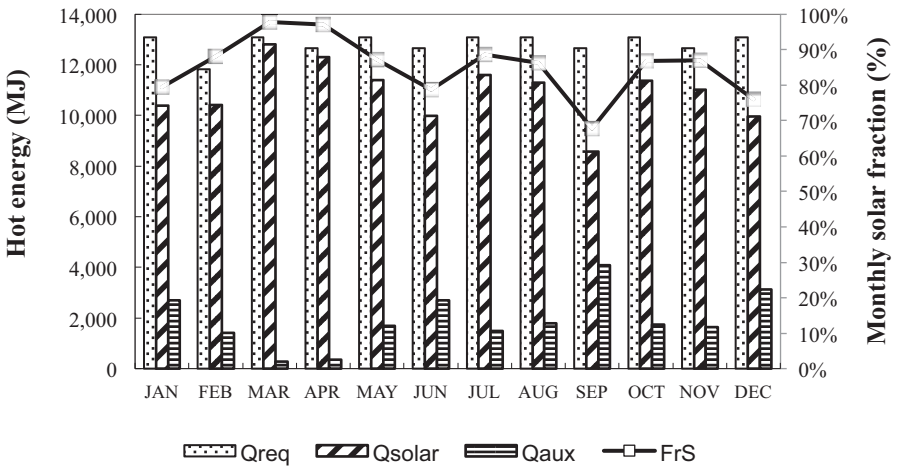

Figure 6. Thermal and energy monthly solar fraction in the solar heating system

The comparative results between the theoretical values obtained in TRNSYS and the experimental values for the outlet water temperature of the solar collector arrangement of 4Sx6P are shown in Figure 7 for a test of one day (May 25th, 2015).

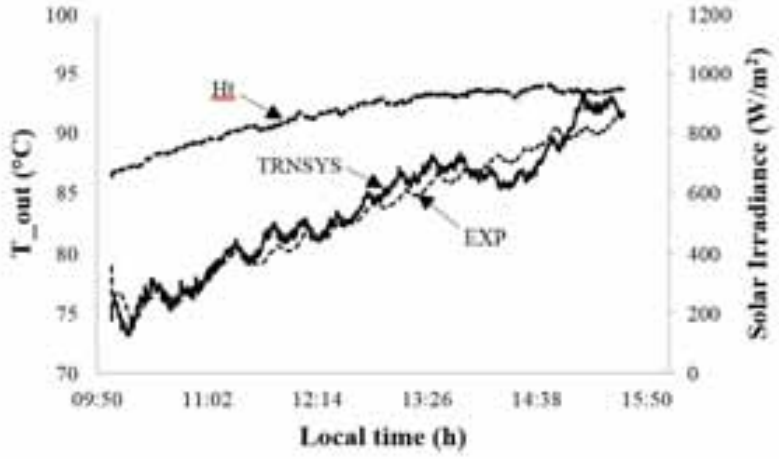

Figure 7. Comparison of outlet water temperature of the solar collector arrangement

The percentage mean absolute error (PMAE) in 10 days of testing performed for the outlet water temperature of the arrangement of flat plate solar collectors in °C is 2.75%, equivalent to ± 2.34°C. These values are within the range of uncertainty cited by Ayompe (Ayompe et. al., 2011). Due to this, the model can be considered in a good agreement with experimental data for the solar collector arrangement.

Validation of the whole solar adsorption cooling system model will be made in the near future when the coupling between the solar collector arrangement and the solar air conditioning system can be completed and experimental data can be obtained for different working conditions.

4. Conclusions

A designed solar cooling system is required to comfortably condition an office of 124 m^2 located in Jiutepec, Morelos, Mexico. The system consists in an 8 kW air conditioning system, 55.8 m^2 of flat plate solar

collectors and 2 m^3 of a thermal storage tank. The annual solar fraction reached with this system is 85%, in addition the proper functioning of equipment and comfort conditions in the offices are reached with this configuration according to the TRNSYS simulated data.

This work was carried out modeling in TRNSYS a solar air conditioning system in Mexico. The solar collector arrangement (4Sx6P) has been validated with experimental data obtained for 10 days. The percentage mean absolute error of these days of testing performed for the outlet water temperature of the arrangement of flat plate solar collectors in °C is 2.75%, equivalent to ± 2.34°C. Due to this, the model can be considered in a good agreement with experimental data for the solar collector arrangement.

Validation of the whole solar adsorption cooling system model will be made in the near future when the coupling between the solar collector arrangement and the solar air conditioning system can be completed and experimental data can be obtained for different working conditions.

The validation of this complete system provides the opportunity to have a reliable tool for the design, dimensioning and analysis of solar cooling systems in other Mexican regions with different weather and working conditions.

Abstract

Currently there is no global approach to model then characterize solar thermal systems for building application. Results of the existing approaches are valid only for specific conditions (climate and thermal building properties). In a previous study a generic methodology to model solar combisystems (SCS) was developed. This methodology was applied to predict the energy consumption of two kinds of systems: SCS combined with a gas boiler and SCS combined with a heat pump. In the current paper, an extension of the methodology to SCS combined with an absorption chiller is presented. The methodology is based on the development of an artificial neural network (ANN) that models the dynamic of the system. The developed neural models were able to predict, with a good precision degree, the annual energy performance of the system in different climates based on a learning sequence of only 12 days. The satisfactory results emphasize the generic character of the methodology and show that it could be used, in the future, as an energy performance evaluation tool. Also, the proposed approach will be helpful in the context of energy performance guarantees.

Keywords: *Thermal systems, Absorption chiller, Performance estimation, Dynamic modelling, Artificial neural networks, System testing.*

Nomenclature

P_{dhw}	Heat flow rate supplied for the Domestic Hot Water (DHW)	(kW)
A	Solar collector area	(m²)
G	Global irradiance	(kW.m^{-2})
P_{sh}	Heat flow rate supplied for space heating	(kW)
P_{aux}	Power of the auxiliary system (electric back up system)	(kW)
P_{sc}	Cooling power	(kW)
TD	Time delay	
AF	Activation function	
F'	Collector efficiency factor	
$(\tau\alpha)_{en}$	Effective transmittance-absorptance product for direct solar radiation at normal incidence	
$K_{\theta d}$	Incidence angle modifier for diffuse radiation	
c_1	Linear heat loss coefficient	(W/m^{2}K)
c_2	Non-linear heat loss coefficient	(W/m^{2}K^2)
β	Collector inclination	(°)
b_0	Constant to calculate the incidence angle	

1. Introduction

Solar thermal systems combined with an auxiliary system such as a boiler, a heat pump or incorporating an absorption chiller, can play an important role in reducing energy consumption of buildings for space heating, cooling and domestic hot water production. In this sense, characterizing the energy performance of solar thermal systems is a crucial issue.

doi:10.18086/swc.2015.10.32 Available at http://proceedings.ises.org

Currently, the available methods are either based on several separate physical tests of the components of the system to be evaluated, which does not take into account the real interactions between them, or on physical models that can be complex and difficult to identify especially because today's systems are compact and prefabricated in the factory (Haller, et al., 2013), (Lazrak, Leconte, Chèze, Fraisse, Papillon, & Souyri, 2015), (Leconte, Achard, & Papillon, 2012). In the absence of a reliable method to estimate the solar thermal systems performance before their integration in the building, their market underwent major difficulties for its development (Eur'Observ'ER, 2013).

In this context it is essential to develop a generic methodology that can be applied to different types of systems which overcomes the difficulties encountered by current methods.

For this reason a generic methodology to model solar combisystems (SCS) was developed previously (Lazrak, Leconte, Chèze, Fraisse, Papillon, & Souyri, 2015), (Lazrak, et al., 2015). This methodology was applied to predict the energy consumption of two kinds of systems: SCS combined with a gas boiler and SCS combined with a heat pump.

In this paper is presented an extension of the developed methodology to SCS combined with an absorption chiller. This new methodology can be used then to characterize any system based only on a short cycle test in a semi-virtual test bench. Also, by means of this technique it will be possible to evaluate the system energy consumption that it will have when installed in the environment that it was chosen for.

2. Methodology

2.1. Overview of the proposed methodology

A more detailed description of the methodology developed could be found in (Lazrak, Leconte, Chèze, Fraisse, Papillon, & Souyri, 2015). It has been shown that the methodology developed is:

- Nonintrusive because there is no need to dismantle the system, to be tested, in order to apply the methodology.
- The method takes into account the whole system so all interactions between subsystems are modelled.
- The system procedure test is short.
- The method allows predicting the system performance for different climates.

These characteristics make the methodology relevant to overcome the weaknesses of the current methods. To show that it could be applied to several kinds of solar systems and thus investigate its generic character this method was applied to solar system combined with an absorption chiller.

The five steps to model and then to evaluate the performance of a system following the proposed approach are represented in Fig.1. Evaluating a system following the methodology developed consists on first testing the system to be characterized in a semi-virtual test bench during a short sequence of time, typically 12 days, and in a dynamic way. This short test is based on the SCSPT method developed at INES, the French solar national institute. Then, data harvested, serve to design a dynamic neural network model of the system (described in section 2.2.). Basically, the ANN learns the internal behavior of the tested system. The goal is to have a global model with good generalization ability such that it can evaluate the system energy consumption, over a year, even with unseen data. The model can then be used to estimate the system's annual performances for different conditions. As a consequence it is not required that the model reproduces faithfully the system behavior in an hourly or daily basis as long as it can estimate well enough the annual performance. The ANN developed is inherent to the system tested and thus cannot be used to replace other different system.

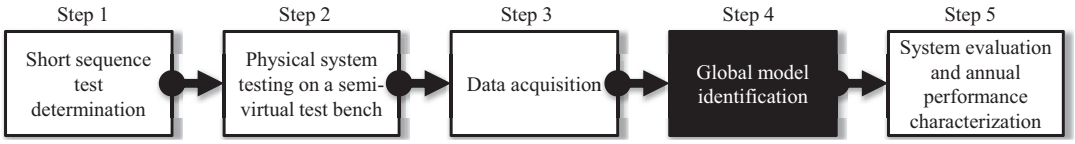

Fig. 1: Process stages of the proposed system's performance evaluation methodology

2.2. Black box modelling using ANN

Using Neural Networks seems to be the most powerful mathematic tool to solve this modelling problem. In fact, it was shown that neural networks are universal function approximators (Cybenko, 1989), so they can be used to approximate the system function. ANN were applied successfully to solve complex, non-linear, dynamic and multivariable problems. They tolerate errors, imprecisions and missing data as well (Kalogirou, 2001). Artificial neural networks were extensively used during the last decade.

The theory of ANN is clearly presented in (Dreyfus, 2005) and (Norgaard, Ravn, Poulsen, & Hansen, 2000). ANNs are parametric analytical functions whose concept takes inspiration from the human central nervous system. A neuron, the basic element of an ANN, can compute values z_l from a weighted summation of its inputs x_j. The summation coefficients ω_j^l are called synaptic weights. The subscript l denotes the neuron number. The neural operation is presented in (eq. 1). The function f_l is called the neural activation function (AF).

$$z_l = f_l\left(\sum_{j=1}^{K} \omega_j^l x_j\right) \qquad \text{(eq. 1)}$$

Inter-connected neurons constitute what is commonly called a neural network. There are several network architectures and each one is more suitable for a specific problem than others. The most common architecture for prediction and fitting problems is the class of multi-layer perceptron (MLP). An MLP is a feed-forward network built of neurons, arranged in layers. It has an input layer, one or more hidden layers and an output layer. In (fig. 2) a MLP, with E inputs, C neurons in the hidden layer and S outputs, is presented. The s^{th} output of the network can be obtained using (eq. 2).

$$y_s = f_s^S\left(\sum_{c=1}^{C} \omega_{c,s}^S f_c^C\left(\sum_{e=1}^{E} \omega_{e,c}^C u_e\right)\right) \qquad \text{(eq. 2)}$$

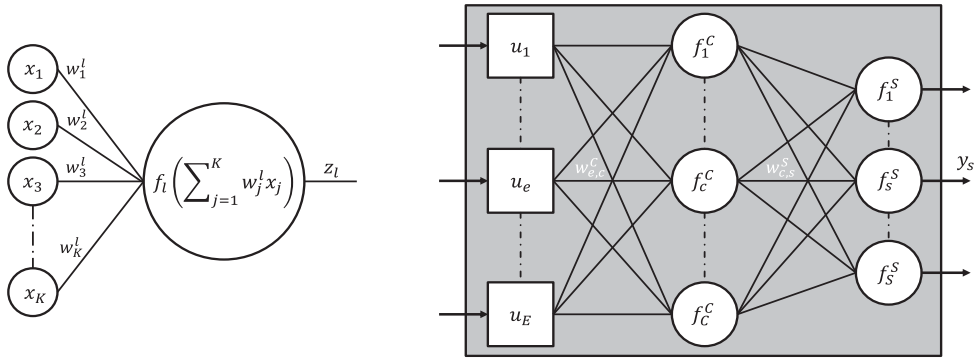

Fig. 2: Neuron formal representation (left), example of a neural network MLP with one hidden layer representation (right)

Neural network learning or training is the process of determination of an ensemble of weights so that the underlying function approximates the real system function. In fact, the objective of the training process is to minimize a cost function, with respect to weights, knowing a set of data. The short time of the system test, which is of 12 days, restricts the amount of available data for training. Therefore it is necessary to use a learning algorithm that can use a restricted data set without compromising the generalization ability of the model. For this reason it is relevant to use regularization method for the learning process. Typically, training aims to reduce the sum of squared errors see (eq. 3) with t_i the target data at the sequence time i and y_i the NN output at the same time. Regularization modifies the objective function by adding an additional term: the sum of squares of the network weights (eq. 4), q is the number of the neural network weights. By constraining the size of weights the training process produce an ANN with good generalization ability (MacKay, 1992). In fact, by keeping the weights small the ANN response will be smooth and so the over-

fitting is supposed to be prevented. In this study the objective function optimization is done using the Levenberg-Marquardt algorithm.

$$\text{sse} = \sum_{i=1}^{N} (t_i - y_i)^2 \qquad \text{(eq. 3)}$$

$$\text{ssw} = \sum_{i=1}^{q} {\omega_i}^2 \qquad \text{(eq. 4)}$$

Determination of the modelling input-output configuration is crucial to develop a generic methodology. Generally, solar thermal systems physical inputs and outputs differ from one to another. They depend on the energy sources used by the system and how this latter was designed by the manufacturer. However, energy systems can be represented in terms of power transformation between the renewable energy source, the loads and auxiliary system. This is why a compact configuration with four inputs: P_{dhw}, $A.G$, P_{sh}, P_{sc} and one output P_{aux} was selected. This open configuration, not particular to a specific system is relevant to develop a global and generic methodology. In (Lazrak, Leconte, Fraisse, Papillon, & Souyri, 2014) results concerning a solar combisystem modeling show that a dynamic ANN model (NARX model) is more efficient than a static one. The latter does not learn the dynamic of the solar system especially due to the heat storage component, for this reason dynamic neural network (fig. 3) was used.

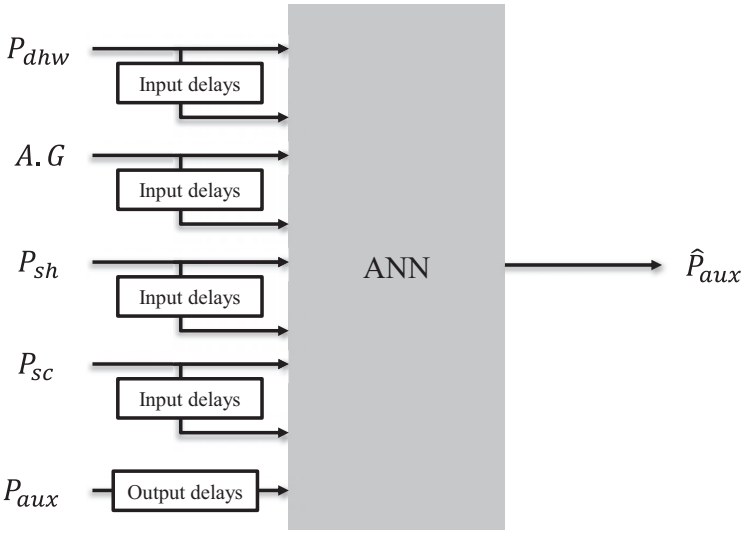

Fig. 3: NARX modelling configuration (open loop architecture), the hat "^" symbol indicates that the variable is predicted and not actual

Usually, regularization does not necessary guarantee the production of efficient networks. This is why it is essential to make some data preprocessing before training. By normalizing the input and target data vectors, the neural network training will be easier, faster and all vectors will be equally taken into account during the learning process. Equation (eq. 5) will be used to pretreat the training data in order to fall between a and b, x represent a vector of raw data through time.

$$Normalized\ variable = \frac{\mathrm{x} - x_{min}}{x_{max} - x_{min}}(b - a) + a \qquad \text{(eq. 5)}$$

The modelling time step is equal to 30 min. It was noted that the on-off cycles of the auxiliary system generate discontinuities in data. To smooth the collected data, a moving average of five time steps was applied to them.

2.3. Model Selection

During the training process, several networks are created with different number of neurons in the hidden layer, re-initializations (in order to ovoid local minima), output AF (tanh and linear functions), time delays (TD) and normalization intervals. The Bayesian information criterion (BIC) was chosen to select the most relevant network (Dreyfus, 2005), (Qia & Zhangb, 2001). It is defined by the following:

$$BIC = \ln MSE + q\frac{\ln N}{N} \qquad \text{(eq. 6)}$$

where q is the number of model weights and N the size of the learning data (number of samples).

The mean squared errors MSE (eq. 6) in BIC is calculated using the training data and in a closed loop architecture (Fig. 4) in which inputs and the initial values of the outputs, are used to predict the outputs (long-term model simulation) at future time steps.

Because the true output is available while the network is being trained, it is efficient to use it instead of feeding back the estimated output. The resulting architecture is called open loop architecture (Figs. 3 and 4). The advantage of this architecture (used only during training) is that the input to the ANN is more accurate.

The BIC selects ANNs (that have a lower BIC value) with a small number of parameters (synaptic weights). This is advantageous because ANNs with few parameters have a better generalization power, as stated in (Khosravi, Nahavandi, Creighton, & Saeid, 2013).

The whole training and selection process was developed in MATLAB R2012b.

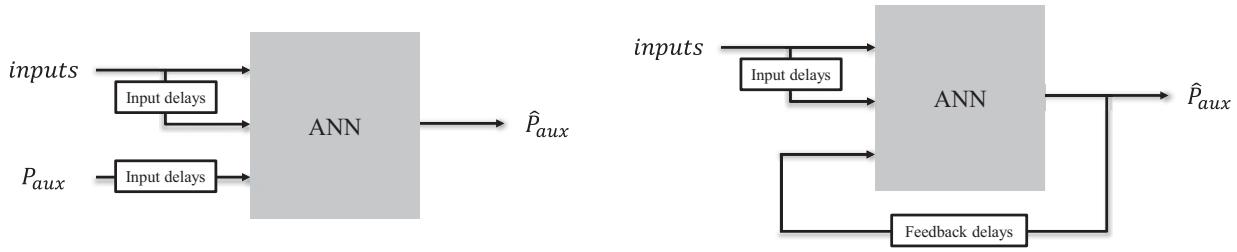

Fig. 4: Open loop architecture (left) and closed loop architecture (right)

In the following, the results of two different models for each system are presented:

- ANN1 is the model that is selected as the best model after the comparison of its performance with all the ANN models created in different boundary conditions (climate, building type).
- ANN2 is the model that would be selected based only on the BIC criterion.

2.4. The solar system evaluated

The system considered is an SCS combined with an absorption chiller. This system has been developed and designed within a national project. The goal of the project was to develop a system architecture that meets the following specifications:

- System intended for certain types of buildings of the Maghreb countries, southern Europe and the United States (Tab. 1).
- Systems with a limited number of hydraulic components (valves, circulation pumps and heat exchangers) to limit the risk of failure.
- Reduced cost
- System with good performance

The system is represented in (Fig. 5). It allows both solar discharge through the cooling tower and direct solar heating (without passing through the absorption chiller), if necessary with an electric online backup. This architecture uses only three-way valves to switch between different operating modes. This architecture uses specific units to prevent the risk of frost.

The physical characteristics of the system used to develop its TRNSYS model are given in (Tab. 2).

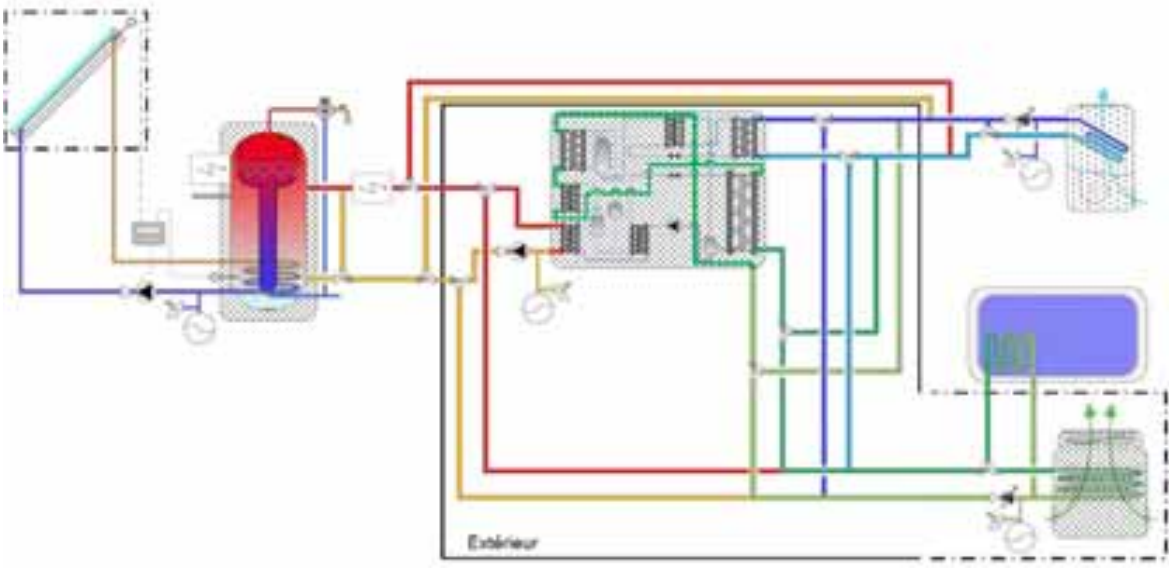

Fig. 5: Solar system combined with an absorption chiller hydraulic scheme

Training data are represented in (Fig. 6). They are the result of the system model simulation, using the Aix-En-Provence climate and a representative building of Maghreb countries, according to the SCSPT method (only 12 days).

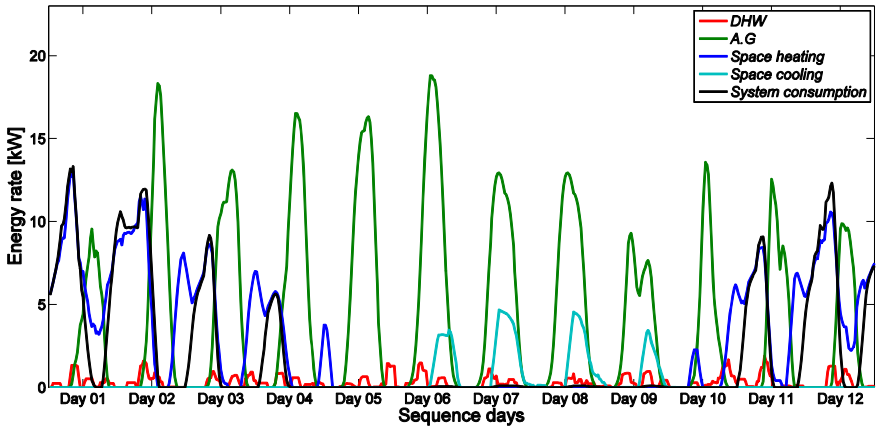

Fig. 6: Training data (SCSPT simulation results)

Tab. 1: Some characteristics of the buildings used as the boundary condition for each region

Region	Europe	USA	Maghreb countries
Area	140m²	300m²	300m²
Reference energy consumption	130 kWh/m² per year in Rennes	130 kWh/m² per year in Washington	60.7 kWh/m² per year in Marrakech
Materials of construction	Brick	Wood frame	Brick

Tab. 2: Physical characteristics of the system used in its TRNSYS model

Remarks	TRNSYS Type	Parameter values
Absorption chiller		
This type is not a standard one. It was developed based on Ziegler works (Ziegler, Hellmann, & Schweigler, 1999)	Type 881	NH_3/H_2O absorption chiller Nominal power: 7 kW.
Electric auxiliary		
Inside the storage tank	Equation bloc	Nominal power: 9 kW
Electric online backup	Equation bloc	Nominal power: 24 kW.
Dry cooler		
Heat exchanger + ventilator	Type 112 and Type 91	Nominal flow rate: 6000kg/h, Ventilator consumption: 190W
Storage		
The heat exchanger for DHW preparation is inside the storage tank	Type 340	1000l of volume 2 m height 10 cm of insulation Coefficient of lateral losses 6.76 W / K and for the upper and lower portions a value of 0.62 W / K
Solar collector		
Developed by (Haller, 2012)	Type 832	$F'(\tau\alpha)_{en}$=0.793 $K_{\theta d}$=0.9 c_1=0,749 (W/m²K) c_2=0,005 (W/m²K²) β=45° b_0=0.18 Collector area = 23 m²

3. Results and discussion

Several annual simulations were done in different boundary conditions (climates and the corresponding building type) using the TRNSYS model. The calculated energy consumptions were used to evaluate the ANN predictions (Fig. 7). The estimation results are represented in (Fig. 8).

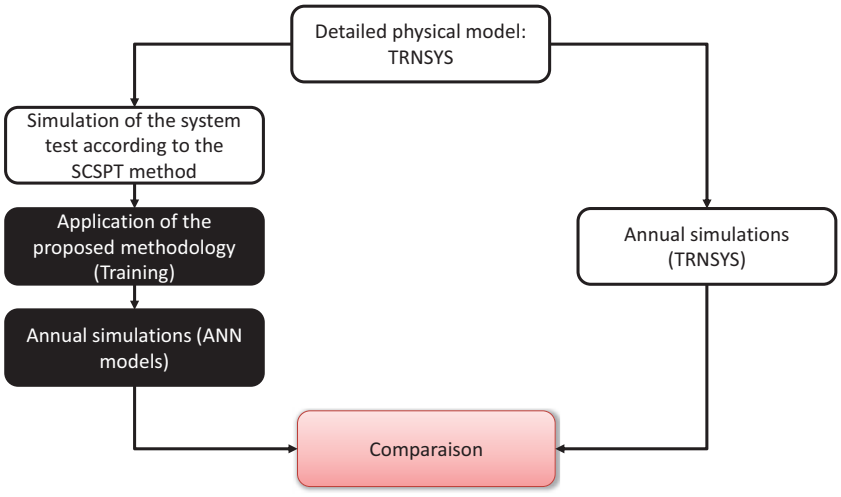

Fig. 7: Validation protocol based on the detailed TRNSYS model

Tab. 3: Characteristics of the selected ANN models

Model	Normalization interval	Number of neurons	Output TD	Input TD	AF	BIC value
ANN1	±1,0	8	3	2	tanh	-0.9946
ANN2	±1,0	12	2	1	linear	-2.2815

Each bar in the graphs represents the annual energy consumption per square meter of each system, estimated or calculated by the corresponding model in one specific environment (boundary conditions): two with ANN and one using the reference model.

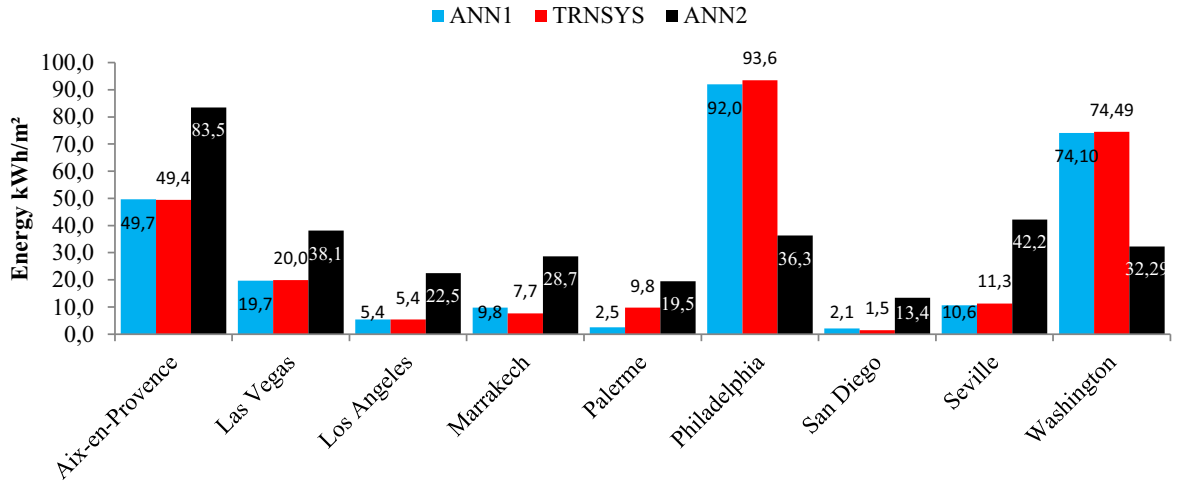

Fig. 8: Comparison of the ANN predictions and the TRNSYS calculations for annual energy consumption

Predictions of the best model ANN1 (Tab. 3) among all those created during the process of the methodology are very accurate. The errors are very low (below 5%) except for certain climates with low heat demand: Marrakech, Palermo and San Diego. However, the absolute differences are small (maximum of 7.3 kWh / m², reached in Palermo). The ANN difficulties for these conditions are due to the large differences between the learning conditions and these three climates.

ANN2 model predictions results, selected based on the BIC, reveal the mediocrity of some neural models as the statistical criterion may select. However, this model is easily detectable from the ones that must be discarded. In fact, according to the ANN2 model the annual consumption of the system in Aix-En-Provence is comparable or even greater than its consumption in Philadelphia or Washington. But this is impossible. Another ANN model that respects the trends of energy consumption depending on the climate, only among the selected models according to each configuration (normalization interval, delays and FA), was selected (Tab. 4). The results of the corresponding estimates are shown in (Fig. 9). Estimates of consumption of the system by the new neural model have greatly improved for all climates.

Tab. 4: Characteristics of the selected ANN model (2nd selection)

Model	Normalization interval	Number of neurons	Output TD	Input TD	AF	BIC value
ANN2	±0,2	7	3	2	tanh	-1.0226

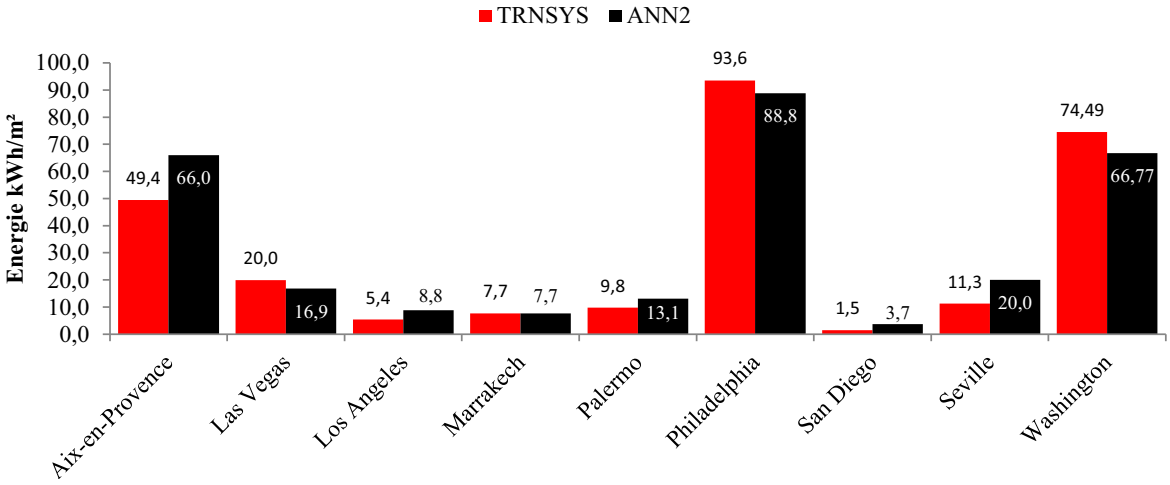

Fig. 9: Comparison of the ANN predictions and the TRNSYS calculations for annual energy consumption. Case of the ANN that has the characteristics presented in (Tab. 4)

In (Fig. 10) is given an example of the power consumption of the system in function of time during the cooling season (case of Philadelphia and ANN2). The goal of the method is to estimate the overall energy consumption and not to reproduce the exact dynamic of the system (however this is needed in the case of a control system). On the whole the model correctly follows the true evolution of the power; this shows that the differences observed in the case of certain climates occur during the heating season (winter). Creating a model per period (heating and cooling) would have probably given better results. This conclusion will be taken into account for future work.

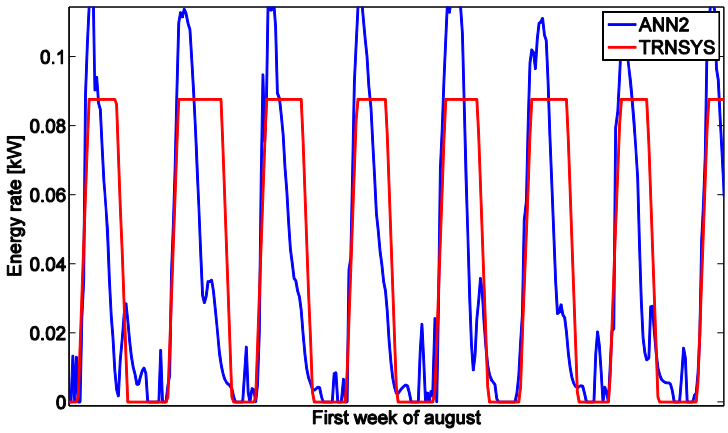

Fig. 10: ANN and TRNSYS outputs, case of the Philadelphia climate

4. Conclusion

The presented results show that the methodology developed extension to new systems such as SCS combined with absorption chillers is possible. In fact the best ANN model was able to predict with a satisfactory degree of precision, the annual energy consumption of the evaluated system, in different conditions, based on a learning sequence lasting only 12 days. In fact, the annual energy prediction errors were less than 5% in most cases. The methodology limitations appear in extreme boundary conditions compared to those used during the ANN training process. Results show also that the statistical criterion BIC is not able to select the best ANN model.

The Night Cooling Effect on a C-PVT Solar Collector

Franz Mantei[1], Mafalda Henriques[2], João Gomes[3,4],Olle Olsson[3,4] Björn Karlsson[4]

Abstract

Night cooling consists in running a fluid through a solar panel during the night in order to reduce the fluid temperature which can be used for cooling applications. Radiative heat losses can allow the fluid to reach temperatures below ambient while conduction and convection works to equalize the collector with the ambient temperature.

This paper analyzes the possibility of using an asymmetric concentrating photovoltaic thermal solar collector (C-PVT) for cooling applications during the night by losing heat through convection, conduction and irradiation. The cooling performance of the C-PVT collector has been measured during the night at different inlet temperatures in the interval of 13 to 38°C which corresponded to a ΔT (between the collector average and the ambient) from 6 to 28°C.

The performance of the tested C-PVT collector has been measured at different inlet temperatures in an interval of 13 to 38°C. During all performed measurements, the radiation losses did not drive the collector temperature below ambient temperature. With high ΔT (between the inlet and the ambient) of 30°C, a 1,85°C temperature decrease in the fluid was obtained. For ΔT of 14°C, the temperature decrease was only 0,88°C. The measurements showed a night U-value for the Solarus C-PVT of 4,2 W/m^{2}K This correlates well with previous papers showing measurements taken during the day.

Heat losses seem to be dominated by convection and conduction due to the existence of the glass in the collector. Despite this, a measurable relation between heat losses and cloudiness factor exists. This shows that the irradiance losses are not negligible.

Only very specific applications can be suited for night cooling with this collector design, since it is not so common to have applications that require low grade cooling during the night time or justify storing this energy. However, if the C-PVT design was made without a glass cover, the results could potentially be very different for locations with many clear nights.

1. Introduction

All objects are exposed to energy flows at all times. Some flows increase the energy level of the object while others decrease and are called energy losses. Energy losses of thermal energy are called heat losses and they occur by three different processes: Conduction, Convection and Irradiation.

Any two materials that are in contact and have different temperatures transfer heat between themselves in the direction of the material with a lowest temperature. This process is called heat conduction and can be calculated with the law of Fourier:

$$\dot{q} = -k\frac{\delta T}{\delta x} \qquad \text{(equation 1)}$$

where k is the heat conductivity and $\frac{\delta T}{\delta x}$ the temperature gradient. In a flowing fluid, it also occurs an energy

doi:10.18086/swc.2015.10.33 Available at http://proceedings.ises.org

transport which depends on the velocity and the level of turbulence, thus on macroscopic movements. This transport is called heat convection and is calculated together with the heat conduction:

$$\dot{q} = \alpha \cdot (T_1 - T_2) \qquad \text{(equation 2)}$$

where α is the heat transfer coefficient which comprises fluid parameters, flow parameters and geometric parameters, and $(T_1 - T_2)$ is the temperature difference between the interacting systems.

The heat radiation denotes the electromagnetic waves which a body emits to its environment on the basis of its temperature. The maximum radiation density of a body is calculated by:

$$\dot{e}_S = \sigma \cdot T^4 \qquad \text{(equation 3)}$$

and is emitted by a so called blackbody (VDI, 2013).

1.1. The Basics behind Night Cooling

During the day, the losses described above are generally lower than the amount of incident solar radiation on the collector and, thus the collector gains energy. However, during the night, since the solar radiation is zero, the energy intake is smaller than the heat losses, which leads to a decrease of the collector temperature. This effect is called night cooling.

For being able to cool during the night two main factors are considered in this paper. One is the cooling on the basis of convectional and conductional heat losses while the other is called night sky radiative cooling.

The heat losses caused by night sky radiative cooling are done by a radiative process which can be separated in two sub processes: One is the radiation from the earth to the clear sky. This can be assumed as a black body radiation whereby the temperature of the black body is giving the surface temperature of the earth or in this case the collector. The other process is the atmospheric radiation caused by water vapor, carbon dioxide and ozone (Armenta-Déu et al., 2003).

Heat losses caused by convection and conduction will cool down the fluid in the collector to no more than the ambient temperature. On the other hand, radiative cooling is able to decrease the temperature level of the fluid below the ambient temperature, if the surface is an adequate emitter. In this way, the fluid gains heat during conductional and convectional heat exchanges (Dobson, 2005).

One final note should be made comparing PVT to standard thermal collectors. PVT panels can go below ambient temperature. This is considerably more difficult in thermal. This is because the PV cells emit much more radiation than the selective surface. Basically, a worse performance during the day by PVT collectors, leads to a better performance in cooling during the night. It is not reasonable to expect to have a panel that performs well in gaining heat during the day and, at the same time, also performs well at loosing heat during the night.

1.2. Possible Applications for Night Cooling

Since night cooling can be able to provide fluid temperatures below the ambient temperature, it can be used to decrease the temperature of materials below the ambient temperature. Three main constrains are limiting the applicability of night cooling: The first constrain is relatively small amount of cooling energy. The second constrain is the small temperature difference to the environment which significantly limit its range of applications. The third constrain is that in cloudy nights, the cooling energy gained will be at best at ambient temperature.

According to Armenta-Déu et al. (2003), possible applications for night cooling are production of fresh water, freezing and food preserving as well as building air-conditioning and energy generation. All of these applications sharing the need of cooling energy, the differences are the temperature ranges and the amount of energy required.

One way to make a night cooling system can be to, during the night, use a normal heating system but this time with the goal of losing heat. Therefore, the fluid would flow through the collector, cool down and gain

energy while passing the heat exchanger. The heat exchanger brings the low temperature energy flow to a thermal storage which will decrease its temperature level during the operation time. The lower the temperature level reached, the more possible applications can be suitable. However, the temperature level is depending on the heat losses of the module, thus if the operating temperature drops under the ambient temperature (due to night sky radiative cooling), the thermal storage could reach a rather low temperature levels.

Another possible application is to use the cooling energy for phase change of PCM (phase change materials). These materials can be used in buildings for cooling during the day. They can be mounted on the ceiling to take the heat during the day to change its phase and thereby cool down the room temperature. During the night with heat losses to the environment and without energy gain from the sun the room temperature decreases and the PCM starts to change back its phase to its previous phase. The cooling energy from the collectors could be used to cool down a bigger area of PCM increasing the potential benefit from this application.

A practical implementation of the above described could be to run the thermal cycle of the collector in the standard way and to attach a heat exchanger. The second thermal cycle could be gaseous and directly blown to the consumer, in this case, the PCM. It could also be a liquid which circulates to the PCM in a pipe system. Additionally, other applications which need space cooling, like rooms for computer servers, show potential (Armenta-Déu et al., 2003).

2. Collector Description and Method

This chapter describes the used testing equipment and system as well as the asymmetric C-PVT collector.

2.1. The Test Setup

The Solarus C-PVT collector has been placed on the rooftop of the university in Gävle, Sweden, and faced to the south with an angle of 60 degrees. The collector total surface is 2.4 m^2 divided between two throughs each with one receiver. Each receiver holds strings of cells on both sides. This strings are either 19-19-19-19 or 6-32-32-6 cell as detailed in Fig. 1 and Figure 3. The collector stand holds a Kipp & Zonen solar radiation sensor at the same tilt as the collector.

Fig. 1: Solarus C-PVT collector and solar radiation sensor

Fig. 2: Thermal system

The thermal system features two loops. In the primary loop, a fluid (water), is passed through the collectors and then to a heat exchanger. This loop is separated in two sub loops, one for each collector through. Each sub-loop has its own Kastrup flowmeter but only one pump is required to run the two sub-loops. An expansion valve is placed in the circuit for safety as shown in figure 2. At the entry and exit of the collector, four PT100 temperature sensors are installed, as show in figure 1. The primary loop also features a small tank for mixing the water and a heater which allows regulating the inlet temperature. This heater can be used

in conjunction with the secondary loop. The secondary loop is merely grid water flowing through the heat exchanger in order to reach lower inlet temperatures. Both the heater and the grid water are designed in order to keep the inlet temperature as steady as possible. A picture of the thermal system is shown in figure 2. The pumps in the thermal system in figure 2 circulate the water to the collector (shown in figure 1) and back.

2.2. Solarus C-PVT collector

The Solarus C-PVT collector design is called Maximum Reflector Concentration (*MaReCo*) and belongs to a family of stationary reflectors patented by the Swedish company Solarus. The reflector has a parabolic and circular shape and is used to concentrate the solar radiation. The reflector is made of anodized aluminum with a total solar reflectance ρ_{total} of 95% (measured according to norm ASTM891-87). A reddish brown silicone is used for electrical insulation between the mono-crystalline PV cell and the receiver core on both the upper and lower side (Gomes et al., 2013).

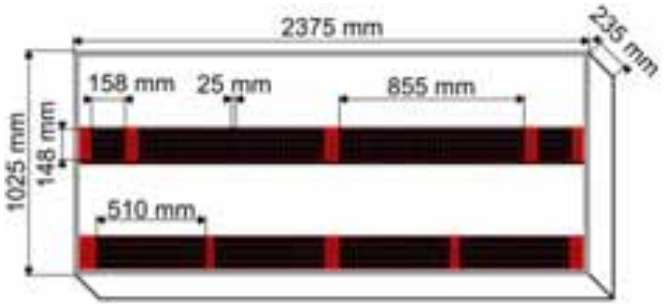

Figure 3: Test module dimensions

The module contains a glazed protection which is made of low iron tempered glass with a solar transmittance τ_{glas} of 95%, measured according to the norm ISO9050 (Giovinazzo et al., 2014) and a supporting structure manufactured out of plastic and metal (Gomes et al., 2013). The efficiency for direct light η_{direct} of the collector reaches 70%, while the efficiency for diffuse light $\eta_{diffuse}$ is 50.8%. Furthermore, the linear loss coefficient a_1 is 4.484 W/(m^{2}K) and the secondary loss coefficient a_2 is 0.0034 W/(m^{2}K) (Gomes et al., 2013).

3. Results and Discussion

For testing the performance of the Solarus C-PVT collector, measurement values from 18 nights between the 5th of September and the 2nd of November of 2014 have been analyzed. Table 1 comprises the night with the maximum (05.09. – 06.09.), average (09.09. – 10.09.) and minimum (28.10. – 29.10.) energy gain, as well as the results of a night in which an electrical heater provided a steady inlet temperature of 40°C (09.10. – 10.10.). The night time period is defined to be between 10PM and 05AM. Appendix 2 contains a wider collection of the measured night.

The following rows of the table show the cooling energy obtained, E_{cold}, in [kWh], the specific heat removal rate $\dot{e}_{cold} = \frac{\dot{E}_{average}}{A}$ in [W/m^2] (with the average energy gain during the night $\dot{E}_{average}$ and the surface area of the module A), the outlet temperature T_{out} in [°C], the ambient temperature T_{amb} [°C], the temperature difference between outlet and the inlet of the collector ΔT [°C], the temperature difference between collector average and ambient $T_{coll} - T_{amb}$ [°C], the cloudiness factor in [%] and the wind velocity v_{wind} [m/s]. The data for cloudiness and the wind velocity have been obtained from the database of the World Weather Website, which contains values for every third hour which have been taken for the time period between 10PM and 05AM and were averaged.

The measurement results show that the circulating water through the collector during the night can lose up to 2 kWh of thermal energy with an average power of more than 60 $\frac{W}{m^2}$. However these values are highly dependent on a number of conditions being met.

Table 1: Results night cooling measurement data

Night [22:00 – 05:00]	E_{cold} [kWh]	$\dot{e}_{cold}$ [W/m²]	T_{out} [°C]	T_{amb} [°C]	ΔT [°C]	$T_{coll} - T_{amb}$ [°K]	Cloudiness [%]	v_{wind} [m/s]
05.09. - 06.09.	-1,08	-63,75	23,0	10,2	-0,88	13,2	5,3	2,1
09.09. - 10.09.	-0,72	-42,23	18,7	8,6	-0,58	10,5	40,7	1,8
09.10. - 10.10.	-2,0	-117,34	35,8	8,7	-1,85	28,1	88,7	1,8
28.10. - 29.10.	-0,44	-25,79	18,6	12,74	-0,37	6,0	54,3	6,7

With a decrease in temperature of less than 1°C few applications are feasible. However, the measurement system is not made for storing the water, thus the water has been cooled down in every loop to about the same temperature.

Table 1 shows that one of the main factors in the night cooling effect of the Solarus collector is the difference between inlet and ambient temperature, as show in table 1. As expected, the larger this difference, the higher the cooling power gained during that night. This is show clearly in figure 4.

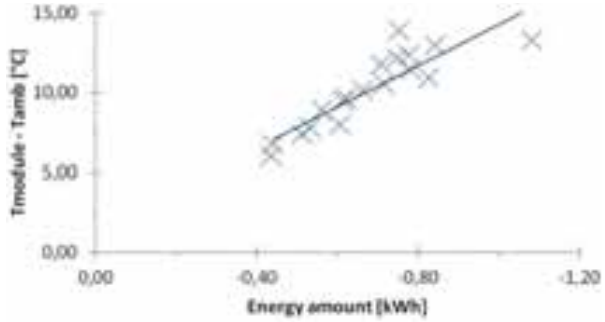

Figure 4: Cooling Energy Collected vs ΔT (Average Collector Temperature – Ambient Temperature)

During a clear night, the exchange of radiation between the collector and the sky is cooling down the collector. This way, clear nights are expected to increase heat losses. For some collector designs, this effect can be so strong that allows the collector to reach temperatures below ambient.

The measurement results listed in Table 2 in appendix can be visualized in Figure . These results show an increase in the collector heat losses when the cloudiness level is reduced. Consequently, it is not just the impact of conductional and convectional heat losses which accounts for the decrease in the fluid temperature.

The cloudiness was expected to correlate to the ambient temperature but our study in Figure **Error! Reference source not found.** did not show a clear dependency between ambient temperature and cloudiness.

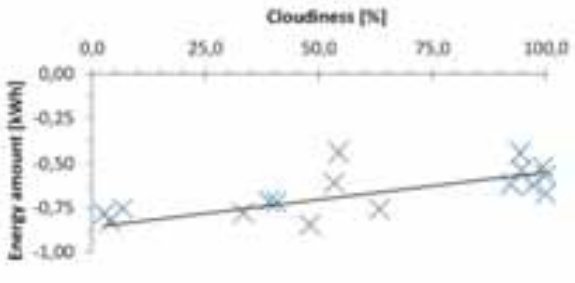

Figure 5: Impact of cloudiness on heat losses

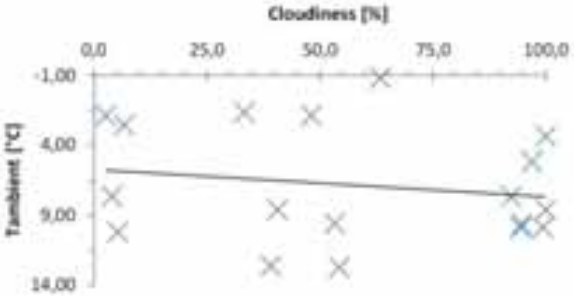

Figure 6: Impact of cloudiness on ambient temperature

In figure 7, we analyze the dependency between the cooling amount gained and the wind velocity. An

increase in wind velocity is expected to directly lead to an increase in convective heat losses. However, our measurement results shown that the heat losses are decreasing with an increasing wind velocity. This is result is an error that may be a result of the fact that the wind measurements were not done exactly in the same location where the collector night cooling power was measured. Nevertheless, these results suggest that the convectional heat losses have a lower impact on the Solarus C-PVT collector than the losses caused by conduction and radiation or, in other words, the effects of the wind velocity is less significant that other factors.

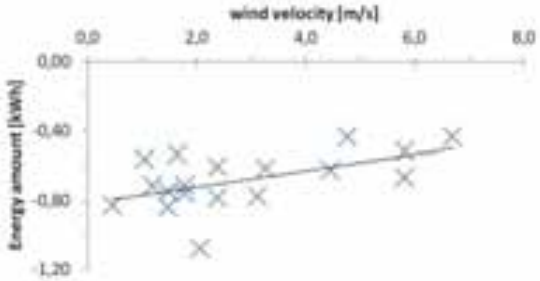

Figure 7: Impact of wind velocity on heat losses

For calculating the amount of cooling energy caused by night radiative cooling several equations are introduced for the sky temperature as well as the sky emissivity (Eicker et Dalibard, 2011). Most of these equations require temperature and pressure parameters which haven´t been measured. Two equations are just depending on the ambient temperature but Eicker et Dalibard (2011) show that the achievable results are fitting inaccurately with the measurement values and are thus not presented.

On the other hand, heat losses caused by conduction and convection can be calculated and subtracted from the entire amount of cooling energy. This method requires accurate values for the wind velocity. Previous consideration values for the wind velocity have been taken from a weather website, which is accurate enough for general statements but not for an accurate calculation of convectional heat losses.

Fig. shows the impact of cloudiness on the obtained cooling power per square meter, as well as the temperature difference between the module average and the ambient. For this graph, we have defined low cloudiness has being smaller than 7%, medium cloudiness between 40% and 60% and high cloudiness bigger than 90%. All measurements in this figure are done on an interval of the temperature difference between 7.5°C and 12.5°C where a more or less linear dependency can be seen for the impact of cloudiness. Furthermore, since many points overlap on the graph, an average of the three points (low, medium and high cloudiness) is also shown in the figure. These three points clearly show an increasing temperature difference with a decreasing level of cloudiness.

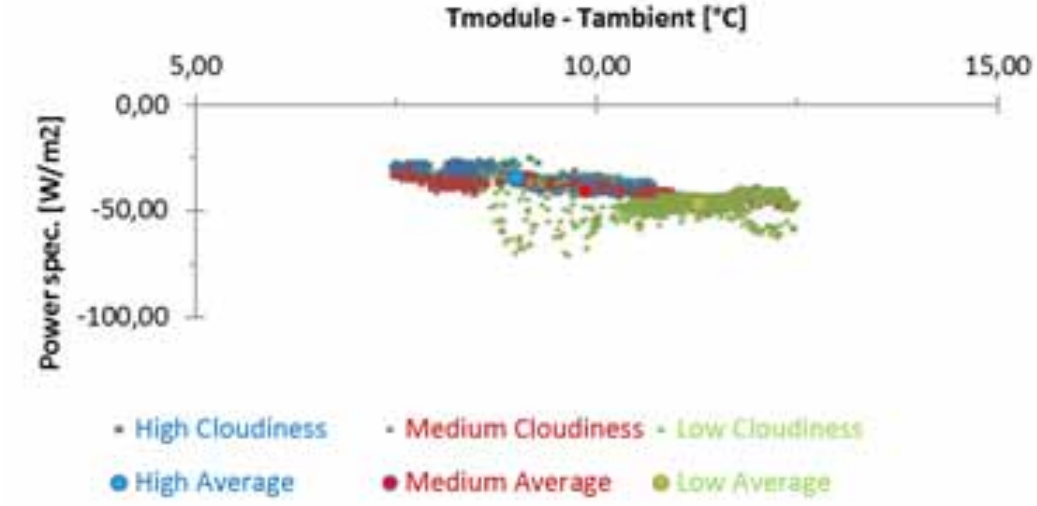

Fig. 8: Impact of cloudiness on power and temperature difference

Figure 9 shows the collector specific power loss during the night. The points measured at higher temperatures difference (inlet=40°C) display a large spread due to the fact that the available thermal test system was not able provide a sufficiently stable temperature. This factor was combined with a relatively low thermal mass of the receiver. Despite this equipment issue, it is still fair to say that the collector night U-value is close to 4.2 W/m^{2}K since there is an acceptable R^2. The U value is given by the slope of the figure 9.

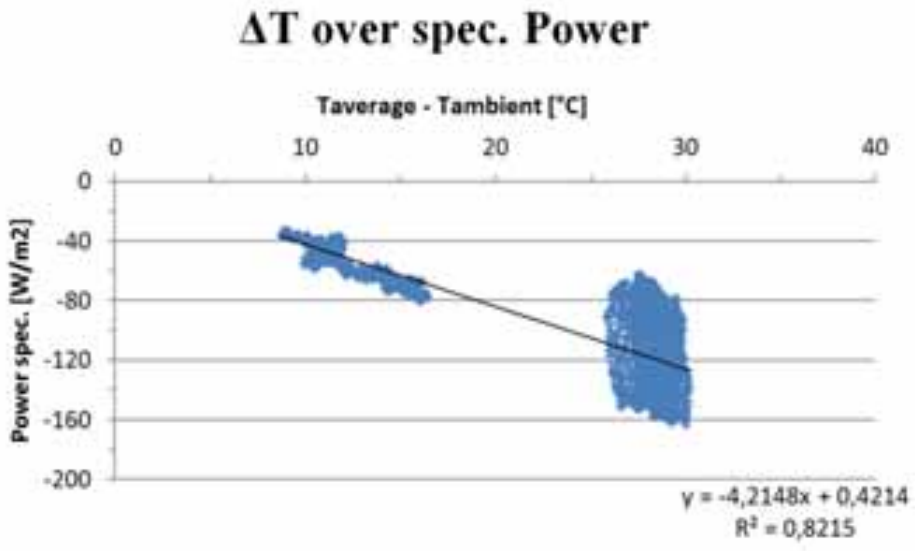

Fig. 9: Specific Power vs ΔT (Tcollector – Tambient)

Table 3 shows the result of annual simulations during the day and compares with the results of the night measurement results. It is important to note that the night cooling results are an extrapolation from an average of the nights (at 6 or 10 C above ambient temperature) to an annual output. The daily simulations were created using the Solarus simulation software. The cooling power obtained is not negligible but the issue remains how to use cooling power above ambient temperature.

Additionally, a comparison between the energy spent in pumping and the cooling gained should be performed.

Table 3: Comparison of annual output of the C-PVT in Stockholm.
Outputs in kWh/m2/day and the temperatures in °C. Tmed is the collector average temperature.

	During the Day			During the Night	
Location: Stockholm	**Tmed-Tamb**	**Heating**	**Electrical**	**Cooling**	**Tmed-Tamb**
Extracting heat at an average of 30C above Ambient	**30**	**1.06**	**0.22**	**0.20**	**6**
Extracting heat at an average of 70C above Ambient	**70**	**0.38**	**0.16**	**0.33**	**10**

4. Conclusion

The performance of the tested C-PVT collector has been measured at different inlet temperatures in an interval of 13 to 38°C.

The factor with the highest impact in the night cooling effect of the Solarus collector is the difference

between inlet and ambient temperature, as show in table 1 and 2 as well as figure 4. This implies that only very specific applications can be performed since it is not so common to have applications that require low grade cooling during the night time or justify storing this energy.

During all performed measurements, the radiation losses did not drive the collector temperature below ambient temperature. In nights, when the heater was not used to keep the inlet temperature steady, the collector temperature could be decreased by a maximum of 14°C during the whole night.

In some night, the heater was used to keep the inlet temperature steady, this leads to higher cooling energy gains being registered over the night, since we are losing energy that is provided by the heater. With high ΔT between the inlet and the ambient, as is the extreme case of a ΔT of 30°C, a 1,85°C temperature decrease in the fluid was obtained and recorded throughout the night. However, for ΔT of 14°C, the temperature decrease was only 0,88°C.

Still, the relatively low impact of cloudiness shown in figure 5 and 8 indicates that the convection and conduction heat losses are more important than the radiation heat loss for this collector design which is reasonable since the glass cover should block most of the IR radiation. Despite the dominance of conduction and convection losses, there is still a clear correlation between heat losses and cloudiness which shows that heat losses due to irradiance are occurring and are measurable.

Furthermore Figure and Figure point out that the impact of wind velocity on the cooling energy, as well as the impact of cloudiness on the ambient temperature seems smaller than expected which leads us to conclude that the dominating factor is the convectional and conductional heat losses.

Figure 9 shows an night U-value of 4,2 W/m^2K which is close to the U-value measured during the day in previous papers.

Some PVT designs can go below ambient temperature. This is much less likely to happen in standard thermal panels. This is because the PV cells emit much more radiation than the selective surface of the thermal panels. Basically, a worse performance during the day by PVT collectors, leads to a better performance in cooling during the night. It is not reasonable to expect that a panel performs well in gaining heat during the day and, at the same time, also performs well at loosing heat during the night.

When speaking about heating, it is generally accepted that energy at ambient temperature has no value. For cooling, the same is generally true. The analyses of the measurements that have been made reveal that the C-PVT collector shows little potential for cooling applications. However, if the C-PVT design was made without a glass cover the results could potentially be very different for locations with many clear nights.

Abstract

Among different strategies available technologically to reduce energy consumption and environmental impact in buildings, there is the use of new thermal-operated air conditioning systems. An available alternative is absorption refrigeration systems, which can operate with renewable energy sources such as solar energy, and use environmentally friendly refrigerant substances.

In Colombia, this type of systems have not been investigated thoroughly nor have carried out developments, because the field of solar energy is emphasized in the use of thermal energy, to be used on a refrigeration cycle that allows to condition an environment of a determined compound, and besides that, this air conditioning going to achieve through intelligent control, it has not been subject of considerable advances, neither in the part of applied research, nor its implementation. According to this, the idea is to use developments of these systems that have been simulated and implemented in other countries, including Spain, for the start in the UPB with research, development and implementation of those after making a literature review about the systems.

To develop the aforementioned system, a comprehensive literature review of the technologies has been made to be implemented in terms of automation and control. A simulation in the TRNSYS® software of the system to be implemented in a building on the campus of the UPB, which requires air conditioning for the comfort of the people who inhabit, is developed. The system will be regulated by a control system that receives information from various parts of the plant with temperature and flow sensors. To carry out the control of this system, classical control techniques are going to be use for some water systems that constitute the demonstrative installation, but for the part of chilled water and air conditioning, intelligent control techniques will be handled, which allows to meet the needs of the air conditioning system that is intended to implement, as this part is quite complex for the management of different variables. This system will operate automatically acting on valves, pumps, fans, Fan-coil and/or mats of water (they act as radiant walls) for correct operation by previously established set points.

1. Introduction

Buildings have an impact on the lives of people and the planet's health. In developed countries, buildings use one third of the total energy, two thirds of the electricity and one eighth part water, and transform land that provides valuable ecological resources. The use of these resources and their impact on the environment may be more relevant in developing countries, such as Colombia, where the technology used for the construction and operation of most buildings is not as advanced. In this context, it has defined "sustainable building" or "green building" has been defined as a final standard that is given by an environmental performance over the life cycle of a building, which is seen and understood as a whole (LEED, 2008).

This situation has caused different institutions, associations, governments and companies to take interest in implementing measures aimed to rationalize the use of natural resources in buildings and make these important structures of society to be in harmony with the environment. The vast majority of current air conditioning systems operate on the principle of the refrigeration cycle vapor compression (El Aire Acondicionado, 2015). It has been found that these contribute significantly in an opposite direction to the concept of sustainable development.

In Latin America the main initiative was the *RIRAAS* network (*Red Iberoamericana de Refrigeración y Aire Acondicionado Solar*), which arose before 2001, with the aim of promoting and disseminating the cold production technologies with solar energy. It was financed by the program *Ciencia y Tecnología para el Desarrollo (CYTED)* and the *Consejo Nacional de Ciencia y Tecnología de México (CONACYT)* until 2004. In Latin America the main facility in solar air conditioning operation currently operates in Mexico, but besides this, there is a lot of prototypes of universities and research centers used for research and development of different technologies for solar cooling (Sparber et al., 2007).

This article aims to present an alternative to the use of air conditioning systems to reach the standard of "sustainable building" in Colombia (LEED, 2008). Under the standard of "sustainable buildings", cold production with unconventional heat sources, such as absorption cooling systems powered by solar energy, energy are potentially attractive in the tertiary sector to meet the cooling demand through air conditioning systems in buildings, important chain stores and shopping malls, among others. Such buildings include institutions such as hospitals, universities, schools, government buildings and offices, where the air conditioning systems represent a large percentage of energy consumption. In the hotel sector, absorption equipment are widely accepted as air conditioning systems, given the publicity that implies offering environmentally friendly facilities (LEED, 2008). In the literature there is not a lot information about this type of systems in which involve research and developments in Colombia.

The Artificial fluids were commercially used in systems of air conditioning in buildings, such as chlorofluorocarbons (CFC), hydrochlorofluorocarbons (HCFC) and hydrofluorocarbons (HFC) they have been considered largely as spoilage of the earth's ozone layer. Favor the greenhouse effect and to some extent, the increase in global average temperature of the planet. Since the 1987 Montreal Protocol, it have been signed international treaties to reduce emissions of these refrigerants; Colombia is part of the Montreal Protocol after the approval of Law 29 of 1992 (Wuebbles, 1994).

The conventional refrigeration cycles operated by electricity contribute significantly to the consumption of electricity and fossil fuels. The International Institute of Refrigeration (IIR) estimated that approximately 15 % of all electricity produced in the world is used in some process of cooling and air conditioning (Pérez, 2013).

Whenever there is the possibility of using thermal energy from renewable energy or effluents from industrial processes or cogeneration systems, the application of absorption systems for cold production will be competitive and interesting, which is why this article seeks to bring out the design and simulation of an air conditioning system operated by solar absorption refrigeration cycle with classic control techniques, some of which later become intelligent control techniques. This approach is intended to experiment with this type of system to find efficient ways of operation and low cost, in the future, to be competitive in the commercial field.

2. Materials and methods

The increased cost of electricity generation and environmental restrictions have strengthened in the scientific research of air conditioning systems and cooling using solar resource as a source of motive power (Vidal and Colle, 2009). The energy consumption of the world's population is constantly growing, as a result bringing the scarcity of natural resources and generate environmental problems, such as thinning of the ozone layer and the greenhouse effect. These effects generate an environmental impact hardly be solvable, therefore it becomes a matter of great concern to many countries, governments and the society. Within this reality, industries hone their processes to include control systems in order to meet the demands of energy efficient, environmentally friendly and more competitive teams. This is the case of systems operating on solar energy and absorption refrigeration cycle. The purpose of the control systems in a plant with absorption refrigeration cycle is focused on providing automatic operation where control is too complex for manual operation. These systems maintain control of the conditions that could be achieved by manual operation, providing maximum efficiency and economy in the process (Trott and T. Welch, 2000).

The process of producing cold is to reduce and maintain the temperature of a space or material below room temperature. For this to happen, it is necessary to remove heat from a low temperature source and transfer it to a high temperature source. Under the second law of thermodynamics, for the process of transfer heat from a cold to a warm body to be made, it is necessary to do a work, because spontaneously, this may not occur (Vidal and Colle, 2009). Some forms of cold production using thermal energy transfer: collection system solar energy, waste heat source, fuel (biomass or fossil) or just an electrical resistance of a transformation system and the energy received refrigeration system using solar energy are available (Vidal and Colle, 2009).

The absorption refrigeration system bases its principle in the affinity of certain substances to absorb each other on contact. Two pairs of substances are commonly used in this type of facilities: bromide water-lithium ($LiBr$-H_2O) and ammonia-water (NH_3-H_2O). The first of these combinations is mostly used for solar assisted applications due to non-toxic and non-flammable properties of water as a coolant and efficiency in terms of energy expenditure (Vidal and Colle, 2009).

The absorption refrigeration systems of single-effect (with a single generator), powered by solar energy require the union of several components for proper operation is achieved. The main components are: Solar Collectors, the Absorption Machine, the Cooling Tower, a Tank of Hot Water, an Auxiliary Heater, Chilled Water Tank and the control system. Figure 1 shows the components required for the operation of an absorption system operated by solar energy.

The use of solar energy in air conditioning systems require to test or develop new economic and efficient equipment for collection of solar radiation; thermodynamic cycles specially adapted to operate under the conditions proposed, refrigerants and refrigerant mixtures with special additives and absorbents capable of achieving high yields in the operation cycle, evaluate, simulate and improve specific cycle processes such as the operation absorption of the process itself; in addition to control systems that enable excellent integration of systems: Solar Collectors, energy storage, production of cold, heat rejection, cold storage and auxiliary or backup subsystem.

Current technology for air conditioning consumes a lot of power, so it is necessary to establish principles and strategies conducive to efficient energy use, this topic directly influence the intelligent control technique that is applied to the system. Furthermore, it is known that certain refrigerants such as Freon, produce an environmental impact when released into the environment, which affect the stratospheric ozone layer and contributes to the greenhouse effect (Edmonds et al., 1987).

In addition, the production of cold thermal energy can make future projects more attractive to be converted to natural gas, since the products of combustion of natural gas are particularly suitable (low dew point temperature) for heat recovery applications, so it is possible to integrate production processes of heat and cold with the same energy source; by including in some cases the production of electricity from diesel, gas turbines, steam cycles and even fuel cells engines; configurations that are best known as CHP (Cooling, Heat and Power) (Duarte, 2011).

The system shown in this article is intended to be implemented practically, for this reason, has been made quotes of various elements that make up the solar air conditioning system, among them are the Absorption Chiller and Solar Collectors. These components were listed in the company Shandong Lucy New Energy Technology Co., Ltd (LUCY, 2015) of China, which beside offer these products, offers to install the solar air conditioning system with absorption refrigeration cycle in any building, this structure is shown in the

Figure 2 is very similar to what is wanted to implement in the UPB, where it is noted the use of three-way valves or two-way and pump to control the flow of water from the system and to generate cooling or heating according to the configuration set you want to allow or not allow the flow of water through different circuits of the system. In this case, a heat exchanger is used, but with the kind of climate of *Medellín*, which is warm, is not need to use it.

3. Results and discussion

For system simulation results of the evaluation of the thermal load integrated with the cycle of single effect absorption $LiBr/H_2O$ and subsystems Solar Collectors, Cooling Tower, chilled water distribution and accumulation of chilled water and hot; TRNSYS® using the computer program. The modeling was carried out using the parameters of the components offered by the program in the TESS library, and the following components were used: 12 modules of Solar Collectors each of 20 tubes, the area of each module is 3 m^2, they are connected in series and form a total area of 36 m^2; an Auxiliary Heater of 20 kW; two tanks of 250 l, one of hot water and other chilled water; it has several pumps and several three-way valves in the different circuits of water from the system, there are several pipes with standard parameters set; an Absorption Machine with a COP of 0.72 and cooling capacity of 11.5 kW; a Fan-coil 36000 BTU/hr (think also experiment with mats of water) and an enclosure to simulate the building of the campus of the UPB to which this system is installed.

For the meteorological data it has been processed actual data of *Medellín* through software Meteonorm® obtained in CALAIRE Laboratory by the *Universidad Nacional de Colombia*, near the UPB, TRNSYS® to understand them in the required formats.

In the simulation model that was held, the following results were obtained:

It was determined that the system will be installed in a building on the campus of the UPB, *Medellín*, air conditioning is needed for the comfort of the people who live there; installing the system in this building allow one to perform actual tests to achieve concrete results and set a starting point for the use of such systems in Colombia. The building that is selected will be used for research and laboratory purposes, it is possible that the building to be selected can be compared with a conventional system and identify pros and cons of both systems.

The simulation presented in this article (see Figure 3) of the demonstrative installation, using TRNSYS® software, shows the application of two PI controls, one for the variation of the fan speed of the cooling tower and the other for varying the flow of chilled water through a three-way valve which is connected to the handling unit (Fan-coil) of chilled water; and two ON-OFF controls, one to pump hot water from the Solar Collector, which is off at night so they are not underutilized and one for the auxiliary heater is always on to reach a temperature of 90 °C on the generator of the Absorption Chiller unless the Solar Collectors can actually reach this temperature in the day, in this case, the auxiliary heater is switched off immediately.

Tests of the preliminary simulation are done in the first week of June 2014 in *Medellín*, where high radiation was obtained, and a consumption of 14.76 kWhr in the Auxiliary Heater is produced by solar thermal energy generated in the Solar Collectors (see Figure 4), an oscillating but relatively acceptable performance air conditioning system around 22 °C (see Figure 5) and a good performance in the cooling tower, where it achieves lower cooling water temperature input 35.11 °C to 30.34 °C (see Figure 6).

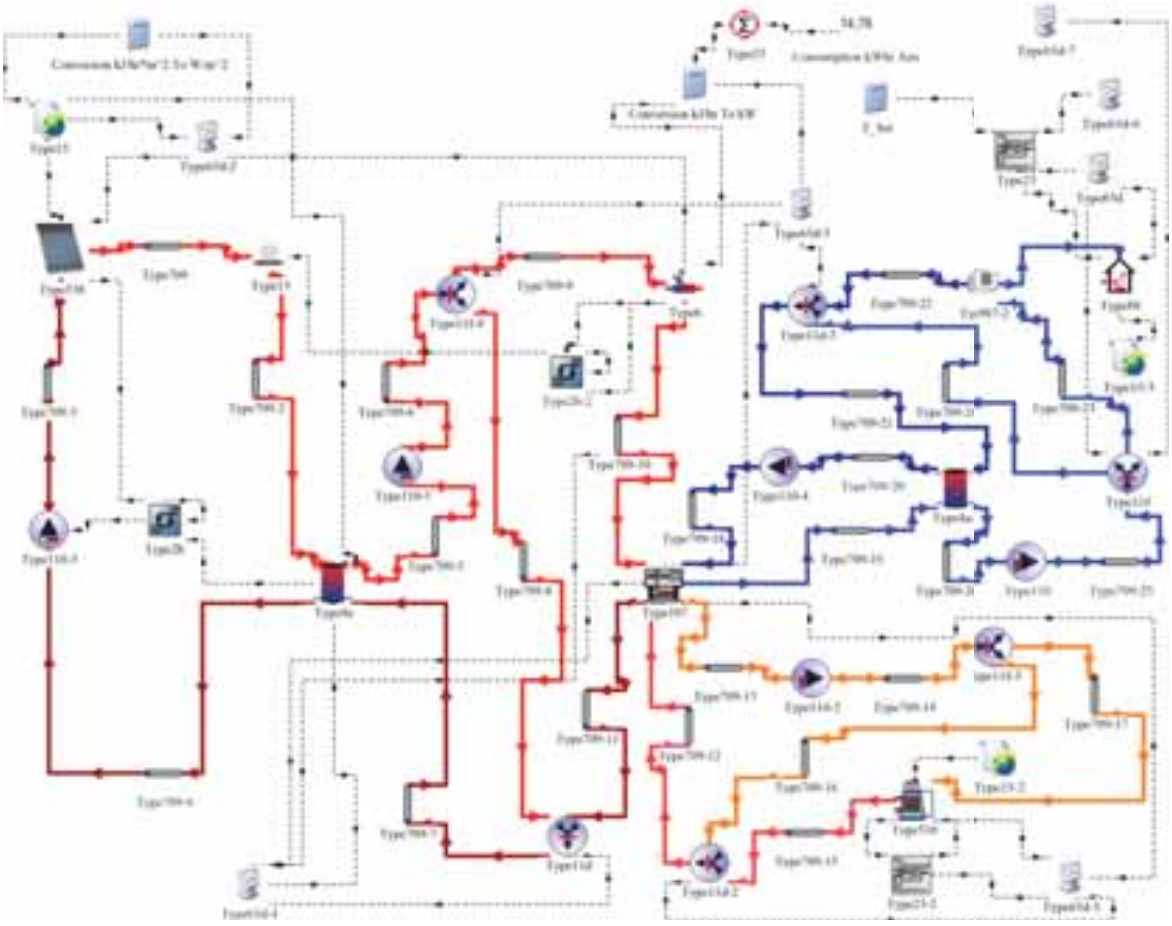

Fig. 3: Simulation of solar air conditioning system and absorption refrigeration cycle

Control techniques applied in this simulation techniques are classic control (ON-OFF and PI), and through these techniques is desired to implement intelligent control schemes. It is determined that the technique of intelligent control required to apply to the part of the air conditioning system is a control technique Fuzzy Logic, which vary PI control then PI Fuzzy control being developed will be applied using the MATLAB® software that has direct connection with TRNSYS®. To achieve this control, heuristic design experimenting with the TRNSYS® simulation software to operate in a relatively wide range model is obtained. The hot water circuit will continue with two ON-OFF controls and the cooling water with PI control in which a constant flow of water will remain. To the chilled water circuit constant water flow in the circuit pumps is maintained, but is changing the flow of water through the three-way valve installed at the inlet of the Fan-coil with PI control, the idea is to further apply a PI Fuzzy control, whether the final control element is the Fan-coil, currently used, or mats of water.

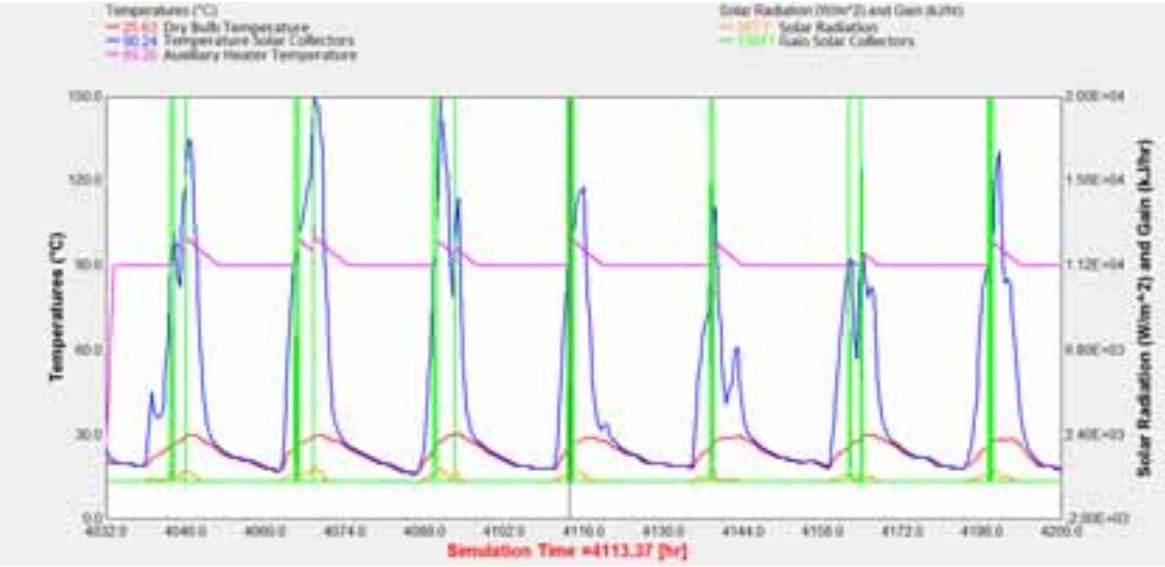

Fig. 4: Auxiliary Heater and Solar Collectors in running during the first week of June 2014 in *Medellín*

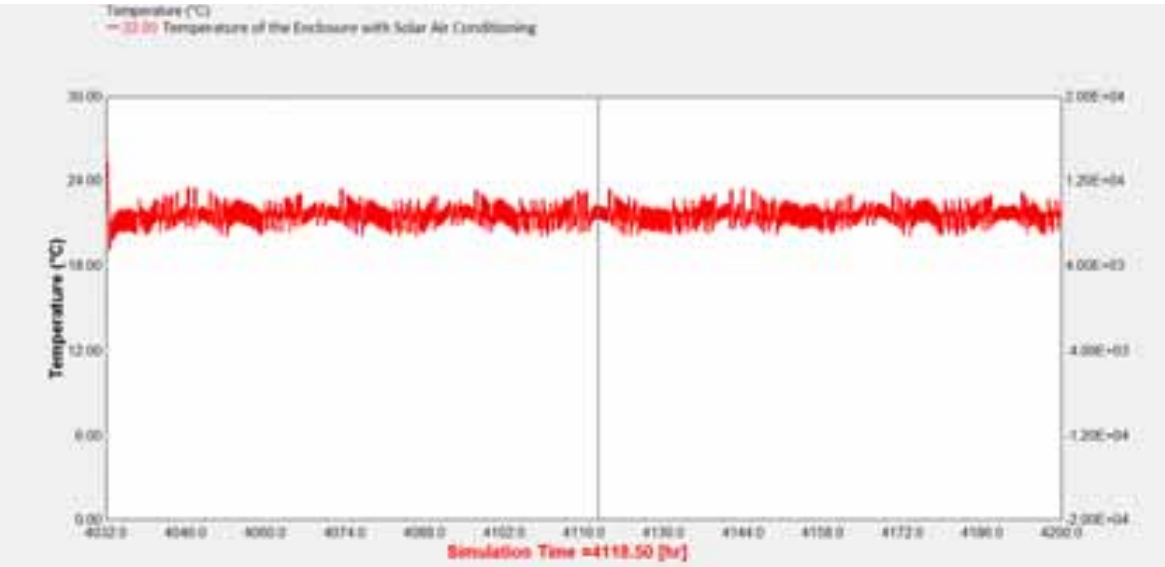

Fig. 5: Temperature of enclosure controlled by PI control

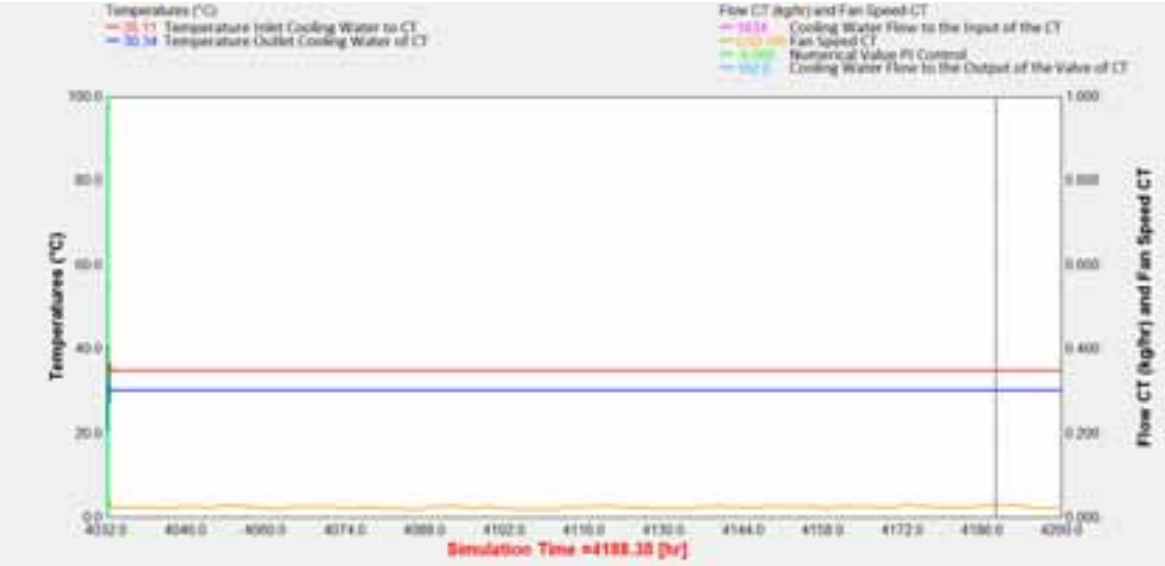

Fig. 6: Inlet and outlet water temperature of the cooling tower and fan speed controlled with PI control

In each figure can be observed the performance of the simulation previously shown in Figure 3 in the software TRNSYS®. In Figure 4, the ON-OFF control applied to the auxiliary heater operates when the Solar Collectors temperature reaches 90 °C reference and immediately turns off the auxiliary heater, this generates energy savings in the operation of the system; in Figure 5 the outlet temperature of the chilled water from the Absorption Machine and how does the PI control applied to Fan-coil to the enclosure is achieved a temperature which is around 22 °C is observed; and Figure 6 shows how does a PI control the fan speed of the cooling tower, to control the cooling water temperature from 30.34 °C to a water inlet 35.11 °C from the Absorption Machine.

4. Conclusions

Making this project generates technological breakthroughs for the industry of refrigeration and air conditioning in Colombia, as a method of renewable energy is obtained, such as solar energy, which is practically infinite and generates no pollution to the environment.

The solar air conditioning system has a nonlinear simulated behavior on the part of the air conditioning, because environmental conditions and thermal loads influence, disrupt and constantly change over time, which is why intelligent control technique (PI Fuzzy) is quite determining, since generates a lower consumption of electrical energy for soft control action applied to the actuators, furthermore it stabilizes in less time the temperature variable, which is the controlled variable.

For many applications in buildings and industrial processes can be considered that cooling through an absorption system is an environmentally responsible choice.

By using water as a coolant, mixed with salt and non-toxic chemical corrosion inhibitors, avoids the use of CFC, HCFC and HFC and management, availability and transport.

The simulation of solar air conditioning system in the TRNSYS® software, thanks to the library TESS and its focus on solar-operated systems, and meteorological data processed in Meteonorm® allow obtaining answers very close to reality and create a solid base to carry out this type of installation in reality without hesitation.

Abstract

Solar water heating systems have been proven to be reliable and economical for producing hot water. In Taiwan, the cumulative area of solar collectors installed by the end of 2014 was approximately 2.39 million m^2, in which approximately 98% of the systems were installed in the domestic sector. Further, preheating water for livestock processing plants, where hogs are killed and processed for consumption, is potential of cost-effective application. Heated water can be used in the plants for evisceration, sanitation during processing, and the daily cleanup of the plant. In Taiwan, the number of pig farming was 8,457, and the supply for slaughtering was approximately 7.47 million heads in 2013. A livestock processing plant using combined solar thermal and heat pumps systems was chosen as the case study by the field measurements. The results showed that the hot water consumption, mass flow rate, operation of circulation pumps and heat pumps would affect the thermal efficiency, economic viability and attractiveness of a system. This study would provide useful information for all parties related to this market, manufacturers, potential users and policy-makers in Taiwan and other countries.

Keywords: *solar water heating; livestock industry; Taiwan*

1. Introduction

Besides the energy savings, applications of renewable energy technologies (e.g. solar, hydroelectric, biomass, wind, ocean and geothermal energy) have environmental benefits, like a reduction in air pollutants and greenhouse gases (Kikuchi, 2011). Therefore, tremendous efforts have been made to formulate and implement favorable policies by the governments throughout the world. In Taiwan, imported fuel accounted for 97.58% of its energy demands in 2013 (BEMOEA, 2014). Thus, renewable energy has received increasing support, particularly with the Renewable Energy Development Bill enacted in April 2010, and is projected to reach 3% of the total energy supply by 2020. Further, water heating constitutes one of the major types of energy consumption in both domestic and commercial sectors (Roulleau and Lloyd, 2008). Taiwan has a subtropical climate (latitude 22° to 25° North). The yearly global solar radiation ranges from 1200 to 1700 kWh/m^2, which is favorable for the use of solar heat. With the subsidy programs (1986–1991, 2000-present) introduced by the Bureau of Energy under the Ministry of Economic Affairs (BEMOEA) for solar water heaters (SWHs), the cumulative area of solar collectors installed was approximately 2.39 million m^2 by the end of 2014, in which approximately 0.3 million systems (or 1.6 million m^2) are in operation. Moreover, dissemination of SWHs in Taiwan was reviewed by Chang *et al.* (2009, 2015) and Lin *et al.* (2012). The major factors included system design, economic/financial considerations, degree of urbanization, and legislative support. More than 98% systems were installed in the domestic sector, and limited commercial application for industrial heat process was due to lack of experience in system design and uncertainty of expected benefits. Nevertheless, solar water heating is still the most successful account of renewable energy application in Taiwan.

Process heat generation is an unexploited application for solar heat in the sectors like food, agro-food, paper, textiles, chemicals and beverages (Karagiorgas *et al.*, 2001; Lauterbach *et al.*, 2012; Mekhilef *et al.*, 2011),

doi:10.18086/swc.2015.10.35 Available at http://proceedings.ises.org

in which the required temperatures for industrial heat processes range from 60°–260°C (Kalogirou, 2003). Lauterbach *et al.* (2014) also indicated that a solar thermal system for industrial applications under a low process temperature and constant load can result in higher system yields. However, the hydraulic setup, solar collectors and hot water consumption patterns on system performance need to be addressed. Further, livestock industry has favorable conditions to use solar heat for evisceration, sanitation during processing, and the daily cleanup of the plant. In Taiwan, pork is the major meat (≈ 40%) and its per capita consumption in average was 37.91 kg/person/year in the period of 2005–2013. The number of pig farming was 8,457, supplying approximately 7.47 million heads in 2013 (NAIF, 2013). To promote SWHs in livestock industry, it is important to analyze system performance and their financial viabilities. Also potential benefits of combined solar thermal with heat pumps for hot water production have been studied (Carbonell *et al.*, 2014). Therefore, field measurements of a combined system installed in a slaughterhouse were conducted in this study.

2. Setup of field measurements

According to the statistics by the NAIF (2013), Yunlin County (1,270 pig farms) was the top one for pig production (24.36%). As mentioned previously, solar heat can be used for evisceration, sanitation during processing, and the daily cleanup of the plant. Therefore, Yunlin meat market, located in southern Taiwan near the Tropic of Cancer, was chosen as our case study (yearly solar radiation = 6,712 MJ/m^2) for evaluating the performance of a combined solar thermal and heat pump system. Note that a boiler using low sulphur light fuel oil is also available. Figure 1 shows the two independent SWHs and heat pumps for scalding and dehairing (required temperature = 60–65°C). The A_{sc} (glazed flat-plate type) was 123.5 m^2 (system 1) and 115.8 m^2 (system 2), respectively. Note that the appropriate A_{sc} of a SWH is in the range of 130 m^2 to 160 m^2 for more reasonable energy and economic performances (Li *et al.*, 2014). The solar collectors facing south were installed on the roof with a tilt angle of 18.5^o. One 10-ton and two 7-ton storage tanks were installed. Pumps were also employed for forced circulation. The setup of mass flow rate was 0.028 and 0.019 kg/m^2/s for system 1 and system 2, respectively. The flow rate of heat pumps ranged from 105 to 118 liters per minute. The systems have been in operation since March 2013.

To evaluate the actual performance of the systems, several monitoring devices were installed. A precision spectral pyranometer (Eppley Laboratory, Inc., model PSP) was installed to measure the incident horizontal solar radiation. Seven Macnaught flow meters (Model M2SSP-1R) were located in the cold water supply line to the hot water storage tank (hot water consumption) and in the circulation line from the bottom of the storage tank to the inlet of the collectors (circulation flow rate), respectively. There were 14 platinum resistance thermometers (T_a, T_0–T_{12}, Izuder Enterprise**,** 1/10 DIN Class B) installed to monitor the ambient and local water temperature. In addition, energy consumption of the heat pumps (HP1: 38.4 kW; HP2, HP3: 40.6 kW) was recorded by the power meters. The data from the monitoring devices were sampled every 10 seconds by National Instrument (NI) data acquisition system (Model cFP-AI-110 and cFP-RTD-124) and transmitted synchronously to the host computer at the Energy Research Center, National Cheng Kung University

3. System operating performance

3.1. SWHs and heat pumps

Certifications of a solar collector or a SWH, in which the standards have been enforced by the BEMOEA, are required when filing for a rebate. The thermal efficiency η (≥ 0.5, Chinese National Standard 12558-B7277) of a SWH is calculated using the following formula. Note that the test conditions under the standard specify the daily horizontal solar radiation per square meter (≥ 7 MJ/m^2).

$$\eta = mC_p(T_f-T_i)/(A_{sc}G)$$

C_p: specific heat, MJ/(kg°C)
m: water mass flow, kg
T_i: initial temperature in the hot water storage tank, ^{o}C
T_f: final temperature in the hot water storage tank, ^{o}C
A_{sc}: effective area of solar collectors, m^2

G: daily horizontal solar radiation per square meter, MJ/m^2

In this study, the data from March 25, 2013 till June 30, 2013 were used to investigate the system's performance. Take the daily record on March 25, 2013 for example. The outdoor temperature ranged from 20 to 30 ^{o}C, and a peak solar radiation of approximately 870 W/m^2 was recorded. The daily solar radiation was approximately 5.77 kWh/m^2, and the solar energy was 712.6 kWh and 668.2 kWh for system 1 and system 2, respectively. For hot water consumption, it was in periods from 08:00 to 17:00. The daily hot water consumption was 26,045 liters. It is also noted that he daily hot water consumption in system 1 is sufficiently lower than that in system 2 in the period of March 25 to June 30, in which the peak values were 13,098 L/day and 26,573 L/day, respectively. For thermal performance of system 1, η increased with G ($\geq$ 6 MJ/m^2). The peak value was 0.476. For system 2, there was large variation of η with G while the peak value reached 0.641. Therefore, hot water usage is considered to be a critical factor for thermal efficiency of SWHs. Further, Li *et al.* (2014) indicated that the combination of SWHs and heat pumps is a very attractive option for hot water production. The COP of heat pumps varied from 2.6 to 4.9 when T_a = 18– 33°C. It is also noted that the COP of HP1 is higher than that of HP2 and HP3.

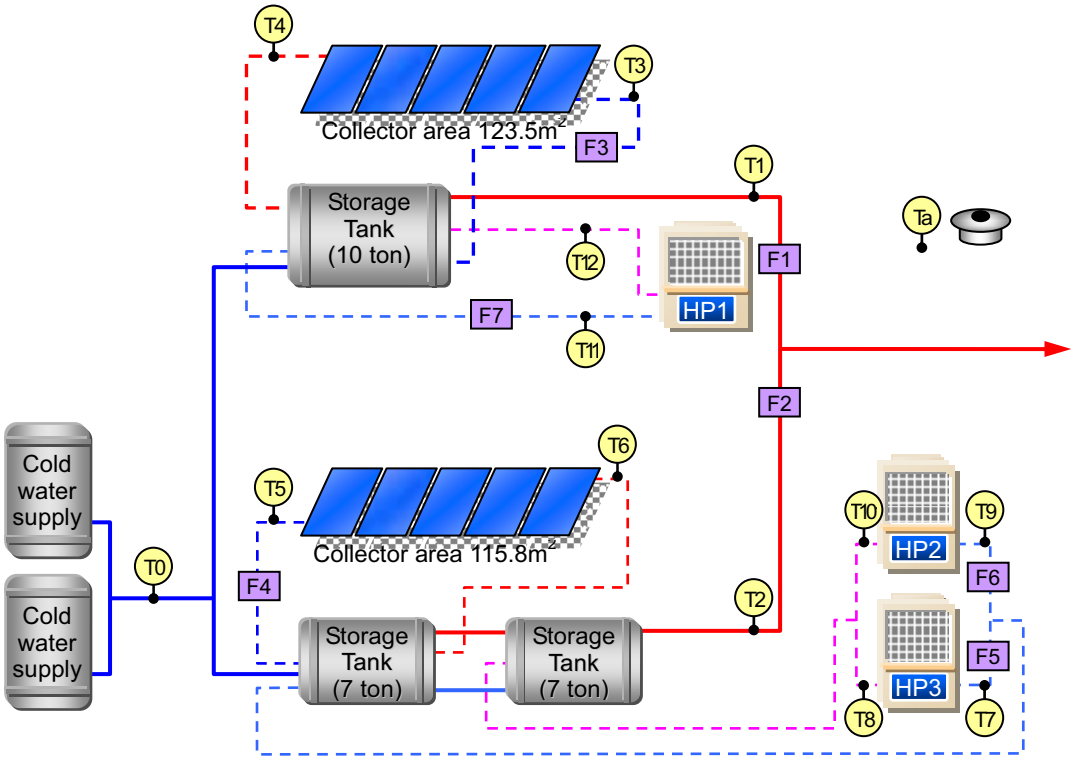

Fig. 1: A schematic drawing of SWHs and monitoring devices

3.2. Operating performance

As mentioned previously, the thermal performance of a SWH is associated with the entering water temperature and water consumption pattern. From April to June, the useful energy gain by the SWHs and HPs are shown in Table 1. For SWHs, the collected solar energy was 44,282 MJ and 58,109 MJ for system 1 and system 2, respectively. Since HP1 was least used or usually kept off in the measurement period, the ratio of collected solar energy divided by total supplied energy of the combined system is 70.8% and 27.8% for system 1 and system 2, respectively. In Table 1, it is also found that only 68% of total collected energy for system 2 was consumed. Inadequate operation of HPs is the major concern and should be taken into account to realize energy savings. Heat loss from the storage tank and piping to the environment during the night hours is also needed to be addressed. Further, the electricity consumption for the circulation pump of system 2 is sufficiently higher than that of system 1. Thus, a suitable control strategy is definitely required to ensure efficient energy savings of the system. Nevertheless, the net energy savings in the period of March 25 to June 30 was 150,655 MJ (or 1,537 MJ/day).

The monthly system operating performance from April to June is shown in Table 2. It can be seen that the solar thermal efficiency (η = 0.170–0.419) is sufficiently lower than the CNS standard, i.e. $\eta \geq 0.5$, particularly in April. This may partially corresponds to lower monthly solar radiation in April. The peak daily hot water consumption of system 1 is approximately half of that of system 2. Thus, it can postulate that a SWH with greater hot water consumption gives better system efficiency. Also, the mass flow rate was 0.028 and 0.019 kg/m^2/s for system 1 and system 2, respectively. Furbo (2005) indicated that a low mass flow rate of a SWH can result in a higher thermal efficiency. Therefore, a reduction in mass flow rate for system 1 may be required to ensure system economics. Also note that the monthly COP for HP1 (= 3.76–4.09) is slightly higher than that for HP2 (= 3.50–3.66) and HP3 (= 3.13–3.53). Further, the system economics is of interest. A simplified break-even analysis is given as below. Note that the maintenance cost and annual price change of the substituted fuel is not included. The initial cost for the SWHs and heat pumps is 2.15 and 1.15 million NT$ (1 US$ ≈ 31 NT$), respectively. The subsidies for the SWHs, based on the area of solar collectors installed, was approximately 0.7 million NT$ by the BEMOEA and Yunlin County. Further, the sales price of low sulphur light fuel oil was 22,779 NT$/kL in 2014, and its heating value is 40.19 MJ per liter (BEMOEA, 2014). Taking heating efficiency of 80%, the substituted fuel savings is estimated to be approximately 0.4 million NTD/year. Therefore, the payback period is estimated to be 6.5 years, which is less than the expected service period of a SWH (≈ 15 years). This validates the financial viability for a combined solar thermal and heat pump system for industrial heat process. As mentioned previously, the thermal performance of a SWH is associated with the entering water temperature and water consumption pattern. From April to June, the useful energy gain by the SWHs and HPs are shown in Table 1. For SWHs, the collected solar energy was 44,282 MJ and 58,109 MJ for system 1 and system 2, respectively. Since HP1 was least used or usually kept off in the measurement period, the ratio of collected solar energy divided by total supplied energy of the combined system is 70.8% and 27.8% for system 1 and system 2, respectively. In Table 1, it is also found that only 68% of total collected energy for system 2 was consumed. Inadequate operation of HPs is the major concern and should be taken into account to realize energy savings. Heat loss from the storage tank and piping to the environment during the night hours is also needed to be addressed. Further, the electricity consumption for the circulation pump of system 2 is sufficiently higher than that of system 1. Thus, a suitable control strategy is definitely required to ensure efficient energy savings of the system. Nevertheless, the net energy savings in the period of March 25 to June 30 was 150,655 MJ (or 1,537 MJ/day).

The monthly system operating performance from April to June is shown in Table 2. It can be seen that the solar thermal efficiency (η = 0.170–0.419) is sufficiently lower than the CNS standard, i.e. $\eta \geq 0.5$, particularly in April. This may partially corresponds to lower monthly solar radiation in April. The peak daily hot water consumption of system 1 is approximately half of that of system 2. Thus, it can postulate that a SWH with greater hot water consumption gives better system efficiency. Also, the mass flow rate was 0.028 and 0.019 kg/m^2/s for system 1 and system 2, respectively. Furbo (2005) indicated that a low mass flow rate of a SWH can result in a higher thermal efficiency. Therefore, a reduction in mass flow rate for system 1 may be required to ensure system economics. Also note that the monthly COP for HP1 (= 3.76–4.09) is slightly higher than that for HP2 (= 3.50–3.66) and HP3 (= 3.13–3.53). Further, the system economics is of interest. 4. Conclusions

The renewable energy usage is critical for its economic development and reduction in greenhouse gas emission. Also thermal uses constitute one of the major types of energy consumption. The need of raising solar thermal energy as a significant energy source is important. So far, solar water heating is the most successful account of renewable energy application for domestic hot water preparation in Taiwan. In the commercial sector, industrial process heating is a very promising application for SWHs. In addition, there are more systems with the combination of solar collectors and heat pumps available on a commercial level during the last decade. Therefore, field measurements of a combined system installed in a slaughterhouse were conducted in this study. The results identify the system as a suitable device for industrial heat process in livestock industry. A simplified break-even analysis also shows the financial viability. However, adequate operation of the system (circulation and heat pumps) is required to maximize energy savings.

VALIDATION OF A SOLAR THERMAL PILOT PLANT MODEL FOR COPPER MINING PROCESSES

Alessandro Gallo[1], Martin Guillaume[1], Carlos Portillo[1] and Edward Fuentealba[1]

[1] University of Antofagasta. Centro de Desarrollo Energético Antofagasta, Chile. Avda. Angamos 601, 1270300, Antofagasta, Chile.

Abstract

In this work, the behavior of a solar thermal pilot plant installed in a copper mine in the north of Chile is investigated. The pilot plant is directly connected to the water circuit used to heat the electrolyte in the electrowinning processes. For a detailed monitoring of the system, the pilot plant counts with several measuring instruments. Recorded data are compared with results obtained in TRNSYS simulations. In addition to that, because of the high dust deposition on the solar plant, effects of soiling on the system are also investigated. Hence, this paper has the twofold objective of validating the TRNSYS model for future scale up of the solar thermal plant and at the same time to determine the effect of the dust on the collector.

Keywords: *Solar thermal plant, copper mining processes, TRNSYS simulations, soiling*.

1. Introduction

Climatic conditions and energy demand are necessary consideration for solar technology development. In that sense, Northern Chile has a high solar radiation, with an annual global horizontal irradiation of more than 2500 kWh m^{-2} (Escobar et al., 2014) and local industry, which is mainly focused on mining in deserted areas, presents an elevated energy consumption of electricity and heat. The principal activity of Chilean mining industry is extraction and production of copper. The energy demand of Chilean copper mining has reached 44.9 TWh in 2014 (including electricity and heat) and it is 60% higher than 2005 (COCHILCO, 2014).

In copper mining, two kind of process are mainly used to produce metallic cathodes, according to the extracted mineral (copper sulfides or copper oxides). Fossils fuels mostly supply the high thermal consumptions of those processes. The huge fuel consumption generated by the mines produces important quantities of greenhouse gases and it could be reduced significantly by the development of solar thermal plants to supply the heat needed in those processes.

There are two possible applications for solar thermal technology as heat source in the sulfides process: the drying and the smelting of the concentrate. In the latter, it is possible to apply the solar concentrating technologies to separate copper from other materials. Moreover, three applications are also conceivable in the oxides process: heating solutions for leach pads, electrowinning process and anodes washing (see Fig. 1).

doi:10.18086/swc.2015.10.36 Available at http://proceedings.ises.org

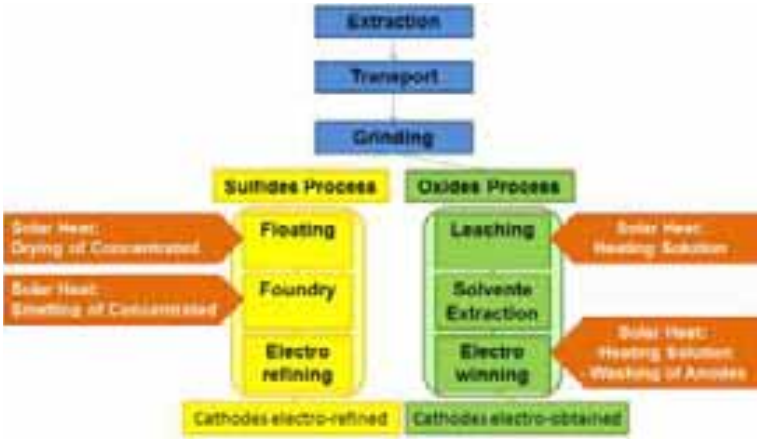

Fig. 1: Solar heat applications in copper mining processes

In Chile, the thermal energy consumption for the process of leaching (LX), solvent extraction (SX) and electrowinning (EW) is 1.5 TWh (COCHILCO, 2014) and it is obtained with fossil fuels, which involves problems for operational costs: price volatility, upward trend and uncertainty of supply. Nevertheless, solar thermal plants can obtain the same amount of heat energy and stabilizing operating costs of mining companies.

The EW process is the last step in the production of copper cathodes. To improve the efficiency of electrodeposition of copper on the plaque it is required that the electrolyte which comes from plant SX, is maintained at temperatures between 45 ° C to 55 ° C (depending on the process). Hot water is also required, at temperatures near to 90 ° C, to wash cathodes and anodes. So far, this task is achieved with a boiler, which also provides heats for the electrolyte using a heat exchanger.

In Chile, the substitution of fossil fuels with solar solutions for the production of thermal energy to the mining process has been implemented only for EW processes. To date, there are only three operating solar plants of this type. (CSP-Today Global Tracker, 2015)

The first solar plant is installed in the copper mine Constanza, and it has been operated since 2012. A surface of 404 m^2 composed of flat plane solar collectors provides energy to heat the electrolyte. The annual generation capacity of this plant is 540 MWh_t. Another solar thermal plant of this type is installed in Gaby mining company and produce 51.800 MWh_t per year, which replace 80% of fossils fuels consumption in the EW process. In this plant, flat plane solar collectors with a surface of 39.300 m^2 are used, too. The third plant has been operated since 2012 in the copper mining El Tesoro and uses parabolic trough technology. The total capacity of this plant is 10 MWt and replace 55% of diesel used in the process. (CSP-Today, 2013).

In the last years, some works have been carried out on this topic. Ushak et al. (2014) studied the behavior and the performance of a thermal solar plant to provide heat for EW process in the copper mine. It was analyzed the global efficiency during four month and the impact on the reduction of CO_2 emission. Another solar application in mining was studied by Gallo et al. (2014). They proposed the integration of thermal collectors with an absorption machine for air-conditioning of containers in mining camps of the Atacama Desert. Currently, at Energy Development Center of Antofagasta several applications for solar energy in mining are being investigated (Portillo et al., 2015).

In this paper is studied the working of a thermal solar pilot plant installed at the end of 2014, by Enermine, in the mine Lomas Bayas, in order to produce thermal energy for the EW process. The pilot plant is currently operating and it is directly connected to the heating circuit of EW system. A TRNSYS (2015) model of the pilot plant has been carried out and simulated results are being compared with operating data during the first months of working. The aim of this paper is the validation of the TRNSYS model in order to design a scaled up solar thermal plant in the near term. Furthermore, because the high rate of soiling on the solar collector can penalizes the performance of the plant (El-Nashar, 2003), simulations help to determine the loss of efficiency due to dust deposition on the collector.

2. Description of the solar thermal pilot plant

Real plant

The pilot solar thermal plant is connected to the water circuit used to heat the electrolyte in the electro-winning processes. One large size solar thermal collector is placed on the roof of a container and it has an active surface of 9.26 m^2 (see Fig. 2a). The rest of the components are protected inside of the container. The storage tank has a volume of 500 liters (see Fig. 2b).

All the elements of the pilot solar plant were installed and tested by the company Enermine. The same enterprise executed the connection between the solar module and the process with standard norms of Lomas Bayas Mining Company. Enermine also provided and disposed the instruments to measure temperatures and flow rates and to calculate the energy captured and dispatched from the solar module to the process.

In order to increase the temperature of electrolyte, the solar module is connected to the output of the main circuit of the heaters. The flow to heat by the pilot plant is obtained directly from the circulation pumps of tempering circuit. This flow is less than what comes out of the heaters (0.2% of the total flow) (Enermine, 2014), so it is possible to observe and measure the temperature rising due to the contribution of the solar module.

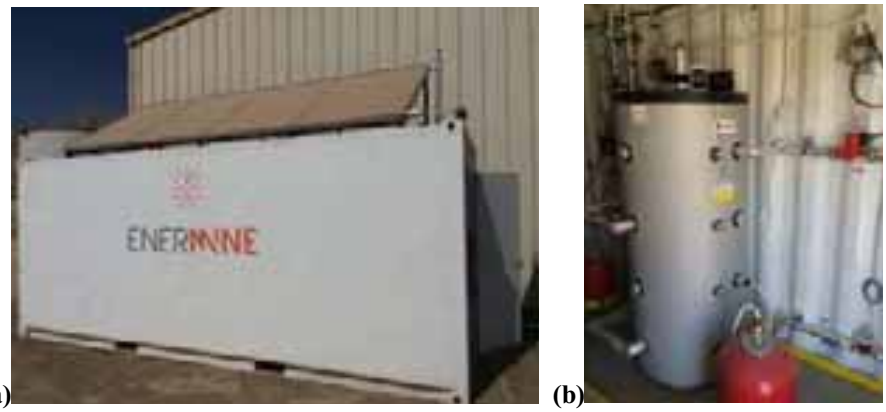

Fig. 2: Pictures of the solar thermal collectors (a) and the storage tank (b) of the pilot plant.

Figure 3 shows a schematic flow sheet of the pilot plant and measuring instruments are indicated in it. The system is composed of four hydraulic circuits: solar, storage, dispatch and process. The first circuit collects solar radiation by means of a large flat plate solar collector, disposed with an inclination of 30 degrees and an orientation of 56.6 degrees toward Northeast. The heat transfer fluid is demineralized water and it flows in the collector by the use of a circulation pump (P1) of 380 watt with a nominal mass flow of 350 kg h^{-1}. The heat is transferred by a heat exchanger (HX1) at the second loop where energy is accumulated in the storage tank (ST). In the third circuit, the water is dispatched from the accumulator to another heat exchanger (HX2). Finally, HX2 transmits the energy to the fluid of the process circuit, heating the electrolyte. In the storage circuit and in the dispatch circuit, two identical circulation pumps (P2, P3) of 100 watt move the water in their correspondent loops with two possible mass flows: 350 or 850 kg h^{-1}.

In addition to that, the system is equipped with several measuring instruments of temperature (T) and mass flow (FM). Three calorimeters (CM) calculate the energy exchanged in the circuits. Moreover, a control system (CS) is installed in the plant to activate the circulation pumps. In the solar loop, the pump is activated when the water temperature at the outlet of the collector is 6 °C higher than the temperature at the top of the storage tank. The same controller stops the circulation when the temperature difference is less than 3 °C. In the dispatch circuit, the water flows when the temperature in the tank is above 60 °C.

Because of the location and the presence of a higher building behind the plant, some shadows fall on the solar collector during the afternoon.

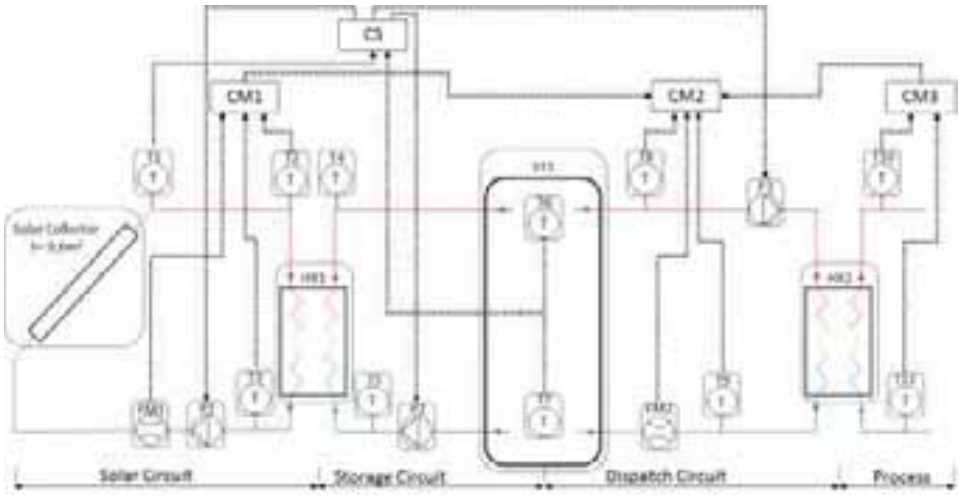

Fig. 3: Pilot plant flow sheet.

TRNSYS model

The same flow sheet of Fig. 3 was modeled in a simulation software to reproduce the pilot plant performances and to validate the model created. In particular, the plant was simulated with a simplified TRNSYS model. The flow scheme consisted in several elements called "Type", which represented the different components of the pilot plant. Table 1 resumes component characteristics. In the model, parameters referring to the size of the components were fixed; other parameters were adjusted to match simulated results with real collected data. Two inputs from collected data were introduced in the model: global radiation on the horizontal that was measured close to the collector and the temperature (T11 in Fig. 3) of the flow entering in HX2 in process circuit.

Tab. 1: summary of elements and parameters values used in simulations for the period from 19 to 31 January.

Component	TRNSYS Type	Main parameter	Value	Unit of measure	Observations
Collector	1b	Absorbing Surface	9.26	m^2 -	
		η_0	0.36	W m^{-2} K^{-1}	Optical efficiency
		K1	2.86	W m^{-2} K^{-2}	Slope efficiency
		K2	0.015		Curvature efficiency
Tank	4a	Volume	500	Liter	
		Thermal losses	2.5	W m^{-2} K^{-1}	Including pipe losses
Pumps	114	Flow P1	205	Kg/hr	
		Flow P2	350	Kg/hr	
		Flow P3	850	Kg/hr	
Heat Exchangers	5b	UA HX1	200	W K^{-1}	
		UA HX2	150	W K^{-1}	
Controllers	2b	DTmax	6	°C	Start the flow in solar circuit
		DTmin	3	°C	Stop the flow in solar circuit
	2	Tmax	59.5	°C	Start the flow in Tank load side
		Tmin	56.5	°C	Stop the flow in Tank load side
Solar Pipe	32	Thermal losses	2.36	W m^{-2} K^{-1}	
		Length	1	m	
		Internal diameter	1.905	cm	

Ambient temperature was also necessary to model thermal collector behavior and heat losses in pipes and storage tank. Because no data of ambient temperature in the site were available for the examined period, this parameter was estimated with the following method. Data of daily maximum and minimum ambient temperature in the site were available for the same period for years 2013 and 2014 and from an online database (TuTiempo, 2015) the same data for Calama, the closest city to Lomas Bayas mine (LB), were also available. Hence, an averaged ratio for the period between maximum temperature in LB and in Calama was calculated. The same operation was repeated for minimum temperature. Then, those ratios were used to estimate temperatures for 2015 in LB from Calama temperature values. Following the method of De wit et al. reported in Reicosky et al., (1989) the hourly temperature was calculated from the daily maximum and minimum values. Finally, a lineal interpolation was carried out to determine the values each minute. According to data availability, a 6-minutes time step was used in simulations. Furthermore, since collector mass flow and optical efficiency decreased in February, analyzed period was divided into four sub-periods.

3. Results

Real data

Since the pilot plant have been installed at the beginning of December, no collector cleaning was done. From data corresponding to initial weeks, a daily solar thermal production of 13.28 kWh was measured. This amount represents less than 0.1 % of energy needed to heat the electrolyte in electrowinning process and global efficiency for that period was 52%. According to information provided by Enermine (2014) maximum temperatures measured at collector outlet overcame 80 °C and effects of dust deposition were not appreciable.

For this work, data from 19 January to 20 February were available. In this period, the maximum temperatures at collector outlet were mostly below 70 °C, with the exception for the first days of February, when they reach values close to 74 °C, as it can be observed in Fig. 4a and 5. Then, a gradual decrement was registered until temperature in the tank was always less than 60 °C and no circulation to the load was observed.

Due to the presence of Andes chain at the east, the circulation inside the collector usually started after 10 a.m. and because of the shadow generated by the building behind the plant, the flow usually stopped at 3.30 p.m. Furthermore, the water circulation in the solar loop presented a minor mass flow that decreased along February.

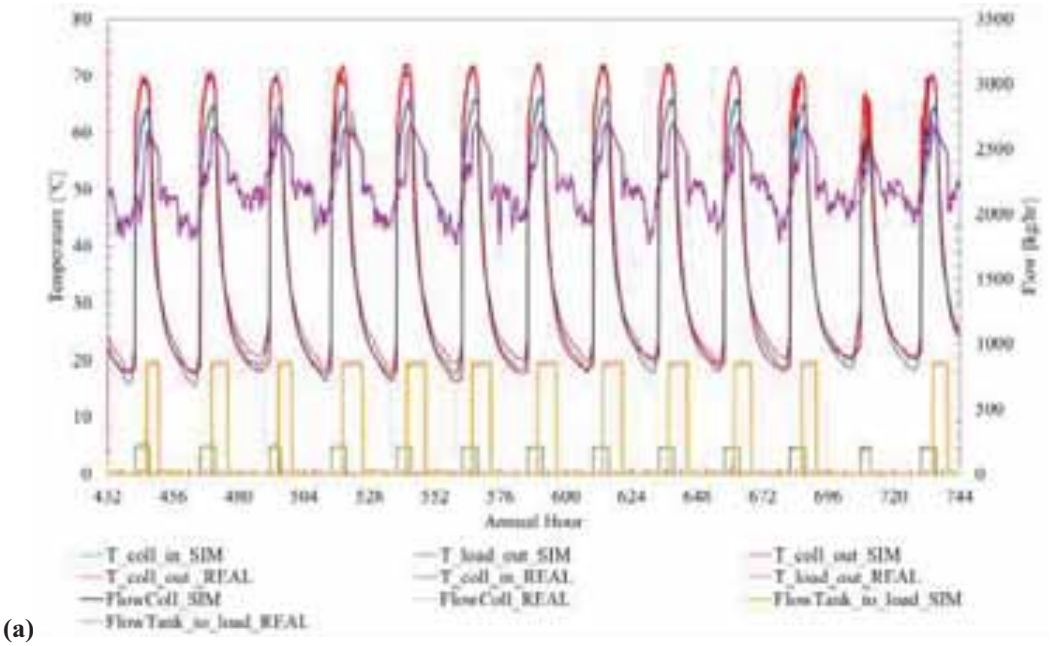
From Fig. 4, 7, 9, 11 low collector efficiencies can be observed, due to the high dust deposition on the panel. Efficiency "Eff" for a period was calculated as the ratio between the harvested energy by the collector and the global irradiance on horizontal "$I_{g,h}$" multiplied by the collector absorbing area "A_{coll}" (see eq.1).

$$Eff = \frac{\sum_i [\dot{m}_i \cdot c_p \cdot (Tout - Tin)_i \cdot \Delta t_i]}{\sum_i (I_{g,h_i} \cdot A_{coll} \cdot \Delta t_i)} \qquad \text{(eq. 1)}$$

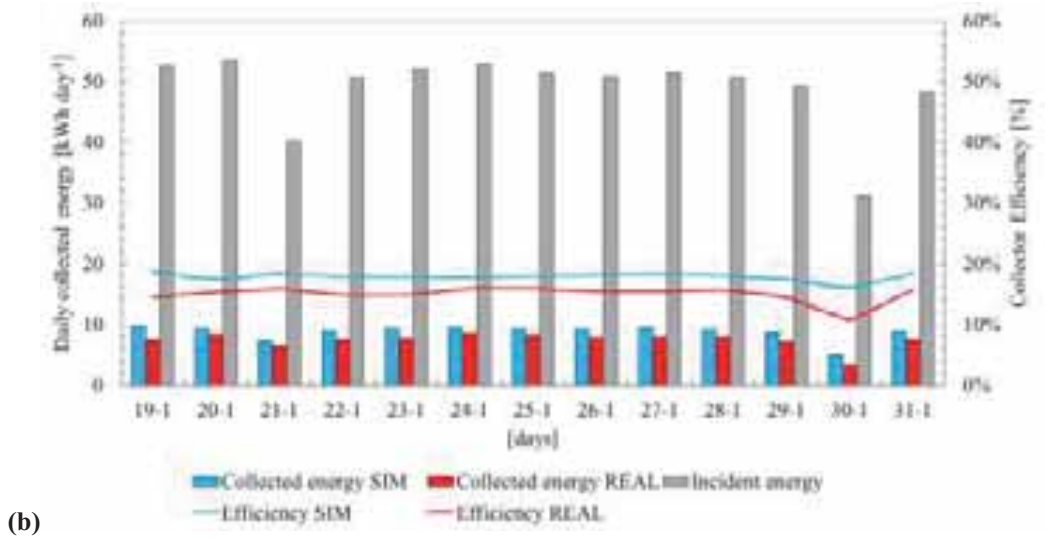
Where $\dot{m}$ represented the mass flow in the collector,· c_p was the specific heat, $Tout$ and Tin were the temperatures at the outlet and at the inlet of solar collector and Δt was the period length while the mass flow was considered constant.

Modeled results

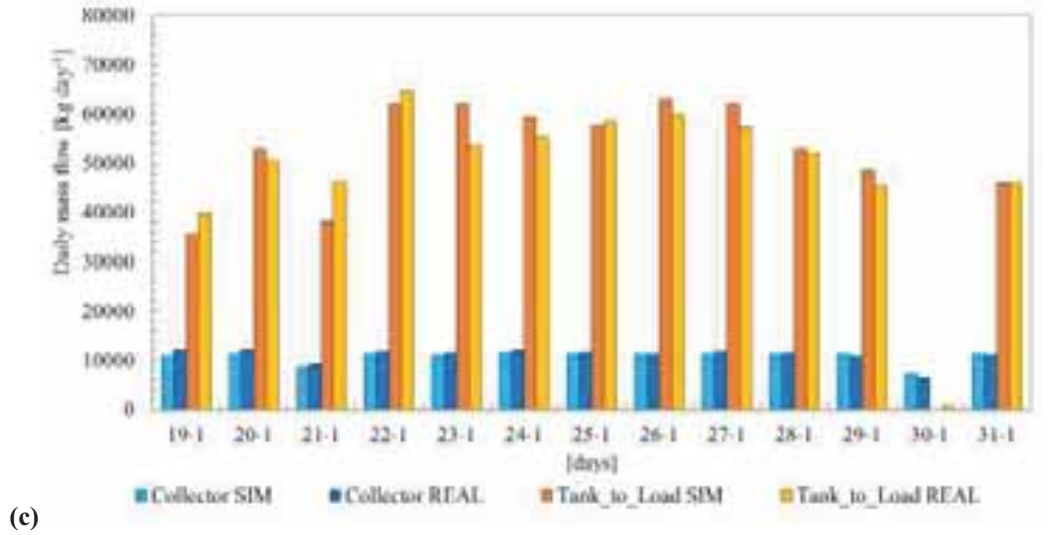
Figure 4 shows results for the first period from 19 to 31 of January: the average mass flow relative error in the solar circuit for the period from 19 to 31 January was 4.3% and the average relative error in the circuit between the tank and the load was almost 6.7%. Average daily efficiency in simulations was 17.9% and it was always higher than in collected data. For real data, calculated average daily efficiency was 15%. Harvested energy by the collector in simulations was very sensible to small variation of temperature difference at collector inlet and outlet, and it causes that discrepancy in efficiency values.



(a)

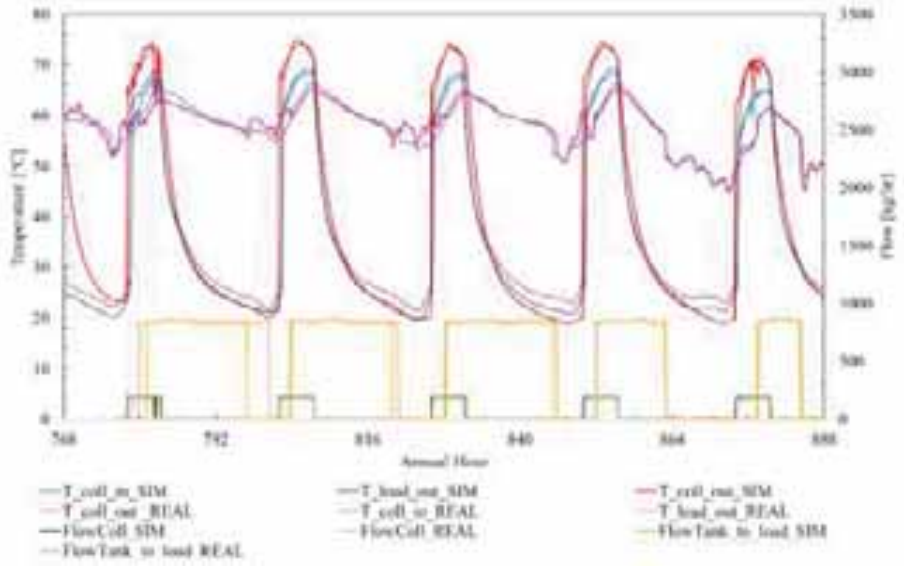


(b)

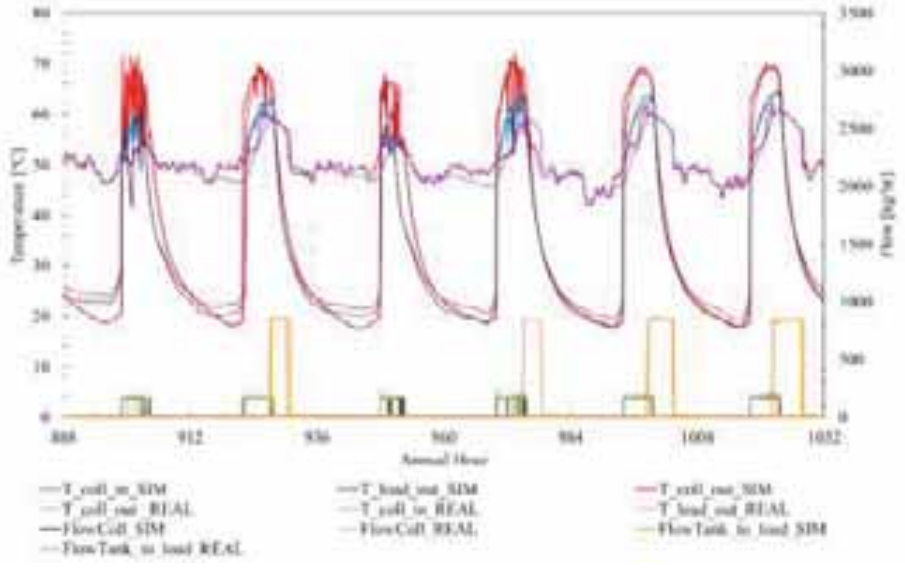


(c)

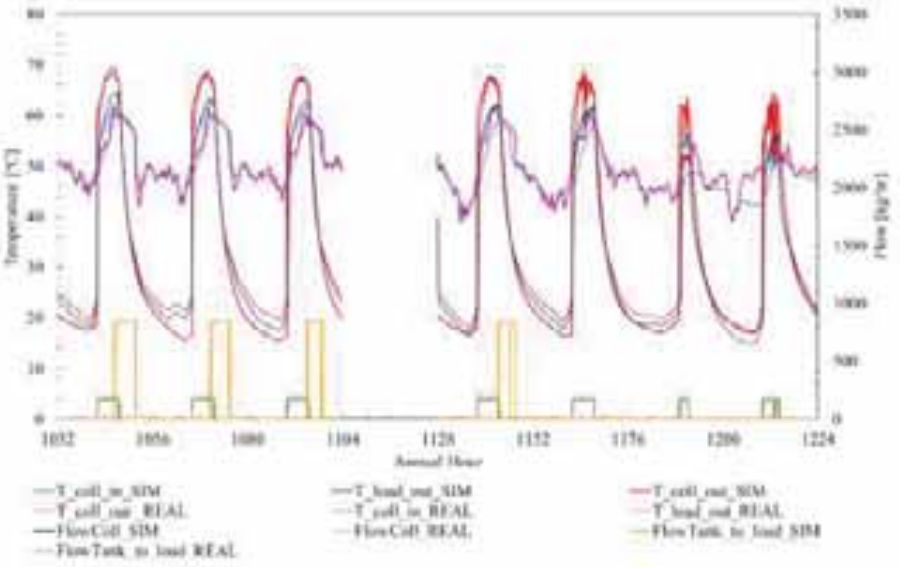
Fig. 4: Simulated and real temperature and mass flow (a), daily collected energy and collector efficiency (b) and comparison of mass flow in the collector and in the circuit tank-to-load (c) from 19 to 31 January.



(a)



(b)



(c)

Fig. 5: Simulated and real temperature and mass flow from 2 to 6 (a), from 7 to 12 (b) and from 13 to 20 February (c).

In the second period (see fig 5a, 6) the optical efficiency was decreased to 0.355 and the mass flow was 190 kg h^{-1}. For the third (see Fig. 5b, 7) and fourth period (see Fig. 5c, 8), optical efficiency was 0.35 and 0.325 respectively and the mass flow was 170 kg h^{-1} for both. In February, results show similar trends even if accuracy is lower. This is due to the changes in some parameters and to the difficulties to find a more accurate set for the model. In general, model accuracy is lower every time a normally constant parameter (i.e. mass flow) changes its value and during partial cloudy days because of a quick variation of radiation impinging on the collector. In Fig. 5, 6, 7 and 8, 1st and 16th February are not represented because there was no data availability.

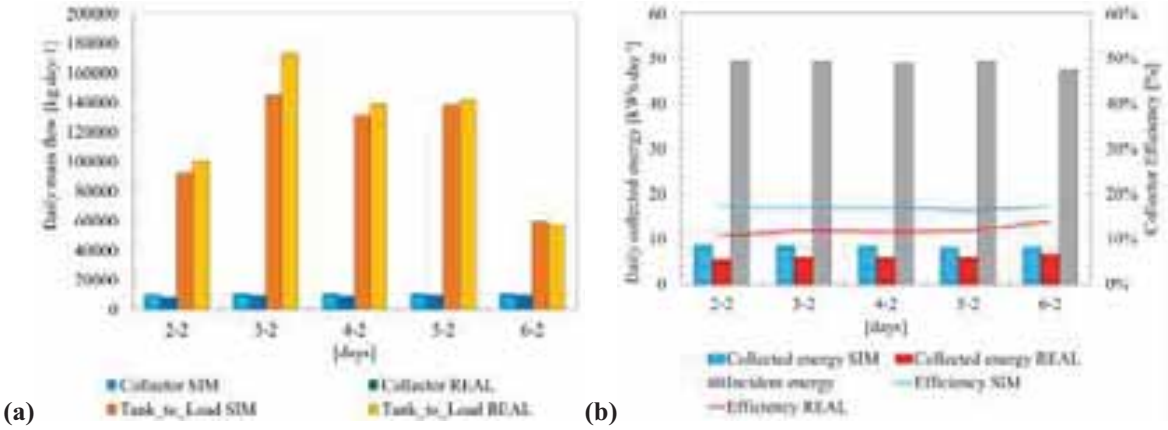


Fig. 6: Comparison of mass flow in the collector and in the circuit tank-to-load (a) and daily collected energy and collector efficiency (b) from 2 to 6 February.

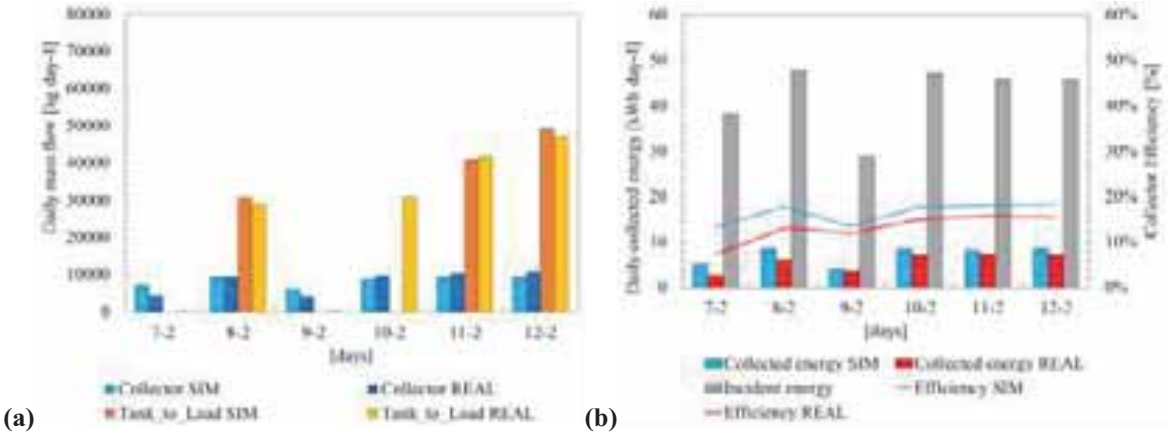

Fig. 7: Comparison of mass flow in the collector and in the circuit tank-to-load (a) and daily collected energy and collector efficiency (b) from 7 to 12 February.

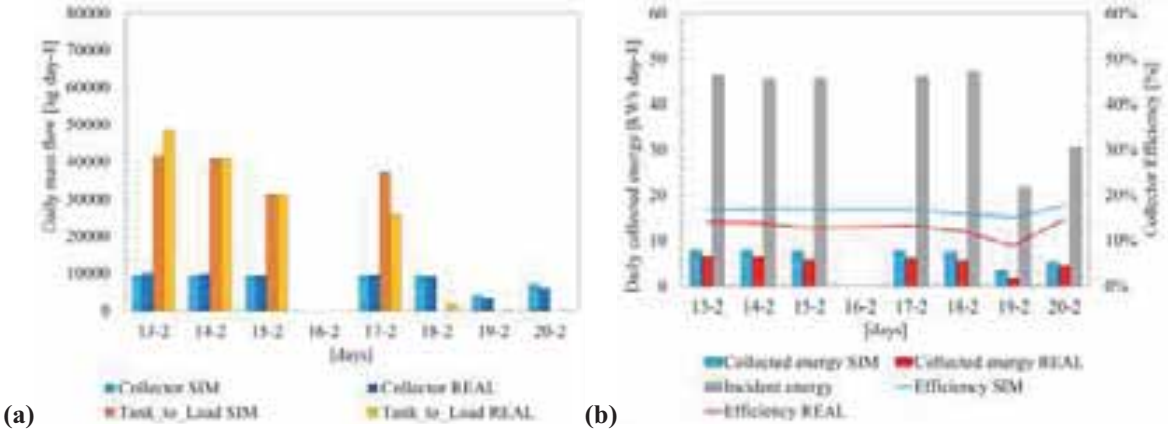

Fig. 8: Comparison of mass flow in the collector and in the circuit tank-to-load (a) and daily collected energy and collector efficiency (b) from 13 to 20 February.

4. Conclusions

In this work, a simplified model of a solar thermal pilot plant was proposed. Simulated results were compared with real data in order to validate the model and at the same time to evaluate the behavior of the plant and the effect of soling on the collector.

Because of data availability, analyzed period started on 19 January and finished 20 February 2015. In that period, daily maximum temperatures at collector outlet were mostly below 70 °C and estimated optical efficiency was 0.36 or less. Hence, outlet temperatures were approximately 10 °C lower then values recorded at the beginning of December by Enermine and optical efficiency was considerable lower than the nominal one, due to the dust deposition on the collector. During the analyzed period was also observed a gradual decrement of daily maximum temperature inside the tank until that value could not achieve 60 °C and no circulation to the load was possible.

The model was realized with TRNSYS and it can estimate the behavior of the solar plant, even if accuracy decreases for partial cloudy days and after a parameter variation (i.e. mass flow or optical efficiency). Average mass flow relative error was 4.3% for solar loop and 6.7% in load-to-tank circuit. However, calculated solar collector efficiency was always higher than the real one because the difficulties to reproduce exactly the temperature difference at collector outlet and inlet during the day.

As future work, a more detailed comparison will be conducted in order to improve achieved results and to determine the optimal frequency for collector cleaning.

Low Concentrating Solar Collectors for Economical Generation of Low-Medium Temperature Industrial Process Heat

Atul S. Jadhav and J. L. (Wikus) van Niekerk

Centre for Renewable and Sustainable Energy Studies (CRSES),

University of Stellenbosch, Stellenbosch(South Africa)

Abstract

A large fraction of the total energy consumption in the industrial sector (approximately 60%) is for direct heat/thermal applications known as Industrial Process Heat (IPH). About half of that energy is used to generate IPH, below the temperature of 300 ^{0}C. To supply this heat energy alternatively, various solar thermal technologies are being utilized. For generating heat at temp below 120 ^{0}C flat plats and evacuated tube collectors are used and for temperature above 150 ^{0}C, high concentrating technologies such as PTC, dish concentrators are used. Flat plats solar water heaters are economical and efficient in generating heat at lower temperatures. But to generate heat at temperature above 150 ^{0}C, more expensive and high concentrating solar collectors are being used. Alternative, less concentrating solar collector with zero or minimum solar tracking, can be used to generate the low-medium temperature industrial process heat. Various, more efficient low concentrating collectors are being developed and tested by researcher which can be used for such applications. These kinds of collector provide more economical solution than high concentrating collectors. In this paper we will look at some of the recently developed low concentrating solar collectors and how they can be utilized to produce low-medium temperature industrial process heat in more economical way compare to high concentrating solar collectors.

Keywords: *Industrial process heat (IPH), Solar Concentrators, Compound Parabolic Collector*

1. Introduction

Energy is the key factor contributing to economic development and quality of life worldwide. It is the basic input required to sustain economic growth. There is direct relation between the level of economic development and per capita energy consumption. Simply speaking more developed a country, higher is the per capita consumption of energy and vice-versa. But conventional energy has two major drawbacks, in the way it is produced and used. Firstly, the overall energy system has been very inefficient in the past. And secondly, major environmental and social problems are associated with the traditional energy system. According to IEA's report greenhouse gases (GHG's) emissions from the traditional energy sector will increase by 130% above 2006 levels by 2050 if new policies and practices are not implemented. (IEA, 2008) Moreover, environmental issues of conventional energy resources such as climate change and global warming are continuously forcing us for alternative sources of energy. According to the statistics released by World Health Organization (WHO), direct and indirect effects of climate change leads to the death of 160,000 people per year and the rate is estimated to be doubled by 2020. (Muneer et al., 2006) Therefore, finding clean sources of energy to satisfy the world's growing demand is one of the society's foremost challenges for the next few decades.

For last couple of decades, there is an accelerated effort, throughout the world, in R&D and implementation of various renewable energy sources i.e. solar, wind, biogas, biomass etc. Among all the renewable energy sources, solar power attracted more attentions as a greatest promising option for energy generation. Solar energy is abundance, free and clean which does not make any kind of pollution to the environment. Amount solar energy received by earth surface in a year is about 885 million terawatthours (TWh). That is 6 200 times the commercial primary energy consumed by humankind in 2008 – and 4 200 times the energy that mankind would consume in 2035 (IEA, 2011). At present consumption rate, proven fossil reserves can last for 46 years (oil), 58 years (natural gas) and almost 150 years (coal) (IEA, 2010), the energy received by the sun in one single year, if entirely captured and stored, would represent more than 6 000 years of total energy

doi:10.18086/swc.2015.10.37 Available at http://proceedings.ises.org

consumption. Capturing and distributing only one tenth of one percent of solar energy will make the energy supply problem disappear.

Presently, solar energy is being widely used for generation of electricity and heat. According to study on the world energy consumption by International Energy Agency (IEA), by 2050 around 45% of energy demand of the world will be supplied using solar energy. As electricity is the highest quality of energy it should be given priority. But energy consumption in the form of direct heat also forms a major mode of energy consumption. The importance of energy in industrial development is very crucial since major fraction of energy is used in industrial processes. It has dominated more than 50% of total energy consumption worldwide.

2. Industrial Process Heat

Industrial sector uses heat for a wide variety of applications, including washing, cooking, sterilizing, drying, preheating of boiler feed water, process heating, and much more. Three different temperature levels are used for describing the quality of the demand for heat in industries: low temperature level is defined as up to 95 °C, corresponding to the typical heat demands for space heating or industrial processes like washing, rinsing and food preparation. Temperatures between 95 ºC and 250 ºC are defined "medium". This heat is normally supplied through steam. Temperatures over 250 ºC are "high" and needed to manufacture metals, ceramics, glass etc. To estimate the potential of solar thermal technologies for industrial process heat generation, knowledge of the required different temperature levels of process heat is essential. Following table 1, gives an overview of various industrial process and their temperature levels.

Tab 1: Temperature ranges for different industrial processes (Kalogirou, 2003a)

Industry	**Process**	**Temperature (°C)**
Dairy	Pressurization	60–80
	Sterilization	100–120
	Drying	120–180
	Boiler feed water	60–90
Tinned food	Sterilization	110–120
	Pasteurization	60–80
	Cooking	60–90
	Bleaching	60–90
Textile	Bleaching, dyeing	60–90
	Drying, degreasing	100-130
	Pressing	80–100
Paper	Cooking, drying	60–80
	Boiler feed water	60–90
	Bleaching	130–150
Chemical	Soaps	200–260
	Synthetic rubber	150–200
	Processing heat	120–180
	Pre-heating water	60–90
Meat	Washing, sterilization	60–90
	Cooking	90–100
Beverages	Washing, sterilization	60–80
	Pasteurization	60–70
Timber by-products	Thermo diffusion beams	80–100
	Drying	60–100
	Pre-heating water	60–90
	Preparation pulp	120–170

Plastics	Preparation	120–140
	Distillation	140–150
	Separation	200–220
	Extension	140–160
	Drying	180–200
	Blending	120–140

These industrial sectors/processes account for a significant share of energy consumption, and currently, energy required for these processes are supplied using fossil fuels. For industrial nation like Germany about 30% of the total energy demand is consumed by industrial sector. About 65% of this energy is used for generating industrial process heat. This energy is further divided, according to temperature level of process heat. Such as, 69 % of the industrial heat is demanded at temperatures above 250 °C (Figure 1). At temperatures below 100 °C, 21 % of the heat can be provided and further 6 % between 100 and 150 °C. And remaining 4 % of the demand occurs between 150 and 250 °C. (Lauterbach et al., 2011) This data is important to understand which solar thermal technology is suitable for specific industrial process.

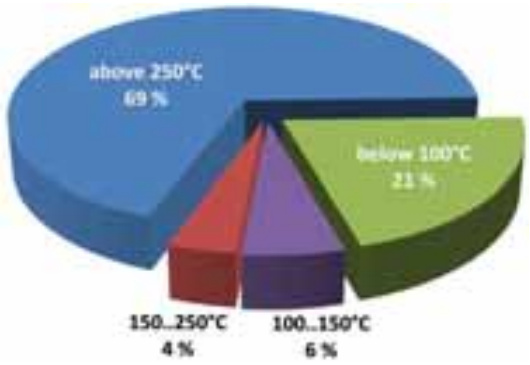

Fig 1: Industrial heat demand in Germany per temperature range. (Lauterbach et al., 2011)

Some of the sectors like steel, aluminium and ceramic have a number of processes which require high-grade heat (temperatures ranging above 800˚C), it would not be possible to provide these temperature levels with solar thermal technologies at reasonable costs. But most of the industrial processes have favourable conditions for the application solar energy. If industrial sectors actively exhibit eagerness, process heat requirement at 400 ^{0}C and below, can be successfully supplied using solar thermal technologies. Overall, an increase in solar energy in industry has the potential to contribute about 10% of all expected GHG emissions reductions in 2050. This is equivalent to the total current CO_2 emissions of France, Germany, Italy and Spain, or around one third of current emissions in the United States. (Thomas, 1995)

3. Solar thermal technologies

Among all the renewable energy sources, solar power attracted more attentions as a greatest promising option to be applied in industries. Solar energy is abundance, free and clean which does not make any kind of pollution to the environment. So far, many attempts have been made to extract solar energy by means of solar collectors, sun trackers and giant mirrors in order to utilize it for industrial purposes. To supply industrial process heat, various solar thermal technologies are being utilized. For generating heat at temp below 120 ^{0}C flat plats and evacuated tube collectors are used and for temperature above 150 ^{0}C, high concentrating technologies such as PTC, dish concentrators are used. Solar thermal technologies utilise the sun radiation to produce heat for many thermal applications. There are various solar thermal technologies available which can be utilized to supply heat at temperature between 60 ^{0}C and 250 ^{0}C. As can be seen in table 2, each technology can be characterised depending on their operating temperature, stationary or tracking etc.

Tab 2: Types of solar thermal collectors (Kalogirou, 2003b)

Motion	Collector type	Absorber type	Concentration ratio	temperature range (ºC)
Stationary	Solar pond		1	30–90
	Flat plate	Flat	1	30–80

	collector (FPC)			
	Evacuated tube collector (ETC)	Flat	1	50–150
	Compound parabolic collector (CPC)	Tubular	1–5	60–240
Single-axis tracking			5–15	60–300
	Fresnel lens collector (FLC)	Tubular	10–40	60–250
	Parabolic trough collector (PTC)	Tubular	15–45	60–300
	Cylindrical trough collector (CTC)	Tubular	10–50	60–300
Two-axes tracking	Parabolic dish reflector (PDR)	Point	100–1000	100–500
	Heliostat field collector (HFC)	Point	100–1500	150–2000

These technologies can also be differentiated by the way they use solar energy. Flat plate and evacuated tube and low concentrating collectors use direct as well as diffuse solar radiation. High concentrating and tracking collector uses only direct normal solar radiation. The main component of any solar thermal technology installation is the solar collector. Solar collector collects the heat from solar radiation and transfers it to a receiver, containing stationery/circulating fluid (usually water or thermal oil). The solar energy thus collected is carried from the circulating fluid either directly to be utilized in many different thermal applications or to a thermal energy storage tank from which can be drawn for use at night and/or cloudy days.

From figure 1, it is evident that the requirement of the low-medium temperature process heat is obvious and significant. However, for the non-concentrating solar collectors, such as evacuated tube and flat plate collector, thermal efficiency of the collector decreases with increasing temperature. Especially above 80 ^{0}C, the thermal efficiency of the solar collector falls sharply, because of which they cannot be used efficiently for these applications. Therefore, to produce process heat at temperature above 80 ^{0}C, it requires solar concentrators, as opposed to non-concentrating collectors [Sardeshpande and Pillai, 2012]. On the other hand, although the high-concentration solar collectors can generate process heat at temperature above 80 ^{0}C, they need a sun tracking system, which further escalates operation and maintenance costs. Which usually make them suitable for large-scale integrated applications, such as high-temperature solar thermal power generation. At the same time, the high-concentration solar collectors, such as tower concentration solar collector and dish concentration solar collector, can get much higher temperature, which is beyond these applications temperature above, and can cause more thermal losses. What is more, high-concentration solar collectors can lead to more diffusion loss as these systems only make use of direct normal solar radiation. Therefore, high-concentration solar collectors also do not fit economically for these low-medium temperature process heat applications.Employment of low concentrating solar collectors is necessary for generating low-medium process heat more efficiently and economically. Researchers developed various efficient and economical low concentrating collector system but very few systems are commercially available.

4. Low Concentrating Solar Collector

Compound parabolic collectors (CPC), evacuated tube collector with/without CPC and flat plate collector sometime with booster reflectors, are employed as stationery and low concentrating systems. One of the main advantages of this type of system is that they can utilise direct as well as some/ all diffuse solar radiation. This make them more efficient for solar radiation collection in a region where atmospheric pollution and dust particles, minimises direct radiation and maximizes diffuse solar radiation. Compound parabolic collector hold great promise to become alternative technology to provide industrial process heat at temperature in range of 150 ^{0}C – 250 ^{0}C. Concept design of CPC was first introduced by Winston in 1974, which is a non-imaging type of concentrator. (Winston, 1974) The basic shape of the compound parabolic concentrator (CPC) is illustrated in Figure 2. A CPC is made of two halves of symmetrical parabola with closely located focal points and their axes inclined to each other, such that rays incident within the angle between the two axes (angle of the CPC) are reflected towards the region between the two focal points and get concentrated in that region, not on a point. Thus, CPCs are non-imaging concentrators and can accept incoming radiation over a relatively wide range of angles.

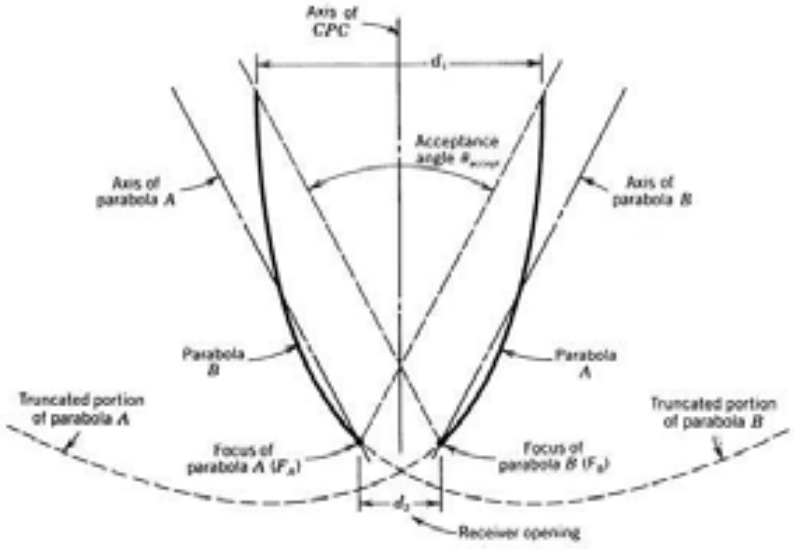

Fig 2: The geometry of conventional compound parabolic concentrator (CPC).

However, there is a trade-off, curve of a parabola has the property that its height increases very slowly as compared to its aperture, until the focal plane is reached; and it increases sharply beyond the focal plane. In the conventional design of CPC, foci of both the parabolas lie at the bottom of the CPC, and sections above the focal points of both are used. This causes rapid increase in height and a low energy concentration performance. Various designs have been proposed by several researchers to successfully overcome these limits to varying degrees.

In 2013 Jadhav et al. (Jadhav et al., 2013) proposed improved design of compound parabolic collector as compared to those reported earlier. Improved design substantially reduced the reflector height without compromising the concentration ratio. The modified design used the region below the common focus of parabolas. Based on their designed, a 100 m2 CPC system was fabricated and investigate, with aperture width 2 m, acceptance angle 3 and receiver pipe of 48 mm outer diameter had a height of around 0.5 m from base of reflector. For the same aperture width, acceptance angle and receiver dimensions, the height for conventional, untruncated CPC is around 38 m. Thus the modified CPC design needs substantially reduced support structure, and consequently, expected to be economical and easy to handle. The receiver wasn't evacuated and system generated steam at 120 ^{0}C with 43% efficiency. Cost of their 100 m^2 system was around 70 US$/m^2 and claimed that same system with few minor refinement can generate steam at around 200 ^{0}C.

Fig. 3. A photo of the experimental 100 m^{2}CPC system.

Recently, Lun Jiang et al. (Jianga et al., 2015) published performance of eXternal Compound Parabolic Concentrator (XCPC). This prototype XCPC, as seen in figure [4] is placed East-West, with pentagon absorber as cross section. Oil is used as the heat transfer fluid in the system. The absorber tube is made of a metal glass vacuum tube due to its improved heat transfer capability compared to the all glass vacuum tubes. Their test result shows that XCPC reach working temperature of 160 ^{0}C, 200 ^{0}C and 230 ^{0}C with efficiency of about 59%, 52% and 43% respectively.

Fig 4: The XCPC collector with east west axis direction. Aperture area for each collector is 4.5 m^2

Lun Jiang et al. (Jianga et al., 2015) also published performance of full size collector of Integrated Compound Parabolic Concentrator (ICPC) (Fig.6). Each of the ICPC tube is eventually fabricated at 85mm width with a absorber of 30mm height, resulting in a concentration ratio of 1.41. The aperture area is 1900mm X 85mm for each tube. A heat pipe of 8mm diameter is inserted into the absorber fin and ultrasonic welded on to the fin to ensure the heat transfer. The reflective coating is using the Flat Plate Collector with Booster Reflectors standard silver mirroring chemical process, with a protective resin to be weather proof. The optics of the ICPC is designed for a 35 degrees acceptance angle and therefore should be positioned east-west direction. But for testing purpose and the trial of the heat pipe as a heat transfer model, we implemented them as north-south aligned, and put them on a tracker to take the measurement. The result is showing a relatively lower performance compared to the XCPC model under the same temperature. However, this is mainly due to the heat pipe not functioning as ideally as a heat transfer mechanism compared to the direct flow mechanism in the XCPC array. The ICPC collectors show 42% efficiency at 200 °C based on global irradiance.

Fig 5: a) The ICPC 3.5 m^2 prototype, with full 1900mm length tube, front view. b) The cross section of the original ICPC prototype design.

Two non-tracking variation of CPC proposed by Wattana Ratismith et al. (Ratismith et al., 2014) one is more conventional double-parabolic trough, has the absorber plate perpendicular to the vertical axis of the trough cross-section. Second one is of a new flat-base shape, has the absorber plate parallel. The collectors have two novel features appropriate to non-tracking. The collectors have two novel features appropriate to non-tracking. The first is a smoothing of the power output over the day by beneficially arranging three troughs

tilted at different angles. The second salient feature in the design of these solar collectors is the use of a trough which utilises the non-focussing advantages of non-parabolic shapes in achieving high acceptance angle, high intercept factor and high concentration of diffuse sunlight.

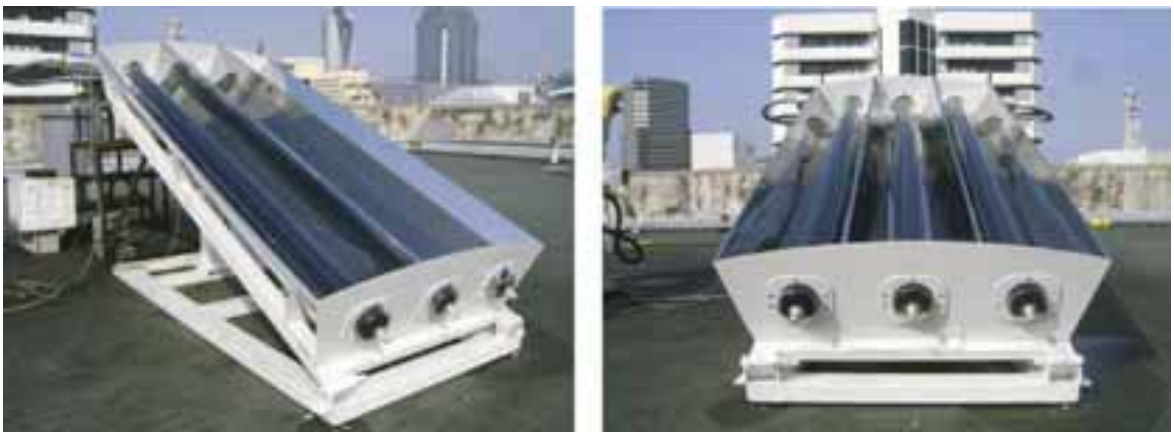

Fig 6: The non-tracking solar collector

They showed that their stationary flat base shape CPC performed better with operating temperature of 180 ^{0}C at 40% efficiency. In the experiment they used the commercially available SUNDA (SEID01) vacuum tubes of length 2.1 m with a planar absorber plate of width 9.0 cm.

Two truncated compound parabolic concentrating (CPC) solar collectors (shown in figure 7a & 7b), which combine the external CPC and the U-shape evacuated tube together, have been developed and tested by X. Li et al. (Li et al., 2013) Their CPC has concentration ratios of 3 and 6 and half-acceptance angles of 10^0 and 3^0, respectively. CPC with 3 concentration ratio will need only seasonal tracking while CPC with 10 concentration ratio will need to track sun 5 times a day. The daily thermal efficiencies of the 3X and the 6X CPC collectors can reach 40% and 46% at the collecting temperature of 200 ^{0}C, respectively. These verify that these kinds of CPC solar collectors are feasible for a wide range of intermediate industrial temperature applications.

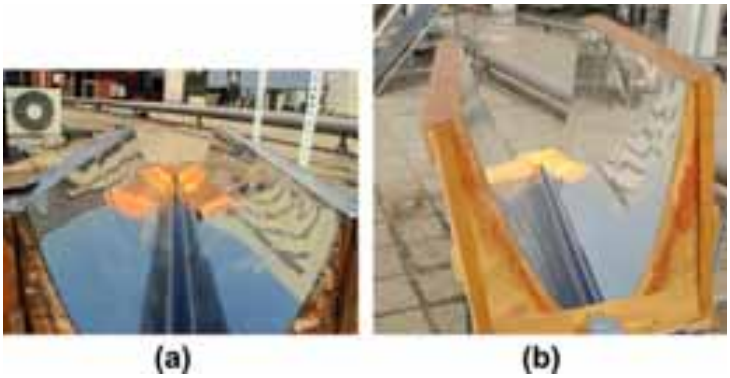

Fig 7: (a) the 3X CPC collector; and (b) the 6X CPC collector.

Last year at an international conference on solar heating and cooling, H.J. Burckhart et al. (Burckhart et al., 2013) presented results on use of novel collectors from the company SRB for heating and cooling of a building in Geneva, Switzerland. SRB Energy developed a two sided vacuum flat-plate collector, combined with CPC reflectors at the bottom side of the receiver (Figure 8a). This holds for both direct and diffuse light, which is of special importance as diffuse light amounts to about half of the total light in middle Europe. This system is stationery and according to the company, the vacuum inside the flat-plate, between 10^{-6} to 10^{-9} mbar,is expected to last for the whole service life of the collector. Figure 5b shows the collection efficiency of this system for different solar irradiations. Temperatures up to 400 °C can be reached. Figure 8b shows, that the 90 °C necessary to drive the absorption unit can easily be reached for irradiations as low as 200 W/m^2 with a reasonable efficiency. The stability and ease of operation of this solar collector has already been proven in existing installations.

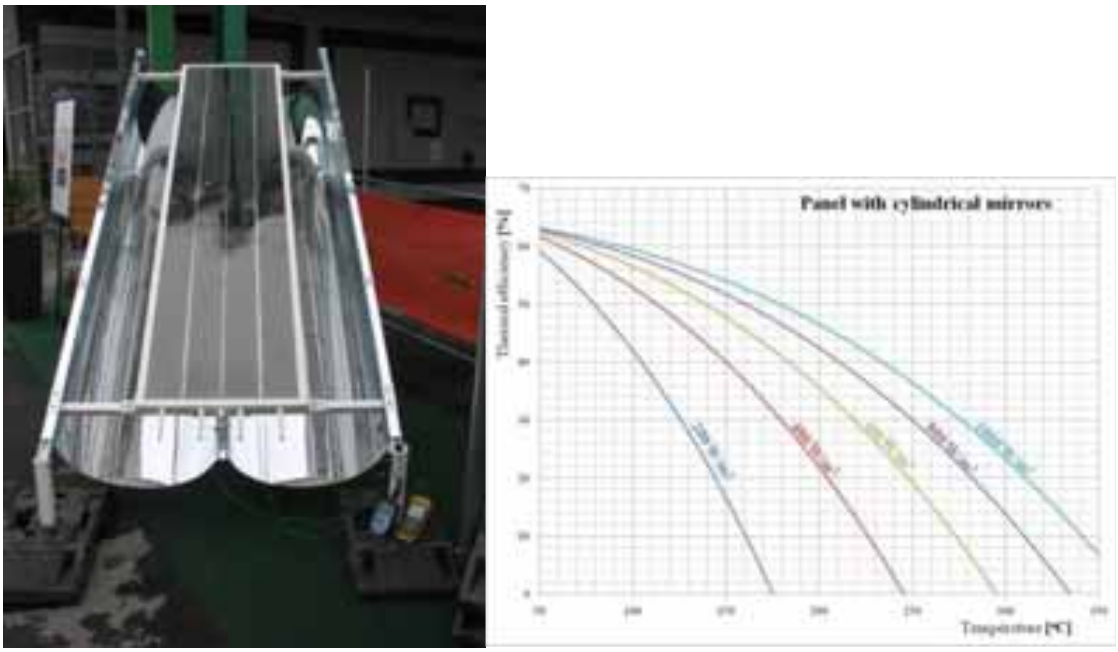

Figure 8: a) Assembly of the absorber panel and the two mirrors b) Thermal efficiency for different solar irradiation

5. Drivers for low concentrating technologies

In previous section we discussed some of stationery and low concentrating technologies, which are being developed and tested to operate at temperatures close to 250 ^{0}C. Most of these technologies, more or less are laboratory based or/and demonstration purposes only. One of the main barriers to increased deployment of solar industrial process heat systems is the high investment cost and lack of finance options. Cost plays important deciding factor for any new technology to become market ready and available to consumer. All solar process heat systems involve high initial investments in advance of a practically cost-free operating period. However, proper maintenance is required to ensure that the systems operate optimally over their full lifetime expectancy. The up-front costs particularly hamper deployment in small and medium size enterprises where financing is not available. (ESTIF, 2014)

The costs of solar thermal process heat installations in Europe range from 180 to 500 Euro / m^2 of aperture area, depending on the system concept, the size of the system, the selected components (e.g. the choice of the collector type) and on country-specific factors (e.g. salaries). Of the total costs in solar thermal technology, between 50-70% are related to the capital, while the remainder covers installation and integration. (IRENA, 2015) Table 3 provides an overview of the costs for solar concentrators: solar parabolic dish and parabolic dish are more expensive than conventional FPC and ETC but permit higher temperature ranges. Aagain these cost can vary from region to region, but for the sake of arguement Indian cost of all these technologies are taken. Comparing cost of stationery and concentrating solar collector one can easily find out that concentrating collector cost at least double than stationery solar collector. This cost difference can easily be a discouraging factor for small and medium scale industries from adopting solar process heat system.

Tab 3: Cost comparison of solar thermal collectors (IRENA, 2015)

	Stationery Solar Collectors		**Tracking Concentrating Solar Collectors**		
	FPC	**ETC**	**Parabolic Dish**	**PTC**	**Linear Fresnel**
Temperature Range ^{0}C	100 ^{0}C	120 ^{0}C	250 ^{0}C-700 ^{0}C	100 ^{0}C-400 ^{0}C	100 ^{0}C-350 ^{0}C
Cost (USD/m^2)	84-302	97-369	300-600	445	650-900
Cost (USD/kW)	216	203	600-1760	1580-2040	1160-1800

Stationery low concentrating collectors can play an important role of supplying low-medium temperature industrial process heat at a cost which can comfortably fit between the costs of stationery and tracking collectors. Theses collectors can be little expensive that stationery collector as they use reflector for concentration of solar radiation. At the same time low concentrating collectors will be less expensive that tracking collectors as they never/occasionally use more precision tracking mechanism and reflector curve. Developing and poor countries with high solar irradiation, small and medium size industries are an interesting market for such low concentrating solar thermal systems. As, these industries often rely on expensive fossil fuels for heat production and solar thermal systems reduce their dependence on fossil fuels and contribute to the reduction of operating costs. Also, the heat demands per plant are relatively small compared to the energy intensive industry, which makes the integration of solar heating systems easier. The sheer number of SMEs present could result in rapidly declining costs due to learning by doing and more effective operations by installers. This could create a virtuous circle in which, with declining costs and more experience, the deployment of solar heating systems is accelerated in this market segment. (IRENA, 2014)

6. Conclusion

A large fraction of energy used in industrial sector, is used for generating industrial process heat at temperature below 300 ^{0}C. To move away from polluting fossile fuel utilization, solar energy is succefully utilized for such applications. Presently, medium temeprature (150 ^{0}C - 300 ^{0}C) industrial process heat is supplied using solar concentrators similar to technologies used to produceconcentrated solar power (CSP). Instead of using the heat to produce power however,the heat is directly used in industrial processes. Such solar concentrators are parabolic dishes, parabolictrough concentrators and Linear Fresnel collectors. These collectors are made with efficient absorber, precision optics and tracking mechanism to produce temperature much greater that medium temperature range. Becuase these charecteristics of high concentrating collectors are expensive than the stationery solar collectors. For cost sensetive market in poor and developing counrties, for successful deplyment of solar industrial process, cost of these technologies needs to be brought down. An alternative for these expesive concentrator will be less concentrating technologies which are still under development stages. Less concentrating solar collector with zero or minimum solar tracking, can be used to generate the low-medium temperature industrial process heat. As discribed in this paper, researchers are developing more efficient low concentrating collectors which can be used for such applications. Cost comparsion of existing technologies shows that there a cost gap and market for low concentrating collectors which can be further explored. If developed further, commercialization of more efficient low concentrating technologies will further intensify the successful deployment of solar industrial process heat.

USE OF FLAT SOLAR COLLECTORS, IN REPLACEMENT OF LPG GAS FOR WATER PRE-HEATING, TO BE USED IN ENGINES OF ELECTRIC POWER THERMAL GENERATION PLANTS

José Bione M. F.[1], Aluísio A. Medeiros Silva[2] and Carlos Salviano[2]

[1] University of Pernambuco and Institute Federal of Pernambuco, Recife (Brazil)

[2] University of Pernambuco – Escola Politécnica, Recife (Brazil)

Abstract

Energy consumption in the world has been growing every year. The industrial sector represents 27.32% of the world energy demand. Implementation of flat solar collectors (temperature > 100°C) replacing the LPG gas to preheat the water used in the electricity industry, for the three engines of the Thermal Power Plant of Electricity Energy Generation – TermoCabo with power 45 MW. Given the importance of the matter, this research project aims a technical analysis and economic evaluation of the use of flat solar collectors, including an analysis in the control system of the plant, besides an adaptation of the collectors to the charge demand and to the thermal energy storage system in order to maintain autonomy of 24 hours. The system consists of a battery of collectors associated to a complex grid of flow control and maintenance of stagnated temperature of 65°C, besides the system working independently, having the heat exchanger as a point of intersection between the primary and the secondary system. The project was planned as three closed and independent systems, because due to load operating complexity (engines) required the collectors independent worked the other parties, and the need to use glycol to increase the boiling water point, plus there a water storage system to maintain the autonomy and the third stage is the engine heating system, which is composed of thermal additive.

1. Introduction

Energy consumption in the world has been growing every year. The industrial sector represents 27.32% of the world energy demand. The search for greater energy efficiency, along with policies of clean development mechanism, has encouraged the study of new techniques for power generation using renewable energy sources with lower generation of pollutants (DINIZ & BERMANN, 2012). Among the alternative energy sources, solar energy is becoming more popular, especially for residential water heating, being a cost-effective alternative to the use of electricity and natural gas (Goldemberg & Lucon, 2007; Luna et al., 2008; Oliveira et al., 2008; Altoé et al., 2012). Heating systems that use solar energy may contribute with a percentage of the total energy required by industries. Heat is often underappreciated in public policy discussions on energy, frequently overshadowed by transportation energy and electric power. However, heat accounts for 37 percent of energy consumed within most developed countries, and 47 percent of the world's energy consumption (IEA 2013). While many people associate solar energy with electricity-producing photovoltaic (PV) panels, solar can also be used for heating purposes. Solar thermal energy is most commonly used to heat outdoor swimming pools and residential water in the United States, but it can also be used for many types of industrial processes (IEA 2014). This issue brief will examine the role that solar thermal technology currently plays in industrial heating processes and outline opportunities for increased application in the world industrial sector.

The industrial sector is the leading source of energy consumption in the United States. At nearly one third of total energy use, it exceeds both the transportation and residential sectors. Within the industrial sector, nearly two thirds of energy used is consumed as heat. Some industries have even higher rates, such as the glass industry, which consumes about 80 percent of its energy for heating purposes. The remaining third can be

doi:10.18086/swc.2015.10.38 Available at http://proceedings.ises.org

attributed to electricity generation or energy lost in transmission within the grid, or by inefficient conversion within the power plant itself.

Depending on how industrial thermal energy is defined, nearly 90 percent of the energy comes from burning fossil fuels, but biomass can count for up to 11 percent.6 The remaining 10 percent of thermal industrial energy comes from electricity, which is often generated by power plants that burn fossil fuels. When including the environmental degradation from extracting fossil fuels, like mountaintop removal mining, water pollution from hydraulic fracturing of shale for natural gas, the air pollution emitted after their combustion, and large emissions of greenhouse gases, there is Environmental and Energy Study Institute a clear social incentive to find alternative sources of energy. Industry's role as the largest consumer of energy in the nation, its large heat requirements, and its heavy reliance on fossil fuels, present tremendous opportunity for application of solar thermal technology.

In Brazil, usually the use of sun energy for the generation of thermal power for industrial use is small. This issue involves the understanding of the relationship between sustainable development, modernity, freedom, market, citizenship, and especially the relationship between the lack of access to energy and technological knowledge. Given the broadness of these aspects, the attention is directed the regulatory framework of the Brazilian energy industry and the use of water heating with solar energy by national industries. Brazil receives high levels of solar radiation incidence during almost every month of the year, including in June, which corresponds to the winter solstice for the Southern Hemisphere.

The average daily distribution of global radiation per region of the country is: North 5,462 Wh/m^2; Northeast 5,688 Wh/m^2; Midwest 5,630 Wh/m^2; Southeast 5,478 Wh/m^2; South 5,015 Wh/m^2. These high solar radiation levels may provide a wide use of solar collectors for water heating, mainly in the industrial sector and can be applied in the reduction of fossil fuels, reducing also the emission of CO_2 into the atmosphere.

Given the importance of the matter, this research study aims for a technical analysis and economic evaluation of the use of solar collectors, replacing the LPG gas for water pre-heating to be used in the engines of the Termocabo plant.

1.1 Characteristics of industrial thermal demand

Industrial heating needs can be categorized into three main temperature ranges. All of them can be achieved with solar. The lowest temperature range consists of everything below 80ºC. Solar collectors are capable of meeting these temperatures and are commercially available today. The medium temperature category is between 80ºC and 250ºC. While the collectors servicing this level of heat demand are relatively limited, they do exist and are on the verge of emerging into competitive commercial production. The highest range includes everything over 250ºC and requires concentrated solar power (CSP) (see appendix) to achieve such temperatures. While CSP furnaces are rare - a few have been installed in the World for electricity production. They can achieve temperatures as high as 800ºC.

The challenge of mitigating imminent risks arising from climate change embraces not only governments, but the civil society and companies; therefore, it is necessary to develop and establish techniques that reduce the concentration of gases causing the greenhouse effect in the atmosphere. In the industry, the use of solar energy has been little explored since the energy obtained via solar collectors may be used for fluid pre-heating, what greatly reduces the amount of fuel material burnt in boilers (KALOGIROU, 2004; ABRAMOVAY, 2010).

Many industries already can take advantage of the commercially available low and mid-range temperature solar thermal collectors. They are particularly suited to meet the heating needs of the food, beverage, textiles, paper and pulp industries. Processes like sterilizing, pasteurizing, drying, hydrolyzing, distillation and evaporation, washing and cleaning, and polymerization do not require high temperatures and can easily benefit from flat plate and evacuated tube collectors (see appendix, table below). According to a study of industrial heating in European countries, 30 percent of industrial processing requires heat below 100ºC and 27 percent of industrial heating needs can be met with heat between 100-400ºC, and 43 percent requires heat over 400^{0}C.18 In the food, wine and beverage, transport equipment, textile, machinery, and pulp and paper industries, roughly 60 percent of the heating requirements can be met by temperatures below 250ºC. Despite tremendous opportunity, solar thermal heating for industrial processes has been insignificant compared to the

residential sector, and the few industrial applications that do exist have been experimental in nature, show in Table 1 different temperatures of process industry.

Tab. 1: Heating process in the different industry (Mekhilef *et al*., 2011).

INDUSTRY	PROCESS	TEMPERATURE(ºC)
Dairy	Pressurization	60-80
	Sterilization	100-120
	Drying	120-180
	Concentrates	60-80
	Boiler feed water	60-90
Tinned food	Sterilization	110-120
	Pasteurization	60-80
	Cooking	70-90
	Bleaching	70-90
Textile	Bleaching, dyeing	60-90
	Drying, degreasing	100-130
	Dyeing	70-90
	Fixing	160-180
	Pressing	80-100
Paper	Cooking, drying	60-80
	Boiler feed water	60-90
	Bleaching	130-150
Chemical	Soaps	200-260
	Synthetic rubber	150-200
	Processing heat	120-180
	Pre-heating water	60-90
Meat	Washing, sterilization	60-90
	Cooking	90-100
Beverages	Washing, sterilization	60-80
	Pasteurization	60-70
Flours and by-products	Sterilization	60-80
Timber by-products	Thermal diffusion beams	80-100
	Drying	60-100

	Extension	140-160
	Drying	180-200
	Blending	120-140
Energy Generation	Thermic	150-800

1.2 Barriers

The main barriers to the implementation of a solar heating system of high performance are the lack of data on collectors when high temperatures are employed, and its actual efficiency under different temperature conditions. In this sense, this study aimed to identify relevant parameters of fluid heating for solar power systems as well as the main process responses. In addition to tests of heat transfer, economic viability studies were performed by calculating the return time and rate on the investment.

Despite the large potential for solar energy to meet industrial thermal demand, there are several barriers to large scale implementation. The most noteworthy barriers are cost, variability of output, energy storage and process integration.

1.2.1 Cost

The economic viability of solar thermal energy depends largely on two factors: the initial cost of the installation and the price of alternatives. High upfront costs often prevent companies from investing in new technology, like solar thermal, even if the overall lifetime cost would be lower. However, while the cost of solar technologies is decreasing, the financial investment in solar remains more stable than many of the markets for fossil fuels. Thus, the largest driver of a collector's cost effectiveness is often the price of alternatives, like coal, oil and natural gas, not the cost of the collector itself. The more expensive fossil fuels become, the easier it is to justify an investment in solar thermal energy. Nevertheless, if the price of solar thermal were to drop, it would certainly enhance its economic viability. With the volatility of fuel prices, some manufacturers opt for the fixed upfront cost (see case studies) with a predictable payback period. In addition to the potential for a lower overall cost, there exists a benefit from having a predictable cost structure which is insulated from fuel market volatility. Approximately 40 percent of industrial primary energy comes from natural gas, and approximately 41 percent comes from petroleum (Kalogirou, Soteris. 2012).

Furthermore, solar thermal collectors can be made even more cost effective when tailored to the specific process heating needs of the plant (see Process Integration below). On the factory level, large-scale applications can benefit from economies of scale and lowered investment costs, increasing its economic viability. On the national level, the IEA estimates that costs can be reduced by as much as 20 percent when a country's total installed capacity doubles.

1.2.2 Variability

Solar energy, like wind energy, can be predicted to a high degree of confidence. Its availability, however, presents challenges for industries that require "24/7" demand. The reliability of the heating supply is of paramount concern to many manufacturers for whom an unanticipated disruption in production can be economically devastating. Solar thermal energy is reliable but not always available. Therefore, industries which either do not require constant production, or for whom the sunlight availability can be aligned with heating requirements, may be more confident about integrating solar thermal energy into their production. The variability of sunlight can also be mitigated by conducting statistical analyses of heating requirements vis-à-vis the regional insolation—the irradiance per square meter over a given period of time. This can be conducted as part of a procedure known as process integration (see below). Another possible solution is to store heat for later use to smooth the gaps in sunlight availability (see below).

1.2.3 Process Integration

Process integration, also known as "pinch analysis," is a field of engineering which seeks to optimize operational energy efficiency, or in other words, to reliably produce a product with the minimum energy inputs necessary. The variability of energy supply must be quantified based on daily solar radiation, ambient temperature profiles, and available storage opportunities, so that the solar collectors can be optimized to reduce economic inefficiencies. Variable energy, like solar and wind, presents a particular challenge for process integration because the supply of energy is non-continuous. Therefore, the nature of solar thermal energy supply must be addressed or it can become unaffordable in some cases.

If solar collectors supply all of the energy, the manufacturer must either align production with the energy supplied, or store the energy for later use. However, even if sunlight is not available to meet all of a factory's thermal energy needs, solar thermal can still play a role by supplying a portion of the total energy required. Under such hybrid systems, solar collectors can provide a baseline energy supply whenever it is available and the remainder can be fulfilled by a complementary fuel source. The commercially available low temperature collectors are especially effective in this strategy and are often used for pre-heating purposes.

1.2.4 Energy Storage Options

Large scale thermal energy storage is a nascent market but it can compensate for the inherent variability of sunlight. For low and medium temperatures, this can usually be performed by storing the heat in a transfer fluid like hot water or oil. Sometimes pressurized steam is used. For higher temperatures, this becomes more difficult, and costly, and requires an alternative heat transfer fluid and storage material.

The most common heat transfer fluid for CSP is molten nitrate salt, which is thermally stable within a temperature range of 220° C to 565°C, below which the salt freezes.32 The molten-salt system is currently the

only practical thermal energy system with hours-long storage potential, and has proven reliable at commercial scales.33 The National Renewable Energy Laboratory (NREL) has called on researchers to develop a heat transfer fluid that can sustain temperatures up to 1300°C and operate as low as 0°C.34 This temperature, according to NREL, is a necessary component in reaching the full potential of solar thermal applications.

1.3 Market Tends

The solar thermal industry has seen steady growth over the last few years. The global solar thermal market grew by 17 percent in 2012 and again by an estimated 42 percent in 2013, largely due to a 45-50 percent surge in the U.S. residential sector. By the end of 2014, the United States and Canada combined for 8.7 percent of the world-wide installed capacity. China led the global market with 58.9 percent of installed capacity, followed by Europe with 18.9 percent.

Excluding solar that is used mainly to heat outdoor swimming pools, the United States ranked 10th in the world in 2009 for overall installed capacity and 36th in the world for per capita capacity. Firms have begun using solar thermal for industrial process heating with a few large-scale projects in Europe and China.

1.3.1 Energy efficiency

According to the DOE's Office of Energy Efficiency and Renewable Energy, best practices in process heating, such as opportunities for heat recovery, can reduce the cost and consumption of energy by as much as 30 percent. Even plants and factories with energy management systems can improve energy efficiency from 10 percent to 15 percent by implementing best practices, thereby reducing energy costs for process heating from 5 percent to 15 percent.

2. Methodology

2.1 Analysis of types of solar thermal technology

There are two main types of solar thermal technology: stationary and concentrating (typically non-stationary). Stationary collectors do not move and can be further subdivided into flat-plate collectors and evacuated tube collectors. Stationary collectors are cheaper and require little maintenance but they can only achieve low to medium temperatures. Alternatively, concentrated solar power (CSP) collectors usually rotate to track the sun's rays and can therefore achieve much higher temperatures. However, they are also more expensive and require more maintenance.

2.1.1 Flat plate collectors

Flat plate collectors are simple, inexpensive and require little maintenance. Most commonly used to heat outdoor swimming pools and home water heating, they consist of an insulated metal box with a glass covering and an absorber plate inside. The absorber plate utilizes the sun's radiation to warm an internal heat transfer fluid (HTF), usually water, oil or air.

Flat plate collectors can be either glazed or unglazed. Unglazed collectors have no insulation over the glass which augments both heat gain and heat loss. These collectors typically reach temperatures of only 30ºC are almost exclusively used to heat outdoor swimming pools. Glazed collectors have an insulated glass covering and can typically achieve temperatures of up to 80ºC and are thus applicable to a number of the industrial heating processes in the chart above. Flat plate collectors can penetrate the medium range and achieve temperatures between 90ºC and 150ºC, but they are not yet economically efficient beyond 80ºC.

2.1.2 Evacuated tube collectors

Evacuated tube collectors are the other stationary collector and they typically consist of a row of parallel tubes which use the sun's rays to heat an absorber plate at the center of a vacuum. These collectors can achieve higher temperatures because the vacuum reduces conductive heat loss and eliminates convective heat loss. However, they are also more expensive to manufacture. Vacuum collectors have reached economically efficient temperatures between 90 oC and 150 oC, making them a useful complement to the flat plate

collectors.55 By adding reflector plates to concentrate the sunlight, these collectors have efficiently reached temperatures up to 200 oC.56

2.1.3 Concentrating Solar Power (CSP) collectors

CSP collectors can achieve the highest temperatures but they are also the most expensive to manufacture and maintain. They are extremely rare for industrial process heating and virtually nonexistent the United States, outside of utility-scale solar power plants. CSP collectors can reach extremely high temperature by rotating to follow the sun and by using arrays of reflectors to focus large amounts of sunlight onto the absorber.

2.2 Step by Step

The first step was to determine the total steam demand of the main equipments from the Termocabo plant, consisting of three generating engines, totaling installed power capacity of 48MW.

By analyzing the thermal charge on one or more items of the plant with heat transfer equations, it may be possible to obtain an estimate for the steam consumption. The mathematical model for each device uses the equations of mass balance and energy balance in control volumes, which were transcribed in an appropriate programming language for the development of applications of technical nature. The thermal charges considered in this study were: 1 Storage (1,495.0m^3), 1 Buffer (85.8m^3), 1 Day (176.0m^3), 3 Lub Oil Separators (5.0m^3), 3 Fuel Oil Separators (5.9m^3) and 3 Preheater Engines (5.5m^3). Vapor pressure is of 7 bar g at any point of the system and the boiler is capable to continuously maintain this pressure. The evaporation heat for 1 kg of steam at 7 bar is of 0.566 kW. It is known that the total heat at 7 bar of steam is 0.700kW (660.8 kcal or 2,764 kJ found in steam tables). However, the condensate still contains some heat that is not released, being completely safe ty o use the indicated value. The main equations used are:

Energy transfer equation (eq. 1).

$$Q = mC_p\left(T_f - T_i\right) \qquad \text{(eq. 1)}$$

where,

C - specific heat for water evaluated at the mean temperature, J/kg K;

m - mass flow, kg/s, and

T_f and T_i - inlet and outlet temperatures of each collector.

(Eq. 2) describes the efficiency of collectors according to local radiation:

$$\eta = \frac{Q_{absorbed}}{Q_{solar\ energy} x A_c} 100 \qquad \text{(eq. 2)}$$

The heat transfer function in the solar collectors is obtained using the Hottel--Whillier Bliss equation (Smith and Weiss, 1977) (eq. 3).

$$Q_{SC}(t) = A_{SC} f_r\left[I_r(t)(\tau\alpha) - U_{SCi}\left(T_{SCi}(t) - T_{amb}(t)\right)\right] \qquad \text{(eq. 3)}$$

The dynamics of the boiler is described by eq. (4) (Duffie and Beckman, 1980):

$$c_p \rho V_{bo} \frac{\partial T_{bo}}{\partial t} = Q_{bo}(t) + Q_{SC}(t) + Q_{cons}(t) + Q_{loss}(t) \qquad \text{(eq. 4)}$$

In Figure 1, the "cold water" of the thermal reservoirs, which due to the physical characteristics is found at the bottom part, is then pumped through the collectors, returning to the reservoir. This process is controlled by ARISTON controller as follows: When temperature T1 of the collector is higher than temperature T2 of the reservoir by a pre-adjusted constant, is actioned by a water circulation pump. The "hot water" that comes out from the thermal reservoir goes to the heat exchangers, pulled by a second pump, located after the heat exchanger, where heat is lost and returns to the thermal reservoir.

On the secondary of the heat exchanger, the mixing valve allows to adjust the temperature of the water supplied to the engine block, when the temperature of the water resulting from solar heating is sufficient to meet the needs of the engine block. In this configuration, the deviating valve controlled by a BUDERUS controller, causes the "cold water" of the engine block, pumped by a third pump, to go past the right side of the heat exchanger, receiving heat from solar heating system and returning to the engine block. If the temperature achieved with this is not sufficient, the deviating valve causes the engine block to receive water from the simulating reservoir of the boiler, where, in this case, water is heated by using electric resistance.

3. Conclusion

While solar thermal use in home water heating is still extremely small, solar thermal use in other sectors of the economy is even smaller, especially in the United States. These technologies are capable of cost-effective integration into many commercial and industrial processess. However, they remain too risky for many businesses and major manufacturers due to the large upfront costs, concerns over availability of heat, and to a lack of understanding of the opportunities it provides. Despite the industrial sector consuming the largest amount of energy in the United States, and the tremendous opportunity which solar thermal technology presents, it has been largely overlooked by both manufacturers and policymakers.

Solar thermal technology is commercially available to meet demand in lower temperature ranges and already can be integrated into the food, beverage, textiles, paper, and pulp industries on a large-scale. Many of the technological barriers can be eliminated through prudent analysis of energy requirements and appropriate mechanisms for energy storage. Solar thermal's opportunity should be viewed as a way to substantially offset fossil-fueled thermal energy. A total replacement of thermal capacity could be appropriate in certain circumstances, for processes that do not require round-the-clock supply, for example, or when integration of energy storage technology to meet longer periods of demand is possible. Solar thermal integration strategies would be even more effective when coupled with energy efficiency strategies.

Incentives should do more to target the industrial heating sector specifically, and expand commercialization of medium temperature collectors and higher temperature storage technology. The economic opportunities are abundant and the environmental payoff will be much larger if policymakers focus more attention on the opportunities to reduce fossil fuel consumption in industry.

Evaluation of a large solar thermal drainback system for hay bales drying

Yoann Louvet, Ruslan Botpaev and Klaus Vajen

Kassel University, Institute of Thermal Engineering, Kassel (Germany)

Abstract

In this paper, over one year of measurement data of a 127 m² drainback solar thermal system for hay drying is analysed. The study shows that high temperatures in the solar collector loop lead to partial boiling when the system starts, slowing down the filling process. More severe, due to siphon establishment, the flow rate drops and the efficiency of the field is impacted anytime the collector outlet temperature exceeds 83 °C. The existing system is then modelled with the simulation software TRNSYS 16, based on measured data. Four other hydraulic designs are as well modelled and simulated for a comparative analysis. Three use the drainback principle and one represents a "conventional" pressurized system. As expected the results demonstrate that the drainback with load-side heat exchanger has the best thermal performance and the "conventional" system the worst one. The energy yield of the drainback design with collector-side heat exchanger is comparable to the one of the "conventional" system. The parasitic electricity consumption of the solar collector loop pump is also calculated. It varies significantly depending on the system, the most demanding one being the drainback without siphon formation, with a total consumption more than doubled compared to the same system with siphon formation.

Nomenclature:

C_p	specific heat, J kg^{-1} K^{-1}	Q_{aux}	auxiliary heater energy consumption, kWh
$E(X)$	expected value, s	Q_{coll}	collector field energy production, kWh
E_{pump}	solar collector loop pump energy consumption, kWh	Q_{ref}	energy consumption for the reference system, kWh
$f_{sav,therm}$	fractional thermal energy savings	t_{fill}	filling time, s
H	pump head, m	$\dot{V}$	volume flow rate, m³ s^{-1}
h_l	head losses between two points of a piping system, Pa	ΔH	height between water surface in the storage and highest point of the hydraulics, m
P_1	power consumed by the pump, W	η_{tot}	total pump efficiency
p_{atm}	atmospheric pressure, Pa	ρ	density, kg m^{-3}
P_H	pump hydraulic power, W	g	gravitational acceleration, m s^{-2}
p_{top}	pressure at the highest point of the hydraulics, Pa	σ	standard deviation, s

Keywords: *Drainback system, Solar process heat*

1. Introduction

In order to decrease the overall costs of solar thermal systems, one option is to use the drainback configuration, which enables the reduction of both initial investment and maintenance costs (Mugnier et al., 2011). For the solar thermal branch, this target is a priority, as the growth of the solar thermal market has been flattening out during the past years, and Europe is especially stricken by this tendency (Mauthner et al., 2015). For large systems, notably dedicated to process heat or district heating, the use of the drainback technology is rarely documented in the literature and the specificities of their functioning barely addressed (Botpaev et al., in press). Bokhoven et al. (2001) and Mugnier et al. (2011) are so far the main resources dealing with large drainback systems. This paper aims at providing more knowledge on their functioning but also at highlighting their specificities compared to "conventional" pressurized glycol systems. For this purpose, extensive measurement data from an existing large drainback system for hay bales drying are analysed. After presenting the system, the focus is on the filling and draining phases, two specific features of drainback systems. The operation of the system is also studied and especially the impacts of siphon formation on the solar thermal energy yield. Finally,

doi:10.18086/swc.2015.10.39 Available at http://proceedings.ises.org

five different collector loop configurations are modelled and their energy performances compared. For smaller, single-family house systems, such detailed simulations and comparisons were already carried out by Goumaz and Duff (1981).

2. The studied system

The studied solar drainback system (DBS) is located at a farm in Frankenhausen in Germany. This DBS was built to supply heat for the drying of hay bales during the summer season. It is designed to cover the drying needs of around 300 bales per year, which corresponds to an annual load of 29 MWh. Additionally, it also covers part of the domestic hot water (DHW) and space heating demands of the farm buildings the yearlong and especially during the winter period. The collector field is showed in Fig. 1. It is composed of ten "Solar Roof" flat plate solar thermal collectors from the company Wagner GmbH. They are connected in parallel according to the Tichelmann principle. The total collector field aperture area is 127 m² (138 m² gross area).

Fig. 1: The collector field of the studied drainback system.

The collector field is connected without heat exchanger to two serially coupled heat stores constructed by the company Fsave Solartechnik GmbH. They have a total volume of 42 m³ and are made of polypropylene (PP). The use of polymers presents several advantages – ease of transport and installation, low thermal conductivity, potential for low costs – but requires the storage to remain unpressurized. This is achieved in a simple manner with the drainback configuration with load-side heat exchanger. In order to avoid any pressure variation, the system needs to be open, i.e. the storages are vented to the atmosphere. For the charge and discharge, no stratification device is installed, but horizontal lances are used to reduce the velocity of the heat transfer fluid (HTF) entering and exiting the storages. As no heat exchanger is applied in the solar collector loop and because of the drainback design, pure water is used as HTF. A single Wilo-Top-S 30/10 pump is installed and serves both as filling and circulation pump. Additionally, a motor valve connected to an air vent opens to trigger the draining phase once the pump stops. In Fig. 2 is presented a detailed hydraulic scheme of the above described system. The hay bales drying process is connected to the storage via a water-to-air heat exchanger. It enables the drying of 20 hay bales simultaneously. During a drying cycle, the relative humidity of the bales is decreased from approx. 30 % to 10 %, depending on the harvesting conditions. An auxiliary wood burner is connected to the storages with an external heat exchanger. The same heat exchanger is used for heat and DHW delivery to the farm buildings.

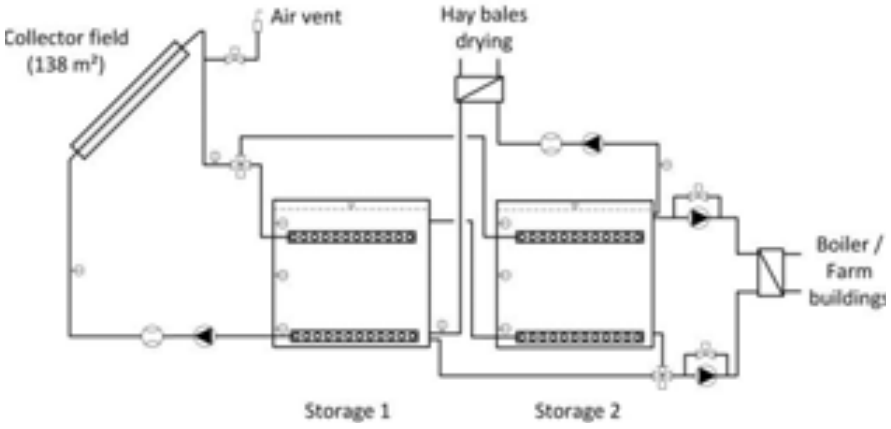

Fig. 2: Detailed hydraulic scheme of the studied system.

The system has been in operation since spring 2012. In August 2014 additional measuring devices were installed, as well as a data logging system. Calibrated temperature sensors were mounted as well as a pyranometer to measure the total irradiation on the collector plane. Fig. 3 presents the energy yield of the collector field over the previous year. In total, with a specific measured radiation of 951 kWh m^{-2} a^{-1}, the collector field delivered about 292 kWh m^{-2} a^{-1} of heat. These values are low as almost two months of data are missing over this period. If only the drying period is considered, between Mai and September, the production amounted to 218 kWh m^{-2}.

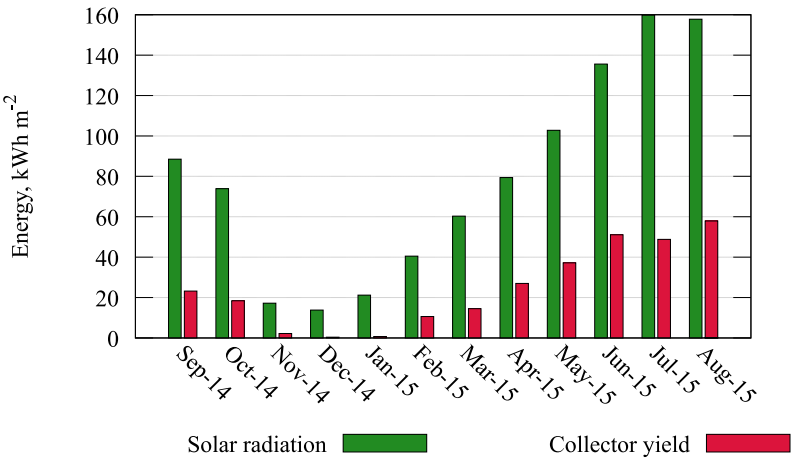

Fig. 3: Measured solar radiation in the collector plane and energy yield from the solar collector field (per m² absorber area) between September 2014 and August 2015. Due to maintenance and monitoring issues 14 days of data are missing in November, 16 between February and March, 12 in April, 12 in May and 3 in June.

3. The filling and draining processes

For a comprehensive analysis of the functioning of DBS, Botpaev et al. (2014) proposed to distinguish the filling and draining phases from the operation phase, the latter being shared by any solar thermal system. In order to better understand the specificities of these two phases in the context of large systems they are examined in detail. The previous work from Jordan et al. (2015) is here extended with additional measurement data, totalling more than 600 complete filling and 300 draining phases. The aim is to identify the phenomena which impact the filling and draining processes of large solar drainback systems.

One should also recall, as stated in Jordan et al. (2015) that the studied system is operated with a so called siphon formation (Fig. 4, left), meaning that water completely fills the flow pipe. Another design, without siphon formation (also called trickle-down design, Fig. 4, right) is also possible and its impact is simulated in section 5. Further details about these configurations can be found in Botpaev et al. (in press).

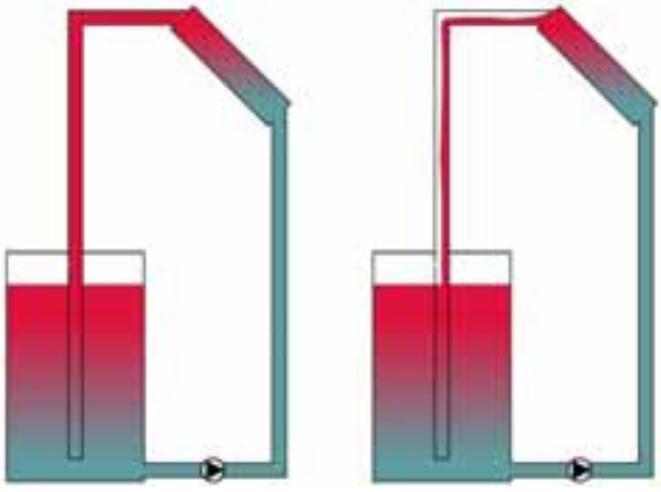

Fig. 4: DBS with siphon formation (left) and without (right). The latter is characterized by the presence of a two-phase flow (air and water) in the flow pipe.

In Fig. 5 and Fig. 6 are shown the relative frequency distribution of the studied filling and draining processes.

Each point has an accuracy of ± 10 s, due to a temporal resolution of the logging device of 10 s. Moreover, from Fig. 7 it appears that the end of the filling phase cannot always be accurately determined, as the flow rate does not always clearly stabilises as the flow rate in case (b) highlights. It was arbitrarily chosen to end a filling phase at the moment when the flow rates does not fluctuate of more than ± 5 % over the next 30 s.

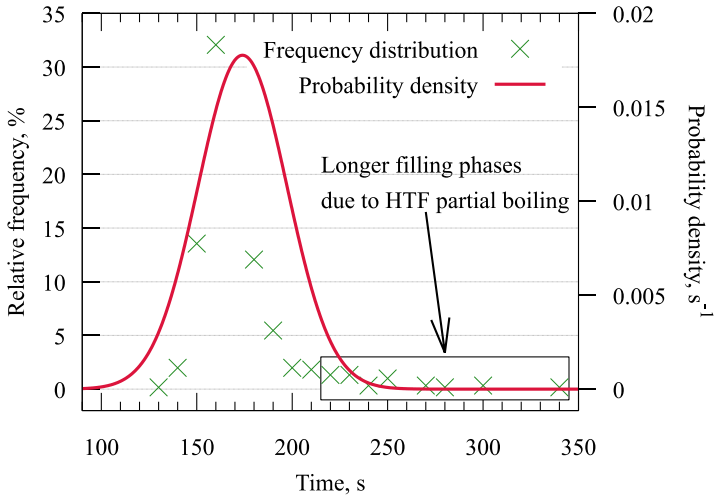

Fig. 5: Frequency distribution and probability density associated to the normal distribution for 605 filling processes. The parameters of the density curve are σ = 22.5, *E(X)* = 170.7.

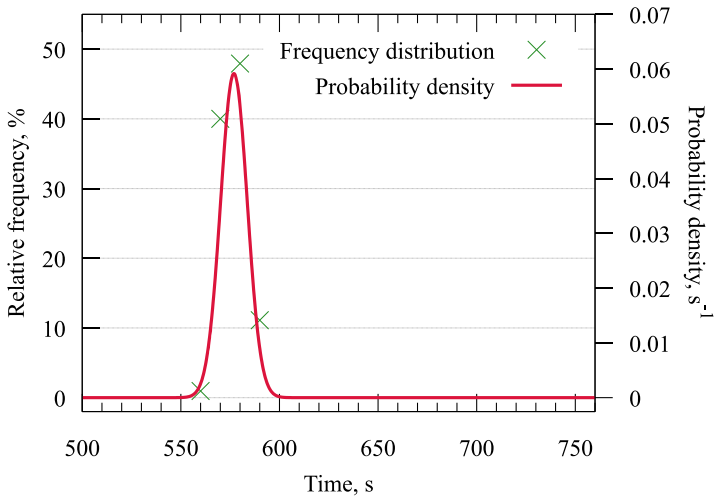

Fig. 6: Frequency distribution and probability density associated to the normal distribution for 315 draining processes. The parameters of the density curve are σ = 6.7, *E(X)* = 576.9.

From the results, it can be seen that the length of the draining phase is rather constant independently from operation conditions, with a standard deviation of 6.7 s (1.2 % of the draining time), in the range of the measurement inaccuracy (Fig. 6). Regarding the filling, the deviation is larger, at 22.5 s (13.1 % of the filling time). This can be explained by the inherent inaccuracy of the measurements as stated previously, but also by the occurrence of longer filling phases lasting up to 340 s, as shown in Fig. 5. A detailed analysis of these longer fillings reveals that they might be caused by a partial boiling of the incoming HTF when inlet temperatures and/or irradiation level are high at the moment of the filling. This conclusion is drawn from Fig. 7. Compared to a "normal" filling process (a), the longer one (b) is characterized by a quick and sharp increase of the collector field outlet temperature shortly after the start of the filling, almost reaching 100 °C. First of all one can notice that the temperature increase in the outlet pipe takes place less than 20 s after the start of the filling, the theoretical minimum time for the fluid to reach the first collector with a flow rate of 1.39 litre s^{-1} (conservative value as the flow rate is fluctuating quite fast during the filling phase). A plausible explanation is that some water should remain in the riser pipe. When the pump starts, it is pushed into the collectors and vaporizes. Secondly it demonstrates that some of the HTF boils in the collector field. This partial boiling most certainly slows down the filling process by increasing the pressure drop in the field. Each significantly longer filling phase is characterized by the same boiling phenomenon. Unfortunately, a lack of sensors did not allow

getting more details of where exactly in the field the boiling takes place.

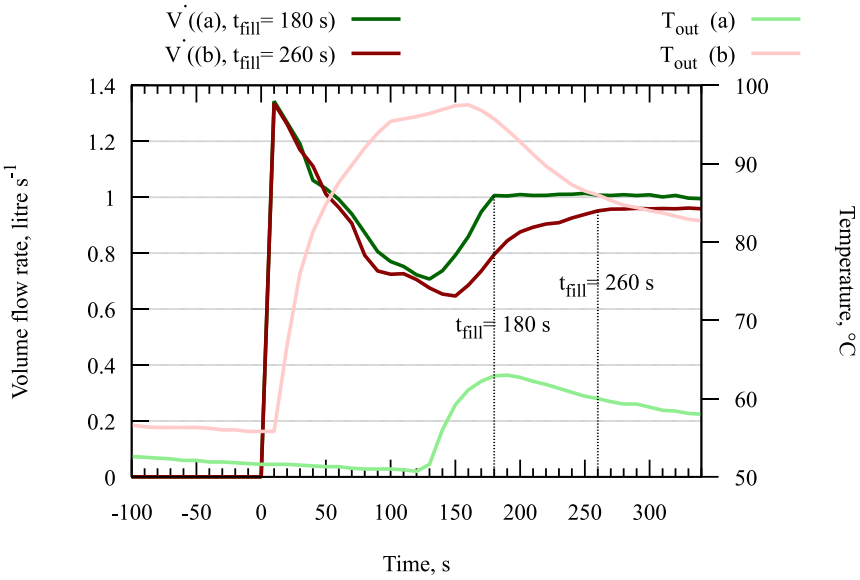

Fig. 7: Flow rate and outlet temperature profiles of two filling processes, one lasting 180 s and one 260 s. t = 0 corresponds to the start of the pump.

In the studied system, the partial boiling of the incoming HTF in the collectors does not appear to prevent the filling process. However depending on the location of the boiling in the field and the position of the collector field temperature sensor, one could imagine a situation where the threshold collector temperature is reached and detected by the sensor (in the studied system 95 °C) thus stopping the pump and causing the system to stagnate. Kratz and van Dam (1999) stated that large drainback fields are difficult to properly fill as siphon creation favours the filling of some rows at the expense of others. This effect contributes to degrade the efficiency of the system as some rows might remain non-filled. The boiling described here might enhance this uncomplete filling as rows where boiling occurs might be even more penalized.

From this analysis it can be concluded that a control strategy for the filling a DBS is always a matter of compromise. The start filling temperature difference should not be too low otherwise the first daily fillings are not stable, i.e. the collectors are cooled down by the incoming HTF which in turns stops the pump. In Frankenhausen, it often happens that the first filling of the day is shortly followed by a draining because of the cooling effect. On the contrary, if the start temperature difference is too high, there is the risk that an already quite warm incoming fluid (in case of relatively high temperatures in the storage) starts to boil. Gößlinghoff (2010) proposed in a patent to fill each parallel row of a drainback collector field successively with the use of motor-valves. Due to the boiling effect highlighted here, such a lengthy filling strategy could in practice not be very effective.

Finally, the power consumption of the pump situated in the solar collector loop was measured during the filling phase. Contrary to what is sometimes mentioned, the power required by the pump during the filling process is on average slightly lower than during operation, with 280 W against 285 W.

4. DBS and underpressure

Having a non-pressurized system vented to the atmosphere presents some advantages such as the reduction of the number of components (no expansion vessel, no safety valve) and the possibility to use of polymer materials. Nevertheless a system with siphon formation requires a careful design especially considering the risk of boiling. Indeed, from a fluid mechanics perspective, when applying an energy balance to the HTF between the highest point of the solar collector loop hydraulics and the end of the flow pipe assuming a turbulent regime, a steady flow and the fluid incompressible, one obtains the following equation (Crowe, 2009):

$$p_{top} = p_{atm} - \rho g \Delta H + h_l \qquad \text{(eq. 1)}$$

Equation 1 shows that the pressure at the top of the hydraulics might be lower than atmospheric pressure due to a siphon-like effect. It also explains that in order to reduce this potential underpressure one might either

decrease the height difference between the water level in the storage and the highest point of the hydraulics (ΔH) or increase the head losses in the flow pipe (h_l). Kratz and van Dam (1999) proposed to use a "trickling-down" flow in the flow pipe also for large solar DBS, avoiding the formation of the siphon. In the drainback configuration with load-side heat exchanger, this issue is particularly relevant as ΔH can be quite important depending on the respective location of the collectors and the storage. In Frankenhausen ΔH is equal to 6.5 m. A first approximate modelling of the pressure drops in the solar collector loop showed that with a flow rate of 0.99 litre s^{-1} (3500 kg h^{-1}) a negative pressure relatively to atmospheric pressure should occur in the solar collector loop. To examine the actual impact of this undesired phenomenon on the performance of the system, two consecutive sunny days with high collector outlet temperatures are presented in Fig. 8.

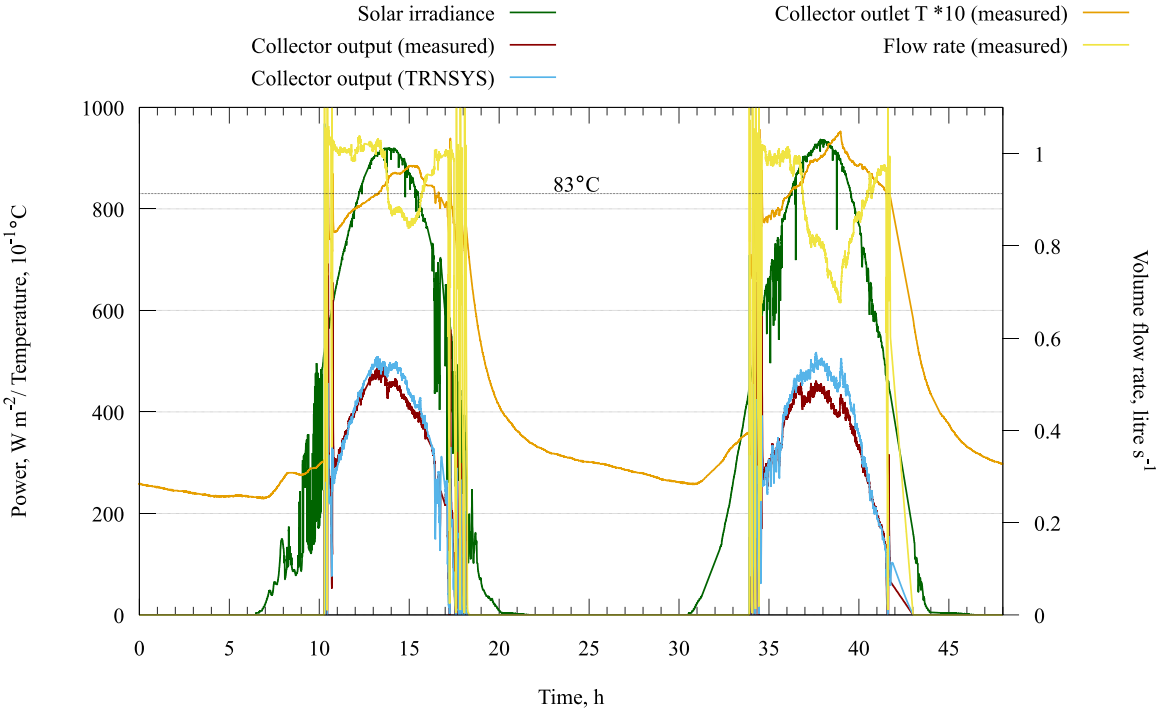

Fig. 8: Measured and calculated collector field power output over two consecutive sunny days in August 2015, with collector outlet temperatures above 83°C.

From the figure it appears that once the outlet temperature of the collector reaches a certain threshold, the flow rate sharply decreases and remains lower than during "normal" operating conditions. From Fig. 9, one can notice that this threshold temperature is around 83 °C and that after this point, the flow rate decreases linearly from 0.028 litre s^{-1} (100 litre h^{-1}) for each degree kelvin the collector field outlet temperature increases. A comparison of a TRNSYS simulation of the solar collector loop power output with actual measured data for these two days also shows that nonetheless drops the flow rate, but the efficiency of the collectors is also affected. While the relative deviation between measured and simulated power output is in a range of ± 5 % during periods when the outlet temperature is lower than the threshold temperature, this deviation reaches up to 15 % after the threshold is passed. It was however not possible to precisely determine the impact of the boiling on the collector efficiency, due to insufficient measurement data. A detailed CFD modelling would be necessary to understand how the heat transfer between the absorber and the collector HTF is affected by partial boiling. However it was not the goal of this paper.

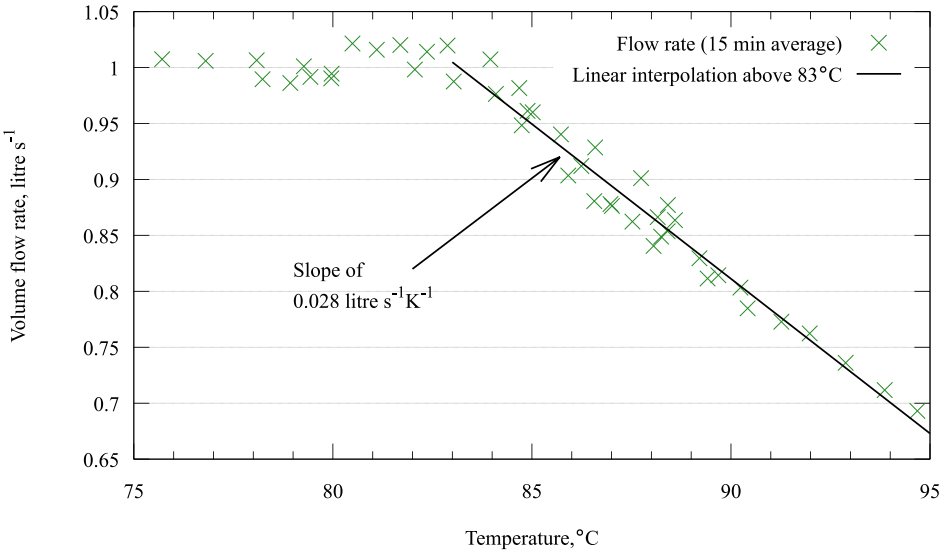

Fig. 9: Solar collector loop flow rate as a function of the collector field outlet temperature during steady irradiation periods for the two days shown in Fig. 8 (15 minutes average values).

5. System simulations

In order to compare the performance of the DBS installed in Frankenhausen with other designs, the actual system was modelled with the use of the simulation software TRNSYS 16. Some parameters were then changed in order to simulate other system designs. In Tab. 1 are summarized the five different system designs simulated. They are based on the work from Botpaev et al. (in press). The parameters of the model were configurated in order to represent as closely as possible the real system. The system was simulated over the period going from the 1st of May to the 30th of September, which corresponds to the hay drying season. The total drying load was adjusted to meet the 29 MWh required to dry 300 bales a year and the total DHW load during the period was set according to measurement data to 6.5 MWh. The load profiles were also extracted from measurement data and slightly adjusted for each simulation in order to reach the same loads in all cases. The weather data applied were extracted from hourly data for Kassel, Germany, a city located 10 km south from Frankenhausen.

Tab. 1: Description of the simulated systems and their main specificities.

System number	Description	Siphon	HTF	Pump capacity, W	Collector-side heat exchanger	Other specificity
1	Actual system: DBS with load-side heat exchanger	Yes	Water	285	No	Decreasing flow rate above 83°C outlet temperature
2	DBS with load-side heat exchanger without siphon formation	No	Water	585	No	
3	"Conventional" system	N/A	Antifreeze mixture	375	Yes	
4	DBS with collector-side heat exchanger	Yes	Water	285	Yes	Additional drainback tank (DBT)
5	DBS with collector-side heat exchanger and glycol	Yes	Antifreeze mixture	375	Yes	Additional DBT

In order to take into account some specificities of a DBS, the boiling effect described before was simulated with a flow rate decreasing above a collector outlet temperature of 83 °C, according to the profile from section 4. When a DBT is present, it was considered that it could be installed high enough to avoid a critical underpressure. Moreover, the collectors were considered with a varying heat capacity depending whether they

are or not filled with HTF. The efficiency parameters of the collector were taken from data from the manufacturer. Some studies highlighted that the type of HTF used has an impact on the efficiency coefficients of a collector (Bava et al., 2014). This effect was however not considered in the simulations, therefore the same collector coefficients were used both with water and a mixture of glycol and water as HTFs.

Concerning the flow rate and the pumping power, the pump in the solar collector loop was run at a fixed speed as in the actual system. For simplification the HTF properties were taken at a temperature of 60 °C and pumping energy needs and flow rates were also assumed constant (except for the actual system above 83 °C) and calculated for this temperature. For water, data were extracted from Verein Deutscher Ingenieure (2006). When a mixture of glycol and water was used, the data were taken from Tyforop Chemie GmbH (2009) for a volume concentration of glycol in the mixture of 40 %. In all cases, the capacity flow rate ($\dot{V}\rho C_p$) was kept constant in the solar collector loop. Moreover in systems with a collector-side heat exchanger, an overall heat transfer coefficient of 5000 W K^{-1} was considered for the heat exchanger. Given the short length of the filling phase compared to the operation phase and the minimal difference of power required by the pump between these two phases (see section 2) the power consumption difference was neglected.

In order to determine the pump capacity required in the solar collector primary loop for each case, measured values for the actual system and the total pump efficiency given by equation 2 (Grundfos, 2004) were used.

$$\eta_{tot} = \frac{P_H}{P_1} = \frac{\rho g \dot{V} H}{P_1} \qquad \text{(eq. 2)}$$

The hydraulics of system 1 was modelled in a spreadsheet and calibrated according to measurement data. In its actual working conditions the total efficiency of the pump amounts to 16 %. To estimate the pumping power required by the other systems, the same hydraulics was assumed in all cases (same pipe diameters). With the help of the model, the working point of each system was calculated. It was then assumed that for this working point a pump of 16 % overall efficiency could be found. Compared to the actual system, the results show that the systems running with glycol require 32 % more pumping power and the needs of the DBS without siphon formation are 106 % higher.

To compare the thermal performance of the systems, the fractional thermal energy savings $f_{sav,therm}$ defined in eq. 3 is used (Letz et al., 2009).

$$f_{sav,therm} = 1 - \frac{Q_{aux}}{Q_{ref}} \qquad \text{(eq. 3)}$$

Q_{aux} designates the energy supplied by the auxiliary wood boiler and Q_{ref} the sum of the different heating loads of the reference system, i.e. the hay drying load, the DHW load and the losses of the two heat stores. The auxiliary wood boiler is also assumed to be the boiler in the reference case, therefore the boiler efficiency is considered equal in both the reference and the simulated systems.

Finally, the main control strategies applied are the following:

- The control of the solar collector loop pump differs depending whether the system is drainback or not. It starts when the difference between the collector temperature and the temperature at the bottom of storage 1 (see Fig. 2) is higher than 12 K respectively higher than 7 K and stops in both cases when it drops below 3 K.
- Storage 2 has priority when the collectors are in use and is loaded as long as the collector temperature is higher than the temperature at its top. If this is not the case, storage 1 is loaded.
- The water returning from the DHW load is directed to the bottom of storage 2 as long as its temperature is higher than the temperature at the top of storage 1. Otherwise it flows at the bottom of storage 1.

The results of the simulations (Tab. 2) show that the system performing thermally the best is the DBS without siphon formation in the flow pipe (2). This is due to the fact that system 1 is penalized due to a lower boiling point in the collector field, which in return affects Q_{coll}. Over the period the collector outlet temperature of system 1 is above the threshold temperature (83 °C) during 27 hours, which corresponds to 3.4 % of the total running time of the solar pump. However to achieve this slightly better performance the energy consumption of the pump in system 2 is more than doubled (108 % increased) due to the fact that the pump continuously needs to overcome the height difference between the storage and the collector field.

The conventional system (3) is thermally performing worst as it is penalised by the presence of the heat exchanger and the use of glycol. Compared to system 1, $f_{sav,therm}$ is 3.9 % lower and the energy required by the pump to circulate the HTF is 46 % higher.

The most widespread drainback design on the market is the DBS with collector-side heat exchanger and an additional DBT (Botpaev and Vajen, 2014). Systems 4 and 5 aim at reproducing these designs, one using water as HTF (4) and the other one a mixture of glycol and water (5). It is indeed nowadays a very common trend to use glycol instead of pure water in DBS (Botpaev and Vajen, 2014). Both systems are performing very similarly to the conventional system. When comparing the two HTF, the difference in thermal performance is negligible, but the system with glycol (5) requires 32 % more electrical energy than the one with water (4) to circulate the HTF in the solar primary loop, due to higher friction losses.

Finally a configuration with a load-side heat exchanger and an additional DBT to avoid the underpressure could also be thought of but was not simulated here as such a design would increase the static pressure in the storages, which is not feasible with the PP storages used in Frankenhausen.

Tab. 2: Simulation results for the different studied systems over the drying period.

System	Q_{aux}, kWh	Q_{ref}, kWh	Q_{coll}, kWh	Q_{coll}, kWh m^{-2}	$f_{sav,therm}$, %	Solar collector loop pump running time, h	E_{pump}, kWh	E_{pump}/Q_{coll}, %
1	13137	39752	27878	219	67.0	787	223	0.8
2	12463	39754	28349	223	68.6	799	467	1.6
3	14646	39700	26082	205	63.1	876	328	1.3
4	14542	39627	26547	209	63.3	905	257	1.0
5	14512	39638	26488	208	63.4	907	340	1.3

6. Discussion and additional knowledge gained from the monitoring

The simulation results show that the two DBS without collector-side heat exchanger performs thermally slightly better than the others. They are therefore the recommended designs when the conditions are favourable, especially when the boiling risk does not exist.

When comparing other systems (notably 3, 4 and 5) the thermal performances are very similar. In these cases one decision criteria could be the pumping energy. Overall, the study showed that the pumping energy can vary quite significantly, from one system to the other. The conventional system requires 46 % more energy over the period than system 1, while the consumption of the DBS without siphon (2) is as much as 108 % higher. With today's efficient pumps sold on the European market, the relative consumption of the pumps between the different systems would not change (assuming that the same efficiency for the different working points can be achieved with actual pumps, which is in reality not the case). In terms of absolute consumption nevertheless choosing one configuration compared to the other has nowadays a much lower impact. For system 1 for instance, with a pump having a total efficiency of 35 %, which is realistic considering today's pumps, the total consumption over the period would drop from 223 kWh down to 102 kWh, which corresponds to 0.4 % of the total solar energy gain.

The results presented here are specific to the studied system and its design. It would be difficult to find a system with similar load profiles, control strategies, impact of the partial boiling on the flow rate, etc. However, they aim at showing some trends of how different DBS system designs would comparatively perform but also how DBS perform against conventional systems. Furthermore, the results might be conservative, as some authors recommend to decrease the collector efficiency when the glycol concentration in the HTF increases (Bava et al., 2014), which was not considered here. In this situation, the conventional system would be further penalized compared to DBS using water as HTF. Finally, the comparison is limited in this paper to the energy performance of the systems. One should additionally carry out a detailed cost analysis to get the whole picture of the respective advantages and drawbacks of each system against the others.

The monitoring of the field over more than a year also gave the opportunity to gain additional knowledge about the design of the system. As it was already mentioned in Jordan et al. (2015) the position in the storage of the sensor controlling the pump is very important. The tank outlet manifold and the sensor should be positioned at the same height. In Frankenhausen, the sensor is slightly lower than the outlet which causes some energy loses, as the pump is running longer as it should. Between September 2014 and August 2015, the measured losses

amount to 16.5 kWh m^{-2} a^{-1} of absorber area, which corresponds to 5.6 % of the total production of the collector field.

Finally a last issue which was encountered with the system is the deposit of lime. Its presence in the water was responsible for the blocking of the heat exchanger between the wood burner and the storage. To solve this problem, the water in the heat stores was then demineralised.

7. Conclusions

In this work several aspects of the functioning of a large drainback system for hay drying have been studied. Extensive measurement data demonstrated that the filling phase might be slowed down when the incoming HTF starts to boil in some parts of the collector field. In Frankenhausen the result is an increase of the length of the filling phase, but on even larger fields the consequences could be worse. Partial filling or early draining could result. To minimize this issue, the position of the collector field temperature sensor appears to be fundamental. The draining phase is on the contrary not significantly impacted by varying operating conditions.

Boiling is also an issue especially with the load-side heat exchanger configuration. In the studied case water starts to boil in the collector around 83 °C because of the underpressure created by the siphon formation. This phenomenon does not completely prevent the functioning of the solar collector loop but reduces the flow rate of 0.028 litre s^{-1} per degree kelvin above 83 °C and degrades the collector efficiency. The degradation is not quantified in this paper.

In a next step, different DBS designs and one “conventional” system have been simulated based on the configuration and the loads of the existing system in Frankenhausen. The simulations ran between May and September, the drying period. The results show that from a thermal point of view the fractional energy savings are 3.9 % higher with the applied drainback design compared to a “conventional” system. This improvement could reach 5.5 % if no boiling occurred in the collector field. This would however be reached at the expense of the pump electrical energy consumption, which would more than double, but still amounting to less than 2 % of the solar thermal energy gain. Overall, when considering pumping energy, resorting to water as HTF is always beneficial. If the system in Frankenhausen had a “conventional” design, the pump would require 46 % more energy. From a thermal perspective it was also shown that a DBS with collector-side heat exchanger performs very similarly to a “conventional” system.

Abstract

The Atacama Desert has both one of the best solar resources in the world, as well as huge mineral deposits that include copper, iron, nitrates, and lithium. In the past these resources were exploited in a non-sustainable way, which led to the burning of the scarce forests that existed and the overexploitation of water resources.

Pioneering work was done there in water desalination, the determination of solar spectra and solar constant and the utilization of solar energy in some mining processes. Today, renewable energy, and especially solar, has lowered the cost of electricity provided to the mining sector, and has also been directly applied in three cases for obtaining process heat to aid copper electrowinning production.

In this paper we present both the past, present and future of the relationship between solar energy and mining in Chile. Special emphasis is given to what is known today and further research topics that must be addressed to properly use this vast resource.

Keywords: *solar energy, process heat, solar desalination, solar electricity production, Atacama desert.*

1. Introduction

Energy and water have always been one of the largest constraints for any sort of activity in the Atacama Desert. This vast expanse of extreme aridity that lies between the Pacific Ocean and the high Andean plateau (the Altiplano region), has nearly zero average rainfall, and only a few oases and places where groundwater is found. The high Andes receive both snowfall and rainfall (concentrated mainly in the summer monsoon season); so water seeps underground to lower altitudes, but along the way picks up significant amounts of salts, boron, arsenic and other contaminants.

The first documented use of solar energy in Chile is a solar desalination plant built by the Swedish engineer Charles Wilson around 1872. It was a basin still system, with a total surface of around 5.000 m² that produced around 20.000 liters of fresh water a day from brackish water pumped from desert wells. This supplied water needs both for the miners and draft animals (mules specially) that worked at the nearby *Caracoles* silver mine district (**Fig. 1**).

This project was first widely reported by Dr. Maria Telkes and later by Prof. Julio Hirschmann (Hirschmann 1961) from Universidad Federico Santa María (Chile). It was a landmark project, and only a few years ago Historian Nelson Arellano (Arellano 2011) found original documentation and discovered that in the period from the late XIXth Century until the early XXth Century, *three* solar desalination plants were built and operated for long periods. This is quite reasonable, since solar desalination was much less expensive than coal fired desalination plants of the period, so the good results of the Wilson plant were replicated.

doi:10.18086/swc.2015.10.40 Available at http://proceedings.ises.org

The next person who did pioneering work in northern Chile was Dr. Charles G. Abbot (Abbot, 1918). This eminent researcher in the field of solar energy and solar radiation built (with the help of the Smithsonian Institution) a network of several solar observatories in different parts of the world. One of the places chosen was *Montezuma,* a mountain nearby Calama and the copper mine in Chuquicamata. This observatory operated from around 1920 until the mid 1950's, conducting systematic measurements of direct solar radiation, solar spectra and studies in the determination of the solar constant and its variability. The measurements made are quite accurate according to modern measurements and the observations of great value.

After the Second World War the low price of fossil fuels discouraged most research on the use of solar energy. A big exception was the use of solar evaporation for nitrate production.

Nitrates are produced from a mixture of naturally occurring salts called *Caliche.* Originally these salts were dissolved in hot water, and then crystallized by fractions (containing different specific salts) as the brine cooled. Since nitrates are highly soluble, this was a simple method of separating nitrate from the other salts. However huge amounts of fuel are needed for an industrial operation. And during the late XIXth Century the natural forest existing in a place called *Pampa del Tamarugal* (The flatlands of Tamarugo's, a tree species), was almost totally wiped out.

Starting in the mid 1950's the ancient method was replaced by solar evaporation of the brines and partial precipitation of the different salt fractions. This is still widely used for the production of nitrates and iodine salts, as well as the large scale production of lithium carbonate from the Atacama Salt Flats.

2. Recent uses of Solar Energy in the Mining Industry

The first oil crisis of 1973 brought renewed interest in the use of solar energy in northern Chile. Several projects went into operation. These include the following:

- A flat plate hot water system that provided up to 40 m³ of hot water a day for the showers of each shift in the El Salvador copper mine. It started operation in 1980 and is still in use (with upgrades and periodic maintenance). This project was designed by Universidad Federico Santa María (**Fig. 2**).
- Copper concentrate was dried using solar energy (250.000 Tons/year) from around 1980 to the year 2000. This simple system was later replaced by drying using mechanical presses. The new method is faster and there's less concentrate loss. There was loss in the old system due to wind blowing some of the concentrate when it was picked up from the drying ponds.
- A passive heating system for a house at the industrial water source in the high Andes in El Salvador. In operation since 1982 (**Fig. 3**).

There were other projects of varying success, but interest waned in the 1990's due to lower fuel prices. Since the early years of the XXIth century rising fuel prices, as well as environmental concerns has sparked renewed interest in the use of solar energy for the mining sector in Chile.

Today, we can divide the uses of energy for mining in Chile in the following areas:

- **Electricity production:** mining accounts for over 25% of total Chilean electrical demand. And the Energy Ministry calculates that 60% of *new* electricity demand will come from the mining sector. Electricity is used mainly in ore milling and processing, as well as conveyor belts, pumps, motors, fans and a host of other equipment.
- **Water production:** mining requires large amounts of water for leaching, flotation and evaporation processes. Water is a scarce resource and already several mines have to desalinate large amounts of seawater and then pump this up to the mines.
- **Process heat:** from an overall view, process heat is not a very large requirement, but it can be a significant amount in the plants that produce copper cathodes by the electrowinning process or the electrorefining process. Each plant requires a thermal power between 5 to 20 MW. There are over 15 plants in Chile and also plants in several other countries. Today there are two solar plants in operation

and several in the planning stages.

- **Transport:** this is a very significant energy demanding sector but, for the moment, the production of fuel for this requirement is not yet feasible.

In the following paragraphs we'll give a brief outline on how renewable energy in general, and solar energy in particular, has already had a large (and growing) impact in the Chilean energy matrix and the mining sector in particular.

3. Solar Energy and Electricity Production in Chile

Up until 2009 the conventional view in Chile was that solar energy was too expensive compared to "conventional" energy sources. Only wind power had a very modest penetration. Electrical production was concentrated in very few companies (three of them controlled over 85% of the market) and prices were very high. Contracts were over US$120/MWh and spot prices exceeded US$160/MWh.

The established companies wanted more of the same. However citizens strongly opposed large scale projects (such as very large coal fired plants or large dams) and several conventional projects were successfully blocked. At the same time several important developments took place:

- Better resource assessment proved that northern Chile had an exceptional solar resource and large scale energy needs.
- The price of solar systems, PV in particular, swiftly dropped, powering a surge in large scale projects.
- New companies decided to invest in this emerging market in Chile.

After only six years the electrical energy panorama in Chile has drastically changed. The present day situation is that over 11% of electrical energy in Chile is produced from nonconventional renewable sources (all renewables excepting large hydro), Electrical production has increased 2,9% between 2014 and 2015, but nonconventional renewables have increased 17,8% (CIFES Report). In Table 1 we show the evolution of renewable capacity generation between 2012 and 2015.

Tab. 1: Non Conventional Renewable Capacity (MW) in Chile Between 2012-2015[1]

	2012 Q1	2013 Q1	2014 Q1	2015 Q1	2015 Q2
Wind	205	205	335	836	901
Solar	0	3,6	6,7	362	741
Biomass	270	394	394	416	417
Mini Hydro	246	278	320	350	390
Geothermal	0	0	0	0	0

The incorporation of large blocks of renewable energy in the matrix, especially in the northern part of the grid, has had a very large impact in prices. Spot prices have dropped from around US$160/MWh in 2010 to less than US$60/MWh today. This is because renewables have displaced diesel fired generation at peak hours. Also overall prices have dropped. Another very important effect is that the Energy Ministry has called for renewable energy blocks to supply the electrical energy matrix, and suppliers have come forth with long term prices of around US$60/MWh.

New solar plants are being installed very quickly, and solar will tend to displace wind as the largest generator in not more than two or three years. One large CSP plant (110 MW with molten salt storage) is being built by Abengoa near Calama. It will come online early 2017. Another 3 or 4 CSP plants are under development or consideration.

So in only three or four years, the electrical energy matrix in Chile has changed significantly. The incorporation of renewables has:

[1] Table data obtained from CIFES reports 2012-2015

- Proceeded at a much faster pace than originally envisioned.
- Renewables have helped lower the price of spot energy, as they have (mostly) displaced diesel systems for peak power demand. And they have also helped lower the average energy price, since due to the excellent solar conditions in Chile, solar can be competitive today with any other energy source, including coal.
- Already provide a significant, and rapidly increasing, amount of electrical energy for the mining sector.

We must also comment that the *average* year round capacity factor of the solar plants already in operation is over 23%. This is computed comparing the nominal power of each plant, and thus the nominal yearly output with the actual energy injected to the grid on a yearly basis. Thus it takes into account of all effects, including soiling, outages, resource variability and so on. By comparison, German solar power plants have an average yearly capacity factor of less than 9%. One axis tracking plants in Chile reach capacity factors of over 30% on a yearly basis.

This panorama also has some problems. They can be summarized as follows:

- There are significant transmission capacity problems. These have resulted in that in many places there are projects that have problems injecting the power they produce. Spot prices have dropped to very low prices in these area.
- In many places there are more projects than what existing power lines can accommodate. This has led to a rethinking of the whole power grid and the interconnection of the Northern and Central power grids which should be accomplished in less than five years.

4. Solar Energy use in Process Heat in the Mining Industry

4.1. Present situation

One of the processes that use significant amounts of thermal energy is copper production by *electrowinning.* This applies mainly to copper oxide ores. The process is as follows:

- Copper ore is extracted from the mine and crushed at the mill to a diameter of around 20-30 mm. This is then conveyed to form large *leaching piles.* These typically are around 10 to 15 m high, 30 meters wide and several hundred meters in length. Under the piles there's an impermeable membrane to prevent the leaching solution from seeping into the ground.
- The leaching piles are irrigated with an acidic solution (water plus sulfuric acid). As this solution seeps through the pile, it picks up copper ore. After seeping it has a copper concentration of around 4 [g/lt].
- The solution is then piped to a *solvent extraction plant.* There, using organic solvents, a fraction is extracted with copper concentration is increased to around 20 to 27 [g/lt]. The rest, with low copper concentration is again pumped to the leaching piles.
- The high copper concentrate solution is first pumped to a special plant that removes the organic solvents, and then is pumped to the *electrowinning* production facility. In it the solution (which must be at a temperature between 55 and 60°C) is submitted to a DC current, and the copper is deposited on stainless steel cathodes. This deposition process takes several days.
- The exhausted solution is extracted from the electrowinning plant, it preheats the incoming solution, and is again incorporated into the solution that goes to the leaching piles.
- Once sufficient copper is deposited, the cathodes are removed, the copper removed, washed and packed for shipment, and the cathodes are again inserted into the electrowinning vats to repeat the process.

Heat is needed at several stages in this process. Hot water is needed to wash and clean the vats, cathodes and anodes. But most importantly to provide enough temperature to have the electrowinning vats at an optimal

point as fresh solution is added.

Normally this is done using diesel fired water heaters, which heat up the incoming solution from anywhere between 50 to 55°C (the final heating is done by the joule effect in the electrowinning vat itself). It's not a large temperature increase, since the outgoing solution preheats the incoming; but flows are very high.

Thermal requirements vary according to the size of the mine, but usually lie between 5 to 20 MWth as a nominal load. Thermal requirements increase in winter, and are higher at night. Even though the electrowinning vats have thermal insulation and systems to reduce evaporative losses, there still are significant thermal losses.

The idea of using solar energy to provide process heat for this requirement dates from the late 1990's. El Abra copper mine conducted several studies in which one of the author's participated. But, at the same time, natural gas was made available from Argentina at a price of 1/3 of diesel fuel. So the project was shelved.

Again in the early years of this century, new projects were studied. Fuel prices were again very high and there was rising concern about greenhouse gas emissions. Finally three projects were commissioned, two large scale systems and a small scale system. The main characteristics of each one is presented in **Table 2.**

Tab. 2: Solar Thermal Plants for Electrowinning Processes

Name	Operator (commissioning)	Technology	Collecting surface (m²)	Capacity factor	Comments
Pukará de Hatur	Enermine 01 Dec 2012	Flat Plate (Wagner Solar)	435	80%	Power purchase agreement
Centinela	Antofagasta Minerals 02 Jan 2013	Parabolic trough (Abengoa)	10.000	50%	Operated by Antofagasta Minerals
Gabriela Mistral	Pampa Elvira Solar 19 Aug 2013	Flat Plate (Sunmark)	39.000	80%	Power purchase agreement

We now compare the two largest plants, as regards their main characteristics:

Tab. 3: Comparison of Centinela and Pampa Elvira Solar Thermal Plants

Name	Technology	Primary circuit	Storage	Thermal delivery	Comments
Centinela	1280 single axis parabolic troughs with polymer reflector	Pressurized water with antifreeze and corrosion inhibitors	Three 120 m³ pressurized water tanks. Operate between 70 to 140°C	Up to 140°C	Can be unfocussed to prevent overheating
	Glass covered non evacuated selective surface receptor	Two collector fields		Heat exchangers for final heat delivery	
Pampa Elvira	39.000 m² flat plate collectors with selective surface	Pressurized water with antifreeze, corrosion inhibitors	4.300 m³ of nonpressurized water operates between 60 to 90°C	Up to 90°C	Tilt of collectors can be seasonally adjusted
		Backup storage for primary fluid	Active stratification control	Heat exchangers for final heat delivery	

From a technical point of view, all three plants have been successful. Only the Centinela plant had some initial

problems due to parabolic trough alignment and the need for special cleaning care due to the reflecting surface (a polymer) and the occasional deposition of acidic mist on the reflecting surface.

Two different economic models were used. In the case of Centinela Mine (Antofagasta Minerals), they called for a turnkey plant and assumed the operation. So investment was upfront, and operation and maintenance was assumed by Antofagasta Minerals. At first there were some teething difficulties, but the system has operated satisfactorily for well over a year and lives up to expectations.

In the case of Minera Gabriela Mistral and Pukará de Hatur, the developers offered a *PPA (power purchase agreement).* In essence there's a contract for selling thermal energy, and the developer takes care of day to day operation and maintenance as well as the operation of the backup fossil fuel heaters.

These authors consider that the *PPA* system has advantages, since experience has shown that this benefits optimal power production and better maintenance.

There are several other plants of this type under consideration. However the low cost of copper during the last year has caused delays in the signing of new contracts for new plants.

4.2. Technical Options and Special Issues

From a strictly technical point of view, systems that use solar tracking (i.e. parabolic troughs or linear Fresnel) should be better than flat plate systems. On a per square meter basis, costs should be lower, tracking improves output during daytime and pressurized water can be used for storage. Also these systems are more resistant to freezing and it's simple to prevent overheating.

But in fact, there's a very limited offer of both small parabolic troughs and/or Fresnel systems. And due to small production runs, the per square meter cost still tend to be high.

Large parabolic troughs are probably not very applicable because winds in excess of 5 [m/s] are common and high winds do exist.

Another problem that must be addressed is soiling. In fact this is quite a complex problem. It's very site dependent, and our experience shows that any activity near the solar fields (unpaved roads and some traffic) can influence soiling very much.

Also in the leaching and electrowinning process, very large amounts of solution that contain sulfuric acid are used. Unless the solar field is very carefully chosen, mist with some acid can affect the collectors. This can both be a problem from the point of view of soiling, as well as affect the materials of the collectors.

To better assess these problems the *Solar Energy Research Center (SERC-Chile)* project is now establishing both an experimental platform as well as specialized researchers in these problems.

4.3. New Applications

There are many other possible applications for large scale solar heat systems. Some of them are quite attractive, but demand further research. In particular:

- Solar desalination: Both the mining industry and coastal cities demand large amounts of (scarce) freshwater. Today the only option studied has been reverse osmosis (RO). However thermal desalination using MED (Multiple Effect Distillation) could be an attractive option. In theory these methods should be cost-competitive with RO. And in fact they could be less expensive, since RO plants have constant problems with membrane durability.
- Solar heating of the leaching piles: the flow of leaching solutions to the leaching piles is huge. On the order of several thousand cubic meters per hour. At the laboratory and small scale level it's been proved that copper recovery and process time are significantly improved with temperature increases of the leaching fluid of not more than 5 to 10°C. This brings significant opportunities to improve the processes and even think of *solar cogeneration.* That is install a large CSP plant near one of the mines, and cool the condensing block by rejecting the heat into the leaching piles. Many problems have to be addressed, but the opportunities for improvement are multifold.

5. Conclusions

The development of solar energy systems in Chile have evolved very rapidly, with no public subsidies. The principal existing advantages have been the need for new energy supplies at competitive costs, and an excellent solar resource.

In this atmosphere many companies have come into the country with new projects. These have had a very large impact on the energy matrix, but there are also emerging problems. These are mainly:

- High concentration of PV projects in certain areas. This has led to a very large drop in spot electricity prices. So only projects with PPA agreements become feasible.
- The shift in the energy market has shown the need for a strong improvement of the electrical transmission grid. This is now being undertaken.
- Soiling is a very variable problem, but collector field cleaning can have a significant effect on both performance and overall costs of the system.
- The (present) low price of copper and other commodities have delayed or postponed projects that are feasible from the technical and economic point of view.

Today there are two active institutions that are addressing these and other problems. These are the *Solar Energy Research Center (SERC-Chile),* a consortium of six Universities and Fundación Chile, that are devoting much manpower for research and development; and *Fraunhofer Solar Chile,* a research and development center established jointly between ISE-Fraunhofer (Germany) and the Catholic University (Chile), with the Chilean Government funding. Both institutions are working in a coordinated fashion.

Many research lines exist. Only to mention a few:

- The study of high penetration of variable renewable energy (both wind and solar) into the existing and future energy grids. These studies are being used for the planned expansion of the grids.
- Better knowledge, modelling and prediction of solar energy (beam, diffuse and global) both on a spatial and time basis for Chile.
- Measurement and effect of solar spectra on the performance and operation of solar systems. Above 2500 meter altitude in the desert, there are significant amounts of short wave UV (UV-A) and less long wave atmospheric absorptance. These are being first measured, and then we will determine if there are significant effects in the performance or durability of solar systems.
- Energy storage (especially thermal storage). The emphasis is on using low cost materials to provide thermal storage for CSP plants.
- *Solar Mining:* the intensive use of solar energy to both improve existing mining processes and reduce the carbon footprint and life cycle cost of the mines (jointly with Suttgart University).
- Other areas: these include water desalination, microgrids, legal issues and other areas

6. Acknowledgements

We must give special thanks to both the Energy Center (Centro de Energía) of Universidad de Chile; the *SERC Chile* project, CONICYT (the Chilean National Science Commission) and the *Solar Mining* project with Stuttgart University which have supported this work.

Techno-economic comparison of solar thermal and PV for heat generation in industrial processes

Steven Meyers[1], Bastian Schmitt[1] and Klaus Vajen[1]

[1] Kassel University, Institute of Thermal Engineering, Kassel (Germany)

Abstract

The interest for renewable based water heating via electricity has increased in recent years due to the reducing costs of photovoltaics (PV) coupled with their inherent ease of installation, especially for domestic hot water applications. In larger scale solar thermal (ST) systems, namely for industrial process heat demand, solar heating has only been done by thermal collectors to date. Given the regular cost reductions for PV, this technology may one day supplant certain segments of the industrial heating market, if renewable based heating is desired. To determine if and when this may happen, a comparative analysis between PV and ST heating systems for three industrial processes operating at different temperatures was undertaken.

Results demonstrated that for applications operating below 100 °C, ST systems will still provide cheaper thermal energy as compared to PV installed between1… 2 €/W_p. To generate saturated steam at 150 °C, PV systems can provide a better economic solution when a parabolic trough ST system specific investment is more than 700 €/m^2 turnkey while being located in a region with less than 1,700 kWh/m^2a beam surface irradiation. In lower irradiation regions, the ST system cost must be even lower to compete. When PV system costs reduce to1 €/W_p, concentrating systems must reduce their costs below 400 €/m^2 to have cost superiority.

Keywords: *industrial process heat, PV, solar thermal, economic comparison*

1. Introduction

Thermal energy is the largest segment of global energy demand, accounting for nearly half of the final energy consumption (Beerepoot and Marmion, 2012). Industrial process heat comprises one third of this end use and it is estimated that solar derived thermal energy can help meet up to 5 % of global industrial demand (Lauterbach, 2014), especially when focusing on temperatures between 50 °C and 150 °C. While an interesting route to reduce fuel consumption, very few projects have been realized due to a host of factors, with high upfront project costs being a main deterrent.

With the recent and rapid improvement of PV technology, ease of installation, and its associated cost reduction, this technology is now being considered for thermal energy projects, simply by using a resistance heating element directly into a fluid stream or connected to an industrial steam boiler. Prior studies have focused mainly on small systems which provide domestic hot water (DHW). An early report (Fanney and Dougherty, 1997) shows that assuming a solar thermal DHW system costs between 4,500…6,000 USD (inflation adjusted), energy cost parity could be reached when a PV system costs between 1.65…2.85 USD/W_p (1.48…2.55 €/W_p). Current DHW systems in developed countries are estimated to cost approximately 4,500 USD turnkey, depending on local labor markets and supplies (DGS, 2012). Current PV systems for electricity generation now cost approximately 1.48 €/W_p for small commercial projects in Germany and 2.06 €/W_p in the United States, with costs reducing for larger projects (Shah and Booream-Phelps, 2015). Prices for both systems are within the range to generate thermal energy competitively. This has also been confirmed by Le Berre et al., (2014).

To date, the use of PV generated electricity to directly provide heat for industrial applications has not been rigorously studied. This is due to the more complicated nature of process integration, as industrial energy demand varies both temporally (hourly, daily and weekly) and energetically, with process temperatures ranging from 50…200 °C, and has no external grid which can be fed (which is the case with electricity). Therefore, it is imperative that an analysis be undertaken to compare both the technical and economic performance of both types of systems to determine their suitability, both now and in the future.

2. Methodology

To determine the feasibility of different solar heating technologies in different industrial applications, three different process and temperatures were selected: from 15...60 °C or stream pre-heating (PH), from 60…90 °C or bath heating (BH), and process steam generation at 150 °C (SG). The heating demand of all three systems was constant throughout the year, which exemplifies the ideal situation for solar thermal (ST), as storage and heat exchange losses are minimized. To dimension and subsequently calculate the energy yield in such systems, a methodology described in VDI - 6002, (2014) and expanded by Lauterbach, (2014) was implemented. This approach analyzes a solar project in terms of specific collector performance, which allows for easy scalability when designing multiple systems. This method begins to size a solar field based on a "good summer day", where the highest daily yield from one square meter of collector (q_{design}), tilted to the latitude of the site, is scaled up to match the daily demand of the process. In this manner, no energy will be wasted during the annual operation of the system, as it will be undersized for the remainder of the year. For example, one process consumes 1.5 MWh/d at a temperature of 60 °C ($Q_{process,day}$). A selected solar collector, on the highest solar irradiation day, can produce 3.6 kWh/m^{2}d (determined via TRNSYS simulation in Lauterbach, 2014). By using (eq. 1), the required field size can be calculated.

$$A_{coll}^{ST} = \frac{Q_{process,day}}{q_{design}} = \frac{1.5\,\frac{MWh}{d}}{3.6\,\frac{kWh}{m^2 d}} = 416\ m^2 \qquad \text{(eq. 1)}$$

Once the collector field size is determined, it can be multiplied by the annual utilization factor (η_{sys}), generated by annual dynamic simulation (Lauterbach, 2014) and the annual irradiation incident on the collector ($H_{t,b}$ for either total or beam radiation on the collector surface) to estimate the yield of the system (eq. 2).

$$Yield_a^{ST,PV} = A_{coll}^{ST,PV} * \eta_{sys} * H_{t,b} \qquad \text{(eq. 2)}$$

Lauterbach (2014) conducted these simulations for various regions in Europe, process temperature levels, demand schedules, and storage sizes. For the PH and BH cases, results were utilized from this work to calculate the energy yields. Flat Plate and Evacuated Tube Collectors were chosen for these cases, respectively. The SG case required additional programming in MATLAB, which simulated the performance of a parabolic trough collector using the same methodology, only forgoing storage, which is rarely used while creating process steam (outside of a small buffer tank). The design yield and utilization factor for four selected regions (Würzburg, Toulouse, Madrid, and Windhoek) was calculated using a simple model with the following input parameters (Tab. 1). It was assumed that the mass flow rate of the collector could be modulated to always produce a thermal oil outlet temperature of 190 °C, required generating steam at 150 °C. Field efficiency incorporated the losses due to solar field shading, piping and heat exchanges with the boiler to generate steam. The effects of the Incident Angle Modifier (IAM) were included; however optical effects for concentrating collectors, such as end losses, were not.

Tab. 1 - Simulation parameters of the steam generation case.

Parabolic Trough Collector (NEP 1800)	η_o	0.689	
	a_1	0.36	(W/m^{2}K)
	a_2	0.0011	(W/m^{2}K^2)
Field Inlet Temperature		140	°C
Field Outlet Temperature		190	°C
Field Efficiency		90	%

Through an annual simulation, sizing parameters for steam generation case were generated. A summary of the sizing parameters used can be found in Tab. 2, Tab. 3, and Tab. 4 in Section 3.

For the PV system, it was assumed that all electrical energy will directly be consumed by the process (via resistance heating) with no storage needed. As this is a highly flexible energy source, if it could not be used directly in the process, additional resistance heaters were assumed to be installed in other processes in the factory. It is important to note that the PV generated electricity can certainly be used to decrease net demand from the electrical grid, but this is not the focus of the work. The sizing of the PV field was done to match the annual energy output of the comparative solar thermal system, as seen in (eq. 3), where the solar thermal yield is divided by the average PV system efficiency (assumed 15 %) and the incident annual irradiation (H_t).

$$A_{coll}^{PV} = \frac{Yield_a^{ST}}{\eta_{pv} * H_t} \qquad \text{(eq. 3)}$$

The financial comparison was conducted by calculating the 20 year Levelized Cost of Energy (LCOE) of both solar heating systems (eq. 4). As the energy yields were calculated in the different cases, systems costs were assumed to be directly related to their size. PV system costs are well known (Shah and Booream-Phelps, 2015) and have been assumed to be 2 €/W_p installed (or 300 €/m^2 assuming again a 15 % system efficiency), inclusive of wiring and heating equipment. ST system costs vary considerably, depending on size, balance of systems, and technology. As such, an array of LCOE calculations were conducted by varying the specific system cost from 200 €/m^2 to 1,200 €/m^2, to capture the lowest flat plate cost to the most expensive parabolic trough cost (including the effect of potential subsidies). The costs of the solar systems ($Cost_{ST,PV}$) were calculated by multiplying the calculated area of collectors or modules ($A_{coll}^{ST,PV}$) in each case by the specific cost. Other important parameters of the LCOE calculation were Discount Rate (*DR*, 5%), Operations and Maintenance (*OM*, 1.5% and 1% of system cost for ST and PV, respectively), and system degradation (*SD*, 0.5% and 1%, for ST and PV, respectively). There was assumed to be no recovery value of the systems.

$$LCOE = \frac{Cost_{ST,PV} + \sum_{n=1}^{20} \frac{OM}{(1+DR)^n}}{\sum_{n=1}^{20} \frac{Yield_a^{ST,PV} * (1-SD)^n}{(1+DR)^n}} \quad \text{(eq. 4)}$$

3. Simulation Yields

The two applications below 100 °C (PH, BH) utilized the same four regions of varying solar resource (Copenhagen, Würzburg, Toulouse, and Madrid). The SG case used the latter three and also included Windhoek, Namibia, a city with rather high direct normal insolation (DNI). Different for this case was the use of direct irradiation (H_b) on a single axis N-S tracking surface due to the parabolic trough concentrators, while the PV system yield was calculated with the global surface irradiation (H_t). The simulations assumed a daily demand of 5 MWh/day during the whole year. Storage was used for the low and medium cases, pegged at 5 kWh/m^2 of collector field size.

Tab. 2 shows the required input data, as referenced in Section 2, necessary to estimate the performance in these four locations for the PH flat plate collector case, along with the resulting annual energy yields for both the ST and PV systems, collector area, and the range of project costs. Tab. 3 depicts the same for the BH evacuated tube collector case, and Tab. 4 for the SG parabolic trough. Fig. 1 summarizes the specific yield (kWh/m^2a) for all collector types in the three cases. The PV yields are the same for the three cases, as it was assumed that the conversion efficiency for resistance heating is temperature insensitive. The results clearly show an increasing yield as a function of higher solar irradiation, and a decreasing trend as the working fluid temperature increases, even if more efficient collectors are used.

4. Comparative Analysis Results

From the previously calculated energy yields and their respective project costs, a relationship was established between them and the available solar irradiation. A metric was created to determine the better financial choice to generate thermal energy. For each financial case (solar costs, case, location), the LCOE for the ST and PV systems were calculated. The ST LCOE was then divided by the PV LCOE, yielding a ratio that if greater than one; the PV system would produce cheaper thermal energy. If less than one, the ST system would be cheaper. The results of the calculated ratio are show in Tab. 5 for the three cases. The assumed specific PV collector cost was 2 €/W_p.

Tab. 5 – Simulated LCOE Ratios for solar process heat projects. The highlighted and bold cells indicate situations where PV heating is more economically viable than ST heating. White cells with regular font show the situations where ST heating is more economically viable.

		Solar Thermal System Investment (€/m²)

These results were further analyzed, generating a relationship between the LCOE ratio, ST system costs, and available solar irradiation, via multiple linear regression, with the following relationship (eq. 5). For the PH and BH cases, H_t was used and H_b for the SG case. Statistics for the curve fit are seen in Tab. 6.

$$Ratio_{LCOE} = b_0 + b_1 * ST_{Specific\ Cost} + b_2 * ST_{Specific\ Cost} * H_{t.b} \quad \text{(eq. 5)}$$

Tab. 6 - Multiple Linear Regression results

	R^2_{adj}	RMSE	F statistic	p-value	b_o	b_1	b_2
Pre-Heating	0.999	0.011	16690	0	0	0.001069	-1.26E-07
Bath Heating	0.995	0.025	5066	0	0	0.00157	-3.36E-07
Steam Generation	0.931	0.188	316	0	0	0.0027	-7.70E-07

The result of (eq. 5) coupled with an array of feasible ST system costs (200…1,200 €/m²) and incident solar irradiation values (1,000…2,600 kWh/m²a) showed the changing feasibility of ST systems to provide thermal energy as compared to PV. The results for the PH case are shown in Fig. 2, the BH case in Fig. 3, and the SG case in Fig. 4. The thick white line indicates the point where PV and ST LCOE's are the same, so parameters right of this line favor ST projects and to the left favor PV projects.

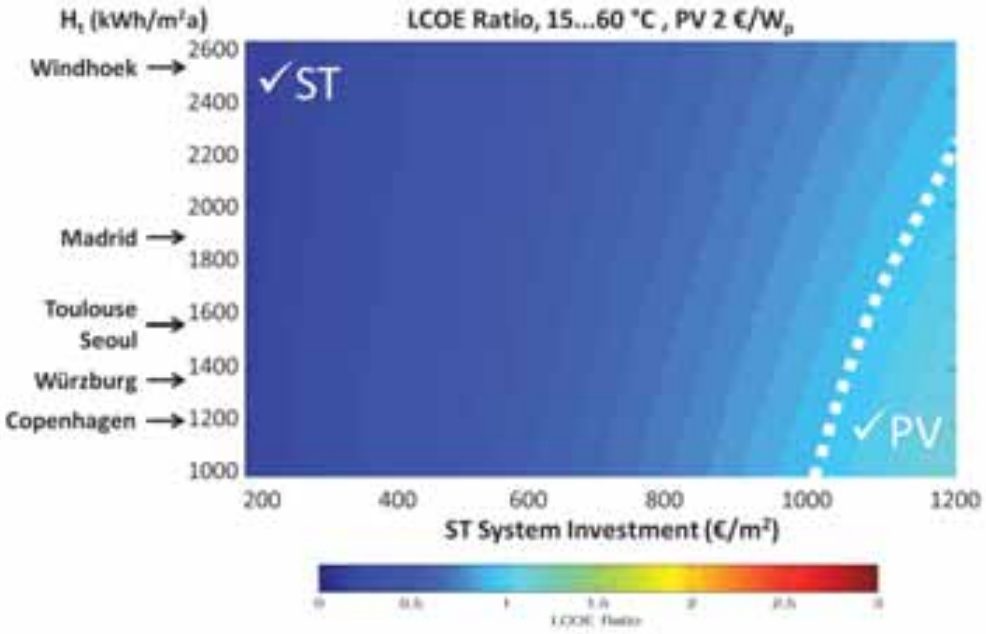

Fig. 2 – Pre-Heating LCOE comparison, where ST is the preferred choice under one, and PV over one.

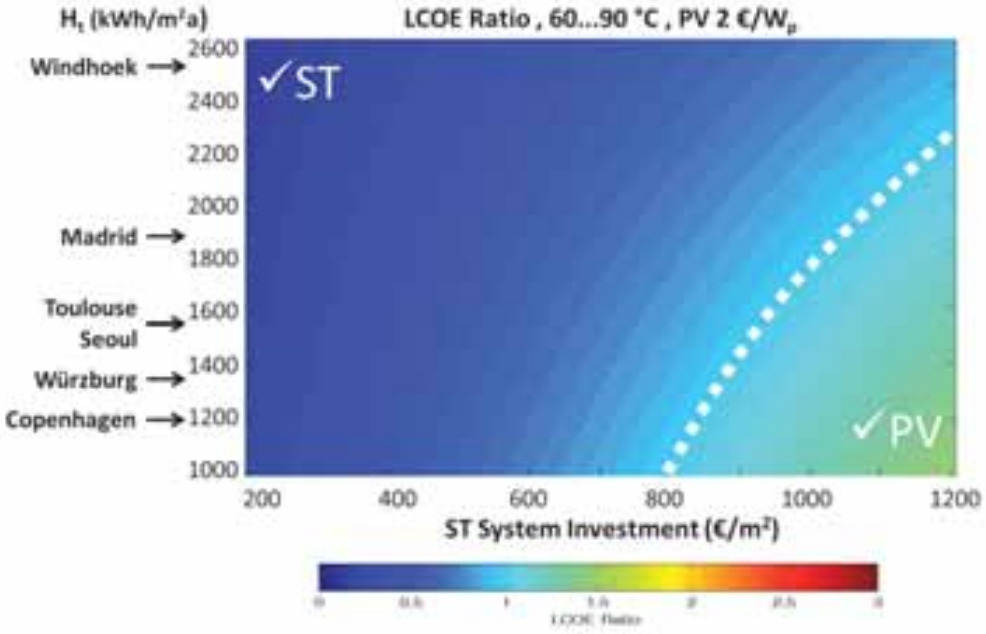

Fig. 3 – Bath Heating LCOE comparison, where ST is the preferred choice under one, and PV over one.

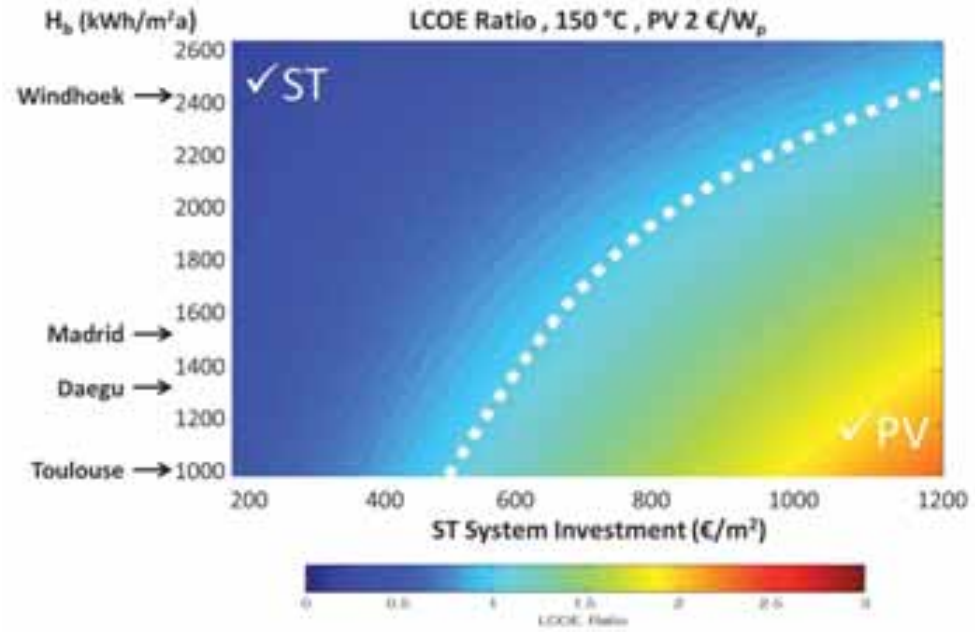

Fig. 4 – Steam Generation LCOE comparison, where ST is the preferred choice under one, and PV over one.

5. Discussion and Example Case

The tabular results in Tab. 5 clearly show that within applications and temperature levels, there are situations where PV heating is more cost effective than ST. This is most notably observed when ST system costs are significantly higher, operating at higher temperatures, and when installed in lower solar resource regions. This trend is progressively seen in Fig. 2, Fig. 3, and Fig. 4. These results are logical, as PV or electrical based heating is temperature insensitive (i.e. near constant thermal conversion efficiency), while the efficiency of a solar thermal collector decreases when operating at higher temperatures. Furthermore, PV can still produce useable energy in lower radiation, while ST struggles since there are inherent thermal losses to overcome. This helps to explain how, for example, PV may be better adapted to generate steam in most regions in Europe, as the beam irradiation is marginal at best while global irradiation is more consistent and beneficial to non-concentrating technologies. It should go without saying that steam generation with flat plate collectors would be rather challenging. Also interpreted from this table is a reason why DHW is at times being heated through PV resistance heating. In very small projects, the specific ST cost can be 900…1200 €/m^2 (DGS, 2012), making the costs very comparable with PV. Given the ease and minimal risk to install PV, this solution is gaining in popularity.

Fig. 2, Fig. 3, and Fig. 4 show a clear trend, that ST performs better compared to PV in higher irradiation regions than lower. The figures also indicate that as ST collector operating temperatures increases, so does the cost feasibility of a PV heating solution. A simple observation in all three figures again points to the fact that the area of acceptable ST projects shrinks as the collector temperature increases, while the PV area increases. This leads to the conclusion that PV heating may soon play a more important role in steam generation applications in relatively lower solar irradiation regions. This is made evident by the greater than one LCOE ratios in Fig. 4 above 700 €/m^2 ST project specific investment cost while H_b remains less than 1,700 kWh/m^{2}a. Both of these keystone values are often observed in projects within Europe.

As steam generation applications have demonstrated the nearest term situation where PV heating may be feasible, a reference case was used to assess its current state. In 2012, NEP Solar built a 627 m^2 parabolic trough collector field for a diary company in Switzerland, which generates 120 °C pressurized hot water for a cheese manufacturing facility. The specific subsidized project investment for the total system was approximately 595 €/m^2 (Frank et al., 2013), of which half was dedicated to the collector field. At this site, the annual DNI was 1,119 kWh/m^{2}a with a reported net specific steam yield of 406 kWh/m^{2}a. This value is comparable when interpreting the parabolic trough simulation results from Tab. 4 (445 kWh/m^{2}a), however operating at a higher mean plate temperature. Interpreting Fig. 4, the LCOE ratio at this point (595 €/m^2 and 1,119 kWh/m^{2}a) is 1.15, clearly indicating that a PV heating system would provide heating at a lower cost. If the solar thermal system investment could be reduced to below 550 €/m^2, it would be competitive against PV. If the incentives were removed, the project cost would increase to 990 €/m^2. To be competitive at this specific collector cost, the beam irradiation H_b must be rather high (2,200 kWh/m^{2}a). If the PV costs increased to 3 €/W$_p$, the competitive H_b changes to 1550 kWh/m^{2}a or ST system costs must be reduced to 825 €/m^2. When the PV cost is greater than 3.65 €/W$_p$, the currently designed and unsubsidized ST system becomes the preferred solution.

While PV may outperform ST in some situations, like above, it is important to point out the practicality of using PV for heating, with respect to the required land area needed to build such a project. Tab. 2, Tab. 3, and Tab. 4 display a significantly higher area required by PV to generate the same amount of thermal energy compared to ST. The multiple of land area required for the PV system relative to the ST system is shown in Tab. 7. The results indicate that PV requires relatively more space in higher solar irradiation regions, but less when operating at higher temperatures.

Tab. 7 - System size comparison between PV and ST, showing the significantly higher space needed for PV to generate thermal energy.

	Copenhagen	Würzburg	Toulouse	Madrid	Windhoek
Pre-Heating	3.6	3.7	3.9	4.0	----------
Bath Heating	2.5	2.6	2.9	3.0	----------
Steam Generation	----------	1.7	1.3	2.3	3.2

In reality, there is often limited available rooftop or land space at an industrial facility to build a solar system. This means that if a larger amount of thermal energy is desired to be displaced by solar on the same rooftop, ST

may still be chosen even if it costs more. This is one major drawback of employing PV heating for industrial heat demand. To combat the greater required PV size, a heat pump could be employed to generate the targeted energy. If the COP of the heat pump can equal the relative size difference in Tab. 7, the PV field can be sized the same as ST, generating the same thermal energy (but not necessarily at the same cost). This also assumes that there is suitable available heat from waste streams. This analysis is not pursued in this paper, but is an interest for future work.

6. Future Scenario

The results from the reference case study show that current costs for ST projects operating at higher temperatures are similar to those of PV, if not higher. While future ST costs are challenging to predict, it is well accepted that PV cost will regularly decrease in the coming years. By setting the price of PV to 1 €/W_p, an understanding can be gained as to which technology may be chosen for future projects. This will also serve as a price target for ST systems to achieve so that PV electrical heating will not supplant them as the chosen technology for thermal energy generation.

In PH applications (Fig. 5), it appears that as long as ST project costs remain under 500 €/m^2, they should be the preferred choice, no matter the available solar irradiation. Similarly in BH applications (Fig. 6), ST should be chosen if costs are below 400 €/m^2 in all irradiation conditions. However, some evacuated tube projects are currently above this cost target, emphasizing the need to still reduce costs. The motivation to reduce costs is clearly evident when using concentrating collectors (Fig. 7), as the breakeven point for concentrating ST collectors generating steam is below 300 €/m^2 for lower irradiation climates and up to 500 €/m^2 in ideal solar locations (2250 kWh/m^2a). The current project costs for SG concentrating collectors are well above this price point and significant efforts must be made to reduce costs, both with the collector and balance-of-systems, in order for ST to generate steam in the future.

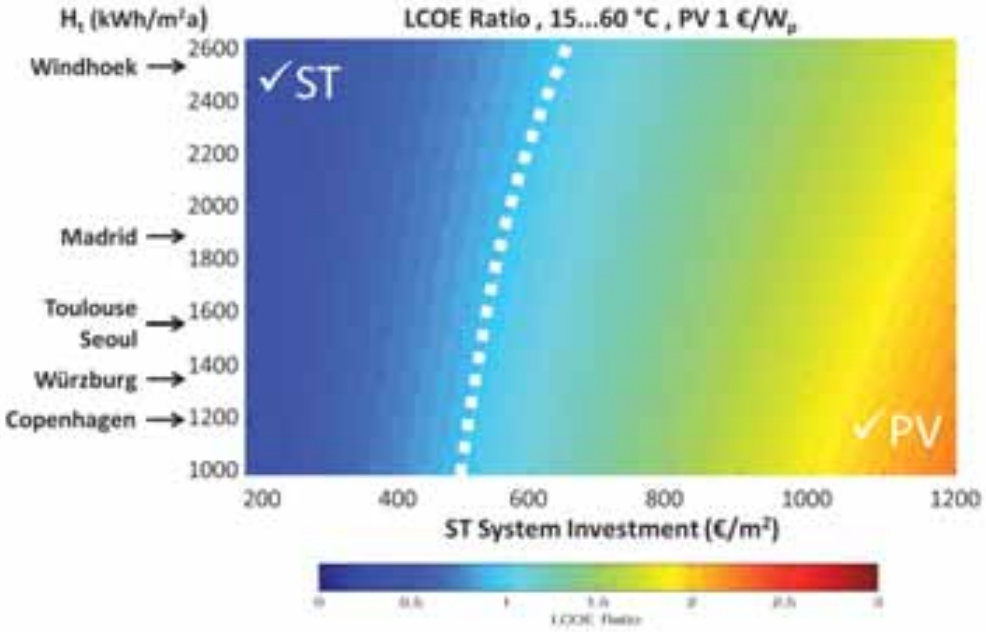

Fig. 5 – Pre Heating LCOE comparison when PV costs 1 €/W_p

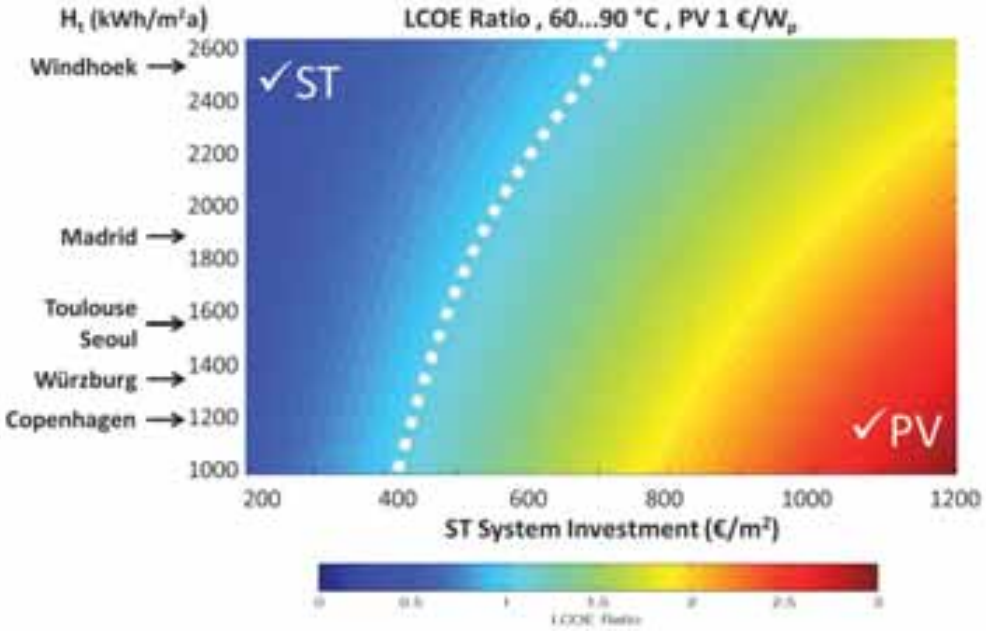

Fig. 6 – Bath Heating LCOE comparison when PV costs 1 €/W_p

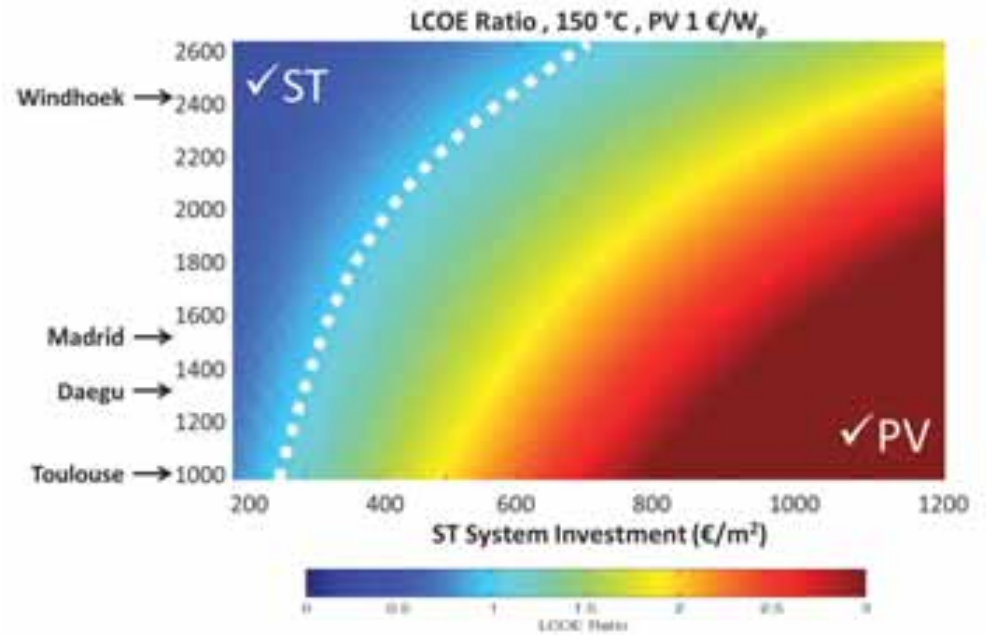

Fig. 7 – Steam Generation LCOE comparison when PV costs 1 €/W_p

7. Conclusions

The previous analysis showcased the comparison between Solar Thermal and Photovoltaics to generate thermal energy for industrial processes. At current costs, ST is still a more economic choice for applications below 100 °C, but when generating steam, PV can provide relatively lower costs when the direct solar resource is less than 1,700 kWh/m^{2}a. From the provided reference case in Switzerland, PV is already a more economical solution, mainly due to the low solar resource and high specific project cost for ST.

The 2020 specific cost goal for non-concentrating systems is 250 €/m^2, and 300 €/m^2 for concentrating, according to (Ivancic et al., 2014). These figures, especially for concentrating collectors, remain good targets to stem the competition from PV based heating. Significant efforts are still needed to realize such goals.

It is important to note that the price of fossil fuel, or its comparison with thermal energy generation, was not mentioned during this analysis. This omission was intentional, as the focus was a technical comparison between the two solar technologies.

Abstract

Since the start of the funding of solar thermal process heat systems in Germany, a growing market has begun to evolve. At the moment roughly 400 m² of collector area for solar process heat systems are submitted for approval each month; four times more than in 2012. All together about 14,000 m² were submitted since 2012 and more than half of the collector area is already in operation, delivering heat for commercial and industrial applications. Although many of these systems are within 20 m² to 40 m² and are used for very simple applications like rearing of piglets and hot water preparation for car washes, there are also bigger systems, up to 960 m², delivering heat for e.g. drying and cleaning applications of production sites and produced goods. Referring to the turnkey system costs, the average cost of nearly 800 €/m² is still quite high and differs significantly depending on the collector technology used and the application.

In addition to the funding of new solar process heat systems, a detailed monitoring of three newly installed systems is financed to gain in depth experience on solar process heat systems. These systems are a metal surface treatment facility, a bitumen production and a gas pressure regulation station. System descriptions and first results are presented.

Keywords: *industrial process heat, solar thermal, German market, monitoring*

1. Introduction

The supply of process heat has become one of the future key markets for solar thermal systems in Germany and Europe due to the significant technical potential for Germany of 130 TWh/a (Lauterbach et al. 2012). This is equivalent to more than 35 million m², with benefits such as year-long heat demand in commerce and industry, giving the opportunity to reach low solar heat generation costs. Since there were only very few systems installed in Germany until 2012, the Federal Ministry for Economic Affairs and Energy (BMWi) released a promotion for solar process heat systems within the Market Incentive Programme (MAP) in August 2012. Since then the supply of solar process heat is supported by an investment grant or subsidy on the loan redemption of up to 50 % according to the chargeable investment costs. With the latest amendment in April 2015, it was confirmed as an important component for the goal to provide 14 % of the German heat demand with renewable energies till 2020 (BMWi, 2015).

To increase the impact and quality of the new solar process heat funding, a scientific project was permitted and funded to be conducted by University of Kassel. The most important task of this scientific institution is to provide technical support and optimization measures to ensure the quality of newly installed systems. Within this scope of duties the detailed monitoring of three selected solar process heat systems is a very important issue. The aim is to gain information about the efficiency in the field of the specific applications, the effectiveness of the respective integration of solar heat, the long term reliability of the systems and possible malfunctions caused by the interaction of different heating systems.

2. Market overview and accompanying project

Since the start of the funding for solar process heat systems in August 2012 until the end of August 2015 more than 240 applications for solar thermal systems with a total gross collector area of 18,000 m² were submitted. Out of these applications only 7 % were rejected for formal reasons e.g. use of heat for domestic

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.10.42 Available at http://proceedings.ises.org

hot water or the use of unglazed collectors. Additional 6 % were cancelled by the applicants themselves for unknown reasons. Nearly 90 % reached the realization phase, equivalent to an area of 13.900 m^2_{gross}. Since there is usually a larger time gap between the application for the funding and the start-up of the realized solar process heat systems, there are currently only 134 systems in operation with a collective collector area of 7,241 m^2_{gross}. Figure 1 shows a yearly breakdown based on the collector area of the application forms that were handed in, the approved applications, the systems that started operation and the systems that are still under construction. In contrast to the other values the last bar also includes the collector area of approved but not yet realized systems of previous years. In this Figure it has to be considered that the funding of solar process heat systems started at the end of August 2012 and the values for the year 2015 only represent the period from January 1st to August 31st.

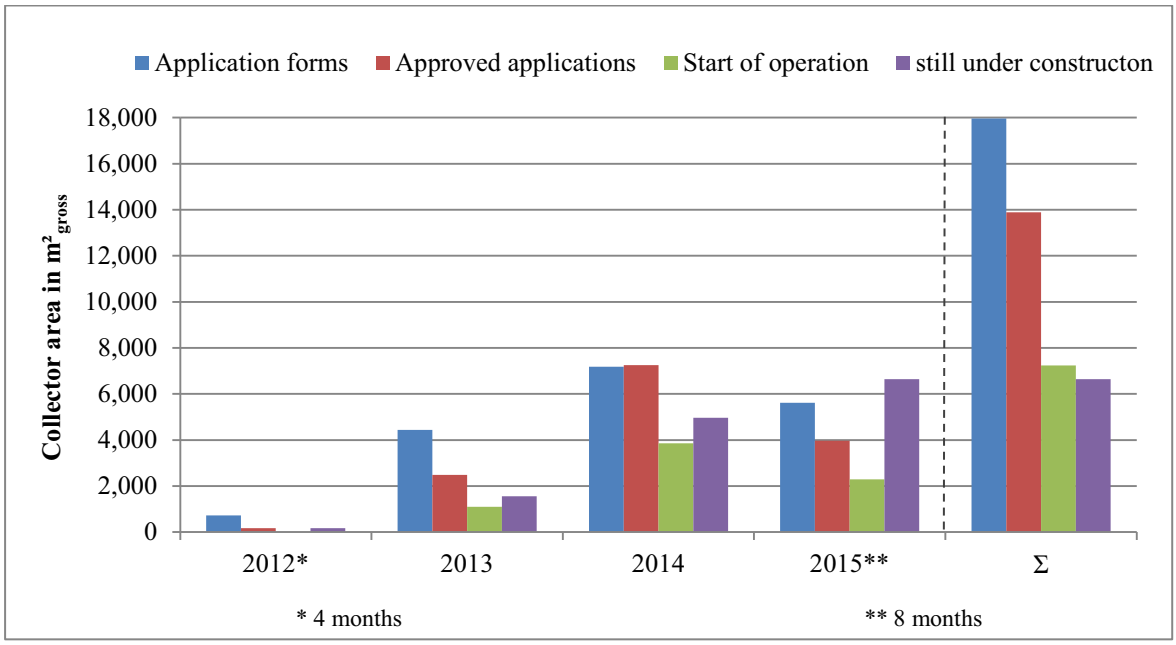

Figure 1: Overview on the German market for solar process heat

A more comparable illustration is an overview of the monthly approved applications according to the collector area as an average value for the particular year. This comparison, as it can be seen in Figure 2, shows a growth of the German market for solar process heat systems until the end of 2014. In 2015 there was a little decrease that can be explained by the restraint of applications caused by the amendment to the Market Incentive Program in April. Because of the weak start of the year 2015 and since there are still four months left, it would be too early to conclude that there is already a slowdown in growth of the German market for solar thermal process heat systems.

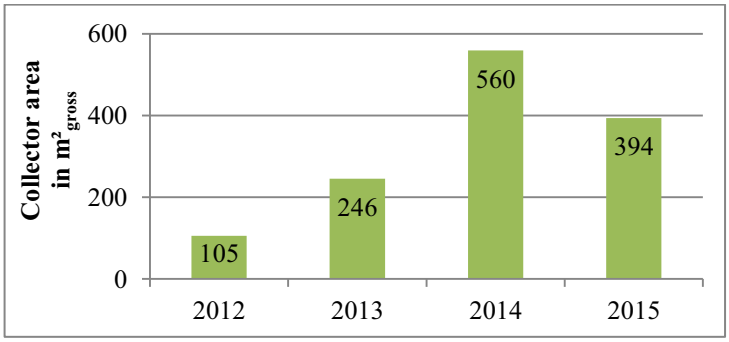

Figure 2: Average value of the monthly approved collector area in m²

At the early stage of the solar process heat funding program, the average collector field size was below 40 m^2_{gross}. Starting with the year 2013 small but constant growth of the average size was seen, reaching a peak in 2014, due to a system with 960 m^2_{gross}. However the average project size in 2015 is 66 m^2_{gross}. Although a large share of the installations is smaller than 40 m², already 22 process heat systems have a

collector field size between 100 m^2_{gross} and 960 $m^2_{gross.}$ The three largest systems that are already in operation are a 297 m² system with CPC-collectors delivering solar heat to the different baths, drying chambers and the air washer of a metal treatment company, a 507 m² air collector system for drying of wood chips and a system with 960 m² with flat plate collectors that are used to deliver heat for the dehumidification and heating of greenhouses to prevent the fouling of vegetables and to extend the growing season.

Analyzing the end use of solar heat, it becomes obvious that over 50 % of all submitted solar process heat systems are used or will be used for only two applications: rearing of piglets and car washes. Beside these two often applied systems, there is a large variety of processes heated by solar thermal systems, especially in the field of drying and cleaning of products and production sites. Other uses of the solar heat are fish farming, production of pharmaceutical goods, heating of baths for plastics testing and surface treatment, hot water production for laundries as well as bitumen processing and others.

As solar thermal systems serve as fuel savers aside from a handful of applications, it is always interesting to refer to the costs of the systems which in combination with the solar yield determine the solar heat generation cost. The breakdown of the system costs including installation and integration into the respective process but independent of the used collector technology or the application down to 1 m^2_{gross} delivers specific system costs of 789 €/m² since the start of the funding in Germany. A deviation of the system costs between the different collector technologies can be observed also varying from year to year. As it can be seen in Figure 3, the costs for solar process heat systems using flat plate collectors are in some degree stable in a range between 760 €/m² and 860 €/m² nevertheless a slight but constant increase over the years can be recognized. According to the costs for systems using air collectors or evacuated tube collectors (ETC) - including CPC - it is very conspicuous, that they are clearly higher in 2012 compared to the other years. This is caused by three systems with very high specific costs in a range between 1.500 €/m² and 2.100 €/m² that could not be compensated by the other systems. But even such expensive systems are sometimes economical feasible depending on the reference price of the conventional heating system. If it is electrical heating, this reference price can exceed 0.20 €/kWh for smaller commercial electricity consumers. On the other hand considering the 50% investment grant, some systems even reach a heat price roughly 0.03 €/kWh, being competitive with modern gas boilers delivering heat for processes. The numbers in the bars in Figure 3 are the average system size for the particular collector type and year (BAFA, 2015 and KfW Group, 2015).

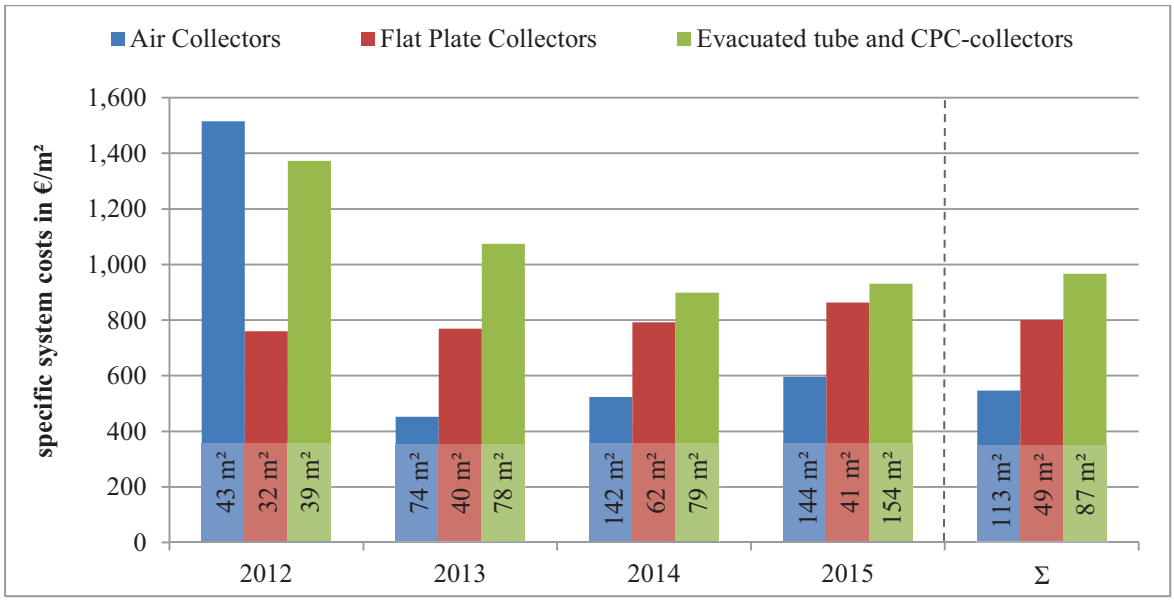

Figure 3: Average system costs for solar process heat systems in Germany according to the collector type

Since solar process heat is an emerging market in Germany and these systems are usually more complex compared to domestic applications, the BMWi is funding a scientific project to analyze and push the German market for solar process heat. As mentioned in the introduction, the University of Kassel has different tasks to ensure the quality of newly installed systems such as technical consultancy for planners, publication of technical recommendations, and identifying optimization measures. Beside this, it is also obligatory to spread the gained knowledge on the market by developing information materials and giving training courses as well

as information sessions to selected target groups. One very important task is the detailed monitoring of three selected process heat systems that were funded within the Market Incentive Program to gain information about the efficiency in the field of the specific applications, the effectiveness of the respective integration of solar heat, the long term reliability of the systems and possible malfunctions caused by the interaction of different heating systems. The requirements according to the measurement devices, the description of the systems and some first results of the monitoring can be found in the following sections.

3. Selected solar process heat systems for the monitoring

For the detailed monitoring, three applications were selected: a metal treatment company, a bitumen production facility and a gas pressure regulation station. The selection of these systems for the detailed monitoring was done using several criteria such as temperature levels, the way of integrating solar heat, the financing model as well as innovative ways of dealing with stagnation or the combination with other heat supply technologies. Table 1 gives an overview on the similarities and differences of the named systems.

Table 1: Description of solar process heat systems for the detailed monitoring

	Metal treatment	Bitumen processing	Gas pressure regulation
Collector type	CPC evacuated tube collector	Flat plate collector	Large-scale flat plate collector
Collector field	300 m^2_{gross}, roof mounted	190 m^2_{gross}, roof mounted	500 m^2_{gross}, ground mounted
Buffer storage	15 m^3	20 m^3	25 m^3
Solar assisted process(es)	Heating of baths Drying of products Heating of air washer Maintain air temperature	Hot water for bitumen emulsion process Boiler make-up water Heating of bitumen tank Steam cleaning	Heating of natural gas pipeline before decompression
Temperature level for solar system	40...70°C	20...130°C	50...60°C
Integration concept	Supply level, all heat sinks are served	Process integration, several heat sinks	Process integration, one heat sink
Combination with other heat generators	Conventional oil burner as backup that is directly loading the upper part of the buffer tank	Hydraulically separated steam boiler as backup	Gas burners as backup. Additional gas-driven heat pumps to reduce natural gas consumption
Charge / discharge of storage	Storage is directly connected to solar heating system and heating network without hydraulic disconnections	External HX for storage charging. Combination of direct hot water use and external HX to discharge the storage	Charging with internal HX, discharging with external HX
Frost prevention	Active frost protection due to water as heat transfer medium	Water glycol mixture	Water glycol mixture
Load profile	More or less constant production over the year (order related production)	Very good match between energy demand for processes and solar radiation (road building)	Highest heat demand in winter (space heating), reduced base load in summer
Financing	Self-investment	Self-investment	ESCO
Planner	Holsmölle 2014	Aschoff 2014	Heinzen 2015

Since the metal treatment facility will be explained in more detail within the following two sections, some information of the bitumen processing and gas pressure regulation station are given below.

Bitumen processing

The produced bitumen emulsion is used for road construction. As these infrastructural projects normally aren't performed in winter, the production period of the company starts around April and ends the latest in November. In addition it is not unusual that weather forecasts are used in this business determining the production output. Therefore the available solar energy and the load profile of the production site have a very good congruence and a very high solar fraction of >70 % is planned. The main energy consumer is the preparation of hot water for the emulsion process where raw bitumen and emulsifiers have to be mixed to obtain a stable product. The second consumer is the pre-heating of boiler make-up water up to 90°C for the high-pressure steam cleaning of tanks and technical equipment. On days with high solar irradiation when the solar loop reaches temperatures of at least 120°C the third consumer, the heating of a raw bitumen tank, is driven by solar thermal energy to reduce the viscosity of the raw bitumen. The internal HX of this tank is directly connected to the solar loop, so this heat sink can also be used as an active stagnation prevention device (Aschoff, 2014).

Gas pressure regulation station

Gas pressure regulation stations are used to reduce the pressure of e.g. 90 bars of the natural gas in the cross-country high-pressure pipelines to a pressure of e.g. 12 bars for the local distribution networks for the final consumers. Caused by the decompression using expansion valves the temperature would decrease below 0°C. To prevent freezing of the regulation equipment and the piping of the local network, the natural gas has to be heated. Normally this heat is provided by gas burners located in the regulation stations but as the operator has to pay market-price for the burned gas, it is possible to compete against the natural gas with solar thermal energy. The highest natural gas consumption in the local grids is always in winter when there is a huge demand for space heating. Depending on how many commercial and industrial consumers with thermal energy demand are connected to the local grid, an appreciable base load is needed to prevent the gas from freezing also in summer. The selected system for the detailed monitoring has two specialties that should be named: First there will be an additional gas-driven heat pump to reduce the natural gas consumption additionally to the heat provided by the solar thermal system. Second the whole system will be financed and operated by an ESCO selling the heat to the gas provider for a lower price compared to the conventional heating using the installed gas burners (Heinzen, 2014).

4. Solar thermal process heat for metal treatment facility

The third named solar thermal process heat system chosen for the detailed monitoring delivers heat for the surface treatment of metallic materials in a medium sized enterprise. The main business of the company is the zinc coating in two automated production lines with a high output of specified mass products. Beside this automated production there is also a manufacturing area where smaller, more individualized charges are produced in small baths that are operated by hand. Beside the main surface treatment of zinc coatings, there are also various other coatings like copper, tin, chrome, nickel or cadmium.

Conventionally the required heat is supplied by two oil burners that worked with a small storage tank. For peak loads that cannot be handled by the oil burners, there is also the possibility to heat with electrical resistant heaters. In the past approximately 15 % of the heat demand was covered by electricity. During installation of the solar thermal system, the small buffer storage was removed and replaced by a 15 m³ buffer storage heated by both heat sources (oil and solar). As mentioned in Table 1 the whole system was planned and realized as an integrated heat network, so there are no hydraulic disconnections between the solar thermal system, the buffer storage and the oil burners. They all use the same heating circuit water.

For delivering the heat to the different processes named in Table 1, there are three circuits directly connected to the storage, taking the water out of three different heights at different temperature levels. The process with the highest temperature demand is drying of coated products within two drying chambers at the production lines. Here, water to air HXs are used, requiring ta temperature up to 70°C. The medium temperature loop is mainly used for heating of different production line baths and those operated by hand. Here the required temperature reaches up to 60°C and internal tube bundles are used as heat exchangers. Additionally the heat

registers that are used for maintaining a specific temperature in the hall around the baths are supplied by the medium temperature loop as well as domestic hot water preparation and the space heating for offices and social rooms in winter. The third loop is supplying low temperature heat to an air washer that is necessary to wash pollutants out of the air. For this application a temperature around 40°C is needed. The return flows of the three heating loops are stratified into the buffer storage at different heights, depending on the temperature. Figure 4 gives an overview of the whole system of heat suppliers and heat consumers.

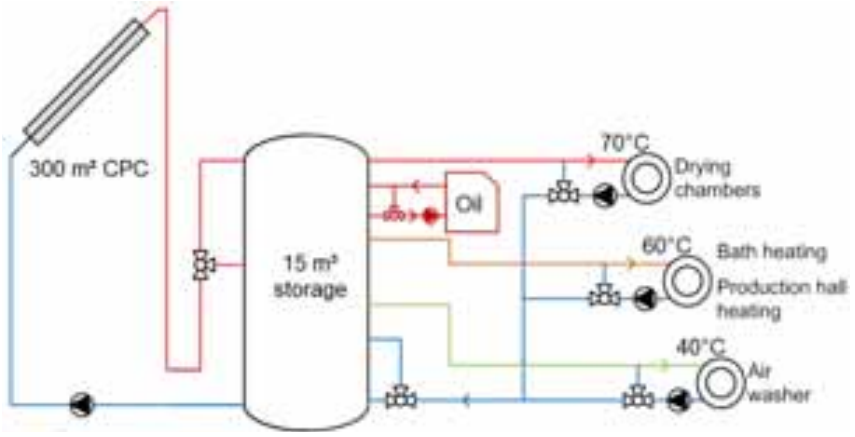

Figure 4: Hydraulic scheme of heating network supported by solar process heat system

The solar thermal process heat system consists of 63 CPC-Collectors with a total gross area of 297 m² and is installed on the roof of the production hall. The field is divided into two subfields each with an inclination of 12°, one north-east orientated with an area of 170 m^2_{gross} and the other one south-west orientated with 127 m^2_{gross}. A picture of the field can be seen in Figure 5: north-east orientated field on the left-hand side, south-west orientated field on the right-hand side.

Figure 5: CPC-collector field on metal treatment factory (Holsmölle 2015)

The control strategy is to feed the solar heat into the top of the storage at a set temperature of at least 65°C up to 100°C depending on the highest temperature of the buffer with the aim of reducing the pulsing of the oil burners. On the one hand this strategy reduces the yield of the solar loop caused by the higher temperatures, but due to the reduction of start-up times of the oil burners with poor efficiencies, a positive effect on the oil consumption can be expected. However, it was not possible so far to quantify this effect due to an increase of the production and a missing reference for the solar control strategy of pre-heating the buffer as soon as the solar flow exceeds the lowest temperature in the stratified storage (Holsmölle, 2014).

According to the detailed monitoring some important requirements were defined like the remote meter reading, the possibility to vary the interval of the data recording, the separate measurement of the heat production, heat consumption of the heat sinks connected to the solar assisted heating network, the flow distribution in every collector row, all done by the recording of the flow temperatures of each row as well as

the measurement of the stratification of the storage using at least three temperature probes (top, middle, bottom). The solar radiation is measured in the collector plane(s) using first class pyranometer(s) to calculate the system efficiency. These requirements are the same for the three systems selected for the monitoring.

5. First measuring results of the described system

As there are still some calibrations necessary to obtain reliable measurement data for the whole system, it is reasonable to present only the solar loop and storage temperatures. As an example Figure 6 depicts a Monday after a sunny weekend in July, where the buffer was nearly completely loaded. On this Monday the solar process heat system is able to cover the whole thermal energy demand of the facility.

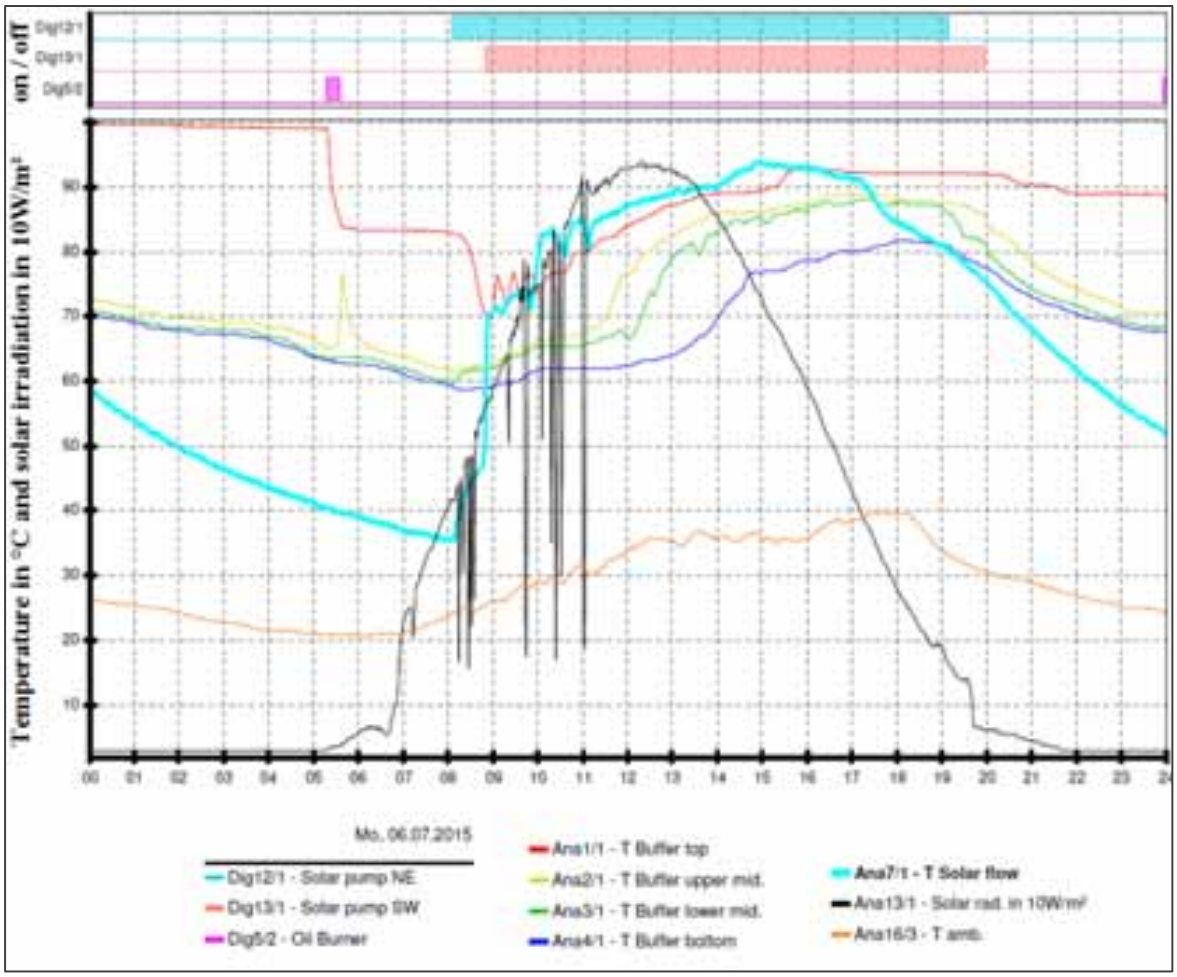

Figure 6: Temperature profiles and solar irradiation on Monday July 6th

This day, July 6th, the heating of the drying chambers and the baths started at 5:20 a.m. using solar heat from the buffer store. In Figure 6 this heating phase in the early morning can be seen with the help of the thin red line dropping from 98°C down to 83°C representing the temperature on the top of the buffer. Shortly before this temperature decrease in the storage caused by the withdrawal of the heat, the oil burners start operation because the temperature in the flow line of the higher temperature loop (not shown in Figure 6) dropped down below 65°C during the weekend.

At 8:05 a.m. the sun started to heat up the collectors and the pump driving the north-east field starts to circulate the solar loop until the temperature in the upper part of the buffer of 70°C was reached at 8:55 a.m. so the solar system started to feed in the heat. At the same time the pump for the south-west orientated field started to operate. This can be seen with the help of the turquoise line, the combined solar flow temperature, whose slope decreases immediately due to the thermal capacities of the south-west field. The maximum temperature of the combined solar flow was reached at 3 p.m. at 94°C. At this time the buffer has a temperature of 77°C at the button and 90°C at the top. After this time the solar system wasn't able to deliver

90°C anymore so it started to feed in the heat into the buffer at different heights and temperature levels until 7 p.m. As the temperature in the solar loop couldn't reach the temperature of the lower part of the storage by circulating the fluid in the collectors, the pumps for the north-east and south-west fields shut off at 7:15 p.m. resp. 8:00 p.m. The latest withdrawal of heat for the processes can be seen at 9:50 p.m. After that the temperature at the top of the storage is only slightly reduced by temperature losses over the next hours. In contrast the temperature in the middle and in the bottom of the tank decreases about 10K caused by the circulation of the medium temperature loop until 10:20 p.m. After that the temperature in the storage is nearly constant until 5:10 a.m. where the heating of the bathes started again.

Another part of the monitoring was the flow distribution in the different collector rows. This is important because if the flow in the rows is non-uniform, there is a risk of partial stagnation and for water based systems with active frost protection also a risk of freezing in single rows. Such poor flow distributions would lead to a reduced solar yield in summer and could cause damages on the collectors in winter. The described system in the metal surface treatment facility consists of 21 collector rows, each with three CPC-collectors. Figure 7 gives an overview on the two collector fields with its 12 collector rows on the north-eastern roof and 9 on the other. The piping was realized according to Tichelmann, so for each row the length of flow and return-flow pipes in sum is of equal length. This kind of piping is used to keep the pressure lost due to the piping the same for each row to ensure an evenly flow in the collectors and therefore a similar flow temperature of the rows.

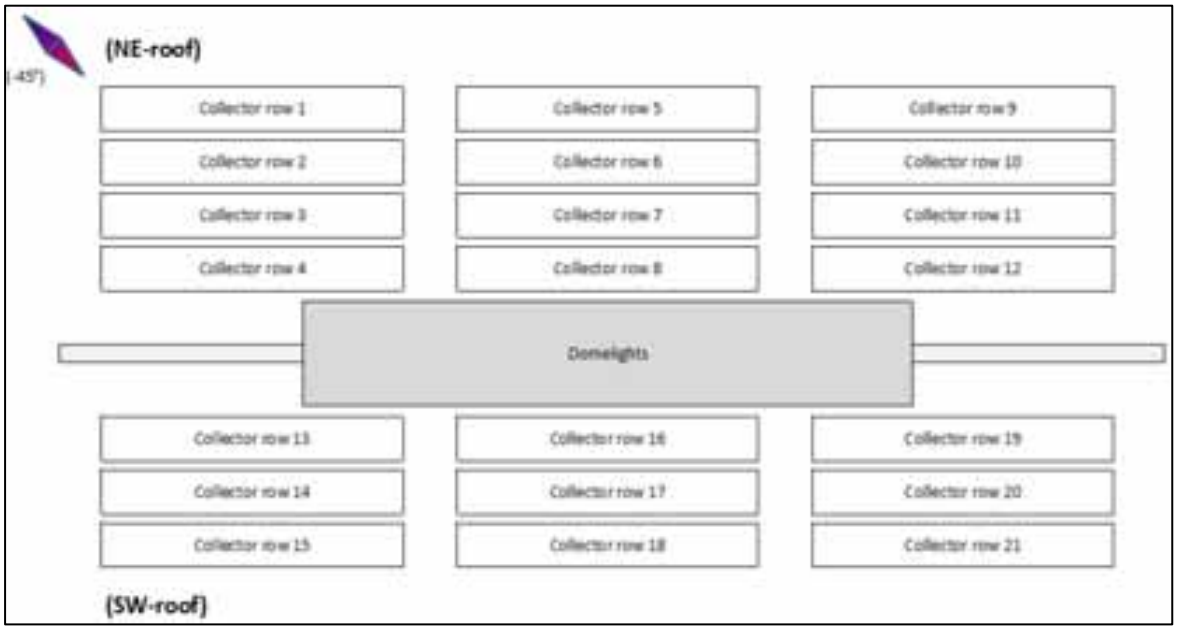

Figure 7: Scheme of the two collector fields with its 21 rows (Holsmölle 2015)

For the detailed monitoring at the end of each row a temperature probe was installed, measuring the flow temperature. In Figure 9 four temperature profiles recorded on September 21st can be seen representing four rows, two out of each field (NE, SW). They were selected because they represent the two collector rows each from the north-east and south-west field that show the largest flow temperature difference during the maximum irradiation on the collector field (760 W/m²) for the selected day.

It can be seen, that for the north-eastern field the largest temperature difference between the 12 rows is 8.2°C at 12:38 p.m. with a maximal flow temperature of 89°C for a single row and nearly half an hour later at 1:10 p.m. the largest difference in the south-west field with its 9 rows occurs with 5.6°C with a maximum temperature of 85°C. These values are reached without any additional valves. Since the working pressure is around 2.5 bars with water as heat transfer fluid, the boiling point amounts to 125...130°C. Since the maximum storage temperature is roughly 100°C and it is directly connected to the solar thermal system, there is only a small risk of stagnation due to this small temperature differences. Until now, stagnation only occurred on weekends or official holidays when the storage was fully charged with temperatures of 90...95°C at the bottom and 98...102°C at the top combined with high solar irradiation.

The breakdowns of the flow temperatures in Figure 9, for example at 12:45 p.m. and around 2:00 p.m., are caused by the controller for the solar pumps, trying to adapt the volume flow in the solar loop to meet the temperature at the top of the buffer. Therefore the volume flow at e.g. 12:45 p.m. is more than doubled from a specific volume flow of 11 l/m²h to 24 l/m²h. As this increase decreases the temperature too much, it must be reduced again. This overshooting according to the adaption of the pump speed could be optimized to obtain more constant flow temperatures.

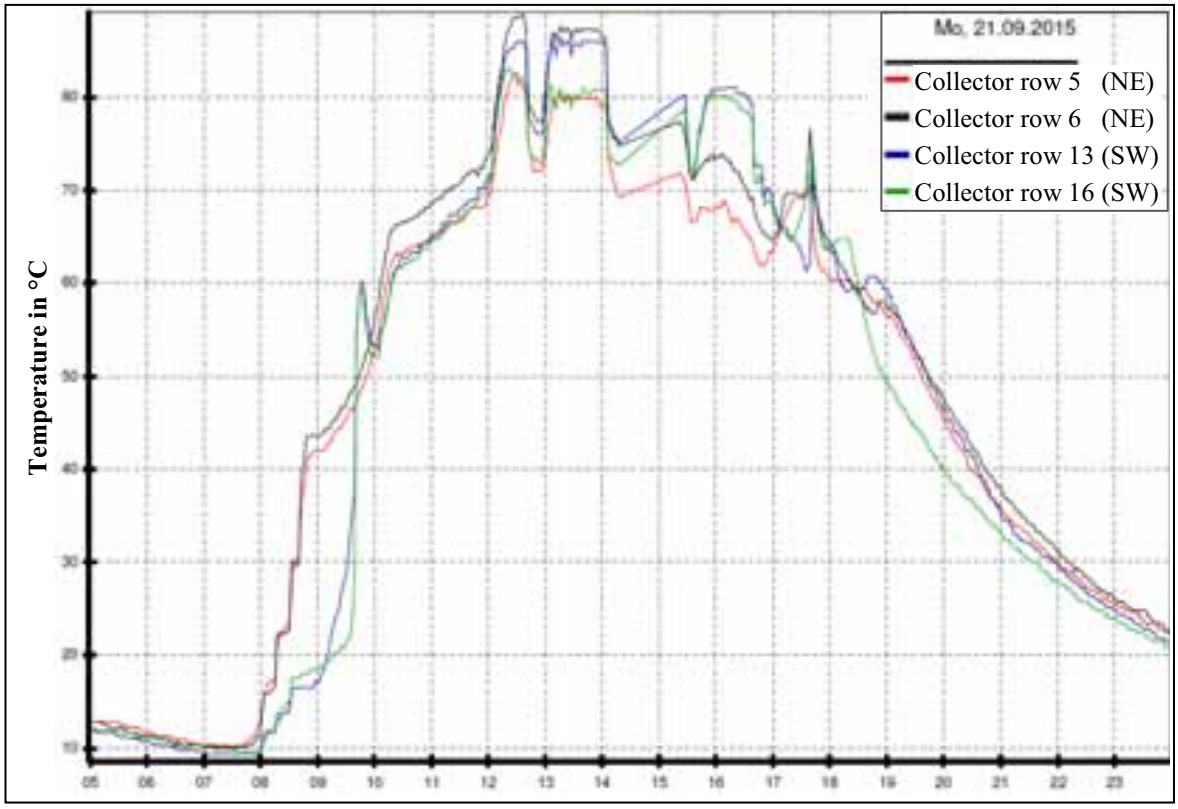

Figure 8: Comparison of the flow temperatures of the four selected collector rows

The first view on the measurement data shown in this section gives a promising first impression according the dimensioning of the solar process heat system avoiding stagnation in summer times and the flow distribution in the collector rows. Only two little optimization measures can be depicted so far: The short start-up of the oil burner shown in Figure 6 and the overshooting of the adaption of the pump speed that can be seen in Figure 9 could be optimized. As soon as the measurement data according the heat consumers and oil burners are validated, energy balances and system efficiencies will be calculated to give an overview on the whole system.

6. Conclusions and outlook

The German market for solar process heat systems is still small but with an increasing trend: Starting from a niche market for eco-minded companies, from August 2012 to August 2015 more than 7,000 m² of collector area are installed and in operation and another 7,000 m² are under construction. Meanwhile the average system size increased about 75% ending up at nearly 70 m² per installation. Although the number of new applications for approval decreased in the first half of 2015 it cannot be seen as a negative trend, because application forms were held back due to the pending novella of the German Market Incentive Programme that became effective in April. Since June the number of submitted application forms increased again, so it is still possible to achieve an increase in applied collector area compared to prior years and therefore another positive growth year for the German solar process heat market.

Although a growing market can be observed, there are still only very few planners and installers dealing with solar process heat systems, so the costs shown Figure 3 are still high due to a lack of competition and sometimes also because of missing expertise. Another fact that keeps the average costs high is the missing

economy of scale due to relatively small systems. Nevertheless 14 systems with average system costs below 500 €/m² including the costs for installation and integration are approved representing a collector area of nearly 3,000 m². These numbers show that there is significant room for cost reduction that will hopefully be exploited with the further development of the German solar process heat market, making this technology more competitive and less funding dependent.

According to the detailed monitoring, three very interesting applications depicted in Table 1 were selected to obtain significant information regarding process integration points, load profiles and combinations of different heat suppliers under real conditions. In addition there is a chance to obtain reliable long term knowledge knowing the monitoring will last for seven years after the start-up of each system. Until now, little validated data from the monitoring of the described system at the metal surface treatment facility could be collected, which is not yet sufficient provide conclusions on the systems performance. Instead, only first impressions on the flow distribution in the collector rows and temperature profiles for a 100% solar fraction working day could be seen. Assessments like the usable solar yield and the overall systems efficiency will be done as soon as the recorded data according to the oil burners and heat consumers are validated.

Abstract

One of the key processes in winemaking is the alcoholic fermentation, an anaerobic process carried out by the metabolic action of a microorganism. During this process, temperature has an important effect on the fermentation kinetics of the process. As the fermentation is an exothermic process most of the wineries use a cooling system composed by mechanical refrigeration cycles and cooling towers in order to control the process temperature during summer and winter, when eventually additional heating might be required. Solar energy could supply both the heating and cooling demands by using an absorption chiller driven by process heat from a solar field. The aim of this study is to assess the thermal performance of the novel system composed by an absorption chiller driven by solar and biomass sources, investigating the behavior of the system in an industrial winemaking process (Miguel Torres Chile). This system consist of a lithium bromide absorption chiller, a flat plate collector solar field and a biomass-burner water heater. The results indicate that the proposed system is able to supply 48% of the cooling demand during the summer and over 90% of the heating demand during the winter

1. Introduction

Chilean winemaking industry is worldwide renowned due to the quality of the wine and the significant annual total production. Regarding the latter, in 2013 Chile was placed as the sixth largest wine producer country and the fourth largest exporter (OIV, 2015). During this year, more than 1.3 million m^3 of wine were produced, which represents an increase of 30% with respect to 2014 (SAG, 2015). In this context, the United States and the United Kingdom are the leading importers of the Chilean wine (Vinos de Chile, 2014). As an globalized industry, the wineries needs to stay at the forefront of green technologies, reducing the carbon footprint associated to their processes, in order to maintain and/or improve the competitiveness of the industry (Christ and Burritt, 2013). In this context, during the last decade, the Chilean winemaking industry has started to adopt several sustainable solutions as an actual measure for increasing sustainability of their processes.

One of the key processes in winemaking is the alcoholic fermentation, since it is when the wine acquire its unique flavor and aroma. The fermentation occurs in the absence of oxygen (anaerobic process) and it is during the metabolic action of yeast cells, that the sugar present in the grapes is converted into ethanol, organic acids and CO_2. The yeast's life cycle and enzymatic activities are highly related to the environment conditions as sugar concentration, pH and temperature, where the latest presents higher impacts the in the process, affecting significantly the quality of the final product (Masneuf-Pomarède et al., 2006; Prusina and Herja, 2008). The

doi:10.18086/swc.2015.10.43 Available at http://proceedings.ises.org

optimal range of temperatures for winemaking fermentations depends on the type of wine, ranging from 15°C for white wines and up to 30°C for red wines (Sablayrolles, 2009). As the fermentation is an exothermic process, the temperature of the wine tends to rise and could surpass the aforementioned temperatures ranges by up to 10°C (Comfort, 2008). If that happens, other microorganism dominates the process (commonly bacteria) affecting the action of the yeast and changing the characteristics of the must. On the other hand, if the temperature is below the lower limit, the yeast's enzymatic activity decreases significantly and the fermentation periods can extend considerably (Calderón and Navascués, 2002). The fermentation typically occurs during the end of summer (March to April in the southern hemisphere). Therefore, wineries need to control the operating temperature of the fermentation vats by using conventional mechanical chillers (Torija et al., 2003). After the fermentation is completed, starts the maceration phase that gives the wine sensory characteristics, and specifically gives red wines its typical pigmentation. Additionally, this process gives wine some of the desire properties for human health, as antioxidants, antibiotics, antiviral, among others (Jackson, 2014). The maceration process occurs at an optimum temperature range between 25 to 30 °C, and it occurs commonly during the winter. Therefore, in order to keep the tanks at that temperature, wineries commonly use gas or diesel heaters.

In this context, aiming to introduce sustainable solutions in the process, several wineries in Europe have implemented absorption chillers in their production process, which allows using residual heat sources to drive the absorption machine and reducing the electricity consumption. For instance, in Austria a 100m^2 solar field was installed to feed a NH_3/H_2O absorption chiller in order to assist the fermentation process and to control and dehumidify the cooling chamber (Zeiler et al., 2000). This scheme has been also use in the sugarcane industry, for the same purposes (namely controlling the temperature of the fermentation) (Magazoni et al., 2010).

The annual global solar irradiation in the winemaking regions of Chile is about 1800 kWh/m^2, according the measurements and estimations reported in the literature (Escobar et al., 2015). This level of global irradiation allows the utilization of almost every solar thermal technology. Hence, the present study proposes a new configuration of an absorption chiller system, driven by solar energy that allow the utilization of the absorption machine as a chiller during the summer and as a heat pump during the winter, attending the energy demands of the production process all over the year. Additionally this system is integrated to a biomass heater were part of burned material is the biomass self-generated by the vineyard, which has high calorific power (Fernández-Puratich et al., 2015).Thus, the present study present the performance assessment of the system proposed through transient numeric simulations, considering the features of a pilot scale plant installed in Chilean central valley.

2. System description

The system considered herein is a pilot installation deployed in an actual industrial environment (Miguel Torres Winery). It considers an 80m^2 flat plate collectors solar field, a 5TR single effect Lithium Bromide absorption chiller and a 150 kW biomass boiler. Besides, the additional components required for integrating both systems to the existing cooling/heating circuits currently existing in the winery, such as pumps and heat exchangers. The original cooling/heating system considers three storage tanks, which one supply cold or heat to the vats at the temperature defined by the operators, depending on the season and the stage of the fermentation or maceration process. Each one of the tanks is kept at different temperature: one tank at low temperature for cooling purposes (7°C), one tank at medium temperature for heating the maceration process (30°C) and one high temperature tank (80°C) for supply heat to the previous one and for cleaning processes.

In order to facilitate the operation during both summer and winter seasons, the system proposed considered a pipe manifold and valves system, so it can operate on two different modes according the demands of the plant. Despite the fact of being a pilot scale (represents 3% of the current cooling capacity), the solar polygeneration system operates integrated directly to the productive process. Hence, in the summer mode (Fig. 1) the solar field supplies the thermal energy for driving the absorption chiller, while the chilling effect is used for reducing the temperature of the water returning from the fermentation vats cooling system. The cooling water for the absorption chiller is supplied from the mid temperature tank, which is kept at 30°C.

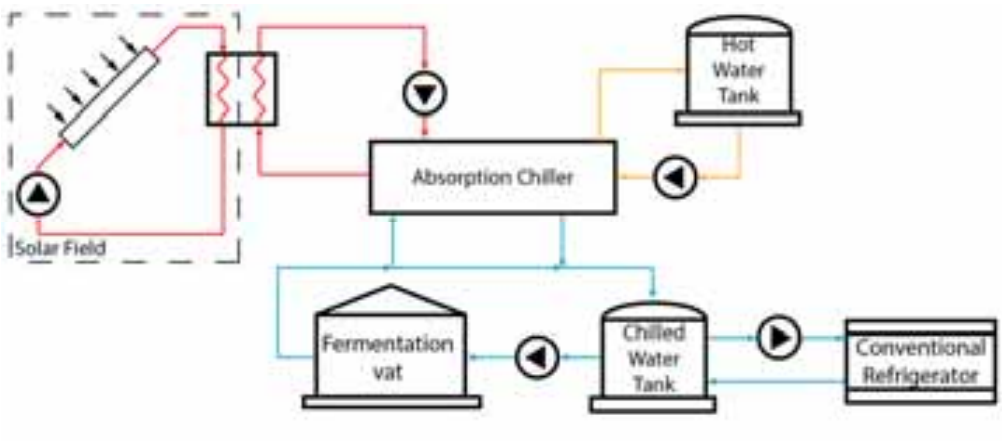

Fig. 1: System configuration in summer mode operation

In the second operation mode, during wintertime (Fig. 2), the solar radiation available is highly reduced, so the heat for driving the absorption chiller comes from the high temperature tank (80°C), which is heated by a biomass water heater. During this operation mode, the energy demanded by the process is heat at 30°C. Therefore, the returning water from the fermentation vats is used as cooling water for the absorption chiller (absorbing heat in the process) and then also absorbs the heat from the solar field. The chilling effect of the absorption machine is received by the low temperature tank, which is kept at 7°C.

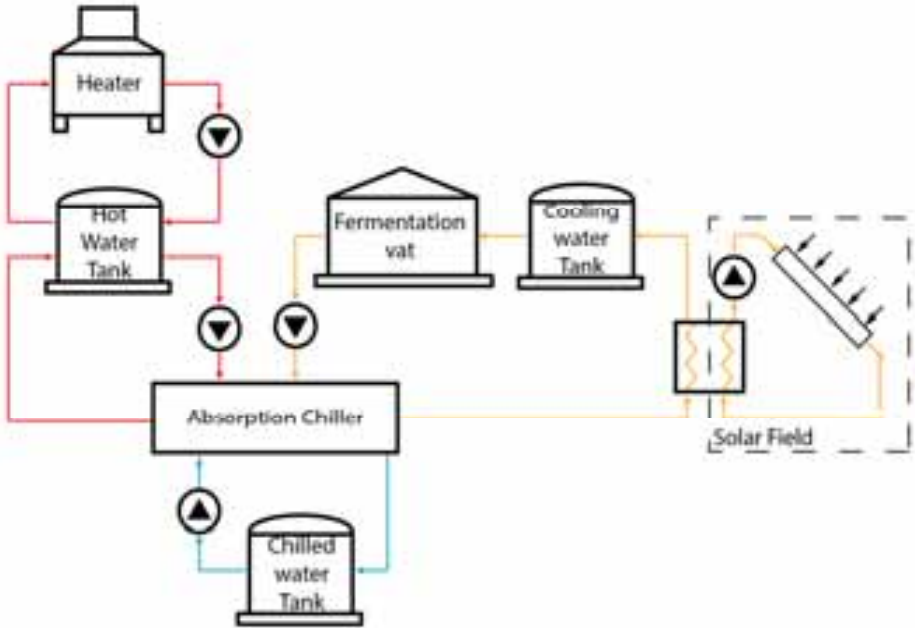

Fig. 2: System configuration in winter mode operation

3. Methodology

The methodology used in this study was adapted from the methodology developed by the Solar Energy Laboratory at the University of Wisconsin-Madison (McMahan et al., 2007). The Transient System Simulation Program (TRNSYS, 2012) was used to carry out the simulations of the complete system, where each component was simulated using a TRNSYS module (Type).

For the case of the absorption chiller, the TRNSYS Type requires the availability of a performance matrix,

which can derived from catalog data. For purpose of this study, a dedicated thermodynamic model was developed using EES software (Klein and Alvarado, 2015), and that model was validated using the datasheet of the actual absorption chiller installed in the winery, manufactured by Yazaki Energy. This approach allows the evaluation of the systems using different component capacities, allowing to optimize the configuration and to analyze the performance of the device, in operating conditions, not necessary reported by the manufactured. Therefore, thermodynamic model was developed using the methodology proposed by (Herold et al., 1996), based on balances of energy, mass and species.

Regarding the solar field, simplified models based on empirical characteristics are commonly employed to simulate transient solar collector performance. In this study, a single glazed flat plate collector was considered, considering a 2nd order incident angle modifier (IAM). Thus, the TRNSYS Type 1b module was employed. This module is based on the quadratic instantaneous efficiency equation, as indicated by (Duffie and Beckman, 2013),

$$\eta_c = F_R(\tau\alpha)_n - F_R U_L \frac{(T_i - T_{amb})}{G_T} - F_R U_{LT} \frac{(T_i - T_{amb})^2}{G_T} \qquad \text{(eq.1)}$$

where G_T is the total incident solar radiation on the collector plane, F_R is the heat removal factor, $(\tau\alpha)_n$ is the effective transmittance-absorptance product normal to the collector, U_L is the overall heat loss coefficient, U_{LT} is the correction factor of overall heat loss coefficient, T_i is the inlet water temperature in the collector, and T_{amb} is the ambient temperature. The collector considered is the FCC-1S, manufactured by Bosch. The efficiency parameters of the collector are $F_R(\tau\alpha)_n$=0.686, $F_R U_L$=3.8622 W/(m^{2}K) and $F_R U_{LT}$=0.01372 W/(m^{2}K^2) (SRCC, 2010). The mass flow rate under the test conditions was $\dot{m}_{test}$=0.0206 kg/(m^{2}s) and the solar collector has an aperture area of 1.94m^2. The solar field comprises 40 collectors in four series of 10 collectors each.

The solar field is coupled to the absorption system by a heat exchanger, which was modelled considering it as a countercurrent heat exchanger with a constant effectiveness of 0.4769, estimated at the nominal operating conditions. The temperatures of the fluids at the inlet of the heat exchanger are evaluated by TRNSYS in every timestamp simulated. Hence, the heat transferred by the solar field determined by a dedicated Type which estimates the heat transfer rate by the following equation

$$\dot{q} = \varepsilon \dot{C}_{min}\left(T_{H,out} - T_{C,in}\right) \qquad \text{(eq.2)}$$

where, $T_{H,out}$ and $T_{C,in}$ are the hot outlet and cold inlet temperatures, respectively. $\dot{C}_{min}$ is the lower capacitance rate of the flows entering the heat exchanger.

The storage tanks allows coupling the production process and the heating/cooling system, ensuring that the fermentation and maceration processes are conducted within the appropriate temperature range. Therefore, a dedicated TRNSYS type was considered in order to take into account the heat fluxes through the storage tanks surfaces as well as the stratification phenomenon. Hence, different heat transfer parameters were defined for the ceiling, floor, and wall of the tanks, depending if it is in contact with air or water, according the methodology proposed by (Kumana & Kathari, 1982).

Within the simulation, the system is controlled by a PID controller, which is simulated using a dedicated TRNSYS Type (type 23). In this simulation the proportional factor (k_p) is considered as 1000, the integral factor (k_i) is assumed as 1, and the derivative response (k_d), which determines the slope of the error is 0.1. Additionally, the mass flow rate is constrained by the operating conditions suggested by the manufacturer of the Absorption Chiller. In this context, the datasheet indicates that the mass flowrate of heat source should be between the 30% and 120% of the nominal flow rate, 1.2 kg/s. On the other hand, both Chilled water and cooling water flow rates are kept at the nominal conditions: 0.77 kg/s and 2.55 kg/s, respectively.

Considering the aforementioned conditions, the system was simulating operating in year period. The summer mode is considered from September to April; meanwhile the heating demand starts in April too. Hence, in April the system operates as summer mode and the heat released by the absorption chiller is used for heating some of the vats. Then, from May to July the system operates in winter mode, as only heating demand is present. Finally, during August neither cooling nor heating is required so the system is shut off.

4. Results

The system was simulated using TRNSYS software, considering the climatic conditions of Curicó, where the actual winery is located. The TMY considered was derived by (GeoModel-Solar, 2015). Figure 3 shows hourly totals of GHI and DNI for each day of the TMY at Curicó (34°5S, 71°1W), where the Miguel Torres Winery is located. Curicó is a small city inserted in an agricultural region where the solar resource variability is high due to its Mediterranean climate with occurrences of cloudy and clear days throughout the year with a strong summer/winter seasonality. Episodes of persistent cloud covers during several days are common during the year although less common in summer. In winter, cloud covers are more common, days are shorter, and radiation levels are highly reduced. The yearly totals are 1791 kWh/m^2 for GHI and 1952 kWh/m^2 for DNI.

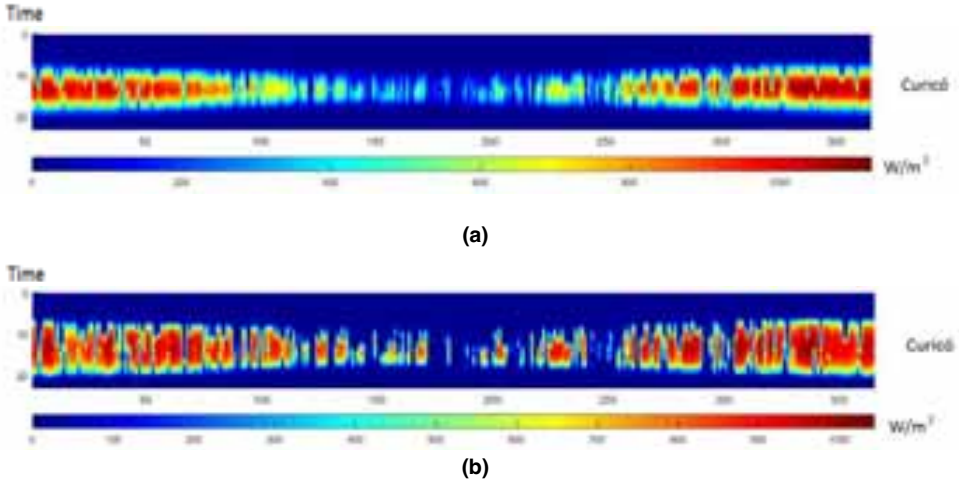

Figure 3: Hourly irradiation values for the TMY in Curicó: a) GHI, and b) DNI.

The irradiation data shows that, although the solar resource available at the site is relatively high in terms of annual totals, it is also very variable during the year and therefore a solar energy conversion system designed to operate throughout the year must include proper thermal storage capacity for acting as a buffer against the resource variability.

Figure 4 shows the hourly temperature profiles in the absorption chiller flows for a clear day in the Summer mode, where CHW corresponds to the chilled water flow temperature, CW is the cooling water flow temperature, and HW is the hot water flow temperature. It can be observed that in a clear sky day the HW inlet temperature decreases after the solar heat supply decreases at the end of the day and then increase after sunrise from approx. 45°C to slightly more than 90°C during the early afternoon when the highest solar resource is available. The HW inlet to the absorption chiller activates the cooling process, and therefore the CHW outlet temperature decreases. In turn, the CW temperature rises in proportion to the CHW temperature decrease. The CHW temperature decrease causes a reduction in the cooling demand at the cold water tank from the mechanical compression chiller, thus producing a net electricity saving. A similar situation is observed for a cloudy sky, although the HW temperature levels increase to a lower maximum level below 80°C. In such a case, the heat supplied to the system is lower, and as it generates a lower cooling effect in the absorption chiller then the electricity saving is also lower.

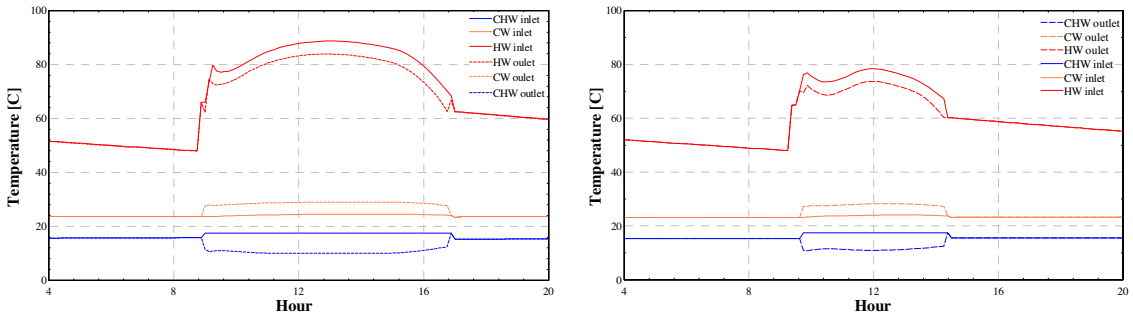

Fig. 4: Hourly temperature profiles in different components of the polygeneration system on summer mode. Left: clear sky day. Right: cloudy sky day.

Figure 5 shows the hourly heat flow rates for the three flows in the absorption chiller: hot, cooling, and chilled water. The absorption chiller is activated by means of automatic pumps that start as the HW temperature reaches a pre-determined level of 75°C. The flow rates during a clear sky day increase after the pumps start, and reach a maximum at the time of highest irradiation, to then remain relatively constant for 2 hours and then decrease until the moment in which the HW temperature reaches a value lower than 75°C when the pumps stop. In total, during a good sunny day in summer the system is capable of operating in solar mode from 9am to 5pm generating savings on LPG and electricity consumption. For a cloudy sky condition (Fig 5 right), the situation is similar to that observed for clear sky, although oscillations on the flow rates are observed as the flow temperatures also oscillate as result of variable solar irradiation. The system is capable of operating for less hours and generates lower savings.

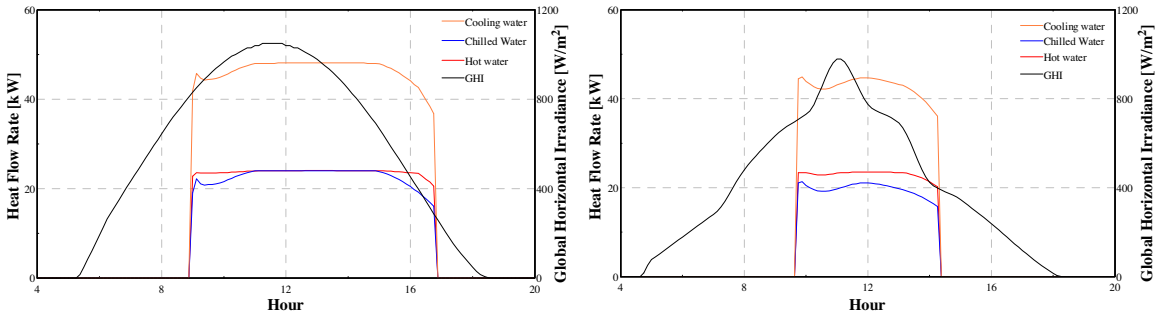

Fig. 5: Hourly heat flow rate profiles in different components of the polygeneration system in summer mode. Left: clear sky day. Right: cloudy sky day.

During winter months, the system operates in the winter mode configuration, in which the mechanical compression chiller is not used, but the absorption machine is operated as a heat pump supplying additional heat to that delivered by the solar field at 30°C water tank, thus generating a net fuel saving on the water heater. Figure 6 shows the heat flow rates in the winter mode for a clear and cloudy sky conditions. It is observed that in clear sky conditions the solar field is able to supply all heat demand, causing that the biomass heater is turn off in 3 to four hours. The operation temperatures during the winter mode operation are stable, since the operation of the absorption machine depend of the temperature of heat medium, which in this case is the biomass heater, set at 95°C. The cooling water temperature is the water returning from the vats, which do not vary significantly and the chilled water temperature is assumed constant at 15°C.

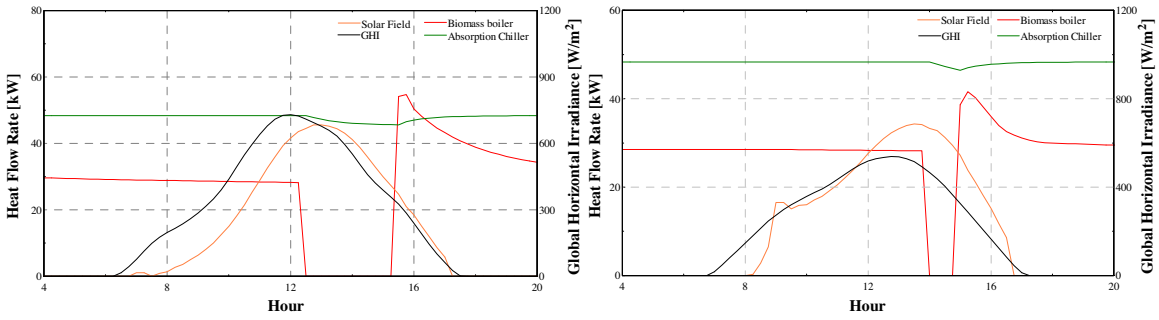

Fig. 6 Winter mode operation during clear sky (left) and cloudy sky (right) conditions. Left: clear sky day. Right: cloudy sky day.

Daily totals of heat and cooling supply for the polygeneration system are summarized in Fig. 7. As observed, the system is able to supply around 150 kWh of cooling per day, during the summer and a similar amount of thermal energy during the winter with peaks over 250 kWh in good days. However, high variability on both the heat and cooling supply are observed, since the system is highly dependent on the availability of solar radiation and the region during most of the year displays a high cloud cover variability as previously indicated. A marked seasonality also exists, with the cooling supply from the absorption chiller being higher during the summer months, decreasing during the fall and then increasing during the spring. The cooling supply from the absorption chiller is directly related to the solar heat production in the collector field. On the other hand, during the winter mode, the biomass boiler is turned on and therefore it is used as a heat source for the absorption chiller, which operates as a heat pump. Because of that, the energy delivered by the system during the winter is higher than the cooling effect supplied during the summer, since it considers the heat released by the absorption machine and the heat delivered by the solar field. Hence, since a significant part of the heat is delivered by the solar field, the high variability on the availability of solar radiation affects significantly the yield of the system.

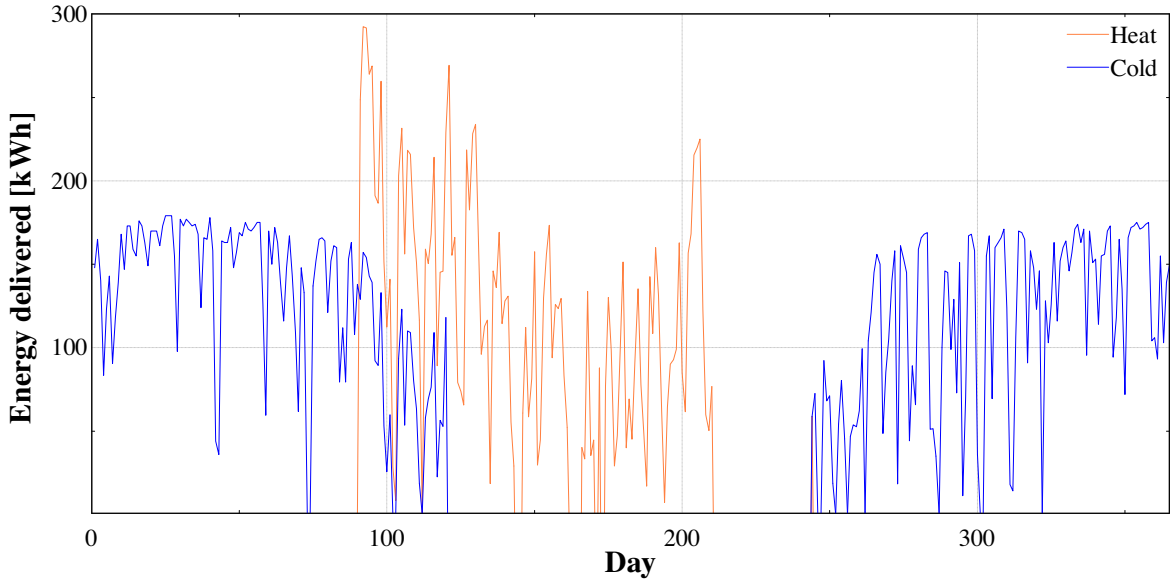

Fig. 7: Thermal energy delivered to processes in a daily basis

The thermal energy displaced by the polygeneration system represents energy savings in terms of the electricity and LPG consumption. The electricity savings are obtained as the absorption chiller cooling supply reduces the cooling supply needed from the compression chiller that keeps the low temperature water tank at 7°C, which is electrically-driven. Therefore, in order to assess the amount of electricity

savings, the simulations consider that the operation of the conventional mechanical compression chiller occurs with a coefficient of performance (COP) of 3, which is a reasonable value for a commercial mechanical compression chiller of the type used in the winery. The combustion efficiency at the gas heater is estimated at 85%, and a net heating value for LPG of 12,100 MJ/kg was considered. With these assumptions, the monthly LPG and electricity savings estimated for to the operation of the pilot system are shown in Fig. 8.

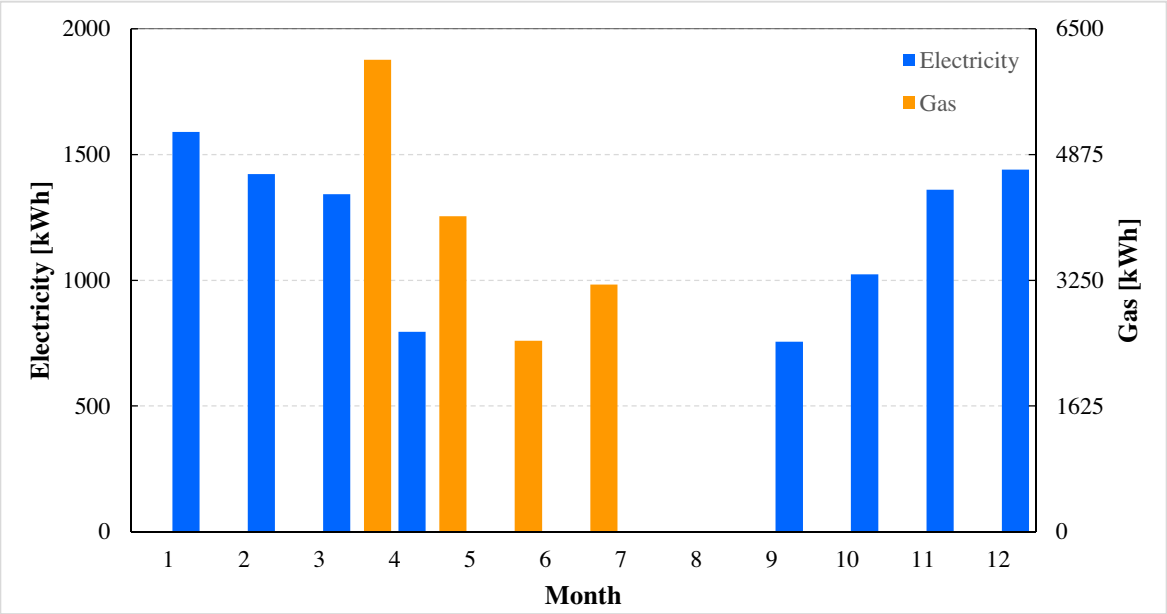

Fig. 8: Energy displaced in a monthly basis

The electricity savings reach a maximum value of 1500 kWh/month for December and January, and then decrease to slightly less than half that value, close to 750kWh/month for April and September, when the solar resource is low at the end of autumn and the beginning of spring. The solar cooling contribution is only a fraction of the available solar heat depending on the typical low value of COP for absorption chillers. From May to August, the heat delivered by the system is due to the solar field and also to the heat released by the absorption chiller. Both contributions results in the LPG savings, which range between approximately 750 kWh/month during June and almost 1400 kWh/month during august. LPG savings are produced when the solar heat is supplied as useful heat to the tank at 30°C. There is a multiplying effect on the LPG savings as the energy conversion chain is as follows: the energy supplied to the 80°C tank is given by the fuel heating value times the boiler efficiency, and then is reduced again by the heat exchanger effectiveness before reaching the 30°C tank. Thus, any heat directly supplied to the 30°C tank as is the solar heat will result in a larger saving of LPG. Additionally, when the operating conditions allow it the hot water delivered by the biomass boiler is used to drive the absorption machine, which released heat at 30°C. The COP of the absorption machine operating as a heat pump is about 1.7, so it allows to amplify the heating effect as a heat transformer, since it absorbs heat from a low temperature source.

5. Conclusions

Winemaking processes utilize heating and cooling systems in order to control the fermentation vat temperatures with variable and seasonal demand. Heating demands are supplied with LPG burning in a water boiler, while cooling demands are met by using a mechanical compression chiller electrically driven. A solar polygeneration system able to supply heat from a solar flat plate collector field and cooling water from an absorption chiller is proposed as an alternative with lower electricity and LPG consumption, thus allowing the winery to decrease its carbon footprint.

The system is composed by a solar field, an absorption chiller, three water tanks of high, medium, and low temperatures, plus the LPG water boilr and the mechanical compression chiller. Two operation modes are proposed for dealing with the high seasonality of both the solar resource and the heating and cooling demands.

The system was simulated using TRNSYS software, complemented with EES routines. Hence, the performance of the system is evaluated in terms of the reduction on the energy consumption, reduction on the carbon footprint and the exergy utilization. The results indicate that the proposed system is able to supply 48% of the cooling demand during the summer and over 90% of the heating demand during the winter, when compared to conventional systems of equivalent capacity of the pilot plant at Miguel Torres winery. This result is even more attractive when the system is scaled up, between 50 to 100% of the current cooling capacity installed at the winery. In addition, an optimization routine has been conducted in order to determine the best operation conditions for the system. Therefore, this hybrid system presents several economic advantages, enabling the possibility of an energetically autonomous winery and presents a vast potential for improvement allowing to produce a zero emissions wine.

Abstract

In the present scenario, heat storage system started to play its role in every field including solar thermal applications. This paper mainly deals with the application of heat storage medium in solar desalination still applications. This research concerns with the theoretical analysis of latent heat energy storage with the incorporation of nano particles. In this research, paraffin wax is selected as the phase change material with 0.3 weight% of nano particles such as TiO_2, CuO and Graphene Oxide. It is found that Graphene Oxide with paraffin gives the higher results comparing with the other nano particles. The thermal conductivity increased to 0.8 W/mK for Graphene Oxide nano composite and the predicted results shows that the productivity is quite high for paraffin wax with Graphene Oxide. Mathematical modeling was carried out and the results indicate that the solar still with phase change material incorporated with nano particles gives higher results than the conventional solar stills and Graphene oxide with paraffin is found to be the best nano particle for solar desalination still application. So it is best to incorporate Graphene oxide nano particle with paraffin for the experimental setup to achieve higher productivity than conventional one.

.

Keywords: Solar still, Nano particles, latent heat energy storage, paraffin, productivity

1. Introduction

Water scarcity is a major issue that affects the world. By the year 2025, it is estimated that 1.8 billion people will be affected by water scarcity, and 2/3 of the world will experience water-stressed conditions, eventually 1/2 of the world will experience high water stress by the year 2030 (72% people will be in water stress). Presently, African regions are experiencing high water stress up to 31 %, followed by Asia, America and Europe with 25%, 7% and 2% of water stress respectively [2][3][4]. Desalination has a growing role to play in meeting the demands for fresh water.

There are various methods of desalinating sea- and brackish water. The methods includes distillation, ion exchange, membrane distillation, freezing desalination, geo-thermal desalination, solar desalination, methane hydrate crystallization, high grade water recycling, and seawater greenhouse technology [5]. The energy for desalination can be obtained from fossil fuel or alternate energy sources. Among various methods of solar desalination, solar desalination using solar stills has several advantages including simplicity, economic, ease of maintenance, and low environmental impact. However, it also disadvantages, in particular low productivity, hindering the commercial uptake of desalination based on solar stills.

In single slope solar still with heat storage, there will be heat energy storage material for absorbing and storing the heat during the peak sunshine hours and it will emit the absorbed heat when the radiation decreases, such that the temperature will be maintained inside the system. Rahim formulated a method to store the heat energy in horizontal solar desalination still. It is about 47.2% efficient during nocturnal period and no external source is required to store and recover heat [6]. Salah et al predicted the thermal performance of solar still with various absorbing materials such as coated and uncoated wiry and found that uncoated sponge has highest water collection rate [7].

doi:10.18086/swc.2015.10.44 Available at http://proceedings.ises.org

Omar et al conducted the experiment in solar still with energy storage material beneath the basin and inferred that it enhances both the productivity and efficiency of the still. It is also found that melting point of phase change material also plays a vital role in productivity yield at night [8]. Dsilva et al conducted the experiment in single slope single basin solar still with roof heat and fornd that the system gives productivity till 8 o clock in the night [9]. The incorporation of TiO_2 Nano particles with stearic acid phase change material by Harikrishnan et al, the result ended with the findings that, thermal stability and thermal conductivity of phase change material is increased with the incorporation of Nano particle [10] [11]. Additionally the research is extended to the incorporation of CuO - Nano particle with Oleic acid for cooling application and ended with the findings of improvement in cooling properties [12] [13].
The inclination angle of the glass affects the parameters such as yield rate, instantaneous efficiency. Different researchers, however, reached different conclusions about the optimal inclination. Tiwari et al made an analysis by varying inclination angle for condensing cover and also done thermal modelling of passive type solar still. It is inferred that in general, 15^o inclination angle provides maximum yield rate compared with other inclination angle. [14].Muhammed et al designed a single basin solar still for south western arid region of Pakistan and concluded that the optimum glass cover angle is 33.3 ^{o} for Islamabad [15]. Rahul Dev et al conducted experiments in solar desalination still with various inclination angles for attaining the maximum instantaneous efficiency and validated the experimental observation with modelled equation and he found that the inclination angle with 45^0 gives the maximum instantaneous efficiency [16].
The double basin solar still gives more productivity during the cooling period whereas single basin solar still gives more productivity during heating period. Elango et al performed an experiment to analyse the relation between water depth and productivity in double basin solar still. The result ends with the conclusion that double basin solar still yields more distillate only when the water depth is maintained at 1 cm [17].Hitesh conducted the experiment in double basin solar still with vacuum tube and black gravel granite attached to it. The result infers that when the still is coupled with vacuum tube and granite, the system gives higher productivity, than they are coupled individually [18]. The listed literature are some of the passive type solar stills, the active type solar stills includes the addition of collector, concentrator, air heaters, condensers etc.

The use of a collector increases the heat input to the still; therefore it may also be necessary to enhance the heat output to achieve condensation. This has been done using a humidifying tower and condensing cover. Farhad et al analysed exergy and energy for solar desalination system with a flat-plate solar collector by both experimentally and theoretically and found that there was a decrease in exergy efficiency by increasing the length of the humidification tower and that the exergy efficiency increased with decrease in inlet air temperature and tower diameter [19].Dimri conducted an experiment with effect of condensing cover with the yield of active solar still and inferred that productivity was directly proportional to the thermal conductivity of material ofthe condensing cover. Thus copper results in greater yield compared to glass and plastic since it has higher thermal conductivity [20].Tiwari et al made an analysis to relate instantaneous thermal efficiency and collector area. In this research the energy balance for each component was considered and the research ended with the formulation of equations for the various components of the still [21]. The coupling of an air heater to the solar still increased the water temperature in the basin and thus promoted the evaporation rate. Sampathkumar et al carried out a study on various active solar stillsand found that the air heater increased productivity by up to 70% [22]. This productivity is high compared with that of stills coupled with flat plate collectors, evacuated tube collectors and concentrators. Various design modifications such as heat storage, and water spraying have been done on solar stills, with air heater to achieve higher productivity. To investigate the effect of heat storage, Abdulha performed an experiment in stepped solar still solar air heater and latent heat energy storage and discussed the method for increasing the performance by adding aluminium filling. It was found that the integration gave 53% more productivity than conventional set up [23].

In active solar stills, solar collectors can be used to boost performance – including flat plate, evacuated tube, and flat plate collectors. Solar ponds and air heaters have also been used. Air heaters are effective combined with energy storage and with water spraying arrangements.

2. Mathematical Modeling

2.1 Assumptions

A solar still utilizes the heat from the sun to heat the water inside a basin. Hence evaporation takes place and the condensate is trapped by the glass cover at the top of the basin and collected through the distillate collector. The base of the still is covered by insulating material to avoid the heat loss. The productivity is about 2–5 L/m^2.day, thus more than 1 m^2 is required to supply the needs of one person. Fig. 1 gives the pictorial representation of solar still in x-y-z coordinate where as fig. 2 represents the layer wise identification of various components of solar still namely Phase change material, water, air, glass and air layers in x-y coordinate. The whole work has been carried in Institute for Energy Studies, Anna University Chennai, India and Aston University, UK.

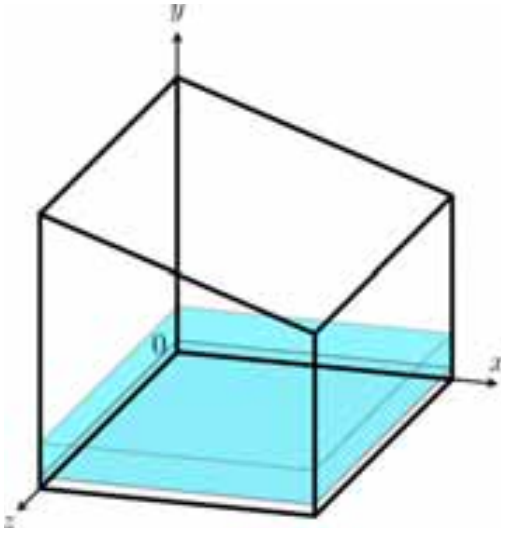

Fig. 1

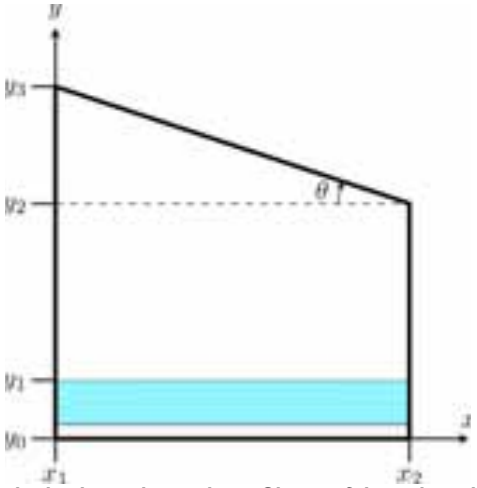

Figure 2: Solar still placed on the horizontal *z*−*x* plane. Shape of the solar still is monotonic in *z* direction.

The following assumptions are made,

a. It is assumed that the shape of the solar still is monotonic un z direction.
b. Energy input is based on only the solar energy (radiation).
c. Intensity of the solar radiation (I) and the ambient temperature (T_a) are controlling the system.
d. I changes gradually in time, I = I (tau), dI/dtau~0.
e. Temperature for water (T_w) and PCM (T_{PCM}) are same. There is no distribution for T_w and T_{PCM}, but T_w and T_{PCM} are function of time (tau). (I and T_a, implicitly, because I=I(tau) and T_a=T_a(tau)).
f. Total energy input to solar still per day, I' * area * time, yields the water production per day (via evaporation and) via condensation of water.

g. Heat capacities of basin liner and insulating material are negligible compared to those for the basin water and phase change material (PCM).
h. The system is vapour tight and the side losses are negligible.
i. PCM and basin liner are in good contact.

Using the above mentioned assumptions the mathematical modeling was carried out using vorticity transport equation, the energy equation and diffusion equation and the analysis has been conducted with respect to Chennai, India climatic condition taking the input from weather data in U.S Department of Energy. The following table represents the data taken for analysis from U.S Department of Energy.

2.2 Mathematical formulation

Two dimensional flow in the vertical (x-y) plane is studied for an incompressible Newtonian Boussinesq fluid. It is convenient to introduce the stream function ψ so that continuity equation is satisfied automatically, because

$$u=\frac{\partial \psi}{\partial y}, \quad v=-\frac{\partial \psi}{\partial x}. \qquad \text{(eq.1)}$$

The governing equation is the vorticity transport equation, the energy equation and diffusion equation for absolute humidity as follow:

$$\frac{\partial \omega}{\partial t}= \frac{\partial \psi}{\partial x}\frac{\partial \omega}{\partial y}-\frac{\partial \psi}{\partial y}\frac{\partial \omega}{\partial x}+\nu\left(\frac{\partial^2 \omega}{\partial x^2}+\frac{\partial \omega}{\partial y^2}\right)+\beta\frac{\partial T}{\partial x}, \quad \text{(eq.2)}$$

$$\frac{\partial T}{\partial t}= \frac{\partial \psi}{\partial x}\frac{\partial T}{\partial y}-\frac{\partial \psi}{\partial y}\frac{\partial T}{\partial x}+\frac{\lambda}{\varrho C_p}\left(\frac{\partial^2 T}{\partial x^2}+\frac{\partial T}{\partial y^2}\right), \quad \text{(eq.3)}$$

$$\frac{\partial e}{\partial t}= \frac{\partial \psi}{\partial x}\frac{\partial e}{\partial y}-\frac{\partial \psi}{\partial y}\frac{\partial e}{\partial x}+\kappa vap\left(\frac{\partial^2 e}{\partial x^2}+\frac{\partial e}{\partial y^2}\right), \quad \text{(eq.4)}$$

where z component of the vorticity (ω) is written in

$$\omega=-\left(\frac{\partial^2 \psi}{\partial x^2}+\frac{\partial \psi}{\partial y^2}\right). \quad \text{(eq.5)}$$

Transformation for general coordinates

Transformation of coordinates system: x=x(ξ,η), y=y(ξ,η).

$$\frac{\partial x}{\partial x}=\frac{1}{J}\left(\frac{\partial y}{\partial \eta}\frac{\partial x}{\partial \xi}-\frac{\partial y}{\partial \xi}\frac{\partial x}{\partial \eta}\right), \quad \frac{\partial x}{\partial y}=\frac{1}{J}\left(\frac{\partial x}{\partial \xi}\frac{\partial x}{\partial \eta}-\frac{\partial x}{\partial \eta}\frac{\partial x}{\partial \xi}\right). \quad \text{(eq.6)}$$

$$\frac{\partial^2 x}{\partial x^2}+\frac{\partial^2 x}{\partial y^2}=\frac{1}{J^2}\left(D+C_\xi\frac{\partial x}{\partial \xi}+C_\eta\frac{\partial x}{\partial \eta}\right). \quad \text{(eq.7)}$$

Herein

$$J=\frac{\partial x}{\partial \xi}\frac{\partial y}{\partial \eta}-\frac{\partial x}{\partial \eta}\frac{\partial y}{\partial \xi}, \quad C_\xi=\frac{1}{J}\left[\frac{\partial x}{\partial \eta}D\,(y)-\frac{\partial y}{\partial \eta}D\,(x)\right], \quad C_\eta=\frac{1}{J}\left[\frac{\partial y}{\partial \xi}D\,(x)-\frac{\partial x}{\partial \xi}D\,(y)\right]. \quad \text{(eq.8)}$$

A linear operator D is defined as

$$D\equiv C_{\xi\xi}\frac{\partial^2 y}{\partial \xi^2}-2C_{\xi\eta}\frac{\partial^2 y}{\partial \xi \partial \eta}+C_{\eta\eta}\frac{\partial^2 y}{\partial \eta^2}, \quad \text{(eq.9)}$$

where

$$C_{\xi\xi}=\left(\frac{\partial x}{\partial \eta}\right)^2+\left(\frac{\partial y}{\partial \eta}\right)^2, \quad C_{\xi\eta}=\frac{\partial x}{\partial \xi}\frac{\partial x}{\partial \eta}+\frac{\partial y}{\partial \xi}\frac{\partial y}{\partial \eta}, \quad C_{\eta\eta}=\left(\frac{\partial x}{\partial \xi}\right)^2+\left(\frac{\partial y}{\partial \xi}\right)^2. \quad \text{(eq.10)}$$

Tetragon $(x_1,y_1)-(x_2,y_1)-(x_2,y_2)-(x_1,y_3)-(x_1,y_1)$ (Figure: 1 and 2) in physical coordinates (x,y) is transformed onto/into a square $|\xi|\le 1$ and $|\eta|\le 1$ in the computational coordinates (ξ,η):

$$x=\frac{\xi+1}{2}\left(x_2-x_1\right)+x_1=x(\xi), \quad \text{(eq.11)}$$

$$y=\frac{\eta+1}{2}\left[\frac{\xi+1}{2}\left(y_2-y_3\right)+\left(y_3-y_1\right)\right]+y_1=y(\xi,\eta). \quad \text{(eq.12)}$$

Then,

$$\frac{\partial x}{\partial \xi}=\frac{x_2-x_1}{2}, \quad \text{(eq.13)}$$

$$\frac{\partial y}{\partial \xi}=\frac{\eta+1}{4}\left(y_2-y_3\right), \quad \text{(eq.14)}$$

$$\frac{\partial y}{\partial \eta}=\frac{\xi+1}{4}\left(y_2-y_3\right)+\frac{1}{2}\left(y_3-y_1\right), \quad \text{(eq.15)}$$

$$\frac{\partial^2 y}{\partial \xi \partial \eta} = \frac{y_2 - y_3}{4}, \quad \text{(eq.16)}$$

$$\frac{\partial x}{\partial \eta} = \frac{\partial^2 x}{\partial \xi^2} = \frac{\partial^2 x}{\partial \xi \eta} = \frac{\partial^2 x}{\partial \eta^2} = \frac{\partial^2 y}{\partial \xi^2} = \frac{\partial^2 y}{\partial \eta^2} = 0. \quad \text{(eq.17)}$$

$$\frac{\partial x}{\partial x} = \frac{1}{J}\left(\frac{\partial y}{\partial \eta}\frac{\partial x}{\partial \xi} - \frac{\partial y}{\partial \xi}\frac{\partial x}{\partial \eta}\right), \quad \text{(eq.18)}$$

$$\frac{\partial x}{\partial y} = \frac{1}{J}\left(\frac{\partial x}{\partial \xi}\frac{\partial x}{\partial \eta}\right), \quad \text{(eq.19)}$$

$$\frac{\partial^2 x}{\partial x^2} + \frac{\partial^2 x}{\partial y^2} = \frac{1}{J^2}\left(C_{\xi\xi}\frac{\partial^2 x}{\partial \xi^2} - 2C_{\xi\eta}\frac{\partial^2 x}{\partial \xi \partial \eta} + C_{\eta\eta}\frac{\partial^2 x}{\partial \eta^2} + C_{\xi}\frac{\partial x}{\partial \xi} + C_{\eta}\frac{\partial x}{\partial \eta}\right). \quad \text{(eq.20)}$$

Here,

$$J = \frac{\partial x}{\partial \xi}\frac{\partial y}{\partial \eta}, \quad \text{(eq.21)}$$

$$C_{\xi\xi} = \left(\frac{\partial y}{\partial \eta}\right)^2, \quad C_{\xi\eta} = \frac{\partial y}{\partial \xi}\frac{\partial y}{\partial \eta}, \quad C_{\eta\eta} = \left(\frac{\partial x}{\partial \xi}\right)^2 + \left(\frac{\partial y}{\partial \xi}\right)^2, \quad \text{(eq.22)}$$

$$C_{\xi} = 0, \quad C_{\eta} = \frac{1}{J}\left(-\frac{\partial x}{\partial \xi}Dy\right), \quad Dx = 0, \quad Dy = -2\beta\frac{\partial^2 y}{\partial \xi \partial \eta}. \quad \text{(eq.23)}$$

$$\frac{\partial x}{\partial \xi} = \frac{x_2 - x_1}{2}, \quad \frac{\partial x}{\partial \eta} = 0, \quad \text{(eq.24)}$$

$$\frac{\partial y}{\partial \xi} = \frac{\eta + 1}{4}\left(y_3 - y_1\right), \quad \frac{\partial y}{\partial \eta} = \frac{1}{4}\left[\xi\left(y_3 - y_1\right) + \left(-2y_1 + y_2 + y_3\right)\right], \quad \text{(eq.25)}$$

$$\frac{\partial^2 y}{\partial \xi \partial \eta} = \frac{y_3 - y_1}{4}. \quad \text{(eq.26)}$$

3. Analysis, Results and Discussion

The analyses are carried out with the codes using FORTRAN software compiler in Aston University, UK. The following results are made

The temperature profile for different layers like Phase change material (PCM), basin liner, water, air, glass, bulk are shown in figure 3 with respect to height of the still. From the figure 3, the water temperature and the basin temperature are more or less equal and the PCM temperature is found to be slightly high compared to basin temperature. Melting point of PCM plays a vital role in the selection of PCM with various applications. This gives the different melting and solidification characteristics of the PCM. Here we have incorporated Nano particles to enhance the heat transfer rate and thermal conductivity of the PCM with the insulation in side and bottom.

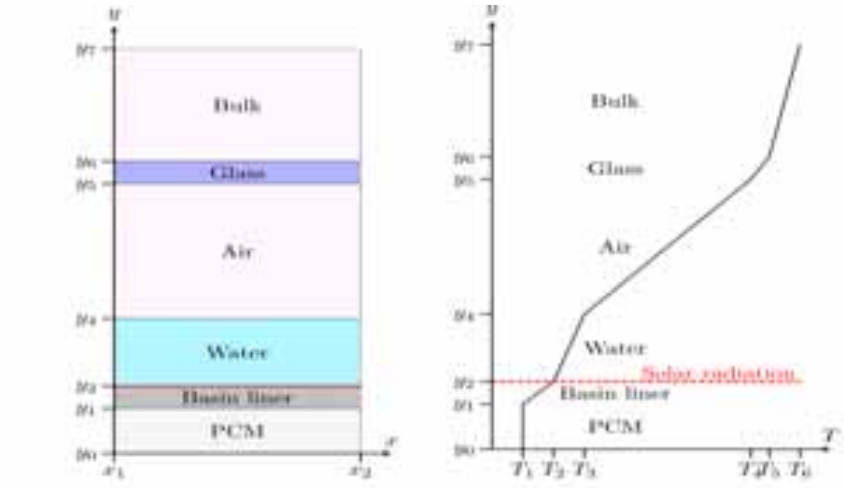

Fig : 3 Temperature profile for various layer

The work carried out with various ambient temperatures such as 20, 30, 40 C and the humidity with 0.1 and 0.2. The results for variation of water temperature and productivity with respect to solar radiation are shown in figure 4 and 5.

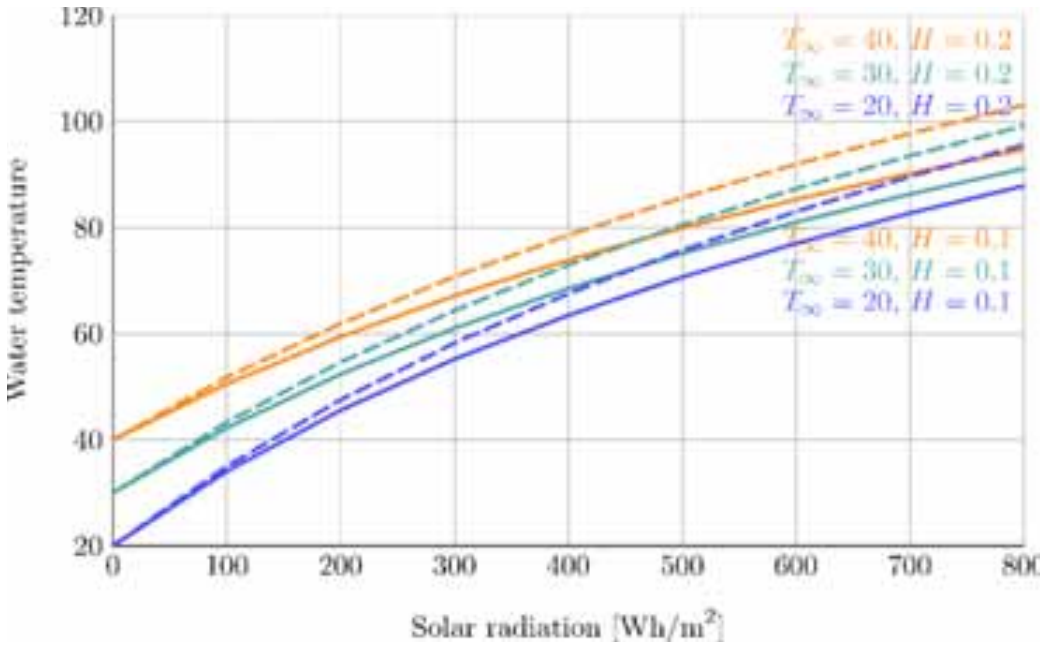

Fig:4 Water temperature Vs Solar radiation

In figure 4, the dotted line represents the water temperature variation with the relative humidity of 10% and the normal line represents the water temperature variation with the humidity of 20% and it indicates that the temperature increases with the decrease in relative humidity and decrease in moisture content. And temperature decreases with the increase in relative humidity and moisture content. From the graph, it is found that the ambient temperature and water temperature are directly proportional to each other.

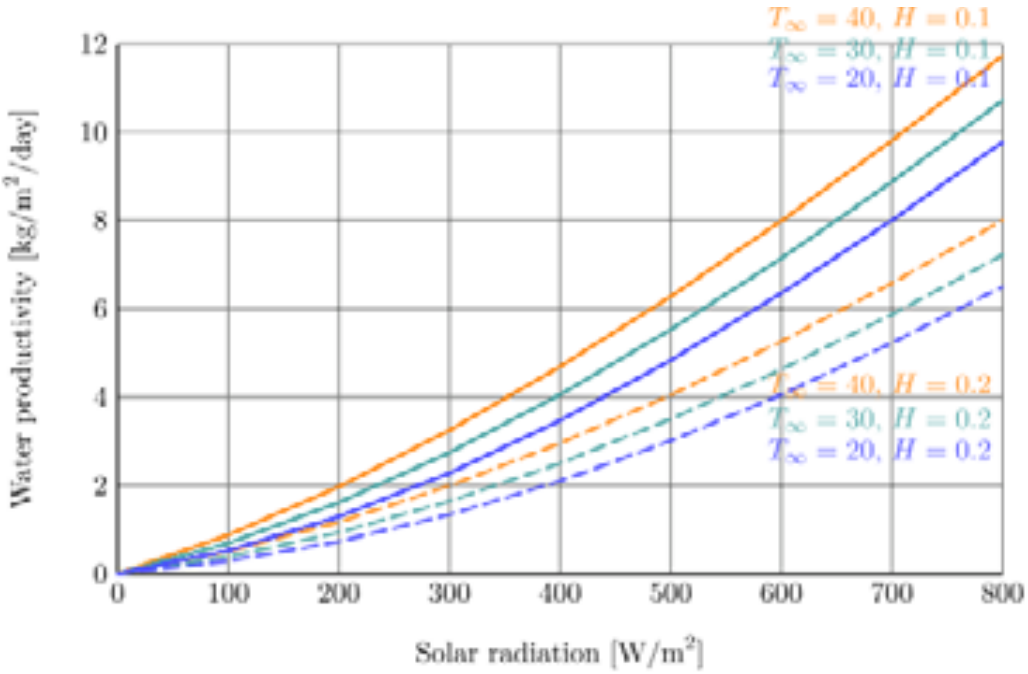

Fig .5: Water productivity Vs Solar radiation

Figure 5 represents the variation of water productivity with respect to solar radiation, Dotted line and normal line represents the variation of 10, 20% relative humidity with different ambient temperatures respectively. As the solar radiation increases, the water productivity increases gradually and there is a huge difference between 10% and 20% relative humidity. The productivity with 20% relative humidity at 40^{o}C ambient temperature was around 8 kg/m^2/day, whereas the productivity with 10% relative humidity at 40^{o}C ambient temperature was around 11.5 kg/m^2/day. The productivity is found to be comparably high for still with phase change material with nano particles, whereas the conventional still yields only 5 kg/m^2/day [9][14]. Our predicted result yields the productivity twice that of the conventional still.

From the graph, it is found that the peak productivity can be achieved during intense solar radiation, and hence the hourly productivity yield can be increased. From the single-effect and multi-effect solar stills, multi-effect solar still gives higher productivity than single-effect still. Now from the modeling result, it is quite clear that the single effect still with phase change material incorporated with nano particles yields the productivity equal to multi-effect solar still.

4. **Conclusion**.

The research aims to incorporate nano particles with phase change material for solar desalination applications. As a part, this paper provides the result of the mathematical modeling done on solar still using phase change material incorporated with nano particles. From the results, it is concluded that the addition of nano particles with phase change material enhances the productivity and the daily yield is achieved up to 12 kg/m^2/day which is quite high than the productivity of other conventional stills. So, from this paper, it is evident that the solar still using phase change materials incorporated with nano particles is superior to other conventional solar stills in all aspects. Therefore further experimental tests and optimization can be carried out as present mathematical modeling gives the concrete evidence for increased performance.

Nomenclature

A_c	Collector area, m^2
C_p	Specific heat, $Jkg^{-1}K^{-1}$
D_h	Hydraulic diameter, m
f	Friction factor, Non dimension
I	Intensity of radiation, Wm^{-2}
k	Thermal conductivity, $W\ m^{-1}K^{-1}$
k_i	Thermal conductivity of insulation material $W\ m^{-1}K^{-1}$
k_w	Thermal conductivity of the tube wall,$W\ m^{-1}K^{-1}$
L	Length of the tube, m
m	mass flow rate, kgs^{-1}
N	Number of tube, Non dimension
Nu	Nusselt number, Non dimension
Pr	Prandtl number, Non dimension
Re	Reynolds number, Non dimension
Q_{ab}	Heat absorbed, W
T_{out}	Outlet temperature of the collector, K
T_{in}	Inlet temperature of the collector, K
T_a	Atmospheric temperature, K
V	Velocity, ms^{-1}

Greek Symbol

ρ	Density, kgm^{-3}
μ	Dynamic viscosity, Nsm^{-2}
μ_w	Dynamic viscosity of tube wall, Nsm^{-2}
η	Efficiency, %

Suffix

PT	Plain tube
RT	Rod as extended surface
TT	Tube as extended surface

DESIGN, CONSTRUCTION AND TESTING OF SOLAR WATER DISTILLATION UNIT FOR RURAL WATER PURIFICATION IN NIGERIA

SAFYANU B. DANJUMA

ABUBAKAR TATARI ALI POLYTECHNIC, BAUCHI. (NIGERIA)

Abstract

This paper presents the design, testing and construction of solar water distillation unit for rural water purification in Nigeria. The construction is done purely with local and affordable materials, for rural dwellers of RafinTambari village of Bauchi, located at Latitude 10.4°N and longitude of 9.5°E. The design consists of twelve stills arrange in two rows of six, with an area of $2m^2$ for each solar still attached together. Over-head storage tank of 2000litres capacity for supplying contaminated water from the stream to the solar still, 500litre of storage tank for collecting distilled water and an output device for flushing out waste product out of the solar still. Ambient and operating conditions of the plant are assumed, the same for the twelve solar still. The overall yield at different water depth of 20, 40, 60mm were 5010ml/m^2.hr, 4465ml/m^2hr and 3776ml/$m.^2$hr respectively and the efficiency of the system at different water depth of 20, 40, 60mm were 50.1%, 44.6% and 37.7% respectively. The prevailing operating conditions were: Ambient temperature; 41°C, solar radiation; 1300W/m^2 and wind speed; 3.08m/s. Microbial load analysis of the water before and after distillations were carried out and the following were found: PH of water; 8.2, TDS of water; 100 and 10 mg/l and E.coli; 120 and 20cfu/100ml. The distilled water was certified safe and potable for human consumption

Keywords: Design, Construction, Testing, Water Analysis, Solar Distillation, and Distillate Yield

1. Introduction

Water is the basic necessity for human along with food and air. There is almost no water left on Earth that is safe to drink without purification. Only 1% of Earth's water is in a fresh, liquid state, and nearly all of this is polluted by both diseases and toxic chemicals (Alpesh et al, 2011). For this reason, purification of water supplies is extremely important. Moreover, typical purification systems are easily damaged or compromised by disasters, natural or otherwise. This results in very challenging situations that may cause for such diseases and toxic chemicals to be present in the untreated water. The need to find out the solutions to these problems needs not to be over emphasis. Fortunately there is a solution to these problems. It is a technology that is not only capable of removing a very wide variety of contaminants in just one step, but is simple, cost-effective, and environmentally friendly, that is the use of solar energy.

In addition, there are many locations where stream water is abundant but portable water is not available. Pure water is also useful for batteries and in hospitals or schools.

Green house solar still generally imitates a part of the natural hydrologic cycle in that the Sun's rays heat the saline water so that the production of water vapor (humidification) increases (Chabi, 2000). Horizontal concentric tube solar still utilizes air as working medium. Air carries the water vapor from the annular space between the clear outer and the inner tube through the inside of the inner tube where the water vapor condenses and gives up its heat of condensation directly to the seawater being sprayed on the outer surface of the inner tube. The water vapor will have the preferential tendency to condense on the inside surface of the clear outer tube (Atagunduz, 2001). Cylindrical parabolic type solar still has a parabolic reflector; the reflector is used to concentrate the incident solar radiation on the black outside surface of a tray located on the focal line of the reflector (Minasian et al, 1997).
The aim and objective of this paper is to design, construction and testing of solar water distillation unit for rural water purification and improving the efficiency and productivity of the distilled water.
A solar powered distillation device contain three basic components: a basin in which the contaminated water is contained, a surface above said feed water for the water vapor to condense onto (i.e. a glass pane), and a catch

doi:10.18086/swc.2015.10.45 Available at http://proceedings.ises.org

basin for the distilled water to drain into. During operation of the distiller, solar energy is collected by the feed water. When enough energy is absorbed by the water, the water undergoes a phase change. The water vapors then rises and comes into contact with the cooler transparent, inclined surface. Here the vapor once again goes through a phase change from vapor back to liquid. The water then condenses and runs off the transparent inclined surface into a collection bin. The distillation process rids the contaminated water of any impurities and most commonly found chemical contaminants within the environment. These contaminants are left behind in the basin (Nafey*et al*, 2000). This process is illustrated in Figure 1 below.

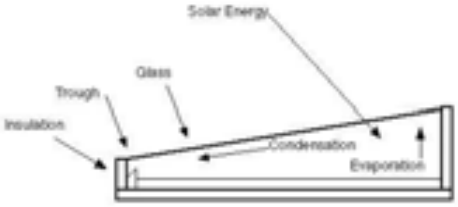

Fig. 1: Basic Solar Powered Water Distiller (Nafey*et al*, 2000).

2.0 Methodology

2.1 Principle of Solar Still Pilot Plant Design and Operation

The solar still pilot plant consists of asymmetrical solar stills arranged in two rows and each of the rows is made of six solar stills, which comprises of total of twelve solar stills. Dimension of 2m², with inclination of 10.4° (base on latitude of Bauchi), orientation of north to south and the same for the entire twelve solar stills.

The solar still consist of three basic components; (a) Basin made of galvanized iron and painted black in which the contaminated water is contained. (b) A glass pane 4mm thickness which covers the solar still and on which vapour condenses. (c) A catch basin, which collects the distilled water into the storage tank (500L).

Each of the stills has an inlet where brackish or contaminated water is fed into the still from the stream via over-head tank (2000L), mark of water depth level of 20mm, 40mm and 60mm and a drain where deposited waste water from the still is flushed after long use. A storage tank (2000L) into which distilled water is pumped from the 500L tank.

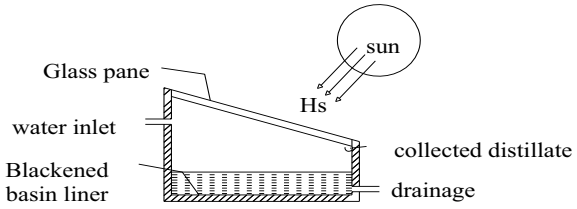

Fig. 2: Conventional solar still (Alkasim, 2012)

3.0 Energy and Mass Balance Method

The performance of a solar still is generally expressed in term of the quantity of water evaporated per unit area of the basin in one day (cubic meters of water per square meter of the basin area per day). This performance of a solar still can be predicted by writing the energy and mass balance equations on the various components of the solar still.

The energy balances for the different components of the solar still are as follows:

3.1 Glass cover

The energy balance for the glass cover can be expressed as follows (Alkasim et al 2012):

$\tau_1 H_S + [\dot{q}_{rw} + \dot{q}_{cw} + \dot{q}_{ew}] = \dot{q}_{rg} + \dot{q}_{cg}$ ……. (eq.1)

H_S – solar radiation on glass cover (W/m^2°C)

$\dot{q}_{rw}$ = internal heat transfer loss by radiation from water surface to the glass

$\dot{q}_{cw}$ = internal heat transfer loss by convention from water surface to the glass

$\dot{q}_{ew}$ = internal heat transfer loss by evaporation

$\dot{q}_{rg}$ = external heat transfer loss by radiation from glass surface to the ambient

$\dot{q}_{cg}$ = external heat transfer loss by convection from glass surface to the ambient

3.2 The Water Content (water mass)

The energy balance for water content inside the solar still is:

$\tau_2 H_S + \dot{q}_w = M_{cw} C_w \frac{dTw}{dt} + \dot{q}_{rw} + \dot{q}_{cw} + \dot{q}_{ew}$ ..... (eq.2)

3.3 The basin liner

The energy balance for the basin liner of the solar still is expressed as

$\tau_3 H_S = \dot{q}_w + \left[\dot{q}_b + \dot{q}_b \left(\frac{A_{ss}}{A}\right)\right]$ ..... (eq.3)

$\dot{q}_w$ = internal heat transfer loss from water
$\dot{q}_b$ = internal heat transfer loss from basin liner
A = still basin area (m^2)
A_{sw} − Side wall area (m^2)

3.4 The Glass Thickness

3.4.1 The External Heat Transfer.

3.4.2 Top loss Coefficient

The glass thickness in most cases is very small. Therefore, the temperature in the glass is assumed uniform. The external heat transfer loss by radiation and convention from the glass cover to ambient, $\dot{q}_g$ can be express as

$\dot{q}_g = \dot{q}_{rg} + \dot{q}_{cg}$ ..... (eq.4)

$\dot{q}_{rg} = h_{rg}(T_g + T_a)$ ..... (eq.5)

Where

$h_{rg} = \frac{\varepsilon_g \sigma[.(T_g + 273)^4 - (T_{sky} + 273)^4]}{(T_g - T_a)}$ ..... (eq.6)

And

$\dot{q}_{cg} = h_{cg}(T_g - T_a)$ ..... (eq.7)

Substituting equations (eq.5) and (eq.7) into equation (eq.4), we get

$\dot{q}_g = h_1(T_g - T_a)$ ..... (eq.8)

Where

$h_1 = h_{rg} + h_{cg}$ ..... (.eq.9)

h_1 is expressed empirically to include the effect of free convection and radiation from the glass cover (Ilaria et al, 2010). The expression is;

$h_1 = 5.7 + 3.8V \quad 0 \leq V \leq 5ms^{-1}$ ..... (eq.10)

Where V is the wind speed measured in ms^{-1}. The expression for a zero wind speed gives heat loss by natural convection.

3.4.3 Bottom and side loss coefficient

The heat loss from the water in the solar still to the ambient through the thick insulation (sawdust) and subsequently by convection and radiation from the bottom, and sides surfaces of the basin, can be written respectively as

$U_b = \left[\frac{1}{h_w} + \frac{1}{h_b}\right]^{-1} = \left[\frac{1}{h_w} + \frac{1}{\frac{K_i}{L_i}} + \frac{1}{h_{cb+h_{rb}}}\right]^{-1}$ ..... (eq.11)

$U_{sw} = U_b F_1 = \left[\frac{1}{h_w} + \frac{1}{\frac{K_i}{L_i}} + \frac{1}{h_{cb+h_{rb}}}\right]^{-1} \left(\frac{A_{ss}}{A}\right)$ ..... (eq.12)

The rate of heat loss from the basin liner to the ambient per m^2 can be written as;

$\dot{q}_b = h_b(T_b - T_a)$ ..... (eq.13)

Where

$h_b = \left[\frac{L_i}{K_i} + \frac{1}{h_{cb} + h_{rb}}\right]^{-1}$ ..... (eq.14)

3.4.4 The internal heat transfer

3.4.5RadiativeLoss Coefficient

The rate of heat transfer, $\dot{q}_{rw}$ from the water surface to the glass for infinite parallel plane is given by (Tiwari 2004, Garba and Maduekwe, 1996 and Alkasim et al, 2012)

$\dot{q}_{rw} = h_{rw}(T_w - T_g)$…… …. (eq.15)
Where h_{rw} is given by
$h_{rw} = \sigma\left[\frac{(T_w+273)^2+(T_w+273)^2}{\left(\frac{1}{\varepsilon_w}+\frac{1}{\varepsilon_w}\right)^{-1}}\right](T_w + T_g + 546)$ …….. ….. (eq.16)
With
$\varepsilon_{eff} = \left(\frac{1}{\varepsilon_w} + \frac{1}{\varepsilon_w} - 1\right)^{-1}$ ……. (eq.17)

3.4.6Convective Loss Coefficient

There is heat transfer across the humid air inside the distiller unit by free convection, which is caused by the effect of buoyancy, due to density variation in the humid fluid, which occurs due to the temperature gradient in this fluid. The rate of heat transfer from the water surface to the glass cover, $\dot{q}_{cw}$by convection in the upward direction through the humid fluid can be estimated as
$\dot{q}_{cw} = h_{cw}(T_w - T_g)$……. (eq.18)
The internal convective heat transfer coefficient, h_{cw}, from heat flow from the horizontal basin (hottest region in the still) to the water mass in the basin and vice-versa is determined from the following relations (Sodar et al, 1980, Egarievwe 1989, Tiwari, 2004, Saini and Saini, 2008 and Alkasim, et al 2012)
Nu = Co (Gr. Pr) ^{no}…….. (eq.19)
Where
$Nu = \frac{h_{cw}X_1}{K_w}$…… (eq.20)
$Gr = \frac{X_1^3\rho_w^2 g\beta\Delta T'}{\mu_w^2}$ …… (eq.21)
$Pr = \frac{C_{pw}\mu_w}{k_w}$…… (eq.22)
$\Delta T' = \left[\Delta T + \frac{(P_w - P_g)(T_w - 273)}{0.2689 - P_w}\right]$ …… (eq.23)
$\Delta T = T_w - T_g$ ……. (eq.24)
And for normal operating temperature range, say 45°C $\Delta'T$ = 17°C, expression for Gr reduces to (Tiwari, 2004)
$Gr = 2.81\times10X_1^3$ …….. (eq.25)

Table 1: values of Grashofnumber, Gr for various average spacing X_1

X1(m)	Gr	Co	no
0.15	0.948×	0.21	¼
0.2	10^5	0.21	¼
0.25	2.248×	0.075	⅓
	10^5		
	4.390×		

Source: (Tiwari, 2004)

As it can be seen from equation (eq.25) (Gr) depends on X_1 (Table 1). This Table gives the value of Gr for different X_1.
The value of *Pr* remains constant and, as given by equation (eq.22). For the normal operating temperature range and at spacing, X_1 = 0.25m; the value of the constant *Co* is: - *Co* = 0.075 and $n_o = \frac{1}{3}$. After substituting for the expressions of *Nu,* Gr and *Pr* in equation (eq.19), the convective heat transfer coefficient h_{cw} becomes
$h_{cw} = \frac{C_o K_w}{X_1}\cdot\left[\frac{X_1^3\rho_w^2 g\beta\Delta T'}{\mu_w^2}\cdot\frac{C_{pw}\mu_w}{k_w}\right]^{1/3}$ …… (eq.26)
Dunkle, (1991) also derived the following expression for h_{cw} as thus:
$h_{cw} = 0.884\left[T_w - T_{g+}\frac{(P_w - P_g)(T_w+273)}{0.2689 - P_w}\right]^{1/3}$ …….. (.eq.27)

3.4.7Evaporative Heat Loss Coefficient

The mass transfer coefficient, h_e , in terms of convective heat transfer coefficient h_{cw} , the total gas pressure, P_T, the mass of the water vapour, M_w, the air mass, M_a, the specific latent heat, L, and specific heat per unit volume at constant pressure, C_{pa} of the mixture is given by (Alkasim et al, 2012) as

$$\frac{h_e}{h_{cw}} = \frac{L}{C_{pa}}\left(\frac{M_w}{M_a}\right)\left(\frac{1}{P_T}\right) \quad \text{..... (eq.28)}$$

The expression in (eq.28) is formulated owing to the assumption that;

(i) The exchange of the water vapour with the boundary layers at both the water and glass surfaces is neglected and (ii) P_w & $P_g$are considered small compared to P_T.

The rate of heat transfer per unit area from the water surface to the glass cover is obtained by substituting the appropriate values for the parameters in equation (eq.28) thus;

$$\dot{q}_{ew} = 0.013h_{ew}(P_w - P_g) \quad \text{..... (eq.29)}$$

$$\dot{q}_{ew} = h_{ew}(T_w - T_g) \quad \text{..... (eq.30)}$$

From (eq.29) and (eq.30) we can write h_{ew} as

$$h_{ew}=1.6273\times10^{-4}h_{cw}\left(\frac{P_w-P_g}{T_w-T_g}\right) \quad \text{..... (eq.31)}$$

It is important to mention here that the value of h_{ew} can be more realistic for larger value of$(T_w - T_g)$. The values of P_W and P_g (for the range of temperature 10°C - 90°C) can be obtained from the expression (Fernandez and Chargoy, 1990).

$$P_T = \exp\left[25.317 - \frac{5144}{(T-273)}\right] \quad \text{..... (eqn.32)}$$

The total internal heat transfer coefficient $h_2$is the sum of the three internal heat transfer coefficient which can be written as:

$$h_2=\left[\frac{(T_w+273)^2-(T_g+273)}{\left(\frac{1}{\varepsilon_w}+\frac{1}{\varepsilon_g}-1\right)}\right](T_w + T_g + 546)+0.884\left[T_w + T_g + \frac{(P_w+P_g)+(T_{w+273})}{268.9\times10P_w}\right]^{1/3} + 16.273\times10^{-3} + 16.273\times10^{-3}h_{cw}\frac{P_w-P_g}{T_w-T_g}$$

4.0 Results and Discussion

In this section, average hourly solar radiation, temperature difference of ambient and still conditions and also average hourly and overall distillate yield of the solar still at water depth of 20, 40, and 60mm respectively was observed and recorded, to evaluate the design, construction and testing of the solar distillation pilot plant rural water supply.

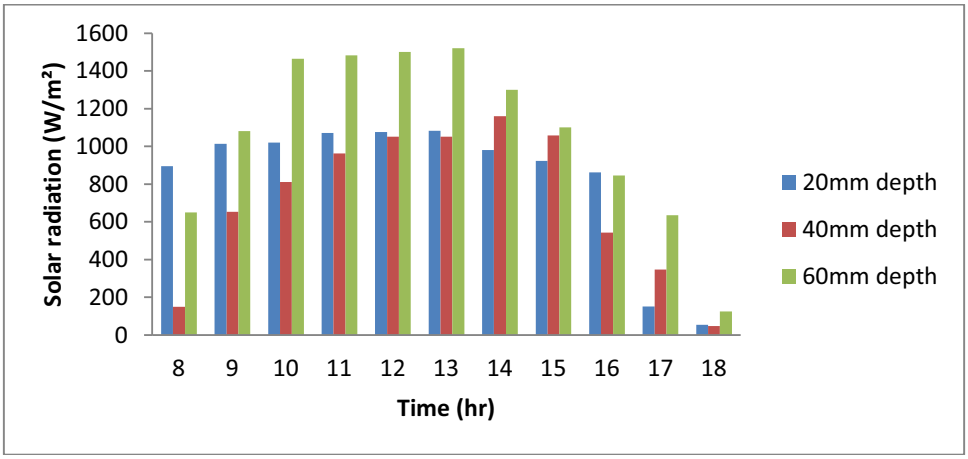

Fig.3: Average Hourly Solar Radiations

Figure 3 depicts Average hourly solar radiation at different water depth of 20, 40, and 60mm which shows highest solar radiation was recorded between 12noon to 13pm.

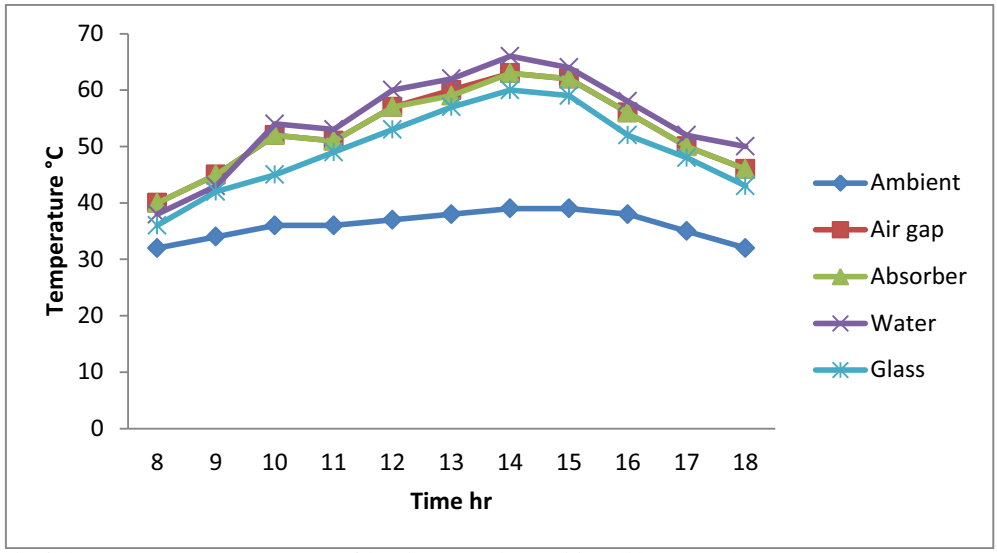

Fig. 4: Average Hourly Temperatures of Ambient and still conditions (20mm depth)

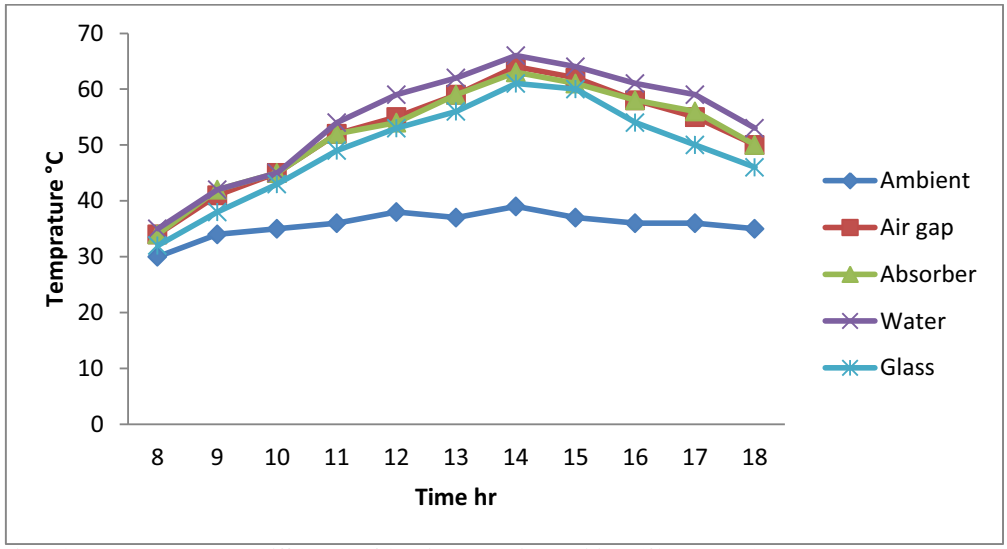

Fig.5: Average Temperature differences of Ambient and still conditions (40mm depth)

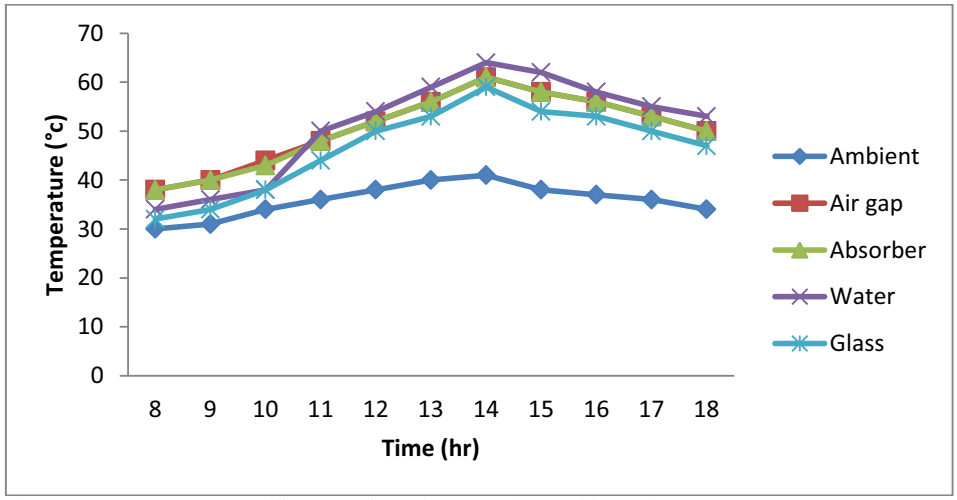

Fig.6:Average Temperature differences of Ambient and still conditions (60mm depth)

Figures (4, 5 and 6) depict Hourly temperature difference of ambient and still conditions at water depth of 20, 40 and 60mm. After observation it shows that the temperature increases with time in ascending order of highest ambient, highest glass, highest air-gap, highest water and highest absorber plate temperatures. This confirmed that the solar radiation energy is directly absorbed by the absorber plate due to high thermal conductivity as heat, which is transfer to the water, then change of state takes place from liquid to vapor as the water evaporate within the air-gap, it increases the temperature of the air-gap. As vapor makes contact with glass cover it condenses due to decrease in temperature difference. Condensations take place because the temperature of the air-gap is greater than the glass temperature and the ambient is lower than the glass temperature (Robert *et al,* 2010)

Table 1: Average Overall Hourly Distillate Yield

Time (hr)	**Yield(ml/m^{2}hr) 20mm depth**	**Yield(ml/m^{2}hr) 40mm depth**	**Yield(ml/m^{2}hr) 60mm depth**
8-9	10	8	4
9-10	17	15	11
10-11	68	60	45
11-12	160	154	123
12-13	342	256	198
13-14	403	389	287
14-15	560	423	396
15-16	602	589	476
16-17	654	603	501
17-18	680	620	512
18-19	701	625	522
19-7	813	723	701

Table 1 shows the average hourly distillate yield. It is obvious that yield of a still is affected by the water depth. The lower the water depth the greater the yield, 20mm water depth yield distillate of 5100ml/m^2.hr and the higher the water depth the lower the yield, 60mm water depth yield distillate of 3776ml/m2.hr

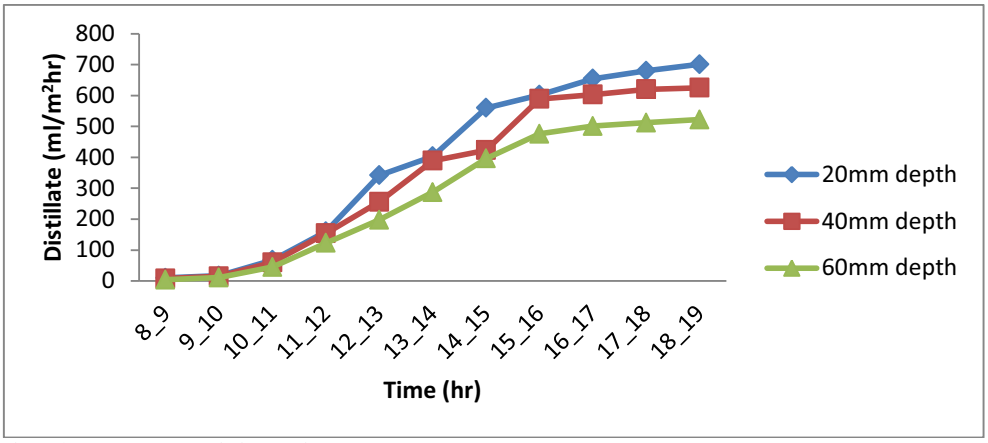

Fig.7: Average Hourly Distillate Yield

Figure 7 shows the hourly distillate yield at 20mm water depth, yield the highest distillate with time and 60mm water depth, yield the lowest distillate with time. Efficiency of the still was also affected by water depth, 20mm water depth with efficiency of 50.1%, 40mm water depth with efficiency of 44.6% and 60mm water depth with efficiency of 37.7%. The efficiency was used to evaluate the performance of the still. (Buros, 20000)

5.0 Conclusion

The design, construction and testing of solar distillation pilot plant was evaluated with water depth was set at 20, 40, and 60mm respectively. Average hourly solar radiation at different water depth mention above, which shows that highest solar radiation was recorded between 12noon to 1pm. Hourly temperature difference of ambient and still conditions were observed which shows that the temperature increases with time in ascending order of highest ambient, glass, air-gap, water, and absorber plate temperatures. Also the average hourly distillate yield was recorded and it is obvious the yield of the still is affected by water depth. Overall yield of distillate were found to be 60.12litre at 20mm water depth, 53.58litre at 40mm water depth and 45.31litres at 60mm respectively and efficiency of the system at different water depth of (20, 40, 60mm) were found to be 50.1%, 44.6% and 37.7% respectively.

Nomenclature

A - Still basin area (m^2)

A_g - Glass covers area (m^2)

A_s - Total still area (m^2)

A_{sw} – Side wall area (m^2)

B - Breadth of still (m)

C_w - Specific heat of water (J/kg°C)

F_1 - Glass area correction factor (A_s/A)

L - Length of still (m)

g -Acceleration due to gravity (m/s^2)

h_1 – Radiative heat transfer coefficient from water to glass cover ($W/m^{2}°C$)

h_2 - Convective heat transfer coefficient from glass cover to ambient ($W/m^{2}°C$)

h_3 - Heat transfer coefficient from water to the basin liner (W/m^2°C)

h_{rw} - Radiative heat transfer coefficient (W/m^2°C)

h_{cw} --Convective heat transfer coefficient (W/m^2°C)

h_{ew} - Evaproative heat transfer coefficient (W/m^2°C)

H_s - Solar radiations on the glass cover (W/m^2)

k_w - Thermal conductivity of the water in the basin (W/m^2)

ℓ - Water depth in the basin (m)

m - Distilled water production rate (kg/min)

m_t - Total distilled water production (kg)

M_w - Water content in the basin (kg)

Gr – Grashof number

Nu – Nusselt number

Pr - Prandtl number

P_g - Water vapour pressure at glass temperature (Pa)

P_w - Water vapour pressure at water temperature (Pa)

Q_{ew} - Mass of evaporated water (kg)

q̇ - Rate of energy transfer (J/s)

R_b - Basin liner reflectivity

R_g - Glass cover reflectivity

R_w - Water surface reflectivity

R.H. - Relative humidity (%)

t - Time (s)

T_a - Ambient temperature (°C)

T_b - Basin liner temperature (°C)

T_g - Glass temperature (°C)

T_w - Water temperature (°C)

U_T - Top loss coefficient (W/m^2°C)

U_B - Bottom loss coefficient (W/m^2°C)

U_{sw} - Overall heat transfer coefficient from the side wall to the ambient (W/m^2°C)

V - The wind velocity (m/s)

X_1 - Water to glass spacing (m)

Abstract

Humidification-dehumidification (HDH) is a carrier gas based thermal technique, which is ideal as a small scale decentralized water desalination system. An innovative design approach is to use the bubble column humidifier to enhance the performance of the HDH water desalination system. Therefore, a novel bubble column humidifier is proposed which is operated through solar thermal energy as the main source of energy input. The overall objective of this work is to develop and test the novel bubble column humidifier to identify the optimum performance operating conditions for its possible integration with a dehumidifier. The design of the bubble column humidifier is optimized in terms of perforated plate geometric features to reduce the overall pressure drop in the system. The study addresses the relation between the air pressure variation with water column height and air superficial velocity varies. The proposed bubble column humidifier is integrated with Fresnel lens to increase the water temperature as it enters the humidifier. The influence of water temperature on the vapor density is investigated at different air superficial velocities. Results indicate that the vapor density in the bubble column humidifier is significantly increased with the increase in the water temperature and air superficial velocity. One major advantages of this proposed humidifier is its ability to have a direct solar thermal heating. Subsequently, it can be located in remote areas.

1. Introduction

The fresh water is the essence of life and its scarcity is the most threatening concern for mankind. The problem is more severe in developing countries where the population growth projection is much higher as compared to developed countries (Fiorenza et al., 2003). The rapid population growth resulted in higher fresh water demands for domestic and agriculture sectors to produce adequate quantities of food. While the fresh water demand is rising exponentially, the industrial revolution is making the fresh water scarcity situation more alarming by polluting the lakes and rivers by industrial waste. Given the fact that the population on earth continues to increase and industrial growth shows no signs of slowing down, it is expected that the number of people affected by clean water scarcity will escalate four times over the next 25 years (Miller, 2003). To alleviate the worries of the existing and approaching fresh water crisis, the answer for water sustainability may lie in developing the decentralized small scale water desalination system.

Solar humidification-dehumidification (HDH) is an appropriate choice for decentralized small scale water desalination system, especially in remote regions where inexpensive land and abundant solar radiations are available. The challenge is to come up with an efficient, reliable, and cost effective design approach to explore the true potential of the HDH water desalination systems. Several studies are available that explore HDH as an effective means of seawater desalination. However, the main focus of these studies is to improve the dehumidification process of the HDH system and very less attention is given towards the improvement of humidification process.

Humidification is one of the fundamental processes in the solar HDH water desalination system. There are many devices which can be used for the humidification purpose. These devices include spray tower, wetted wall tower,

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.10.46 Available at http://proceedings.ises.org

packed bed tower, and bubble column (Treybal, 1980). The aim of all these devices is to raise the humidity of the air by diffusion of water into unsaturated air stream. This diffusion process is caused by the concentration difference between the water vapor in the air and air-water interface.

Several studies considered using spray tower as a humidification device in theair HDH system. In the spray tower, water is sprayed in the form of droplets that falls under the force of gravity. Air is injected from the bottom to come in a direct contact with the falling water droplets in a counterflow arrangement. These type of devices have low humidification effectiveness due to the low water holdup. Other limitations include the use of mist eliminators which are essential to avoid the water entrainment in the air at the exit of the spray tower. Furthermore, the losses in the spray nozzles caused a high pressure drop in the water stream. Younis et al. (1993), Ben-Amara et al. (2004), and Orfi et al. (2004) used spray tower as a humidification device and studied the effect of water-to-air mass flow rate ratio on the humidification efficiency. They varied the water-to-air mass flow rate ratio while keeping the absolute humidity and inlet water temperature constant. Moreover, the sprayed water temperature (60 ˚C) was kept less than the inlet air temperature (80 ˚C). The results showed that the absolute outlet humidity increased with increasing the amount of sprayed water to a certain level. However, further increase in the quantity of water initiated the air cooling and condensation of water vapor in the air. This process resulted in the decrease of absolute humidity although the outlet air is always saturated. This implies that air heated HDH cycle provides maximum air humidity at an optimum water-to-air mass flow rate ratio. Therefore, use of the multi stage air heated HDH system increases the production of fresh water.

Wetted wall towers could also be used in an HDH system for air humidification purpose. In this type, thin water film flows downward on the inner perimeter to form a wetted surface along a tower length. The air stream can either flow upward or downward to have a direct contact with the falling water thin film. These towers have a higher humidification efficiency and a lower air side pressure drop as compared to other humidification towers. However, the water flow rate is restricted to a lower capacity due to the limitation of the thin film water flow only on the inner perimeter of the tower. Wallis and Aull (1999) used polypropylene made vertically hanging fleeces for their wetted wall humidifier. The thin film of the heated water was distributed and trickled downward along the inner perimeter of the fleeces to form a wetted surface. The dry air streamed upwards and came out saturated at the outlet of the humidifier. Orfi et al. (2004) employed an improved heat and mass exchange design for a wetted wall humidifier. In their design, the water flowing velocity was reduced for better heat and mass exchange. The reduction in water flow velocity was ensured by covering the wooden vertical wetted walls with a cotton wick. The wooden vertical walls were always kept wet using capillary force. This design improvement ensued higher humidifier performance and claimed to achieve around 100 % humidification efficiency.

The packed bed tower is a widely practiced humidification device in the HDH water desalination system owing to its better performance. It is similar to the spray towers in which water is sprayed in the form of droplets that fall under the force of gravity. However, in the packed bed tower, the packing material is used to improve the humidification efficiency. The use of packing material makes the water droplets more dispersed which increases the area and time of contact between both water and air. However, this improvement leads to a higher pressure drop in the packed bed humidifier. Tab. 1 shows different packing materials. Several factors affect the choice of the packing materials and their heat and mass transfer, e.g. pressure drop, durability, cost, and quality of water. Development of packing materials in the HDH systems were reported by Mirsky and Bauthier (1993) and the performance of different packing materials in such systems were investigated by Aull and Krell (2000). Wallis and Aull (1999) showed a gradual change of fills types in packed bed towers. Introduction of film fills caused a tremendous change by providing higher thermal performance by reducing pressure drop and increasing water to air contact area. However, older splash type fill packing is being used because all these benefits are lost pertaining to high fouling potential.

1.1 Bubble Column humidifier

An innovative design approach is to use the bubble column as a humidification device for a HDH water desalination system. The choice of a bubble column as a humidifier has been inspired due to the higher rate of heat and mass transfer in the liquid-gas dispersion. In this humidifier configuration, air is passed through perforated plates to form bubbles in the hot water column. As the air bubbles propagate through the hot water column, simultaneous heat and mass transfer take place where air becomes hot and humid at the outlet of the humidifier. Heat transfer to the liquid-gas diffusion has been studied by many researchers who suggested different models to analyze the effect of heat transfer coefficient on different system parameters. Kobel et.al (1958) showed that the liquid properties and gas velocity have the main impact on the heat transfer coefficient. Kast (1962) studied the effect of rising a bubble in the fluid and indicated that the fluid element in the front of the rising

bubble moves toward the wall due to the radial momentum that it received by uprising the bubble. This radial momentum of the fluid breaks the boundary layer at the wall and the boundary layer assumption is not valid, especially in the case of high bubbles concentration. Conversely, the uprising bubble form a wake underneath sucks the fluid radially. The fast radial exchange flow due to uprising bubble results in a capacitive heat transfer. The flow around rising bubble and air humidification in the bubble column humidifier is illustrated in Fig. 1.

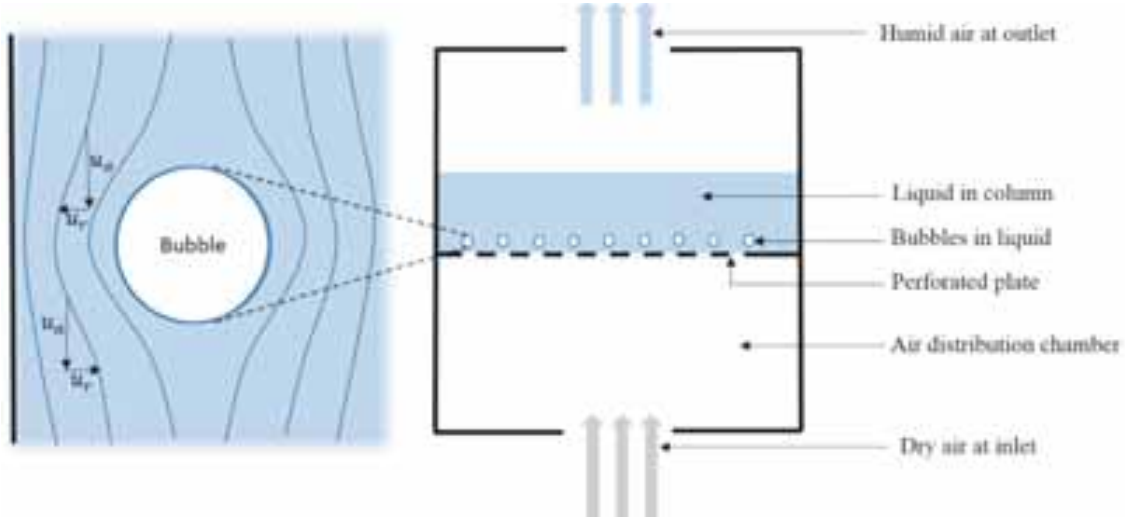

Fig. 1: Flow around rising bubble and air humidification in bubble column humidifier.

The higher rate of heat and mass transfer in a bubble column inspired the researchers to extensively practice these devices as multiphase reactor in chemical process like fisher-tropsch process, in metallurgical and many biomedical applications. However, the use of bubble column humidifier in HDH water desalination is very limited and there are very few studies that investigate the bubble column as a humidifier for HDH water desalination system. El-Agouz and Abugderah (2008) carried out an experimental investigation of a single stage bubble column humidifier. An evaporator column of 500 mm x 250 mm cross section was used in this experiment. The air stream is introduced by a 75 mm diameter PVC pipe having 32 holes of 10 mm diameter on both sides. The pipe was submerged in the water and acted as a sparger to form bubbles in the pool of water. They considered the effect of different operating parameters on the humidifier efficiency. These operating parameters include water inlet temperature, the air inlet temperature, and the air inlet velocity. Their results specified that the performance of the bubble column humidifier is considerably affected by the inlet air velocity and the inlet water temperature. The air inlet temperature has a small influence on the vapor content difference in the air. The highest efficiency achieved for the bubble column humidifier was reported as 95 % with 222 gw/kga at 75 °C of air and water temperatures. Geometrical features, such as the number of holes, holes diameter, open area ratio, and water column height were not considered in this study. El-Agouz (2010) performed another experimental study to analyze the effect of water column height, water column temperature, and air flow rate on the performance of bubble column humidifier. The effect of water column height on the efficiency of the bubble column humidifier was not significant. However, the performance of bubble column humidifier was increased with the increase in the water column temperature and air flow rate. The maximum efficiency achieved for the bubble column humidifier was reported as 98 % at air flow rate of 14 kg/hr and water temperature of 85 °C.

Zhang et al. (2011) performed an experiment on a single stage bubble column humidifier to analyze the effect of air flow rate and water level on the pressure drop and the relative humidity of air. A cylindrical column of 198 mm diameter was used as an evaporator chamber in their experiment. A sieve plate of 8 mm thickness having 91 holes of 1 mm diameter was used as sparger. Their experimental work aimed to achieve higher water vapor in the air at the exit of humidifier with less pressure drop and less blower power consumption. The results showed that the increase in the water level and air flow rate caused greater pressure drop and higher blower energy consumption. The moisture contents at the exit of the humidifier were increased with the increase of the water and air temperatures. In the range of experimental operating conditions, the experimental results showed that the air reached 100 % relative humidity.

In all the aforementioned experimental investigation of the bubble column humidifier, water is heated by an electric heater that limits the use of these devices in remote areas where electricity availability is scarce. Therefore, a novel bubble column humidifier is proposed that is operated through solar thermal energy as the main source of energy input. In this novel humidifier, the absorber plate and bubble column were incorporated in

a single frame design, as shown in Fig. 2. The absorber plate was painted black and titled to an angle equal to the latitude of Dhahran to absorb the maximum solar radiations. This design improvement has the following advantages:

- The tilted absorber plate acts as a sloped surface to create a thin film of water over the absorber plate. The minimum water depth over the absorber plate leads to better heat transfer and higher water temperature is achieved at the exit of absorber plate. It also results in minimum pressure drop in the air-side.
- The hot humid air at the exit of bubble column further passed over the thin film of hot water flowing over absorber plate to absorb more moisture and higher vapor contents are achieved at the exit of humidifier.

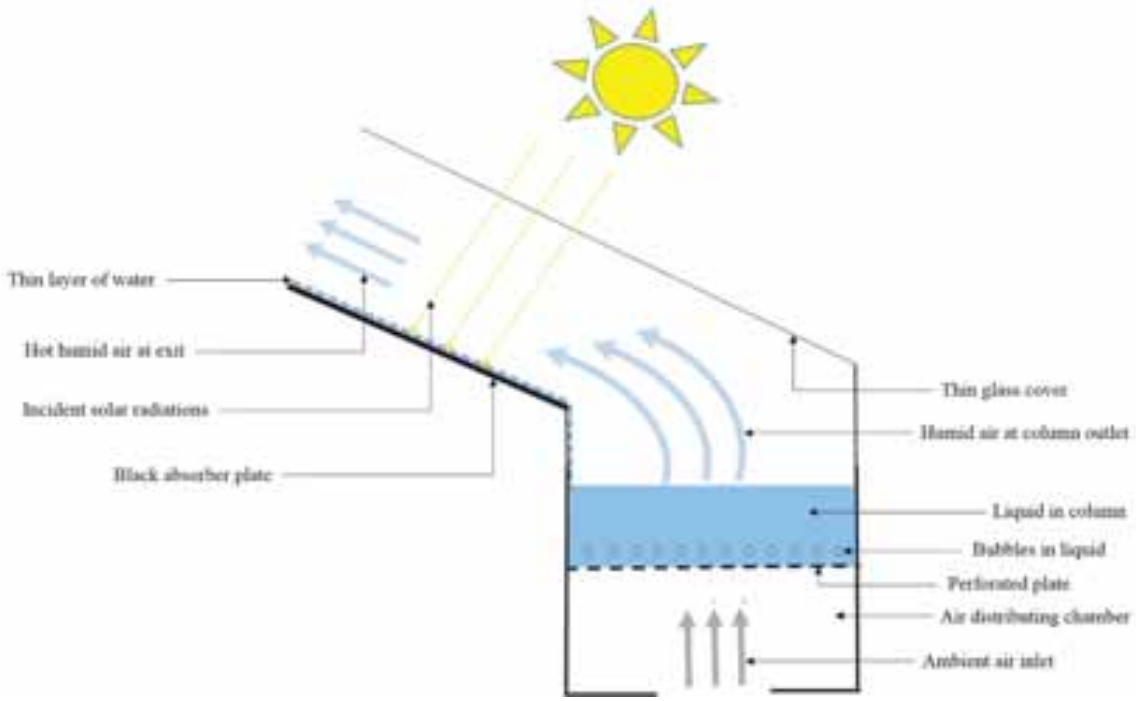

Fig. 2: Bubble column humidifier incorporated with absorber plate.

The overall objective of this work is to develop and test a new humidifier design to identify the optimum operating conditions for possible integration with a dehumidifier. Consequently, an improved HDH performance design is obtained. One major advantage of this proposed humidifier is its ability to have direct solar thermal heating. Subsequently, it can be located in remote areas.

2. Experimental Setup

A laboratory scale setup for the proposed bubble column humidifier was designed and built as shown in Fig. 3. The frame of the experimental setup was constructed of 100 mm thick Plexiglas sheet. Plexiglas is a transparent thermoplastic material that has a thermal conductivity of 0.19 W/m.K. The use of such transparent material is advantageous in a sense that it allows the observer to see what is happening inside the unit while performing the experiment. Another advantage of using the Plexiglas is its low thermal conductivity that reduces the heat loses from the system. Plexiglas sheet was also used to build the bubble column of 300 mm x 300 mm cross section and 400 mm height. A perforated plate was used as a sparger to form the bubbles in a pool of hot water in the bubble column. The perforated plate is made of a 2 mm thick black acrylic Plexiglas 300 mm x 300 mm in cross section. The perforated plate splits the bubble column into lower and upper compartments. Air ~~was~~ introduced by a 400 W adjustable blower to the lower compartment of the bubble column through a 25 mm diameter CPVC pipe. The lower compartment of the bubble column is 300 mm high. It was used to distribute the air stream uniformly through the perforated plate. The upper compartment of the bubble column is 100 mm high. It was used as a pool for hot water. Water level in the pool was measured and controlled.

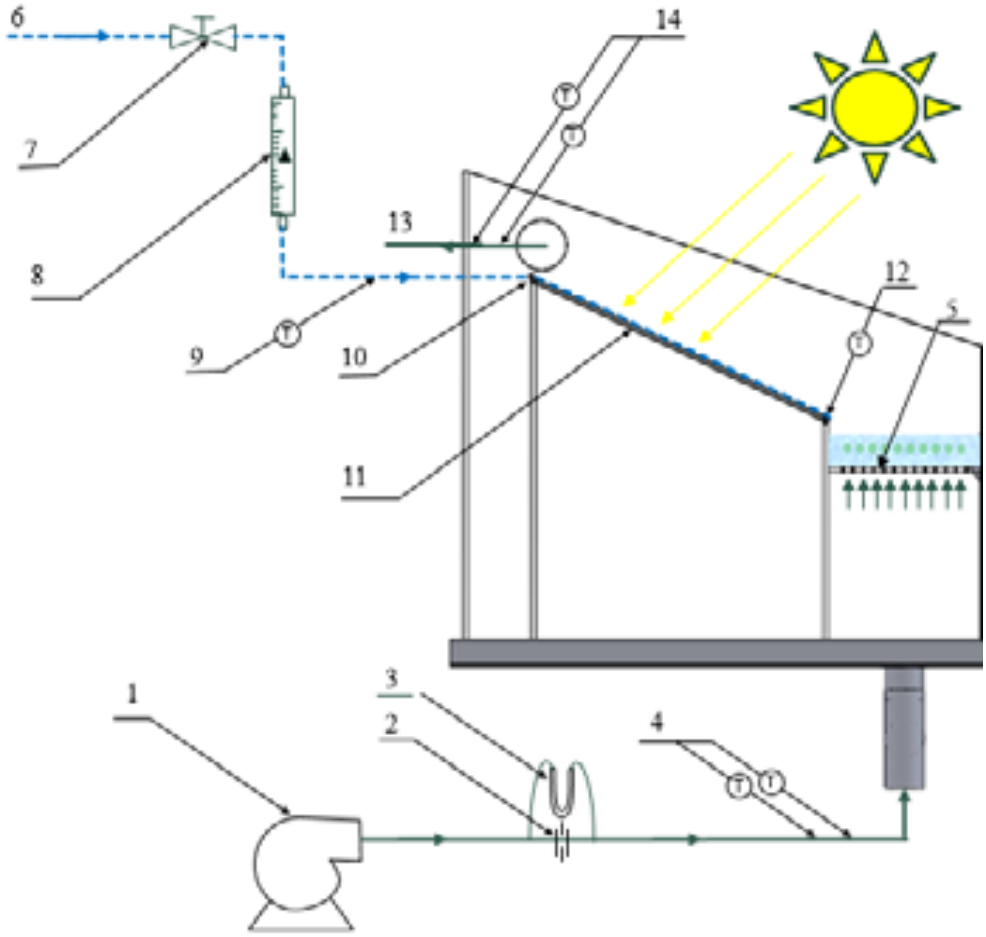

Fig. 3: Schematic diagram of experimental setup.

(1) Air blower, (2) Orifice meter, (3) Manometer, (4, 9, 12, 14) Thermocouples, (5) Perforated plate, (6) Water supply, (7) Throttle valve, (8) Rotameter, (10) Humidifier water inlet, (11) Absorber plate, (13) Humidifier air outlet

The experiment starts by blowing air using the air blower (1). The reason for blowing air first is that if the water flows first, it will penetrate down through the perforated plates (5). The blower is adjustable for the desired volumetric flow rate of the air stream that is measured by an orifice meter (2) connected to a manometer (3) to measure the pressure drop across the orifice plate and hence calculate air flow rate. The air dry-bulb / wet-bulb temperatures are measured by K-type thermocouples (4) before the air stream is admitted into the humidifier. Water supply (6) valve is then opened. The volumetric flow rate of the water was measured by a rotameter (8) adjusted to the desired value by a throttle valve (7). Water temperature is measured by a thermocouple (9) before entering the humidifier (10). A water film is distributed evenly over the black absorber plate (11) and flows by gravity. Water temperature increases as it flows over the absorber plate that is heated by solar radiations. Water temperature is measured at the exit of the absorber plate using thermocouples (12). Hot water then moves to a the bubble column chamber where air is passed through the perforated plate to form bubbles in the pool of the hot water. As the air bubbles propagate through the hot water column, simultaneous heat and mass transfer take place such that air is heated and humidified till it reaches the exit of the humidifier (13). Dry-bulb / wet-bulb temperatures of the hot and humid air are recorded using thermocouples (14) at the exit of the humidifier.

3. Data acquisition system

A data acquisition consisting of two NI 9213 thermocouple input modules installed in a NI cDAQ-9178 USB chassis is connected to a computer. Thermocouples measurements are displayed and stored using a Labview program. Real-time processed thermocouple readings are measured every 2 seconds and the average temperatures of every 5 minutes were recorded using the developed Labview program.

3.1 Instrumentation

K-type thermocouples were used to measure water temperature as well as air dry-bulb/wet-bulb temperatures. The volumetric flow rate of the water was measured by using FL5000 series rotameter of OMEGA. The

volumetric flow rate of air is measured by an orifice meter connected to a manometer to read the pressure drop across the orifice plate. The orifice meter is designed and installed according to the ISO 5167 benchmark design recommendations. Solar radiation is measured using a handheld pyranometer. The measurement devices along with their range and accuracy are summarized in Tab. 1.

Tab. 1: Measurement devices along with their range and accuracy.

Properties	Instruments	Range	Accuracy
Temperature	NI cDAQ-9178, K-Type thermocouple	-267 – 316 °C	± 0.1 °C
Relative humidity		0 - 100 % RH	± 0.1 % RH
Pressure	U-Tube manometer	0.1 - 50 cm H_2O	± 1 mm
Water flow rate	Rotameter	1 - 7 LPM	± 5 % of full scale
Water column height	Graduate level	0.1 - 20 cm	± 1 mm
Air superficial velocity	Orifice meter	10-50 cm/s	± 1 cm/s
Solar radiations	Pyranometer	0-2000 W/m2	± 5 % of full scale

Thermocouple probes are calibrated before installing them in the experimental setup. Errors in the measurement devices is calculated as the ratio of the device least count to the minimum value of the output measured by that instrument. The uncertainty in the measurements is calculated as the root sum square of the fixed error of the instrumentation and the random error observed during different measurements. The resulting uncertainties are ± 0.79 cm/s and ± 0.93 % in the air superficial velocity and vapor density, respectively.

4. Results and Discussion

4.1 Influence of geometry of the perforated plate

The optimum design consideration of the perforated plate is an important aspect in the experimental investigation of the bubble column humidifier. In the design of the perforated plate, the perforations geometric configuration should be optimized to reduce air pressure drop. Another important aspect in the perforated design is to avoid water leakage through the perforations. Keeping in mind the aforementioned aspects, three different perforated plates were designed and tested to analyze the effect of perforation geometry on the performance of the bubble column humidifier. The geometric features of the three spargers used during the experimental work are listed in Tab. 2.

Tab. 2: Geometric features of different designs of perforated plate tested during experimentation.

	Number of holes	Hole Diameter (mm)	Pitch size (mm)	Open Area Ratio (%)
Design 1	105	3	25	0.77
Design 2	105	2	25	0.33
Design 3	149	2	20	0.49

Three different designs of perforated plates were tested at different air superficial velocities. Results are shown in Fig. 4. The minimum pressure drop is achieved using design 1 due to the bigger hole diameter and higher open area ratio compared to the other two designs. However, water leakage was observed from the perforations during the experiments that showed that this design is not useful. To overcome the problem of the water leakage, design 2 was tested with the same number of holes as in design 1 but the hole diameter was reduced from 3 mm to 2 mm. Design 2 was successful in preventing water leakage from the perforations but the pressure drop was high. The high pressure drop is due to the low open area ratio in design 2. Therefore, design 3 was tested with 149 holes with 2 mm-hole diameter. The higher number of holes increased the open area ratio and reduced the pressure drop compared to design 2. Moreover, no leakage was observed with design 3 during the experiment. Therefore,

design 3 was selected as the best choice for our experimental setup. The perforated plate dimensions and hole geometry of design 3 are shown in Fig. 4. The perforated plate is 300 mm x 300 mm in cross section and it consists of 149 holes, 2 mm-diameter each. The holes are made in equilateral triangular configuration where the distance between any two adjacent holes is 20 mm. The holes are distributed 40 mm away from the boundary of the perforated plate to avoid the shear stresses near the wall of the bubble column.

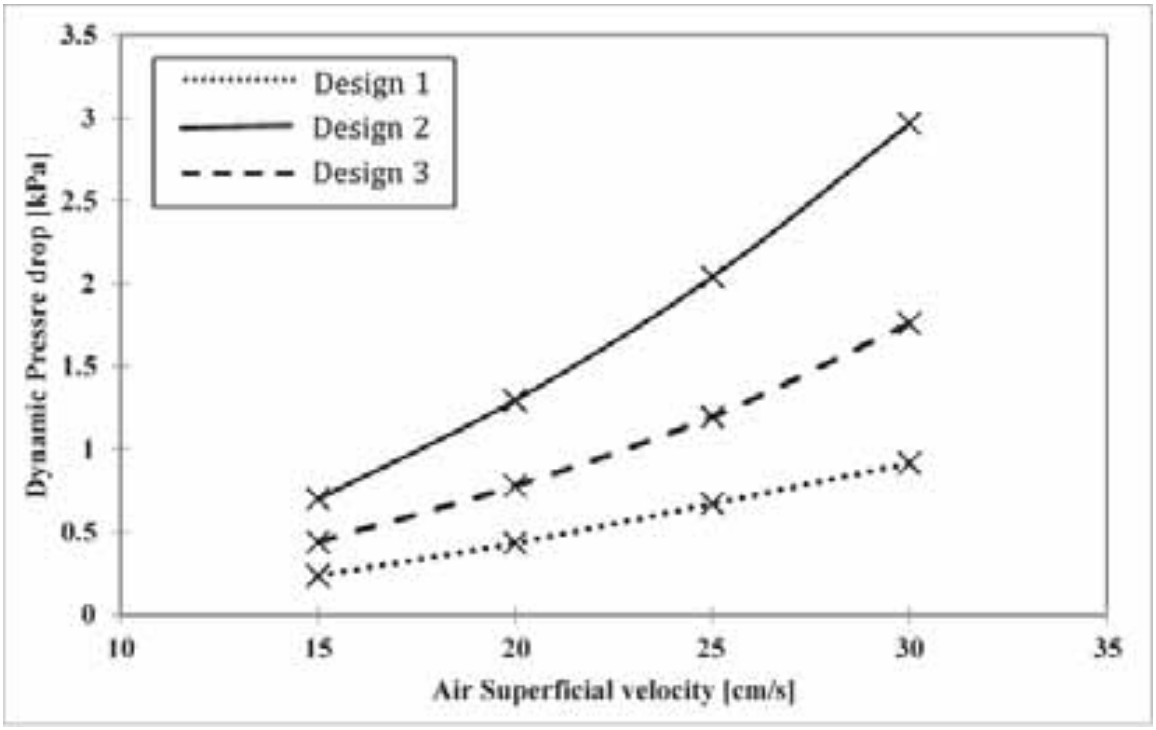

Fig. 4: Influence of air superficial velocity on the dynamic pressure drop under different design considerations of perforated plate.

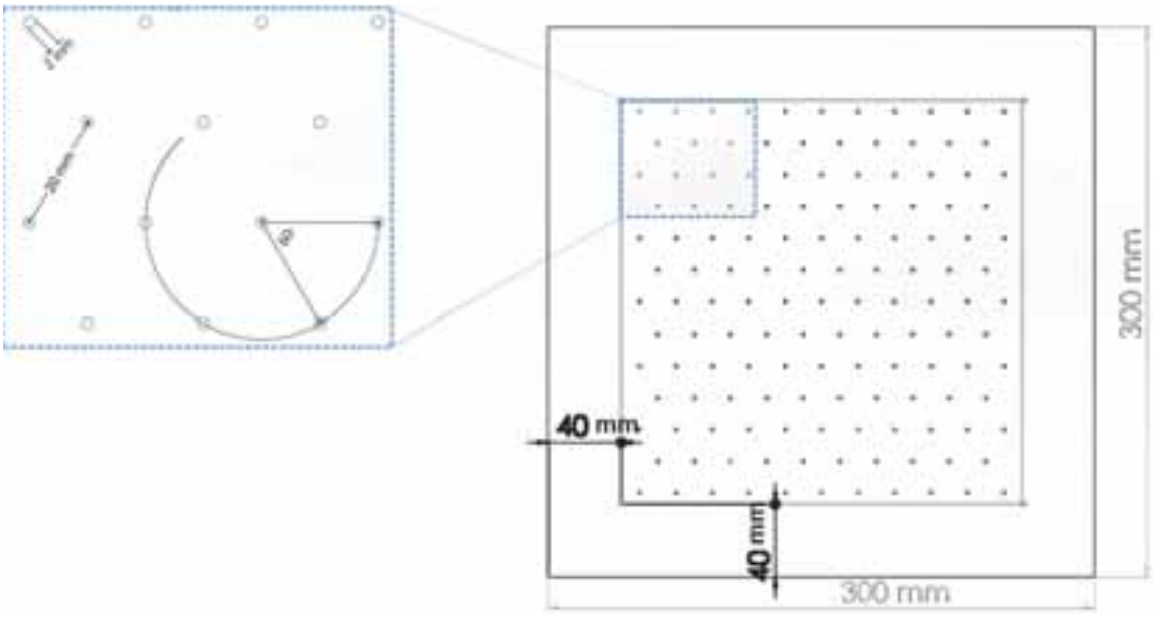

Fig. 5: Dimensioning and geometric features of the selected perforated plate.

Figure 6 shows the effect of water column height on the total air pressure drop at different air superficial velocities. The figure shows that the minimum pressure drop is attained at the lowest water column height of 1 cm and with 15 cm/s air superficial velocity. Increasing water column height to 3 cm and then to 5 cm while keeping the air superficial velocity at 15 cm/s results in a significant increase in the pressure drop. Furthermore, the air superficial velocity at 15 cm/s is not sufficient to completely overcome the static pressure head of the 5

cm water column height such that some water leaked through the perforations. Therefore, air superficial velocity at 15 cm/s is not taken into consideration for further investigations. The maximum pressure drop is monitored with a higher air superficial velocity of 30 cm/s. On contrary to the air superficial velocity of 15 cm/s, there is a slight increase in the pressure drop at higher water column heights.

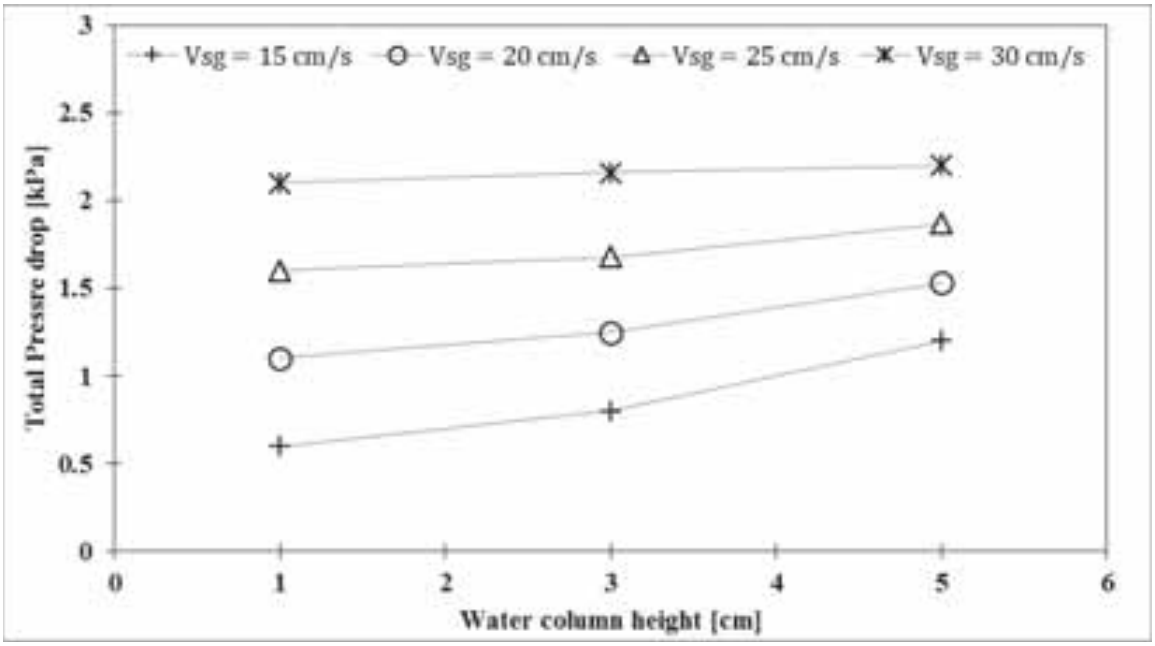

Fig. 6: Effect of water column height on the total pressure drop at different air superficial velocities.

4.2 Influence of water temperature

The major advantage of the proposed humidifier is its ability to have direct solar thermal heating for water flowing through the humidifier, the day round performance of the system was tested under climatic conditions of Dhahran, Saudi Arabia. The system was operated with and without Fresnel lens from 7 am to 5 pm in the month of June. The system performance without and with Fresnel lens was analyzed in terms of vapor density (absolute humidity) of the moist air at the exit of humidifier. Fig. 7 shows the solar heat flux, air and water inlet temperatures, and the water temperature after passing over absorber plate with and without the use of Fresnel lens. It can be seen that the solar radiation and ambient air temperature increases in the morning hours, reaching their maximum values around mid-day, and then decrease in the afternoon. Water temperature followed the same trend since it is directly influenced by the solar radiations. The black absorber plate was heated by solar radiation. Accordingly, water temperature was increased as it flows over the absorber plate. A higher water temperature was achieved by using Fresnel lens that concentrates the solar radiations on the absorber plate and, consequently, heats the water to a higher temperature.

Since the core objective of the bubble column humidifier is to effectively humidify the air, the day round performance of the proposed design is analyzed in terms of the vapor density in the moist air at the exit of humidifier. The influence of water temperature on the vapor density was investigated at different air superficial velocities. The results of the proposed design without and with Fresnel lens are presented in Fig. 8 and Fig. 9, respectively. Results indicate that the vapor density (Air humidity) in the humidifier is strongly influenced by the amount of the heat received by flowing water over the hot absorber plate. The integration of Fresnel lens increased the concentration of solar radiation on the absorber plate and heated the water to a higher temperature. The increase in the water temperature enhanced the ability of air to absorb more moisture and, consequently, higher humidity ratio is achieved at the outlet of humidifier. The increase in air superficial velocity also contributed significantly in increasing the vapor density in the moist air at the exit of humidifier. The increase in vapor density with the increase in air superficial velocity is attributed to the rise in velocity of comparatively bigger air bubbles. Moreover, the number of air bubbles increases with the increase in air superficial velocity and, consequently, provides higher interfacial area for better heat and mass transfer.

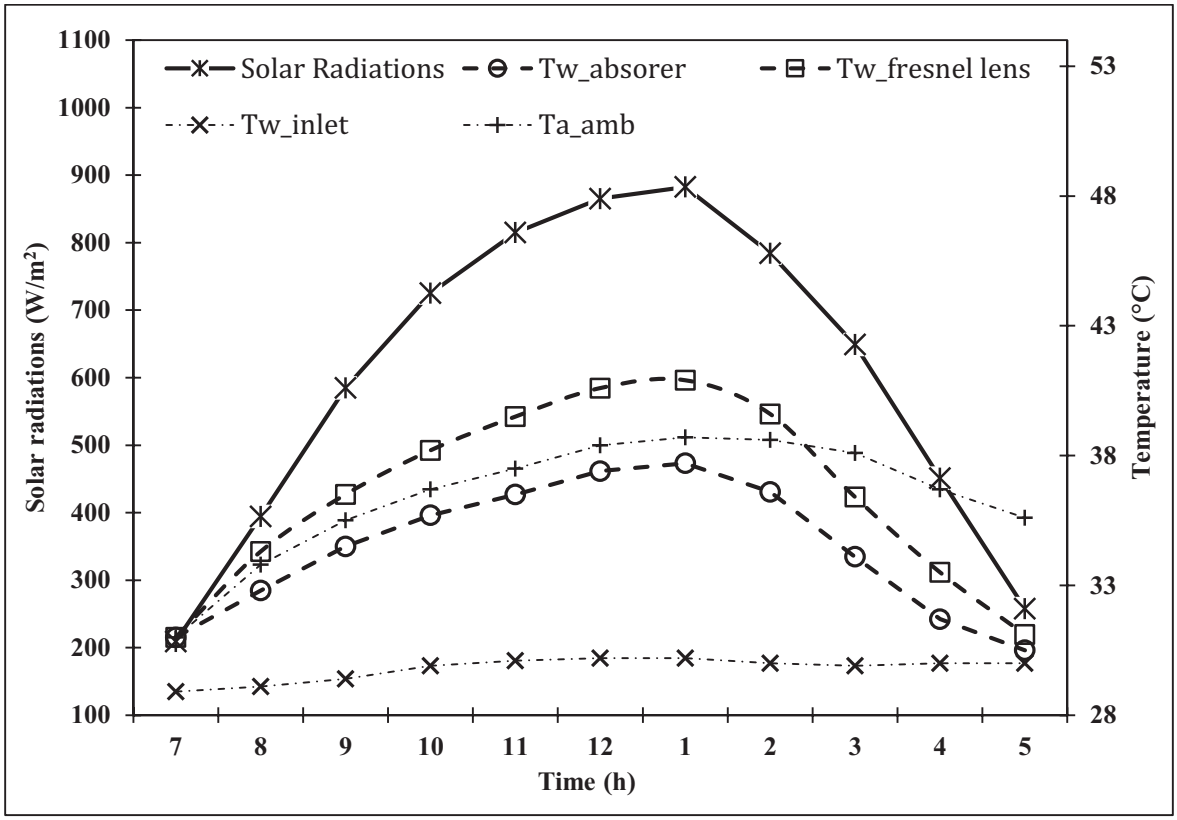

Fig. 7: The influence of solar radiations on the water temperature in the bubble column humidifier.

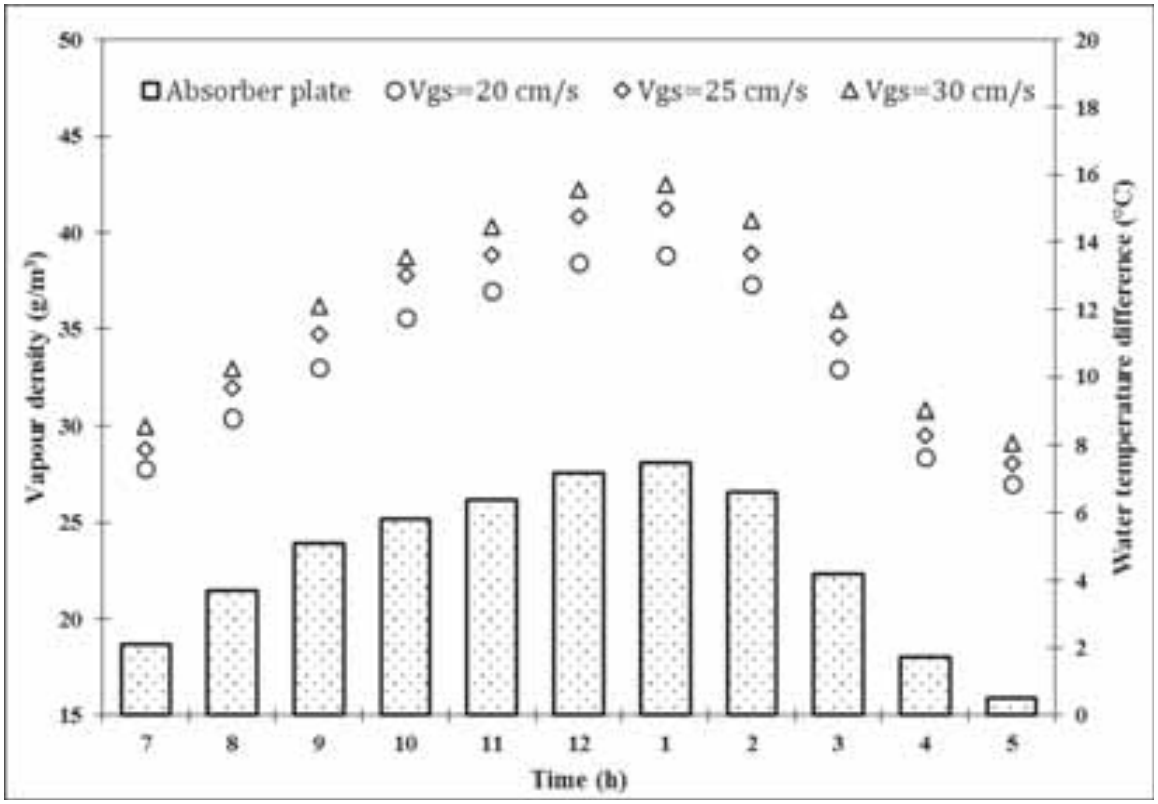

Fig. 8: Influence of water temperature and air superficial velocity on the vapor density in the moist air at the exit of humidifier.

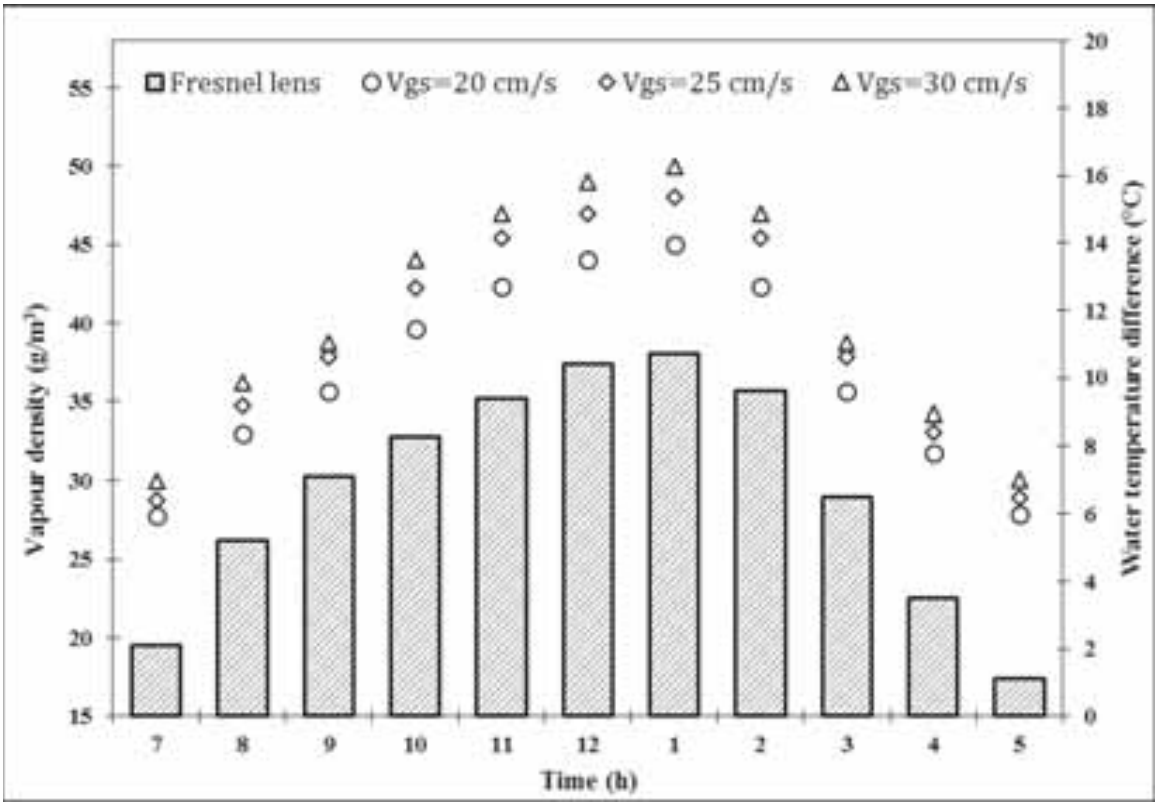

Fig. 9: Fresnel lens integration in the proposed design to increase the vapor density in the moist air at the exit of humidifier.

5. Conclusions

- The use of the bubble column humidification is an attractive option for solar humidification-dehumidification (HDH) water desalination systems. Therefore, a novel bubble column humidifier was developed and tested to identify the optimum performance operating conditions for its possible integration with a dehumidifier. One major advantage of this proposed humidifier is its ability to have a direct solar thermal heating. Subsequently, it can be located in remote areas.

- The optimum design for the perforated plate is an important aspect in the experimental investigation of bubble column humidifier. Different design configurations of the perforated plate were tested in order to achieve the lower pressure drop in the system. Findings revealed that the minimum pressure drop was experienced at a lower water column height and a lower air superficial velocity. However, the water column height and air superficial velocity should be optimized according to the geometry of the perforated plate in order to avoid water leakage through the perforations.

- The proposed design of the bubble column humidifier was integrated with the Fresnel lens in order to achieve a higher water temperature. The influence of water temperature on the vapor density was investigated at different air superficial velocities. Results indicate that the vapor density in the bubble column humidifier was significantly increased with the increase in water temperature and air superficial velocity. The increase in water temperature enhanced the ability of air to absorb more moisture and consequently higher vapor density was achieved at the outlet of bubble column humidifier.

Abstract

Water treatment using solar thermal energy is more attractive for rural and remote communities as both desalination and detoxification can be carried out effectively in a single unit. In the present investigation, a hybrid solar still which has the capability to generate both potable water and hot water has been proposed and its performance has been simulated using transient mathematical modeling. The proposed still incorporates both inclined still and conventional basin type still and is ease of construction. The distillate yield from the proposed system is nearly 107 % higher than conventional inclined type solar still. The optimum gap between evaporating and condensing surface is 0.10 m. The optimum thickness of fluid film and depth of water in the basin is 0.001 m and 0.01 m. The unit is capable of generating 7.12 kg/d of distillate. The average temperature of hot water generated by the unit during summer and winter is 56.28 ° C and 45.09 ° C, respectively. The average overall efficiency of the unit is around 67.018 % and 59.61 % during summer and winter, respectively. The unit is found to meet the drinking water and hot water requirements of remote and rural communities.

1. Introduction

Rapid growth in population and change in life style of human beings along side with industrialization has increased the demand for fresh water. Available limited fresh water bodies are being polluted continuously making them unfit for human consumption. The increasing demand of fresh water can be met by desalination of saline water which is available in plenty (Tabrizi et al., 2010a). Large number of desalination units fueled by conventional energy sources is being operated throughout the world but their negative impacts on atmosphere and marine environment makes their sustainability questionable (Younos and Tulou, 2005; Jijakli et al., 2012). Nearly, 40% of the mother earth's land is arid and semi-arid; supplying treated water from decentralized distillation units to these regions is found to uneconomical. But, these regions are blessed with abundant solar energy which can be used as a source to desalinate saline water for human consumption and domestic usage (Mink et al., 1998).

Solar basin type stills have been widely studied and depth of water in the evaporation basin plays a major role in their yield (Mathioulakis and Belessiotis, 2003; Khalifa and Hamood, 2009). Compared to basin stills, inclined solar stills are cheap, portable and can produce more distillate for the same absorber area (Sodha et al., 1981). Different techniques have been adopted by researchers around the globe to enhance the yield of inclined stills. Techniques like reduction of feed water mass flow rate (Aybar et al., 2005), shading of glass cover (Deniz, 2013), use of external reflectors (Tanaka and Nakatake, 2009; Tanaka, 2009), construction of weirs for increasing the residence time of water in the absorber plate (Ziabari et al., 2013) and lining of absorber plate with wicks (Hansen et al., 2015) have helped to enhance the yield of inclined stills. Phase change materials based storage units have also been integrated with inclined stills for their distillate yield

doi:10.18086/swc.2015.10.47 Available at http://proceedings.ises.org

enhancement. Phase change material based units are costly and are recommended only for cloudy weather conditions (Tabrizi et al., 2010b). It could be seen that the productivity of conventional basin type stills and vertical stills have been enhanced to large extent by making them to operate under active mode (Sampathkumar et al., 2010; Sharon and Reddy, 2015).

However, the work associated with enhancement of distillate yield from inclined stills by active mode operation is very scarce in literature and is available as a gap. Distillation units capable of producing both potable water and hot water would be of great beneficial for rural and remote locations which can be achieved by active mode operation of inclined solar stills. Omara et al., (2013) has reported that the yield from the inclined still can be enhanced by 114% by supplying the unit with preheated feed water from Evacuated Tube Collectors (ETCs). However, distillation units with low cost, simplicity and low maintenance are very important for rural based applications. Hence, in this work a hybrid solar distillation unit has been proposed which combines both inclined still and conventional still for better performance.

2. System description

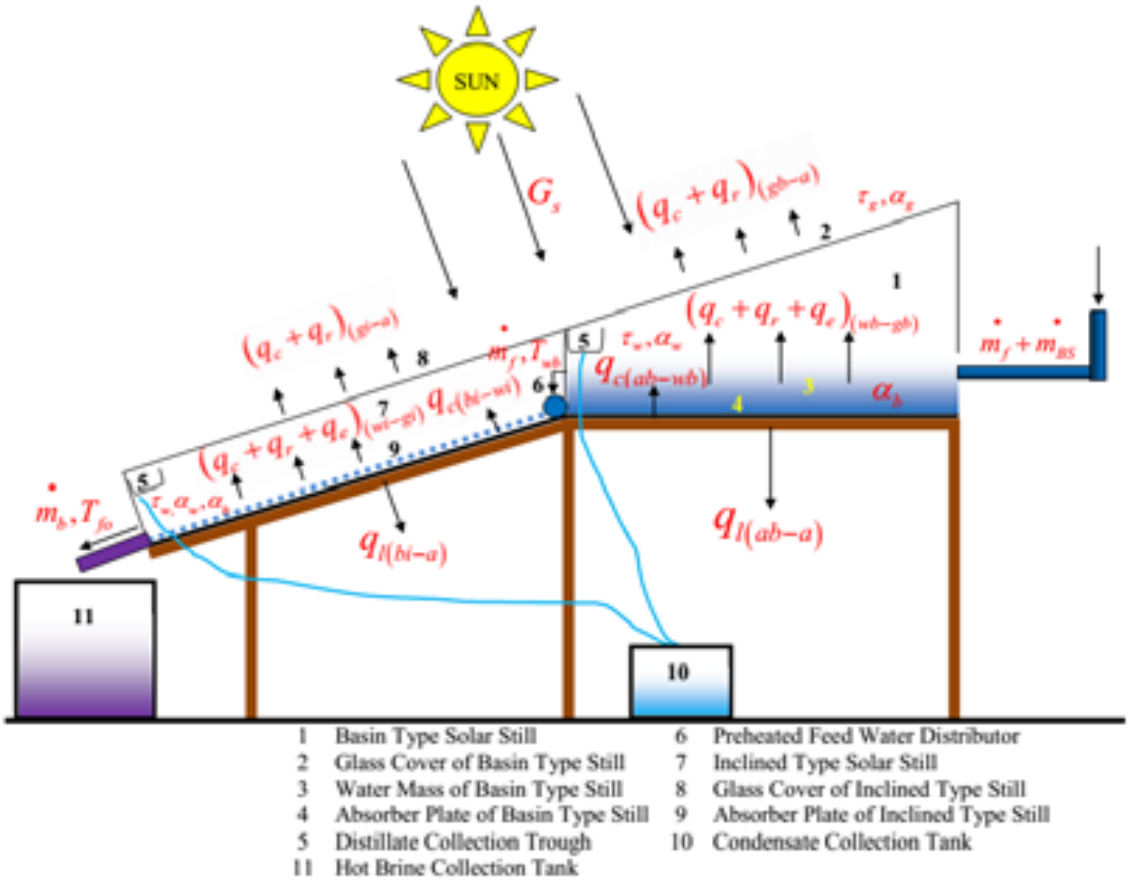

Fig. 1: Schematic represenation of the hybrid solar still along with the necessary energy transport processes

The schematic representation of the proposed hybrid solar still along with necessary energy transport processes is depicted in **Fig.1**. In the proposed system, active mode of operation of inclined still is achieved by coupling inclined still (1 m^2 area) with conventional basin type solar still (1 m^2 area). The inclination of glass cover of basin type still and inclined still is 13 $^\circ$ facing south, corresponding to the local latitude considered in this study. The integrated conventional basin type solar still acts as feed water storage and preheating unit. Preheated feed water from conventional basin type still is allowed to flow as thin over the absorber plate of inclined solar still. The absorber plate of inclined still heat ups the preheated feed water to high temperature by receiving additional solar radiation hence enhanced evaporation begins and the condensate is collected using suitable provisions. The high temperature operation of distillation unit favors efficient removal of bacteria (Sodha et al., 1981) hence the rejected hot water from inclined still can be used

for domestic purposes (Aybar, 2006). Additional distillate is also obtained from conventional basin type still. The effect of gap between condensing and evaporating surface of inclined still, thickness of fluid film, mass flow rate of feed, depth of water in the basin for summer and winter seasons on distillate yield has been simulated using the developed transient mathematical model.

3. Mathematical modeling of the proposed unit

The major assumptions that have been considered during modeling of hybrid still are given below:

a) The unit is air tight and free from vapor leakage
b) The heat capacity of glass cover, absorber plate and water mass are considered
c) There is no temperature gradient across the thickness of glass cover and water mass
d) The water level in the preheating unit (conventional still) is always maintained constant by supplying feed water
e) Heat transfer from the evaporating surface to the condensing surface is by convection, radiation and evaporation
f) Heat loss to the ambient is by convection and radiation from the glass cover and by conduction through the insulation

The energy transport process for different components of the proposed unit is given below:

Basin liner of Integrated Single Slope Still (ISSS),

$$(MC)_{ab}\frac{dT_{ab}}{dt} = G_s\tau_g\tau_w\alpha_p A_{ab} - q_{c(ab-wb)} - q_{l(ab-a)} \qquad (eq.1)$$

Water mass of Integrated Single Slope Still (ISSS),

$$(MC)_{wb}\frac{dT_{wb}}{dt} = G_s\tau_g\alpha_w A_{wb} + q_{c(ab-wb)} + \left(\dot{m}_f + \dot{m_{BS}}\right)C_{pw}T_{fi} - (q_c + q_r + q_e)_{(wb-gb)} - \dot{m}_f C_{pw}T_{wb} \qquad (eq.\ 2)$$

Glass cover of Integrated Single Slope Still (ISSS),

$$(MC)_{gb}\frac{dT_{gb}}{dt} = G_s\alpha_g A_{gb} + (q_c + q_r + q_e)_{(wb-gb)} - (q_c + q_r)_{(gb-a)} \qquad (eq.3)$$

Basin liner of Active Inclined Still (AIS),

$$(MC)_{ai}\frac{dT_{ai}}{dt} = G_s\tau_g\tau_w\alpha_p A_{ai} - q_{c(ai-wi)} - q_{l(ai-a)} \qquad (eq.4)$$

Water mass of Active Inclined Still (AIS),

$$(MC)_{wi}\frac{dT_{wi}}{dt} = G_s\tau_g\alpha_w A_{wi} + q_{c(ai-wi)} + \dot{m}_f C_{pw}T_{wb} - (q_c + q_r + q_e)_{(wi-gi)} - \dot{m}_b C_{pb}T_{fo} \qquad (eq.5)$$

Glass cover of Active Inclined Still (AIS),

$$(MC)_{gi}\frac{dT_{gi}}{dt} = G_s\alpha_g A_{gi} + (q_c + q_r + q_e)_{(wi-gi)} - (q_c + q_r)_{(gi-a)} \qquad (eq.6)$$

Convective heat transfer between the basin liner and water is given as,

For basin type still, (Zurigat and Abu-Arabi, 2004)

$$q_{c(ab-wb)} = 135.0A_{ab}(T_{ab} - T_{wb}) \qquad (eq.7)$$

For inclined type still,

$$q_{c(ai-wi)} = h_{c(ai-wi)}A_{ai}(T_{ai} - T_{wi}) \qquad (eq.8)$$

Convective heat transfer coefficient between the basin liner and flowing feed water film is given as, (El-Samadony and Kabeel, 2014)

$$h_{c(ai-wi)} = 0.664 \frac{k_f}{L} Re_L^{\frac{1}{2}} Pr_f^{\frac{1}{3}}$$

If $Re_L \leq 500000$

$$h_{c(ai-wi)} = 0.037 \frac{k_f}{L} \left(Re_L^{\frac{4}{5}} - 871 \right) Pr_f^{\frac{1}{3}}$$

If $Re_L \geq 500000$

Convective heat transfer between evaporating and condensing surface of basin type still is given as,

$$q_{c(wb-gb)} = h_{c(wb-gb)} A_{wb} \left(T_{wb} - T_{gb} \right) \quad (eq.9)$$

Heat transfer coefficient is estimated as, (Hongfei et al., 2002)

$$h_{c(wb-gb)} = 0.2 Ra'^{0.26} \frac{k_{av}}{w}$$

Evaporative heat transfer between evaporating and condensing surface of basin type still is given as,

$$q_{e(wb-gb)} = \dot{m_{BS}} h_{fg} \quad (eq.10)$$

Distillate yield is given as, (Hongfei et al., 2002)

$$\dot{m}_{BS} = \frac{h_{c(wb-gb)}}{\rho_{av} C_{pav} Le^{(1-0.26)}} \frac{M_v}{R} \left(\frac{P_{wb}}{T_{wb}} - \frac{P_{gb}}{T_{gb}} \right) A_{wb}$$

Radiative heat transfer between evaporating and condensing surface of basin type of still is given as,

$$q_{r(wb-gb)} = \frac{\sigma A_{wb} \left(T_{wb}^4 - T_{gb}^4 \right)}{\left(\frac{1}{\varepsilon_w} + \frac{1}{\varepsilon_g} - 1 \right)} \quad (eq.11)$$

Heat loss from the absorber plate to the ambient through insulation is given as,

$$q_{l(ab-a)} = k_d A_{ab} \frac{(T_{ab} - T_a)}{x_d} \quad (eq.12)$$

Convective heat transfer between the glass cover of basin type still and ambient is given as, (Zurigat and Abu-Arabi, 2004)

$$q_{c(gb-a)} = \left(2.8 + (3V) \right) A_{gb} \left(T_{gb} - T_a \right) \quad (eq.13)$$

Radiative heat transfer between the glass cover of basin type still and ambient is given as,

$$q_{r(gb-a)} = \sigma \varepsilon_g A_{gb} \left(T_{gb}^4 - T_a^4 \right) \quad (eq.14)$$

The convective, evaporative and radiative heat transfer occurring in the inclined still is found by replacing $(wb - gb)$ by $(wi - gi)$ in eq. 9 to eq. 11 and $(gb - a)$ by $(gi - a)$ in eq.12 to eq. 14.

The distillation efficiency is given as,

$$\eta_{di} = \frac{(\dot{m}_{BS} + \dot{m}_{is}) \times h_{fg} \times \Delta t}{\left(G_s \times \Delta t \times \left(A_{gb} + A_{gi} \right) \right)} \times 100 \quad (eq.15)$$

The overall efficiency is given as,

$$\eta_o = \frac{\left[\left(\dot{m}_b C_{pb} \left(T_{fo} - T_a \right) \right) + \left((\dot{m}_{BS} + \dot{m}_{is}) \times h_{fg} \right) \right] \times \Delta t}{\left[G_s \times \Delta t \times \left(A_{gb} + A_{gi} \right) \right]} \times 100 \quad (eq.16)$$

The above mentioned differential equations eq. 1 to eq. 6 were first discretized using finite difference method and were converted into algebraic equations. The obtained algebraic equations were solved using iteration method using the program written in FORTRAN language. The necessary input files were fed as separate file

for solving the equations. The time step size and convergence criteria were kept as 10 s and 0.001, respectively. The solar radiation profile for Chennai location was simulated using the method given by (Katiyar and Pandey, 2011). The monthly average wind velocity and hourly ambient temperature for the months of April and December were used for simulation.

4. Results and discussion

Effect of different parameters on the performance of the hybrid still was simulated for summer and winter months and is presented in this section. The solar radiation profile simulated for the month of April and December along with the ambient temperature is shown in **Fig. 2**. The maximum solar radiation was around 896.27 W/m^2 and 661.54 W/m^2 for summer and winter months, respectively.

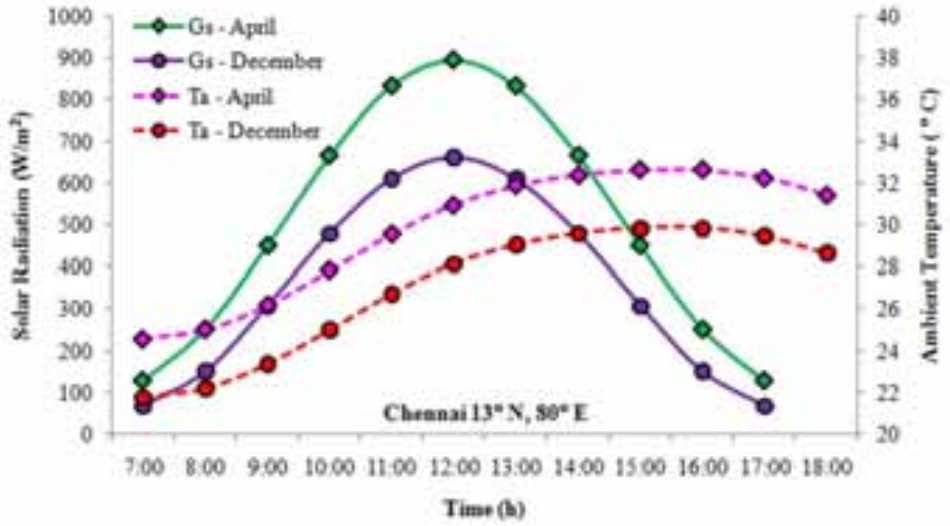

Fig. 2: Solar radiation and ambient temperature profile of Chennai during April and December

4.1. Gap between evaporating and condensing surface

The simulation was carried out for the month of April and December for 0.05 m feed water depth in basin, 0.005 kg/s feed water mass flow rate and 0.002 m fluid film thickness in inclined still. The impact of gap between the evaporating and condensing surface on the distillate yield of active inclined still during summer and winter is shown in **Fig. 3**. The yield is found to decrease from 3.11 kg/m^2-d to 2.44 kg/m^2-d with the increase in gap from 0.05 m to 0.50 m during summer. Increase in gap denotes increased air volume within the system which acts as resistance to the transfer of vapors from the evaporating surface to the condensing surface. The yield is found to decrease by 21.79 % and 25.58 %, during summer and winter with the increase in gap from 0.05 m to 0.50 m. The distillate yield during summer and winter for a gap of 0.05 m is only 6.87 % and 8.86 % higher than the yield for a gap of 0.10 m. The optimum gap can be kept as 0.10 m by considering operation and maintenance point of view.

4.2. Thickness of feed water film and mass flow rate

The simulation was carried out for the month of April and December for 0.05 m feed water depth in basin, 0.10 m gap between condensing and evaporating surface and mass flow rate of 0.005 kg/s. The impact of thickness of fluid film on the distillate yield of active inclined still during summer and winter is shown in **Fig. 4**. The yield is found to decrease from 2.94 to 2.80 kg/m^2-d while increasing the thickness of fluid film from 0.001 m to 0.01 m during summer and from 1.60 to 1.53 kg/m^2-d during winter for a mass flow of 0.005 kg/s. As the thickness increases, heat capacity of fluid film increases leading to reduced heat transfer from the absorber plate to the fluid film. Hence, it is necessary to maintain reduced fluid film thickness for the inclined still for better yield. The thin fluid film can be achieved by spreading thin metal wire mesh or porous cloth of required thickness over the absorber plate and allowing feed water to drip over these surfaces (Aybar, 2006).

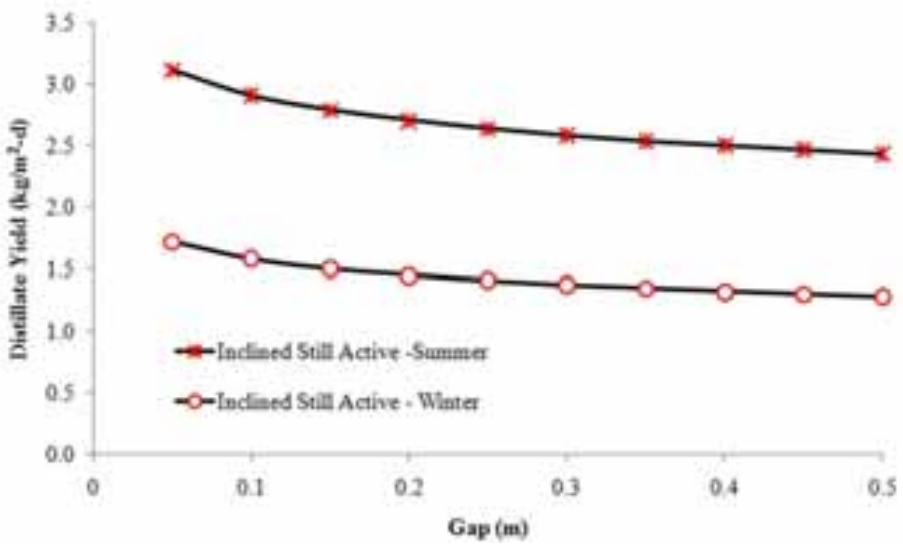

Fig. 3: Impact of gap between evaporating and condensing surface on distillate yield of active inclined still

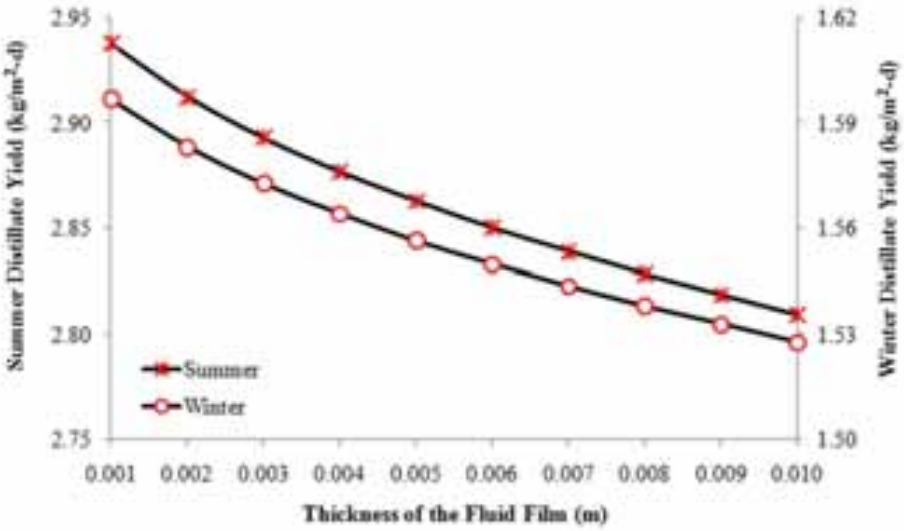

Fig. 4: Impact of thickness of fluid layer on distillate yield of active inclined still

The simulation was carried out for the month of April and December for 0.05 m feed water depth in basin, 0.10 m gap between condensing and evaporating surface and 0.001 m fluid film thickness in inclined still. The impact of mass flow rate of feed water on the distillate yield of the active inclined still is shown in **Fig. 5**. The yield is found to decrease from 9.10 kg/m^2-d to 1.24 kg/m^2-d with the increase in mass flow rate from 0.001 kg/s to 0.01 kg/s, during summer. At lower mass flow rates, the operating temperature will be higher leading to increased evaporative heat transfer and yield. At higher mass flow rates, the residence time of the feed water inside the distillation unit decreases leading to lower heat transfer from the absorber plate to water film causing reduced yield (Tabrizi et al., 2010a). The mass flow rate must be selected properly such that the feed water wets the entire absdorber plate and prevents the formation of dry patches on the surface. For a mass flow rate of 0.003 kg/s, the yield is found to be around 4.82 and 2.59 kg/m^2-d during summer and winter, respectively.

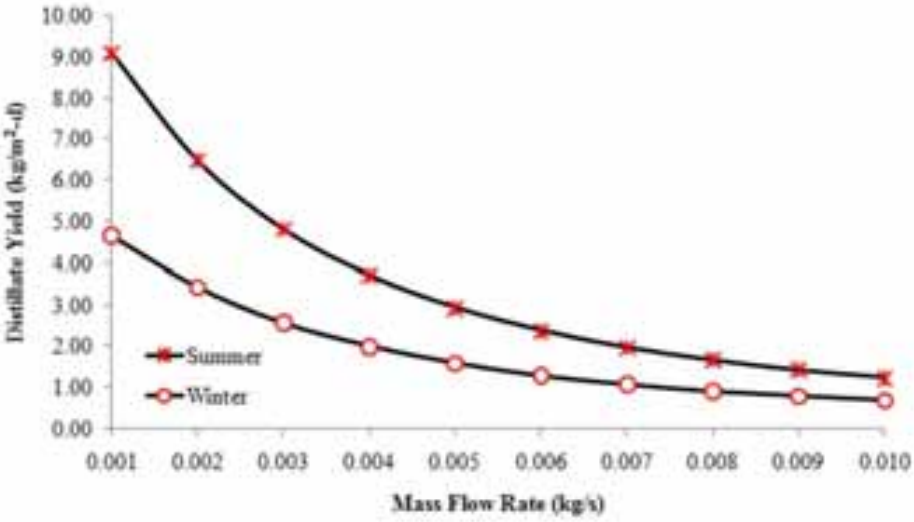

Fig. 5: Impact of mass flow rate of feed water on distillate yield of active inclined still

4.3. Depth of feed water in basin

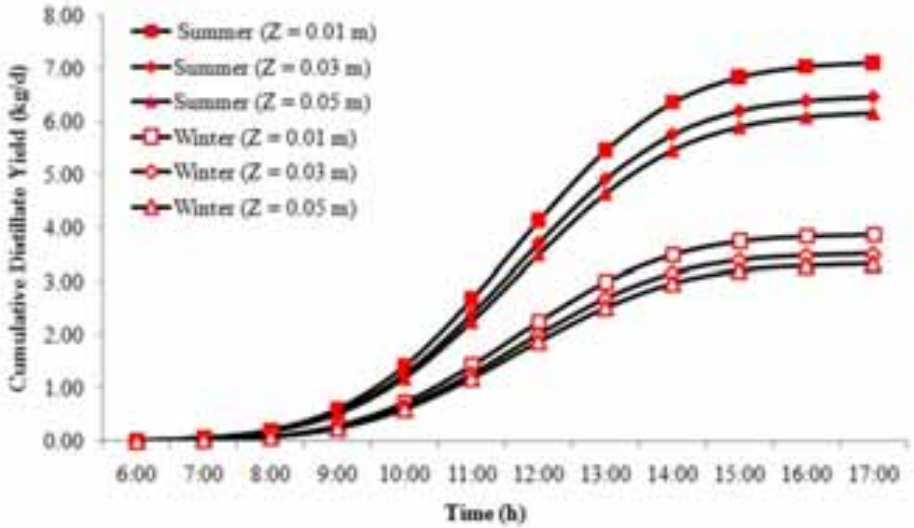

Fig. 6: Impact of depth of feed water in basin on cumulative distillate yield of the hybrid still

Feed water preheated in the basin type still is fed as input to the inclined still hence it is necessary to achieve maximum temperature using the basin type still for improved yield and hot water from inclined still. Depth of feed water in the basin type still is a major parameter which influences the yield from the hybrid still. The simulation was carried out for the month of April and December for 0.10 m gap between condensing and evaporating surface, mass flow rate of 0.003 kg/s, fluid film thickness of 0.001 m in inclined still and feed water depth of 0.01 m, 0.03 m and 0.05 m in basin. The impact of depth of feed water in basin on the distillate yield of hybrid still during summer and winter is shown in **Fig. 6**. The distillate yield is found to increase with the reduction in depth of feed water in the basin from 0.05 m to 0.01 m. Reduced yield at high depth is due to the increased mass of water in the basin which increases the heat capacity and reduces the transmissivity of the water leading to reduced radiation reaching the absorber plate of the basin type still (El-Sebaii, 2000). For a depth of 0.01 m the hybrid still produces a distillate yield of 7.12 and 3.86 kg/d during summer and winter, respectively. The yield is nearly 15.39 % and 15.91 % higher than the yield during summer and winter, respectively for a depth of 0.05 m.

4.4 Performance of the optimized hybrid distillation unit - hourly distillate and hot water productivity

The cumulative distillate yield of hybrid still is compared with passive inclined still and is shown in **Fig. 7.** Cumulative yield from passive inclined still and active inclined still is 2.54 kg/d and 5.31 kg/d, respectively. Cumulative yield of integrated single slope still (ISSS) which acts as the preheating unit for the active inclined is 1.81 kg/d. Hence, the total yield form the hybrid still (AIS +ISSS) is 7.11 kg/d. The distillate yield is found to be minimum during 6:00 to 9:00 due to reduced solar intensity and the yield increases steadily from 9:00 to 14:00, beyond 14:00 cumulative increase in yield remains nearly constant for the distillate units considered for study

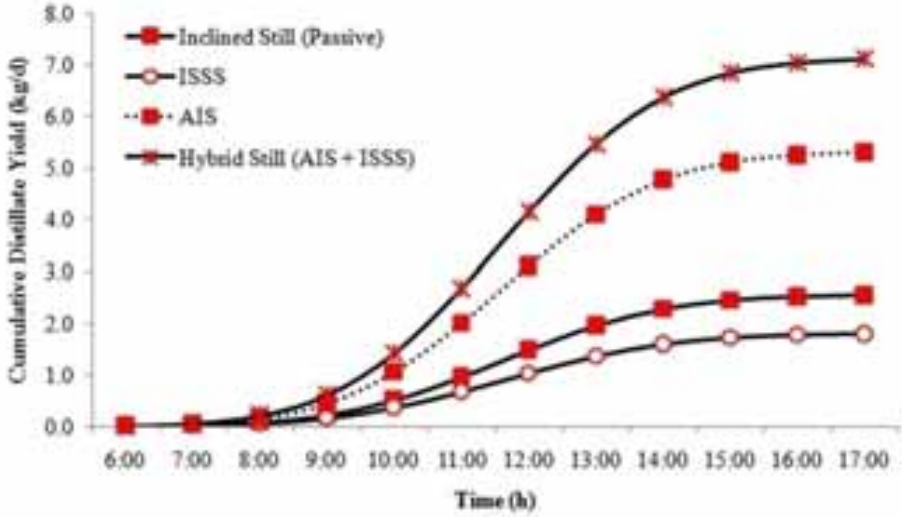

Fig. 7: Comparison of cumulative distillate yield of different distillation units

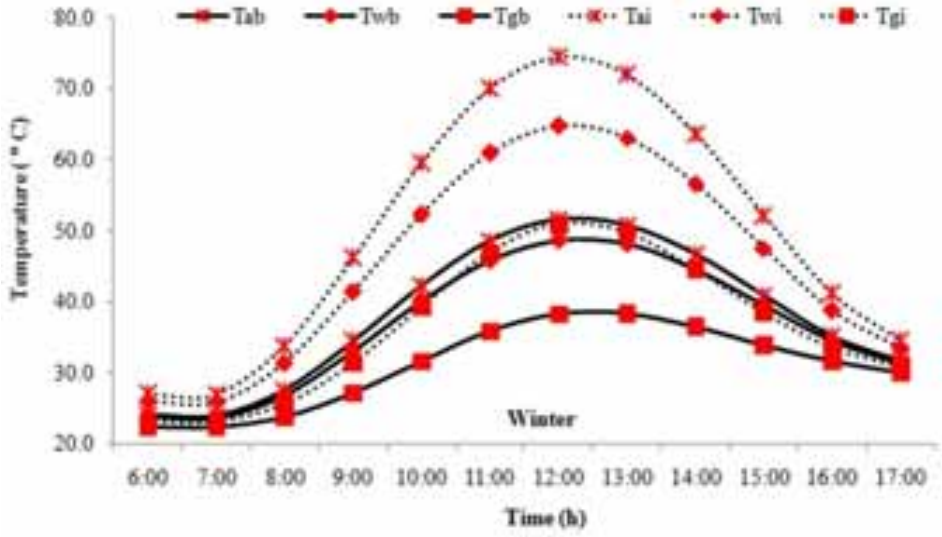

Fig. 8: Hourly variation of temperature for different components of the hybrid still

The hourly temperature profile of different components of hybrid still for the month of December is shown in **Fig. 8**. The temperature profile is found to follow the solar radiation profile for the considered day. The temperature is found to increase with the increase in solar radiation up to 12:00 and then starts decreasing beyond 12:00. The maximum temperature of the absorber plate of integrated solar still and active inclined still is 51.48 ˚C and 74.35 ˚C, respectively. Maximum temperature of the feed water while leaving basin type still is 48.59 ˚C and it reaches 64.65 ˚C while leaving the absorber plate of the inclined still. Maximum glass temperature of the basin type still and inclined still is 38.33 ˚C and 50.86 ˚C, respectively.

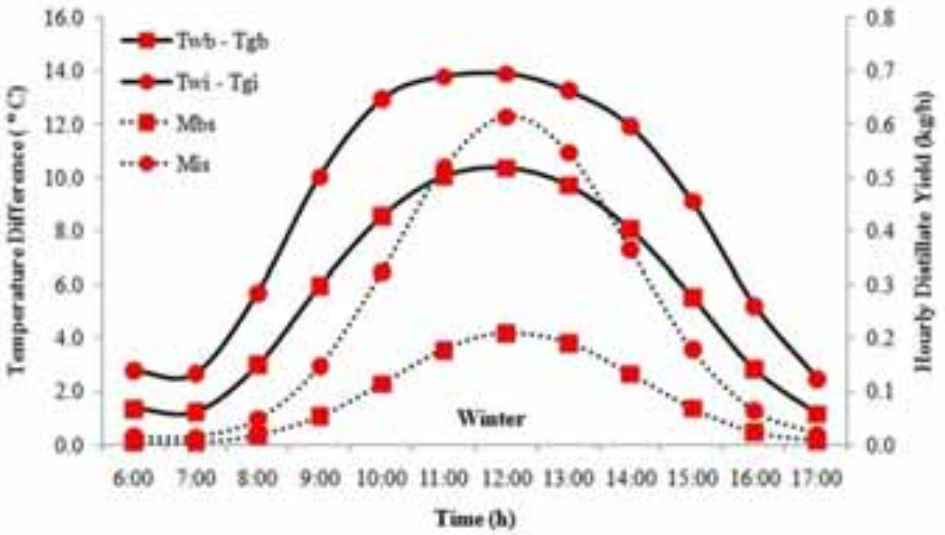

Fig. 9: Hourly distillate yield and temperature difference between evaporating and condensing surface of the hybrid still

The temperature difference between the evaporating and condensing surface of hybrid still along with its hourly distillate productivity for the month of December is shown in **Fig. 9**. The maximum temperature difference between the evaporating and condensing surface of the integrated single slope still and active inclined still is 10.35 ˚C and 13.90 ˚C, respectively. The maximum hourly productivity of the integrated single slope still and active inclined still is 0.21 kg/h and 0.61 kg/h, respectively making the total hourly productivity of the hybrid still to be around 0.82 kg/h.

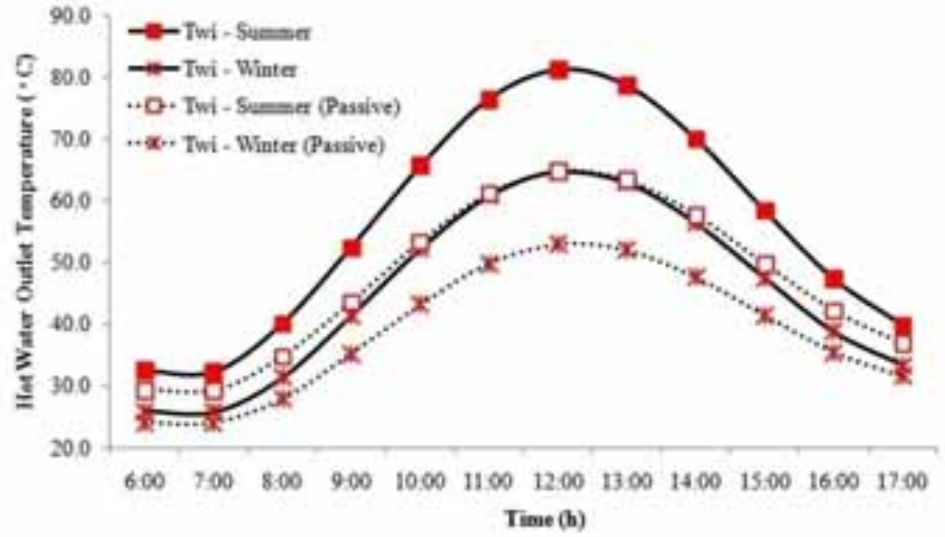

Fig. 10: Hourly temperature variation of hot water generated by the active and passive inclined still

The hourly temperature profile of the hot water generated by hybrid still during summer and winter in comparison with passive inclined still is shown in **Fig. 10.** The maximum temperature of hot water produced by passive inclined still is 64.84 ˚C and 52.91 ˚C, respectively during summer and winter. The maximum temperature of hot water produced by hybrid still is 81.29 ˚C and 64.65 ˚C during summer and winter which is higher than passive inclined still by 16.45 ˚C and 11.74 ˚C, respectively. The increase in hot water temperature of active inclined still is mainly due to preheating of feed water in the integrated single slope still of hybrid still. The average temperature of hot water generated by hybrid still is around 56.28 ˚C and 45.09 ˚C during summer and winter, respectively and the amount of hot water generated is more than 100 kg/d for both the seasons. The produced hot water can be used for domestic purposes like washing, flushing and it depends on the salinity of the feed water too (Aybar, 2006).

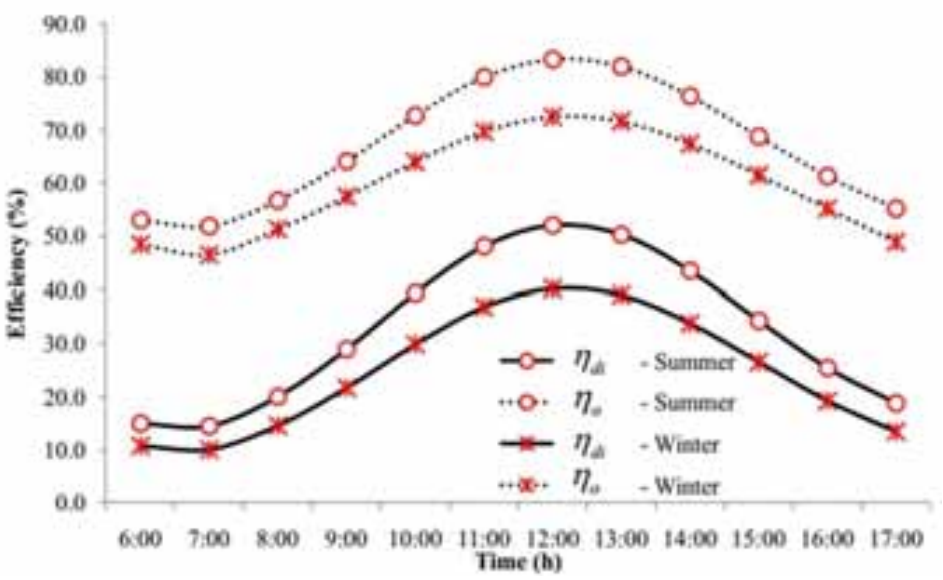

Fig. 11: Hourly variation of distillation and overall efficiency of hybrid still

The hourly variation of distillation efficiency and overall efficiency of hybrid still for summer and winter months is shown in **Fig. 11**. Distillation efficiency represents the ratio between energy content of the fresh water generated to the solar radiation input to the system. Overall efficiency represents the ratio between the energy content of the fresh water generated and useful energy of the hot water generated to the solar radiation input to the system. The efficiency varies with time due to variation in solar intensity and it reaches maximum during noon. The maximum distillation efficiency during summer and winter day is 52.14 % and 40.30 %, respectively. The maximum overall efficiency during summer and winter day is 83.40 % and 72.57 %, respectively. The average distillation efficiency and overall efficiency of the system is 32.59 % and 67.18 %, 24.73 % and 59.61 % for summer and winter, respectively.

5. Conclusion

Solar stills can carry out both desalination and detoxification in a single unit and are highly suitable for remote applications. In this study, transient simulation of hybrid solar still which has the ability to generate both potable water and hot water was carried out successfully. The distillate yield from hybrid still is found to increase with the decrease in depth of feed water in the basin type still, feed water mass flow rate and thickness of fluid film. Distillate yield from hybrid solar still is around 7.12 kg/d and 3.86 kg/d during summer and winter, respectively. Average temperature of hot water generated by the unit is around 56.28 ˚C and 45.09 ˚C during summer and winter, respectively. Overall efficiency of the hybrid unit is around 67.18 % and 59.61 % during summer and winter, respectively. The amount of hot water generated is more than 100 kg/d which is fairly sufficient for domestic activities like washing and flushing. The proposed unit will be of great benefit to rural and remote communities.

Opportunities of Renewable Energies in the Mexican Legal Framework Strategy for Energy Transition in Response to International Environmental Agreements

Karla E. García García[1], María F. Sánchez Medina[1], Martha F. Mohedano Castillo[1] y Dr. Iván Galileo Martínez Cienfuegos[1]

[1] Facultad de Ingeniería, Universidad Autónoma del Estado de México (UAEMEX), Cerro de Coatepec, Paseo Universidad s/n, Toluca de Lerdo, Estado de México,C.P. 50130, México

Abstract

Electricity is one of the world´s most primary resources. Its cost and availability, have a bearing on a person´s quality of life. Mexico´s ability to satisfy the public demand for energy from renewable sources has been between 8.5% and 10.9%. As one of the undersigned countries in multilateral environmental agreements, Mexico has created laws and development initiatives in name of sustainability. In this article we will analyze data on the current energy panorama in Mexico, taken from accredited national and international sources. This will allow us to have a holistic view of the current state implementation of technology which makes good use of renewable energy. In this way, we will be able to detect investment and development opportunities in Mexico.

Key words: *Sustainable energy, energy reform, multilateral agreements, energy transition, plans for development, investment opportunities.*

1. The energy sector in Mexico

Mexico has at its disposal a vast quantity of hydrocarbons, which means that throughout history Mexico´s energy sector has come principally from fossil fuels-crude oil and natural gas. These sources provide nearly 90% of Mexico´s total energy production nationally (PROSENER, 2013).

The main task of the energy sector is to provide an energy service that will be efficient at a competitive price for the entire population. This will help the country socially and economically. In case more energy is produced than is consumed, this surplus will fall due to the decline in the production of oil and natural gas, versus the grown in consumption of energy resources nationally - around 2.7% over the last decade (PNI, 2014).

To date, more than 20% of energy generated for the public comes from fuel oil and diesel (PNASE, 2014). This is considerably more expensive than clean energy sources and natural gas. Mexico has great potential for producing gasoline, diesel, turbosine, natural gas, among many others, but this is not well financed and, as such, the necessary processes of transformation and extraction are stifled. PEMEX is a good example of the inability to produce natural gas due to the great demand. Because of this, Mexico imports natural gas; paying more than it would if it produced its own natural gas.

The energy sector in Mexico faces great challenges. The cost of electricity is high and not competitive. Compared to the US, the cost of electricity is 25% higher in Mexico, even with a government subsidy. Without which, the cost would be 73% more expensive (PNASE, 2014). This hinders the Mexican economy given that electricity is a basic need for industry, business and other services.

The slow pace of switching from fossil fuel energy centers to clean energy centers is mainly due to the monopoly which the Federal Electricity Commission has over public energy sector. Although individuals are now permitted to participate in the industry, the Federal Electricity Commission still controls all large scale energy projects which are limited by state budgets. This has become a bottle neck that impedes the speedy development of potential sources that could generate low cost electricity.[1]

The statistics for renewable energy usage in Mexico was 8.9% (around 440PJ) in 2013, as shown in figure 1. Almost 60% of which was due to traditional biomass generation.

doi:10.18086/swc.2015.09.01 Available at http://proceedings.ises.org

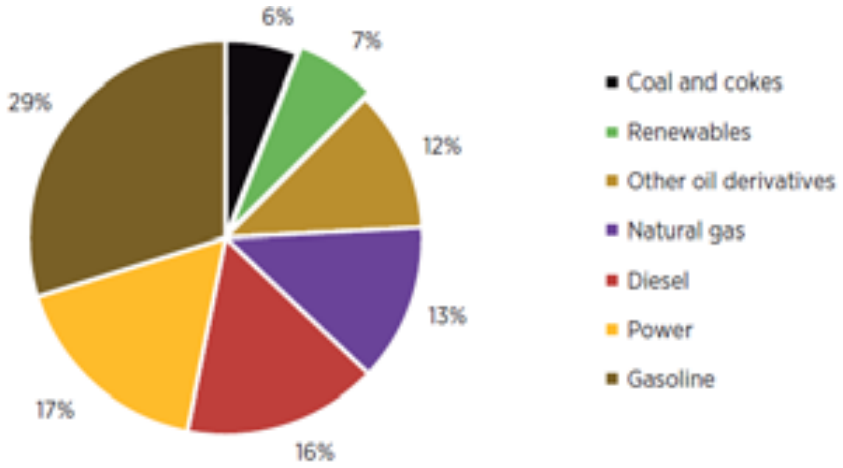

Figure 1: Total end energy consumption in Mexico, 2013 (Renewable Energy Prospects: Mexico, 2015)

2. Multilateral agreements on environmental matters

Globally, energy systems are among the biggest sources of emissions which severely compromise public health and cause global climate change.

With the aim of promoting international teamwork and implementing clean energy solutions in terms of the supply, delivery and energy demand which benefits people locally and globally, every country should implement national strategies that try to adopt production and consumption methods that protect the Earth´s ability to regenerate. Countries need to be moderate and efficient in terms of energy use and try to depend more and more on renewable energy sources such as solar energy and wind energy.

According to the United Nations Framework Convention on Climate Change (UNFCCC) we must, as a country, take control of the emission of greenhouse gases into the atmosphere in order to avoid dangerous anthropogenic interference in the climate. For this, economic development must be sustainable.

The Cancun Agreements gave a boost to international negotiations which gave the developing world the necessary technological tools, finance, adaptation and mitigation that form the basis of a greater collective effort to reduce emissions which will bear fruits for all those involved. We need officially registered projects nationally and internationally as part of the UNFCCC.

Mexico has signed bilateral agreements with Canada, US, Germany, Norway, Korea, among others in which they agree on technical cooperation and research into clean energy sources (energy efficiency, capture and storage of carbon, electrical connections, intelligent networks) and into hydrocarbons (transport and chemical treatment of heavy crude oils, unconventional gas); furthermore, we seek an interchange of experiences on the best regulatory practices and methods for designing public policy. The same is true of projects and initiatives which are created to promote the use of renewable energy, innovative technology and energy efficiency as a means of combating climate change.

2.1 Business and the Environment

Essential negotiations concerning business and the environment are being treating in all levels, including: multilateral, regional, bilateral and national. This has presented a challenge for the undersigned countries, given that taking on these commitments if which you do not fulfill, will incur fines because it is not easy to implement a manner of organizing the environment that guarantees the effective fulfillment of environmental legislation and the adequate use of natural resources.

The main multilateral environmental agreements have been signed by most countries; international development banks and agencies Inter-American Development Bank, The World Bank, International Monetary Fund, to mention a few who contribute to the subject of the environment as part of their terms and conditions by donating resources or by giving credit away. The private sector has incorporated the question of the environment in their production processes and has even imposed restrictions on business. Proactive work on the environment is increasingly common in civil organizations working alongside the government; above all in

developing countries which have had to accept the environment as an important factor in regional and bilateral agreements when such agreements are reached with countries such as Canada or the US or with the European Union. In these cases the environment is included as a legal requirement (Murillo C., 2008)

2.2 North American Free Trade Agreement (NAFTA)

The North American Free Trade Agreement is an important first step in terms of the environment as a concern for business. In this agreement environmental legislation is a priority. There is a commitment to making sure that countries respect and improve their own environmental legislation.

Despite the fact that the introduction of some topics about environment in negotiations was initially seen as an imposition, the agreement between Mexico, the US and Canada has been an important step in the development of the environmental subject in Mexico.

A notable contribution came from the promotion of public participation by means of an improved access to information, financing of public projects, public hearings for academic bodies, establishing mechanisms allowing people to report failures to follow national environmental law.

The influence of NAFTA in the institutional nature of the environment in Mexico has been unquestionable. Mexico has improved its public policies and the institutional nature of the environment and although not all changes were made to be adapted to NAFTA. To a great extent the requirements of this agreement are to enhance the process of change.

2.3 Perspectives on Renewable Energy in Mexico: REmap 2030

In 2011, SE4ALL was launched with three related objectives that need to be reached before 2030: assure universal access to energy and modern energy services, double energy efficiency and multiply the universal budget for renewable energy resources. In this context, IRENA has developed a world route for renewable energy (Remap 2030), in which Mexico has decided participate and has declared its objectives for energetic reform before 2030 in which the increase of renewable energy would put Mexico on the right track for reducing greenhouse gases significantly given that it has the potential to reduce the carbon demand in Mexico by 62%, natural gas by 21% and oil by 6% by 2030 (PNASE, 2014).

Among the challenges that Mexico faces we find the raising of consciousness, improving information about renewable energies for politicians, manufacturers, project developers and installers and users. In this way, we will be able to show an idea of how high level renewable energy generation can be incorporated into the transmission system.

According to predictions made by SENER and the Asia-Pacific Economic Cooperation, Mexico has the potential to generate 280 TW hourly of energy from renewable sources in 2030. This represents a six-fold increase on the current level of 48 TW hourly, that could be achieved with a diverse mixture of wind, solar, hydraulic, geothermic and biomass energy.

Wind and solar voltaic energy combined would represent almost 60% of renewable energy generation in Mexico and 26% of the total generation in 2030 (PNASE, 2014). Photovoltaic solar energy could contribute 30 GW in energy generation. This would be 66 TW hourly annually by 2030.

3. Reforms in Mexican legislation

In the energy sector we can identify the need to reach higher levels of production of primary energy, improve transport services, energy storage and distribution; make sure the supply is reliable; improve the efficiency and quality of the product and reduce the cost of electrical and its negative impact. The objective of this is to allow the country to make the most of its energy resources to a greater extent in order to benefit the population.

Until recently, the Mexican constitution hindered the participation of private companies in the production and extraction of energy sources from fossil fuels. This works against the development and adequate distribution of energy. Thanks to energy reforms and the secondary laws that were approved between 2013 and 2014 which allowed private companies to gain contracts the monopoly over the oil industry nationally broke, allowing PEMEX to strengthen its strategic role in the oil industry. It also acted to help competition and the implementation of a national strategy for sustainable industrial development. It also included sustainability as one of the important constitutional criteria to which private and public companies will have to adhere.

Likewise, energy reform takes into account the fact that the energy sector should act in a fashion that promotes

justice, equality, development, democracy and economic growth. In the same sense, the supply of energy should reach all the population. This will boost their potential for development in many senses. With this, we bolster the commitment to improve energy access to communities where it is not currently available. In 2011 around 20% of the population of the world didn't have access to electricity. Of this 20%, 85% were in rural areas. Also, one thousand million more only have intermittent access to electricity; their access is frequently cut (PSE, 2012).

As well as guaranteeing a good quality energy supply at competitive prices. Recent energy reforms have also sought to promote the participation of private generators and, in this way, benefit projects which allow the best use of renewable energy resources. By applying Energy Reforms we hope to gain private investment for energy generation projects and we hope that this private investment can reach 15% of the total investment in the year 2018.

While trying to promote investment into renewable energies, Mexico has worked to create and modify laws that incentivize their use and reduce the dependence on fossil fuels. In the National Plan for Energy we find an objective of 35% of electrical energy being generated with clean technology by the year 2024. The Law for Harnessing Renewable Energies and Financing the Energy Transition sets out the plans and objectives in the current availability and generation of electricity in the country. They follow the objectives set out the in National Development Plan.

Our goal as a country is to try to avoid the use of crude oil in the future. This comes from so-called unconventional resources such as shale gas and deep water. This severely damages the environment during extraction as well as increasing our dependence on fossil fuels for energy production.

3.1 General Laws on Climate Change

The objective of this law is to promote efficient energy practices and the development of low carbon technologies. According to the national objectives for emissions reduction for the year 2020, we must create a system of subsidies that promotes the main advantages of the use of non-fossil fuels, energy efficiency and sustainable public transport. We must also build up a system of incentives that promotes and permits profitable energy generation through means of renewable energies; such as wind, solar and hydraulic energy managed by the Federal Commission for Electricity. The Energy Secretary working with the Federal Commission for Electricity and the Regulatory Body for Energy will promote electrical generation from clean energy sources for at least 35% by the year 2024 (LGCC, 2012).

3.2 Energy Reform

Mexico has made substantial changes to the energy sector in an effort to increase productivity in the country. One of the main goals is to increase the level of investment and jobs available. Also, PEMEX and the Federal Commission for Electricity need to be given greater liberties to modernize. In terms of oil and gas, the reform aims to have a greater production at a lower cost. It also aims to improve competency in refining, transport and storage by involving private companies who adhere to state rules as well as the development of clean technologies.

With Energy Reform, articles 25, 27 and 28 of the constitution were all amended which opened the extraction and exploitation of hydrocarbons to private companies nationally and from abroad. This allows the state to make private service contracts which modernizes and strengthens PEMEX and the Federal Commission for Electricity without privatizing them. They remain completely Mexican companies.

Allowing the country to take full control over the planning and control of the national electricity system works to benefit a competitive system which lowers prices, provides more energy at better prices, guarantees international standards of efficiency, transparency and economic gain which will bring investment to the Mexican energy industry which will, in turn, help the country to develop. These are all other goals we hope to achieve.

In August of 2014 secondary laws on energy reform were passed. The most important of which are new laws such as: the Law on Profits Made from Hydrocarbons, the Law on Mexican Oil Reserves for Stability and Development, the Law on the Electricity Industry, the Law on Geothermic Energy, the Law on Regulatory Bodies for Energy, the National Agency's Law for Industry Safety and Environmental Protection in the Oil Sector, the Hydrocarbons Law, the Law on Mexican Oil, the Federal Commission for Electricity's Law. Other laws which were reformed include: the National Water Laws, the Law on Foreign Investment, the Mining Law,

the Law of Public and Private Associations; the Law of State Entities, Acquisition Laws, the Law of Public Sector Services, the Law of Public Building and Related Services.

3.3 Challenges for Energy Reform

In the electricity industry, clean energy generation is not always the easiest option for the development of new projects. Resources with great potential are in rural parts and to transmit this energy and interconnect the two sites, large-scale developments are required. Furthermore, clean technologies present risks and challenges in terms of use and development.

The state must guarantee the constitutional right to a healthy environment. To achieve this, we must take measures to prevent the deterioration of the environment. We must also sanction those who harm the environment and they should pay for the damage caused. This should be strictly controlled and should allow the best use be made of the available resources. This is an important step on the road to sustainability.

We must take into account that according to the Law for Harnessing Renewable Energies and the Financing of Energy Reform, energy generation from fossil fuels shouldn't exceed 65% of the total. This is a challenging target for the energy sector. This will involve new technologies for generating electricity that use renewable energy resources, such as nuclear and co-generational energy. In this way, we will be able to face up to the challenges of diversification and safety in the energy sector (PNASE, 2014).

In recent years many projects and programs have been developed with the aim of guaranteeing Mexicans' rights to basic electricity services, this idea is supported by the PND. They also want to increase electricity coverage to a greater extent. At the end of 2012, 98.11% of the population had access to electricity. This means that Mexico, on a global scale, is one of the countries with best electricity coverage. However, there are still more than 2.3 million Mexicans who do not have access to this basic service. This is around 42,945 houses (PROSENER, 2013).

4. National plan for energy reform

The national plan tries to regulate the harnessing of renewable energy resources and clean technologies for generating electricity not destined to the public. It also seeks to create a decent strategy with enough support and financing to help Mexico move along the road to energy reform. This includes the use of sustainable, low-carbon systems that help to combat the effects of climate change.

Through political incentives, programs, actions and projects that seek to increase the use of renewable energy resources and clean technology and as a response to the growing demand on energy resources and to the need to have reliable energy system, energy efficiency is highly important.

The transition to a sustainable energy system requires diversification in the energy field, a boost in the use of clean technologies and an efficient harnessing of energy resources that we have at our disposal.

Diversifying energy sources prioritizes the extended use of non-fossil technologies, bio-energies or energy produced by sustainable technologies represent a viable alternative in the process of energy diversification and sustainable development given that they substitute fossil fuels and they also contribute to reducing greenhouse gases into the atmosphere.

Within this framework and with the backing of the Law for the Promotion and Development of Bio-energy and its Control, Mexico has set itself the target of creating a policy to support bioenergy.

We need to increase efficiency in the levels of energy consumption in all sectors to reduce energy losses in the production chain which will lead to a reduction in the environmental impact. A reduction in the use of energy while providing the same level of service contributes to a more rational level of energy consumption.

To reduce the environmental impact caused by the production and consumption for which the energy sector is responsible, we need to create a series of actions focused on prevention, contention, remediation and compensation for the effects it causes. Linking these objectives within the energy and environmental sector is extremely necessary to reduce the environmental impact. Creating projects with similar goals in terms of energy reform and the harnessing sustainable energy are key factors.

Strengthening and modernizing the infrastructure in the energy sector as well as maintaining the reliability and integrity of the system involves efficiency, safety, sustainability, availability and reliability of the energy transmission and distribution lines. Projects focused on an economic infrastructure for electricity aim to create a

reliable and modern transmission network which allows for a better use to be made of Mexico's capacity for energy generation.

5. The potential to generate electricity from renewable resources

During 2013 SENER created the National Inventory of Renewable Energy in which, a geographic system provides information about the electricity generation inventory for public supply, where is possible to see the potential of renewable resources that can be used. In table 1, it is shown an example of the use of these data, in which renewable resources are classified as approved, probable and possible depending in its potential for generating electricity.

Tab 1: Potential for Generating Electricity with Renewable Resources (GWh). Source: PEAER, 2014

Resource	Geothermic	Mini-Hydraulic	Wind	Solar	Biomass
Possible	78799	N/A	87600	6500000	11485
Probable	60286	23028		N/A	391
Approved	892	2378	10513	843	592

5.1 Main projects for investment into renewable energies announce in the PNI 2014-2018

In an attempt to satisfy the increasing demand on the electricity system, we will need to develop a greater potential for generating electricity in accordance with predictions for electricity consumption nationally. In this sense, by using Energy Reform we will be able to complement the Federal Commission for Electricity's investment with the participation of individuals in electricity generation. Private investors will have the potential to generate electricity; with the exception of nuclear energy and form long term contracts with qualified experts in the area.

5.2 Wind farms in the South-East II, III, IV and V.

As a whole, they generate 1169 MW in the South-South-West region. For this project we expect an investment of around 25955 million pesos.

5.3 Small Scale Photovoltaic Solar Panel

This refers to a group of 14 plants each one with a capacity of 30MW to be developed in the north of the country. The total investment of each plant is around 884 million pesos. Together, they will generate 420MW and will require a total investment of 12378 million pesos.

5.4 Mexicali

In Mexicali there is a geothermic plant which produces 27MW. The project is designed to be built in Baja California. The total estimated cost is 267 million dollars.

6. Tenders for potential areas for development

Round Zero is an Energy Reform proposal that tries to directly assign resources for the exploitation of petroleum which guarantees a certain level of investment into PEMEX without the need to tender. This is the way it will work for private companies in later rounds.

Round one has two stages, each one with its respective tender. The first one took place on July 15 2015 where 14 areas of potential in deep waters. The second of these is planned for September 30th in which 9 plants, grouped into 5 contracts will need to be assigned. It is worth mentioning that this work will be coordinated by the National Commission for Hydrocarbons.

In round one, the committee will be made up of the following companies: Sierra Oil & Gas (Mexico), Talos Energy (USA) and Premier Oil (England). From this there were two blocks tendered on and the remaining twelve were considered deserted.

7. Conclusion

Mexico still does not have a clear idea what the implementation of renewable energy implies for the complete supply of energy. However, most laws and initiatives that have been created in the context of sustainable

energy and the substitution of fossil fuels are now considered important and almost obligatory. Possible future projects should include energy reform as something standard and obligatory to be considered.

Despite the fact that the transition to clean energy has been imperious for some years now, if it hadn't been for the international agreements in which Mexico forms part, especially the TLCAN which it signed just a year ago. Without this, Mexico would not have taken an important step on the road to energy reform. The insufficient energy supply at the Canterell Complex, among others, shows that despite having fossil fuels, we cannot continue to depend on them. This is equally true because of its cost of extraction economically as well as for the environment. We also need complex technology for their extraction.

Thanks to Mexico's fortunate location and diversity, it has enough potential to make use of different types of renewable energy. This potential is reflected in projects such as wind farms in Oaxaca and proposed projects for the Special Program for Making the Best Use of Renewable Energy. It is worth mentioning that we currently there are many available ways of gaining economic support for investors and researchers in the field of sustainability, energy efficiency and electricity from non-fossil fuels.

Allowing private investment forms part of the process of energy production and distribution opens the door to the inclusion of technological advances; this helps with efficiency and the use of renewable and fossil fuels given that it is not enough to generate energy purely from clean energies; we also need to make better use of the energy that is produced with the technology currently available. Despite the fact that energy reform was approved principally to allow technological cooperation and improve the production and distribution of energy generated from fossil fuels, it is opportune to allow private companies and national and international scientist to be part of the process. From this we will have a fair access to this service.

Mexico, to all intents and purposes is new in the field of energy from sources other than fossil fuels, it has its problems in Mexican law and the consequences of this are being lived today with unfavorable results from tenders from Round Zero and Round One. We see that there is a degree of mistrust on part of foreign and national investors. This may be the reason why expectations were not met.

As a developing country and as one of the undersigned on many international economic and environmental agreements, Mexico has to fulfill certain environmental commitments. Nevertheless, it has been shown that it is still incapable of reaching these agreements alone. There needs to be a greater role played by the population and the state to ensure that new production mechanisms can be implemented. This must also come from researchers by providing adequate conditions and support so that this task can be brought about. Also, in many international agreements on the environment we can see the role that developed countries should play in this process. This includes economic support but, more importantly, a greater level of cooperation working towards a better planet.

The bases for tenders should be changed and we should consider the conditions for their implementation by private companies that work to generate energy from different available resources. We should always keep the importance of national sovereignty in mind given that it is not easy to chain the system of energy supply so radically when the economy of the country is based largely on fossil resources. However, we need to create a decent productive reconversion program in which innovative programs for renewable energy and energy efficiency are supported.

Despite the legal deficiencies we may still be experiencing their possible future reforms, as well as economic instability, we have before us a great opportunity which we did not have previously. The opening of the market to private investors and the restructuring of the energy system which includes extraction and distribution, these tasks previously belonged exclusively to the state and are now allowing the support of third parties to reduce Mexico's technological stagnation.

Recently, it was declared that Mexico should have 35% of its electricity generated from renewable

resources. To reach this goal will require large scale legal reform. This work should be done in a team to achieve a higher percentage production from non-fossil fuels; in this way the Mexican government will be able to achieve its goals. In this regard, it is well known that Mexico has great potential and as such, it is an opportune moment to implement projects that meet current needs determined by programs designed to mitigate environmental damage and that help economically too. Investing in renewable energies is not particularly high risk given their high potential for development. In the same sense, for the proposed objective to be reached, adequate support is required for those who can help the country to reach its goals.

In conclusion, Mexico needs to improve in many areas: legislation, economy, energy supply, among others but if we do not allow and contribute to a generation of change by putting our faith in the country, it is very possible that the process of change will be severely held back.

Solar for All (Making Solar Available to Everyone), Striking a Balance for Sustainable Growth

Ignacio R. Smith[1] and Sherry Mc Millan[2]

[1] SM Solar and Wind Energy Systems Limited, Port of Spain (Republic of Trinidad and Tobago)

[2] SM Solar and Wind Energy Systems Limited, Port of Spain (Republic of Trinidad and Tobago)

Abstract

A lot of effort is being placed on bridging the gap and allowing the financially challenged sector of the population to reap the benefits of solar. However, the biggest hurdle for local and state governments is the impact that these programs may have on their treasuries. So what can regulators and decision makers do, to fund these programs efficiently.

The merging of Community Based Solar initiatives in combination with enhanced revolving funds accompanied by a change in the utility business model, can generate sustainable growth and allow everyone to enjoy cleaner forms of electricity generation.

The key is to strike a balance among all these strategies so that the subscribers will be able to access the service.

Keywords: Cash flow, Pigovian Tax, Paradigm Shift, and Community Solar.

1. Introduction

The energy requirements of the world are in a state of constant growth, this demands greater improvements in generation, transmission and distribution of electricity. The increasing demand is coupled with the need for considerable reductions in the fossil fuel bill making economic growth extremely difficult.

When faced with a reduction in their fossil fuel bill, countries also encounter challenges in areas, such as: high ratio of debt to Gross Domestic Product; low Income per Capita and absence of a legal framework for alternative generation and / or in a setting of subsidized Levelized Cost of Electricity.

Governments in developing countries seek solutions that can create jobs and job opportunities while reducing the dependency on fossil fuels, reduce its annual budget deficit that constrains its expenditure on developmental initiatives, and last offer diversification away from our predominant source of income, to overcome the boom and bust cycles to which single product economies are always exposed too.

As the countries in Latin America and the Caribbean grapple with a difficult path to economic growth with the on-going economic downturn, what can we do to bring change, what savings will it represent, how do we face these challenges, without creating additional burden to the treasury.

Opportunities and market conditions can differ from Region to Region; however, in Latin America and The Caribbean, there are several patterns that are common to most, these trends and conditions are:

— **Subsidies**. For most of Latin America and the Caribbean power generation, transmission and distribution is provided by the state at a price that gives access to the bulk of the population. This hides the true cost of the service from the subscriber promoting inefficiencies.

doi:10.18086/swc.2015.09.02 Available at http://proceedings.ises.org

- **Poverty**. For many years it was believed that Globalization was the key answer to economic growth, reduction of poverty, etc. Although this might be true, the Caribbean and Latin America has not benefit entirely from this growing trend. Poverty and growth are issues carry a high priority in governments on this side of the world.
- **Competition**. Market forces demand that companies competing in the global arena become more efficient. As they seek lower production costs, the demand more energy efficient systems.
- **Limits in Power Generation and Supply**. Generally speaking the demand for electricity expands faster than its supply. It is a fact that many developing nations experience a shortage in their supply that often threaten economic growth.
- **Environmental concerns**.

Given the current state of affairs, it is safe to say that emerging markets pose a unique opportunity to alternative energy solutions. It is in this context that it is important that governments have the vision to implement such solutions, and in so doing, improving the quality of life of their citizens.

In seizing the opportunity emerging market governments must realize that the implementation of such solutions will have to compete for financial and other resources that may be otherwise used for development projects. However, in executing their vision for the improvement of the life of the citizens, governments must make hard choices in order to guarantee the sustainability of their countries' economies.

There is a need to institute a balance between the people, time, resources and deliverables – an important aspect that it is not usually considered in economic models - a subject which has been the debate among many economists.

It is often difficult to balance economic growth models while satisfying the needs of the less fortunate. As expressed by Finn Kidland and Norman C. Prescott in their classic 1977 article "Rules vs. Discretion" which points to the fact that a:

> *"**Time-inconsistent policy may make the public happy in the short run but will ultimately fail to produce the long-run policy goal. A time-consistent policy, in contrast, nails the long-run policy goal but does not make people happy in the short run."***

Hence the reason why pondering the long term policy goals vs. the immediate goals is so important. Trinidad and Tobago is in no way different to any of its neighbors in the Caribbean and Latin America. Everyday our governments are faced with time inconsistent decisions and time consistent policy.

The renewable energy market is no different, solar power; wind generation, solar thermal and its counterparts face these crossroads. In a highly subsidized electricity generation industry responsible for dumping some fourteen million tons of carbon dioxide into the atmosphere, how is it possible to bring on stream electricity generation by means of renewable energy which have significant startup cost to the end user, way in excess to what they are currently paying.

To policy makers the answer is easy, maintain status quo – a time-inconsistent policy. Add the fact that main sources of revenue are under pressure, treaties that you are in breach of, a stagnant economy and rising unemployment, a formula for a very fragile, increasingly skeptical and hostile environment. The question must be put forward, time-consistent or time-inconsistent. Clearly, the population will favor a time-inconsistent policy. The question remains – what consequences will this policy have in the near future?

In contrast, choosing a time-consistent solution can be a cause for concern among the population making the policy an unpopular one. It then becomes a question of good governance, making a hard choice now which will benefit future generations.

This is the dilemma facing the renewable energy industry today, curb carbon dioxide emissions or hinder immediate economic growth.

2. Programs

Over the years research has shown that the development of a strong Solar Electric Generation Industry is tied three basic elements:

- Gross Domestic Product per Capita,
- Having a Legislation to Support the Industry,
- Levelized Cost of Electricity that will allow the penetration of Photovoltaic.

Figure 2.1 Elements that Support a Solar Electric Generation Industry

For Latin America and the Caribbean, we notice that one or two of the three elements are always missing, the chart below shows countries that have had a successful migration from fossil fuels to cleaner forms of electricity generation and those that are currently trying to move towards that path (Table 2.1).

Country	GPD per Capita in Real Values Expressed in US$	Energy from Renewables		
		Wind Power in Gwh	Biomas	Solar
Germany	$ 41,514.00	45,300.00	40,900.00	28,000.00
Spain	$ 29,195.00	42,400.00	9,120.00	7,280.00
Italy	$ 33,049.00	13,333	9821	18,637
Japan	$ 46,720.00	4,350.00	2,310.00	3,800.00
United States	$ 49,965.00	70,800.00	54,300.00	808.00
Trinidad and Tobago	$ 17,934.00	0.00	0.00	0.00
Venezuela	$ 12,767.00	0.00	0.00	0.00
Mexico	$ 9,742.00	86.75	823.00	9.00

Table 2.1

2.1 Paradigm Shift

A lot of ideas have been put forward to bridge the gap for solar electricity generation, notwithstanding, one model that comes to mind is the Grid Tied Utility Assisted Model, due to its nature, this paradigm shift in the way utility conducts their activities, offers a smooth transition from fossil fuel power generation systems to cleaner forms of energy, mainly solar and wind power systems in an environment of subsidized rates and in the absence of a legal framework.

This is achieved utilizing the Utility Company as the vehicle for change. Instead of being another player, the Utility acts as the supplier of the solar modules and /or other forms of alternative energy, by means of a lease agreement. The subscriber provides the space for the unit or units; the Utility provides the installation and sale of electricity power by leasing the power generating system where the homeowner pays the Utility the rate currently applied.

Because the equipment is leased to the property holder, the excess power goes back to the grid at no benefit to the homeowner. This cogeneration arrangement permits the gradual adjustment of rates, while reducing inflationary fears.

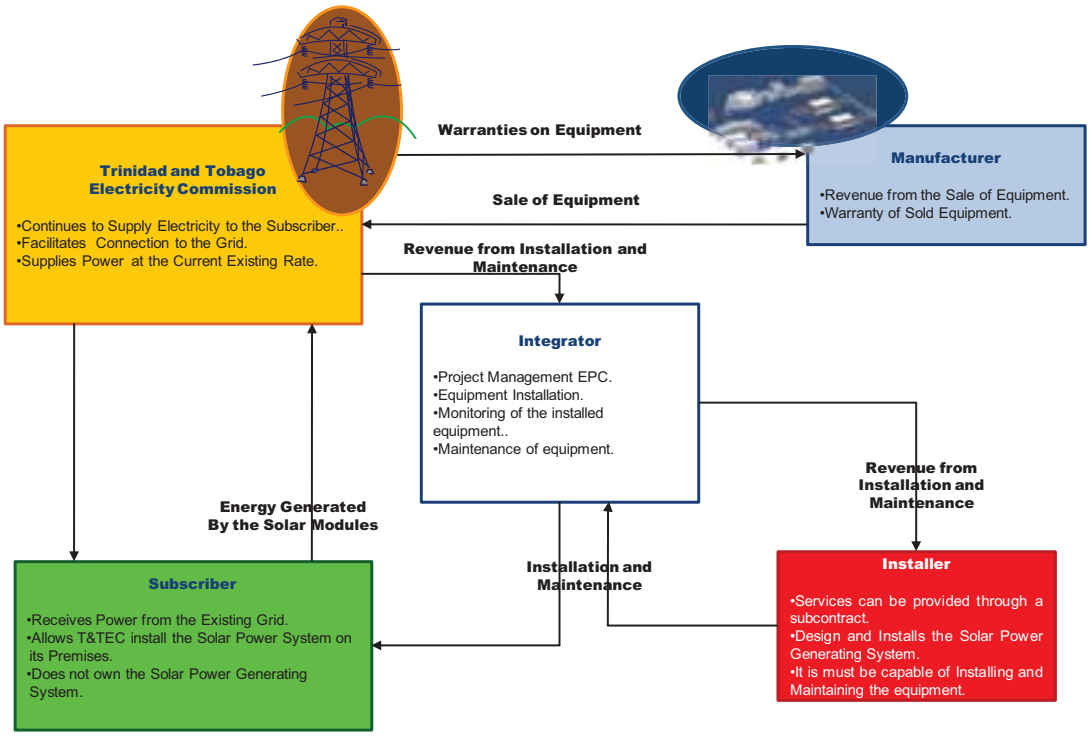

Figure 2.1.1, Inner workings of the Grid Tied Utility Assisted Model

2.2 Enhanced Revolving Fund

Unlike financial instruments such as Climate Bonds, Zero Coupon Indexed Bonds and other mechanisms used in investing in renewable energy projects, an Enhanced Revolving Fund is a mandatory contribution imposed on the industries that account for at least seventy percent (70%) of the GHG emissions released, in the form of tax. The program would mirror a trust fund that will use these contributions to finance small distributed generation projects.

An initiative such as this, is essentially a localized, downsized version of the United Nations Convention on Climate Change Clean Development Mechanism, with one fundamental difference, funding is made available to anyone who complies with the requirements.

Such schemes can operate under the supervision of Multilateral Organizations. Its primary function is the award of grants to allow organizations interested in migrating from fossil fuel electricity generation to renewable forms of electricity generation (PV and / or Wind).

The collection monies come from mandatory contributions made from the major players responsible for Carbon Dioxide Emissions and the Certificates of Emission Reductions generated in the process. This Pigouvian Tax Regime System imposed by Governments of the Region can look at: 0.5% of the total revenue of the organization and / or a ten percent 10% of the country's total carbon dioxide emissions (Table 2.2.1) at a rate of US$ 3.50 per CO_2 per ton. Similar to CDMs, guidelines for the approvals of projects must be in place. Once approved, the recipient will be in a position to give back to fund in the form of Certificates of Emission Reductions. These CERs can then be used to offset CO_2 emissions from those companies who have made payments to the fund.

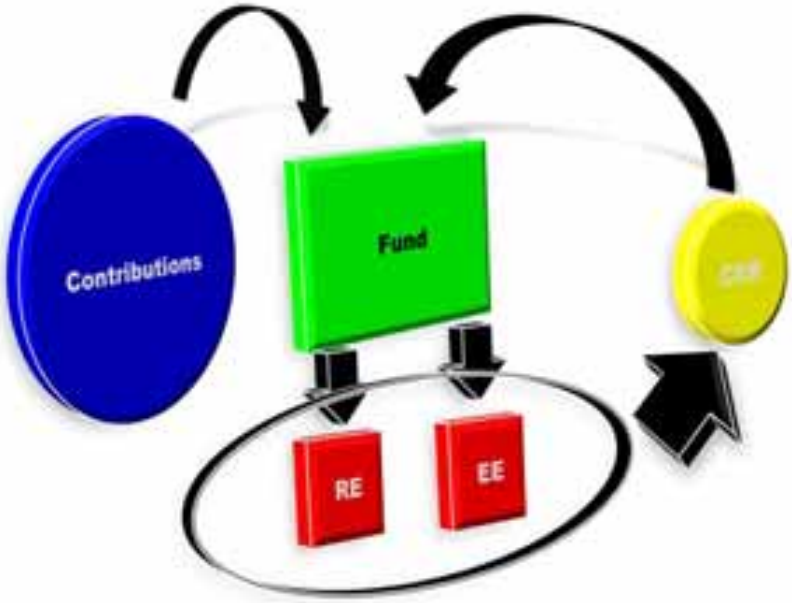

Figure 2.2.1, Enhanced Revolving Fund

The thought of using a neutral body to act the regulator and to pool the resources of the region, will move the Caribbean and Latin America closer to significantly reducing their CO_2 while democratizing renewable energy.

Country	Millions of CO2 Tons per Year
Argentina	191
Brazil	475
Venezuela	183
Trinidad and Tobago	52
Chile	80
Colombia	71
Peru	38
Puerto Rico	29
Dominican Republic	21
Ecuador	29
Total	**1,169**

Table 2.2.1

The Collection of ten percent (10%) of a total of 1,688,909,000 Tons that the Region generates at the above mentioned Carbon Dioxide per ton rate will yield US$ 590,000,000 a year, which will translate to 234 Mega Watts of Distributed Generation installed per year. At such levels the Enhanced Revolving Fund will in a position to remove from the less fortunate nations of the region their dependency of fossil fuels in a short space of time (Table 2.2.1).

2.3 Community Solar

Another model that has gained a lot of acceptance in recent years has been the creation of co-operative by communities with the purpose of using their pooled resources to provide electricity to their community members (Figure 2.3.1).

Figure 2.3.1 Graphic Representation of a Community Solar Initiative

Based on motives, the format of a community solar may vary. But undoubtedly, the most commonly used formats of this type of agreement are as follows:

- Utility Sponsored Model,
- Special Purpose Entity,
- Non – Profit "Buy a Brick" Model.

Notwithstanding, and depending on the financial benefits that the community solar format is pursuing, these alternatives can be divided as follows:

- Allocation of Cost and Benefits,
- Financial and Tax Considerations,
- Other Legal Issues.

Ultimately, when a group of people or community chooses an arrangement such as the one we have just described, they understand the complexity of the project that they are going to undertake and different elements that a venture of this nature entails.

3. Striking a Balance

Many solutions come to mind, however, the most popular and effective ones are those that we are currently considering. We begin with The Grid Tied Utility Assisted Model with roots originating from the Property Asses Clean Energy Program and the Solar Power Purchase Agreement. Then there are Community Based Solar Initiatives and last the consolidation of a Pigovian Tax System.

Bear in mind that all the proposals above mentioned qualify for Certificates of Emission Reductions, which at the end add that element that improves the returns on any of the projects that can be undertaken.

The question of striking a balance is not one that can be answered in simple terms, however, in maximizing the use of the resources, Gross Domestic Product per Capita, CO2 emission generation and society stratification play important roles.

Notwithstanding, by establishing the energy needs of the different sectors of the population, we can determine what program or combination of program works best, and therefore minimizing the levels of investment which otherwise would have been disbursed if just one solution had been considered (Figure 3.1).

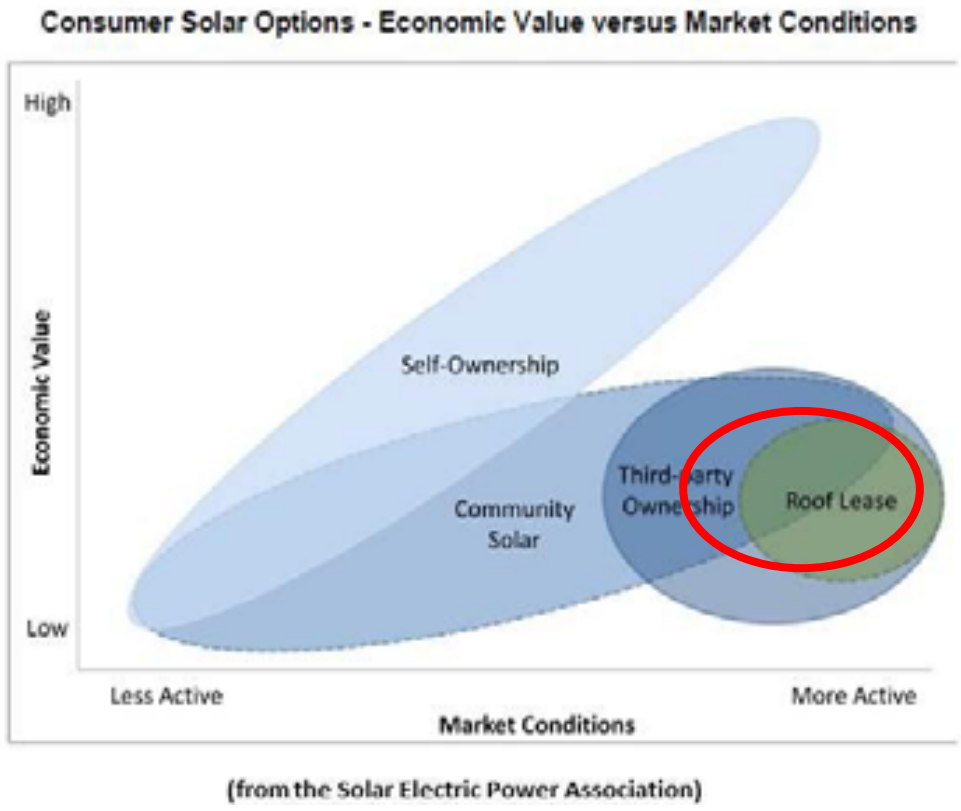

Figure 3.1

This is achieved by developing a linear model where the objective is to maximize photovoltaic penetration subject a group of constraints. Where the objective function represents what we intend to maximize or minimize and the constraints symbolize the limitation to which the model is subject to.

Our model can be expressed as follows:

Max Total PV Penetration: Max: $\sum c_i x_i = c_1x_1 + c_2x_2 + \ldots\ldots\ldots\ldots\ldots + c_nx_n$

Subject to:

$c_1x_1 + \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots + c_nx_n < m_1$

.

.

.

$c_mx_m + \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots + c_nx_n < m_n$

Once the model is constructed, we determine the value of our variables by applying the simplex method. After several iterations, for a population with a low GDP per capita, where the population is skewed more to low middle and low income.

The solution is weighted to a combination of an enhanced revolving with a Grid Tied Utility Assisted model.

Figure 3.2 Graphical Representation of the Results of the Model

CONCLUSIONS

The benefits of undertaking such a venture are many, however, we will limit ourselves to listing those that we consider to be the most important ones, they are as follows:

- **Reduction In Carbon Dioxide Emission**
- **Elimination of the Gas Subsidy**
- **Job Creation**
- **Export Opportunities**
- **Boost to the local assembly industry**
- **Downstream Development**

Benefits to the Nations

- **Creates permanent jobs –** nationwide and across a range of skills**.**
- **Promotes energy security** – without federal regulation or taxes that drive up energy costs.
- **Avoids costly power plants** – increasingly difficult to site.
- **No budgetary impact** - voluntary participants pay all fees and expenses.
- **Improves air quality** - reduced exhaust emissions make communities healthier.

Benefits to Property Owners

- **No upfront cost** - financing spreads costs over the life of UTILITY return on their investment.
- **Owners save money** – The absence of financing reduces the homeowner bill for the equipment that at the end of the period can be bought for residual value amount thereby allowing for the widest possible participation by the national community.
- **Assessment transfers upon sale** - new owner benefits from improvements that stay with the property.
- **Safety** - assured by best practices and guidelines established to protect all program participants.

— **Broad applicability** – residential, industrial and commercial properties. Cross border, government or privately owned Electricity Companies.
— **Voluntary** Homeowners benefit from the improvements.
— **Comfort** – efficient buildings are healthier and more comfortable.

Economics of global gas-to-liquids (GtL) fuels trading based on hybrid PV-Wind power plants

Mahdi Fasihi, Dmitrii Bogdanov and Christian Breyer

Lappeenranta University of Technology, Lappeenranta (Finland)

E-mails: mahdi.fasihi@lut.fi, dmitrii.bogdanov@lut.fi, christian.breyer@lut.fi

Abstract

With growing demand for transportation fuels such as diesel and concerns about climate change, this paper introduces a new value chain design for transportation fuels and a respective business case taking into account hybrid PV-Wind power plants. The value chain is based on renewable electricity (RE) converted by power-to-gas (PtG) facilities into synthetic natural gas (SNG), which is finally converted to mainly diesel in gas-to-liquid (GtL) facilities. This RE-diesel can be shipped to everywhere in the world. The calculations for the hybrid PV-Wind power plants, electrolysis and methanation are done based on annual full load hours (FLh). A combination of 5 GW_p single-axis tracking PV and wind power have been applied. Results show that the proposed RE-diesel value chain is competitive for crude oil prices within a minimum price range of about 121 - 191 USD/barrel (0.67 – 1.06 €/l of diesel production cost), depending on assumptions for cost of capital, available oxygen sales and CO_2 emission costs. RE-diesel is competitive with conventional diesel from an economic perspective, while removing environmental concerns. The cost range would be an upper limit for the conventional diesel price in the long-term and RE-diesel can become competitive whenever the fossil fuel prices are higher than the level mentioned and the cost assumptions expected for the year 2030 are achieved. A sensitivity analysis indicates that the RE-PtG-GtL value chain needs to be located at the best complemented solar and wind sites in the world combined with a de-risking strategy and a special focus on mid to long term electrolyzer efficiency improvements. The substitution of fossil fuels by hybrid PV-Wind power plants could create a PV-wind market potential in the order of terawatts.

Keywords: *Hybrid PV-Wind, Power-to-gas (PtG), SNG, Gas-to-liquids (GtL), Power-based fuels, Economics, business model, Argentina*

1. Introduction

The demand for transportation fuels is high in the world and it is growing (IEA, 2014), but fossil fuel resources are limited and we do not know how much affordable crude oil is available for transportation fuels in the long-term (EWG, 2013). Besides, it is still impossible to use electricity in some sectors, like aviation. On the other hand, our planet is facing a dramatic climate change problem (IPCC, 2014), thus even with adequate fossil fuel reserves, CO_2 emissions still would be a limiting constraint in the long-term (Carbon Tracker, 2013; 2015). Methanation (PtG) plants (Breyer et al., 2015) converting electricity into synthetic natural gas (SNG) and Gas-to-Liquids (GtL) plants (Wood et al., 2012) converting natural gas (NG) to liquid fuels (with higher heating value and easier transportation) already exist on a commercial scale.

By using solar photovoltaic (PV) and wind energy based renewable electricity (RE) for PtG and GtL plants, RE-SNG and then RE-diesel can be produced, respectively, to overcome the constraints of resource limitation and CO_2 emissions in the conventional diesel value chain. Figure 1 shows the simplified value chain of the whole process. The main components are: hybrid PV-Wind plants, electrolyzer and methanation plants, CO_2 from air scrubbing units, syngas production unit, Fischer-Tropsch synthesis plant, products upgrading plant and fuels shipping. The integrated system introduces some potentials for utilization of waste energy and by-products. This will also result in the elimination of some sub-components of the major components of the integrated system, such as gas treatment facilities and oxygen production units, which will increase the overall efficiency and will decrease the costs.

Selection and/or peer review under responsibility of Scientific Committee

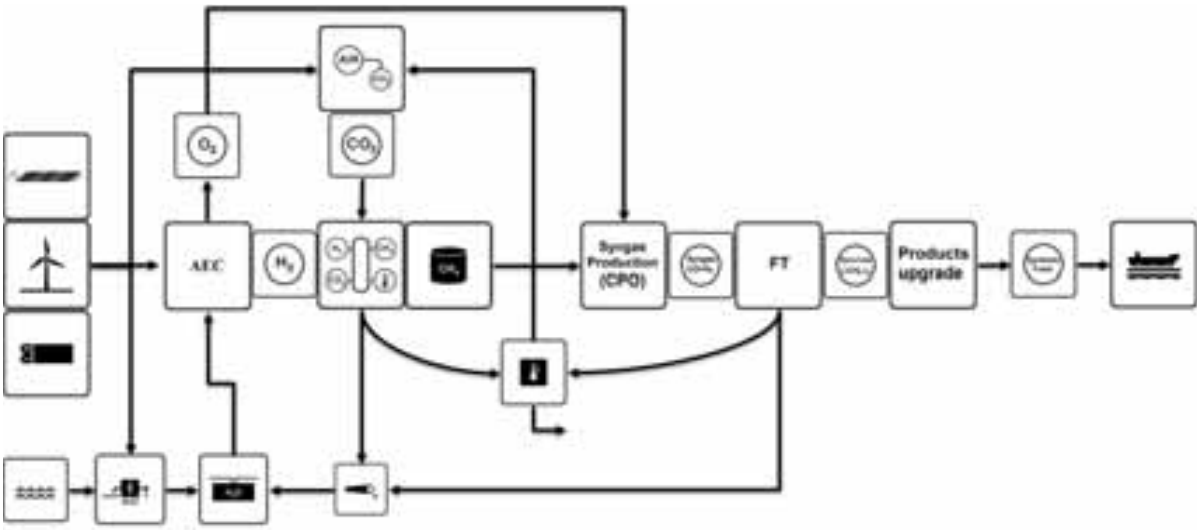

Fig. 1: The hybrid PV-Wind-PtG-GtL value chain. The main components are: hybrid PV-Wind plants, electrolyser and methanation units, CO_2 from air scrubbing units, syngas production unit, Fischer-Tropsch synthesis unit, products upgrading unit and fuels shipping. Abbreviations: alkaline electrolysis (AEC), catalytic partial oxidation (CPO), Fischer-Tropsch (FT) and reverse osmosis desalination (RO).

There are several technical options to produce hydrocarbon fuels based on hybrid PV-wind plants for the transport and mobility sector: mainly RE-PtG, RE-PtG-LNG (Fasihi et al., 2015), RE-power-to-liquids (PtL) and RE-PtG-GtL. All options can be used to buffer and store intermittent renewable electricity. This paper is focused on the RE-PtG-GtL option. Some mobility sectors like aviation, maritime transportation or heavy vehicles cannot be easily operated by batteries or natural gas (NG). Thus even in the long term, liquid hydrocarbon fuels will have a high demand. PtL is the technology to produce liquid fuels directly from renewable electricity, water and CO_2, but this technology is still under development. On the other hand, PtG and GtL technologies are well known and already run on an industrial scale. Thus, in the short term, PtG-GtL seems to be the applicatory method to produce RE-liquid fuels. This paper is an attempt to investigate the costs of this value chain.

2. Methodology

The RE-diesel production system has been divided into two main parts: RE-based SNG production and the GtL downstream value chain. In this paper, two models are used for describing the SNG production for considerations on an annual, but also on an hourly, basis.

The Annual Basis Model represents a hybrid PV-Wind power plant with 5 GW capacity for both single-axis tracking PV and Wind energy. The cost assumptions are based on expected 2030 values and that highly cost competitive components can be sourced for such very large-scale investments. No fixed tilted PV or battery is considered to be part of the plant and the produced electricity and respective calculations are based on annual full load hours (FLh) of the hybrid PV-Wind plants, which can be seen in **Table 1**. The estimate on an annual FLh basis can be surprisingly accurate if applied carefully (Breyer et al., 2011; Pleßmann et al., 2014). The annual basis plants' specification can be seen in **Table 2**. An important piece of information is the level of curtailment, or so-called overlap FLh, i.e. an equivalent of energy which cannot be used. For the special case of hybrid PV-Wind plants, a conservative estimate is 5% (Gerlach et al., 2011). This model will give a rough estimation of a system working with equal PV and wind power capacity.

The Hourly Basis Model uses the optimised combination of PV (fixed-tilted or single-axis tracking), wind power and battery capacity based on an hourly availability of the solar and wind resources to minimize the levelized cost of electricity (LCOE) and cost of SNG. Low cost batteries are added to harvest the excess electricity during overlap times to increase the FLh whenever it is beneficial. More detailed information for this approach is provided by Fasihi et al. (2015).

The full GtL value chain is only analyzed within the annual basis model because with gas storage for output SNG, the GtL plant can work on baseload conditions, which is the cost optimal solution for the GtL value chain.

The equations below have been used to calculate the LCOE of hybrid PV-Wind power plants and the subsequent value chain. Abbreviations: capital expenditures, *capex*, operational expenditures, *opex*, full load hours, *FLh*, fuel

costs, *fuel*, efficiency, η, annuity factor, *crf*, weighted average cost of capital, *WACC*, lifetime, *N*, performance ration, *PR*, overlap FLh, *overlap*.

$$LCOE_i = \frac{Capex_i \cdot \mathrm{crf} + Opex_{i,fix}}{FLh_i} + Opex_{i,var} + \frac{\mathrm{fuel}}{\eta_i} \quad \text{(Eq. 1)}$$

$$\mathrm{crf} = \frac{\mathrm{WACC} \cdot (1+\mathrm{WACC})^{\mathrm{N}}}{(1+\mathrm{WACC})^{\mathrm{N}} - 1} \quad \text{(Eq. 2)}$$

$$FLh_{PV,el} = PV_{irradiation} \cdot PR \quad \text{(Eq. 3)}$$

$$LCOE_{gross} = \frac{Wind_{FLh} \times Wind_{LCOE} + PV_{FLh} \times PV_{LCOE}}{(Wind_{FLh} + PV_{FLh})} \quad \text{(Eq. 4)}$$

$$LCOE_{net} = \frac{LCOE_{gross}}{1 - \mathrm{overlap}} \quad \text{(Eq. 5)}$$

2.1. Power-to-SNG

2.1.1. Hybrid PV-Wind power plant and battery

In this research, hybrid PV-Wind power plants are taken into account as the resource of renewable electricity. The hybrid PV-Wind power plants should be located in the regions of very high FLh to reduce LCOE of power production and subsequently the LCOE of electrolysis and methanation. **Figure 2** shows the FLh for hybrid PV-wind power plant sites in the world, where the best sites are indicated by a red colour coding. In this study, the plant is located in Patagonia, Argentina, which is among the best places in the world for solar and wind resources. The produced RE-based hydrocarbons are assumed to be shipped to Rotterdam in the European Union.

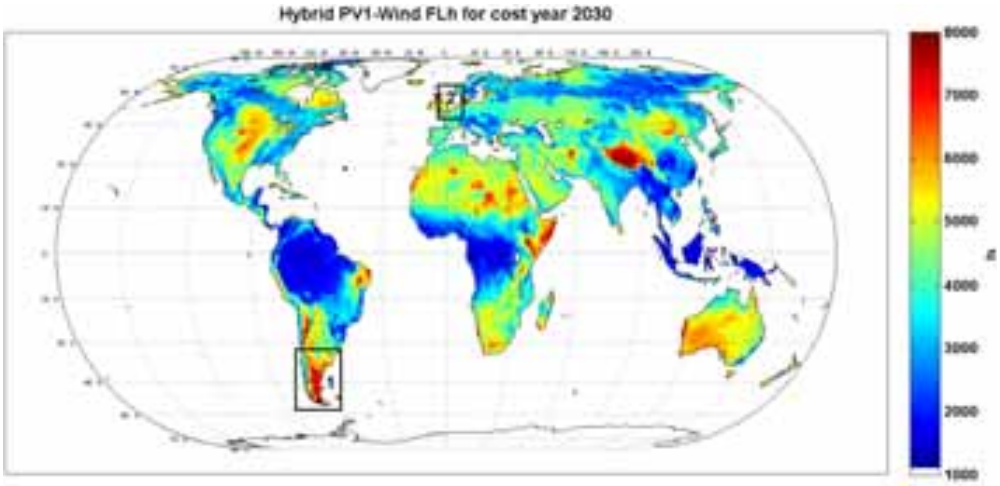

Fig. 2: World's hybrid PV-Wind power plant FLh map. The numbers refer to the place of RE-diesel production (1) and diesel demand (2).

Wind installed capacity	GW	5			

2.1.2. Electrolysis and methanation

SNG production consists of two main steps: hydrogen production (Eq. 6) and methanation (Eq. 7), which are shown in **Figure 3**. Water and electricity are the inputs for the electrolysis plant, while electrical power converts water to H_2 and O_2 as products of this endothermic process. Generated H_2 and CO_2 obtained from CO_2 from ambient air capture plants are used in the exothermic process of methanation based on the Sabatier reaction to produce SNG (Bandi et al., 1995; Specht et al., 2009; Sterner, 2009).

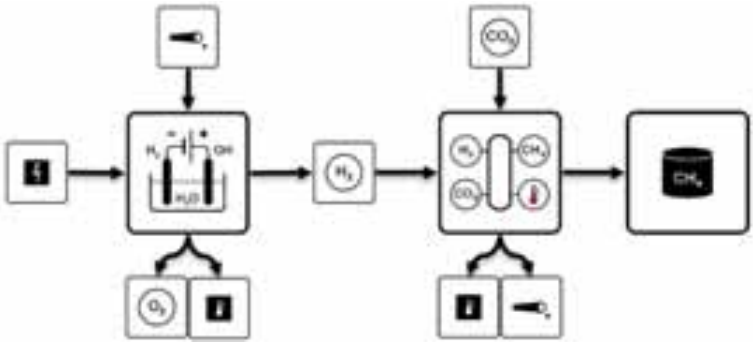

Fig 3: Power-to-Gas (electrolysis and methanation) process.

Electrolysis: $\mathrm{E} + 2H_2\mathrm{O} \rightarrow 2H_2 + O_2 + \mathrm{Q}$ (Eq. 6)

Methanation: $CO_2 + 4H_2 \rightarrow CH_4 + 2H_2\mathrm{O} + \mathrm{Q}$ (Eq. 7)

The alkaline electrolysis cell (AEC) is the well-known and a mature technology for water electrolysis (Millet and Grigoriev, 2013), while the proton exchange membrane electrolysis cell (PEMEC) (Millet and Grigoriev, 2013; Millet, 2015) and solid oxide electrolysis cell (SOEC) (Millet and Grigoriev, 2013; Elder et al., 2015) are technologies in the commercialization phase or still under development. PEMEC shows a slightly better efficiency and shorter startup time in comparison to AEC, which is an advantage while using fluctuating RE as a source of power. SOEC operates at higher temperatures and pressure. The higher temperature offers the chance to replace a part of the electricity needed for the reaction by heat. Furthermore, the produced hydrogen is at a high pressure, which decreases the required energy and cost for compressing hydrogen for the methanation process. However, the startup time of SOEC is higher than AEC and PEMEC. The reported costs for PEMEC and SOEC are higher and in a wider range than those for AEC in 2030**.** The projected specifications for these three types of electrolysers and the methanation process are shown in **Tables 3 and 4** (Agora Energiewende, 2014; Breyer et al., 2015; Energinet.dk, 2012; ETOGAS, 2015; FCH JU, 2015; Götz et al., 2015)**.** In addition, there are more uncertainties about the achievement of techno-economic targets for 2030. Therefore, alkaline high pressure electrolysis has been used in our model. Moreover, the lower capex for AEC is very important in achieving optimized SNG cost.

Tab. 3: Electrolyzers' specification. Abbreviations: electricity-to-hydrogen, *EtH_2*, efficiency, *eff.*

	Unit	AEC	PEMEC	SOEC
Capex	€/kW_{el}	319	250-1270	625-100

Capex	€/kW_{H2}	215
Opex	% of capex p.a.	3
Lifetime	years	30
H_2-to-SNG eff. (HHV)	%	77.9
H_2-to-Heat eff. (HHV)	%	14

2.1.3. CO_2 from ambient air scrubber

CO_2 can be supplied from different sources such as large power plants, or ambient air. To have a sustainable energy system with carbon neutral products, CO_2 needs to be obtained from a sustainable CO_2 source such as a biomass plants with carbon capture and utilization (CCU) or it can be captured from ambient air, which is assumed in this work. The chosen CO_2 source is independent of the location, thus carbon supply would not restrict the best places for the PtG plant.

The CO_2 capture from ambient air approach from Climeworks (Climeworks, 2015a) has been used for the energy system in this work, since between 80-90% of energy needed for this plant can be supplied by heat, rather than electricity (Wurzbacher, 2014). In this case the output heat of the methanation and electrolysis units can be used to fulfill this heat demand, which will increase the overall efficiency of the system. The output heat of alkaline electrolysis and methanation processes, via a heat exchanger with 90% efficiency, perfectly matches the heat demand of the CO_2 capture plant of the required capacity. To capture 1 ton of carbon dioxide out of ambient air, this system requires 1300-1700 kWh_{th} of thermal energy at 100-110°C and 200-250 kWh_{el} electricity (Climeworks, 2015b). The average numbers which have been used in our calculations can be seen in **Table 5**. In case of a lack of internal heat, the heat from the GtL section or heat pumps could be used to deliver the heat needed for the CO_2 capture plant.

Tab. 5: CO_2 capture plant specification

	Unit	Amount
Capex	€/(t_{CO2}·a)	356
Opex	% of capex p.a.	4
Lifetime	years	30
Electricity demand	kWh_{el}/t_{CO2}	225
Heat demand	kWh_{th}/t_{CO2}	1500

2.1.4. Water desalination

The steam output of methanation goes through the heat exchanger first, providing the heat for the CO_2 capture plant and the condensed water can be reused in electrolysis. In addition, the output water of the Fischer-Tropsch (FT) process in the GtL section can be recycled and reused in the electrolysis, but these water sources are not enough to supply all the water needed for electrolysis. Thus, a part of water needed for the electrolyzers has to be supplied from an external source. In some regions there might not be enough clean water available for electrolysis. The plant is located along a sea shore, thus seawater reverse osmosis (SWRO) desalination is used, whenever clean water demand for any other activity in the region is more than half of sustainable clean water available in the region (water stress higher than 0.5). Water desalination plant specifications can be found in **Table 6**. More details on RE-powered SWRO desalination plants are provided by Caldera et al. (2015).

PtG and liquefaction plants are built along the sea shore and electricity from hybrid PV-Wind plants is transmitted to the site. In this case, there would be no cost for water piping and pumping from the coast, where the seawater is desalinated. In addition, the GtL plant is located just beside the PtG plant and thus no SNG transportation cost has to be taken into account and the liquid fuels transportation cost to the port will be minimized as well.

Tab. 6: Water desalination and storage plants' specification (Caldera et al., 2015)

	Unit	Amount		Unit	Amount
SWRO Desalination			*Water storage*		
Capex	€/(m^3·a)	2.23	Capex	€/(m^3·a)	0.0074
Opex	% of capex p.a.	4.3	Opex	% of capex p.a.	1.5
Lifetime	years	30	Lifetime		50
Electricity consumption	kWh/m^3	3.0			
Water extraction efficiency	%	45			

2.1.5. Oxygen

Oxygen as a byproduct of electrolysis, has a very important role in the technology used in the GtL process, particularly in the syngas production. The downstream GtL plant needs about 25% of generated oxygen in the PtG plant. This is explained in more detail in Section *2.2.1. Syngas production*. In case of a potential market, it can also have a very important role in the final cost of produced SNG. The market price of oxygen for industrial purposes can be up to 80 €/t_{O2} (Breyer et al., 2015). It might be too optimistic to assume that all the produced oxygen could be sold for this price. Moreover, in case of a potential market, oxygen storage and transportation costs have to be applied. To have a rough assumption, considering all these effects, there is no benefit from oxygen in the base scenario. The projection of a maximum 20 €/t_{O2} benefit from oxygen is assumed in another study for RE-PtG-LNG (Fasihi et al., 2015), when all the produced oxygen was for sale. In the PtG-GtL case, only 75% is available for the potential market. Thus, to have the same impact by the selling of oxygen, the projection of a maximum 30 €/t_{O2} benefit from unused oxygen has been assumed in the PtG-GtL model.

2.2. Gas-to-Liquids

The GtL process provides the opportunity to convert NG or SNG to liquid fuels through a series of chemical reactions. The liquid products are easier and cheaper to transport to remote regions but also internationally, and offer new applications. The GtL process consists of three main steps: ***syngas production***, ***Fischer-Tropsch Synthesis (FTS)*** and ***products upgrading*** (Wood et al., 2012). Although these process steps are well-known, at the same time, the combined technology is complex and well-protected by limited companies developing them. GtL plants are typically capital intensive and, so far, have been affected by economies of scale which have made them viable only at large scales. Thus, the GtL plants should be built near large scale reserves of NG on a low price level. Recently some companies, such as *Velocys* (Velocys, 2015a), have developed new technologies which have made GtL viable for a lower range of capacities (1500 – 15,000 barrels of crude oil equivalent per day). Until now, there has been a limited number of actual GtL plants in operating mode, which makes it even harder to have good, publically accessible information about these systems on an industrial scale. On the other hand, the quality of input gas, selectivity of the desired products and the regional conditions have led to a development of different minor technologies.

In our model, the feedstock of the GtL plant is RE-SNG produced in a PtG system. This pure and fixed feedstock can decrease the number of determinative variables in this process. This can result in focus on a unique method, which can result in a faster improvement of the technology and decrease in the cost of the system. As an example, no gas treatment would be required in the very first step, which can decrease the cost of the system. The new companies working on affordable, small scale GtL plants can also be a big help for further applications and development of GtL plants.

2.2.1. Syngas production

SNG, as the output of the PtG plant, is the feedstock for the GtL plant. In the first step, SNG needs to be converted to syngas (mixture of CO and H_2) as the feedstock for the FT section. The desired CO:H_2 ratio for FT process is 1:2. There are different reforming technologies to produce syngas from natural gas, including catalytic partial oxidation (CPO) (Eq. 8), auto thermal reforming (ATR) (Eq. 9-11), steam methane reforming (SMR) (Eq. 12, 13) or a combination of these technologies. The main reactions of these processes are as follow (Rostrup-Nielsen, 2000):

CPO: $CH_4 + 0.5\ O_2 \rightarrow CO + 2H_2$ $\Delta H^0 = -38$ kJ/mol (Eq. 8)

ATR: $CH_4 + 1.5\ O_2 \rightarrow CO + 2H_2O$ $\Delta H^0 = -520$ kJ/mol (Eq. 9)

$H_2O + CH_4 \rightarrow CO + 3H_2$ $\Delta H^0 = 206$ kJ/mol (Eq. 10)

$CO + H_2O \rightarrow CO + H_2$ $\Delta H^0 = -41$ kJ/mol (Eq. 11)

SMR: $CH_4 + H_2O \rightarrow CO + 3H_2$ $\Delta H^0 = 206$ kJ/mol (Eq. 12)

$CO + H_2 \rightarrow CO_2 + H_2$ $\Delta H^0 = -41$ kJ/mol (Eq. 13)

Catalytic partial oxidation provides the syngas with the desired CO:H_2 ratio for the FT process, but air separation units (ASU) are needed to produce the required oxygen for this reaction. The cost of an air separation unit is reported to be at least 8% of the capital cost of GtL facilities (Maitlis and Klerk, 2013). Thus, other technologies have also been developed and used by industrial companies in syngas production from natural gas. In our model, pure oxygen is already available as the by-product of electrolysis in the PtG plants. Thus, partial oxidation is the technology that makes the most sense for syngas production within the approach of this paper. The real model would not be this simple and efficient. CO_2 would be produced in the following side reaction (Eq. 14):

$CH_4 + O_2 \rightarrow CO_2 + 2\ H_2O$ (Eq. 14)

Nothing can be done about the inherent energy loss through water made in the CPO main reaction, but there is a potential to increase the thermal energy efficiency by further advances in technologies to reduce CO_2 formation in the side reaction. This technology is used by the Shell middle distillates synthesis (SMDS) plant in Bintulu, Malaysia, and the carbon to CO conversion is reported to be 94% (Hoek, 2006). The CPO reaction happens at high temperatures, about 1000 °C, and the released heat in this reaction is used to keep it in an autothermal mode (Al-Sayari, 2013) and cannot be used for other purposes.

Table 7: GtL capital expenditures breakdown (Maitlis and Klerk, 2013)

Unit	%

2.2.2. Fischer-Tropsch synthesis

The Fischer-Tropsch process converts syngas to different chains of synthetic hydrocarbons $(-CH_2-)_n$, which is also known as syncrude (Eq. 15). This reaction is highly exothermic (Graves et al., 2011). In our model, the water produced in this reaction is recycled and reused in the water electrolysis at the PtG section. Also, the released heat can be used for any purpose through a heat exchanger.

Fischer-Tropsch Synthesis (FTS): $n\ CO + 2n\ H_2 \rightarrow (-CH_2-)_n + n\ H_2O$ $\Delta H^0 = -209$ kJ/mol (Eq. 15)

This reaction is mainly based on cobalt (Co) or iron (Fe) catalysts, which are operated at different temperatures. The properties of produced syncrude are mainly defined by the chosen catalyst and process conditions. Table 8 shows the different options and their specifications (Klerk, 2014; 2008).

Tab. 8: Characteristics of different types of Fischer-Tropsch synthesis practiced industrially (Klerk, 2014; 2008). Abbreviations: Low Temperature Fischer-Tropsch, *LTFT*, and High Temperature Fischer-Tropsch, *HTFT*.

Description	Fe-LTFT	Co-LTFT	Fe-HTFT
Operating temperature (°C)	200-270	170-230	320-360
Operating pressure (MPa)	2-2.5	2-2.5	2-2.5
Water gas shift active	Yes	No	No
Synthetic products composition (mass %):			
Light gas (C_1-C_2)	6	7	23
Liquid petroleum gas (C_3-C_4)	8	5	24
Naphtha (C_5-C_{10})	12	20	33
Distillate (C_{11}-C_{22})	20	22	7
Paraffin wax	50	44	-
Aromatic residue	-	-	3
Water-soluble oxygenates	4	2	10

The major products of low temperature Fischer-Tropsch (LTFT) and high temperature Fischer-Tropsch (HTFT) are mainly paraffin and olefin hydrocarbons, respectively. In addition, the products of HTFT contain aromatics which are not desired. HTFT produces a large amount of light gas (C_1-C_2) which is not favourable. In conclusion, although any FT syncrude can be refined to gasoline, jet fuel, diesel fuel and petrochemicals, LTFT seems to be a better option, when aiming for fuels with a longer chain of hydrocarbons, such as diesel.

2.2.3. Products upgrade

The syncrude contains hydrocarbons of different lengths. By adding hydrogen and hydrocracking of long chain syncrude, the hydrocarbons with a desired length can be produced as products in the upgrading unit. Equation 16 shows the simplified reaction at this step. If needed, the hydrogen used in this step can be supplied by water electrolyzer units in the PtG plant.

Products upgrade: $(-CH_2-)_n + H_2 \rightarrow C_nH_{2n+2}$ (Eq. 16)

The GtL final products can include up to 30% wax. Maximizing wax configuration in the output will increase profit, but the demand for wax is much less than diesel. Thus, in a global model, the aim is to maximize the diesel share in the output. The outputs of GtL in some publications are shown in Table 9.

Tab. 9: GtL final products composition (vol%). Abbreviations: liquefied petroleum gas, *LPG*.

Source	LPG	Naphtha	Middle distillates		Lubes & Wax	Comment
			Jet fuel / Kerosene	Diesel		
Fleisch et al. (2002)		15-25	65-85		0-30	
Brown (2013)	5	20	75			typical GtL
Velocys (2015b)		20	80			
Chedid et al. (2007)	6	26			68	
NPC (2007)		25		70	5	
Khalilpour, Karimi (2012)	5	20		75		
Bao (2010)	3	30		67		
FVV (2013)		15	25	60		Diesel mode
		25	50	25		Kerosene mode

Aiming for the maximum middle distillates share, the numbers provided by (FVV, 2013) have been used for the model of this paper, and represent naphtha, jet fuel and diesel with a share of 15%, 25% and 60%, respectively.

Considering diesel and jet fuel as the target products of this process, the potential revenue of sold by-products from the total costs and therefore the levelised cost of fuel (LCOF) of the target products in the value chain should be investigated. Paraffin wax, as a potential product of the GtL process has a higher financial value than crude oil (Jensen et al., 2013), but it is not in the slot of final products in our model. All products of the GtL process are

a function of the crude oil price, as they compete with refinery products of crude oil. Naphtha has approximately the same market value as crude oil, thus it has no additional effect than the crude oil price on the results (Globova, 2013).

GtL plants benefit a lot from economies of scale, meaning that larger plants would be lower in specific cost. The capex for a typical GtL plant with a capacity of 50,000 barrels per day (bpd) is reported to be 110,000 USD/bbl (Wood et al., 2012). The plant assumed in this paper with an approximate capacity of 26,000 bpd, is on the edge between small scale and large scale plants. *Velocys*, as a manufacturer of small scale GtL plants, reports a capex of 100,000 USD/bbl which is in the range of capex of large scale plants (Velocys, 2015a). As explained in *Section 2.2.1*., the availability of oxygen for zero marginal cost can reduce the total costs by 8%. Thus, with a USD/€ exchange rate of 1.35 (Tab. 12),, the capex of the GtL plant would be about 68 k€/bbl and it is expected to be at the same level for the year 2030.

A lifetime of 25, 25, 30 and 25 years have been reported by Udaeta et al. (2007), Velasco et al. (2010), Wood et al. (2012), (Velocys, 2015b) and FVV (2013) for GtL plants, respectively. According to the project timing (2030), and due to unfailing RE-SNG reserves as the feedstock of the GtL plant, the higher reported lifetime of 30 years should be acceptable. Table 10 shows all the assumptions for the specifications of the GtL plant in the model used in this paper.

Tab. 10: Base case specification of a hypothetical GtL plant assumed for this paper

		Unit	Amount
Capex		k€/bpd	68
Opex		% of capex p.a.	3

Heat release		% of inlet SNG	22

2.2.4. Products shipping

GtL products can be shipped by a product tanker fleet. The deadweight (DW) of large range vessels (LR2) is between 80,000 to 120,000 tons. The ship can carry a weight of approximately 90% of its DW (EIA, 2014b). The shipping specifications are shown in Table 11, assuming a shipping from Patagonia to Rotterdam. The data have been taken from Konovessis (2012), MAN (2013), Sea distances (2015), UNCTAD (2009) and Khalilpour (2012).

Tab. 11: Shipping specification

	Unit	Amount

3. Results

3.1. RE-PtG-GtL case study, annual basis model

Integrating all the system's elements offers some chances to increase the overall efficiency. Figure 4 shows the Sankey diagram of the entire system, depicting the energy and material flows within the entire RE-PtG-GtL value chain. The figure is the sample of a system with 1 MWh_{el} specific annual electricity input. As can be seen, the alkaline electrolyzer, at 97%, is the main electricity consuming element, while the excess heat by-product of the electrolyzer and the methanation plant is the main source of energy for the CO_2 capture plant. The heat released in the FT process accounts for 14% of initial electricity and 22% of energy content of inlet SNG to the GtL system. The overall PtG-GtL efficiency of this system, without FT heat utilization, would be 42.5%, while 65% of inlet SNG is converted to liquid fuels in the GtL plant. The 15% naphtha share is finally not available for transport fuels. However, this is no financial burden since it can be sold on the market for an attractive value which should be cost neutral.

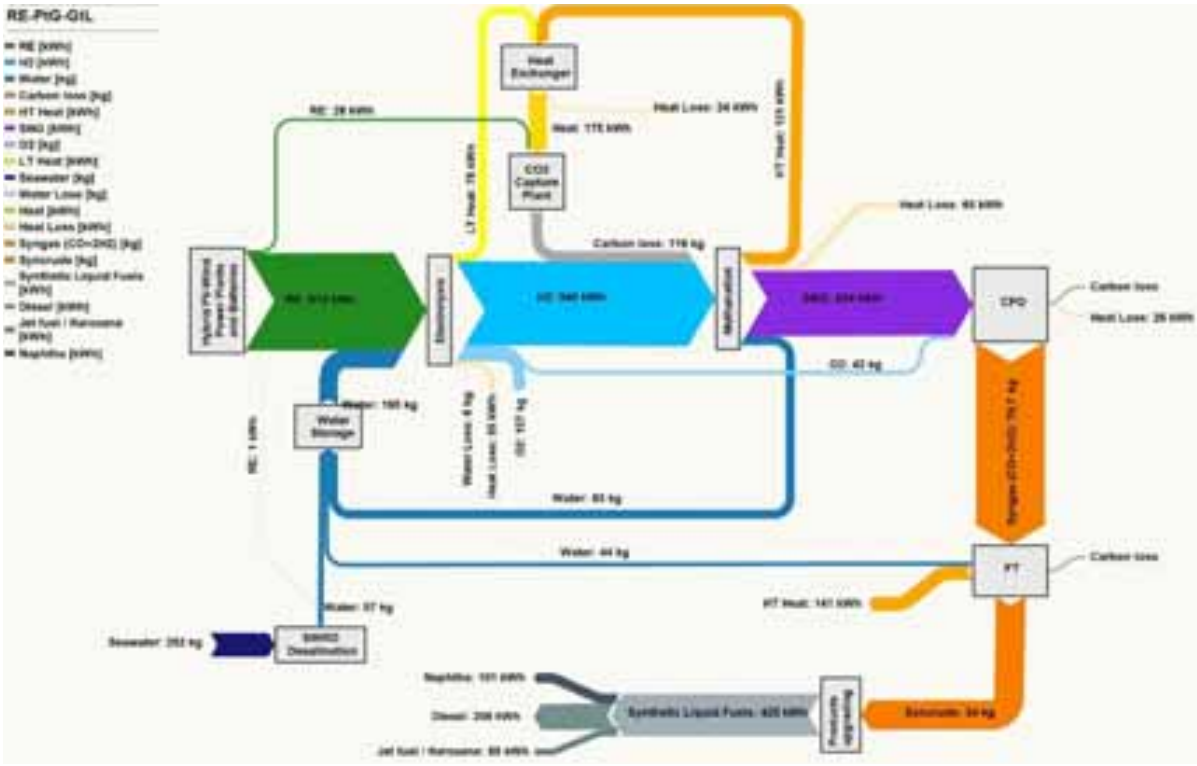

Fig. 4: RE-PtG-GtL energy and material flow diagram.

Unlike RE-SNG, RE-diesel production cost can be a function of crude oil price if there are by-products for selling on the market. All the general assumptions in the calculations of the base case can be found in **Table 12**.

Tab. 12: General assumptions in base case calculations

	Unit	Amount
WACC	%	7
Exchange rate	USD/€	1.35
Brent crude oil price	USD/bbl	80

The LCOE of wind energy and solar PV are 20.35 €/MWh and 25.36 €/MWh, respectively. The hybrid PV-Wind power plant of 5 GW produces 34,688 GWh of electricity per year and the weighted average cost is 22.89 €/MWh. The CO_2 captured from ambient air and the desalinated water cost 40.42 €/t_{CO2} and 0.52 €/m^3, respectively. A summary of all production costs for the base scenario can be found in **Table 13**.

The diesel produced in the FT-process has different characteristics than the conventional diesel produced by a

petroleum refinery. The term "FT-diesel" is used to emphasize the quality of final product. Although the quality of FT-diesel can differ from plant by plant, in this paper the density (at 20 ºC) and higher heating value (HHV) of FT-diesel are assumed to be 766 kg/m^3 and 45.471 MJ/kg, respectively (Glebova, 2013; GREET, 2010). On the other hand, the term RE-diesel is used to emphasize the source of primary energy (PE) in diesel production, while referring to the same product.

Table 13: Production cost in base scenario

	Unit	Amount
Renewable Electricity (RE)	€/MWh$_{el}$	22.89
CO_2	€/t$_{CO2}$	40.42
Desalinated water	€/m^3	0.52
RE-SNG	€/MWh$_{th,gas}$	53.31
RE-SNG	USD/MMBtu	20.85
RE-SNG	USD/bbl	120.95
RE-SNG	€/m^3	0.55
RE-PtG-GtL average product at production site	€/MWh$_{th}$	98.94
FT-diesel at destination	USD/MMBtu	39.13
FT-diesel at destination	€/MWh$_{th}$	100.03
FT-diesel at destination	€/l	0.97

Figure 5 shows the levelized costs in the RE-diesel value chain with two scenarios for the weighted average cost of capital (WACC): 7% and 5%. RE-diesel cost distribution as a share of the total is not dependent on the WACC. GtL and methanation have the highest share (45.6% and 30.4%, respectively) in the total cost. At 1.1%, shipping has the lowest share in this process. Thus, it is more important to have the plants located in regions of the highest solar and wind potential than in regions close to the target market in order to reduce the final cost.

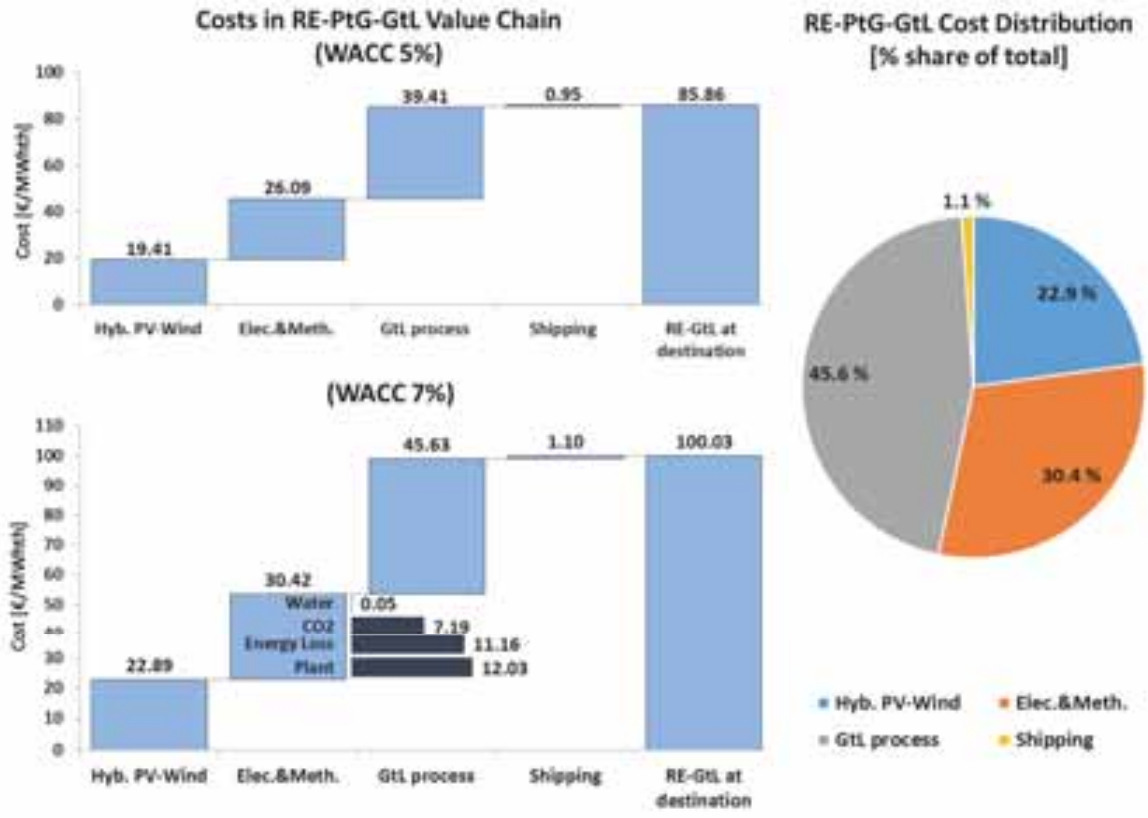

Fig. 5: RE-diesel production cost breakdown for WACC of 5% (top) and 7% (bottom).

Water and CO_2 costs are included in the electrolysis and methanation part of the value chain. With 12.03 €/MWh$_{th,gs}$, the share of the PtG plant itself in the final cost of methanation is 39.5%, while energy losses in the

electrolysis and exothermic reaction of methanation account for 36.7% of the cost of this process. At 7.19 €/$MWh_{th,gas}$, the cost of CO_2 has only a 23.6% share in the methanation plant cost, which is due to internal heat utilization for the CO_2 scrubbing process (Fig. 5).

For the assumptions of the base case scenario, the final cost of RE-diesel in Rotterdam would be 100.03 €/MWh_{th}, which is equal to 204.38 USD/bbl, 39.13 USD/MMBtu or 0.97 €/l of diesel. The RE-diesel cost is a function of the crude oil price and refining cost. **Figure 6** shows the historical trends for the crude oil price, refining cost, diesel cost and crude oil cost to diesel price ratio in percentage.

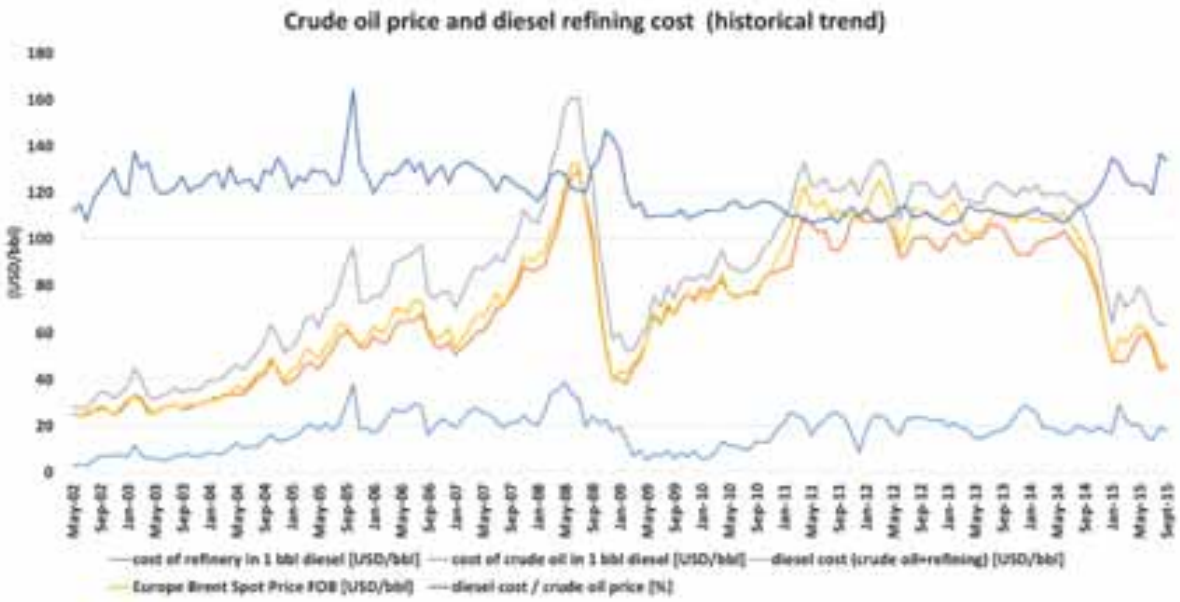

Fig. 6: Crude oil price, diesel refining cost and ratio diesel cost to crude oil price. Data taken from (EIA, 2015).

The long term (13 years) average ratio of one barrel diesel cost (crude oil consumption and refinery cost) to crude oil price is 118.76% and has been taken in this work. The ratio for the full year 2014 was 113.5%. With a crude oil price of 80 USD/bbl, the cost of conventional diesel would be equivalent to 95.01 USD/bbl, 16.38 USD/MMBtu or 0.44 €/l. Thus, the base scenario, accounting for a RE-diesel of 227 USD/bbl, is not directly competitive to the conventional diesel price, but there are some potential game changers:

A) WACC: For a WACC of 7% in the base scenario, the cost of debt and return on equity are 5% and 12%, respectively, for a debt to equity ratio of 70:30. For a WACC of 5%, the corresponding numbers would be 4% and 7%, which could be realized for a risk minimized business case. With this scenario the cost of RE-diesel in Rotterdam could be decreased by 14.2% to 85.86 €/MWh_{th}, 33.59 USD/MMBtu, 194.8 USD/bbl or 0.83 €/l of diesel equivalent. Figure 7 shows the effect of WACC on the final cost.

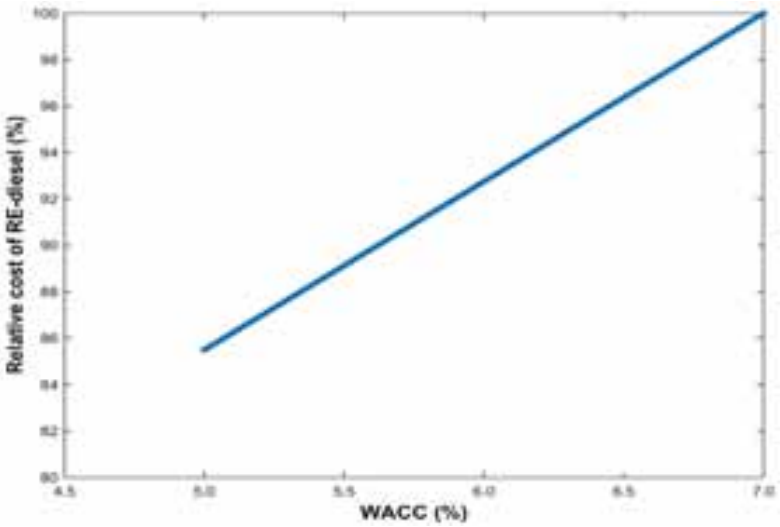

Fig. 7: Effect of WACC on final product's cost in comparison to base case scenario.

B) CO_2 emission cost: CO_2 emission cost for fossil fuels can have a huge impact on the competitiveness of RE-diesel and conventional diesel, as it increases the total cost of fossil fuels. The conventional diesel carbon emissions are 20.2 t_C/TJ (ton carbon per tera joule) (IPCC, 1996), which is equal to 74.02 t_{CO2}/TJ. The additional cost of CO_2 emissions with a maximum price of 50 €/t_{CO2} on the conventional diesel price can be seen in **Figure 8**. Assuming a crude oil price of 80 USD/bbl and 101.44 USD/bbl as the corresponding price for diesel for the base case (including the cost for refinery), a CO_2 price of up to 50 €/t_{CO2} is equivalent to a price increase of the diesel of 13.48 €/MWh_{th}, 5.27 USD/MMBtu, 30.57 USD/bbl and 0.14 €/l.

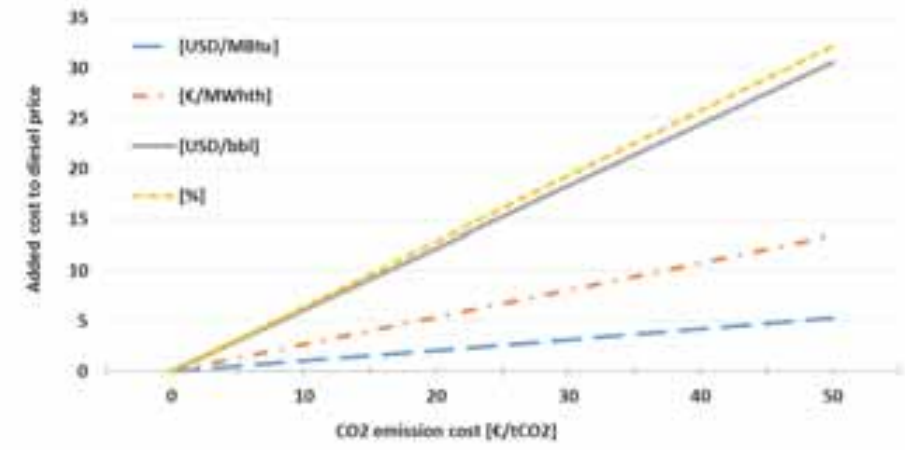

Fig. 8: The additional cost of CO_2 emissions on the conventional diesel price for a CO_2 price of up to 50 €/t_{CO2} in absolute numbers and relative for a basis crude oil price of 80 USD/bbl.

C) Oxygen: 25% of the produced oxygen by the electrolyzer units is used in the syngas production unit, but there is no financial benefit assumed from the rest of oxygen in the base scenario. The projection of a maximum average benefit of 30 €/t_{O2} is shown in **Figure 9**. An oxygen price of up to 30 €/t_{O2} is equivalent to a cost decrease of the RE-diesel of 9.00 €/MWh_{th}, 3.52 USD/MMBtu, 20.42 USD/bbl and 0.08 €/l of diesel, which is equal to a 9.00% decrease in the final cost.

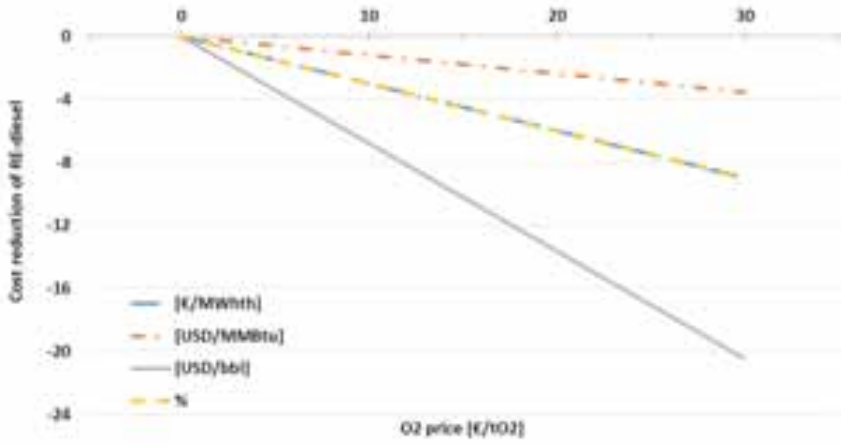

Fig. 9: Effect of oxygen benefit for an oxygen price of up to 30 €/t_{O2} on RE-diesel in absolute numbers and relative ones for the base scenario cost.

As a conclusion, an increase in crude oil price or CO_2 emission cost will increase the cost of conventional diesel, while a profitable business case for O_2 or a reliable business case at a de-risked 5% WACC level can lead to lower cost for RE-diesel cost. The effects of all these potential game changers have been summarised in **Figure 10**. The price of diesel in the EU is based on:

- the global crude oil price as depicted in Figure 10 for a price range of 40 – 200 USD/barrel,
- three scenarios for CO_2 emission cost,
- three scenarios for benefits from O_2 sales, and
- the cost of delivered RE-methane based on two different WACC levels

All projections are for the year 2030.

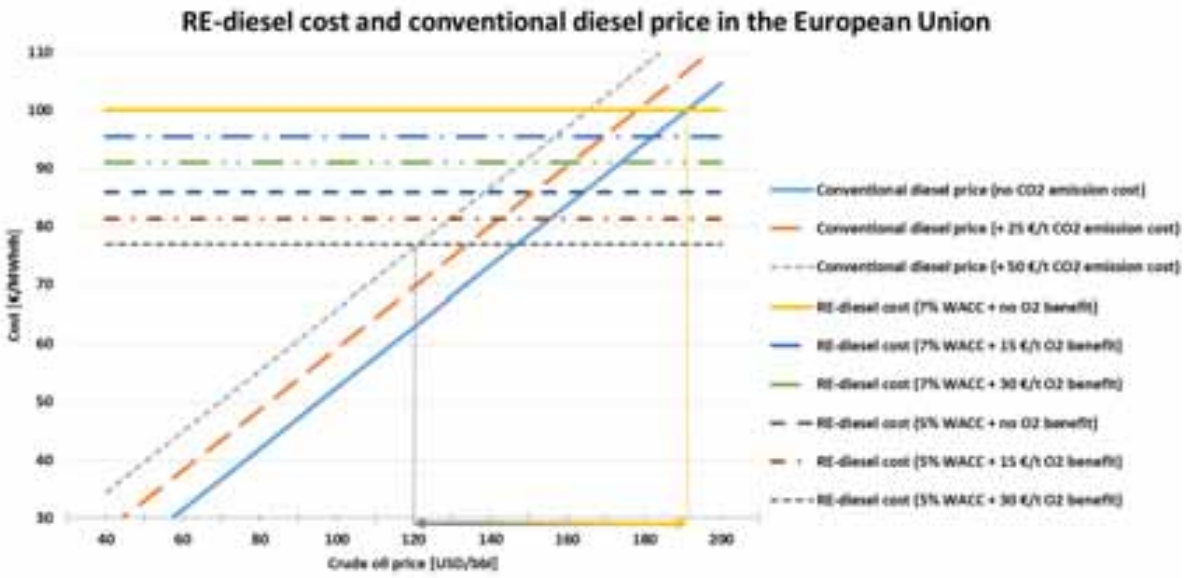

Fig. 10: All possible scenarios for the RE-diesel price in the EU based on the production costs in Patagonia. Reading example: For a crude oil price of 100 USD/bbl the conventional diesel price varies from 66 – 52 €/MWh$_{th}$ (depending on the CO_2 emission costs), while the RE-diesel cost varies from 77 – 100 €/MWh$_{th}$ (depending on WACC and O_2 benefit), i.e. for 121 USD/bbl, 50 €/t$_{CO2}$, 5% WACC and 30 €/t$_{O2}$ the RE-diesel is competitive to the conventional one without any further assumptions.

The first breakeven point can be expected for a produced RE-diesel with a WACC of 5%, CO_2 emission cost of 50 €/t$_{CO2}$, accessible oxygen price of 30 €/t$_{O2}$ and a crude oil price of about 121 USD/bbl. While RE-diesel produced under the base case (WACC of 7%, no CO_2 emission cost and no O_2 sales) can compete with conventional diesel whenever the crude oil price is higher than about 191 USD/bbl. This represents a very high difference and the base case may not easily match with market prices. But the additional assumptions are not far from reality, since a CO_2 emission cost is already applied in some countries (OECD, 2013).

To have a better understanding about the scale of the project, **Table 14** lists the physical and economic aspects of the 5 GW case assumption.

Tab. 14: The annual consumption/ production and economic aspects of the 5 GW case assumption. Abbreviations: million ton per annum, *MMTPA,* barrel per day, *bpd*.

	Unit	Amount		Unit	Amount
Hybrid PV-Wind power plant			*GtL plant*		
PV single-axis installed capacity	GW_p	5	Capacity	bpd GTL	27,720

Capital expenditure	m€	10	Capital expenditure	m€	75
Water production	mio m^3	3.5			

The capital expenditure breakdown of the total value chain has been shown in Figure 11. The total capital cost is 13.31 bn€, while the electricity generation solely requires 59% of the capital expenditure. With 0.6% and 0.04% respectively, the capital expenditures of ships and the desalination plant are almost negligible.

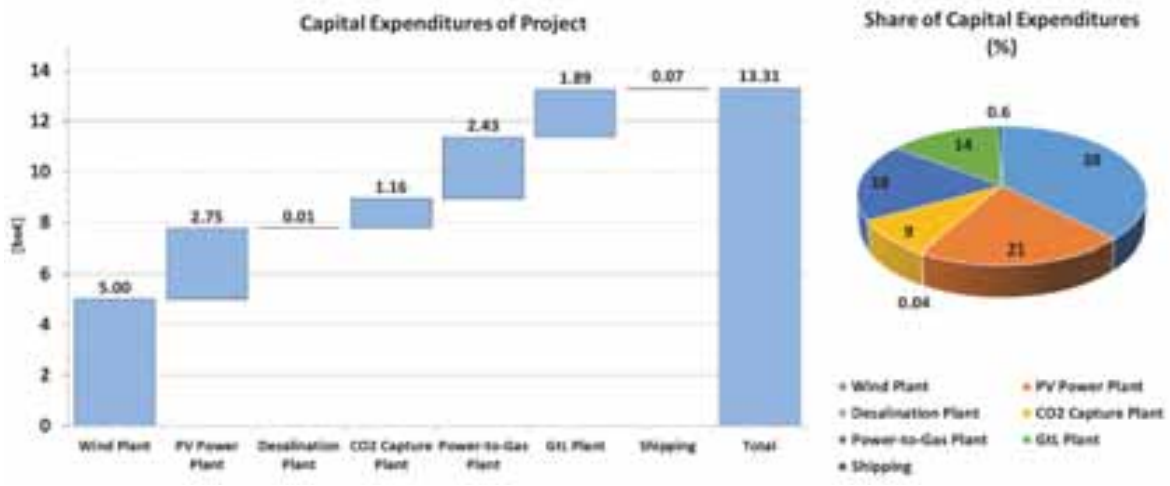

Fig. 11: The capital expenditure breakdown of hybrid PV-Wind-PtG-GtL value chain.

To have an overview on the data available to the public, one should take it into consideration that not even two GtL plants designed by one company are the same. The quality of feedstock, applied technology and desired outputs and the corresponding costs could be quite different case by case. In response to these uncertainties, a series of sensitivity analyses have been done for ±10% change in the capex, efficiency and other inputs of major elements. Figure 12 illustrate these analyses in the categories of economic changes, geographical changes and changes in plant efficiency.

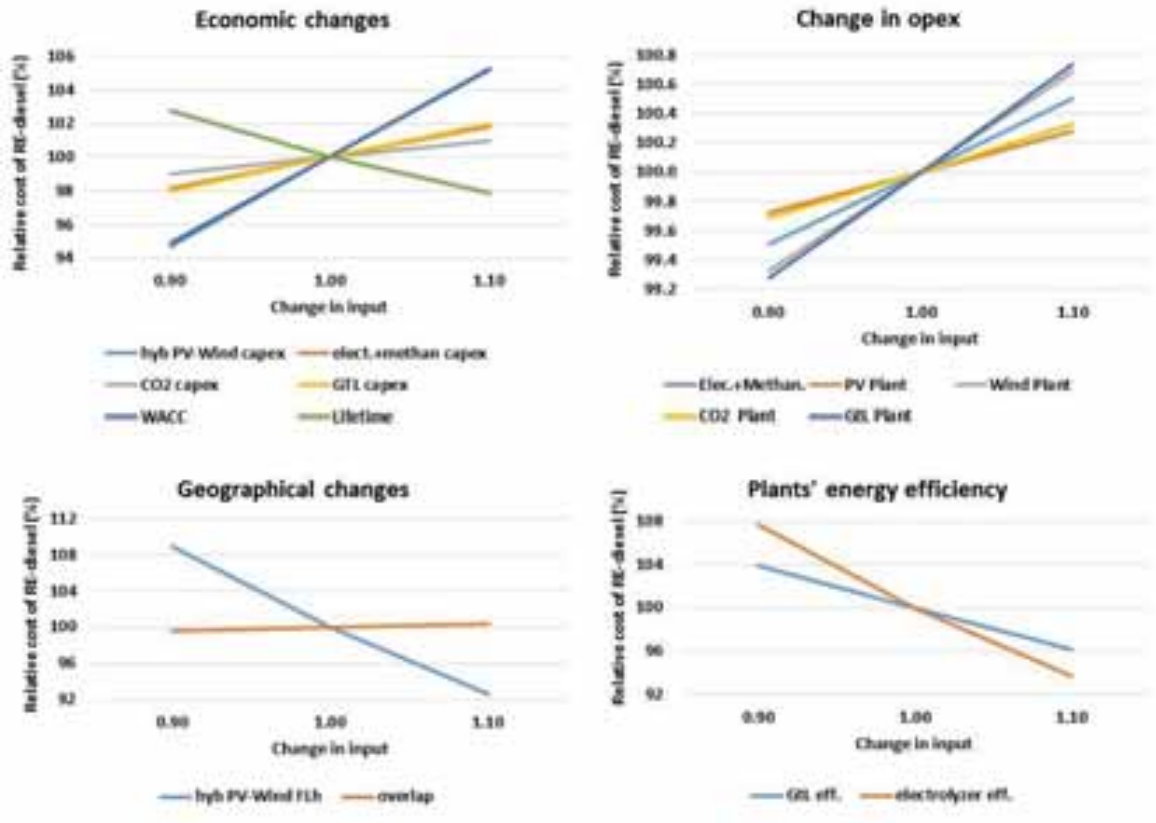

Fig. 12: Sensitivity analysis of input data based on economic changes (top, left), change in plants' opex (top, right), geographical changes (bottom, left) and plants' energy efficiency (bottom, right).

The economic changes graph illustrates that a 10% decrease in the capex of a hybrid PV-Wind power plant will result in a 5.5% decrease in the final LCOF of diesel, which is 2.5 times more than the effect of changes in the capex of the electrolysis or GtL plant. On the other hand, changes in opex shows that no single plant can cause more than a 1% change in the final production cost if the opex divergence is up to 10%. The geographical changes graph shows that a 10% decrease in the FLh of hybrid PV-Wind plant will increase the final LCOF by 9%, while a 10% increase in the efficiency will just result in a 7.5% decrease in the final products' cost. A 10% change in the amount of overlap is a very small number and it does not bring any significant change to the system. As it is expected, plants' energy efficiency analysis shows that a 10% increase in the efficiency of electrolysis and GtL plants would decrease diesel production cost by 6% and 11%, respectively. Thus, while there is no difference in the LCOF of the GtL plant, electrolysis and methanation capex, the GtL plant efficiency has a higher effect on the final product's cost. Summing up, the three final RE-diesel LCOF influencing factors are the full load hours of the hybrid PV-Wind power plant, the electrolyzer efficiency and the WACC for the entire investment. As a consequence, the RE-PtG-GtL value chain needs to be located at the best complemented solar and wind sites in the world combined with a de-risking strategy and a special focus on mid to long term electrolyzer efficiency improvements.

3.2. Optimal RE-PtG-GtL global potential, hourly basis model

The global RE-SNG generation potential has been studied by Fasihi et al. (2015) on an hourly basis. The hourly model enables the best combination of PV (fixed-tilted or single-axis tracking), wind energy and battery capacities based on an hourly availability of the solar and wind resources to minimize the levelized cost of electricity (LCOE) and cost of SNG. Low cost batteries are added to harvest the excess electricity during overlap times to increase the FLh whenever it is beneficial. Applying this approach on all regions in the world with a minimum of 6000 FLh for hybrid PV-Wind power plants and setting an upper limitation of maximum 10% area use by both PV and wind power plants, the global map of optimal electricity and SNG generation potential and the corresponding prices have been shown in Figure 13 (Fasihi et al., 2015).

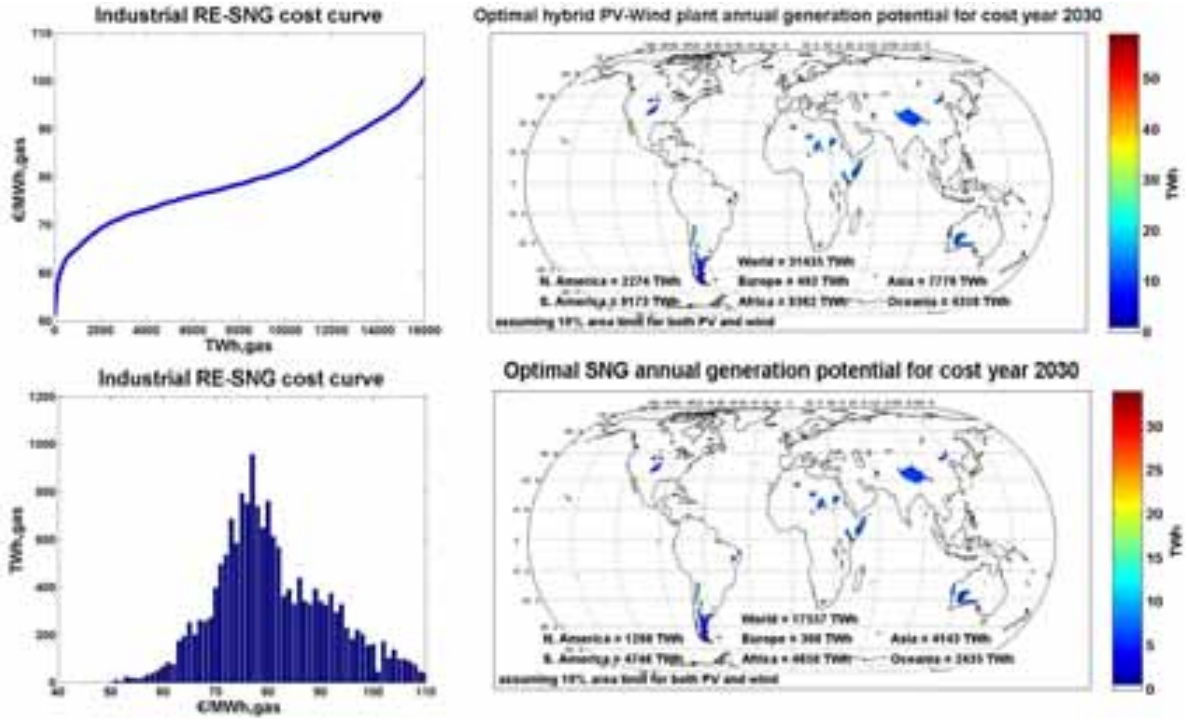

Fig. 13: Optimal hybrid PV-Wind plant annual electricity generation potential (top, right), optimal PtG plant annual SNG generation potential (bottom, right) and SNG cost curve for cost optimized SNG generation in a cumulative (top, left) and a spectral (bottom, right) distribution for the cost year 2030.

Figure 13 illustrates that the generation potential for PtG is less than the electricity generation, which is due to the electricity consumption in the desalination and CO_2 capture plant, and efficiency losses in the PtG plant and power transmission lines. The global annual optimal electricity and SNG production potential are about 31,400 TWh_{el} and 17,600 $TWh_{th,gas}$, respectively. More SNG could be produced in South America (4,750 $TWh_{th,gas}$), while the hybrid PV-Wind power plant generation in Africa (8,360 TWh_{el}) is comparable to the potential of South

America (8170 TWh_{el}). Europe has the lowest electricity and SNG production. But with 62.6%, it has the highest electricity to SNG conversion rate among all continents. With respect to global production numbers in the figure, the average electricity to SNG conversion rate can be estimated to be about 56%.

Based on Figure 13, the global optimal SNG potential is about 17,560 $TWh_{th,gas}$, which results by applying a GtL efficiency of 65% at a production of about 11,410 $TWh_{th,fuel}$ GtL products. This is equal to about 7,540 million barrel GtL products. Figure 14 illustrates the GtL industrial cost curve for global optimal SNG production as feedstock.

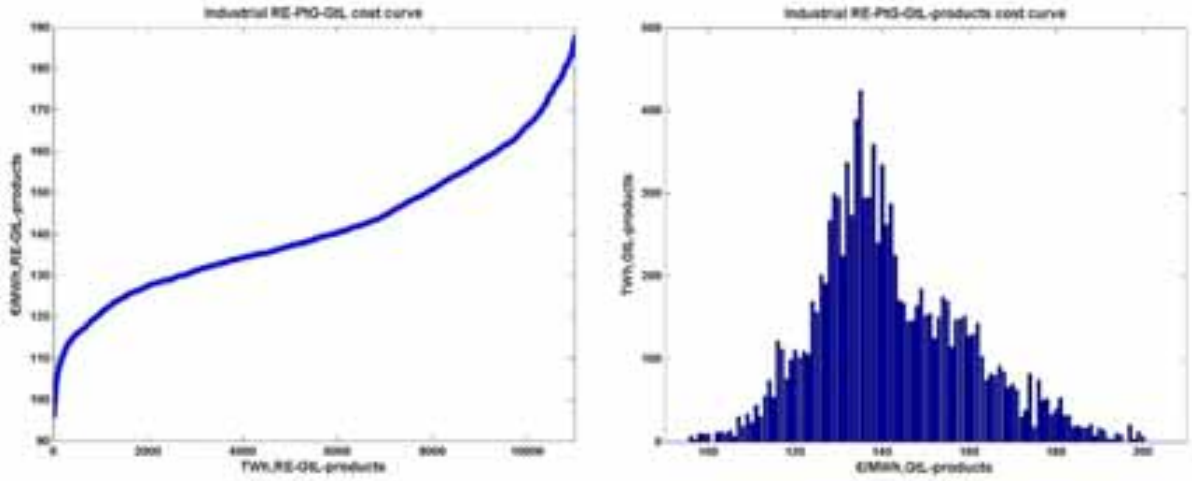

Fig. 14: GtL industrial cost curve for cost optimized GtL production based on RE-PtG in a cumulative (left) and a spectral (right) distribution for the cost year 2030.

The global GtL plants with an inlet SNG cost range of 50 to 100 €/$MWh_{th,gas}$ will result in production costs of RE-diesel in the range of 93.8 to 170.8 €/$MWh_{th,fuel}$, equal to 212.9 to 387.5 USD/bbl or 0.91 to 1.66 €/l.

4. Conclusion

Due to their emissions, there is no place for fossil fuels in a fully sustainable energy system. On the other hand, a ful substitution of fossil fuels by renewable electricity is not possible, as electricity cannot be directly used in some sectors such as aviation or heavy vehicles in all cases. Thus, renewable electricity based fuels are essential to fulfill this demand. The RE-SNG can be further converted to RE-diesel and other fuels in a liquid phase in GtL plants. Modelling an energy system without fossil fuels, the carbon source of this process cannot be from the flue gas of power plants fired by fossil fuels. Moreover, in a global scale energy system, the carbon source should be accessible wherever the renewable power is available. To have a carbon neutral product, CO_2 needed for this process should be captured from ambient air and water desalination should be applied whenever there is a certain levels of water stress in the region. All the technologies for this energy system already exist on a commercial scale and it can become operational whenever investors decide to go for it. All this being said, the system cannot run if the final product is not cost competitive.

This study shows that, with about a 191 USD per oil equivalent barrel, RE-diesel (produced in the RE-PtG-GtL chain) costs more than conventional fossil diesel in today's market. But this price difference is not like a dead end for this energy system. There are different factors which can improve the competitiveness of RE-diesel with conventional fossil diesel in the long term and not all of these factors are internal issues related to this energy system.

- The crude oil price is the very first factor. The long term change in the crude oil price is a function of production cost, production and consumption rate, reserves and political issues. On the other hand, in the short term and as long as production cost of RE-diesel is higher than the production cost of conventional fossil diesel, RE-diesel can be kept away from the market if the crude oil price is set less than RE-diesel production cost. But in the long term, when the crude oil reserves are not sufficient to cover the demand, then the market is likely to follow the RE-diesel production cost.
- Environmental concerns and fuel quality will put additional costs on the conventional fossil diesel price.

CO_2 emission cost has been already set in some countries. Moreover, the standards for fuel quality may rise to a limit at which conventional diesel cannot be produced at that quality anymore. In that case, carbon-neutral and sulphur-free RE-FT-diesel can be considered as one of the main substitutions, also for a production cost 50-100% higher than conventional fossil diesel.

- The by-products of the RE-PtG-GtL value chain can play a significant role in some regional cases, if not globally. A RE-PtG-GtL plant located in a region with high demand for oxygen can decrease the production cost of diesel by 20%. Thus, this system can still run for some special cases, if not globally.
- The other regional effect would be the risk of investment. The impact of de-risking measures have been found to be of high relevance for the economics, since reduced risks which could decrease the WACC from 7% to 5% would reduce the production cost throughout the entire value chain by about 14.2%.
- The heating value of released heat in the FT process is equal to 14% of inlet electricity to the system. A permanent (not seasonal) plan for monetizing this heat can significantly increase the overall efficiency and would decrease the costs.
- Last but not least, a revised technical system design with the same inputs and outputs might result in lower production cost. This is due to the fact that the current system cost breakdown shows that about ¾ of production cost is related to the PtG-GtL section and only 25% is related to the cost of electricity. As an example, eliminating the SNG production step in this energy system and focusing on direct production of RE-diesel from water and CO_2 will increase the efficiency, which might decrease the production cost further. But so far, PtL technology has been operating on a laboratory and pre-commercial scale only and the capex for this process is still high. Thus, it depends on the advances in the technology and the balance between increase in the efficiency and capex and their effects on the production cost. A cost comparison among these different routes is needed for a better understanding of the most promising options.

In conclusion, the external factors can have a strong impact on the competitiveness of the RE-PtG-Gtl system and in a beneficial combination they can reduce the cost of RE-diesel from the aforementioned 191 USD per oil equivalent barrel to about 121 USD, which had been a crude oil price level for already some years in the recent past (BP, 2015). These results have a significant impact on the discussions of the energy transformation towards sustainability ahead. If not concurring with the market, the hybrid PV-Wind-RE-PtG-GtL system could set an upper limit for fossil fuel prices, globally. It would also further increase the demand for solar PV systems, wind turbines, water electrolyzers, methanation plants and CO_2 capture plants. The additional market for solar PV and wind energy can be estimated to be in the terawatt scale. This potentially huge market itself would further reduce production costs and increase research and development investments in the field for more efficient technologies.

PROGRESS IN SOLAR ENERGY R&D IN NORTH OF CHILE: SOLAR PLATFORM OF ATACAMA DESERT PROJECT AND ONGOING ACTIVITIES

Carlos Portillo[1], Elisa Alonso[1], Angel Fernández[1], Pablo Ferrada[1], Alessandro Gallo[1], Martin Guillaume[1], Aitor Marzo[1] and Edward Fuentealba[1]

[1]University of Antofagasta. Centro de Desarrollo Energético Antofagasta, Chile. Avda. Angamos 601, 1270300, Antofagasta, Chile.

Abstract

Chile is now considered one of the highest potential markets for solar energy, due to the very high solar resource existing particularly in the North and the political boosting by means of becoming legislation. In the Atacama Desert highest irradiation levels in the world are achieved, over 8 kWh m^2 per day. In order to take advantage of it, the Chilean government is intended that 20% of the country's energy from renewable sources in 2025. Under this context, PV and solar thermal commercial plants, including CSP, are already operating and others under construction. In order to actively contribute to the solar resource exploitation in North of Chile, new R&D activities are being developed in the last few years by the local universities and research centers. They include the foundations of the Solar Platform of Atacama Desert (PSDA), in the Antofagasta Region, which aims to host R&D pilot-scale solar facilities for demonstrative tests under the natural environment of Atacama Desert. An overview of the related ongoing activities is presented in this work.

Keywords:*North of Chile, Solar Energy Research, Solar Platform, Atacama Desert*

1. Introduction

The Atacama Desert exhibits the highest solar radiation levels in the world with a low frequency of cloudiness in areas apart from the coast. Data showed in Fig. 1 are available in Solargis (Geomodel, 2015) and illustrate the direct normal irradiation (DNI) in the world and global horizontal irradiation (GHI) in Chile. As observed, average annual DNI of 3800 kWh/m^2 is achieved only in the Atacama Desert.

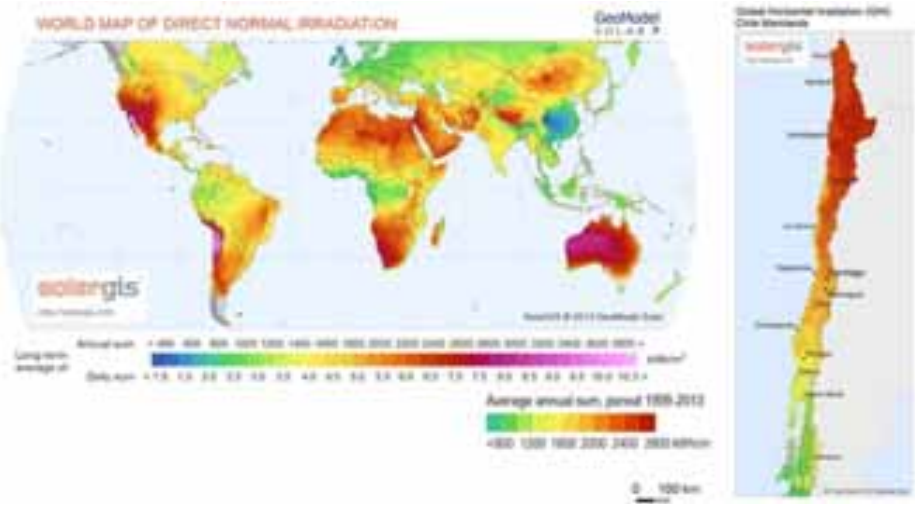

Fig. 1: World DNI and Chile GHI maps taken from Solargis.

doi:10.18086/swc.2015.09.04 Available at http://proceedings.ises.org

Despite this potential, Chile still imports the 70% of its primary energy and electricity prices have increased significantly in the last decade. Energy sources are mainly fossil fuels (coal, GNL and diesel). Moreover, Chilean industry, mostly mining, has high demands of electricity (90 % of the Northern electric system, SING) and heat (Ministerio de Energía, 2016). Although the current solar contribution to SING is yet only 1.91%, the construction of new commercial PV, solar thermal and CSP plants is ongoing since last few years. In order to contribute to this development, new local R&D activities are also being started. One of them is the PSDA, which is projected as an in-situ pilot plant to demonstrate and test solar energy technologies under the natural environment of the Atacama Desert.

2. Solar Platform of Atacama Desert Project

2.1. Objectives

Solar Platform of Atacama Desert was conceived as a technological project with the following objetives:

- To promote and carry out R&D according to the guidelines emanating from different government agencies.
- To promote collaboration with universities and national and international R&D centers in various technological areas related to solar energy.
- To provide specific knowledge opportunities that can meet the future needs of advanced human capital and technical product specialists.
- To promote collaboration with regional and national companies that allow for adequate transfer and commercialization of the developed technologies.
- To promote the productive chain and the creation of spin-offs.
- To provide technical services, including advice and consultancy services to both public and private institutions.
- To foster scientific and technological diffusion, promoting general public to aware of the advantages and benefits of the solar energy technologies.
- To become a reference center in solar energy technologies, not only in Chile but also in the whole Latin American context.

2.2. Funding and political coordination

Funds invested so far in the PSDA are contributions of the Regional Government and the University of Antofagasta which reached US $ 1.35 Million. Currently, the PSDA is considered as the Chilean Laboratory for Solar Energy Research, defined by the Corporation for promotion of production (CORFO), through the National Center for Innovation and the Sustainable Energy Development (CIFES) who is applying resources to the National Strategic Investment Fund (FIE) to cover the operating costs of the Strategic Solar Programme. It considers promoting the development of the solar industry in Chile between 2015 and 2025. For the PSDA are an approximate amount of US $ 50 Million are being evaluated for facilities, laboratories and physical adjustments. These investments are being proposed through Solar Energy Research Center (SERC Chile) and international centres based in Chile.

2.3. Current status

Currently , the land of PSDA is available and the first studies have been already carried out or are financed for the next future. Such studies are the following.

- Study on the "Structural Design and Operational Research and Development of Solar Energy in Northern Chile." STA-CDEA-UA. 2010

- Framework agreement between Centre for Energy, Environment and Technological Investigations (CIEMAT) of Spain and the University of Antofagasta. 2010
- Award of "Fourth National Competition for Centers of Excellence in Research on Priority Areas FONDAP 2013-2018." Chilean project Solar Energy Research Center (SERC-Chile).
- Award of performance agreement for higher education "Strengthening the University of Antofagasta as Regional and National Reference in Non-Conventional Renewable Energy (ERNC)." 2013-2015.
- FIC-R 2013 (Innovation Fund for Competitiveness) "Implementation, development and diffusion of the Plataforma Solar Atacama Desert inserted into the system of regional technology parks first stage". 2013 - 2014.
- FIC-R 2014 (Innovation Fund for Competitiveness) "Implementation of advanced instrumentation system as technological support of the PSDA project, first stage". 2014 – 2015
- FIC-R 2015 (Innovation Fund for Competitiveness) "Positioning of in-situ solar technology laboratory (PSDA) for the purpose of applied research, extension and training of technicians from the Region of Antofagasta. 2015 – 2017.
- Tender for design and feasibility analysis of a solar platform technology development in northern Chile funded by CORFO. It consist in an update and the business model definition of a study made in 2010

2.3. Future projection

PSDA is projected as an applied research platform in-situ , destined to test new technologies and materials considering the conditions of high radiation. In addition, it will be used to support the productive chain of the solar energy local industry, technical certificates for PV and CSP facilities and certification of products to high radiation. Complementary technologies to supply heat and miners processes of the Atacama Desert will be analyzed.

3. Current R&D Activities

3.1. Radiometry and Calibration Laboratory applied to solar technologies (RCL) and Solar resource

Due to the high levels of solar radiation and the low frequency of cloudiness in areas out from the coast, below the 10% on most sites at north (see fig. 2), the Atacama Desert rises like a promising area for solar power plants implementation.

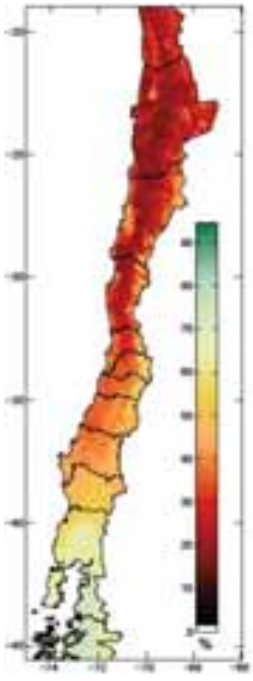

Fig. 2: Annual cloudiness in Chile (Molina Monje and Rondanelli Roias. 2012)

Accurate solar radiation measurements are necessary for the implementation of solar power plants anywhere. Especially, they are essential for centers which aim research on solar technologies. Precise solar radiation measurements are crucial to determine, e.g. the efficiency of the tested prototypes or the degradation of materials used in solar technologies. Such applications involve a series of records of terrestrial surface radiation components and other meteorological components.

The PSDA is implementing a meteorological station focused on measuring solar radiation, but also for other generic weather variables, such as temperature, atmospheric pressure and relative humidity, wind speed and direction, etc. The meteo station counts on the most advanced radiometric instrumentation. Within its equipment for solar resource, it has several types of pyranometers based on photo-cells and thermopile with individually optimised temperature compensation for measuring the Global and Diffuse Horizontal and Tilted Radiation, First Class pyrheliometers for measuring Direct Normal Irradiance, UV Radiometers to

measure the horizontal UV-A and UV-B horizontal irradiance, several two-axis solar trackers, shadow balls, etc.

Research on solar resource have shown the high radiation levels available in Atacama Desert. For example, in Fig. 3, monthly global horizontal irradiation, H_m [kWh m^{-2}], is compared with three available satellite-derived solar radiation datasets: the 22-year average data from the NASA-SSE (Surface Meteorology and Solar Energy programme) (Stackhouse, 2011), the Solar GIS (Geomodel, 2015) and the Explorador de Energía Solar (EE Solar) model (Ministerio de Energía, 2015; Ministerio de Energía et al., 2015). The total annual irradiation achieved a value of 2554 kWh m^{-2} $year^{-1}$ during the period of measurement. This is a high value that overcomes the values achieved in, e.g., Doha (Qatar) with 2048 kWh m^{-2} $year^{-1}$ (Bachour and Perez-Astudillo, 2014) or the 2190 kWh m^{-2} $year^{-1}$ achieved in Abu Dhabi, the highest one of the Arab state capitals according to Islam (Islam et al., 2010, 2009).

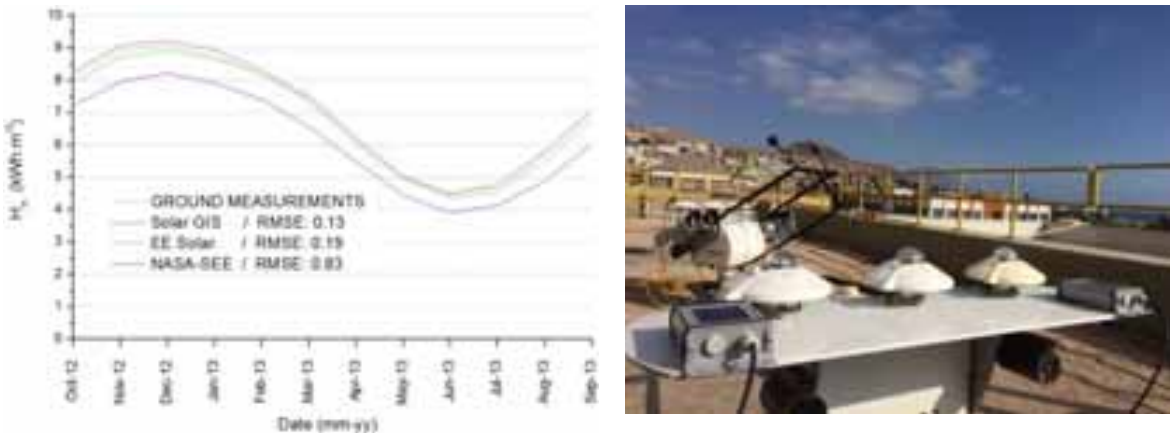

Fig. 3: Left, results of the comparison of monthly average of Global Horizontal Irradiation values derived from ground measurements against three typical years derived from satellite data: Solar GIS, EE Solar and NASA-SEE. This task was developed for a local mining company sited in Atacama Desert. Right , validation of pyranometers and pyrheliometers performance by comparison with reference instrumentetion at Universidad de Antofagasta.

The PSDA Radiometry Area tasks have been defined to provide support to the local industry in different research areas. These tasks may be summarised in four groups:

1. Instrumentation checking: testing, validation and calibration tasks to ensure the accuracy of the measurements;
2. Data evaluation: generating an accurate database and studies related to the physics of the atmosphere and the solar resource assessment;
3. Optics: optical characterisation of surfaces used in solar technologies;
4. Measurement methodologies and instrumentation development: provide tools by developing and/or adapting instrumentation with different applications to solve the measurement problems related with the new research studies to develop on solar energy area.

To achieve said goals, collaboration is ongoing with a number of national and international research centers, such as the Plataforma Solar de Almería (PSA, Spain), Universidad de Almería (UAL, Spain), and the universities belonging to the Solar Energy Research Center (SERC-Chile).

3.2. Solar PV

In collaboration with the PSDA Radiometry Area, there are also developing studies of how the Atacama environment affects the optical properties of mirrors and glasses used for solar technologies. These studies are focused on relating the surface optical degradation with the deposition rate of soiling and dust over the time. With the common aim of studying the effect of soiling on solar technologies efficiency, the

performance ratio (PR) is the most used indicator, also at the PSDA, to investigate the degradation at PV plants (IEC, 1998). The goal is to relate and correlate optical degradation of PV glass with the PR and examine the causes for this degradation. Thus, tasks within PV area include:

- Precise inspection of PV plants with current-voltage (IV) curve tracers.
- Characterization of optical properties of PV glass.
- Determination of the physical-chemical properties of accumulated dust.
- Inspection o PV plants with IV tracers, IR cameras and, in the near future, with electroluminescence.
- Study of bifacial PV modules.
- Calculation of the Levelized Cost of Electricity (LCOE)

Currently, PV plants of different technologies are being installed and will be fully operational in 2015. The technologies include mc-Si, monocrystalline Si and HIT (heterostructure with intrinsic thin layer) modules. In total, 6 plants of the size of ≈1.2 kWp each of several features such as potential induced degradation (PID) free, monofacial and bifacial glass to glass will be used to compare in situ the performance and soiling effects. The comparison goes further as the same installations will be available at the coastal zone of the Atacama Desert, in the campus of the Antofagasta University. Examples of such studies at the coastal zone of the Atacama Desert are found in Ferrada et al. (2015). It was pointed out that the maximum PR at these conditions for mc-Si modules of 230 Wp was 85% and that the rate by which PR can degrade was up to 4.5%/month. Studies regarding the resulting levelized cost of electricity (LCOE) for PV plants athe coastal zone of Atacama Desert are addressed in Fuentealba et al. (2015). Since the characteristics of the environment and solar resource may be much different at the PSDA compared to the coastal zone of Atacama Desert, detailed studies under local conditions are required.

In addition, the existing collaboration between the Centro de Desarrollo Energético Antofagasta and SERC with the International Solar Energy Research Center Konstanz (ISC Konstanz) in Germany focuses on the development of AtaMo, the solar module for the Atacama Desert. The project consists on the selection of best materials for the PV module which perform best in the Atacama Desert. Sets of solar cells based on crystalline silicon are constantly fabricated in Konstanz, and then mini modules of 1 to 4 cells are produced. The mini modules are tested in situ at the PSDA by using a current-voltage (IV) curve tracer of same technology and same measurement principle as the indoor sun simulator existing at the laboratories of ISC Konstanz. The solar cells used are monofacial on p-type mono and multi crystalline silicon substrates and bifacial on n-type monocrystalline silicon wafers, both of the size 15.6 by 15.6 cm^2. Mini modules are fabricated with PV glass of several thicknesses (from 3.2 standard down to 2 mm, 1.5 mm and 1 mm), different encapsulants such as Ethylene vinyl acetate (EVA), thermoplastic materials (TM) and low UV light cut-off (U encapsulant). The backsheets (BS) consist of standard (white), transparent and desert type sheets (optimized in terms of hardness and thickness for desert regions), as well as glass (as BS) are employed.

An AAA class solar simulator is used to measure the IV characteristics indoor at standard testing conditions (STC) before and after the lamination step to determine the cell to module losses (CTM). For the last experiment a total of 37 groups were fabricated, from which 14 groups were based on mc-Si cells for damp heat (DH), humidity freeze (HF) and ultraviolet (UV) degradation test, and 23 groups based on bifacial n-type cell for thermos cycling (TC) test and outdoor measurements at the PSDA. Fig. 4 illustrates a measurement campaign at the PSDA.

Fig. 4. Left: Set of mini modules and testing configuration at the PSDA. Right: Albedometer to quantify solar resource for mini modules.

A first evaluation of results point out to the optimum combination of materials. It consists of the use of thinner glass-glass module (1.0 to 2.0 mm thickness) showing better resistivity against thermal stress compared to glass-transparent back sheet. The encapsulant shall be used as due to its high robustness against long-term humidity exposure and higher transmissivity expected in the UV-B range. Modules with halved cells resulted to perform better in the field due to lower electrical power losses at high irradiation conditions. For full details, refer to Cabrera et al. (2015). A very preliminary estimation based on a maximum PR value of 85% for conventional mc-Si modules, bifacial AtaMo modules could generate between 29% to 32% more energy compared to mc-Si modules utilizing 23% to 33% less area, both assuming a 1 MWp PV plant.

3.3. Solar thermal and CSP systems

In the field of solar thermal technologies, several plants have been installed in the North of Chile in the last few years. Flat and parabolic trough collectors were mounted to provide heat for mining processes, mainly, where the energy consumption has reached 161.716 TJ in 2014 (including electricity and fuel). Currently, analyses of all the possible applications of solar energy in mining are being investigated. In particular, attention is paid to that processes which require the use of heat. In Fig. 5, several applications to processes sulfides and oxides are highligthed. In particular, electro-winning and anodes washing present high heat consumption and temperatures below 100°C in copper production processes.

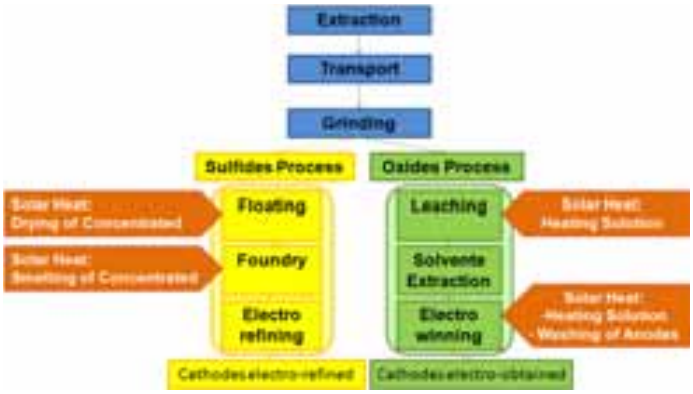

Fig. 5: Possibility for solar heat applications in copper mining processes

Researchers at University of Antofagasta are having the opportunity to collaborate with the most important local mines and to monitor the proper working of those solar facilities. Some studies have been carried out: in one case it was analysed the behaviour of the solar plant (Ushak et al., 2014) and in another one, a TRNSYS model is compared with a solar thermal pilot plant (Gallo et al., 2015). The next scheduled study concerns a parabolic trough system for heating the electrolyte in another mining company.

In Gallo et al. (2014) the integration of thermal collectors with an absorption machine was proposed for the air-conditioning of container in mining camps of the Atacama Desert. At Energy Development Center of Antofagasta, a demonstrative solar thermal plant for hot water heating is currently under installation and it is planned to install another one in the PSDA to study the effect of soiling on such systems with different environmental conditions.

A 7 kW_e solar simulator has been recently acquired in the Energy Development Center at Antofagasta University and will be shortly implemented together with a flux measurement system. Such a device will be employed as high flux radiation source until a real solar system is developed in the Solar Platform of Atacama Desert. Studies at high temperature are programmed to be addressed using the solar simulator. Most of them are focused on the solar energy usage in copper mining. Since copper extraction involves metallurgical processes at 1200 ºC they are being analysed from the point of view of their integration with concentrating solar energy systems. On the future development axis of the Solar Platform will be the proof of concept of these solar mining processes for what pre-industrial scale facilities are planned.

3.4 Thermal storage of concentrating solar energy

Chilean salt deposits have the potential to be exploited to obtain new molten fluids with the possibility to improve the properties currently associated to the solar binary salt (60% $NaNO_3$ + 40% KNO_3) used for Thermal Energy Storage (TES) in CSP plants. In this line, research and development in the solar energy sector is focussed on reducing the high cost of the operation and maintenance of these plants. One of the most important research lines in this context is the study, design and characterisation of salts that are used as energy storage fluids.

Binary mixtures of alkali molten nitrates/nitrites present phase diagrams with simple eutectic point and byadding one or more components, it is expected that the resulting mixture will have a lower melting point compared to the initial eutectic binary mixture. The design of multicomponent mixtures by the addition ofalkali/alkaline earth nitrates could extend the working temperature range of thermal energy storage (Bauer et al., 2014; Cordaro et al., 2011; Fernández et al., 2012; Gil et al., 2010; Mantha et al., 2012; Medrano et al., 2010; Olivares, 2012; Peng et al., 2010; Raade and Padowitz, 2011). The additives that present greater potential to be used for solar energy storage are $Ca(NO_3)_2$ and $LiNO_3$ as these salts decrease the melting point and improve the thermal stability, respectively.

Tab. 1: Thermophysical properties of Chilean lithium/calcium nitrate containing molten salts.

Molten salt mixture (wt.%)	Work temp. range (°C)	Viscosity at 250°C (cP)	Corrosion rate of A516 Steel at 390°C (mm/year)	Electrical conductivity at 390°C (Ω-1m-1)	Energy density (MJ/m3)	Salt Price (US$/Ton)	Two-tanks system cost/stored energy (US$/kWhth)
Solar Salt	221–589	5.51	0.97	0.37	550	893	11.67
20 $LiNO_3$ – 52 KNO_3 – 28 $NaNO_3$	130–600	6.3	0.31	0.67	513	1161	16.35
30 $LiNO_3$ – 10 $Ca(NO_3)_2$ – 60 KNO_3	134–567	5.72	0.027	0.56	607	1274	15.07
10 $LiNO_3$ – 10 $Ca(NO_3)_2$ – 60 KNO_3 – 20 $NaNO_3$	132–580	5.78	0.013	0.45	680	1038	10.98

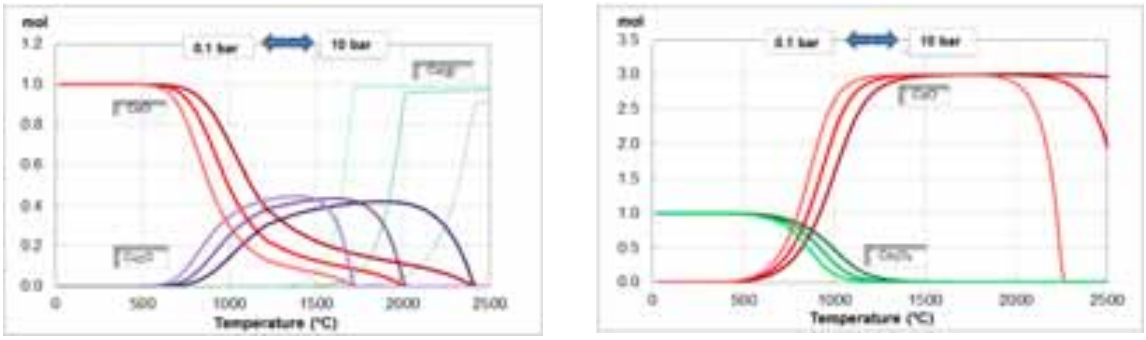
Some researches leading by Antofagasta University (Fernández et al., 2015, 2014) have proposed the study of molten salts of more than three components as a new possibility, showing a higher energy density, based on the heat capacity, which represents an important improvement over the solar salt currently used. It is important to note that based on this parameter, a smaller amount of salt could be used to store the same amount of energy.Results obtained for the new molten salts developed at Antofagasta University were compared to baseline Solar Salt (60wt.% $NaNO_3$ – 40wt.% KNO_3) properties found in the literature (Fernández et al., 2015, 2014).

The production of $LiNO_3$ at industrial scale is the current challenge in northern Chile and could be the key for a successful development of the new generation of CSP plants but it is necessary to perform storage tests in a bigger scale and real conditions.

In this respect, the Energy Development Center at Antofagasta University is equipped with a loop of molten salts with a working range of 130-500ºC, to test the performance of new raw materials potentially suitable for its use as solar storage in the existing solar technologies using molten salt storage. In addition, the current facilities also include systems for testing the dynamic corrosion produced by the molten salts on different carbon steels, stainless steels and other coated steels, under different flow rates. Results obtained and lessons learned will be applied in the molten salt loop to be build in the Atacama Solar Platform.

A different approach to thermal storage using materials widely available in Northern Chile is based on thermochemical redox cycles of metals oxides. The interest is significant because Chile produces 34% of the global mined copper, what means that it is the larger producer in the world. The impact of copper industry in the Chilean economy is very high: it represents more than 12% of the Chilean GDP.

The redox pair CuO/Cu_2O was proposed by Wong et al. (2010, 2011) as a possible candidate for thermochemical storage of solar energy. Its viability was demonstrated in a solar rotary reactor where the reduction from CuO into Cu_2O was achieved at temperature up to 1000 ºC (Alonso et al., 2015). This study was carried out in the framework of a colaboration between the Energy Development Center at Antofagasta University and the Renewable Energy Institute of Universidad Autónoma de México (UNAM). The solar furnace at Institue of Renewable Enrgy (HoSIER) of UNAM was employed as radiation source. The progress of the reduction was monitored by recording the amount of oxygen delivered inside the solar reactor. 10 g of CuO were introduced in batch mode into the reactor as starting reactant. Gas flow was 10 Nl/min and pressure was very close to atmospheric during all the experiments. 80% of the starting CuO could be reduced into Cu_2O. Also, several cycles of reduction and oxidation were achieved. However, chemical conversion for both, reduction and oxidation was not complete. Different improvements are currently under study and development to be applied to the experimental procedure with the objective of increasing the fraction of active material. Firstly, a theoretical analysis of the operation parameters influence on the thermodynamic equilibrium was realized. As an example of this work, Fig. 6 shows the effect of the total pressure and the atmosphere composition in the equilibrium of the copper oxides system. The lower the pressure, the lower the temperature at which the reduction of CuO starts as expected according to Le Chatelier principle. The maximum conversion of CuO into Cu_2O (87.7%) occurred at 1600ºC at 1 bar of total pressure. By decreasing the pressure to 0.1 bar, the maximum conversion rises to 89.9% and it is achieved at 1400 ºC. On the contrary, the higher the pressure, the higher the temperature at which the maximum conversion is reached. At 10 bar, the maximum conversion is achieved at 1875 ºC and has a value of 84.6%. When applied for TCS, these redox processes are proposed in air because of economic reasons. However, it could be assessed to carry out the reduction stage in inert atmosphere since it would benefit the reaction. In Fig. 6b the graphs indicate that the lower the O_2 concentration the lower the equilibrium temperature. For copper oxides, the maximum conversions are 89.2% at 1575 ºC and 90.4% at 1550 ºC for 10/90 and 5/95 O_2/N_2 relations respectively. The advantages compared to air composition are not very significant in terms of conversion increasing and temperature decreasing. However, if the carrier gas is pure N_2, conversion can be increased to 93.4% at 1475 ºC, what represents an augmentation of 5.7% in the maximum conversion value at temperature 125 ºC lower than the process in air. More details can be found in Alonso et al. (2016).



(a) (b)

Fig. 6: Effect of (a) total pressure on the thermodynamic equilibrium with a ratio air/reactant of 30. b) CuO/Cu_2O and b) gas composition in the thermodynamic equilibrium with 1 bar of total pressure and gas/solid molar ratio of 30

Experimental investigations of this system are currently under development. A lab scale facility based in a solar reactor is being constructed to be coupled with the solar simulator. The reactor consists on a rotary ceramic cavity provided with a transparent window and a gas inlet and outlet (Fig. 7). This prototype is designed to optimize the redox reactions for thermochemical storage with direct absorption of solar radiation.

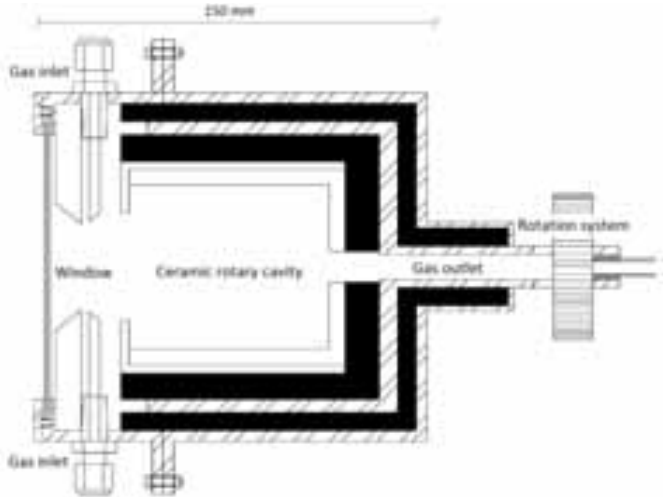


Fig. 7:Lab scale solar reactor sketch for thermochemical storage based on metal oxides based with direct radiation absorption.

In parallel to the design of the reactor, a numerical model to study the thermal behavior of the cavity was carried out. The aim of the work was to analyze how the use of different concentrators affects the cavity wall temperature. To do that, different flux distributions obtained with a ray tracing software were integrated in a CFD model. The first case was a flat profile radiation that impinged on the rear part of the reactor. Then, flux distributions generated by a solar simulator composed of an elliptical mirror and a high power lamp and by a multi-faceted concentrator was considered for the analysis. It was found a relation between the flux profile and the temperature distribution. In particular, higher temperatures were achieved at the back side of the cavity, where the most part of the radiation impinged. The most homogeneous temperature distribution was achieved for the multi-faceted concentrator case. More details can be found in Gallo et al. (2016). For the future, a more accurate model, which includes the solid phase, will be added and it will be validated with experimental tests.

With respect to the Solar Platform, future plans include the development of a scaled-up realistic facility to work under the local solar conditions. Thus current works are focused to study the performance and optimize a directly irradiated thermochemical solar energy storage system based on metal oxide particles.

4. Conclusions

Chile has a great opportunity to participate in the development and future trends of concentrated solar technology due to its potential for exploiting existing raw materials for solar energy storage and the great solar resource in the north of the country.

The proposal of new storage material using by-products and the consolidation of pilot plants in the Atacama Solar Platform, in order to obtain potential TES material is a growing trend in the institutional and private research initiatives in Chile. However, the lack of reliable and accurate data related to this topic requires a reinforcement of the relationship between Chilean institutions and solar market companies.

Due to the high demand of energy associate to mining industry, solar energy explotation in North of Chile has a special focus on this sector. In fact, mining energy demand is the most important of the country and a part of it is the form of heat. The application of solar heat is being evaluated for different stages of the cupper extraction process: floating, leaching and electrowining are examples of low temperature processes while foundry could be addressed with concentrated solar energy. R&D studies are being started in both directions and some of them count with the support of mining companies. Finally, electricy production by PV or CSP (with different types of thermal storage) is also expected to has a significant contribution to the electricity demand flat curve that characterize the mining zones of Northem Chile.

On the economic effects of metering schemes in community owned residential PV systems

Nelson Sommerfeldt

KTH Royal Institute of Technology, Stockholm (Sweden)

Abstract

Community-owned, grid-connected solar photovoltaic (PV) systems in multi-family housing offer the potential for large scale installations with favorable costs as compared to single family systems. However, traditional utility metering schemes often define boundaries which result in high sales of PV generation to the grid, lowering the economic value for the cooperative. This study explores two alternative metering schemes which better represent the interests of cooperative as a single PV owner by aggregating meters within and across buildings. Measured communal load data from a cooperative in western Sweden is combined with modeled PV generation and apartment load data to calculate the net present value (NPV) of the various meter schemes under several subsidies policies. The results show that under a traditional metering scheme, 40% of the PV generation is considered sold to the network, even though only 3% of the electricity physically leaves the buildings and none leaves the estate. Reclassifying this sold electricity as self-consumed results in an increase in NPV by as much as €60,000, which is €15,000 more than the value added by subsidies. The results of this paper are useful for community organizers, PV installers, utilities, and lawmakers interested in next generation electricity markets based on distributed generation.

Keywords: *Community solar, cooperative, self-consumption, techno-economic, utility 2.0*

1. Introduction

Multi-family housing cooperatives, such as those common in Scandinavia, have the potential for procuring large, commercial scale (30-700 kW_p) solar photovoltaic (PV) systems as a single project. These types of installations can mean increased rates of PV deployment at lower costs, but coordinating many households into an economically optimal configuration presents multiple challenges. Traditional electric utility billing structures are based on a single meter per household, so when a single PV system covers the roof of many independent meters they may not be able to access the PV generated electricity. Likewise, cooperatives often consist of multiple buildings, each with their own meter, meaning buildings with PV cannot easily share it with those that do not. This internal metering division of the cooperative can lead to high volumes of PV overproduction sold to the grid, which is economically detrimental when net metering or feed-in tariffs are not present.

Using the case of a large cooperative in western Sweden, this paper quantifies the economic effects of an internally segregated metering scheme within a single PV system owner. Two integration schemes are introduced, horizontal and vertical, and are compared with the default metering conditions. The techno-economic analysis is performed using metered load data, simulated PV production, and comparisons are made using NPV. The metering schemes are also contrasted to the economic impacts of the three primary subsidy policies for distributed PV in Sweden. The results are followed with a discussion of techniques cooperatives can and have used to desegregate their metering, their limitations, and potential for improvement. The motivation for this work is to highlight the need for solutions, whether technical, political or entrepreneurial, which can lower the barriers to community owned PV systems.

2. Background

This section provides background information regarding the structure and operation of cooperative housing in Sweden, and the context of greater electricity and PV markets which investments must be considered.

2.1 Swedish cooperative housing

Swedish housing cooperatives, which make up 22% of all residences in Sweden, are non-profit associations that typically own one housing estate or multi-family dwelling (Statsitics Sweden, 2012). They are owned exclusively by the residents of the estate, who are then given the right to reside in a portion of the building (e.g. apartment) and pay an annual fee for the operational and financial management of the association. The annual

doi:10.18086/swc.2015.09.05 Available at http://proceedings.ises.org

fee is determined on a per square meter basis, meaning larger apartments pay larger fees. A well maintained building with low operations costs results in higher property values and thus higher returns for the owners. Therefore cooperatives have an incentive to invest in cost-reduction schemes, such as self-generated electricity, in order to boost market value.

An executive board elected from the members for a period of two years acts as a governing agent for the cooperative. Each member is given a single vote during the annual meeting, but it is exercised only on issues the board deems necessary to call a general vote for. Typically, investment decisions which might have a significant effect on the annual fee paid by each member, such as major energy installations, are brought to a general vote.

Electricity use in cooperatives can be split into two categories; communal and private. Communal electricity includes stairwell and exterior lighting, HVAC, and laundry rooms, while private electricity is that which is used in individual apartments. Typically, the cooperative purchases communal electricity and the costs are distributed in the annual fee, while apartments have their own meters and purchase electricity from the retailer of their choice. It is also possible for apartment electricity to be included in the communal fee, particularly if there is electric heating which dominates the load. Another structure is for the cooperative to have a single meter with the utility and for apartments to be metered and billed internally by the cooperative. This structure has the advantage of reducing fixed grid fees, which are highest for apartments due to their relatively low demand.

2.2 The Swedish electricity market

Swedish electricity supply is dominated by two sources; hydro and nuclear power, which make up 90% of the supply, with the remaining 10% being primarily biomass fueled co-generation (Swedish Energy Agency, 2015). The annual demand is typically 140-150 TWh, or 15.3 MWh per capita, and peaks during the winter months due to a high use of electric heating. Sweden has high voltage links between Norway, Finland, Denmark, Germany, and Poland, and is typically a net exporter of electricity.

The wholesale and retail electricity markets are both deregulated. The majority of electricity is traded in the Nord Pool Spot wholesale market, where hourly prices are set one day-ahead. Retailers purchase electricity from Nord Pool and resell it to end consumers, who are free to choose any retailer they wish. They can also choose the frequency to which their tariffs follow the market, from several years to hourly. The most popular and fastest growing contract type is variable price adjusted monthly (Ei, 2015).

When Sweden joined Nord Pool in 1996, the average spot that first year was 0.032 €/kWh. Immediately after prices fell to 0.015 €/kWh and stayed there until 2001, when prices rose rapidly and became more volatile. Since 2013, there has been relatively low demand and considerable oversupply such that prices are now back to the same level as 2001(Nord Pool Spot, 2015). Low price combined with unfavorable government policy, has caused two large utilities, Vattenfall and E.On to announce early retirement of four of their oldest reactors, set to close by 2020 (World Nuclear Association, 2015; World Nuclear News, 2015).

To support renewable energy development, Sweden has a quota system, known as green certificates, which is accessible by any renewable source. Demand for certificates is set by the government, and free moving prices signal potential suppliers to build. One certificate is earned for each MWh generated, and a facility is able to earn and sell its certificates for a maximum of 15 years. The green certificate program has been mostly utilized by wind and biomass based CHP (Swedish Energy Agency, 2015).

2.3 The Swedish PV market

Relative to many other countries in Europe, the Swedish market for solar PV is small. In 2014, 36.2 MW_p were installed for a cumulative total of nearly 80 MW_p (Lindahl, 2015). As shown in Figure 1, the market has been growing rapidly in recent years in conjunction with rapidly dropping in costs, which are currently 1.3–1.6[1] €/W_p (excluding VAT) for a rooftop mounted system. A well oriented, unshaded rooftop system can be expected to produce 900-1000 kWh/kW_p per year, which results in a LCOE of 0.11-0.13 €/kWh (Stridh et al., 2014).

[1] Original price figures are in Swedish crowns (SEK) and converted to Euros (€) using a 9.5 SEK/€ exchange rate throughout (Sweden Central Bank, 2015).

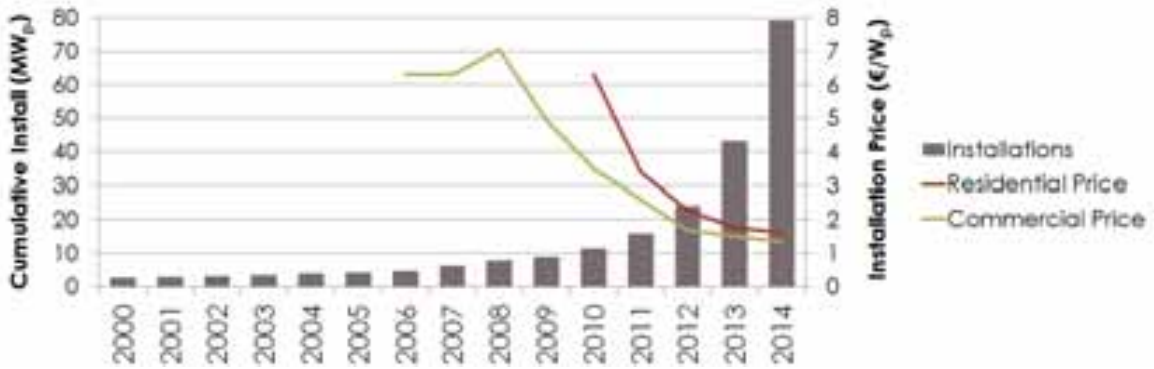

Fig. 1: Cumulative solar PV installations in Sweden (MW_p) and installation prices (excl. VAT) (€/W_p)

Another market driver has been the capital rebate subsidy which has been available at various levels from the national government since 2006. In 2009 the program was rewritten to include any micro-generation system, gave a 45% rebate on total installation cost, and was scheduled to run through 2011. This was eventually extended through 2012 and then rewritten with a new budget awarding a 35% rebate to run from 2013 to 2016 (Lindahl, 2015). The budget for this program was exhausted in 2014 and a queue of 3400 applications formed (Swedish Energy Agency, 2014). The program was modestly refunded in early 2015 (without enough to cover the queue) and the support reduced to 20% of total costs. The latest government budget proposal has once again refunded the program for the long term (2016 to 2019) and the support reduced 15%.

Building applied PV systems are subject to the same deregulated market as any other generator, so it is common for utilities to pay the wholesale market price for overproduction. One support measure allows micro-producers/prosumers (43.5 kW_p and smaller) to earn a tax rebate on overproduced electricity. This policy began in January 2015 and acts as a feed-in bonus, giving 0.063 €/kWh up to a maximum of 1900 €/year per tax payer. A small number of utilities have offered above market rates for overproduced electricity, but contracts are usually short term and it is uncertain how many will continue under the new feed-in bonus. The micro-producer subsidy will be reviewed in 2018 to determine the need for it to continue (Lindahl, 2015).

3. Methodology

The default meter configuration for this study assumes a cooperative has multiple buildings, each with its own meter on a communal electricity account. The apartments are all metered independently with separate accounts. The vertical expansion in metering occurs within a single building and combines all of apartments with the cooperative's meter. A horizontal expansion occurs between buildings, where the cooperative's individual meters can be aggregated as if they are one large meter. The two expansions are also combined, where the entire cooperative acts as a single generation source and electricity load. A graphical representation of the concepts is shown in Figure 2. In all cases, the same PV system is installed and the same load profile is present, only the way in which the boundaries for the metering are drawn changes.

Fig. 2: Diagram of the horizontal and vertical meter expansion concepts

3.1 PV production and building loads

The input values for this study are based on a cooperative in the western Swedish city of Gothenburg. There are 312 apartments divided into 13 buildings, six of which have 16 kW_p PV systems on their roofs. PV production is generated using the CEC performance model in System Advisor Model (National Renewable Energy Laboratory, 2015) using TMY2 weather data. The PV system model inputs are listed in Table 1.

Tab. 1: PV system inputs for SAM

Variable	Value	Note
Weather data	Göteborg Landvetter airport	TMY2
Modules	IBC Polysol 250 DC, p-Si	64 per array (384 total)
Inverter	SMA 15000TL-10	1 per array (6 total)
Azimuth (γ)	180°	-
Tilt (β)	30°	-
Degradation rate	0.5%	(Jordan and Kurtz, 2013)
System losses	10.0%	Annual average

Measured communal load data for 2013 and 2014 for the six PV equipped buildings has been supplied, several of which also have laundry rooms. The remaining buildings are assumed to not have laundry rooms. The load data from one of these buildings has been supplied and is multiplied to represent the remaining unsupplied meter data. The final load curve is an average of the two years of measurements. All production and building loads are considered on an hourly basis, which is necessary to determine the self-use fraction. The communal and apartment load data, along with the first year solar production is shown in Figure 3. First year solar production is 970 kWh/kW_p.

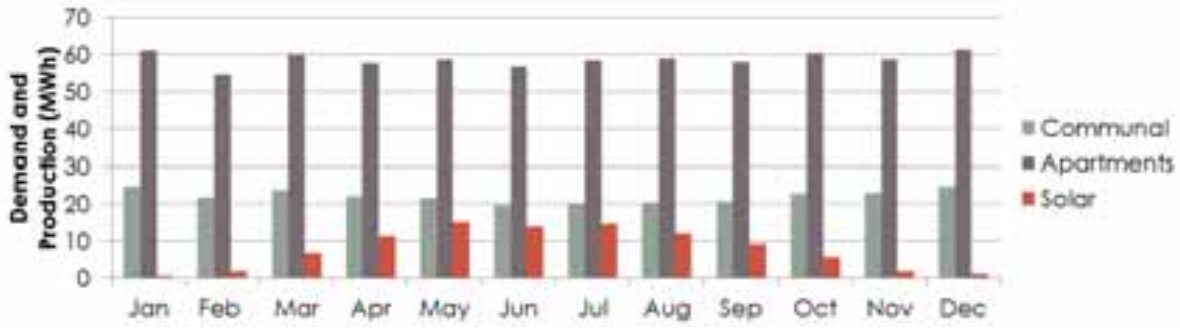

Fig. 3: Monthly data for all communal and apartment loads and solar PV production

Apartment loads are constructed using the Markov chain model developed by Widén and Wäceklgård (2010) which is based on measured plug loads of several hundred households. Since their model is stochastic and this study is deterministic, a single, unique load profile for each building is generated and used across all cases. Demand from the apartments is approximately 2260 kWh per apartment per year.

3.2 Economic calculations

Comparisons between the schemes are done with net present value (NPV, Eq. 1Eq. 1Eq. 1) using traditional deterministic engineering economics. Costs (C) can be divided into one-time and reoccurring costs, seen in Eq. 2. One-time costs include installation cost (I_0) and VAT tax (T_0), while reoccurring costs include fixed operations and maintenance (O&M, OM_t), inverter replacement (IR_t), financing interest, and taxes on the sale of electricity. This study is done assuming self-financing, and is presented before income taxes. Benefits (B) also have one-time and reoccurring components, shown in Eq. 3. The one-time capital subsidy (S_0) is assumed to be awarded in year zero, while reoccurring benefits include; the value of differed electricity purchases (self-consumption, Q_dP_r), the value of sold electricity (overproduction, Q_oP_w), and the value of meter subsidies (Q_sP_s). Inflation is not considered; therefore the discount rate (d) is real. Table 3 lists a summary of all economic input values.

$$NPV = \sum_{t=0}^{L} \frac{C_t + B_t}{(1+d)^t} \qquad \text{(Eq. 1)}$$

$$C = I_0 + T_0 + \sum_{t=0}^{L} (OM_t + IR_t) \quad \text{(Eq. 2)}$$

$$B = S_0 + \sum_{t=0}^{L} \left[(Q_d P_r) + (Q_o P_w) + \sum (Q_s P_s) \right]_t \quad \text{(Eq. 3)}$$

Tab. 3: Economic variable input values

Variable	Symbol	Unit Value	Absolute Value
Installation Cost	I_0	1.36 €/W_p	130,360 €
VAT	T_0	25% of I_0	32,590 €
Capital Subsidy	S_0	15% of I_0+T_0	24,440 €
Fixed O&M (Year 1)	OM	0.25% of I_0	325 €/yr
O&M Cost Escalation Rate	-	1%/year	-
Inverter Replacement Cost	IR	0.157 €/W_p	2525 €/inverter
Inverter Lifetime	-	15 years	-
System Lifetime	L	30 years	-
Real Discount Rate	d	3%	-
Retail Price (Year 1)	P_r	0.098 €/kWh	-
Wholesale Price (Year 1)	P_w	0.021 €/kWh	-
Green Cert. Price (Year 1)	P_s	0.016 €/kWh	-

Future electricity prices are taken from a policy comparison study for Sweden modeled with Times/Markal (Profu, 2014). The wholesale prices for the four scenarios as well as the historical annual averages are shown in Figure 4 (Nord Pool Spot, 2015). All scenarios are assumed to have an equal chance of occurring, and are therefore averaged together. Retail prices (P_r) are calculated each year based on the wholesale price, renewable support subsidies, network fee (0.021 €/kWh), electricity tax (0.030 €/kWh), retailer markup (0.005 €/kWh), and a 25% VAT applied to the sum. Network fees and electricity taxes are assumed to increase at 1% per year, which is relatively conservative compared to the historic rates (Svensk Energi, 2015). Retailer markup and VAT remain constant.

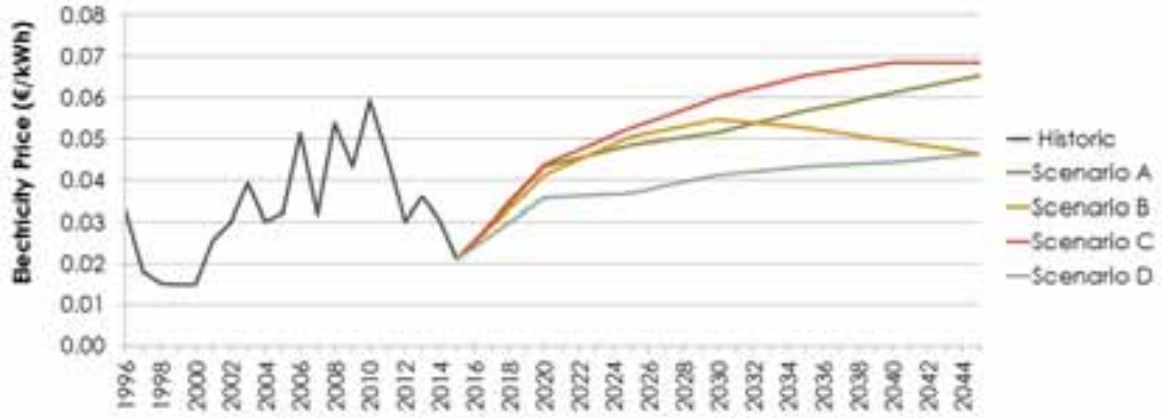

Fig. 4: Wholesale electricity price (P_w) history and future scenarios prior to averaging

3.3 Policy cases

Four policy cases are compared based on the three primary subsidies for solar PV in Sweden. The first case considers no subsidies, and the following cases are built by cumulatively adding another subsidy. The subsidies are added from the most secure (i.e. the subsidy most likely to remain long term) to the least, starting with green certificates, then the capital subsidy, and finally the feed-in bonus. Green certificates and the feed-in bonus only apply to overproduction, making $Q_s = Q_o$ in Eq. 3. The current price for green certificates is 0.016 €/kWh, which is assumed to return to the historic mean (0.022 €/kWh) by 2020 and remain at that level for the remaining 10 years which the system qualifies (Swedish Energy Agency, 2015). The feed-in bonus is assumed

to be renewed until 2020, making it a 5 year program. The capital subsidy is 15%, which matches the most recent update to the policy.

4. Results

The motivation for the alternative metering schemes is to increase the self-consumption rate, which is shown for each scheme in Figure 5. It can be seen that the vertical scheme has a greater impact on self-consumption than the horizontal, due to the apartments demanding twice as much electricity as the communal loads. It can also be seen that the combined scheme has a 100% self-consumption rate, meaning that none of the electricity generated on the cooperative's estate physically leaves it, even though the meters indicate otherwise.

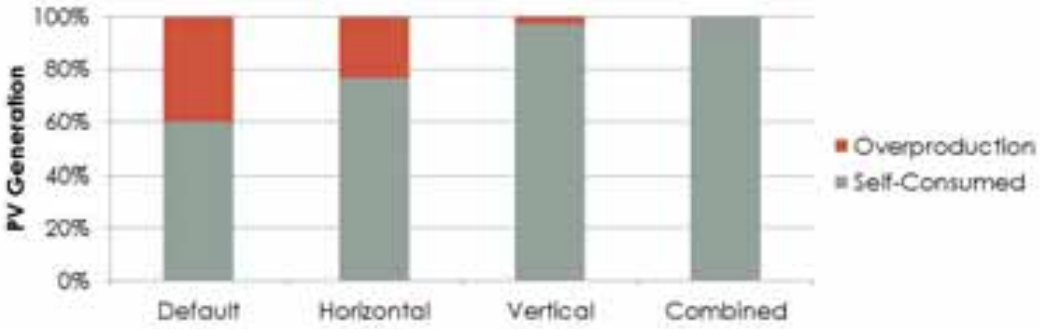

Fig. 5: Self-consumption rates between metering schemes

The effect of self-consumption on the profitability can be significant, as Figure 6 shows. The vertical scheme adds over €60,000 of value to the PV system, significantly more than any of the subsidies which only add about €44,000 put together. The horizontal scheme adds over €27,000, nearly €3000 more than the capital subsidy. As would be expected, the green certificates and feed-in bonus becomes less significant with less overproduction. In the horizontal scheme they each add about €6000, become less than €1000 in the vertical scheme, and reach zero in the combined scheme.

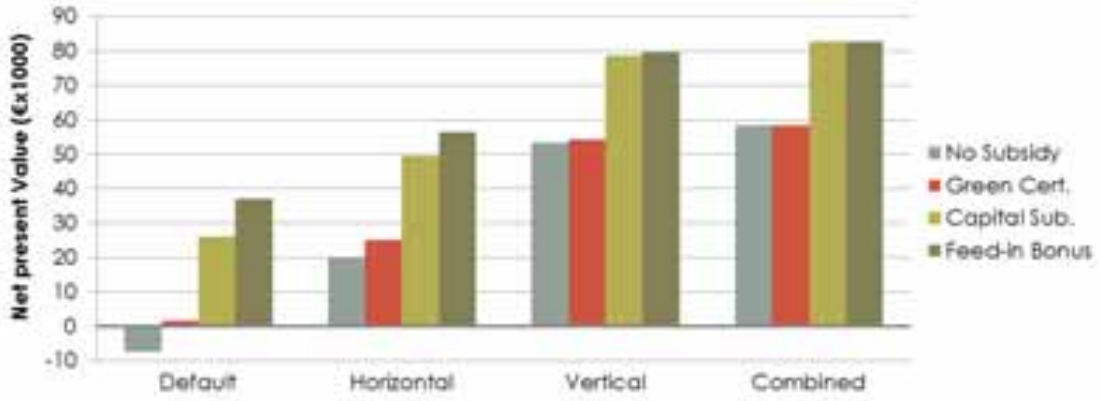

Fig. 6: Net present value of each meter scheme under the various subsidy policies

If this cooperative were to make a PV installation decision using this information only on economic rational, only the default, no subsidy case presented would be rejected. The production conditions here are relatively good, with the system oriented at nearly the optimal position and completely unshaded. Naturally these conditions do not exist everywhere. To extract these results to a more general case, the effects of a range of self-consumption and annual production values on specific NPV (€/W_p) are shown in Figure 7, without subsidies, using the same inputs presented above. The break-even line can be seen between the dark red and black contours, which will move down and to the left as installation costs decrease.

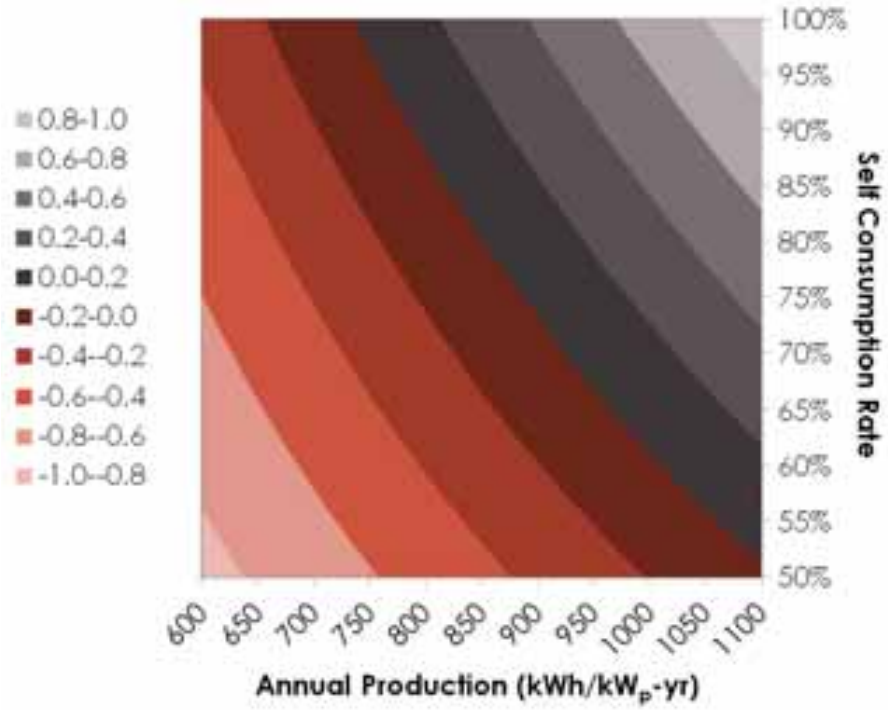

Fig. 7: Specific NPV (€/W_p) as a function of annual production and self-consumption rate

5. Discussion

The benefits of removing internal metering divides in cooperative housing can be clearly seen in the results. This is certainly known to cooperatives who have installed large scale solar PV systems, as there are examples of vertical and combined metering across Sweden (Sommerfeldt and Muyingo, 2015). However, for a cooperative which is currently using default metering, expanding the metering schemes requires overcoming some barriers.

Vertical metering schemes are actually not entirely uncommon in Sweden as mentioned in the background. However the majority of multi-family houses would need to convert, which requires replacing the utility's meters with cooperative owned versions which are then used for internal billing. The cost of this conversion would be approximately €35,000, which is nearly half of the benefit of switching to the vertical scheme, plus the cost and effort of administration over time. Also not accounted for in the results is the benefit of lower fixed network fees, since apartments typically have much higher fixed fees than high demand customers. This value varies significantly by location and should be considered on a case basis.

Expanding the metering scheme horizontally can be considerably more difficult. With the current system, the only way is to physically connect buildings behind the utility meter so that PV generation can be shared between them. Naturally, costs for this will vary depending on the current wiring and if any new wiring needs to be done internally or externally to the buildings. In one case, a large cooperative buried DC cables between the buildings. Given that this measure is taken only because of the location of the meters, one might consider the added cost and materials is unnecessary.

The results presented here indicate that there is a significant amount of PV value being captured by utilities due to the location of meters, and not because of any added service. At the same time, state sponsored subsidies are supporting PV development that may not be necessary in some cases if the meter barriers are lowered. The idea that electricity could be generated and shared between neighbors, across meters, is not particularly novel, but does go against the interests of the utilities who own those meters and the control the structure of the current system. The current technological solutions are expensive and could be considered wastefully unnecessary infrastructure. Restructuring the electricity market and tax code to enable more fluid buying and selling directly between prosumers, combined with ICT solutions, may make it possible to reduce or eliminate subsidies faster. The example presented here is within the well-defined boundaries of a cooperative, but the concept can easily be expanded to neighborhoods, districts, or even cities if the electric network can manage. Reaching a sustainable electricity market built on central and distributed generation sources, utility 2.0, should be a goal for many utilities, citizens, and politicians motivated to develop solar PV.

6. Acknowledgements

This project is funded by The Swedish Research Council Formas (no. 2012-256) and performed in conjunction with Riksbyggen and Sustainable Innovation (SUST). The author would also like to thank Johan Paradis for access to installation and meter data.

Parabolic Solar Cooker Cooking: Heat Pipes OR Spiral Copper Tubes

Omotoyosi O. Craig[1], Robert T. Dobson[1] and Wikus van Niekerk[1, 2]

[1] Department of Mechanical and Mechatronics Engineering, Stellenbosch University, Stellenbosch, 7602, South Africa

[2] Director, Centre for Renewable and Sustainable Energy Studies at Stellenbosch University, Stellenbosch, 7602, South Africa

Abstract

The idea of cooking with the sun is not new and most recently solar energy has been identified by many researchers as a solution to the challenges of poverty and hunger in the world. Solar coking is believed to be a contributor to the fight for the elimination of insufficient and or expensive energy supply for homes and industrial cooking. The parabolic types of solar cookers have been identified to cook faster at high temperatures and when they are used indirectly with the cooking section separated from the dish, they often abolish the exposure of the user to the sun and can thus be incorporated to kitchen designs. Despite this breakthrough, indirect parabolic cookers still faces a major problem, which is identifying the right cooking section type as most of the ones in existence often achieve a low utilisation efficiency as compared to their potentials. In order to analyse and predict the best cooking section type for parabolic cookers an experimental cooking was performed at Stellenbosch University, South Africa using two different types of cooker sections, the first being using coiled spiral copper tube and the other using heat pipes of 2 l volume. The cooking section was separated from the dish and was not exposed to the sun, the working fluid was transferred using high temperature flexible hose. Both types of cookers were found to be effective with the heat pipes boiling water in a record time but no heat control; the spiral copper tube also reached boiled water although at a little longer time but the flow of heat to it could be regulated. Both were seen to have their advantages and disadvantages and the selection would be based on the desired use of the cooker by the manufacturer, but base on cost, the use of spiral copper tube is recommended in this report.

Keywords: *Parabolic Solar cookers, Heat pipes, Spiral copper tube*

1. Introduction

Over one-third of the world population has been identified to be using wood as a source of energy either for general heating purpose or specifically for heating (Wentzel & Pouris 2007). This case is worse in Africa where in South Africa (which is one of the least countries with wood usage in Africa) over 84, 000 m^3 of wood is used per year (Christie & Gandar 1994). The continuous reliance on wood has led to deforestation in some communities and frustrations in many others (Diabaté et al. 2004) although over the recent years, many nations has increased their energy generation thereby reducing the over-dependency on wood and many are supporting other renewable energy alternatives. Solar cooking had been described by several authors as having the potential of leading rural industrialisation, elimination hunger and providing employment and can serve as a means of reducing the dependence on gas or electricity for cooking (Craig & Dobson 2015; Yettou et al. 2014; Al-Soud et al. 2010; Cochetel 2012), the need for its optimisation therefore is of utmost importance.

Parabolic types of solar cookers had been identified as the most efficient in terms of heat generation of all the types of solar cookers (Reddy & Ranjan 2003) and they often cook food faster than any other types of solar cooker in existence (Panwar et al. 2012). Some of the problems facing social acceptance of parabolic cookers have been identified as i) exposure to sun by the users ii) the complexity that sets up as a result of need for accurate sun tracking iii) low utilisation efficiencies among others and iv) selecting the right cooking section types.

However, the first problem identified had been overcome by the developing of indirect parabolic cooking systems (Otte 2013; Cuce & Cuce 2013; Muthusivagami et al. 2010; Schwarzer & da Silva 2008). The need for

doi:10.18086/swc.2015.09.06 Available at http://proceedings.ises.org

accurate tracking had also been overcome by development of simple dual tracking systems (Yao et al. 2014; Arbab et al. 2009; Arturo & Alejandro 2010). Effort to raise the of low utilisation efficiency of parabolic cookers are still continuous (Öztürk 2004; Kaushik & Gupta 2008; Ozturk 2007) and in this research the two popular types of cooking section used for parabolic cookers were tested and the necessary comparison was made.

2. Experimental Set Up

The experiment was performed in Stellenbosch University with location coordinates of 33˚ 55' 42.81" S, 18˚ 51'55.08" E, Elevation: 119 m. The heat transfer fluid used was shell oil S2 with maximum fil temperature of 315 °C and maximum bulk temperature of 290 °C. The experiments were carried in winter conditions in June, 2015 in South Africa. The sun path for the location of the tests are shown in figure 1 a and b which were generated from running necessary scripts on University of Oregon Solar Radiation Monitoring Laboratory (2007) online sun path calculator

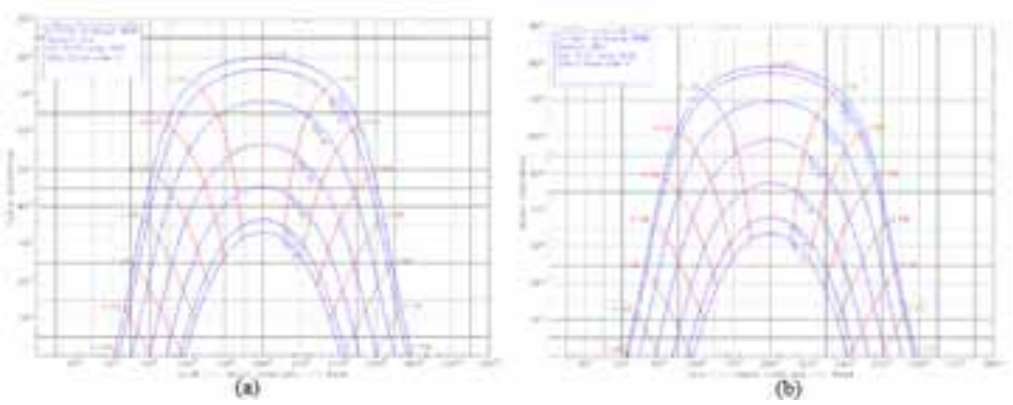

Figure 1: Stellenbosch University sun's path: December to June (a), June to December (a)

The diagram in figure 1 a shows the sun path for December to June while in figure 1 b is displayed the path of the sun for June to December for the location specified above in Stellenbosch, South Africa. The necessary angles of the sun was thus calculated using these data.

Figure 2 below is a CAD drawing of the experimental set up and how the cooking system is separated from the solar energy collection section.

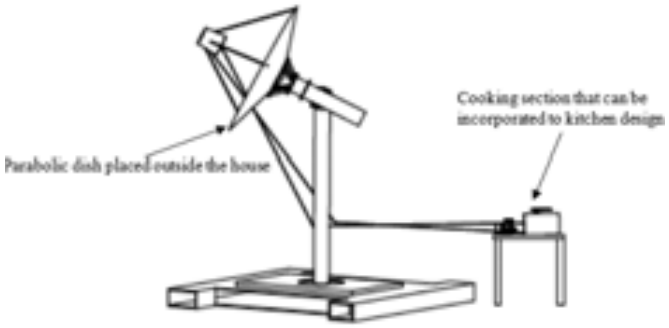

Figure 2: Complete CAD drawing of the experimental setup

A storage tank of 40 l volume was filled with the heat transfer fluid HTF, and a specially modified car pump was used to circulate the HTF throughout the system. The gasket in the automotive car pump was replaced with a high temperature Klingersil C-4430 gasket material to make the modified pump be able to withstand the temperature under which it will be functioning. High temperature hose was used to transfer the oil, the hose was insulated with a black rubber insulation clip. A depression was made inside the storage tank to allow direct cooking on in the storage and to provide a space for the two cooking section to be made. The direct placing of the cooking section in the hot oil was to reduce the heat loss between the storage tank and the cooker. A variable speed drive was connected to a three phase electric motor which was then connected to the pump to power it and also to vary the speed of the motor and ultimately vary the flow rate of the oil in the system.

The parabolic dish used was placed outside on a two axis tracker stand by Prinsloo et al. (2014) and the storage and cooking section was placed under a shade. The parabolic dish on the tracker is shown in figure 3. The two sets of cooking section manufactured is discussed in the following sections

Figure 3: Parabolic dish on tracker stand

2.1. Heat pipe cooking

The first cooking heat type was a heat pipe cooker with methanol and copper material an while the evaporator side was dipped in the storage tank, the condenser part was made to form a pot head and placed on another container beside the tank as shown in figure 4 and the heat transfer analysis is represented in figure 5

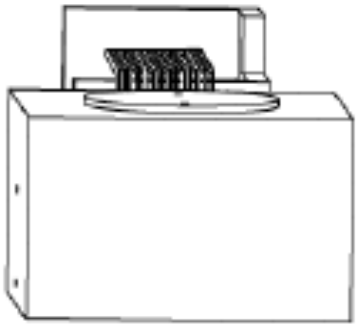

Figure 4: CAD drawing of heat pipe cooking section

The heat energy transfer analysis for the heat pipe experimental set up was performed based on the thermal resistances presented in figure 4 below.

In order to solve for the temperature and resistance in the cooking section the conservation of energy law was applied

$$\dot{Q}_{in} = \dot{Q}_{out} + \dot{Q}_{losses} \qquad (\text{eq. } 1)$$

Considering the temperature of the oil supplied by the inlet heat transfer hose in relation to the heat supplied to the oil, a balance in the thermal resistances was developed as

$$\frac{T_{in} - T_{h\_oil}}{R_{sto-in}} = \frac{T_{h\_oil} - T_{out}}{R_{sto-out}} + \frac{T_{h\_oil} - T_a}{R_{sto-amb}} + \frac{T_{h_{oil}} - T_a}{R_{sto-ck}} \qquad (\text{eq. } 2)$$

Re-arranging eq. 2 above and solving for the T_{h_oil} gives eq. 3

$$T_{h\_oil} = \left(\frac{T_{in}}{R_{sto-in}} + \frac{T_{out}}{R_{sto-out}} + \frac{T_a}{R_{sto-amb}} + \frac{T_a}{R_{sto-ck}}\right) * \left(\frac{1}{R_{sto-in}} + \frac{1}{R_{sto-out}} + \frac{1}{R_{sto-amb}} + \frac{1}{R_{sto-ck}}\right) \qquad (\text{eq. } 3)$$

Likewise, the solution for the return temperature (T_{out}) that is fed back to the heat transfer return pipe and from there carried to the receiver cavity was determined as

$$T_{out} = \left(\frac{T_{in} - T_{h\_oil}}{R_{sto-in}} - \frac{T_{h\_oil} - T_a}{R_{sto-amb}} - \frac{T_{h\_oil} - T_a}{R_{sto-ck}} - \frac{T_{h\_oil}}{R_{sto-out}}\right) * R_{sto-out} \qquad (\text{eq. } 4)$$

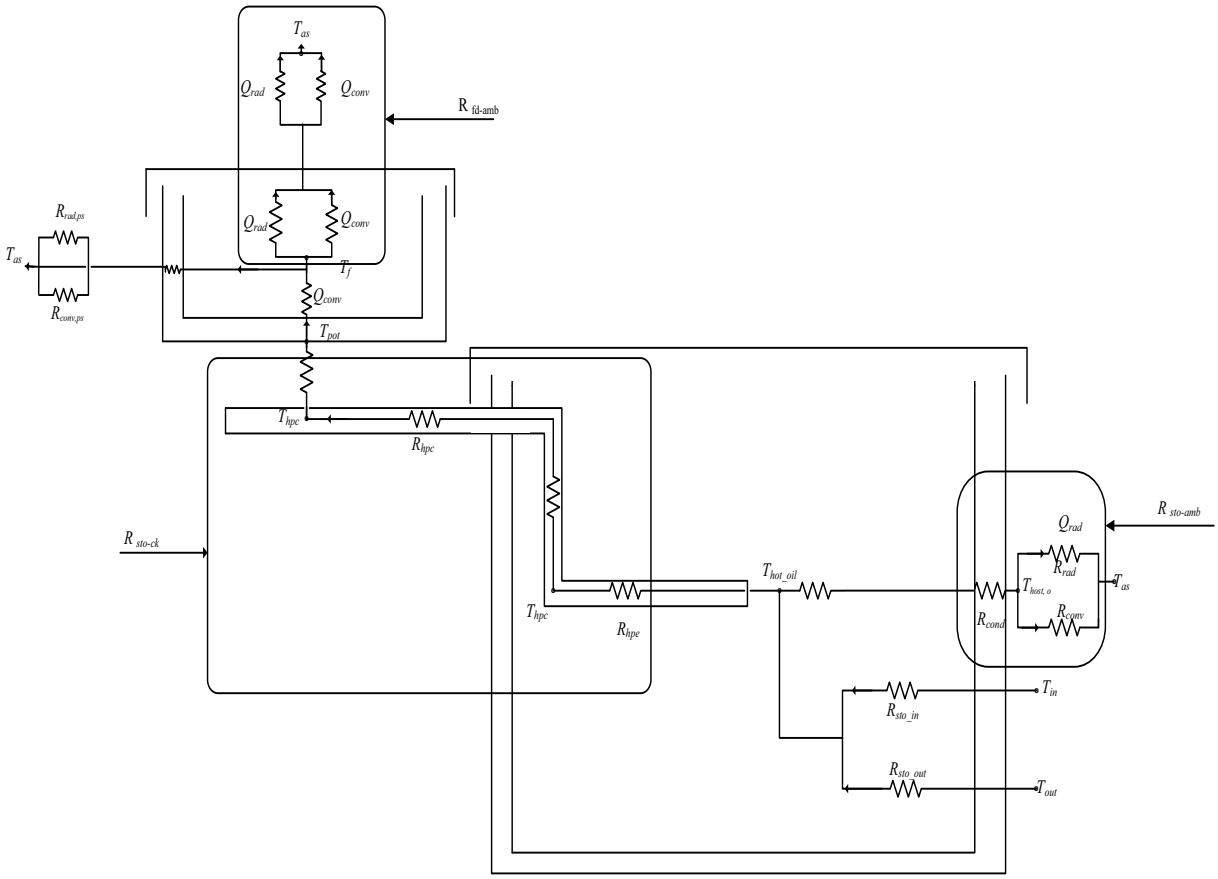

Figure 5: Thermal resistance diagram for heat pipe cooker

In order to solve for the temperature of the food item that was heated in the coking section of the solar cooker an equation for the temperature T_{fd} is developed.

The energy balance for the food can be expressed as

$$\dot{Q}_{fd} = \dot{Q}_{hp} - \left(\dot{Q}_{pot,s} + \dot{Q}_{pot,b} + \dot{Q}_{pot,cov}\right) \qquad \text{(eq. 5)}$$

When eq. 5 was expressed in terms of the temperatures and the resistances, eq. 6 was developed

$$\frac{T_{fd} - T_{hot\_oil}}{R_{ho-conv} + R_{hp} + R_{pot} + R_{sto-amb}} = \frac{T_{hp} - T_{hot\_oil}}{R_{hp} + R_{sto-amb}} - \frac{T_{fd} - T_a}{R_{pot,s}} - \frac{T_{fd} - T_a}{R_{pot,cov}} \qquad \text{(eq. 6)}$$

Rearranging the above equation, collecting the like terms and solving for T_{fd} gives

$$T_{fd} = \left[\left(R_{sto-a} + R_{ho-conv} + R_{hp} + R_{pot}\right)\left(R_{pot,s} * R_{pot,cov}\right)\left(\frac{T_{hp} - T_{hot\_oil}}{R_{hp} + R_{sto-amb}}\right)\right]$$

$$+ \left[T_a * \left(R_{ho-conv} + R_{hp} + R_{pot} + R_{sto-amb}\right)\left(R_{pot,s} * R_{pot,cov}\right)\right] \qquad \text{(eq. 7)}$$

The temperature of the food when cooked using the condenser part of heat pipe as a cooker head was thus determined using equation 7 presented above.

2.2. Spiral Copper tube

The second type of cooking section made was the spiral copper tub the diameter of the tube used is 3/8 inch and this was rolled into a flat spiral form as shown in figure 6b and this was then placed in the depression made in the cooking section as shown in figure 6a. One arm of the spiral tube enters the side wall of the depression and at a higher level than the second arm which enters the tank at a lower level, this allows hot oil to flow in freely and the cold oil flows back to the tank and the cycles repeated.

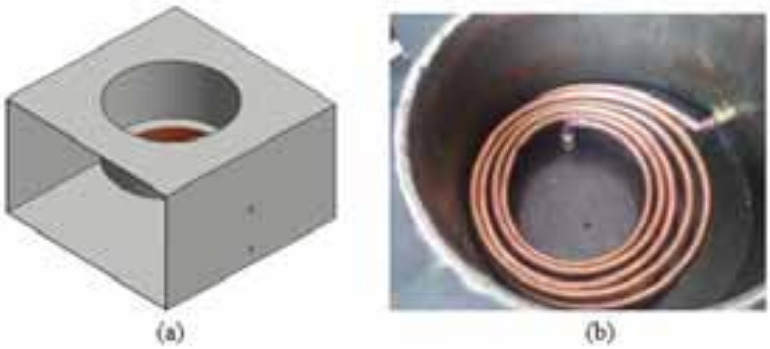

Figure 6: Thermal energy storage and cooker: cut-away 3D CAD drawing (a), spiral cook top (b)

The cooking pot was placed on the spiral head and the section was covered appropriately. The temperature of the food in the cooking pot was determined by analysing the heat transfer between the from the hot oil in the storage tank to the spiral cooker head as shown in figure 7

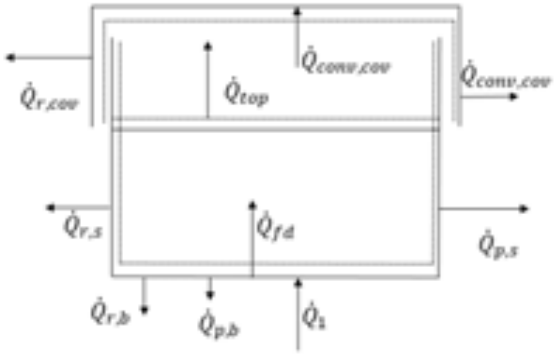

Figure 7: Heat transfer in spiral cooking section

The energy supplied the food $\dot{Q}_{fd}$ was assumed to be performing dual function, first is to overcome the internal energy of the food and the second is to balance the convection losses that occurs through the upper part of the pot and this shown in equation 8

$$\dot{Q}_{fd} = \dot{Q}_{top} + U_{fd,i} \quad \text{(eq. 8)}$$

If the mass of fluid to be cooked is taken to be m_{fd} and the temperature is considered instantaneous, then eq. 8 can be expressed explicitly as

$$\dot{Q}_{fd} = \dot{Q}_{top} + m_{fd} c_{fd} \frac{dT_{fd}}{dt} = h_{fd} A_{fd} \left(T_{pot} - T_{fd}\right) \quad \text{(eq. 9)}$$

The total heat supplied to the pot from the spiral copper tube can be taken as $\dot{Q}_1$ and it is used overcome the resistance of the pot, $\dot{Q}_{fd}$ and the convection losses through the side $\dot{Q}_{c,s}$ and the bottom of the pot $\dot{Q}_{c,b}$ as well as the radiation losses through the side $\dot{Q}_{r,s}$and bottom $\dot{Q}_{r,b}$ respectively s shown in eq. 10

$$\dot{Q}_1 = m_{pot}\, c_{pot}\, \frac{dT_{pot}}{dt} + \dot{Q}_{fd} + \dot{Q}_{c,s} + \dot{Q}_{r,s} + \dot{Q}_{c,b} + \dot{Q}_{r,b} \quad \text{(eq. 10)}$$

The various terms in eq. 10 above can be expressed shown in equation 11 to 15

$$\dot{Q}_{c,s} = h_g\, A_{side} \left(T_{pot} - T_a\right) \quad \text{(eq. 11)}$$

$$\dot{Q}_{c,b} = h_a\, A_{top} \left(T_{top} - T_a\right) \quad \text{(eq. 12)}$$

$$\dot{Q}_{r,b} = \sigma\, \varepsilon_{pot}\, A_{top} \left({T_{pot}}^4 - {T_a}^4\right) \quad \text{(eq. 13)}$$

$$\dot{Q}_{r,s} = \sigma\, A_{side} \left({T_{pot}}^4 - {T_a}^4\right)\left(1/\varepsilon_{pot} - 1/\varepsilon_{cover} - 1\right) \quad \text{(eq. 14)}$$

$$\dot{Q}_{p,s} + \dot{Q}_{top} + \dot{Q}_{p,s2} = m_a c_a \frac{dT_g}{dt} \quad \text{(eq. 15)}$$

Re-arranging the above Equations to form a first order differential Equation that can be solved numerically gives the following sets of Equation:

$$\frac{dT_{fd}}{dt} = F_{fd} \left(T_{fd}, T_{pot}, t\right) \quad \text{(eq. 16)}$$

$$\frac{dT_{pot}}{dt} = F_{pot} \left(T_{fd}, T_{pot}, T_g, t\right) \quad \text{(eq. 17)}$$

$$\frac{dT_g}{dt} = F_g\left(T_{fd}, T_{pot}, T_g, t\right) \quad \text{(eq. 18)}$$

The generated equations was then be solved numerically using Runge-Kutta fourth-order algorithm.

3. Experimental Result and Discussion

An initial experiments without any load was performed on the two types of cooking sections made. The evaporator arm of the cooker was deepen into the oil and all leaked were blocked. The electric motor was turned on using the variable speed drive and the HTF is transferred to a cavity receiver placed at the focus of the parabolic dish and the cycle continued. No cooking was performed because the aim of the experiment was to determine the variation of the heat pipe temperature with the temperature inside the tank.
The result is diagrammatically presented in figure 8 below, where the maximum difference between

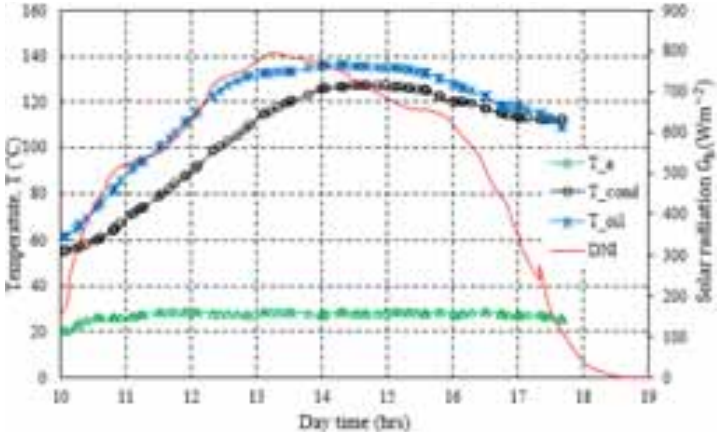

Figure 8: Condenser, oil and ambient temperature as a function of day time

the temperature of the condenser and the average oil temperature was 25 ˚C during charging of the storage system and the temperature difference reduced with time. An interesting discovery was that the temperature difference was less than 5 ˚C during discharging which predicts that the heat pipe will work well if the cooking is done in close doors or during night cooking.
Cooking experiment was done on this system by boiling 2.5 kg of water on the following day. Two sets of water was boiled by placing an aluminium pot container on the condenser part of the heat pipe and the results are displayed in figure 9. The first boiling took 2 hours 30 minutes before boiling while in the second experiment, the water boiled in 1 hour and 10 minutes, the difference can be said to be because the first experiment began when the system is still charging while the second was done when the system is fully charged.

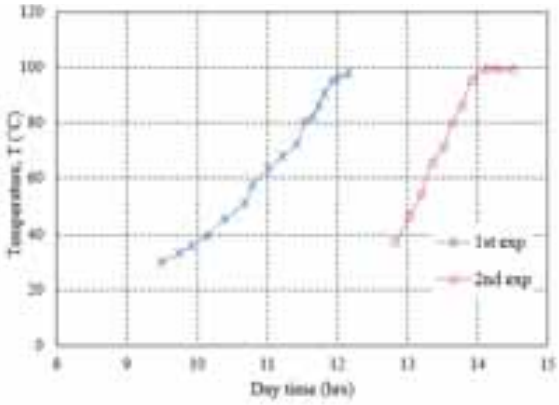

Figure 9: Water boiling Experiments on the heat pipe

The no load experiment was also performed on the spiral copper head cooking type and the result is shown in figure 10 below

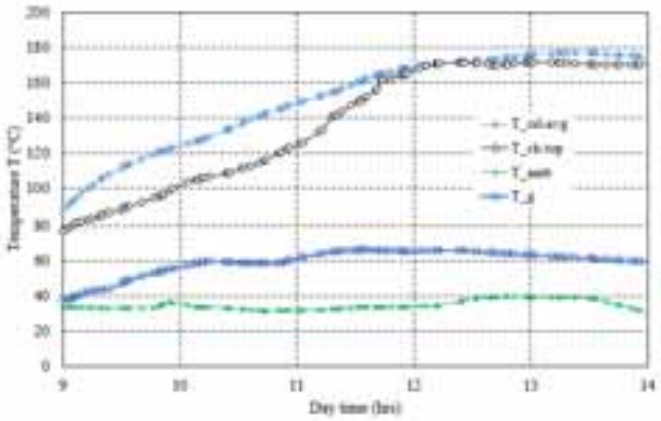

Figure 10: Cook top, oil and ambient temperature as a function of day time (08 June 2015)

The average solar radiation during the testing was 601Wm^{-2}, the storage tank became fully charged after four hours although the oil temperature was above 80 ˚C when the reading began. The initial temperature difference was less than 10 ˚C because the spiral tube was left inserted in the oil from the previous day experiment, however during the oil charging the temperature difference increased to above 20 ˚C and this temperature difference however diminished towards the time the system was almost going to be fully charged. This predict that the spiral cooker can only be effective when the system is fully charged and when the storage oil temperature fluctuation is reduced.

Cooking oil of 3 kg was used as food to be cooked on the spiral copper tube and the result is shown in figure 11 but a great temperature difference was recorded between the oil and the spiral copper tube.

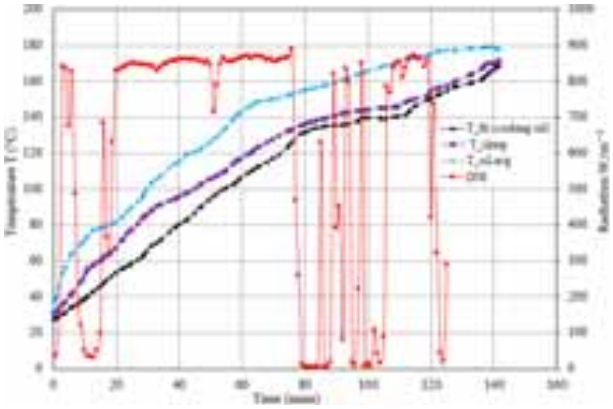

Figure 11: Cooking oil, storage oil, cook top, solar radiation as a function of experiment time

The cooking oil reached 100 ˚C after 60 minutes; the cooking oil temperature and the temperature of the spiral cooker head displayed a reduction in their temperature difference as the cooking continued and at 160 ˚C, the two temperature were almost at parity.

4. Conclusions and Recommendations

In the experiments presented in this paper, the two most popular cooking section types for indirect solar parabolic cookers had been tested under similar conditions at the same location. It can be concluded that the two types are actually a viable technology for the future. The heat pipe was noticed to transfer heat from the storage tank to the cooking section faster than the spiral cooker head and was seen to be able to work more effectively during discharging. However the spiral copper tube also performed well when the cooking was be done for a longer period, the spiral cooker head is cheap and the longer cooking time could be traced to the small surface area (single arm sucking the hot oil) of the tube inserted in the oil, as compared to the heat pipes in which several pipes were inserted into the oil. The spiral cooker is expected to perform better if an array of the tubes are combine to allow more hot oil flow to the head. Although the heat pipe cooked faster, the spiral head was preferred in this experiment because of the simplicity of its manufacturing and less complexity in its theoretical analysis. More experiments are still ongoing to use other criteria for this comparison to make necessary recommendations.

A simple low cost Solar Panel/Cell Characterization Experiment for Senior Undergraduate Students

Sebastian Waita*, Justus Simiyu, Alexander N. Kiragu, Vivian Imali and Bernard Aduda
University of Nairobi, Department of Physics, P.O BOX 30197-00100, Nairobi, Kenya

Abstract

A simple low cost solar cell characterization experiment has been developed for senior undergraduate students in the Department of Physics, University of Nairobi. Experiments were conducted with solar panels (also called solar modules/photovoltaic modules) rated 20 W and 40 W peak power on different sunny days on the roof top of Physics Department, University of Nairobi. It was observed that the current- voltage (I-V) curves obtained for all the measurements for each panel were comparable. The fill factor (FF), short circuit current (I_{sc}), open circuit voltage (V_{oc}), current at maximum power point (I_m) and voltage at maximum power point (V_m) were within acceptable margins when compared with the manufacturer's rated values, an indication of the reliability and accuracy of the method. The method eliminates the need for expensive characterization equipment like solar simulators, unaffordable by many developing country institutions. The experiment is recommended for senior undergraduate students with an interest in renewable energy as one way of introducing them to renewable energy. The experiment may also help in arousing the learner's interest in solar energy.

Key words: cost, solar cell, characterization, experiment, panel, solar panel, undergraduate, solar energy

1.0 Introduction

In 2004, the Government of Kenya through the Ministry of Energy developed the sessional paper No. 4 on energy which created the background for the energy act of 2006. The energy act in turn provided the legal framework for the enactment of the national energy policy on renewable energy in 2012 which was revised last year, 2014[1]. The action by the government was interpreted by stake holders in the renewable energy sector as an act of seriousness and commitment in promoting renewable energy, prompting them into action. As a result, there has been a lot of renewed effort and activity in the renewable energy sector in Kenya. Workshops and seminars to develop training curriculum and build Human technical capacity in renewable energy especially photovoltaic have been on the increase. Similarly, photovoltaic training centers have sprung up in large numbers in various institutions in the last two years.

The high demand in the photovoltaic training has been necessitated by the government's requirement that solar photovoltaic design and installations be done by only those licensed by the Energy Regulatory Commission (ERC), a government agency created to regulate the energy sector. Further, the government also made it compulsory for vendors, importers and contractors to employ technical people who have undergone formal training and have been licensed by ERC[2]. Currently, most training is being carried out in government institutions and by staff who work in the same intuitions after going through training. It has been observed that most of the participants (trainees) in the trainings are mainly fresh school leavers, entrepreneurs and even people working in

doi:10.18086/swc.2015.09.07 Available at http://proceedings.ises.org

other sectors of the economy[3]. It is interesting to note that the same institutions have done little if any, to develop such training or relevant laboratory experiments for their students in the institutions, especially at the University undergraduate level. There is therefore need to introduce students to these technologies at early stages. Besides, developing theoretical courses, there is need to design and develop related experiments to run parallel to the theory work. In the Department of Physics, University of Nairobi, a simple and low cost experiment for analyzing the performance of a solar panel has been developed. The experiment has been found to be useful to senior undergraduate students in creating interest as well as introducing them into solar energy. The experimental details of the set up are outlined below.

2.0 Experiment Title: Photovoltaic solar panel characterization

2.1 Objectives

The objectives of the experiment were:

1. To understand how electricity is generated from a solar cell

2. To establish the difference between a solar cell and solar panel

3. To determine the total number of solar cells in a solar panel

4. To determine the variation of current and voltage for the solar panel

5. To understand the meaning of characterization parameters: Fill Factor (FF), Short circuit current (I_{sc}), Open circuit voltage (V_{oc}), Maximum current (I_m), Maximum voltage (V_m and Maximum power (P_m).

6. To determine the: Fill Factor (FF), Short circuit current (I_{sc}), Open circuit voltage (V_{oc}), Maximum power point (P_m), Current at maximum power point (I_m), Voltage at maximum power point (V_m and compare with the rated values.

2.2 Theoretical Background

2.2.1 How a Solar Cell generates an electric current

Solar radiation consists of photons of different wavelengths and therefore with various amounts of energy. As these photons fall on a photoelectric surface, they may be reflected, absorbed or transmitted. The absorbed photons transfer their energy to electrons in the atom of the surface material. If the photons have enough energy to break the electron-atom energy bond, then the electron is dislodged from the atom and becomes a free electron, available for electric conduction. The electron leaves its normal position and becomes part of the current in the external circuit. This effect is called “photoelectric effect". The vacant site is a positive charge called a “hole”. In the process, there is separation of charges, electrons and holes and an electric field is build up providing the voltage needed to drive the current through an external load.

2.2.2 Solar Cell Characterization

A solar cell can be considered as a current generator with a diode and in cooperating series and parallel (shunt) resistances within the cell. The performance of a solar cell or solar panel (many solar cells make a solar panel) is done through characterization. Characterization mainly involves determination of the Fill Factor (FF)-a measure of how ideal the solar cell is. The variation of current (I) and voltage (V) of a solar cell in dark resembles the diode characteristics as show in Figure 1 (a) below (solid curve). On illumination, the photo voltage and photocurrent increases resulting in the broken curve[4]. However, in normal analysis and plotting, we usually translate the I-V curve to the first quadrant (Figure 1 (b)). An ideal solar cell I-V curve is also shown in Figure 1(b).

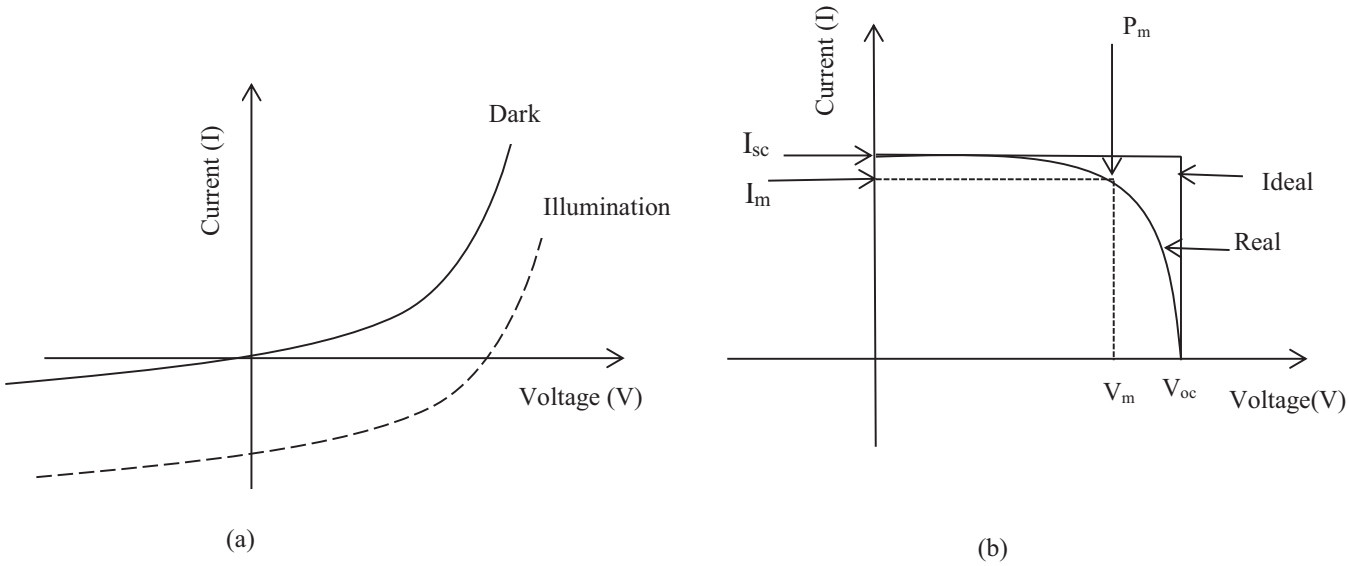

Fig. 1: The current (I)-Voltage (V) characteristics of a solar cell: in dark-solid curve and on illumination-dotted curve (a), under illumination after reflection into the first quadrant (b).

The power, P, of a solar cell is given by the product of the current and the voltage [4, 5]:

$$P = IV \quad (1)$$

Where I is the current (A) and V is the voltage (V).

The maximum power, Pm (W) is normally represented by the area of the largest rectangle that can be fitted under the curve and is defined by:

$$P_m = I_m V_m \quad (2)$$

Where I_m is the current at the maximum power point and the V_m is the voltage at the maximum power point.

The ability of a solar cell to convert incident radiation into electrical power is commonly referred to as the conversion efficiency of the solar cell. The conversion efficiency (η) of a solar cell is the maximum output power (P_m) expressed as a percentage of the input (incident) power P_{in}:

$$\eta = \frac{P_m}{P_{in}} \quad (3)$$

Thus for a practical (real) solar cell, the closer the I-V curve to the ideal case, the higher the maximum power and so is the conversion efficiency. The fitting of a solar cell I-V curve to the ideal rectangular shape is measured by the fill factor (FF) defined as:

$$FF = \frac{P_m}{I_{sc}V_{oc}} \quad (4)$$

Where I_{sc} is the short circuit current (current at zero voltage) and V_{oc} is the open circuit current (voltage when the circuit is open (no load)).

Inserting equation (2) in equation (4), we get equation 5 below:

$$FF = \frac{I_m V_m}{I_{sc}V_{oc}} \quad (5)$$

For an ideal solar cell (see Fig 1 (b)), the fill factor should be unity (1).

2.2.3 Apparatus

The following apparatus were used: A monocrystalline Silicon PSS 1220 (20 W) solar panel, a muilticrystalline Silicon PSS 1240 (40 W) solar panel, both from a local distributor company, digital multimeters (Ammeter and Voltmeter), a rheostat (0-10 KΩ), connecting wires and a Switch.

2.2.4 Experimental Procedure

The number of solar cells in each panel were counted and noted. The circuit was then connected as shown in Figure 2 below.

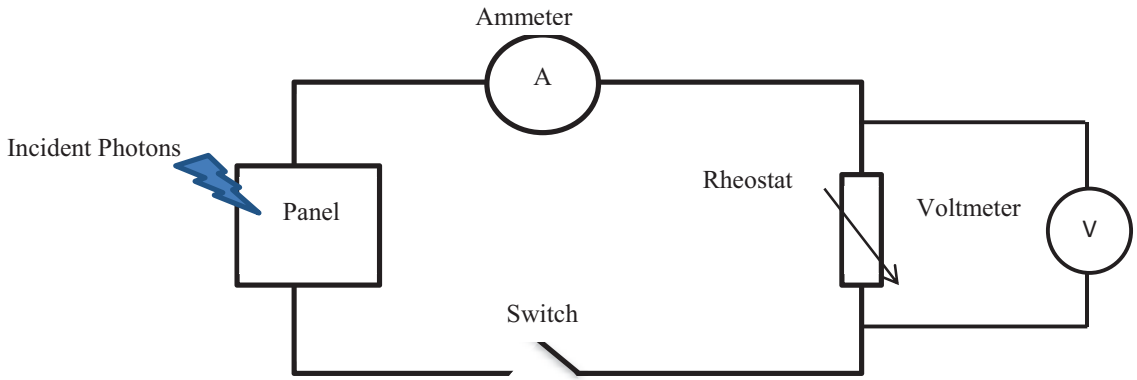

Fig. 2: The experimental set up for the solar panel characterization.

The resistance in the circuit was varied using the rheostat as the values of the current and the voltage were recorded and the data tabulated. The maximum power point was obtained from the product of current and voltage at each point. A graph of current versus voltage was plotted and the parameters FF, I_{sc},V_{oc}, I_m, V_m and P_m were obtained. The data was taken in two days that were clear and sunny.

2.2.5 Results and discussion

2.2.5.1. The 20 W solar panel

The solar panel had 36 solar cells.

Figure 3 below shows the variation of current and voltage for the 20 W solar panel (We show one curve here because all the other measurements generated similar curves). At zero voltage, the current flowing is maximum

and the circuit is shorted. As the voltage is increased (by varying the resistance), the current reduces slowly up to a voltage of about 13 V when further voltage increase leads to a large current decrease, until there is zero current at the open circuit voltage, V_{oc}.

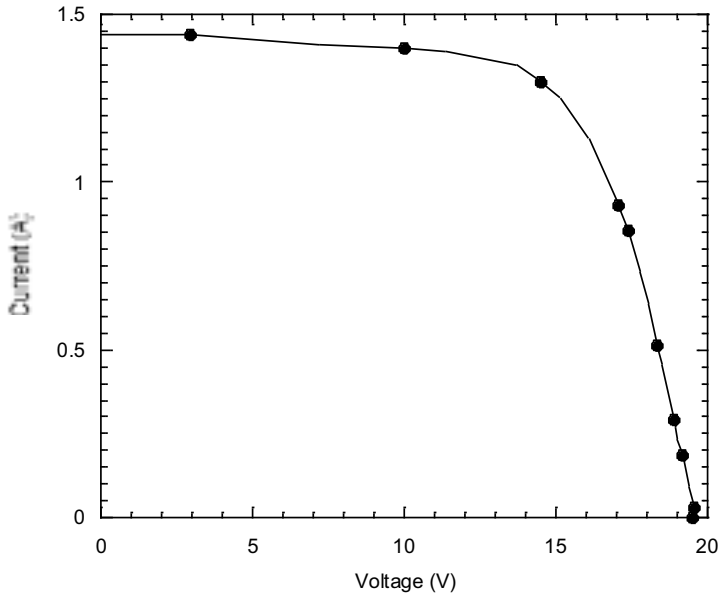

Fig. 3: Current –Voltage characteristics of the 20 W solar panel at 11.20 am of the first day.

Table 1 shows a summary of the solar cell parameters obtained from our I-V curve in Figure 3. The parameters do not show major differences from each other, because the time when measurement was done did not vary much and the weather was similar on both days and times. The manufacturer's values (rated) are shown to the extreme right of the table. As can be seen, there is quite good agreement between the experimental values obtained and the manufacturer's values.

Table 1 Summary of the measured solar Panel parameters and the manufacturer's rating.

Parameter	Day 1			Day 2		Manufacurers Rating
	11.20 am	12.00 pm	2.00 pm	12.00 pm	2.00 pm	
Im (A)	1.25	1.31	1.33	1.14	1.35	1.2
Vm (V)	15.18	14.59	13.61	15.96	13.58	16.8
Pm (W)	18.97	16.49	18.16	18.15	18.26	20
Isc (A)	1.44	1.44	1.43	1.41	1.39	1.4
Voc (V)	19.67	19.48	19.53	19.23	19.28	21
FF	0.67	0.68	0.65	0.69	0.68	0.69

2.2.5.2. The 40 W panel

The experiment was repeated with a multicrystalline 40 W solar panel of 36 solar cells.

Figure 4 shows the current -voltage spectra obtained at 12.20 pm on the first day (Again we show one curve since the other curves were similar). As can be observed, the curves are similar to those for the 20 W except for the higher values of both current and voltage. The graph can be explained in the same way as for the 20 W solar panel above.

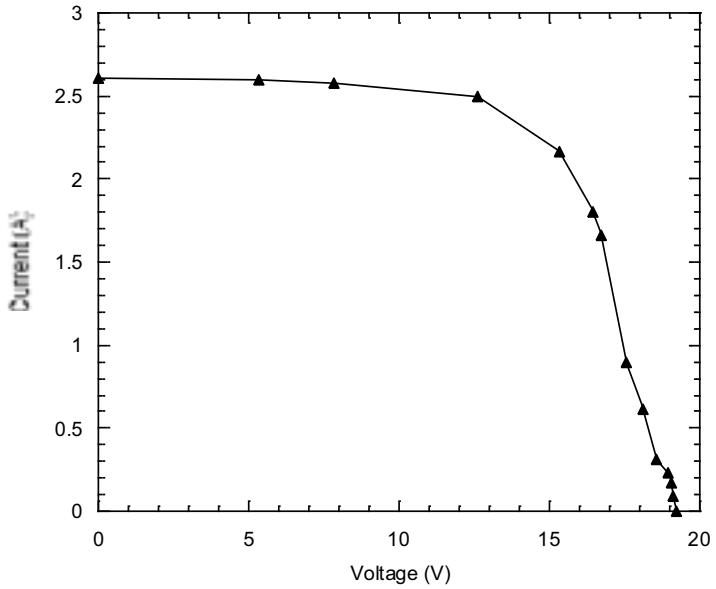

Fig 4: Current –Voltage characteristics of a 40 W solar panel: at 12.20 pm

In Table 2 below, the experimental values extracted from Figure 4 are displayed with the manufacture's rating appearing on the extreme right of the table. We notice a close relationship between our experimental values and the manufacturer's data. This consistency confirms the reliability of the experimental set up.

Table 2 Summary of the measured parameters for the 40 W solar panel and the manufacturers specifications

Parameter	Day 1			Day 2	Manufacturer's Rating
	12.20 pm	12.40 pm	2.50 pm	2.06 pm	
Im (A)	2.17	1.93	2.22	2.30	2.4
Vm (V)	15.33	15.60	13.53	13.27	16.8
Pm (W)	33.24	30.04	30.12	30.57	40
Isc (A)	2.60	2.56	2.40	2.59	2.75
Voc (V)	19.22	19.05	19.07	19.10	21
FF	0.66	0.62	0.66	0.62	0.698

3.0 Conclusion

A solar cell is the basic unit of the solar panel. A solar panel is therefore a combination of many solar cells. The solar panels used in our experiment had 36 solar cells. The current –voltage graphs obtained from the experiment were very similar in shape and values for each solar panel, though measured on different days and times, but similar climatic conditions in the sun.

The parameters obtained from the experiment for both panels were comparable to the parameters provided by the manufacturer, despite the fact that our measurements were done in real environment while the manufacturers was under STC (standard test conditions). Therefore, in Kenya and perhaps within the tropics, the experiment can be carried out successfully outdoors, eliminating the need for expensive equipment like the solar simulator. The experiment is recommended for senior undergraduate students.

THE ROLE OF HISTORY IN REDISCOVERING THE LOST CULTURE OF SOLAR ENERGY

Cesare Silvi

Italian Group for the History of Solar Energy, Rome (Italy)

Abstract

This paper presents an update regarding the ongoing project of an Italian Archive and Museum on the History of Solar Energy, i.e. the energy contained in the direct and diffuse energy radiated every day from the Sun to Earth as well as its indirect forms of air and water currents and forests and other forms of biomass resulting from photosynthesis. The purpose of the Archive and Museum is to make available literary sources and archeological evidences of significant inventions for the use of solar energy preserved at Italian historic sites and Museums.

The focus of the Solar Archive and Museum (SAM) is on two solar ages: the primitive or ancient solar age, from antiquity up to 200 years ago, essentially based on empirical solutions, and the modern or future solar age, which has just begun, based on the knowledge and methods acquired from the scientific and technological revolutions of the last 500 years, primarily on the understanding of the composition of light and how it can be manipulated for producing steam, electricity, and fuels.

Keywords: *Solar energy, solar light, solar energy history, Italian solar energy pioneers, solar heat, solar steam, solar electricity, solar fuels, solar energy in agriculture, solar energy in architecture and urban planning, climate change, solar culture, solar education.*

1. Introduction

The 50th anniversary of the first international solar congress in 1955 in Arizona was celebrated in Florida (USA) on the occasion of the ISES SWC 2005. A book on The Fifty-Year History of the International Solar Energy Society and its National Sections was published in two volumes (Böer, 2005). This celebration emphasized an interest in the history of solar energy use, which in Italy has continued to be promoted and developed over the last ten years by the Italian Group for the History of Solar Energy (GSES, www.gses.it).

The recorded history of solar energy use by humans is a discipline that crosses many years and many disciplines. The work of GSES focuses on what it considers to be two distinct solar ages: the ***primitive or ancient solar age***, from antiquity up to 200 years ago, essentially based on empirical solutions, and the ***modern or future solar age***, which has just begun, based on the knowledge and methods acquired from the scientific and technological revolutions of the last 500 years, primarily on the understanding of the composition of light and how it can be manipulated for producing steam, electricity, and fuels.

GSES has placed special attention on research concerning discoveries and inventions that have had a great impact over centuries and millennia, which are likely to have a lasting impact on human life for much time to come.

Another important area of research for GSES has been that of the many events marking the past few decades with hopes as well as disappointment of those who expected major summits and international conferences to result in concrete programs.

The UN adopted programs, such as "Nairobi Programme of Action for the Development and Utilization of New and Renewable Sources of Energy" in the eighties and Agenda 21 following the 1992 UN Conference on Environment and Development (UNCED) held in Rio de Janeiro, are nowadays for the most part forgotten.

The cycle of major summits and international meetings continues. In 2015 there is a great deal of attention by science, business, environmental and media communities on events by international and national institutions such as the four listed below:

- Year of Light and Light-based Technologies (IYL 2015), http://www.light2015.org/Home.html
- International Year of Soils, http://www.fao.org/soils-2015/en/
- Universal Exhibition, Feeding the Planet, Energy for Life, http://www.expo2015.org/it
- 21st Session of the Conference of the Parties to the UNFCCC, http://www.cop21.gouv.fr/fr

doi:10.18086/swc.2015.09.08 Available at http://proceedings.ises.org

The topics of these four events, in principle, are all closely related and linked to solar energy. In practice, however, the lack of communication and interaction among the four events, treated as separate subjects, shows that the challenges we are facing today are not only specific, technical and scientific issues, but first and foremost cultural. Our lack of capacity to connect various topics to others, in order to understand the key problems that world faces, from climate change, to energy and scarceness of resources, to poverty, geopolitical conflicts, etc..

The use of solar energy is an age-old experience marked by fundamental discoveries in different ages, to artificially convert it into other useful forms for human beings: food, heat, fuel, mechanical energy, chemical energy, and, more recently, since the late 1800s, electricity from hydro, wind and light energy directly or indirectly coming from the Sun.

The introduction and diffusion of fossil and nuclear fuels derailed the solar energy civilizations developed over millennia, which were built on the basis of centuries old inventions that are still valuable in our lives today.

The ***primitive or ancient solar age*** was characterized by discoveries such as: fire, which enabled humans to use the solar energy stored in forest wood and other forms of biomass; agriculture and the first human settlements; solar architecture and urban planning, in which streets and buildings were oriented so as to exploit the sun's light and heat directly and naturally as well as to protect inhabitants from the sun's rays, a concept used over and over and handed down for centuries by all civilizations.

One important example of this is the Romans' discovery of transparent window-pane glass in the first century A.D., to bring daylight inside buildings and at the same time preventing cold and winds from entering them.

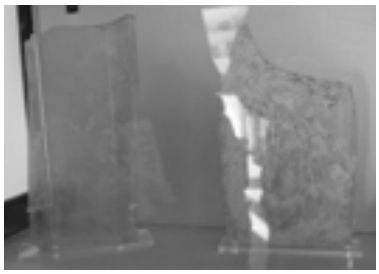

Fig. 1: Flat transparent window-pane glass from Pompeii, 1st century A.D. to capture sun's light and heat for houses and baths (Photo National Archaeological Museum, Naples, Italy)

These discoveries evolved over the ages and are still of the greatest importance in our daily lives. Think of the millions upon millions of window-panes that provide day lighting to homes and workplaces all over the world, thereby saving on artificial light from electricity generated by fossil and nuclear fuels. Think of the role of solar energy as a primary and principle source in farming. Think of solar architecture and urban planning that have shaped entire territories, from small villages to large cities, as well as the construction of buildings.

Fig. 2: An aerial view of Spello, a typical Italian small town, whose shape and relationship with the surrounding farmland is a clear reminder of its past. Ancient cities' near total dependence on solar energy set a limit on their size (Photo G. Reveane, 1993)

Prior to the discovery of fossil fuels and the beginning of the industrial revolution, human civilizations subsisted for thousands of years exclusively on solar renewable energy in its direct and indirect forms, in Italy

up to 100-150 years ago. Therefore, the importance of the sun is deeply engraved in the history of our living and working environments, in large cities and small towns, in rural areas and their landscapes.

An example is illustrated by the photograph in Fig. 2, which shows the small Umbrian town of Spello, surrounded by farmland, where the production of food and its transportation to the places of consumption depended entirely on solar energy. Spello and the hundreds of similar towns throughout Italy, show us how it was possible in the past to develop "solar energy systems" in which the built environment and the agricultural fields around it worked together as a "whole" relying exclusively on solar energy, even though in a "primitive or ancient," way, namely on an empirical basis.

This ancient renewable-solar-energy "system" still exists in our modern world. It is like an ancient "solar soul" we are used to, that we take for granted, nearly forgotten, certainly not accounted in official energy-use and economic data statistics, it is fully part of us. In fact, this solar heritage, even if widely present in modern societies and in our daily life, is often unnoticed and unknown.

In the last century people saw the rapid growth of a new energy infrastructure based on abundant use of fossil and nuclear fuels and with it, the growth of cities' in size and population. Urbanization and mega cities, and the depopulation of rural areas became the sides of the same coin.

Over the last decades, hundreds of millions of people throughout the world left their villages and moved to cities in search of new opportunities and welfare.

"With 75 per cent of Chinese expected to be living in cities within 20 years, the demand for more transport, energy, water and other vital infrastructure is set to test resources and city planners" (Simpson, 2012).

Fig. 3:The city of São Paulo, Brazil. With about 20 million inhabitants, it is one of the most populated cities in South America. We can only imagine, but we can not see the farm fields that produce food for the city as in the case of Spello in Fig.2. Photo www.scattidigusto.it (2014).

A trend that started with the discovery and diffusion of fossil fuels continues today everywhere in the world. According to experts, urbanization is an irreversible phenomena. Is it really? We will consider this question again in the Section 6 Habitat and Agriculture.

According to The United Nations Population Fund, "Urbanization has the potential to usher in a new era of well-being, resource efficiency and economic growth. But cities are also home to high concentrations of poverty. Nowhere is the rise of inequality clearer than in urban areas, where wealthy communities coexist alongside, and separate from, slums and informal settlements" (UNFPA, 2015).

Our grandparents and great-grandparents would certainly never have imagined a transition from solar energy to fossil and nuclear fuels in the proportions we see today. It's impossible to imagine what the world might look like in 2100. However, we should ask ourselves whether it's reasonable to think of an epochal transformation in which our industrially and technologically advanced societies make the switch to a ***modern or future solar age***, in which we return to the exclusive use of solar energy.

History can have an important role in helping and educating us in rediscovering the lost culture of solar energy, making it possible to power advanced societies only with solar energy.

In the following pages we treat five topics seen in a historical perspective, enriched here and there with information from The Italian National Archive and Museum on the History of Solar Energy:

- Terminology concerning energy sources on Earth;

- Earth systems and science;
- Ancient and modern solar ages;
- Solar or nuclear in the 1950s and today;
- Habitat and agriculture.

2. Terminology concerning energy sources on Earth

An important aspect in dealing with solar energy is represented by the continuous change of the terms we use when referring to it in different periods of human existence on our planet.

Energy, Solar Energy, Renewable Energy, wind energy, hydro energy, biomass etc., are common words for us today. It is very likely that they would not be understood just a few decades ago, even by the most educated people, and they were not known at all by our most recent ancestors.

What about the future? As we see it, the current terminology, though widely used, is still far from being valid for the promotion of solar energy use.

Indeed, the term “renewable energies” leads people to believe that various energy forms, such as wind, biomass, hydro, each originate from different source, with their own market niche and technology, whereas in reality they all come from the same source - the Sun. The more the solar market and technologies are integrated and promoted as a whole, the better they can be understood and defended from other proposed energy sources. There have been extraordinary developments on our understanding of how the Earth works and of its relationship with our life and the radiant light energy from the Sun. We need to develop the terminology to reflect these developments.

At the beginning of the 1900s, the Italian chemist Giacomo Ciamician (1857-1922), founder of the Institute of Chemistry of Bologna, Italy, which bears his name, in his famous speech, "The photochemistry of the future” (Ciamician, 1912), called the energy coming from the Sun *current solar energy*, i.e. the energy that the earth receives from the sun every day to distinguish it from *fossil solar energy*, i.e. solar energy accumulated by nature over centuries. Ciamician asked himself: “Is fossil solar energy the only energy source that may be used in modern life and civilization? He then concluded that it would be better to use the daily “current solar energy.”

In 1951, on behalf of the USA Atomic Energy Commission, Palmer Putnam conducted a study on the future energy for the period 1950-2050. He grouped energy sources on Earth into three broad categories: a) capital energy sources (coal, oil, gas, etc.); b) Income energy sources (direct and indirect solar energy and other forms of income energy); c) nuclear fuels. The language used by Putnam implies an economic characteristic for sources a) and b).

Fossil fuels are a "capital" created for us by the savings made by nature over millions of years. The use of “renewable energy” is an income energy that comes from the Sun and it does not undermine the consistency of our annuity that is available for us and will be for future generations. The terms used by Putnam have by now been forgotten.

The term "renewable energies" came into common use in 1981, when the United Nations organized the Nairobi Conference on New and Renewable Sources of Energy in Kenya. Its predecessor, the 1961 U.N. Conference on New Sources of Energy in Rome (Italy), presented solar, wind and geothermal energy as if they were new sources, while they had existed on Earth from the start.

Agostino Capocaccia from the University of Genoa (Italy) in 1972 reminds us that for centuries man used only *surface energies* (living beings, water, wind, wood). In the last two centuries, *energies of darkness* (coal, oil, endogenous forces, uranium), responsible for most of the pollution, have taken over. He also gathers energy resources on Earth in energies with limited supplies and energies with an unlimited supply (Capocaccia, 1972).

Most of the terms reviewed above became obsolete after the first oil shock of 1973, with the introduction of the term "alternative energy", still often used to indicate the energy from the sun, but at the time referring to all forms of energy alternatives to oil, including nuclear power.

As this brief review shows, energy forms have been referred to by different names at different times. Currently, the most prevalent terms contain the word “renewable” or “solar”.

However, drawing inspiration from "The International Year of Light and Light based Technologies,"

proclaimed by the United Nations for the year 2015, we might want to consider using more widely another word: LIGHT! Over the past five hundred years giant steps have been made in the understanding of what light is and how light works by great scientists such as Galileo, Leonardo da Vinci, Newton, Huygens, Maxwell, Planck and Einstein.

More information on these developments can be found at the web site of the International Year of Light and Light Based Technologies (www.light2015.org) and at the GSES web site www.gses.it, devoted to the Year of Light, in particular the articles in English published in Clean Technica (Perlin, 2015).

The explanation of the photoelectric effect by Einstein contributed to underscore other aspects of the structure of the atom, the nature of light and the electrical origin of the cohesive forces in molecules and matter. All this has opened fascinating prospects for the use of direct solar energy in the modern or future solar age, from solar photovoltaic cells with efficiency ratings of 50% or more to smart glass, photon solar architecture and city planning.

We might propose to gather energy sources on Earth in two categories:

- ***Light energies***, energies from the direct or indirect solar radiation: those above the surface of the Earth, that include direct and diffuse solar radiation and indirect air and water currents, naturally or artificially powered by Sun's energy, and photosynthetic phenomena which are the source of biomass. Sun's light energies can be seen by anyone, anywhere, anytime.

- ***Darkness energies***, energies stored underground, below the surface of the Earth, that include fossil fuels - coal, oil, natural gas – nuclear fuels, and the internal heat of the Earth. Until a few centuries ago we did not even know about their existence. Today we continue to discover new fossil fuels fields.

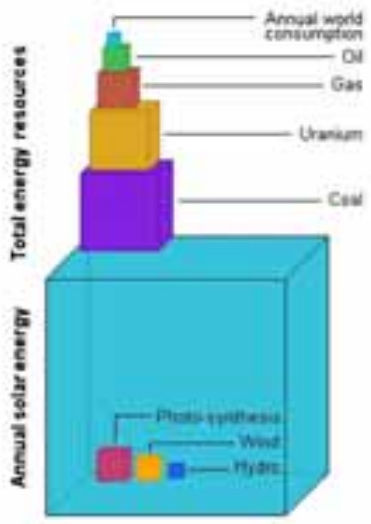

Fig. 4: Order of magnitude of energy sources on Earth (Lomborg 2001)

3. Earth systems and science

We live on Earth and need to understand how it works.

Think of it as a system made up of three subsystems, Earth's matter, Earth's energy and Earth's life, as suggested by Dr. Art Sussman in his Guide to Planet Earth (Sussman, 2000).

In terms of matter, the Earth is a closed system. It has practically the same amount of matter that it had at its origin and that cycles over and over. In terms of energy, the Earth is an open system, except for its internal heat. It receives a certain amount of energy from the sun and, after transforming it through the myriad natural processes operating on our planet, from the growth of plants to wind and water cycles, radiates that same amount back into space. As to the living world, the Earth is an interconnected system. The existence of every living being depends on a ramified network of relations with other living beings and with the matter and energy systems.

Today we're in the midst of a great new challenge: understanding that the Earth and its three subsystems work

as a whole, and that for the first time ever, their operation can be affected by human activities, partly because never before have there been so many people living on the Earth, and partly because we humans are engaged in more and more activities that can significantly affect the natural mechanisms that make our planet work.

This new awareness of how the Earth works is gaining ground through increasingly evident cultural and political processes, as in the case of climate change due to greenhouse gases as well as to the production of artificial heat on the Earth's surface, as proposed by Prof. Giovanni Francia (1911-1980) in the seventies.

Despite the scientific uncertainty that veils phenomena as complex as climate change, we can plainly no longer shut our eyes to the way the Earth works. This should be standard knowledge for everyone, just like the knowledge that the Earth is not flat but spheroid.

Once we've learned how the Earth works, it should be easier to determine the best ways to know and use its natural resources, in particular its energy resources and solar energy, so as to maintain the environmental balances on which our lives depend.

4. Ancient and modern solar ages

It often happens that we think of solar energy as an aspect of our modern world, although it had powered everything on Earth until 150-200 years ago.

We should impress in our minds that for thousands and thousands of years, light, heat and fuel from solar energy alone shaped human settlements and cities, farming and forestry, architecture and buildings, landscapes and territories, religious beliefs and cultures, social relations and lifestyles - in a word, whole civilizations. The use of renewable solar energy is thus an age-old experience and we need clearly to make a distinction between ancient and modern solar ages and understand what has been changed moving from one to the other.

Solar energy resources, at least over the last 10.000 years, have not changed. What has changed is our knowledge of them. Our ancestors had neither the scientific knowledge nor the technical means available to us today to observe, measure and monitor direct solar radiation and its indirect forms, wind, falling water, biomass and other forms over days, months, seasons and years. With a combination of satellite data and field measurements, we can estimate the amount of direct solar radiation that reaches any part of the Earth. In a word, we can find out what energy resources are available at any point on our planet.

Basic principles of solar architecture and urban planning also have not changed, nor have the basic principles used to collect, convert or store sun's heat. What has changed, and that must be underlined, is that we have learned to convert solar energy into electricity, an expression of our modern solar age.

Since the 1800s we learned first to convert power of falling water into electric energy and, more recently also that of the winds and of sun's heat and light.

The foundations of these advancements are in the many discoveries and inventions made in the last five hundred years and lie chiefly in our ever more advanced understanding of optics, light and the structure of matter, which has opened fascinating prospects for the use of solar energy in the modern age, from solar cells with efficiency ratings of 50% or more to smart glass and photon solar architecture and city planning (Perlin, 2015).

By now we know for certain that it is possible to build large and sophisticated energy infrastructure powered by solar energy to produce electricity, low-, medium- and high-temperature heat, fuels and other useful forms of energy.

It must be recalled that electricity consumption in advanced societies accounts for less than 20% of the total, while 80% is in the form of fuels and heat, the last at low temperatures, i.e. those that the Sun makes available naturally.

What we do not know today is how to build a modern solar energy system as a ***whole,*** which is something we think necessarily in order to replicate in a modern way the ancient solar energy systems. Today, the idea that the systemic aspect of the use of solar energy, which was implicit in the lives of our forebears, is overlooked. It is a cultural deficit that span all fields: science, technology, organization, sociology, economics, politics, even our terminology and ways of communicating.

A cultural deficit that regards also the recent history of modern solar energy. In 1955, on the occasion of the

first World Solar Symposium held in Arizona, the first comprehensive Directory of World Activities and Bibliography of Significant Literature on Applied Solar Energy Research was published and distributed by Stanford Research Institute for the Association for Applied Solar Energy (Stanford Research Institute, 1955).

Approximately 4000 citations relevant to 27 countries, from 1850 to 1955, are reported in this Directory. They show the human effort made to pursue solar energy in modern times, but strange to say, the prophetic visions, the inventions and the work of so many pioneers in the late 19th and early 20th century are little known today, even to solar specialists. Yet many of them, farsighted and with clear vision, anticipated problems that appear are constantly in the news today. They also anticipated the technical solutions or proposals necessary to deal with important dilemma, such as the question of favoring "Nuclear energy or Solar energy?"

5. Solar or nuclear in the 1950s and today

The solar or nuclear debate: Nuclear YES, Nuclear NO, Solar or Nuclear, continues today as did was fifty years ago.

Ahead of the Climate Change International Summit in Paris in December 2015, there are more and more voices claiming that climate change requires a technological response, and nuclear power could be an important element of that response (Guyer and Golay, 2015).

In the 1950s, solar pushed to the side with the promises of nuclear power. In fact, in the aftermath of WWII, modern solar technologies, except for hydro, and peaceful uses of nuclear energy to produce electricity were both in their infancies.

In January 1951, United States President Harry S. Truman appointed William Paley to chair the President's Materials Policy Commission to investigate the long-term availability of raw materials, making a clear distinction between those necessary for defense and those essential for the country's development. Paley thought that the United States could not afford a shortage of raw materials to jeopardize the nation's security or create a bottleneck in its economic expansion. On June 2, 1952, Paley submitted his report to the President. The committee had consulted experts in industry, academia and government, and one of the four volumes of its report on the analyses and conclusions of the study had a whole chapter devoted to what Paley called **"The possibilities of solar energy"** (Paley, 1952)**.**

The chapter summarized the results of a broader study made by Palmer Putnam in July 1951 for the US Atomic Energy Commission, in which he had reviewed all the methods for collecting solar energy and converting it into commonly used forms of energy: natural photosynthesis, heat pumps, thermal solar collectors, solar-heated homes (13 million were expected to be built in the United States by the end of 1975), water desalination, electricity generation with solar concentration systems, the exploitation of solar energy through wind and the thermal gradients of tropical waters, controlled biological photosynthesis, non-biological photosynthesis and photovoltaic.

The Paley Report concluded that up till then only tiny steps had been taken to promote solar energy, and emphasized the importance of adopting an aggressive policy to develop the entire solar-energy sector, a sector in which the United States would be able to make a huge contribution toward the well-being of the free world.

Under the Truman administration, this prospect was one of many considerations, including the idea that the development of nuclear energy to generate electricity would contribute significantly to increase the risk of proliferation of nuclear arsenals and the threat of atomic war. These fears explain Truman's decision to keep all information on nuclear energy secret. But this policy soon proved pointless, because the Soviet Union was quickly equipping itself with nuclear weapons. Truman's approach was overturned when Eisenhower won the 1952 election and entered the White House.

In a speech delivered at the United Nations General Assembly on December 8, 1953, Eisenhower announced the "Atoms for Peace" program that, according to solar energy historian John Perlin, became the ace in America's hand to win the Cold War (Perlin, 2000). With international political commitment and economic support, nuclear power took off while Paley's report was forgotten and solar energy left behind.

We wanted to recall the nuclear or solar debate in the 1950s, because nuclear energy, in spite of its technological and economic limits, which clearly emerged with great evidence during the Chernobyl and Fukushima accidents, continues to be considered a valid option to fight climate change because it does not produce greenhouse gases as do fossil fuels. Too often, nuclear energy is inappropriately considered, along with

solar energy, as a solution to the issue of climate change.

Today, unfortunately, this idea is widespread. In order to counter this misconception, in my view, we should consider Prof. Giovanni Francia's research on the Earth's thermal equilibrium, illustrated in a paper he wrote in the early 1970s titled "The Sun and the Limits of Energy on the Earth" (Francia, 1973).

Francia, a mathematician and physicist, teaching at the University of Genoa, devoted more than 20 years of his life to studying and experimenting with solar energy systems and concepts from the early sixties up to his death in 1980. He is considered by GSES the foremost Italian solar energy pioneer of the 1900s (Silvi, 2005).

In February 2005, I discovered Prof. Francia's undated paper on the Earth's thermal balance in his personal archive, donated by his heirs to the Museum of Industry and Work in Brescia (www.musilbrescia.it).

To my knowledge, the complete Italian version of Francia's paper has remained unpublished until today. We can be reasonably sure that he wrote it between late 1973 and early 1974, because a summarized French version appeared in the second half of 1974 in the Revue international d'héliotechnique, a journal published by COMPLES (Coopération Méditerranée pour l'Énergie Solaire), of which a one of a kind collection is kept at the Italian Archive and Museum on the History of Solar Energy in Brescia (Italy).

I outlined Francia's views about the thermal equilibrium of Earth in a paper about his pioneering activities that I presented in August 2005 at the World Congress organized by the International Solar Energy Society in the United States (Silvi, 2005). The interest aroused by his approach encouraged me to try to broaden knowledge of his paper.

As it was partly typewritten and partly written in longhand, it was not easy to read it. Accordingly, I transcribed it in electronic format and made a short summary of its contents that follows.

In this study, Francia focuses on the Earth's surface temperature, the point of equilibrium between the energy radiated by the Earth into space and the energy that the Earth receives from the sun. Throughout historical time, he says, the amount of thermal energy generated on Earth by natural phenomena has remained practically constant, except for changes caused by the fluctuations in solar power that occur in eleven-year cycles.

Over the last two centuries, though, energy generated artificially by human beings, above all by burning fossil fuels, has been added to the amount of naturally generated thermal energy.

Since the amount of thermal solar energy that reaches the Earth is thousands of times greater than the sum of non-solar energies, and since the uncertainties regarding its estimation are on the same order of magnitude as the latter, according to Francia the modest amount of thermal energy generated artificially by humans might seem at first sight to lead one to conclude that it has no effect at all on the Earth's thermal equilibrium.

But this is not so, as Francia explains in a few pages with a series of observations regarding the ways in which our planet's various surfaces (water, snow, soil) absorb and reflect solar radiation in different seasons and at different latitudes.

To the contrary: if in a hundred years' time this small amount of thermal energy generated continuously by humans were to reach amounts tens of times higher than those of 1974, according to Francia, it would produce phenomena of thermal instability on the Earth, triggering a chain of events with positive retrospective effects that could shift our planet into an equilibrium very far from the initial one, and at speeds much faster than living beings can adapt to.

Prof. Francia concludes that, ***"It would seem that the production of even small quantities of energy on the surface of the Earth alters the climate dramatically, and that henceforth it will be necessary to use solar energy, the only kind that does not generate thermal pollution."***

From Francia's research, which did not include the effects of greenhouse gases, one can conclude that climate change seems also to be connected to the production of artificial heat on Earth, which is added to natural thermal heat from solar radiation, by burning fossil and nuclear fuels, and by extracting the Earth's internal heat. What has not been studied, is the combined effect of the two.

6. Habitat and Agriculture

The importance of sun's energy use and human life on Earth is deeply inscribed in the history of human habitats and surrounding farmlands. Since prehistoric civilizations, habitat and farming were always based on

the same energy principles. As energy historian Vaclav Smil points out, "all agriculture was based on the conversion of solar radiation through the process of photosynthesis. Photosynthesis produced food for humans and livestock, recycled waste to fertilize the soil, and provided the fuel needed to melt the metals with which primitive farming tools were made. Traditional farming methods were thus based entirely on solar energy. Except for cutting down old forests, they did not impoverish energy stocks. The whole process was based on a virtually immediate capacity to convert solar energy flows." (Smil 1999).

Then came fossil fuels – first coal, then oil, then natural gas – and later nuclear energy. In less than a hundred years, we've built huge and efficient energy infrastructure – coal and oil shipping terminals, oil and gas pipelines, power plants and power lines, and so on – that have assured abundant energy, development and well-being, but have also had ever more obvious effects on the environment and led to profound changes in the socioeconomic geography, habitats, farming and lifestyles of whole civilizations that had grown over the centuries with the use of solar energy alone.

Mega-cities grew rapidly, as well as rural depopulated areas, altering relationships among the different functions of cities and their surroundings.

A thesis presented in Genoa in 2006 by GSES was that in order to bring the modern solar city into being we must intelligently combine and integrate the experience gained by the ancient cities – not only in terms of technical know-how, but also of art, culture, relations and communication – with the many solutions made available by the scientific discoveries and extraordinary technological developments of the past two hundred years, especially in the most recent decades (Silvi et al., 2006).

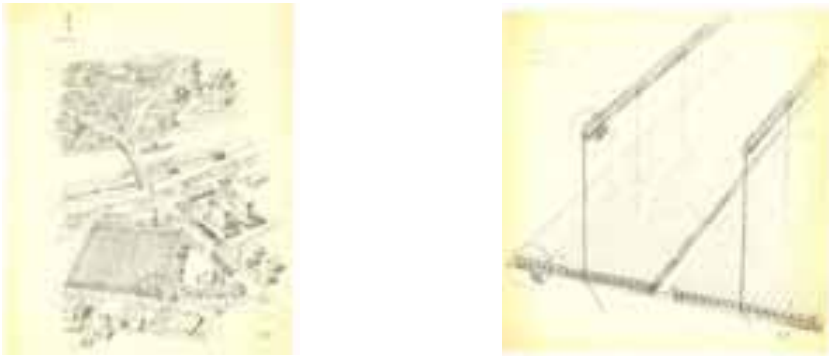

Fig. 5: Drawings of large Linear Fresnel Reflector Solar Power Plants integrated in a city designed by Francia in 1965 circa (Francia Archive donated to the Museum of Industry and Work in Brescia by his heirs in 2005)

In the "Solar City Project – Ideas for an Urban Structure", Prof. Giovanni Francia and his collaborators (Francia, 1971 et al.) discussed whether and how the discoveries, suggestions and results that solar energy science has produced in the past few decades are compatible with the new directions that architecture is taking.

They were convinced – and they believed many other people were as well – **"that in the near future scientists, architects, economists and sociologists will have to study the large-scale use of solar energy, and that (as far as they could tell at the time) for the most part their studies will focus on electricity generation and the heating and cooling of cities."**

Fig.6: Francia, right, showing a model of the solar city project, Genoa (Italy), 1978.

The Solar city exhibition held in Genoa by GSES in 2006, to honour Francia's vision of a Solar city, recounted the vicissitudes of cities, of architecture, energy and food-supply infrastructures, and the scientific discoveries

and technological developments that marked the major stages in their history, with special focus on day lighting, heating and cooling of buildings.

Gaetano Vinaccia (1889-1971), an Italian architect of the early 1900's and solar pioneer, author of more than 200 publications, most of which devoted to solar energy, in his book "The City of Tomorrow" wrote: **"To reach the city of tomorrow, we need first of all – to save time and effort – to retrieve old paths considered useless by people who think the past is a ball and chain bound to humanity's feet so as to prevent our triumphant march toward progress. The fruit of thousands of years of intelligent work, the selection that centuries of experience has contributed to, cannot be bypassed, cannot be modified, cannot be refuted except through centuries of hard and serious work. And there are absolute truths that no one can modify, much less destroy" (Vinaccia, 1939).**

Fig. 7: Front cover of Vinaccia's book "Il corso del Sole in urbanistica ed edilizia." The Course of the Sun in Urban Planning and Construction (Vinaccia, 1939).

In Genoa GSES's solar city exhibition drew inspiration from the pioneering works of two Italian important solar scientists, Francia and Vinaccia, intelligently combining our millennia experiences and principles in solar energy use with the most advanced technologies from the extraordinary scientific advancements of the last 500 years. In other words, as put by Norbert Lechner, "Use the best of the old and the best of the new" (Lechner, 2000).

Is Urbanization an irreversible phenomena? Will 75% of 10 billion people, as we are expected to become in 2015, live in cities? We do not know. For certain we might reconsider historically and scientifically what options we had in the past and what we can have in the future.

A key aspect of solar energy use is its intermittency. Until 200 years ago we knew how to use solar energy stored by nature through photosynthesis in a common fuel: fire wood.

Today there are many scientists who are working to store solar energy in a fuel that can become as commonly available as fire wood has been for centuries.

Among scientists that conquered global media attention on this possibility is Daniel Nocera. During the impact of the Arab oil embargo and other oil crises of the 70s and 80s, Nocera envisioned his scientific career as one of a humanitarian activity focused on the discovery of the "guarded secret of plants", a concept which was introduced into the scientific debate in 1912 by Italian chemist Ciamician in his paper The photochemistry of the future (Ciamician 1912, Venturi et al. 2005, Nebbia and Kauffman 2007, Nocera, 2011).

In 2011 Nocera presented a cheap coated-silicon sheet, referred to as an artificial leaf, which, when placed in a glass of tap water and exposed to sunlight, was able to split water into hydrogen and oxygen. "If there is one thing that's unique to this technological development," said Nocera, "it is that it was done with the very poor in mind."

Fig. 8: A slide by Daniel Nocera in which power lines are no longer needed. Electricity and fuel will be provided by the artificial leaf, which when placed in a glass of tap water and exposed to sunlight, is able to split water into hydrogen and oxygen

If in the last century millions moved from villages to cities, is it possible that in the future might millions move back from cities to villages? Is a modern new solar colonization of Earth thinkable and possible?

7. Italian Archive and Museum on the History of Solar Energy

The idea of Italy's Archive and Museum on the History of Solar Energy started to take shape within GSES in 2003, with the main purpose being to preserve and make widely available the Italian heritage of solar energy use in our country (Silvi, 2008).

The Archive and Museum, whose initial core has been taking shape in the past few years in Brescia, in northern Italy, at the Luigi Micheletti Foundation and the Eugenio Battisti Museum of Industry and Work (www.musilbrescia.it), is being organized around the following topics: solar pioneers and devices starting in the early years of industrialization; solar architecture and city planning; the use of solar energy in agriculture.

In this paper we have provided examples of the kind of contributions that can come from knowing the work of great Italian pioneers such as: Giovanni Francia, mathematician and physicist; Giacomo Ciamician, chemist; Gaetano Vinaccia, architect. Their stories and work are documented at the web site of GSES www.gses.it, mainly in Italian.

8. Conclusions

The "easy" and "abundant" energy provided by fossil fuels permitted architects and engineers to ignore the fundamental rules of solar architecture and city planning which had been used as guides for thirty-five hundred years – proper insolation, building orientation – and led to major changes in our society that will not be easily reversed. Perhaps, still more important, this "easy" energy resulted in the loss of the ancient culture that was necessarily sophisticated and frugal in the use of natural resources.

Today it would probably be much easier to continue, as we are doing, along the same path, continuing to build energy infrastructures based on fossil and nuclear fuels, than it would be to create an entirely new energy infrastructure that enables widespread use of solar energy.

However, human societies progress when they face difficult challenges and manage to come up with new solutions, rather than falling back on easier and conventional ones. The solar challenge is indeed a difficult one, but that's exactly why it ought to interest us and why we should work harder at advancing it.

Abstract

Thermal energy storage (TES) is core advantage for the concentrated solar power (CSP) technologies. A packed bed of rocks or other ceramic is especially suitable when gas is used as the heat transfer fluid. The heat transfer performance of thermal energy storage (TES) device which use the air as the heat transfer fluid and the honeycomb ceramic as the storage material was researched by experimental in this paper. The results showed that the temperature distribution was obvious thermocline distribution when charging and discharging process. The charging efficiency of the TES device was higher than 75%, and the discharging efficiency was higher than 85%.

Key words: *thermal energy storage; honeycomb ceramic thermal storage; heat transfer performance*

1 Introduction

Thermal energy storage (TES) is core advantage for the concentrated solar power (CSP) technologies. TES appears to be an important solution to correcting the mismatch between the thermal energy availability and demand of energy. Sensible heat storage is the most simply and inexpensive way of energy storage system although there are few advantage of phase change energy storage over sensible heat storage, but the technological and economical aspects make sensible heat storage superior[Sigh et al, 2010]. For CSP plants operating with air as the heat transfer fluid [Bader et al, 2011, Wang et al, 2015], TES using a packed bed of rocks has been shown to offer a simple and efficient technical solution for overcoming the intermittency of solar radiation [Zanganeh et al, 2012, Meier et al, 1991, Hänchen et al, 2011, Gross et al, 1980]. A packed bed of rocks or other ceramic is especially suitable when a gas is used as the heat transfer fluid [Sigh et al, 2010, Hanchen et al, 2011, Coutier and Faber, 1982, Hasnain 1998]. The numerical and experimental results show that the porous structure which maximize heat transfer between fluid and storage media and minimize heat transport inside the storage media [Xu et al, 2013, Zavatoni et al, 2014, Zanganeh et al, 2012]. The heat storage performance of two tanks TES and single TES had been researched by EPRI [Palo, 2010], the results showed that the cost of a single TES using fluid and solid material as the thermal storage media can reduce 33%. TES using a packed bed of sensible-latent material has been shown that a PCM volume of 1.33% of the total storage volume was sufficient to achieve stabilization of the outflow air temperature around the PCM's melting point [Zanganeh et al, 2014].

Nomenclature

L	TES storage length
$\dot{m}$	Mass flow rate, kg/h
T	Temperature, ℃
z	Axial position
η	Efficiency
t	Time, s
c_p	Heat capacity, kJ/kg.K

Subscripts/Superscripts

i	The test section number of honeycomb ceramic of TES device
j	The thermocouple number in each test section
air	Heat Transfer fluid-air
$area$	The position of test section of TES
s	Honeycomb ceramic material
in	inlet
out	outlet
c	Charging process
d	Discharging process

In this paper, the solid thermal storage system which use the air as the heat transfer fluid and the honeycomb ceramic as the storage material was built-up and the heat transfer performance under different condition were investigated.

2 A honeycomb ceramic TES system

2.1 A honeycomb ceramic TES device

Fig.1 shows the schematic of the honeycomb ceramic TES device. The honeycomb ceramic TES device is a box which is consisted of inlet pipe, outlet pipe, cover plates and the TES materials. The size of the TES device is 1512×1412×1584mm. The air was used as the heat transfer fluid during the charging and discharging process. Honeycomb ceramics were used as the TES materials, and 4000 pieces of honeycomb ceramic were inserted into the TES device. Fig.2 is the photo of honeycomb ceramic material. The size of the honeycomb ceramic is 34.3×34.3×100mm. The property of honeycomb ceramic was shown in Table1.

Fig.1. The schematic of packed-bed TES device

Fig.2. The photo of honeycomb ceramic

Table 1 Property of honeycomb ceramic material

74	42	45	197	10.7

2.2 A honeycomb ceramic TES system

In order to analyze the heat transfer performance of the packed-bed thermal storage, an experimental system of thermal storage was built up. Fig.3 is the layout of the packed-bed thermal storage system using honeycomb ceramic as the thermal storage material.

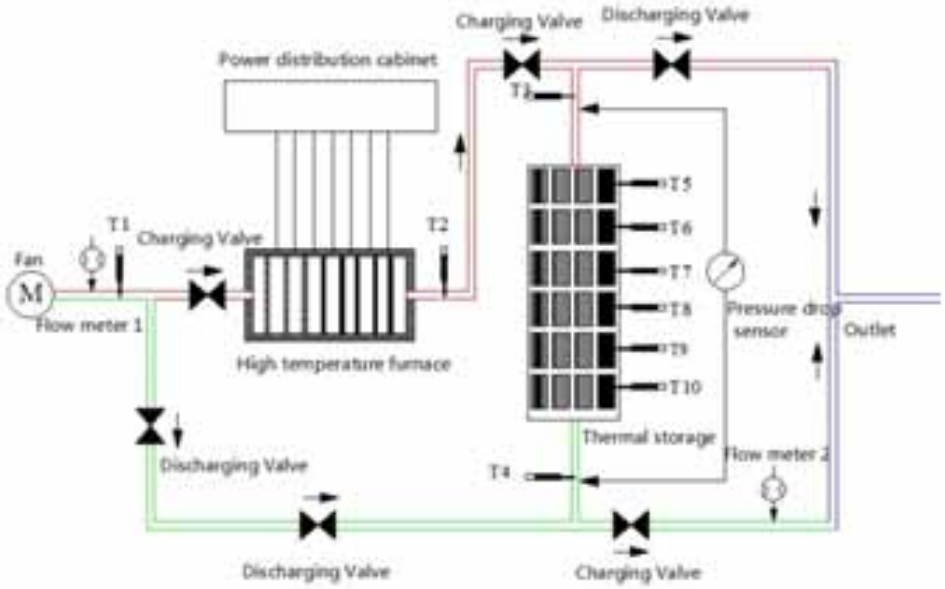

Fig.3. Schematic of packed-bed TES system

The thermal storage system is consisted of fan, high temperature air furnace, a honeycomb ceramic TES device, pressure drop sensor, thermocouple and flow meter. In the system, the fan transported air from the environment to the furnace or pipes. The high temperature furnace is the heating apparatus to heat the air.

The pressure drop when air flows through the thermal storage device were measured by the pressure drop sensor. The air temperature, honeycomb ceramic temperature and the surface temperature of the thermal storage were measured by several thermocouples. Fig.4 is the photo of the packed-bed thermal storage system.

Fig.4 The photo of the thermal storage system

In order to analyze the performance of the thermal storage device and the heat transfer between air and honeycomb ceramic, air volumetric flux, temperatures of air, honeycomb ceramic and the surface of the thermal storage device, the pressure drop of the thermal storage device were measured. The inlet air flow rate was measured by a volumetric flow meter with the range from 15 to 300m^3/h and the error is ±0.5%. The outlet air flow rate was measured by a vortex flow meter with the range from 80 to 800m^3/h and the error is ±0.5%. The pressure drop of the thermal storage was measured by the pressure drop sensor which the error is ±0.5%.

The temperatures of air, honeycomb ceramic and the surface of the thermal storage device were measured by thirty eight K-type or S-type thermocouples, which all error is ±0.1℃. The positions of the thermocouple inserted into the thermal storage device are shown in Fig.5.

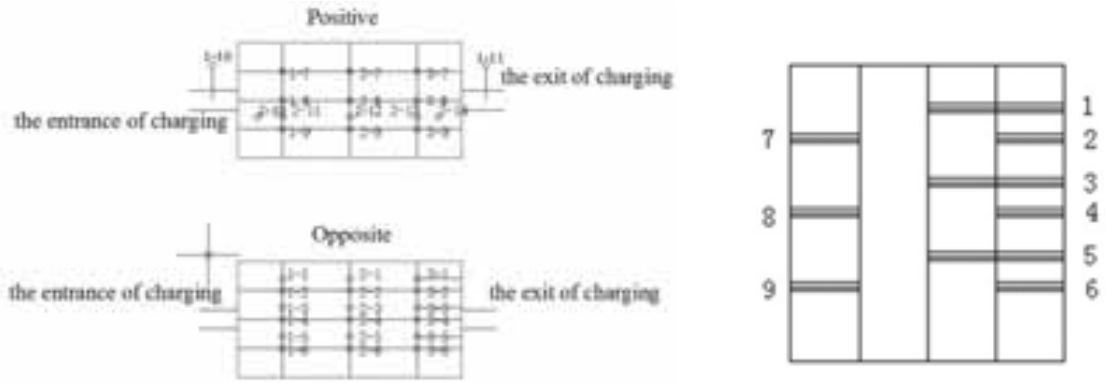

Fig.5 The position of the thermocouple in the packed bed thermal storage device

The thermocouples of 1-10 and 1-11 were measured the air inlet temperature and the air outlet temperature.

In order to measure the temperatures of honeycomb ceramic, 27 thermocouples were inserted into the thermal storage device and attached to the honeycomb ceramic surface. The thermal storage device is divided into three blocks along the length by thermocouples. The thermocouples of 1-1 to 1-9, 2-1 to 2-9 and 3-1 to 3-9 which were measured the honeycomb ceramic temperatures of the first block, the second block and the third block. The thermocouples of 2-10 to 2-14 were measured the surface temperature of the thermal storage device.

3 Experimental data analysis method

As shown in Fig.5, the arithmetic average temperature of each section is calculated as Equation (1):

$$T_{i,area} = \frac{\sum_{j=1}^{j=9} T_{i,j}}{9} \quad (i=1,2,3;\ j=1,2,\ldots 9) \qquad \text{(eq. 1)}$$

The average temperature of all the honeycomb ceramic in TES device is calculated as Equation (2):

$$T_s = \frac{\sum_{i=1}^{i=3} T_{i,area}}{3} \quad (i=1,2,3) \qquad \text{(eq. 2)}$$

The efficiency of the charging process is defined as the ratio of the net heat stored by thermal energy storage material and the total heat released by the hot air in the charging process, which can be expressed as the following equation:

$$\eta_c = \frac{M_S c_S [T_S(t_c) - T_S(0)]}{\int_0^{t_c} [T_{air,in} - T_{air,out}] c_{p_{air}} \dot{m}_{air}\, dt} \times 100\ \% \qquad \text{(eq. 3)}$$

The efficiency of the discharging process is defined as the ratio of the net heat which removed by the cold air and the total heat released by the thermal energy storage material during the whole discharging process, which can be expressed as the following equation:

$$\eta_d = \frac{\int_0^{t_d} [T_{air,out} - T_{air,in}] c_{p_{air}} \dot{m}_{air}\, dt}{M_S c_S [T_S(0) - T_S(t_d)]} \times 100\ \% \qquad \text{(eq. 4)}$$

4 Results and discussion

Several experiments under different thermal storage temperatures and air flow rates have been carried out and the thermal performance of the TES device was analyzed.

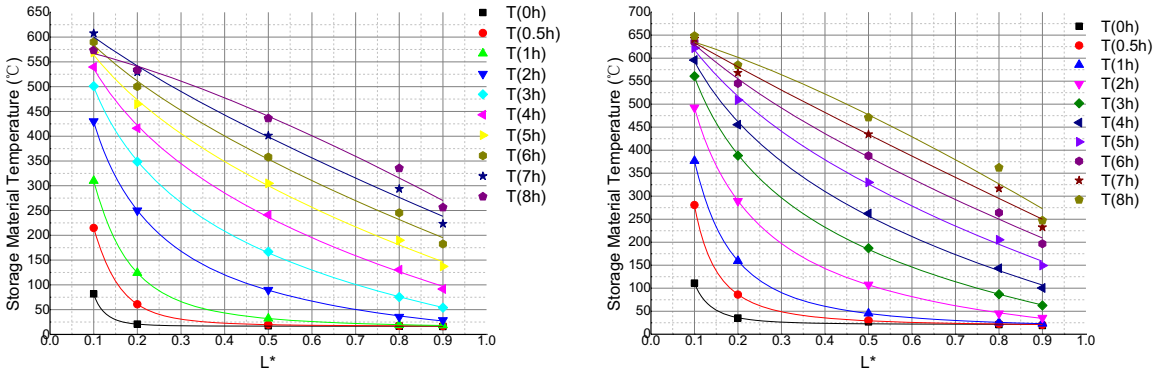
4.1 Temperature distribution

Fig.6 shows the temperature distribution in TES device during the charging process. To better compare the charging behaviour among TES, the temperature results of storage materials are reported using dimensionlesss coefficiencies for axial length, which was defined by equation (5). In this way, the L* can assume value between 0 and 1.

$$L^* = \frac{z}{L} \qquad \text{(eq. 5)}$$

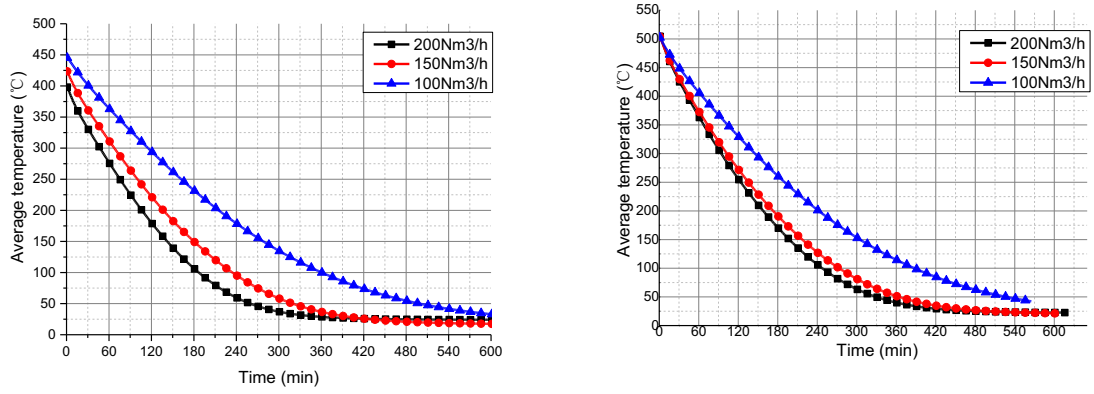
As shown in Figure.6, from the inlet to the outlet, the temperature distribution is obvious thermocline distribution. At the beginning, the temperature gradient is very steep, but the temperature gradient is more and more gently during charging process. When the charging temperature is higher, the temperature difference of thermocline is greater.

Fig.7 shows the average temperature distribution of storage material under different flow rates respectively at the initial temperature of 400℃ and 500℃during discharging.



（a）400℃　　（b）500℃

Fig.6 Storage material temperature distribution of charging process

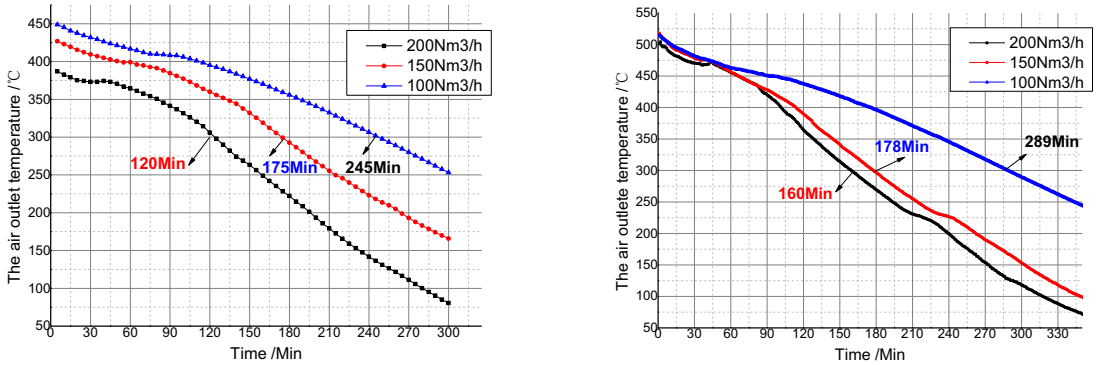


（a）400℃　　（b）500℃

Fig.7. Average temperature distribution of discharging process

From the figures, the average temperature drop of honeycomb ceramic material increases with the increasing air flow rates. The rate of temperature drop at the beginning discharging in TES device is significantly greater than the late stage of discharging. This is because the heat transfer rate between the air and the honeycomb ceramic material increases with the temperature differences increase.

Fig.8 shows the air outlet temperature variations under different air flow rates during discharging.



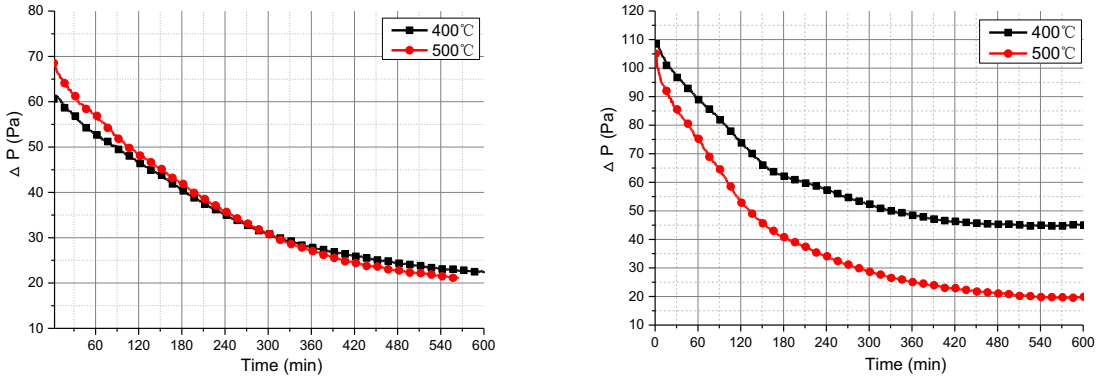
（a）400℃　　（b）500℃

Fig.8. Air outlet temperature variations of discharging process

Fig.8 indicated that the discharging time can be extended with the air flow rate decreased. The numbers in the figure mean the time that the air outlet temperature decreases from the initial temperature to 300℃. It can be seen that the time for the air outlet temperature declining to a specified value increases with the air flow rates decreases. The outlet temperature of air is higher when the temperature of honeycomb ceramic is higher at the begging of discharging.

4.2 Pressure Drop distribution

Fig.9 shows the pressure drop distribution in the TES device under different air flow rates.



(a) 100Nm^3/h (b) 150Nm^3/h

Fig.9 Pressure drop distribution with time

The pressure drop when air flowing through the TES device was kept below 110Pa under different discharging temperature. The pressure drop increases with the increasing air flow rate, and decreases with the decreasing air outlet temperature. From the pressure drop results it can be seen that porous structure material as the thermal storage material and air as the heat transfer fluid is feasible.

4.3 The thermal storage efficiency

In order to analyze heat transfer performance of the solid thermal storage system, the charging efficiency and the discharging efficiency under different flow rates and temperature have calculated using the equation (3) and equation (4).

Fig.10 shows the charging efficiency with time of the TES device under different air flow rate. Under different flow rate the highest charging efficiency have reached about 90%, and there was a maximum efficiency within 30Min, then the charging efficiency decreased with time. The reason is that convection and conduction between air and honeycomb ceramic are weakened with the temperature difference decreased. More and more heat can be exchanged to the honeycomb ceramic.

Fig.11 shows the discharging efficiency with time of the TES under different air flow rate and initial discharging temperature. As shown in Fig.11, the discharging efficiencies of the TES are higher than 85% under different air flow rate in 300 minutes. Under the same air flow rate, even though with the different initial discharging temperature, the discharging efficiencies of the TES are nearly same in 3 hours. It clearly indicates that the honeycomb ceramic material has a good thermal stability and high heat transfer performance. Besides, the greater the air flow rate in discharging process, the higher the heat efficiency of the TES. The heat transfer rate between the air and storage material increased with the air flow rate.

Fig.11 Discharging efficiency under different air flow rate

5 Conclusions

In this paper, the heat transfer characteristic of charging and discharging were researched by experimentally.

(1) A single tank TES of packed bed using air as heat transfer fluid and honeycomb ceramic as storage material is feasible. The temperature distribution is obvious thermocline in TES when charging and discharging processes. The discharging time can be extended with the air flow rate decreased.

(2) The charging efficiency of the developed TES device was higher than 75%, and the discharging efficiency was higher than 85%.

Analysis of a silica glass based high temperature thermal energy storage unit for concentrated solar power applications

Bruno Cárdenas[1], Noel León[1], Martin H. Bremer[1] and John Pye[2]

[1] Tecnologico de Monterrey, Campus Monterrey, Monterrey (México)

[2] Australian National University, Canberra (Australia)

Abstract

The design of a directly-charged high temperature thermal energy storage (TES) unit based on molten silica-glass is presented. The 126 kWh_{th} thermal storage unit developed is aimed to operate within a solar-driven domestic scale power generation system.

The paper discusses the proposed design for the unit as well as the restrictions set by the power generation system's requirements. The transient mathematical model used to analyze the behavior and performance of the thermal energy storage unit during the different stages of the intended work cycle is thoroughly explained. An important feature of the mathematical model is that the performance of the unit is not only evaluated from an energy viewpoint, but an in-depth exergy analysis has been additionally carried out.

The results obtained through the model are exhaustively analyzed; special focus has been given to the assessment of the performance of the storage unit to guarantee that the operational requirements of the power generation system are met. The overall performance of the TES unit is satisfactory; the unit is capable of supplying the required 4 kW_{th} output throughout the 16-hour discharge while it reaches its fully charged state during the subsequent 8-hour recharge. The proposed designed for the TES unit exhibits a round trip exergy-efficiency of 59%.

Keywords: *Solar thermal energy storage, molten silica glass, high temperature heat storage, thermal storage exergy analysis*

1. Introduction

One of the major difficulties solar based electric power generation systems face is the intermittent nature of the solar resource; therefore effective methods for storing the excess thermal energy collected during periods of high solar irradiation or periods of low energy demand are needed (Hasnain,1998).

Thermal energy can be stored in three different ways: as sensible heat, as latent heat or as chemical potential through reversible chemical reactions. (Sharma et al. 2009). Latent heat storage (LHS) offer a number of benefits over sensible heat storage systems (SHS) such as higher energy densities and a nearly isothermal energy output at the phase change temperature (Zalba et al. 2003, Farid et al. 2004, Kenisarin, 2010).

An enormous amount of research has been devoted to the development of LHS systems, which are deemed as a very promising technology; however, their widespread utilization has been slowed down by the low thermal conductivity of phase change materials (PCM) and other drawbacks related to their use. (Liu et al. 2012, Cárdenas and León, 2013. Liu et al. 2015). Nowadays, large scale concentrated solar power (CSP) plants still use sensible heat materials such as rocks, synthetic oils and molten salts. A more thorough description of the state of the art of thermal energy storage for power generation can be found in the literature (Gil et al. 2010, Medrano et al. 2010, Ushak, 2015, Steinmann, 2015),

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.02.02 Available at http://proceedings.ises.org

It has been broadly demonstrated that LHS has many advantages over SHS; however, there are materials whose potential as sensible storage medium has not been carefully considered yet, despite possessing outstanding properties, as is the case of soda-lime silica glass, which has high specific heat capacity, it is remarkably cheap and it is neither flammable, corrosive nor toxic.

The present research work focuses on the design and modeling of a soda-lime silica glass based high temperature thermal energy storage (TES) unit with the objective of laying the groundwork on the utilization of recycled soda-lime silica glass as a thermal energy storade medium. The unit will work in a novel solar driven micro-CHP (combined heating and power) system; however, it is thought that the concept could be scaled-up for larger CSP applications.

2. Operation within the micro-CHP system

The TES unit will operate within a solar-driven domestic distributed power generation system in which solar radiation is captured through a 30 m^2 Fresnel lens (Ramirez, 2015). Considering the solar irradiation in Monterrey, Mexico, the Fresnel Lens supplies an average power of 18.75 kW_{th} during daytime (idealized as an 8-hour period). The concentration spot of the lens strikes directly onto the reception surface of the TES unit, whose interior is filled with soda-lime silica glass (recycled from windows and bottles) that acts as the heat storage medium. As the solar radiation enters the TES unit the temperature of the storage medium increases until reaching approximately 1000°C; storing thus the incoming solar energy in the form of heat. The TES unit is connected through a heat exchanger to a 1 kW_e Stirling engine with an estimated efficiency of 30 %, which will generate electric power continuously throughout the day.

The TES unit will operate in a temperature range from 500°C to 1000°C; below 500°C the TES unit is not able to maintain the Stirling engine operating. The cyclic operation of the unit comprises two stages: an 8-hour charge (storage) period and a 16-hour discharge period . In addition to that, there is an initial charging step (not part of the cycle) in which the TES unit is brought from ambient temperature to its operating temperature of 1000°C at the heat extraction surface.

During the 16-hour (corresponding to the remaining 2/3 of the day) discharge step, the TES unit has to deliver 4 kW_{th} (defined based on the Stirling efficiency and heat exchanger losses) with no solar input. The temperature of the heat extraction surface must remain above 500 °C during the whole period. Then follows the 8-hour recharge stage in which the TES receives solar radiation once again but still maintains the 4 kW_{th} output. At the end of the recharge period, the temperature of the heat extraction surface must have reached 1000°C, so that the TES unit is fully charged and is able to undergo the subsequent 16-hour discharge period, thus maintaining a cyclic operation.

3. Concept developed for the TES unit

The TES unit proposed, shown in Figure 1, consists of a prismatic refractory concrete container whose interior is divided into smaller cavities by several equidistant vertical graphite slabs (walls), between which the approximate 82 L of glass are distributed. Two grooved rectangular graphite plaques keep the walls in vertical position and evenly spaced inside the container. The TES unit has a storage capacity of 126.3 kWh_{th} when fully charged (i.e. when the heat extraction surface is at 1000° C). The outer dimensions of the unit including insulation are: a length of 143.2 cm, a depth of 90.5 cm and a total height of 68.4 cm.

The concentrated solar radiation coming from the lens enters the TES unit through its top side (due to a system requirement) and is conducted inwards by means of the vertical walls. The walls are designed to enhance the internal heat transfer, as the soda-lime silica glass to be used has a very low thermal conductivity; facilitating thus the charge and discharge of the TES unit and helping to achieve a uniform temperature distribution throughout its interior.

The heat extraction is carried out by means of a heat transfer fluid (HTF) in contact with the bottommost graphite surface; the design of the heat exchanger design is out of the scope of the present paper and will not be discussed. In addition to the use of a heat transfer enhancement method (the vertical graphite walls), the height of the TES unit was kept to a minimum for allowing the heat stored in the upper portions of glass to

reach the discharge area rapidly and impeding it from prematurely reaching the 500°C limit.

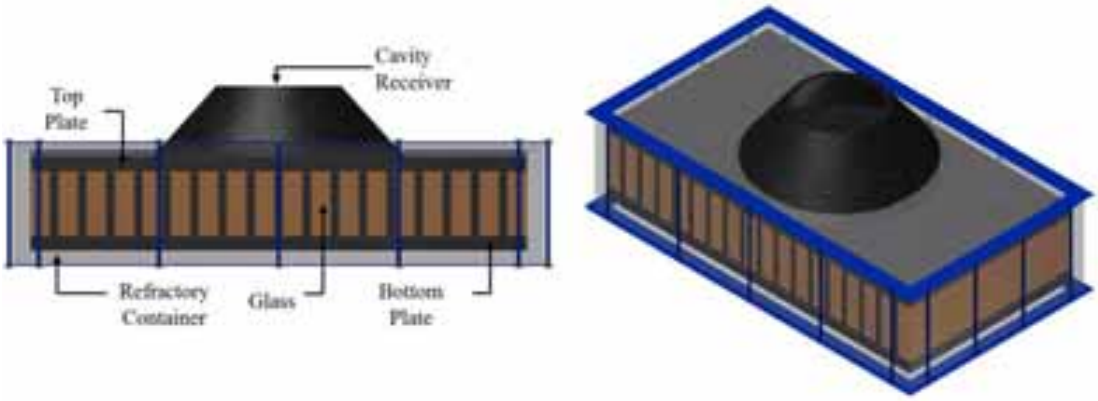

Figure 1. Views of the core of the proposed TES unit design

The cavity receiver was designed trying to emulate a blackbody, although further work is intended to refine the design. The incident solar rays are reflected many times on the interior before finally escaping from the aperture; with each reflection a fraction of the energy, is absorbed and after many reflections, the incoming radiation is mostly absorbed. The temperature of the material will increase, it will start to radiate heat and the same effect will occur; the cavity wall will absorb its own radiation and heat losses will be minimized. A radiation shape factor $F_{1\text{-}2}$ of 0.205 was achieved, which means that 20.5% of the heat that the bottom surface irradiates escapes through the aperture while 79.5 % is re-absorbed by the lateral wall of the cavity.

4. Mathematical modeling of the performance of the TES unit

4.1 Transient mathematical model developed

A transient mathematical model was developed for analyzing the thermal behavior of the TES unit throughout the cyclic operation. The model is primarily based on equations (Eq.1) and (Eq.2), the former being the one-dimensional heat conduction equation and the latter being the first law of thermodynamics for an incompressible material:

$$Q = (k \cdot A \cdot \Delta T \cdot \Delta t)/\Delta x \quad \text{(Eq.1)}$$

$$Q = m \cdot C_p \cdot \Delta T \quad \text{(Eq.2)}$$

The model originates with two main assumptions; the first one is that within a component there are no temperature gradients, meaning that the temperature is uniform over the cross-sectional area of each element. The second one is that there is no convection in the molten glass due to its elevated viscosity, which is 104 Pa·s at the flow point (920 °C) for the average composition of soda–lime silica glass. (Shand, 1958); thus, all the internal heat transfer during the complete work cycle of the TES unit is assumed to be due only to conduction.

To perform the calculations each component of the geometry of interest is divided into elements. Thereafter, an energy balance is made for each element stating that the difference between the energy entering and the energy leaving the element over a certain time-step is equal to the energy that is stored by the element.

The energy balance is performed for every element over n time-steps until a certain time or condition such as a final temperature is reached. During a given time-step a certain amount of heat is received by an element n at a temperature *T*. During the same time-step some energy leaves the element *n*, which is still at the same temperature *T*; a part of the energy leaving the element goes into the next element *n+1* while another part of it is lost to the ambient, depending the case. The difference between the energy that the element n received minus the energy conducted from the element n to the element *n+1* and the lost heat, is the energy stored by the element *n* during that particular time-step.

The energy stored by the element causes an increase in its temperature, given by Eq.2; this increase in temperature entails a change in the specific heat capacity and thermal conductivity of the material. It is

important to mention that in order for the model to have numerical stability and accurately simulate the real heat transfer phenomena a previous study (sensibility analysis) for determining the maximum time step permissible, which is a function of mesh size and temperature differences, must be carried out.

The interactions between elements are explained graphically in Figure 2. A power input of 18.75 kW_{th} (average power supplied by the Fresnel lens) is applied to the top-most surface of the top graphite plate, which conducts energy to both, glass and graphite elements in contact with its lower surface.

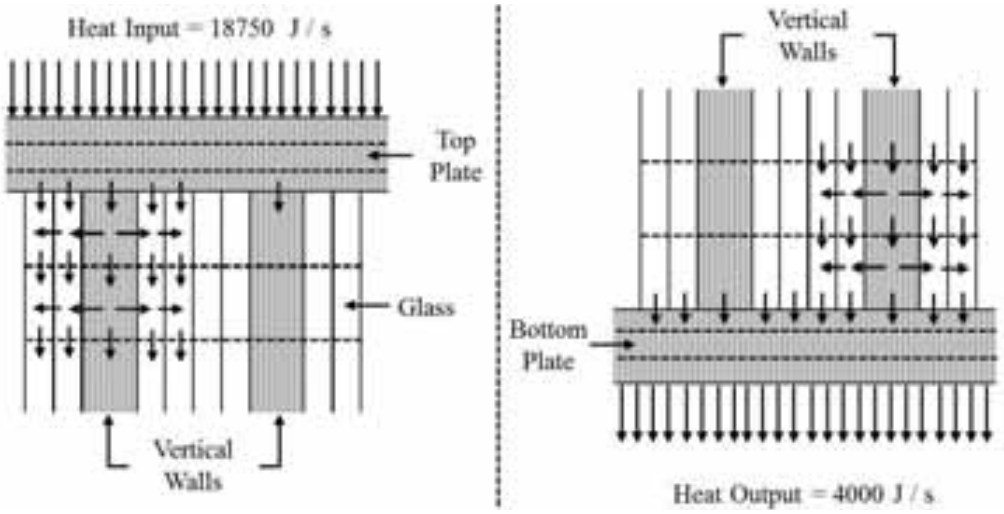

Figure 2. Thermal interactions between elements of the geometry defined for the model

The behavior of every graphite wall and the glass in the cavity next to it is assumed to be the same for every wall-cavity set; therefore only one graphite wall and the glass at one if its sides are calculated. The elements of the graphite wall conduct heat downwards to the next element of the wall and sideways to the glass next to them. The first element of glass, in a similar fashion, conducts heat to the glass element below it and to the glass element on its side; finally, the second glass element conducts heat exclusively downwards into the glass element below it. The other half of the glass in the cavity is assumed to be heated by the contiguous graphite wall; i.e. each graphite wall only interacts with half of the glass on the cavity next to it.

The bottom graphite plate receives heat from the glass and graphite elements above it, as shown in Figure 4. Except for the initial charge period, a load of 4 kW_{th} is permanently applied to its bottom-most surface to simulate the energy discharge.

The model does not calculate the temperature increase of the graphite frustum. It is assumed that the piece is able to absorb all the incident radiation that is reflected by itself; therefore, an absorptivity of 1.0 was employed for the graphite. The radiative losses were calculated based on the area of the bottom surface of the frustum and the calculated shape factor of 0.205; as aforementioned, only 20.5% of what the surface is emitting is actually lost to the surroundings.

Polynomial equations were created for the temperature dependent properties of the main materials, i.e. graphite and an average composition of soda-lime silica glass. The equations created follow the general form shown in Eq.3 and represent the average of the experimental data presented by several authors. Table 1 provides the coefficients for the calculation of the specific heat capacity (C_p) and thermal conductivity (k) of both materials.

$$C_p, k = AT^5 + BT^4 + CT^3 + DT^2 + ET + F \quad \text{(Eq.3)}$$

An important aspect of the mathematical model is the exergy analysis of the TES unit. In addition to calculating via the energy balance the energy stored by an element *n* during every time-step, the total energy accumulated by each element is also accounted for. This makes possible calculating the total exergy stored by the element through the exergy equation for an incompressible mass (Eq.4), and consequently, the exergy destroyed as well as the exergy-based efficiency of the TES unit.

$$X = (U - U_0) - T_0(S - S_0) \quad \text{(Eq.4)}$$

In the model, an exergy balance (Eq.5) is performed every time-step for each of the elements defined to obtain the exergy destruction at every element of the system. One of the difficulties the exergy analysis presents is quantifying the exergy content of the incident solar radiation, since the balance requires an exergy input for the calculation. Eq.6 is used as the exergy input for the balance (Petela, 2003) in which i is the amount of solar radiation, α is the absorptance of the material, and T_{sun} is considered as 5778 K.

$$X_{in} - X_{out} - X_{dest} = \Delta X_{system} \quad \text{(Eq.5)}$$

$$X_{Sun} = i\left[1 + \frac{1}{3}\left(\frac{T_0}{T_{sun}}\right)^4 - \frac{4}{3}\left(\frac{T_0}{T_{sun}}\right)\right]\alpha \quad \text{(Eq.6)}$$

The exergy transfer (X_{in}, X_{out}) comes from the heat transfer (Q) from an element at a certain temperature T to another element, for the case of conducted heat it may be accounted for as follows:

$$X_{heat} = (1 - T_0/T) \cdot Q \quad \text{(Eq.7)}$$

Evaluating a system exclusively through an energy-based efficiency could be misleading; because, even though most of the incoming energy is conserved or recovered, it will be degraded by all the internal heat transfer that occurs during the storage process causing the loss of some potential for performing work.

A notable aspect of the model developed is that it can be used for a different storage material other than soda-lime silica glass as long as the consideration of no convection is not overlooked. If it is desired to calculate the performance of a TES unit with a different storage material that undergoes a phase transition from solid to liquid, or is liquid the whole time, it is very important to evaluate if due to its viscosity and the size of the cavities in which it is contained the assumption of no convection is valid. If the storage medium is a solid material, either crystalline or amorphous, and stays solid throughout the work cycle, the model is applicable right away.

4.2 Analysis of the behavior and performance of the TES unit

Not all of the temperature profiles calculated through the mathematical model are displayed in the following Figures for the sake of an easier understanding; however, the profiles presented depict accurately the overall behavior of the TES unit. Figure 3 shows the geometric location within the unit of each of the temperature profiles shown further on in the graphs, i.e. where the temperatures are “measured”.

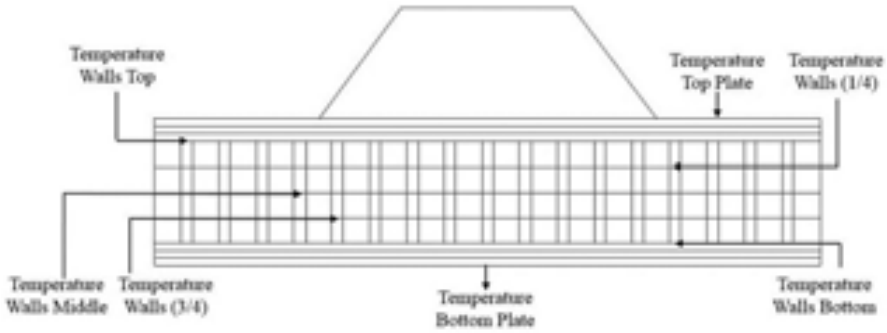

Figure 3. Geometric locations within the TES unit of some representative temperature profiles

Figure 4 shows the temperature profiles of some elements during the initial charge period, in which the 4 kW output is not present. As expected, the temperature of the first element of the top plate (where radiation strikes) is the first to increase followed by the temperatures of the rest of the elements of the different components. The temperatures, except for a short period at the beginning of the heating, increase at a very constant rate; the maximum difference between the temperature of the top plate and the temperature of the bottom plate recorded during the heating process is 87.8°C while an average difference of 76.7°C was observed throughout the heating process.

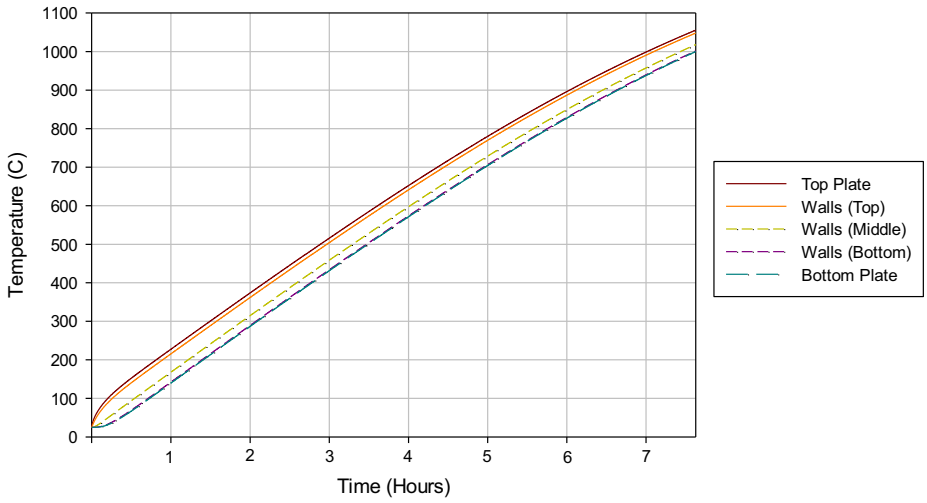

Figure 4. Representative temperature profiles during the initial charge period

The TES unit reaches its goal temperature of 1000°C in the lower surface of the bottom plate in approximately 7 hours and 38 minutes. From a micro-CHP system point of view, this is quite convenient since the TES unit could be heated up from ambient temperature to its operating temperature in 1-day time with the Fresnel lens and no external aid.

It is noteworthy that the temperature profiles of the glass elements are not included in Figure 4; the reason for this is that throughout the entire heating process the profiles of the two glass elements adjacent to each of the 30 vertical graphite wall elements maintain a very close temperature to that of their respective wall element. During the complete heating process, the difference between the temperature of the glass elements and the graphite wall element never surpassed 4°C, this rather small temperature difference suggests that the vertical graphite walls are well spaced inside the refractory container and that they are indeed facilitating the distribution of the thermal energy in the interior of the TES unit.

Figure 5 shows the temperature profiles of some representative elements of the TES unit during the discharge (or cooling) period obtained through the mathematical model. The state of the elements after the last time-step of the initial charge period is used as the starting point for the discharge stage. A load of 4 kW_{th} is applied to the bottom-most element of the bottom plate and both, the heat input and radiation losses, are set to zero; assuming that during the discharge period the cavity could be covered with insulation since there need not be an aperture for the concentrated beam from the lens.

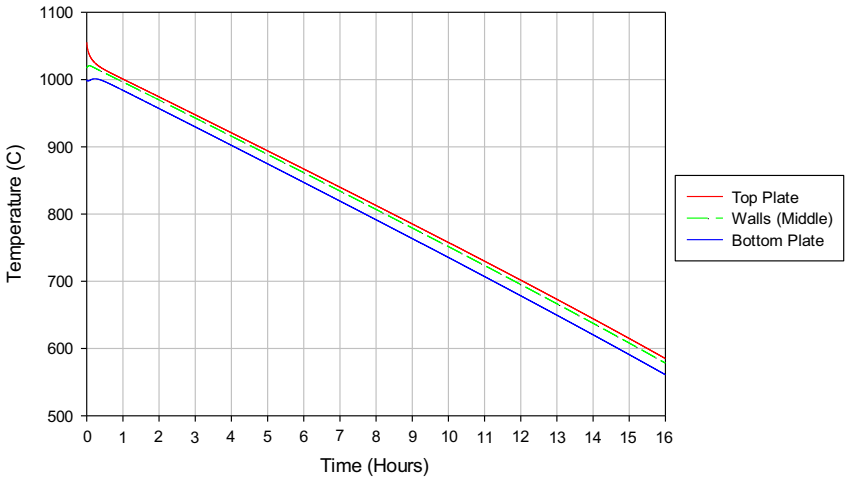

Figure 5. Representative temperature profiles during the 16-hour discharge period

As can be seen, the TES unit is capable of supplying the constant 4 kWth during the required 16-hour period, at the end of which the temperature of the bottom plate is 561°C while the temperature of the top plate is 585°C, a difference of just 24°C. The reduced height of the unit helped to minimize the temperature difference between the top and bottom plates; having such a small temperature difference at the end of the discharge period indicates a very thorough discharge of the TES unit.

Similarly to the initial charge period, the temperatures of the two glass elements adjacent to each of the 30 vertical graphite wall elements remain very similar to the temperature of their respective wall element throughout the complete discharge period. The difference between the temperature of the glass elements and the elements of the vertical wall never exceeds 2.5°C.

Figure 6 shows the temperature profiles of some representative elements during the recharge (storage) period, in which the heat input from the Fresnel is available once again but the 4 kWth output is still supplied. The last time step of the discharge process is used as the starting point for the 8-hour recharge stage. During this period, the lower surface of the bottom plate must reach 1000 °C so the TES unit is able to undergo the following 16-hour discharge period, thus maintaining a cyclic operation.

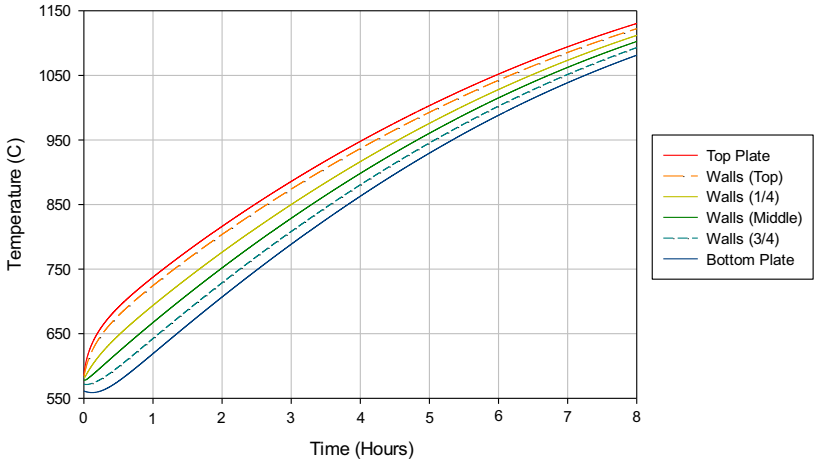

Figure 6. Representative temperature profiles during the 8-hour recharge period

The temperature profiles spread at the beginning of the heating; slightly before the first hour of heating the maximum temperature difference between the top and bottom plates of 118.8°C is reached; after this point the temperature difference between elements decreases with time. The average temperature difference between the topmost and bottommost temperature profiles throughout the complete period is 84.1°C. The temperature of the glass elements is, like in the initial charge and discharge periods, still very close to the temperature of their respective wall elements.

It may be noted that higher temperatures than those used at the starting point of the discharge are reached.

This overshoot may be eliminated, for instance, by defocusing the Fresnel lens of the micro-CHP system; however, it is not necessarily an issue. Reaching higher temperatures than necessary at the end of the recharge means that there is some tolerance in the system that would allow the TES to be fully charged in days with less-than-average conditions when the Fresnel is not capable of supplying the average 18.75 kW_{th} considered in the model. The complete work cycle of the TES unit is shown in Figure 7; the highest and lowest temperature profiles within the unit are displayed in red and blue, respectively. All the other profiles comprised between them are not presented for an easier understanding.

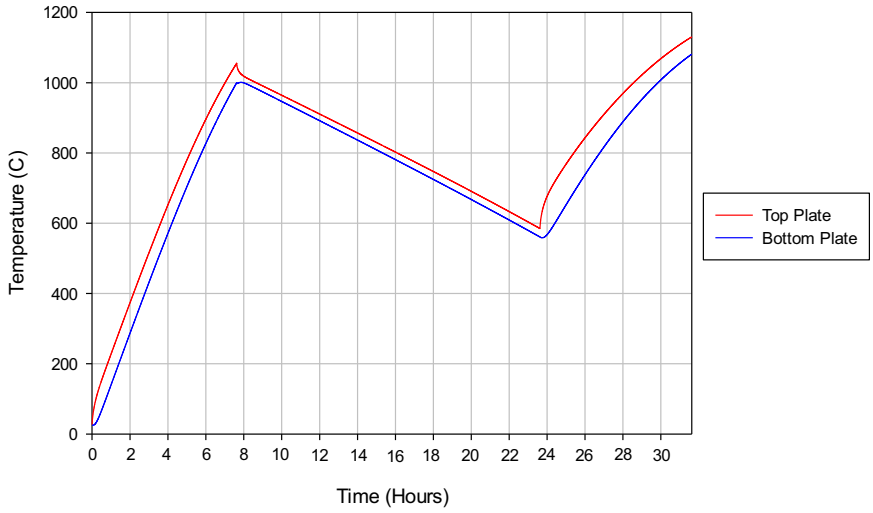

Figure 7. Highest and lowest temperature profiles throughout the complete work cycle

The change in the energy stored by the TES unit throughout the complete work cycle and its distribution in each of the components is shown in Figure 8. At the end of the initial charge period the TES unit has 454.87 MJ (126.35 kWh_{th}) of thermal energy stored, of which 51% is stored in the glass, 19.2 % in the graphite walls, 15.4 % in the top plate and 14.4 % in the bottom plate.

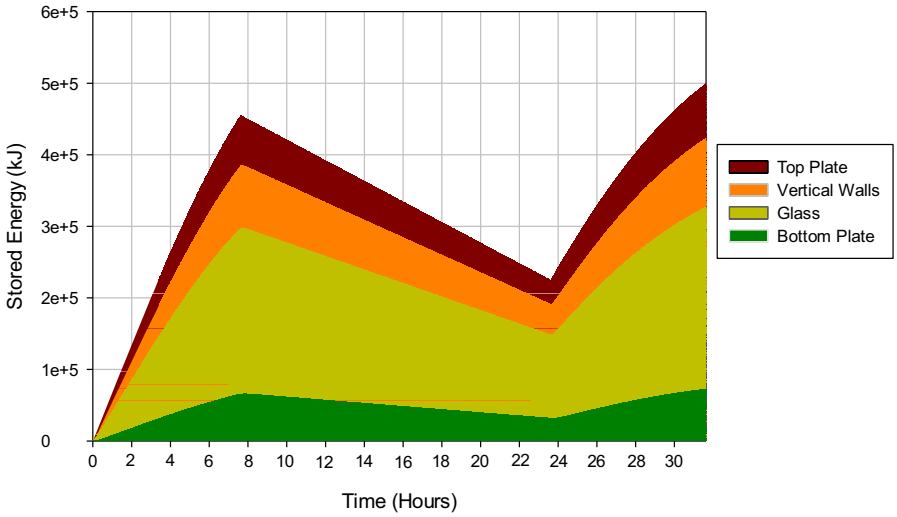

Figure 8. Energy stored in the TES unit throughout the complete work cycle

At the end of the discharge the TES unit is practically out of usable energy, only 0.964 MJ (0.26 kWh_{th}) are left in the unit, meaning that the concept developed allows a very thorough heat extraction. It is important to emphasize though, that the energy stored in the components as sensible heat from ambient temperature to 500°C, approximately 223.5 MJ (62.08 kWh_{th}), remains permanently stored in the TES unit as there is a defined minimum temperature limit for the heat extraction. Certainly those 62.08 kWh_{th} stored below 500°C could be used for low temperature applications such as heating water; however, the present modeling of the TES unit is not considering heat extraction below the established lower limit of 500°C.

Figure 9 shows the change in the exergy stored by the unit throughout the complete work cycle and its distribution in each of the components, calculated through Eq.4. At the last time-step of the initial charge (when the unit is fully charged) 268.4 MJ of exergy are stored, which is 59 % of the total energy stored. This value represents the maximum theoretical limit for the amount of the energy stored that could be transformed into work by an ideal engine or work producing device.

The exergy stored in the TES unit follows a very similar distribution than that of the energy, at the end of the initial charge period, 51.2% of the total exergy is stored in the glass, 19.1 % in the vertical walls, 15.3 % in the top plate and 14.4 % in the bottom plate. The stored exergy increase rate becomes smaller as the temperature of the elements rise because entropy becomes greater with increasing temperatures.

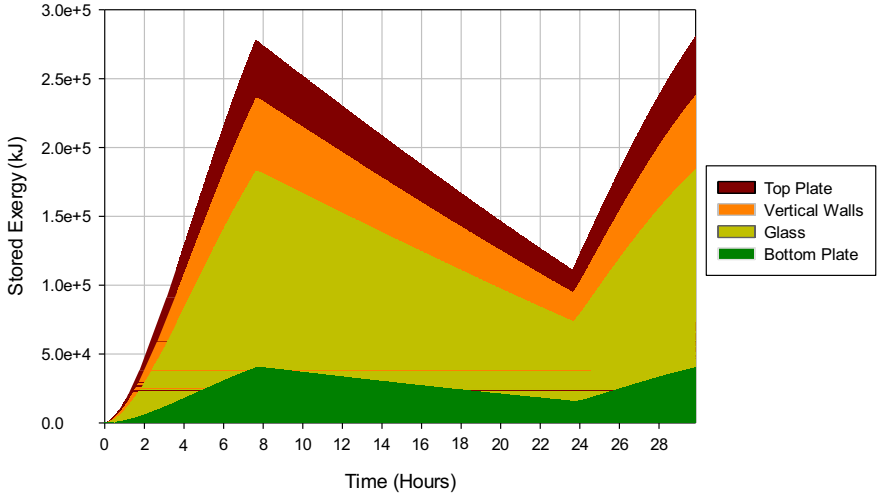

Figure 9. Exergy (work potential) stored in the TES unit throughout the complete work cycle

In order to have a proper closed cycle, the recharge period is cut before the 8 hours at the point in which the TES unit reaches its full-charge state, thus the overshoot that occurs at the end of the recharge is not considered for the round-trip exergy efficiency.

At the end of the discharge the total exergy destroyed is 0.866 MJ; which is less than 1% of the exergy stored at the beginning of the discharge. As the temperatures of the components decrease and become closer to each other the exergy destruction rate becomes smaller. Of the exergy destroyed during the discharge 50.8% occurs in the graphite walls, while the glass accounts for 26.45%, the bottom plate 22.6% and the top plate a minimal 0.14%.

During the recharge period, up to the point where the TES unit returns to the cycle initial state, the total exergy destroyed is 86.43 MJ, which represents 22.1 % of the exergy supplied by the Fresnel during that period. The amount of exergy destroyed during the discharge period is considerably smaller than during the recharge because during discharge there is only destruction due to the little heat conduction between components and the temperatures are very close to each other, while during the recharge there is a great amount of exergy input, with bigger temperature gaps and exergy is destroyed due to the actual process of storing energy.

As the temperatures of the components increase and become closer to each other the exergy destruction rate becomes smaller. Approximately 94.4% of the exergy destruction during the recharge occurs in the top plate where concentrated radiation is received, graphite walls account for 3.7 % while 1.7% is destroyed in the glass and only 0.2 % in the bottom plate.

Figure 10 presents a summary of the exergy balance of the TES unit during the discharge and recharge periods, the initial charge is not considered since it is not part of the cyclic operation, it occurs sporadically when the unit is discharged below the lower limit due to a cloudy day, for instance. Of the total 390.88 MJ (108.58 kWh_{th}) of exergy supplied by the Fresnel lens during the recharge period considered, 58.5 % is extracted from the TES for driving the Stirling engine during the discharge and recharge periods, 42.2% and 16.3% respectively, 18.7 % is lost as thermal radiation at the cavity and 22.3% is destroyed: 22.1 % during

the recharge and an almost negligible 0.22% during the discharge period.

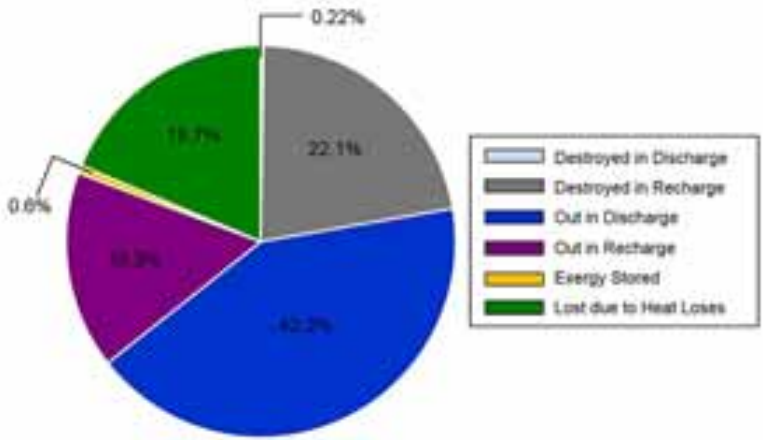

Figure 10. Exergy balance of the TES unit for the discharge and recharge periods

The TES unit has an energy-based efficiency of 72.2 % while it presents an exergy-based efficiency of 59%. In general, the energy efficiency of renewable energy systems has been found to be always greater than their exergy efficiency (Park et al. 2014), with which the analysis shown in the present paper is in agreement.

5. Shortcomings and opportunity areas in the design

This study presents a functional design for a glass-based TES unit capable of meeting the requirements of the solar driven micro-CHP system within which it will operate; nonetheless, there are still opportunity areas for the betterment of the concept, therefore optimization works should be carried out.

Preliminary tests have shown that graphite at high temperatures experiences a severe oxidation when exposed to air. The inner components are protected by contact with the molten glass; however, the issue remains for the exposed upper graphite components such as the cavity. The use of a layer of molten glass covering the interior of the receiver will be assessed, although stainless steel shields are still deemed as a good option.

The frustum-shaped receiver allows reducing radiative losses from the TES unit's inlet surface; however, its configuration has not been yet optimized. Covering the opening of the cavity with a glass plate, which is translucent to concentrated solar radiation but opaque to thermal radiation emitted by the graphite surface could help to achieve a further reduction of the radiative losses.

Although no concluding signs were found in the post-experimental assessments, devitrification of the storage medium is a latent possibility. Assuring a sufficient cooling rate for the glass in the unit is important, otherwise, it would start to devitrificate, (i.e. decompose into the elements from which it is formed). A cooling rate of approximately $8.7x10^{-3}$ Ks^{-1} is expected during the discharge of the TES unit. The critical cooling rate for silica glasses oscillates between 10^{-2} and 10^{-3} Ks^{-1} (Le Bourhis, 2008), thus the expected cooling rate of the glass in the TES unit should be sufficient for avoiding crystallization.

Theoretically, devitrification should not alter greatly the storage capacity of the TES unit. The heat capacities of silicate glasses can be closely approximated by the partial contribution of each component according to their percentage in the composition (Stebbins et al.1984, Richet, 1987), Consequently, if devitrification did occur, there would not be a significant loss in the storage capacity per unit mass of the storage medium; however, the internal thermal behavior of the TES unit could be largely modified by the different thermal conductivities of the components.

Another important area for improvement is the exergy efficiency of the storage unit. The design hereby presented attained an exergy efficiency of 59%. The internal graphite components account for a big part (~20%) of the exergy destruction. The development of a parametric model would allow improving the system in this sense by allowing exploring changes in the geometry that improve performance but don't alter much the cost of the system.

6. Concluding remarks

Soda-lime silica glass is exceedingly interesting as a sensible heat storage medium because of its elevated specific heat capacity, high chemical stability, low toxicity and flammability, and a remarkably low cost; however its use for said purpose has not been sufficiently evaluated.

A concept for a silica-glass based thermal energy storage unit for a micro-CHP system is presented. In this directly charged concept, the molten glass is enclosed in a refractory concrete container together with several narrowly spaced vertical graphite walls, whose purpose is distributing the energy uniformly throughout the storage medium. A transient mathematical model was developed for analyzing the thermal behavior of the proposed TES unit throughout the cyclic operation. The results obtained reveal a satisfactory overall performance and provide important and encouraging information. The following points may be highlighted:

- The initial charge of the unit lasts approx. 7 ⅔ hours, meaning that a unit at ambient temperature can be fully charged in 1 day time using exclusively solar power.
- Due to its effective internal design, the unit is capable of supplying the 4 kW output during the entire 16-hour discharge period maintaining a temperature superior to the 500 °C lower limit.
- During the 8-hour recharge, the unit reaches its fully charged state, whereby the continuous operation of the system is assured.

An important aspect of the mathematical modeling is the exergy analysis that was carried out. It has been found that of the total exergy (108 kWh) supplied by the solar concentrator during the recharge period, 59 % is used for driving the Stirling, 19 % is lost due to heat losses in the cavity receiver and 22 % is destroyed. The TES unit exhibits therefore an exergy efficiency of 59% while it presents an energy efficiency of 72.2%. Once the system has been further optimized, it is hoped that the combination of low-cost materials and simple fabrication could make this a cost-effective system able to meet the long term goal of $15 USD per stored kWh of heat (U.S Department of Energy, 2013).

The article presents a functional design capable of meeting the requirements of a novel solar-driven power-generation system; nonetheless, there is still a vast area of opportunity for the improvement and optimization of the proposed glass-based thermal energy storage unit.

Analysis of Fluid Flow and Heat Transfer inside a Spherical Container Encapsulated by Molten Salt

Adrián Belinchón Ovejero, Selvan Bellan, José González-Aguilar, and Manuel Romero

IMDEA Energy Institute, Ramon de la Sagra 3, 28935 Móstoles, Spain

Abstract

A mathematical model of melting process inside a spherical container, which is filled with phase change material, is developed to describe the characteristics of heat transfer and flow inside the capsule for high temperature storage systems. The finite element method is used to solve continuity, momentum and energy equations. The main intention of this investigation is to derive a dimensionless correlation for effective thermal conductivity. The correlation can be used in packed bed models to study the thermal performance of the thermal energy storage systems. The capsule is filled with sodium nitrate since its melting point is in the operation range of concentrated solar power plant. The shell of the capsule is made up of nickel, which is uniformly heated at the external surface. The enthalpy-porosity method is used to track the solid-liquid interface. The model is, validated with the reported experimental results, used to investigate the influence of pellet size and Stefan number.

Keywords: *Thermal energy storage system; Latent heat; Melting of PCM; Effective thermal conductivity*

1. Introduction

In latent heat thermal energy storage systems packed with spherical pellets, the phase change process inside the pellets plays a vital role since the overall performance of the storage tank depends on this process. Thus, it has been received great importance, considerable number of investigations on this subject has been made by both theoretically and experimentally (Assis et al., 2007; Felix et al., 2006; Hosseinizadeh et al., 2012; Ismail and Henríquez, 2000). One dimensional conduction models were developed, to study the phase change process inside a spherical capsule, by assuming the solid portion of the PCM remains at the center of the sphere, neglecting the solid core movements (e.g. Felix et al., 2006; Ismail and Henríquez, 2000). Two dimensional axisymmetric models were developed to study the flow, natural convection-dominated melting, and the movement of the solid PCM portion during melting process (e.g. Assis et al., 2007; Hosseinizadeh et al., 2012). The melting of n-octadecane in a glass spherical container was investigated numerically and experimentally by Moore and Bayazitoglu (1982) and found that the natural convection effects can be neglected at small Stefan numbers. Bareiss and Beer (1984) investigated the phase change process in cylindrical geometries; the predicted melting rate showed good agreement with the experimental data presented by Moore and Bayazitoglu (1982). Using the analysis made by Bareiss and Beer (1984), an analytical solution for the melting rate at the lower surface of the solid core in a spherical capsule was presented by Roy and Sengupta (1987).

The melting process of n-octadecane in an open spherical glass container was numerically investigated by Hosseinizadeh et al. (2012). A uniform temperature boundary condition was imposed at the outer wall of the shell. The developed model was validated with the experimental results reported by Tan (2008). Furthermore, a number of experimental and analytical investigations have been made on the heat transfer and buoyancy driven flow during melting of PCM inside spherical capsules. However, the literature survey shows that most of the past studies focused on low temperature storage applications. The literature is lack of

doi:10.18086/swc.2015.02.03 Available at http://proceedings.ises.org

melting of PCM in the closed container in high temperature range, especially in the operation range of parabolic CSP plants (300-500 °C). Accordingly, this study aims at developing a two dimensional axisymmetric model to study the natural convection dominated melting process inside a spherical container in high temperature range and, to derive the dimensionless correlation of effective thermal conductivity for packed bed models.

2. Mathematical modeling

The computational domain is shown in Fig.1. An axi-symmetric model is developed by assuming the solid and liquid phases of the PCM are homogeneous and isotropic; the flow is laminar and incompressible; the phase change process takes place in the interval between 306.3°C and 306.8°C; where the density in the mushy zone varies linearly from 2130 kg/m^3 to 1908 kg/m^3. The temperature dependent liquid phase density is defined as (Archibold et al., 2014)

$$\rho_{liq} = \rho_m / \beta(T - T_m) + 1 \qquad \text{(eq. 1)}$$

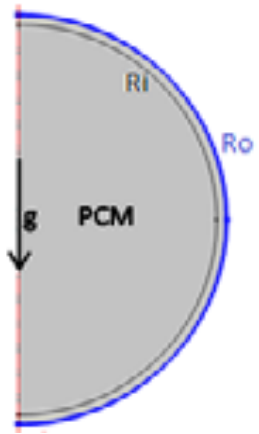

Fig.1: The computational domain

As the PCM volume changes during the phase change process, the elastic deformation takes place in the shell material (Archibold et al., 2014; Tanvir et al., 2015). The enthalpy-porosity method is used in the phase change range, by which the porosity in each element is equal to the liquid fraction in that element. Thus, the porosity is zero in solid regions. Based on the foregoing assumptions, the governing equations; continuity, momentum, and energy, are;

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \vec{\mathrm{V}}) = 0 \qquad \text{(eq. 2)}$$

$$\rho \frac{\partial \vec{\mathrm{V}}}{\partial t} + \rho(\vec{\mathrm{V}}.\nabla)\vec{\mathrm{V}} = -\nabla P + \nabla.\left[\mu\left(\nabla\vec{\mathrm{V}} + \left(\nabla\vec{\mathrm{V}}\right)^T\right)\right] + \rho\vec{g} + A(\gamma)\vec{\mathrm{V}} \qquad \text{(eq. 3)}$$

$$\rho \frac{\partial h}{\partial t} + \rho\,\vec{\mathrm{V}}.\nabla h = \nabla.(k\nabla T) \qquad \text{(eq. 4)}$$

where ρ, $\vec{\mathrm{V}}$, P, μ, k, h and T are density, velocity vector, pressure, dynamic viscosity, thermal conductivity, specific enthalpy and temperature respectively. The porosity function A(γ) is defined by Eq. (5)

$$A(\gamma) = \frac{C(1-\gamma)^2}{\gamma^3 + \varepsilon} \qquad \text{(eq. 5)}$$

where the computational constant (ε), and the melting front morphology constant (C) are 0.001 and 10^5 kg/m^{3}s respectively. The specific enthalpy (h) is defined as the sum of the sensible enthalpy h_{sen} and enthalpy change due to phase change γL, where L is the latent heat of the material. The melt fraction, γ, is defined by eq. (6). Thermo-physical properties of the sodium nitrate are given in Table 1. The finite element method based commercial software COMSOL multiphysics 4.2 (2014) is used to solve the governing equations. In

order to optimize the mesh of the model, grid dependent tests were carried out for four various mesh distributions; the total number of elements was 5012, 10046, 14066 and 18506 respectively. The results given by the mesh generated with 10046 elements were, significantly deviated from the mesh with 5012 elements, analogous to the results produced by 14066 and 18506 elements. Thus, the mesh with 10046 elements was used for all calculations.

$$\gamma = \begin{cases} 0 & if\ T < T_{sol} \\ \dfrac{T - T_{sol}}{T_{liq} - T_{sol}} & if\ T_{sol} \le T \le T_{liq} \\ 1 & if\ T > T_{liq} \end{cases} \qquad \text{(eq. 6)}$$

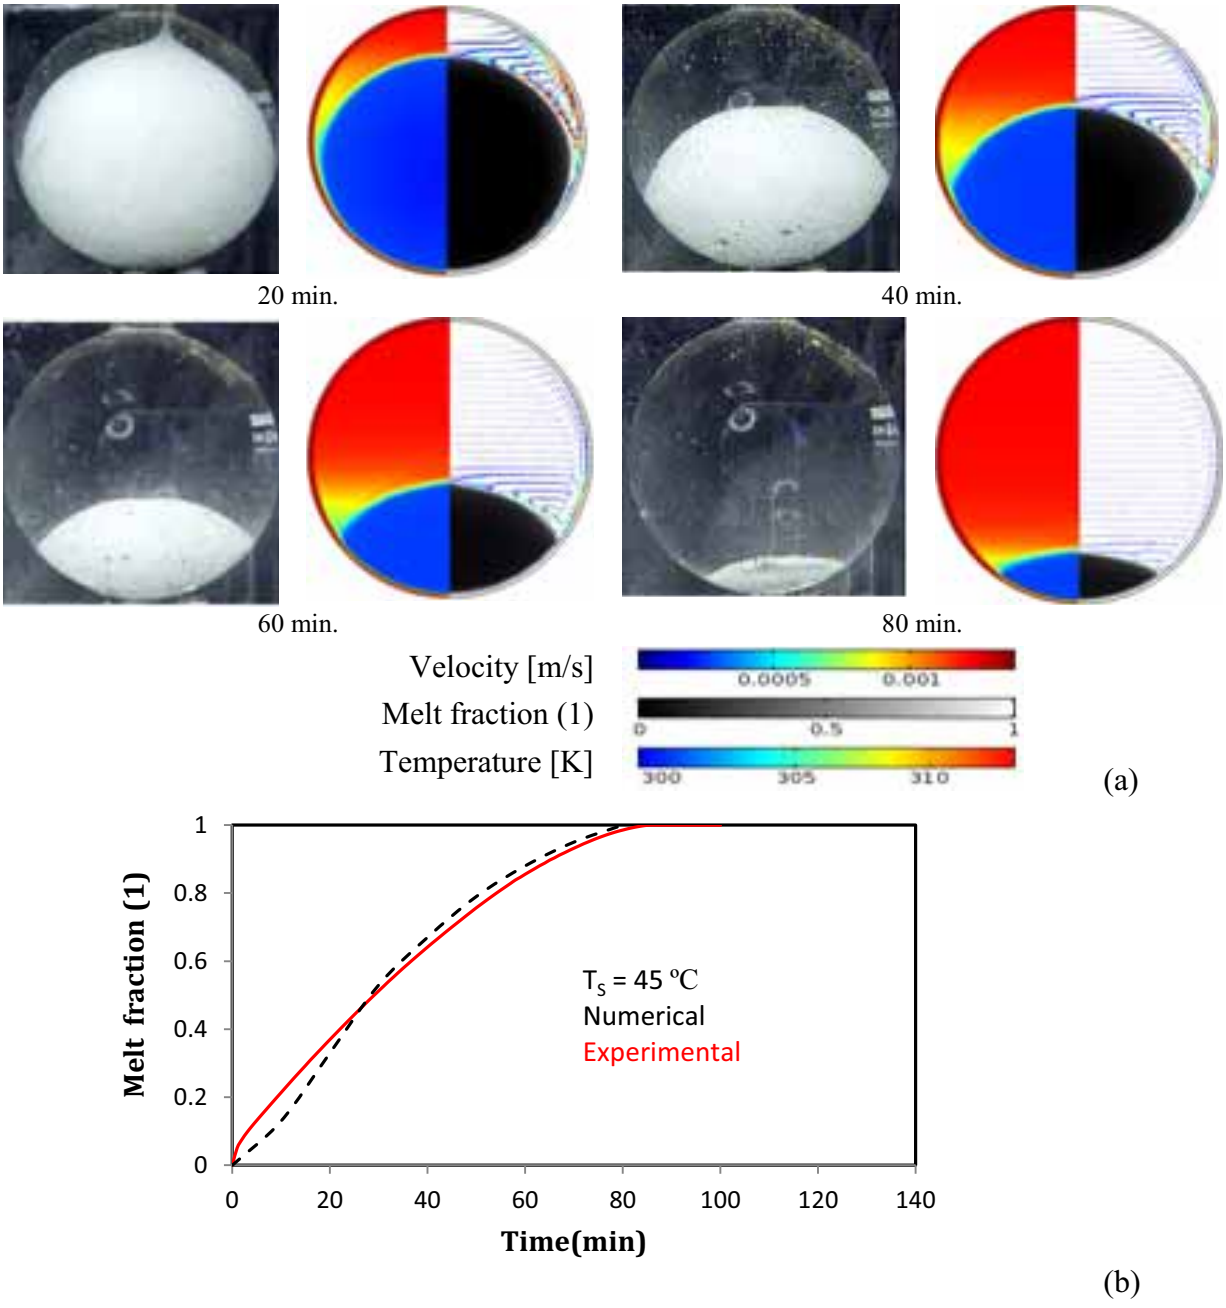

Fig. 2: Experimentally captured (Tan, 2008) and numerically predicted (a) melting front at various stages for T_s = 40ºC (b) melt fraction as a function of time for T_s = 45ºC

In order to validate the model, simulations were performed for the experimental conditions reported by Tan

(2008). In their experiments, the n-octadecane was, used as PCM, filled in a 50.83 mm inner radius capsule and 1.5 mm wall thickness. Initially, the capsule was kept at 1°C less than the melting point (29°C), when t>0 the outer surface of the capsule was fixed at 40°C. Simulation was performed for the same condition. The melting phase front, temperature and velocity distribution of the capsule during melting process are shown in Fig. 2(a) at 20 minutes intervals. Experimental photographs of melting process of the capsule are compared with the numerical results. In simulation results, the left side represents the temperature distribution and the right side represents the melt fraction and the velocity vector. Similarly, simulation was carried out for another case, where the outer surface temperature was fixed at 45°C. Fig. 2 (b) shows the comparison of experimentally measured (Tan, 2008) and numerically predicted melt fraction of the capsule. As can be seen in the figure, a good agreement is found between the numerical and experimental results.

Table 1. Thermo-physical properties of sodium nitrate

Properties	Sodium Nitrate
Density (kg/m^3)	
solid phase	2130
mushy zone	*Linear interpolation*
liquid phase	$\rho_{liq} = \rho_m / \beta(T - T_m) + 1$
ρ_m	1908
Dynamic viscosity (kg/m s)	$0.0119 - 1.53x10^{-5}T$
Latent heat of fusion (J/kg)	178000
Melting temperature (℃)	306.8
Specific heat (J/kg/K)	$444.53 + 2.18T$
Thermal expansion coef.(1/K)	$6.6x10^{-4}$
Thermal conductivity (W/m/K)	$0.3057 + 4.47x10^{-4}T$

3. Results and discussion

Using the validated model, simulation was performed to predict the melting process of a nickel spherical shell (thickness=0.5 mm) of radius 10mm, completely filled with molten salt. Initially, the capsule was kept at 301.5 °C and at t>0, the outer wall temperature was fixed at 311.5° C. Fig. 3 shows the temperature distribution and the corresponding melting process of the capsule at different stages. Each subfigure shows temperature distribution (left), melt fraction (right; black and white gradient), and natural convection flow velocity in the PCM liquid phase (right). During the initial stage of melting, the heat is transferred to the PCM through shell by conduction.

Once the melting process started at the inner surface of the shell, the natural convection starts to influences the melting process, the formed liquid PCM is heated by the inner surface of the shell. As the density changes between the solid and liquid phases, the solid part comes down due to gravity and the liquid flows upward and generates buoyancy driven flow. The heated fluid at the inner surface of the shell transfers the heat to the cold fluid close to the solid-fluid interface. Thus, an unsteady counter-clockwise circulating flow is formed above the solid part of the PCM during melting process. As a result, the melting process is faster at the top part of the solid phase and changes the spherical shape of the solid part into oblate spheroid shape as shown in the figure.

Influence of Stefan number and the capsule size on the melting process of the capsule is studied by various cases as shown in Table 2. By keeping the capsule size constant, simulations were carried out for cases 1-3 to study the effect of thermo-physical condition of the capsule (difference between the initial and outer wall temperature). Fig. 4 shows the melt fraction of the capsule as a function of time. As can be seen in the figure, an increase of temperature difference between the initial and outer wall temperature (T_S-T_0) can decrease the complete melting time. The complete melting time decreases about 8.5% and 4.5% respectively when increasing the temperature difference around 33% and 25%. The effect of pellet size on the melting rate for constant boundary conditions is presented in Fig. 5. The initial temperature and the wall temperature are

fixed and simulations were carried out for various capsule radii: 10, 15 and 20 mm. As expected, the complete melting time is decreased when the capsule size is reduced.

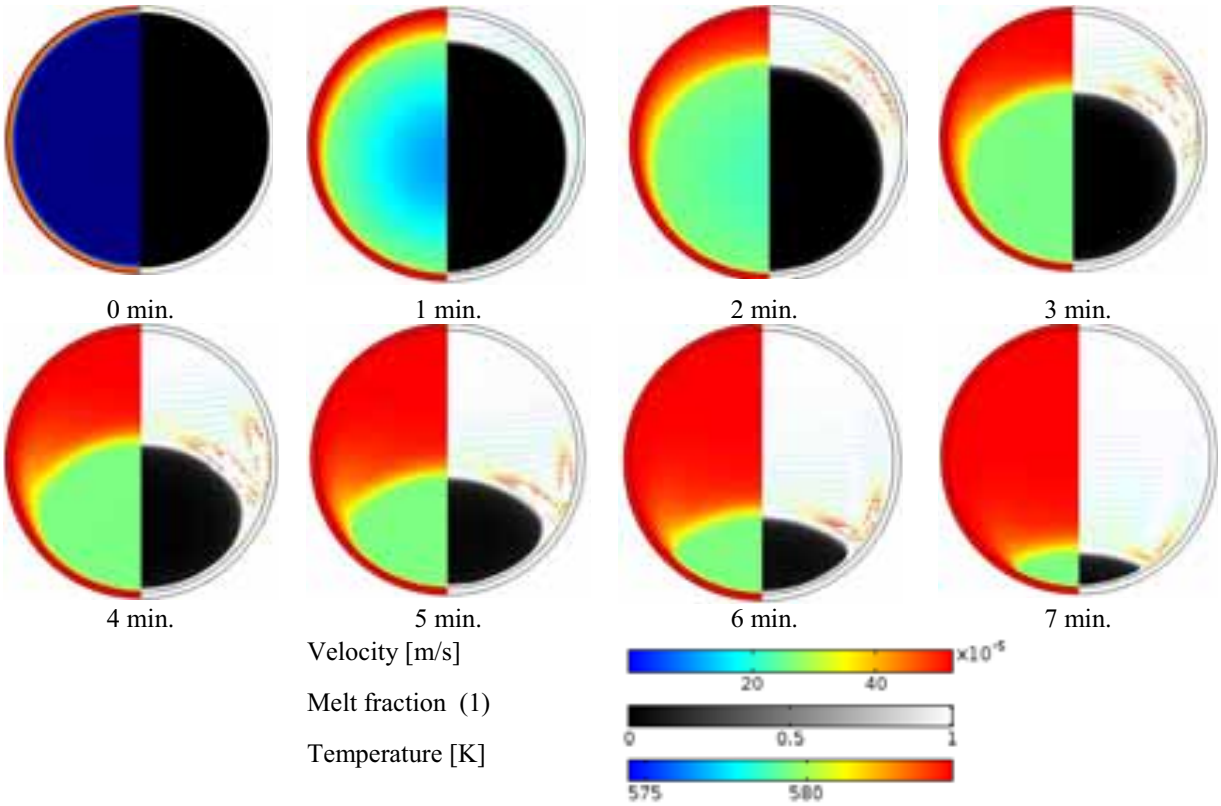

Fig. 3: Temperature distribution and the corresponding melting process of the capsule at different stages

Table 2 Analyzed cases

Case	Pellet radius (R_i) [m]	Initial Temperature (T_0) [ºC]	Surface Temperature (T_S) [ºC]	T_S-T_0 [ºC]
1	0.010	301.5	311.5	10

In order to study the performance of the thermal energy storage system packed with spherical PCM capsules, various packed bed numerical models have been developed in the past few decades (e.g. Bellan et al., 2014a, 2015a, 2015b). As explained in the previous sections, natural convection plays vital role during melting process. However, most of the melting process models only considered the thermal conduction due to complexity in incorporating the natural convection effect during melting process. The convective effect present in the liquid region during melting can be incorporated to the packed bed system by using the effective thermal conductivity correlation. To derive that correlation for the given set of cases as shown in Table 2, one dimensional conduction model for phase change process inside a capsule has been developed by enthalpy formulation method, based on the literature models (Bellan et al., 2014b; 2014c). The correlation given in eq. (7) is used to calculate the effective thermal conductivity

$$k_{ef} = k_L C Ra^m \qquad \text{(eq. 7)}$$

In order to obtain the *C* and *m* coefficients, various values were assumed and the corresponding melt fraction evolution was predicted as a function of time. Then, the appropriate coefficients were obtained by comparing the 2D axi-symmetric model results obtained in the previous section. Initially, the coefficient of *C* was fixed at 0.18 (Bellan et al.,2015b), and calculations were made for case 1. Fig. 6 (case 1) shows the complete melting time predicted by the given correlation (Eq. 7) for various m coefficients. The complete melting time predicted by the 2D model is marked by asterisk symbol. Thus, the coefficient *m* is predicted for case 1, which is 0.26. Similarly, the coefficient *m* is predicted for other cases as shown in the figure. From this approximation, the generalized correlation is derived and given in eq. 8, which produces the same results of axisymmetric model.

$$k_{ef} = k_L 0.18 Ra^{0,243} \qquad \text{(eq. 8)}$$

4. Conclusion

An axisymmetric model has been developed to predict the heat transfer, fluid flow due to natural convection, and phase change process. The developed model has been validated with reported experimental and numerical results. Then the influence of pellet size and the Stefan number on the heat transfer characteristics and the melting process have been studied. From the axisymmetric model results, an effective thermal conductivity correlation has been derived using one dimensional model. The derived correlation can be used to simulate the charging behavior of packed bed thermal energy storage system with spherical capsules.

Experimental investigation of the heat performance using a packed bed of ceramic balls for high temperature thermal energy storage unit

Bei Yang[1], Yan Wang[1], Fengwu Bai[1]

[1] Key Laboratory of Solar Thermal Energy and Photovoltaic System,

Institute of Electrical Engineering, Chinese Academy of Sciences, Beijing 100190, China

Abstract

A thermal energy storage (TES) system was designed based on a packed bed of ceramic balls as storage material and air as heat transfer fluid (HTF). A series of contrast experiments were carried out under specified working conditions to analyze the heat performance of TES unit. The results showed that temperature distribution in axial direction of the packed bed and thickness of thermal stratification can be manually controlled by adjusting the air flow rate or the heating power during charging to achieve a better discharging performance. The packed bed has a good temperature uniformity along the radial direction which means a less exergy loss and smaller convective mixing radially. It was also shown that the TES unit has a highest discharging heat power of 16.5 kW, and discharging efficiency of 90%, indicating that the TES unit can achieve to store and release heat effectively.

Keywords: *Packed bed, Thermal storage, Sensible heat, Air, Ceramic balls*

1. Introduction

TES is vital for the solar thermal electricity technologies due to the random solar irradiations. The form of sensible heat storage in packed-bed of solid material is especially suitable for the system whose heat transfer fluid is air, and the cost of fabrication of tank and the heat storage material is significantly lower than other methods (Markus Hanchen et.al 2011). A wide body of publications describes numerical models for sensible heat storage in packed-beds (Antoni Gil et al., 2010; G. Zanganeh et al., 2012, 2015; Jon T. et al. , 2011; Opitz and Treffinger, 2014), but only a few include experimental investigation. The numerical results show that the porous structure maximizes heat transfer between fluid and storage media and minimizes heat transport inside the storage media.

In this paper, the design, fabrication, test of a packed-bed TES unit were described. And indicators including thermal stratification, radial temperature difference, discharge outflow temperature, discharging power output and thermal efficiency were analyzed to evaluate the heat performance.

2. Pilot-scale TES design and experimental setup

2.1. A packed-bed TES device

The packed-bed TES unit is shown schematically in Fig.1, which consists of one cylindrical shell and two conical shells. The two conical shells are arranged on the top and the bottom of the tank respectively, used to be connected with the pipes and form a raletively uniform air flow. The tank has a circular cross section with a inner diameter of 0.7 m, and a total height of 4 m. The circular tank wall is made of refractory bricks, with a thick of 100 mm. The refractory brick has a a small coefficient of thermal expansion and a raletively high strength, which can help to reduce the effect of thermal ratcheting caused by thermal expansion of the storing material; In addition, the low thermal conductivity of the refractory brick can help to reduce the heat loss as

doi:10.18086/swc.2015.02.04 Available at http://proceedings.ises.org

well. Outside the refractory bricks is a 100-mm layer of asbestos insulation, while outside which covered a 6-mm layer of stainless steel shell.

The tank is filled to the height of 2.3 m with high alumina ceramic balls with an equivalent sphere diameter of 25mm, shown as Fig.2. The physical parameters of the ceramic balls are shown in table 1. A porous metal perforated strainer is installed inside the bottom of the tank, supporting the weight of the storage materials, and avoiding the ceramic balls and debris dropping and blocking the following pipes at the same time.

Fig.1 Photo of packed-bed TES unit

Fig.2 Photo of ceramic balls

Table1. Physical parameters of ceramic ball and packed bed

Al_2O_3(%)	Packed-bed Porosity*	Density (kg m^{-3})	Specific Heat Capacity (kJ $kg^{-1}K^{-1}$)
65	0.463	2200	1.0

*Remarks: porosity is calculated as the ratio between the volume of solid material and the tank capacity in packed height.

2.2. A packed-bed TES testing system

Fig.3 shows the layout of the packed-bed TES testing system. The testing system consists of a blower, an air heating furnace, a packed-bed TES unit using ceramic balls as TES material, and regulating valves. The ambient air pumped from the blower can be heated to 600-900℃ by the 60 kW electric heating furnace, and then the hot air enters through the inlet pipe from the top, flows through the packed bed to charge the ceramic balls. Charging from the top allows the exploitation of the buoyancy effect to create and maintain thermal stratification inside the packed bed, keeping the hottest region being at the top. During discharging, the direction of the flow is reversed as cold air is circulated through the tank from the bottom.

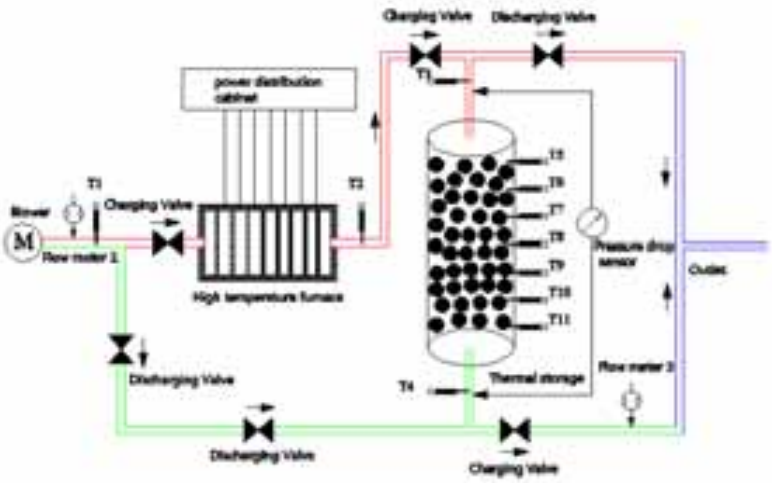

Fig.3. Schematic of packed-bed TES system

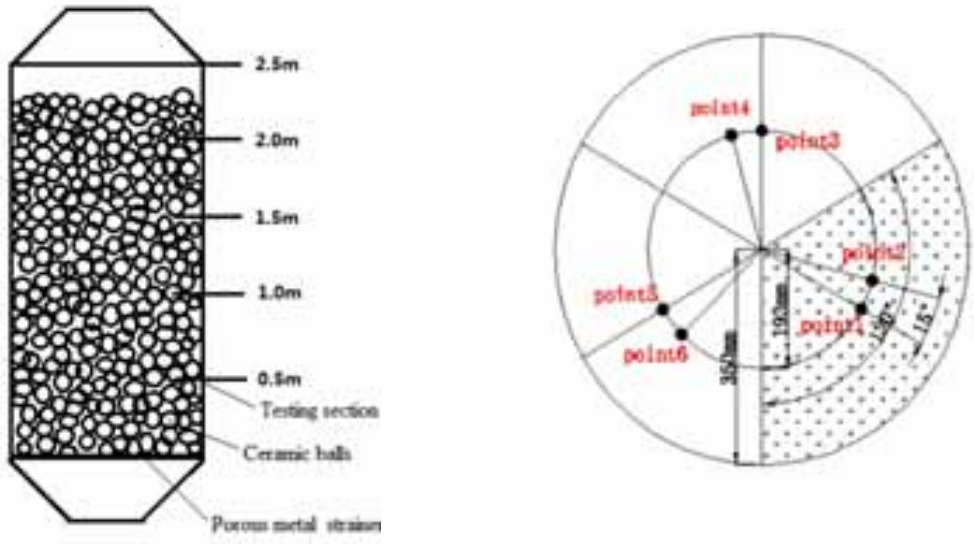
During the charging and discharging processes, the temperature is recorded by 43 K-type or S-type thermocouples throughout the system, of which 30 thermocouples are located inside the packed bed at different vertical positions. Along the height of packed bed, 5 measurement sections are arranged in every 0.5-m high, and 6 thermocouples are arranged in each section, shown as figure 4, notably that the thermocouples at the height of 2.5 m are not covered with ceramic balls; 2 thermocouples measure the temperature just above the packed bed on the tank axis and 2 in the bottom outlet pipe. In addition, other measurements include: ambient air temperature, the air flow rates at the inlet and outlet of TES system, and pressure drop when the air flowing through the packed bed. The thermocouples have an accuracy of ±0.5%. The flow meters installed at the inlet of system is a volumetric flowmeter with a measuring range of 15~300m^3/h and outlet a vortex-shedding flowmeter with range of 80~800m3/h, both of which share a common accuracy of ±0.5%.



(a) (b)

Fig.4. Distribution of testing sections in packed bed (a) and testing points in each section (b)

3. Results and Discussion

In order to analyze the charging and discharging performance of the packed-bed TES system, several experiments were carried out under different working conditions with an initial discharging temperature of solid storage material about 500℃ and a discharging air flow rate of 50 Nm³/h, 100 Nm³/h, 150 Nm³/h respectively.

3.1. Temperature distribution

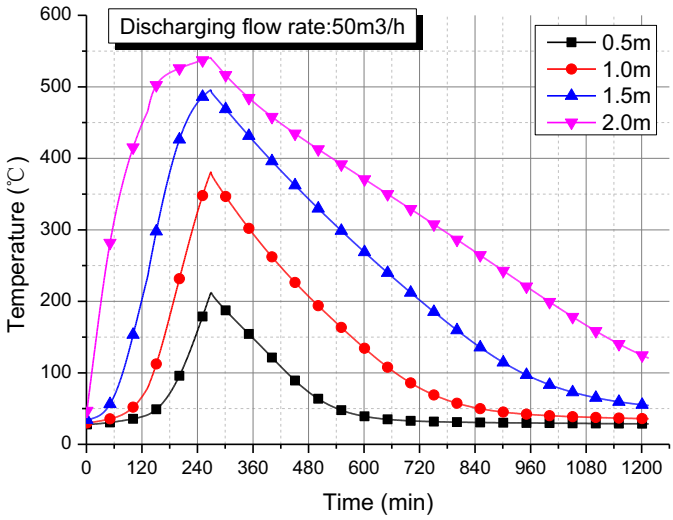
During the charging and discharging processes, the transient temperatures of ceramic balls were recorded by the thermocouples arranged at different heights of the packed bed. 6 thermocouples were adopted in each measuring section to ensure measurement accuracy. Thus, the average temperature at each section can be calculated as equation (1):

$$T_i = \frac{\sum_{j=1}^{j=6} T_{i,j}}{6} (\mathrm{i} = 1, 2, 3, 4) \qquad \text{(eq.1)}$$

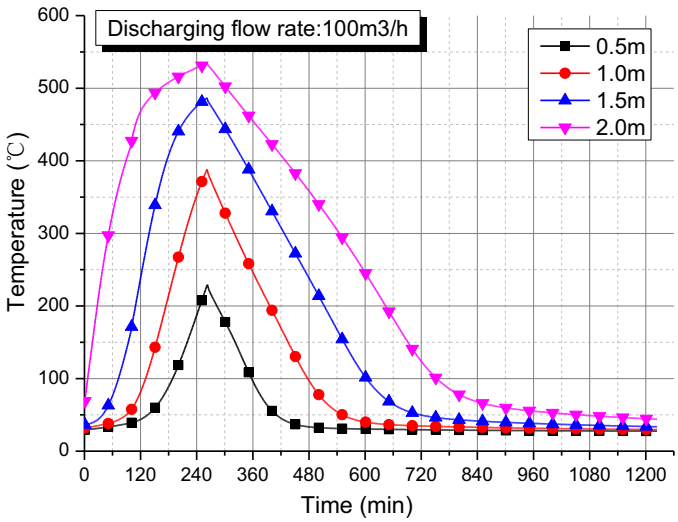
Where, i=1,2,3,4 refers to the temperature testing section at the height of 0.5m, 1.0m, 1.5m, 2.0m respectively.

3.1.1 Transient temperature distribution of the ceramic balls

(a)



(b)



(c)

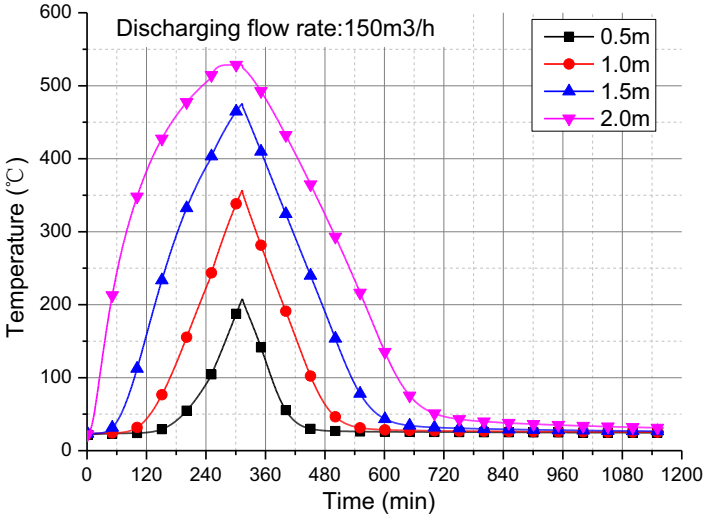


Fig.5. Transient changes of temperature distribution of ceramic balls under various conditions

(a.50 Nm³/h b. 100 Nm³/h c.150Nm³/h)

Figure 5 show the temperature distribution of ceramic balls under three different conditions. The charging conditions were not strictly controlled but manually adjusted to ensure a similar initial discharging temperature distribution of the packed bed at the end of charging. Seen from the figures, at the end of

charging temperature of ceramic balls at the height of 2.0 m is up to around 530 ℃, while at the height of 0.5 m around 210 ℃, which means the temperature difference between the top and the bottom is over 300℃. The reason for this obvious thermal stratification inside the packed bed is mainly that the air buoyancy effect was fully exploited by charging from the top and discharging reversed which keeping the hottest region being at the top and the coldest at the bottom. The experimental experience indicated that temperature distribution of packed bed and thickness of thermal stratification could be manually controlled by adjusting the air flow rate or the heating power during charging.

While during discharging the air flow rate was strictly controlled to be 50 Nm³/h, 100Nm³/h, 150Nm³/h respectively. Seen from figure 5, temperature drops of the ceramic balls increase obviously with the increasing air discharging flow rate, since the convective heat transfer between air and solid material is distinctly enhanced with a higher air velocity. After cold air enters the packed bed from the bottom, it exchanges heat with the ceramic balls from bottom to top, and the temperature of air is gradually raised while the heat energy is extracted for its further use.

It's worth noting that the air temperature rising during discharging is directly related to the thermal stratification of packed bed at the end of charging. Therefore, it is possible to match the air temperature rising and the thermal stratification of packed bed by the means of charging process control and air preheating before discharging etc., which can minimize the heat transfer temperature difference between air and solid materials, namely minimize the irreversible energy loss, and maximize the exergy efficiency of the TES system eventually.

3.1.2 Transient discharging outflow temperature

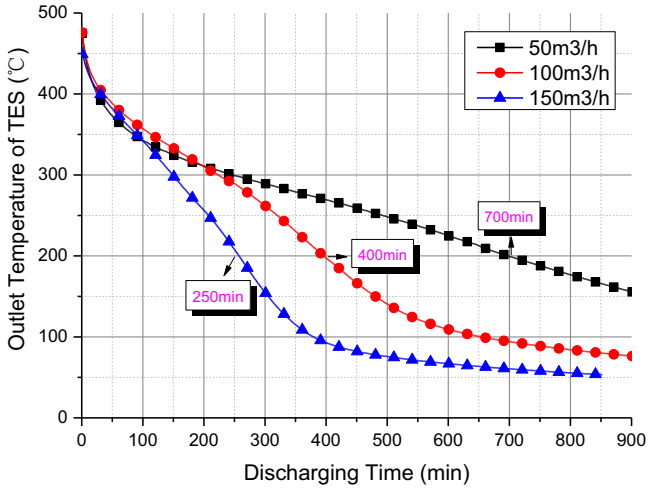

Fig.6. Transient changes of dischaging outflow temperature under different flow rates

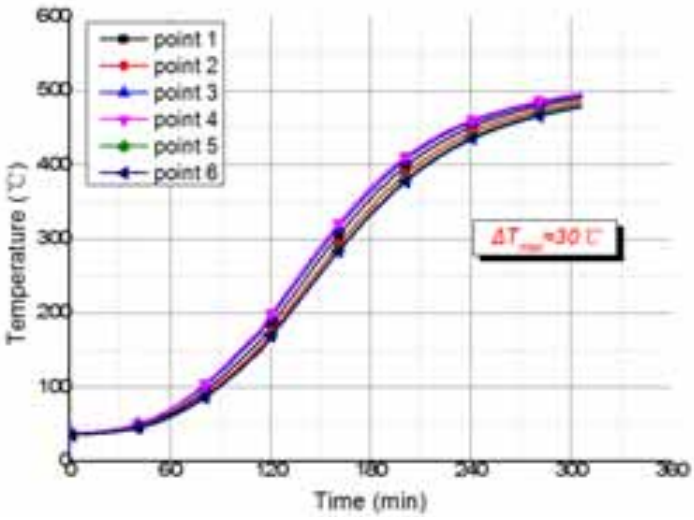
Figure 6 shows the variation of outlet air temperature under different air discharging flow rates. Seen from it, the highest air outlet temperature is up to about 480 ℃, and it takes a period of 250min, 400min, and 700min for the outflow temperature decreasing from 480℃ to 200℃under the discharging flow rate of 50 Nm³/h, 100 Nm³/h, 150 Nm³/h respectively when the initial discharging temperature distributions are roughly the same. The results indicated that certain air outlet temperature and certain quantity of heat extracted can be obtained by controlling the discharging air flow rates, which leads the discharging process to last for various period of time, and then meets demand of various thermal storage applications.

3.1.2 Radial temperature difference in top testing section

Figure 7 shows the transient changes of radial temperature difference in the top testing section, which reflects uniformity of radial temperature distribution in the packed bed. As can be seen from the figure, the radial teperature difference is respectively about 30 ℃ and 10 ℃ during charging and discharging process when the discharging air flow rate is 100Nm³/h, showing that the packed bed has a good uniformity along the radial direction. The main reason for this phenomenon is that the packed bed has a raletively high porosity of 0.463, which makes it possible for air to flow evenly in packed bed and maximizes heat transfer between air and ceramic balls.

(a)



(b)

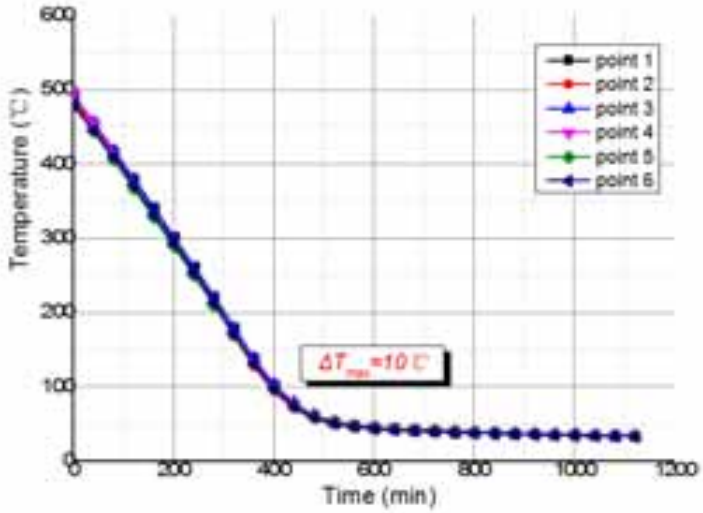


Figure 7. Radial temperature difference in top testing section
(a. Charing; b. Discharging; Discharging flow rate: 100Nm³/h)

This uniformity has advantages that exergy loss is reduced caused by heat exchanges within certain temperature ranges and radial convective mixing of air is lightened as well, resulting in a great improvement for exergy efficiency of the TES unit.

3.2 Net discharging power output

Net discharging power is defined as the heat extracted from solid materials by air in unit discharging time, which can be calculated as equation (2):

$$P_d = c\,\dot{m}\,\Delta T = c\,\dot{m}\,(T_{ao} - T_{ai}) \qquad \text{(eq.2)}$$

The temperature-dependent thermal properties of air are considered in the calculation, and density of air is determined by empirical correlation (3):

$$\rho = 0.72447e^{(-T/532)} + 0.39845e^{(-T/125.93)} + 0.16623 \qquad \text{(eq.3)}$$

Figure 8 shows variation of net discharging power under various air flow rates. As can be seen from it, the highest power can be up to 16.5 kW with a flow rate of 150 Nm³/h; and the lower the air flow rate is, the more fully heat transfer between air and ceramic balls developed, and the more stable the net discharging power output. The power curve under a certain flow rate declines slightly at the beginning of discharging, then increases to the highest value, and then continues to slowly drop eventually. The reason for this trend is that the pipe at the top of packed bed remains hot at the end of charging, while during discharging the top pipe will be cooled down at first and then heated by the discharging air, and it takes a while for the temperature difference between air outlet and inlet to reach a consistent variation.

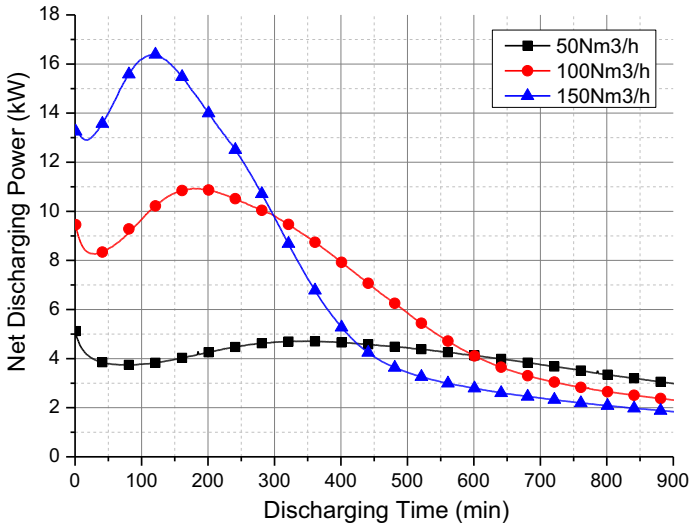

Figure 8. Transient changes of net discharging power under various air flow rates

Area between the single curve and abscissa represents the quantity of heat ectracted by air, and the results shows that the higher the air flow rate is, the larger quantity heat extracted in the first part of discharging. Therefore, it's critical to control appropriate discharging flow rate to adapt for different energy needs.

3.3 Thermal efficiency of TES unit

The heat performance of TES unit can be evaluated by the value of its thermal efficiency, including the charging and discharging efficiency. Charging efficiency is defined as the ratio of the net heat stored by solid material and the total heat released by the hot air during the charging process, which can be expressed as equation (3):

$$\eta_c = \frac{A(1-\varepsilon)\rho c_s \int_0^H [T(t_c, h) - T(t_0, h)]dh}{\int_0^{t_c} [T_{ai} - T_{ao}]\, c_a \dot{m}_a\, dt} \times 100\% \qquad \text{(eq.4)}$$

While discharging efficiency is defined as the ratio of the net heat extracted by cold air and the total heat released by the solid materials during a certain period of discharging time, which can be expressed as equation (4):

$$\eta_d = \frac{\int_0^{t_d} [T_{ai} - T_{ao}] c_a \dot{m}_a \, dt}{A(1-\varepsilon)\rho c_s \int_0^H [T(t_0, h) - T(t_d, h)] dh} \times 100\% \qquad \text{(eq.5)}$$

Figure 9 shows the charging and discharging efficiency changes of the TES unit under various working conditions, in which the discharging peirod of time is chosen as the moments before the discharging outflow temperature is not less than 100℃.

From the figure, the highest charging and discharging efficiency are respectively about 80% and 90%, which indicates that the TES unit can achieve to store and release heat effectively.

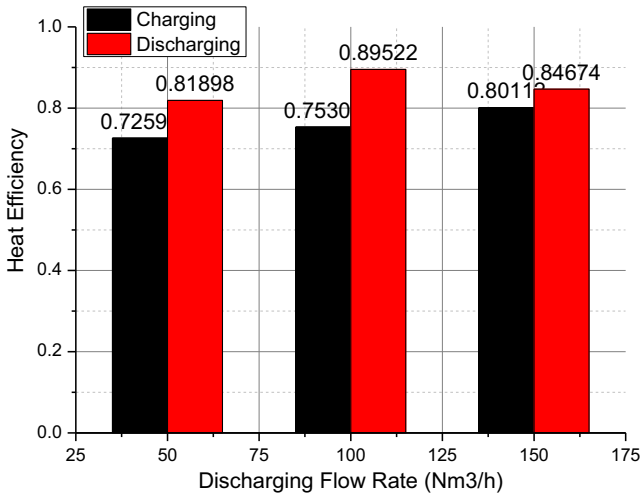

Figure 9. Charging and discharging efficiency changes of TES unit under various working conditions

Thermal efficiency of TES unit is directly related to its heat loss to the surrounding environment. Seen from the figure, the value of thermal efficiency is not so much high which indicates that the insulation measures of the TES unit remains to be further strengthened. However, it's worth noting that heat capacity of this system is limited due to a lab-scale device, and heat loss accounted for a larger proportion with a samller scale compared to the total storage heat. Therefore, the heat loss can be almost negligible and the thermal efficiency will be raised by big percentages when the heat storage system expand to the industrial scale.

4. Conclusions

A pilot-scale TES system based on a packed bed of ceramic balls with air as heat transfer fluid was designed, built, tested, and evaluated. Seris of contrast experiments under specified working conditions were carried out and the indicators including thermal stratification, radial temperature difference, discharge outflow temperature, discharging power output and thermal efficiency were analyzed to assess the heat performance of the TES unit. It was shown that temperature distribution in axial direction of the packed bed and thickness of thermal stratification can be manually controlled by adjusting the air flow rate or the heating power during charging to achieve a better discharging performance. The packed bed has a good temperature uniformity along the radial direction which means a less exergy loss and smaller convective mixing radially. The TES unit has a highest discharging heat power of 16.5 kW, and discharging efficiency of 90%, indicating that the

TES unit could achieve to storage and release heat effectively. However, good performance as the TES unit has, some optimization measures need to be further taken both in strucutres and controlling strategies optimization, such as the strengthened insulation, the expended scale and the optimally designed and controlled charging conditions etc..

Innovative PCM Storage as Power-to-Heat Unit for Process Heat Applications

Doerte Laing-Nepustil, Ulrich Nepustil, Rameesh Sivabalan and Detlev Lodemann

Hochschule Esslingen – University of Applied Sciences, Göppingen (Germany)

Abstract

An innovative high temperature latent heat storage concept for power-to-heat application is presented. The storage is equipped with electrical heating elements, directly immerged into the phase change material to achieve best conversion efficiency. Discharging takes place by an oil cooled plate heat exchanger. For heat transfer enhancement during discharging, a new concept, using moving blades to scrape off the solidifying material, was developed. With this method, the solidified layer of phase change material on the heat exchanger surface is kept at constant thickness, allowing for constant heat flux during the major period of the discharging process. Feasibility of the concept with moving scrapers was demonstrated, showing advantages over the passive concept. First investigations on the crystal size and hardness of Sodium Nitrate were performed to improve the scraper design. A concept for separation of capacity and heat rate is described.

1. Introduction

The German Federal Government has set the goal to reduce greenhouse gas emissions until 2020 by 40 % compared to 1990 levels, and cut primary energy consumption by 20 % over rates for 2008. Renewables are to have a 40-45 % share in electricity production by 2025, and a 55-60 % share by 2035. By 2050, the Federal Government seeks to increase the share of renewables in the electricity mix to at least 80 %. This is a tremendous change for Germany's electricity market. The rate of surplus electricity will rise because the average load factor of renewable technologies like wind power and photovoltaic is significant lower than that of conventional power plants. Therefore the required installed capacity needs to be much higher than for the conventional electricity market. The current German electricity market, with approx. 25% of renewable electricity, has still a residual load of ca. 15 GW. In 2035, with a renewable share of 60%, the minimal residual load is expected to fall to minus 25 GW (Federal Ministry for Economic Affairs and Energy (BMWi) 2014).

The increasing share of renewables in today's generation mix and the accompanying fluctuation in generation requires large scale as well as decentralized storage capacities to secure grid stability. In the proposed power-to-heat concept, electricity, produced from PV-plants or small scale wind farms, will be used to heat up high temperature latent heat storages. The heat can be used in industrial processes, e.g. industrial bakeries.

Thermal energy storages can be differentiated into sensible, latent and thermochemical technics depending on the physical principle. The selection of storage type depends on the demands and boundary conditions of the application (temperature range, heat transfer fluid, storage duration, storage capacity, heating rates) (Laing et al. 2012).

Latent heat storage with phase change material (PCM) is using the heat of fusion and offers the possibility of efficient storage of heat with high energy density in a small temperature range. One of the main challenge of PCM storages lies in the low thermal conductivity of the phase change materials. This leads to insufficient heat transfer between the storage medium and the heat transfer fluid, resulting in an unfavorable characteristic within the discharging process. When the discharging process starts, the PCM begins to solidify first at the heat exchanger plates and forms a steadily growing insulating layer. Because of that, the heat transfer from the liquid PCM to the heat exchanger plates drops dramatically. The current state of the art is to build some kind of heat transfer structures into the storage. This can be done by using finned tubes or specially formed structures, preferably made of aluminum (Laing et al. 2013). These build in structures

improve the heat transfer but cannot solve the problem satisfactorily and they reduce the amount of PCM inside the storage and for this the thermal capacity of the storage.

The newly developed active latent heat storage concept combines three innovative aspects:

1. Electrical heating elements ("power-to-heat"), directly immerged into the phase change material to achieve best conversion efficiency.
2. Moving scrapers to improve discharge and to achieve high and near constant heat rates during discharging. The moving scrapers control the freezing front inside the latent heat storage by keeping the solidified layer of phase change material on the heat exchanger surface at constant thickness.
3. Separation of capacity and heat rate: The concept with moving scrapers requires operation in a mixture of liquid PCM with solidified PCM-particles. Therefore, in the active stage the storage cannot be discharged completely (fully discharge means total amount of PCM is solidified, thus no more movement possible). However, this concept allows for active pumping and moving of salt. During discharging the solidified PCM grains can be removed from the liquid pool and stored in an insulated "cold" tank, while liquid PCM is refilled into the heat exchanger unit from an insulated "hot" tank. During charging, the solid particles will be poured into the heat exchanger unit from the "cold" tank, while liquefied PCM is pumped into the "hot" storage tank.

The current focus lies on the first two points, to proof feasibility of the active concept.

2. Description of concept

Fig. 1 shows a scheme of the newly developed active latent heat storage concept with moving scrapers (Laing et al. 2015). For electrical heating, heating elements are used that are integrated in aluminum plates to have very good heat conduction and therefore near constant temperature over a large heat exchange surface. Discharging will take place by oil cooled flat plate heat exchangers. Here the so called "pillow plate" method was applied as a cheap design applicable to higher pressures. For heat transfer enhancement during discharging, a new concept, using moving scrapers to scrape off the solidifying material, was developed. With this method it is intended to keep the solidified layer of phase change material on the heat exchanger surface at a thin and constant thickness, allowing for constant heat flux during the major period of the discharging process.

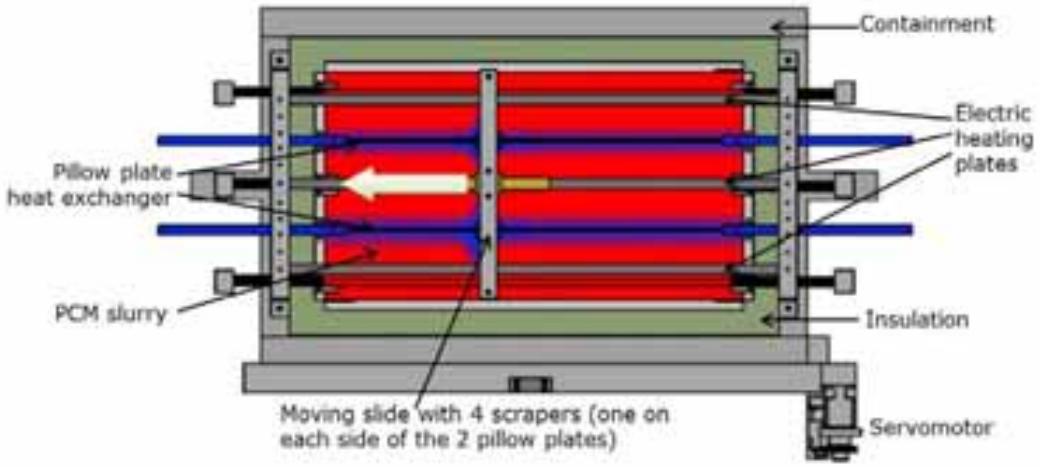

Fig. 1: Principle of the new storage concept with three heating plates, two pillow plates as heat exchanger plates and the scraper mechanic at the beginning of the discharging phase.

A first test storage unit was built and integrated in the test loop (Fig. 2). It has a total volume of 0.36 m³ and is currently filled up with ca. 375 kg of Sodium Nitrate (approx. 65% of complete filling). The storage is equipped with three specially designed electrically heated aluminum plates with an electrical heating power of 4 kW, each. For discharging, two oil cooled pillow plates are emerged into the salt. The moving scrapers are located on each side of both pillow plates, with a gap of approximately 8 mm between scraping surface and pillow plate surface. They are mounted with a metal slide on a rod, supported on the top of the storage

tank, and are moved linearly back and forth from one end to the other by a servomotor. With the current setting, the scraper takes about 14 seconds for one direction. The velocity is continuously adjustable. When the discharging process starts, the scrapers begin to move. By stirring the liquid PCM, the heat transfer on the freezing front is improved. Once the solid PCM has filled up the gap between heat exchanger surface and scraper, the thickness of the solid layer of the PCM on the pillow plates is limited to this size by the scrapers. This is the point, from which the heat rate stays almost constant, as the temperature in the liquid PCM-volume is at phase change temperature and the heat resistance is constant due to the constant thickness of the solid layer.

The storage unit is connected to a temperature control unit for heating and cooling, using synthetic thermal oil, stable up to 350°C. It has a heating rate of 20 kW and a cooling rate of 80 kW. For cycling tests, the storage unit will be heated directly through the electric heating plates immersed into the PCM. However, for preheating of the PCM close to the melting temperature, heating can be supported by the thermal oil loop to accelerate testing.

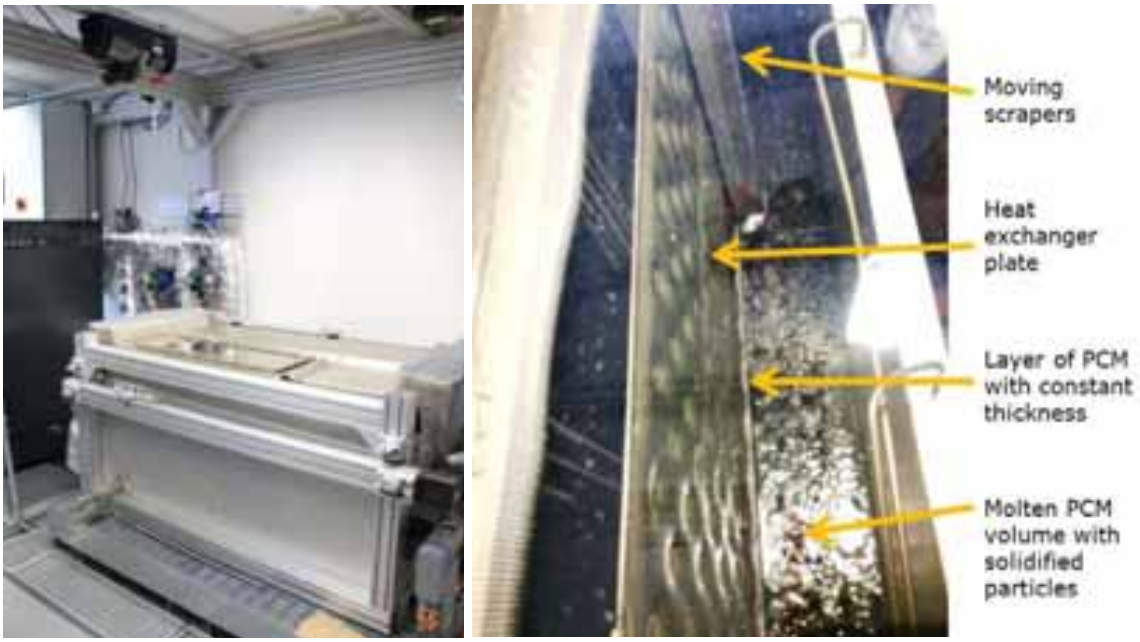

Fig. 2: Test facility with storage unit (left). Storage during commissioning, showing moving scraper that keeps frozen PCM layer at constant thickness (right).

3. Results and Discussion

3.1 Test results of storage operation

Figure 3 shows a comparison of storage discharge with and without movement of the linear scrapers. In both cases the complete storage mass was at 330 °C before discharge was started with a set temperature of 295 °C for the heat transfer fluid (HTF) at storage inlet. The dashed lines represent behavior without and full lines with scraper movement. Volume flow for the thermal oil is 20 l/min for all cases. Heat flow is calculated with the measured values and the temperature dependent density and specific heat capacity of the HTF. Apart from HTF inlet and outlet temperatures (Temp-HTF-inlet, Temp-HTF-outlet), the average temperatures of the PCM next to the cooling plates (Temp-PCM-HX) and in the middle between heating and cooling plates (Temp-PCM-liquid) are shown. To indicate the load on the scraper, the current for the scraper engine is measured (Current for scraper movement). The distance between scrapers and heat exchanger plates of the four different scrapers is not the same, due to thermal distortions of the plates and the containment. Therefore, the value of the current, shown here, is just a rough indication of the contact between scraper and solid PCM. The oscillation of the HTF temperatures and therefore the heat flow at the beginning of the discharge process is caused by the temperature control process of the cooling system.

The following advantages can be observed from the test with scraper movement (Fig. 3).

1. By stirring the hot salt, the heat transfer rate is higher than without, as long as the salt temperature is above the phase change temperature because of convection and delayed beginning of solidification. The higher heat flow in the first 45 minutes clearly proofs this statement.
2. With scraper movement, the temperature in the liquid PCM-volume reaches the phase change temperature of 306 °C after 56 minutes. Without scraper this temperature is reached only 17 minutes later.
3. Once the whole storage is at phase change temperature, the scraper movement is controlling the thickness of the solidified layer on the heat exchanger surface at constant level, resulting in a constant heat flow. This can be well observed in the last one hour of the scraper movement (scraper stopped after approx. 2 h of operation).

It can be observed that the current for scraper movement is still rising, even when there is a constant thickness of the solidified layer on all four heat exchanger surfaces and after approx. 2 hours of discharge operation the scraper movement stops. Due to the heat losses of the storage, PCM also solidifies on the containment walls. Once this layer of solidified PCM at the bottom of the storage unit reaches the front end of the scraper, there is a significant additional load on the scraper. It is assumed, that this load is the reason for the further rising current of the servomotor and that it finally causes the scrapers to stop due to overload.

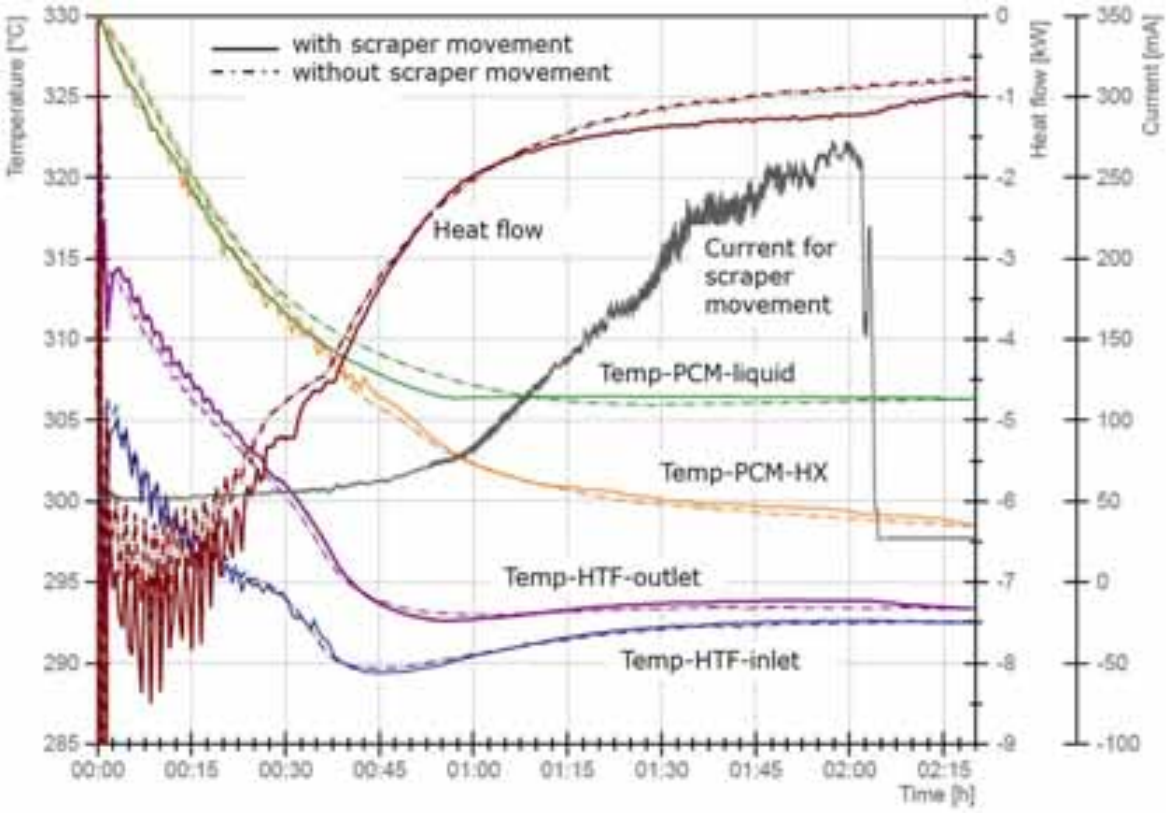

Fig. 3: Comparison of temperatures and heat flow for storage operation with and without scraper movement; current of servomotor for scraper movement.

3.2 Material aspects

In order to minimize the own power consumption of the scraper unit a more detailed knowledge of the properties of the salt is required. For this purpose, various investigations on separate samples and on samples from the storage were conducted.

The force needed to scrape off a layer of salt has been measured at ambient temperature on a sample shown in Figure 4. The sample was molten in the oven in a ceramic crucible and was left in the oven to solidify. The crystal size of the sodium nitrate changes from the surface to the inner part of the sample. On the surface, the first 3 mm have very small crystal size, followed by larger crystals. Inside the sample is a large void and the

salt can be damaged manually. Cooling on the surface occurred faster than inside the probe, therefore the crystals on the outer layer are smaller and less homogenous than inside. Fig. 4 (left) shows a cross section of the sample with the outer layer on top.

For the force measurement, the sample has been prepared with a defined edge (Fig. 4, right). Then a chisel with 6 mm width has been moved along the surface with different depths. Measurements with 0.1 mm and 0.2 mm depth are shown in Fig. 5. Two aspects can be observed. First, the force needed for the first 12 mm is higher than that needed for the second 12 mm section. Secondly, the force doubles, when the thickness of the layer is doubled. The oscillation of the signal is probably due to the inhomogeneous crystal structure.

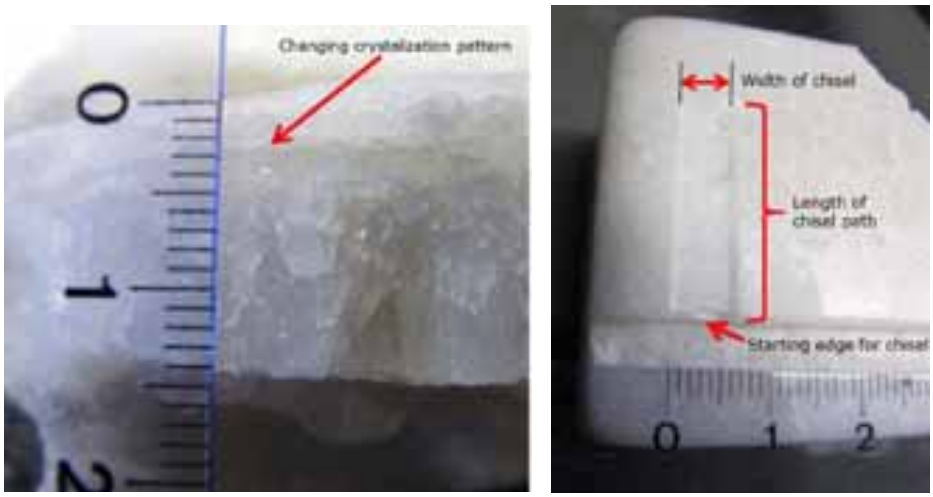

Fig. 4: Sodium Nitrate sample; left: cross section, right: chisel path.

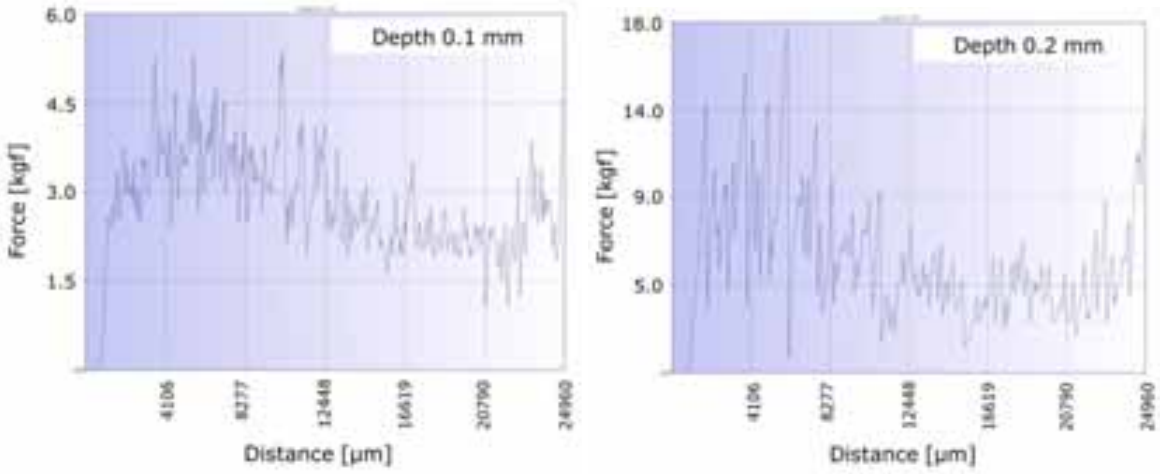

Fig. 5: Load-displacement diagram of Sodium Nitrate sample; left with 0.1 mm depth, right with 0.2 mm depth of the chisel

The examination of the sample as well as samples of the salt from inside the storage unit showed that the cooling rate affects the crystal size (see Fig. 6). As long as the scraper moves, not only a removal of the solidifying salt takes place but also a higher temperature is at the boundary layer between the solid and liquid PCM. As a result of this, the growing of the crystals is slower and it looks more homogeneous. This further improves the heat conduction in the already solidified PCM.

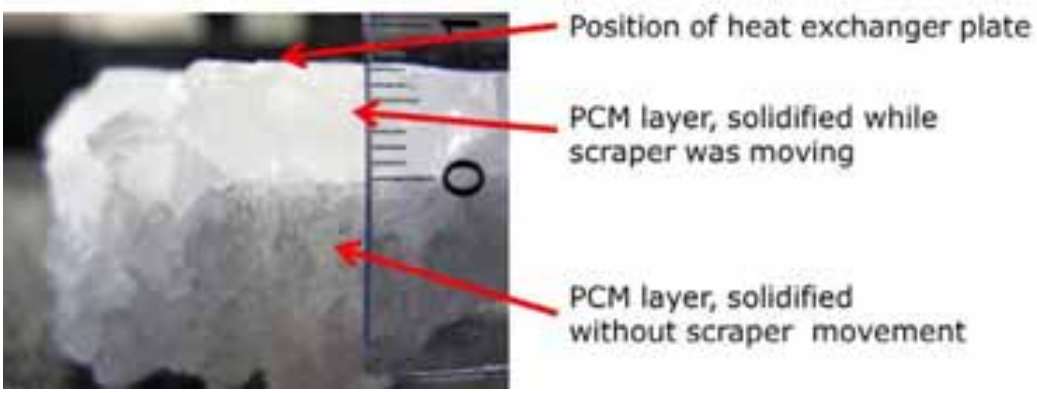

Fig. 6: Sodium Nitrate sample from inside the storage, showing the layer between heat exchanger plate and scraper on the top.

4. Conclusions and Outlook

Feasibility of the concept with moving scrapers was demonstrated, showing advantages of the active over the passive concept. With this first prototype, scraper movement stopped after approx. 2 hours of discharge operation. Due to the heat losses of the storage, PCM also solidifies on the containment walls. Once this layer of solidified PCM at the bottom of the storage unit reaches the front end of the scraper, there is a significant additional load on the scraper, which finally causes the scraper to stop. In the next generation design, the scrapers will be redesigned, to also scratch off the salt freezing at the bottom. The early limitation of the scraper movement did not allow the investigation of the maximum discharge capacity.

The cooling rate has a significant influence on the crystal size. For further design of the scrapers, a better understanding of the required forces is needed. Especially the hardness of the solid Sodium Nitrate close to melting temperature needs to be investigated.

In the second generation design it is intended to combine the electrical heating with the cooling plate to minimize the amount of components and material inside the storage and to maximize the available heat exchanger surface. With this solution, the same heat exchanger surface can be used for charging or discharging. For low temperature applications, using paraffin as phase change materials, first prototypes have been built, using resistance heating foils glued onto the heat exchanger surface. If possible, a smooth surface will be chosen, to allow a very narrow gap between scraper and heat exchanger plate. In addition investigation will be done, if the adhesion between PCM and heat exchanger surface can be reduced by nanotechnology or any other means.

The proposed concept with moving scrapers has the one disadvantage that the storage unit can never be discharged completely when using the scraper. However, it allows for a major advantage, to be able to remove solidified particles during discharge from the heat exchanger unit, while at the same time filling up the unit with liquid salt. During charging, solid particles can be refilled into the unit and liquid salt pumped back into an external storage tank. This concept (see Fig. 7) will allow for separate dimensioning of the heat exchanger unit and the storage capacity. Additional electrical charging can be easily done by immersion heaters in the “hot” tank. This would even allow for a certain power-to-heat buffer when the heat exchange unit is only charged through the heat transfer medium.

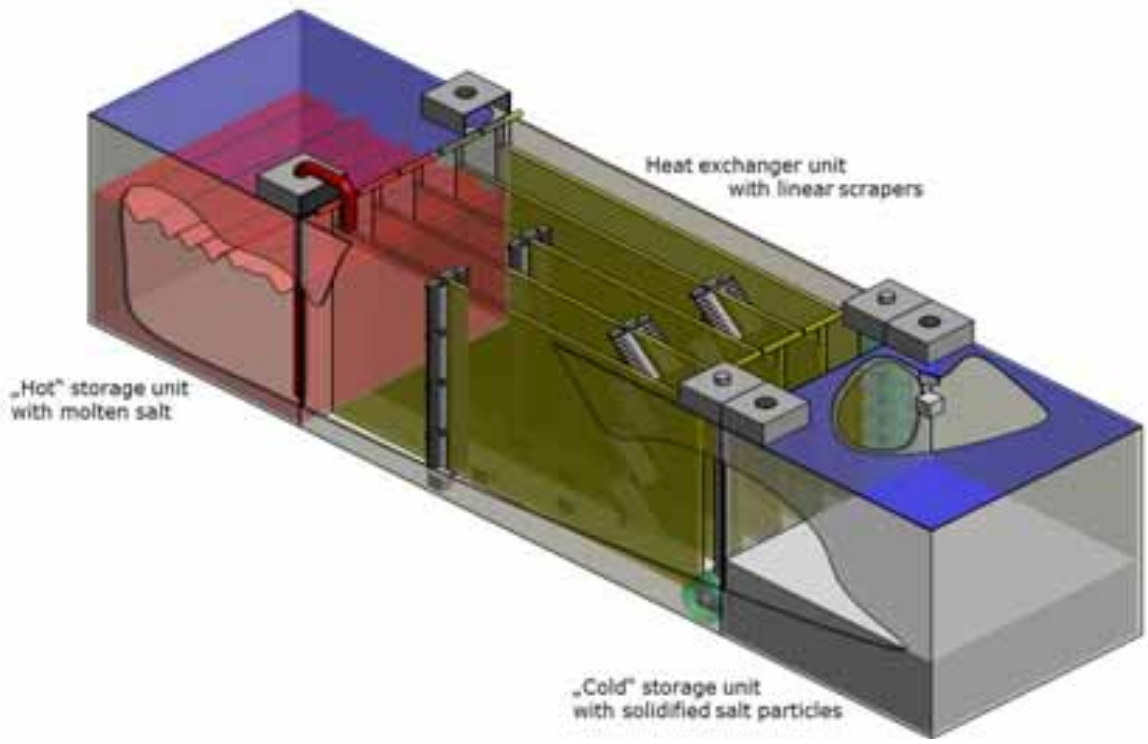

Fig. 7: Principal scheme of the storage concept with separation of capacity and heat rate

The solidified salt that is scraped off by the scraper accumulates on the bottom of the storage tank in fine granular form, due to the higher density of the solid phase. First tests with a manual slider plate showed that the grains can be easily moved to the edge of the storage. A device to remove the solidified PCM grains from the liquid volume, e.g. a conveyor screw, needs to be integrated on one side of the heat exchanger unit.

Abstract

Latent heat storage and efficient heat transport technology helps to utilize the intermittent solar energy for continuous and near isothermal applications. Nonetheless, latent heat storages face challenges of storage charging, heat retaining, and discharging the stored heat. The focus point of solar concentrators is the ideal position to collect maximum thermal power; however, this place is not convenient. Therefore, it is important to transport the concentrated heat from the focus to some place efficiently in order to utilize it safely. This paper addresses the challenges of heat transportation and storage charging-discharging issues. The heat transportation from the receiver over some distance is carried out with a pipe lines and water as heat transfer fluids. However, the charging-discharging process was carried by pipe less method with the help of fins. In addition, the stored heat was retained for a couple of days by using appropriate insulation material. The latent heat is stored in a phase change material (PCM) of nitrate salt (mixture of 60%NaNO3 and 40%KNO3), which melts at 222ºC and has 109 J/g specific heat of fusion. The storage was designed to supply nearly isothermal heat during the liquid-solid phase transition and the sensible heat stored in the solid and liquid form is used to perform additional applications that do not require uniform heat. The low thermal conductivity of the PCM is improved by using extended fins, which enhance the thermal conductivity within the storage. In this article, two-phase loop thermosyphon of steam was used to manage long distance heat transportation between the receiver and the storage. The steam in the thermosyphon flow was restricted to a maximum working temperature of 250ºC. Steam is selected for its highest heat capacity, easily availability and stable nature. The steam carries the heat from the collector focus point and condenses in a coiled pipe imbedded in aluminum plate placed on top of the storage. Many fins have solidly attached to this plate to conduct this heat down to the PCM inside the storage during charging. This design configuration avoids pressure development inside the PCM storage. The charging-discharging temperature of the storage is recorded in three zones (top, middle and bottom) of the storage. The experimental and numerical results show the heat transportation, retention and charging-discharging methods are effective.

1. Introduction

Solar thermal energy can be stored by using sensible heat storage (SHS) or latent heat storage (LHS) using a Phase change material (PCM). The stored heat can be used for different application such as cooking, space heating, hot water supply and etc. Latent heat storage provides higher storage capacity, compact size, and nearly isothermal heat supply. However, SHS such as Rock bed, water, oil etc. are larger storage and have faster temperature decay compared to LHS of the same capacity. These characterstics SHS can be improved by combining PCM material in their design as studied by D. Okello et al. [1].]. Latent heat storage using phase change materials (PCMs) can be designed to have much higher energy storage density than the sensible heat storage [2].

doi:10.18086/swc.2015.02.06 Available at http://proceedings.ises.org

Generally, PCMs have low thermal conductivities and took longer time of charging [3]. A number of methods have been proposed to increase the thermal conductivity of PCMs [4]. The finned tube configuration [4], metal structure insertion into the PCMs [4], and dispersion of thermally conductive nano or micro particles within the PCM matrix [4] are some of the widely studied approaches. In addition to thermal conductivity, mass flow rate and inlet temperature of the heat transfer fluid (HTF) has also affected the charging-discharging process [5]. PCM charging-discharging process can be improved by designing multi stage storages with different thermo physical properties [6]. Furthermore, it can be improved by using fast flowing HTF instead of slow flowing HTF [7]. On the other hand, there is a pressure build-up concern associated with PCMs due to the expansion of air at elevated temperatures and due to volume change of PCMs. The design of this paper has tried to avoid any possible contact between the HTF and PCM and possibilities of pressure buildup by providing a 10% extra volume.

The objective of this paper was to develop thermal energy storage to store the surplus solar energy during the day and keep it for later use by supplying nearly isothermal heat during discharging. To realize this, two-phase closed loop thermosyphon based heat transfer was used to charge the PCM storage. This design provides threshold height difference between evaporator and condenser of the thermosyphon loop to initiate natural circulation by density difference. Two-phase closed loop thermosyphon was selected because it is capable of transferring heat from a heat source to a separate heat sink over some distance [8]. This heat transfer mechanism is used in many applications such as nuclear cooling and electronic cooling [9]. However, this method of charging thermal storage has rarely employed in small-scale applications such as cooking. The prime objective of this study has focused to give solutions to the alarming deforestation, energy poverty, and related ecological impacts of developing countries associated with cooking. The cooking application experiment of this paper's design has documented in an accompanied paper submitted and presented in parallel by the authors.

2. Materials and Methodology

The methodology followed in this study includes identification of appropriate PCM material that has a solid-liquid phase transition temperature of 222ºC, storage design, thermal analysis, modeling and simulation, prototype development and test.

2.1. Phase change material

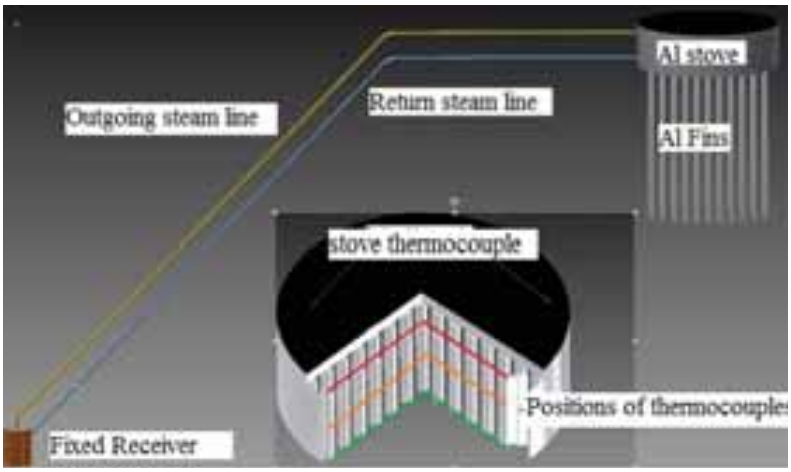
The PCM used in the experiment of this study was 20 kg of solar salt (nitrate salt mixture 40% KNO_3 and 60% $NaKO_3$). For computational simplicity, the latent heat was described in terms of an effective heat capacity in a narrow temperature range of melting [10].

$$Q = \int_{T_i}^{T_f} mC_p \mathrm{dT} \tag{1}$$

$$C_P[kJ/kg] = \begin{cases} 0.75 & T < 110^0C \\ 4.2 & 110^0C \le T \le 120^0C \\ 1.4 & 120^0C < T < 210^0C \\ 12 & 210^0C \le T \le 220^0C \\ 1.6 & T > 220^0C \end{cases} \tag{2}$$

2.2. Storage design

The PCM storage is designed to be charged by a two-phase self-circulatig closed loop heat carrier, a polar mounted parabolic dish with sun tracker, a fixed receiver was designed to act as an evaporator and an aluminum casted plate with extruded fins down to the PCM was placed on top of the storage. The heat transfer fluid used was water and the receiver converts this water in to steam. Figure 1 shows a schematic and actual picture of the system.



(a)

(b)

Figure 1: Design and development process of a PCM storage

The Al plate has an embedded stainless steel (SS) steam pipe that acts as heating element. The heat storage was coupled to parabolic dish filmed with 5cm glass tiles. The polar mounted technique of the concentrator's design gave a suitable platform for the fixed receiver. This concentrator is coupled to PCM storage with a thermosyphon loop. The system was tested on a real sun and artificial heating to charge the storage. In this experiment mainly K-type thermocouples, pressure gage, and photo sensors were used to measure temperature distribution, regulate steam pressure and control the tracking mechanisms of the system respectively.the complete list of items is given in Table 1.

Table 1: system instruments and sensors

Label	Description	Label	Description
A	Pressure relief valve	F	Inlet, out let and directional control valves
B	Pressure gauge	G	DC Power regulator
C	Tracking sensor	H	Parabolic dish reflector
D	Sprocket and chain drive	I	Data logger
E	DC motor	J	Thermocouples

2.3. Heat transfer mechanisms

PCM storage charging with hot water or oil utilizes the medium's sensible heat capacity, in which the amount of energy released per unit volume is relatively small. However, charging with saturated steam employs the latent heat released during its phase change. The condensate exits the PCM storage at temperatures close to the inlet steam temperature. The thermosyphon loop was first flushed to free any trapped air and filled 2/3 of its volume with water. There is no expansion tank in this loop design. A boiling-condensing mode of heat transfer technique was followed to transport the heat from the receiver to the storage. Theoretically, the mass flow rate of the fluid circulating in the loop can be found by conducting a momentum balance around the loop [11] and the heat transfer in the imbedded pipe is treated as film condensation in nearly horizontal pipes.

The mode of heat transfer between the stainless steel pipe and aluminum block is treated as a pure conduction

between composite solids as shown in Figure 2. This heat was analyzed using Fourier's conduction equations (3-5).

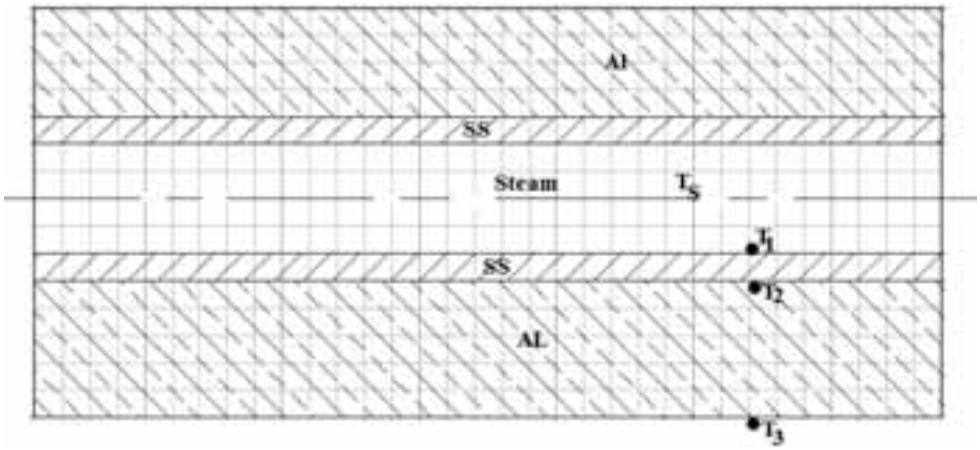


Figure 2: Composite materials of aluminum and SS

Assuming small pipe wall thickness (L) compared to pipe diameter:

$$\dot{Q}_{cond} = -kA\frac{dT}{dx} \tag{3}$$

$$\frac{\dot{Q}}{A}\int_0^L dx = -\int_{T_1}^{T_2} kdT \tag{4}$$

If the small variation of k is ignored the equation simplifies in to:

$$\dot{Q} = \frac{kA}{L}(T_1 - T_2) \tag{5}$$

Where $\frac{L}{kA}$ is the thermal resistance of the material

The overall thermal resistances of composite wall are treated in the same way as total series resistance of electric circuit. Assuming 2D geometry for simplicity: the fin and the plate temperature progress is the same and change in area (A) and thermal conductivity (k) with temperature is negligible, T_3 (fin temperature) was then calculated by:

$$T_3 - T_1 = \dot{Q}\left(\frac{L_{SS}}{k_{SS}A} + \frac{L_{Al}}{k_{Al}A}\right) \tag{6}$$

In a heating plate temperature-time profile, the analysis of the heat transfer rate from the heating plate (frying pan) to the fins and from the fins to the PCM was analyzed using eq. (7 and 8) respectively [11].

$$\dot{Q}_{p,f} = \frac{T_p - T_f}{R_{P,f}} \tag{7}$$

$$\dot{Q}_{f,PCM} = \frac{T_f - T_{PCM}}{R_{f,PCM}} \tag{8}$$

Theoretically, the temperature development of the fin is found by using eq. (9) and the heat transfer rate from the fin at temperature,T_f, to the PCM at temperature,T_{hp} , in the storage must equal to the heat transfer rate from the plate to the fin as shown in eq. (10).

$$\frac{dT_f}{dt} = \frac{\dot{Q}_{P,f} - \dot{Q}_{f,Pcm}}{m_f c_{v,f}} \tag{9}$$

$$\dot{Q}_{f,\mathrm{PCM}} = \frac{T_f - T_{PCM}}{R_{f,PCM}} = \dot{Q}_{P,f} = \frac{T_P - T_f}{R_{P,f}} \tag{10}$$

On rearranging of eq. (10), the PCM temperature simplifies to eq. (11). Figure 3 shows the COMSOL mesh of the PCM material adjacent to the fin.

$$T_{PCM} = \frac{T_f R_{PCM,f} + T_f R_{f,\mathrm{PCM},}}{R_{P,f} + R_{f,PCM}} \tag{11}$$

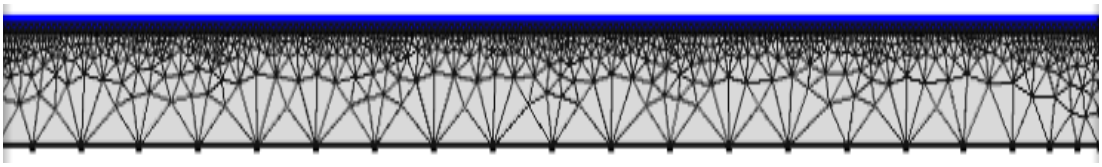

Figure 3: Mesh of PCM material during conduction charging

2.4. Thermal performance

The thermal performance of the system is given by the ratio of the useful energy stored to the energy incident at the concentrator's aperture. The storage energy is the sum of the energy stored in the PCM and in the aluminum fin. Therefore, the thermal efficiency of the system is computed by:

$$\eta_{th} = \frac{c_{Al} m_{Al} (T_f - T_i) + m \int_{T_i}^{T_f} c_p dT}{A_a I_B} \tag{12}$$

Where cp is the effective heat capacity of the PCM (eq.2)

Both normal and diffuse radiation enters the aperture area of any solar collectors. However, in concentrating collectors only the direct radiation can be focused on the receiver. In this paper, the thermal analysis of the system was performed only for its solid phase sensible heat-storing ability as it was not fully charged. The systems developed here reached 157°C of maximum temperature during the experiments of this study. Therefore, the thermal performance during these days was calculated 19%. The performance of the system was affected mainly by the heat loss from the receiver.

2.5. Insulation

Aerogel and Rockwool insulations were used to insulate the storage and the steam pipelines respectively. Although the insulations maximum working temperature is about 650°C, the maximum working temperature of the systems' was set to 250°C (by adjusting the pressure relief valve) and the design thickness of the insulation is 25mm for the storage and 50mm for the pipeline. The insulations thermal conductivity is 0.03W/Km and 0.07 W/Km respectively and they have the same surface emissivity of 0.05.

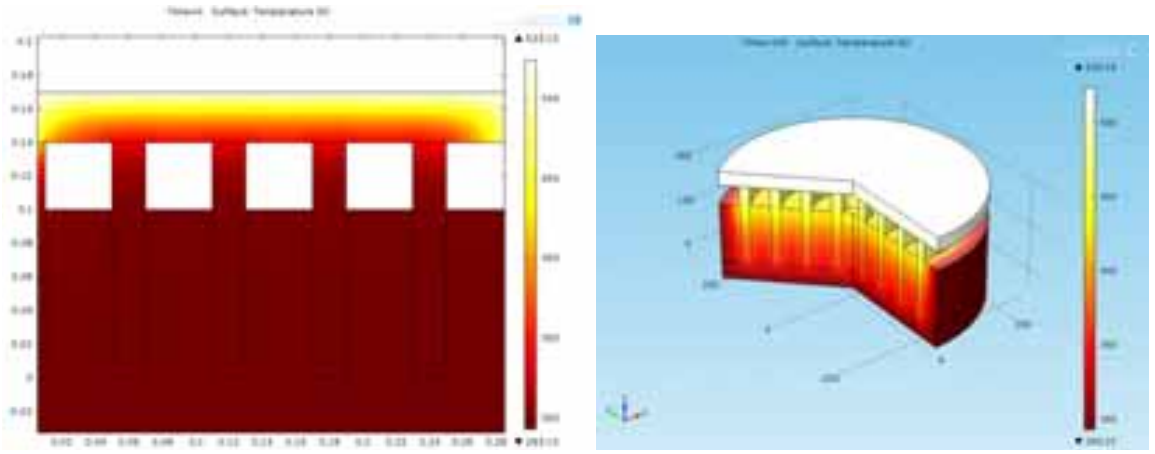
2.6. Pipe lines

The size of the steam pipeline was 10mm and 8mm with 1mm thickness. The SS pipe is used as a pipeline in the heat transfer loop and as a heating element of the Al plate respectively. The pipe has 100bar design pressure and was used for 40bar working pressure. The pipeline used Swagelok connectors and valves. A pressure gage is used to measure the pressure of the steam and regulated with the help of a safety valve that reliefs the pressure when it passed the pre-set value (40bar). The pipeline was flashed before the beginning of experiment to avoid air inclusion.

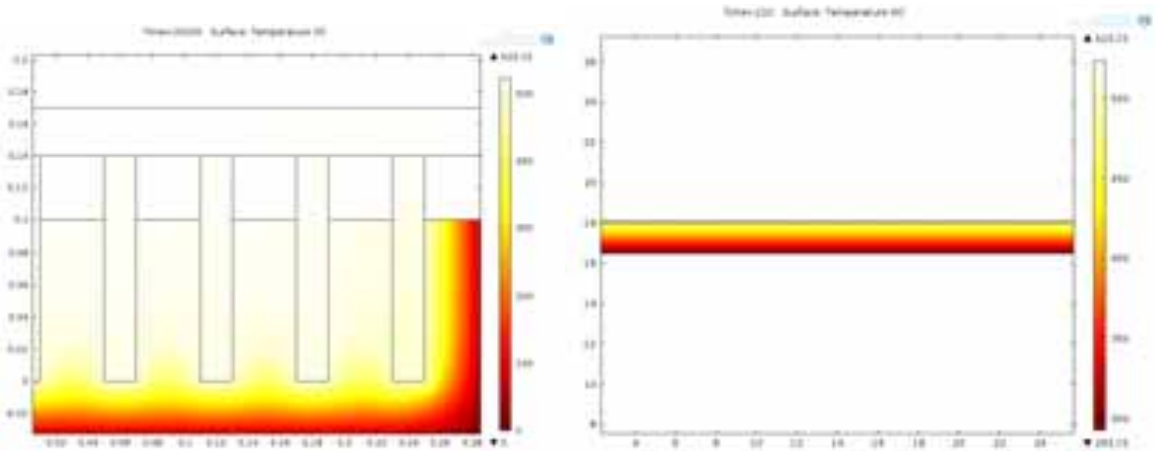
3. Results and discussion

3.1. Modelling and simulation

The storage charging process has simulated using COMSOL multiphysics 4.3. The simulation work was run for 2D and 3D models. The simulation results showed the storage is fully charged in about seven hours, when it is heated by a 250°C continuously circulating steam. The simulation considers a constant loss of 15°C from the storage. For model simplicity, the fin in the COMSOL simulation used in Figure 4 (a-c) has considered circularly rolled plate fins instead of the many cylindrical fins in the actual prototype. This fin assumption has an impact on lowering the overall charging time of the storage. The simulation shows the charging of the PCM sanduched between two fins is very quick as shown in Fig. 10(c), however, the PCM adjacent to the storage wall and bottom changes its phase very slowly. This simulation result suggests to half the dimension of the gap between the fin and the storage wall and bottom. Therefore, the PCM thickness between the fin and the wall and between the fin and the bottom should be 20mm. Moreover, it was found rolled plate fins charge the PCM quicker than rod fins. In addition to the PCM charging development, the simulation has also run to show the thermal resistance effect of the SS pipe wall on the Al plate as shown in Fig. 4(d).



(a) (b)



(C) (D)

Figure 4: COMSOL simulation of PCM charging and heat transfer between SS and aluminum wall

3.2. Experimental Test

The polar mounted concept eases the tracking mechanism in the secondary axis and the fixed focus receiver, was found suitable for steam generation. The steam circulates between the evaporator (receiver) and Al plate (condenser) in a closed loop naturally. The steam carries the heat from the receiver and drops it on the

aluminum plate. The fins attached to this plate in return carries this energy to the PCM storage. The test unit of this paper is shown in Figure 5.

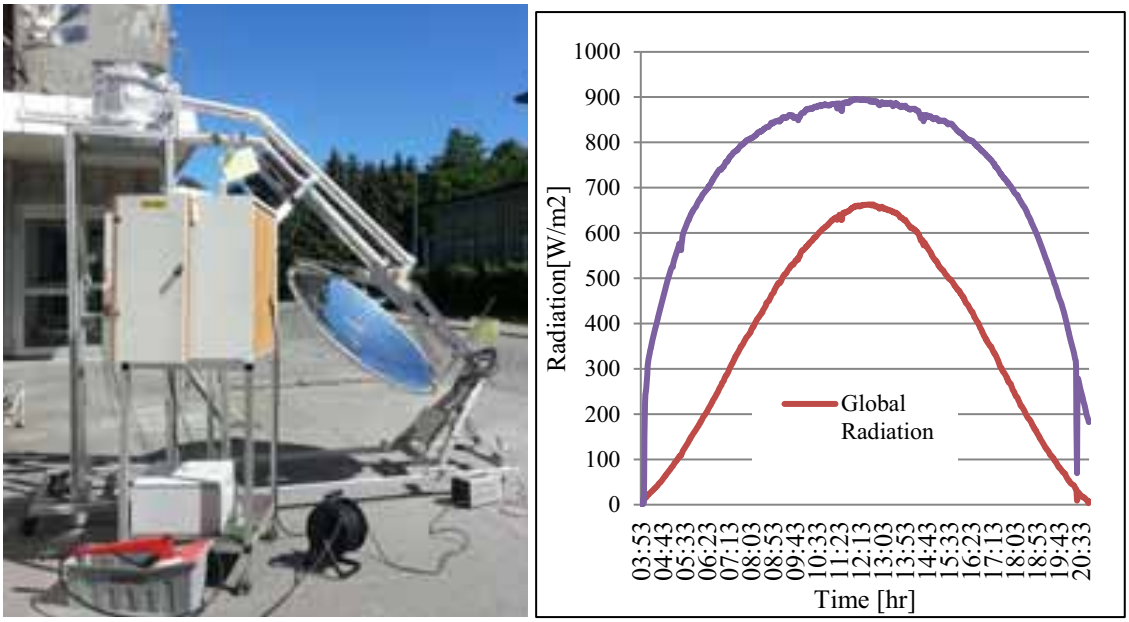


Figure 5: Parabolic dish with PCM storage Trondheim's global and normal beam radiation for 25-07-2013

a) Charging of storage on natural sun

When the solar reflector starts focusing the solar radiation on the receiver, the water inside the receiver starts boiling and a vapor at low temperature starts circulating. The stagnation temperature of this unit could not reach the melting point of the PCM. The storage was tried to be charged in successive days using the advantage of the PCM material's heat retention ability. However, this did not help to charge it fully; this was probably due to the losses at the receiver. The maximum temperature attained in the PCM storage had reached a temperature range of 130°C to157°C as shown in Figure 6.

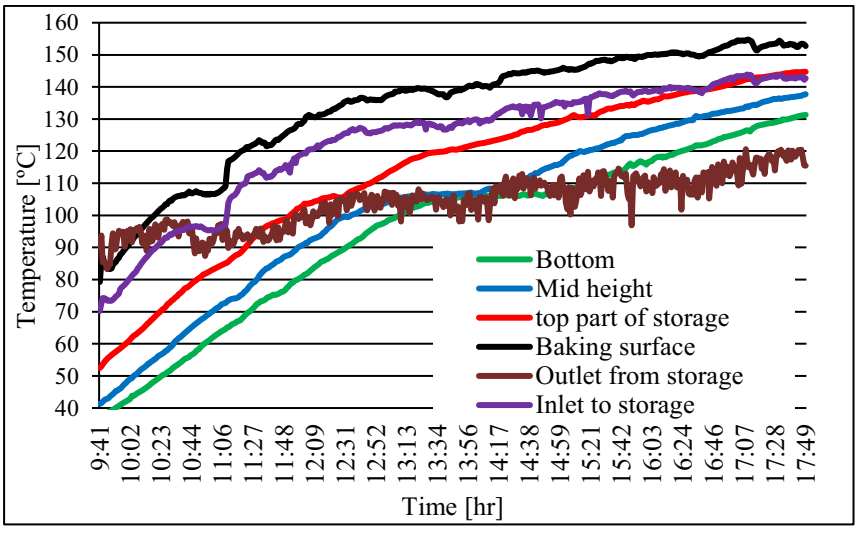

Figure 6: PCM charging practice

b) Charging of PCM storage Artificially

An artificial heating element was coiled around the receiver in order to obtain a regulated temperature at the receiver that is capable of generating steam at elevated temperature, see Figure7(b). The heating element was set to a maximum temperature of 450°C, at which it was delivering an average power of 700W to the receiver.

This power was equivalent to the solar power supply obtained from a 1.2 m parabolic dish concentrator with 80% optical efficiency and $800w/m^2$ average beam radiation. The PCM storage took about eight hours of phase change duration. The temperature development of the steam and the PCM during the charging process are shown in Figure 8.

(a) (b)

Figure 7: Receiver of a parabolic dish collector: (a) solar test and (b) heating element (before insulation)

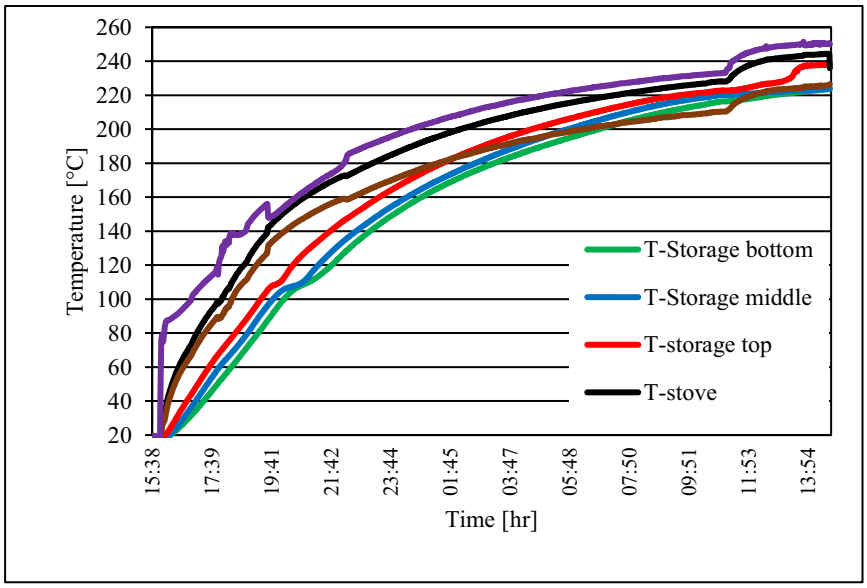

Figure 2: Artificial charging of PCM storage

The experimental result shows a close resemblance to the simulation result of charging time. This indicates the input power at the receiver is small and needs to increase it by using larger aperture area inorder to reduce the charging time.

4. Conclusion

In this paper a concept of steam based heat storage charging by using polar mounted solar concentrator has been developed and demonstrated. Heat is transfer by a thermosyphon principle, with water as the working fluid at about 35-bar pressure. Vapor is generated at the heat absorber in the focus point of the parabolic concentrator and condenses in a coiled tube, which is in Al plate. The plate has heat-conducting rods extending into latent heat storage ("solar salt", Nitrate mixture). A boiling/condensing natural circulation loop (thermosyphon) is feasible with water as the heat transfer fluid. As the water volume is small, the high pressure is manageable but requires high quality pipe and valve components. A boil-off startup procedure is operationally easy. The system can be optimized with respect to losses in the heat transfer loop, in particular

at the absorber. The absorber is a spherical boiler in a fixed position, with the solar illuminated area moving from one side to the other during the daily sun tracking

Design for a Solar Thermal Energy Storage System

Ramón Gutiérrez Razo[1], Bruno Cárdenas Castañeda[1], Noel Leon Rovira[1]

Tecnológico de Monterrey - Centro de Innovación en Diseño y Tecnología, Monterrey, Nuevo León, México

Abstract

The design of a Thermal Energy Storage unit (TES) is shown to use solar energy at times where there is intermittent, shortage or lack of solar radiation. The TES unit is made of five parts: heat reservoir, heat reservoir container, heat receptor – transmitter system, thermal insulator and structural support. The TES unit material's must be abundant, be of common usage in industry, obtained either from recycling or industrial wastes. Also the materials must be non – toxic and non – flammable. Three TES designs will be shown pointing out the opportunity areas found in each one in order to achieve a TES unit with the best performance possible.

Keywords: *Solar energy, Latent heat, glass, TES*

1. Introduction

Fossil fuels domain the market to cover the world's ever growing energy demands [1]. However the extended use of fossil fuels involve environmental consequences, can cause disturbances in the global economy to sudden shortage or surplus of fossil fuels, and at one time these kind of fuels will end. Renewable energies can be a solution to the dependency of fossil fuels. Renewable energies are at the time in development, the initial investment can be high and use to be intermittent.

Currently there are solar concentration systems such as solar power towers and parabolic trough for storing heat in molten salts. However these systems require large areas of land for installation and complex piping and pumping system to withstand temperatures from 300°C to 500°C besides the corrosion caused by the salts. Both systems also require an active tracking of the sun throughout the day which increases the cost and complexity of the system [2, 3].

Solar energy has the characteristic of being abundant and clean, however the development of technologies that exploit this resource have high investments and are still under development. A disadvantage of solar energy is to be intermittent, available only in daylight and depend to weather conditions. In order to solve the aforementioned problem TES units have been developed so that solar energy can be used during periods when solar radiation is not favorable or not present.

Research of a concept of electric and mechanical energy generation has been made by the usage of stored thermal energy from the concentration of solar radiation. The search of material of common usage in industry, recyclable, or from industrial waste has been priority in the design of TES units in order to reduce costs and promote the use of solar energy.

The TES unit requires materials with good thermal conductivity, high energy density per unit of volume and mass for the heat reservoir; in the zone where energy is inserted and extracted the materials require high temperature resistance and good thermal conductivity, besides good solar radiation absorptance for the energy receptor zone; for the materials to be used as heat reservoir container and thermal insulator in order to decrease the reservoir container temperature as close to room temperature requires low thermal conductivity and high temperature resistance.

All material must be non-toxic, and non – auto ignitable at the working temperature of the TES unit.

As a first approach the research aspire to design a TES unit to supply 20 kWh of electric energy. This electricity consume is the average consume of each domestic user in Mexico.

2. Experiment

For the development of the TES unit finite element method simulations by computer and experimental tests have been made. The finite element method takes into account the variation of the thermal conductivity and specific heat values according to changes in the temperature of the material. Three different designs of TES units will be shown pointing out the most relevant results and the opportunity areas found.

The three TES units have in common the usage of soda lime glass as a heat reservoir obtained from wastes; all the TES units use graphite obtained from industrial wastes as the energy reception – extraction system; the three heat reservoir containers are made of alumina; the thermal insulator in the three units is made of ceramic fiber and the external container is made of steel A – 36. The last three aforementioned materials are of common usage in the industry and of lower cost compared with other options.

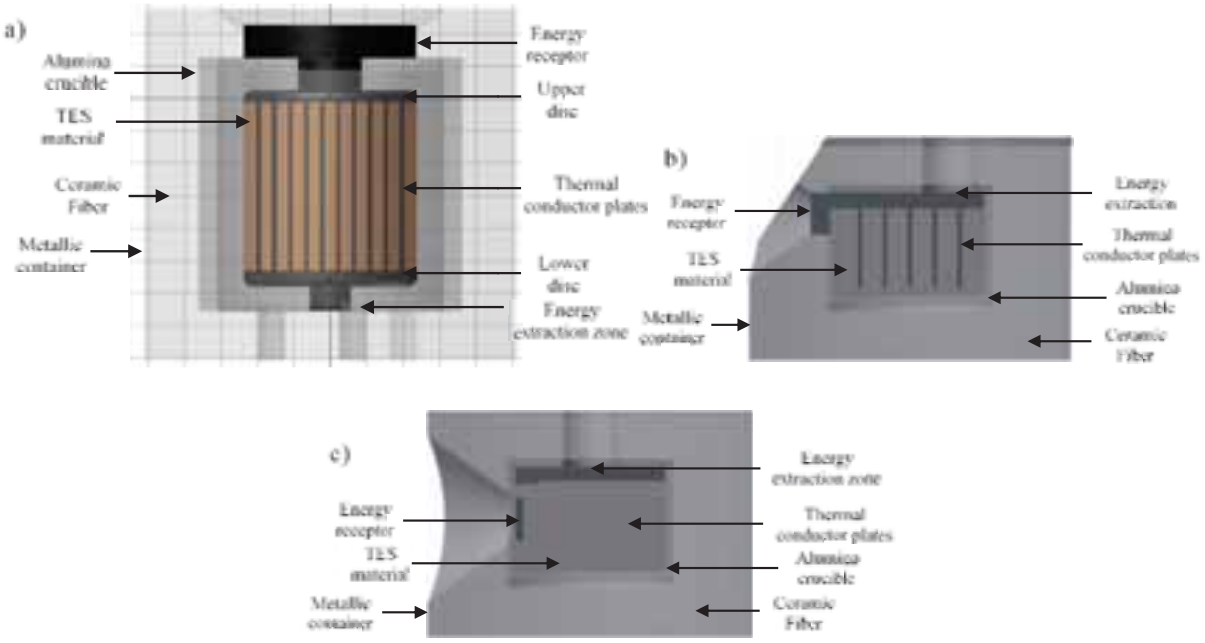

Fig. 1: TES designs. Each grid represent 4inches (around 10 cm.) The three TES drawings are at the same scale for comparative reasons.

Soda lime glass selection as a heat reservoir was based on having a good heat capacity per unit of mass. Graphite was chosen as a thermal receiver - transmitter based on its working temperature which is around 2500°C and 3000°C whenever it is protected from an oxidizing atmosphere [4], and having a good heat conductivity. Both materials share the characteristic of being abundant, and can be obtained from waste or recycled materials.
The A TES design was built and experimental tests were run. With the results obtained in the design A designs B and C were made in order to solve the shortcomings in the performance of this first design. Finite element method analysis of the TES units B and C were made in order to show the improvement in latter TES design compared with previous ones.
Designs B and C were made with 62% and 55% of the heat reservoir mass of the Design A respectively with the intention of get experimental test quicker. Designs B and C have in common the diminishing in weight and number of components of graphite and have the energy receptor as close as possible to the heat reservoir.

Tab. 1: Volume and mass of the heat reservoir of the TES units

Heat Reservoir	Volume [m³]	Mass [Kg]
Design A	0.06949	173.725
Design B	0.04303	107.575
Design C	0.0385	96.25

In the design B the thermal conductor plates made of graphite are at 90° of the direction of the incoming heat flux from the energy receptor, in the design C these plate are in the same direction of the incoming heat flux. In the

design B the energy receptor is in the upper part of the TES unit and connected to the heat reservoir by an area equivalent to the third part of the energy spot, in the design C the energy receptor is at the middle of the TES unit and is slightly inside of the heat reservoir container connected to a graphite plate non – existent in the design B.

The TES unit is designed to be connected to a Stirling Engine with a capacity of 1 kW and with a thermal efficiency of 0.25. The Stirling Engine needs a temperature of 500°C or more to operate.

For the computer simulation the Autodesk Simulation Mechanical 2014 software was used.

The following mathematical models were used to take into account the changes in the specific heat and thermal conductivity values as the temperature fluctuates.

$$C_p = 2.268 - 10.153 \times 10^{-6}T - 377.70014T^{-1} - 181791.8712T^{-2} + 6.66548856 \times 10^{7}T^{-3} - 6.011905920 \times 10^{9}T^{-4} \left[\frac{J}{g-K}\right] \quad \text{(eq. 1)}$$

$$k = \frac{418.4}{2.4 + 3.46 \times 10^{-3}T + 8.5 \times 10^{11}e^{-8.9\times10^{4}/T}} \left[\frac{w}{m-K}\right] \quad \text{(eq. 2)}$$

$$C_p = 9.474 \times 10^{-15}T^5 - 3.923 \times 10^{-11}T^4 + 6.221 \times 10^{-8}T^3 - 4.746 \times 10^{-5}T^2 + 1.814 \times 10^{-2}T - 1.833 \left[\frac{J}{g-K}\right] \quad \text{(eq. 3)}$$

$$k = -1.413 \times 10^{-14}T^5 + 6.083 \times 10^{-11}T^4 - 3.120 \times 10^{-8}T^3 - 2.853 \times 10^{-5}T^2 + 2.512 \times 10^{-2}T - 3.668 \left[\frac{w}{m-K}\right] \quad \text{(eq. 4)}$$

The specific heat of the graphite model was obtained by the fitting of two mathematical models [1]. The specific heat graphite model is useful in the range of 200K to 1000K, however the model can be expanded to temperatures of 3270K where the specific heat value almost stabilize (Eq. 1). For the thermal conductivity graphite model it was used a mathematical model made by N.S. Rasor and J.D. McClelland [8] and is useful in the range of 300K to 3270K (Eq. 2). It is assumed that the graphite used is of commercial grade quality and with isotropic properties.

The soda – lime glass store thermal energy as sensible heat. In the industry of soda – lime glass it is considered a value of 2550 kJ to bring 1 kg of soda lime glass to a working temperature [9]. The specific heat of the soda – lime glass model shown in the following section is useful in the range of 270K and 1350K (Eq. 3) [1] for higher temperature values a constant soda lime glass Cp of 1.4 kJ/kg-°C was used in the simulation. The thermal conductivity of soda lime glass model was created by the fitting of three mathematical models (Eq. 4) [1], this model is useful in the range of 270K to 1580K, for higher temperature values a constant soda lime glass thermal conductivity value of 82.4 w/m-°C was used in the simulation [6]. In the figures 2 and 3 are shown the values of the specific heat and thermal conductivity values respectively. More information about the values taken into account in the simulation for the refractory concrete, ceramic fiber and A-36 steel can be found in [6] and [13].

Tab. 2: Material density values

Material	Density [Kg/m³]	Reference
Graphite	1700	[1]
Soda Lime Glass	2500	[1]
Refractory	2630	[10,11]
Ceramic Fiber	96	[12]
Steel A - 36	7850	[13]

A finite element method of the design B and C was made for 10 days of operation. Each TES unit will receive 5.625 kW at the energy receptor zone daily by 8 hours receiving a total of 45.0 kWh (Charge cycle) followed by 16 hours of zero entry and extraction energy (Rest cycle). The energy receptor spot had a value of emissivity of 0.95 during the charging periods and a value of zero during the rest of the day. A convection coefficient of 3.22 w/°C-m² was used over the exterior of the TES unit. At days 9 and 10 an extraction of 4.0 kW of heat over the extraction zone was applied. (Heat extraction cycle).

The central point of the energy receptor and extraction zone was taken in the finite element method simulations of the designs B and C and was assumed that the whole zone had a similar temperature. Using the Stephan Boltzmann Black Radiation (Eq. 5) [14] model for black body at the energy receptor zone was possible to calculate and estimate for the radiation heat losses. Checking at the time that the energy extraction point was above 500°C was possible to estimate how much energy was extracted by the Stirling engine.

$$Q_{RadLosses} = \varepsilon\sigma A(T_S^4 - T_{Amb}^4) \qquad \text{(eq. 5)}$$

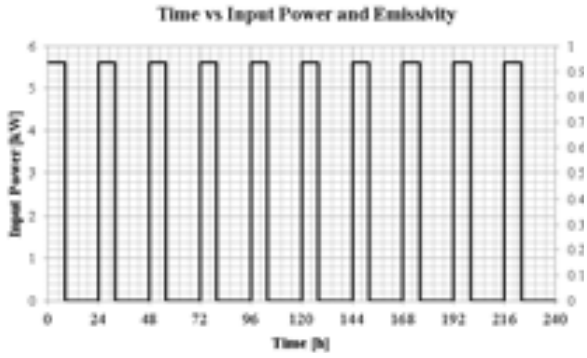

Fig. 4: Time vs Input Power and Emissivity

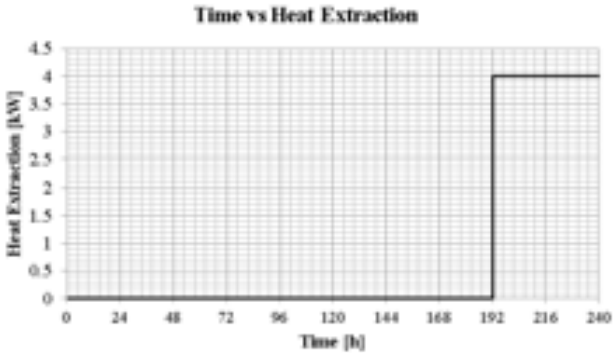

Fig. 5: Time vs Heat Extraction

All the nodes of the finite element method model started with a temperature of 20°C, the room temperature is also the same. The 10 days of simulation were divided among 1000 steps, each step represents a time of 14.4 minutes. The Autodesk Simulation Mechanical 2014 software at the end of the simulation assign a temperature for each node that compose the model. The nodes form brick, pyramidal, tetrahedral and wedges elements. Knowing the volume and density of each element can be obtained the mass. With the mass information and with mathematical models from the C_p of each material can be obtained the change in the energy stored or released.

3. Results

The solar concentrator was unavailable at the time of the A design construction, a gas furnace was built over the energy receptor. It was found that the graphite exposed at a temperature of 400°C and higher in contact with the air oxidize damaging the graphite parts until the whole part sublimates into CO_2 [17]. However, if the graphite is submerged into the heat reservoir the wear of the graphite parts use to be little to non – existent. By means of thermocouples it was found that between the energy receptor and the upper graphite disc was a temperature difference between 140°C and 200°C. This means the presence of a bottleneck to the heat flow between the aforementioned parts [1].

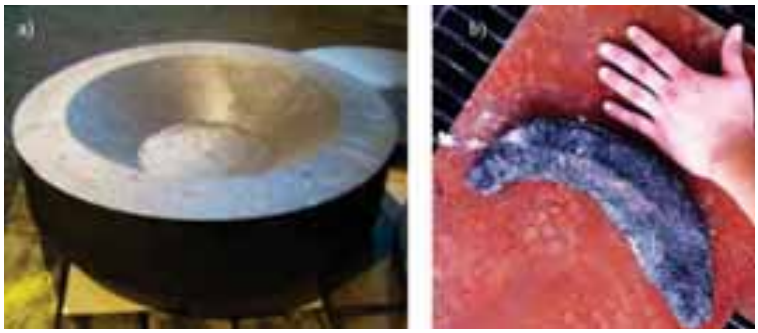

Fig. 6: Energy receptor. a) Before the charge of the TES unit b) After the charge of the TES unit.

Fig. 7: Lower graphite disc after the charge of the TES unit. a) Face of the lower disc pointing inside the crucible in direct contact with the glass melt. b) Face of the lower disc pointing outside of the crucible in contact with the atmosphere.

The TES unit was charged over a period of 6 days and 20 hours, followed this period by 9 days of cooling, with two periods of recharge of 8 hours each during the cooling stage. By using thermocouples and a data acquisition module it was possible to take and record samples of the temperature of the glass melt and the thermal insulation. The glass melt reach an average temperature between 900°C and 980°C at the end of the charge stage; the energy receptor zone reached a maximum temperature of 1200°C and the energy extraction zone reached an estimate maximum temperature of 880°C. During the charge and cooling of the TES prototype there was no device to convert the thermal energy to either mechanical or electrical energy.

Due to the aggressive degree of oxidation the following TES designs tried to diminish as much as possible the graphite parts in size and number and avoid exposing them as much as possible from the atmosphere.

The radiation reception area has a size of roughly 150 cm². In figure 9 can be seen that radiation heat losses through this area are a maximum of 72% for design B and 61% for design C from the total radiation received daily.

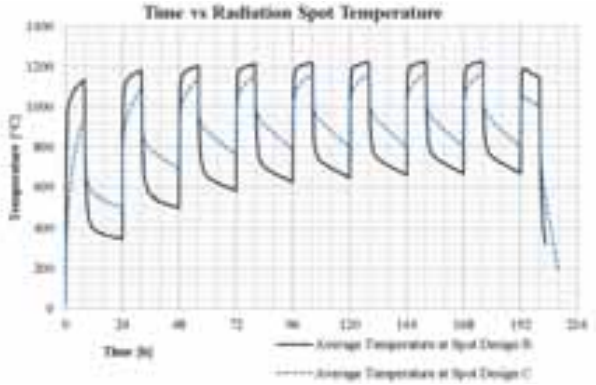

Fig. 8: Time vs Radiation Spot Temperature

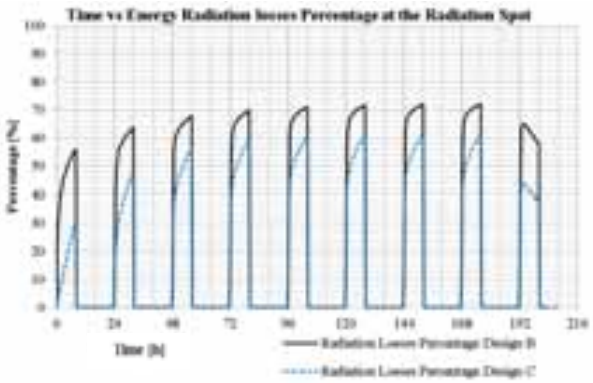

Fig. 9: Time vs Energy Radiation Losses Percentage at the Radiation Spot

The radiation losses during the charging cycle where obtained using the Eq. 5. The temperature of the central point of the energy receptor surface was taken and was assumed to be representative of the whole area. It is known that each day 45 kWh arrive at the energy receptor area. The value of 45 kWh minus the radiation losses is the energy that is stored inside the TES unit.

$$Q_{\text{Stored}} = \text{Daily Solar Energy} - \text{Radiation Losses} \qquad \text{(eq. 6)}$$

With the information from the Table 3 where energy that is stored in each material is known from the finite element method analysis, the net energy can be obtained by subtracting the total energy stored at the end of the charging state minus the total energy value at the beginning of that day.

$$Q_{\text{Net Stored}} = \text{Total Energy}_{End\ of\ Charging\ cycle} - \text{Total Energy}_{Start\ of\ the\ day} \qquad \text{(eq.7)}$$

The absolute energy losses by heat convection during the charging state can be obtained with the following equation.

$$Q_{\text{Convection losses, charging cycle}} = Q_{\text{Stored}} - Q_{\text{Net Stored}} \qquad \text{(eq. 8)}$$

The absolute energy losses by heat convection during the rest stage can be obtained with the subtraction of total energy at the end of the rest cycle to the total energy stored at the end of the charging cycle

$$Q_{\text{Convection losses ,rest cycle}} = \text{Total Energy}_{End\ charging\ cycle} - \text{Total Energy}_{End\ rest\ cycle} \qquad \text{(eq. 9)}$$

In the Figure 10 is shown the temperature in the extraction zone. If the time that the extraction zone is above 500°C is known the total energy that can be extracted from the TES unit can be obtained by multiplying the time with the heat power extracted by the Stirling Engine. The design B and C worked around 12.8 minutes and 4.2 hours respectively. The values of the total energy extracted by the Stirling Engine, the radiation and convection heat losses are shown in the summary of the Table 4.

$$Q_{\text{Extracted}} = Q_{\text{Stirlign Engine Requiered}} * t \qquad \text{(eq. 10)}$$

The Table 3 shows the total amount of energy that is stored in every material that forms the TES units. The maximum and minimum temperature of each material as a sample of how uniformly the temperature is distributed is shown as well. The figures 11 and 12 are the summarized results of the finite element method for the TES design's B and C in order to facilitate the comparison of the amount of total heat stored in the designs B and C and in which materials the heat is stored. All these results will be commented in extend in the conclusion section.

Tab. 4: Energy gain and losses of the TES units design B and C

Summary	Design B	Design C
Radiation losses during charging stage [kWh]	30.79	24.57
Net energy stored during charging stage [kWh]	14.21	20.43
Energy stored at the end of the charging stage [kWh]	8.93	15.20
Heat losses by convection during charging stage [kWh]	5.28	5.24
Heat losses by convection during rest stage [kWh]	9.53	15.16
Total energy extracted by Stirling engine [kWh]	0.85	16.80
Useful energy remained in the TES unit [kWh]	13.77	18.82

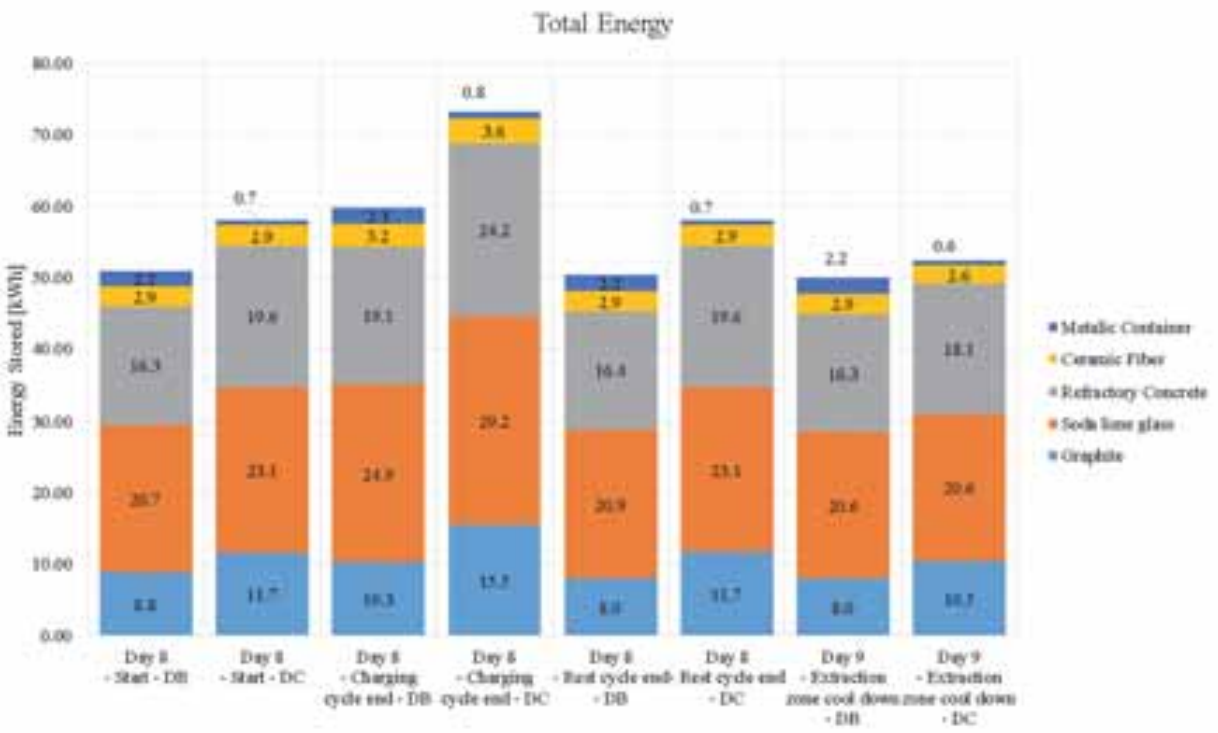

Fig. 11: Total energy stored by material between days 8 and 9 designs B and C.

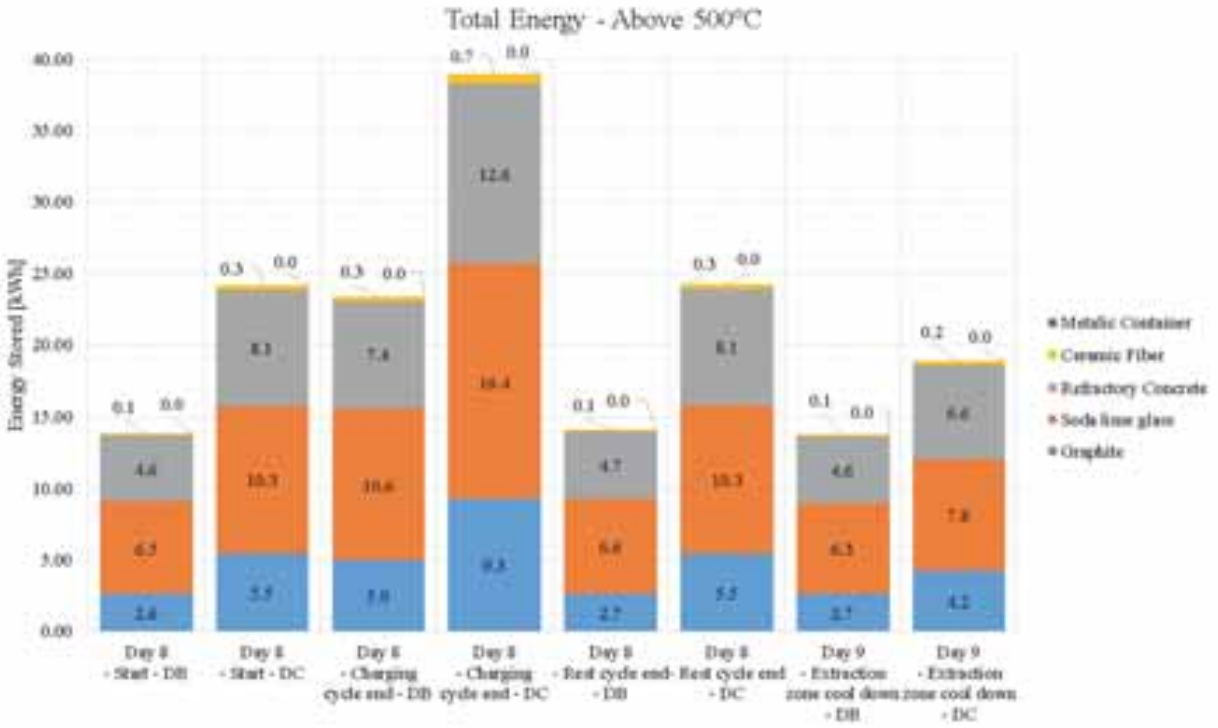

Fig. 12: Total energy above 500°C by material between days 8 and 9 designs B and C.

For the Design B four control points where taken to get an idea about the inside temperature of the reservoir heat body. Point a) and d) were taken because along the simulation they shown the highest and lowest temperature points respectively during the charging cycles. Point b) shown the highest temperature during the rest cycles, during the rest cycles point a) took the lowest temperature values. Point c) shown the lowest temperature values during the energy extraction stage.

For the Design C five control points where taken. Point a) and e) were taken because along the simulation they shown the highest and lowest temperature points respectively during the charging cycles. Point d) and b) shown the highest and lowest temperature during the rest cycles. Point c) shown the lowest temperature values during the energy extraction stage. In the figure 13b all control points are slightly off center of the model cut, just point b) is near the periphery of the crucible base normal to the TES unit cut.
This analysis consist in take the highest and lowest temperature values of the heat reservoir, any other point should lie between these two values. This should be a good approximation of the temperature of the heat reservoir and how well the heat flows through it.

4. Conclusions

After many days of charging the TES units they reach a cyclical behavior, no matter how many days the system charges. The TES units shown can be consider charged after the day 4 or 5. Any gain in energy from more charge cycles are negligible (Figures 14 and 15).

The energy exchanged between the ambient and the energy receptor represent radiation heat losses from 60% to 70% of the total energy received daily. The design of a radiation cavity is a must to reduce the radiation losses. The view factor from the receptor to the environment was omitted in the equation 5 in order to get a better understanding of the radiation heat losses at their full potential, thus promoting attention to a meticulous research of the design of a radiation cavity in the near future and supporting the idea of adding an additional component to a system that tries to be has simple has possible.

The total amount of heat stored available to conversion in the TES units shown in the Figure 11 is reduced to the values shown in the Figure 12 because it must be above the working temperature of the conversion engine. For the present designs, must be above 500°C.

The design B and C both had useful energy above the 500°C after the extraction zone reached a temperature below the Stirling Engine working temperature, however the thermal conductivity of the soda lime glass is not good enough to transport the useful energy above 500°C along all its mass to the extraction point at the required heat rate.

Increase the temperature of the heat reservoir can enhance the thermal conductivity value of the glass dramatically (Fig 3) in order to increase the heat extraction rate and as a side effect improve the performance of the heat input.

Augment the area of heat extraction can uniformly consume the energy of the heat reservoir body delaying the event of reaching at the energy extraction zone a temperature below the working temperature of the conversion engine.

Shorten the length dimensions in the heat reservoir can improve the speed at which the heat spread uniformly through the heat reservoir.

In the ideal case as the heat flow cross a body mass the temperature should change homogeneously in every point of its lump in a short time, in reality this is not the case. Design C has a better spread of the heat across its heat reservoir body during the charging and rest cycles than the Design B as shown in figures 14 and 15. The sample point in both figures represent the highest and lowest temperature values inside the lump of the glass heat reservoir. In the case of the Design C the graphic lines are closer than those of the Design B. Once the TES units have achieved a cyclical behavior the maximum difference of temperature at the end of the charging cycle of the day 8 are 279°C and 110°C for the designs B and C respectively. A reason why the Design C has a better heat flow through its heat reservoir is that the energy receptor zone is slightly inside the heat reservoir container and is communicated to the inside of the TES unit through a bigger area than in the case of the Design B.
The removal of the bottlenecks between the energy receptor and heat reservoir have a great impact in the performance of the TES unit. Besides the heat flow bottle neck present in the TES unit B design, absent in the TES unit C, the graphite conductor plates in the unit B are perpendicular to the heat flow instead of being in

the same direction as in the TES unit C providing an easier path to the heat flow and increasing the amount of heat being stored inside the TES unit in this last design. The previous reasons explain why the TES unit C store more heat than the unit B.

Once the heat extraction stage begins has seen in the figures 14 and 15 the graph lines of the Design C are closer than those in the Design B. The heat flow through the heat reservoir of the Design C is more efficiently compared to the Design B. As the TES unit C store more heat, higher temperatures are achieved in the glass heat reservoir, this means that the overall glass lump thermal conductivity values will be higher in the TES unit C compared with the unit B. Once both TES units achieve a cycle behavior the glass inside the TES unit B has thermal conductivity values between 6.36 w/m-°C and 10.61 w/m-°C, meanwhile the TES unit C has thermal conductivity values between 12.92 w/m-°C and 28.30 w/m-°C. In the rest stages in designs B and C the temperature tend to homogenize uniformly in a relative short time (Figures 13, 14, 15).

The alumina crucible store a similar amount of energy compared to the main heat reservoir of soda lime glass, however the alumina has a poor thermal conduction value, so extract this energy from the crucible at the desired output power may not by viable.

The combined energy losses by radiation and by convection during the charging stage almost equals the convection heat losses during the rest stage once the system has achieve a cyclical behavior.

Even if the designed TES unit keep using graphite for the receptor and extraction heat system the number and size of these parts have diminished. To protect the graphite from the oxidation at high temperatures in the presence of air strategies like surrounding the graphite parts with an inert atmosphere or covering them with a coating of silica, silicon or silicon carbide are available[15, 16]. The designs B and C keep their graphite parts as close to the core of each design in order to avoid as much as possible the contact of the graphite parts with the atmosphere. The Design C fulfill the aforementioned requirement better than the Design B.

In a general way the TES unit B has a lower performance than the unit C due to physical flaws in its design that hinders the amount of heat rate that can be directed into the core of the TES unit B.

Work on the development of a TES unit that can work 24 hours uninterruptedly is in advance as well as new experimental tests. The research group is currently working on the design of radiation cavity to minimize the radiation heat losses and in a phase change material system to be installed on the original energy extraction zone to be in contact with the full upper area to enhance the energy extraction zone in order to extract as much a useful energy as possible before this area reach a temperature below the working temperature of the engine device.

De-stratification and heat loss comparison of three thermal oils in a small storage tank

Ashmore Mawire[1], Abigail Phori[1] and Simeon Taole[1]

[1] North West University, Mafikeng Campus, Private Bag X2046, Mmabatho 2745, South Africa

Abstract

An experimental comparison of de-stratification and heat loss characteristics of three different thermal oils in a storage tank is presented in this paper. The three thermal oils evaluated are Sunflower Oil, Shell Thermia C and Shell Thermia B. A small insulated 20 liter storage tank is firstly charged up with the use of an electrical heater in thermal contact with an oil circulating copper spiral coil. After charging, the storage tank is left to cool down for 24 hr cycles. Cool-down experimental thermal cycles are carried out with the three different oils. De-stratification and heat loss parameters are evaluated. The stratification number is evaluated and it signifies the degree of thermal stratification. Stratification numbers are seen to be slightly higher for Sunflower Oil as compared to the other oils at the later stages of cool-down. The heat loss factor for Sunflower Oil is lower when compared to the other thermal oils, suggesting that it is the superior oil in terms of heat retention.

Keywords: *De-stratification, heat loss, thermal oils, storage tank*

1. Introduction

In any domestic heat storage application, the rate of thermal degradation is directly related to the heat losses and the period of useful storage during cool-down thermal cycles. Heat retention or cool-down thermal cycles are essential to obtain a measure of how long the stored heat can be kept without considerable degradation which makes it un-useable. Recent work has been done to study heat losses and stratification in low temperature water storage tanks during cool-down thermal cycles (Cruickshank and Harrison, 2010; Fan and Furbo, 2012; Fernandez-Seara et al., 2011; Oliveski et al., 2003) . Limited studies have been done on heat losses during cool-down cycles using other thermal energy storage (TES) media other than water for higher temperatures (Mawire, 2013; Park et al., 2014; Okello et al., 2014; Oliveski et al., 2005; Suárez et al., 2015). According to our literature review, very little work has been done on experimental heat losses and thermal de-stratification comparisons of different TES media which operate above the boiling point of water. For small domestic scale applications during heat retention periods, it is thus necessary to do this study. In this particular paper, simplified experimental thermal de-stratification and heat loss characteristics of a small domestic oil storage tank using three different thermal oils are presented.

2. Experimental method

The schematic diagram of Fig. 1 shows the operation of the charging cycle before cooling occurs. A positive displacement charging pump (3) controlled by a variable DC power supply (4) is used to circulate oil through a copper spiral coil that is in thermal contact with an electrical heating element (1). The DC power supply is adjusted manually to vary or maintain the average charging flow-rate. An oval gear volumetric flow-meter (5) is at the bottom of a 20 litre thermal oil storage tank (6) such that it records the volumetric flow-rate during charging . The charging pump extracts oil at the bottom of the tank and pushes it through an electrical heater with an oil charging coil (1). The oil enters the charging coil at a temperature T_{in} and exits the coil at a temperature T_{out} after absorbing heat from the electrical heater controlled by a variac (2). The oil enters the top of the storage tank at a hotter temperature as compared to the bottom of the tank. The charging cycle is repeated until the bottom of the storage tank attains a relatively high temperature (~100 ^{o}C).

doi:10.18086/swc.2015.02.08 Available at http://proceedings.ises.org

For the heat retention tests, the pumps and the electrical heating elements are switched off. The storage tank is then left to cool-down naturally for 24 hrs as temperature data are recorded with a data-logger every 10 s. The storage tank is insulated with 50 cm thick rock wool that this wrapped around its walls. The insulation is placed inside an aluminium thermal shield that surrounds the storage tank.

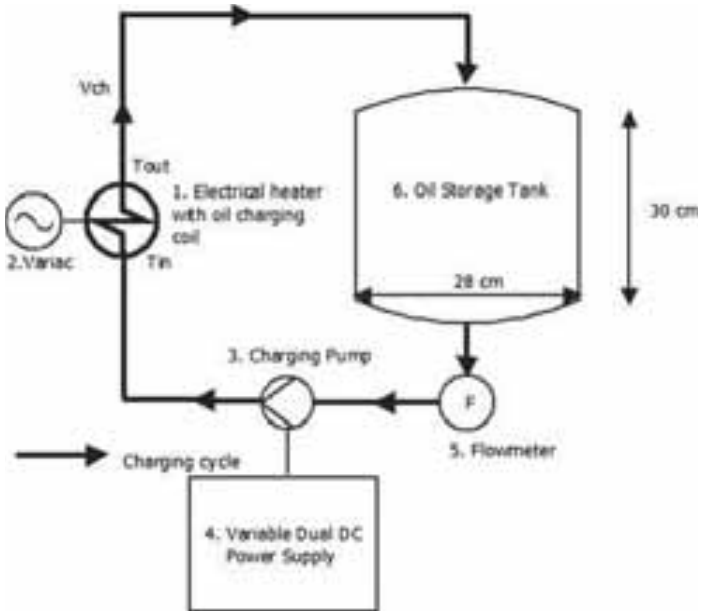

Figure 1: Experimental setup and operation (Mawire and Taole, 2013).

The temperatures in the storage tank during cool-down are monitored with 15 K-type of thermocouples placed inside the storage as shown in Fig. 2. The 15 K-type thermocouples are placed at three radial positions at five different levels along the height of the storage tank (5 axial levels). Thermocouples at Level 5 (T51, T52, T53) measure the radial temperature distribution at the top of the storage and an average temperature at this axial position is determined using these measurements. . Other average temperatures from Levels 4 - 1 are determined in a similar manner. An average storage tank temperature is thus determined from these average temperature measurements. The top thermocouples are placed at a level 50 mm below the top of the storage tank, while the bottom thermocouples (Level 1) are placed at a level 50 mm above the bottom of the storage tank.

Figure 2: The arrangements of the 15 thermocouples in the storage tank. All dimensions are in mm (Mawire and Taole, 2013).

3. Experimental thermal analysis

During the heat retention thermal cycles, the stratification number is defined by Fernandez-Seara et al. (2007) as the ratio of the mean of the thermal gradients at each time interval to that of the beginning (t = 0) and it is expressed as

$$Str = \frac{\left(\frac{\partial T}{\partial y}\right)_t}{\left(\frac{\partial T}{\partial y}\right)_{t=0}} \quad (1)$$

where

$$\frac{\partial T}{\partial y} = \frac{1}{j-1}\left[\sum_{j=1}^{j}\left(\frac{T_{j+1}-T_j}{\Delta y}\right)\right]. \quad (2)$$

where T is the average temperature at an axial level and $\Delta y = 0.05$ m is the axial distance between two adjacent thermocouple levels.

The energy lost during a 4 hr heat retention process is given as

$$E_L = \rho_{av} c_{av} V_{ST} \left(T_{iniav} - T_{finav}\right) \quad (3)$$

where ρ_{av} is the average density of the storage tank segments, c_{av} is the average specific heat capacity of the storage tank segments, V_{ST} is the total volume of the segments, T_{iniav} is the initial average temperature of the storage tank segments and T_{finav} is the final average temperature of the storage tank segments. The total rate of heat loss (which is inclusive of the insulating material, oil and tank conductivity e.t.c) during heat retention processes can be expressed as (Cruickshank and Harrison, 2010)

$$P_L = \frac{\rho_{av} c_{av} V_{ST} \left(T_{iniav} - T_{finav}\right)}{\Delta t} \quad (4)$$

where Δt is the 4 hr time interval. Heat loss to the surroundings can also be expressed as

$$P_L = U_L^{'}\left(T_{av} - T_{amb}\right) \quad (5)$$

where T_{av} is the average temperature of the segments and $U_L^{'}$ is the heat loss factor given by

$$U_L^{'} = U_L A_{ST}. \quad (6)$$

where U_L is the heat loss coefficient and A_{ST} is the overall area of the storage tank segments where the temperature is measured.

The thermal properties of the oils are temperature dependent and their temperature dependent equations are calculated from their datasheets and research papers published in literature from experimental tests (Shell Thermia B Datasheet, 2014; Shell Thermia C Datasheet, 2014; Esteban et al., 2012; Fasina and Colley, 2008; Turgurt et al., 2008). Table 1 shows the thermal properties of the different oils as a function of the temperature in ^{o}C. Sunflower Oil has the highest temperature dependent density and specific heat capacity. The thermal conductivities are seen to be within the same range. Information regarding the viscosity change with temperature of the oils was not available in literature therefore experiments need to be done.

Table 1: Temperature dependent thermal properties of the heat transfer oils

Thermal Oil	Density (kg/m^3)	Specific Heat Capacity (J/kgK)	Thermal Conductivity (W/mK)
Sunflower Oil	ρ_S = 930.62-0.65T	c_S = 2115.00+3.13T	k_S = 0.161+0.018exp(-T/26.142)
Shell Thermia C	ρ_C = 893.00-0.67T	c_C = 1798.00+3.58T	k_C = 0.121+0.132exp(-T/18.659)
Shell Thermia B	β_B = 876.00-0.65T	c_B = 1809.00+3.50T	k_S = 0.118+0.018exp(-T/168.660)

4. Results and discussion

Dimensionless thermal profiles are presented in Fig. 3, since the initial TES temperatures were slightly different for the three thermal oils due to slightly different initial charging conditions. Dimensionless temperature profiles ($T' = \frac{T}{T_{ini}}$) enable a fairer comparison of the thermal distributions during heat retention since the temperature distributions are relative to the initial conditions. The heat retention process is started when the bottom of the storage tank has reached a limiting temperature of approximately 100 ^{o}C during the charging process. This limit was set because the flow-meter could with-stand temperatures of only up to 120 ^{o}C.

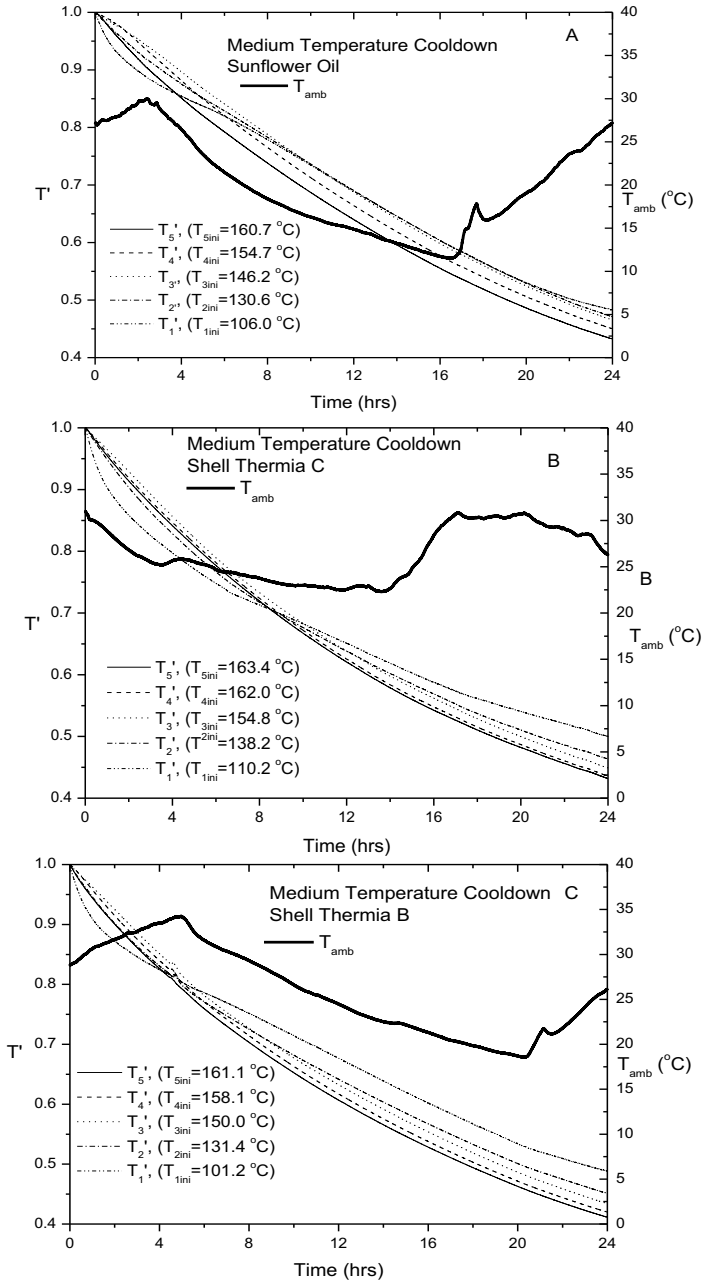

Figure 3: Dimensionless thermal profiles during 24 hr cool-down cycles for the three thermal oils.

Fig. 3 shows a general trend of similar drops in initial temperatures at a faster rate at T_5 (at the top of the storage tank) for the three thermal oils, thus implying more heat losses. T_1 has a slow rate of drop at the later

stages of heat retention when compared to T_5 for all the three thermal oils. This is because the density at the bottom of the storage tank becomes appreciably larger than at the top as time progresses because of the lower temperature at the bottom. This implies a larger thermal mass at the bottom of the storage tank at the later stages which results in a low rate of drop in the temperature. The slower rate of drop at T_1 relative to T_5 for Shell Thermia C occurs at a later time due to the higher storage temperatures. Sunflower Oil attains larger average temperatures at the end of 24 hrs suggesting that this the best oil in terms of heat retention even though its initial top storage tank temperatures are less than that of the other two oils. This suggests that the thermal mass effect is more pronounced for Sunflower Oil, the oil with the greatest density. The variations of the ambient temperatures are in accordance to the time of day when the experiments were carried out and these do not any effect on the heat loss process since the storage tank is insulated with a heat loss factor value of around 0.11 W/K.

Fig. 4 shows stratification number profiles for the three thermal oils during 24 hr heat retention cycles. The stratification number profiles decrease with time due to heat losses induced by natural convection. Shell Thermia C shows a delayed drop in stratification number as compared to the other thermal oils. This is because of the higher initial temperatures which promote a higher degree of thermal stratification. The stratification number profiles for Shell Thermia B and Sunflower Oil are almost identical during the first 4.5 hrs of cool-down possibly due to similar temperature profiles. After 4.5 hrs, Sunflower Oil shows greater values of the stratification number. This is because of the larger thermal mass due to the larger density of Sunflower Oil at the later stages. This larger thermal mass results in lower heat losses. The thermal mass effect is also evident after around 13 hrs where the stratification number profile for Sunflower Oil becomes larger than that of Shell Thermia C.

.

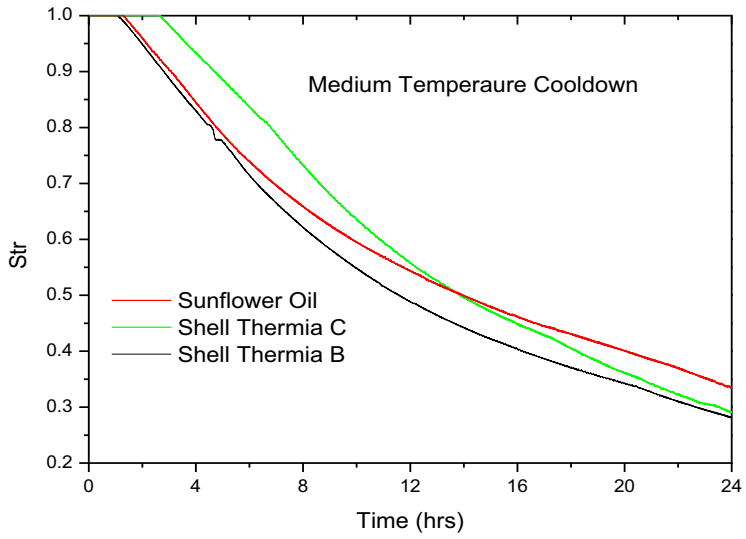

Figure 4. Stratification number profiles during 24 hr cool-down cycles for the three thermal oils.

Fig. 5 shows heat loss factors for the three thermal oils indicated by the slopes of the linear fits. Sunflower Oil is seen to have the least heat loss factor (lower gradient) as compared to the other thermal oils due to its larger thermal mass. Shell Thermia B shows the greatest heat loss factor due to its lower thermal mass. This result suggests that Sunflower Oil has better heat retention as compared to the other thermal oils.

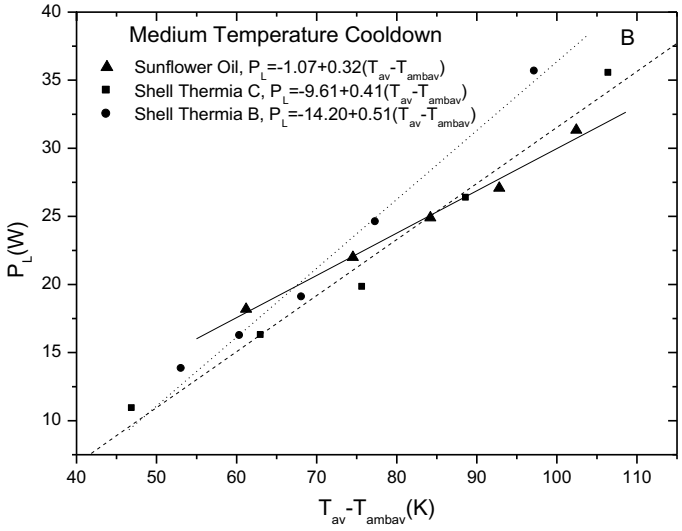

Figure 5. Heat loss factors for the three thermal oils.

5. Conclusion

Experimental results for the comparison of de-stratification and heat loss characteristics of three different thermal oils in a small storage tank were presented in this paper. The three thermal oils evaluated were Sunflower Oil (an edible oil), Shell Thermia C and Shell Thermia B. De-stratification and heat loss parameters were evaluated from cool-down thermal profiles. The stratification number was evaluated and it signified the degree of thermal stratification. Stratification numbers were seen to be slightly higher for Sunflower Oil when compared to the other oils at the later stages of cool-down due its larger thermal mass. The heat loss factor for Sunflower Oil was lower as compared to the other thermal oils, suggesting that it was the superior oil in terms of heat retention.

Abstract

The present work deals with improving the operation of a multi-energy district boiler by adding to the plant an optimally-designed thermal storage tank and developing a model-based predictive controller in order to manage it. The proposed architecture generates optimal command sequences dealing with the amount of thermal energy to be stored or released. In order to implement such a controller, one needs to forecast the power demand. As a consequence, a short-term forecast method, based on both a Multi-Resolution Analysis (MRA) and feedforward (multilayer) Artificial Neural Networks (ANN) is proposed. The present paper mainly focuses on the impact of Thermal Energy Storage (TES) on the functioning of a northeast France multi-energy district boiler selected as a case study. As a result, both the fossil energy consumption and CO_2 emissions are significantly reduced while the economic gain is increased.

Keywords: *multi-energy district boiler, thermal energy storage, model predictive control, artificial neural networks, power demand.*

1. Introduction

Because of the global energy crisis, the French government supports the renewable energy production. As buildings account for about 40% of total final energy consumption (more than half of this consumption is due to heating), France makes a specific effort in this sector. In addition, using biomass materials such as wood in industrial and residential heating can significantly reduce the reliance on fossil fuels and limit the CO_2 emissions (Kitzing et al., 2012). In 2000, Tanaka et al. showed that a seasonal storage system is able to decrease the consumption of energy by about 26% in a District Heating and Cooling (DHC) plant (Tanaka et al., 2000). As another interesting work, Smith et al. highlighted the benefits of storing thermal energy, in combination with CHP (Combined Heat and Power) technology (Smith et al., 2013). In 2011, Verda and Colella evaluated the effects of thermal energy storage on both the primary energy consumption and cash flows in district heating networks (Verda and Colella, 2011). Gustafsson and Karlsson showed how a thermal storage system can be used in a CHP plant for decreasing both the demand in district heating and the consumption of electricity (Gustafsson and Karlsson, 1992). In 2010, Kavvadias et al. proposed a parametric analysis as an efficient way to design CHP plants optimally (Kavvadias et al., 2010).

As a key point, advanced control techniques and management strategies are needed to improve the operation of multi-energy district boilers managed by Cofely GDF-Suez, our industrial partner. In this sense, the OptiEnR research project focuses on optimizing performance by adding thermal storage systems to the plants. First, we assessed a specific case study (Eynard et al., 2012) and we are now developing a flexible and generalized approach. It has been highlighted in a previous work that once optimally designed and managed using a sequential approach based on logical conditions, a thermal storage tank can significantly improve the overall efficiency of a plant, in particular in case of badly-sized heat generators (Labidi et al., 2014). So, the present paper deals with the optimal management of a thermal storage tank using a Model Predictive Controller (MPC). We focused on analyzing the energy savings one can achieve using such an

doi:10.18086/swc.2015.02.09 Available at http://proceedings.ises.org

advanced control approach. The power demand is forecasted using the MRA-ANN methodology. Its particularity comes from the combination of signal processing (a wavelet-based multi-resolution analysis) and artificial intelligence (multilayer artificial neural networks) tools. Lastly, a case study is selected in order to evaluate the predictive control approach.

The next section of the paper (section 2) provides a brief description of multi-energy district boiler operation. Then, the performance indicators are presented (section 3). In section 4, the design of the MPC controller allowing the thermal storage tank to be efficiently managed is carried out. Next, the developed MRA-ANN methodology is presented (section 5). Such an approach has proven to be effective in forecasting time series. It should also be noted that several other methods for power demand forecasting have been suggested and implemented (Amjady and Keynia, 2009; Dotzauer, 2002). The particularity of the proposed methodology comes from the combination of signal processing and artificial intelligence tools. Lastly, a case study is selected in order to both validate the MRA-ANN forecasting methodology and evaluate the predictive control approach (section 6). In particular, it is highlighted that the way the tank is designed and managed is a key factor in plant operation improvement. The paper ends with a conclusion and an outlook to future work.

2. Multi-energy district boiler operation

Typically, in multi-energy district boilers, the biomass units (characterized by a minimum (P_{WB}^{min}) and a maximum (P_{WB}^{max}) heat production capacity are generally sized in order to meet the major part of the power demand but they lack the capability of covering the peak loads. So, auxiliary fossil boilers are used during the coldest periods of the year, in case of shutdown maintenance activities or when the power demand is lower than P_{WB}^{min}. As stated in section 1, the main purpose of the present study is to optimize the operation of multi-energy district boilers by adding to the plants optimally-managed thermal storage tanks. Because the sequential approach we proposed initially does not take into account future power demand values, such an approach seems to be sometimes unable to optimize the whole system, in particular in case of high variability in the power demand. For this reason, we propose here an advanced strategy based on both a Model Predictive Controller (MPC) and a forecasting approach.

3. Performance indicators

In order to assess the impact of both the thermal storage system and the management strategy, energy, economic and environmental criteria are suggested as performance indicators. Because the main purpose of thermal energy storage is to decrease the consumption of gas, the gas coverage rate (C_{gas}) is proposed as an energy indicator (eq. 1). It is calculated from the thermal energy produced by the combustion of gas (E_{gas}) and wood (E_{wood}) during the considered period:

$$C_{gas} = \frac{E_{gas}}{E_{gas} + E_{wood}} \quad \text{(eq. 1)}$$

The wood coverage rate (C_{wood}) is computed in the same way than C_{gas} and is subject to contract (eq. 2):

$$C_{wood} = \frac{E_{wood}}{E_{gas} + E_{wood}} \quad \text{(eq. 2)}$$

With the aim of highlighting the economic benefits of energy savings, a criterion (Ec) is defined from E_{gas}, E_{wood}, UP_{gas} (the unitary price of gas), and UP_{wood} (the unitary price of wood) (eq. 3):

$$Ec = E_{gas} \times UP_{gas} + E_{wood} \times UP_{wood} \quad \text{(eq. 3)}$$

In order to put in perspective these economic benefits, the economic gain G is evaluated (eq. 4). It is defined as the difference between $Ec(V)$, the economic cost related to energy consumption, considering a storage

volume V, and $Ec(V = 0)$, the economic cost related to energy consumption without storage of thermal energy ($V = 0$ m^3):

$$G(V) = Ec(V) - Ec(V = 0) \quad \text{(eq. 4)}$$

The environmental impact of such a technology is evaluated thanks to criterion L_{CO2}, which is about CO_2 emissions (eq. 5). L_{CO2} is expressed from Ec_{gas}, Ec_{wood} and the Life-Cycle Assessment of CO_2 emissions from gas (U_{CO2}^{gas}) and wood (U_{CO2}^{wood}):

$$L_{CO2} = Ec_{gas} \times U_{CO2}^{gas} + Ec_{wood} \times U_{CO2}^{wood} \quad \text{(eq. 5)}$$

It should also be noted that new buildings connected to the heat network as well as future expansions of existing buildings are factors to be taken into account in order to evaluate the proposed strategy accurately. As a result, one can consider an increase in the power demand P_{net} up to 30 % and evaluate the impact of such an increase on plant operation.

4. Design of the Model-based Predictive Controller (MPC)

4.1. Principles of MPC

It is somewhat curious to note that the concept of Model-based Predictive Controller (MPC) has a long history that began during the 1970's when Engineers at Shell Oil developed their own dependent technology with an initial application in 1973 (Garcia et al., 1989). Nowadays, this concept is widely used in the control of industrial processes. Its popularity in industry is mainly due to the possibility it offers to treat operating specifications and constraints jointly during the development phase of the controller. For instance, MPC is commonly used to manage thermal comfort (Castilla et al., 2014) and energy resources (Ma et al., 2012) in buildings.

The philosophy of MPC is down to use a model to forecast the behavior of the system to be controlled and choose the best decision in the sense of an objective function while satisfying constraints. Usually, the aim is to ensure the desired set-point, regardless of disturbances with minimal effort. Constraints deal with physical limitations and are introduced for economic or security reasons. The forecast horizon is the time interval during which the objective function is minimized using an optimization algorithm (Manenti, 2011).

4.2. Structure of the controller

In this subsection of the paper, the proposed model-based predictive controller is presented. It uses a model of the multi-energy district boiler (section 4.2.1) as well as a forecast unit allowing the power demand (P_{net}) to be accurately estimated over the next 24 hours (section 4.2.2). This unit makes use of both a wavelet-based Multi-Resolution Analysis (MRA) and feedforward (multilayer) Artificial Neural Networks (ANN). The optimization problem is solved using the fmincon (*find minimum of constrained nonlinear multivariable function*) algorithm of Matlab® (sections 4.2.3 and 4.2.4). The controller's structure is depicted by Fig. 1:

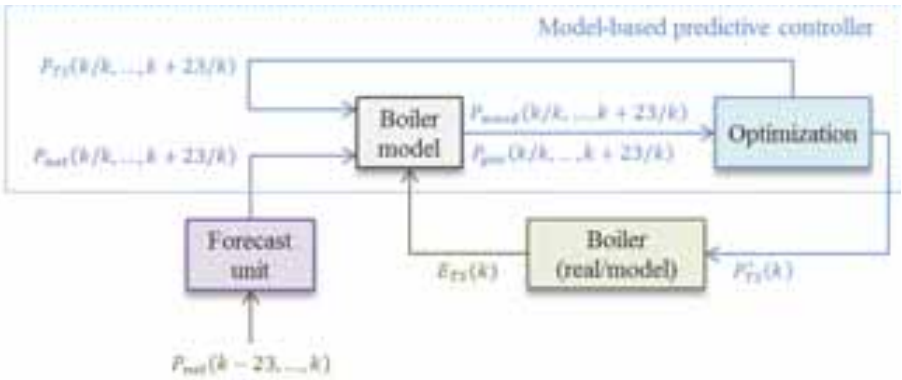

Fig. 1: Structure of the proposed controller (P_{net} is the power demand, P_{TS} is the thermal charging/discharging power, E_{TS} is the amount of energy stored or released, P_{gas} is the gas power, and P_{wood} is the wood power)

4.2.1. Model of the multi-energy district boiler

The proposed predictive controller uses the model of a multi-energy district boiler equipped with a thermal storage tank we developed and described in a previous work (Labidi et al., 2013). P_{gas} (the gas power) and P_{wood} (the wood power) are defined as functions of both the charging/discharging power of the storage tank (P_{TS}) and the power demand (P_{net}). k is the time step. The model is based on the 3 following cases, with P_{WB}^{min} and P_{WB}^{min} the wood boiler(s) minimum and maximum heat production capacities, respectively (eqs. 6 to 8):

$$\text{if } P_{WB}^{min} \leq P_{net}(k) \leq P_{WB}^{max} \text{ then } P_{wood}(k) = P_{net}(k) + P_{TS}(k) \text{ and } P_{gas}(k) = 0 \quad \text{(eq. 6)}$$

$$\text{if } P_{net}(k) \geq P_{WB}^{max} \text{ then } P_{wood}(k) = \max\left(P_{WB}^{max}, P_{net}(k) - P_{TS}(k)\right) \text{ and } P_{gas}(k) = P_{net}(k) - P_{wood}(k) \quad \text{(eq. 7)}$$

$$\text{if } P_{net}(k) \leq P_{WB}^{min} \text{ then } P_{wood}(k) = \max\left(P_{WB}^{min}, P_{net}(k) + P_{TS}(k)\right) \text{ and } P_{gas}(k) = 0 \quad \text{(eq. 8)}$$

4.2.2. Concept of time series for power demand forecasting

As it is mentioned in the previous section, P_{net} (the power demand) is a district boiler model input. So, it has to be accurately forecasted. So, a methodology based on a Multi-Resolution Analysis (MRA) and feedforward (multilayer) Artificial Neural Networks (ANN) is proposed in order to forecast time series (Brockwell and Davis, 1991, 1997). The main idea behind such a methodology is to replace the forecasting of an original signal with high variability by the estimation of its wavelet coefficients (Fig. 2). These coefficients are distinguished by specific levels of frequency as well as a variability which is lower than the variability of the original signal. As a result, the forecasting process is easier. Such an advanced approach has been developed because linear approaches like AR, ARMA or ARIMA proved to be insufficiently efficient, due to a high variability in power demand.

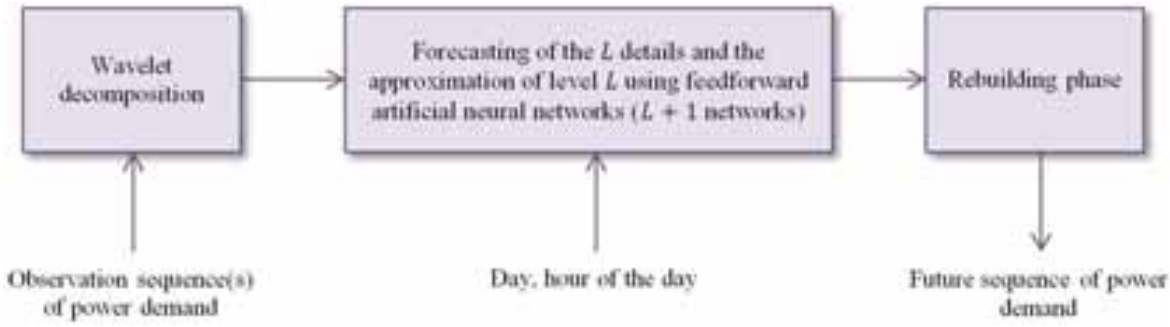

Fig. 2: MRA-ANN forecasting methodology

A time series can be defined as a sequence of numerical data points in successive order, usually occurring in uniform intervals. According to that, time series forecasting consists in using a model to estimate future values on the basis of observations. In our case, the model aims at estimating the power demand over the next 24 hours, using a set of M observation sequences whose length is also 24 hours (because of the daily cycles we observed in the data). We decided for a forecast horizon (H_f) of 24 hours as an interesting compromise between forecasting accuracy and periodicity in power demand. In addition, such horizon is well adapted to the charging and discharging cycles of the tank.

4.2.2.1. Wavelet-based multi-resolution analysis

The wavelet transform aims at decomposing a given signal into wavelets (i.e., highly localized small oscillations) (Heil and Walnut, 1989; Gubner and Chang, 1995). Unlike the Fourier transform, it offers time and frequency localization. There are two types of wavelet transforms: the Continuous Wavelet Transform (CWT) and the Discrete Wavelet Transform (DWT). We focus here on the second one. First, through Low Pass (LP) and High Pass (HP) filters, an original signal S is decomposed into low (approximations) and high (details) frequency coefficients of level 1. By decomposing successively the low frequency coefficients only,

we can produce L levels of decomposition. Fig. 3 shows the decomposition of level L of a signal x. In order to rebuild that signal, we have just to sum the L details (D_1, D_2, D_3, …, D_L) and the approximation of level L (A_L) (Mallat, 1989). It should also be noted that different families of wavelets may be chosen. Because the Daubechies wavelets (Daubechies, 1992) have the highest number of vanishing moments, this family has been chosen. Finally, the impact on performance of both the decomposition level and the wavelet order has been studied.

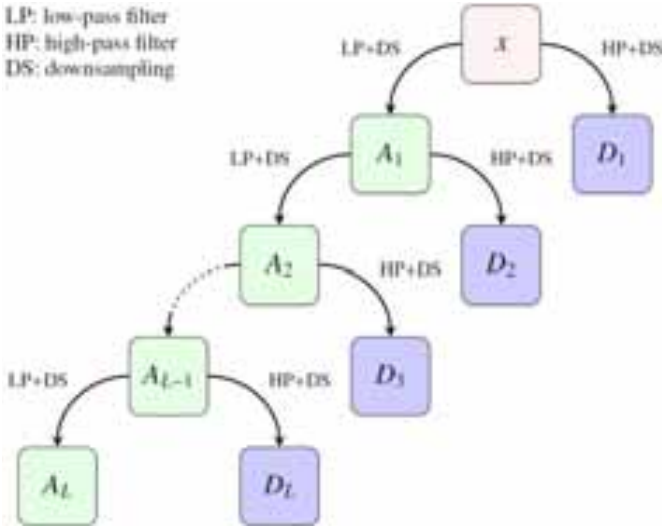

Fig. 3: Wavelet-based multi-resolution analysis leading to the decomposition of level L of a signal x

4.2.2.2. Feedforward artificial neural networks

Multilayer artificial neural networks can be used to forecast time series (Hornik et al., 1989; Kourentzes et al., 2014). Usually, each network consists in one layer of linear output neurons and one or more hidden layers of nonlinear neurons. As it is well known, the research for the adequate topology of a neural network (i.e., its number of hidden layers and neurons) is a key point. Such a research is based on a training (learning) phase during which the generalization capability of the network is controlled and its parameters are identified (Charalambous, 1992, Hagan and Menhaj, 1994).

4.2.2.3. Optimal configuration

Tab. 1: Optimal configuration and evaluation of performance

Parameter	Value
Wavelet family	Daubechies
Wavelet order	4
Decomposition level	1
Number of observation sequences	1
Number of hidden neurons	17
FIT	72.26%
MAE (Mean Absolute Error)	299.57 kW
MRE (Mean Relative Error)	5.9%

First, the time series (i.e., historical data covering a period of six months, from September 21 to April 16) is split into sequences of 24 hours, with a sampling time of 1 hour. Then, the wavelet-based multi-resolution analysis allows these sequences to be decomposed into subsequences (i.e., approximation and details coefficients). Using this database, multilayer artificial neural networks can be trained. As a key point, one network is used in order to forecast each subsequence. So, $L + 1$ networks are needed to forecast L detail coefficients and the approximation coefficient of level L. The hour of the day and the day of the year are complementary model inputs. Once all the subsequences are forecasted, they are summed to obtain the values of power demand over the next 24 hours. In order to improve forecast accuracy, we optimized the topology of the networks (note that we considered single-hidden layer structures and searched for a common

topology for all the networks so as to simplify the optimization process), the decomposition level (L) and the number of observation sequences (M). Table 1 deals with the optimal configuration and performance. Results highlight the ability of such an approach to achieve the task of prediction with accuracy.

4.2.3. Optimization problem

At each time step, the controller defines the optimal values of the charging/discharging power (P_{TS}), along the forecast horizon H_f (i.e., over the next 24 hours). Note that a positive value ($P_{TS} > 0$) stands for the charging (storage) mode whereas a negative value ($P_{TS} < 0$) is for the discharging (release) mode. So, the main goal of the control approach is to minimize the use of fossil energy by optimizing the storage process during low-demand periods and releasing the thermal energy stored when the power demand is high. Thus, the objective function J is defined as the quadratic sum of the gas power consumed at each time step, along the forecast horizon (i.e., over the next 24 hours). The optimization problem comes down to find, at each time step, the charging/discharging power (P_{TS}) such that J is minimized (eq. 9) and the constraints are met (eqs. 10 and 11):

$$\min_{[P_{TS}(k/k),\dots,P_{TS}(k+H_f-1/k)]}\left(J=\sum_{k=1}^{H_f}P_{gas}(k)^2\right) \qquad \text{(eq. 9)}$$

Two constraints ensure that thermal energy is stored or released adequately. The first one (eq. 10) is introduced in order to limit the interval of the possible values for P_{TS}. This constraint is related to the characteristics of the storage tank feed pumps. The second constraint (eq. 11) makes reference to the design of the storage system. In other words, it is related to the capacity of the tank ($E_{max} = \rho \cdot C_p \cdot V \cdot \Delta T$, with ρ the water density, C_p the specific heat of water, V the volume of the storage system and ΔT the difference in temperature between hot and cold water). E_{init} is the amount of thermal energy initially stored in the tank. So, at each time step, the amount of energy stored has to be positive and lower than E_{max}:

$$-P_{TS}^{max} \le P_{TS}(k+j/k) \le P_{TS}^{max}, \forall j \in [\![0; H_f - 1]\!] \qquad \text{(eq. 10)}$$

$$0 \le E_{init} + \sum_{i=0}^{j} P_{TS}(k+i/k) \le E_{max}, \forall j \in [\![0; H_f - 1]\!] \qquad \text{(eq. 11)}$$

4.2.4. MPC algorithm

Fig. 4 depicts the MPC algorithm used. At each time step k, a simulation over the forecast horizon based on the non-predictive (sequential) strategy (Labidi et al., 2014), the current amount of energy stored in the tank, and the forecasted values of P_{net} is performed in order for the values of $\left[P_{TS}(k/k), \dots, P_{TS}\left(k+H_f-1/k\right)\right]$ to be initialized. These values are then optimized using both the non-linear optimization algorithm "fmincon" from Matlab® and the developed model of the multi-energy district-boiler. The first optimized value is applied to the model which stands for the real system and so on until the end of the simulation process. Then, the performance indicators are computed for an off-line analysis of the results.

4.2.5. Non-predictive strategy

This strategy is based on the three following operation modes (Labidi et al., 2014):

- **Operation mode 1**: When the power demand is high (in particular during the coldest months of winter), instead of modulating the biomass power, all the (biomass) units available operate at maximum power to meet requirements and charge the tank. Once the power demand is upper than P_{WB}^{max}, the stored energy is released. In this way, the auxiliary gas unit is only switched on when the tank is empty and the power demand still exceeds P_{WB}^{max}.
- **Operation mode 2**: This second operation mode is for a moderate power demand. When $P_{net} < P_{WB}^{max}$, due to the variability in the demand, the biomass boiler (or one of the two biomass units installed at the plant) operates at minimum power (or higher) and the excees of energy produced is stored in order to be used later. If two biomass boilers are available, both can also operate at minimum power. In this way,

these units operate continuously and the number of on/off transitions is reduced. As a consequence, fossil energy can be saved.

- **Operation mode 3**: For some periods of the year (in particular during the hottest months of summer), most of the buildings connected to a heat network do not need to be heated and, as a consequence, only domestic hot water is required (low-demand periods). Instead of using the auxiliary gas unit to meet low power requirements (biomass boilers are usually oversized), the biomass unit (or the smallest boiler in case of two units being installed at the plant) and the thermal storage system can be operated as follows: first, the biomass unit runs at minimum power, what allows both the power demand to be met and the tank to be charged. Once the thermal storage system is completely filled with hot water, the boiler is shut down and the stored energy is released to afford domestic hot water. The boiler is switched on again when the tank is empty. Such a mode prevents the use of gas and favors the use of renewable energy during low-demand periods.

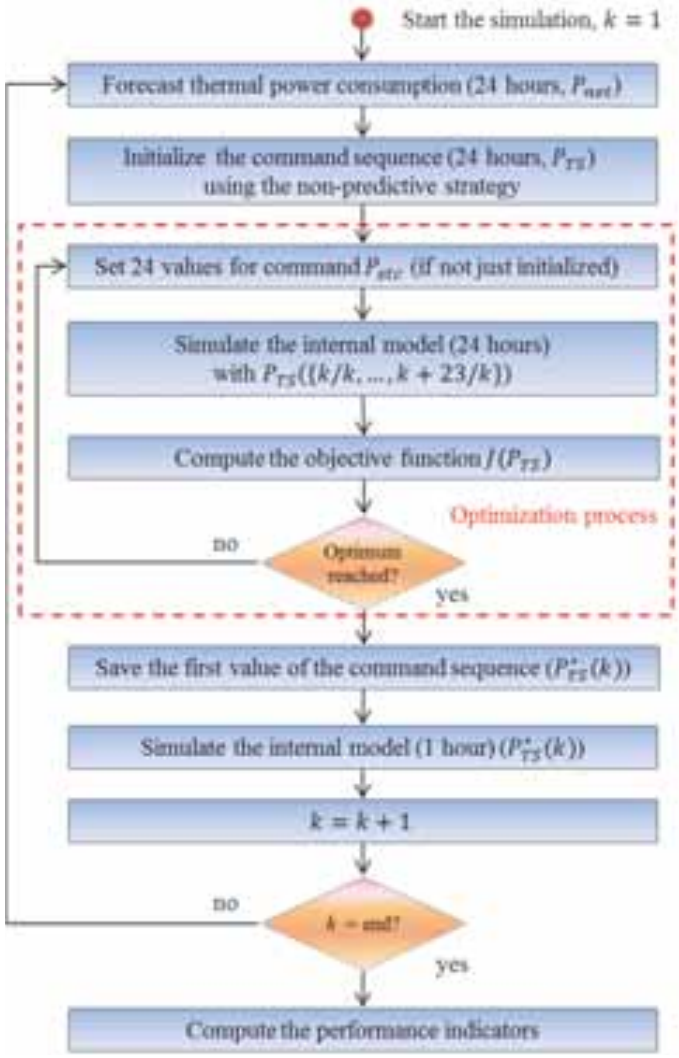

Fig. 4: MPC algorithm

5. Simulation results

5.1. Case study

We selected as a case study a multi-energy district boiler managed by Cofely GDF-Suez and located in the northeast of France, in the Alsace region (Haut-Rhin). Alsace has a semi-continental climate with cold and dry winters and hot summers. Winter starts in December and ends in February and has an average temperature of around 2 degrees Celsius across the season. January is the coldest month of the year with the

lowest average temperature of 1 degree Celsius. Winter is also the time of year with the lowest levels of precipitation. Summer starts in June and ends in August. It sees the highest levels of rainfall of the year as well as the highest temperatures with an average temperature of 18 degrees Celsius across the season. The plant is composed of three heat generators (Fig. 5).

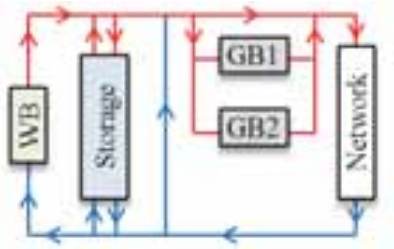

Fig. 5: Synoptic of the multi-energy district boiler

The first generator (WB) is a biomass boiler whose minimum power (P_{WB}^{min}) is 1050 kW. Its maximum power (P_{WB}^{max}) is 4200 kW. This unit is designed to ensure the basic production. A 7000 kW gas boiler (GB1) operates jointly with it during peak demand periods or alone when the power demand is lower than P_{WB}^{min}. A 9000 kW gas boiler (GB2) is switched on in case of malfunction or during maintenance phases only. Table 2 summarizes the characteristics of the boiler units.

Tab. 2: Characteristics of the boiler units

Boiler unit	Power (kW)	Efficiency (-)
WB	1050	0.70
	2100	0.75
	3150	0.88
	4200	0.95
GB1	140	0.97
	7000	0.97
GB2	180	0.97
	9000	0.97

5.2. Control results

Tab. 3: Simulation parameters

Parameter	Value
Simulation period	From September 1 to April 16
Sampling time	1 hour
Forecast horizon (H_f)	24 hours
UP_{gas}	40 € MWh^{-1}
UP_{wood}	17 € MWh^{-1}
U_{CO2}^{gas}	234 $kgCO_2$ MWh^{-1}
U_{CO2}^{wood}	13 $kgCO_2$ MWh^{-1}

Table 3 summarizes the main simulation parameters. Concerning the impact of the proposed strategy, simulation results show that the biomass boiler is sized to ensure around 85% of the power demand during the simulation period without thermal storage tank. Fig. 6 depicts the way both the gas coverage rate and the CO_2 emissions evolve according to the volume of the tank. One can clearly note that the MPC strategy allows a significant decrease in gas consumption and consequently in CO_2 emissions. Fig. 7 depicts the way the size of the tank impacts on Ec and G, respectively. One can highlight that Ec decreases with the size of the tank. Furthermore, using the proposed MPC strategy, a considerable economic gain is realized. Regarding the ability of the thermal storage tank to cope with a possible increase in power demand, one can observe (Fig. 8) that the proposed strategy allows the wood coverage rate to be 4 to 10 points higher than

when the reference scenario (RS) is considered (i.e., no thermal energy storage). In addition, on the basis of the parametric study, one can define the optimal size of the tank. For this case study, 300 m^3 can be chosen.

6. Conclusion

The present paper deals with optimizing the performance of a multi-energy district boiler. The plant is connected to a heat network for thermal energy distribution. First, a model predictive controller has been developed in order to optimize the use of the thermal storage tank. In order to implement this controller, the power demand has to be accurately forecasted. As a result, a methodology based on a Multi-Resolution Analysis (MRA) and multilayer Artificial Neural Networks (ANN) is proposed. One can highlight that the proposed control scheme allows the fossil energy consumption to be significantly reduced. The same remark applies to the functioning costs and CO_2 emissions. Future work will focus on improving the forecasted model, using self-growing artificial neural networks trained with the cascade correlation algorithm, and considering other objective functions. Finally, the proposed approach will be implemented *in situ*.

Ageing stability of sodium acetate trihydrate with and without additives for seasonal heat storage

Weiqiang Kong, Mark Dannemand, Jakob Berg Johansen, Jianhua Fan, Janne Dragsted and Simon Furbo

Technical University of Denmark, Department of Civil Engineering, Kgs. Lyngby 2800, Denmark

Abstract

Sodium acetate trihydrate is a promising phase change material used for seasonal heat storage because it can supercool in a stable way down to ambient temperature. One challenge of this material is that it might suffer from phase separation resulting in a low utilization of the heat of fusion. Adding extra water or thickening additive has been suggested as an effective way to reduce the phase separation problem and thereby maximize the heat content of the sodium acetate trihydrate. Investigations of phase separation and heat content of supercooled sodium acetate trihydrate with and without extra water and additives were carried out under different test conditions. It was found that sodium acetate water mixtures with water contents lower than or equal to 42% would suffer from phase separation for the height of heat storage up to 8 cm. The heat content of sodium acetate trihydrate will be decreased by adding extra water. Sodium acetate trihydrate with Carboxy-Methyl Cellulose and Xanthan Gum as additives are promising heat storage materials with high heat contents and ageing stability.

Keywords: *sodium acetate trihydrate, phase change material, ageing stability, phase separation*

1. Introduction

Sodium acetate trihydrate ($NaCH_3COO \cdot 3H_2O$), consisting of 60.3% (weight %) sodium acetate and 39.7% (weight %) water, is a promising Phase Change Material (PCM) used for seasonal heat storage because of its relative high heat of fusion at the melting point of 58˚C and its long term stable supercooling ability (Furbo et al., 2010). Sodium acetate trihydrate or its water mixture is long time stable and no ageing effects are known. Experiments have shown that the salt water mixture can be stable supercooled for years. Fig. 1 shows supercooled sodium acetate water mixture samples which have been in supercooled state for approximately 3 years at indoor temperature. Even impurities such as rusty iron immersed in the supercooled sodium acetate water mixture has not influenced the stability of the supercooling, see the right sample of Fig. 1.

Fig. 1: Long term supercooled sodium acetate trihydrate water mixture samples

doi:10.18086/swc.2015.02.10 Available at http://proceedings.ises.org

In practical applications sodium acetate trihydrate might suffer from phase separation especially in the supercooled state. This is the phenomenon where anhydrous salt settles to the bottom due to its higher density compared to the density of saturated sodium acetate water solution. The heat released from the crystallization of the supercooled sodium acetate trihydrate with phase separation will be lower compared to the heat released from supercooled sodium acetate trihydrate without phase separation. Adding extra water (Furbo and Svendsen, 1977) or thickening agent (Cabeza et al., 2003) has been suggested as effective ways to reduce the phase separation and to maximize the heat content of the sodium acetate trihydrate.

This paper investigates phase separation for different heights of long term supercooled sodium acetate water mixtures by measuring the water contents in different layers, the heat content of different sodium acetate water mixtures after short and long periods with supercooling and the heat content of sodium acetate trihydrate with thickening agents CMC and X-Gum by cycle and long term tests. The test results show that sodium acetate trihydrate with CMC and with X-Gum as additives is promising heat storage materials with high heat contents and long term stability.

2. Phase separation investigations for different heights of long term supercooled sodium acetate water mixtures

The test method is described as follows:

Step 1: Prepare samples of sodium acetate water mixtures with 40%, 42%, 45%, and 46% (weight %) water with the same height in the plastic bottles shown in Fig. 2.

Step 2: Heat the samples in the oven to a temperature between 80 °C and 85 °C until the salt water mixture is fully melted.

Step 3: Take the samples out from the oven. Let them cool down to indoor ambient temperature and let them stay in a supercooled state for the desired duration.

Step 4: Initialize the crystallization of the samples, so that the salt water mixtures solidifies. The samples are left to cool down to the ambient temperature.

Step 5: Cut each sample evenly into 3 or 4 horizontal layers and put into glass bowl as shown in Fig. 3. Measure the mass of the empty glass bowls and the glass bowls with salt water mixtures before heating.

Step 6: Put the glass bowls with salt water mixtures into an oven with the temperature above 100 °C and measure the mass when all water is evaporated.

Step 7: The water percentages of each layer of the samples are determined based on the mass measurements.

Fig. 2: Plastic bottles with sodium acetate water mixtures

Fig. 3: Empty glass bowls

Experiments were carried out with 4 cm, 5 cm and 8 cm heights of the liquid sodium acetate water mixtures.

Four samples of sodium acetate water mixture of each height were made: 40% water & 60% sodium acetate, 42% water & 58% sodium acetate, 45% water & 65% sodium acetate and 46% water & 54% sodium acetate. All 12 samples was left unmoved in supercooled state for approximately 130 days and then activated by dropping seed crystals in the plastic bottle. The photos of supercooled samples of different heights before activation are shown in Figs. 4-6.

Fig. 4: 4 cm salt water mixtures after 126 days supercooling, 46%, 45%, 42%, 40% water samples from left to right

Fig. 5: 5 cm salt water mixtures after 129 days supercooling, 46%, 45%, 42%, 40% water samples from left to right

Fig. 6: 8 cm salt water mixtures after 131 days supercooling, 46%, 45%, 42%, 40% water samples from left to right

From Fig. 4 to Fig. 6 it can be seen that all the 40% and 42% salt water mixtures had visible solid segregations, while the 45% and 46% salt water mixtures remained clear and transparent after 120 days in supercooled state. The segregated salt in the 40% and 42% salt water mixtures was “soft” and “loose”. Both the 40% and 42% salt water mixtures had a clear solution layer on the top.

Table 1 to Table 3 show the water contents distribution in the layers of each sample indicated by “Top”, “Middle” and “Bottom”. The four layers used in the 8 cm samples are referred as “Top”, “Upper Middle”, “Lower Middle” and “Bottom”. The accuracy of measured mass is 0.1 g. It is assumed that if the water content in a layer is lower than the 39.7% of the trihydrate composition then phase separation is occurring. The water percentages which were lower than 39.7% are shown with red color indicating phase separation. The last row is used for checking the total water content of samples after cutting and heating by summing up evaporated water and salt water mixture of all layers.

Tab. 1 Water content distribution in 4 cm high salt water mixture samples after 126 days supercooling

4 cm samples	40% water sample (%)	42% water sample (%)	45% water sample (%)	46% water sample (%)
Top	44.7	43.5	45.4	45.8
Middle	38.6	42.1	45.3	46.0
Bottom	37.3	42.0	45.6	45.9
Water Recheck	40.2	42.5	45.4	45.9

Tab. 2 Water content distribution in 5 cm high salt water mixture samples after 129 days supercooling

5 cm samples	40% water sample (%)	42% water sample (%)	45% water sample (%)	46% water sample (%)
Top	43.9	45.0	45.4	46.4
Middle	39.4	44.9	45.6	46.4
Bottom	38.0	39.5	45.2	46.6
Water Recheck	40.0	42.4	45.4	46.5

Tab. 3 Water content distribution in 8 cm high salt water mixture samples after 131 days supercooling

8 cm samples	40% water sample (%)	42% water sample (%)	45% water sample (%)	46% water sample (%)
Top	44.7	44.9	45.9	46.5
Upper Middle	40.2	43.5	45.8	46.5
Lower Middle	38.6	40.1	45.5	46.2
Bottom	37.0	39.7	44.3	46.0
Water Recheck	39.9	42.0	45.2	46.3

From Table 1 to 3 it can be seen that the 40% water content salt water mixtures of 4 cm, 5 cm and 8 cm height all suffered from phase separation because the water content of the bottom layer was lower than 39.7% after 120 days in supercooled state which means sodium acetate trihydrate cannot be used as a stable heat storage material for container height higher than or equal to 4 cm.

All the 42% water content salt water mixtures had water contents in the lower parts of the samples of minimum 40%. The smaller the height of the salt water mixture is, the lower the difference between the water content from the bottom to the top of the sample will be. The results indicates that sodium acetate water mixtures consisting of 42% water and 58% sodium acetate won’t suffer from phase separation problems as long as the salt water mixture height is lower than 8 cm. However, conclusions on the long term stability of 42% mixtures must also include considerations of the heat content stability, see section 3.

All the 45% and 46% water content samples have relatively even water content in each layer and don't suffer from phase separation.

It can be concluded from the experiments that too low water content and a too high sample height will cause phase separation problems for long term supercooled sodium acetate water mixtures.

3. Heat content measurements of supercooled sodium acetate samples

3.1. Experimental method and test facilities

A simple heat loss method was used to determine the heat content of different supercooled sodium acetate trihydrate samples with and without additives. This was done by recording the temperature history after starting the crystallization of the supercooled samples at ambient temperature. The crystallizations were started by dropping crystals into the samples, which were placed in a glass jars. After crystallization the samples cooled down to ambient temperature again inside a well-insulated box. When the heat loss coefficient of the glass jar in the well-insulated box is determined the heat released from the samples cooling down can be calculated by Eq. (1).

$$E = \int_{t_b}^{t_e} UA(t) \cdot \left[T_s(t) - T_a(t) \right] \cdot dt / m \qquad \text{(eq.1)}$$

Where E (kJ/kg) is the measured heat content, T_s (°C) and T_a (°C) are the sample and ambient temperature. t_b (s) and t_e (s) are the begin and end time during the heat release process. m (kg) is the sample mass. UA (W/K) is the heat loss coefficient of the glass jar in the well-insulated box determined by testing the cooling process of hot water in the same glass jars with the same height as sodium acetate samples. The UA can be calculated by Eq. (2).

$$UA = \frac{mC}{t_e - t_b} ln \frac{T_e - T_a}{T_b - T_a} \qquad \text{(eq.2)}$$

Where mC (J/K) is the total heat capacity including water, glass jars and lid. T_b (°C) and T_e (°C) are the start and end sample temperature during the period from t_b to t_e.

The samples were all prepared in glass jars as shown in Fig. 7(c) with the height of 5 cm. Three thermocouples pasted outside were used to estimate the average sample temperature, see Fig. 7(b). One thermocouple was fixed outside of the box for recording the ambient temperature, see Fig. 7(a).

Fig. 7: (a) The well insulted box (b) Temperature locations (c) Glass jar

3.2. Heat content measurement of sodium acetate water mixtures with different supercooled duration

Samples of sodium acetate water mixtures with 40%, 42%, 45% and 46% water content with a sample height

of 5 cm were prepared in glass jars. Three glass jars of each sodium acetate water mixture, in total 12 glass jars were prepared. The sodium acetate water mixtures were tested with different durations of the supercooled period: short supercooled period less than 14 days, 41 days and 100 days. The tests with the short period of less than 14 days were repeated several times and the average results are given. The results are shown in Table 4 and plotted in Fig. 8 (D2.4, 2015).

It can be seen that for the short term supercooled duration tests the 42% mixture had the highest heat content. If the water content was decreased to lower values than 42% or increased to higher values than 42%, the heat content will decrease. By increasing the supercooled duration to 41 days, the heat content was only reduced for the 42% mixture. By increasing the supercooled duration to 100 days, the heat content of both the 40% and 42% mixtures were significant lower compared to the shorter supercooled duration, while the heat content of the 45% and 46% mixtures were not decreased. The reduced heat contents are marked with red color.

The results of the heat content investigations are in line with the findings of phase separation investigations in section 2. The 40% and 42% salt water mixtures with 5 cm heights suffered from phase separation problems for long term heat storage periods. Adding more extra water is an effective way to solve the phase separation problem but the heat content will be decreased.

Tab. 4 Heat content of the 40%, 42%, 45% and 46% water salt mixtures

Water content of salt water mixture	Heat content (kJ/kg)		
	Short term average	Long term (41 days)	long term (100 days)
40%	162	162	99
42%	194	162	165
45%	165	163	172
46%	159	156	150

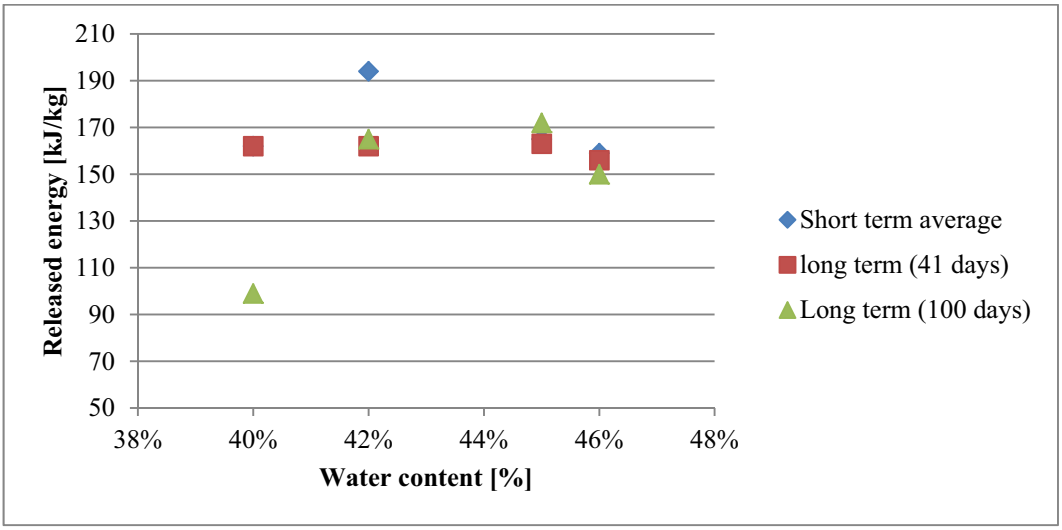

Fig. 8: Heat content of the 40%, 42%, 45% and 46% water salt mixtures

3.3 Heat content measurement of sodium acetate trihydrate with thickening additives

Carboxymethyl Cellulose (CMC) and Xanthan Gum (X-Gum) are thickening agents widely used in the food industry. The thickening effect can increase the viscosity of the liquid sodium acetate trihydrate and suspend the anhydrous salt in the container so that phase separation is reduced.

In small scale experiments, previous studies (Kong et al., 2015) showed that the heat content of sodium acetate trihydrate with 0.5% to 2% CMC or 0.3% to 0.5% X-Gum was increased typically 30% compared to pure sodium acetate trihydrate suffering from phase separation in short supercooled periods, see Fig. 9. The

green line and the purple line are the average heat contents of the 40% and 42% water content salt water mixtures. The blue and red pillars represent the results of the heat contents of sodium acetate trihydrate with different quantities of X-Gum and CMC.

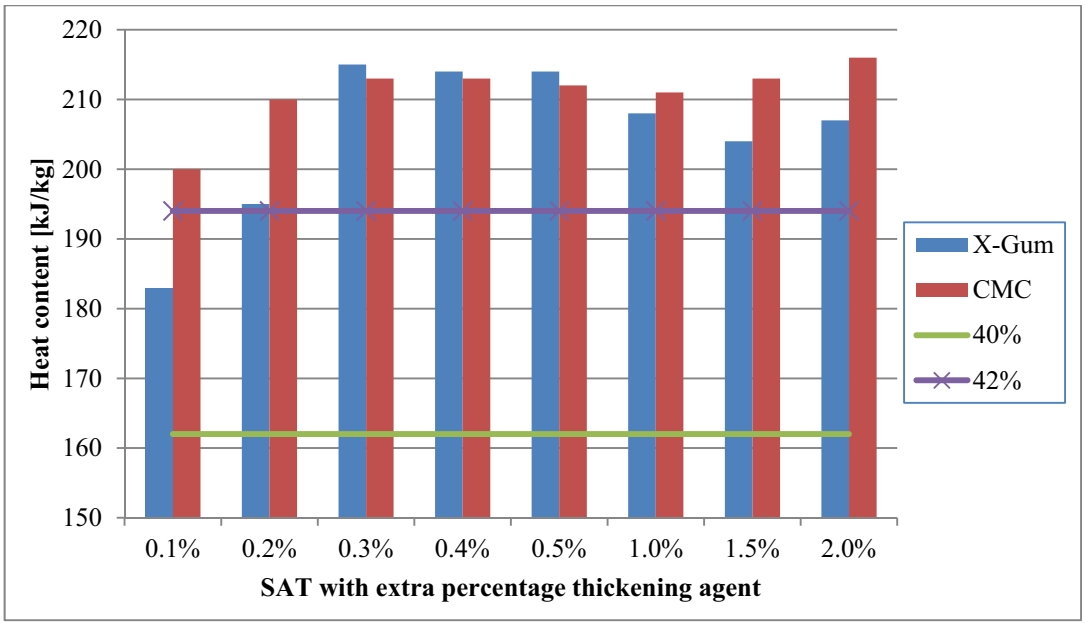

Fig. 9: Heat content of sodium acetate trihydrate with different quantities of thickening agents in short term supercooled period (Kong et al., 2015)

Ageing stability tests of sodium acetate trihydrate with extra water and with CMC were carried out through prototype modules which were designed for a demonstration seasonal heat storage system (Dannemand et al., 2015). The module was constructed by Nilan A/S as a flat plate shape. The chamber with the height of 5 cm containing PCM materials lies in the middle of module. An extension chamber is incorporated in one end at the top surface allowing for expansion of the PCMs when they are heated. An expansion bag or expansion vessel is connected to the extension chamber. Two heat exchangers with manifolds are attached on the top and bottom of the PCM chamber with the height of 4 mm. Parallel channels inside of the heat exchanger covered the entire area of the top and bottom surface of the PCM container aiming to guide a uniform flow distribution. Water is used as the heat transfer fluid running through the heat exchangers for transferring energy between PCM and test facility. The diagram and photo of the flat plate module can be seen in Figs. 10 and 11.

Fig. 10: Diagram of the prototype module (Dannemand et al., 2015)

Two flat plate modules with different PCM materials were tested. One module was filled with 199.5 kg of sodium acetate water mixture consisting of 44.8 % water and 55.2 % sodium acetate by weight. Repeating tests were carried out for 20 times with different flow rates, charge and discharge powers, temperatures settings and durations for a period of 8 month. The longest stable supercoooled duration of the module at indoor ambient temperature was two months. Then it was activated manually and the latent energy was discharged. The energy discharged of the first test cycle was 194 kJ/kg and then it dropped to 179 kJ/kg in the later test cycles. That is a 7.5 % decrease of energy released after repeating test cycles.

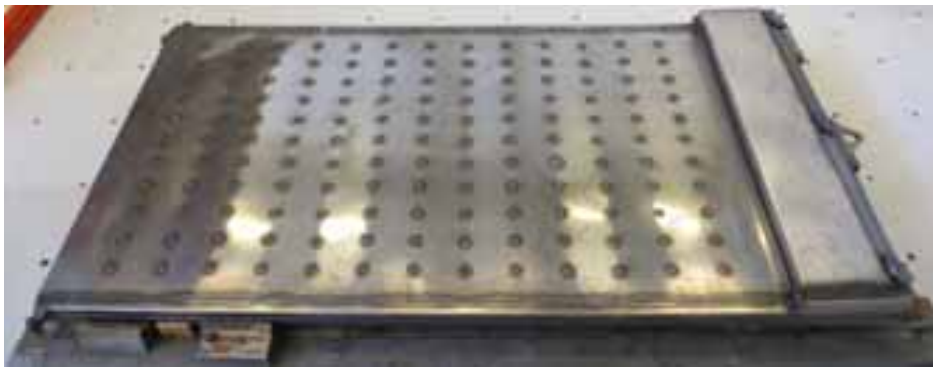

Fig. 11: Photo of the prototype module (Dannemand et al., 2015)

Another module was filled with sodium acetate trihydrate with 1% CMC, 2% graphite powder and 5 liter paraffin oil, totally 202 kg. The purpose of adding graphite and oil is to increase the heat exchange capacity rate. 10 repeating tests with similar flow rates, charge and discharge powers and temperatures settings were carried out over 2 month period. The energy discharged of the sodium acetate trihydrate with these additives was 200 kJ/kg in the first test cycle and kept stable around 201 kJ/kg in the following test cycles. The module reached stable supercooled at indoor ambient temperature for 8 days and then activated spontaneously. The energy discharged after 8 days was still 200 kJ/kg which illustrated that sodium acetate trihydrate with CMC as heat storage material had heat content stability after repeating tests and long term supercooling.

Ageing stability tests of sodium acetate trihydrate with X-Gum were carried out with another kind of prototype module which was designed as a vertical cylindrical container made of stainless steel by H.M. Heizkörper GmbH & Co. KG (Dannemand and Furbo, 2014). The module with EPP insulation is shown in Fig. 12. A plastic tube is installed with one end connecting to the top of the module and with the other end connecting to an air filter. The design can keep the same pressure of inside and outside module by allowing air exchange through the tube and the air filter. There is a heat exchanger inside the cylindrical module which consist stainless steel pipes in a circular formation with thin aluminum fins attached and manifolds located on the top and the bottom. The module is connected to a heating and cooling test facility. Water is used as the heat transfer fluid passing through the heat exchanger from bottom to top.

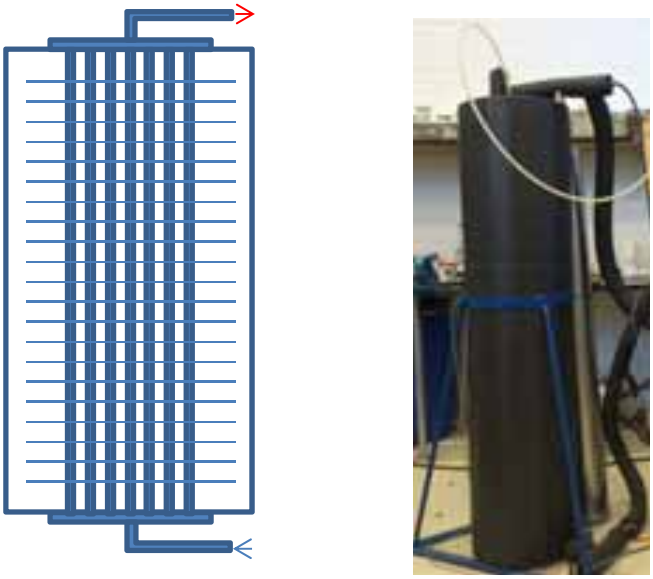

Fig. 12: Diagram and photo of cylinder module

The module contained sodium acetate trihydrate with 0.48% fine powder of Xanthan Gum (X-Gum-F) and 4.4% fine powder of graphite, totally 116.3 kg. The PCM material filled approximately 90% of the total

volume inside of the module. 20 repeating tests with similar charge and discharge flow rates, heating powers and temperature settings were carried out over four months. The module still had problems with stable supercooling possibly due to dust which caused spontaneous crystallization through the air filter and the tube into the top of the module. The longest supercooling period during these test cycles was 9 days. The energy discharged from the PCM was 205 kJ/kg at the first test cycle and stable at this level in the following test cycles.

Tab. 5 Summary of prototype module tests

PCM material	Prototype module	Heat content of the first test (kJ/kg)	Number of cycle tests	Heat content of last test (kJ/kg)	Longest supercooling duration (days)	Heat content after longest supercooled duration (kJ/kg)
44.8% water +55.2% sodium acetate	Flat plate	194	20	179	60	179
Sodium acetate trihydrate +1% CMC+2% graphite+5 liter paraffin oil	Flat plate	200	10	200	8	200
Sodium acetate trihydrate +0.48% X-Gum+4.4% graphite	Vertical cylinder	205	20	206	9	207

The prototype module test results are summarized in Table 5. It can be concluded from the laboratory prototype module tests that a sodium acetate water mixture with 44.8% water will suffer from phase separation and the energy released will decrease after repeating cycles and long term supercooled period. The sodium acetate trihydrate with CMC and X-Gum have high stability of released energy for repeating test cycles and are promising for stability for long term supercooling.

4. Conclusions

Phase separation is a key problem related to long term stability of seasonal heat storages based on stable supercooling of sodium acetate trihydrate with and without additives. Water content measurements in different layers of sodium acetate water mixtures after long term supercooled periods and heat contents measurements of sodium acetate trihydrate with additives in repeating and long term supercooled periods were investigated and presented in this paper. Based on the investigations it is concluded that:

Sodium acetate trihydrate and sodium acetate water mixtures with water contents lower than or equal to 42% will suffer from phase separation problems for the height of heat storage less than or equal to 8 cm. Sodium acetate water mixtures with water contents higher than 42% will not suffer from the phase separation if the heat storage height is lower than or equal to 8 cm. However, the heat content of the heat storage material will be decreased by adding extra water.

Sodium acetate trihydrate with the additive CMC and X-Gum are promising seasonal heat storage materials since they have high heat contents and ageing stabilities in repeating tests and long term supercooled durations.

Abstract

This paper reports a theoretical study about the thermal performance of the new design of solar water heater with a latent heat storage unit. The new design is a solar water heater system consisting of an array of evacuated tube heat pipe solar collectors connected to a common manifold filled with phase change material and acting as a latent heat storage tank. Solar energy incident on the evacuated tube is collected and stored in the latent heat storage tank. The stored heat is then transferred to the domestic hot water supply via a finned pipe placed inside the tank. The performance is analyzed based on an accurate set of mathematical equations. The various climatic conditions of a tropical region are considered as operating environment of the device. The thermal performance of the new design is compared with the conventional evacuated tube heat pipe solar water heater to have a better observation about the differences and advantageous of the new design. The results showed that the thermal performance of the proposed system is higher than a conventional system at certain conditions, which depend to the weather conditions and flowrates, but the sensitivity of the efficiency of the proposed system to the supply water flowrate is less than the conventional system.

Keywords: *solar water heater, evacuated tube, heat pipe, phase change material, thermal energy storage, comparative study*

1. Introduction

Many different combinations of solar thermal systems in integration with phase change material (PCM) for latent heat storage (LHS) have been developed for hot water production, air heating/cooling and power generation [1-6]. Using LHS for solar water heating (SWH) systems received many attractions by researchers. In most of the designs, the PCM was placed in the storage tank [7-13]. A general finding from the most of these researches is that under certain conditions such as system configuration, type of PCM, inlet water temperature and water flow rate, there are improvements in the performance of the SWH-PCM systems.

Al-Hinti et al. [13] experimentally investigated the performance of water-PCM for use with conventional SWH systems. PCM contained in small cylindrical aluminum containers. It was found that the use of the suggested configuration could result in a 13-14^{o}C advantage in the stored hot water temperature over extended periods of time. The hot water storage performance was also investigated when connected to flat plate collectors in a closed-loop system with conventional natural circulation. Over a test period of 24 hour, the stored water temperature remained at least 30^{o}C higher than the ambient temperature. The use of short periods of forced circulation was found to have minimum effect on the performance of the system. Nallusamy and Velraj [14] investigation on a packed bed combined sensible and latent heat storage unit integrated with solar water heating system. It was observed that the mass flow rate has a significant effect on the heat extraction rate from the collector, which in turn affects the rate of charging of the thermal energy storage (TES) tank.

Varol et al. [15] attempted to forecast the performance of a solar collector system using PCM in the hot water storage tank and compared the collector efficiency with the convectional system. In this design, PCM was placed to the bottom of the collector and hot water pipe lines were pathing under the absorber plate, through the PCM slab. It was found that the solar collector system with PCM is more effective than convectional systems. Padovan and Manzan [16] developed an algorithm to optimize a simple configuration of the SWH, which features a plane solar collector, a boiler and a PCM enhanced tank. In parallel with the optimization a sensitivity analysis was carried on in order to find out the relation between the design parameters of the tank

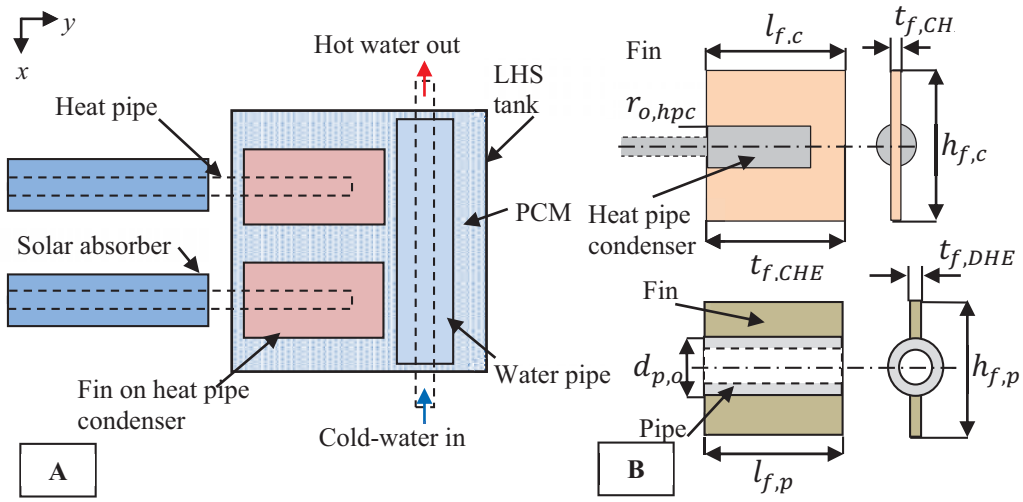

Fig. 1: A. HPSC-PCM system; B. Fin designs for condenser shell (top) and water supply pipe (bottom)

(geometry, phase change temperature of the PCM, and insulation) and the performance of the system. The main outcome of this research was that for this design, the PCM did not have major impact on the results, while other parameters play a more significant role.

To the authors' knowledge, although there are few research works on the combination of heat pipe solar collectors and PCMs in storage tanks [17, 18], there is no work done on the proposed HPSC-PCM system where there is an intermediate heat exchanger on the manifold (condenser side) of the heat pipe. A new HPSC-PCM system is described in the following section. This research plans to examine, analytically, the feasibility of this system in different climatic conditions in a tropical country (Malaysia). The charging/discharging processes during the day/night times are determined. The performance of a conventional HPSC (HPSC-C) theoretically compared with this innovative design. PCM melting/solidifying processes are determined by a one-phase Stefan problem quasi-stationary approximation method, which is one of the more widely used standard analytical solutions. Calculations are done by a computational code developed in Matlab.

2. A description of the proposed system

Fig. 1A displays the recommended HPSC-PCM system which comprises an arrangement of evacuated tube heat pipe solar collectors linked to a shared manifold loaded with PCM. This manifold functions as a LHS tank. The evaporator segments of the heat pipes are subjected to solar radiation while the condenser segments are slotted into finned sockets which have been inserted onto the manifold. The evaporator performs as an absorber of solar energy which is then conveyed to the condenser by way of heat pipe action involving evaporation and condensation. This energy is stockpiled in the PCM-filled LHS tank. Household cold water delivered by way of a finned pipe rises in temperature as it makes its way through the LHS tank. Heat transfer efficiency is raised through the welding of single-row vertical fins onto the heat pipe condenser shell and also onto the finned pipe line (Fig. 1B). Table 1 exhibits the dimensions of the LHS tank, HPSC and fins.

3. Hypothetical model

This section provides a concise presentation of equations for the arithmetical modelling of heat transfer. A comprehensive array of equations and flow charts was forwarded in a previous paper [19]. During the process of charging and discharging of heat within the PCM, three separate heat transfer developments take place. To begin with, the evaporator section of the HPSC soaks up heat from solar energy which is then conveyed to the condenser section. Subsequently, the heat transfers to the PCM through the condenser shell. The accumulated heat discharges from the PCM to the finned pipeline and warm up the water passing through it. The computations for these procedures are carried out separately and in accordance to the sequence during which they take place.

3.1. Charging mode

The main factors influencing absorbable solar radiation are ground reflectance, angle and the material employed as collector. For the purpose of assessing these factors, we harnessed the process launched by Duffie and Beckman [20]. The temperature of heat pipe segments was ascertained through an equation forwarded by Zue and Vafai [21]. Through this equation, a methodical resolution to problems related to the surface temperature along the span of a low temperature heat pipe can be realized.

Table 1, Dimensions of LHS tank, HPSC and fins

Manifold and Evacuated tube		Heat pipe	
Item	Value	Item	Value
Number of heat pipes	20	Evaporator length (mm)	1675.00
Glass tube outer diameter (mm)	58	Adiabatic length (mm)	30.00
Glass tube thickness (mm)	2	Condenser length (mm)	70.00
Absorber plate thickness (mm)	1	Evaporator outer radius (mm)	4.00
Evacuated tube length (mm)	1675	Condenser outer radius (mm)	12.00
Fin thickness on the CHE (mm)	2	Wall thickness (mm)	0.50
Storage tank height (mm)	204	Wick thickness (mm)	1.00
Storage tank width (mm)	204	Vapor core radius (mm)	3.00
Storage tank length (mm)	1725	Thermal conductivity of liquid (W/mK)	0.63
Fin height on the CHE (mm)	200	Thermal conductivity of wall (W/mK)	385
Fin length on the CHE (mm)	200	Porosity	0.5
Fin thickness on DHE (mm)	2	Permeability	1.5×10^{-9}
Fin height on DHE (mm)	91	Thickness of the fiber (mm)	2×10^{-7}
Pipe outer diameter (mm)	18	Number of meshes per unit length	4000
Length of a section (mm)	142		
Slope of solar collector (°)	20		
Glass emittance	0.88		
Plate emittance	0.95		
Reflective Index of glass	1.53		

The PCM heat equation is deemed a 2nd order linear partial differential equation with heterogeneous boundary conditions. As the transfer of heat from the condenser shell to the PCM occurs in an arrangement that is similar for both sides, computations for the PCM are ascertained based solely on one side of the condenser shell. A significant presumption regarding the quasi-stationary one-phase Stefan problem is that the hot plate (which is the finned condenser shell) is subjected to a consistent temperature. Also presumed is that heat transference from the fin on the shell to the PCM is a one-dimensional occurrence and that the temperature of the PCM at the outset is at melting point.

Expressed as $T(x,t)$, the PCM temperature is a function of position and time. At a consistent temperature, a slab of the PCM ($0 \le x \le l$) is deemed to be solid. The imposed temperature at the interface of the PCM and the HPC fin facilitates the transference of heat through the PCM. It is taken for granted that the remaining three edges are in an insulated state. The following is an expression of the mathematical model for the one-dimensional transient heating procedure.

$$\rho_s c_s \frac{\partial T}{\partial t} = k_s \frac{\partial^2 T}{\partial x^2}, \quad \text{(eq. 1)}$$

It is essential that this equation be solved in accordance to the preliminary and boundary conditions for the scale of $0 < x < X(t)$:

$$T_{pcm}(0,t) = T_{hp}(t), \quad \text{(eq. 2a)}$$

$$T_{pcm}\big(X_{pcm}(t),t\big) = T_m, \quad \text{(eq. 2b)}$$

$$\rho_l L {X_{pcm}}'(t) = -k_l \frac{\partial T_{pcm}}{\partial t}|_{x=X_{pcm}(t)}, \quad \text{(eq. 2c)}$$

$$X_{pcm}(0) = 0 \quad \text{(eq. 2d)}$$

where X(t) denotes the position of the interface. The heat equation is rendered exceedingly complex by the need to meet boundary conditions (eq. 2c). In line with the Neumann solution to the one-phase Stefan problem [22], the quasi-stationary solution for expressing the interface position and temperature dissemination in the PCM (in the context of primary physical variables related to the charging procedure) assumes the following configuration:

$$X_{pcm}(t) = \eta_{f,c}\sqrt{(2k_l St_l t)/(\rho c_l)} \quad \text{(eq. 3)}$$

$$T_{pcm}(x,t) = T_{hpc}(t) - \Delta T_l \frac{x}{X_{pcm}(t)}, 0 \le x \le X_{pcm}(t), \quad \text{(eq. 4)}$$

where, $\Delta T_l = T_{hpc}(t) - T_m$.

The heat transfer from the object to the surrounding material is accelerated by the presence of fins on the condenser shell. Consistency in terms of heat dispersal on the surface of the fin was taken as fact. For the purpose of incorporating the impact of this presupposition into the computation procedure, the effectiveness of the fin is roped in through the array of equations cited in [19].

3.2. Discharging mode

As portrayed in Figure 2, the PCM within the LHS tank is split into a fixed number of slabs (*j*). Each slab is subjected to the application of energy balance. The outlet water temperature of each slab matches that of the inlet water temperature of the neighbouring slab. The inlet water temperature determines the pace of PCM solidification for every slab. The finned pipe is positioned at the centre of the tank. This serves to partition every slab into two identical segments on both the upper and lower sides of the finned pipe. Both sides of the fin come into play during the heat transfer process.

The solidification of the PCM is attributed to the flow of cold water into the storage tank at a velocity of *v* and a temperature of $T_{w,i,i}$. Each slab's solid-liquid interface progression speed and their outlet water temperature are the undetermined variables. It is essential that the verification of these variables be carried out in unison. It is supposed that in the event the Stefan number is inconsequential ($St < 2$) during the discharging procedure, the temperature of the PCM will stay unremittingly within reach of melting point while the solid-liquid interface is advancing [22]. Hence, the supply water temperature rises in tandem with the solidification process of the slab *j*. Subsequent to complete solidification, slab *j* loses its thermal inertia, its temperature will quickly decline to match the inlet water temperature at its location, and the water will swiftly react to one fewer slab. In other words, at the outset, *N* slabs were raising the temperature of the supply water. However, upon the solidification of the initial PCM slabs, the supply water temperature elevation was attributed to *N-1* slabs. The presumptions that require contemplation for the application of this solution process are: (a) during the process of discharging, the transference of thermal energy from the PCM to the finned pipe is exclusively one-directional (i.e. on the *y* axis), (b) when the fall in the axial temperature is not excessive, the transmission of heat in the direction of x can be disregarded, (c) heat conduction within water that is thermally stable is inconsequential, (d) the latent heat of the PCM is so substantial that the surface temperature of the PCM at the fins and walls of the pipe can, for the most part, be deemed equivalent to T_m during the whole process of solidification. This presumption is believable if one takes into consideration the fact that with a raised latent temperature (insignificant Stefan number), the front will not make much headway into the PCM, while an elevated degree of conductivity will lead to the tendency to round up the temperature. In a situation where the PCM does not melt completely during charging, it follows that during the discharging process only the PCM molten mass fraction is regarded as an active mass of the PCM slab.

Heat transference to the finned pipe from the melted PCM is realized through:

$$\dot{q}(t) = \dot{q}_p(\mathrm{t}) + \dot{q}_{f,p}(\mathrm{t}) \qquad \text{(eq. 5)}$$

where $\dot{q}_p(\mathrm{t})$ denotes the heat flux to the pipe and $\dot{q}_{f,p}(\mathrm{t})$ denotes the heat flux through the fins. An array of equations for ascertaining the heat flux can be observed in [19].

Efforts to determine the solidification time of the PCM slabs necessitate a repeat solution to eq. 1 with altered initial and boundary circumstances. In such a situation, it is imperative that the heat equation be worked out in accordance with the imposed heat flux ($\dot{q} < 0$):

$$T_{pcm}(x, 0) = T_m, \qquad \text{(eq. 6a)}$$

$$\rho_s \bar{L} {Y_{pcm}}'(t) = -k_s \frac{\partial T_{pcm}}{\partial t}|_{y=Y_{pcm}(t)}, \qquad \text{(eq. 6b)}$$

$$-k_s \frac{\partial T_{pcm}}{\partial t}|_{y=0} = \dot{q}(t), \qquad \text{(eq. 6c)}$$

$$Y_{pcm}(0) = 0 \qquad \text{(eq. 6d)}$$

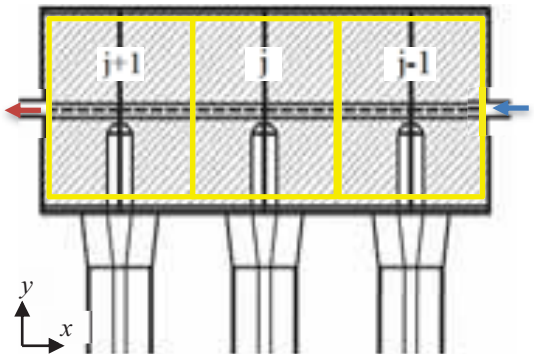

Fig. 2: Arrangement of PCM slabs

In this approach, a molten slab at its melt temperature of T_m is undergoing solidification through an imposed flux $\dot{q}(t)$ at the exteriors of the fins. In line with the Neumann solution technique for the management of a one-phase quasi-stationary Stefan problem, the inclusion of initial and boundary conditions gives rise to the following equation for the solid-liquid interface location:

$$Y_{pcm}(t) = \dot{q}(t)\, t/\rho_s\, \bar{L} \quad \text{(eq. 7)}$$

In a circumstance where the temperature of the molten PCM slabs exceeds that of the melting point, the effect of stored sensible heat can be realized by modifying the latent heat magnitude through the following equation [22]:

$$\bar{L} = L + \frac{1}{2} c_l (T_L - T_m) \quad \text{(eq. 8)}$$

where $T_L = mean\left(T_{pcm}\left(x = 0{:}\, l_{pcm}\, , t_{end}\right)\right)$ represents the mean temperature of the PCM at the culmination of the melting time.

3.3. Exploitable heated water and performance efficiency

In this segment, an evaluation is conducted on the effectiveness of the recommended scheme in comparison to a conventional scheme. In a conventional scheme (deemed a baseline system), heated water is amassed in a tank without any draining off of water in day time. The effectiveness and potential of a scheme for hot water delivery can be determined through a calculation involving the effects of stratification.

The baseline SWH system entails the passage of cold water directly across the heat pipe condenser in the manifold. The resulting hot water is then amassed in an insulated reservoir. The degree of heat transfer from the condenser to the supply water can be ascertained through equations which are also used for computing the temperature of the heat pipe surface (refer to Section 3.1). The equations for calculating heat transfer from the condenser to the supply water can be observed in [19].

Solar heat is accumulated during daylight hours and saved in the storage tank. No water is drawn out during daytime. The main purpose of the storage tank is to preserve the temperature of the heated water. It is thus essential that the degree to which heat diminishes over time be calculated. Natural thermal stratification is a significant factor in operations involving the storage of heated water in a tank[23]. Even in a circumstance where there is no water draw-off, heat convection from the hot water layer to layers of a lower temperature, and vertical conduction in the wall of the storage tank can lead to destratification [24].

Of late, a study conducted by Armstrong et al. [25], succeeded in establishing the destratification-related deficit rate of utilizable heated water in a reserve tank. This investigation revealed that a 74 litre capacity copper tank with a thickness of 0.7mm, and cladded with an outer 50mm layer of rigid polyurethane insulating foam (0.028 W/mK) [26], underwent a usable hot water volume loss rate of 2.1 litres per hour over a period of 12 hours. A division of the tank capacity by the usable volume loss rate led to the presumption that 3% of usable heated water in the tank will be done away with. An additional presumption is that the loss of heat to the environment from the wall of the tank is insignificant in comparison to the conjugate exchange with the water.

In the opinion of Armstrong [23] the utilizable heated water volume is identical to the volume of fluid from a tank that can be mixed to a favourable ultimate operational temperature (T_u.) The utilizable heated water volume can be calculated through the equation:

$$V_u(t) = m_w \times \sum_{hr=1}^{12} \frac{T_{w,t,o}(t) - T_u}{T_u - T_{w,t,i}(t)} \quad \text{(eq. 9)}$$

Bearing in mind that the tank is deemed to be in an inactive mode, and taking into consideration the usable volume loss rate percentage (*Lr*), the usable volume obliteration can be calculated through the equation below:

$$V_{u,\mathrm{d}}(t) = V_u(t) \times Lr \times (12 - t) \quad \text{(eq. 10)}$$

The expression $(12 - t)$ denotes the period that the generated heated water in the solar collector will be standing by in the tank. Thus, the volume of left over utilizable hot water after a period of 12 hours can be calculated through the equation:

$$V_{u,\mathrm{r}} = \sum_{hr=1}^{12} V_u(t) - V_{u,\mathrm{d}}(t) \quad \text{(eq. 11)}$$

As destratification does not transpire in the PCM tank, the presence of detrimental energy in this tank can be discounted ($V_{u,\mathrm{d}}(t) = 0$). In keeping with equations (9) and (11), the volume of usable hot water and total usable hot water generated by the PCM tank is calculable.

The total energy liberated by usable hot water from the water and PCM tanks can be determined through the equation:

The total delivered energy by usable hot water from the water tank and from the PCM tank can be calculated by:

$$E_d = V_{u,\mathrm{r}}\, c_{p,w}\, (T_u - T_{w,t,i}(t)) \quad \text{(eq. 12)}$$

The systems' energy efficiency is computed through:

$$\eta_{tot} = \frac{E_d}{S} \quad \text{(eq. 13)}$$

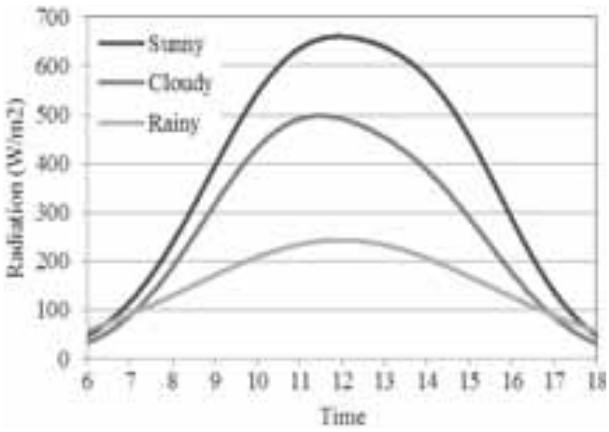

Fig. 3: Solar radiation

4. Results and discussion

The predominant objective of this endeavour is to hypothetically assess the thermal capacity of the combined HPSC-LHS systems for storage in various climate conditions and compare it with the baseline system. In this investigation, water does not flow across the manifold during the day. It is only after sunset, when the system controller allows water to flow through the inbuilt pipe in the tank, then the system is in discharging mode. The precision of this hypothetical approach is examined in [19].

Authentic meteorological data stretching over a time span of two years (2008-2009) was acquired from the Kuala Lumpur International Airport meteorological station (Lat. 2.44^{o}& Long. 101.42^{o}) to assess the twelve-monthly solar radiation concentration. As for the daily solar radiation, the days were classified as sunny (I>18 MJ/m^2/day), cloudy (18>I>13 MJ/m^2/day) and rainy (13>I MJ/m^2/day) days. The average solar radiation level for each classification is displayed in Figure 3.

4.1. PCM charging and discharging processes

At the outset, the PCM is in a solid form. The liquefaction process of the PCM is triggered upon its arrival at the melting temperature. Table 2 displays the features of the paraffin utilized as the PCM and copper fin properties. The temperature of the melted fraction climbs unremittingly on condition that the supply of heat is uninterrupted. The rise and fall of the temperature gradient is directly linked to heat flux discrepancies. The efficiency of the finned shell on the heat pipe condenser is approximately 90% for copper materials. As previously stated, the system involves the employment of 20 steel pipes. During charging mode, the storage tank remains on standby and no supply water flows through the pipe. As such, for all 20 slabs, the PCM thermoclines and interface growth designs are identical. Figure 4 portrays the progressions of the liquid-solid interfaces for the three distinct weather conditions. At the conclusion of a sunny day, it was observed that melting of roughly 60mm of the PCM thickness had occurred at each side of the finned shell. As for a cloudy and rainy day, the level of melting was approximately 52mm and 43mm, respectively. It is apparent that during the morning hours, the interface progression rate is accelerated. The two explanations for this circumstance are (a) the elevated temperature gradient between the condenser and the PCM during the morning heating up period and (b) the attendance of liquid PCM surrounding the fin with its intrinsic depleted convective heat transfer coefficient. As heat transmission through the heat pipe takes place purely in one direction, specifically from the evaporator section to the condenser section (resembling a one-way valve [27]), energy wastage from the storage tank is averted.

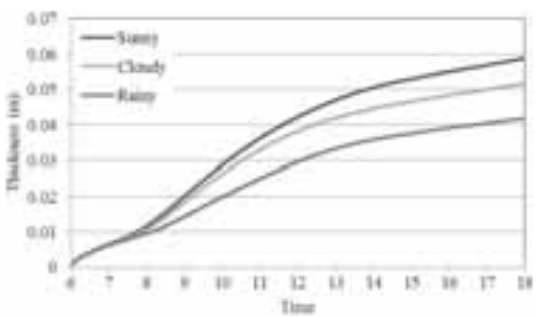

Fig. 4: Liquid-solid interface in charging mode

Tab. 2: Physical properties of paraffin wax and copper fins [28, 29]

Property	PCM	Fin (Solid)
Melting point (°C)	64	-
Density solid / liquid at 15/70°C (kg/m^3)	990 / 916	2713
Thermal conductivity of solid / liquid (W/mK)	0.349 / 0.167	380
Specific heat solid / liquid (kJ/kgK)	2.76 / 2.48	0.96
Volume expansion at ΔT=20°C (%)	0.293	-
Heat storage capacity (kJ/kg)	174	-
Dynamic viscosity (kg/ms)	0.00385	-

While the heat transfer route in the charging mode runs parallel to the *x* axis, in the discharging mode it runs parallel to the *y* axis (Figure 1). It is taken for granted that the discharge procedure begins subsequent to sunset as soon as the controller permits the flow of supply water through the finned pipe. Due to the fact that in the discharging mode, the transference of convective heat within the pipe is paired to heat deletion from the PCM, the most significant parameters to scrutinize in the storage reservoir are the outlet water temperature and solid-liquid interface progression of the various slabs.

As described in Section 3.2 and Figure 2, as a result of the elevation in water temperature while flowing through the finned pipe during discharging mode, the phase alteration performance of the PCM fluctuates across the span of the storage tank. In both rectangular slabs, heat transfer from the molten PCM to the finned pipe is symmetrical. The progression of the solid-liquid interface in relation to three slabs of the PCM tank for two flow rates and three weather conditions is exhibited in Figure 5. The outcomes imply that former PCM slabs experience solidification quicker than latter ones. This is attributed to the greater temperature disparity of the inlet supply water and PCM.

Owing to the elevated temperature of the molten PCM at the extremity of the charging mode (refer to Equation 8), a customized latent heat value of 229*kJ/kg* was utilized to ascertain the interface progression.

4.2. Temperature of supply water

The simulation outcomes for the outlet supply water temperature after 18:00 at flow velocities of 50 litres and 70 litres per hour (lph) are displayed in Figure 6. The inlet cold water temperature is maintained at 29ºC. An elevation in the flow rate brings about a decrease in the system's operating time. The proposed operational temperature for household usage is between 38ºC and 41ºC [30]. For this study, the operational temperature was presumed to be 40ºC. As such, the system's operating time with an outlet water temperature in excess of 40ºC is downgraded from more than four hours to just about three hours. The maximum outlet supply water temperature on days that are sunny was recorded as 53ºC for a flow rate of 50 lph, and close to 47ºC for a flow rate of 70 lph.

The HPSC-C system equipped with 20 heat pipes was simulated at two flow rates for three weather conditions to evaluate the outlet water temperature. According to the graphs, the peak usage period is during noontime, and the highest hot water temperatures in the HPSC-C system in various circumstances are below

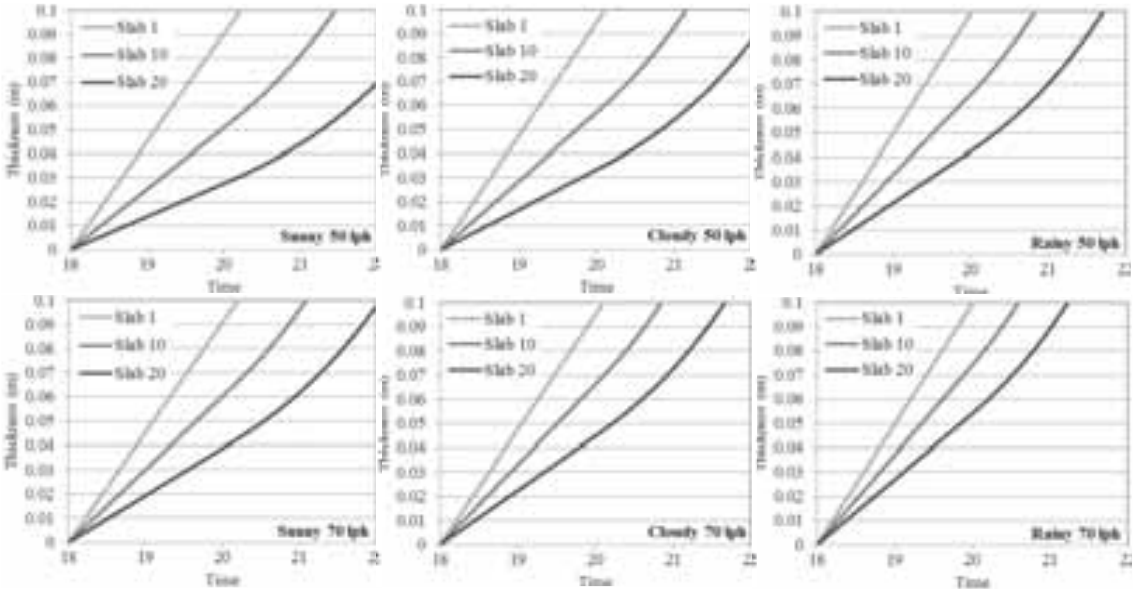

Fig. 5: Progression of solid-liquid interface in slabs 1, 10 and 20 of PCM tank

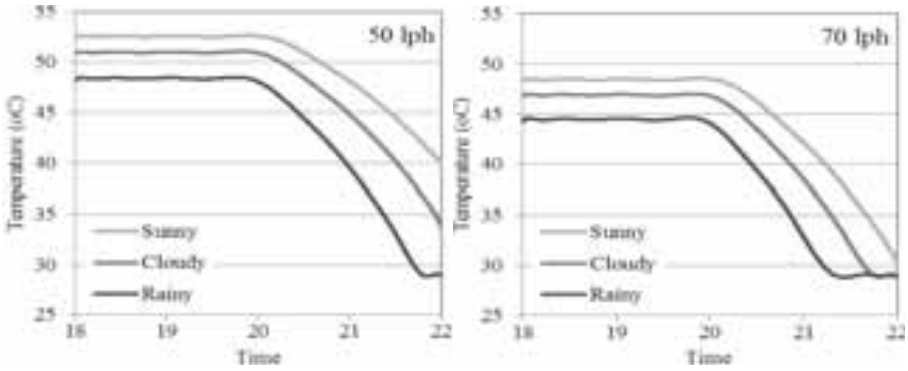

Fig. 6: Outlet supply water temperature ($T_{w,i,o}$) for ETHPSC-PCM system

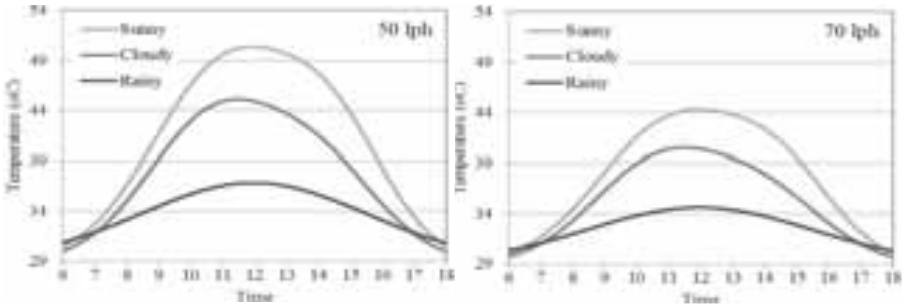

Fig. 7: Outlet water temperature ($T_{w,b,o}$) for ETHPSC-C system

those in the HPSC-PCM system. As the demand for domestic heated water is at its highest at sundown, the usefulness of the recommended system is enhanced by the moving of the peak time to this period.

4.3. Comparative investigation

In order to compare the baseline and proposed systems, it is presumed that the produced hot water in the storage tank of the baseline system remains in the storage tank until evening. The releasing water from the hot water storage tank and the LHS tank start at the same time. As the temperature of the outlet water from the tank is above that of the operating temperature (39°C), it is essential that it be mixed with cold water (29°C).

The scale of generated heated water at operating temperature as well as the total effectiveness of the systems can be approximated through the equations presented in Section 3.3. A comparison between the HPSC-PCM system and the HPSC-C system in terms of efficiency (η_{tot}) and usable volume (V_u) for two flow rates and

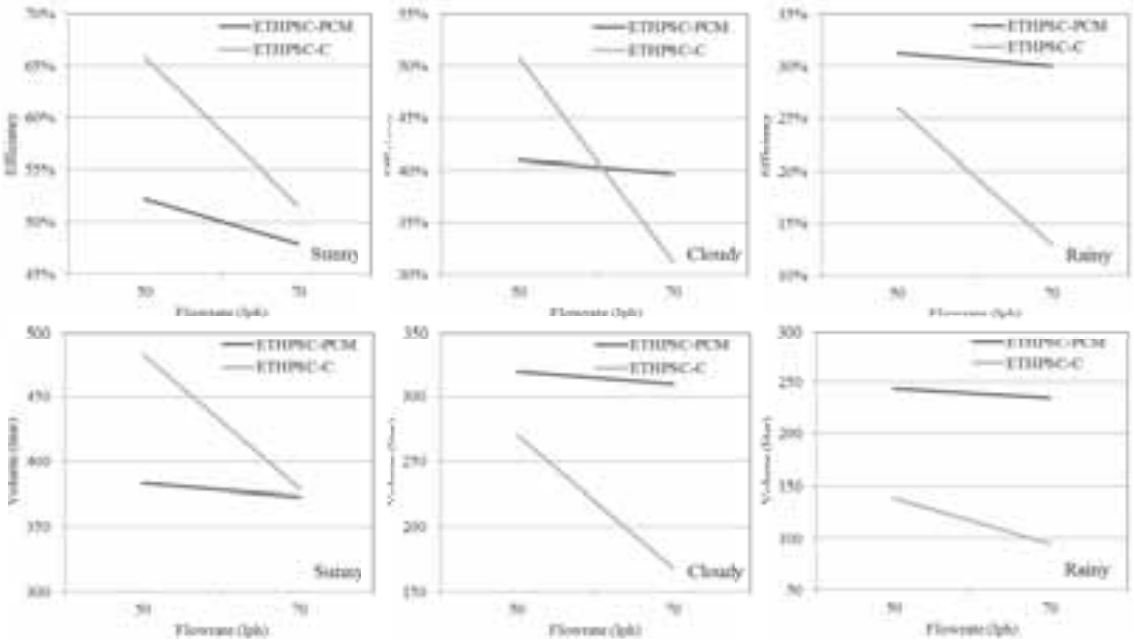

Fig. 8: Comparison of efficiency and usable hot water volume

three weather conditions are shown in Figure 8. As the thermal operational level of the HPSC-C system plunges drastically upon elevations in the draw-off flow rates, it follows that the volume of usable heated water also plummets. As for the proposed system, by increasing the flowrate, although a decrease in thermal efficiency is unavoidable, this decrease is not as rapid as in the conventional system. On a sunny day, the efficiency of the HPSC-PCM system ranges between 53% and 48% upon an elevation in the flow rate from 50 lph to 70 lph. Under a similar circumstance, the efficiency level of the HPSC-C fluctuates between 61% and 52%. During harsh (rainy) weather conditions, the effectiveness of the HPSC-C system ranges from 26% at 50 lph, to below 13% at 70 lph. In a similar situation, the efficiency of the HPSC-PCM system varies between 32% and 30%. Generally, the efficiency range of the HPSC-PCM system extends between 53% and 30%, while that of the HPSC-C system stretches between 65% and higher to 14% and below. This is an indication that the innovative system is superior to the conventional system in terms of stability. A similar efficiency trend was observed in the context of water capacity. The most outstanding revelation is the fact that the innovative system is capable of offering at least 200 litres of heated water under the harshest of weather conditions, while the conventional system is unable to meet the demand for domestic hot water on rainy, and perhaps even on cloudy days.

To be able to have a more detailed view about the effectiveness of the performance of the HPSC-PCM in a tropical climate, the available data of three meteorological stations in Malaysia for two years were studied. The number of days in a year with different weather conditions are shown in Table 3 and Figure 9. It is observed that averagly 45% of the days in a year are mostly sunny and rests are in mostly cloudy or rainy conditions. According to Figure 9, the ratio of sunny days could be even as low as ~32% in a year. Refer to the Figure 8, both designs have suffiecent performance in sunny days. However, in non-sunny days the new design provide more hot water volume and more stable operation, which this illustrates the advantageous of the new design in comparison with the conventional model.

Tab. 3: Number of the sunny, cloudy and rainy days in a year

Station	Location (Lat./Long.)	Sunny	Cloudy	Rainy
Mersing (2007)	2° 27' N / 103° 50' E	164	121	80
Mersing (2008)	2° 27' N / 103° 50' E	145	136	84
Subang (2008)	3° 07' N / 101° 33' E	188	121	56
Subang (2009)	3° 07' N / 101° 33' E	202	116	47
KLIA (2008)	2° 44' N / 101° 42' E	121	165	79
KLIA (2009)	2° 44' N / 101° 42' E	169	129	67
	Average	**45%**	**36%**	**19%**

5. Conclusion

A hypothetical study was conducted on the feasibility of integrating an evacuated tube heat pipe solar collector and a latent heat storage tank. This study was based on authentic meteorological data as regards to

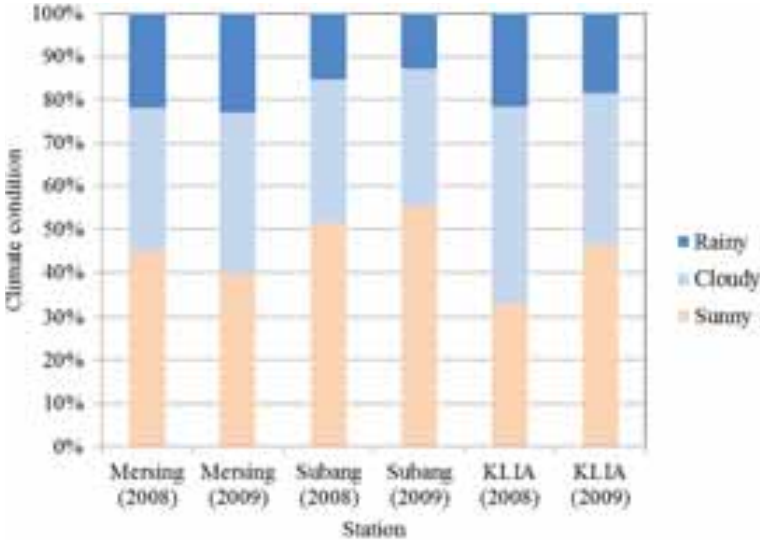

Fig. 9: The ratio of climatic condition during a year

three Malaysian weather conditions. An examination of the HPSC-PCM charging/discharging procedures revealed that under certain circumstances, the thermal performance of the recommended system is superior to that of a standard system. While the HPSC-C system and the HPSC-PCM function are in satisfactory level on sunny days, at a certain flow rate on cloudy and rainy days the HPSC-PCM system exhibited a higher level of effectiveness. This investigation also uncovered that the degree of sensitivity to the supply water flow rate is lower for the recommended system than the conventional system.

Combined heat and power generation of the hydrogen chain based on MYRTE platform

Auline Rodler, Pierrick Haurant, Ghjuvan-Antone Faggianelli , Guillaume Pigelet , Philippe Poggi

University of Corsica, UMR SPE CNRS 6134, F-20000 Ajaccio, France

Abstract

The objective of this paper is to present the thermal recovery system of the MYRTE hydrogen chain. This system recaptures the thermal energy produced by the proton exchange membrane (PEM) fuel cell (100 kW) and a PEM electrolyzer (10 Nm^3/h). The recovery system must insure to maintain the set point temperature of the inlet cooling water to the facilities. In that view, the heat is collected and stored in a water storage tank and the rest is dissipated using a turbofan. In this paper, the power dissipated and stored in the recovery system is evaluated based on measurements. The results show that the fuel cell generates at its maximal electrical power an equivalent amount of thermal power. Finally, a model coupling the fuel cell and the heat recovery system is implemented in TRNSYS®, showing a good agreement to the measurements.

Keywords: Co-generation**,** Hydrogen, Fuel cell, Electrolyzer, Solar energy

1. Introduction: Energy Context in Corsica

Corsica Island is located in the Genova golf in the Mediterranean Sea and therefore exposed to the Mediterranean climate, characterized by hot and dry summers and mild and humid winters. Its solar energy potential is one of the most important of France. As Corsica is very hilly in the centre, we can find different climates via the island. The solar resource distribution is very heterogeneous and the solar radiation can be very fluctuating.

Besides, the Corsican electrical grid is typical of an insular electrical network: it is weakly connected to the mainland grid, small-sized and sensitive to variations in electrical production. The threshold of maximum 30% of integration of fatal intermittent production, fixed by the French law to insure the insular grid's stability, was overpassed in 2012[1]. However, photovoltaic plants projects are still considered.

Therefore, storage systems to smooth the intermittency of the solar production seem necessary. Hydrogen production and consumption can help to manage electrical power fluctuations of intermittent renewable energy sources integrated into the electrical grid.

In this context, the hybrid MYRTE (mission hydrogen for the integration of renewable into the electrical grid) demonstration platform has been built: it combines a photovoltaic array and a hydrogen chain used as a storage solution.

2. The hydrogen solution: MYRTE project

The first aim is to test hydrogen storage solutions as an alternative to the peak shaving of electrical demand (Darras, 2010). Another aim of this platform is to monitor the photovoltaic power output smoothing and to reduce the PV fluctuations (Darras et al., 2012). Finally, the development of algorithms and optimal strategy

doi:10.18086/swc.2015.02.12 Available at http://proceedings.ises.org

management coupling the processes (PV production – Hydrogen chain) is another target.

2.1 Presentation of the experimental platform

The experimental MYRTE platform is a technological platform dedicated to the coupled studies between PV/hydrogen chains. This platform has been inaugurated on January 2012.

MYRTE platform is composed of the following sub systems (Fig. 1):

- A photovoltaic array of 560 kW_p (3700 m^2 covered by 2240 PV TENESOL TE2200 modules);
- 28 DC/AC three-phase 17 kW inverters (SMA SUNNY TRIPOWER 17000TL);
- The fuel cell subsystem (SSPAC), composed of a PEM (proton exchange membrane) fuel cell with a power of 100 kW supplied by AREVA ;
- The subsystem electrolyser (SSEL), composed of a PEM electrolyzer of a nominal power of 50 kW with a H_2 flowrate which can reach 10 Nm^3/h, developed by AREVA ;
- The storage subsystem, composed of drying and purification systems of gases as well as two H_2 storage tanks and one O_2 tank (GLI ETS Citergaz) each with a volume of 28 m^3, under a maximal pressure of 35 bars (1400 Nm^3 d'H_2 and 700 Nm^3 d'O_2) ;
- A 800 kVA transformer to inject electrical production on the high voltage network ;
- The thermal recovery subsystem to recover heat from the electrolyzer and the fuel cell to maintain the operative temperature of both systems.

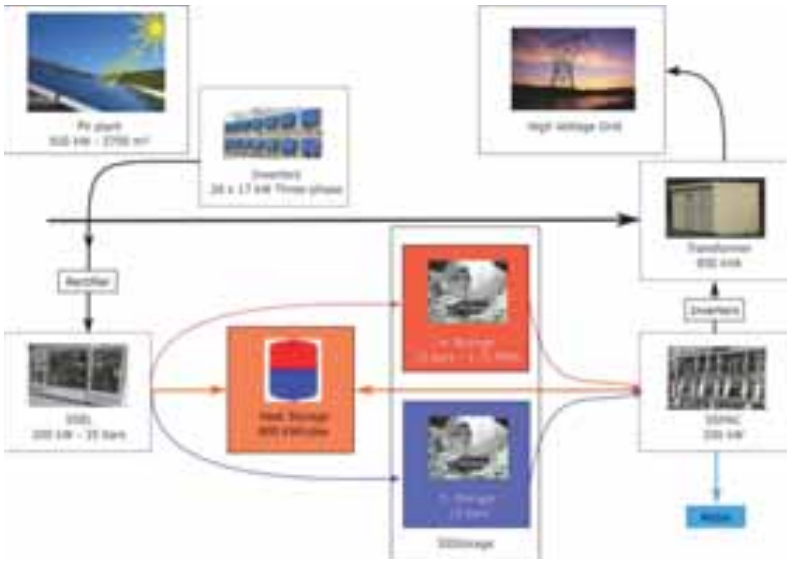

Figure 1: Operating of MYRTE

The electrical mean efficiency of the hydrogen chain is of about 23 – 25 %. The facilities as the fuel cells release heat when they generate electricity and are therefore interesting for combined heat and power (CHP) applications, also known as cogeneration. CHP hydrogen system time-averaged electrical, thermal and global (combining both heat and electrical powers) efficiencies have been evaluated by Hwang et al. (2013) to about 37 %, 24 % and 61 % respectively. To conclude, recovering the thermal heat of fuel cell systems strongly increases the overall energy efficiency of the global system.

2.2 Heat recovery

To increase the global efficiency of the hydrogen chain, the heat recovery system is composed of a thermal energy storage system to store the heat produced by the fuel cell (FC) and electrolyzer (EL). This heat can then be used in a secondary loop, for example for a residential application.

The cooling loop will systematically act on both electrolyzer and fuel cell, that is, the water passes through their heat exchangers to guaranty the operating temperature which is 60 °C for the electrolyzer and 70 °C for the fuel cell. The maximal overall operating temperature not to overpass is fixed to 75 °C, for security reasons. The absorbed heat is then stored or dissipated by turbofans (Fig 2). The glycolic liquid is kept in movement

by a pump (KQ500) and goes to the heat exchanger of the tank where the heat can be stored. The maximal temperature of the water which will go back to the electrolyzer and fuel cell is fixed in between 35 – 40 °C. This set point temperature is ensured by turbofans which will dissipate the heat if the sensor KT501 indicates a temperature above the set point temperature. The cooling overall flow rate depends on the electrolyzer or fuel cell system working order and depends on the opening percentage of the regulation valves. For the moment, the experimental set up is not connected to any secondary loop which could allow exploiting the heat. As seen on the schematic drawing of the thermal recovery system (Fig.2), the water can follow different paths in the circuit. It is possible to cool down the electrolyzer and fuel cell systems, to recover the heat from them and exploit it or absorb the heat without recovering it.

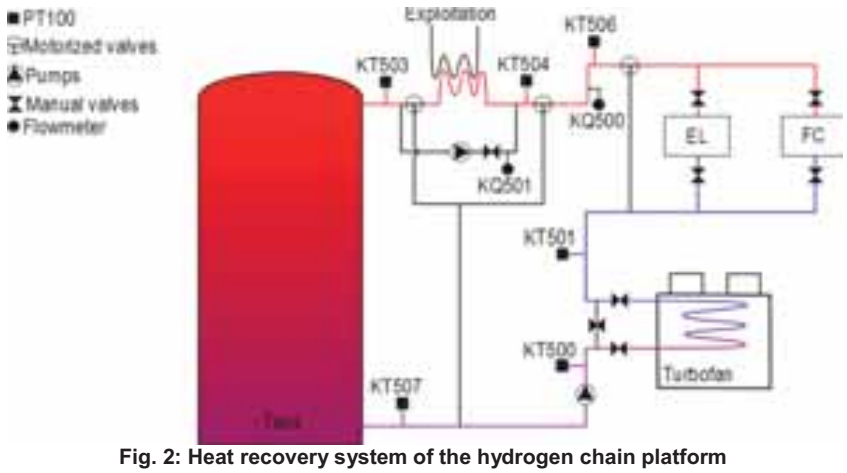

Fig. 2: Heat recovery system of the hydrogen chain platform

Different modes in the circuit are possible:

- **Mode to cool down the system** which is ordered by the control system. Different cases are possible depending if the storage is full and depending on the water temperature of the sensor KT501 placed before electrolyzer and fuel cell heat exchangers:
    1. If the storage is not full and KT501 < set point temperature (35 °C): we will store the heat;
    2. If the storage is not full and KT501 > set point temperature: we will store the heat and dissipate the heat by the two turbofans;
    3. If the storage is full and KT501 > set point temperature: the turbofan is used (frequency of the fan is function of the overtaking of the set point temperature);
    4. If the storage is full and KT501 < set point temperature: the turbofan is used (at its minimal working).
- **Mode to recover the heat to a second water circuit:** the system would allow the water to go to a second circuit. The water would be in between 45 and 55°C for the heating system of a building. Until now, this mode is not possible as there is no connection to a building.
- **Mode to take out the heat without recovering the heat:** the heat is transferred to the storage tank and to the turbofan.
- **Stopping mode or manual mode.**

3. Modelling

3.1 Presentation of the measurements feedback

In this paper, we present results for a three day period in May 2014, when the platform was working in a peak shaving mode: each day, the electrolyzer consumed 46 kW during the day and the fuel cell produced a maximum of 95 kW between 08.30 pm and 10.30 pm (Fig. 3). The peak shaving mode consists in using additional sources of energy at moments when the electricity demand is important. That is, the MYRTE platform is used at moments of peak shaving: the fuel cell is used to supply electricity to the grid. The heat recovery system is turned on only when the electrolyzer or fuel cell is operating. The set point temperature of the KT501 was fixed to 35°C.

The heat recovery system is turned on only when the electrolyzer or fuel cell are used. The set point temperature of the KT501 was fixed to 35°C. For the moment, the experimental set up is not connected to any secondary loop which could allow exploiting the heat.

The electrical power generated by the fuel cell and the power consumed by the electrolyzer were measured (Fig. 3) as well as different temperatures (KT506, KT507 and KT501 show in Fig. 3). The outside temperature was also measured and a flowmeter gave the flowrate in the recovery loop. All measures are given at a minute time step.

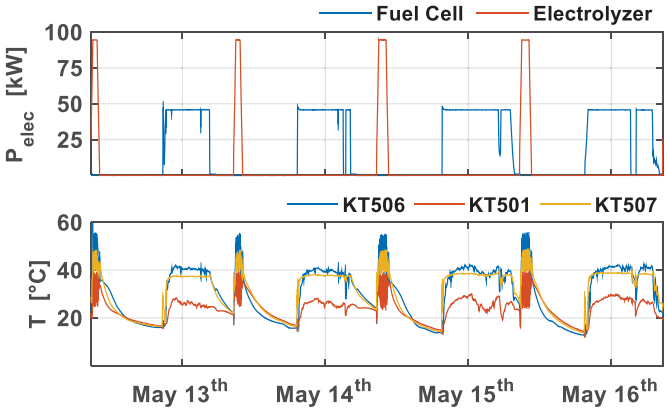

Figure 3: Electrolyzer and fuel cell electrical power

We can observe in Fig. 3 that the inlet fluid temperature in the thermal recovery system, measured by sensor KT506:

- reaches 40°C to 42°C when the electrolyzer works;
- varies between 41°C and 53°C when the fuel cell works.

Whatever the time considered, these temperatures are below the optimal temperatures of both systems, and far from their maximal operating temperatures: the hydrogen systems seem to be cooled down too much.

Besides, these fluid temperature ranges indicate that the heat recovered could be used for residential applications, as for the heating or pre-heating systems.

The fluid temperature decreases from 2 to 3 °C when the electrolyzer works and from 5 to 7 °C when the fuel cell works when it passes through the storage tank. Then, the water circulates through the turbofan and its temperature decreases strongly whatever its input temperature. When the electrolyzer works, the glycolic water temperature drops always below 30°C when measured on KT501. It oscillates between 32°C and 38°C when the fuel cell is on. The turbofan dissipates too much heat since it is oversized or not well controlled, so that the heat recovery system overcools the systems.

3.2 Sub-system parametrisation

A transient model adapted to the case study MYRTE, and particularly to the heat recovery system, is being developed using TrnSys® (TRNSYS, 1996). It is a software with a modular structure dedicated to dynamical simulation of complex energy systems. It aims at considering the global system composed by a set of interconnected subsystems modelled in 'types'. The thermal behaviour of the sub-systems has been modelled thanks to 'types' stemming from TRNSYS library (Tab. 1).

Table 1 Elements of TRNSYS model

Elements	Type	Comment
Data reader	9	Flowrate, ambiant temperature, fuel cell control signal and electrolyzer control signal
Pipe	31	Hypothesis on the sizes and the thermal losses
Turbofan	Macro	Pipe and forced convection simulated
Water Tank	60d	With internal exchangers and taken into account the stratification (20 nodes)
Electrolyzer	Macro	Only the thermal aspect of the electrolyzer is considered
Fuel cell	170 k	FC O_2/H_2 controlled with the intensity

The inputs of the model are:

1. the outdoor temperature ;
2. the flowrate of the glycolic fluid (KQ500);
3. heat generated by the electrolyzer.

The outputs of the model are:

1. the water temperature before, in and after the storage tank ;
2. the inlet and outlet temperature of the turbofan ;
3. the power and energy dissipated by the turbofan ;
4. the power and energy stored by the tank.

3.2.1 Tank

The water storage tank was modelled by using the Type 60d, which is a dynamical model for thermal stratified storage. It includes heat exchangers and auxiliary heaters. In this model, the tank is divided in N volumes or nodes. The water temperature for node i is evaluated according to the energy balance (Eq.1):

$$m_{w,i}c_p\frac{dT_{w,i}}{dt} = Q_{HEX,i} + Q_{AUX,i} + Q_{loss,i} + Q_{cond,tank,i} + Q_{conv,tank,i} + Q_{fconv,inout,i} \quad \text{(eq. 1)}$$

where

- $Q_{HEX,i}$ and $Q_{AUX,i}$ are the heat from the exchanger and auxiliairies
- $Q_{loss,i}$ is the thermal losses to the outside
- $Q_{cond,tank,i}$ is the thermal exchanges by conduction of the fluid in the tank between node i and nodes $i+1$ and $i-1$
- $Q_{conv,tank}$ is the thermal exchanges due to convection in the tank
- $Q_{conv,inout}$ is the bleedoff exchanges and the exchanges of the water supply in the tank to the N inputs/outputs of the tank.

This model is dynamic and zonal as it calculates the thermal transfers between control volumes, so it considers the stratification in the tank. The parametrization of the tank is sensitive as the geometry of its heat exchanger is particular. The tank is composed of 4 connected metal plates filled in with water and in contact with the exterior surface of the tank. The water tank is 4m high and has a 2m diameter, with a total volume reaching 14 m^3.

The circulation of the fluid for this type of exchanger and the heat exchanges by conduction with the water of the tank differ from the exchanges of a tank with a coil. The circulation speed is smaller whereas the contact surfaces are more important. This is why we have considered a very long exchanger and we have overestimated the thermal exchange coefficients.

3.2.2 Electrolyzer

In TrnSys we do not have a ‘type’ modelling the electrolyzer PEM so that in this study the electrolyzer has

been considered as a constant heating source when operating. The heat has been evaluated from differences between the measured KT501 and KT506 temperatures.

This first very simple modelling does not allow simulating the thermal dynamic behaviour of the heat recovery system of MYRTE in a reliable way. The model validation will have a critical sense only when the fuel cell is operating. It is necessary that the model evaluates several levels of temperatures and heat supply. However, this simple modelling is necessary so that the global model can evaluate the average heat generated by the electrolyzer and can insure a continuity through the simulations between each operating period of the fuel cell.

3.2.3 Fuel cell

The fuel cell model implemented in the type 170 is composed of an electrochemical, a thermodynamic and a thermal model. Different outputs are calculated: the stack temperature, the electrical production and the gas consumption.

The electrochemical model is based on different works (Amphlett et al., 1996; Ulleberg 1998). The voltage of a single cell is:

$$U_{cell} = E + \eta_{act} + \eta_{\Omega} \qquad \text{(eq. 2)}$$

where E is the thermodynamic potential given by Nernst equation, η_{act} is the anode and cathode activation over-voltage and η_{Ω} the ohmic over-voltage, quantifying the transport losses due to the proton conductivity.

The thermodynamical model has been set up to establish the inlet flowrates for the oxygen $\dot{n}_{O_2,in}$ and hydrogen $\dot{n}_{H_2,in}$, according to Faraday's law. With this law the real consumption of the gas considering the stoichiometrical coefficients S_{H_2} et S_{O_2} are calculated:

$$\dot{n}_{H_2,in} = S_{H_2} \frac{N_{cell} I_{FC}}{n.F} \text{ and } \dot{n}_{O_2,in} = S_{O_2} \frac{1}{2} \dot{n}_{H_2,cons} \qquad \text{(eq. 3)}$$

The stack temperatures T_{stack} are evaluated according to the thermal model where c_t is the thermal capacity of the stacks:

$$c_t \frac{dT_{FC}}{dt} = Q_{gen} - Q_{loss} - Q_{cool} - Q_{evap} \qquad \text{(eq. 4)}$$

Q_{gen} is the heat generated by the fuel cell, Q_{loss} the heat dissipated in the environment, Q_{evap} the heat dissipated by evaporation at the cathode and Q_{cool} the heat dissipated thanks to an auxiliary.

The principal parameters used for one stack are listed in the table below (Tab. 2) where the eventual connections between parameters and other types are indicated.

Table 2: Elements of the model

Characteristic elements /parameters			**Inputs**			**Outputs**		
Number of cells per stack	N_{cell}	100	Control signal	δ	$\delta = (P_{FC} > 0)$	Power per stack	P_{stack}	Graph (Type 65)
Number of stacks	N_{stack}	4	Intensity of the cell	I_{FC}	$I_{FC} = f(V, P_{FC})$	Current (stack)	U_{stack}	Graph (Type 65)
Electrodes surface	A_{PEM}	400 cm²	Input pressure	$p_{gaz,in}$	1.5 Bars	Gas consumption	$\dot{n}_{H_2,in}$	H_2 tank
Ambient temperature	T_{amb}	Inputs (Type 9)	Stochiometric coefficients	S_{gaz}	1.15 (H2) ; 2.5 (O2)		$\dot{n}_{O_2,in}$	O_2 tank
Connexion to TrnSys Types			Input fluid temperature	T_{cool}	Inputs (Type 9)	Heat	Q	$T_{out} = f(T_{in}, Q)$
Constants			Set point temperature in the stack	T_{stack}	Macro Fan			
Connexion to Calculators			Set point temperature in the stack	T_{stack}	70 °C			

3.2.4 Turbofan

The turbofan has been modelled associating it to a dissipating cooling system. This system depends on an all or nothing controller. The heat dissipated by the fan is a function of the set point temperature and the flowrate.

The turbofan in composed of a very long heat exchanger of 500 m of 13 mm of diameter with a fin and two fans. There is no existing model in the TrnSys library able to model this kind of turbofan, so that a macro has been developed composed of a pump (Type 3b), managing the water flowrate in the pipe (Type 31) where the sizes are the one of the heat exchanger. The effect of the fins allows increasing the contact area, and therefore increasing the conduction transfer. In the model, the thermal loss coefficient of the pipe is increased so that the conduction transfers due to the fins are well modelled. The cooling of the fluid is accelerated by using fans. This phenomenon is modelled by using a resulting temperature: it corresponds to the outside air temperature adjusted with a negative offset. The resulting temperature is used only when the set point temperature (T_{sp} = 35 °C) is overpassed by at least 2°C ($\Delta T_+ = 2$ °C) and is not used when the temperature is under the set point temperature by 3 °C: $T = T_{sp} - \Delta T_-$ where $\Delta T_- = 3$ °C

The parameters ΔT_+ and ΔT_- are the dead-bands of the fans regulator which is at the origin of the oscillations seen on the temperatures measured by the sensors when the fuel cell operates.

4. Simulation Results

4.1 Electrical outputs

The electrical characteristics of the fuel cell and its sizes are implemented in the Type 170 (Tab. 2). With these parameters we have plot the current–voltage (I–U) characteristics of the PEM fuel cell (Fig 4). This simulation has been compared to the measurements. The measurements stem from a test (blue curve) while the fuel cell was operating in a dynamic mode during 8 hours. We have also represented the I-U curve of this stack, initially characterized (red curve). We can notice that the voltage simulated is always higher than the measured one. Around the nominal operation of the fuel cell, for a current of 333 A, the measured voltage of a stack was initially of 75.1 and of 74.8 V during the test, whereas it is of 79.5 V in the simulations. The curves $P_{FC} = f(I_{FC})$ around the nominal power of the fuel cell are very close to each other. For I = 333 A, the electrical measured powers are of 100 kW, against 105 kW for the simulated powers.

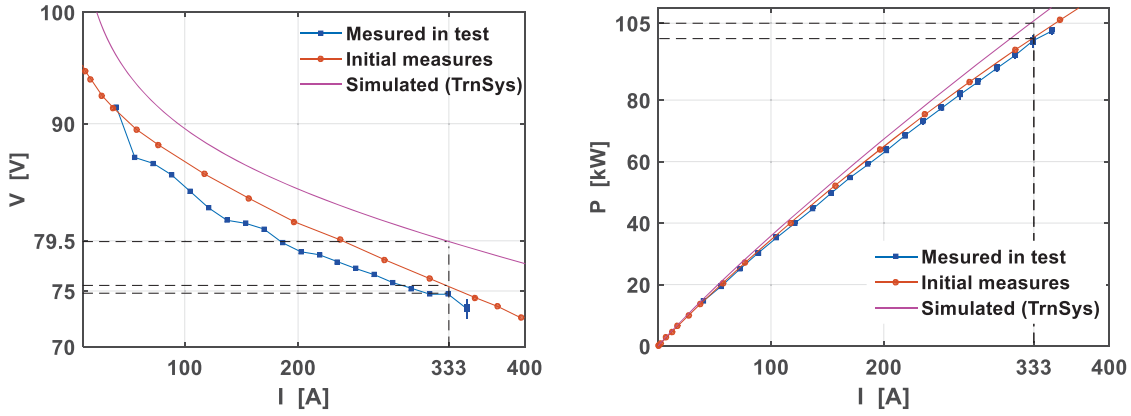

Figure 1: Measured current-voltage curve (blue), current-voltage curve obtained of a stack during the initial characterization (red) and current-voltage curve generated by TrnSys (pink). b.) Current-power characterisation of the fuel cell.

The electrical simulated and measured powers generated by the fuel cell during the period studied are represented on Fig. 5. For both cases, the powers are lower than the powers provided by the curves $P_{FC} = f(I_{FC})$ of Fig. 4 for I = 333 A. This means that during this period the fuel cell was not used exactly at its nominal capacity. The simulation tends to overestimate the electrical power generated by the fuel cell by 5 to 7 kW: the simulated power is of 100 kW whereas the measured power is of 94 kW. These differences are due to the fact that the measured power is the active power whereas the simulated power is the DC power.

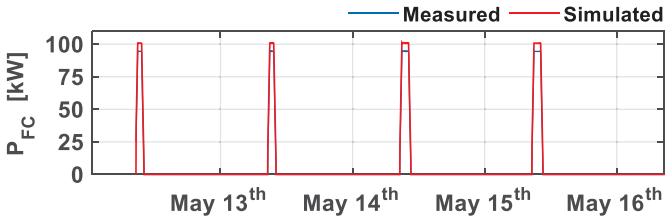

Figure 2: Measured and simulated electrical fuel cell powers

To conclude, the fuel cell type seems correctly parametrized.

4.2 Simulated fluid temperatures

The thermal model and its outputs are the specificity of this model and paper. The outlet water temperatures evaluated by the model after the hydrogen systems, the tank and the turbofan are going to be compared to the measurements with the use of the sensors: KT506, KT507 and KT501 (Fig 6). Whatever the fluid temperature, we focus on if the trends of the simulations are correctly calculated:

1. The simulated temperature increases when one of the hydrogen systems operates. When the fuel cell is on, we can observe oscillations on the KT501 which are due to the turbofan and the valves operation. These oscillations are reproduced by the model but their frequency and phasing are not respected. These results could be improved by characterizing more in detail the control of the turbofan and implementing it in the model. The fluctuations on the simulated temperatures are under evaluated:

   - for KT501: local maximal and minimal temperatures are reproduced with root mean square errors of respectively 1.96 °C and 1.77 °C. These fluctuations are linked to the turbofan regulator bandwidth. These differences show that the limits of the band have to be improved;
   - for KT506, these temperatures are evaluated with root mean square errors of 3.46 °C and 1.77 °C. The heat generated by the model tends to smoothen the inlet temperature;
   - for KT507, the root mean square maximal and minimal errors are respectively of 1.0 °C and 1.71 °C.

2. We see that the temperature decreases due to the thermal losses when no hydrogen system is operating, that is when the water stagnates. These losses are slightly under evaluated by the model. Indeed, concerning the measurements done by KT506, the temperature difference between a moment when the fuel cell starts and a moment when it ends up is of 19.7°C for the first day, of 20.3°C for the second, of 21.5°C for the third and finally of 23°C for the last day. The simulated temperatures show respectively differences of 14.0 °C, 17.2 °C, 11.3 °C and 12.4 °C. When the fuel cell stops operating we can see differences of 8 – 10 °C between simulation and measurement at the KT501 sensor. These differences are mainly explained by the phase shift of the fluctuations produced by the turbofan regulation. At given moments, the measured temperature is at its maximum of the oscillation whereas the simulated temperature is at the minimal.

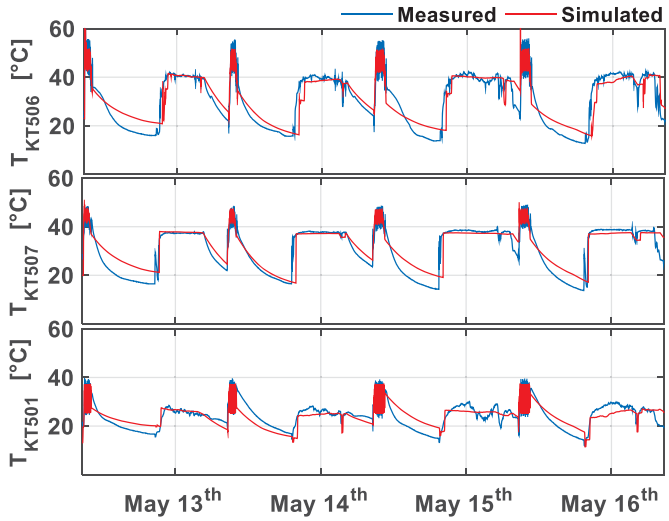

Figure 3: Measured (KT506, KT507 and KT501) and simulated temperatures

4.3 Thermal power

The thermal behaviour of the different elements of the heat recovery system, when the fuel cell operates, is presented on Figs. 7 and 8. Fig. 8 is a boxplot summing up the statistical weights of the heat evaluated: on each box, the horizontal line represents the median, the points is the mean, the vertical line links up the maximum and minimum values, and the horizontal bottom and upper edges of the box are respectively the 25th and 75th percentiles. Thus the spacing between the edges of the box indicates the degree of dispersion of the values.

We can notice that the heat produced by the fuel cell is correctly evaluated: the mean heat produced is of about 70 kW (Fig. 8). However, the fluctuations observed on the measurements are not reproduced by the model when the fuel cell operates at its nominal power. The heat calculated at its nominal power is of about 86 kW whereas the measured power is between 82 and 101 kW.

When the fuel cell reaches its nominal power, the thermal simulated exchanges in the tank are of 15.2 kW against 14.5 kW with the measures (Fig. 8). We notice that the simulated power fluctuates less compared to the measured (between 0-20 kW for the simulation against 0-46 kW for the measurements). This is due to the simulated temperature located after the fuel cell, which is less varying. The simulated heat generated by the fuel cell seems too smooth and stable.

Finally, the thermal dissipated power by the turbofan is slightly under evaluated but acceptable. In average the turbofan model dissipates 54.2 kW whereas the measurements show 55.6 kW. Here, the fluctuations are suitably evaluated.

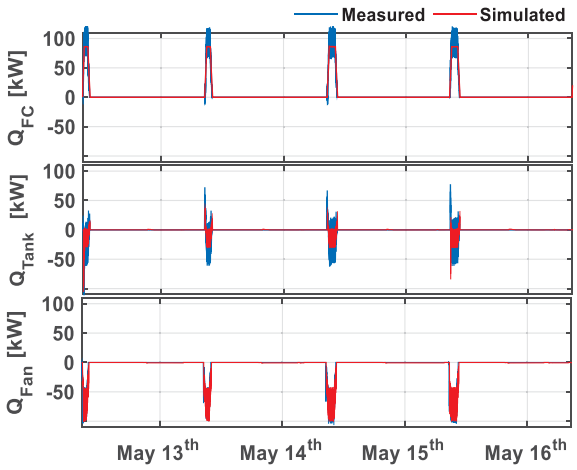

Figure 4: Temporal simulated and measured thermal powers when the fuel cell operates

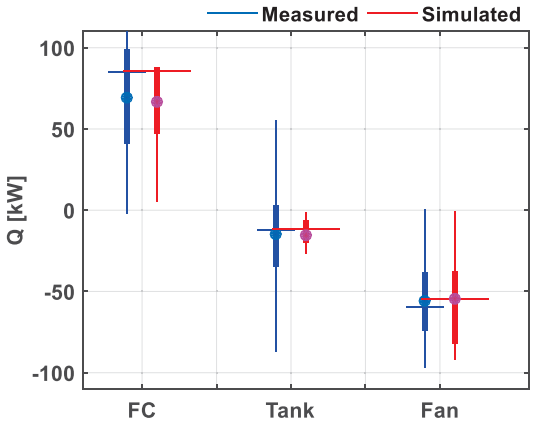

Figure 5 : Thermal measured and simulated boxplot powers when the fuel cell operates

To conclude, the model tends to agree with the measurements for both transient temperature and thermal exchanges simulations. Certain aspects need to be improved: the thermal losses on the pipes as well as the tank thermal exchanges. When looking at the transient evolution of the temperatures and heat exchanges we have often noticed that the fluctuations are less well represented with the model.

5. Conclusion

The experimental MYRTE platform is dedicated to PV/ hydrogen studies. It is composed of a 560 kW_p PV array, of a fuel cell with a nominal power of 100 kW, an electrolyzer with a nominal power of 50 kW and a hydrogen flowrate reaching 10 Nm^3/h. It is composed of hydrogen and oxygen tanks for the storage. The heat generated by the electrolyzer and fuel cell is recovered via the heat recovery system in order to maintain a set point temperature.

This paper focusses on the transient modelling of the heat recovery system. The different sub-models are introduced and the global electrical and thermal performances are presented. First the PEM fuel cell is modelled using type 170 of TrnSys. The model seems to be correctly parameterized: the electrical and thermal outputs agree and are correlated to the measurements. The turbofan seems to reproduce the heat dissipated though its regulation needs to be improved. The losses in the pipes are under estimated by the model but the

global trend is acceptable. Finally, the TrnSys type 60d used for the tank is acceptable but we know that our tank has a particular geometry so further measurements need to be done to characterize the tank model and to know whether we can improve type 60d. The heat generated by the electrolyzer has been measured and the average measured heat generated has been used in the model as an input.

The next step is to model the thermal exchanges in the electrolyzer and to transform it in a TrnSys Type. This model will be based on (Agbli et al., 2011, Gorgun, 2006) works and further measurements will be required to set the current-voltage curves for different operating temperatures. If a more detailed performance of the global model is expected then we will need to work on the regulation of some sub-models in order to increase the transient responses accuracy.

The final aim of this work is to be able to exploit the heat generated by the platform in order to recover it for residential applications. A future study, coupling an efficient building's behaviour and this experimental platform will be done in order to quantify the global energy saving which could be achieved. Also, for the moment, this platform is used for electrical demands, whereas we have seen that the heat generated can be as important as the electricity produced. A future application will be to prioritize the heat and consider electricity as a residual power. Finally, a technical and economic analysis will lead to be able to propose the best application to increase the global platform's energy and exergy efficiency.

Abstract

Sun drying is a well known method of food preservation in countries with high level of solar irradiation and one of the ancient applications of solar energy. This method is widely applied for drying different agricultural products, meat and fish in rural areas of Mozambique. However, sun drying is ineffective method for food preservation and lead to poor product quality and post harvest losses. A more effective method of solar radiation deployment for food preservation is solar drying, which involves solar dryers. But many of them are direct solar dryers. Therefore they exhibit the same intermittent nature as the source of radiation does, which turn them useless devices during off-sun conditions. In order to extend the usefulness of solar dryers even in off-sun conditions, heat storage must be incorporated. In this study, in an in-door test, the potential of a direct illuminated rock-bed heat storage based on natural convection of air is experimentally investigated. The results show a good potential of rock-bed heat storage to supply thermal energy for low-to-medium temperature applications.

Keywords: *Direct illumination, heat storage, solar drying, space heating, sun drying, natural convection and food preservation*.

1. Introduction

Mozambique is a Southern African country and share common characteristics with the other African countries in that the majority of its population lives dispersed in rural areas, far from the national electricity grid. In fact only 18 % of Mozambican population is connected to national electricity grid (IRENA, 2012). The major fraction of population has biomass as major source of energy for different domestic needs. According to IRENA (2012), biomass contributes with more than 78 % of primary energy.

A source of growing concern, however, is the fact that one of the major sources of biomass is increasingly becoming scarcer due to unsustainable use of forest resources, land use change and also desertification (Cuamba et al, 2006; Chikukwa, 2008). While the burning of biomass has become a common practice among the emerging small commercial farmers in Mozambique for drying tobacco, the gains from this agricultural crop may be reduced if this trend remains as it is.

Fortunately, the country is among those possessing high levels of solar radiation (Nijegorodov et al, 2003; Cuamba et al; 2006). Therefore, solar thermal energy may be useful for drying different agricultural products including tobacco and other foodstuff either used as a solely source or used in a complementary way with the other sustainable sources of thermal energy.

Sun drying is well known method of food preservation in countries with high level of solar radiation and one

doi:10.18086/swc.2015.02.13 Available at http://proceedings.ises.org

of ancient applications of solar energy. However, sun drying as it is done under environmental conditions is ineffective method of food preservation due to constraints it presents and lead to poor product quality and spoilage leading thereby to postharvest losses, as discussed in Weiss & Buchinger (2012) and also by Raman et al. (2012).

Some of the pitfalls imposed by sun drying can be removed by the adoption of solar drying techniques. Solar drying involves the use of solar dryers and leads to more heat supply to the products than that available in natural conditions thereby turning the use of solar radiation into a more effective process (Weiss & Buchinger, 2012; Bala & Debnath, 2012: Raman et al. 2012).

Solar dryers can be natural convection and forced convection based. But many solar dryers enable the drying activity while solar radiation is present and are not useful during off-sun conditions. For this to happen, heat storage must be integrated.

The integration of heat storage enables the collection of solar thermal energy during day light and its storage for later use. The stored thermal energy can be used either to supply heat to the dryer or to be used for the space comfort in winter in absence of solar radiation, enabling this way overnight drying process of the products and space heating.

There are different ways to charge the storage. In one of the ways, the absorbing material and the storage are separate units; in this case a carrier medium is needed to transport heat from the absorber and charge the storage. In the other, in which the need of a carrier medium is bypassed, the absorber is an integrated part of the storage, in which case the storage is directly illuminated.

Although, in general, forced convection solar drying is an advantageous process as compared to natural convection solar drying, the requirements of forced convection solar dryers are not affordable to many rural families in Mozambique due to additional costs the forced convection generator brings. In fact, the cost associated with the forced convection generator is pointed as a constraint to implementation of forced convection solar dryers in low income families (Bala & Debnath, 2012).

Thus, despite the limitations of indirect natural convection solar dryers when applied to commercial and industrial scales as argued by (Bala & Debnath, 2012), some of them may be suitable to domestic applications for drying agricultural products and space heating. Thus, in this study, the potential of a side illuminated Rock-bed heat storage with natural convection as heat transfer mechanism to enable off-sun indirect solar drying of food and space heating is experimentally investigated.

2. Background Information

Solar drying of agricultural crops and different foodstuff is recognized as a midterm between the expensive and environmental damaging process of burning wood and fossil fuels and the traditional and vulnerable process of sun drying (Raman et al, 2012). In its extensive and comprehensive review Raman et al (2012) provides the state of art in solar drying technologies in developing countries, giving more emphasis to technologies enabling off-sun drying, and recognizes the benefits arising from its adoption from financial and environmental point of view.

Off-sun drying requires integration of heat storage. Then solar thermal energy must be collected during day light and carried to the storage; from which it can be extracted when needed. At some point in this paper two modes of charging the storage were mentioned: one that requires a heat carrier medium from the collector to the storage, and the other where the need of a heat carrier medium is bypassed. In the later, the storage is directly illuminated and heat is absorbed by the storage material.

During heat extraction, a fluid must be heated in interaction with the storage material. Then, the fluid carries the heat to the dryer. Again, the process can be carried out through two different modes of heat transfer namely natural convection which depends entirely on buoyancy force, and forced convection which require the forced convection generator.

Some studies devoted their attention in reviewing different types of dryers and discussing their performances and applicability in developing countries. In addition, they presented the current status of solar dryers and discussed the potentials of solar drying technology by revisiting their experimental performance in tropic and sub tropic regions as well as simulation of some of the types of dryers (Weiss & Buchinger, 2012) and others

designed, developed and tested a forced/ Natural convection solar vegetable dryer with heat storage (Babagana et al., 2012).
It is widely recognized that forced convection is an advantageous process over natural convection. In fact, (Babagana et al. 2012) found that forced convection mode was more efficient in that it enabled higher air flow and control in addition to reduced drying time. Due to additional costs that the forced convection generator brings, it may be suitable for commercial and industrial dryers**,** but not adequate for low income rural families, in which case the natural convection based solar dryers may be useful as a tool for drying agricultural products and other kinds of food at small scale applications and also for space heating applications. In fact in Raman et al. (2012) review, one of the focuses was on indirect natural convection based solar dryers with heat storage. Several studies referred in this review paper related to this type of dryers recognize the suitability and benefits of indirect natural convection based solar dryers to be applied in small farms in rural areas of developing countries. Bergman et al. (2011) also recognize that whenever and wherever heat transfer and operating costs have to be minimized, then natural convection based systems is the recommended choice.

Natural convection dryers are more popular for drying agricultural products owing to their low cost, simplicity in operation and maintenance; but presents lower drying rates, hence longer drying time than their counterpart (Babagana et al., 2012; Bala & Debnath, 2012). However, solar dryers regardless of their category are more effective than sun drying, because they lead to reduced drying time and good quality product.
In their turn Othman et al. (2006) devoted their attention to solar dryers with heat storage, that also integrate auxiliary sources of energy and controlling structure to allow off-sun drying activity of agricultural products.

With the similar purpose and recognition of the need to supplant the pitfalls brought about by the intermittent nature of the solar radiation, five years later after Othman's paper, Bal et al.(2011) published a review paper that focused to solar dryers with PCM heat storage.

2.1. The Physics of Natural Convection

The extent to which natural convection of a fluid occurs is dependent on buoyancy force. The driving force of this agent is density gradient which in turn is caused by temperature gradient within the fluid (Bergman et al. 2011). In most of the cases, the ultimate driving force of a natural convection of a fluid is the interaction between temperature gradient and gravitational field.

The arising motion of the fluid must be determined by considering heat and mass transfers coupled with the fluid flow mechanisms.

The density of the fluid is a function of its temperature and their dependence at constant pressure can be expressed through the volumetric expansion coefficient β:

$$\beta = -\frac{1}{\rho}\left(\frac{\partial \rho}{\partial T}\right)_P \qquad \text{(eq.1)}$$

For the finite variation of temperature at constant pressure, the following approximation can be used:

$$\beta \approx -\frac{1}{\rho}\left(\frac{\Delta \rho}{\Delta T}\right) \Rightarrow \Delta \rho \approx -\beta.\rho.\Delta T \qquad \text{(eq.2)}$$

Buoyancy force is proportional to density difference.

Whenever there is a relative motion between two bodies in contact, a friction forces arise at their interface; opposing to the motion.

Under steady state conditions, air flow rates driven by buoyancy are established by balancing buoyancy and frictional forces. Then, the ratio of the buoyancy force to the viscous force acting on the fluid, define the Grashof number:

$$Gr = \frac{g.\Delta\rho.V}{\rho.\nu^2} = \frac{g.\beta.\Delta T.V}{\nu^2} = \frac{g.\beta.(T_s - T_\infty).\delta^3}{\nu^2} \qquad \text{(eq.3)}$$

Natural convection over a surface, besides depending on its temperature variation and thermophysical properties of the fluid, is also geometry and surface orientation dependent.

Simple analytical relations are difficult to obtain in natural convection regimes due to the complex nature of the fluid flow. Therefore, most of the relations used to describe natural convection are experiment based

correlations:

In our case, during the illumination of the storage, heated air at the entrance of the cavity rise carrying with it thermal energy; and as it goes through the voids of storage material it releases the heat to the rocks. Thus, we assume non-local equilibrium case. Then, the source of heat is interrupted.

Now we have the rocks, at the cavity entrance, at higher temperature. Therefore, the air at the vicinity of the cavity interacts with hot rocks from which it absorbs heat. Again as it goes through the voids, thermal interaction occurs and emerges at the top at temperature suitable for drying food products or space heating.

The pressure drop within the packed bed can be given by Carman-Kozeny equation:

$$\frac{\Delta p}{\Delta z} = -\frac{180.\mu.v_o.(1-\varepsilon)^2}{{d_s}^2.\varepsilon^3} \quad \text{(eq.4)}$$

Where μ is fluid viscosity, v_o is the superficial velocity, ε is the bed void fraction and Δz, the bed height.

The pebble rock particles are assumed as of spherical form having a diameter d_s. Thus, characteristic length δ will be given by:

$$\delta = \frac{\pi.d_s}{2} \quad \text{(eq.5)}$$

Then, heat transfer coefficient between rock pebbles and air is a function of Nusselt number, thermal conductivity of rocks and characteristic length: $h = \frac{k.N_u}{\delta}$ (eq.6)

In this equation Nusselt number expression for external convection between air and spherical rock surface is adopted. Thus, (eq.7)

$$N_u = 2 + \frac{0.589.Ra^{\frac{1}{4}}}{\left[1+\left(\frac{0.469}{\Pr}\right)^{\frac{9}{16}}\right]^{\frac{4}{9}}}$$

Where Ra is the Rayleigh Number and $\Pr$, the Prandlt number.

The Rayleigh number is defined as the product of the Grashof and Prandtl numbers:

$$Ra = Gr.\Pr = \frac{g.\beta.(T_s - T\infty).\delta^3}{\nu^2}.\Pr \quad \text{(eq.8)}$$

The Nusselt Number in natural convection is also given by:

$$Nu = \frac{h.\delta}{k} = C.Ra^n \quad \text{(eq.9)}$$

Where n and C are constants that depend on the geometry of the surface and the flow regime.

3. Material and Methods

In this study a 400 mm diameter and 1000 mm height stainless steel cylinder, was adopted as a container for the storage material. Then, a cavity with same dimensions as the concentrator opening was made at its bottom side and a steel grid was welded at the cavity to hold the storage material.

The storage material comprises 257.5 kg of pebble rocks with 28 mm equivalent diameter. Afterwards two layers, of 50 mm thick, rock wool were used as thermal insulation for the heat storage.

The test was done using a solar simulator comprising a set of 7 halogen lamps and a concentrator to focus the light flux on the cavity located at the bottom side of the storage.

Experiments were performed in two different situations: At first with unglazed cavity and then with glazed

cavity using borosilicate glass. In each experiment, lamps were left on for almost 4 hours and then turned off.

To monitor temperatures at different levels along the storage and also to monitor heat front progression, three thermocouples were used. Then, the sensors were connected to a dataloger interfaced to a PC through labview program to read temperatures each second.
A thermografic camera was also used to scan temperatures at the cavity.

Table 1. *Thermophysical properties of pebble rocks*

Property	Density, $\rho\left[\frac{kg}{m^3}\right]$	Specific Heat, $c_P\left[\frac{J}{kg.K}\right]$	Thermal Conductivity, $k\left[\frac{W}{m.K}\right]$	Volumetric Heat capacity, $\rho.c_P\left[\frac{MJ}{m^3K}\right]$	Void Fraction	Average diameter, m

The schematic representation of the storage and the measuring points is given in the figure below.

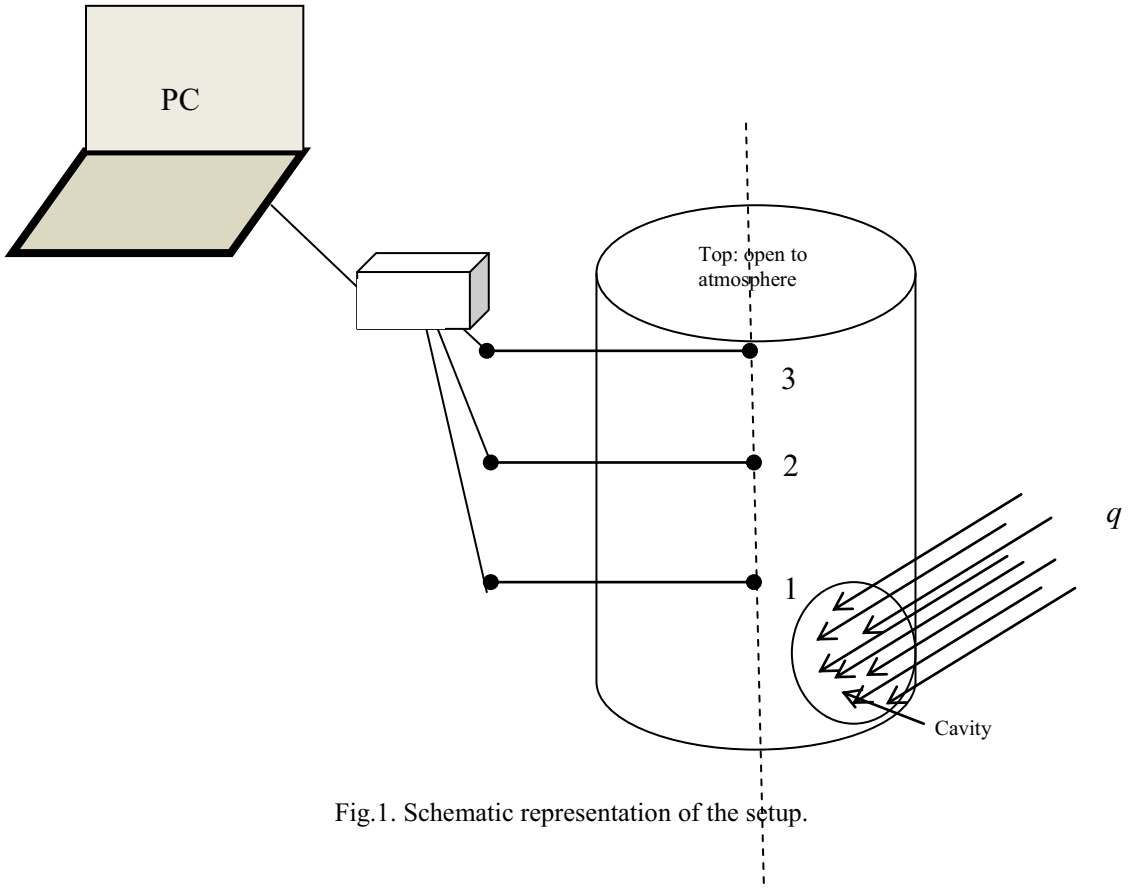

Fig.1. Schematic representation of the setup.

4. Results and Discussion

The following charts in figs.2 and 3 show temperature profiles at different levels of the HS for the unglazed and glazed cavity setup, respectively.

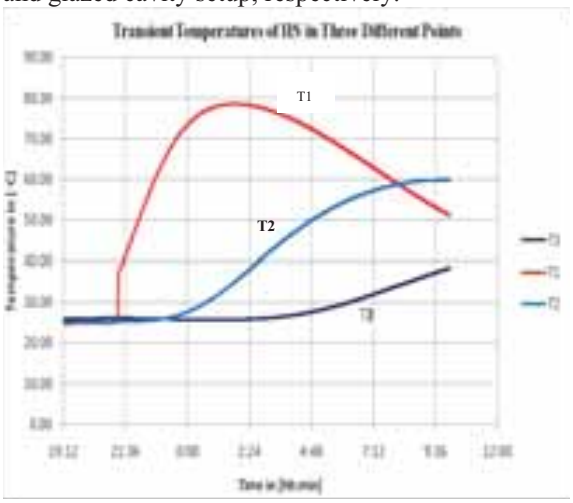

Fig.2. Chart showing temperature profiles at three different levels of HS for the unglazed cavity setup.

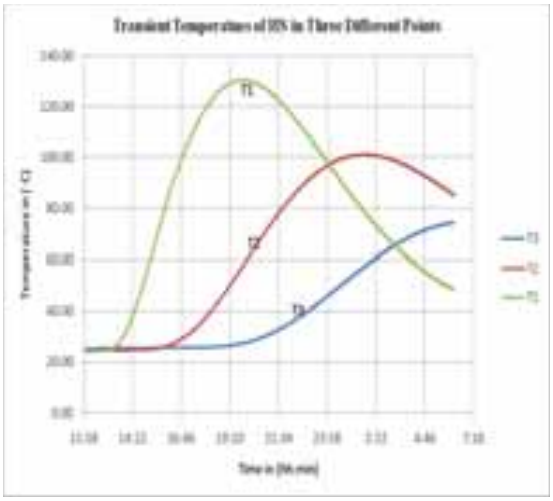

Fig.3. Chart showing temperature profiles at three different levels of HS for the glazed cavity setup.

The experiment that is referred in fig.2, was done with unglazed cavity. As can be seen from fig.2 the highest temperature registered by the first thermocouple, located 20 cm above the cavity, at the end of charging process was about 80 ^{o}C. Readings from the sensor located at the top of the HS show that until the time reading process was interrupted, temperature went from 25^{o}C to around 40^{o}C in about 13.5 hrs and was still in rise. This represents 15^{o}C above initial temperature and almost 20^{o}C above ambient temperature.

The experiment related to the chart in fig.3 was done with the cavity covered with borosilicate glass. In order to allow the air to go through the cavity a slit of about 5 cm was left at the bottom side of the cover. From the chart in fig.3 it can be seen that the first thermocouple went until 130 ^{o}C by the end of the charging process. The topmost sensor went until 75 ^{o}C by the end of measurement process. This represents almost 55^{o}C above ambient temperature. After about 13.5 hrs temperature at the top was above 60^{o}C.

The fact that temperature rise at the top of the storage is observed long after the charging process is particularly important in this case because the purpose of integrating the heat storage would be fulfilled. That is, it will allow the collection of thermal energy during sunlight and its storage to enable drying of the products or space heating in the absence of sunlight (overnight or cloudy day food drying/space heating). In either case the top of the storage needs to be connected to a drying chamber or to a house through appropriate channel to allow the hot air to go through.

It is reasonable to affirm that in both cases (with or without borosilicate glass cover at the cavity) the levels of temperatures registered is consistent with drying temperatures of many agricultural products and also suitable for space heating in the regions of Mozambique presenting cold winter. However, the performance of the heat storage needs to be tested through its integration with solar thermal collection system and a drying chamber or a house in order to assure the temperature of the air delivered to the final application its indeed appropriate for the purpose.

By integrating solar thermal energy collection, thermal storage and a drying system/or a house it is possible to achieve a fairly natural convection based efficient system. Then, the updraft driving pressure difference in the system may be given by:

$$\Delta p = \rho . \frac{\Delta T}{T} . g . \Delta z \qquad \text{(eq.10)}$$

Δz is the height difference between the air input and air exit levels (bed height)

This pressure difference will be balanced against flow friction to determine the air flow through the system.

By locating the drying and transport volumes above the solar collection and storage systems it is possible to increase the draft through the system owing to the fact that friction per unit height difference is normally smaller for the drying and transport regions than for the solar collection. In fact, Phueakphun & Fuenkajorn (2010) used a similar setup for space heating and their reasoning may be adapted in the present context to describe system‘s behavior and performance.

In our case, the storage is directly illuminated through a cavity at its bottom side by a concentrated radiation thereby being charged with thermal energy. In an outdoor experiment, a Scheffler reflector can be used to direct solar radiation to the storage’s cavity. In its turn, the storage may be connected to the drying chamber or a house, accordingly.

It should be noted that the glazed cavity setup leads to an increase of at least 62 % on the temperatures of the HS in different levels as compared to unglazed cavity setup. This difference may be attributed to the fact that the glazing decreased convective and radiactive heat loss from the cavity.
The storage is a biphasic system comprising rock pebbles and air.

Some assumptions can be adopted here, namely one-dimensional heat flow, no temperature gradients within rock particles and air is only heated by thermal energy from the rocks either reflected or by convection. The heat absorbed by the container is also neglected and the walls of the storage, but the open parts, are adiabatic.

During the performed tests in the present system, two stages can be distinguished:

1. The Storage is being illuminated by the system of lamps:

During this stage, it can be said that, heat flux impinges directly on the rocks surrounding the cavity (directly or after is transmitted by borosilicate glass cover) and is absorbed by the rocks..Then, as a consequence of heat absorption the temperature of rocks is raised. From there, heat is transferred to the flowing air at the cavity by convection. The air is heated as it goes through the voids in the bed thereby interacting with hot rock pebbles. Then, it is cooled when it faces the uppermost rock pebbles, which are at relatively low temperature, by convection. Thus, energy is gained by the rock pebble system by absorbing heat flux and is lost to the air by convection through the top open side of the storage. Energy balance equation can be written as:

$$m_{rP} c_{rP} \frac{dT_{rP}}{dt} = \alpha_{rP} q A_{cav} - h_{rP} A_r \left(T_{rP} - T_{airb}\right) \quad \text{(eq.11)}$$

The air in the storage gain heat from heat reflected at rock pebbles, radiation and convection heat transfer from rock particles and loses energy to the surrounding at the open top of the storage by convection:

$$m_{air} c_{air} \frac{dT_{airb}}{dt} = f_{ab}\left(1-\alpha_{rP}\right) q A_{cav} + h_r A_r \left(T_{rP} - T_{airb}\right) - \dot{m}.c_{air}\left(T_{airb} - T_{sur}\right) \quad \text{(eq.12)}$$

2. System of lamps is turned-off:

In this stage, cold air enters the storage through the cavity and absorbs heat from the rock pebbles:

$$m_{rP}.c_{rP} \frac{dT_{rP}}{dt} = -h_{rP} A_r \left(T_{rP} - T_{airb}\right) \quad \text{(eq.13)}$$

$$m_{air} c_{air} \frac{dT_{airb}}{dt} = h_{rP} A_r \left(T_{rP} - T_{airb}\right) - \dot{m} c_{air}\left(T_{airb} - T_{sur}\right) \quad \text{(eq.14)}$$

5. Conclusion

The potential of a natural convection based and direct illuminated rock bed heat storage has been experimentally investigated. A solar simulator comprising 7 halogen lamps and a solar concentrator coupled to the lamp system to focus the light flux to a storage cavity located at the bottom side of the storage have been used during the experiment.

The experiments were done in two different conditions. In one setup the cavity was not covered and the concentrated light flux went through the cavity and thermally interacted with the rock pebbles. In the other, the storage cavity was covered with a borosilicate glass, with 5 cm gap left to let the air go through.

Temperatures at three different positions within the storage were monitored using type-k thermocouples.

In both setups temperatures at the top part of the storage (air exit) are suitable for the intended applications, with even good performance with the borosilicate cover at the cavity, representing 62 % increase as compared to the levels of temperature achieved with uncovered cavity. However, further experiments need to be done with the heat storage integrated to the solar concentrator and a drying system or space to be heated in order to assure the performance of the system.

Abstract

Thermal stratification in heat storage tank has a major influence on the thermal performance of the heating system. For heat storage tank heated from the bottom, the whole tank is heated in order to provide hot water for the consumer. A new stratification device has been developed to place the heated water at the top of the tank, therefore allowing the energy usage to be reduced since the whole tank does not need to be heated to provide hot water. The aim of the paper is to investigate the performance of the newly developed thermal stratification device by means of experiments and computational fluid dynamics (CFD) simulations. Experiments have been carried out to measure water temperatures at different levels of the tank during charging by a vertical heating element integrated in the stratification device. A simplified CFD model of the cylindrical heat storage tank with the stratification device and a heating element at the bottom of the tank is created in Ansys Fluent 15.0. Transient fluid flow and heat transfer in the tank during charging are calculated. The CFD calculated water temperatures are compared to the measured temperatures. A parametric study has been carried out to investigate how thermal stratification in the tank is influenced by the design of the stratifier such as pipe thickness, material type, diameter of the pipe, by dimensions of the tank and by power of the heating element, etc.

The investigations elucidate how well a hot water tank heated at the bottom with a vertical heating element can be stratified by using the new stratifier design. Based on the CFD calculations, design of the stratification device is optimized.

Keywords: Heat storage tank, thermal stratification, stratification device, Computational fluid dynamics (CFD), Experiments

1. Introduction

Thermal stratification in heat storage tanks has a major influence on the thermal performance of solar heating systems. A high degree of thermal stratification in the storage tank increases the thermal performance of a solar heating system because the return temperature to the solar collector is lowered (Furbo 1984, van Koppen C 1979, Furbo 1987). A lower inlet temperature to the solar collector will increase the efficiency and operating hours of the solar collector. Further, the temperature at the top of the storage will be closer to the desired load temperature. Therefore the auxiliary energy consumption will be decreased which increases the solar fraction (Hollands 1989, Furbo 2006). Thermal stratification and natural convection flow in a vertical cylindrical hot water tank during standby periods were investigated in previous investigations (Andersen 2007, Fan 2012a, 2012b). Transient, three-dimensional CFD models of hot water storage tanks were developed and validated against thermal measurements. The results show that the CFD calculation predicts satisfactorily the water temperatures in the tank during cooling of the tank. The natural convection flow along the tank sides is strongly influenced by the thermal stratification in the tank.

A tank heated from the bottom could be used as heat storage in a solar heating system, or as heat storage for PV heating. Compared to conventional tank, it is more difficult to ensure high degree of thermal stratification in the tank heated from the bottom as natural convection in the tank created by the heating element will mix water in the tank therefore destroying thermal stratification in the tank. Typically the whole tank is heated in order to provide hot water for the consumer. A new stratification device has been developed to place the

heated water at the top of the tank, therefore allowing the energy usage to be reduced since the whole tank does not need to be heated to provide hot water for the consumer.

The aim of the paper is to analyze performance of the newly developed thermal stratification device by means of experiments and computational fluid dynamics (CFD) simulations.

2. The investigation methods

Experiments have been carried out to investigate thermal performance of the newly developed stratification device. Fig. 1 shows test setup a cylindrical heat storage tank of 110 liters installed with a stratification device. The tank is made of 2 mm steel. The stratification device is mounted at the bottom of the cylindrical tank, see Fig. 1A. The stratification device consists of two parts: A steel pipe with a diameter of 115 mm at the bottom and a plastic pipe with a diameter of 20 mm at the top, see Fig. 1B. Inside the steel pipe of the stratification device there is a vertical electrical heating element of 2.91 kW installed. When heated by the heating element, water in the stratification device rises up and enters in the tank though an opening at the top of the plastic pipe, while there are gaps at the bottom of the stratification device, allowing water from the tank to enter into the inlet stratification device. This forms a circulation of water flow driven by natural convection. Photo of the tank is shown in Fig. 1C. Experiments have been carried out to measure water temperatures at different levels of the tank during charging at different operation conditions.

(A) design of the tank (B) photo of the stratification device (C) photo of the tank

Fig. 1: Experimental setup of a heat storage tank with a stratification device

A simplified CFD model of the cylindrical heat storage tank charged with a heating element at the bottom of the tank is created in Ansys Fluent 15.0, see Fig. 2. The tank has a diameter of 394 mm and a height of 841 mm, resulting in a volume of 110 liters. The stratification device is placed in the middle of the tank, stretching from the bottom to the top of the tank. The bottom part of the device is a steel pipe with a diameter of 115 mm and a thickness of 4.3 mm, while the upper part of the device is a plastic pipe with a diameter of 20 mm and a thickness of 2.3 mm, see Fig. 2. The parabolic top end and bottom end of the tank are made flat in order to facilitate good meshing. The water volume above the opening of the plastic pipe and the dead volume at the bottom of the tank were kept the same as the tank in experiment, therefore influences on thermal stratification by the simplification is minimized. The 3D tank model includes the steel tank wall as a solid region and the hot water volume of the tank as a fluid region while the insulation materials are not directly modelled. The effect of the insulation materials is considered by the heat loss coefficients measured by the experiment. The heat loss coefficient of the tank is divided into three parts: heat loss coefficient of the top surface, of the side surface and of the bottom surface. The heat loss coefficients measured by the experiments are used as input to the model. The following equations are used to calculate temperature

dependent heat loss coefficients of the tank:

$$K_{top} = 0.24 + 0.00015 * t \quad [W/K] \quad \text{(eq. 1)}$$

$$K_{side} = 1.75 + 0.00148 * t \quad [W/K] \quad \text{(eq. 2)}$$

$$K_{bottom} = 0.41 + 0.00034 * t \quad [W/K] \quad \text{(eq. 3)}$$

$$K_{total} = 2.4 + 0.00198 * t \quad [W/K] \quad \text{(eq. 4)}$$

where t is the water temperature in the tank, [˚C].
Mean average ambient air temperature during the experiment is used as the free stream temperature of the tank surfaces. The tank wall material, steel, has a thermal conductivity of 60 W/K/m and a density of 7850 kg/m^3.

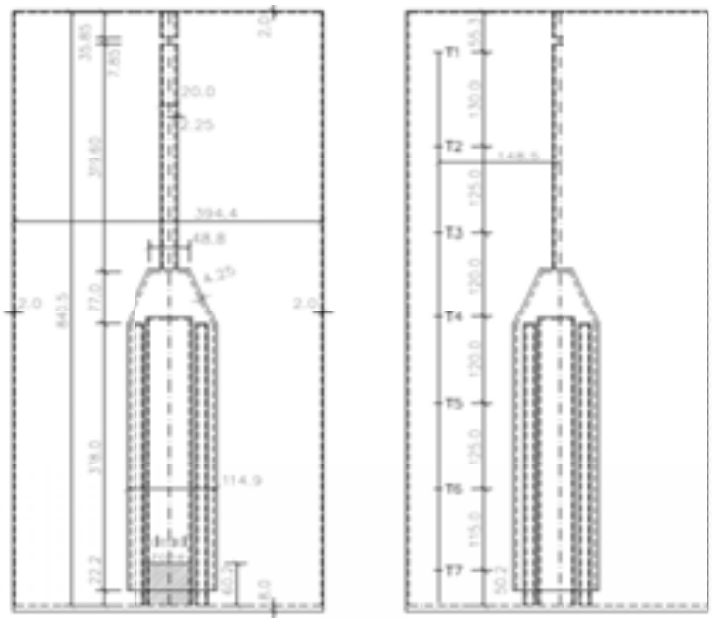

Fig. 2: Simplified CFD model of the tank with a stratification device

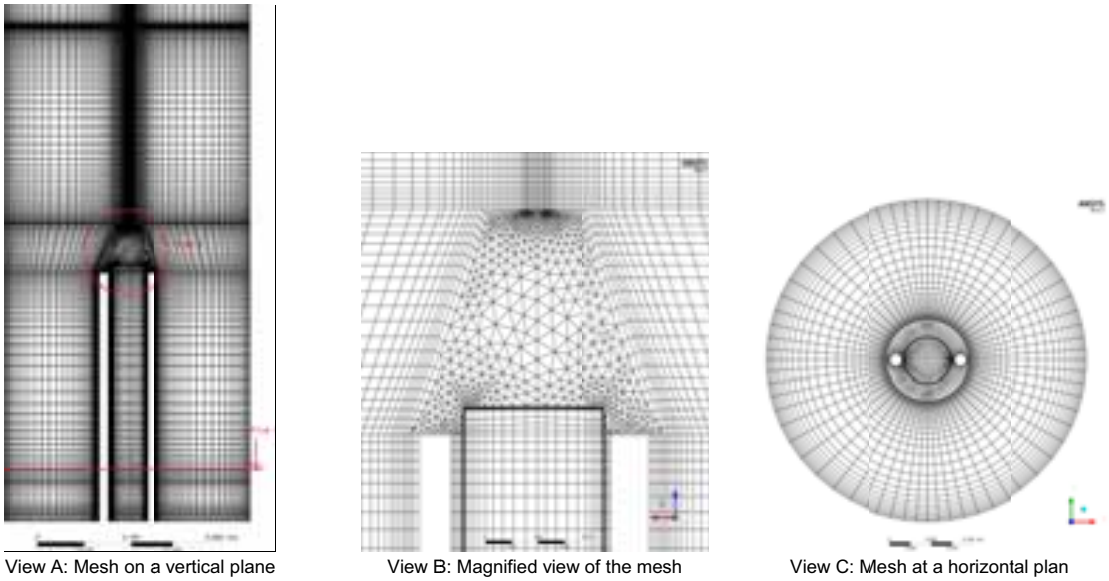
The mesh on the vertical cut-plane of the tank is shown in Fig. 3A. In order to better resolve the heat transfer and fluid flow in the region adjacent to the tank wall, a boundary layer mesh is applied so that there is a fine and dense mesh in the area close to the wall, see Fig. 3B and 3C.



View A: Mesh on a vertical plane | View B: Magnified view of the mesh | View C: Mesh at a horizontal plan

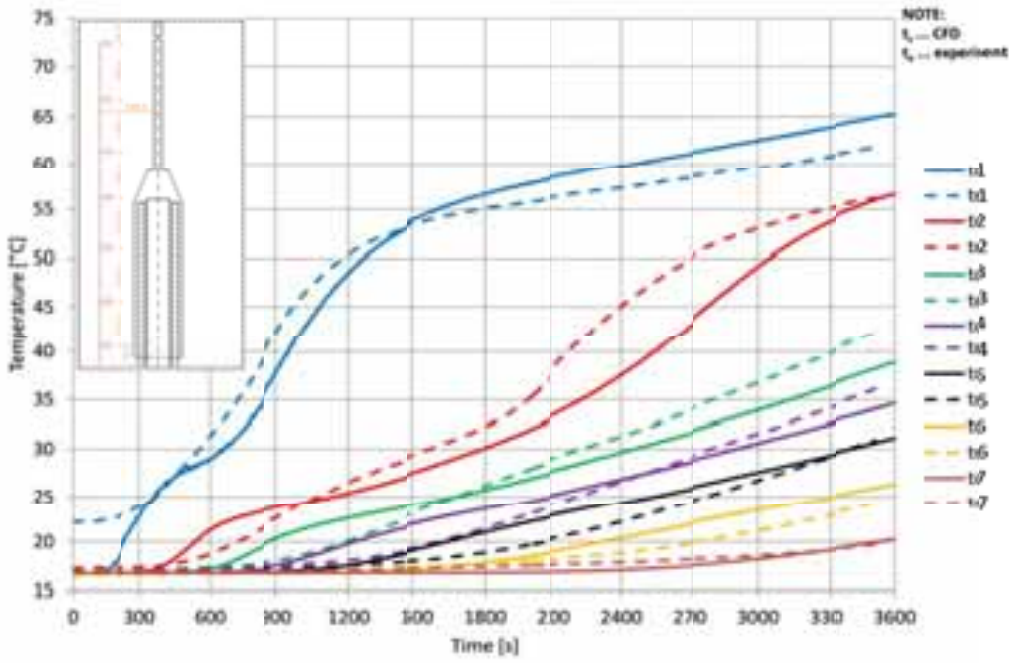
Fig. 3: Mesh of the CFD model of the tank

Calculation of Rayleigh number shows that the flow in the tank is turbulent, therefore the k-ε turbulent model is used in the calculation. Transient CFD calculations are performed with Boussinesq approximation. The PRESTO and second order upwind method are used for the discretization of the pressure and the momentum/energy equations respectively. The SIMPLE algorithm is used to treat the pressure-velocity coupling. The transient simulations start with a cold tank with temperature close to the ambient air temperature. A zero velocity field is assumed at the start of all simulations. The calculation is considered convergent if the scaled residual for the continuity equation, the momentum equations and the energy equation are less than 10^{-3}, 10^{-3} and 10^{-6} respectively. The simulation runs with a time step of 1 s and a duration of 1 h. One simulation takes approximately 24 hours for a quad-core processor computer with 4 X 3 GHz CPU frequency and 8G memory.

3. Validation of the CFD model

Transient fluid flow and heat transfer in the tank during charging are calculated. The CFD calculated water temperatures are compared to the measured temperatures. Fig. 4 shows measured and calculated temperatures in the tank at 7 different levels of the tank after 1 hour of charging from a cold tank. Locations of the temperature sensors are illustrated in Fig. 1A. Measured temperatures are shown with a title 't_e*' while CFD calculated temperatures are shown with a title 't_c*'. The last number in the title '*' indicates the location of temperature sensor. The charging power is 2.91 kW. At the start of the charging, the measured temperature at the top of the tank was 5 K higher than the temperature used in the CFD model. This difference in temperatures will influence the difference between measured and calculated temperature as water at the top of the tank will slowly flow towards the bottom of the tank during charging.

The difference between the measured and the calculated temperatures is within the range of 0-4 K at the end of the charging. It can be seen that there is a good agreement between the measured and the CFD calculated temperatures through the whole tank, therefore the CFD model is considered reliable. The validated CFD will then be used to investigate how thermal stratification in the tank is influenced by different designs of the stratification device.



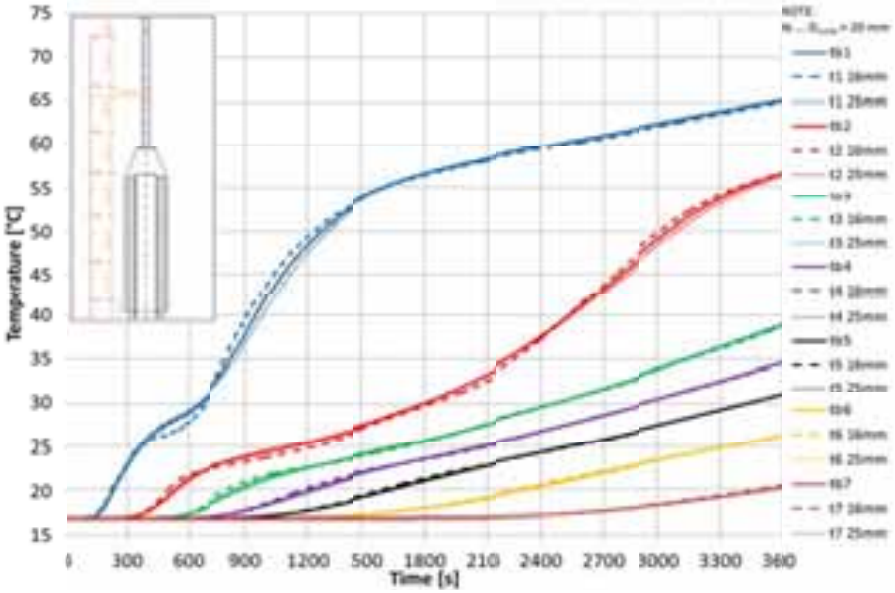
Figur 4. Measured and calculated temperatures in the tank during a 1h charge (t_c.., CFD; t_e…, experiment).

4. Parametric analysis

The validated CFD model is used to calculate water temperatures in the 110 l Metro tank after 1 hour of charging. At the start of the charging, the tank has a uniform tank temperature of 16.5°C. Calculations are carried out to investigate the influence of the design of the stratification device on thermal stratification in the tank. The investigations focuses on diameter and wall thickness of the PEX pipe, opening area of the PEX pipe, diameter of the hole separating the plastic pipe and the steel pipe as well as dimeter, wall thickness for the steel pipe around the heating element. Also calculations with a PP pipe around the heating element were carried out. The charging power is 2.91 kW in the calculations.

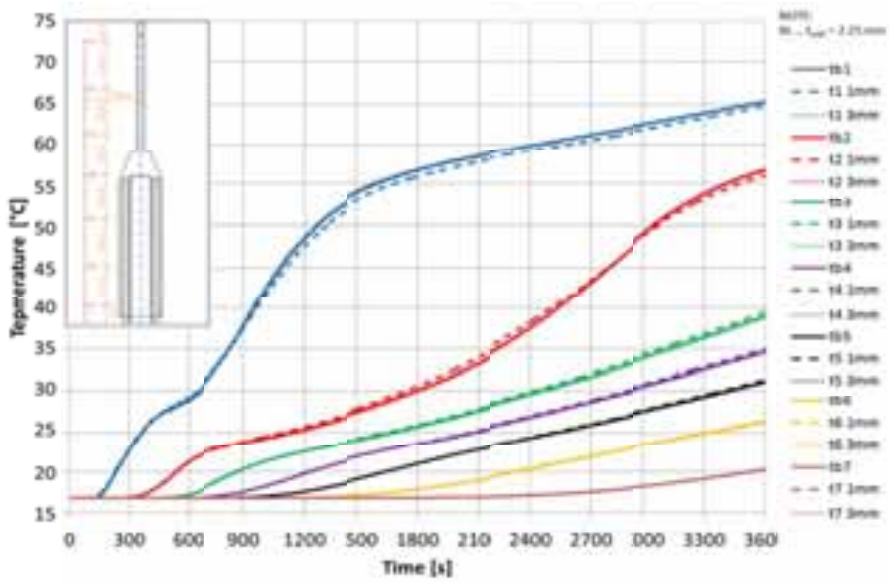
4.1 Diameter and wall thickness of the PEX pipe

Fig. 5 shows calculated temperatures in the tank during a 1 hour charge with different diameters of the PEX pipe. The PEX pipe in the experiments has an outer diameter of 20 mm and an inner diameter of 15.5 mm, therefore 20/15.5 mm is used as a reference. In Fig. 5, 'tb*', 't* 16mm' and 't* 25mm' represent the reference pipe of 20/15.5 mm, a pipe of 16/12 mm and a pipe of 25/20.4 mm respectively. The last number in the title '*' indicates the location of temperature sensor. It can be seen that the diameter of the PEX pipe has almost no influence on water temperatures in the tank, therefore it can be concluded that thermal stratification is not influenced by diameter of the PEX pipe if pipe diameter lies within the range from 16-25 mm. It indicates that the investigated pipe diameters are sufficient large so that they will not create significant friction loss for the natural convection flow in the pipe during charging.



Figur 5. Calculated tank temperatures during a 1 (h) charge for different PEX pipe diameters.

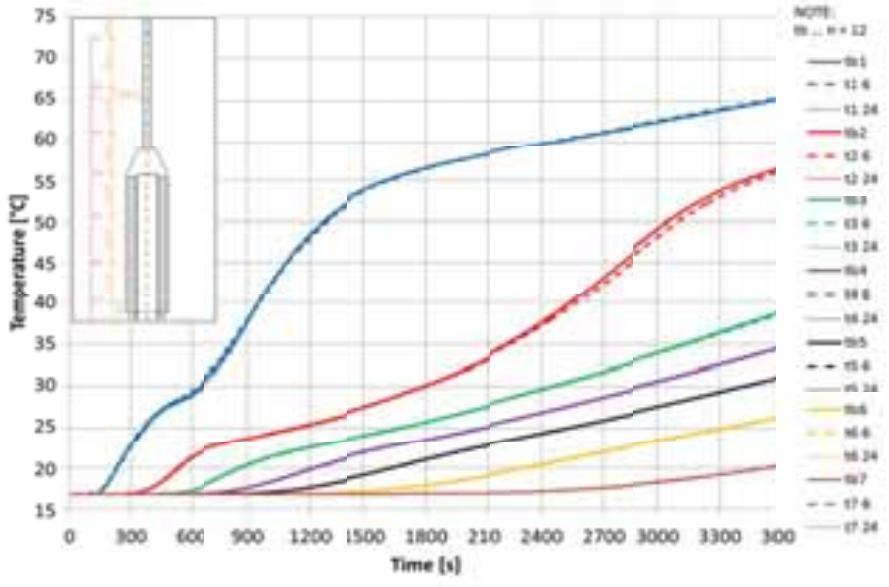
Fig. 6 shows calculated water temperatures during a 1 hour charge with different wall thicknesses of the PEX pipe. The PEX pipe in the experiments has a wall thickness of 2.25 mm, which is shown as reference in Fig. 6. The text 'tb*', 't* 1mm' and 't* 3mm' represent respectively wall thickness of 2.25 mm, 1 mm and 3 mm. The last number in the title '*' indicates the location of temperature sensor. It shows that the wall thickness has insignificant influence on water temperatures in the tank. The tank with a PEX pipe wall thickness of 2.25 mm has almost the same temperature as the tank with a pipe wall thickness of 3 mm while with a wall thickness of 1 mm, there is a larger temperature difference. The largest temperature difference between the three tanks is smaller than 1 K. It means that further increase of wall thickness will not make any influence on thermal stratification in the tank while the thermal stratification tends to get worse with a decrease of wall thickness to be below 1 mm. This could be explained by a larger heat transfer from the hot water in the pipe to water in the tank through the pipe wall.



Figur 6. Calculated tank temperatures during a 1 (h) charge for different PEX pipe wall thicknesses.

4.2 Opening area at the top of the PEX pipe

Water heated by the heating element will rise up and enter into the PEX pipe. At the top of the PEX pipe, there are holes in the pipe that allow heated water enter into the tank. With an increase of the number of holes, the opening area increases. Fig. 7 shows calculated water temperatures after 1 (h)s of charging with different opening areas at the top of the PEX pipe. The reference number is 12 holes, represented by 'tb*', where * represents an integral number from 1 to 7. 't* 6' and 't* 24' show the result for 6 holes and 24 holes respectively. It is shown that thermal stratification in the tank is not influenced by varying the number of holes from 6 to 24.

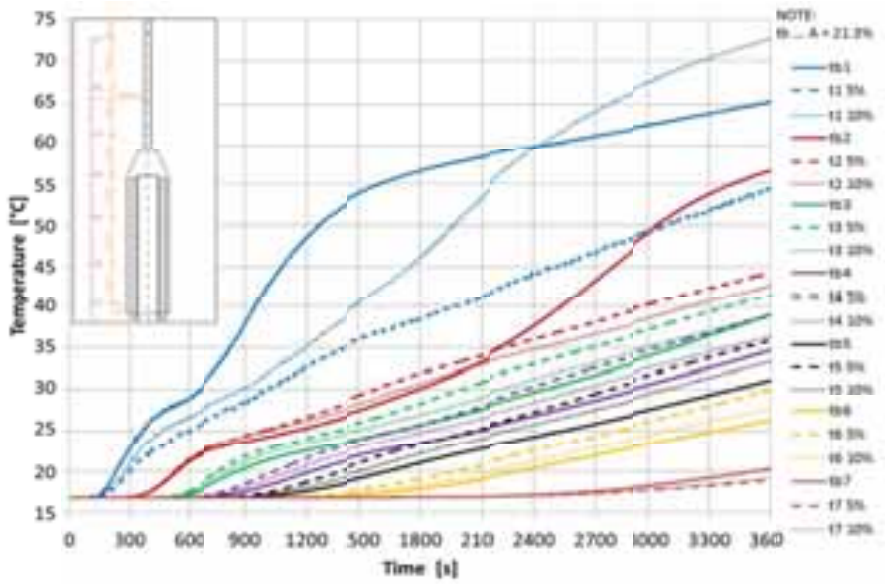


Figur 7. Calculated tank temperatures during a 1 (h) charge for different opening areas at the top of the PEX pipe.

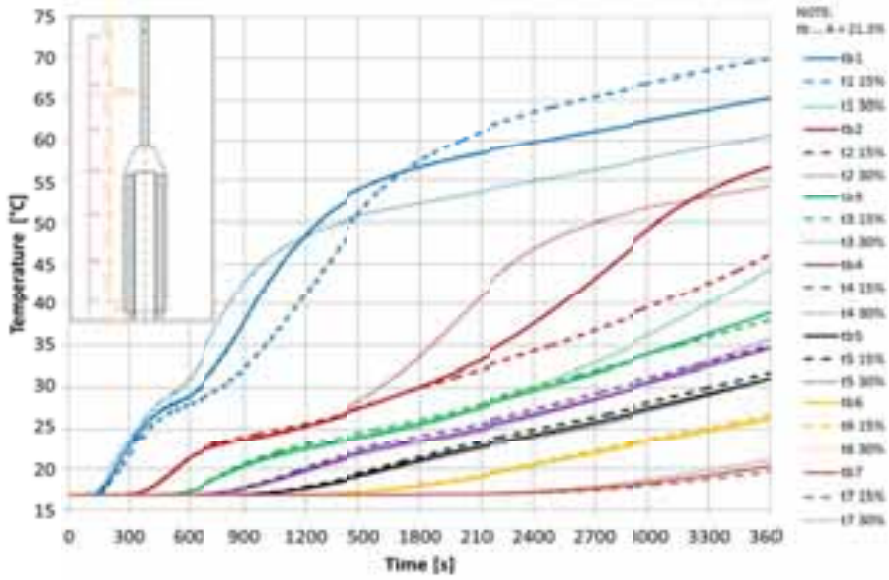
4.3 Opening area between the steel pipe and the PEX pipe

In between the conic top of the steel pipe and the PEX pipe, there is a hole with smaller diameter than both the steel pipe and the PEX pipe. In the experiment, the opening area is 21.3% of the PEX cross section area. Investigations were carried out to study the influence of diameter of the opening area on calculated temperatures. The following opening areas were calculated: 5%, 10%, 15%, 30% and 40% of the PEX cross section area. The results of the calculation with different opening areas are shown in Fig. 14, 15 and 16. It

can be seen that the opening area influences significantly water temperatures in the tank. After 1 hour of charging the water temperature at the top of the tank is the highest for the tank with an opening area of 10% in between the steel pipe and the PEX pipe.

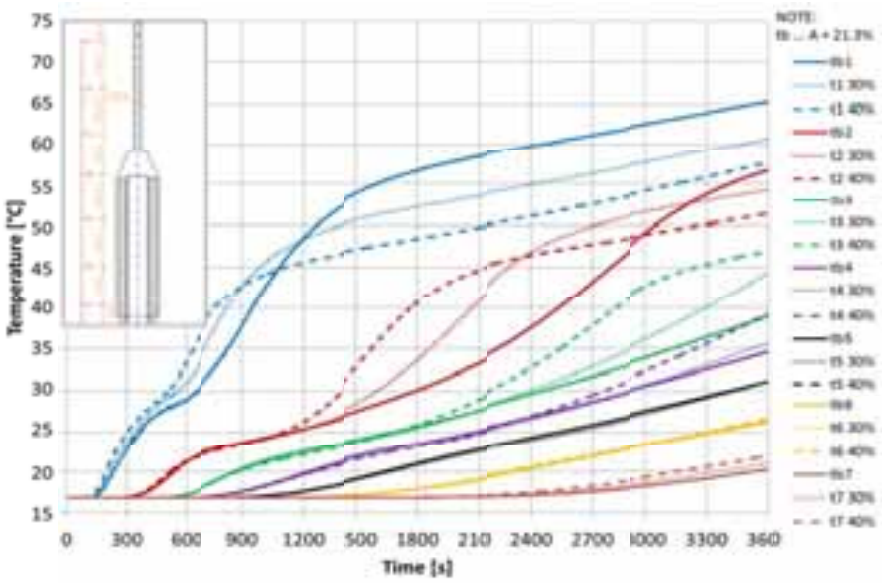


Figur 8. Calculated tank temperatures during a 1h charge for different opening areas between the conic steel pipe and the PEX pipe.



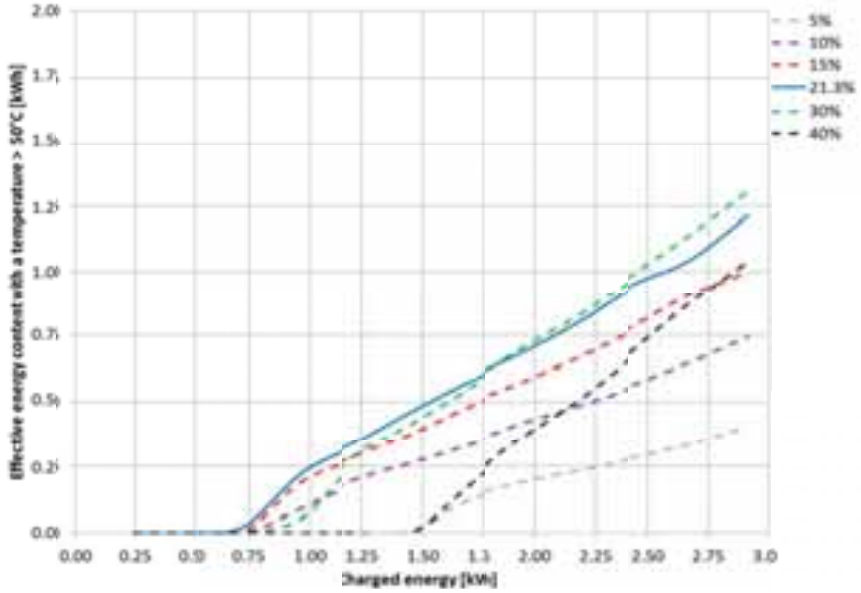
Figur 9. Calculated tank temperatures during a 1 (h) of charge for different opening areas between the conic steel pipe and the PEX pipe.

The reason of the best thermal stratification for an opening area of 10% could be explained by the buoyancy driven flow due to charging. For a slower movement of the buoyancy driven flow, water will have adequate time to be heated to a higher temperature. On the other hand, if the flow is too slow, heat will be lost from the heated water to water in the tank through the pipe walls. Therefore a decrease of the opening area from 10% to 5% will result in a lower water temperature at the top of the tank, see Fig. 8, while with an increase of the opening area from 10% to 15% or larger, the buoyancy driven flow in the pipe will be increased therefore resulting in a lower water temperature at the top of the tank.



Figur 10. Calculated tank temperatures during a 1 (h) of charge for different opening areas between the conic steel pipe and the PEX pipe.

Fig. 11 shows calculated effective energy content of the tank for different opening areas between the conic steel pipe and the PEX pipe. The effective energy of the tank is obtained by summing up energy content of water in the tank with a temperature higher than 50°C. Therefore it determines the useful energy of the tank after charging. It shows that the opening area has a significant influence on the effective energy content of the tank. Charging of a tank with an opening area in between 21.3% and 30% of the cross section area of the PEX pipe will result in the largest effective energy content. It means that although an opening area of 10% will result in the highest water temperature in the tank but the effectively energy content of the tank is not the largest because the relative slower fluid flow in the pipe means smaller water volume heated to 50°C at the end of charging.



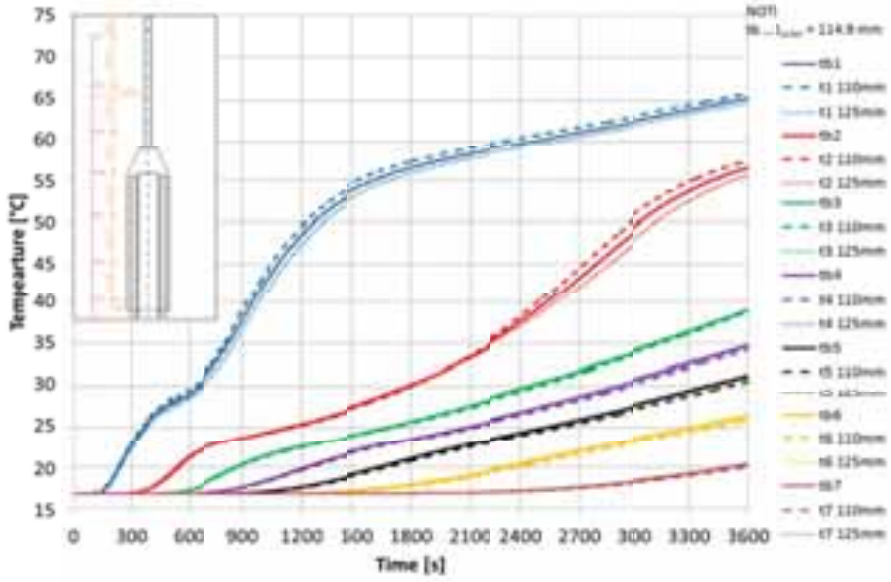
Figur 11. Calculated effective energy content of the tank for different opening areas between the conic steel pipe and the PEX pipe.

4.4 Diameter and wall thickness of the steel pipe

Fig. 12 shows calculated water temperatures in the tank for different diameters of the steel pipe. In the experiment the steel pipe has a diameter of 114.9 mm and a wall thickness of 4.25 mm, therefore it is used as reference. A diameter of 110 mm and 125 mm are used in the investigations. It can be seen in Fig. 12 that

the diameter of the steel pipe has insignificant influence on water temperature in the tank after 1 hour of charging.

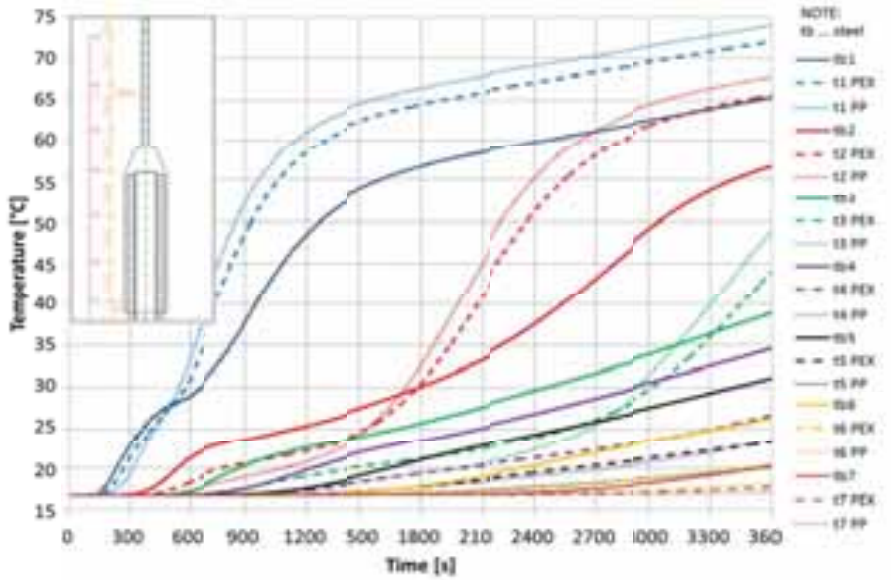
Calculations were carried out for a wall thickness of 1 mm and 2 mm. The results show that there is almost no difference in temperatures with a decrease of wall thickness from 4.25 mm to 1 mm and 2 mm.



Figur 12. Calculated tank temperatures during a 1 (h) of charge for different diameters of the steel pipe.

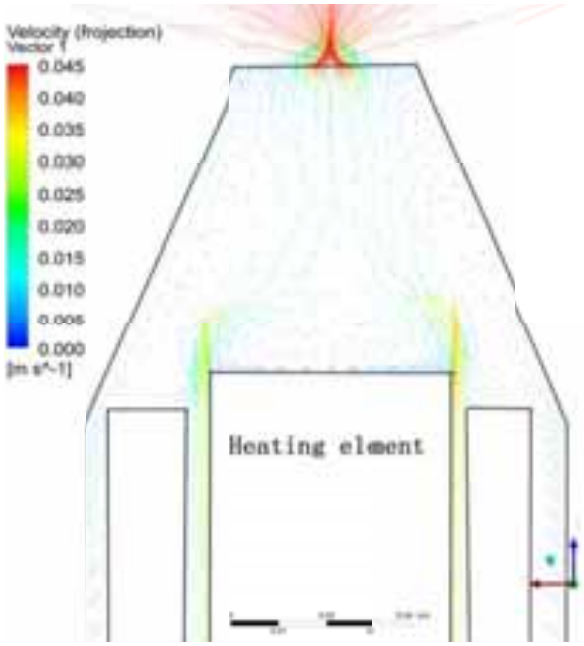
4.5 Different materials of the pipe around the heating element

In the experiment the pipe around the heating element is made of steel. Investigations were carried out to study the influence of material of the pipe on water temperature in the tank. In addition to steel as a reference, PEX and PP are used as pipe materials. The results are shown in Fig. 13. It can be seen that pipe material has a strong influence on water temperature in the tank. The lower the thermal conductivity of the pipe material, the better the thermal stratification in the tank is. For a pipe made of material with a higher thermal conductivity for example steel, the water temperature at the bottom part of the tank will be higher due to heating by horizontal heat transfer across the pipe. On the other hand, the lower the thermal conductivity of the pipe around the heating element, the higher the water temperature at the top of the tank will be, for example, when PP is used as pipe material.

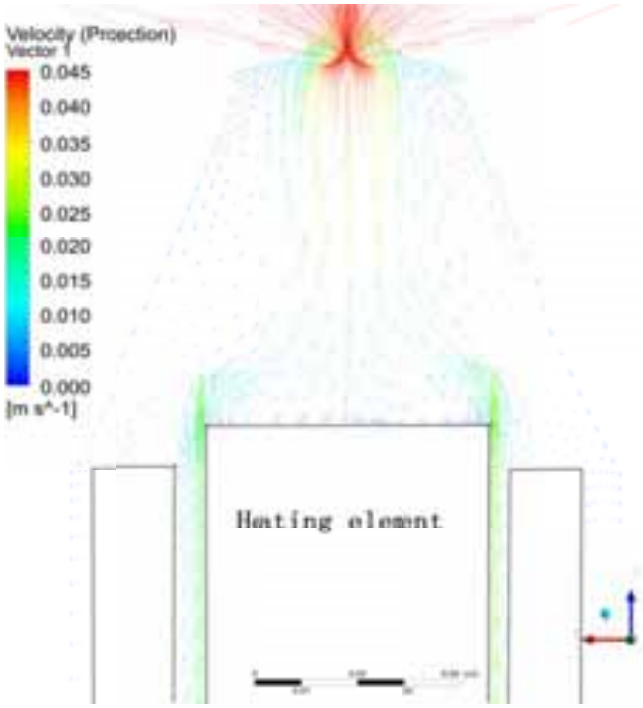


Figur 13. Calculated tank temperatures during a 1 (h) of charge for different pipe materials.

Fig. 14 and 15 show velocity vectors around the heating element with steel and with PP as pipe material respectively. As shown in Fig. 14, there is a dominant upward flow around the heating element due to heating of water in the stratification device, while along the pipe wall there is an apparent downward flow caused by heat loss from the steel pipe wall in the horizontal direction. The uprising flow collides with the downward flow, creating flow circulations in the conic top.



Figur 14. Velocity vectors around the heating element with steel as pipe material.



Figur 15. Velocity vectors around the heating element with PP as pipe material.

When PP is used as pipe material, the downward flow along the pipe wall is minimized, which can be explained by lower thermal conductivity of PP compared to steel. Since heat loss from the pipe is significantly reduced, the driving force of the downward flow becomes smaller. As a result water flow around and above the heating element is more regular, resulting in a higher water temperature when it enters the plastic pipe. Therefore it can be concluded that use of a material with lower thermal conductivity for the pipe around the heating element has the following advantages:

(1) increased temperature at the top of the tank

(2) decreased heat transfer between the stratification device and the bottom of the tank

(3) better thermal stratification in the tank and thus higher effective energy content of the tank after charging.

5. Conclusions

A newly developed thermal stratification device was investigated by means of experiments and computational fluid dynamics (CFD) simulations. Experiments have been carried out to measure water temperatures at different levels of the tank during charging by a vertical heating element integrated in the stratification device. Transient fluid flow and heat transfer in the tank during charging are calculated by a simplified CFD model. The CFD calculated water temperatures are compared to the measured temperatures. The results show that the CFD model can satisfactory predict thermal stratification in the tank during charging.

A parametric study has been carried out to investigate how thermal stratification in the tank is influenced by design of the stratifier such as pipe thickness, material type, diameter of the pipe, opening area etc. The investigations elucidate how well a hot water tank heated at the bottom with a vertical heating element can be stratified by using the new stratifier design. The results show that diameter and wall thickness of the PEX pipe have minor influence on thermal stratification in the tank if the diameter of the pipe is in the range of 16-25 mm and the wall thickness is in the range of 1-3 mm. Opening area at the top of the PEX pipe has insignificant influence on water temperature in the tank during charging while opening area in between the PEX pipe and the conic pipe has a significant influence. The calculations show that an opening area of 10% of the cross section area of the PEX pipe gives the highest water temperature at the top of the tank but the effective energy content of the tank is the largest if an opening area in between 21.3% and 30% is used.

Concerning the pipe around the heating element, diameter and wall thickness has almost no influence on water temperature in the tank if steel is used as pipe material. Use of a material with lower thermal conductivity for the pipe around the heating element will result in a higher temperature at the top of the tank and an increased degree of thermal stratification in the tank.

Abstract

The transient fluid flow and heat transfer in a hot water tank during cooling caused by standby heat loss were investigated by computational fluid dynamics (CFD) calculations and by thermal measurements in previous investigation. It is elucidated how thermal stratification in the tank is influenced by the natural convection and how the heat loss from the tank sides will be distributed at different levels of the tank at different thermal conditions.

A heat loss removal factor is introduced to characterize the effect of the buoyancy driven flow on exchange of heat loss between tank layers by natural convection. Based on results of the CFD calculations, a generalized equation of the heat loss removal factor is obtained by regression which calculates the heat loss removal factor for a given temperature gradient in the tank. The equation takes into account the influences of tank volume, height to diameter ratio, tank insulation, thickness and material property of the tank wall and initial thermal conditions of the tank. The equation is validated for a tank volume in the range of 150 l and 500 l and a height to diameter ratio of 1-5. The equation is implemented in a simulation program for a solar domestic hot water (SDHW) system with a hot water tank charged by a built-in heat exchanger spiral. The program can calculate thermal performance of a SDHW system. Thermal performance calculated by the program will be compared to the measurements. The investigations elucidate accuracy and reliability of the program for calculation of temperatures and thermal performance of a solar domestic hot water system.

Keywords: Hot water tank, thermal stratification, performance calculation program, Computational fluid dynamics (CFD), Heat loss removal factor

1. Introduction

Thermal stratification in solar storage tanks has a major influence on the thermal performance of solar heating systems. A high degree of thermal stratification in the storage tank increases the thermal performance of a solar heating system because the return temperature to the solar collector is lowered (Furbo 1984, van Koppen C 1979, Furbo 1987, Haller 2009, Haller 2010). A lower inlet temperature to the solar collector will increase the efficiency and operating hours of the solar collector. Further, the temperature at the top of the storage will be closer to the desired load temperature. Therefore the auxiliary energy consumption will be decreased which increases the solar fraction (Hollands 1989, Furbo 2006).

Heat loss from the tank sides helps to build up thermal stratification in the tank. Due to heat loss to the surroundings, the fluid close to the tank wall has a lower temperature than the fluid at the centre of the tank. The relative colder fluid flows downwards along the tank wall while the fluid with higher temperature rises up in the centre of the tank.

Thermal stratification and natural convection flow in a vertical cylindrical hot water tank during standby periods were investigated in the literature (Andersen 2007, Fan 2012a). Transient, three-dimensional CFD models of hot water storage tanks were developed and validated against thermal measurements. Zachar carried out a numerical analysis of flow distributors to improve temperature stratification in storage tanks (Zachar 2007). Neural network modelling was used for calculation of thermal stratification in a solar DHW storage (Geczy-Vig 2010).

The aim of the investigation is to elucidate how thermal stratification in the tank is influenced by the natural

doi:10.18086/swc.2015.02.15 Available at http://proceedings.ises.org

convection and how the heat loss from the tank sides will be distributed at different levels of the tank at different thermal conditions. The ultimate goal of the investigation is to improve an existing program for performance calculation of solar domestic hot water systems in terms of prediction of thermal stratification in the tank.

2. The experimental and numerical investigations

Experimental investigations were carried out on a slim 150 l tank with a diameter of 0.34 m and a height of 1.68 m in order to evaluate the effect of heat loss on thermal stratification in a tank. The height to diameter ratio of the tank is 5.0. The tank is made of steel with a thickness of 5 mm and is insulated with 5 cm mineral wool. Temperature distribution of the tank is measured with 14 copper/constantan thermocouples (type TT) equally placed from the bottom to the top of the tank. The heat loss coefficient from different parts of the tank is measured with the setup shown in Fig. 1. During the measurements, the tank is heated by an electric heating element to a uniform constant temperature. The electric heating element is placed at the very bottom of the tank. The heat loss from the tank is therefore equal to the power consumption of the electric heating element under steady state conditions. Measurement of the heat loss coefficient from different parts of the tank is possible with help of the iso-temperature box which is kept at the same temperature as the water temperature in the tank. A uniform temperature of the air in the box is achieved as the air is fully mixed by means of a fan inside the box. Therefore there is no heat loss from the part of the tank covered by the box. Air temperature in the box and ambient air temperature are measured by copper/constantan thermocouples, type TT. By means of measurements with different positions of the box and with two temperature levels of 76.0˚C and 36.5˚C, the distribution of the heat loss coefficient for the different parts of the tank is determined for different temperature levels. The measurement accuracy of temperatures is 0.5 K. For the temperature level of 36.5ºC, the total heat loss coefficient of the tank is measured. The heat loss coefficients for the different parts of the tank are obtained by assuming the same distribution of the heat loss coefficients among the different tank parts as with a hot water temperature of 76 ºC. Since the distribution of the heat loss coefficient for different parts of the tank is mainly dependent on the tank design and insulation, the assumption will not introduce significant errors in the analysis. Linearly temperature dependent heat loss coefficients for different parts of the tank are then obtained, see Equation 1-4.

$$K_{top} = 0.24 + 0.00015*(T - 273.15) \quad [W/K] \quad \text{(eq. 1)}$$

$$K_{side} = 1.75 + 0.00148*(T - 273.15) \quad [W/K] \quad \text{(eq. 2)}$$

$$K_{bottom} = 0.41 + 0.00034*(T - 273.15) \quad [W/K] \quad \text{(eq. 3)}$$

$$K_{total} = 2.4 + 0.00198*(T - 273.15) \quad [W/K] \quad \text{(eq. 4)}$$

where T is the water temperature in the tank, [K].
The measured heat loss coefficients of the tank are used as inputs to the numerical investigations.

Figure 1. Experimental setup

A tank simulation program (SpiralSol) has been developed to calculate water temperatures in a tank with a built-in heat exchanger spiral (Furbo 1984). Thermal stratification in the tank under different operating conditions is considered. The program is able to determine the thermal performance of a solar heating system taking into consideration thermal stratification in the tank. The program is improved in this paper in the term of prediction of thermal stratification by considering the influence of buoyancy driven flow along the tank side wall.

In the program, the tank is equally divided into a number of layers (N=10), numbered sequentially from the bottom to the top of the tank, see Fig. 2. Heat loss from the side of the layer I is defined as $Q_{loss}(I)$ calculated based on conventional heat transfer theory while the heat loss moving from the layer above (I+1) to the layer (I) due to the buoyancy driven flow is defined as $Q_{flow}(I)$. A heat loss removal factor $a(I)$ for interface I is defined as the ratio between the heat loss moved down by natural convection and the total amount of heat loss of the layer. The heat loss of the layer includes both heat loss from the side of the tank and the heat loss moved down from the layer above.

$$a(I) = \frac{Q_{flow}(I)}{Q_{flow}(I+1) + Q_{loss}(I+1)} \qquad \text{(eq. 5)}$$

For the top layer N, the heat loss moving from the layer above is replaced by the heat loss from the top of the tank.

$$a(N-1) = \frac{Q_{flow}(N-1)}{Q_{\text{top loss}} + Q_{loss}(N)} \qquad \text{(eq. 6)}$$

Thermal stratification in the tank is characterized by a temperature gradient Gr(I).

$$Gr(I) = \frac{T_{layer}(I+1) - T_{layer}(I)}{H_{layer}(I+1) - H_{layer}(I)} \qquad \text{(eq. 7)}$$

where T_{layer} (I) is the average fluid temperature of layer I in K, while H_{layer} (I) is the average height of layer I in m measured from the bottom of the tank.

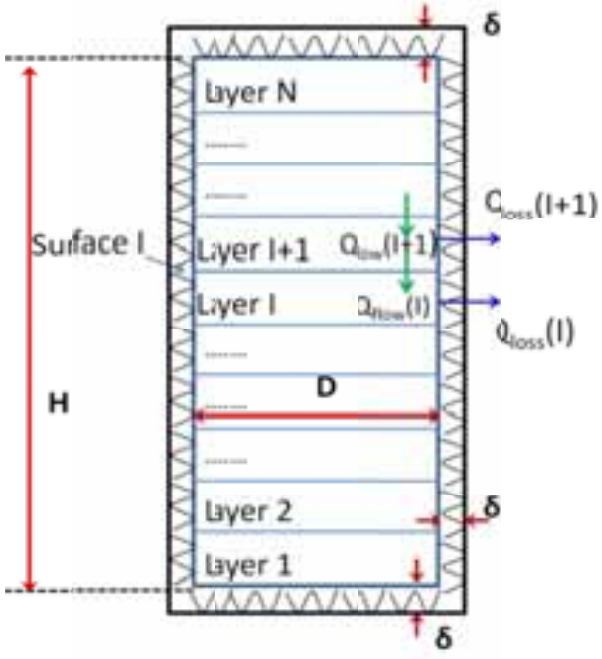

Fig. 2 Schematic illustration of a tank consisting of N layers.

3. The downwards flow along tank wall due to heat loss from the tank

3.1 The initial conditions of the tank

CFD model of the slim hot water tank has been developed and validated against measurements (Fan 2012a). Calculations have been made using the validated CFD models to investigate the influence of the downward flow along the tank wall due to heat loss from the tank. The initial condition of the tank was either a fully charged tank with a uniform water temperature of 80 ˚C or a stratified tank after a hot water draw-off. In the stratified tank, the water temperature at the upper part of the tank is 80 ˚C while it is 17 ˚C at the bottom of the tank. Fig. 3 shows the temperature profile of the stratified tank after a hot water draw-off. The stratified tank corresponds to a tank after a hot water draw-off of 75 liters.

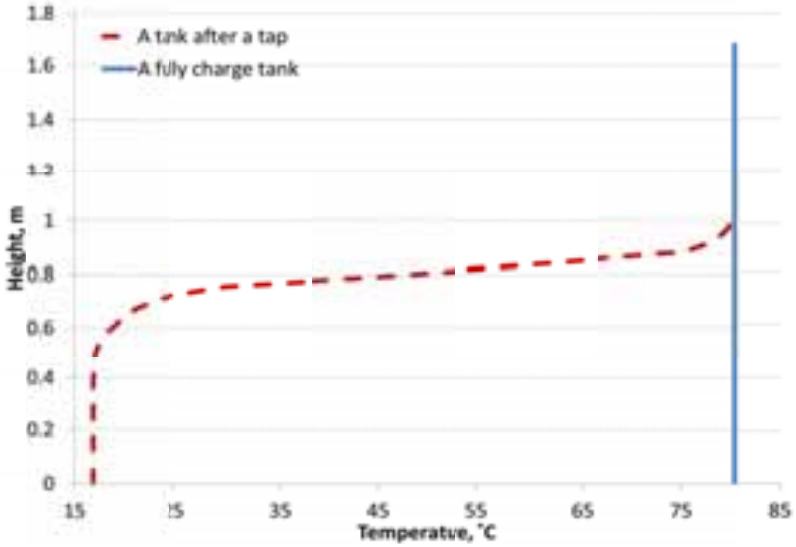

Fig. 3 Temperature profile of a fully charged tank and of a stratified tank after a hot water draw-off

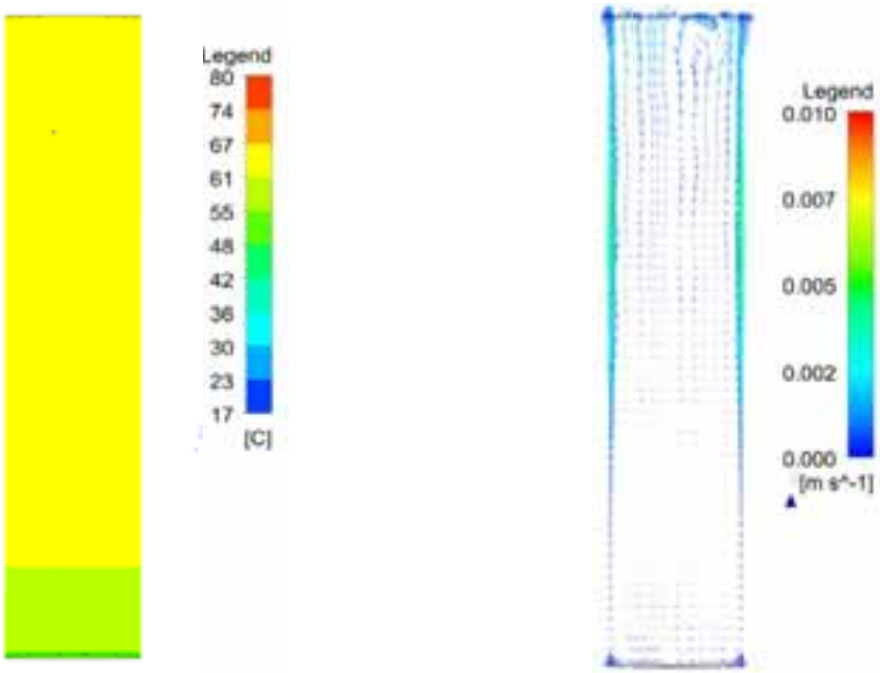
3.2 The dependence of downward velocity on temperature gradient during standby period of a fully charged tank

Fig. 4A shows water temperatures in the tank after 24 hours standby of a fully charged tank. Due to heat loss from the tank, water temperature at the upper part of the tank drops by 14 K, while at the bottom of the tank water temperatures decreases by 27 K. In the tank with a height 0.24 m-1.68 m from the bottom of the tank, there is a temperature of 64-66˚C, indicating a small temperature gradient. In the lower 24 cm of the tank there is a larger temperature difference.



A. Temperature distribution B. Velocity vectors

Fig. 4 CFD calculated velocity vectors and temperature distribution in the tank after a 24 hours standby period with an originally fully charged tank.

Fig. 4B shows velocity vectors of fluid flow in the tank after a 24 hours standby period starting with a fully charged tank. Due to heat loss from the tank side, water close to the tank side has a lower temperature than water in the center of the tank at the same height. The colder water tends to flow downwards along the tank side wall as its density is higher, while in the center of the tank warmer fluid tends to flow upwards, creating a water circulation in the tank. The buoyancy induced flow will drive fluid with lower temperature from the upper part of the tank to the bottom part of the tank, consequently establishing thermal stratification during standby period of the tank. Temperature gradient in the tank has a significant influence on the downward flow along the tank side wall. Fig. 5 shows dependence of downward velocity on temperature gradient in the tank after 24 hours standby cooling of a fully charged tank. It is shown that the larger the temperature gradient, the lower the downward flow is. At height in the range of 0.7-1.68 m where the temperature gradient is as low as 0-2 K/m, the average downward flow velocity is 1 mm/s-7 mm/s. While at the bottom of the tank (at height 0-0.6 m) where there is a larger temperature gradient in the range of 3-25 K/m, the downward flow is significantly reduced to be lower than 1 mm/s.

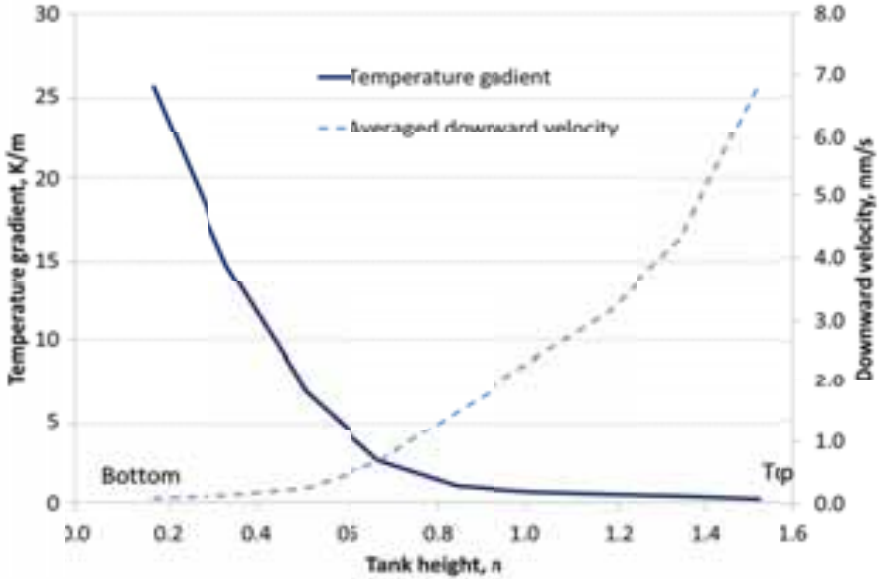


Fig. 5 Dependence of downward velocity on temperature gradient in the tank after a 24 hours standby period starting with a fully charged tank.

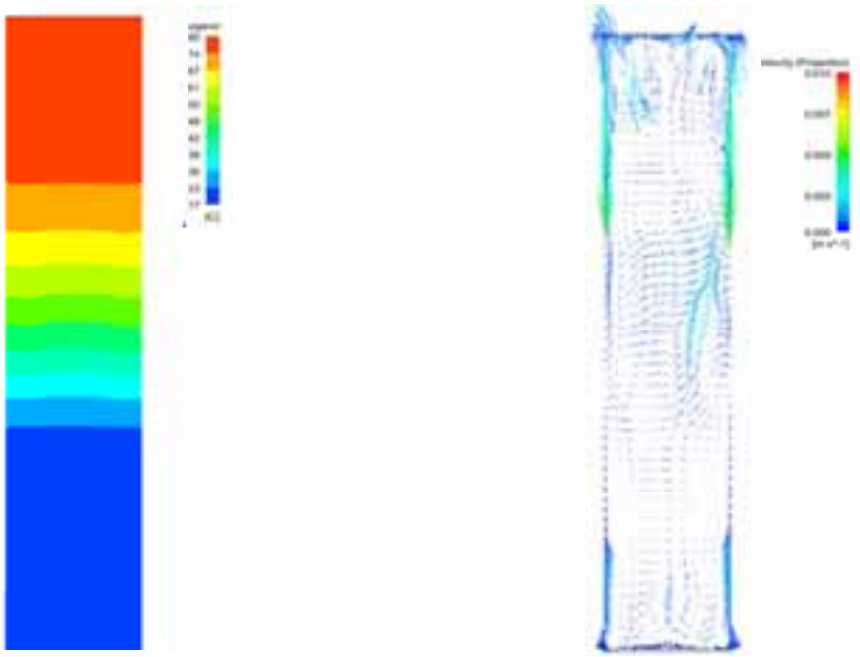
3.3 The dependence of downward velocity on temperature gradient during standby period of a stratified tank

The buoyancy driven flow in a stratified tank is investigated as well. Fig. 6A shows the temperature distribution in the tank at 5 hours standby of a stratified tank. At the upper part of the tank there is a water temperature of 70-75˚C while the water temperature at the bottom of the tank is almost constant at 17˚C. Fig. 7 shows temperature gradient versus water temperatures in the tank. In the middle part of the tank there is a strong thermal stratification with a temperature increase of 47 K from 0.5 m to 1.2 m height of the tank, corresponding to a temperature gradient in the range from 44 K/m to 99 K/m. At the top of the tank with a height in the range from 1.2 to 1.68 m, the temperature gradient is smaller than 20 K/m. The temperature gradient is small as well at the bottom of the tank with a height from 0 to 0.4 m.

From Fig. 6B it can be seen that there is a downward flow along the tank wall at the height of 1.4 m or higher due to the absence of stratification. Water in the central parts of the tank water is flowing upwards as water in the center of the tank is relatively warmer. At the height of 1.1 m, the downward flow is reduced significantly, which can be explained by the presence of strong stratification at that part of the tank. At the bottom of the tank there is a small temperature gradient but the downward buoyancy driven flow is not present. However a small uprising flow along the tank wall can be observed. The rising flow has the magnitude of approx. 0.4 mm/s. This can be explained by a warmer steel tank wall at the bottom of the tank caused by heat gain from the upper part of the tank due to thermal conduction through the tank wall and from the ambient air which has a slightly higher temperature. The heat gain heats up the fluid adjacent to the wall, creating upward flow.



A. Temperature distribution B. Velocity vectors

Fig. 6 CFD calculated velocity vectors and temperature distribution in the tank after 5 hours of standby with an originally stratified tank.

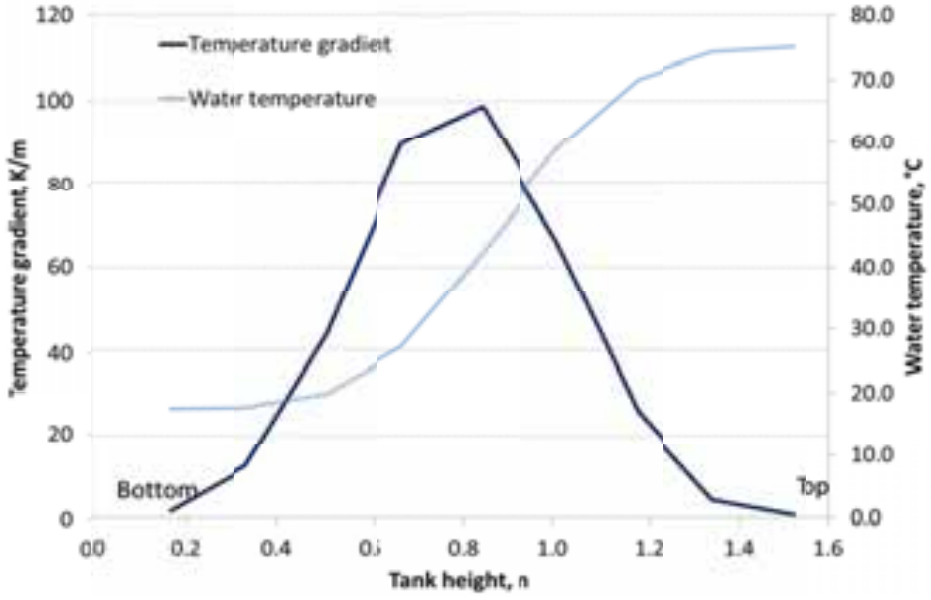


Fig. 7 Temperature gradient in the tank after 5 hours of standby for a stratified tank.

Fig. 8 shows the dependence of downward flow along the tank side wall on temperature gradient in the tank. At the top of the tank where there is a small temperature gradient, the downward flow has an average speed of 1 mm/s- 4.5 mm/s. While the flow is significantly reduced in the middle part of the tank with a height from 0.4 m to 1.2 m where there is a temperature gradient higher than 20 K/m.

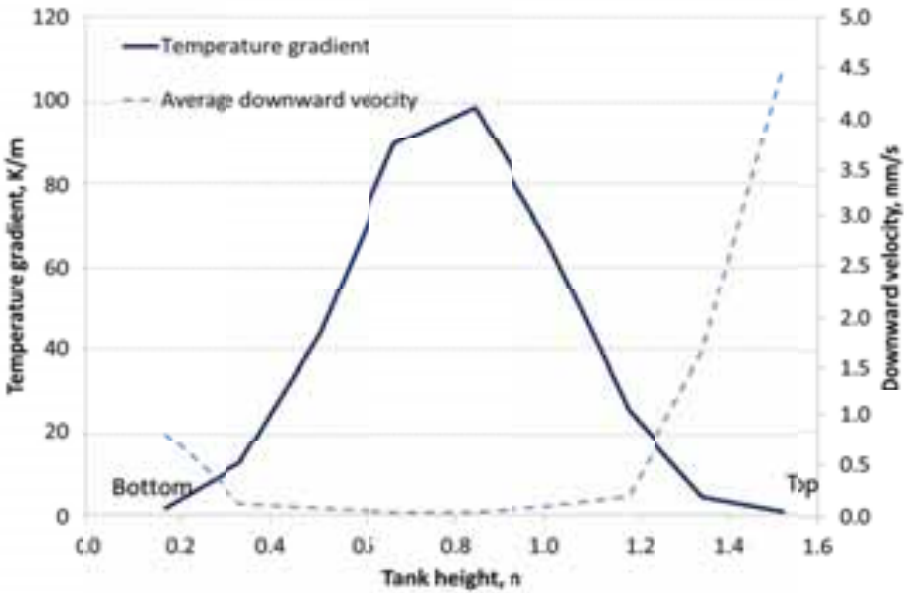

Fig. 8 Dependence of downward velocity on temperature gradient in the tank after 5 hours of standby for a stratified tank.

4. The heat loss removal factor

4.1 Equation of the heat loss removal factor

In order to quantify the effect of the buoyancy driven flow on exchange of heat loss between tank layers by natural convection, a heat loss removal factor is introduced. Based on the results of previous CFD investigations, a simple equation is obtained by regression that calculates the heat loss removal factor for a given temperature gradient in the tank (Fan 2012b). The equation takes into account the influences of tank volume, tank height to diameter ratio, tank insulation, thickness and property of the tank wall and initial conditions of the tank, see equation (8).

$$Gr(I) \le 0.25: \quad a(I) = 0.65 - Gr(I)$$

$$Gr(I) > 0.25: \quad a(I) = \frac{1}{2.32 + 1.39D^2H + 0.116H/D} \ln\left(\frac{Q_{loss}(I+1)}{8.12H + 2.23D + 4.71/H/D}\right) Gr(I)^{\frac{T_{layer}(I+1) - T_a}{85.8 + 39.5D^2H + 18.3H/D} - 1}$$

(eq. 8)

where $a(I)$ is the heat loss removal factor of the ith tank layer;

H is the tank height in m;

D is the tank diameter in m;

$Q_{loss}(I+1)$ is the heat loss from the side of the tank layer $I+1$ in W/m^2.

$T_{layer}(I+1)$ is the average water temperature in the tank layer I+1, ºC;

T_a is the ambient air temperature, ºC;

$Gr(I)$ is temperature gradient of the ith tank layer in K/m.

Fig. 9 shows the heat loss removal factor as a function of temperature gradient. In the calculation a tank with a volume of 150 l and a height to diameter ratio of 5 is used. Water temperature in the tank and ambient air temperature is assumed to be 80ºC and 20ºC respectively. It is clearly shown that when there is almost no temperature gradient (< 5 K/m), the heat loss removal factor lies in the range from 0.1 to 0.7, meaning that 10-70% of the heat loss accumulated in the layer will be transported downwards. In the region where there is a temperature gradient larger than 5 K/m, the heat loss removal factor is smaller than 0.1, which means that

only an insignificant part of the heat loss is transported downward.

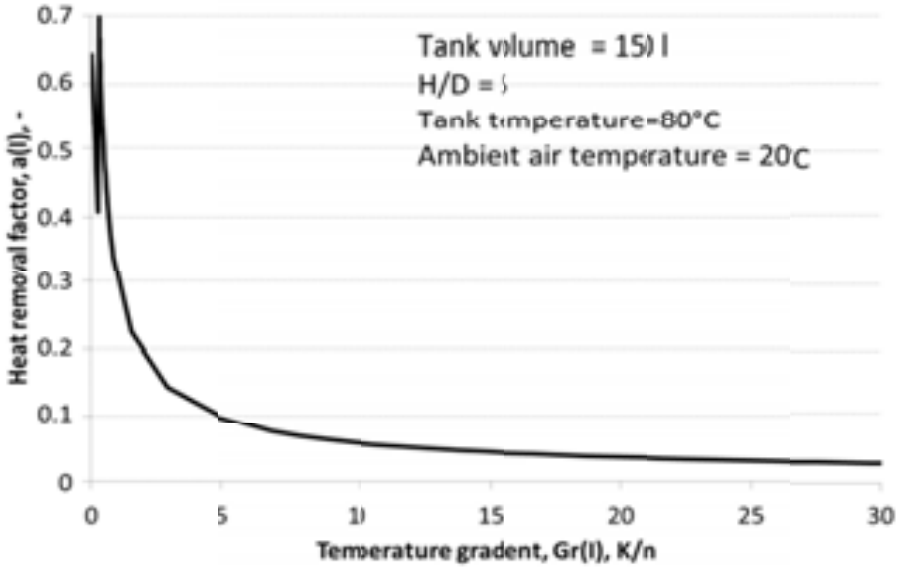

Fig. 9 Heat loss removal factor as a function of temperature gradient in the tank.

4.2 Comparison between the measured and the simulated water temperatures

The equation (eq. 8) is implemented in the tank simulation program SpiralSol. Water temperatures calculated by the program is compared to the measured temperatures. Fig. 10 shows a comparison between the measured water temperatures and the simulated water temperatures by the programs with and without using the heat removal factor. The initial condition of the tank is a fully charged tank with a uniform water temperature of 80ºC. The measured water temperatures are shown in curves while the simulated water temperatures are shown by dots and crosses. After one hour of standby cooling, the water temperature at the bottom of the tank is decreased to 75ºC while there is a temperature decrease of 0.5 K in the rest of the tank. After 24 hours standby cooling of the tank, the water temperature at the top of the tank was measured to be 66.4 ºC. Water at the bottom of the tank was cooled down to 54.6 ºC. The program without the heat removal factor predicts water temperatures of 65.7 ºC and 55.7 ºC at the top and at the bottom of the tank respectively. The disagreement between the measured and the simulated temperatures is -0.7 K at the top of the tank and 0.9 K at the bottom of the tank. With the heat loss removal factor considered in the program, the prediction accuracy of the program is improved slightly. The error of prediction is decreased to -0.4 K at the top of the tank and to 0.6 K at the bottom of the tank. The existing disagreement could be explained by the numerical method of the program. As the tank is divided into 16 layers in the simulation, there is a uniform temperature in each layer. This is not true in reality. The error could be decreased by increasing the number of layers in the calculation but it will significantly increase simulation time. The error could also be due to measurement uncertainty of the heat loss coefficients which are used as inputs in the program.

Fig. 11 shows comparison between simulated water temperatures with and without using the heat loss removal factor. It is shown that there is a similar improvement after 12 hour, 24 hour, 36 hour and 48 hour of natural cooling by using the heat loss removal factor.

A comparison between the measured and the simulated water temperatures is presented in Fig. 12 for an initially stratified tank. There is a good agreement between the simulations and the measurements. Consideration of the heat loss removal factor in the program makes only insignificantly improvement. This could be explained by the fact that the heat loss removal factor will be small for a tank with a large temperature gradient, therefore for a majority part of the tank the difference with and without considering the heat loss removal factor is marginal.

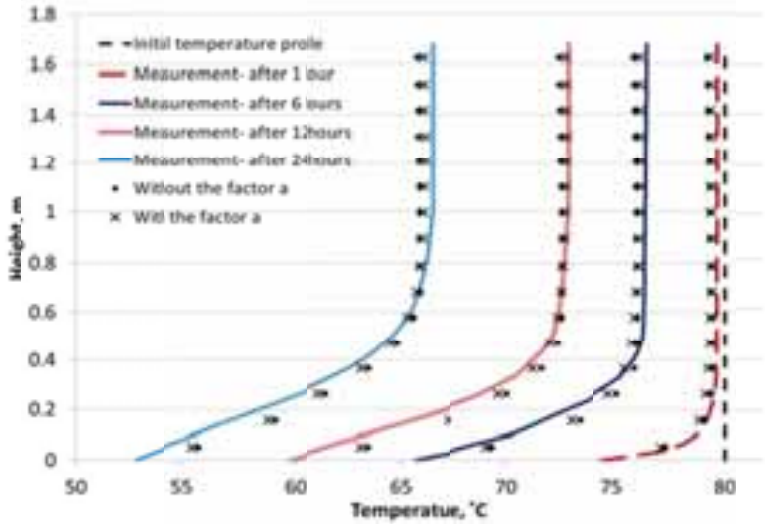

Figure 10. Comparisons between measured and simulated temperatures starting with a fully charged tank.

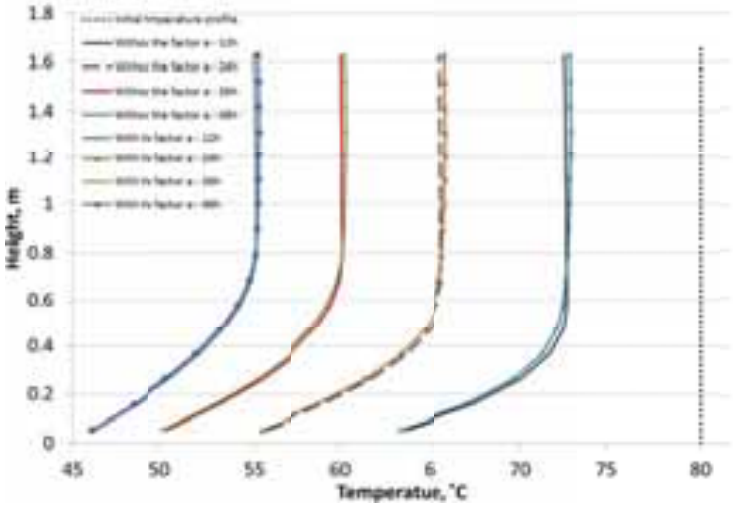

Figure 11. Comparisons between simulated temperatures starting with a fully charged tank.

It can be concluded that for a fully charged tank the prediction accuracy of the program is improved by taking into consideration the heat loss removal factor, while the improvement is marginal for an already stratified tank. Generally there is a good agreement between the simulated and the measured water temperatures, which documents credibility of the program.

The program is then used to calculate thermal performance of a solar heating system with a solar collector of 2 m^2, a tank volume of 150 l and a daily tapping of 100 liters. The results show that there is a marginal difference between thermal performance calculated by the program with and without using the heat loss removal factor. This could be explained by the fact that the tank in most of the time is stratified due to 3 times of hot water tapping per day. In a stratified tank the removal of heat loss between layers is minimized due to the presence of temperature gradient in the tank.

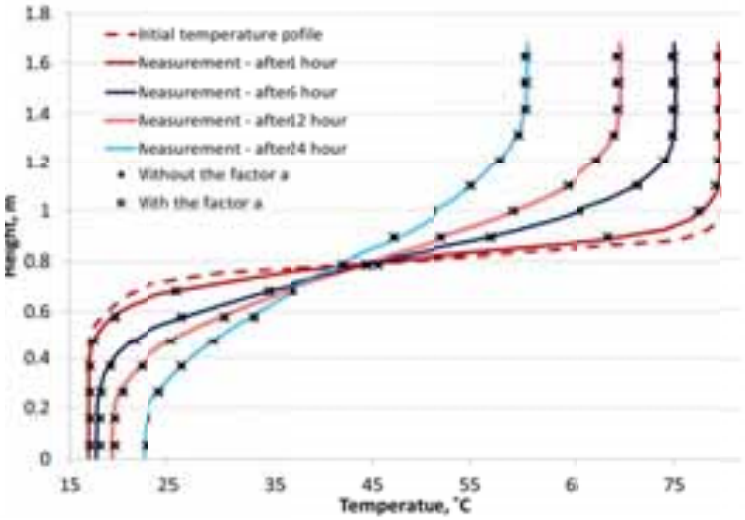

Figure 11. Comparisons between measured and simulated temperatures starting with a stratified tank.

5. Conclusions

The downward flow along the tank side wall caused by natural cooling of the tank is investigated by means of validated CFD models. The results show that the downward flow moves water with colder temperature down to a lower level of the tank, thus helping to establish thermal stratification in the tank. The magnitude of the downward flow is significantly influenced by the temperature gradient in the tank. The higher the temperature gradient in the tank, the lower the downward fluid velocity is. For a fully charged tank there is a strong downward flow in most of the tank where the temperature gradient is smaller than 5 K/m. For a stratified tank the downward flow is only apparent in the upper part of the tank where there is a high water temperature and a low temperature gradient. In the rest of the tank there is limited flow along the tank side wall.

A heat loss removal factor is introduced in the tank simulation program Spiralsol to quantify the effect of the buoyancy driven flow on exchange of heat loss between tank layers by natural convection. A generalized equation of the heat loss removal factor is implemented in the program. The simulated water temperatures in the tank are compared to the measured ones. The results show that for a fully charged tank the prediction accuracy of the program is improved by taking into consideration the heat loss removal factor, while the improvement is marginal for an already stratified tank. Generally there is a good agreement between the simulated and the measured water temperatures, which documents credibility of the program.

The program is then used to calculate thermal performance of a solar heating system with a solar collector of 2 m^2, a tank volume of 150 l and a daily tapping of 100 liters. The results show that there is a marginal difference between thermal performance calculated by the program with and without using the heat loss removal factor. This could be explained by the fact that the tank in most of the time is stratified due to 3 times of tapping per day. In a stratified tank the removal of heat loss between layers is minimized due to the presence of temperature gradient in the tank.

Value of Energy Continuity for Commercial Photovoltaic Systems with Battery Storage

Sasha Merigan and Deborah Sunter, Ph. D.

Johns Hopkins University, Washington, DC (USA)

Abstract

This paper presents a model that computes the payback period of photovoltaic systems with battery storage (PVBS). The model, termed SPPEEDI (SAIDI Payback Period Evaluation for Extended Duration Interruption), incorporates savings from avoided business interruption with utilization of PVBS. While the PVBS system can produce clean energy and maintain energy continuity, its prohibitive cost of installation is a barrier to widespread adoption. By using the SPPEEDI model and incorporating avoided business interruption in evaluating PVBS payback periods, the model allows for a more accurate estimate of the return on investment for PVBS. This analysis identifies key grid outage thresholds where commercial PVBS could be a better investment than conventional photovoltaic systems.

Keywords: *Commercial battery storage, photovoltaics, energy continuity, SAIDI, electric grid interruption,*

1. Introduction

Business continuity should be considered when analyzing the value of photovoltaic systems with battery storage (PVBS). Grid interruption can be very costly to businesses and PVBS can maintain electricity throughout an outage, preventing potential business interruptions and related financial losses. Accurate evaluation of payback periods requires that the value of energy continuity during grid outages be taken into account. This paper introduces a model, termed SPPEEDI (SAIDI Payback Period Evaluation for Extended Duration Interruption), that more accurately evaluates payback periods of PVBS by taking avoided lost revenue from grid outages into consideration. By comparing investments in PVBS to investments in PV, this paper identifies grid outage levels necessary for PVBS to surpass PV as an investment opportunity.

To account for grid outages, the SPPEEDI model uses the System Average Interruption Duration Index (SAIDI), an international standard used to quantify reported outage duration. SAIDI represents the annual cumulative amount of grid interruption experienced by the average customer. It is calculated by dividing the total minutes of sustained customer interruption (interruptions over 1-5 minutes, depending on the local definition) (CPUC 2015, NERC 2010) in a given year by the number of total customers served by the utility (eq. 1). Thus, this measure provides an estimate of the average number of minutes of sustained grid downtime a single customer would experience in a given year. Outages shorter than "sustained customer interruptions" are defined as momentary outages and are not considered in this analysis.

$$\frac{\text{Sum of annual sustained interruption durations for all customers}}{\text{Total number of customers served}} = \text{SAIDI} \qquad \text{(eq. 1)}$$

SAIDI is useful for estimating losses to individual customers and can be translated into the additional value of PVBS as avoided losses. Many commercial entities track these statistics themselves for internal use. For application in analyzing investments in PVBS for a single business, internally collected data is often more reliable than utility provided data and can provide customized estimates of PVBS payback periods when applied to the SPPEEDI model. Although the quality of reported SAIDI data is inconsistent and often incomplete (LaCommare & Eto, 2004), it can be useful as a broad average. Readers can replace SAIDI figures and financial loss estimates used in this analysis directly with internally collected data for more accurate estimates of PVBS payback periods on a case-by-case basis. In this analysis, the SPPEEDI model is applied to a broad range of reported SAIDI values reflecting 12-years of reported outage data covering 150

doi:10.18086/swc.2015.02.16 Available at http://proceedings.ises.org

US utilities (Larsen et al. 2014). A range of 0-15,000 minutes of SAIDI was chosen for this analysis to reflect the content of this data set.

2. Methodology

2.1. Case Study Specifications

This analysis uses a commercial sector case study because commercial losses from grid interruption far outpace losses in the residential and industrial sectors, making up 72% of total losses in the US in 2004 (LaCommare & Eto, 2004). Since Walmart has already introduced PV installations on a large scale to existing stores to cut energy costs and was ranked #1 in installed solar capacity among commercial entities in the US in 2014 (SEIA 2014), it is reasonable to assume Walmart would continue to invest in solar, specifically PVBS if it becomes a more attractive investment than PV. Hence, a typical Walmart Supercenter will serve as the analysis case study. For this case study, nine scenarios are considered, taking into account variability in solar insolation and total installed system costs. These scenarios can be seen in Table 1.

Table 1: Walmart Superstore Case Study Scenarios

Current costs, Low Insolation	Current costs, Medium Insolation	Current costs, High Insolation
Near-term costs, Low Insolation	Near-term costs, Medium Insolation	Near-term costs, High Insolation
Long-term costs, Low Insolation	Long-term costs, Medium Insolation	Long-term costs, High Insolation

Solar insolation levels of 4.5 kWh/m^2/d, 6.0 kWh/m^2/d and 7.5 kWh/m^2/d are used for this study. These values were chosen by creating a histogram of the continental US solar insolation data (NREL 2015b). It was determined that 63% of the data points fall between 4.5-7.5 kWh/m^2/d, with a mean of 5.1 kWh/m^2/d and a standard deviation of 1.2 kWh/m^2/d. To calculate the total installed system costs of silicon solar panels and lithium ion battery systems, three investment levels are analyzed using current cost estimates (2014 values, NREL 2015a, DOE 2013c), near-term (2020 values, NREL 2015a, DOE 2013b) and long-term (2035 values, NREL 2015a, DOE 2013b) cost projections. The values are compared using real 2015 dollars.

The analysis also takes into account annual operation and maintenance costs (SAM 2015), increasing cost of electricity over time (SAM 2015), panel degradation (SAM 2015), and discount and inflation rates (SAM 2015). To calculate the value of energy produced, the average cost of commercial electricity in the US (EIA 2015) is used. The value of avoided grid interruption is quantified by the amount of revenue that would have been lost had the business been forced to close due to grid outage. Model input values can be found in Table 2.

2.2. Analysis Calculations

The SPPEEDI model executes the following equations in Excel in order to calculate payback periods in all nine scenarios with grid outages varying between 0 –15000 minutes at intervals of 10 minutes.

The SPPEEDI model calculates the avoided revenue losses from using PVBS systems for energy and business continuity during grid outages. Before the losses can be calculated, the average revenue per minute is calculated by dividing Walmart's annual total sales by the total number of Walmart stores (SBRI 2015, eq. 2). This analysis doesn't take into account that this average includes Walmart stores of different sizes. The current average is assumed to be sufficient for use in the case study.

$$\frac{\text{Walmart annual total sales}\left(\frac{\$}{\text{year}}\right)}{\text{\# of Walmarts}\times 365\left(\frac{\text{days}}{\text{year}}\right)\times 24\left(\frac{\text{hours}}{\text{day}}\right)\times 60\left(\frac{\text{minutes}}{\text{hour}}\right)} = \text{Revenue per minute}\ \left(\frac{\$}{\text{min}}\right) \quad \text{(eq. 2)}$$

Table 2: Model Inputs (real 2015 dollars)

		References
Battery Storage Installed Costs		
Current Installed Costs (2014)	$1025/kWh	DOE 2013c
Near-term Installed Costs (2020)	$256/kWh	DOE 2013b
Long-term Installed Costs (2035)	$154/kWh	DOE 2013b
Photovoltaics Installed Costs		
Current Installed Costs (2014)	$2760/kW	NREL 2015a
Near-term Installed Costs (2020)	$2500/kW	NREL 2015a
Long-term Installed Costs (2035)	$1750/kW	NREL 2015a
Insolation Values		
Low	4.5 kWh/m^2/d	NREL 2015b
Medium	6 kWh/m^2/d	NREL 2015b
High	7.5 kWh/m^2/d	NREL 2015b
Other Model Inputs		
Walmart Supercenter Revenue per Minute	$181	Eq. 2
Installed PV Capacity	2600 kW	Eq. 5
Installed Battery Storage	17,400 kWh	Eq. 7
PV Energy Density	148.5 W/m^2	SPR 2015
Walmart Supercenter Average Square Footage	18,300 m^2	SBRI 2015
Walmart Annual Total Sales	$405 billion	SBRI 2015
Number of Walmart Stores	4255	SBRI 2015
Annual Average Energy Use of Retail Buildings	231.4 kWh/m^2	EIA 2006
Cost of Electricity ($/kWh)	$0.1075	EIA 2015
Annual Increase in Cost of Electricity	5%	SAM 2015
Annual PV Degradation Rate	0.5%	SAM 2015
PVBS System Lifetime	25 years	SAM 2015
PV System Lifetime	25 years	SAM 2015
Annual O & M Costs	$20/yr/kW	SAM 2015
Discount Rate	5.5%	SAM 2015
Inflation Rate	2.5%	SAM 2015

Average revenue per minute for the case study is then multiplied by total annual duration of grid outage experienced, using SAIDI, to find annual avoided revenue losses (eq. 3). The annual avoided revenue losses represent the revenue that would have been lost if PVBS had not been installed. This value will later be applied directly towards paying back the initial cost of the system as savings. This value is calculated for each year throughout the lifetime of the system, in this case 25 years, adjusting for net present value by incorporating inflation and the discount rate. This equation is not applied to PV systems without battery storage because they stop functioning in the case of grid interruption due to safety regulations common throughout the world (IEA 2009), and therefore do not provide energy continuity during grid outage. Net present value was also taken into account by incorporating annually compounding inflation and the discount rate.

$$\text{Revenue per minute } \left(\frac{\$}{\text{min}}\right) \times \text{Annual SAIDI } \left(\frac{\text{minutes of outage}}{\text{year}}\right) = \text{Annual avoided revenue losses } \left(\frac{\$}{\text{year}}\right) \quad \text{(eq. 3)}$$

Sullivan et al. (2009) explores the financial losses incurred during grid outages, finding a range of $8.1-$93.3/kWh for electrical interruption cost at multiple outage durations for medium and large commercial and industrial customers, with an average cost per kWh across all outage durations of $28.04/kWh. The Walmart Superstore case study under consideration assumes an electrical interruption cost of $22/kWh, a value consistent with the results from Sullivan et al. The interruption cost per unit energy ($/kWh) is found by dividing the average revenue per minute (eq. 2) by the energy use per minute (eq. 4). The energy use per minute is calculated directly from annual energy use from the Walmart case study (Table 2), assuming that energy use is evenly distributed throughout each day and throughout the year. These values are taken from the first year after investment, with subsequent years being impacted by a discount rate and inflation.

$$\frac{\text{Average revenue per minute}}{\text{Average energy use per minute}} = \text{Interruption cost per unit energy } \left(\frac{\$}{\text{kWh}}\right) \quad \text{(eq. 4)}$$

It is important to note the large range for electrical interruption costs found by Sullivan et al. Depending on the commercial activities, the vulnerability to grid outages can vary by an order of magnitude. The analysis shown in this paper explores an average risk. However, the SPEEDI model can easily be modified to analyze any electrical interruption costs by simply modifying the input parameters in Table 2. This is particularly attractive to businesses that already have estimates for revenue losses during grid outages.

The installed PV capacity for both PVBS and PV is calculated by dividing the annual average energy use by the average annual solar insolation (eq. 5). The annual average energy use is found by multiplying the annual average energy use of retail buildings in the US per m^2 (EIA 2006) by the average Walmart Supercenter floor space (SBRI 2015). The insolation level of 4.5kWh/m^2/d was chosen for sizing the system because it is the lowest insolation included in this analysis and ensures that all systems considered produced enough electricity to supply the Walmart Supercenter case study's needs. The roof space requirements of the system are calculated by multiplying the system size by the average energy density of a range of common solar panels (SPR 2015, eq. 6). The result requires a capacity of at least 2578 kW, with a 2600 kW PV system used for this analysis covering 17,372 m^2, fitting within typical Walmart Supercenter rooftop constraints (SBRI 2015). System losses beyond the photovoltaic efficiency, such as losses in the inverter and wiring, are not considered in this analysis for simplicity.

$$\frac{Annual\ average\ energy\ use\left(\frac{kWh}{year}\right)}{Solar\ insolation\left(\frac{kWh}{m^2 day}\right)\times\frac{365\ days}{year}\times\frac{1\ m^2}{1\ kW}} = Installed\ PV\ Capacity\ (kW) \quad \text{(eq. 5)}$$

$$\frac{\text{Installed PV capacity (kW)}}{Energy\ density\ \left(\frac{kW}{m^2}\right)} = PV\ system\ roof\ space\ requirements\ (m^2) \quad \text{(eq.6)}$$

The installed battery storage for the PVBS system is calculated based on surviving a 36-hour break in grid access, the average time of cloud cover during a hurricane (NOAA 2015), at normal electricity consumption levels without losing power. This is done by multiplying the average hourly energy use by a 36-hour break in grid access (eq. 7). Battery discharge factors are not included in this analysis for simplicity.

$$\frac{\text{Annual average energy use}\left(\frac{\text{kWh}}{\text{year}}\right)}{\frac{365\ \text{days}}{\text{year}}\times\frac{24\ \text{hours}}{\text{day}}}\times 36\ \text{hours} = \text{Installed battery storage (kWh)} \quad \text{(eq. 7)}$$

The annual electricity production by the PV and PVBS systems is then calculated by multiplying the installed capacity by the selected insolation levels, taking panel degradation into account (eq. 8). Without battery storage, revenue flow is assumed to cease during periods of outage. It was also assumed that the PV system without battery storage would stop functioning during grid downtime, as is the current practice in the United States and around the world (IEA 2009). Although the battery-connected PVBS would continue to operate during grid interruption, demonstrating "islanding" capability, production during grid outage was also assumed to be zero because heavy cloud cover during extreme weather would severely limit production. The solar production during outage needs to be subtracted from annual production of both PV and PVBS for this reason (eq. 9).

$$\left(\text{PV installed capacity(kW)} - \text{Degradation (kW)}\right)\times\text{solar insolation}\left(\frac{\text{kWh}}{\text{m}^2\text{d}}\right)\times\frac{1\ \text{m}^2}{1\ \text{kW}}\times\frac{365\ \text{days}}{1\ \text{year}} = \text{Uncorrected annual electricity production}\left(\frac{\text{kWh}}{\text{year}}\right) \quad \text{(eq. 8)}$$

$$\text{Uncorrected annual solar production}\left(\frac{\text{kW}}{year}\right) - \text{Average energy production}\left(\frac{\text{kWh}}{\text{min}}\right)\times\text{Annual SAIDI}\left(\frac{\text{minutes of outage}}{\text{year}}\right) = \text{Annual electricity production}\left(\frac{\text{kWh}}{\text{year}}\right) \quad \text{(eq. 9)}$$

The value of the PV electricity production is then calculated by multiplying the average cost of electricity from the grid by the Annual PV electricity production (eq. 10). Annual PV savings can be viewed as profit from electricity that is sold into the grid or savings from electricity not purchased from the grid. Depending on local net metering regulations, prices for electricity purchased from the grid and sold to the grid may differ and should be accounted for when considering other case studies. In this case, they are assumed to be

equal. Net present value is also taken into account by incorporating annually compounding inflation and the discount rate, as well as annual predicted increases in electricity cost.

$$\text{Annual electricity production } \left(\frac{\text{kWh}}{\text{year}}\right) \times \text{grid electricity cost } \left(\frac{\$}{\text{kWh}}\right) = \text{Annual PV savings } \left(\frac{\$}{\text{year}}\right) \quad \text{(eq. 10)}$$

The annual avoided revenue losses (eq. 3) and annual PV savings (eq. 10) are then added to find annual total savings (eq. 11). This sum represents the total amount of value received from PV solar production and avoided grid outage each year. The annual avoided revenue losses and annual PV savings are assumed to be evenly distributed throughout the year. Please note that companies can substitute annual avoided revenue losses with their own internally collected figures on outage losses at this point to tailor the SPPEEDI model to analyzing PVBS investments in their own particular situation.

$$\text{Annual avoided revenue losses } \left(\frac{\$}{\text{year}}\right) + \text{Annual PV savings } \left(\frac{\$}{\text{year}}\right) = \text{Annual total savings } \left(\frac{\$}{\text{year}}\right) \quad \text{(eq. 11)}$$

The initial cost of the PVBS system is calculated by multiplying the cost of PV panels per kW by the capacity to be installed, multiplying the cost of battery storage by the capacity to be installed, and adding these two products (eq. 12). For conventional PV systems, the installed battery storage capacity is set to zero.

$$\text{PV panel cost per kW } \left(\frac{\$}{\text{kW}}\right) \times \text{Installed PV capacity (kW)} +$$
$$\text{Battery cost per kWh } \left(\frac{\$}{\text{kWh}}\right) \times \text{Installed battery storage capacity (kWh)} = \text{Initial system cost (\$)} \quad \text{(eq. 12)}$$

The cumulative total savings is then calculated for each year of system operation for each SAIDI value. The whole year payback periods are found with a LOOKUP function that identifies how many years there are before the cumulative total savings exceeds the initial investment cost of the system (eq. 13).

$$\sum_{\text{year}=1}^{\text{Payback period (years)}} \text{Annual total savings (\$)} > \text{Initial system cost (\$)} \quad \text{(eq. 13)}$$

To find payback periods with greater resolution, linear interpolation is used.

2.3. Model Limitations

The SPPEEDI model is based on losses from sustained grid outage, which despite being a large part of costs caused by grid outage, has less total financial impact nationwide in the US than momentary outage. Momentary outages are responsible for 67%, while sustained interruptions account for only 33% of total losses from outages in the US (LaCommare & Eto 2004). In its present form, the SPPEEDI model may underestimate outage losses by not incorporating losses from momentary outages. The SPPEEDI model may also underestimate grid outage losses because extended loss may be compounding, yielding higher loss as duration increases (NARUC 2013b).

A number of other potential financial losses from grid outage are not considered in SPPEEDI, although their financial impact is likely to be smaller than that of either momentary outages or revenue losses (LaCommare & Eto 2004). Lost product, food spoilage, damage to equipment, lack of productivity, restart costs, and data loss can add additional financial loss from grid outages. Furthermore, labor costs could add to losses, if overtime pay is necessary for made-up time, or deduct from losses if worker hours are cut as a result. In calculating financial loss, the SPPEEDI model also does not take into account high-resolution variations, such as season, day of the week, and time of day of outages. The value of supply management optimization (e.g. storing energy at times of low energy prices and selling energy to the grid at time of high energy prices) is also not incorporated into the model and may have an impact on payback periods of PVBS. Opportunity cost of investments in PVBS over competing energy continuity technologies, such as diesel generation, could impact payback period as well. Although the diesel generator is the current standard backup power system for commercial applications, Hotchkiss et al. (2013) showed that microgrids are less likely to survive an outage relying on diesel generators than on PVBS and can create significant costs from both installation and fuel consumption (NARUC 2013a).

The inputs used in this analysis present uncertainty. Future cost projections of PV and battery storage, electricity, and annual operation and maintenance could be effected by many economic or technological factors. Current cost estimates are also averages that may not apply accurately in all regions and in all applications.

While including all of these dimensions in future iterations of the SPPEEDI model could improve accuracy, it is likely to complicate calculations and may decrease broad applicability as companies would have to collect more extensive data for analysis. The current model allows for ease of use and functions with minimal inputs. By inputting data that many companies may already have at hand, this model can easily be applied to investments in PVBS based on the reader's needs.

3. Results

To show the impact of incorporating grid disruption on payback periods, the results compare the payback periods for conventional grid-attached solar systems (PV), PVBS omitting SAIDI, and PVBS including SAIDI. Next, to provide context to the model, PVBS and PV payback periods are compared based on US national SAIDI statistics (Larson 2014). Lastly, the relationship between SAIDI and payback period is explored by showing percent change in payback period for investments in PVBS as a function of SAIDI.

Figure 1: The payback period of PVBS decreases with increases in SAIDI, surpassing the payback period of PV at a SAIDI of 2640 minutes for near-term costs, and medium insolation.

3.1. The Value Of Incorporating Grid Outage

Figure 1 illustrates the change in payback periods by incorporating SAIDI when analyzing the value of PVBS. Without SAIDI (green line), the payback period of PVBS is always higher than that of PV (red line) because of its higher initial investment cost. However, when incorporating SAIDI (blue curve), the payback period for PVBS decreases with additional avoided outage duration, improving on the investment potential in places vulnerable to grid interruption. At the point where the blue curve crosses the red line, PVBS becomes a better investment than PV and has a shorter payback period with SAIDI being taken into account. Current evaluations do not account for SAIDI and are represented by the green curve. The valuation represented by the blue curve internalizes the value of energy continuity and more accurately portrays the investment potential of PVBS. The two PVBS curves diverge significantly as SAIDI continues to increase, showing that PVBS investment analyses in areas vulnerable to extreme weather will be strongly impacted by this novel evaluation.

Table 3: Investments in PVBS vs PV (These are the amounts of SAIDI minutes required for PVBS to become a better investment than PV in different cost scenarios and at different levels of solar insolation)

	Low Insolation	Medium Insolation	High Insolation
Current Cost	7750 minutes	10820 minutes	11690 minutes
Near-term Cost	2090 minutes	2640 minutes	3200 minutes
Long-term Cost	1640 minutes	2120 minutes	2590 minutes

Figure 2: Although high solar insolation decreases payback periods, PVBS financially outperforms PV better in areas of low insolation. Values shown are derived from near-term cost projections.

Table 3 shows the minimum annual SAIDI values required for an investment in PVBS to outperform conventional PV financially. In all scenarios, PV systems without battery storage have the shortest payback period assuming a SAIDI of 0 minutes, where there is no grid interruption throughout the year or SAIDI is not considered. However, at higher levels of SAIDI, PVBS has a shorter payback period than PV. With system costs decreasing, as is predicted in the near and long- term, investments in PVBS outperform PV with increasingly lower SAIDI values. Higher insolation values favor PV systems relative to PVBS (Figure 2). PV systems rely solely on energy production for revenue; whereas, PVBS revenues also incorporate avoided revenue losses from grid interruption. Note the slight upward slope of the PV payback period lines (dark red). This is because PV systems cease functioning during periods of grid outage, losing revenue and increasing payback periods. The effect of this on payback periods is weak compared to that of grid downtime, mainly because the value of electricity production per minute is much lower than the value of avoided revenue losses from grid downtime per minute, as can be seen in Table 4.

Table 4: Value of 1 Minute of Grid Interruption (For each minute of grid interruption, the value of avoided lost revenue from business continuity due to PVBS far exceeds losses from the PV system not producing electricity)

PV Production	-$1.06
Avoided Lost Revenue	$181

Figure 3 shows payback periods in current, near-term, and long-term cost conditions at medium insolation levels. PVBS becomes more competitive at predicted long-term cost levels, because the price of batteries is expected to drop faster than the price of PV. As the cost of batteries continues to account for a smaller portion of the total cost, PVBS becomes competitive with PV at even lower levels of SAIDI.

Figure 3: As prices decrease in the near- and long-term cost scenarios, PVBS becomes competitive with PV at much lower levels of SAIDI. Values shown are derived from medium insolation scenarios.

3.2. Payback Periods With US National SAIDI Values

In a study containing 12 years of data from over 150 utilities nationwide in the United States, Larsen et al. (2014) reported that SAIDI including outages resulting from extreme weather averaged 372.2 minutes in the US. The minimum, maximum, median, and mean of this data set are run through the SPPEEDI model to find nationally relevant payback periods based on actual conditions (Tables 5-7). The "Impact of SAIDI on Payback Period" column in Tables 5-7 shows the percent change in payback periods at each level of grid interruption relative to the base case with no grid interruption. This impact is calculated in eq. 14. The mean, while at the lower end of the SAIDI scale used in this analysis, shows an impact of SAIDI on payback periods between 6.0% and 9.5%. Although the reported maximum value has very short payback periods, this is representative of only a single year at a single utility and does not represent the data as a whole, as shown by the median being lower than the mean. This also points to the fact that although adoption of the SPPEEDI model would accelerate PVBS's progress towards achieving grid parity even at low levels of SAIDI, it will have the most impact on businesses in areas that experience higher SAIDI values, such as those vulnerable to extreme weather or located in regions with unreliable grid access.

$$\left(1-\frac{\text{PVBS payback period with SAIDI (years)}}{\text{PVBS payback period base case (years)}}\right)\times 100\% = \text{Percent change in PVBS payback period (\%)} \quad \text{(eq. 14)}$$

Table 5: At low insolation (4.5 kWh/m^{2}d), including SAIDI in evaluating PVBS investment decreases the payback period by 8% on average based on near-term cost projections, but could have an impact as high as 84% in regions vulnerable to extreme weather and grid outages.

US National SAIDI Statistics (2000-2012) at Low Insolation	SAIDI (outage minutes)	Payback period (years)			Percent Change in Payback Period		
		Current Costs	Near-term Costs	Long-term Costs	Current Costs	Near-term Costs	Long-term Costs
PVBS Base Case	0	>25	22.1	15.5	NA	0	0
Minimum	1.2	>25	22.1	15.5	NA	~0	~0
Median	173.0	>25	21.3	14.8	NA	-3.8%	-4.5%
Mean	372.2	>25	20.4	14.0	NA	-8.0%	-9.5%
Maximum	14,437.6	9.1	3.8	2.4	NA	-83.0%	-84.3%
PV Base Case	0	15.363	14.084	10.222	0	0	0
PV Mean	372.2	15.377	14.097	10.231	+0.093%	+0.093%	+0.096%

Table 6: At medium insolation (6.0 kWh/m²d), including SAIDI in evaluating PVBS investment decreases the payback period by 6.9% on average based on near-term cost projections, but could have an impact as high as 80% in regions vulnerable to extreme weather and grid outages.

US National SAIDI Statistics (2000-2012) at Medium Insolation	SAIDI (outage minutes)	Payback Period (years)			Percent Change in Payback Period		
		Current Costs	Near-term Costs	Long-term Costs	Current Costs	Near-term Costs	Long-term Costs
PVBS Base Case	0	>25	17.0	11.7	0	0	0
Minimum	1.2	>25	17.0	11.7	~0	~0	~0
Median	173.0	>25	16.5	11.3	NA	-3.2%	-3.8%
Mean	372.2	>25	15.9	10.8	NA	-6.9%	-7.9%
Maximum	14,437.6	9.5	3.6	2.3	NA	-79.1%	-80.3%
PV Base Case	0	11.641	10.639	7.647	0	0	0
PV Mean	372.2	11.650	10.646	7.653	+0.071	+0.071%	+0.073%

Table 7: At high insolation (7.5 kWh/m²d), including SAIDI in evaluating PVBS investment decreases the payback period by 6% on average based on near-term cost projections, but could have an impact as high as 75% in regions vulnerable to extreme weather and grid outages.

US National SAIDI Statistics (2000-2012) at High Insolation	SAIDI (outage minutes)	Payback Period (years)			Percent Change in Payback Period		
		Current Costs	Near-term Costs	Long-term Costs	Current Costs	Near-term Costs	Long-term Costs
PVBS Base Case	0	>25	13.8	9.4	0	0	0
Minimum	1.2	>25	13.8	9.4	NA	~0	~0
Median	173.0	>25	13.4	9.1	NA	-2.8 %	-3.2%
Mean	372.2	>25	13.0	8.8	NA	-6.0%	-6.8%
Maximum	14,437.6	8.1	3.4	2.2	NA	-75.5%	-76.7
PV Base	0	9.360	8.538	6.104	0	0	0
PV Mean	372.2	9.366	8.543	6.107	+0.056%	+0.057%	+0.057

Figure 4 shows the percent change of payback periods for PVBS at different costs and levels of grid outage at medium insolation. This figure draws from the same data as Tables 5-7 and is also calculated using eq. 14. The current cost curve (blue) is set apart from the near- and long-term cost curves because at this cost, the PVBS system does not pay itself off within its 25-year lifetime at SAIDI levels below 2770 minutes.

Fig. 4: The percent change in payback periods from additional SAIDI increases dramatically with additional grid interruption, making investment in PVBS particularly attractive to potential customers in areas vulnerable to grid outage.

4. Conclusion

The model developed for this study incorporates avoided revenue losses from grid outages in evaluating payback periods of investments in PVBS. Grid outages, measured as minutes of SAIDI, can significantly affect payback periods of PVBS and should, therefore, be considered in valuation and investment decisions. Such valuation of investments in PVBS more accurately portrays pertinent financial considerations by internalizing impacts on business continuity of such an investment. Including SAIDI in PVBS valuation also inevitably improves prospective investment in this technology, as grid outages are a consistent challenge of doing business in a grid-connected environment. PVBS can be a better financial investment than PV as well as a more reliable energy continuity measure than backup diesel generators. PVBS investment evaluations are impacted most by including SAIDI in regions vulnerable to extreme weather, as these are the areas that experience the greatest benefits from bolstered energy continuity. Payback periods of PVBS are effected between 6.0-9.5% by incorporating average US national SAIDI values, with outliers experiencing as much as 84% shorter payback periods. As climate change continues to increase the severity and frequency of storms throughout the world (Fischer and Knutti 2015; IPCC 2013), investments in these systems may become even more attractive. The SPPEEDI model, although applied in this study to the United States, can be applied internationally as well. Countries with unreliable grid service or vulnerability to extreme weather would particularly benefit from this model. This model is also very applicable for private industry, allowing businesses to input their own company-specific internal data to calculate the value of an investment in PVBS for themselves. This robust analysis of the value of PVBS can help investors make more informed decisions regarding solar energy and battery storage systems.

Novel Encapsulation Technique to Upscale Latent Heat Storage Capacity in Steam Accumulators

Hakeem Niyas, P. Muthukumar

Department of Mechanical Engineering, Indian Institute of Technology Guwahati, Assam, India

Abstract

Cylindrical latent heat storage (LHS) capsules are used in steam accumulators for reducing the pressure drop in the vessel. Due to the high thermal resistance offered by the phase change material (PCM) in capsules with a higher diameter, more number of less diameter capsules need to be used for a particular storage capacity. In the present study, a novel encapsulation technique is proposed for effective heat transfer in cylindrical LHS capsules. With this technique, less number of capsules can yield the similar or higher storage capacity in a comparatively lesser charging time. A numerical model is developed to study the performance characteristics of the proposed novel encapsulation technique. In the numerical model, the effective heat capacity method is applied to consider the latent heat of the PCM and Boussinesq approximation is used to include the natural convection of the molten layer of the PCM. Darcy law's source term is added in the momentum equation to deduce the velocities of the PCM in its actual form in the mushy zone.

Keywords: *Heat transfer enhancement, Latent heat storage, Novel encapsulation, Phase change material.*

1. Introduction

Steam accumulators are applied as buffer storage devices between steam generators and consumers in case of a mismatch between the steam production and consumption (Stevanovic et al., 2012). During discharge in a steam accumulator, the steam pressure drops. Two viable techniques such as incorporating a flash evaporator or an encapsulated latent heat storage (LHS) capsule are preferred to avoid the pressure drop. Due to the exergy loss by mixing in the flash evaporator system, encapsulated LHS capsule is advantageous (Steinmann and Eck, 2006). Cylindrical capsules were being used normally in commercial steam accumulators (Medrano et al., 2010). Several experimental and numerical studies were carried out to study the LHS characteristics of cylindrical capsules during both charging and discharging processes (Bourdillon et al., 2015; Himeno et al., 1988; Steinmann and Tamme, 2008). Certain reviews encompass the major research works on encapsulated systems (Farid et al., 2004; Su et al., 2015). Despite of several advantages like reduction of temperature transients in steam accumulator, high volume-specific storage capacity, etc. (Medrano et al., 2010), the major disadvantage of encapsulated LHS capsule is the limitation in the diameter of the cylindrical capsules. With an increase of diameter, the resistance to heat transfer also increases due to the low thermal conductivity of the phase change material (PCM). In the present study, a novel encapsulation technique is proposed to alleviate this. The novelty proposed here is to use a shell-and-tube LHS system with a very small inner tube. With this, the heat transfer would be enhanced due to lesser thickness of PCM and increased heat transfer area when compared to the LHS capsule having basic encapsulation. For comparing the performance characteristics of the basic and proposed novel technique, capsules having a LHS capacity of 0.25 MJ are considered. Sodium nitrate and SS304 are selected as the PCM and encapsulating material. The thermo-physical properties of sodium nitrate are given in Tab. 1. Figure 1 shows the schematic of the cylindrical capsule and novel encapsulated cylindrical capsule. The diameter of the LHS capsules having basic and novel encapsulation for storing the corresponding LHS capacity are 63.5 mm and 64.3 mm. A small tube of diameter 6 mm is used as the inner tube for the novel capsule. The design of capsules is made in such a way that the volume of PCM in both the capsules are same.

2. Numerical model

Three physical processes are to be simulated to study the LHS behavior of encapsulated LHS capsules, i.e. conduction, phase change and convection. A 2-D axisymmetric model is developed in view of the symmetry of flow and heat transfer around the vertical axis. Molten PCM movement due to natural convection heat transfer within the capsules is assumed to be laminar, Newtonian and incompressible. The major difficulty in the modeling of LHS system is the inclusion of latent heat and this is implemented using effective heat capacity method wherein a single term called effective heat capacity is used to consider both sensible and latent heat. The simulation is modelled using COMSOL Multiphysics software and the discontinuous effective heat capacity is applied using a Heaviside function. Buoyancy effect of the molten PCM is incorporated using Boussinesq approximation. To properly interpret the velocities in mushy zone, Darcy law's source term is added in the momentum equation. The governing equations and their corresponding sub-equations are given in Eqs. (1-8). Capsules are initially kept at 564.95 K and 594.95 K during charging and discharging processes. At any time ($t > 0$), the boundaries are given a temperature of 594.95 K and 564.95 K during charging and discharging processes thereby making a temperature swing of 30 K. The major performance parameter used in LHS is melt fraction. Melt fraction of the PCM can be calculated based on the lever rule applied between the solidus and liquidus temperatures and it is given by Eq. (8). During charging / discharging, melt fraction of the PCM possess a value of 0 / 1 initially and when it reaches a value of 1 / 0, it is said to be completely charged / discharged.

$$c = \begin{cases} c_{ps} & for\ T < T_S \\ c_{p,eff} & for\ T_S \le T \le T_L \\ c_{pl} & for\ T > T_L \end{cases} \quad \text{(Eq. 1)}$$

$$c_{p,eff} = \frac{c_{ps} + c_{pl}}{2} + \frac{\Delta H_f}{2\Delta T_m} \quad \text{(Eq. 2)}$$

$$\vec{S} = \frac{(1-\theta)^2}{(\theta^3 + \varepsilon)} A_{mush} \vec{V} \quad \text{(Eq. 7)}$$

$$\theta = \frac{T - T_S}{T_L - T_S} = \frac{T - T_m + \Delta T_m}{2\Delta T_m} = \begin{cases} 0 & for\ T < T_S \\ 0-1 & for\ T_S \le T \le T_L \\ 1 & for\ T > T_L \end{cases} \quad \text{(Eq. 8)}$$

3. Results and discussions

3.1. Grid Independency Test

Free triangular mesh is adapted in the developed numerical model. In order to test the dependency of numerical results on the mesh element size, a simulation is ran with the novel cylindrical capsule for charging process. The LHS capsule is initially at 564.95 K. At any time t > 0, the boundaries of the capsule are given 594.95 K. The average temperature of the capsule is compared for different element sizes viz. 10408, 12031 and 14410 elements. It is observed from Fig. 2 that the model with 12031 elements is found to be grid independent. Similarly, grid independency test carried out for the basic cylindrical capsule yields an optimum mesh size with 11672 elements.

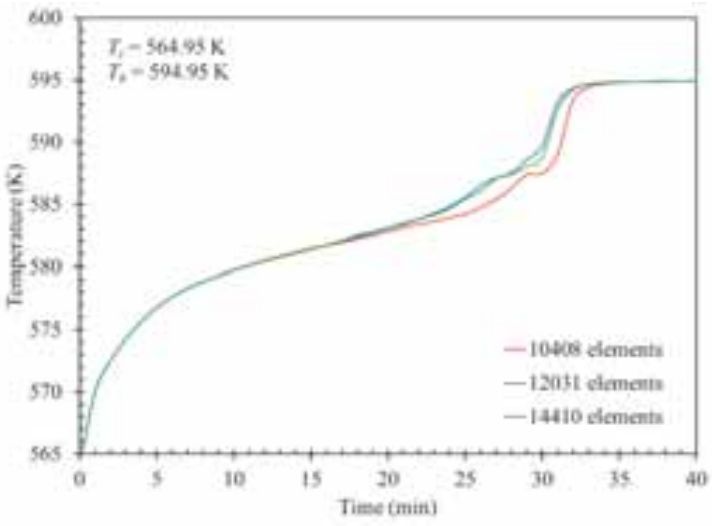

Fig. 2: Grid independent test

3.2. Temperature Distribution – Charging

Figure. 3 shows the comparison of the average temperature variation of the basic and novel LHS capsules during charging process. PCM kept in the capsules during charging is initially in the solid state at 564.95 K. When an uniform high temperature of 594.95 K is given on the boundary of the capsule, heat is transferred from periphery of the capsules and stored in the form of sensible and latent heat. It is inferred from Fig. 3 that the increase in average temperature is faster in LHS capsule having novel encapsulation than basic encapsulation. This is due to 2 reasons viz., increased surface area available for heat transfer and reduced thickness of the PCM layer.

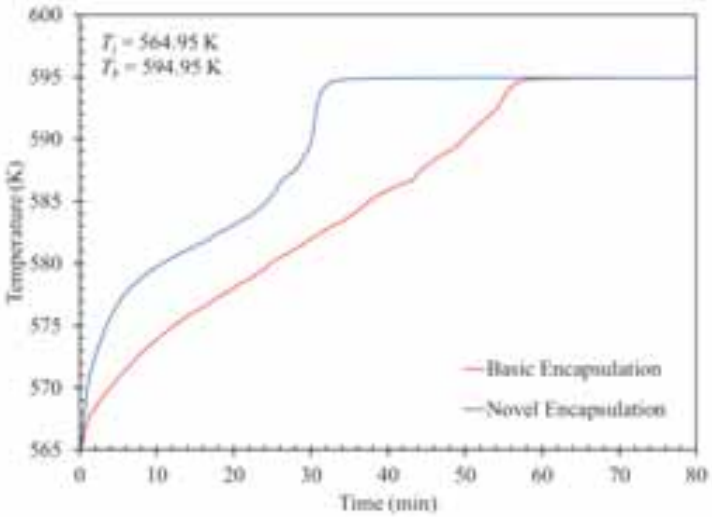

Fig. 3: Temperature distribution during charging

3.3. Charging Time

Charging time of the LHS capsule is defined with respect to the melt fraction of the PCM. The LHS capsule is said to be fully charged when the melt fraction of the PCM reaches unity. Figure. 4 shows the comparison of average melt fraction variation of basic and novel LHS capsules. It can be noted from Fig. 4 that the charging time of novel capsules is lesser than the basic capsule. It takes about 57 min and 32 min for complete charging of the PCM in LHS capsules having basic and novel encapsulation. There is a charging time reduction of 44 % in capsule having novel encapsulation when compared with the basic encapsulation. Screenshots of melt fraction variation of LHS capsules during charging are given in Fig. 5. The effect of natural convective heat transfer can be seen from the asymmetric temperature variation in the capsules at 15, 30, 45 min (basic encapsulation) and 30 min (novel encapsulation).

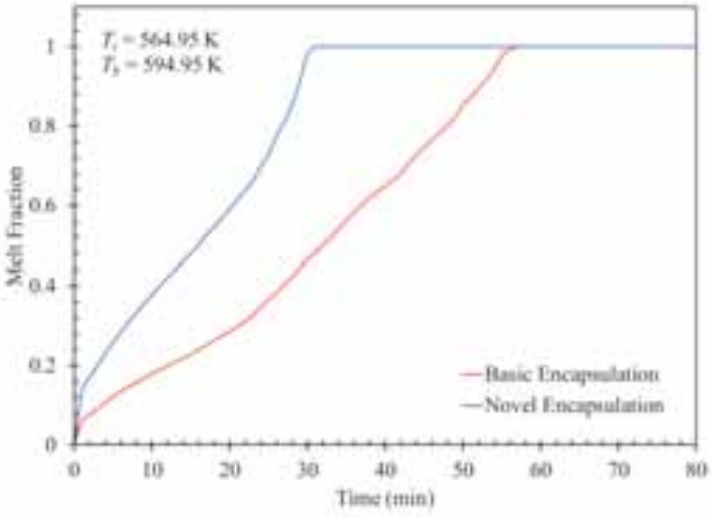

Fig. 4: Melt fraction distribution during charging

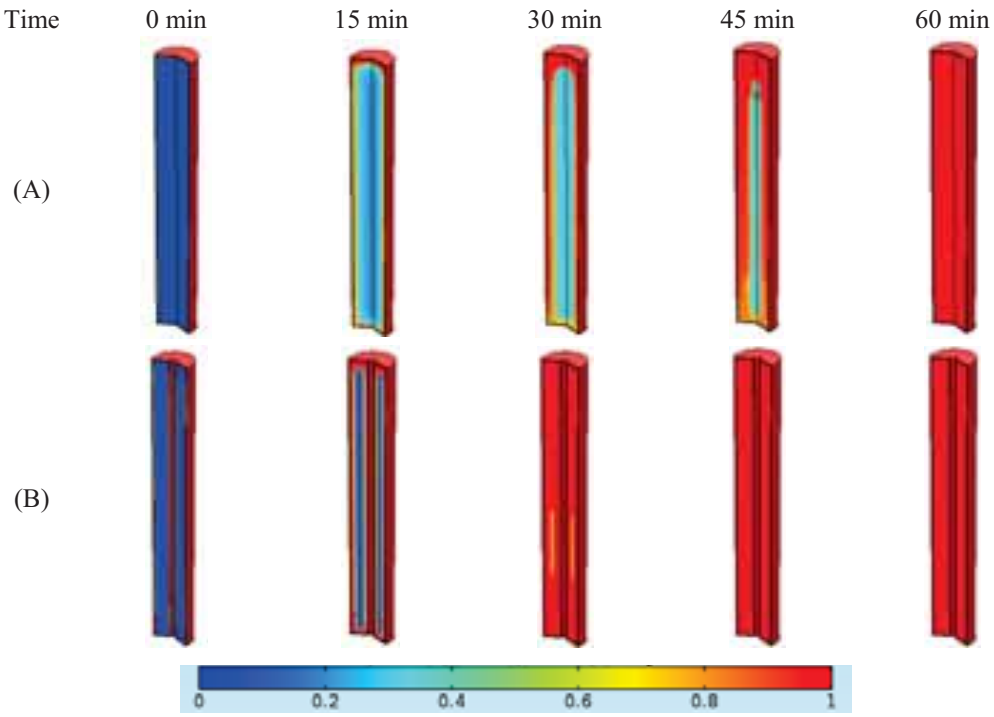

Fig. 5: Melt fraction distribution during charging (A) Basic encapsulation (B) Novel encapsulation

3.4. Temperature Distribution – Discharging

Figure. 6 shows the comparison of the average temperature variation of the LHS capsules having basic and novel encapsulation during discharging process. PCM kept in the capsules during discharging is initially in the liquid state at 594.95 K. When an uniform low temperature of 564.95 K is given on the boundary of the capsule, heat is transferred from the capsules and gets discharged in the form of sensible and latent heat. It is inferred from Fig. 6 that the decrease in average temperature is faster in LHS capsule having novel encapsulation than the basic encapsulation similar to the charging process.

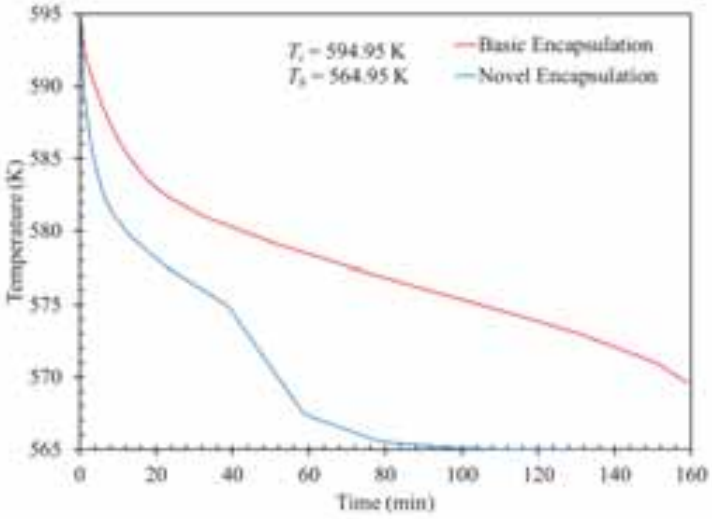

Fig. 6: Temperature distribution during discharging

3.5. Discharging Time

Discharging time of the LHS capsule is defined similarly with respect to the melt fraction of the PCM. The LHS capsule is said to be fully discharged when the melt fraction of the PCM reaches zero. Figure. 7 shows the comparison of average melt fraction variation LHS capsules having basic and novel encapsulation. It can

be noted from Fig. 7 that the discharging time of novel capsules is much lesser than the basic capsule. It takes about 158 min and 48 min for complete discharging of the PCM in LHS capsules having basic and novel encapsulation. There is a discharging time reduction of 70 % in capsule having novel encapsulation when compared with the basic encapsulation. Screenshots of melt fraction variation of LHS capsules during discharging are given in Fig. 8. It can be understood from Fig. 8 that solidification of PCM is highly dominated by conductive heat transfer and less or no influence by natural convection heat transfer.

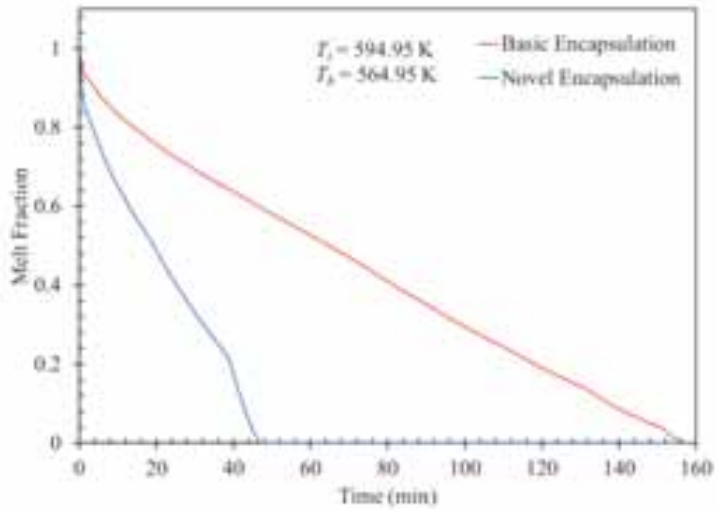

Fig. 7: Melt fraction distribution during charging

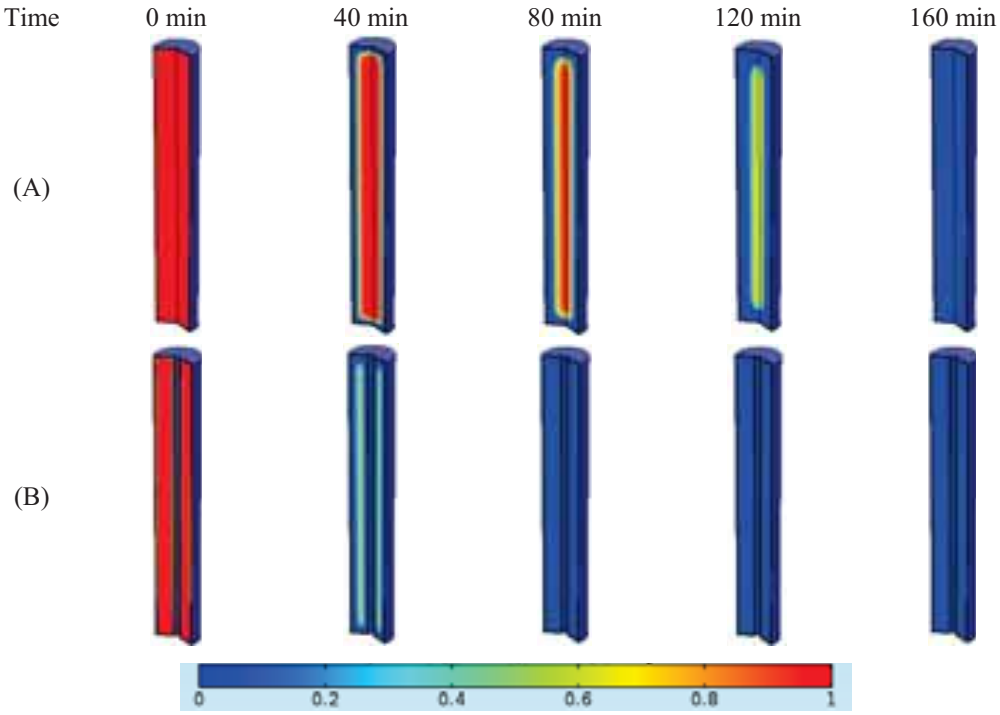

Fig. 8: Melt fraction distribution during charging

4. Conclusions

A thermal model was developed to compare the performance of LHS capsules having basic and novel encapsulation during charging and discharging processes. It was found that the charging of PCMs in both the models was dominated by natural convection. Numerical results shown that for the same mass of PCM, LHS capsules with novel encapsulation yields lesser charging and discharging time than the capsule with basic

encapsulation. This is due to 2 reasons viz., increased surface area available for heat transfer and reduced thickness of the PCM layer. It took about 57 min and 32 min for complete charging and 158 min and 48 min for complete discharging in the LHS capsules with basic and novel encapsulation. It can be noted that the charging and discharging time of the LHS capsule with novel encapsulation shown a reduction of about 44 % and 70 % respectively when compared with the LHS capsule with basic encapsulation. The results of the current study will be useful in the design of compact and efficient LHS encapsulated capsules.

Novel Fin for Effective Heat Transfer in Shell-and-Tube Latent Heat Storage System

Hakeem Niyas, P. Muthukumar

Department of Mechanical Engineering, Indian Institute of Technology Guwahati, Assam, India

Abstract

Due to the low thermal conductivity of phase change materials (PCMs), latent heat storage (LHS) technology has not yet commercialized to its fullest capability. Many heat transfer enhancement techniques were studied by several researchers and each of the techniques put forward has its own pros and cons. In the present study, a novel fin is proposed for effective heat transfer in shell-and-tube LHS devices. A numerical model is developed to study the performance characteristics of the proposed novel fin and to compare it with no fin and standard fin configurations. Effective heat capacity method is used to simulate the phase change mechanism. Sodium nitrate is used as the PCM and air is used as the heat transfer fluid. Performance parameters such as melt fraction and charging time are evaluated. Axial temperature variation of PCM in the LHS models is also studied.

Keywords: *Heat transfer enhancement, Latent heat storage, Novel fin, Phase change material.*

1. Introduction

The most intensely examined LHS system is the shell-and-tube system. This is due to the fact that many engineering systems employ cylindrical pipes and also heat loss from the shell-and-tube system is minimal (Agyenim et al., 2010). Several techniques were reported to improve the overall heat transfer effectiveness of the LHS system (Kurnia et al., 2013; Li et al., 2013; Rathod and Banerjee, 2015). Extensive reviews in this context were also published (Fan and Khodadadi, 2011; Kenisarin and Mahkamov, 2007; Liu et al., 2012). Every heat transfer enhancement technique has certain disadvantages:

- Sprinkling of high thermal conductivity metallic particles – the metallic particles settle down due to its high density after repeated charging and discharging cycles.
- Extended heat transfer surfaces (Fins) – materials having a high corrosion resistance and high/moderate thermal conductivity are suitable for heat transfer media in LHS systems. Materials having these properties (eg: stainless steel) are denser and hence the total weight of the system becomes high.

To increase the overall heat transfer in the LHS devices, a novel fin is proposed in the present study. Figure 1 shows the schematic of the shell-and-tube LHS module and the inner tube with and without novel/standard fins. The novel fin proposed here is half of the standard fin cut diagonally. This will reduce the weight and cost of the fin material by a factor of 0.5 and hence making the LHS system, light weight and cost-effective. For comparing the performance characteristics of the basic and proposed novel technique, capsules having a LHS capacity of 0.5 MJ are considered. Sodium nitrate and air are selected as the PCM and heat transfer fluid (HTF). SS 304 is selected as the HTF tube. The thermo-physical properties of sodium nitrate are given in Tab. 1. Figure 1 shows the schematic of the no fin, standard fin and novel fin configurations. The length of the LHS models is 0.5 m. The height and width of the fin is 10 mm and 2 mm in the standard fin configuration. The design of LHS models is made in such a way that the volume of PCM in all the configurations are same.

2. Numerical Model

A 3-D conjugate heat transfer model is developed to simulate the flow characteristics of HTF and heat transfer characteristics of PCM. The major difficulty in the modeling of LHS system is the inclusion of latent heat and this has been implemented using effective heat capacity method. The simulation is modelled using COMSOL Multiphysics software. Buoyancy effect has been incorporated using Boussinesq approximation. To properly interpret the velocities in mushy zone, Darcy law's source term was added in the momentum equation. The governing equations and their corresponding sub-equations are given in Eqs. (1-8). LHS models are initially kept at 564.95 K during the charging process. At any time ($t > 0$), the inlet of the model is given a temperature of 594.95 K and a constant velocity of 2 m/s. The major performance parameter used in LHS is melt fraction. Melt fraction of the PCM can be calculated based on the lever rule applied between the solidus and liquidus temperatures and it is given by Eq. (8). During charging, melt fraction of the PCM possess a value of 0 initially and when it reaches a value of 1, it is said to be completely charged.

3. Results and discussions

3.1. Temperature Distribution

Figure. 2 shows the comparison of the average temperature variation of the single tube shell-and-tube LHS model with no fin, standard fin and novel fin during charging process. PCM kept in the capsules is initially in the solid state at 564.95 K. When an uniform high temperature of 594.95 K and velocity of 2 m/s are given on the inlet of the LHS model, heat is transferred from the fluid and gets stored in PCM in the form of sensible and latent heat. It is inferred from Fig. 2 that the increase in average temperature is faster in LHS model having standard fin than that of no fin and novel fin, initially. This is due to the higher surface area available for heat transfer. But after a certain period of time, say t = 360 min, the increase in average temperature is faster in LHS model having novel fin than that of other two cases. The reason for this is the configuration of the novel fin, wherein the heat transfer area is more in the less heat transfer potential region, i.e. near the outlet portion of the model. Screenshots of temperature variation at different times are given in

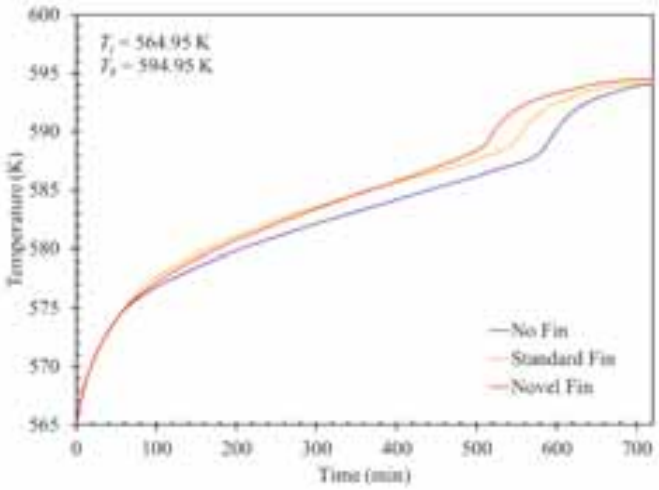

Fig. 2: Temperature distribution

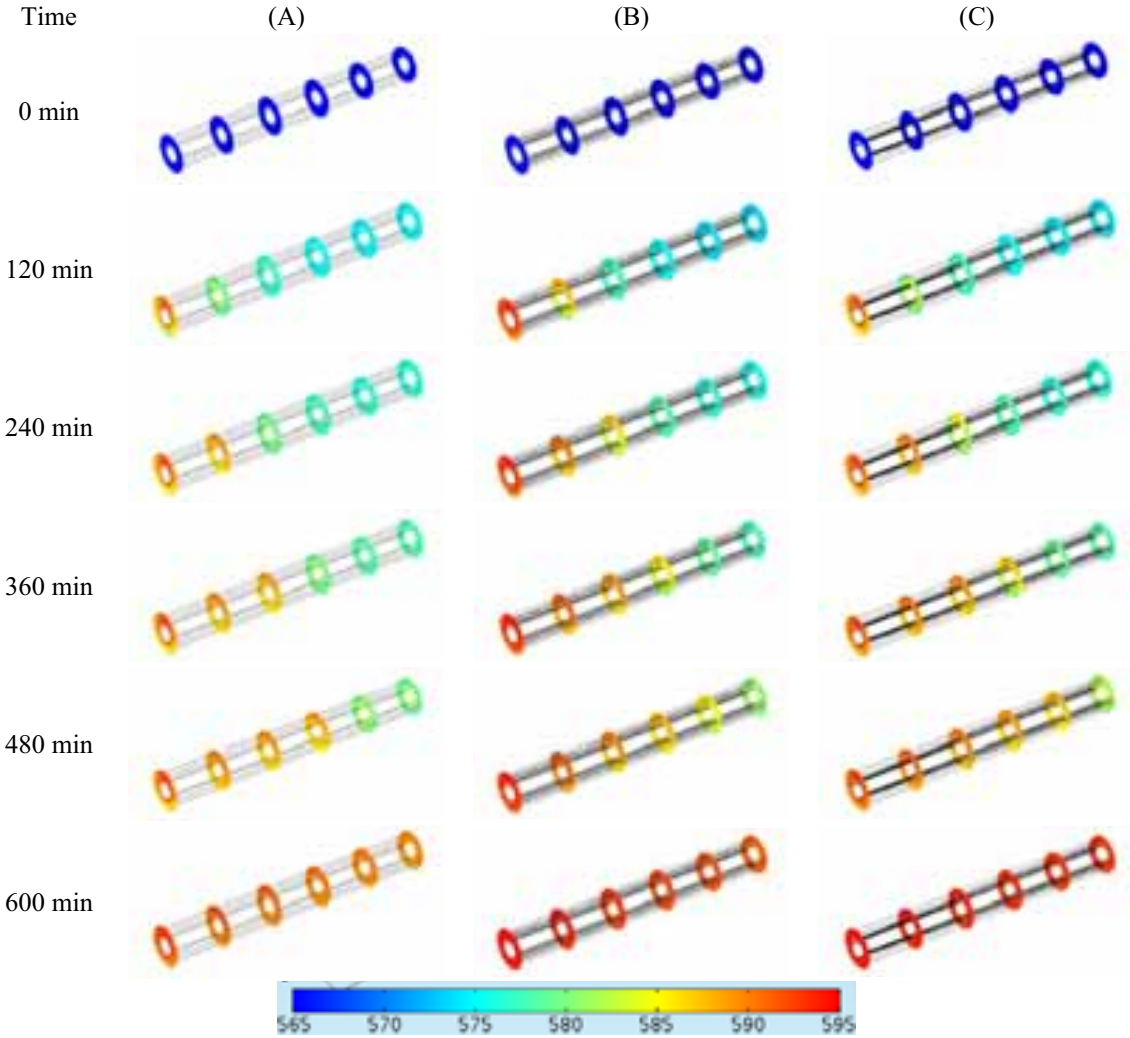

Fig. 3: Temperature distribution at different times

Fig. 3. It can be noted from Fig. 3 that the standard fin configuration dominates in temperature rise of PCM than the other two configurations, initially (t = 120 min, 240 min, 360 min) and novel fin configuration dominates in temperature rise of PCM during the last period (t = 480 min, 600 min).

3.2. Charging Time

Charging time of the LHS model is defined with respect to the melt fraction of the PCM. The LHS model is said to be fully charged when the melt fraction of the PCM reaches unity. Figure. 4 shows the comparison of average melt fraction variation of LHS model with no fin, standard fin and novel fin during charging process. It can be noted from Fig. 4 that the charging time of novel fin configuration is lesser than the no fin and standard fin configurations. It takes about 597 min, 551 min and 518 min for complete charging in the LHS model with no fin, standard fin and novel fin. It can be noted that the charging time has decreased by about 13.2 % and 6 % when using novel fin configuration with respect to no fin and standard fin configurations.

3.3. Axial Temperature Variation

Figure. 5 shows the axial temperature variation of the PCM in the LHS model. Surface average temperature of LHS model at x/L = 0, 0.1, 0.2, 0.3, 0.4 and 0.5 are plotted with respect to time. It can be noted from Fig. 5 that temperature of PCM in the inlet side of the LHS module increased faster in all the three configurations than that of the outlet side which is due to the presence of high temperature difference between the PCM and HTF at the inlet side. It is also noted from Fig. 5 that in both no fin and standard fin configurations, the difference between the temperature of PCM in the inlet and outlet portion is more than that of the novel fin configuration.

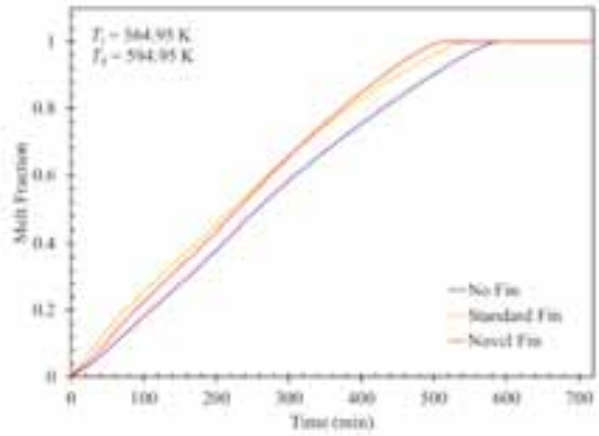

Fig. 4: Melt fraction distribution

(A)

(B)

(C)

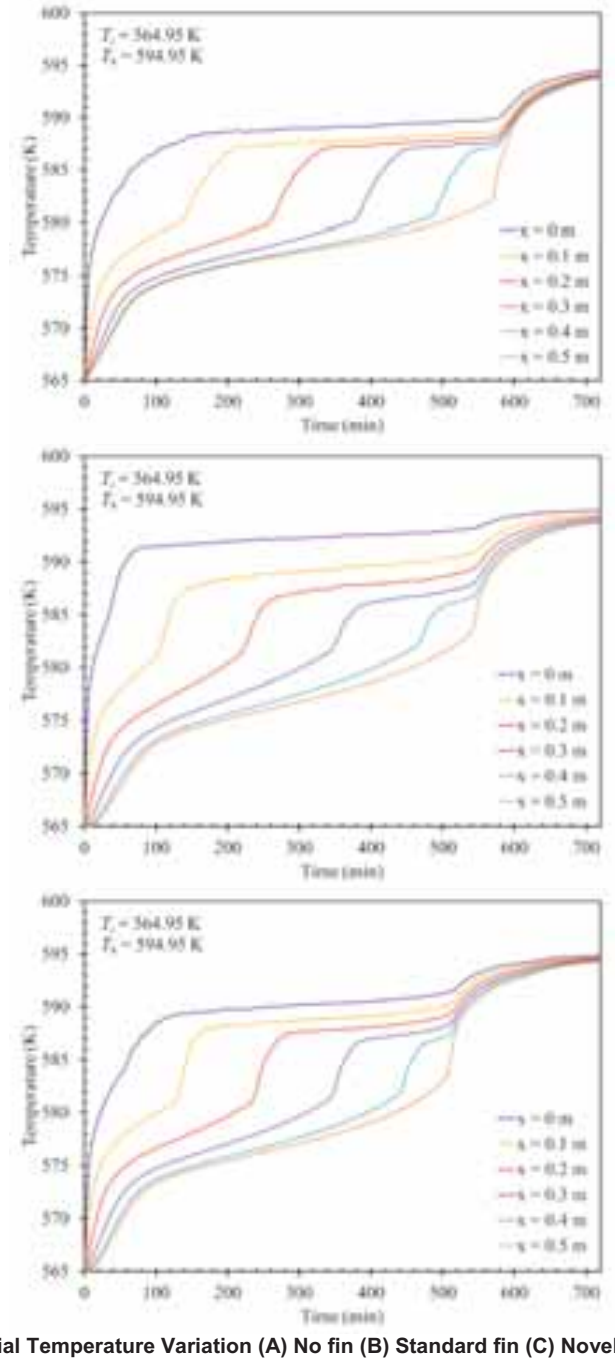

Fig. 5: Axial Temperature Variation (A) No fin (B) Standard fin (C) Novel fin

4. Conclusions

A novel fin is proposed for effective heat transfer in shell-and-tube LHS devices. A numerical model is developed to study the performance characteristics of the proposed novel fin and compare it with no fin and standard fin configurations. It is found from the numerical study that it takes about 597 min, 551 min and 518 min for complete charging in the LHS system with no fin, standard fin and novel fin. It can be noted that the charging time has decreased by about 13.2 % and 6 % when using novel fin system with respect to no fin and standard fin configurations. The novel fin proposed has also an additional advantage of weight and cost reduction by a factor of 0.5.

E-mail: Dmitrii.Bogdanov@lut.fi, Christian.Breyer@lut.fi

Abstract

Increasing ecological problems provoked by human activities, including the fossil fuel based energy sector, emerge the development of a renewable energy (RE) based system as the way to stop pollution and global warming but also to reduce total energy system cost. Small population density and availability of various types of RE resources in Eurasian regions including solar, wind, hydro, biomass and geothermal energy resources enables the very promising project of building a Super Grid connecting different Eurasian regions' energy resources to reach synergy effects and make a 100% RE supply possible. For every sub-region it is defined a cost-optimal distributed and centralized mix of energy technologies and storage options, optimal capacities and hourly generation. Charge and discharge profiles of storages are computed for regions interconnected by high-voltage direct current (HVDC) power lines. System cost and levelized cost of electricity (LCOE) for each sub-region are computed. The results show that a 100% RE-based system is lower in cost than nuclear and fossil carbon capture and storage (CCS) alternatives.

Keywords: *100% Renewable Energy, Eurasia, Russia, energy system optimization, storage, grid integration, Economic Analysis.*

1. Introduction

Installation of distributed small-scale and centralized PV plants is already profitable in numerous regions in the word and PV electricity generation cost tends to decrease further (Breyer and Gerlach, 2013; Vartiainen et al., 2015). However, the share of PV generation is bound by the need to install storage systems in order to reach a high PV share of more than about 30% in total energy supply. Interconnection of various regions with different demand and renewable energy (RE) resource profiles can decrease the need for storage solutions and increase the reliability of the RE-based system for reaching a 100% RE supply in the very end. A cost competitive 100% RE system can be reached in case of optimal design and wise utilization of all available RE resources in order to reach maximum synergy between various resources and different regions.

The idea of a global Super Grid for power supply was already discussed some years ago (Komoto et al., 2009) and again recently (State Grid Corporation of China, 2015), but attracted new attention by the Gobitec and North-East Asian Super Grid initiative, which considers the eastern parts of Eurasia as part of the North-East Asian Super Grid (Mano et al., 2014; Komoto et al., 2009; Taggart et al., 2012; Song, 2012; Song, 2014; Komoto et al., 2013; Breyer et al., 2015), influenced by the EU-MENA Desertec (Dii, 2012; Knies, 2009). Bridging technologies such as power-to-heat and heat storage (Böttger et al., 2014) will convert electricity generation losses and electricity curtailment to valuable heat for residential and industrial needs. Power-to-water in the form of seawater reverse osmosis (SWRO) desalination starts to play a major role for the clean water targets. Power-to-Gas (PtG) technology based on water electrolysis, CO_2 from air, and methanation reactors will provide 100% renewable synthetic natural gas supply for chemicals, fertilizers, other industries, transportation and other non-power sectors (Sterner, 2009; Agora Energiewende, 2014a). All these technologies and high renewable energy potentials of Eurasia makes the installation of a RE-based system in the region possible. However, a cost competitive 100% RE system can be reached in case of optimal design and wise utilization of all available RE resources in order to reach a maximum synergy between various resources, different regions and the integration of energy sectors. Design of optimal energy system is the main

doi:10.18086/swc.2015.06.01 Available at http://proceedings.ises.org

aim of this paper.

2. Methodology

In order to define a cost optimal 100% RE system we have created a model based on linear optimization of energy system parameters under given constrains. The energy system model includes various power generation and storage technologies, as well as water desalination and synthetic gas generation sectors, which operate as flexible demand.

2.1 Model overview

The energy system optimization model is based on a linear optimization of the system parameters under a set of applied constraints with the assumption of a perfect foresight of RE power generation and power demand. A multi-node approach enables the description of any desired configuration of sub-regions and power transmission interconnections, i.e. not all the sub-regions have to be interconnected, but a grid configuration can be defined in scenario assumptions or can be chosen close to an existing grid configuration. The main constraint for the optimization is the matching of the demand and generation of every sector for every hour of the applied year. The hourly resolution of the model significantly increases the computation time; however, it guarantees that for every hour of the year the total generation within a sub-region covers the local demand from all the sectors and enables a more precise system description including synergy effects of different system components for the power system balance.

The target of the system optimization is the minimization of the total annual cost of the system including the power sector and additional flexible electricity demand sectors (water desalination and gas synthesis sectors). System cost is calculated as the sum of the annual costs of installed capacities of the different technologies, costs of energy generation and generation ramping. The system also includes distributed generation and self-consumption of residential, commercial and industrial electricity consumers (prosumers) by installing respective capacities of rooftop PV systems and batteries. For these prosumers, the target function is minimal cost of consumed energy calculated as the sum of self-generation, annual cost and cost of electricity consumed from the grid, minus benefits from the sale of excess energy.

2.2 Input data

The model uses several types of input datasets and constraints:

- historical weather data for direct and diffuse solar irradiation, wind speed and precipitation amounts,
- historical daily water flow data in the major rivers and water reservoirs,
- synthetic geothermal energy potential data,
- synthetic load data for every sub-region,
- non-energy sector natural gas consumption for every sub-region,
- projected water desalination demand for every sub-region,
- technical characteristics of used energy generation, storage and transmission technologies, such as power yield, energy conversion efficiency, power losses in transmission lines and storage roundtrip efficiency,
- technical characteristics of used SWRO desalination,
- capital expenditures, operational expenditures and ramping costs for all technologies,
- electricity costs for residential, commercial and industrial consumers,
- limits for minimum and maximum installed capacity for all energy technologies,
- configuration of regions and interconnections.

The datasets for solar irradiation components, wind speed and precipitation are taken from NASA databases (Stackhouse and Whitlock, 2008; Stackhouse and Whitlock, 2009) and partly reprocessed by the German Aerospace Center (Gerlach et al., 2011; Stetter, 2012). The spatial resolution of the data is 0.45˚x0.45˚. The time resolution is hourly for wind speed and solar irradiation, and monthly for precipitation. The feed-in time series for fixed optimally tilted solar photovoltaic (PV) systems is computed in accordance to Gerlach et al. (2011), based on Huld et al. (2008) and for single-axis north-south oriented continuous horizontal tracking, on

Duffie and Beckmann (2013). The feed-in time series for wind power plants is computed in accordance to Gerlach et al. (2011) for standard 3 MW wind turbines (E-101) for hub height conditions of 150 meters (Enercon, 2014).

Geothermal data are evaluated based on existing information on the surface heat flow rate (IASPEI, 2015; AAPG, 2015) and surface ambient temperature for the year 2005 globally. For areas where surface heat flow data are not available, the extrapolation of existing heat flow data were performed. Based on that, temperature levels and available heat of the middle depth point of each 1 km thick layer, between depths of 1 km and 10 km (Chamorro et al., 2014a,b; Huenges, 2012) globally with 0.45˚x0.45˚ spatial resolution, are derived.

Water demand is calculated based on water consumption projections and future water stress (Luck et al., 2015). It is assumed that water stress greater than 50% shall be covered by seawater desalination. Transportation costs are also taken into account; calculations are described in Caldera et al. (2015). Industrial gas consumption is based on consumption and distribution data from central statistical database of the Federal State Statistics Service of Russia (2015), BP gas consumption data (BP, 2014) and IEA gas consumption projections to the year 2030 (IEA, 2014; IEA, 2013).The synthetic load data are based on public available hourly load data on a national level, e.g. for Japan but also European countries, and takes into account local data such as gross domestic product, population, temperature and power plant structure.

2.3 Applied technologies

The technologies applied in the Eurasian energy system optimization can be grouped into three main categories: conversion of RE resources into electricity, energy storage, and electricity transmission.

The technologies for converting RE resources into electricity applied in the model are ground-mounted (optimally tilted and single-axis north-south oriented horizontal continuous tracking) and rooftop solar PV systems, concentrating solar thermal power (CSP), wind onshore, hydro power (run-of-river and dams), biomass plants (solid biomass and biogas), waste-to-energy power plants and geothermal energy.

The energy storage technologies used in the model are battery storage, pumped hydro storage (PHS), adiabatic compressed air energy storage (A-CAES), thermal energy storage (TES) and power-to-gas (PtG) technology. PtG includes synthetic natural gas (SNG) synthesis technologies: water electrolysis, methanation, CO_2 scrubbing from air, gas storage, and both combined and open cycle gas turbines (CCGT, OCGT). SNG synthesis process technologies have to be operated in synchronization because of hydrogen and CO_2 storage absence. Additionally, there is a 48-hour biogas buffer storage and a part of the biogas can be upgraded to biomethane and injected to the gas storage.

The electricity transmission technologies are represented on two levels: power distribution and transmission within the sub-regions are assumed to be based on standard alternating current (AC) grids and inter-regional transmission grids are modelled on high voltage direct current (HVDC) technology. Power losses in the HVDC grids consist of two major components: length dependent electricity losses of the power lines and losses in the converter stations at the interconnection with the AC grid. The full model block diagram is presented in Figure 1.

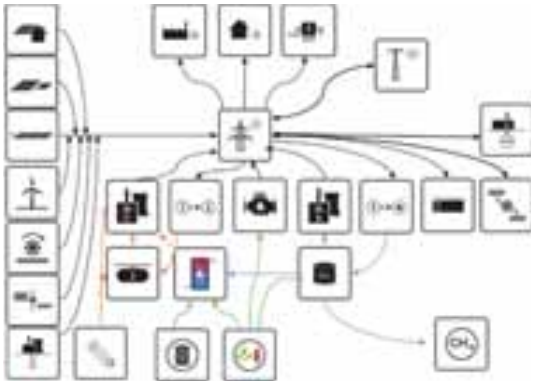

Fig. 1. Block diagram of the energy system model for Eurasia.

3. Scenario assumptions

3.1 Regions subdivision and grid structure

The Eurasian region is divided into 13 sub-regions. These are seven Federal Districts of Russia, Belarus, Kazakhstan, Uzbekistan, Turkmenistan, Caucasus regions including Armenia, Azerbaijan and Georgia, and Pamir including republics of Kirgizstan and Tajikistan. In this paper we discuss four scenarios of energy system development options:

- Region-wide energy systems, in which all the regions are independent (no HVDC grid interconnections) and the electricity demand has to be covered by the respective region's own generation;
- country-wide energy system, in which the regional energy systems are interconnected by HVDC grids within the borders of nations;
- area-wide energy system, in which the country-based energy systems are interconnected;
- integrated scenario: area-wide energy system with water desalination and industrial gas demand, in which the PtG technology is used not only as a storage option within the system, but also covering the industrial gas demand.

The Eurasian region's subdivision and grid configuration are presented in Figure 2. Structure of HVDC grid based on existing configuration of Integrated Power System (IPS) grid.

Fig.2. Eurasian sub-regions and HVDC transmission lines configuration.

3.2 Financial and technical assumptions

The model optimization is carried out on an assumed cost basis and technological status for the year 2030 and the overnight building approach. The investment cost (capex) and operation and maintenance (opex) numbers refer in general to a kW of electrical power, in case of water electrolysis to a kW of hydrogen thermal combustion energy, and for CO_2 scrubbing, methanation and gas storage to a kW of methane thermal combustion energy. Efficiencies of water electrolysis, CO_2 scrubbing and methanation refer to the higher heating value of hydrogen and methane, respectively. The financial assumptions for the energy system components including HVDC transmission lines for the 2030 reference year are provided in the Supplementary Material (Table I). The financial assumptions for storage systems refer to a kWh of electricity, and gas storage refers to a thermal kWh of methane at the lower heating value. Financial numbers for HVDC transmission lines and converter stations are given for the net transmission capacity (NTC). Assumptions are mainly taken from Pleßmann et al. (2014) but also other sources (Komoto et al., 2009; Hoffmann, 2014, Fraunhofer ISE, 2014; Urban et al., 2009; European Commission, 2014a). The technical assumptions concerning power to energy ratios for storage technologies, efficiency numbers for generation and storage technologies and power losses in HVDC power lines and converters are provided in the Supplementary Material (Tables II, III and IV, respectively). Electricity prices for residential, commercial and industrial consumers in Russia for the year 2030 are taken from Gerlach et al. (2014) and applied for all other regions. Prices are provided in the Supplementary Material (in Table V). Excess generation, which cannot be self-consumed by the prosumers, is assumed to be fed into the grid for a transfer price of 2 €cents/kWh. Prosumers cannot sell to the grid more power than their own annual consumption.

3.3 Feed-in for solar and wind energy

The feed-in profiles for solar CSP, optimally tilted, single-axis tracking PV and wind energy are calculated based on NASA data on direct and diffuse solar irradiation, wind speed, temperature and surface roughness for the year 2005 reprocessed by the German Aerospace Center. The assumed wind power plants consist of 3 MW wind turbines at 150 meters hub height. The dataset is used in a 0.45˚x0.45˚ spatial and hourly temporal resolution for the real weather conditions of the year 2005. Feed-in full load hours for sub-regions are computed on the basis of the 0.45˚x0.45˚ spatially resolved single sub-area data using a weighted average formula. The sub-regions' numbers are calculated using the rule: 0%-10% best sub-areas of a region are weighted by 0.3, 10%-20% best sub-areas of a region are weighted by 0.3, 20%-30% best sub-areas of a region are weighted by 0.2, 30%-40% best sub-areas of a region are weighted by 0.1 and 40%-50% best sub-areas of a region are weighted by 0.1. The computed average full load hours for CSP, optimally tilted, single-axis tracking PV systems and wind power plants are provided in the Supplementary Material (Table VI).

The aggregated profiles of solar PV generation (optimally tilted, single-axis tracking), CSP solar field and wind energy power generation, normalized to maximum capacity averaged for Eurasia, are presented in Figures 3.

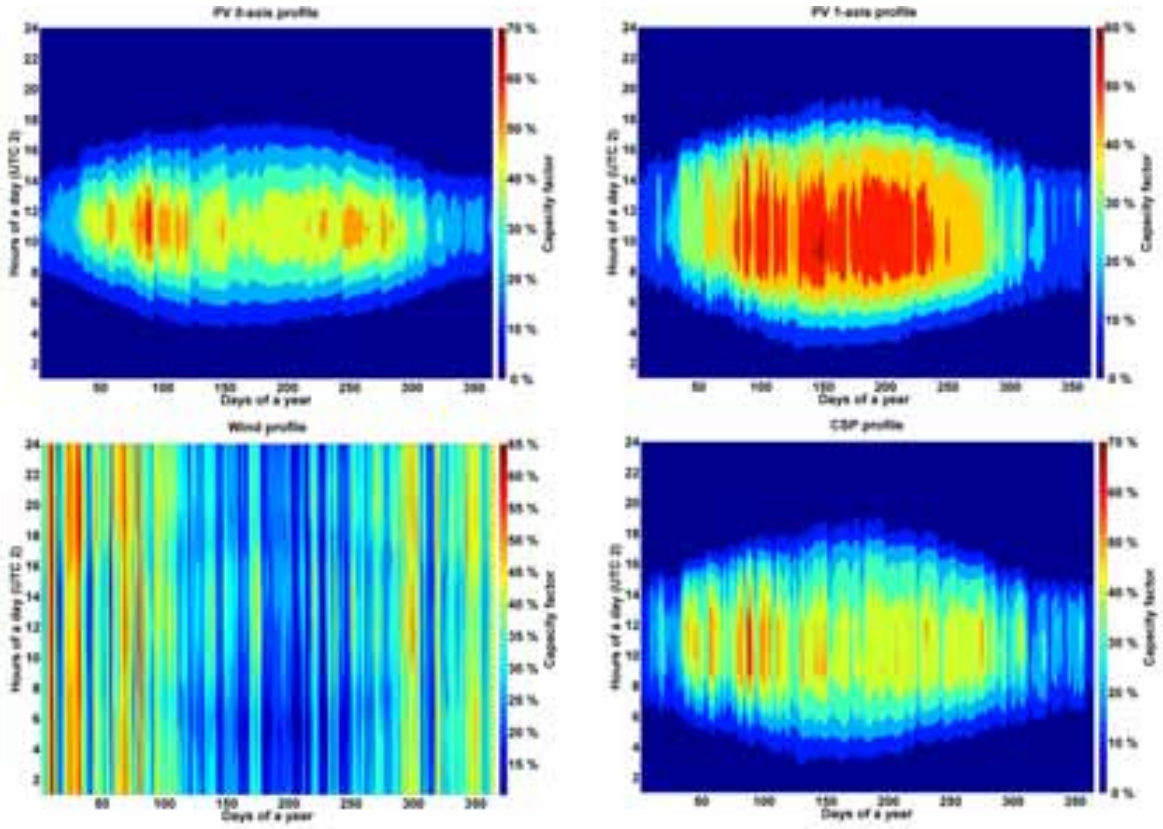

Fig.3. Aggregated feed-in profiles for optimally tilted PV (top left), single-axis tracking PV (top right), 3 MW 150 m hub height wind turbine (bottom left) and CSP solar field (bottom right).

3.3 Biomass and geothermal heat potentials

Biomass and waste resource potentials are mainly taken from DBFZ (2009). All bio-waste is divided in three components: solid waste, solid biomass and biogas sources. Solid waste is comprised of municipal and industrial used wood; solid biomass includes straw, wood and coconut residues; biogas sources are excrements, municipal bio-waste and bagasse. Costs for biomass are calculated using data from the International Energy Agency (IEA, 2012) and Intergovernmental panel on climate change (IPCC, 2011). For municipal solid waste a 50 €/ton gate fee is assumed for waste incineration. Calculated solid biomass, biogas, solid waste and geothermal heat potentials are provided in the Supplementary Material (Table VII). Prices for biomass fuels are provided in the Supplementary Material (Table VIII), and price differences between countries are explained

by various waste and residue component shares.

Regional geothermal heat potentials are calculated based on spatial data for available heat, temperature and geothermal plants for depths from 1 km to 10 km. For each 0.45˚x0.45˚ area and depth, geothermal LCOE is calculated and optimal well depth is determined. It is assumed that only 25% of available heat will be utilised as an upper resource limit. The total available heat for the region is calculated using the same weighed average formula as for solar and wind feed-in, except for the fact that areas with geothermal LCOE exceeding 100 €/MWh are excluded.

3.4 Upper and lower limitations on installed capacities

Lower and upper limits are applied to renewable energy sources (PV, wind onshore, and hydro power) and pumped hydro storage. For CSP, biomass, biogas, waste-to-energy power plants, gas turbines, battery and gas storage, and units of the power-to-gas process, the lower limit is set to zero. For lower limitations of PV systems, wind power plants, hydropower plants and PHS storage systems, data of existing installed capacities in Eurasian sub-regions have been taken mainly from the GlobalData (2015) database and the Platts (2012) database . Lower limits on already installed capacities in Eurasian sub-regions are provided in the Supplementary Material (Table IX).

Upper limits for CSP, PV systems (optimally tilted, single-axis tracking) and wind power plants are based on land use limitations and the density of capacity. The maximum area covered by solar systems is set to 6% of the total sub-regions' territories and for wind power plants to 4%, respectively. The capacity densities are 225 MW_{th}/km^2 for the CSP solar field, 75 MW/km^2 for PV systems (optimally tilted, single-axis tracking) and 8.4 MW/km^2 for wind onshore power plants. For hydro power plants and PHS storage, upper limits are set to 150% and 200% of already installed capacities by the end of 2013. All upper limits of installable capacities in Eurasian sub-regions are summarized in the Supplementary Material (Table X). For all other technologies, upper limits are not specified. However, for biomass residues, biogas and waste-to-energy plants it is assumed, due to energy efficiency reasons, that the available and specified amount of the fuel is used during the year.

3.5 Load

The demand profiles for sub-regions are computed as a fraction of the total country demand based on synthetic load data weighted by the sub-regions' populations. Figure 4 represents the area-aggregated demand of all sub-regions in Eurasia. Electricity demand increase by year 2030 is estimated using IEA data (IEA, 2014), numbers for Kazakhstan and Belarus are based on GlobalData assumptions (GlobalData, 2010; GlobalData, 2013).

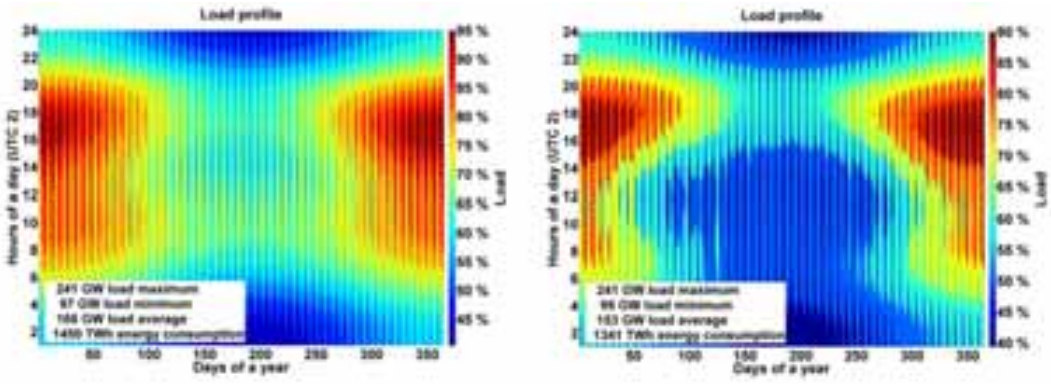

Fig. 4. Aggregated load curve (left) and system load curve with prosumers influence (right) for the year 2030.

Industrial gas demand values (gas demand excluding electricity generation and residential sectors) and desalinated water demand for Eurasia sub-regions are presented in the Supplementary Material (Table XI), gas demand values are based on the IEA data and the Federal State Statistics Service of Russia. Desalination demand numbers are based on water stress and water consumption projection.

4. Results

To analyze the cost structure of the different scenarios, a set of fundamental parameters are computed according to methodology described in Breyer et al. (2015).

4.1 Main findings on the optimized energy system structure and costs

For all scenarios optimized electrical energy system configurations are derived and characterized by optimized installed capacities of RE electricity generation, storage and transmission for every modelled technology, leading to respective hourly electricity generation, storage charging and discharging, electricity export, import and curtailment. The average financial results of the different scenarios for the total system (including PV self-consumption and the centralized system) are expressed as levelized cost of electricity (LCOE), levelized cost of electricity for primary generation (LCOE primary), levelized cost of curtailment (LCOC), levelized cost of storage (LCOS), levelized cost of transmission (LCOT), total annualized cost, total capital expenditures, total renewables capacity and total primary generation, as presented in Table I. Weighted average cost of capital (WACC) is set to 7% for all scenarios, but for residential PV self-consumption WACC is set to 4%.

From Table I it can be easily seen that the installation of HVDC transmission lines has a positive impact on the electricity cost and annual expenditures of the system; electricity cost of the entire system in the case of area-wide open trade power transmission decreases 6.0% and 14.6% compared to the country-wide and region-wide scenarios, respectively. Grid utilization decreases the primary energy conversion capacities and generation by 10.0% and 21.0% in terms of installed capacities and by 4.0% and 8.9% in terms of generated electricity in reference to country-wide and region-wide scenarios, respectively. Grid utilization leads to a significant decrease of storage utilization, whereas cost of transmission is relatively small in comparison to the decrease in primary generation and storage costs. Curtailment costs do not decrease as much as storage cost in the case of broader grid utilization; however, the impact of excess energy on total cost is rather low. The rather small difference between area-wide and country-wide scenarios can be explained by the dominant share of Russia in the total electricity demand.

The integration of water desalination and industrial gas synthesis sectors results in a further decrease in LCOE of 18.9% compared to the area-wide open trade scenario. This cost reduction is mainly explained by a reduction of storage cost by 82% due to additional flexibility provided by the gas synthesis and desalination sectors decreasing the need of storage utilization. Primary electricity generation cost decreased by 5.3%, mainly because of increased flexibility of the system. Flexible demand simplifies utilization of low-cost wind and solar electricity, and that leads to a decrease of flexible geothermal and biomass power plants capacities, as can be seen in Table II. For the case of biogas a substantial fraction is re-allocated from the electricity sector to the industrial gas demand for efficiency reasons. The share of hydro dam power plants does not change since flexibility provided by this source is still needed and the upper limit is reached for most of the regions, even interregional electricity trade decreases, which leads to a 40% fall in electricity transmission cost.

Whereas the total installed capacity of RE decreases with an increase of grid utilization, the installed capacity of wind turbines increases the more the energy system is interconnected and integrated. For Eurasia wind is the least cost RE source, thus wind energy imports displace a part of higher cost inland solar PV generation. Optimally tilted PV share is close to zero in almost all regions. However, for the region-wide and country-wide scenarios in the Caucasus region the installed capacity of optimally tilted PV exceeds single-axis tracking PV capacity and is 77.5% of total power system PV capacities in the region due to the less favorable solar irradiation conditions, which decrease the benefits of the single-axis tracking PV technology. Obviously, transmission lines decrease the need for energy storage options; installed capacities of batteries, PHS, A-CAES, heat storage, Power-to-Gas and gas turbines decrease with the grid expansion. PHS capacity stays the same for all scenarios and equal to lower limit of installation.

Table I: Financial results for the four scenarios applied in Eurasian regions.

	Total LCOE	LCOE primary	LCOC	LCOS	LCOT	Total ann. cost	Total CAPEX	RE capacities	Generated electricity
	[€/MWh]	[€/MWh]	[€/MWh]	[€/MWh]	[€/MWh]	[b€]	[b€]	[GW]	[TWh]

In the case of the region-wide open trade scenario, all sub-regions of Eurasia need to match their demand using only their own RE resources. In the case of the country-wide and area-wide open trade scenarios, a division of regions into net exporters and net importers can be observed. An annual import and export diagram for area-wide open trade is presented in Figure 5. Differences in generation and demand are mainly due to export and import, but in a minor quantity also due to storage losses, and for the area-wide integrated sector scenario (not shown in Fig. 5) due to energy consumption for SNG production. Figure 5 also gives a good overview on regions' RE resources; net exporters are sub-regions with the best renewable resources and net importers are sub-regions with moderate ones.

Fig. 5. Annual generation and demand diagrams for area-wide open trade scenario.

Figure 5 reveals the net exporter regions: North-West Russia and Pamir regions. Net importers are Central Russia and Belarus. Hourly resolved profiles for regional generation in Importer region (Central Russia), Balancing region (Kazakhstan) and Exporting region (North-West Russia) are presented in the Supplementary Material (Fig. 1, 2 and 3, respectively). For the integrated scenario a drastically increased electricity demand for the desalination and SNG producing sectors changes the picture dramatically; SNG producing regions tend to increase the intra-regional electricity generation to fulfill the increased demand.

PV self-consumption overview is given in the Supplementary Material (Table XII). Self-generation does not play a significant role due to low electricity price and covers only 37.3% of residential prosumers' demand, 30.7% and 31.8% of demand for commercial and industrial prosumers. An overview of installed capacities for the sub-regional energy system structures is presented for three different scenarios (region-wide, area-wide and integrated scenario) in Figure 6.

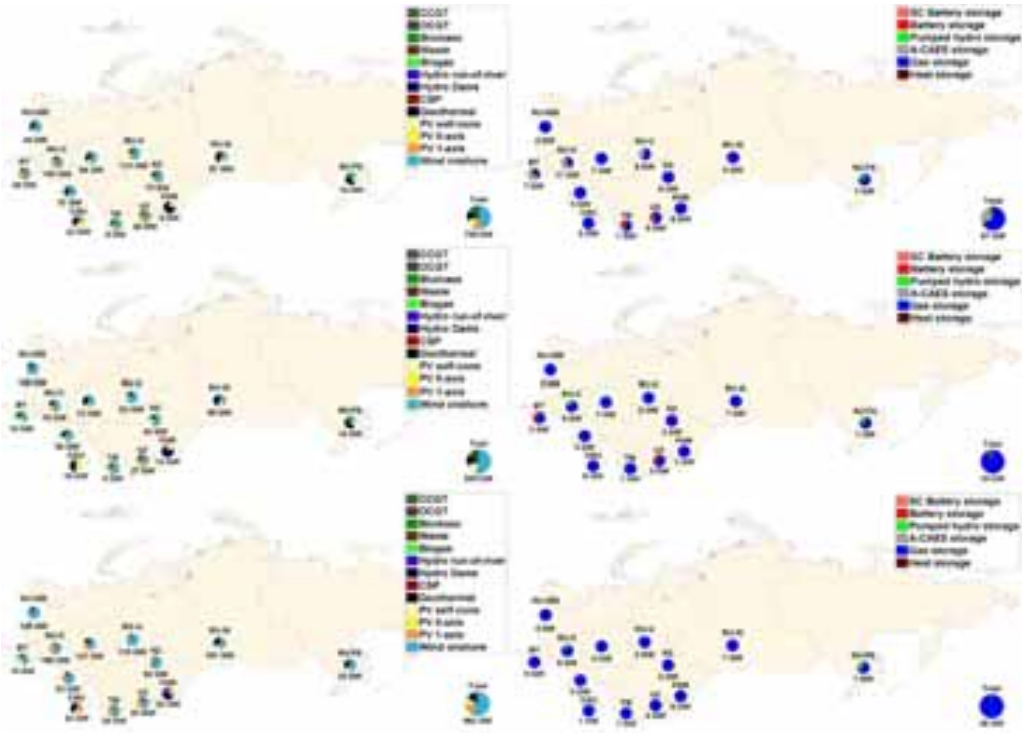

Fig. 6. Installed capacities of RE generation (left) and storages (right) for region-wide (top), area-wide (center) open trade and integrated (bottom) scenarios.

From Figure 6 we can see that in the case of region-wide open trade in the sub-regions of Belarus, Central

Russia and Caucasus, the solar PV capacities exceed 30% of all installed power capacities despite the fact that wind power FLH in these regions are better or comparable to PV FLH. Upper limit for wind is not reached as well, but optimal mix of capacities in these regions includes high share of PV. The interconnected HVDC transmission grid significantly decreases total installed capacities (Fig. 6 and Tab. II) and especially solar PV capacities, whereas installed capacities are increased in wind resource rich regions, such as North-West Russia.

For the integrated scenario the installed capacities of PV increase again because of a higher electricity demand and increased system flexibility. Additional demand in the case of a RE-based energy system can change the entire system structure because of shifting optimal cost structure parameters and areas being confronted with their upper resource limits.

The structure of HVDC power lines and utilized RE resources strongly influences the total storage capacity needed, but also interferes with the composition of different storage technologies for the energy system in the same area. Data of storage systems discharge capacities, annual energy throughput and full load cycles per year are summarized in the Supplementary Material (Table XIII). The generation capacities of storage technologies decrease with integrations of the HVDC grid. However, for the integrated scenario capacities of storage technologies increase in absolute numbers. State-of-charge profiles for the area-wide scenario for battery, PHS, A-CAES and Gas storages are provided in the Supplementary Material (Fig. 4)

The findings for the aggregated area integrated scenario can be summarized in an energy flow diagram comprised of the primary RE resource converters, the energy storage technologies and the HVDC transmission grid. The difference of primary power generation and final electricity demand is subdivided into potentially usable heat and ultimate system losses. Both are comprised of curtailed electricity, heat produced by biomass, biogas and waste-to-energy power plants, heat of transforming power-to-hydrogen in the electrolyzers, hydrogen-to-methane in methanation and methane-to-power in the gas turbines, and the efficiency loss in A-CAES, PHS, battery storage, as well as by the HVDC transmission grid. This energy flow for the integrated system is presented in Figure 7; diagrams for the region-wide and area-wide scenarios are presented in the Supplementary Material (Fig. 5).

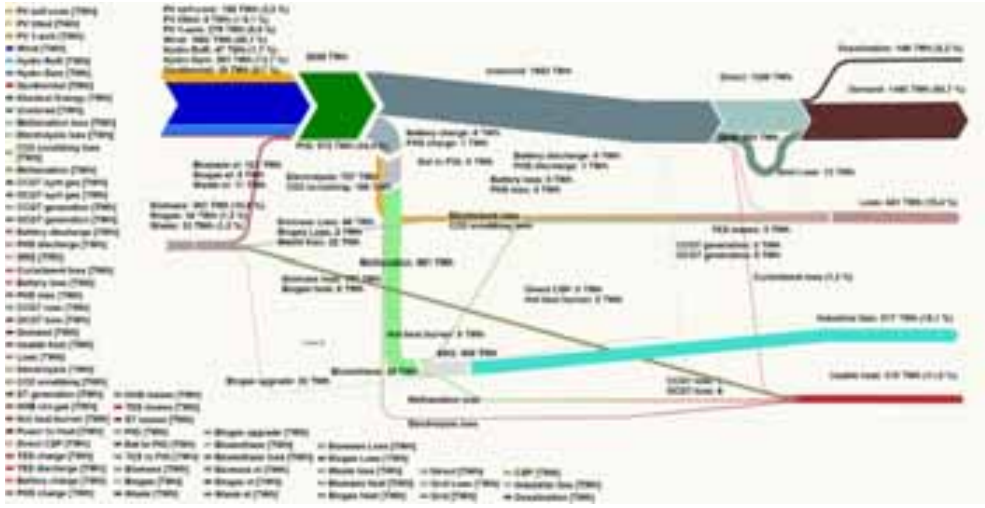

Fig. 7. Energy flow of the system for the integrated scenario.

The numeric values for LCOE components and the import/export share in all regions and scenarios are summarized in the Supplementary Material (Table XIV). The share of export is defined as the ratio of net exported electricity to the generated primary electricity of a sub-region and the share of import is defined as the ratio of imported electricity to the electricity demand. The area average is composed of sub-regions' values weighted by the electricity demand.

5. Discussion

The installation of a HVDC transmission grid enables a significant decrease in the cost of electricity in the RE-based system. The total levelized cost of electricity in the region decreased from 62.6 €/MWh for the region-wide open trade scenario to 56.8 €/MWh for the country-wide open trade scenario and 53.5 €/MWh for the area-wide open trade scenario. The total annualized cost of the system decreased from 91 b€ to 77 b€. In parallel the capex requirements are reduced from 837 b€ for the region-wide open trade to 758 b€ and 713 b€ for the country-wide and area-wide open trade scenarios, respectively. Additional costs of HVDC transmission lines (annual cost 5.6 b€, capex 61 b€ for area-wide scenario) are compensated by a substantial decrease in generation and storage capacities enabled by lower losses and costs of energy transmission compared to energy storage, and access to low cost electricity generation in other regions. In addition, the HVDC transmission grid enables additional benefits due to the large spatial east-west dimension of the Eurasian region.

PV self-consumption influences the power sector in an interesting way. The region-wide, country-wide and area-wide open trade scenarios are also calculated without PV self-consumption and the total demand is assumed to be covered by a more centralized system. The annualized costs for the more centralized 100% RE system is 1.7% lower for the region-wide scenario (89.5 b€ against 91 b€ base scenario), and 2.2% lower for the country-wide scenario, and 2.4% lower for the area-wide open trade scenario. PV self-consumption provokes additional costs because of a different target function of prosumers. Prosumers tend to reach their minimum annual cost of electricity consumption. The LCOE of PV self-consumption then must be lower than the grid electricity selling price, but can be higher than the total system LCOE. In addition to higher generation cost, prosumers' electricity generation provokes some positive and negative distortion in the system demand profile, i.e. the system reacts by installing more flexibility granting capacities, such as low cost RE or further storage capacities, which increases the system costs as well. The peak load in the system is not reduced due to the fact that peaks occurs in the winter time, when solar PV generation is negligible in the major parts of Eurasia, however the load gradients in the system are reduced from spring to autumn during daylight hours. For the region-wide scenario a comparable low cost increase due to the decentralized generation can be explained by the fact that additional disturbance cost in the system (provoked by prosumers) is compensated by access to low cost residential electricity (for residential consumers WACC is assumed to be 4%). Finally, PV self-consumption is in particular valuable in area constraint regions, since zero impact areas on rooftops can be utilized for local electricity generation, which in turn reduces the requirement of imports. This may be in some regions a policy option for reaching higher local value creation and less foreign policy risk, induced by higher electricity imports.

The fourth scenario, integration, represents the possibility to cover projected natural gas demand (except the gas demand for power generation and residential purposes), and clean water demand by SNG generation and SWRO desalination, respectively. In parallel with supplying demand, such an integration gives the system additional flexibility, especially for seasonal fluctuation compensation. The availability of RE in Eurasia is sufficient to cover additional electricity demand for producing 517 TWh_{th} (49 bcm) of SNG and 18.3 billion m^3 of clean water. Adding 1100 TWh_{el} for gas synthesis and SWRO desalination induces an additional installation of RE generation capacities of 150 GW of PV and about 260 GW of wind energy. As well, former long-term gas storage is partly substituted by short-term battery storage. Next, there is a significant increase in electrolyzer units of about 90 GW and substantially reduced gas turbines and biomass powered plants capacities.

The system generates excess heat as a byproduct of biogas and biomass CHP plants, waste-to-energy incinerators, gas turbines, electrolyzers and methanation units. In addition, there is excess electricity, which can be curtailed or converted to heat, stored in heat storage and used finally in the heat sector. The usable heat amount varies from 223 TWh_{th} per year for the area-wide scenario up to 301 TWh_{th} for the region-wide scenario. The waste heat from biomass and gas power plants is evenly distributed over the year. At the same time, excess electricity is generated mainly during the period from October to April, when heat is most valuable. Cooling demand is included in electricity demand numbers and therefore does not generate an additional demand. For the integrated scenario the amount of usable heat is even higher, at 315 TWh_{th}, due to higher curtailment, whereas the heat profile distribution is mainly the same. In total the integration benefit for the electricity, water and industrial gas sectors is estimated to be about 37.7 b€ of the annual system cost. There

are also decreases in the electricity demand by 355 TWh and the curtailed electricity by 46.6 TWh. These benefits account to 23%, 12% and 41%, respectively, compared to the non-integrated, separate systems. Further, the cost of clean water seems to be quite affordable at 1.49 €/m^3 and the cost of electricity decreases by 18.9% to 43 €/MWh for the integrated scenario compared to the area-wide open trade scenario without sector integration. However, the cost of synthetic gas, at 112.5 €/MWh, appears to be significantly higher than the current price.

The findings for the Eurasian 100% renewable resource-based energy system can be compared to recent insights in Europe about non-renewable options, such as nuclear energy, natural gas and coal carbon capture and storage (CCS) alternatives (Agora Energiewende, 2014). These alternatives could also lead to a low carbon energy system, which is of highest relevance for a climate change mitigation strategy. The LCOE of the alternatives are as follows (Agora Energiewende, 2014): 112 €/MWh for new nuclear (assumed for 2023 in the UK and Czech Republic), 112 €/MWh for gas CCS (assumed for 2019 in the UK) and 126 €/MWh for coal CCS (assumed for 2019 in the UK). However, a report published by the European Commission (European Commission, 2014b) concludes that CCS technology is not likely to be commercially available before the year 2030. The findings for Europe are assumed to be also valid for Eurasia in the mid-term. The 100% renewable resource-based energy system options for Eurasia presented in this work are considerably lower in cost (about 44 - 61%) than the higher risk options, which have still further disadvantages. These include nuclear melt-down risk, nuclear terrorism risk, unsolved nuclear waste disposal, remaining CO_2 emissions of power plants with CCS technology, a diminishing conventional energy resource base and high health cost due to heavy metal emissions of coal fired power plants. Dittmar (2012) also emphasizes the mentioned limitations on nuclear fission, but also points out that the financial and human research and development resources spent for nuclear fusion are no help either for the energy problems in the world and even worse these resources are not available for research of pathways towards a low cost energy future.

6. Conclusion

Existing RE technologies can generate enough energy to cover all electricity demand for the year 2030 on a significantly lower price level of 43 - 61 €/MWh_{el}, compared to non-renewable options, depending on geographical and sectoral integration. It is also possible to cover the gas demand of the industrial and transportation sectors with PtG technology, however for a gas price which is substantially higher than today. Heat generated as a byproduct of electricity, synthetic natural gas generation and curtailed electricity conversion can cover up to 300 TWh_{th} of heat demand. For the region-wide scenario PV plays the role of the main energy supply in some regions, however, with integration of the HVDC grid, the role of PV decreases in a first step, but it is increased again for a broader sectoral integration in a second step. The HVDC transmission grid plays a key role since the established Super Grid enables a significant cost decrease within the renewable resource-based energy system. The utilization of a HVDC transmission grid leads to a cut-off of storage utilization and significantly reduces primary generation capacities. At the same time, PV self-consumption induces a moderate increase of total electricity costs of 1.5 - 2.5%. This is due to the fact that consumers tend to utilize solar energy at a higher cost level and the excess electricity from prosumer generation provokes additional disturbances in the system. In turn, this increases the system need for flexibility.

For the integrated scenario it was found that industrial SNG generation displaces SNG storage as seasonal storage for the electricity sector. Instead of gas turbine utilization in case of an energy deficit, the system curtails the SNG generation in that system set-up as a major source of flexibility to the system.

More research is needed for a better understanding of a fully integrated renewable energy system in Eurasia. However, this research work clearly indicates that a 100% renewable resources-based energy system is a real low cost and low risk policy option.

Real-time Simulations of 15,000+ Distributed PV Arrays at Sub-Grid Level using the Regional PV Simulation System (RPSS)

Nicholas A. Engerer[1], James Hansard[2]

[1] The Fenner School of Environment and Society, The Australian National University (Australia)

[2] College of Engineering and Computer Science, The Australian National University

Abstract

The Regional PV Simulation System (RPSS), recently jointly developed by The Australian National University and National ICT Australia (NICTA), has been created to assist in the integration of high penetrations of small-scale, distributed solar PV energy systems. This system is capable of simulating many thousands of small-scale PV systems with input from only a small number (~1%) of the total installed fleet. This distributed solar PV simulation system is the first step towards delivering forecasts of their collective power output, and will serve as a very useful tool to electrical utilities and energy markets. Through cooperation with the local distribution network service provider, ActewAGL, the RPSS has been deployed in the Canberra, Australia region delivering real-time simulations of distributed PV power output as grouped by transformer. Canberra, the capital city of Australia, and has some of the highest penetrations of solar PV in the country, and has set a renewable energy target of 90% by 2020, making it a prime candidate for the application of these real-time simulations. Herein, the methodology used in this real-time version of the RPSS are presented, as well as a case study which highlights its usefulness under strong variability in distributed PV system power output.

Keywords: *Solar Energy, Distribution, Grid Integration, Simulation, Solar PV*

1. Introduction

As the number of distributed photovoltaic arrays installed worldwide continues to grow, so does the need for real-time simulations systems that are capable of assessing their impact on the electrical grids to which they connect. In the case of micro-generators, which are defined here as small-scale PV systems with rated capacities less than 100 kW, this is often extraordinarily challenging, due to the lack of information available about their instantaneous power output. In Australia, over 1.4 million individual systems have been installed, the vast majority of which are unmonitored, and therefore their interval-level contributions to the electrical grid are unknown. Their total installed PV capacity now exceeds 4.5 GW as of June 2015, with an average system size of 4.5 kW (APVI 2015). This represents substantial growth from only 41 kW of capacity at the start of 2009. As a result of this impressive uptake, 20% of Australian households now have a solar PV system installed at their residence (ABS 2014). Looking forward, the installed cost of PV is approximately $1.75/W for systems >10 kW, and thus continued strong uptake is anticipated, particularly in commercial site applications (APVI 2015). Moderate uptake scenarios from Australian solar analytics company SunWiz project installed distributed PV capacity to exceed 7 GW by 2020 (SunWiz 2015). For perspective, Australia's largest electricity market, the National Electricity Market (NEM), has a total large-scale generation capacity of approximately 50 GW.

What these statistics represent is that distributed small-scale solar installations represent a fast growing and increasingly robust energy generation source in Australia. Its penetrations of PV are among the highest in the world, with cost parity being reached throughout the continent (Chen and Franklin 2011). However,

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.06.02 Available at http://proceedings.ises.org

these developments place Australia on the forefront of the challenges associated with high-penetration distributed PV integration into the electricity grid. At the time of writing, Australian utilities had already begun to ban grid export or limit the total installed capacity permitted per individual system (Ergon Energy 2015, Horizon Power 2012). This represents a reactive, rather than proactive response to the intermittency challenges faced by distributed solar resources, which have been documented to induce intolerable voltage fluctuations within Australian distribution networks (Noone 2013).

One of the key barriers to increasing the penetrations of distributed PV in these areas is lack of information regarding the real-time power output of these distributed PV generators. Without this information, utilities will remain unable to impose mitigative solutions via emerging technologies such as distributed energy storage systems, because they will remain naïve on where and when large changes in solar power output will occur. This has necessitated the creation of a simulation system that is able to produce real-time estimates of the contributions of distributed PV systems to the electrical grid, entitled the Regional PV Simulation System (RPSS), whose initial version was developed in the doctoral thesis of the first author (Engerer 2015a).

The RPSS is a real-time capable, scalable, robust computational system that is capable of producing power output estimates from many thousands of distributed small-scale PV systems. This is accomplished through use of monitored PV system power output as the sole operational input, using the K_{PV} methodology of Engerer and Mills (2014). This methodology has been demonstrated to produce excellent results (Tan et. a. 2014; Engerer and Mills 2014; Engerer 2015b). The initial version of the RPSS was shown to produce accurate city-scale simulations across the Canberra region with active reporting from less than 1% of the total PV generators (Engerer 2015a). These simulations were generated for 12,000+ PV systems using suburb-level PV data provided by local distributor ActewAGL, and presented under several different strong collective ramp events.

A further iteration of the RPSS is the subject of this manuscript. Whereas, the previous system computed only aggregate estimates using suburb-level data, version 2 applies these same methods to simulation of 15,000+ micro-generators installed in Canberra, Australia, as organized by transformer (referred to interchangeably herein as a "node"). A beta version of this product will run in real-time from November 2015, with its official launch coinciding with the delivery of this manuscript. The remainder of this paper will detail its data sources and methodology, as well as explore a case study highlighting its usefulness.

2. Data

There are two primary sources of data used within this simulation system. Firstly, the local distribution network service provider, ActewAGL, has provided system information for 15,638 installed micro-generators. This includes the locations of each PV system, the nominal rated capacity and the node on which these systems are installed within ActewAGL's network. Together, these 15,000+ systems comprise 45 MW of distributed generation capacity. Secondly, five-minute interval PV system power output is now available from over 200 sites across Canberra, which are actively reporting on the webpage PVOutput.org in near real-time. These data are actively collected every five minutes by this simulation system through the PVOutput.org Application Programming Interface (API), before being quality controlled and ingested into the simulation system. PVOutput.org users also provide system meta-characteristics, including the module and inverter types, array system layout (e.g. numbers of modules, parallel strings) and the system tilt and azimuth. The collected data are processed through a quality control algorithm, which extracts the exact orientation of each array and removes any erroneous data (Engerer 2015b).

Fig. 1: PV systems in Canberra which are actively reporting their power output every five minutes to PVOutput.org, before being ingested into the Regional PV Simulation System. The black lines are the boundaries of Canberra suburbs

3. Methods

3.1. Modelling PV system characteristics

Given that only the rated capacity, suburb level location and node of each unmonitored PV system is provided, there is a built-in uncertainty in the simulation data. PV systems can have a wide-variety of azimuths and orientations, module and inverter types and system layouts. They are also subject to many different soiling and shading conditions. The lack of availability of the meta-characteristics data (or, rather, its lack of provision) necessitates that the azimuth, tilt and array layouts be selected statistically, requires that the system layouts be assigned randomly and means the de-ratings are simulated.

Before delving into the uncertainty issues at hand, it is worth noting that these issues will not necessarily be present in future modelling studies. Plans for these limitations to be removed in future versions of the RPSS are in place through continued cooperation from ActewAGL, and therefore it is completely possible to know these characteristics with certainty and remove these constraints on the modelling process.

3.1.1 PV system orientations

For the systems' orientation in space, the uncertainty was reduced significantly by sampling the PV systems installed throughout the Canberra region. This was accomplished through a partnership with SolarHub, a local solar installer, who provided extensive detail about 535 PV arrays that they installed in Canberra. Through this information, and that from an additional 74 unique locations gathered from PVOutput.org, it is possible to extract a distribution of tilts and azimuths that are common for Canberra rooftops, and use these as the basis for making assumptions about the remaining 15,000+ sites.

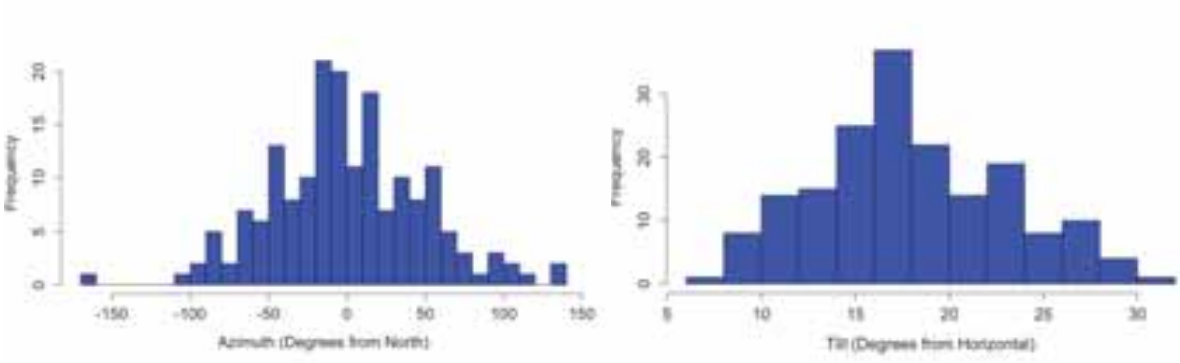

Fig. 2: Histogram of observed azimuths (left) and tilts (right) from over 600 Canberra homes

Figure 2 demonstrates a decidedly Gaussian distribution in the observed tilts and azimuths. This provides a solid statistical basis from which to model the azimuth and tilts of the remaining unmonitored PV systems. These data demonstrate a mean of 0.85° with a standard deviation of 48.5° for the azimuth and a mean of 18.3° and standard deviation of 4.9° for the tilts. From this, a Gaussian distribution of azimuths and tilts is modelled, from which the uncertain PV systems can be assigned an estimated pair of values through a probability weighted, random selection. This process allows for significant removal of uncertainty in system orientation from the modelling process.

3.1.2 PV system layouts

System layouts are more complicated, but are ameliorated indirectly through the limitations of the PV and inverter modelling software, and, again, through statistical sampling. The Sandia Performance and Inverter models are limited to databases of approximately 520 different PV modules and 460 inverter types, which cover a wide array of rated capacities. It is therefore possible, at this time, to simulate only modules that are present in these databases. The modules and inverters chosen from these databases in representation of each system were selected randomly with several constraints. First, only module combinations that were able to satisfy the reported rated capacity were permitted. This means, for example, a 1.4 kW array could not be simulated using 250 W modules, as no combination of 250W modules can create an array of 1.4 kW capacity. Second, from the possible combinations, a random solution was selected from a modelled Gaussian distribution based on the observed installed modules. This is to ensure that it is more likely to select 7 x 200 W modules to build the 1.4 kW array rather than to use 20 x 70 W modules, as the observed dataset has a mean module rating of 245 W and a standard deviation of 27 W. Inverters were chosen randomly from those whose ratings equalled or exceeded the installed capacity, but were limited to a doubling of the installed capacity.

3.1.3 PV system locations

Lastly, the locations of the PV systems were assigned randomly about each transformer node and constrained to lie within the reported suburb. Suburbs in Canberra have an average area of approximately 3 km^2, but can reach as large as 11 km^2 or as small as 0.4 km^2 in some cases. The suburbs of Canberra are outlined by the polygons in Figure 1 above. There will some sensitivity to this random assignment of site locations, particularly within the timing of ramp events, however, these issues have not been quantified, based on the rationale that this limitation will be removed once the exact locations of the installed systems are known as will be the case in future collaborative data provided by ActewAGL.

3.2. Application of the K_{PV} Methodology

The primary input data to the simulation system is the recorded power output from the sub-set of monitored PV systems within the modeled network. The power output from the monitored sub-set of PV systems can be used to simulate the performance of all the nearby PV systems on the modeled network via the clear-sky index for photovoltaics, K_{PV} (Engerer and Mills 2014):

$$K_{PV} = \frac{PV_{meas}}{PV_{clr}} \qquad \text{(eq. 1)}$$

where PV_{meas} is the reported power output and PV_{clr} is the simulated clear sky power output.

If two sites are close enough to one another (nearby), the KPV values between sites can be assumed to be equivalent. This means that the estimation of a nearby PV system's performance can be computed via:

$$PV_{est_2} = \frac{PV_{meas_1}}{PV_{clr_1}} \bullet PV_{clr_2} \quad \text{(eq. 2)}$$

where site 1 is the monitored site and site 2 is the nearby un-monitored site.

In order to apply this method at scale, each simulated system requires the computation of its clear-sky performance. These can be populated using the system level information provided by ActewAGL, following the clear sky simulation procedure outlined in Engerer and Mills (2014).

In order to estimate the power output of each simulated site, a K_{PV} value must be assigned based on the performance of nearby monitored systems. Rather than simply use a single nearby site, an average of the nearby K_{PV} values is used, computed using η closest sites.

$$PV_{est_2} = \frac{1}{\eta}\sum_{i=1}^{\eta} K_{PV_i} \bullet PV_{clr_2} \quad \text{(eq. 3)}$$

Where η is chosen on-the-fly, in a manner that maximizes the simulation accuracy. This is determined by using the sub-set of monitored sites to estimate one another at each time step, to determine which number of neighboring sites (η) minimizes the RMSE error.

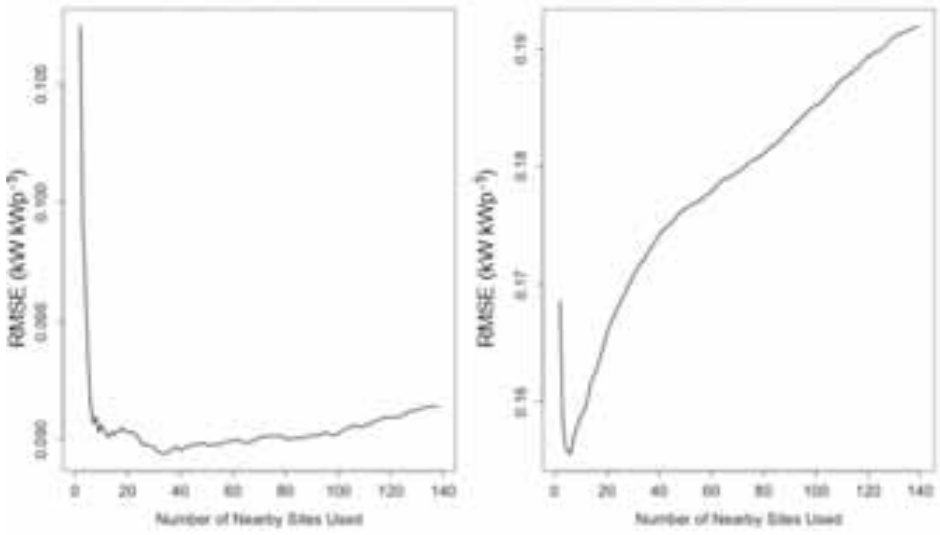

Fig. 3: RMSE values plotted against the number of neighbouring sites used in the K_{PV} based estimate. At left, an example from a clear sky day, at right, that from a partly cloudy day.

3.2.1 Simulated De-rating

An important step in the simulation process is the inclusion of de-rating from soiling, shading and other inefficiencies. These values are very difficult to quantify for non-monitored PV systems. Herein, the simulated behavior of the unmonitored sites will be based on the observed de-ratings of the monitored sites. This is based on the K_{PV90} calculation (Engerer 2015b), which is the running 90th percentile of K_{PV} from the past 30 days. Each unmonitored site is randomly assigned a K_{PV90} profile from one of the monitored sites for a given day. This allows for de-rating to be partially accounted for. At the time of writing, there is not any available research on this topic in the literature, and thus how to simulate PV system de-rating at this scale is not presently well understood. Future research work extending from this manuscript will explore this topic through a sensitivity analysis, simulating many thousands of possible shading scenarios to better quantify these uncertainties

4. Result: Real-time Operations

Through combination of the above data sources and methodologies, city-wide simulations of distributed PV power output across Canberra can now be created in real-time. The result is a live, operational version of the RPSS, which is now hosted and displayed in real-time at http://rpss.info. This online system produces city-wide simulations of PV system power output, mapped to ActewAGL's distribution network by transformer. This result, made possible by an up-scaling of the K_{PV} methodology, represents a significant, unique and promising tool for scientific, engineering and operational purposes. For the first time, it is now possible to quantify the power production of unmonitored distributed PV assets in near real-time, as grouped by distribution asset. The usefulness of this tool can be demonstrated through the following case study, from a particularly high variability day from 5 March 2014.

3.1 Operational Example: 5 March 2014

The meteorological conditions of 5 March 2014 were dominated by passing convective cloud embedded in westerly wind flow, which consequently produced large solar variability throughout the daylight period. The day began with partly cloudy conditions that persisted through 10:00 AEDT. At this time, there was a brief, but significant clearing of cloud cover, with a corresponding 12 MW increase in collective power output over only 10 minutes. From 10:20 AEDT, a very rapid drop in collective power output is observed as a uniform, opaque cloud deck moved in from the southwest, resulting in a 16 MW fall in collective power output over the 60 minute period to 11:20 AEDT. During the period between 10:05 AEDT and 11:00 AEDT, the apparent leading edge of the cloud shadow can be observed within the simulation (Figure 4).

Here, three nodes with particularly high penetrations (>40%) have been selected and highlighted, in order to demonstrate the temporal separation in ramp events across the geographic region (Figures 4 and 5). Node 2498 experiences the negative ramp event first, followed by node 2440, which is part-way through the negative ramp event, as can be seen in the right hand image of Figure 4. Node 2078, however, still experiences relatively clear conditions at this time, and has not yet ramped down its power output. This separation in the timing of these negative ramp events can be observed more clearly in Figure 5, which displays a 20 minute difference between the negative ramp at node 2498 and 2078. Given the separation distance of 20 km this implies a cloud speed of approximately 16.5 m s^{-1} (60 km $h^{-1)}$. Additionally, a strong positive ramp follows at approximately 12:05 AEDT through 1:15 AEDT. Again, a sequential pattern is observed, with node 2498 reaching a peak first, followed by node 2440 and then 2078.

This transformer level breakdown is also useful for comparing the ramp rates experienced by these individual nodes to that experienced collectively across the network. Using the most extreme 10 minute negative ramp events for the 10:00 - 11:00 time period, the collective ramp rate across all sites was 0.03 kW kWp^{-1} min^{-1}, while the three nodes experienced ramp rates of 0.04 kW kWp^{-1} min^{-1}, 0.072 kW kWp^{-1} min^{-1} and 0.057 kW kWp^{-1} min^{-1}. So, perhaps unsurprisingly, the ramps experienced by individual nodes can be shown to be more extreme than that experience by the collective system. We expect that by tracking these types of events over time, the most extreme events can be characterised, and the distribution systems engineered to withstand them. Plausibly, this simulation system could also be used to test the theoretical limits of distribution networks, by adding additional simulated PV systems to transformer nodes under strong ramp events like this one until the variability exceeds the capability of the given transformer to respond.

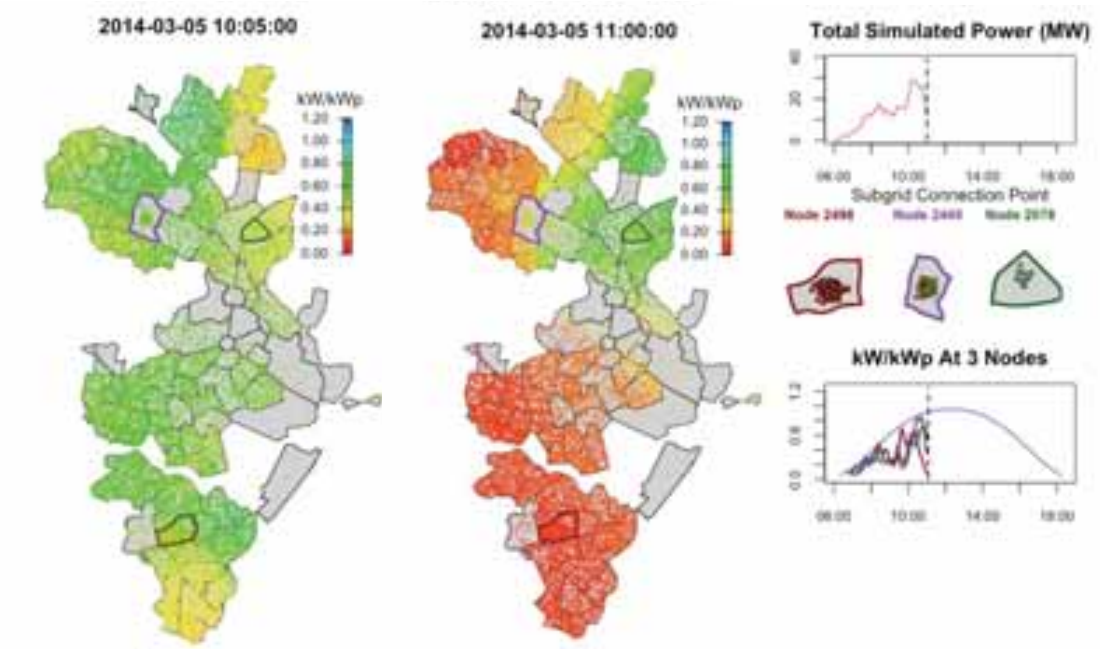

Fig. 4: These two images display the simulated power output from 15,000+ PV systems at two different times (10:05 and 11:00 AEDT) during a high variability day on 5 March 2014. Each point on the map represents a simulated PV system, with colour varying from red through to blue as power output (kW kW_p^{-1}) increases. Grey polygons display the boundaries of the major Canberra suburbs. At right, the power output is displayed as a time series, in both total power (MW) output and by three selected transformers (kW kW_p^{-1}). In the top time series plot, the blue line depicts the clear-sky curve for the collective output from all simulated PV systems. This simulation can be viewed online at bit.ly/ARENA_DNSPs.

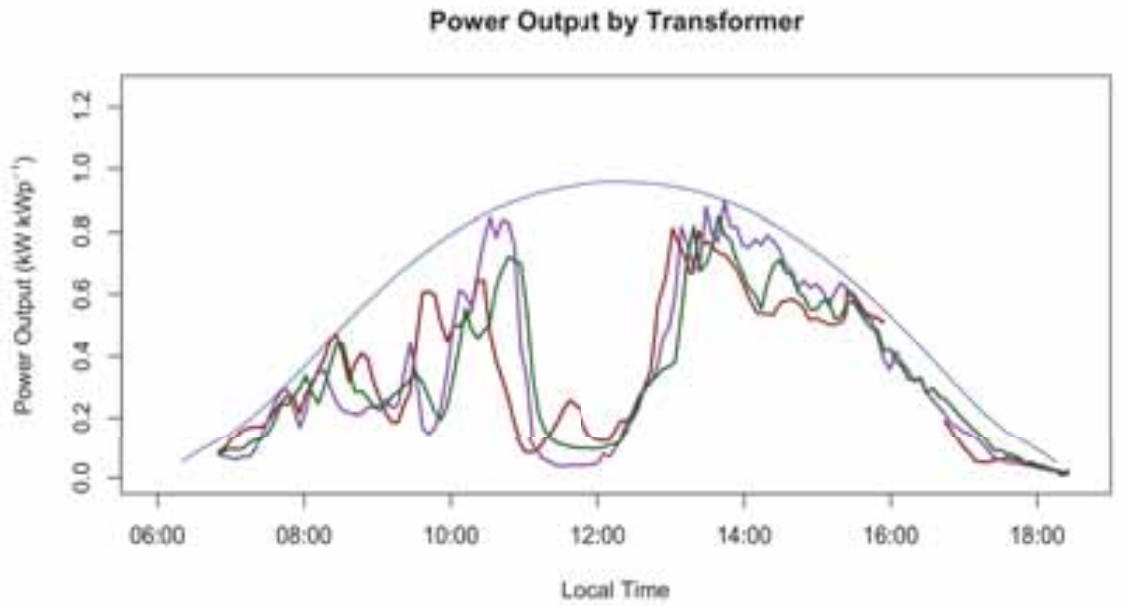

Fig. 5: The simulated power output (kW kW_p^{-1}) is presented for each of the three selected transformers (red 2498, purple 2440 and green 2078) during the high variability day of 5 March 2014.

5. Future Work

With the presented version of the RPSS in place, future efforts will work to increase the amount of monitored PV data ingested into the system, blend this surface data with satellite inputs and incorporate short-term forecasting methods to bring the system to true real-time status. Efforts are currently underway, which will double the current monitoring network, through deployment of tens of data-logging devices through funding from the Australian Renewable Energy Agency (ARENA), as well as to include data from inverter companies SMA and Fronius. Through these cooperative efforts, we expect to increase the total number of monitored sites in Canberra to 500-700 over the next two years. This will allow for more extensive validation of the present modeling methods.

Additionally, Australia has recently begun to receive 1 km^2 satellite data every 10 minutes from the new Himawari 8 satellite, which is a substantial improvement over the 4 km^2 hourly data from its predecessor. This will create the opportunity to develop model blending techniques which will be used to combine the K_{PV} and satellite derived irradiances, as well as cross-validate these two methods. Recent advances in solar PV analytics technology have even shown that PV systems can be used to extract the diffuse and beam components of radiation (Engerer and Xu 2015), raising the prospect of satellite derived irradiance validation or spatio-temporal analyses of solar radiation using large PV monitoring networks like the one being used by the RPSS.

Furthermore, this system, despite the inclusion of additional sites and the satellite data, will still only operate in near real-time, without the inclusion of short-term solar forecasting. This is due to the inherent time-lagged nature of the reporting data and the time taken to complete the modeling process and deliver the result. For this tool to truly provide proactive decision making capability, it must be incorporate short-term solar forecasting technologies. In the near future, we intend to apply the latest in short-term, distributed solar forecasting technology to this problem, thereby advancing the RPSS to true real-time operational status.

6. Conclusions

This version of the Regional PV Simulation System, which is now capable of simulating 15,000+ PV systems at transformer level in Canberra, Australia, is a unique and promising tool for distribution network service providers and energy markets in Australia. For the first time, the contributions of small-scale, monitored solar PV assets can be quantified for distribution networks, as organised by distribution asset. This information will be a key enabler for future scenarios that increase the allowable penetrations of solar PV via combinations of accurate distributed PV forecasting and energy storage technologies. With the information provided by this simulation system, distribution networks will no longer be naïve with respect to the real-time behaviour of their distributed PV assets, removing one of the most significant sources of uncertainty within Australian electrical grids. This tool, made possible through an up-scaling of the K_{PV} methodology, is now running in real-time, and can be located at http://rpss.info. Soon, this operational system will begin delivering near real-time information to local utility ActewAGL, with plans to incorporate short-term solar forecasting and high-resolution satellite imagery into its operations. Future work will aim to increase the accuracy and robustness of the modelling methods, with emphasis on increasing the number of ingested monitoring sites and blending surface based K_{PV} estimates with those based on satellite-derived irradiance.

PROTECTION OF ELECTRICAL DISTRIBUTION SYSTEMS BY SMART GRID, CONSIDERING SOLAR PHOTOVOLTAIC GENERATION

José Bione de Melo Filho[1] and José Aderaldo Lopes[2]

[1] Federal Institute of Education, Science and Technology of Pernambuco and University of Pernambuco

[2] Companhia Energética de Pernambuco, Recife (Brasil)

Abstract

According to resolution 482 of the Brazilian National Electric Energy Agency (ANEEL), connection of micro and mini generation directly on power distribution grids are now possible in Brazil, in both cases only from renewable sources. This resolution provides that each customer can have a photovoltaic system producing energy to complement the own consumption and can inject the excess energy in the power grid, establishing a power compensation cycle, with credits valid for some months (net metering). Massive connections of distributed micro and mini generation demands a centralized control and an intelligent management system that only will be possible with use of smart grid technologies, including telecommunications infrastructure, computing facilities, smart metering and advanced protection/automation. This paper presents an assessment of impacts on the protection in electrical power distribution systems when micro and mini generators are connected on grid, considering solar photovoltaic and smart grid concepts.

Keywords: Smart Grid, Protection Grid, PV connect on Grid, Solar Energy, Distributed Generation,

1. Introduction

Power generation by photovoltaic panels, is a widely used technology in Europe and the United States. The great motivation for use of this technology is the reduction of environmental impacts, as well as, the attractiveness of generation systems using distributed, low voltage, as shown in research carried out by Angelopoulos (2004) and Guan, et al. (2009) on the integration of distributed generation in low voltage circuits and their impact on power systems, analyzing power quality and the technical and economic feasibility of the connection.

As the resolution 482, it is possible to micro and mini connection generation distributed electricity from renewable sources, with the low voltage electrical grid. The publication of this resolution is a regulatory framework in Brazil. This resolution states that each client, whether residential, commercial or industrial, may have on the roof or other location of your unit consuming a photovoltaic central producing energy to complement the own consumption. The excess energy is injected into the grid and through the power compensation system used in the subsequent months, the consumer unit or other consumer property. So with the established regulations is underway in Brazil the development of a market with the implementation of various plants, micro and mini generation distributed in consumer units connected to electrical grids of distributors.

According Toledo et al. (2012), the massive connections of micro and mini generation distributed require a control and an intelligent management, which will be possible with the use of smart grid technologies, such as

doi:10.18086/swc.2015.06.03 Available at http://proceedings.ises.org

telecommunications infrastructure, computing, smart metering and protection and automation advanced. According to Toyama et al. (2010), the connection and protection of small generators to operate in parallel with the utility grid present some significant challenges, especially in relation to security and protection of persons and facilities. There are therefore a number of technical concerns about small connected generation systems, such as risks to grid security and other consumers, provided power quality, islanding, frequency variation, harmonic distortion, power factor and influence in action the grid protection systems. The departure from the standards set by rules and procedures characterizes an abnormal condition of operation, and the connection of protection to be able to identify this gap and isolate the systems ceasing the mains power supply.

Before the described scenario, this paper presents an assessment of impacts on the protection of electrical distribution systems by generation micro and mini connection, considering solar photovoltaic generation and smart grid concepts. Article make a contribution to consolidating the micro central connection and mini generation to the electrical distribution grid with reliability and safety of people and facilities, contributing important insights for consumers, equipment manufacturers, installers and electric utilities in Brazil. The article is a master's thesis summary developed / directed by the authors at the University of Pernambuco and Federal Institute of Pernambuco, Recife, Brazil.

2. Overview of smart grids in Brazil

In Brazil, the practical initiatives for implementation of smart grids (REI) are still timid, limited to a number of pilot projects. The implementation of motivation of smart grids in Brazil are: improving grid reliability, improved quality of supply, reduction of non-technical losses of energy, energy efficiency and renewable energy deployment. However, the regulatory framework is being prepared to receive the new technology in the distribution system. Several studies have been and are being conducted by government agencies and the private sector.

The research and development projects in the area of smart grids that are being carried out by partnerships between electric utilities, universities, research centers, laboratories and manufacturers have been important in assessing the performance and benefits resulting from the implantation of REI in Brazil. Including quotes to the strategic project and call cooperated No 011/2010, ANEEL, "Brazilian Program for Electric Smart Grid" which was proposed by CEMIG, with participation of other thirty-six companies and six research institutions, and the coordination of implementation carried out by the Institute of the Brazilian Association of Electricity Distributors (IABRADEE).

According to the Ministry of Science report, Technology and Innovation (MCTI) (2014) and according to data released by the Brazilian Agency for Industrial Development (ABDI) in partnership with the Owning Companies Association Institute for Infrastructure and Private Systems telecom (iAptel), in Brazil there are more than 200 ongoing projects on the KING theme. These initiatives involve about 450 institutions, covering more than 300 suppliers, 126 research centers and 60 concessionaires in the electricity sector, as well as ministries, regulatory agencies and universities. It is estimated that the amount of investments of these types of projects will reach R $ 1.6 billion considering initiatives in the generation, transmission and distribution.

Application of R & D resources in demonstration projects or pilots, ie projects that evaluate the concept of KING on the whole, has given up in the distribution segment, considering that is the most affected sector by the changes arising from the implementation of the REI. Among these projects, according to data from the first half of 2013, more than half of the investments made and planned the projects were part of the stage of the innovation chain: experimental development, showing the importance given by the concessionaires to real trials of the concept of REI.

Figure 1 shows eight of the main statements designs or REI pilots in Brazil. These projects make up an investment made / provided over R $ 200 million, according to 2013 data.

Fig. 1 - Main Projects of REI in Brazil

The first pilot projects have been conducted by Light and Cemig, being followed by others in the industry. Light within the Inova Energy program is developing an REI project with the installation of about one million smart meters, whose main objective is to reduce non-technical losses. So this is the first step to implement the large-scale project in Brazil smart grids.

3. Micro and Mini generation distributed in Brazil

In April 2012, the National Electric Energy Agency (ANEEL) published the resolution in 482 (2012), which establishes the general conditions for access of micro and mini generation distributed to power distribution systems in Brazil.

With the advent of this Resolution was revised module three (3) of the Electricity Distribution Procedures in the National Electricity System (ANEEL) (2013), introducing the section 3.7, guidelines for micro access and mini generation distributed where the requirements are indicated minimum required for generating central connection point. The proposed protection system must be assessed and studied, to identify whether its implementation ensures the sensitivity requirements, reliability and selectivity of the protection of the interconnected distribution system, utilities and micro or mini generation as well as the safety of installations and operating personnel and maintenance.

The resolution in the 482 states that distributed micro (Micro GD) are electric power generating plants, with lower installed power than or equal to 100kW, using sources based on hydropower, solar, wind, biomass or qualified cogeneration, connected to the distribution grid through plants consuming units (RU). Already distributed mini generation (Mini GD) are the power plants with the same characteristics, however, with installed power greater than 100kW and 1MW or less.

In order to enable the micro and mini generation, the resolution in the 482 also established the power compensation system (metering net), in which the surplus active energy injected into the grid, generated by consumer unit with micro or mini generation distributed, compensate the consumer active electricity. The implementation of micro power plants and photovoltaic solar mini generation provides the technical basis for developing the use of solar energy, and build skills to assess the technical and commercial arrangements of small distributed generation with grid-connected photovoltaic systems.

However, by injection directly into electric energy distribution systems, because of the existence of micro central and distributed minigeneration, these become active systems, may generate energy consumption and at the same time. As is the case for most distribution systems, these were not designed for two-way flow of energy, and, therefore, are likely to have problems with the growth of distributed generation.

According Thong, et al. (2005), the connection of distributed generation (DG) in distribution systems can impact various parameters of these systems, for example, power flow (which now becomes bidirectional), the voltage profile, voltage stability , current imbalances, protective systems and, finally, as a result of these changes, the quality of electricity.

The inclusion of micro and / or mini generation distributed impacts in many processes of a company that distributes electricity, for example: planning, operation, protection study, among others, thus presenting great challenges and requiring new techniques to optimize and operate these systems. According to Cabello and Pompermayer (2013), in Brazil, the legislation only allows access to the electrical system of the central distributors of micro and renewable mini generation and not allowed these plants operate in isolation, but in an integrated way, reason in which shall be automatic devices which prevent "islanding" ie when the automated system of micro and mini generation detecting a power failure from the grid should automatically disconnect and interrupt the supply of power from generation of the consumer unit to the grid distribution. Brazilian law also does not allow the direct sale of the energy generated, just compensation through credits, the slaughter of consumption. The production of electricity from solar photovoltaic systems today is among the generation of alternatives, the most viable technical and economically, to the core of micro and mini generation, as a direct result of the fall in the price of photovoltaic modules, good availability, speed and ease of installation.

It should be noted that the deployment, operation and maintenance of micro centers and distributed mini generation as well as their connection to the electrical systems of distributors must meet the requirements of standards and regulatory regulations issued by the competent bodies, since they dictate rules to be followed by those involved, party accessing (owner of consumer micro or mini generation) and accessed (electricity distribution), so that the interconnected micro or mini system generation x distributor to operate safely and reliably meeting all the technical requirements.

4. Assessment of Impacts on the Protection of Electrical Systems Distribution Micro Centers connection and Mini generation Solar Photovoltaic

This topic assess the impacts on the protection of electrical distribution systems of micro central connection and photovoltaic solar mini generation considering the security aspects and operation of facilities as well as the operation and maintenance personnel involved and the concepts of electrical smart grid.

4.1 Initial considerations

The increasing penetration of micro plants and mini generation brings new challenges for the planning, operation, maintenance, protection and control of electrical distribution systems. Currently, most electrical distribution systems in Brazil, operates radial configuration, that is, energy flows in one direction. The implementation of micro centers and distributed mini generation changes the system topology, passing the energy to flow in several directions, impacting the protection of electrical distribution systems. The current distribution protection systems use simple schemes based on switches and fuses, sectionalizers, reclosers line and substation, associated with overcurrent and automatic reclosing relays. These simple schemes may require adjustments and upgrades to support the connection of micro and minigeneration centers. According to the Institute of Electrical and Electronics Engineers (IEEE) (2004), advanced protection schemes that can adapt to changes in the distribution system configuration can be essential for distributed generation plants connection. They will depend on the data collection in strategic locations and communication of data between intelligent relays for distribution system protection, through the protection to be an integral part of the automation of distribution systems. Great micro central numbers and mini generation can bring problems of stability and frequency control, just a few issues that are relevant in the generation and transmission systems

become relevant also in the electric distribution system. However, new automation technology, protection, control, communication and information systems, applied to electrical distribution systems will bring many benefits to the operation, supervision and monitoring system, improving the quality of power supply to customers.

Next is to assess the impacts on the protection of electrical distribution systems micro central connection and photovoltaic solar minigeneration, using inverters to transform the direct current generated in PV modules into alternating current. It makes up the assessment comparing the distribution system with and without the central considering the topology, currently adopted by the distributors, specifically the Energy Company of Pernambuco (CELPE), distributor of electricity in the state of Pernambuco. For example, using distribution transformers with delta connection, in 13.8kV, the side of the distributor and grounded wye, 380 / 220V, the side of the consumer units (loads). All evaluations are carried out considering the distribution of figure 2 circuit, the data presented in Table 1.

Figure 2 shows the Jordan River substation Celpe 69 / 13.8kV-10 / 12,5MVA three feeders, be simulated in the feeder 2, the connection of a central microgeneration 71,91kWp and mini generation center 989, 82kWp. The central micro and mini generation were designed based on the maximum values adopted by CELPE (2013 and 2014) for micro connection and mini generation, based on the resolution at 482. The maximum values were chosen to simulate the extremes of micro connection and distributed mini generation.

For simulations we considered the central microgeneration 71,91kWp made up of eighteen (18) photovoltaic series in parallel, each series with seventeen (17) Solar modules from Bosch. The connection to the grid is performed by a three-phase central inverter with an output of 75kW. For simulations it considered the center of mini generation 989,82kWp formed by 234 (two hundred thirty-four) photovoltaic series in parallel, each set with 18 (eighteen) modules from Bosch Solar. The connection to the grid is performed by a three-phase central inverter with an output of 1000kW.

Tab. 1: The electrical distribution system data

Components of the Distribution System	Impedances (pu base of 100 MVA and voltage system)		
	Positive sequence (Z_1)	Negative sequence (Z_2)	Zero sequence (Z_0)
Equivalent system equivalente 69kV – SE Rio Jordão	0,0331+j0,1222 pu	0,0331+j0,1222 pu	0,0610+j0,5221 pu
Transformer 69/13,8kV -10/12,5MVA	j0,6716 pu	j0,6716 pu	j0,6716 pu
Transformer 13,8/0,38kV -1,0MVA	j7,5 pu	j7,5 pu	j7,5 pu
Transformador 13,8/0,38kV -0,15MVA	j23,33 pu	j23,33 pu	j23,33 pu
Cable 185mm^2 -AL	0,1107+j0,1359(pu/km)	0,1107+j0,1359(pu/km)	0,2041+j1,3623(pu/km)
Cable 70mm^2 -AL	0,2984+j0,1559(pu/km)	0,2984+j0,1559(pu/km)	0,3914+j1,4022(pu/km)

It is noteworthy that the distribution grid shown in Figure 4 has aluminum cable protected in the primary, and the trunk line in the 185mm2 section and the lead in the 70mm2 section. The secondary grid has aluminum multiplexed cable in the 120mm2 section.

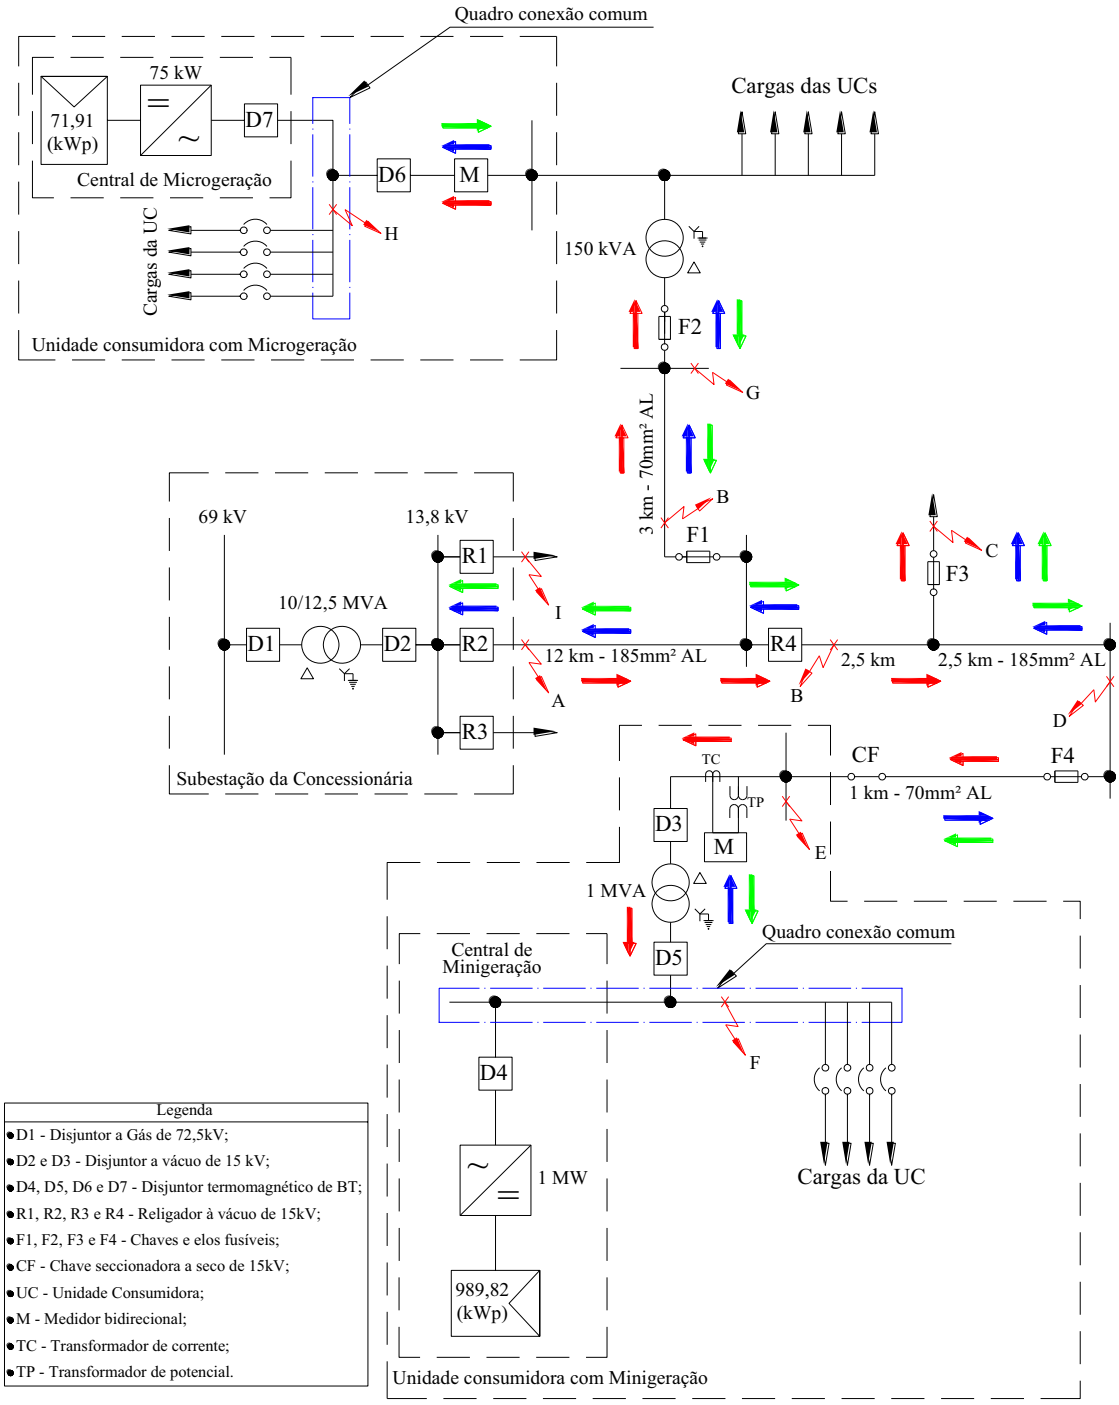

Fig. 2 - Distribution system - ways of short-circuit currents

4.2 Evaluation of short circuit of the electrical distribution system with connection of micro and mini generation.

When you have central micro and / or mini generators connected to the distribution gridsnetwork, their short-circuit levels have changes due to redistribution of possible fault current sources in the feeder. This change may cause undesirable effects in the operation and coordination of protection of the electrical distribution system, considering that proper coordination of relays, reclosers, fuses, sectionalizers is based on contribution to current lack of available sources that feed the defect. It is desirable to maintain a good coordination of relays, reclosers and fuses on the utility system with and without the core of micro and mini generation connected to the network.

According Sidhu and Bejmert (2012), the central micro and / or mini generation can be represented by a Norton equivalent circuit, where it has an ideal current source, a diode, and a resistor connected in parallel with the current source and resistor in series.

To calculate the short-circuit fault point of current, whereas the central micro and / or mini generation there is shown the system of distributing the Thevenin equivalent circuit at the point and the sources of micro and / or mini generation the equivalent circuit Norton and through the superposition theorem obtaining the total fault current.

For the circuit of Figure 2 were calculated short-circuit currents in given points, using the program: Analysis of simultaneous faults (ANAFAS) developed by Cepel. The ANAFAS is a interactive and friendly tool for analyzing faults in electrical systems, allowing the modeling system (prefault loading, representing the capacitance of the lines and loads, etc.) and the simulation of different types of defect that can be defined for compounds of simultaneous faults.

In Tables 2 and 3 show the results of simulation of a short circuit, three-phase, two-phase, open and single-phase single phase with 40Ω of contact resistance, showing the contributions of the Celpe system, Central micro and Central mini generation. It is noteworthy that the contributions of micro GD and mini GD were calculated considering that at the time of short circuit they are injecting all power on the network.

According Katiraei, et al. (2012), the central contribution of micro and / or mini generation to lack depends on the inverter design, and in most models can reach up to 120% of rated drive current. For the simulations presented considered for contribution of micro plants and mini generation this maximum value, é 120% of rated current of inverter 75kW and 1000kW.

The results shown in Tables 2 and 3 show that the contributions of the central micro GD and mini GD and for the current total short circuit, at various points of simulated faults when they occur in the medium voltage (13.8 kV) is very small and to zero if the defect is phase-ground due to the delta connection on the high side of the transformer Celpe and the high side of the transformer consuming unit mini GD, given that due to the transformer connection, there zero sequence component. The results also show that the system Celpe source of contributions are significant, especially when the short circuit is three-phase or two-phase and occurs in low voltage on the AC side.

It is noteworthy that in the medium voltage contributions of the central micro and / or mini generation for short circuits and three-phase two-phase currents are small due to the same are connected to the low voltage side; therefore, the values should be reflected for medium voltage using the transformer turns ratio, as shown in Table 2. To short-circuit the low voltage on the DC side of photovoltaic solar plant, do not have Celpe source contribution, given that the drive does not work as a rectifier.

Tab.2: Results of short circuit current, three-phase and two-phase

According to Sidhu and Béjart (2012), when the PV plant is well protected (overcurrent, overvoltage, anti ilhamento) their contribution to fault current is also limited in time. For this reason there is no problem with the coordination of protection when a high-powered photovoltaic power plant is connected to the distribution grid. However, the distributor of the operation should be careful when the photovoltaic penetration level is high; in this case it is recommended to conduct special studies for the feeder and some coordination with directional relays may be required.

When the short circuit occurs in the low voltage from the point of view of the concessionaire, independent of whether or not central micro and / or connected min Generation for the micro and / or mini generadores acessantes, it is recommended to check the suitability of the breaking capacity of their protective equipment, circuit breakers and fuses.

4.3 Evaluation of Micro and Mini generadores connection in relation to the Coordination and Selectivity Protection

The evaluation of micro central connection and mini generation, regarding the coordination and selectivity of protection of electrical distribution systems, is performed based on the circuit of Figure 2. It is considered that without the plants, the protection is set, serving the criteria established by the concessionaires, according to the settings in Table 4.

Tab. 4: Settings of protection devices

Substation or Grid/ Equipament	Voltage (kV)	RTC (A)	Phase Protection		Neutal Protection	
			Manufacturer and type	Setting	Manufacturer and type	Setting

Reclosing relays (79) and the fuses are set as follows:

- ✓ number of apertures (NA): 3;

- ✓ number of reclosing(NR): 2;
- ✓ intervals reclosing: 1o 7s e 2o 7s;
- ✓ time of reset: 120s
- ✓ fuse link F1: 40k
- ✓ fuse link F2: 8k
- ✓ fuse link F3: 50k
- ✓ fuse link F4: 80k

In Figure 2 the arrows in red color represents the Celpe substation contribution to short circuits and arrows in blue and green colors represent the contribution of the central mini generation and micro respectively. With the micro connection and / or distributed mini generation feeders, the values of short circuit currents considered fuse and recloser operation will be changed. Then, to the circuit of Figure 2 analyzes the coordination and selectivity of network protections for short circuit in the various points shown in the figure.

4.3.1 Short-circuit at point A or AB grid

In the short-circuit point A or AEB grid must be eliminated by R2 recloser, whose performance conditions do not change with micro central connection and mini generation. However, it has been contributing to the short circuit of micro and mini generation plants, until the R2 recloser open and plants are disconnected for lack of tension. Thus, one should assess whether the fuses F1 and F2 keys support the short-circuit current from Central micro and R4 recloser settings and the key fuse link F4 support the short-circuit current from the central mini generation, thereby avoiding the undue opening of these protection devices. By evaluating the values of short-circuits shown in Tables 2 and 3, and R4 recloser settings and the nominal values of links, it can be stated, for the example given, which does not have any problem, but for a greater amount of core It may need to make some adjustments in these protective devices.

4.3.2 Short-circuit at point B and BDE grid

Short circuits at point B, after R4 recloser or BDE network must be eliminated by R4 recloser, whose performance conditions do not change with micro central connection and mini generation and may even improve as short chain passing the R4 recloser is the sum of the Celpe contribution to the Central microgeneration. However, it has been contributing to the short circuit Central mini generation until the R4 recloser open and the center is disconnected for lack of tension. Thus, one should assess whether the F4 key fusible link supports the short-circuit current from the central mini generation, thereby avoiding the undue opening of these protection devices. Assessing the short-circuit values shown in Tables 2 and 3 and the nominal value of the bond, it can be said, for our example, there would be no problem, but for a larger number of plants can be necessary to make some adjustment in this protection device.

4.3.3 Short-circuit at point C

Short circuits in C must be disposed of by the key fusible link F3, so be selective with the R4 recloser, to test if the defects are temporary or permanent. With the connection of micro power plants and minigeneration has contributions from central to short circuits, however, while the micro central contribution through the R4 recloser contributing to improve the sensitivity of protection, the central contribution of minigeneration no more R4 in recloser, which may cause the selectivity between the fuse F3 key and R4 recloser is lost. With the connection of power stations, utilities must well evaluate the selectivity of the protections of extensions with fusible link and reclosers. Due to the small contribution minigeneration center for short, as shown in Tables 2 and 3, it can be stated, for the example given, which does not have any problem, but to a larger number of plants and to a system with low currents short circuits, rural feeders may be necessary to change settings of reclosers or replace the extension of fuses for seccionalizador or recloser.

4.3.4 Short-circuit at point B and BG grid

Short circuits at point B after the fuse F1 key or BG network must be eliminated by F1 recloser, so be selective with the R2 recloser, to test if the defects are temporary or permanent. With the connection of the central micro and mini generation has contributions from central to short circuits until the R2 recloser open and plants are disconnected for lack of tension. Thus, one should assess whether the F2 key fusible link supports short-circuit

current from Central micro and R4 recloser settings and the key fuse link F4 support the short-circuit current from Central mini generation, thereby avoiding the undue opening of these protection devices. The mini generation central contribution fails the recloser R2, which may cause the selectivity between the fuse F1 key and the recloser R2, is lost. As noted above, with the connection of power stations, utilities must well evaluate the selectivity between protections extensions with fusible link and reclosers. Due to the small contribution minigeneration center for short, as shown in Tables 2 and 3, it can be stated, for the example given, which does not have any problem, but to a larger number of plants and to a system with low currents short circuits, rural feeders may be necessary to change settings of reclosers or replace the extension of fuses for seccionalizador or recloser.

4.3.5 Short-circuit at point I

Short circuits in point they must be eliminated by the recloser R1, whose performance conditions do not change with micro central connection and minigeneration. However, it has been contributing to the short circuit of plants and micro minigeneration until the open recloser R1. In this situation, the central remain connected, because the short-circuit occurs in an adjacent tray. However, it has short-circuit current passing in the opposite direction R2 and R4 reclosers. Thus, one should assess whether the currents flowing in the opposite direction to normal load flow, by R2 and R4 are enough to make the protection work by turning off all or part of the load feeder 2, which characterizes lack of selectivity protection. To solve this problem you should use directional overcurrent relays in the protection of reclosers substations that have a high amount of core micro and minigeneration. It should be noted that the opening of R2 or R4, and stop the service consumers or cause undesirable ilhamentos hampers the fault location, increasing the time of the interruption and the cost of maintenance.

4.3.6 Short-circuit at point F and H

Short circuits in F and H points are defects that occur in consumer units, where the plants are installed, and must be eliminated by D6 and D7 Breakers to the central micro and D5 and D4 to the central minigeneration. For those short, the contribution of Celpe for short is added to the central contribution; therefore, should be assessed to the new situation the breaking capacities of circuit breakers remain adequate. The influence of the central contributions to the defect, circulating on the medium voltage grid.

5. Conclusion

In the assessments it was observed that the micro central connection and / or minigeneration in distribution system designed to feed the radially load may bring a number of problems with the coordination of the protective devices, because the actual distribution system It has several load leads over the circuits may have more than one protective device on the line between the substation and the central connection.

The example showed that for connecting small amount of core micro and / or mini generation the influence in protection systems is not significant, but for mass connection, the protection system of distribution and transformer feeders should be well assessed through coordination studies of protection. Micro connections and / or distributed mini generation should take the utilities to make adjustments in the distribution protection systems, so that system performance is not reduced, which will probably lead to the implementation of smart grid technologies.

The assessments also show that the addition of plants and micro mini generation distributed to a distribution system has the potential to impact protection and beyond the point of common coupling. The greatest concern are the effects on the protection systems traditionally designed for radial operation. Among the issues that must be considered has two-way flows, increased fault levels, safety, voltage control, equipment capacity, automatic restart, islanding and coordination and selectivity. These effects are not limited to grids in which the control panel is connected, and can affect the relay protection in adjacent grids as well. Thus, careful studies to identify and solve these problems are needed whenever a plant is added in order to ensure continued safe and reliable operation of the system.

The implementation of smart grid technologies that enable communication between protection devices, enabling the control and supervision of the interconnected utility system with the center of the party accessing,

enabling direct disarm distributor breaker Central micro or mini generation, will bring greater reliability and security for system operation and maintenance.

Abstract

Hybrid renewable energy utilization in residential and commercial building become an important issue in the world. IEA policy on renewable heat says that expanding the use of modern biomass, geothermal energy, solar energy and ambient energy to produce heat and power could contribute substantially to meet energy security objectives and mitigate climate change. Based on that background, in this study, two different renewable energy systems, which are photovoltaic/thermal (PVT) and ground source heat pump (GSHP) were combined together to produce heating, cooling and electricity simultaneously so-called tri-generation. This hybrid technology has been introduced and analyzed in terms of energy savings compared to the conventional system which uses a boiler and chiller to produce heating, cooling and electricity from the grid. For one house and one office, conventional system consumed 276.7kWh/m2-yr of energy and the combination of three renewable energy systems save the primary energy up to 97.9kWh/m2-yr or 35.4% energy reduction. An impact of Advance control system by using artificial neural network and fuzzy logic control system will be explained and analyze in order to achieve better energy savings. By these two techniques, it showed that for one single residential house, 11%-36% primary energy reduction by using ANN and 11%-23% primary energy reduction by using Fuzzy Logic control could be achieved.

Keywords: *artificial control system, ground source heat pump, photovoltaic/thermal, renewable energy, Trigeneration.*

1. Introduction

The urge of renewable energy utilization in the world become higher and higher as the new policy scenario of energy in the world published. The share of renewables in primary energy use in the New Policies Scenario rises to 18% in 2035, from 13% in 2011. This resulting from the rapidly increasing demand for modern renewables to generate power, produce heat and make transport fuels based on world energy outlook 2013[1]. Power generation from renewables increases by over 7000 TWh from 2011 to 2035, making up almost half of increase in total generation. Renewables become second-largest source of electricity before 2015 and approach coal as the primary source by 2035, with continued growth of hydropower and bioenergy, plus rapid expansion of wind and solar PV as shown in Fig.1.

doi:10.18086/swc.2015.06.04 Available at http://proceedings.ises.org

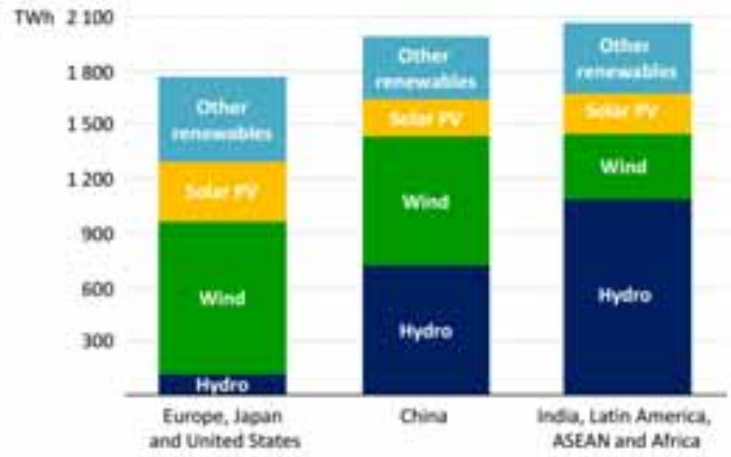

Fig. 1 Growth in electricity production from renewable sources 2011-2035[2]

Based on those background, utilization of renewable energy technologies will be explained not only one source of renewable energy but combination of two renewable energies will be covered and the impact of the advance control system on energy saving. Combination of Photovoltaic/Thermal or known as PVT and Ground Source Heat Pump (GSHP) or Geothermal Heat Pump have been chosen as the system that will be covered in this paper. Photovoltaic/Thermal or PVT is a combination of photovoltaic (PV) and solar thermal components/system which produce both electricity and heat from one integrated component system [3]. Typically, commercially available PV modules are only able to convert 6-18% of the incident radiation falling on them into electricity, with the remainder lost by reflection or as heat [4]. One of the characteristics of photovoltaic is that as the surface temperature of the panel goes up, the efficiency of the system itself decreasing [5]. Ground Source Heat Pump (GSHP) is one of the promising technologies for space heating and cooling applications A GSHP extracts heat energy stored below the ground during the winter for heating applications. As the ground temperature at which heat is absorbed is higher than the ambient temperature, the coefficient of performance of GSHP becomes higher than the system that would operate directly taking heat from the ambient which very low during winter [6]. As what have mentioned before, an impact of advance control system such as Artificial Neural Network and Fuzzy Logic will be analyzed here. Fuzzy logic is a logical system, which is an extension of multivalued logic. However, in a wider sense, fuzzy logic (FL) is almost synonymous with the theory of fuzzy sets, a theory that relates to classes to objects with unsharp boundaries in which membership is a matter of degree. On the other hand, ANN is a type of artificial intelligence that mimics the behavior of human brain and is famous for its robustness due to the use of a generalization technique instead of memorization. By using these two artificial intelligence control, an improvement in energy saving can be achieved. These two intelligence control were chosen because of their capability to deal with lots of dynamic variable of the systems.

2. System Modeling

Two renewable energy system was chosen as the subject of this study which is the combination of the PVT and GSHP system for the single residential house of 200m2 as its described on Fig. 2 and it's component on Table 1:

Table 1 Main Component of PVT-GSHP system

#	1	2	3	4	5	6	7	8	9	10

Quantity	n/m	n+m	1	1	1	1	1	1	1	1

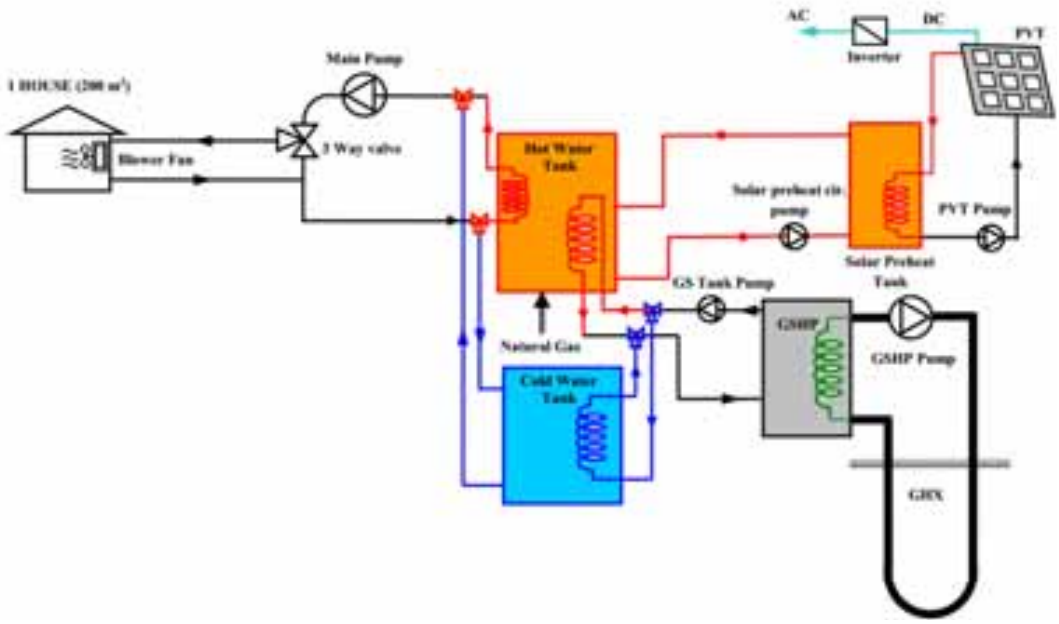

Fig.2 Schematic Diagram of PVT-GSHP system

GHSP system and PVT module that used on the simulation are based on the TRNSYS 17 library. Ground heat exchanger was modelled as a vertical, single U-tube heat exchanger that interacts thermally with the ground. Type 557 ground heat exchanger model was considered to be the state-of-the-art in dynamic simulation of ground heat exchanger and is most commonly used in ground heat exchanger application. It is a water-to water heat pump with 5 ton rated heating capacity and 2.5 ton rated cooling capacity. For the PVT part, TRNSYS17 provides three major model in the library which are Type 50, Type 555 and type 56(mode). All the models are largely theoretical based. These TRNSYS PVT models were reviewed under IEA, Solar Heating and Cooling Program, Task 35. The electrical output for PVT is 295W and the thermal output is 1.5kW

The simulation models were run in Incheon, South Korea weather data over a year to simulate and analyze the energy system's performance while satisfying the building heating and cooling demands. The control and management of microgeneration systems is very important for their optimal operation. Simple On-Off control strategy is often used, but its major disadvantage is not being able to allow part load operation of devices. The efficient operation of the microgeneration systems, especially for single dwellings, has the following attributes: nonlinear behavior uncertainties of electrical and thermal demands; and vagueness of the performance of the microgeneration system. Due to these attributes, an intelligent approach is required. Fuzzy Logic (FL) control approach was chosen because FL linguistic rules can simplify the control of the PVT-GHSP system given its complexity. MATLAB Fuzzy Logic Toolbox was used for the implementation of the FL controller and then integrated to the system models. Also another advance control system called Artificial Neural Network (ANN) will be implemented on this systems. Comparative study was conducted to see the impact of the artificial intelligence control to the possibility energy and cost savings compare to the conventional On-Off strategy.

3. METHODOLOGY

Two artificial control system were introduced (Fuzzy Logic and ANN). Fuzzy Logic system that applied on this study consist of two control strategies, FL for GSHP and FL for PVT.

The operation of the heat pump is controlled by two input variables: the storage tank temperature and the temperature difference between the actual room temperature and the thermostat set-point. The output of the fuzzy logic controller is the fractional state of operation of the ground source heat pump with a number ranging from 0 to 1 with 0 turning the device OFF and 1 representing full load operation. On the other side, the operation of PVT system is controlled by 2 input variables: the electrical demand and the temperature

difference between panel and the bottom of the tank. The fuzzy logic if-then rules for GSHP and PVT control signal are presented in Table 2 and Table 3 for heating and cooling period respectively. The rules are chosen intuitively based on the research team's experiences.

Table 2 If then rules for GSHP operational state

Electrical Demand	dTtank = Tpanel – Tbottom			
	Vlow	Low	Medium	High
L	Off	L	L	M
M	Off	L	M	H
H	Off	L	M	H

The control strategies using artificial neural network investigated in this study consist with 1 input layer with 11 inputs, 2 hidden layers with 20 neurons each and 1 output layer with 1 output as it described in Table 4. Matlab® Neural Network Toolbox was used to train and test the ANN models. The hyperbolic tangent sigmoid transfer function was used in the hidden layers and the linear transfer function was applied in the output layer because of the two-layer sigmoid/linear network usually can represent any functional relationship between inputs and outputs if the sigmoid later has enough neurons. The simulation was done for both heating and cooling season.

Table 4 ANN layers in PVT-GSHP system

1 Output	T_{room} (+3h)	T_{room} (+4h)	T_{room} (+5h)	T_{room} (+6h)
11 Inputs	Current ambient temperature			
	Ambient temperature 7.5 minutes before			
	Ambient temperature 3 hours later	Ambient temperature 4 hours later	Ambient temperature 5 hours later	Ambient temperature 6 hours later
	Current solar irradiance			
	Solar irradiance 7.5 minutes before			
	Solar irradiance 3 hours later	Solar irradiance 4 hours later	Solar irradiance 5 hours later	Solar irradiance 6 hours later
	Current internal gains			
	Internal gains 7.5 minutes before			
	Internal gains 3 hours later	Internal gains 4 hours later	Internal gains 5 hours later	Internal gains 6 hours later
	Current room temperature			
	Room temperature 7.5 minutes before			

The control algorithms were made based on the output variables on the ANN simulations for heating and cooling. 6 logics for heating and cooling were introduced in this control system as those can be seen in Table 5 and Table 6.

Table 5 ANN based control for heating period

Table 6 ANN based control for cooling period

		System components controlled by the ANNs based controller	Input variables used by the ANNs based controller	Condition to be satisfied	Output of ANN controller in case of the previous condition is satisfied
Cooling period	ANN_LOGIC C1	Blower Fan, Main Pump	$T_{coll}(+3h)$, $T_{coll}(+4h)$, $T_{coll}(+5h)$, $T_{coll}(+6h)$	At least 2 of $T_{coll}(+3h)$, $T_{coll}(+4h)$, $T_{coll}(+5h)$, $T_{coll}(+6h)$ lower than 20.5 °C	Blower Fan & Main Pump: OFF
	ANN_LOGIC C2	Blower Fan, Main Pump			
	ANN_LOGIC C3	Blower Fan, Main Pump, GSHP, GSHP Pump, GS Tank Pump	$T_{coll}(+3h)$, $T_{coll}(+4h)$, $T_{coll}(+5h)$, $T_{coll}(+6h)$, Cold Water Tank Temperature at levels 2 & 9	At least 1 of $T_{coll}(+3h)$, $T_{coll}(+4h)$, $T_{coll}(+5h)$, $T_{coll}(+6h)$ lower than 20.5 °C	Blower Fan & Main Pump: OFF; GSHP & GSHP Pump & GS Tank Pump: ON if T2≥15 °C, OFF if T9≤12 °C
	ANN_LOGIC C4		$T_{coll}(+3h)$, $T_{coll}(+4h)$, $T_{coll}(+5h)$, $T_{coll}(+6h)$		Blower Fan & Main Pump: OFF; GSHP & GSHP Pump & GS Tank Pump: OFF;
	ANN_LOGIC C5	Blower Fan, Main Pump, GSHP			Blower Fan & Main Pump: OFF; GSHP: operation at lower cooling capacity (1.5 ton)
	ANN_LOGIC C6	GSHP			GSHP: operation at lower cooling capacity (1.5 ton)

On-off control strategy of GSHP is controlled by an aquastat in hot water and cold-water tank for both heating and cooling season. PVT panels that are controlled by on-off strategy, use the temperature difference between tank top and hot water storage tank bottom as the control variable. Table 7 and Table 8 describe the control strategy of on-off control system:

Table 7 On-off control strategy for GSHP

GSHP		Aux. heater	
ON	OFF	ON	OFF
T2[a](HT[b]) ≤ 50 °C T9[a](CT[b]) ≥ 12 °C	T9[a] (HT[b]) ≥ 55 °C T9[a] (CT[b]) ≤ 8 °C	T2[a](HT[b]) ≤ 45 °C	T9[a](HT[b]) ≥ 55 °C

[a] T2, T5, T9 are the temperature sensors in tank node 2, 5 and 9 respectively. Each storage tank is divided into 10 isothermal nodes, 1 at the tank top and 10 at the tank bottom.
[b] HT: hot water storage tank; CT: cold water storage tank (when GSHP in cooling mode operation).

Table 8 On-off control strategy for PVT

PVT circulation pump		Solar preheat tank circulation pump	
ON	OFF	ON	OFF
$\Delta T^a \geq 10°C$	$\Delta T^a \leq 3°C$	$\Delta T^b \geq 7°C$	$\Delta T^b \leq 2°C$

[a] ΔT is the temperature difference between the PVT panel and solar preheat tank bottom.
[b] ΔT is the temperature difference between the solar preheat tank top and hot water storage tank bottom.

4. RESULT AND DISCUSSION

The impact of artificial intelligence, fuzzy logic control and ANN control system on PVT-GSHP are explained below:

The result of the usage of fuzzy logic compared to the on-off control system for PVT-GSHP can be seen in Fig.7 and Fig. 8:

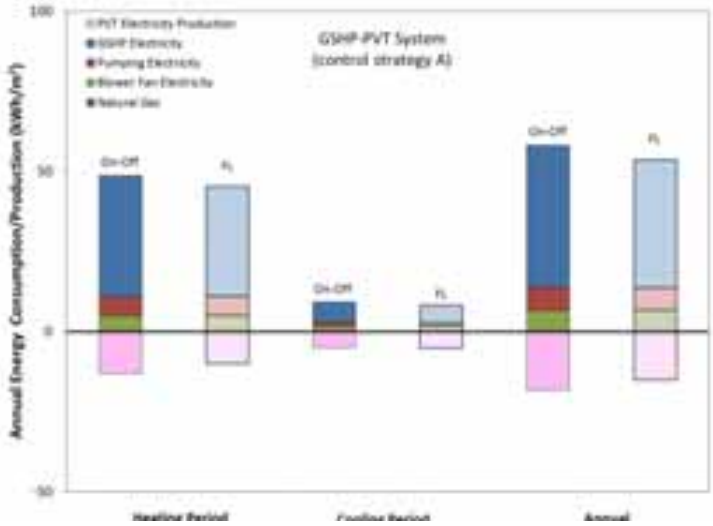

Fig. 7 (A) GSHP and PVT system with FL control

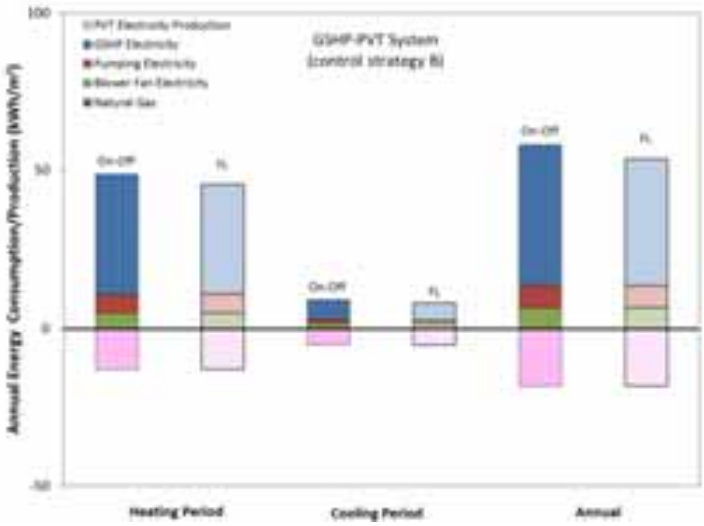

Fig. 8 (B) GSHP with FL control and PVT system with On-off control

The result shown in Fig. 7 and Fig. 8, indicate that the GSHP and blower fan electricity consumption are approximately the same and the pumping energy is slightly higher for the system with control strategy B. The main difference resulted from the two control for the PVT system resulted in higher electricity production, since all PVT panels are circulated with glycol fluid which reduces panel surface temperature and subsequently increases electric efficiency (production). Conversely, in the case of PVT system is controlled with FL strategy (strategy A), a fraction of total installed PVT panels is circulated with fluid to provide thermal energy depending on solar pre-heat tank temperature and electric demand. This causes the panel surface temperature and subsequently increases for PVT panels without circulation fluid and

consequently reduces electric efficiency and overall electricity production.

In Artificial Neural Network Part, TRNSYS software is used for the system models development and the MATLAB® Neural Networks Toolbox is used for the implementation of the ANN controllers. The result shows that control logic H4, H5, C4 and C5 shows the best energy saving compared to the on-off control system among all the other control logic strategies. Fig. 9 shows the result of ANN control on PVT-GSHP system.

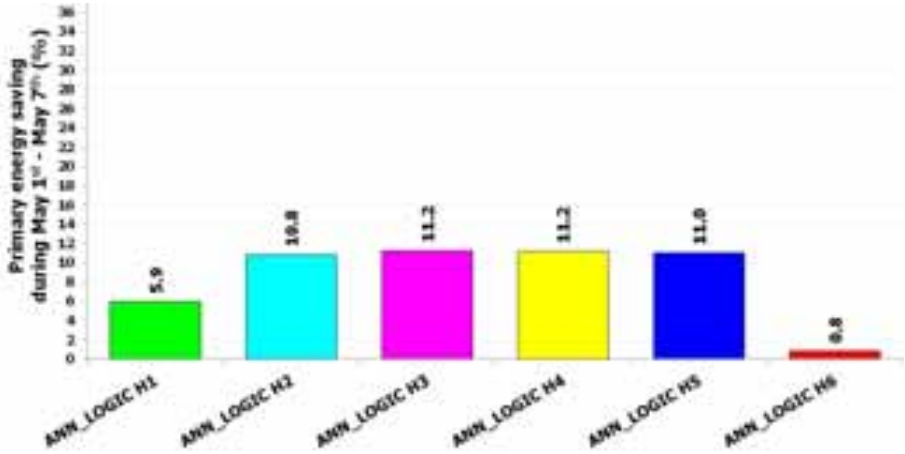

Fig. 9 Primary energy saving on ANN control during heating season

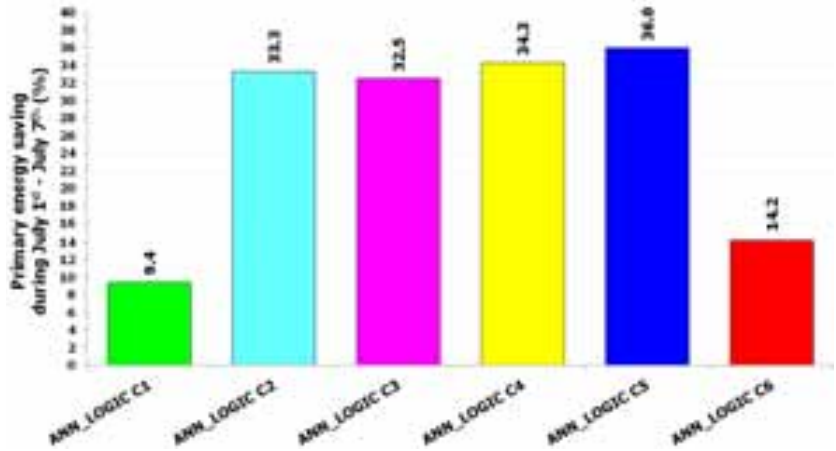

Fig. 10 Primary energy saving on ANN control during cooling season

The result show that the GSHP-PVT system with the ANN based strategies has low primary energy consumption if compared to the On-Off logic in particular, the strategies ANN_LOGIC H4 and ANN_LOGIC H5 result in approximately 11% total primary energy saving while ANN_LOGIC C4 and ANN_LOGIC C5 allow to reduce the primary energy consumption approximately 35% during a week.

5. Conclusion

In this study, as the main objectives, PVT-GSHP was developed, analyzed and optimized by using Fuzzy Logic control system, artificial neural network and on-off control system for application in residential buildings with 200m2 size. Energy consumption by utilize GSHP and PVT system analysis had been done on the previous research and showed a significant energy reduction. By using artificial intelligence control (fuzzy logic, artificial neural network and on-off control), system was calculated using TRNSYS 17 and MATLAB software and these are the conclusions:

- With the application of the FL control strategy and Artificial Neural Network instead of conventional On-Off control, the GSHP and GSHP-PVT systems are able to show a promising result in reduction of energy consumption in residential building with 200m2 size compared to the

building (residential)

- Energy reduction of PVT-GSHP system while using fuzzy logic controller is quite significant for FL(A) is 15.8% and FL (B) with 18.3%. FL(B) strategy has the better energy reduction because of all the PVT works which reduce the surface panel temperature and increase the efficiency of the system.
- With the utilization of ANN control to the system, system could save energy up to 11% during heating period (May 1st – May 7th) and 36% during the cooling period (July 1st – July 7th)

It is expected that in future study, cost analysis also will be performed in the future research to see the effect of the system cost, fuel cost, control cost and also payback period of the system. Comparison with the another advance control systems also will be done to see the effect of Fuzzy Logic and ANN control compared to another control system such as PID controller. Also with the application of advanced control strategies and system optimization, a microgeneration system will be able to achieve further energy and cost savings.

6. ACKNOWLEDGEMENT

This research was supported by a grant (16CTAP-CO096424-02) from Technology Advancement Research Program (TARP) funded by Ministry of Land, Infrastructure and Transport of Korean government.

Abstract

The first decades of phenomenal growth in the solar industry the focus was on getting more systems installed. Today, with the plummeting costs of photovoltaics, the emphasis in many projects has shifted towards getting as much economic, social and environmental value as possible from the installed systems, and this is increasingly made possible by installations at the community scale. Increasingly individuals, communities and cities are looking to utilize the ability to balance supply and demand with energy storage and controls in local energy micro-grids to maximize the use of locally generated energy within the generating communities. This paper review a range of European projects that aim to manage the production and the consumption of electricity within communities that generate their own energy with renewable energy resources and compares the approaches and results of these projects and discusses what appears to work best at motivating and engaging communities in the orchestration of local energy demand and supply. Building on experiences of community energy projects in South Australia it then provides a summary of the real world market constraints with the related issues of writing lease agreements, models and IP agreements and concludes with a short discussion of the drivers and barriers encountered in the market led model in Australia and in the European research domain of funded research.

1. Introduction

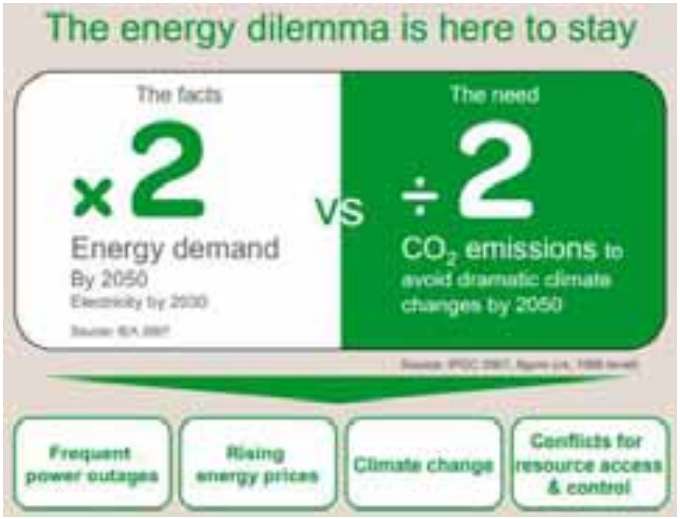

Fig.1: Diagram simplifying the universal Energy Dilemma

doi:10.18086/swc.2015.06.05 Available at http://proceedings.ises.org

Globally nations are caught in the same energy dilemma, with multiple and complex drivers pushing consumers away from the use of large scale, fossil fuel derived power sources to more regionally sourced, secure and renewable energy supplies. However it is increasingly appreciated that it is not only a modal shift in energy sourcing but also a step change approach to the yield that can be harvested from different energy sources that is needed to meet the ever more stringent ghg emissions reductions targets mooted to deal with the rapidly evolving climate threats. The European union, under its FP7 research funding round, has financed over two dozen community energy projects with a view to exploring the relative merits of different approaches to the orchestration of local energy supply and demand models. This paper outlines these projects and characterizes their properties and rationales. In order to start on the path of orchestration of supply and demand it is important to understand the nature of energy demand patterns in a region.

1.1 Electricity consumption in European households

Despite the fact that the production of construction materials emits CO_2 which increases the ecological footprint of buildings, the bulk of the CO_2 emissions from a building stem from use throughout its service life, proportionally depending on the life of the building. Energy and CO2 emissions, however, are not limited to our housing and transport needs. Higher living standards lead to a rising demand for goods such as computers, phones, music systems etc. that require regular re-charges of energy, particularly in the high tech, electric loads dominated lifestyles of many in Western Europe. The growing peak loads associated with such lifestyles have stimulated a plethora of European research projects by research centers, universities, product suppliers and electric power companies, often working together to explore the extent to which the orchestration of local renewable energy supply and local energy demand can be achieved in micro-grid systems and communities. The objectives of these European projects are largely driven by pressing need to meet climate change targets, the need to integrate a bigger share of renewable energies sources in the electricity generation to reduce carbon footprint, greenhouse gas emissions and dependence on fossil fuels and the desire to grow and flourish in the burgeoning markets for related products. The new markets promise not only profits from new product ranges and environmental benefits but also stimulation of local economy, new jobs, the ability to develop locally 'self-repairing' systems and in turn a degree of energy resilience and security which explains why there are high levels of support for investment in such projects by some politicians.

A major challenge is seen to be the turning of a generation of entrenched energy 'consumers' into the next generation of people involved also in the generation of their own electricity generation and consumption, turning consumers into 'prosumers'. Whether this goal can be achieved by raising environmental awareness, reducing power bills or helping consumers to install innovative technologies in their homes to participate actively in the process is explored in many of the local micro-grid projects outline below.

While across Europe there has been a decline in space heating consumption (-25 Mtoe) , water heating figures remain fairly constant (13% of load), while the share of load for electrical appliances from rose from 9 percent to 11 per cent between 2004 and 2012. Average dwelling sizes across Europe increased by c. 4 per cent since 2000 being now around 87 m2 per dwelling on average and consequently energy consumption per dwelling decreased slightly less, at 2 percent per year, than consumption per m2 at 2.4 per cent per year. This means that almost 20% of the energy efficiency progress for thermal uses has been offset, all things being equal, by the larger size of dwellings.

A major part of the story has been the soaring use of energy in appliances and in 2012 EU house-holds consumed around 40% more for small appliances than in 2000 (~ 990 kWh/year up from 700 kWh/year) although there has been a slight decreases of the annual consumption per dwelling for large appliances (- 142 kWh). Refrigerators, freezers and washing machines' consumption decreased, mainly due to substantial electricity savings with the diffusion of efficient new equipment.

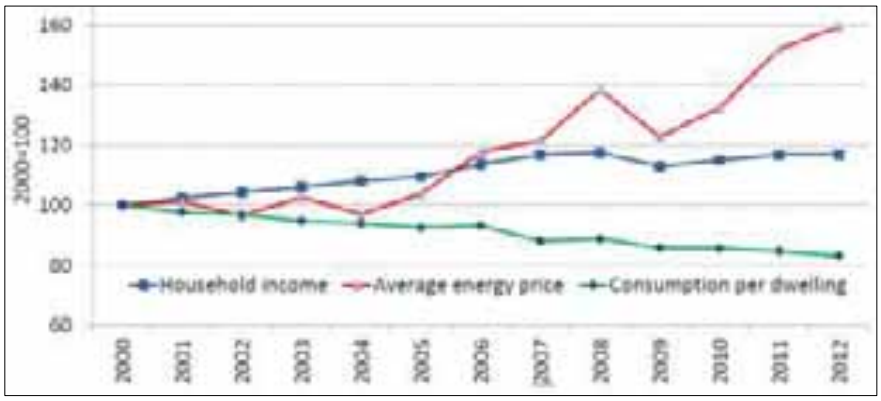

Fig. 1: Specific consumption per European dwellings, energy price and income. The figure shows the average price of gas, electricity and heating oil weighted with energy market shares (at constant prices). Income capture by private household consumption. Energy prices in Europe for households have increased by 64% between 2004 and 2012[1] (6.4%/year).

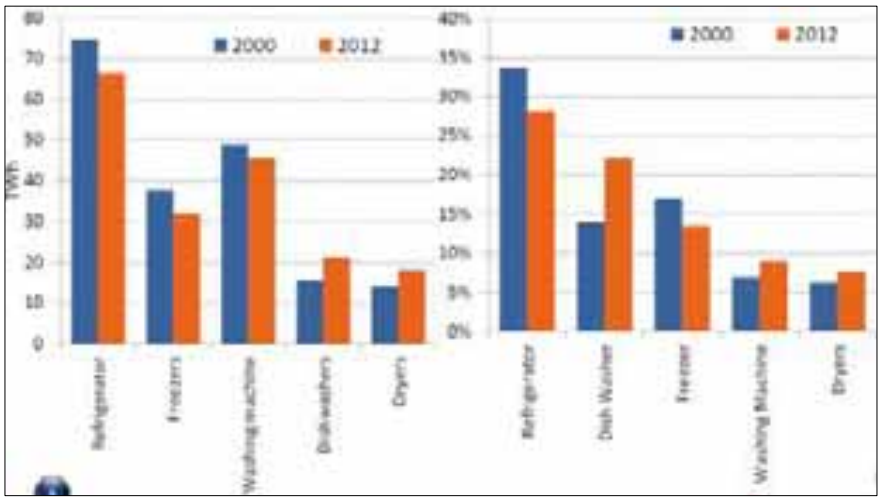

Fig. 2: Consumption of large electrical appliances by type (EU 27). Average number of appliance per dwelling in the EU shown here.

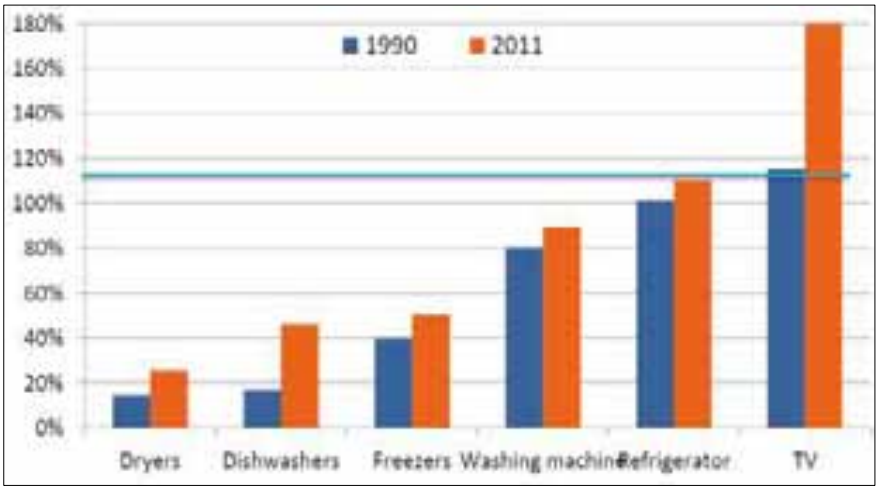

Fig. 3: Average number of appliance per dwelling in the EU

[1] http://www.odyssee-mure.eu/publications/efficiency-by-sector/household/

Energy efficiency improved for EU households by 21 percent over the period 2000-2013, ie by 1.8 per cent per year. The efficiency improvement for heating reaches 20 per cent since 2000, 15 per cent for water heating, and 14 per cent for large electrical appliances.

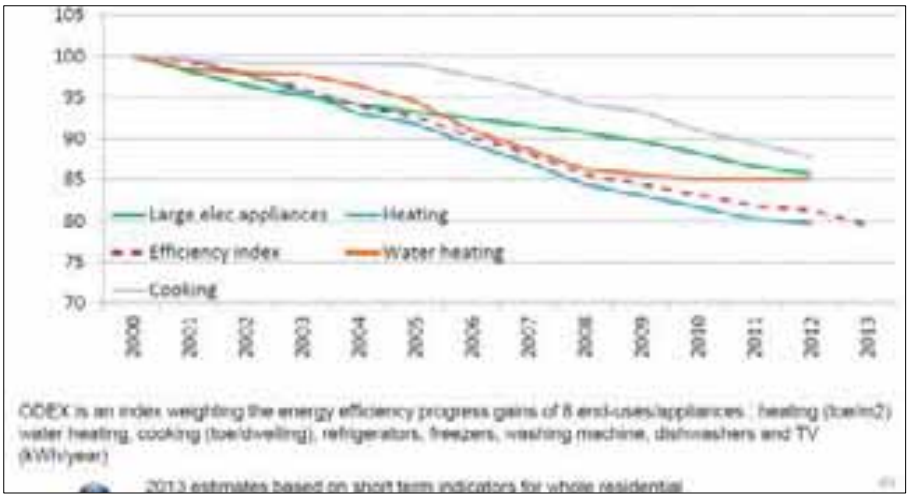

Fig. 4: Energy efficiency progress for households in the EU: ODEX

However, set again the overall trends for increased space size of households and increased use of appliances the equipment efficiency gains in themselves do not offer the hope of any radical reduction energy consumption per household and hence the widescale interest in more radical schemes to effect major emissions reductions from the energy sector and the growing interest in renewable energy micro-grids structured at a community level where the benefits of the final emissions reductions achieved can be accrued by the local users in the form of reduced costs per household in imported fossil fuel, or nuclear generated electricity.

Within the EU countries are required to develope National Energy Efficiency Action Plans (NEEAPs) set out estimated energy consumption, planned energy efficiency measures and the improvements individual EU countries expect to achieve. Under the Energy Efficiency Directive, they must draw up these plans every three years and also provide annual reports. Central to new thinking here is the idea of the Smart Grid.

2. European Initiatives: The Smart Grid

A Smart grid is defined in the report about Smart Grids by Felix Covrig et al. (2014) for the Joint Research Center of the European Commission as “an electricity network that can intelligently integrate the behavior and actions of all users connected to it in order to deliver sustainable economic and secure electricity supplies” and is an emerging concept for electricity networks across Europe[2].

The development of electric utilities and generation from renewable energy creates new constraints on electrical systems. These trends, together with the high price of primary energy sources and an awareness of climate issues at a national level, make a better management of electricity demand, a better pilotage and better efficiency of the whole electrical system necessary. Issues for the consumer and the citizen are three: improvement of the quality and continuity of the electrical supply necessary to allow the supply of the required services to the consumer, guarantee the safety of supply and the management of energy billing.

According to the International Energy Agency (IEA), European electricity consumption is projected to

[2] http://ec.europa.eu/research/energy/pdf/smartgrids_en.pdf

increase at an average annual rate of 1.4 percent up to 2030 and the share of renewables in Europe's electricity generation will double; from 13 percent now to 26 percent in 2030. Smart Grids do not represent a simple product development step and cannot be developed 'in-house'. Their supply chains are not the same as their procurement chains which brings risks with it that have to be managed. New grid technology cannot be fully proven in the laboratory or on a simulator but needs real world pilot operations, in a controlled situation on a real grid as a prerequisite for adoption. However there is little value in one-off new technology installations and as wide area adoption, through commercial mechanisms, is needed to attain its benefits the EU instituted a large funded trench of projects under its FP7 research programme to explore and develop such pilot schemes.

3. 12 European Micro-Grid Research Pilot Projects Described

The 12 demonstration sites reviewed here are located in different climate zones and are characterized by different energy generation and consumption habits. Their characteristics are review in Table 1. With their project titles, locations and climates summarised. They are grouped by types of project under headings covering projects that cover distributed renewable energy systems, district energy management, user participation of users in the projects, scoping different approaches to the challenge of engaging users in managing demand.

3.1 Electricty generation: distributed RES.

EEPOS

Energy management and decision support systems for Energy POSitive neighborhoods

The EEPOS system shows a semi-centralized structure where energy management is carried out on two levels: neighborhood (centralized) and building (decentralized). The main aims of the neighborhood level energy management system are described by **Klebow et al. (2013)**, and they are: matching of local electricity generation and consumption, congestion management in local electricity grids and power balancing on electricity market level. These objectives will be achieved by shifting of controllable electrical loads. Additional functions of the EEPOS system are statistical data analysis and end-user involvement in energy management processes.

At high RES penetration, in times of low renewable energy production, energy shortages can occur, whereas in times of high wind or PV power production, electricity production rates may even exceed those of consumption. Without proper energy management, grid instabilities can occur, and generated energy may be lost. **Automation of low voltage distribution grids** is one of the steps towards smart grids and successful integration of RES.

Bidirectional energy management systems can, for instance, help to cope with the mentioned challenges by the automated exploitation of load shifting or virtual storage potentials. Additionally, bidirectional data communication allows smart meters to send information on current electricity prices to the end-user. In this way, the end-user obtains the opportunity to manually maintain energy consumption in a cost effective and grid supporting way.

Table 1. Characteristics of the 12 reviewed FP7 micro-grid projects

One of the subsystems of the Information and Decision Support System is the end-user collaboration tool that engages and motivates end-users to decrease their energy consumption and to shift energy appliances from peak hours to off-peak hours of the day. To achieve this, the main functions of the tool are end-user energy performance reporting, benchmarking and guidance, neighbourhood discussion forums, energy saving games or contests in the neighbourhood, and targeted energy saving group actions trough **crowdsourcing**[3].

NEXT-buildings project:

Next zero energy buildings at lowest cost using competitive sustainable technology.

The innovative technologies[4] developed in Next-Buildings are some dual function building elements (insulation/photovoltaic), innovative windows, and ICT solutions. The first one will be applied cost-effectively and will improve aesthetics and easiness of handling. Then the second one will enable daulight steering based on micro-lamellas in the glass. Finally the third one will optimize the use of locally produced electricity, heat and cooling, and will provide inhabitant feedback based on smart metering and near real time data gathering. This project shows the next generation of low energy buildings. However, the scope goes beyond low energy buildings only. At the demonstration sites also smart technologies and ICT are applied, to enable efficient integration of locally generated renewable energy. Solutions will reduce CO_2 at negative or no cost.

Nice Grid

NICE Grid in the south of France has been developed with a consortium of 10 companies and with funding from the European Commission (FP7 scheme) and the French Agency ADEME also this larger is dealing with PV integration within a 10,500 inhabitant city with the objectives of: 1) PV integration, load shedding and islanding in 7 identified district called “solar districts”; 2) energy storage and the shift of residential appliances consumption allows for reducing the grid constraints due to PV. Load shedding consists in reducing the peak demand in winter by 3.5 MW at the primary substation level, by combining residential and commercial demand side management and 3) disconnecting for a limited duration a commercial district from the main grid, and supplying it only with PV generation and grid batteries.

3.2 Electricty generation: district energy management

Demand Response (DR) is defined as: “Changes in electric usage by customers from their normal consumption patterns in response to changes in the price of electricity over time, or to incentive payments designed to induce lower electricity use at times of high wholesale market prices or when system reliability is jeopardised.”

AMBASSADOR project

Real-time optimization **strategies**[5] at district level by combining ecosystem awareness (models, usages, prediction), flexibility (through horizontal energy flows), resources sharing (centralized and mutualized) and energy management strategies (advanced analytics, ICT, anticipation).

[3] Definition : it is the process of obtaining needed services, ideas, or content by soliciting contributions from a large group of people, and especially from an online community, rather than from traditional employees or suppliers (from https://en.wikipedia.org/wiki/Crowdsourcing).
[4] http://next-buildings.com/images/next-buildings%20d7.3%20v1.0.pdf
[5] http://ambassador-fp7.eu/wp-content/uploads/2013/01/AMBASSADOR_ICT4SusPlaces.pdf

EPIC-HUB project

The Energy-Hub model identifies and optimises the interactions between different input energy sources in order to satisfy electricity and heating/cooling demands. In the energy hub model, you consider a given load (or loads, electricity, heating or cooling demands); the system will optimise the hub's inputs (energy imports, from the grids or RES) by using the consumption forecasts (future demand in a given time horizon). In addition to these data, in this model, you know the hub nodes (e.g. CHP, batteries, boilers, and so on) where each of them has its own configuration parameters.

The optimisation process will state which the best configuration of the "battery element" (node of the hub) by selecting/suggesting: a) the best technical solution if you are planning investments in your facility or b) the best strategy to manage/control that energy system (i.e. batteries) at operation time in the given time horizon of the optimisation process. In this last case, you have to consider that the strategy optimises the overall energy behaviour of the hub (facility or district) without any specific optimisation of the usage related to the specific energy system (e.g. battery or boiler).

3.3 Participation of users in the projects: surveys

In many countries, the transition to sustainable energy supply and the emergence of smart grids are in progress. The deployment of distributed Renewable Energy Sources (RES) for the energy supply for buildings and residential areas has been increasing significantly in the recent years. Many people living in residential areas have already begun to produce electricity locally, e. g. through the installation of photovoltaic (PV) panels on the roofs of their houses. Their role has thus evolved from being only consumers of energy to becoming prosumers, not only consuming but also producing energy.

e-balance project

The project has been created to develop solutions for residential customers by taking into account technical and non-technical aspects, with the goal of improving the energy efficiency in small scale communities. The moto is to involve participants to offer innovative technologies that suit them most. Therefore e-balance project collects participants' views through online survey. By assessing users' feedback it can know what is appreciated about the energy management system (EMS). Among their three demonstration sites in Portugal, the Netherlands and Poland, with respectively 1661, 1632 and 1647 participants, they discovered what the habitants like most about the system was to save money (reduction of the power bills), although for Dutch habitants the benefits from energy consumption monitoring and data analyses made by the system are more appreciated than the savings. On the other hand, 71% of Polish people want free installation be encouraged joining the project and a 50% share of them will enjoy free maintenance of the system. Finally half of the Portuguese are very interested in forecasting of their monthly energy consumption.

Moreover, they have questioned the habitants about their enthusiasm to join the project to be aware of the factors that could discourage them to enable the EMS be implemented in their houses. Generally people are afraid of losing control of their home appliances and that frequent failures will appear that require repairs too expensive for them. One third of the respondents think that they will not get any return on the initial investment they have made. The last factor discouraging from using the system is about privacy reasons.

ADDRESS project

In this project the incentives of participants[6] on the French demonstration site of the ADDRESS project in Houat and Hoëdic are for 30% about the protection of the environment and the same share for their attraction

[6] More than 7% of the consumers participate in the field tests (among the 373 consumers of the two islands).

to the new technologies. And then, 20% of the respondents' motivation is about saving money and also an equal part of them desire to obtain a secured electrical supply.

ORIGIN project

In the ORIGIN concept, a behavioral study has been made among two of its communities, Tamera and Findhorn, with respectively 19 and 40 participants. On a five-step scale from strongly agree to strongly disagree, when it is asked how much they feel concerned about data protection there is an average value for Tamera of 3.8 and only 2.9 for Findhorn. Both communities agree on an average of 4.2 to have access to personal historical consumption data. They are also mostly interested in the forecast on the availability of renewable energy with a total average of 4.3. Finally it is asked what should be the main aim of the project. In average, the optimization of CO2 emissions and protection of the environment is seen as most important. And then economic benefits for the community are rated second highest.

3.4 Participation of users in the projects: variable tariffs

CoSSMic project

"In the CoSSMic concept the user leaves to the control system to decide exactly when an appliance is used, for example the user readies the washing machine in the evening and states when it should be finished, for example the next afternoon. Then the control system will start it when at the most optimal times taking into account both the output from local (to the neighborhood) PV system and the grid price."

"Yes, the users must provide constraints on that are adhered to by the control system, and the control system take into account predicted variation in prices. In the trial site only static price schemes are available, where the variation over the day is known in advance, but we plan to do simulations with more dynamic market driven pricing."

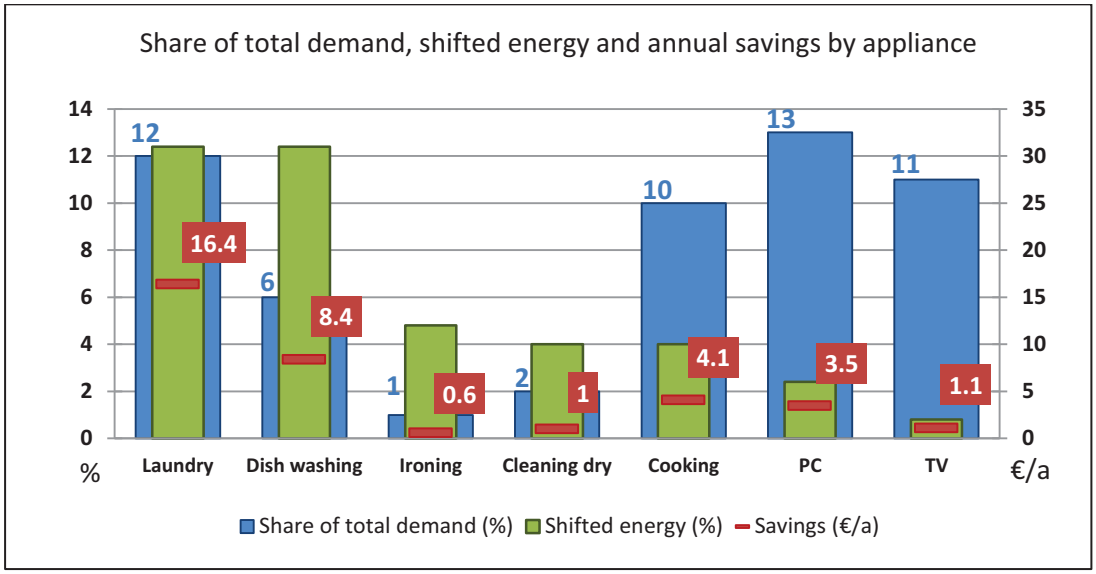

Figure 5. ORIGIN project Chart based on Fischer et al. (2015)'s paper (see references).

EEPOS project
Energy management and decision support systems for Energy POSitive neighbourhoods.

It was aimed at developing a new system for energy management and automated load control on the neighbourhood level, the EEPOS Neighbourhood Energy Management System. With the new system, designed to use automated load shifting of controllable electrical loads and active end-user envolvement in energy management processes to:

- Match of local electricity generation and consumption
- Management congestion in local electricity grids
- Increase energy efficiency within the system

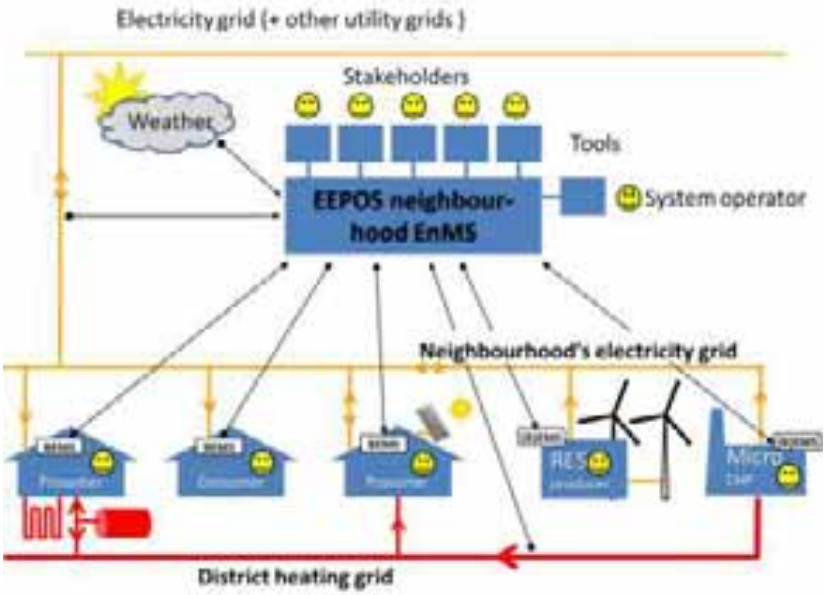

Figure 6. System diagram for the EEPOS project
http://eepos-project.eu/eepos/eepos-project/an-eepos-neighbourhood/

4 Thermal and Electrical storage in the projects

A range of different kinds of energy storage are described by Mohd et al. (2008), and they discuss the difficulty of their integration into a smart grid, not least because of it expense. However due to the pressing need to integrate increasing shares of renewable energy generation in future power supply systems and to shave ever growing peak loads on energy supply systems energy storage is expected to take place at all grid levels in the electrical network in future. Some projects within the twelve reviewed have no storage at all like the EPIC-HUB project while others like **Nice Grid** have storage media and strategies integrated at every stage of the project. The AMBASSADOR project includes 30 kWh Zebra batteries (sodium), 25 kWh Li-ion batteries and 50kWh Lead acid batteries.

RESILIENT incorporates both thermal and electrical storagewith two differnt storage media being both sodium nickel molten salts (sonick fiamm - 470 ah, voltage: 278 v so 104,5 kwh - total charge/discharge maximum time: 2 hours an inverter maximum power 70 kw) and hitachi li-on batteries with a 25 kwh capacity (c. 30 minutes charging/discharging time). This demosite is deemed to be a polygenerative site where Electrical and Thermal Energy production are constantly monitored and managed in an optimal way that enables them to respond to demand (over which they have no control) in with optimal energy responses.

The EU EINSTEIN project was implemented to reduce the consumption of primary energy in buildings

using solar thermal energy in combination with heat pumps and Seasonal Thermal Energy Storage (STES) for space heating and domestic hot water requirements[7]. The research is turned to existing building which have particular requirements and constraints that requires new developments and adaptation of existing technologies. Two pilot plants have been build, one at building level in Bilbao, Spain, and the other at district level in Warsaw, Poland. The decision for a certain type of storage mainly depends on the local requisites like the geological and hydro-geological situation in the underground of the respective construction site. Above all an economical rating of possible storages according to the costs for a kWh of thermal energy that can be used from the storage allows the choice of the best storage technology for every single project. The installation of solar panels is not the main objectives of the project, this is why there is no electrical storage created on the demonstration sites: the electricity is entirely fed back in the main grid when it is not consumed.

5 Legal and Fiscal Frameworks for Community Energy

What is not being funded within such European projects is research into the legal and fiscal mechanisms that will be essential for locally owned micro-grid and other distributed energy supply and generation systems including legal frameworks for the drafting of lease agreements, company models and IP agreements, such as are being pursued currently in the South Australian solar community movement. Monica Oliphant Research, in collaboration with Finlaysons and Solar Wind Systems has been developing one such model is being developed for the City of Campbelltown in South Australia[8].

The Model has been designed to lower energy use costs across the community through the application energy efficiency strategies and embedded solar installations. Electricity pricing will be locked in for life of the project which is between 7-10 years depending on the site, paid for in part by the capital raised through sale of $600 shares. Shareholders are given a return on investment annually for life of the project. Governance is through a new Trading Cooperative or through an existing organization whose constitution allows them to raise capital. Approval of a prospectus needs to be gained from the Office of Consumer and Business Affairs and at the end of the project (7-10 years) shareholders have their $600 returned and the installed equipment is transferred to the building owner providing fee electricity for the remaining life of the equipment. All measures are tailored to suit each building/site and are 'behind the meter' to avoid having to operate as an electricity retailer. An initial audit determines the current energy usage and identifies energy efficiency options. This provides sufficient preliminary data to enable building owners to determine if they wish to go to next step. The cost of this preliminary audit is $1,500. A full audit costs between $5,000 and $10,000 depending on size and complexity of the facility. This will provide accurate costing and data for input into the model to verify 'return on investment' to shareholders. The prospectus is prepared and approval sought from OCBA (Office of Business and Community Affaires) and voted on at a local public with a local board of directors. The lease agreement is signed with building owner and at that point the capital raising commences and the fully subscribed Community Energy Project is launched. In South Australia the Bendigo Bank is supporting the project and will maintain bank records and provide advice on engagement, capital raising etc.

6 Conclusions

Much research in Europe is currently being funded through the strategic European research mechanisms and within the 'Big Energy' industry on mechanisms for maximizing the growing contribution of distributed renewable generation through the use of energy demand and supply orchestration, through the exploitation of changing behaviors and local energy controls and management, with or without energy storage integrated into local distributed energy micro-grids. The South Australian case study has been included to emphasize the multiply complex nature of not only optimizing the value of distributed energy within national grids in theory and reality, but also enabling them to happen locally in practice, in the emerging energy revolution.

RURAL ELECTRIFICATION AT THE ECUADORIAN JUNGLE A NEW MANAGEMENT MODEL, PREPAID SYSTEM

Robert Peñaranda Loayza

Empresa Eléctrica Quito. Quito, Ecuador.

Abstract

A new management model for rural electrification with off grid photovoltaic systems is presented. This management model is based in a prepaid meter for each house that has a photovoltaic kit, where the electrical distribution company sells days of energy to the client. This model requires that the user visits an agency at least once every two months to recharge more days. The prepaid system allows to monitoring in a better way how the systems are working and how the clients interact with the new photovoltaic kits. The advantages of this management model are on the one hand that the electrical distribution company is closer to the client and achieves a better monitoring; on the other hand the system is implemented without additional communication equipment. This is made possible by the use of a prepaid key to recharge days of energy. The system is analyzed, data about clients is presented, and the future of the project is discussed

Keywords: *Rural electrification, prepaid meter, solar home system, solar energy, off grid system*.

1. Introduction

Ecuador has 4 regions: The Sierra, The Coast, Amazonia, where the jungle is, and the Galapagos Islands. The project is developed in two provinces of Amazonia: Sucumbíos and Orellana. These provinces are some of the ones with the least access to electrical energy. Indeed, according to the last census from 2010, 73,43% [1] of the people have access to electrical energy in Sucumbíos and Orellana. Consequently the object of the present program is to increment the access to electrical energy in order to reach the government plan of 96% of the population with access to electrical energy in the rural area.

To achieve this ambitious objective a new management model for rural electrification has been developed with individual isolated "Photovoltaic Systems" (PVS) including a prepaid meter. The main objective is to be able to monitor the PVS systems without additional communications equipment and without needing anybody to travel to the houses where the PVS have been installed. Trying to avoid old practices where the systems are installed, but no proper maintenances is given to the equipment. This causes some consequences like that the photovoltaic systems get broken and people lose trust in solar energy.

The aim is to reduce cost in maintenance and give a better service to the systems that are being installed in really remote communities, some accessible only by boat or small aircraft.

One additional objective is to encourage people to be responsible for the PVS. The prepaid meter system makes people think that the electric company is monitoring them and this will help to avoid the misuse of the equipments.

doi:10.18086/swc.2015.03.01 Available at http://proceedings.ises.org

2. System Overview

The new photovoltaic systems which are being installed in communities of the Ecuadorian jungle (Sucumbíos and Orellana) have two circuits, one for the DC lighting and the other for the AC part including the inverter. It is composed of the following elements:

- 3 Solar Panels (130 Wp)
- 1 Charge Controller + Prepaid System
- 1 Inverter (700W)
- 2 LED lamps (7W DC)
- 4 LED lamps (11W DC)
- 1 Portable lamp/ cell phone charger.
- 2 AGM Batteries (300Ah 6V)

The system is based in older systems to which some improvements have been added. One of them is the LED lighting, which permits illumination without depending on the inverter as well as being more efficient. The other significant improvement is the addition of a controller and a prepaid meter, which cut the energy in the house if there are no remaining days of energy. The meter helps to have a better control of the PVS, so people paid for consumption and also functions as a data logger. The following graph shows the schematic of the Photovoltaic systems.

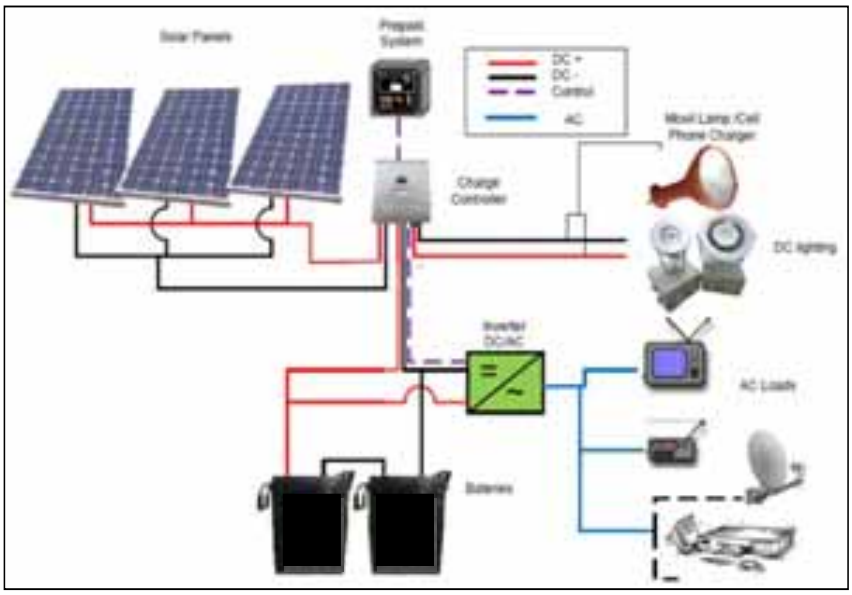

Figure 1: Photovoltaic system with prepaid meter scheme

3. Prepaid System

The prepaid system allows users to have energy for a given number of days, depending on the credit acquired. All the information of the PVS as the operation of the solar systems, how much credit is available, is saved in the prepaid system and a prepaid key. This small key permit to buy days of energy and to download the information of the PVS when it is connected to a recharge center, then new data is downloaded and additional energy days are sold to the client.

One special feature is if the user, for any reason, has no credit in the system. He could request a maximum of

10 more days until he could go to a recharge center with only pressing a button on the prepaid equipment. The credit can be acquired in any authorized recharge center. In case the prepaid key is remove from the prepaid systems, all the equipment continues to work.

The prepaid system methodology forces the people to bring the key to an authorized recharge center in order to get more days of energy. In case the prepaid system does not have days, the controller shuts down the DC lights and the inverter. A maximum of 60 days of energy can be charged in this management model. This allows the energy company to get data on the PVS at least every 2 months for better monitoring. The recharge centers are usually in the main town where people from the communities go at least one time per month for trade, medical assistance and other activities.

The main requirement for the recharge centers is to have access to internet. Indeed, it enables to save data of the different prepaid keys and send it to a main database, where it could be used for further analysis.

Among the advantages that the prepaid system presents are:

- To be able to know the production of the solar panels
- State of the batteries, voltage of battery.
- Alarms in the system, low battery, over charge, days without energy.
- How many days of energy the client has left and when was his last recharge.

3.1. Prepaid system implementation.

This new management model is already implemented in some areas around Quito and it has been installed in the Ecuadorian jungle. After the installation of some photovoltaic systems, the distribution company observes that the users come to the recharge centers at least once per month to acquire credit for their PVS. The data obtained permits us to know how the system is working and monitor the systems, consequently the customer feels more responsible with the solar equipment and the electrical distribution company has a bigger income for future maintenance and most importantly, the change of batteries after 5 years.

One of the major challenges that the project is facing is the interconnectivity of the recharge centers with the database. This is due to the fact that some of the recharge centers are in remote cities and consequently the internet connections are poor, which can prohibit getting the data from PVS. Recharge centers must have a secure internet connection for these kinds of projects to be successful.

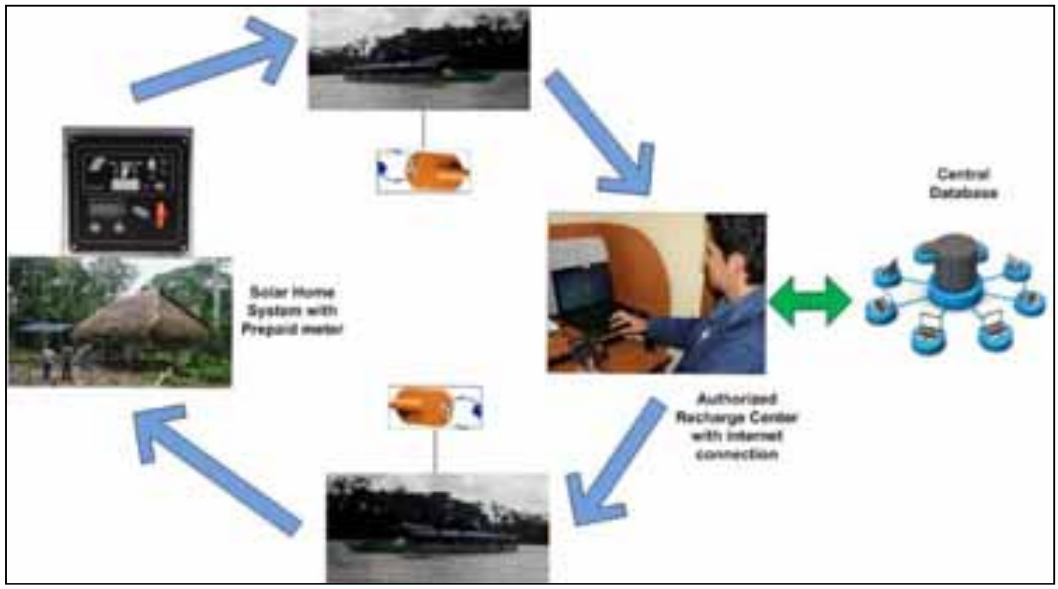

Figure 2: Prepaid system management model schematic

Figure 3: Typical installation of prepaid system and inverter.

4. The Overall Cost

The investment for each individual photovoltaic system with the prepaid meter is around $ 2400.00 which includes all the components of figure 1 and installation.

At the provinces of Sucumbíos and Orellana 500 new prepaid photovoltaic systems and 500 prepaid meters for repowering old systems, will be installed. The investment for the first phase of the project is $1,575,152.80 for the installation and purchase of the 500 new PVS and 500 prepaid systems for repowering.

The project has social interests, such as an understanding of the social costs of not having electrical energy as well as the benefits that the project will produce like:

- Savings in the cost of transportation to bring diesel for gen sets.

- Prevent migration to big cities

-Access to information and communication

-Improve the service of utilities, education, health and drinking water.

The PVS systems have an expected life time of 20 years and the batteries will be changed 3 times in the life time of the system.

5. Results

The project developed in the surroundings of Quito permit us to evaluate how the system will work in the Ecuadorian jungle. The data is obtained when the client goes to charge days on the prepaid key, the data from the PVS is downloaded to the database and we obtained the basic information to evaluate the system as shown below:

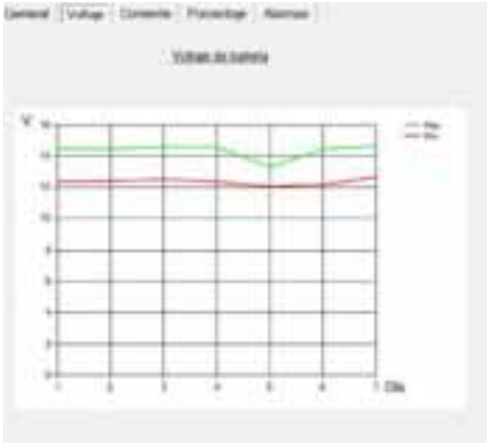

Figure 4: Battery voltage of a PVS, actual data download from a prepaid key. [2]

Figure 5: General Data of the PVS, downloaded from the prepaid key. [2]

This information allows to know if the system is operating properly, giving us an idea of the consumption and the production of solar panels. Some important information is how many times the user acquires credit for the prepaid system, which could show if the system was manipulated by the user. For example if the user does not recharge the prepaid key in more than two months, perhaps they are taking energy directly from the batteries.

The expected result in the jungle is to have a power of 195kW installed with solar power and a daily production of 780kWh. The new individual solar systems will provide electricity to around 500 families and repower 500 more systems in the Ecuadorian jungle, which are going to be monitored by the prepaid meter.

6. Conclusions and Outlook

This article presents the implementation of the prepaid system in individual photovoltaic systems for rural electrification and the expectations for monitoring in the Ecuadorian jungle.

By the end of the project 500 new PVS will be installed in the provinces of Sucumbios and Orellana, and 500 more will be repowered.

One of the advantages of the present project is that it is being carried out without additional communication lines or communication devices for monitoring. The prepaid meter and its key permit to obtain data of the PVS, when the users acquire more days of energy.

A recommendation for this type of projects is that the recharge centers should have a secure internet

connection in order to send data to the servers and the database. Additionally one person should be in charge of the database to monitor the data and observe for inconsistencies of the system.

These new photovoltaic systems allow access to electrical energy to people who live in communities at the middle of the jungle, the access to communication, a better education and an improvement in their economy.

As complement of the project new hybrid (solar-genset) microgrids will be developed in some communities, installation of solar water pumpers and solar public lighting as part of a big plan to provide electrical energy service to communities in the Ecuadorian jungle.

Rural Electrification Initiatives in Fiji – A Case Study of Solar Home Systems

Ravinesh Tendra Nand[1] and Atul Raturi[2]

[1]Department of Energy, Suva, Fiji

[2] The University of the South Pacific, Suva, Fiji

Abstract

Fiji is striving towards to provide its entire population with access to modern forms of energy, especially access to electricity. In 2007, 89% of the population had access to electricity which comprised 82% of rural and 96% of urban dwellers. Although access to electricity in rural areas is still significantly low compared with urban areas , it represents a marked improvement from 69 % in 2003. The current (2014) estimates of overall national electrification rate are 92- 95% .The progress in rural electrification can mainly be attributed to a number of on-going initiatives including main grid extensions, solar home systems, diesel mini-grids and pico-hydro schemes but the solar home systems (SHS) program is the most popular and preferred option in remote rural and maritime regions.

Keywords: *Electrification rate, Solar Home System (SHS), Fiji*

1. Introduction

The challenges of providing electricity services to communities in smaller islands and remote rural areas of Fiji are multi-faceted and are further compounded by their geographical distances from the main electrical grids. Also, as the infrastructure developments for electricity supply are capital intensive, the typically lower power demands and low returns in these areas do not generally encourage investments from the power utility or any other private investors. Thus, the members of the public in such localities mainly rely on State assistance for their electricity needs.

In addition to grid extension wherever feasible, there are two common options for electrification in Fijian rural communities are (i) village diesel generator based mini-grid systems and (jj) Solar Home Systems (SHS). The main criterion underpinning the preferred option includes utilization of clean energy resources, affordable and reliable power system and more importantly, the least-cost option.

The SHS initiative has been found to be the most cost-effective and affordable to the end users. By the end of 2014, the Department of Energy (DoE) under its Rural Electrification initiative had installed over 5,700 SHS, directly assisting over 28, 000 people across the country (DoE, 2014 II).

2. Policy Frameworks

The overarching policy guideline for national development in Fiji is the Green Growth Framework (GGF) of 2015 (PIDF,2014). The GGF has ten thematic focus areas which include Energy Security as well as Technology and Innovation respectively. The GGF is closely aligned to the National Sustainable Energy for All (SE4All) Initiative and the National Energy Policy. The main targets are that all households be electrified by 2020 and the share of renewable energy in electricity generation will be 80 % by 2020. Long term targets are to double the share of renewable energy in the overall energy mix to up to 25 % by 2030. Moreover, energy supplies should be clean, affordable, environmentally friendly and sustainable.

doi:10.18086/swc.2015.03.02 Available at http://proceedings.ises.org

Government also has a Rural Electrification Policy through which the costs for energy infrastructure are largely subsided in order to provide electricity to the rural, remote and maritime communities (DoE, 2014 I). The SHS program is one of the major programs under the Rural Electrification initiatives. The Department of Energy (DoE) manages the rural electricity programme which is heavily subsidised by the government. This has resulted in the establishment of 500 diesel generator based mini-grids and more than 1500 grid extensions since the programme began in 1994(DoE, 2014 III).

3. Quasi-RESCO Model

The SHS project implementation, maintenance and management approach is an extension of the Renewable Energy Service Company (RESCO) model. The SHSs are fully funded, maintained and owned by the Government, which partners with RESCOs through formal contracts for servicing and maintenance works. The end-users are levied a reasonable and affordable service fee per month, which is paid 6 monthly in advance. The table below summarizes the details of the SHS program.

Table 1: Details of Government funded Solar Home Systems

Project Type	SHS Type I (2009 – 2013)	SHS Type II (2014 to present)
Major components	Solar Panels 2 x 50Wp Battery 100Ah DC LED lights: 1 x 1W DC CFL lights: 3 x 11W & 1 x 7W Charge Controller 1 x 10A	Solar Panels 2 x 135 Wp Battery 200Ah DC LED lights: 3 x 9 W, 1 x 7W, 1 x 1W Charge Controller 1 x 20A, Inverter 300 W
No. Installed (2014)	3460	2346
Refundable End User Contribution (FJD)	84	108
Monthly service fee (FJD)	14	18

However, there are only a small number of RESCOs operating in Fiji and even fewer in rural and maritime areas. Usually, either two or at most three RESCOs are contracted on an annual basis through DoE's tendering process to carry out servicing and maintenance works. Each household with SHS is assigned to one of the six Service Zones, where each RESCO has a defined non-overlapping geographical boundary as its area of operations.

Table 2: Summary of SHS servicing and maintenance plan – 2015 (source: DoE)

Service Zone	1	2	3	4	5	6
Service Areas	Bua	Macuata	Cakaudrove	Lomaiviti, Kadavu, Rewa	Yasawa, Rotuma, Viti Levu	Lau
No. of SHS	992	1078	1640	802	873	421

Basically, service zones 1, 2, 3 and part of zone 5 are SHS on rural and remote mainland's predominantly on second largest island of Vanualevu and the other zones cover the maritime islands. At the end of 2015, a total of 5806 SHS were on ground.

The DOE SHS programme has been rolled out in 10 phases with the pilot phase implemented in 2002 when 259 systems were installed in Vanua Levu. As fig.1 shows, by the end of current 11th phase, a total of 9,000 SHS systems would be in existence across Fiji.

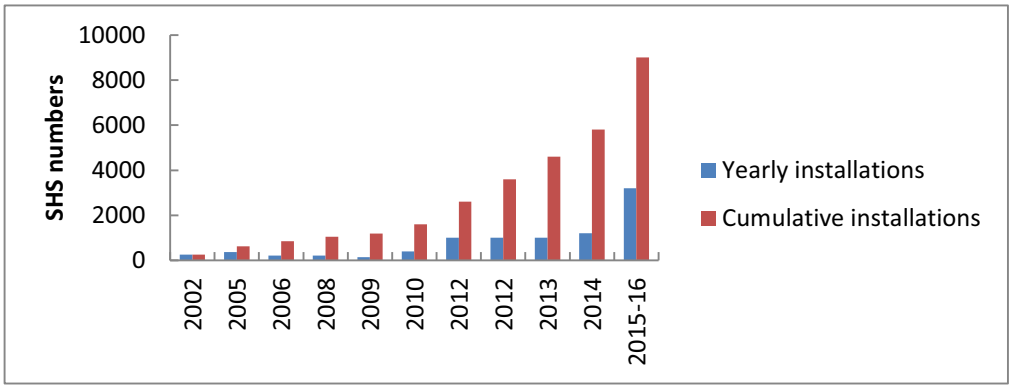

Figure 1: Yearly and cumulative SHS installations (source: DoE)

4. SWOT Analysis of Quasi-RESCO Model

Table 3: SWOT analysis of the Government funded Solar Home Systems

Strengths	Weaknesses
• Provision of clean and affordable electricity services. • Sustainability of the projects is guaranteed as SHS is maintained by a government entity(DoE). • Rural and remote communities are not burdened with maintenance and servicing costs. • In some communities, village solar managers collect monthly rental from individual households and handover to designated Revenue collectors from DoE.	• Rural market for SHS maintenance and backup support is restricted to Government contracted service providers. • Accumulating arrears due to defaulting SHS customers. • Limited transfer of Technical knowledge to SHS households. • Recurring annual cost to Government for procurement of replacement equipment and costs for payments of maintenance contractors. • Irresponsible use of SHS by households; battery misuse and system overloading impacts battery life. • Not all households could be visited by DoE officials during the scheduled revenue collection trips, given the geographical spread of SHS customers and transport logistics.
Opportunities	**Threats**
• To open up the market for RESCOs for SHS service and maintenance works, enabling business opportunities for more companies, SME's and individuals that would generate economic activities in rural areas. • Upgrade of system sizes/capacity to cater for growing electricity demand by households. • Training and knowledge transfer to communities on SHS technical aspects. • Government to transfer the ownership of SHS to individual households and the savings from the	• Lack of care for SHS by individual households. • Misuse of the SHS by households reduces project components lifetime. • Non-payment for maintenance jeopardise the whole initiative.

avoided costs of service and maintenance can be diverted to other projects.	

5. Impacts of SHS Program

Most SHS recipients have directly benefitted through having improved basic lighting in their homes and consequently reducing their dependence on expensive fuels like kerosene, benzene and diesel which were previously used for lighting. Also, the time spent and transportation costs to reach the usually distant commercial centers to purchase fuels are now utilized for other income generation activities including farming.. The extended lighting hours in these households as a result of SHS has enabled improved night time study facilities for school children and also assist the women with their daily household chores/weaving etc. Similarly, the introduction of Type II SHS with inverters has provided the supporting infrastructure for better communications and entertainment such as radios/TVs, and use of computers. With the spread of cellular network in remote areas, phone charging has become a daily need for most of the remote population. Moreover, fuel supply chain issues with associated logistical challenges of transportation to remote rural and maritime locations from the main business centers is of much lesser concern to the recipients of SHSs. The families assisted through the SHS are relieved of their former regular financial costs of repair and periodic maintenance of their kerosene and/or benzene lamps and in few cases diesel generator systems. In addition, the numerous health and environmental benefits of the use of clean, affordable, renewable solar energy has catalyzed positive social changes into these communities. Above all, the avoided dependence on fossil fuels for lighting purposes in these communities, contributes towards the national goal of reducing fuel imports and increasing the share of renewable energy into our national energy mix. Furthermore, the SHS program has had significant impacts on improving Fiji's national electrification rate.

A 2012 study (Urmee and Harries, 2012) surveyed one hundred and five SHS using households in Fiji and found that 84% of the respondents had an increase in their quality of life. They did not report any significant income-generation activities emanating from this initiative. However, a similar study conducted in Bangladesh (Urmee and Harries,2011) reported that SHS can be used productively to create extra income. Some of the driving factors for a successful SHS programme were identified as systems designed to fulfil user's needs and a sense of ownership.

Figure 2: A typical Solar Home System in rural Fiji (Photo: DoE)

Figure 3: SHS lighting for income generation: an example from Tonga (Photo: IUCN/Atul Raturi)

6. Challenges

The main challenge is ensuring the sustainability of these solar projects and improving the overall management of the SHS program. The current practice of managing the SHSs entails the government issuing short-term service and maintenance contracts to RESCOs for specific project localities. However, the RESCOs are not necessarily the same as the ones that initially designed and installed the SHSs. This discontinuation of services from RESCOs does not guarantee a commitment from their end to see successful operation of the SHSs for the expected project lifetime. Also there are no incentives for the RESCOs to make every SHS work properly because it could be perceived as limiting future business opportunities for the RESCOs. As such, there is high possibility that standards of service and maintenance works carried out by RESCOs could be compromised compared with if there was some system of direct financial reward to the RESCOs for ensuring continued operations of SHSs.

The current practice of SHS maintenance requires RESCOs to visit their designated service areas at least once every 3 months and any requests to attend to technical issues that arise after the RESCOs scheduled visit usually takes considerably longer period of time to respond. This warrants a significant shift in the current practice.

Another significant challenge is the recovery of arrears (maintenance fee) as a result of defaulting customers, which was around 1000 SHS customers in 2015. However, this challenge is mostly a result of those SHS where the pre-payment meters were either non-functional and households had to pay a standard monthly fee or where pre-payment meters and/or cut-off switches were not part of the SHS installed. However, the DoE through a dedicated consultations program targeting such defaulting SHS customers can improve the situation if not solved completely. On the other hand, although relatively expensive but upgrading the SHS with technical features such as cut-off switches as part of charge controller would be better.

Another area of concern for the rural electrification projects including SHSs is the absence of private sector investments in electricity generation for the rural and maritime areas. The numerous incentives provided by the Government including supportive national policies for uptake of renewable energy projects, have failed to materialize into a truly RESCO model for electricity supply at community level. The greatest challenge faced by the Government is to find ways to reduce its direct role in the RESCO process and focus on a regulatory framework for anexpanded RESCO model.

7. Way Forward for SHS program

SHS program has not been operating under a true RESCO model because Governmenet is still financing the servicing and maintaemanace as well as having absolute control over the projects. Moreover, most of the SHS

capital financing is donor-funded . Thus, there is a need to open the market and let the SHS households and RESCOs to operate freely. This will result in fewer blackout periods for customers as they will not have to wait for the periodic visit by Government contracted service providers and the Government can concentrate on other energy projects since the DoE will not be involved in maintenance and revenue collections. This presents an opportunity for Government to become more strategic and focus more on its core role in the energy sector of providing access to electricity rather than managing energy projects. Overall, the removal of government control over the SHS will enhance the sense of ownership for SHS customers.

Alternatively, in view of the present system of contracting RESCOs by Government, there is a need for long term contracts with RESCOs which bundles together; system design, supply, installation and service & maintenance contracts, which could bring about more RESCOs to participate through competitive tender process, conducted periodically by government. This would also encourage more genuine commitments from RESCOs leading to enhancement in their standards of service delivery as well. Either way, the monitoring system for SHS program within DoE needs strengthening and timely evaluations for continuous improvements.

Furthermore, Government needs to come up with other options to enable financing for SHS rather than people just waiting for DoE to roll out SHS projects annually, where households have to wait on average between 14 to 18 months from the time of payment of their contribution to DoE and the time they get a SHS installed. With alternative financing options, people can still benefit from a reasonable level of subsidy from Government for their capital costs and hence can have other arrangements for regular system servicing and maintenance with their preferred RESCO. This would not only open up the market for more RESCOs to participate in SHS program but provide options for households to acquire different sizes of SHS, usually slightly larger than the Type II systems supplied by DoE, depending on the energy needs of households. With the above, the DoE can provide standard designs and technical requirements for a range of SHS sizes that the people can choose from. However, the Government needs to ensure at the same time, that the alternative financing mechanism(s) is accessible, affordable and reliable to ordinary Fijians.

Moreover, some changes to policies and regulations governing the energy sector is necessary. Especially, the review of national rural electrification policy and its limitations on SHS program beneficiaries. Likewise, regulations need reconsiderations to allow some level of flexibility and inclusivity with regards to registartion and licencing of electricians and RESCOs, in view of potential solar technicians and smaller RESCOs that could participate in SHS program from a broader spectrum of the society. In addition, the abovementioned regulatory changes would enable more choices for SHS customers and provide certainity and confidence to all stakeholders. Similarly, enforcement of technical standards for SHS installations including for servicing and maintenance works and ensuring compliance by all stakeholders through a more responsive regulatory framework can contribute immensely to the sustainability of SHS program in Fiji.

8. Conclusions

The SHS program has over the years provided affordable lighting solutions to many Fijian households in rural, remote and maritime communities. It has helped bring positive changes to the lifestyles of the common people enabling better environment for children's education, connecting people with modern means of communication through cell phones, televisions etc. In short, SHS program is a critical factor towards Fiji achieving its Sustainable Energy for All goals and hence supporting SDG goal seven. Cutting down the use of kerosene for lighting will also have an immediate impact on black-carbon emissions which is considered a potent short-lived climate pollutant.

Fiji could consider provision of electricity to the remaining rural and maritime communities by grouping all such SHS projects into a single national comprehensive project and possibly make submissions to the Green Climate Fund (GCF) for financing. This comprehensive SHS program could be part of a broader national Green House Gas (GHG) mitigation program. Training and capacity building are of paramount importance to make the SHS programme a sustainable initiative.

SWC_ Off-grid rural electrification approaches – Lesson learnt from ASEAN

Badariah Yosiyana[1] and Susy Simarangkir[2]

[1, 2] ASEAN Centre for Energy, Jakarta (Indonesia)

Abstract

The Association of Southeast Asian Nations (ASEAN) has a population of approximately 625 million people, of which around 50% live in rural areas. More than 20% of ASEAN Member States's (AMS) population still does not have access to reliable, affordable and sustainable sources of electricity that impede economic development and an improved standard of living. Providing their citizens with electricity access and increasing their respective electrification ratio has been a constant effort and become high priority over the last decades. The challenges to improve electricity access are diverse including institutional, governance barriers, financial and technical.

Successful examples of rural electrification based on renewable energy can be found all over ASEAN. However, less successful examples are equally widespread since renewable energy utilization often lacked a sound long term strategy or feasible business models which are crucial to ensure the sustainability. The lessons learnt from these rural electrification projects prove that the ASEAN region is still facing many challenges.

This paper presents the rural electrification situation at the regional as well as country level in ASEAN. The paper also does comparative analysis- based on the literature review, survey, interview and workshop- to explore cross learning potential and give recommendation that could serve as input for policy review, evaluation and improvement to assist future electrification efforts in the region.

The paper focuses on six aspects of off-grid rural electrification in ASEAN: (1) Policy framework; (2) Financing mechanisms and required support policies; (3) Project setup and business models; (4) Appropriate technology solutions; (5) Socio-economic aspects and community involvement; and (6) Capacity building and training. For each aspect, a number of successful approaches and lessons learnt were analysed.

Keywords: *Rural electrification, off-grid, renewable energy, ASEAN*

1. Introduction

Access to energy must be assured for development of a region, a process in which living standard (e.g. electricity, heat, mobility) of its people improves. Energy consumption in ASEAN has grown rapidly especially in megacities. However, energy (electricity) distribution to rural area remains as a challenge due to geographic and demographic characteristic of the region spread widely across southeast Asia. Rural electrification was therefore high on political agenda of the countries over the last decades and continues to be an important issue for a number of countries in the region, especially in Cambodia, Lao PDR, Indonesia and Myanmar. The reasons for low electrification rates differ from country to country: high generation costs and low income as well as adverse topographic conditions and high transportation costs are potential obstacles to successful rural electrification in those countries.

Nevertheless, the ASEAN region and its member countries are endowed with vast renewable energy resources. Hydropower, biomass, solar or wind power are feasible and often cost-efficient alternatives to conventional means of rural electrification, in particular in areas with high grid extension costs or a sparse density of population.

doi:10.18086/swc.2015.03.03 Available at http://proceedings.ises.org

There are many examples of successful and sustainable rural electrification utilizing renewable energy in the ASEAN region. Less successful examples, however, are equally existed and lead to a waste of financial resources and;/ an unnecessary high number of households without access to modern energy services. Lack of knowledge and technical skills, ineffective and unsustainable project design and the absence of financial resources undermine the long term impact of many rural electrification efforts.

This paper presents the current rural electrification trends at the regional level and at the same time review the development and lesson learnt in Cambodia, Indonesia, Lao PDR and Myanmar. These countries were selected since the electrification rate are relatively low, therefore the rural electrification activities has been significant. This work makes use of both preliminary and secondary data in presenting the current status of rural electrification in ASEAN. The data are collated from past and recent studies on rural electrification in ASEAN. A stakeholder surveys, interviews and workshop with related stakeholders and experts were also conducted for this study.

The categories studied include policy framework, financing mechanism and required support policies, project setup and business model, appropriate technology solution, socio-economic aspects and community involvement and capacity building and training.

2. Rural Electrification in ASEAN

The current level of electrification rate in the region is around 81.2% (ACE, 2015a). Wide disparity in electrification rate exists in ASEAN. Singapore, Brunei Darussalam and Malaysia has reached (almost) 100% of electrification rate, while only 33% of the population in Myanmar have access to electricity. With high priority putting by AMS to provide access to electricity, the percentage of population with electricity access has increased during the last decade. Constant effort to increase their respective electrification rate resulting the number of people without access to electricity has went down from an estimated 190 million in 2015 (IEA, 2006) to 118 million in 2013 (ASEAN Secretariat, 2015) (Table 1).

Despite the efforts and important improvements in some of the countries, to date more than 18% of ASEAN's population still does not have access to affordable, reliable and sustainable sources of electricity. The absent of electricity access hampers economic development and an improved standard of living in entire regions. The region without access to electricity usually locate in isolated communities, such as islands, forests fringes and hilly settlements. These communities are generally small, consisting of low income households – with characteristic that may be economically less attractive to electricity distribution companies or even government electrification program that usually prioritizes the allocation of the scarce resources.

Tab. 1 Rural electricity access in ASEAN (as of 2013)

Country	Total Population (Thousand)[1]	Population without Electricity (Thousand, approx.)	Electrification Rate (%)[2]	GDP Per Capita at Current Market Prices in USD[1]
Brunei Darussalam	406	1	99.8	39,679
Cambodia	14,963	9,876	34	1,037
Indonesia	248,818	48,520	80.5	3,460
Lao PDR	6,644	841	87.34	1,548
Malaysia	29,948	180	99.4	10,420
Myanmar	61,568	41,251	33	888
Philippines	99,385	9,442	90.5	2,707
Singapore	3,845	0	100	55,182
Thailand	68,251	7,030	89.7	5,679
Vietnam	89,709	1,794	98	1,909
ASEAN	623,536	118,933	81.2	3,832

2.1 Cambodia

Electrification rate of Cambodia is very low with only 34% of the population have access to electricity (ACE, 2015a). The Royal Government of Cambodia has set an ambitious target to reach 100% of the village with certain type of electricity by 2020 (including battery power) and 70% of household connected with grid-quality electricity by 2030. This target is further detailed in the National Strategic Development Plan Update 2009-2013 and Rural Electrification Master Plan (REMP) with Ministry of Mines and Energy as the focal point.

According to REMP, the total cost to electrify all village is about US$ 427 million or US$ 490 per household with 872,000 households to be connected. A total of 272,000 households will be electrified in the off-grid areas by decentralized mini-grids and solar battery chargings by the target year 2020. The gross investment costs will amount to about $147 million. While the remaining villages will be connected to the grid through grid extension. Electricity Authority of Cambodia or EAC (2014) reported that all the licenses issued covered 11,218 villages which was 79.716% of the number of villages in Cambodia. However, the distribution network developed until 2013 covered only 7,187 villages amounting to 51.07% of the total villages. Electricity prices in Cambodia are among the highest in the region between US$ 0.14 in urban areas to almost US$ 1 per kWh in rural areas (ACE, 2015b). It is mainly due to small diesel fuelled isolated generation system completely dependent on high-cost fuel imported from foreign countries, and not having interconnected system and high power losses in the distribution network (EAC, 2007).

The Royal Government of Cambodia has issued a Royal Decree to establish a public institution the Rural Electrification Fund (REF). The objectives of the REF are to facilitate access to electricity infrastructure and provide a secure, reliable, environmentally safe, and sustainable energy supply of various types, at reasonable and affordable price. The funding for REF shall be through donations and grants whose sources and terms shall be acceptable to the Ministry of Industry, Mines and Energy and to the Ministry of Economy and Finance and other sources from the government. The REF has received funds from Government of Cambodia through loan from World Bank and grant from Global Environment Facility Trust Fund (GEF). The funds provided grant assistance to licensees for new connections to households and for installation of mini and micro hydro projects and renewable energy projects, including solar home system. During 2012, REF, which was working as an independent organization was transferred to the control of Electricite Du Cambodge (EDC), the state own electricity company.

Over the years, a number of REF programs (such as Power to the Poor (P2P) Program, Program for Providing Assistance to Develop Electricity Infrastructure in Rural Areas, and Expansion of Grid Networks) attempted to enhance electricity access either as part of overall rural development or specifically targeting rural electrification. At present around 12,000 Solar Home System and about 60 Rural Electricity Enterprises (REE) that run biomass gasifier and numerous small mini hydro sites have been implemented under REF (Sovanna, 2012). P2P program provided interest free loan for: (i) costs for the connection fees of the electricity supplier, (ii) costs for deposit to be deposited with the electricity supplier, (iii) costs for purchase of materials and labour for the installation of wires from the connection point to its house, and (iv) costs for purchase of materials and labour for the installation of in-house wiring. The loan was disbursed through the licensee who is responsible to pay back to REF by collecting from the Borrower in easy monthly instalments within a specific period (EAC, 2014).

2.2 Indonesia

Rural electrification has been one of the development program priorities set by the Government of Indonesia since mid-1980s given that electrification and village electrification ratio was low at that time. In spite of difficult geographical and financial barriers, Indonesia continues to make measured progress towards providing access to electricity to the majority of its rural population. According to Indonesia Central Bureau of Statistic (BPS, 2014), in 2013, number of village in Indonesia was 74,093 that covered around 59 million households. The number of village with electricity has reached 62,682 or 80.5% percent of total village (Ministry of Energy and Mineral Resources, 2014).

On a regional basis, the electrification rate varies from below 30% in very isolated areas (e.g. Papua and East Nusa Tenggara) to over 99% in the urban centers of Java (e.g. Jakarta, Bandung and Surabaya). The successful

electrification program has increased both electrification and village electrification ratio tremendously in the last 20 years. The lack of a unified land, low population densities particularly in the eastern part of Indonesia and low average consumption per capita makes economies of scale difficult to achieve. In this case, utilization of local energy resources that predominantly renewable energy are the best option to cope with this situation.

The government categorizes rural electrification in two stages, namely pre-electrification and rural electrification (Ministry of Energy and Mineral Resources, 2010). The pre-electrification was program that provide minimum electricity supply for lightning and other minimum use of appliances (such as radio) for the household with power limited up to 100 W, powered by photovoltaic (typically Solar Home System) and micro-hydro power plant. The rural electrification was considered as full electrification program where household is connected to 220 VA or 450 VA. The electricity could be generated by diesel generator and/or hybrid power plant that combining diesel generator and renewable energy technologies such as centralized photovoltaic and wind turbine.

As rural development and its energy service provision are one of key development priorities, there are various government agencies and ministries that involve in rural electrification, i.e. Ministry of Finance, National Planning Agencies, Ministry of Home Affairs, Ministry of Rural Area and Development of Disadvantage Region, Ministry of Cooperative and Small Medium Enterprise, Ministry of Public Work and Housing, and State Electricity Company. Most of these ministries implementing renewable-based rural electrification projects through different model of delivery: directly carry out project procurement, channeling special allocation fund through provincial government, or by carrying research and development project in the beginning, followed by handing over the system to local government and State Electricity Company after the research project completed. Funding for rural electrification project comes from various sources: annual national budget, annual regional budget, multilateral and bilateral grant/technical assistance, international donor organization/NGOs, CSR and others.

2.3 Lao PDR

In 2006, electrification rate of Lao was only 47 percent (Malaykham, 2006), significantly improve to 87 percent in 2013 (ACE, 2015). Rural electrification was set as power sector priority with clear target of 70% by 2010 and 90% by 2020, as stated in Rural Electrification Master Plan (REMP) (Institute of Renewable Energy Promotion, Ministry of Energy and Mines, 2013). According to Ministry of Energy and Mines (MEM, 2004), the electrification rate expansion are conducted in two methods: (i) to expand the grid to comparatively easily accessible areas and (ii) provide off-grid supplies to remote areas where it is difficult to expand the present grid due to environment or cost reasons. Development of off-grid renewable energy sources such as SHP, solar, wind, biomass increases the energy self-sufficiency and security as well as sustainability. Currently, more than 20,000 households have been connected to solar home systems and Small Hydropower (SHP) have been providing electricity to people living in rural and remote area (MEM, 2011).

Vongsay and Bounsou (2014) mentioned that electric power system of Lao PDR is separated into three parts by regions (Northern, Central and Southern region) because there is no national grid connected from north to south. The extensions of electric power grids to remote households are either prohibitively expensive or economically unjustified. The main problems to implement off-grid renewable energy technology for rural electrification are: high initial investment cost with low rate of return and unavailability of tools for management and technical standards.

The Law on Electricity, first published in 1997 and revised in 2009 then later in 2011, appointed Ministry of Energy and Mines (MEM) for framing policies and strategies for the energy sector including developing Laws and Regulation on electricity business. The responsibility of MEM included supervision of electricity companies and assisting the government in deciding the tariff. The Institute of Renewable Energy Promotion (IREP) under MEM oversees the implementation of renewable energy, energy efficiency and rural electrification programs in Lao PDR. The Law on Electricity has recommended the utilization of RE-based power plants for rural electrification, either in grid tied or off-grid mode. The law also has provision for generating funds for rural electrification.

The Lao government has successfully implemented few off-grid renewable energy-based rural electrification

Programs with the help of international funding (World Bank, JICA). The public-private partnership models like those of Provincial Energy Service Companies (PESCOs) and Sunlabob (100% Lao owned company engaged in selling hardware and providing commercially viable energy services for remote areas), have been successfully implemented. However, these programs have not resulted in large scale deployment of off-grid renewable energy technologies for rural electrification due to dependence on subsidy.

2.4 Myanmar

Myanmar has one of the lowest electrification rate in ASEAN. According to Ministry of Livestock, Fisheries and Rural Development (2014), there are 63,899 villages in Myanmar, of which only 36% of the villages having access to electricity. The remaining of 40,865 villages need to be electrified. The disparity of electricity access between rural and urban area is huge. Yangon and Mandalay, the biggest cities in Myanmar, have the electrification rate of 75%; while the rural areas have electrification rate as low as 16 percent. In fact, most of rural communities in border areas have no access to the grid-based electricity at all, while some regions and states with a high share of rural population (e.g. Ayeyarwady and Magway Regions and Rakhine State) have access to grid-based electricity below 10 percent (World Bank, 2014).

The main mode of electrification has been the utilization of diesel generator followed by the extension of national grid. The utilization of renewable energy has been constantly promoted, such as single house solar system (SHS), solar lamp charging system, small scale hydropower and biogas system. Government of Myanmar has appointed several ministries to boost the electrification rate. Ministry of Livestock, Fisheries and Rural Development (MoLFRD) is the main implementer for rural electrification, both off-grid and on-grid; Ministry of Electrical Power (MoEP) is responsible for national grid, which mainly electrifies urban areas; Ministry of Industry is helping and encouraging small and medium enterprises to invest on electricity supply; Ministry of Science and Technology undertakes researches for rural electrification especially on biomass and biogas in cooperation with Ministry of Agriculture and Irrigation.

In order to escalate the rural development and poverty reduction activities, on August 2013, Ministry of Livestock and Fisheries was reorganized as the MoFLRD, and assigned as the Focal Ministry for rural development. Under MoFLRD, Department of Rural Development (DRD) is responsible for all rural infrastructures, including electricity access. To promote the off-grid rural electrification, DRD has organized rural development and electrification committee in village and township, surveyed the community needs, allocated budget according to parliament's decision and cooperate with private sectors, UN agencies, and NGO to achieve the electrification target.

Myanmar National Electrification Plan (NEP) 2015 – 2030 is being formulised by MoEP and MoLFRD with the help from the global Sustainable Energy for All (SE4All) initiatives, led by the World Bank and the United Nations. The NEP is envision to be a comprehensive action plan for developing, financing, and implementing electricity access scale-up program in the whole country, with the target of achieving universal access by 2030. Its aims to align support from different stakeholders with the implementation program for achieving national access targets and syndicates financing on a timely, ongoing and programmatic basis. NEP also proposed institutional reforms required to ensure alignment of funding sources and accountabilities for effective and timely implementation of the electrification program.

3. Off-grid Rural Electrification Approaches

The success (or failure) of off-grid rural electrification approaches with Renewable Energy Technology (RET) depends not only on a broad range of influencing factors: geography, availability of natural resources, reliability of technical solutions, financial feasibility; but also human capacity and dedication of individuals to name only few of them. These factors vary greatly from country to country and framework conditions are comparable only to a limited extent.

However, there are certain factors which are considered to be indispensable for successful rural electrification approaches which shall be carefully considered for planning and implementation of such projects. These factors comprise: (i) a stable and predictable policy framework; (ii) reliable support policies and a feasible

financing mechanism; (iii) a sustainable project setup and business models; (iv) the application of appropriate technology; (v) the due consideration of socio-economic aspects and community involvement; and (vi) continuous training and capacity building.

3.1 Policy Framework for Off-grid Rural Electrification

Most of the countries in the region have established rural electrification bodies or formulated schemes with supportive legislation to extend the rural electrification. However, there has been no separate policy framework for off-grid rural electrification. Provisions regarding off-grid electrification are usually included in the policies and plans for rural electrification in general, which most often focus on grid extension as the least-cost solution for many rural areas.

The REF in Cambodia started a pilot project in Kampong Speu with the first US$ 10,000 repaid from the 12,000 SHS rent-to-own programme. The target of this pilot project was 1,000 households. REFs were identifying the families and managing the loans with customers. The similar project has been very successful in Lao PDR. The REMP in Lao PDR set a National Electrification Target of 94.7% on household basis by 2020, which will be achieved by on-grid system, i.e. grid extension (90.9%) and by off-grid system using mini/micro hydropower and SHS (3.8%) (MEM, 2010). REMP considered affordability as the most important criterion. At initial stage, the project developers were required to visit the village with a sample of SHS kit and explains its technical features and application as well as the payment schemes to the villagers in detail prior to list potential customers. If the percentage of candidates that was able to pay less than 50% of total households, this village would not be selected for SHS-based electrification.

While in Indonesia, the enactment of Law No.30/2007 on Energy affirmed the right of citizen to the access to energy. The law made improving access of energy for the poor and community lives in remote area as one of the key objectives of national energy management. Energy access could be achieved through providing assistance/support to the poor to improve access to energy and developed energy infrastructure in the underdeveloped region to reduce regional disparities (Government of Indonesia, 2007).

Table 2 presents common key policies to promote off-grid rural electrification prevalent in the ASEAN region.

Tab. 2 Key policies for promoting off-grid rural electrification in the ASEAN

Key Policies	Main content of the policy
Strategies	- Long term objectives and strategic goals; - Transparent overall rules and guidance regarding development plans and financial; - Roles and responsibilities among the relevant institutions and stakeholders.
Development plans	- Review of energy access in the country (i.e. detailed electrification rates in different areas); - Criteria for the selection of target areas/communities; - Resource mapping for target areas/communities (i.e. water course, biomass, wind, solar, etc.); - Action plans including prioritization of areas/communities to be electrified; - Data collection on location, socio-economic conditions, electricity demand, etc. for the targeted villages.
Financial incentives	- Specification on types and amounts of financial incentives for off-grid electrification projects (e.g. investment subsidies, VAT exemption, import duty exemption, income tax holidays, etc.); - Criteria for the entities eligible for financial incentives (e.g. power producers, project owners, end-user, community, etc.); - General pricing principles for off-grid electrification (i.e. tariff structure for off-grid applications).
Financing mobilization	Mechanism for mobilizing funds for off-grid rural electrification (including domestic as well as international sources).

3.2 Financing Mechanism and Required Support Policies

There are several possibilities that can be applied to finance off-grid rural electrification projects. The option most commonly applied in the ASEAN are private financing, financing through the public power utility, government financing, and Public Private Partnerships (PPP)[1]. Table 3 summarizes the financing mechanism and required support policies in ASEAN.

Tab. 3 Financing mechanisms and required support policies

Financing mechanisms	Financing sources	Key support policies required
Private financing	• Equity • Commercial and/or soft loans	• Market-based electricity pricing policy in target areas; • Clear legal framework on private financing in off-grid rural electrification; • Indirect subsidies (e.g. technical assistance, free land use, VAT and import duty exemption, income tax holidays, etc.); • Soft loan policy for RET-based rural electrification projects.
Public power utility financing	• Equity • Commercial and/or soft loans	• Inclusion of off-grid electrification into the utility's work program (e.g. through regulation); • Policy on cross-subsidized tariffs; • Indirect subsidies (e.g. technical assistance, free land use, VAT and import duty exemption, income tax holidays, etc.); • Soft loan policy for RET-based rural electrification projects.
Government financing	• Government budget • International/local grant (ODA) • Local/international long-term soft loans	• Policy on off-grid rural electrification; • Institutional setup to implement off-grid rural electrification programs; • Financial incentives including direct and indirect subsidies.
Public Private Partnership (PPP) financing	• Private financing • Government budget • Grants and loans	• Grants (e.g. project preparation, seed investment, etc.); • Soft loans policy for RE-based rural electrification projects; • Financial incentives including direct and indirect subsidies.

The public power utilities (e.g. PLN in Indonesia and EDL in Lao PDR) are investing in off-grid rural electrification projects using their equity capital and (soft) loans from local and/or international financing institutions, thereby cross-subsidizing rural electrification activities and – in some cases – creating business cases for private developers. Subsidies are regularly provided by the government or international partners in order to ensure financial viability for the project developers/investors and affordability for the customers at the same time. In a SHS project in Cambodia with 12,000 planned installations, US$ 100 were granted for each supplied household. The subsidy made the rental fee payment to the developer affordable for the customers at US$ 4.86 per month for a 50-Wp SHS and US$ 3.35 per month for a 30-Wp SHS over a 4-year period without interest (ACE, 2012).

3.3 Project Setup and Business Models

One of the big hurdles for off-grid rural electrification is the fact that private investments are not economically viable or the return on investment is comparably low. Thus, a sound project setup including a feasible business model indispensably ensures effectiveness and sustainability of rural electrification projects

[1] The term "PPP" is widely used in different contexts. Within this paper, PPP refers to a project where the public and the private sector cooperate and both parties provide investments.

The lack of organizational structures, high levels of initial capital investments, and lack of ability or willingness to pay by rural customers are some of the major issues that make it challenging to develop a business model for off-grid rural electrification.

A large variety of business models for off-grid rural electrification exist in the ASEAN region, depending largely on local conditions and political objectives. Table 4 summarizes the successful business model applied in AMS. In reality, however, a hybrid types of these models are often applied, combining the advantages of different approaches.

Tab. 4 Project types and business models

Business model	Key features
	Market-based models
Fee-for-service model	A project investor/developer invests in and owns the off-grid power generating system and supplies electricity to rural customers. The investor/developer ensures operation, maintenance and replacement of the power system. The customers pay for the electricity they use either based on metering (kW/h) or a fixed (monthly) charge. The electricity tariffs are usually set at a financially viable level (cost covering) and are relatively high compared to other approaches.
Dealer model	Customers/end-users purchase the power system either with own cash and/or loans. The customer is normally a household or a facility owner (e.g. rice miller). Beyond warranty service, the customer assumes responsibility for all operational and replacement costs. There is no payment for consumed electricity, only consumables and spare parts required for the operation and maintenance of the power system have to be purchased.
Lease model	In contrast to the dealer model, the equipment is owned by the lessor (e.g. ESCO) and transferred to the customer only at the end of the leasing period. The lessor remains responsible for maintenance and repair, while the customer pays a (monthly) rental fee during the leasing period.
	Government induced community-based business models
Fully grant-based model or Partially grant-based model	An off-grid power system is 100% grant-financed, usually by government or international partners, while the projects implemented under the partially grant-based business model will be financed by a mix of grant and long-term soft loans and/or local contributions (e.g. from the government budget or the community). The power system is usually owned, operated and maintained by a community- based entity such as village committee, community cooperative, etc.
	Public Private Partnership (PPP) models
Operation-Maintenance PPP model	The Operation-Maintenance model is a partnership, in which a public partner invests in an off-grid power generating system and contracts a private partner to operate and maintain the system. The public partner retains ownership and overall management of the power system.
Operation-Maintenance-Management PPP model	Under the Operation-Maintenance-Management model, a public partner enters a contract with a private partner to operate, maintain and manage the off-grid power system. The public partner remains the owner of the system, but the private partner may invest own capital in the system.

Fee-for-service business models helped attract the private sector to invest in off-grid rural electrification. This model applied in Shwe Hlay Chaung village in Myanmar which was implemented in 2008 to replace diesel-based battery charging system by a rice husk gasification power using a dual-fuel engine. The system included a rice husk gasifier, a 30 HP dual gas engine, a 20 kV electric generator, power distribution to supply electricity

to 50 households and a battery charging system and also free of charge electricity supply to a pagoda and monastery. The project was owned by a private developer who operated and maintained the system. Total investment was around US$ 6,100 financed by a commercial loan with 7% interest rate per annum. The total income was around US$ 500. Taking into account the cost of equipment maintenance, the investment was paid back in 2 years (ACE, 2012).

3.4 Appropriate Technology Solutions

Technology choice is one of the most critical factors that affect the success and sustainability of an off-grid rural electrification project. There are several types of technologies that can be utilized for off-grid rural electrification: diesel generators, hydro power (mini, micro or pico system), biomass gasification power system, biogas-based power system, wind power (home-scale system), solar PV (mini, home-scale or pico systems), hybrid power system. However, the most common technologies used are solar photovoltaic (PV) – both SNS as well as mini grids- and mini/micro hydro systems.

Typical SHS includes a 10 to 130 Wp PV array, a rechargeable battery for energy storage, one or more high efficiency lamps and an outlet for television or radio. The mini/mico/pico-grids are typically in the range of 5 to 1,000 kW and provide water pumping and in-house appliances. Almost all the countries reviewed have used SHS as a means for extending lighting to areas that could not be reached by the grid. A key factor of the success of the solar PV programme in different countries is due to quality standards ensured for PV panels, batteries and other components as approved by the technical standards committees in respective countries.

Two steps should be carried out in order to select an appropriate technology for an off-grid rural electrification project:

- A technical analysis to preliminarily identify the appropriate technologies; and
- Economic and financial analysis of different possible technologies.

The technical analysis includes the collection and assessment of the main input data such as local renewable energy resources, population, dispersion of customers, energy consumption, income level, willingness to pay, requirement on reliability of electricity supply, productive use of energy, etc. The technical analysis should also take into account the efficiency, reliability and expected lifetime.

The economic and financial analysis includes the capital costs, O&M costs, and other related costs (e.g. O&M training cost, environmental protection cost) of each technology, the tariff system proposed and the subsidies offered. These assessments are usually conducted technology neutral and are not pre-determined by choosing a particular technology.

3.5 Socio-Economic Aspects and Community Involvement

Socio-economic and environmental aspects as well as potential impacts on the community need to be taken into consideration in off-grid project planning and implementation. It is observed from the rural electrification efforts in all the study countries, the benefits of electricity increased standard of living, productive activities and social institutions. Environmental benefits include positive impacts on soil, water and air pollution.

In addition, local community involvement is an essential aspect in rural electrification projects. If a project is not well explained, accepted or appreciated by the community beneficiaries, sustainability can be hampered. Community involvement is therefore important at all stages of the project cycle, from planning and project development to project implementation and long- term operation. It is crucial to understand the community's needs and potential before starting with the actual planning of a project. For example the chosen project design (e.g. business model) will only work, if gain acceptance from the villagers. The communities and their representatives play furthermore a crucial role in supporting the construction works (especially for hydropower projects) as well as in operating and maintaining the power system in case this task is not carried out by a private entity.

A close monitoring and evaluation of the socio- economic and environmental impacts of off- grid rural electrification are particular interest in order to asses and understand the long-term impacts and benefits of

the measure. Since rural electrification programs most often have a political and development objective, the monitoring of economic progress, social and welfare impacts as well as environmental consequences of a particular off-grid electrification program is essential.

3.6 Capacity Building and Training

Capacity Building and Training (CB&T) is fundamental for all involved stakeholders to ensure that they can fulfil their roles and responsibilities in an off-grid rural electrification project. The Mini Hydro Power Project for Capacity Development (MHPP) in Indonesia promotes the dissemination and exchange of know-how on mini hydropower, as well as the sharing of best practices in the building of sustainable facilities (MHPP, 2011). Typically, the following stakeholders are eligible for targeted CB&T measures:

- Policy makers and government officials (central and local level);
- Project developers;
- Financial institutions and private investors;
- Equipment manufacturers and construction companies;
- Power plant operators and managers;
- Local communities/end-users

General information on aspects such as policy, technology, financing, project impacts and benefits, etc. are to be provided to most of the stakeholders in order to raise awareness and general knowledge on off-grid rural electrification. Various formats of CB&T measures such as seminars, workshops, study tours, site visits, classroom and on-site training were applied in ASEAN region. The selection of an appropriate type of CB&T depends on the target stakeholders as well as the topics presented.

4. Conclusion and recommendations

Rural electrification is one of the keys to rural development and gaining high priority in ASEAN region to meet the economic and social development goals, as well as political priority. Though all countries reviewed here have developed policy frameworks and envisage bringing more areas under electrification, some countries have no specific policy framework for off-grid rural electrification and have not shown specific initiatives to improve the overall household connection level.

Further, source of funding for rural electrification programs were in the form of private financing, government financing and PPP. Private financing is used for commercially viable projects. Government financing can offer low, affordable electricity tariffs to rural villagers, however the investment are hardly paid back while PPP combines the advantages of the private and the government financing mechanism. Subsidy component either to improve the infrastructure or through cross subsidization of tariffs for poor customers are observed in all rural electrification program in the region.

The off-grid technologies prioritized seem to fit to a large extent with the geographical characteristics of the demand, resources potential and distribution system. The distribution system and technological performance are relatively better placed for solar PV than for micro hydro and biomass gasifier.

This paper shared the rural electrification experiences and lesson learnt from four selected countries of ASEAN for cross learning potential across the region as well as other developing countries. This review presents a number of recommendations for the planning and implementation of off-grid rural electrification:

- Policy makers shall develop the key policies for promoting off-grid rural electrification which shall include a development strategy and concrete action plans, a suitable electricity pricing policy, financial incentives and a framework on funding mobilization;
- A clear legal framework for private investment in off-grid rural electrification needs to be established in order to mobilize the private sector to become actively involved in this market;
- A central institution/agency shall be created to coordinate the planning and implementation of all off-grid rural electrification activities in a country;
- The public sector should use its resources to finance off-grid projects in poor rural areas where business

models can hardly be established and projects are less or not profitable. Wherever possible and economically viable, priority should be given to the private sector to get engaged for investment and project development;

- The business model selected for an off- grid rural electrification project shall have some degree of flexibility and fit the specific conditions of the community implementing the project. The business model may have to be modified along the way in order to cater to the actual developments and changes in the project structure during project implementation;
- Whatever is the selected business model, maintenance should be taken to ensure that end-users have access to quality electricity services at affordable prices;
- The project design must not be technology driven. Technology choices are to be based on practical considerations. A cost-benefit analysis of different technology options (including grid extension) should be carried out to determine the least-cost solution;
- Productive and institutional applications of electricity not only help to improve standards of living (e.g. job creation, better health care) but also increase the economic attractiveness of the off-grid power project. The project developers therefore must consider initiating or enhancing productive activities as they significantly increase the sustainability of the project;
- Maximizing the awareness and involvement of the benefitting community in the early stages of the project cycle, especially during the project assessment phase, is vital to the success of off-grid project implementation. Key activities include public awareness campaign, regular meetings with community leaders and focus-group meetings;
- Capacity building and training to develop local capacities in design, implementation, management and O&M is essential for the success of off-grid rural electrification projects. Therefore, adequate resources should be devoted to developing local capacities.

Abstract

Solar water pumping is a mature, reliable, and economically attractive solution for off-grid irrigation, livestock water, and community water supply. With increasing reliance on water pumping for food security needs, and limited access to conventional energy sources for many communities most in need of water pumping, development programs around the world are accelerating market development for solar powered water pumping systems. Financial, managerial, technical, market access, and educational challenges exist. However, examples from Kenya and Nepal demonstrate how successful initiatives have developed to overcome such barriers. These examples demonstrate that challenges can be overcome through public-private partnerships that take advantage of relative cost savings, increased reliability of both solar power and irrigation systems, and improved technology access through innovative financing models. These interventions help accelerate solar water pumping adoption in Kenya, Nepal, and elsewhere.

Keywords: *Photovoltaics, solar water pumps, renewable energy*

1. Introduction

Solar photovoltaic water pumping (PVWP) is one of the most economically attractive solar energy applications with installed systems proven to provide 20 or more years of reliable service. There is an excellent match between seasonal solar resource and seasonal water needs (Foster, 2009). A wide range of water supply needs can be met by PVWP, from livestock and community water supply, to small and even large-scale irrigation needs. PVWP system costs have declined significantly, from over US$25 per peak watt over 15 years ago (Foster, 1998), to total PVWP system costs under US$5 a peak Watt possible today (Foster and Cota, 2013).

Irrigation is a critical tool in addressing food security challenges; however, conventional grid or fossil fuel energy sources are not adequate to meet global irrigation needs. There are new opportunities emerging in the transition from diesel to solar powered pumps to reach farmers who cannot access traditional energy sources. A significant shift has begun in the rural water pumping industry where previous diesel pump dealers now provide solar powered pumping systems that are outpacing diesel systems sales due to lower life cycle costs. Some vendors in South Asia that previously sold only diesel/gas pumps, have expanded their product lines to include PVWPs and now report selling more PVWPs than diesel pumps. Ambitious targets for PV water pumps in South Asia are indicative of the promise of this technology. Bangladesh's Infrastructure Development Company Limited aims to finance 50,000 PVWPs by 2025 (Rahman, 2015), the Alternative Energy Promotion Center of Nepal plans 500 PVWPs by 2017, and India's Ministry of New and Renewable Energy target is 100,000 PVWPs by 2015 and one million installations by 2021 (International Centre for Integrated Mountain Development, 2015).

Key challenges faced in markets where PVWP development has been implemented, as well as in those areas where it has not yet materialized, illuminate several challenges, including financial, managerial, technical, and market access challenges. A key challenge for PV water pumping systems is the upfront cost. The lifetime cost of irrigation varies depending on the system, its maintenance, and inputs. Analyses have shown PV water pumping systems have payback times of two to three years (Foster and Cota, 2013). PV capital costs require financing schemes that can help farmers realize financial savings in a few years and over the lifetime of the

doi:10.18086/swc.2015.03.04 Available at http://proceedings.ises.org

system. Many existing PVWP projects are subsidy driven, funded by grants, or financed through loans that farmers obtain from banks. The overall challenges are not just related to PVWP technologies, but the entirety of the system that the energy is a part of, including for irrigation, agriculture, and community systems.

2. Solar Water Pumping Advances

A PVWP system is similar to any other conventional water pumping system except that the power source is solar energy. PVWP systems have, as a minimum, a PV array, a motor, a pump, and normally a water storage tank. The PV arrays are sometimes mounted on passive trackers (which use no motors) to follow the sun throughout the day for increasing pumping time and water volume. Alternating current and direct current motors are used to power centrifugal, displacement like piston or helical rotor pumps. Water is more cheaply and effectively stored in a tank rather than storing electro-chemical energy with batteries. Pump motors are normally direct drive from the PV array using a maximum power point tracking (MPPT) controller, thus eliminating batteries, decreasing system costs while increasing reliability (Foster, 2009).

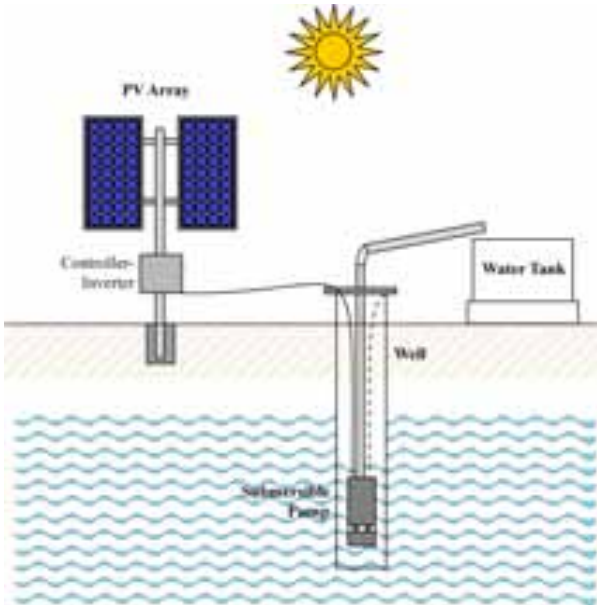

Fig. 1: Typical PV water pumping system components.

General size categories of PV water pumping systems are based on motor power output (Watts or kW):

- *Small* >50 W to < 1 kW
- *Medium* 1 to 5 kW
- *Large* >5 to 100 kW

The size categories tend to correlate with the differing technologies used for solar pumping. Small PVWPs have the longest history for commercial application and show the most technology diversity. Small, low-power systems can provide large amounts of water by pumping throughout the entire day, which provides affordable water pumping solutions for even poor, smallholder farmers in remote regions.

2.1 Helical rotor water pumps

One of the most important developments to advance PV water pumping over the past 15 years has been the development of helical rotor submersible pumps. The helical rotor is a positive displacement pump mechanism that is mounted to a submersible motor. The motor is similar to that used for centrifugal submersible pumps. Like the centrifugal submersible pump, the helical rotor submersible pump can last for many years with no regular maintenance required. Most new PVWPs use this type of design. Table 1 provides a comparison of basic advantages and disadvantages for different pump types.

Fig. 2: Example helical rotor pump end commonly used for solar water pumping.

Tab. 1: Typical operational characteristics of different PV water pump types.

Type of PV Water Pump	Advantages	Disadvantages
Submersible centrifugal	•Simple, with one moving part. •Regular maintenance not required. •Efficient at high flow rates or low lift. •Good tolerance for moderate amounts of sand and silt. •Most conventional, widely available.	•Poor efficiency at low volumes (<30 liters per minute) or high lift. •Capacity is reduced disproportionately at low speeds (in low-sun conditions). •Impellers can fill with sediments and may require periodic cleaning.
Helical rotor, submersible or surface	•Simple, with one moving part. •Regular maintenance not required. •Highly efficient at low flow rates (4-50 liters per minute). •Maintains full lift capacity at all speeds. •Good tolerance for moderate amounts of sand and silt.	•No major disadvantages.
Diaphragm, submersible or surface rotary vane	•Relatively low initial cost. •Efficient at very low flow rates (4-20 liters per minute). •Maintains full lift capacity at all speeds.	•Requires preventive maintenance. •Poor tolerance for sand and silt. •Requires filtration (rotary vane pump).
Surface centrifugal	•Relatively low cost. •Efficient for low lift and high flow rates. •Easy to inspect and maintain due to surface location. •Good tolerance for moderate amounts of sand and silt.	•Suction limit is about 6 meters or less. •Requires priming (filling the intake). •May be damaged by running dry if it loses prime.

2.2 Affordable solar water pumps

PVWP system costs have rapidly declined due to the decreasing cost of PV modules. PVWP system costs are now one quarter of what they were 20 years ago (Foster, 1998). PV module prices have dropped by over 80 percent over the past 8 years, and are expected to drop about another 50 percent in the next five years or so. This cost decrease has made it possible to obtain small-scale PVWP systems for only a few hundred dollars. These systems are cheaper to install than competing diesel systems or often even electric grid options if no power is already on site.

Typical mid-size PVWP systems range from 1-2 kWp and cost about US$4,000-7,000 installed depending on location. Payback for many PVWP systems is typically only two to three years, with expected lifetimes of over 25 years for alternating current pumps, while direct current pumps need replacement every five to seven years, depending on water quality.

One example of an affordable small PVWP is the Futurepump manufactured in India, shown in Figures 3 and 4. This is an inexpensive piston pump that sells for about US$400 and operates on only an 80 Wp solar module. It is very simple to operate and can replace treadle pumps. Futurepump provides 900 liters per hour at six meter total dynamic head (TDH), or 2,000 liters per hour at one meter TDH. This pump is limited to about eight meter TDH.

Fig. 3: The Futurepump piston water pumping system manufactured in India retails for US$400 with the PV module.

Fig. 4: SunFlower 80 Wp module name plate used for the Futurepump PV water pumping systems.

3. Kenya Smallholder Solar Irrigation

Agriculture makes up the largest share of Kenya's GDP (25%), but only 6% of agricultural land is irrigated. With a labor force of almost 18 million, 75% of which are engaged in the agricultural sector, Kenya has huge potential to increase its agricultural output if irrigation can be accessed for smallholder farmers. However, "[irrigation-based farming] is developed under large-scale irrigation schemes for crops like rice, a few farmers have their own irrigation systems for export crops like horticultural produce, and a limited number of smallholders practice small scale irrigation farming" (Aila and Atieno, 2006).

The U.S. Agency for International Development (USAID) funded Kenya Smallholder Solar Irrigation Project (KSSI) is being implemented by Winrock International (WI), in partnership with DuPont Kenya, SunCulture, Futurepump Ltd, the USAID-funded Kenya Agricultural Value Chains Enterprises Project (KAVES), and others. KSSI is part of the Renewable Energy Leader with Associates (RELWA) program, which aims to scale up access to, and adoption of, renewable energy globally, with a focus on increasing farmer access to renewable energy technologies that can improve agricultural productivity, sustainability, and income.

KSSI aims to improve quality of PVWP systems in Kenya while facilitating an increase in commercial sales of PVWPs to smallholder farmers who benefit by either eliminating use of costly diesel fuel or by converting from rain-fed to irrigated farming in arid areas that have never used pumps. KSSI is setting up PVWP demonstration sites around the country. Although the Government of Kenya is implementing an expanded rural electrification program, over two-thirds of the country does not have access to grid power. KSSI targets farmer groups that will not be reached by the grid in the next 5-10 years. As of September 2015, some farmers choose to buy the less expensive PVWPs even in areas where the grid is nearby. Some success factors of PVWP market acceleration in Kenya under KSSI are illustrated through the following examples.

3.1 Kenya PVWP market dynamics

The market for PVWPs in Kenya is changing rapidly. In January 2015, a WI survey of PVWP retailers with products affordable to smallholder farmers identified several companies present in the Kenyan market. SunCulture sells a 300 Wp pump kit that retails for US $2,200. Futurepump Ltd has an 80 Wp SunFlower pump kit that retails for US $400. Davis and Shirtliff is the PVWP national leader and sells a small Shurflo direct current diaphragm pump for US$400 (pump only). This company has sold over 4,000 units and is now developing a 120 Watt solar pump kit to retail for US $700. A new company, KickStart, recently entered the market with a 120Wp MoneyMaker solar pump that retails for US $395. PVWP vendors in Kenya vary greatly in numbers of sales and maintenance staff, ability to respond to increasing demand for their products, and ability to reach smallholder farmers to raise awareness about their products.

3.2 Overcoming educational barriers to commercialization of PVWPs in Kenya

WI found that the key barriers to increased commercialization of PVWPs are not technological but instead center around the need to directly reach thousands of smallholder farmers with information on cost, performance, installation, and maintenance of PVWPs. In this regard, WI functions as a neutral intermediary between farmers and PVWP companies. Working in partnership with large agricultural initiatives, such as the USAID-funded KAVES project and its 500,000 participating farmers, WI ensures that two or three PVWP companies attend farmer field days so that farmers can compare products and choose one that best suits particular farm needs. WI also set up PVWP demonstration sites for early adopter farms in several counties and is arranging for farmer groups affiliated with KAVES and DuPont to attend demonstrations at these sites. WI reaches out to banks and cooperative savings organizations to ensure that farmers have financing options for PVWP purchases and technical trainings for PVWP companies to ensure they can provide high-quality products, installation, and maintenance. Some example KSSI cases of PVWP in Kenya are provided in the following sections.

Fig. 5: Winrock invited PVWP retailers Futurepump (at left, with green hose) and KickStart to display their mobile units at a KAVES Field Day in Kenya, October 2015.

3.3 PVWP for drip irrigation in Nyahururu

Patrick Mwendwa is a typical farmer in Nyahururu who owns five acres, one of which is for his homestead. He uses one acre for apiculture, two acres for onions under drip irrigation, and one acre for various vegetable crops for domestic use. Before installing a PVWP, Mr. Mwendwa hand watered his vegetable crops using a water can, which was cumbersome. Prior to the PVWP, he could not grow onions because of the high water requirements of the crop.

After attending a training facilitated by WI at a SunCulture (KSSI partner) demonstration plot, Mr. Mwendwa purchased a complete PVWP system with a one acre drip kit to improve his farm productivity. He financed the PVWP from his savings for a total cost of US$3,320, including the drip irrigation system. The SunCulture PVWP is set in a 20 meter hand dug well and fills a 10 cubic meter water storage tank at a height of four meters in about five hours.

Mr. Mwendwa planted onions, a high value crop, using the one acre drip irrigation system. He found ready markets for his produce and realizes high returns on his investment. He plans to expand his drip-irrigated acreage by another acre since the PVWP has additional capacity that he is not using.

Fig. 6: One acre drip irrigation system using a PVWP on the Mwendwa farm in Nyahururu, Kenya.

3.4 PVWP for drip irrigation in Bogoria

The Noroloro Women's Group in Bogoria (Baringo County) was formed in 2006. This Group initially worked with livestock and later transitioned to fruit and vegetable production, which needed irrigation to be productive during the dry seasons. This Group began using an NGO-donated SunCulture pump in August 2014 to irrigate two acres through drip tape irrigation. The SunCulture PVWP pumps about 10,000 liters per day from a five foot depth pond which obtains water from a diverted canal.

Fig. 7: The SunCulture 300 Wp PVWP, owned by the Noroloro Womens Group, provides 10,000 liters per day for two acres of drip irrigation.

3.5 PV water pumping for aquaculture and irrigation in Kendu Bay

WI is collaborating with Futurepump at a demonstration site in Kendu Bay and nearby farms, where farmer Joshua Okundi purchased a SunFlower PVWP. Mr. Okundi owns five acres of farmland, which he uses to grow corn, passion fruit, tomato, banana, French beans, sweet pepper, kale, carrot, potato, peanut, avocado, and mango. He also has two fishponds, with 1,000 and 1,500 fish each, in which he grows tilapia. Mr. Okundi uses the 80 Wp Sunflower PVWP for the following activities at his farm:

- Pump water from the canal to the elevated tank for later use irrigate his crops.
- Pump water from the canal to the tilapia fishponds for oxygenation.
- Furrow irrigate passion fruit, avocado, banana, and a mango tree nursery.
- Pump water from the canal for domestic use.

The PVWP has enabled Mr. Okundi to save about US$20 per day from avoided fuel costs for a diesel pump he used to run. The SunFlower pump was purchased for US$400, achieving payback in about one month. The PVWP also allowed Mr. Okundi to start four new money-generating farming activities at his farm, hence improving his income. WI is conducting a detailed cost-benefit analysis at these demonstration sites to document the income benefits of PVWPs.

Fig. 8: Mr. Joshua Okundi with his Futurepump PVWP, used to recirculate water for a tilapia pond for oxygenation and also to irrigate a banana grove. The farm is located near Kendu Bay on Lake Victoria in Kenya.

3.6 PV water pumping for drip irrigation in Thika

A SunCulture demonstration site near Thika irrigates two acres of land that is not connected to a grid. The SunCulture submersible helical rotor pump (from China) sits one meter below the water surface in a pond. The head is about 20 meters to reach the 10 cubic meter tank at the top of a hill. The tank is filled twice a week and takes about four hours to fill. The community uses water from the tank daily to drip irrigate two acres and a nursery. The PVWP was installed in July, 2015 for US$2,200 and was a more inexpensive option compared with connecting to the nearby electric grid which was quoted at US$3,700 along with an energy consumption charge of US$0.19/kWh. This cost is more than the amortized cost of a direct drive PVWP over 20 years (estimated at about US$0.12/kWh).

Fig. 9: Thika solar water pumping system used for drip irrigation.

4. Accelerated Commercialization of PV Water Pumping in Nepal

Nepal is an agriculturally dependent country with a majority of its people involved either directly or indirectly in agriculture. Traditional agriculture in Nepal is rain-fed and depends on rainfall during the summer monsoon season. Farmers generally grow cereal crops like rice and wheat during the monsoon season. In the dry season, from November to March, many farmers leave their land barren due to lack of water, while more wealthy farmers can grow high value vegetables using either diesel or grid powered electric pumps for irrigation. With the high cost of fossil fuel along with maintenance costs, farmers have to bear huge financials burden for operation and maintenance of diesel pumps. Nepal suffers from severe electric power shortages, which causes frequent power cuts and load-shedding, so grid powered electric pumps are often unreliable. PVWPs are a reasonable irrigation solution for the dry season to increase farmer incomes. PVWPs also provide opportunity for high value horticulture farming in the off-season, which can generate even higher incomes for farmers.

Market challenges in Nepal include: limited PVWP products options; relatively few PVWP suppliers; limited access to finance; inadequate information and understanding about PVWP among farmers hesitant to change farming practices; and lack of coordination between government agencies, the solar power industry, promoters and organizations working to improve agriculture and irrigation efficiencies. USAID funds the Accelerated Commercialization Solar Photovoltaic Water Pumping (AC-PVWP) project, implemented by WI, that focuses on capacity building and market development activities to expand commercialization and adoption of PVWP systems for irrigation, livestock watering, and community water supply. There is a large demand for water pumping, but due to the high initial capital costs, many Nepalese farmers are unable to afford the technology. WI is working with SunFarmer Nepal and local cooperatives for investment capital to provide equity and loans to farmers so they can obtain PVWPs and increase their farm productivity. Some example AC-PVWP cases of PV water pumping in Nepal are described below.

Fig. 10: Winrock International demonstration PVWP unit at Khajura, Banke, Nepal.

4.1 SunFarmer financial loan model for PVWP installations in Nepal

The SunFarmer loan model is aimed at creating access to PVWP irrigation services for the farmers of Nepal through innovation in technology, finance, and long-term service commitments. The model serves as a platform to converge multiple stakeholders to accelerate commercialization of PVWP. Under this model, SunFarmer invests up to 50% of the initial capital for PVWP system installation and farmers pay off the loan in installments through the designated cooperative within the Power Purchase Agreement (PPA) period (e.g., two years). With this financing scheme, more farmers can install PVWP systems for irrigation. In addition to financing, SunFarmer performs technical and financial assessments to ensure that the system is properly

installed and guarantees free repair and maintenance, to ensure system performance within the PPA period. SunFarmer supports farmers to identify the most affordable and reliable systems tailored their needs. Upon successful completion of the agreement period, SunFarmer hands over ownership of the project and PVWP system to the farmers.

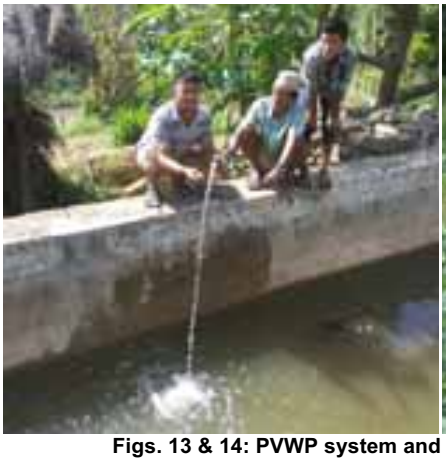
4.2 *PV water pumping for vegetable farming in Pokharikada*

A demonstration PVWP unit with the Pokharikada Village Development Committee in Surkhet district was installed by Suryodaya Urja Private Ltd., irrigating 4.4 acres of land for a group of 20 farmers. The system consists of a 1.4 kW Grundfos submersible helical rotor pump, 1,260 Wp PV array, grounding system, and accessories as shown in Figures 11 and 12. The submersible pump is placed in an 8 m^3 water tank in a spring box. The system is designed to lift 10,000 liters of water 60 meters up to a 20 m^3 collection tank. The water is then fed to drip and sprinkler system and the farmers use the water in queue. The total cost of the system was US$4,988 and the civil component was US$4,260, which included the water tank, reservoir tank, and the distribution pipes. The demonstration system was financially supported by the Government of Nepal, the Village Development Committee, the Raising Income of Small and Medium Farmers Project (RISMFP), USAID's Knowledge-based Integrated Sustainable Agriculture and Nutrition (KISAN) Project, and AC-PVWP.

Figs. 11 & 12: PVWP system and water storage tank used for vegetable farming at Pokharikada, Surkhet, Nepal.

4.3 Cooperative loan for PVWP installation at Chinchu

Suryodaya Urja installed a PVWP demonstration unit in Chinchu, Surkhet to irrigate 2.8 acres of land for 10 farmers. The 1.4kW Grundfos submersible helical rotor pump, much like the Pokharikada system, is placed in a 5 m^3 water tank serving as a spring box. The system is designed to lift 10,000 liters of water 60 meters up to a 24 m^3 collection tank. The water is then fed to a drip and sprinkle system and the farmers use the water in queue. The total cost of the system was US$4,988 excluding the civil components. Small Farmer Saving and Credit Cooperative, a local cooperative in the village, financed US$3,000 for the PVWP system at an interest of 18%. In addition, the Municipality Office, USAID's KISAN project, and WI through the AC-PVWP also provided financial support. This system is able to irrigate several crops, such as tomatoes, cauliflower, cabbage, black eyed beans, string beans, potatoes, chile, cucumber, and bitter gourd. With PV water pumping, the farmers group is now able to irrigate throughout the year, have produced their first crop of vegetables, and have paid the first loan installment. It is expected that farmers will fully repay their loan within two years.



Figs. 13 & 14: PVWP system and vegetable farming at Chinchu, Surkhet, Nepal.

Demonstration projects in Surkhet have attracted other stakeholders, projects, and organizations working in the agricultural and irrigation sectors. Government agencies, including the District Development Committee, Village Development Committee, and Municipalities, as well as projects like RISMFP and High Value Agriculture Project (HVAP) have also shown interest in the PVWPs and plan to integrate PV water pumping technology in their projects.

4.4 PVWP for poultry farming in Chitwan

A PVWP is used for pumping water for a poultry farm in Madi, Chitwan. The system was installed by Madi Saurya Urja, a local agent of the Rural and Alternative Energy Service Centre. The PVWP can provide 4,000 liters per day of water, as required by the poultry farm. The system consists of a 300 Wp PV array with battery storage using a 150 AH deep cycle lead-acid battery. The 0.5 kW alternating current pump operates from a 1 kVA inverter connected to the battery. The total cost of the PVWP system was US$830, excluding civil works and was purchased directly by the farmer from his operational profits.

Figs. 15 & 16: PVWP system using a battery and inverter used at a Madi, Chitwan poultry farm in Nepal.

5. Conclusions

The solar water pumping examples in Kenya and Nepal, along with others around the world demonstrate overcoming barriers for commercial sales of solar water pumps by taking advantage of relative cost savings, increased reliability of PV and irrigation, increased technical access through innovative financing models, and educating farmers on pump choices. These successes have been possible through technical and market advances that have lowered costs and increased market access for PVWP. The real challenges now for wide-scale adoption of PVWP are not technological in nature, but rather pertaining to market and educational barriers. When compared to diesel or grid-electricity powered pumps, solar water pumping systems offer better returns on investments and more reliable electricity and water supplies.

Efforts to commercialize PVWP technology for irrigation are on-going. By embedding the technologies in value chain productive use projects that support farmers to increase income by growing and selling off-season produce, there are increased opportunities to demonstrate financial benefits. Current commercialization barriers are overcome through public-private partnerships that emphasize quality systems, education and demonstrations, and linkages with innovative micro-finance institutions, and partnerships with technology providers.

The challenges and successes of PVWP initiatives demonstrate lessons learned that can be applied in other regions, such as Sub-Saharan Africa, where only four percent of land area is irrigated, despite having areas with potentially sustainable water supplies (Giordano et al., 2012). With continued expansion of irrigated land, and demand further still for irrigation solutions in food insecure regions, there is great potential for accelerating and commercializing PVWP systems for irrigation. The scalability and cross regional applicability of these technologies though will depend on the water resources, market linkages, financing options, and management systems.

Abstract

The USAID Photovoltaics for Sustainable Milk for Africa through Refrigeration Technology *(PV-SMART)* project is a new and creative concept of providing on-farm solar milk refrigeration for off-grid dairy farmers in Kenya. It uses a modified off the shelf direct drive photovoltaic refrigerator (PVR) technology, coupled with innovative cooling and energy storage approaches to chill evening milk on the farm for later transport the next morning to dairy collection centers. The battery-free PVR unit is designed to work optimally in locations with at least 4 average peak sun-hours per day. Farmers can receive a premium price for providing higher quality, refrigerated evening milk to dairy processors that would otherwise spoil. Dairy processors can also charge a premium for better quality and tasting dairy products from better quality milk that is maintained chilled from farm to factory. These solar farm milk coolers (FMC) are the first of their kind anywhere in the world and are a unique refrigeration system that uses thermal ice storage in lieu of electrochemical batteries and can operate directly on dc power from a PV module powering a variable speed dc compressor. The initial 40 pilot Solar FMC units have performed well in Kenya and lab and field assessments are discussed.

Keywords: *photovoltaics, direct drive solar refrigeration, milk chilling, Kenya*

1. Kenyan Dairy Sector

The ***Photovoltaics for Sustainable Milk for Africa through Refrigeration Technology (PV-SMART)*** project aims to tackle off-grid milk cooling under the United States Agency for International Development (USAID) Powering Agriculture Energy Grand Challenge Program (PAEGC). In collaboration with Winrock International (WI), SunDanzer Refrigeration Inc. (SDZR), a leading US solar refrigeration technology company, was awarded a highly competitive USAID grant to implement the project. The 3-year project began in 2014 and is implemented in collaboration with the County Governments and Agriculture Ministries of Baringo and Nakuru, and the Department of Dairy and Food Science and Technology at Egerton University located at Njoro, and various partner dairy cooperatives all in Kenya

There are over 850,000 small holder dairy farmers in Kenya, about 85 percent of whom do not have access to the national electric power grid. Diesel fuel is expensive and logistics difficult to deliver to small rural dairy farmers. Thus, there has not been an economical method available for on-farm milk chilling for the vast majority small holder dairy farmers in Kenya and other less developed regions globally. The typical Kenyan dairy farmer has about 3 to 5 cows, producing an average of about 8 liters per day of milk per cow (typically ~60% as morning milk and ~40% as evening milk). Dairy cooperatives have an organized morning milk collection system, but normally do not accept evening milk since by morning it has a high bacteriological count. Due to the lack of on-farm refrigeration, evening milk for which there is no milk collection has to be

doi:10.18086/swc.2015.03.05 Available at http://proceedings.ises.org

either forced consumed, sold cheaply to nearby neighbors or hawkers, or is lost. In Kenya, only about 40% of milk produced is processed nationally.

This failing in upstream milk production causes milk spoilage and lost farm earnings. It also causes poor quality milk and further losses in earnings along the downstream dairy value chain. Of the milk that does arrive, much of it still has a high bacterial count due to lack of refrigeration, resulting in poor quality dairy products. Farmers could receive a premium price for better quality, refrigerated milk; dairy processors could charge a premium for better quality products if milk can be kept cool all the way from cow to consumer; especially during the all-important first four hours after milking that determine quality.

In order to enhance the value of milk from remote producers, *PV-SMART* has developed an affordable solar powered farm milk cooler (FMC) so these producers can deliver cool milk rather than warm to the central collection stations. The farmers also use FMCs on the farm to preserve other produce such as eggs, meat, fruits and vegetables. Besides demonstrating the technology proof of concept, *PV-SMART* is also working with stakeholders to open up financing for solar technologies like PVRs that can increase on-farm productivity and increase incomes. Farmers need access to technology and credit on reasonable terms to finance the initial purchase of solar power systems, which have higher capital costs but lower operating costs when compared to traditional remote generation energy technologies like diesel gen-sets.

PV-SMART has a three-phase implementation strategy for developing, disseminating, and financing FMCs in Kenya as follows:

- **Pilot Phase 1 (Year 1):** Develop a FMC by enhancing an established off the shelf PVR model adapted as a Solar FMC and field tested on 40 farms in Baringo and Nyandarua Counties, and at Egerton University. A small wire basket for perishable household food is included, as well as two 5V USB ports for daytime cell phone charging.

- **Prototype field testing Phase 2 (Year 2):** A second generation prototype Solar FMC will be further tested on another 40 farms and with milk transporter-collectors and other potential dairy users.
- **Commercial roll-out Phase 3 (Year 3):** Based on feedback from field testing the final prototype design will be: (i) adapted, (ii) a local dealer network established and (iii) the Solar FMC commercially launched on to the Kenyan market and other countries in the region; and further afield.

PV-SMART initial pilots are underway with the Mogotio and Ngorika Dairy Cooperatives near Nakuru working in collaboration with a local Kenyan dairy processor experimenting with a milk quality payment system for the very first time in Kenya.

The project is also collaborating with established financial service associations such as the Savings and Credit Cooperative Societys (SACCOS) that already work with dairy cooperatives. The SACCOS can easily provide affordable financing for farmers for solar FMC systems. The estimated return on investment for the dairy farmer is from 1 to 3 years, depending on farm milk production levels. In March, 2015, the first 40 pilot units were deployed to the dairy cooperatives, as well as with the Egerton university dairy research unit. Performance of these units and farmer feedback on the early pilot systems are being used to make further design refinements.

2.0 Direct Drive Photovoltaic Refrigeration

The PVR has thermal storage (ice storage) instead of electro-chemical battery storage, and a direct connection is made between the cooling system and the PV panel. The embodied technologies were originally developed in support of NASA's future planetary mission's refrigeration requirements about a decade ago (Foster et al., 2001). This is accomplished by integrating water as a phase-change material into a well-insulated refrigerator cabinet and by developing a microprocessor-based control system that allows

direct connection of a PV panel to a variable-speed dc compressor. By storing ice in the walls of the refrigerator, it eliminaes the needs of battery storage. The refrigerator uses a vapor compression cooling cycle with an integral thermal storage liner, PV modules, and a controller. The refrigerator employs a variable-speed dc compressor.

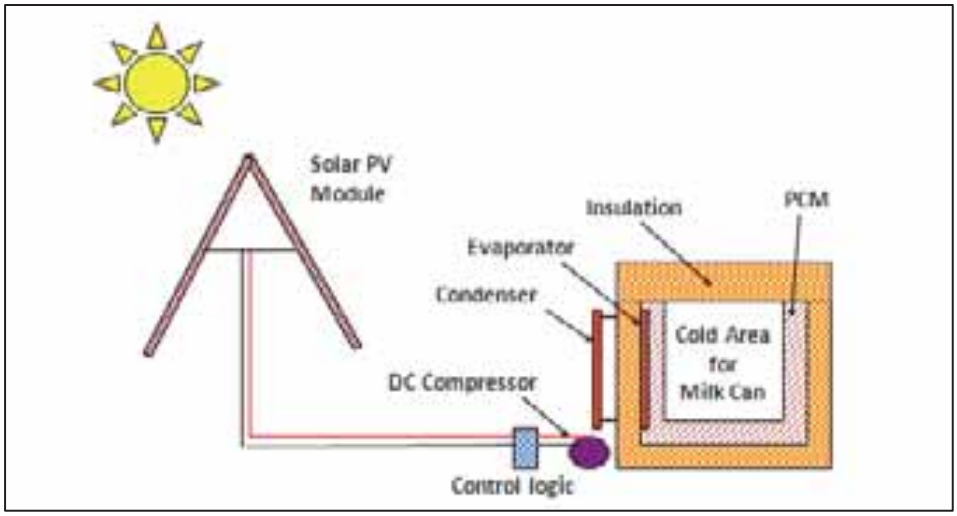

Fig. 1: Solar direct drive refrigerator with variable speed DC compressor and E-W "fixed tracking" array.

The PVR uses a fixed axis East-West tracker. This allows the variable speed dc compressor to start to spin earlier and until much later in the day, providing additional hours of refrigeration over a traditional equatorial facing fixed array. PV prices have come down sufficiently that "fixed tracking" is a viable economic option over tracking without the future maintenance concerns. This type of approach works especially well in lower latitudes like Kenya. This innovative simple approach provides superior performance.

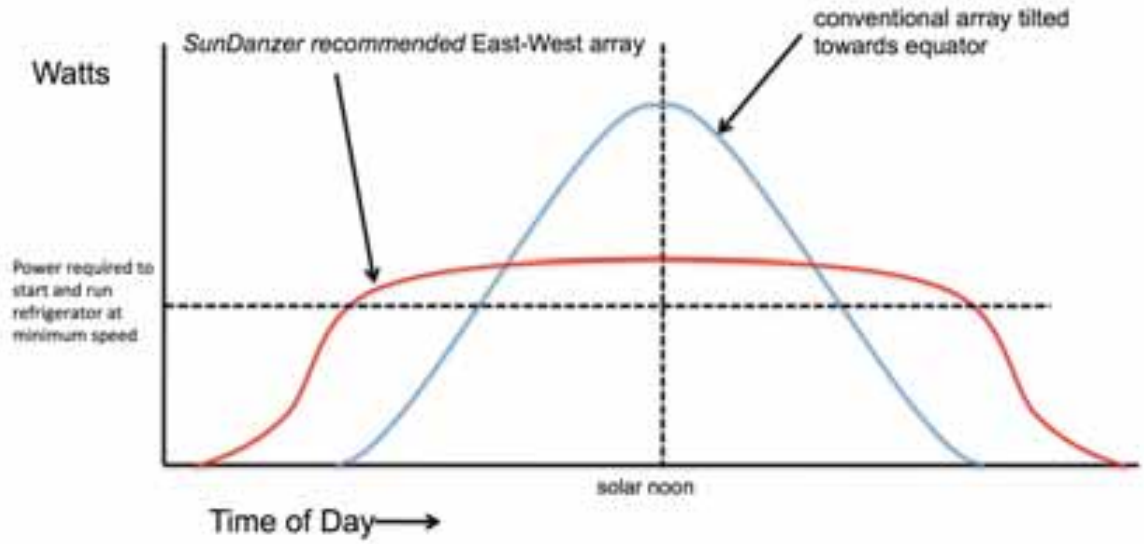

Fig. 2. E-W "fixed tracking" array designed to maximize compressor run time rather than energy capture.

With the compressor running most of the daylight hours due to the E-W "fixed tracking" array (the array is not actually moving like a conventional tracker, but is fixed with half the array facing East and the other half facing West to maximize daily compressor run time). Ice is formed and stored into the walls of the PVR. Thus, there is no need for expensive battery storage and replacements. Ice does not wear out. Testing at New Mexico State University for NASA and SDZR on an early prototype PVR with ice storage was successful for over a decade (Foster et al., 2001), which led to the development 5 years ago of direct drive vaccine PVRs using ice storage. The proven PVR technology is now expanded to FMCs.

In order to maximize heat transfer, the FMC incorporates brine bags which do not freeze at 0°C that are placed around the milk cans to increase heat transfer and cool milk quickly. As well as providing a complete and well-balanced diet for the newborn calf, kid or human baby, milk also contains antibacterial agents to protect the suckling young from potential infectious diseases; these antibacterial agents also slow bacteriological growth – the cause of milk souring. This effective natural protection is called the lactoperoxidase system, and has both bacteristatic and bactericidal effects against some milk spoilage microflora for about the first four hours after milking. Bacteriological growth is futher retarded when mik temperatures fall below 10°C and is essentially halted at 4°C. The FMC chills 25 liters of milk down to 10°C in a couple of hours, and the milk temperature in the morning is about 4°C as shown in Fig. 4.

Fig. 3: PV using thermal ice storage and brine bags to chill evening milk.

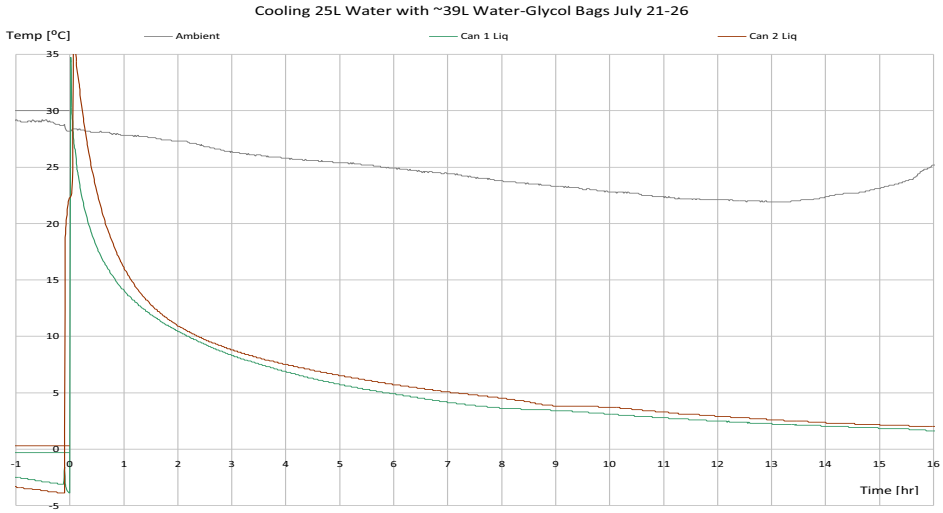

Fig. 4: Solar milk chilling lab test temperature reduction results for 2 milk cans. Bacteriological growth in milk largely becomes inactive below about 7°C. There is about a 4 hour window before significant bacterial growth starts in milk. The FMC unit successfully meets this threshold for 25 liters of milk.

Fig. 5: Dairy farmer from Ngorika shown with his E-W fixed tracking array for a Solar FMC.

3.0 Preliminary FMC field Operational and Technical Findings

WI in collaboration with Egerton University (Kenya's leading agricultural university) has been monitoring and evaluating (M&E) the performance and benefits of the Solar FMCs installed on the Mogotio and Ngorika Cooperative dairy farms. The WI team developed a '*PVSMART* Milk Chillers User Satisfaction Survey' form that Egerton has been using to survey half of the farmers with FMCs as of Oct. 1, 2015 after 5 to 6 months of operation.

PV-SMART team is also monitoring solar irradiance at Ngorika and Egerton sites. A few selected milk cans have a Hobo data logger installed on them to monior milk can temperature data. The temperature probe is installed on the can with foam over it so that it measures true milk can temperature only, see Figure 6.

Fig. 6: Brian Jensen of SDZR and Bruce Knight of WI install a temperature probe and small datalogger on a 10 liter milk can at Egerton University Dairy Lab.

The preliminary findings are based on meetings with users, milk can temperature data, and field observations by the WI and Egerton University team. All solar milk chillers visited are functioning properly except one unit which had a refrigerant leak upon delivery probably due to some of the extremely rough roads traversed for delivery; easily repaired by a local refrigeration technician.

Fig. 7: Johnson Mwove of Egerton University dairy lab surveying a dairy farmer with a solar FMC near Mogotio.

Installation: The units are all very well-installed. However installation costs were somewhat high for the Phase 1 pilot and will decrease in subsequent phases with the normal learning curve.

User operation: No major issues were found with user operation. Most users were not cooling milk to full capacity (25 liters), while two farmers were exceeding capacity and successfully cooling 40 liters a night. There was one farm where the woman operator had no prior experience operating a refrigerator before and had misunderstood the sign on top of the refrigerator to keep the chest lid open when "not in use" as to leave the lid open during the day when there was no milk. Her misinterpretation was corrected and the unit now operates correctly.

Milk temperature: The FMCs work well to chill 25 liters of evening milk to 4^{O}C and lower. If some milk is not removed the next morning and left throughout the day, small quantities of milk can freeze, indicating the prototype FMC may have 'spare' cooling capacity for Kenya. Figure 8 below shows daily milk cooling cycle for one of the farmers, milk temperature is repeatedly cooled to about 5°C. Note that the farmer puts the milk can outside for drying after cleaning representing the daily peak temperatures.

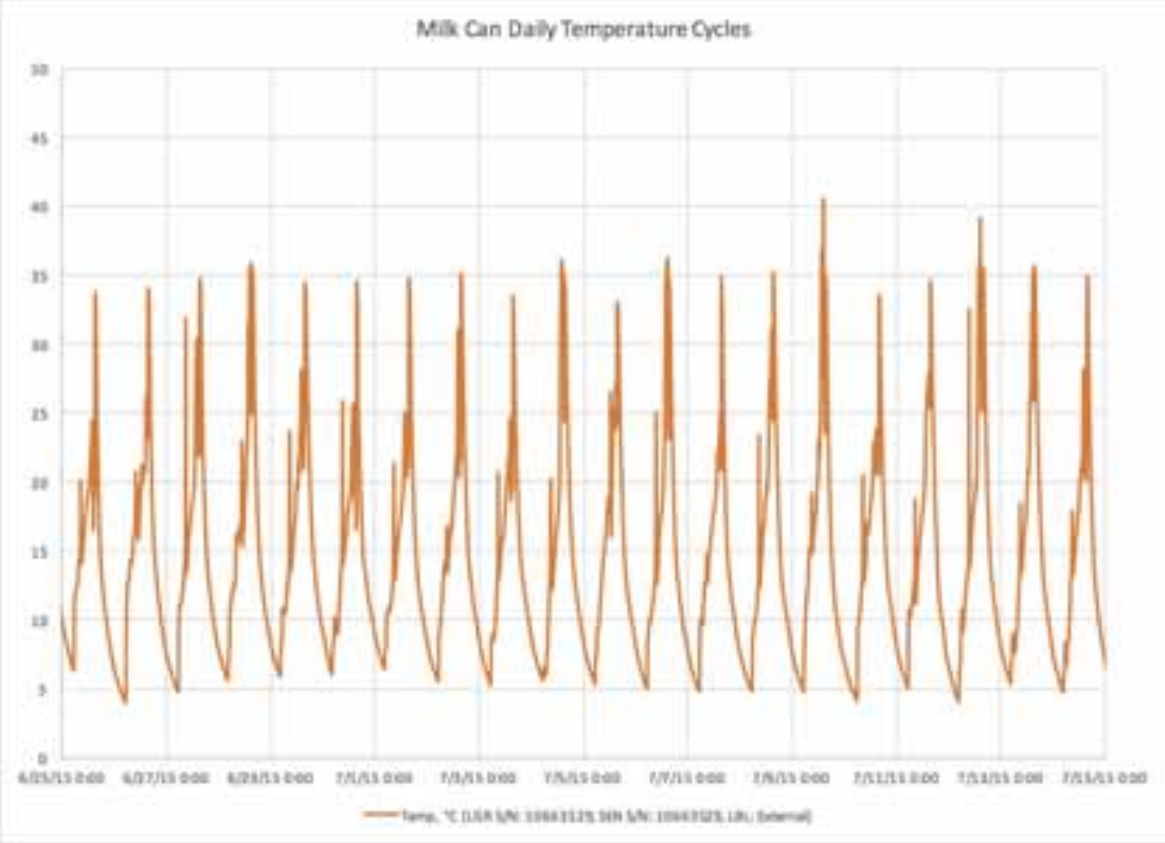

Fig. 8: Daily milk cooling cycles at a farmer's location: milk can temperatures. Note they clean and put the milk can outside in the sun to dry during the day.

Cooling Capacity: About half the users did not have enough evening milk to fill the pilot FMC. About ¼ of users utilize full capacity at 25 liters either from their own production or by also combining production with that of their neighbors, thus earning extra income for milk handling/bulking. Another user also earns extra income from charging cell phones from the two USB ports installed on the refrigeration unit, as much as US$1 per day (rate of US$0.10 per phone charge).

About ten percent of users have too much evening milk, i.e. more than 25 liters. These users and the cooperative managements want the FMC to be able to chill 50 liters milk in the standard 50 liters can. Some users are storing/cooling milk in plastic containers in the FMC and already exceeding the original design capacity. One cooler in Ngorika is chilling 40 liters milk in a food grade plastic water barrel, achieving overnight cooling to 'below 10^{O}C, indicating the potential of the unit to chill more milk adequately.

Other uses: Dairy value chain actors have been innovative in finding novel and remunerative uses for their prototype FMCs including:

- Standard cooling of evening milk by individual farmers;
- Bulk cooling of milk assembled from a number of local farmers by a farmer-collector;
- Bulk cooling of milk assembled from a number of local farmers by a collector-transporter;
- Keeping pasteurized milk chilled prior to sale in the immediate locality;
- Cold storage of perishable fresh foods; and,
- Cell phones charging.

3.1 Ngorika Dairy Association Observations

The Ngorika dairy farmers are overall satisfied with the cooling capacity of the FMCs and consider that the pilot project is going well. One farmer noted that small quantities of milk left in for longer time periods rather than just overnight sometimes might freeze. Since Ngorika is much higher (>2,500 meters above sea level) and thus much cooler due to the altitude, they have historically been able to sell some excess evening milk. The Ngorika farmers using the Solar FMCs have had no milk rejections whatsoever, so there is still an additional income increase due to quality. One farmer actually cools 40 liters of evening milk to $4^{O}C$ overnight in a 40 liter food grade plastic container rather than a traditional milk can. Their potential incremental gross earnings gain at current milk price was about KES51,300 (US$488) per month. This farmer produces more milk and is interested in increasing cooling capacity, or obtaining a second unit. Another farmer was found to have a potential incremental gross earnings gain at current milk price through the Solar FMC of about (US$564) per month (for own farm & farms serviced by collector).

Fig. 9: Satisfied Ngorika dairy farmer is happy with the Solar FMC and is actually exceeding recommended design cooling capacity by successfully cooling 40 liters of evening milk overnight.

3.2 Mogotio Dairy Cooperative Observations

The Mogotio dairy farmers have 18 Solar FMCs, as well as one unit at the dairy cooperative headquarters. The Co-op considers the Solar pilot as 'going very well' and they are interested in more units. Mogotio farmers are seeing significant increased income by selling evening milk stored overnight in the Solar FMCs, more so than Ngorika. This is due to the much hotter climate. Some users are even buying their neighbors evening milk and refrigerating to sell the next morning. The Solar FMCs benefit farmers because they can: (i) sell more milk; (ii) boost farmer earnings by collecting milk from neighbors, (iii) charge a cooling fee;

and (iv) keep drinks and perishable food cool and fresh for longer periods. For example one farmer was able to sell an extra ~8.5 liters of milk daily. Another farmer, besides chillng milk, also charges cell phones for 10 neighbors daily at US$0.10 each; the earnings are used to hire a 'Boda-Boda' (motor-cycle taxi) to transport her 2 teenage daughters to and from school. Her potential incremental gross earnings gain at the current milk price is about US$125 per month (including cell phone charging). Other smaller dairy farmers not utilizing the Solar FMC to full capacity (e.g, 5 lpd) had a potential incremental gross earnings gain at current milk price as low as US$23 per month.

So hotter climates are better as far as payback. But everyone surveyed likes and wants the Solar FMCs. The neighboring dairy cooperative next to Mogotio now wants their own Solar FMCs after seeing the successful results of their neighbors.

Fig. 10: Mogotio dairy farmer with his fixed E-W tracking array powering the Solar FMC.

4.0 Cost Benefit

Milk quantity and potential incremental gross earnings gain at current milk prices is already quite good for these pilot units, with simple payback ranging anywhere from one to three years depending on user milk production. From the initial surveys users sell between 2 and 45 liters of extra evening milk each day, indicating gross incremental income gains ranging from US$23 to $650 per month. These figures factor in gains by users bulking milk or charging cell phones on behalf of neighbors.

A complete cost benefit analysis will be done after one year of operation during Phase 2 to determine an acceptable/optimum Solar FMC price for SDZR and farmers. For Phase 2, SDZR plans to distribute units with end user cost share; for the initial pilot, farmers were not asked to cost share the Solar FMC price (only their time and milk cans); USAID PAEGC funded the units to buy down the technology risk for demonstrating a completely new concept with relatively poor rural small holder dairy farmers.

5.0 Conclusions

The key technical and operational take aways from the preliminary assessment of the *PV-SMART* Phase 1 pilot PVR units are that Solar FMCs offer small off-grid dairy farmers and milk collector/transporters the affordable opportunity for a value adding route to market that delivers better quality milk attracting premium

prices, especially for evening milk. All units are working well with no complaints from farmers. A couple of farmers already are chilling 40 liters of evening milk with success. Consideration may be given to increasing the cooling capacity to cool a 40 or 50 liter milk can. From the initial surveys users sell between 2 and 45 liters of extra evening milk each day, indicating gross incremental income gains ranging from US$23 to $650 per month with expected paybacks ranging from 1 to 3 years for the Solar FMCs. A cost benefit analysis will be done during Phase 2 to determine an acceptable/optimum Solar FMC price for users and SDZR. There is also huge market potential in other countries in Africa, Asia, and Latin America; there are from 3 to 5 million off-grid small dairy farmers in the African Tripartite Free Trade Area (TFTA). The project is now planning to leverage the technical and operational achievements achieved during first phase and apply lessons learned to the upcoming Phases 2 and 3.

Ray Tracing for Evaluation of the SK14 Solar Concentrator as a Solar Fryer

Ole Jorgen Nydal[1] and Asfafaw Tesfay[2]

[1] Norwegian University of Science and Technology, Trondheim (Norway)

[2] Ethiopian Institute of Technology – Mekelle, Mekelle, (Ethiopia)

Abstract

SK14 is a well known solar dish reflector which is made for cooking in a pot positioned at the focal point. The reflector consists of aluminium sector sheets which are attached to a light frame designed for manual solar tracking. The SK14 is here evaluated as a reflector for frying of the Ethiopian injera bread. Ray tracing shows that the reflected rays spread more evenly on the pan, but also gives higher losses compared with an ideally smooth reflector. A test on heating a frying pan which was custom made for the SK14 showed that frying temperatures for injera baking can be reached with the SK14 reflector. High thermal losses and illumination of the pan at an angle results in quite long heating time for the pan.

Keywords: *Solar fryer, SK14, ray tracing, solar cooker, concentrating solar heat*

1. Introduction

The SK14 (Seifert EG-Solar 2007) is a parabolic dish, made up of sector shaped elements of reflecting aluminium. The light weight frame has a support structure for a cooking pan in the focal point of the dish. SK14 offers a low cost solution for cooking in the sun, using manual solar tracking.

Baking of the injera bread is common in Ethiopia, most often with firewood as the energy source. Electrical stoves for injera baking is available, but most households in Ethiopia are not connected to the electrical grid. As the deforestation is severe, and as Ethiopia has very good solar potentials, solar powered injera baking could be an attractive solution.

Solar baking of the injera bread has been considered earlier with direct methods (Gallagher 2011, Asfafaw et.al 2014) and with indirect methods by positioning the pan on top of a heat storage charged by steam from a solar concentrator (Asfafaw at al 2014). Systems with integrated storage units offer flexibility for the user, but tend to become more complex requiring solar tracking, heat transfer systems and storage methods.

The SK14 reflector has been designed for solar cooking. This work explores the use of SK14 for frying of injera. Ray tracing is applied for evaluation of differences between an ideal reflector and the SK14. Some tests have also been made on the heating time for an aluminium frying pan designed for the SK14.

2. Experiment

Figure 1 shows a photo of the SK14 reflector, with a cooking pot and a frying pan in the focal area. The sun tracking is made by manually turning the parabola every few minutes.

doi:10.18086/swc.2015.03.06 Available at http://proceedings.ises.org

Fig. 1: SK14 with a pot and a frying pan

Two aluminum plates have been constructed (2 cm thickness each) to fit with the standard holder for the SK14 (hexagonal shape). One is anodized black, the other has no surface treatment.

A feasibility experiment was made to see if frying temperatures could be reached at non-ideal conditions, as experienced with a low solar angle in Norway (see Figure 1). Thermocouples are inserted into the plates from the side and logged during the charging of the plate in the reflector. After the baking plate is heated, the reflector is turned, giving easy access to the baking plate. The pan should have sufficient energy for 1-3 injera bakings, depending on the pan thickness.

Figure 2 shows the temperature rise of the pan in two tests. The stagnation temperatures in these tests are quite low, about 130 degrees C in the first one. The sun angle in this test was low, and midway in the first test a cold Norwegian wind started blowing, effectively halting the further temperature rise. In the second test, the response to spraying the pan with water was included. Earlier work has shown that injera can be baked on a metal surface at temperatures down to 150 degrees. Using SK14 for injera frying is therefore expected to be feasible under the more favourable conditions of the Ethiopian sun (about 13 degrees latitude).

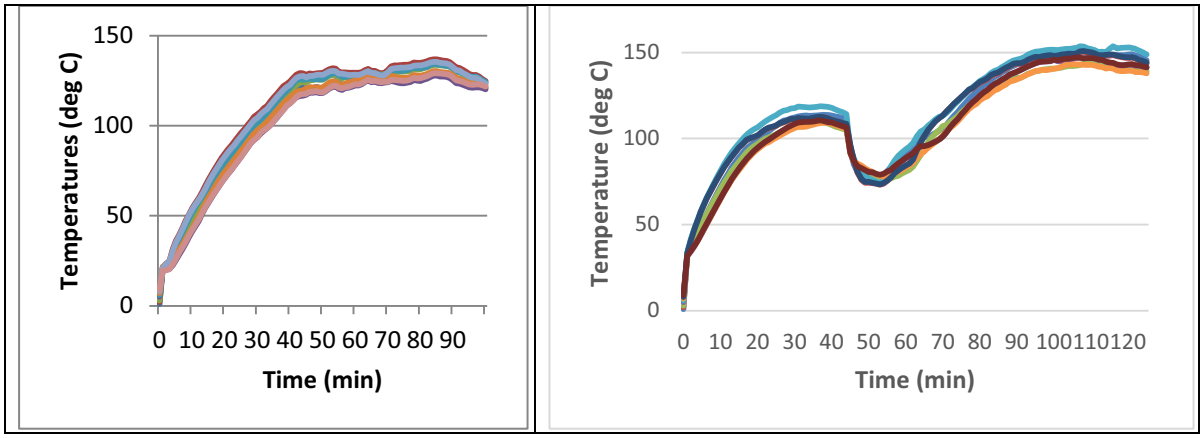

Fig. 2: Temperature rise on a hexagonal frying pan heated in the SK14 concentrator. Left: The temperature rise halted when a cold wind started blowing. Right: Water spraying of the pan after 40 minutes

3. Ray tracing

The illumination of the plates is investigated with a ray tracer, in order to optimize the position of the pan. The ray tracer is described in (Nydal, 2013, 2015). The tracer is programmed in C++, with the Qt library for the GUI and with OpenGL for the visualization. The tracer gives the user the options to assemble different kinds of reflectors and absorbers (trough, dish, plate, sphere, pipe, Scheffler reflector) for analysis with a user specified sun (density of sun points and direction). Each element can be assemblies of discretized mirror tiles or smooth mathematical surfaces. A screen shot with a 1D sun is shown in Figure 3.

The basic equation solved in a ray tracer is to find the intersectionsbetween a line and a surface and then to compute the reflected ray from the incoming ray and the surface normal vector at the intersection point. An intersected point (P) on the surface is u units in length from the origin point (S) of a ray having vector (d) as

the direction.

$$\vec{P} = \vec{S} + u\vec{d} \quad (1)$$

A surface (flat plate, sphere, cylinder, paraboloid etc.) can be described by an algebraic relation

$$p(x, y, x) = 0 \quad (2)$$

Eq.1 on component form is then substituted into Eq. 2 (for the coordinates x,y,z) which gives an equation for u. With the normal vector (n) computed at the resulting intersection point (P), the reflected ray has the direction (r):

$$\vec{r} = \vec{d} - 2(\vec{d} \cdot \vec{n})\vec{n} \quad (3)$$

The ray tracing is then the management of the rays, taking also into account shading effects

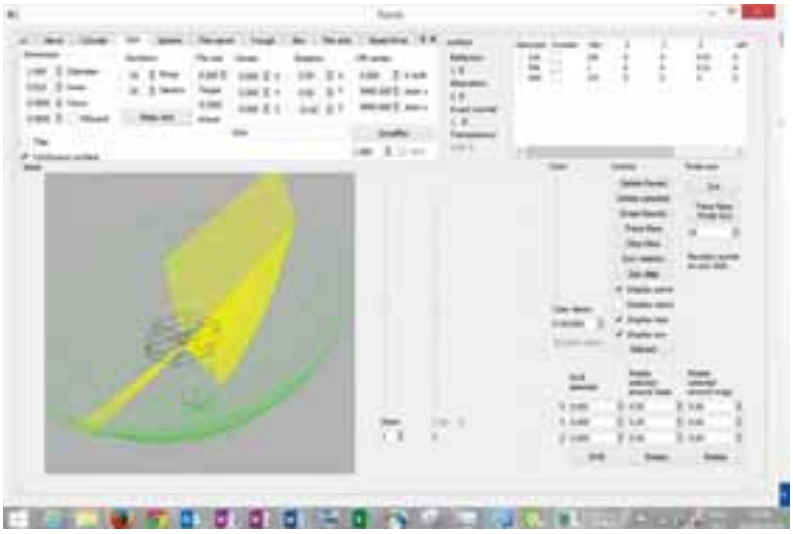

Fig. 3: Screen capture of the ray tracer program

Figure 3 shows screen captures of a case with 40 degrees sun inclination (morning or afternoon sun). The frying pan is positioned with the focal point of the concentrator at the centre point of the pan. At low solar angles, the plate will be illuminated from both sides, giving a non-symmetric heating of the plate. With an ideal reflector, all rays are captured by the plate. With a sector tiled reflector (the SK14 geometry is approximated with tiles generated from 16 sectors and 16 rings), the illumination is more spread out on the plate and the losses increases, depending on the vertical positioning of the plate (20-30% in this case).

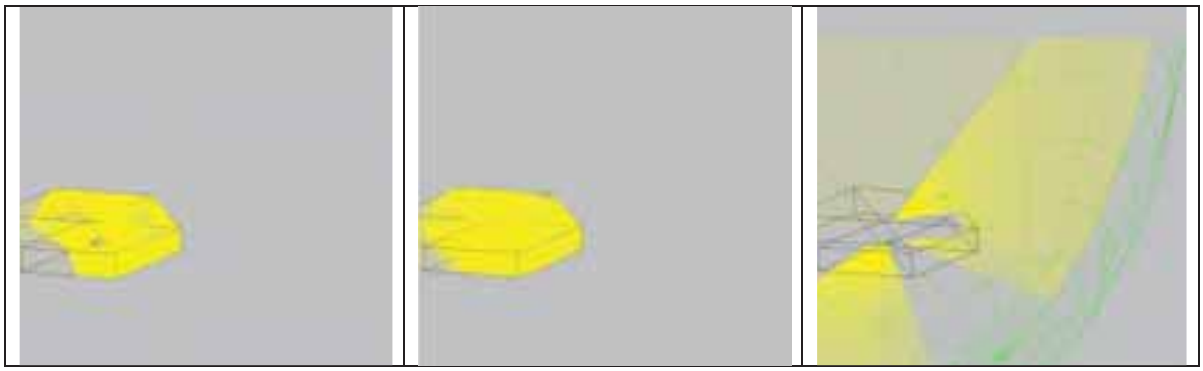

Fig. 4: Screenshots of the pan illumination at 40 degrees solar angle. Left: ideal concentrator. Centre: SK14 concentrator. Right: Test with a 1 dimensional sun (sun rays on a line)

Figures 5 and 6 show sensitivities to the vertical positioning of the pan by adjusting the height such that the focal point is at the bottom, centre and top of the pan. The simulations are made with a sun covering half of the concentrator.

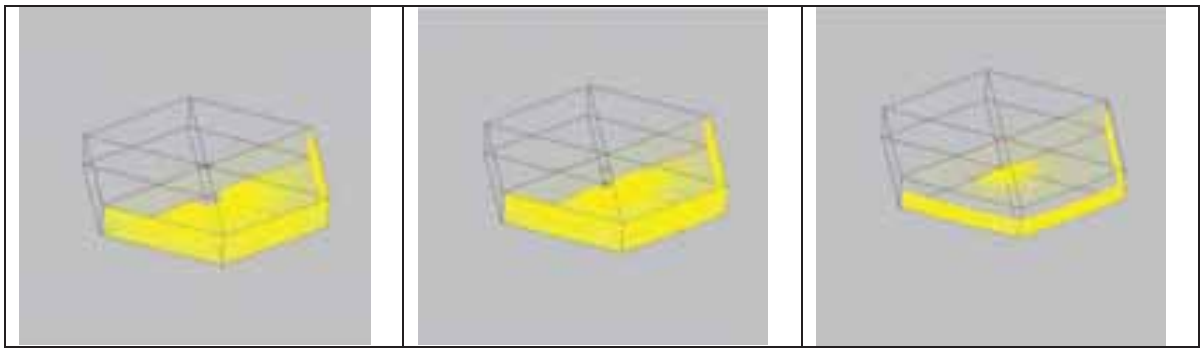

Fig. 5: Screenshots of the pan illumination at different vertical positions. Smooth concentrator, half illuminated Left: Focal point on top. Centre: focal point in the centre of the pan. Right: focal point at the bottom

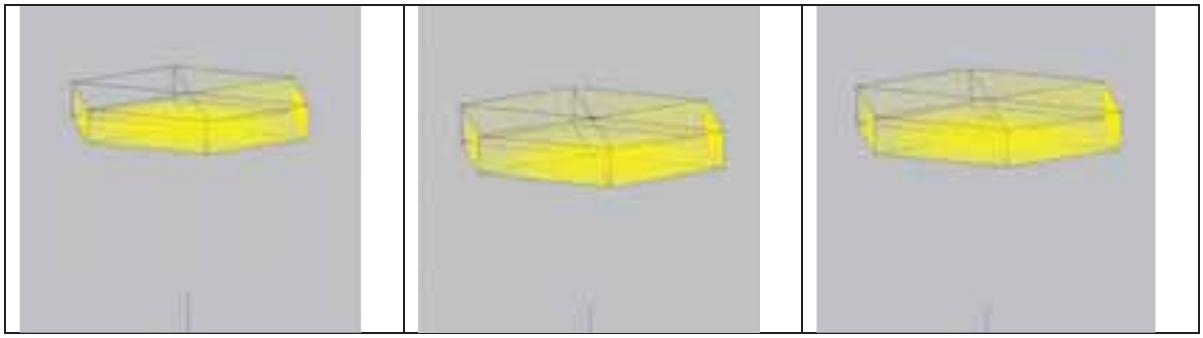

Fig. 6: Screenshots of the pan illumination at different vertical positions. SK14 concentrator, half illuminated Left: Focal point on top. Centre: focal point in the centre of the pan. Right: focal point at the bottom

The SK14 concentrator spreads the reflected rays significantly more than the ideal smooth reflector. This gives less sensitivity to the positioning of the pan, but does also give higher losses. The ideal reflector shows a more critical sensitivity to the positioning of the pan, with also a higher risk of generating hot spots on the pan.

4. Discussion

Figure 7 shows the temperature time recordings of Figure 2 plotted with a time shift to allow for comparisons of trends. The temperature measurements in Figure 2 do show some variations for the different thermocouples. The illumination is not uniform across the plate, nor at the different sides of the plate. Figure 7 includes the band of the measurements.

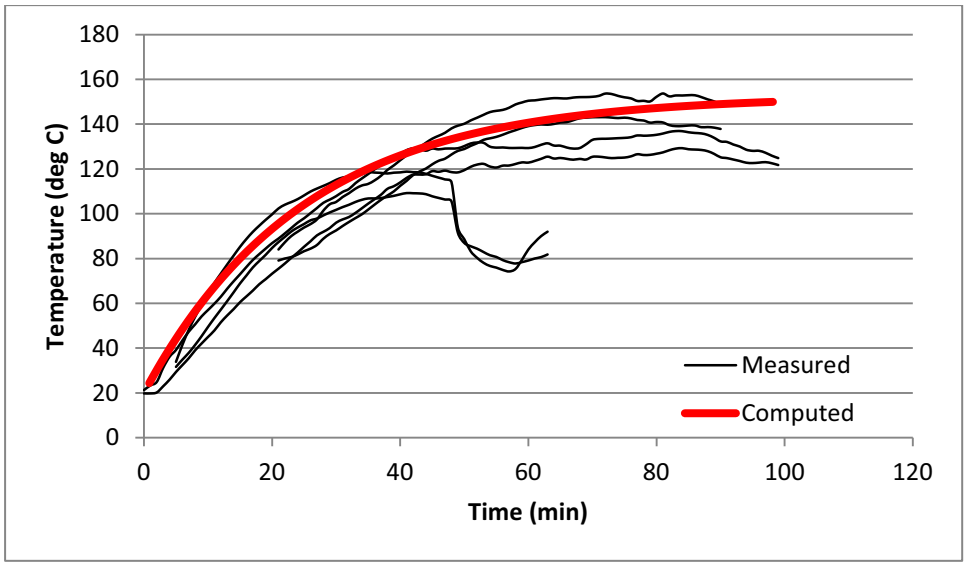

Fig. 7: Overlapped temperature measurements from Figure 2 (thin lines) and computational estimates (thick line)

A simple computational estimate can be made by neglecting the internal heat transfer dynamics (heat conduction) and consider the pan to have uniform temperature. The temperature evolution can then be computed from estimates of the solar radiation and of the losses. Figure 7 shows the integrated temperature from the energy balance:

$$\frac{\partial \rho A d c T}{\partial x} = \rho C_r A - h A_i (T - T_a) \qquad (4)$$

The definition of the variables and the numbers which have been applied are given in Table 1.

Table 1 Values for the temperature computations

Variable	Value	Comments
ρ - density	2800 kg/m^3	The temperature dependency is neglected
A - plate area	0.0706 m^2	The plate is hexagonal, but the area is for simplicity estimated from a circle with a diameter of 30 cm
A_l- area for heat losses	2A m^2	The plate is hexagonal, but the loss area is for simplicity estimated from the top and bottom surfaces, sides neglected
d - plate thickness	0.02 m	
c - heat capacity	910 J/KgK	The temperature dependency is neglected
T - temperature		
h - heat transfer coefficient	9 W/m^{2}K	This value is tuned based on the experiments
T_a - ambient temperature	20 degrees C	
q - solar radiation	900 W/m^2	This is a typical value measured in Trondheim on a clear and sunny day. The solar intensity was not measured at the day of the experiments, so the value is an estimate
C_r- effective concentration ratio	5	This value is tuned based on the experiments, and includes all optical losses

From Figure 7 it can be seen that the uncertainty in the heating and loss conditions of the plate in the SK14 concentrator can be quite large. The solar tracking is manual and the ambient conditions can change during the heating – wind has a strong effect on the heat losses from the plate. This rough estimate, based on tuning of the heat supply (the effective concentration ratio) and the losses (the effective heat transfer coefficient for the top and bottom surfaces) indicates that the stagnation temperature will in this Norwegian case be quite low. Frying temperatures can be reached, but after considerable time.

If one side of the pan could be insulated, the losses could potentially be reduced. Figure 8 shows ray tracer results for two latitude cases: Trondheim in Norway (about 60 degrees) and Mekelle in Ethiopia (about 13 degrees).

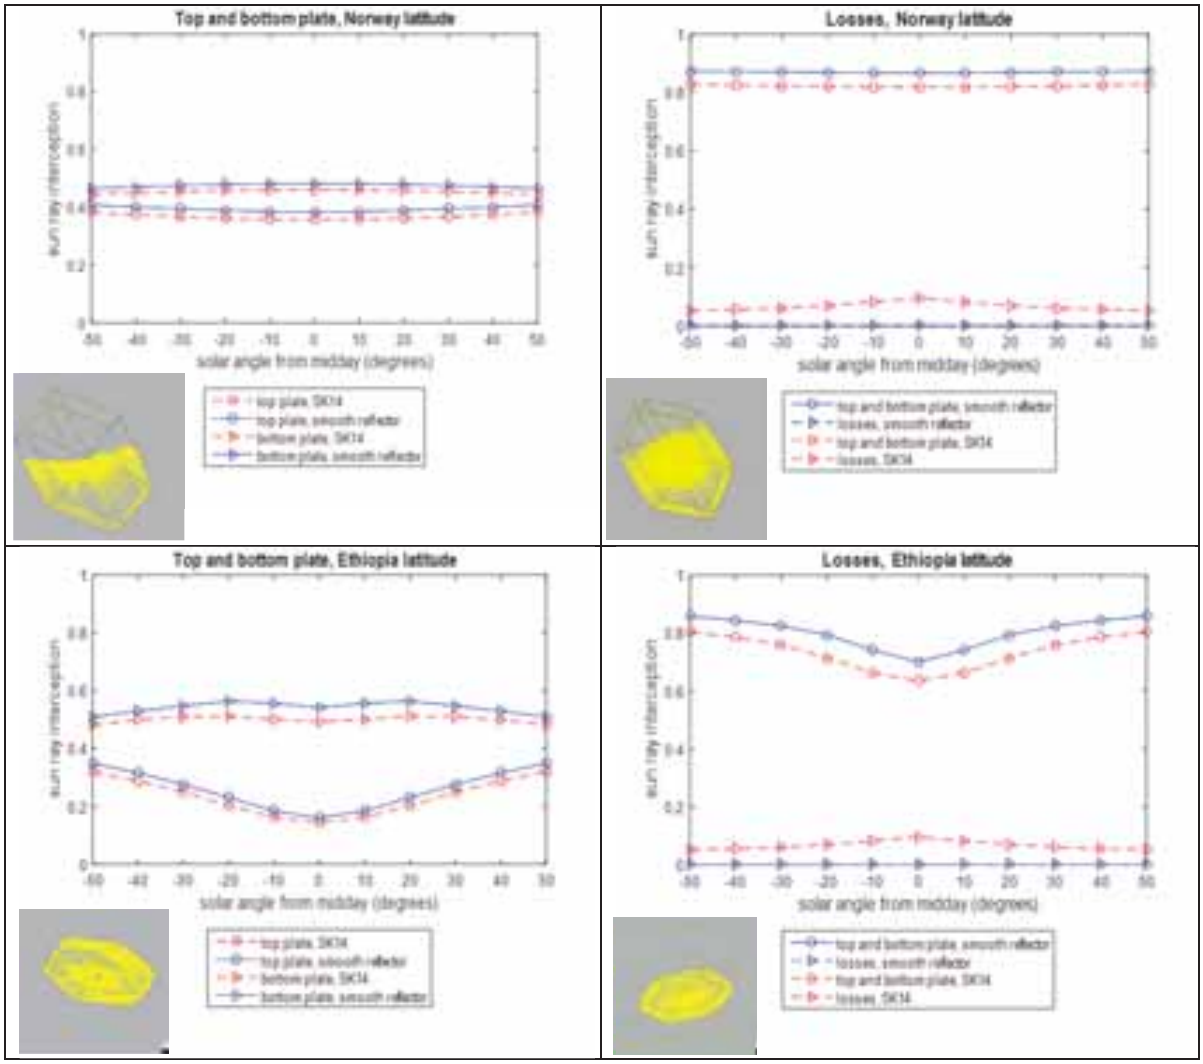

Fig. 8 Ray tracing results for solar tracking during a day in Norway and in Ethiopia

With the frying pan kept in a horizontal position the angle with the concentrator will be larger in Norway than in Ethiopia. This means that both sides of the pan will be illuminated more in the Norwegian case than in the Ethiopian case. Insulating the top plate during heating of the plate may not provide a strong benefit even for the Ethiopian case, as the top illumination is still quite large also at Ethiopian latitudes. The illumination of the sides of the plate is also significant (about 10%).

5. Conclusions

From previous tests, it has been demonstrated that the Ethiopian injera bread can be baked on an aluminium surface. The tests made in this work shows that frying temperatures can be reached in an SK14 concentrator, fitted with a custom made aluminium pan. The SK14 can then be a low cost alternative for direct solar injera baking.

The pan is exposed to the ambient, so the thermal losses will reduce the performance of the fryer. The sector tiled geometry of the SK14 spreads the reflected sun rays more on the pan, but also gives higher losses due to rays missing the pan, compared with an ideal concentrator. An ideal reflector surface can, however, give a too concentrated illumination of the pan depending on the positioning in relation to the focal point.

The direct frying system can be optimized by using a concentrator with a smaller rim angle. If only one side

of the pan is illuminated, it can open for insulation of the other side, and similarly during frying.

Performance of a Solar EV Charger in the Pacific Island Countries

Alvin. A. Datt, Aman Singh and Atul Raturi

University of the South Pacific, Suva (Fiji)

Abstract

The unsustainable dependence of the Pacific Island Countries (PICs) on imported fossil fuels and climate change concerns have made the region to look for alternative sources for energy. A major portion of fossil fuels goes towards transportation and it is imperative that other options such as biofuels and hybrids/ EVs are seriously explored. Considering the small distances involved, EVs can be profitably deployed in urban areas and also within the myriad tourist resorts spread across the Pacific islands. Solar PV based charging stations can play a major role in this endeavor. This paper describes the design and performance of first solar electric vehicle (EV) charging station in the Pacific Island Countries. The actual performance of this 2.6 kW_P station is compared with the simulated results obtained using HOMER. Finally, the paper also looks at the way forward for development of electric mobility in the region.

Keywords: Pacific Island Countries (PICs), Electric Vehicles, Solar PV

1.0 Introduction

1.1 Energy situation in Fiji and the Pacific Island Countries

The Pacific Island Countries (PICs) are heavily dependent on the imported fossil fuels for their day to day energy needs. These countries end up spending huge amount of their budget on fossil imports. For instance, the petroleum imports for Fiji have increased from about $400million in 2004 to over $1.2billion in 2008 which tends to account for a quarter of country's total imports[1]. The dominance of transportation sector in the imported fuel usage in Fiji is quite evident from the figs.1 & 2:

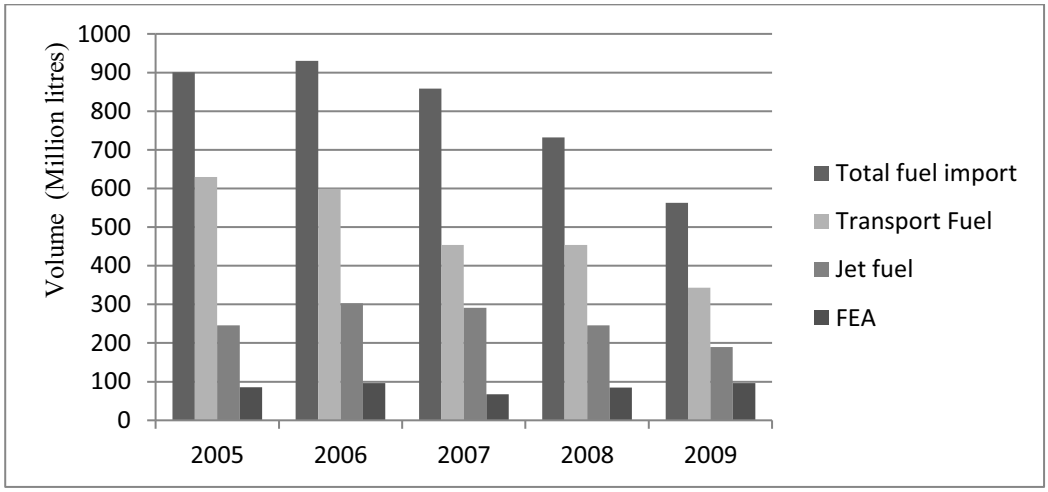

Figure 1: Fuel Import Levels in Fiji
(Source: http://www.irena.org)

doi:10.18086/swc.2015.01.01 Available at http://proceedings.ises.org

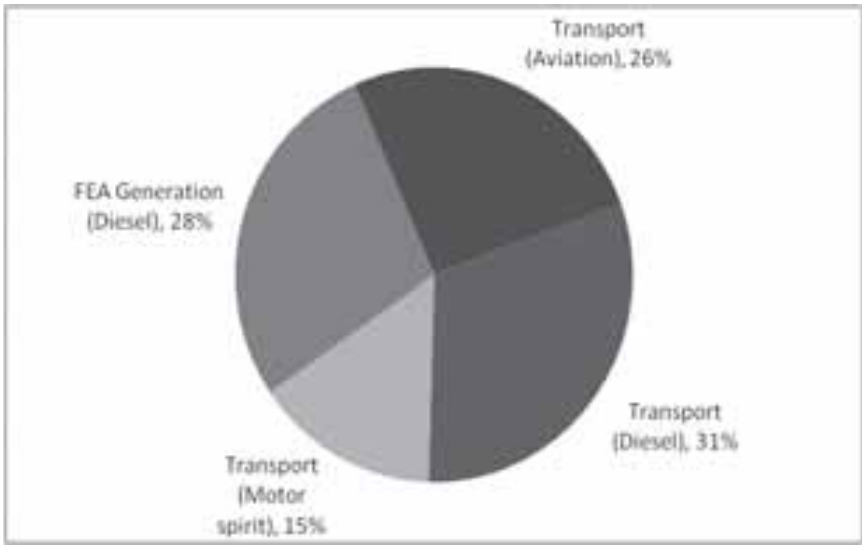

Figure 2: Oil Imports – RBF Estimates (2008 – 2011)
(Source: National Energy Forum - Reserve Bank of Fiji)

The Asian Development Bank's report launched in 2013, projects that under the present scenario, Fiji's energy demand will increase at an annual rate of 1.7 percent through the year 2035[2]. It also highlights the fact that the price of fuel in the Pacific is one of the highest in the world and only about 30% of households have access to electricity on average. Hence, the dependency of the PIC's on imported fuels for power generation hinders economical development since energy is a major driving force for the industrial and transportation sectors.
The PICs' heavy dependence on the fossil fuels can also be noticed by the figures discussed in International Renewable Energy Associations policy report where it estimates that 80 percent of regions primary energy consumption is based on oil of which 75 percent is used by the transportation sector and more than 20 percent is being used for electricity generation [3]..

1.2 The Development of Solar Electric Vehicles

An important development in terms of photovoltaic technology has been the introduction of solar charging stations for the charging of electric plug – in vehicles. The whole idea to use solar powered electric vehicles is to increase the use of renewable energy, and provide electric vehicle owners with a greener charging option. According to [4] "Electric cars are already among the cleanest-running vehicles on the road—charging them on solar makes them that much better".Obviously, if a EV charging station uses electricity mostly from burning fossil fuels, then the EV is simply outsourcing the pollution to the power plant.. But using electricity from solar panels erases this predicament [5].

A plug-in electric vehicle (PEV) is defined as any motor vehicle that can be recharged from any external source of electricity and the electricity is stored in rechargeable battery packs. PEV is a subcategory of electric vehicles that includes all-electric or battery electric vehicles (BEVs), plug-in hybrid vehicles, (PHEVs), and electric vehicle conversions of hybrid electric vehicles[6]. In the recent years, environmental and climate-change impacts of the petroleum-based transportation infrastructure, along with the uncertain oil prices, have led to renewed interest in an electric transportation infrastructure.

A recent study investigated the question of which alternative energy (Photovoltaic or biofuel) would be best for powering electric vehicles. The study explored the impacts of biofuels and PV on direct land use, greenhouse gas emissions, and lifecycle greenhousegas emissions. In all three categories Photovoltaic technology was found to bemore efficient and beneficial [7].

A number of companies like Ford, Toyota, Nissan, and of course Tesla to mention a few, have been quite active in the development of electric vehicles and more car manufacturers are now developing their electric

versions [8,9] However with the widespread implementation of electric vehicle networks within large cities, such as those provided by POD Point [6] in the UK and Europe, EV users can plug in their cars while at work and leave them to charge throughout the day for charging, hence solving the problem of driving range of the EV as enough charge would be available all the time.

Furthermore, Electric car maker Tesla has installed its "Supercharger" rapid car charging network at different locations throughout California. Superchargers are powered by solar technology, developed by solar installer Solar. The Superchargers can charge the Model S cars with 100 kilowatts of power and provide three hours of driving at 60 mph in about half an hour [9].

The solar-assisted charging stations use solar photovoltaic (PV) arrays to generate electricity to charge the electric vehicles. The Oak Ridge National Laboratory (ORNL) conducted a demonstration project involving solar assisted charging stations for EVs (2009-2014) . The project objective were to install 125 solar EV chargers and study their impact on the grid . The systems were grid-connected to enable charging at all times .and an external battery was employed to offset grid demand if needed.. The installed PV power per parking space was sufficient to support 10,000 miles driving per year.. One of the project collborators, Nissan North America, installed 30 solar powered carging stations.[10].

After going through the developments in the sector of electric vehicles and the solar charging stations globally, it can be realized that the potential for such a development is high but there are certain factors like the availability of enough solar charging stations, and the driving range of the electric vehicles that need to be considered. The idea of battery swapping at stations located on regular distance can prove to be a solutionfor the driving range problem of EV's considering that installing solar charging stations on a number of locations would become an expensive course. According to [11] instead of recharging EVs from electric socket, their batteries could be mechanically replaced on special stations in a few minutes.

1.0 The Solar Charging Station

2.1An Overview

An important aspect of any solar charging station is the installation of the panel and other components such as battery and the charge controller of the system.

Solar Panel –A solar panel is made up of a number of series and parallel combinations of identical individual cells to generate the desired power output (current and voltage). Panels are assigned a power rating in watts based on the maximum power they can produce under ideal sun and temperature conditions. The rated power output is used to help determine how many panels are needed to meet the electrical load demands. Multiple panels combined together are called solar arrays [11]. PV solar array is normally mounted on a canopy above the solar-assisted EV parking spaces. In addition to providing a mounting structure for the solar PV array, the canopy provides shading and protection for the components and also helps to keep the vehicle cool during charging. The canopy solar PV modules are electrically connected in a parallel/series arrangement to supply the optimal direct current (DC) voltage to the inverter. The inverter converts direct current from the array to alternating current to feed to the power grid through a transformer [10]**.**

Battery – electrical utility supplying power for the charging stations and is concerned about surge loads on the grid from vehicle charging. The function of the battery banks is to store energy on site, charging the batteries during periods of low charging demand, and discharging the batteries back into the electrical grid during high demand to minimize the surge load on the grid [10].

Charge Controller - a device that is very important because it blocks reverse current, prevents overcharging and discharging of the batteries and protects battery from overloading [12].Hence it prevents the battery from reduced lifespan. Charge controllers come in all sizes, and protection and monitoring features. The selection depends on the size of installed solar panel(s) and the complexity of loads and future expansion possibility. Different charging and maintenance algorithms are used depending on the type of the battery [11].

2.1.1 An Overview of the Project

The project of solar charging station at The University of the South Pacific was funded by the French Government under the Pacific Funding Programme. The major aim of the project is demonstrate one of the the climate change mitigation strategies in the region by moving towards a more sustainable form of energy for the transportation sector, help the students at the university with research in the field area and create awareness of the solar charging stations for electric vehicles..

Figure 3.The solar charging station roof mounted panels with two supports to allow for vehicle parking and charging area

2.1.1.2 Station Design

The solar array is mounted on the roof on top of the equipment hut using Unirac rails and clips. The roof of the hut is tilted at latitude angle (18 degrees) and faces due north for the best annual performance of the

panels. Four Haze (Gel) batteries , a charge regulator and an inverter are mounted inside the hut.

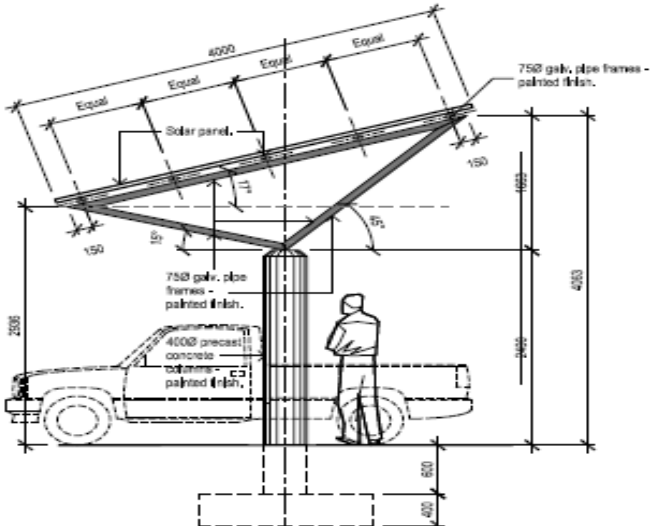

Figure 4. Construction plan for the charging station

2.1.1.3 System Features

A fully integrated and automated monitoring Outback system is installed to monitor the performance of the system. The FlexNET DC coupled with MATE3 provides advanced monitoring and control features. The MATE3 has an integrated data logger which can record system readouts for up to a year and hence allows for remote access and control. FlexNET DC collects, monitors and records time based battery amp, watt and voltage data for display on Outback MATE components. This provides data for precise battery recharging. There are five LEDs on the FlexNET DC that act as state of charge indicator bar. The advanced recording features of the system allows for the remote access of data for PV array performance, battery usage and load parameters.

2.1.1.6 Battery

Haze – HZYSL6 – 225 Gel series is lead acid type batteries. Advanced Gel design is used in these batteries and is highly suitable of cyclic solar Photo voltaic applications [13]. Some of the important Features of the battery includes**;** repeat cycling for daily usage, good performance over long discharges, good tolerance to high temperature applications, less self discharge, good charge acceptance due to low internal resistance and it can be discharged even when not fully charged without the loss of battery capacity [13].

2.1.1.7 Solar Regulator

The FLEXmax (OutBack FM60-150 MPPT Solar Controller) Maximum Power Point Tracking (MPPT) is continuous and active and helps increase the photovoltaic power yield to about 30 percent more compared to non – MPPT controllers [14]. It is able to function at ambient temperature of as high as 40° C. It also has the ability to step-down a higher voltage solar array for the recharging of a lower voltage battery bank and is able to display the current status and logged performance data for past 128 days.

2.1.1.8 Inverter

The OutBack inverter (GFX 1424, 1400W, 24V) is designed for applications to lower power demands. It comprises of a DC to AC sine wave inverter, battery charger and an AC transfer relay. It provides power back up in the event of an outage through the in- built transfer relay which acts by disconnecting the loads from the grid and powers them from the inverter [15]. Hence it helps reduce disruption in power supply in times of usage.

Results and Discussions

2.0 Solar Resource

3.1 Solar Resource at the Charging Station Site

Panel Orientation: Tilt=18° -- Azimuth=0° (Due North) -- **Skyline Heading=0°**
GPS Location: Latitude=18.14996°S -- Longitude=178.44655°E
Solar Access: Annual: 95% -- winter (May-Oct): 94% -- summer (Nov-Apr): 95%

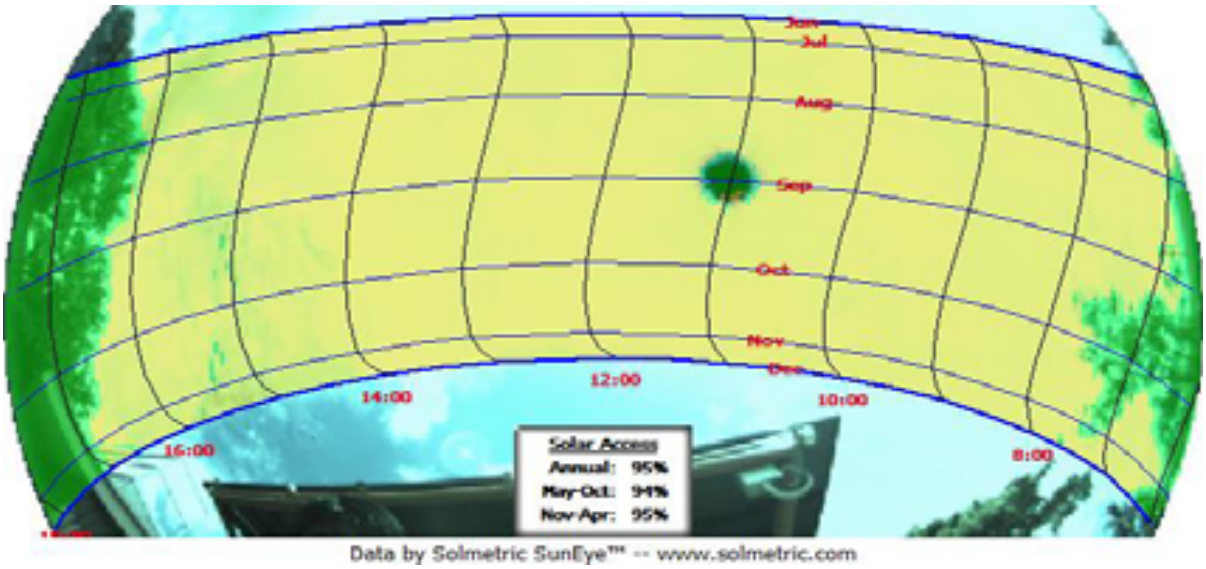

Figure7. Sunpath close to the charging station ataround 11:00 a.m

The view in fig. 7 shows the annual sunpaths drawn on top of the captured skyline. The open sky is shown in yellow and the detected shade-causing obstructions are indicated in green. Fig. 8 shows the solar access percentages at the site.

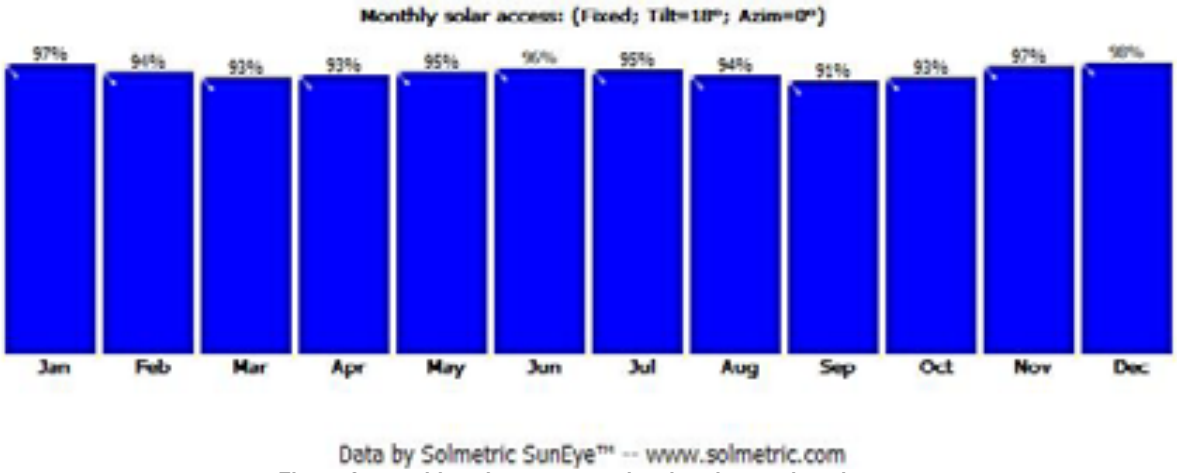

Figure 8. monthly solar access at the charging station site

4.0 Performance of Solar Charging Station

4.1

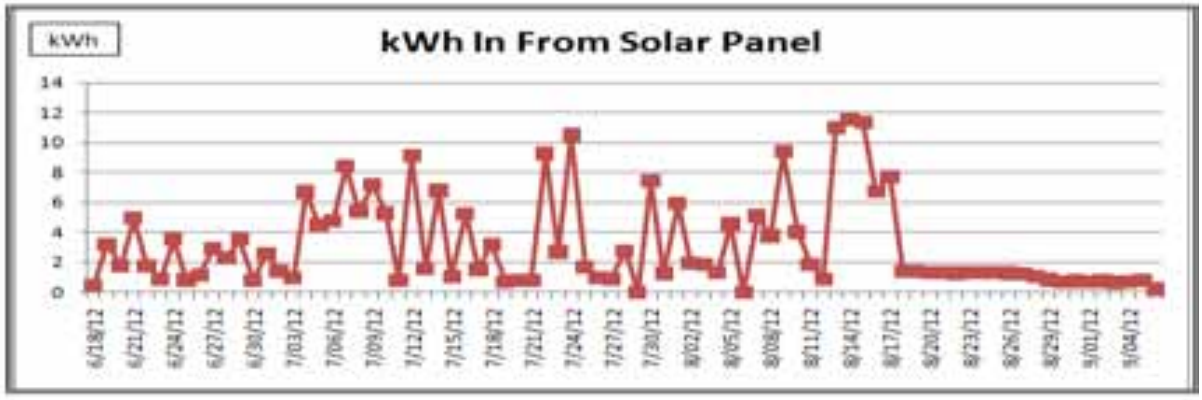

Figure 9

Fig. 9 shows the energy generation by the solar panel in kWh. The fluctuation in the production is dependent on the charging/discharging activities at the solar charging station.

The graphs in fig.10 and fig. 11 showthe relationship between the energy supplied and the stste-of-charge of the system battery.

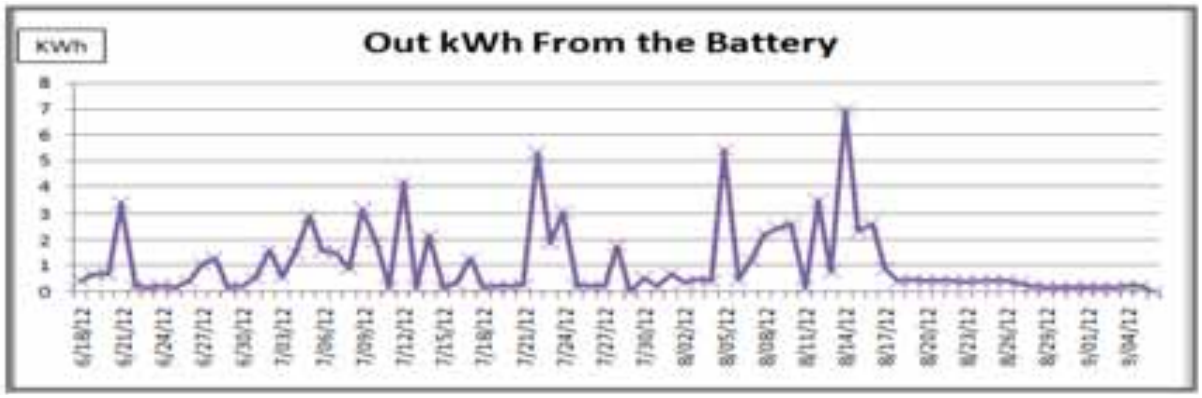

Figure 10

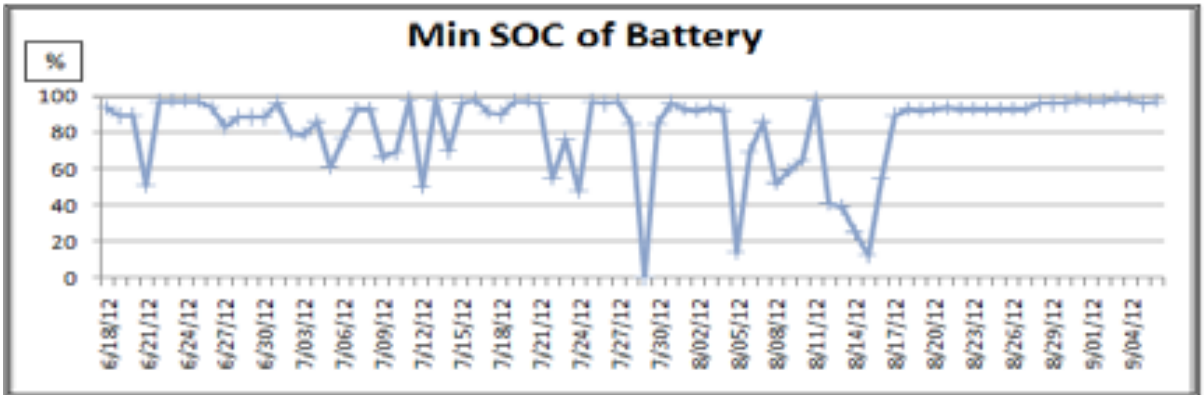

Figure 11

From the three sets of graphs above, it can be noticed that whenever there is low usage of power from the station, the state of charge of the battery is maintained above 90% and hence there is low input from the panels. However when the charging activity is high, the state of charge drops and the energy supply by the panels increases. For example, at 8/14/12, the usage is about 7 kWh, state of charge decreases below 20% and the panel produces about 12 kWh to maintain the charge status of the battery. Moreover, after 8/20/12 the charging activity is almost zero, state of charge is seen to be very close to 100% and hence the power production from the panel is also close to zero.

4.2 The Projected Output Simulations for the Charging Station

The EV charging PV system was also simulated using HOMER Software. The simulated results were given through the analysis of the input data of the system components of the solar charging station and the solar radiation data available at the location of the station. The scaled annual average horizontal solar radiation at the station location was 5.21 kWh/m^2/day.

From the PV Output graph and simulation result it can be seen that an average system value of around 0.47 kW can be taken on a monthly basis. However, there are times when the panel is capable of producing around 2 kW and even higher during peak months. This result campares well with the actual production witha mean out put of around 11 kWh/day.

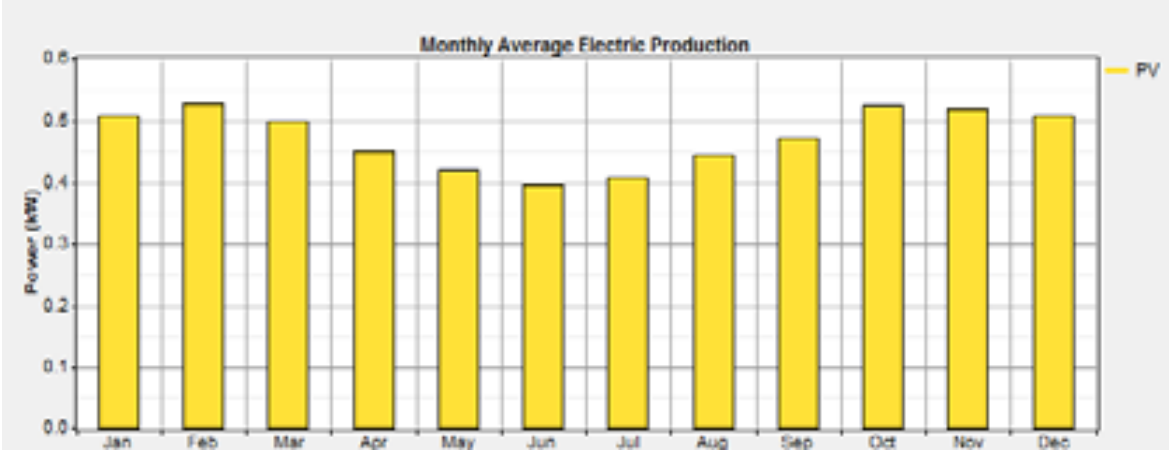

Figure 12: Monthly Average Electric Production

Table 3. The Charging Station Projected Performance

Quantity	Value	Units
Rated capacity	2.65	kW
Mean Output	0.47	kW
Mean energy Output	11.3	kWh/d
Capacity Factor	17.8	%

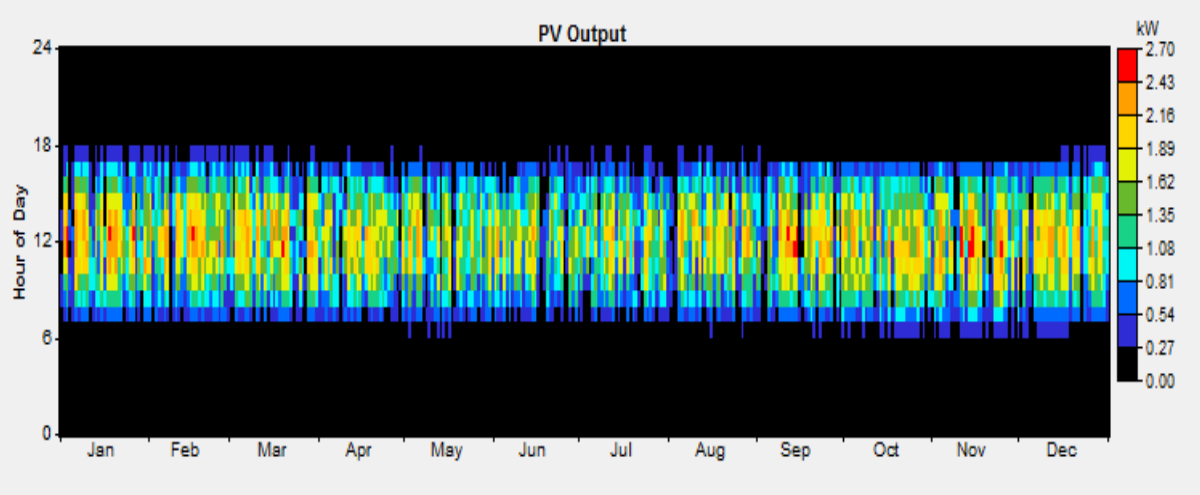

Figure 13: Ouput projection of the solar panel

5.0 The Scope of Solar Charging Station and Electric Vehicles in Fiji and Pacific Island Countries

The solar charging stations have a good potential in the Pacific island countries due to the availability of high solar radiation in the region. The geographical location of the PIC's gives them an advantage as they are located near the equator. For this reason charging stations can be erected at a number of places around the Pacific.
The charging stations and solar electric vehicles would be of great use to the resorts around the islands. It would provide them with an opportunity to help minimize pollution by using green energy like solar while cutting down their electrcity bills and crabon footprint.. The only cost involved is in the setting up of the charging station and purchasing of electric vehicle. Most of the resorts operate electric buggies/carts to transport gusets and also for their golf courses. Deploying solar chargers on the myriad of resorts in the region will reduce their dependence on fossil fueled utility power or thier own generators.

Moreover, the private transport companies and government can also invest in the charging stations and develop a solar EV charging car park. For example, some of the parking lots of Suva City Council and the government can be turned into solar charging stations.Most of the office/factory workers travel short distances and hence they can plug in their vehicles in the car park while they attend to their routine work.. The main business districts are quite small and electric three-wheelers can be efficiently utilized for delivery etc. The government and companies can also think on the line for use of the vehicles for business purposes. Recently, electric three- wheelers have been launched in Fiji and a transport company is introducing all electric buses. The car dealers in Fiji have also started importing plug-in vehicles like Nissan Leaf and with the Fijian govenment's zero tax policy on Evs/hybrids, theier populariity market is quickly grwing. The need for developing sustainable transport solutions inthe Pacific cannot be overemphasised and solar-charged EVs present a great way forward

6.0 Conclusion

Solar charged EVs present a significant potential for moving the Pacific Island Countries towards a sustainable transportation sector. The devployment of solar charging stations similar to the one presented here would help the EV market grow and protect vehicle owners from the rising fuel prices. It would also help to the issue of climate change mitigation by reducing the GHG emissions in the land transpaortation section.. The analysis of the performance of the solar charging station indicate that a 2.65kW system at the University of the South Pacific is capable of producing a between 10-12 kWh/day. It is envisaged that in not too distant future the EV numbers would increae sizably and the solar chargers will play an important role in expanding their reach. The recent drastic reduction in solar panel pricesmeans decreasing installation cost of charging stations and establishing solar PV as a major contributor to suatinable transport solutions. .

The Battery Energy Storage System (BESS) Design Option for On-Campus Photovoltaic Charging Station (PV-CS)

Ayda Esfandyari[1], Brian Norton[1], Michael Conlon[1], Sarah.J McCormack[2]

[1] Dublin Energy Lab/Dublin Institute of Technology, Dublin (Ireland)

[2] Trinity College Dublin, Dublin (Ireland)

Abstract

As the application of Light weight Electric Vehicles (LEVs) increase in communities, Dublin Institute of Technology (DIT) uses these small vehicles for short distance journeys around its 78 acre campus of "Grangegorman" located in inner Dublin city, Ireland. This paper presents an introduction to the campus Photovoltaic Charging Station (PV-CS) that generates clean electricity from the sun and charges the LEVs batteries which can lead to reduction of CO_2 emissions, along with fulfillment of national and international green sustainability targets. Based on the evaluation of possible options for PV-CS design, the optimal design configuration was chosen as a "Battery Energy Storage System (BESS)". The PV generated electricity that is stored in battery banks will serve as the primary source for charging the campus vehicles, with any surplus demand being met by the utility grid. Batteries have been included in the design due to intermittent nature of Irish sunshine and the charge time requirements of campus load. This paper concentrates on the detailed sizing of the BESS via two approaches: BESS with DC generation and BESS with LEV load demand. In the first approach the outputs were normalized and grouped into specified generation categories in MATLAB. To establish the accurate BESS capacity the load demand variations of the LEVs were monitored. Based on DC generation and demand profile, the optimal capacity of BESS was chosen to be in the range of 6-8 kWh, which can accommodate up to 6 LEVs.

Keywords: *Renewable Energy Resources (RES), Battery Electric Vehicle (BEV), Light weight Electric Vehicle (LEV), Battery Energy Storage System (BESS), Greenhouse Gases (GHG),*

1. Introduction

Transport is the second biggest emission intensive sector in Europe, accounting for nearly a quarter of Greenhouse Gases (GHG) pollutions (European Commission, 2013). Since the energy consumption of transport heavily depends on fossil fuels, Battery Electric Vehicle (BEV), an alternative to conventional vehicles, can help to minimize emission levels at the usage point. Moreover, with the trends encouraged by governments and political parties, strong commitments have been made on both European and International levels to increase the penetration of Renewable Energy Resources (RES) (Da Graça Carvalho, 2012). BEVs have significant benefits in an urban context, mainly due to shorter trips, lower speed and power requirements (Smith, 2010). As shown in Table 1, BEVs capacity and technology can vary and subsequently are influenced by the size of the vehicle (SEI, 2007; World Electrified Vehicle Sales, 2013). Applications of small utility vehicles are gaining interest in both public and local sectors such as: night time deliveries, airports, in parks and golfing facilities (Standford, 2007; Heathrow Airport, 2011). Our focus is on CarryAll 13.76 kWh vehicles, which throughout this paper is referred to as Light weight Electric Vehicle (LEV).

doi:10.18086/swc.2015.01.02 Available at http://proceedings.ises.org

Table. 1: Various BEV Battery Capacities

Vehicle	EV Type	Battery Technology	Battery Capacity
Nissan Leaf	BEV	Lithium-ion	24 kWh
Tesla Model S	BEV	Lithium-ion	60/85 kWh
Renault Zoe	BEV	Lithium-ion	22 kWh
Renault Kangoo ZE	BEV	Lithium-ion	22 kWh
Small Utility	BEV	Lead-Acid	13.76 kWh

Solar energy in particular has emerged as one of the prominent sources of alternative energy, with significant potential for reducing CO_2 emissions at the generation point (SEAI, 2010). Furthermore, Photovoltaic (PV) panels can be used in charging stations to accommodate the BEV's batteries charge demand (Hamilton, et al., 2010; Abella & Chenlo, 2003). This research proposes an application, where the PV-CS is used to supply the required charge of the campus LEVs. The campus fleets are adopted for short distance commutes at day/night time around Grangegorman's expanding campus allowing the generation of reliable green electricity, thus fulfilling campus's sustainability targets.

2. Solar Climate and Potential (in Ireland) :

PV systems use the photovoltaic effect to convert solar radiation directly into electricity. Solar radiation reaching the Earth's surfaces includes both direct and diffuse insolation, where the most common measurement for quantifying solar radiation is the total radiation on a horizontal surface, often referred to as global radiation (Duffie & Beckman, 2013). PV generation is directly related to the solar radiation intensity, i.e., higher solar radiation levels provide greater electricity output. Figure 1(a) from Met Éireann data (Irish Meteorological Service, 2011), illustrates the sunshine profile of Ireland. Based on this information, the annual sunshine hours for the temperate region of Ireland is between 1100-1600, where May and June are the sunniest periods during the year with average sunshine durations of 5 and 6.5 hours per day. During the month of December, the average sunshine values can be extremely low and available for only one hour (Flood, et al., 2011).

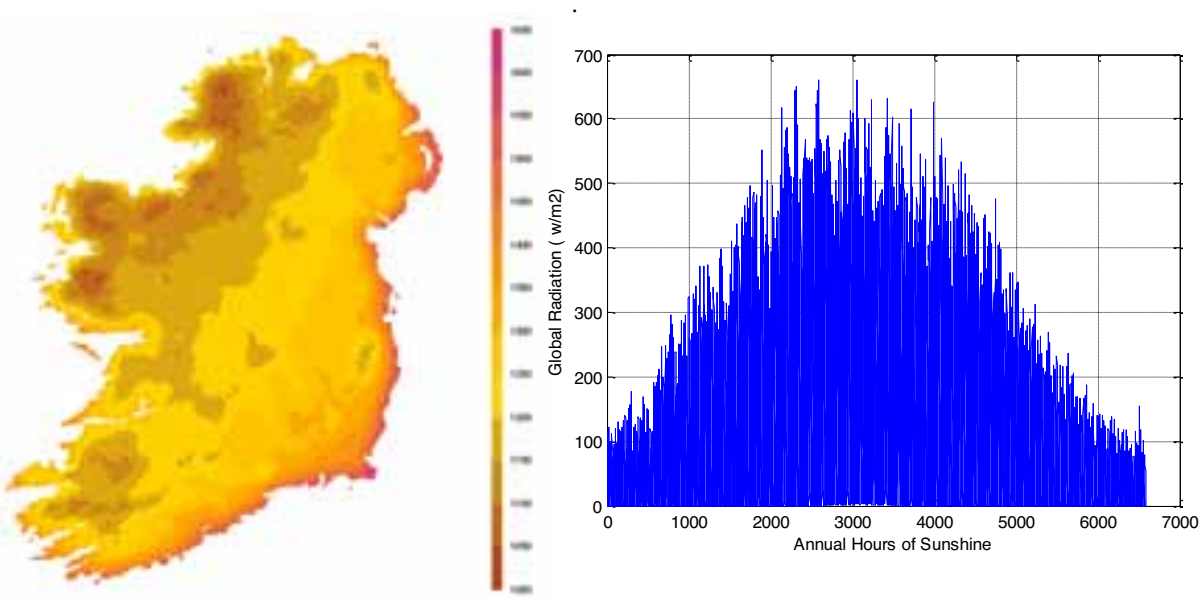

Figure. 1: Met Éireann Data: (a) Annual Hours, (b) Averaged out Global Radiation (W/m^2) of 10 years

Figure 1(b) signifies the "annual averaged global solar radiation" profile of Dublin, using 10 years of measured data by Met Éireann. The irradiance data (W/m^2) accounts for seasonal (monthly) sunshine variations and has been captured hourly every day from 04:00 – 21:00 at Dublin airport meteorological

station. As can be observed from the graph, the insolation levels are greater during the summer period, reaching a maximum level of 660 W/m^2/day, while the mean value of the global radiation is ~ 140W/m^2/day. These fluctuations in solar radiation levels, and DIT campus's expansion targets, will require a sizable PV covered roof area that can harvest sufficient electricity for the campus LEVs demand.

The PV system will be installed on the Orchard-House building; it is shown along with the building plan in Figure 2 (a) & (b). This is the current charging point for the campus LEVs the CarryAll 500 which is illustrated in Figure 2 (c). The vehicle specification is summarized in Table 2. Since Orchard house is situated near the main access point of university, it is a favourable location for deploying PV-CS. The total available roof area is 3700 m^2 but the dedicated south facing area of this roof (highlighted with red-lines in figure 2(a)), is ~ 69 m^2 at an inclination of ~ 36 degrees. When considering a regular 250 W monocrystalline PV panel of 1.63 m^2, the purposed area can accommodate a 10.5 kW system composed of 42 panels.

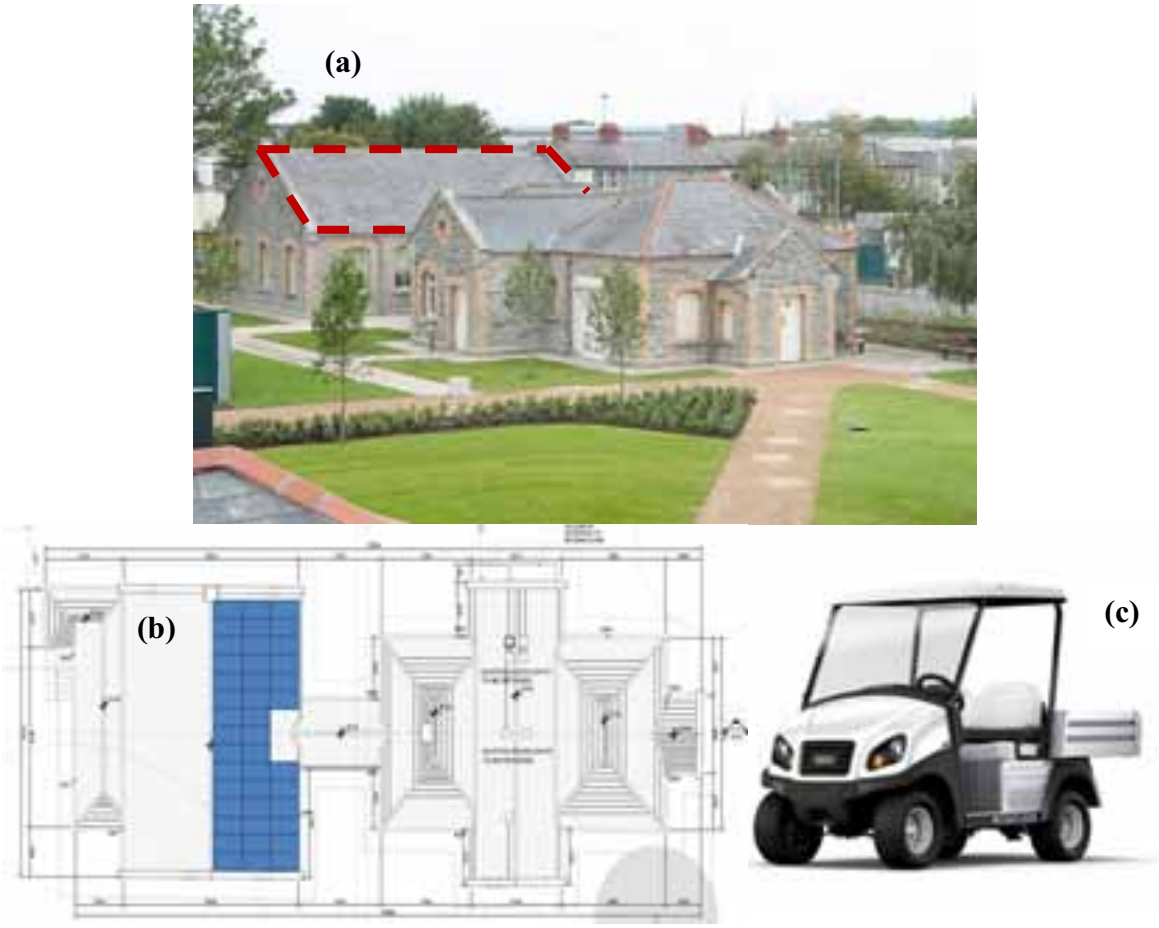

Figure.2: Orchard-House Building site (a), Roof schematic plans (b), CarryAll 500 LEV (c)

Table. 2: Specifications of the CarryAll 500 LEV

Motor Type	48 V DC
Horse Power Rated	3.7 hp (2.7 kW) rated; Peak 20 hp (14.9 kW)
Transmission	Direct/ Drive Double Reduction
Speed	15 mph (~ 25 km/h)
Battery Model	Trojan (T-145) with Flip-Flops x 8Units
Battery Voltage	48 Volts (6 Volts x 8Units)
Battery Capacity	13.76 kWh (1.72 kWh Each Unit)
Battery Capacity	260 Ah kWh (Each Unit)

3. PV-CS Design Options

In order to advance the PV-CS design, it is vital to identify the optimal design option, which has the potential to deliver electricity in a sufficient, reliable and cost effective manner. Sizing and deployment of the PV installation tends to be an iterative process, in which numerous design factors need to be examined, such as: solar potential of the site, array size, available cost, nature of the load, demand profile, operating voltage, choice of the storage unit and or grid integration (Lee, et al., 2012; Esfandyari, et al., 2015). PV-CS can be divided into a number of segments (Esfandyari, et al., 2014) such as PV and system components, cabling, protection and mounting elements, charge controller, inverter, battery storage unit and the load. Integration of each of these components can lead to a distinct system design arrangement. (Esfandyari, et al., 2015) determined the hypothetical design set-ups for the campus PV-CS and grouped the outcomes into five possible options; (i): decoupled grid (AC); (ii): decoupled direct PV (DC); (iii): decoupled PV with storage (DC); (iv): coupled PV-grid without storage and (v): coupled PV-grid with storage. These configurations are summarized in Figure 3. Furthermore, the average cost for each system component and various installation categories is presented in Table 3. These figures are quoted from PV suppliers and data reported by Sustainable Energy Authority of Ireland (SEAI, 2013).

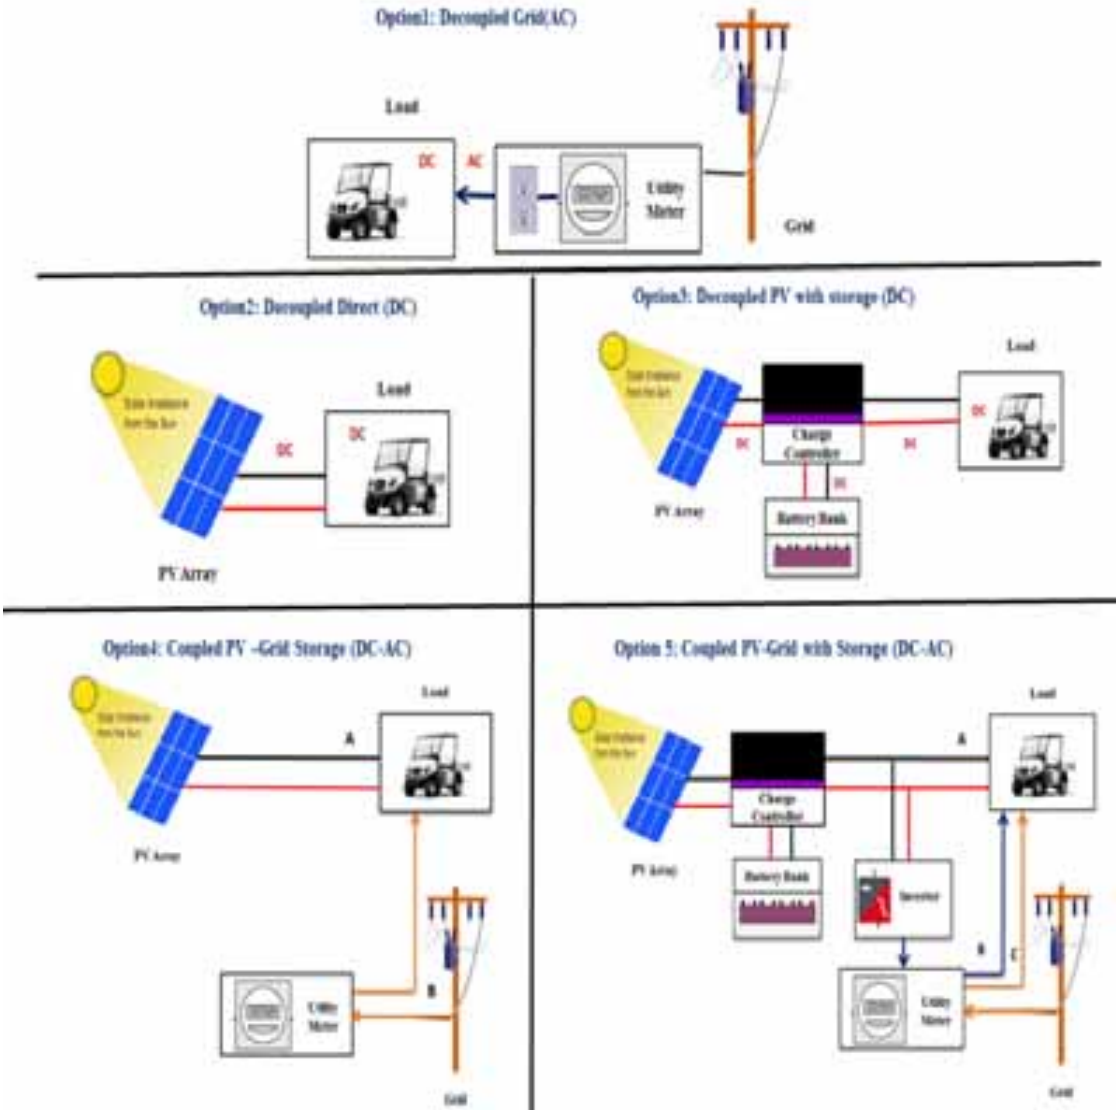

Figure. 3: Detailed Schematic for Design Options of Campus PV-CS

Table. 3: Cost breakdown for PV-CS system components and installation (SEAI, 2013)

Component	Average Cost
Solar Photovoltaic Panels	€854 per kW
Inverter	€619 per kW
Instrumentation and Control	€177
Battery (Lead Acid)	€350 (400 Ah)
Installation-Electrical	€543
Installation-Civil	€904
Installation-Mechanical	€191
Maintenance	€109
Other	€88

From Figure 3, option 1 "decoupled grid (AC);" is the existing scheme for charging the cars, where LEVs are directly fed by the grid. In this case the electricity is supplied to the load in the form of AC, via standard three pin plug sockets at 230 Volts/13 Amps. Since the LEV batteries run on the DC voltage, and each vehicle is comprised of 8 Trojan lead acid batteries at a total of 48 Volts, the AC quantities must be converted into their DC equivalent. This is achieved through the internal inverter of the vehicles. However this is not a sustainable way for energy generation, as ~76% of Ireland's primary energy is generated from fossil fuels (SEAI, 2014). In order to address sustainability targets of: self-sufficiency in energy, improvements of security of supply and reduction of amount of GHG, solar energy was proposed as a method of green electricity generation.

Option 2, considered the possibility of synchronized design, where LEVs are directly charged using PV. In this case, solar panels are used as the primary and only source of power. The PV panels will need to be arranged on the roof of the vehicle, where DC electricity directly fed to the Trojan batteries and/or DC brushed motor. While the capital cost of system components for the case "decoupled direct PV (DC)", will be at the lower end of spectrum (due to incorporation of minimum ancillary elements), the fluctuation in solar radiation and absence of any secondary generation will require a large LEV roof coverage. In other words, with particularly low average winter sunshine durations, (only for one hour), and the demand profile of Trojan batteries (Esfandyari, et al., 2015) that can be as high as 13.76 kWh, the installed PV capacity needs be substantial for the vehicle's rooftop (at least 1.75 kW which will take up ~ 11.4 m^2). Thus, this option was not a viable choice.

Option 3 examined a set-up where the PV panels are installed in a standalone configuration. The "decoupled PV with Storage (DC)" will operate on DC voltage only, where the electricity generated from the fitted panels on the roof of Orchard house will be regulated through the charge controller and stored in a number of battery banks. The storage unit will serve as the primary source of energy, which will accommodate the vehicles load requirements. However, due to the absence of any back-up generator, the reliability of this set-up will be poor. Where in the event of lower sunshine hours, the depleted charge of the storage unit might not be restored leaving the LEVs batteries exhausted, unless the of the PV-array and subsequently the battery banks can be oversized to guarantee meeting the maximum load requirement but this can increase the capital cost significantly. As the result, this option was not identified as a practical choice.

Option 4 considered the possibility of running a coupled configured system. Coupled PV-grid without storage allows the load to be charged on both DC-AC voltages, depending on the available sunshine levels. The coupled possibilities are labelled as A and B in Figure 3 option 4. 'A' is the daytime scenario where the solar radiation is utilized as the primary source for charge generation. This means parking the LEVs during the hours of sunlight and recharging the batteries directly via the DC voltage. In the case of low solar radiation and/or higher demands, the load could be supplied by the utility grid as shown by in 'B'. However, as the LEVs are normally used during the day and charged at night time, this option was also not appropriate.

The choice of "coupled PV-grid with storage"/Option 5 completed the design scenarios, by combining all the

system configurations retrieved from the previous options. In this case the practicable methods for charge restoration of LEVs are described in sections: A, B and C. In 'A' PV will be used during daylight to generate electricity and this electricity will be stored in the battery storage unit. The storage unit charge could be used afterwards to charge the LEVs, thus it will not pose any limitations on user's driving needs. In 'B', any surplus in PV generation where the storage batteries are full is sent to the grid. Finally 'C' includes the grid as the back-up generation for the load, in the event of low solar radiation and consequently resulting in no charge in the storage batteries. This design option was chosen to be the most viable choice for Grangegorman PV-CS.

4. Battery Energy Storage System (BESS) Design Option

To consistently utilize the solar generated electricity in Grangegorman where solar radiation and charging habits of the users fluctuate, the designated PV-CS design will incorporate a battery storage unit. As described in the earlier section Option 5 the "Battery Energy Storage System (BESS) design option will be examined further. Since the storage component is the predominant module of this configuration, the accurate sizing of this unit is imperative. Previously, (Esfandyari, et al., 2015) applied a methodology which was adapted from (Lee, et al., 2012 ; Masters, 2004). In this manner, the battery capacity was altered with respect to: maximum daily load demand, days of autonomy, Depth of Discharge (DOD), efficiency and voltage level. The days of autonomy which accounted for the number of the days that the storage batteries need to accommodate the load, were calculated based on Peak Sunshine Hours (PSH) of 2.83 hours for a typical day in Dublin (Ayompe, et al., 2011). Thus, the selected lead acid batteries were settled to the capacity value of ~ 390-400 Ah as advised by the battery suppliers., with 40% DOD and 85% efficiency and a voltage level similar to voltage level of LEVs Trojan Lead acid batteries, i.e., 8 batteries with at 6 volts-260 Ah. Based on this methodology and with 95% system availability, the recommended storage days for the PV-CS was estimated as 4.93 days, which resulted in 72 or 32 batteries for summer and winter load profiles respectively. Yet, as stated by the authors, due to auxiliary issues associated with: efficiency, cost, sheltering and maintenance of the estimated batteries, the work required further justifications and a more pragmatic capacity value for BESS.

As mentioned earlier, BESS will be exploited as the preeminent energy source, for storing the available PV generated DC output and subsequently dispatching the charge to the load. Inappropriate sizing of the batteries, (over-sizing or under-sizing the BESS unit), will have ramifications on the cost and or reliability of the campus PV-CS. In exchange, optimization of BESS capacity will depend on a number of constraints such as: obtainable solar resource, mandatory LEV demand, available budgets and cumulative project size. The adopted approach here has examined the first two constraints; DC generation and LEV load demand, where the proposed storage size was formulated.

4.1. BESS with DC generation

Hourly recorded meteorological insolation data at Dublin airport station is presented in figure 4 where the seasonal variations in solar intensity are clear. The roof plan of the chosen building and its accessible area as illustrated in figure 4, acts as a constraint for PV deployment. The total daily horizontal insolation values (kW/m^2) were scaled to correspond to the roof area of 69 m^2. Moreover, as the designated panels are 15.4% efficient, the DC generated output was calculated (gray cross line) and is presented in Figure 4. As displayed in figure 4, the magnitude of total daily DC output varies between the minimum of 3.56 kWh/day which occurred on the 31th of December to the maximum value of ~ 63 kWh/day occurred on 15th of June. Due to the overcast climate of Ireland, the total numbers of the days with high output and close to the maximum point are quite low (especially from November-March). Previously statistical tools were adopted (Arthur, et al., 1988; Lee, et al., 2012; Ibrahim, et al., 2012), such as curve fitting, regression model and probability density distributions, for analyzing the solar radiation distribution. The approach adopted in this study was essentially based on investigating the DC generation and determining the distribution of specified generation categories in MATLAB. After inspection of several groups, case 1 and 2 were designated as the best representative scenarios.

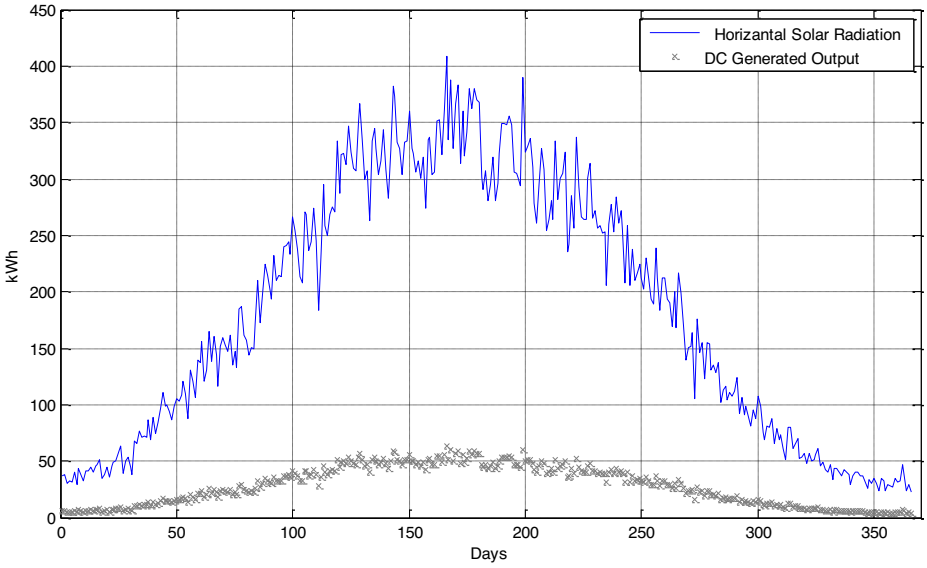

Figure. 4: Orchard House Horizontal Solar Radiation (Blue), DC Generated Output (Gray Cross Line)

The bin interval for the first case was selected as 1kW which resulted in 60 incremental generation groups. Furthermore, the bin intervals were extended to 2 kW for the second category, which reduced the incremental generation groups to 30. This was merely to examine the population density of each group profile with respect to the count of intervals. These two cases are illustrated in Figure 5, where x axis represents the generation bins and y axis depicts the population or number of occurrence for generation days.

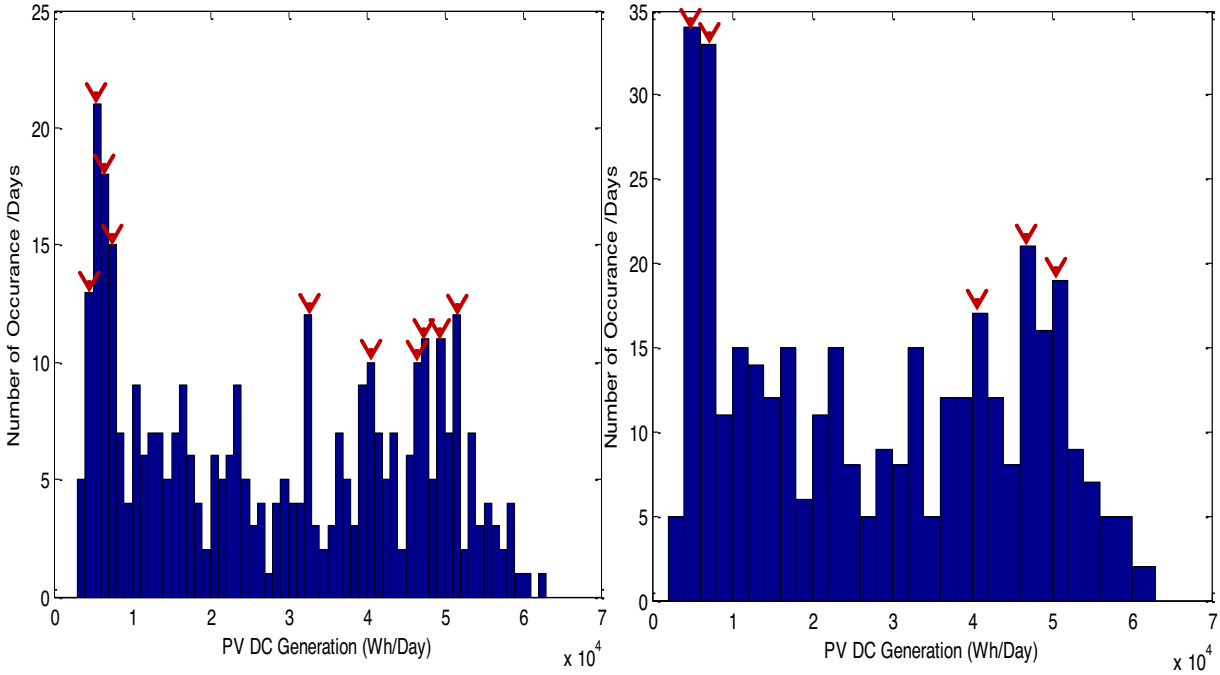

Figure. 5: PV DC Generation: (a) 1000 Watts group segmentations, (b) 1000 Watts group segmentations

In order to identify the most applicable generation band for BESS sizing, the maximum peak values in each category were extracted, tabulated and is presented in Table 4. Table 4 reports on the number of the occurrence (population intensity) of the individual peak values, the associated bin range and percentage of divergence from the potential maximum day of generation. There were 10 chosen peaks for the first case, and the peak numbers were reduced to 5 for the second case. Nevertheless the population intensity of the second category peaks contains more days of occurrence.

Table. 4: DC Generation Normalised Peak Density

Peak	Number of Occurrence /Days (Case 1 = 1k)	Bin Range (Case 1 = 1k)	Deviation from the Max (Case 1= 1k)	Percentage Of generation	Number of Occurrence /Days (Case 1 = 2k)	Bin Range (Case 1 = 2k)	Deviation from the Max (Case 1= 2k)
1	13	4-5 kWh	92%	8%	-	-	-
2	21	5-6 kWh	90.5%	9.5%	34	4-6 kWh	90.5%
3	18	6-7 kWh	88.89%	11.11%	33	6-8 kWh	88.89%
4	15	7-8 kWh	87.3%	12.7%	-	-	-
5	12	32-33 kWh	48%	52%	-	-	-
6	10	40-41 kWh	35%	65%	17	40-42 kWh	35%
7	10	46-47 kWh	26%	74%	-	-	-
8	11	47-48 kWh	24%	76%	21	46-48 kWh	24%
9	11	49-50 kWh	22.3%	77.7%	-	-	-
10	12	51-52 kWh	17.5%	82.5%	19	50-52 kWh	17.5%

As it can be seen from the table, over the course of the year the generation bands which had the higher distribution densities were between 4-6 kWh, 6-8 kWh 40-42 kWh, 46-48 kWh and 50-52 kWh. Thus, the battery size/days of autonomy would need to be matched to the most appropriate generation band.

4.2. BESS with LEV Load Demand

In order to determine the prospective PV-CS BESS unit, the second technique inspected the daily load profile of the campus vehicles. This was to quantify the accurate demand band of the LEVs as well as average and maximum demand bands. The demand profile was measured using a designated power meter "Hawk5000". The Hawk meter with its capability to monitor the electricity supply and consumption by means of Current Transformers (CTs), was wired up to the current charging point. The energy meter captured: current, voltage, real power, power factor, and energy at a specified sampling interval.

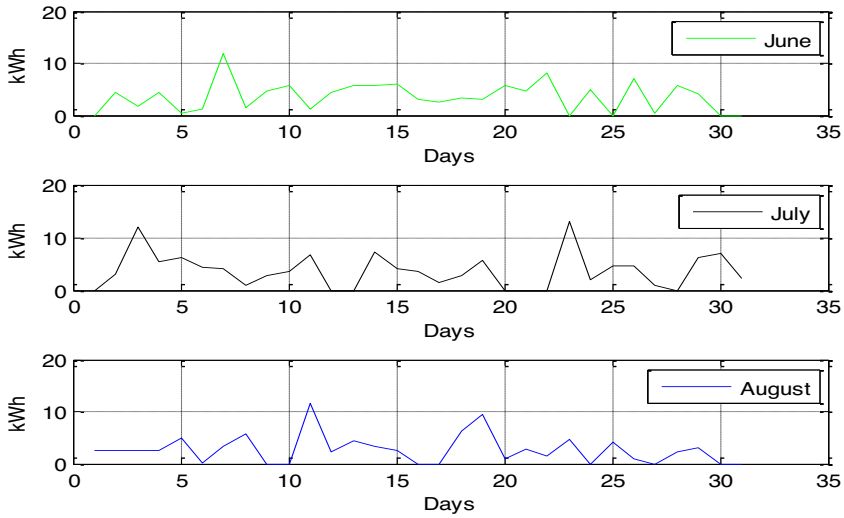

Figure. 6: Load Demand Profile of two LEVS (June-July-August 2015)

The desired sampling rate in this case was selected and varied between 1 to 5 minutes. Every time a load was plugged in to the charging point, the variations of measurement signals were sensed by CTs and stored in the data logger. Figure 6 presents the daily energy requirements of the two LEVs. The data was collected for

over 3 months (June - July - August 2015). It is summarized in Table 5, the maximum load demand of the LEVs was on 23th of July (13.03 kWh/day - close to the total capacity of one vehicle). The average demand of the total load was 2.11 kWh/day. This value emphasises the variation of the rate of charge.

Table. 5: Load Demand profile of Two LEVs (Maximum and Average)

Generation	Maximum DC Generation Output	Maximum Load Demand	Average DC Generation Output	Average Load Demand
10.5 kW (STC)	62 kWh/day	13.03 kWh	28 kWh/day	2.11 kWh/day

In order to identify the most appropriate size of BESS, generation potential and demand profiles were measured. As the average load demand of each vehicle is limited (2.11 kWh/day for the total campus load), when the cost factor of the batteries were considered the generation ranges of 4-6kW, 6-8kW were viable. Moreover, with the new battery technologies in the market, for example the Tesla Powerwall (Tesla, 2015), which are lightweight rechargeable batteries offering reliable operation and security at 7 kWh per unit, the 6-8 kW range was perceived as a better option. In other words, if the BESS unit was matched to 6-8kW, it could accommodate almost 6 campus vehicles.

5. Conclusion

Introduction of a PV-CS in DIT Grangegorman campus, Dublin, Ireland that generates clean electricity from the sun and charges the campus LEVs batteries, can substitute a portion of the charge supplied from the conventional utility grid, and further help to achieve suitability targets. In this paper design options for PV-CS were discussed. Due to intermittent nature of Irish sunshine and user's charging habit, the choice of coupled PV-Grid with storage unit/ BESS was identified as the most viable solution. Yearly averaged values of solar insolation for Dublin were examined and appropriately scaled to represent the DC generated output of 10.5 kW PV array with 15.4% efficiency. In order to size the BESS unit accordingly BESS was investigated in conjunction with generation and demand requirements. Since the load demand of the two LEVs was, within the DC generation ranges of 4-6kW, 6-8k, these ranges were selected for BESS sizing. With reference to the new technologies in the battery industry for example Tesla Powerwall at 7kWh, the 6kw-8kW range was recognised as possibly a better option. This capacity band with reference to the average load demand of 2.11 for two LEVs could accommodate up to 6 cars. .

6. Acknowledgment

Authors would like to thank Dr Agata Świerc Dublin Energy Lab (DEL) Visiting Assistant Professor for her enormous level of support and advice. Also authors would like to acknowledge the Fiosraigh scholarship (DIT), Grangegorman Development Agency, Dublin Institute of Technology, and Trinity College Dublin for all the support and facilities. Finally authors wish to thank, Mr Paul McDunphy, Mr Terry Maher, Mr Eamonn Murphy, Mr Alan Keyes as well as all the porters and night time securities in Grangegorman.

Abstract

To fight weather anomaly affected by greenhouse gases due to rapid industrialization, the Korean government enforced the Act on the Promotion of the Development, Use and Dissemination of new renewable Energy since 2004, according to which 15% of the energy (as of 2015) that is expected to be used in a public building whose total floor area is at least 1,000 ㎡ should be provided with new renewable energy system when the building is constructed, reconstructed, or extended.

However, this act just presents an obligatory provision ratio of new renewable energy system and do not provide an optimal installation ratio of the system optimal to characteristics of energy use of building and demands of building users. In this context, the purpose of this study is to develop a program for deducting an optimal ratio of a new renewable energy system and to verify the program′s validity when compared to a simulation.

As for comparison and verification, the researcher compared the coefficient of determination values of factors related to economic, environmental and technical aspects to determine higher or lower correlation.

Keywords*: New &Renewable-energy, Economy Analysis, Technical Analysis, Environment Analysis, Optimize the ratio*

1. Introduction

1.1. Background and purpose

To fight severe environmental problems such as weather accidents and ozone layer destruction due to greenhouse gases, the Korean government enforced the Act on the Promotion of the Development, Use and Dissemination of new renewable Energy since 2004, according to which a new public building whose total floor area is at least 3,000 ㎡ should be applied by a new renewable energy system to the amount of 5% of the total construction expenses. Later the act was so revised that it was applied to construction, reconstruction and extension of a public building whose total floor area is at least 1,000 ㎡ and the expected amount of energy used (not the total construction expenses). However, the act just presents an obligatory provision ratio of new renewable energy system and do not provide an optimal installation ratio of the system optimal to characteristics and use of building and demands of building users. Thus, in case of lack of professional knowledge, it is difficult to select a new renewable energy system for a building and to deduce an optimal ratio of installing the system for complex application.

In this context, the researcher in this study developed a program for selecting a new renewable energy system and deducing an optimal ratio of installing during planning and designing a building (KRESS) and compared & verified reliability of the program for deducing an optimal ratio with which various systems are enabled to be

doi:10.18086/swc.2015.01.03 Available at http://proceedings.ises.org

combined and designed by selecting an appropriate source of new renewable energy and then calculating capacity of the system in the phase of initial designing.

1.2 Methods and scope

As a study of comparison and verification of a program for deducing an optimal ratio of a new renewable energy system, the methods and scope of this study are as follows.

The researcher compared and verified the validity of the developed program by using a developing tool (KRESS) and a simulation tool (Energy Plus) for selecting an optimal ratio of installing a new renewable energy system for public office buildings.

For comparison & verification of validity, the researcher assessed correlations of sub-items based on economic, environmental and technical aspects, a data that was used to compare and verify optimal application by evaluation priority for designing a new renewable energy system and optimal ratio of installing the system.

2. Overview of the developed program and buildings for comparison and verification

2.1 Overview of the developed program

The KRESS program developed in this study was developed by using of the MS-Excel VBA. As seen in the flow chart in Figure 1, the program can deduce an optimal ratio of installing a new renewable energy system on the expected amount of energy use of a building when considering solar power, solar collector, and heat pump, sources that can be easily applied to buildings among the 11 sources of new renewable energy designated domestically.

Fig 1. Develop program's Flow Chart & User Interface

When basic data such as building use and area are entered, the program calculates the energy consumption of the building based on the database, estimates the obligatory energy supply and the capacity of a new renewable energy system based on the calculation, and then presents application methods and optimal ratio of installing for evaluation items including economic, environmental and technical aspects based on evaluation priority of the energy.

2.2 Selection of buildings for comparison and verification

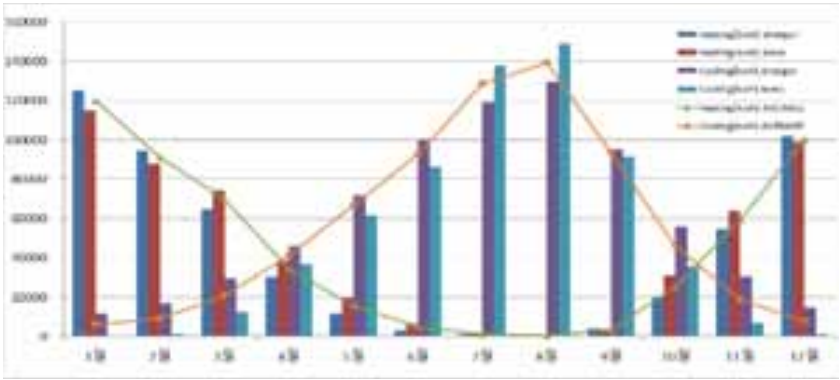
For verifying the validity of the developed program, the researcher performed a simulation analysis in which variables such as capacity of air conditioning and heating, number of occupants, and lighting equipment were applied by zone-based schedules based on weather data according to the current state of buildings (as seen in Table 1), by using the KRESS and the Energy Plus tools.

Table. 1 Overview of the subject building.

Area (㎡)	Construction area	2,929.27
	Total floor area	10,320.48
	Parking area	1,533.98
Thermal perfusion (W/㎡.K)	Exterior wall	0.47
	Windows	2.7
Internal heating value (W/㎡)	Person	0.15
	lighting	20
	Electrical equipment	22
direction	East	

According to the results of the simulation (see Table 2), the total energy requirement was 2,806,648 kWh by the KRESS and 3,232,935 kWh by the Energy Plus, with the deviation of 13.2%. In the Energy Plus, changes in daily air conditioning & heating and amount of electricity used were applied because of application of local weather data, while the KRESS uniformly calculated amount demanded based on the unit equation presented by legislation. This is the reason that the energy requirement deduced by the KRESS was less than that by the Energy Plus, requiring further examination Tables, figures, equations, and lists

Table. 2 Estimated energy consumption of the subject building



End Uses Energy	KRESS	Energy plus	measuring efficiency
Heating	464,623 (kwh)	538,793 (kwh)	13.8 %
Cooling	514,935 (kwh)	619,694 (kwh)	16.9 %
Hot water	132,893 (kwh)	154,227 (kwh)	13.8 %
Electronic Equipment	1,694,197 (kwh)	1,920,224 (kwh)	11.8 %
Total End Uses	2,806,648 (kwh)	3,232,935 (kwh)	13.2 %

3. Comparison & verification and optimal ratio of new renewable energy system

3.1 Comparison & verification of new renewable energy system

For comparison & verification of new renewable energy system, the researcher classified methods of application of [C01～66] (see Figure 2) so that at least 671.157kWh of new renewable energy could be produced when the ratio of obligatory installation was 12 % based on the Act (as of 2014), investigating the reliability of the developed program via comparison & verification of correlations based on the KRESS and the Energy Plus. For comparison & verification of correlations, higher or lower correlation was determined via comparing the coefficient of determination (R^2) values of the factors of economic, environmental and technical aspects of the KRESS and the Energy Plus.

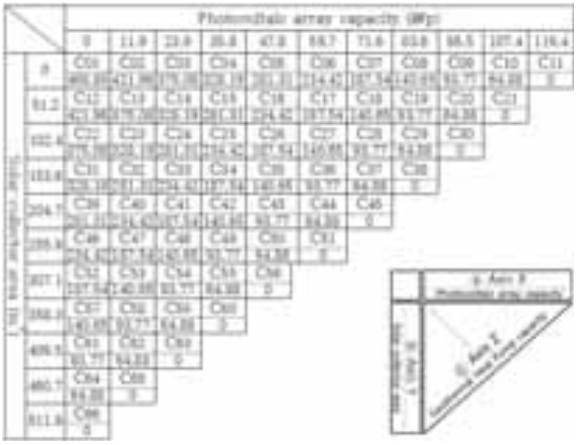


Fig 2. Categories of application plans of a new and renewable energy system

As for the correlations of economic aspects by the KRESS and the Energy Plus, among the sub-items of the economic aspects (see Figure 3), the R^2 value of initial investment costs used for installing and applying a new renewable energy system was 1.0 [Eic], that of maintenance and management cost used for maintaining and managing the system for certain period was 1.0 [Emrc], and that of energy cost that could be reduced by the system was 0.92 [Eec]. As for the correlations of technical aspects (see Figure 4), the R^2 value of supply reliability for safe supply of energy was 0.97 [Tesr] and that of energy efficiency as a rate of energy production on initial investment cost was 0.95 [Tee]. For the correlations of environmental aspects (see Figure 5), the R^2 value of CO2 emission for reducing greenhouse gases was 0.81 [Ecey].

As for correlations based on economic and technical aspects, the R^2 values were consistent as the entered values of the main items in the KRESS and the Energy Plus. However, the environmental aspects showed deviations in the correlation R^2 due to difference in the total energy demands between the KRESS and the Energy Plus.

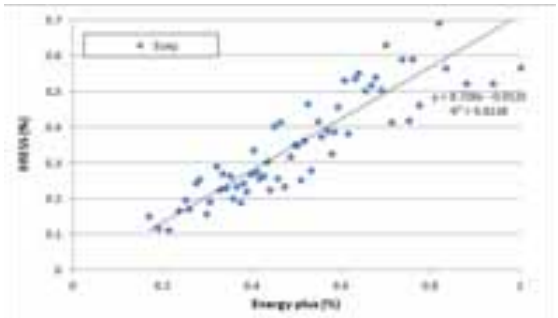

Fig 5. Comparison and testing of correlations according to environmentality

3.2 Optimal ratio of installing a new renewable energy system

Via analysis of economic, environmental and technical aspects per each alternative [$C_{01\sim66}$], an optimal ratio of installment was analyzed (see Table 3).

As for an optimal system based on the economic aspects of a building, C_{11} : PV (100%) was assessed as an optimal system both by the KRESS and the Energy Plus. For an optimal system based on technical aspects, the KRESS assessed only C_{11} : PV (100%) as optimal one, while the Energy Plus assessed C_{11} : PV (100%) and C_{21} : PV (90%)+SC(10%) as optimal ones. For an optimal system based on environmental aspects, both the KRESS and the Energy Plus assessed C_{21} : PV (90%)+SC(10%) as an optimal system. As for an optimal ratio of installment based on complexity, the KRESS assessed C_{11} : PV (100%) as an optimal system, while the Energy Plus assessed a (complex) C_{21} : PV (90%)+SC(10%) as an optimal system reflecting characteristics of building use and zone-based energy use schedule. As mentioned above, in the simulation of subject building for comparison and verification by the KRESS and the Energy Plus, a system was assessed as an optimal one as the PV was more applied in a single or complex system. For the subject building, thus, at least 90% of PV in a system may be most efficient ratio for a new renewable energy system.

Table. 3 Optimal installation percentage of multiple applications of new renewable energy by the programs

[unit:%]

	KRESS	Energy plus
Optimal installation percentage		The Economy Analysis	C_{11}	C_{11}
	PV (100%)	PV (100%)
The technical Analysis	C_{11}	C_{11}, C_{21}
	PV (100%)	PV (100%), PV (90%) +SC (10%)
The Environment Analysis	C_{21}	C_{21}
	PV (90%) +SC (10%)	PV (90%) +SC (10%)
The Optimize Analysis	C_{11}	C_{21}
	PV (100%)	PV (90%) +SC (10%)

*[SC]:Solar Collector ,[PV]:Photo Voltaic, [GH]:Ground Heat`

4. Conclusion

As a study of comparison and verification of a program for deducing an optimal ratio of a new renewable energy system, the results of this study are as follows.

1) The researcher investigated verification of the developed program by calculating the total amount of energy use using the KRESS and the Energy Plus; the amount simulated by the Energy Plus was 13.2% higher than that by the KRESS because the former reflected characteristics of energy consumption based on building use, energy production based on surrounding weather, and requirements by users.

2) The R^2 values of economic and technical aspects by application methods [$C_{01\sim66}$] in the KRESS and the Energy Plus were 0.97 and 0.96, respectively, indicating that the deviation of coefficient of determination in the A Study of Optimal Design Techniques for the Application of Renewable Energy Combination Systems in School Facilities correlation was slight because the main items entered for the two simulations were consistent. The R2 value based on the environmental aspects was relatively lower, or 0.81, due to the difference in total energy requirement between the KRESS and the Energy Plus. However, the overall R^2 value was 0.91, indicating a favorable correlation.

3) As for an optimal sy stem of new renewable energy assessed by analysis of technical & environmental aspects per each alternative [$C_{01\sim66}$] for the subject building, both the KRESS and the Energy Plus assessed a system in which PV was more applied among the new renewable energy sources as an optimal one. For application methods of a new renewable energy system appropriate for the subject building, C_{11} : PV (100%) (A single system) and C_{21} : PV (90%)+SC(10%) (A complex system) may be optimal ones.

In developing a program for deducing an optimal ratio of a new renewable energy system for public buildings, selecting an appropriate energy source and calculating energy capacity & combining various systems, the comparison & verification of the results by the KRESS and the Energy Plus simulations was determined to be favorable. Improvements in reliability are required through further verification of various variables and consistent supplementation.
