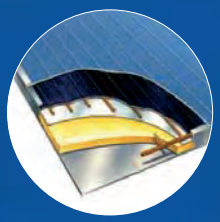
International Solar Energy Society

ISES Solar World Congress 2015



November 8 - 12, 2015
Daegu, Korea

Conference Proceedings

Organized by ISES International Solar Energy Society

Hosted by 사단법인 한국태양에너지학회 THE KOREAN SOLAR ENERGY SOCIETY

Proceedings of the ISES Solar World Conference 2015

Edited by
Dr. Manuel Romero, Vice President of ISES
Solar World Congress 2015, Co-Chair of Scientific Committee

Dr. Taebeom Seo, President of KSES
Solar World Congress 2015, Co-Chair of Scientific Committee

Dr. David Renné, ISES President
Solar World Congress 2015, Chair of Organizing Committee

ISES Solar World Congress 2015 Proclamation

Achieving the Renewable Energy Transformation

The International Solar Energy Society is committed to accelerating the transformation of the global energy system to 100% renewable energy for all, used wisely and efficiently. This transformation is necessary for the long, and short, term health and wellbeing of our planet and our people. We know this goal is technically and economically achievable and we know the challenges this entails. The renewable energy movement needs a strong, unified voice to accelerate this transformation, and ISES is expanding its mission to be this voice. To do this, ISES will continue to grow its strong core of solar energy and related renewable energy and environmental professionals, essential for the technical foundations of the movement. In addition ISES will expand its partnership building and outreach with like-minded groups and individuals who can help strengthen the movement through their support. Future ISES events, webinars, publications, participation in global decision making, and other outreach activities will continue to provide the highest quality information on solar energy, and through collaboration with its growing partnership base, address the other wide range of issues central to achieving a 100% renewable energy world.

The Congress brought together a wide range of contributors to the renewable energy movement. Hundreds of participants from 58 countries presented recent developments in solar technologies, and latest updates on financing, policies, access and public support around the world. Young professionals joined with long time solar energy mentors to enrich the discussion of challenges and opportunities for making a difference in all of these areas. The Congress provided an excellent environment for fruitful collaboration and planning, and resulted in the affirmation that we can and will attain the needed energy transformation.

ISES Solar World Congress 2015 participants at the closing ceremony

Welcome of KSES

It is a great pleasure and honor for us to welcome you to the Solar World Congress 2015 which will be held on November 8 to 12, 2015 at EXCO, Daegu, Korea. We aim to help you accomplish ISES's objectives of developing and expanding renewable energy technologies throughout the world.

The Solar World Congress in 2015 would provide an excellent opportunity for renewable energy experts and companies from many nations to meet their colleagues, and offer visitors a chance to discover and enjoy Korean culture during your stay. Based on our successful experience of hosting the SWC1997 in Korea, we expect to achieve outstanding results through the Solar World Congress in 2015, encouraging international colleagues to develop and deploy the renewable energy technologies in the world.

Besides thought-provoking academic challenges and discussions, SWC 2015 also offers a lovely time to enjoy Korea through diverse social programs featuring Korean history, culture and natural scenery.

Korea boasts an enticing blend of modern and traditional culture, warm hospitality and collection of tempting food. In particular, Daegu has been designated as solar city, in recognition of its efforts to apply the renewable energy technology into their daily life.

We assure you that this congress will be an academically enriching, socially enjoyable, and truly memorable experience for all the delegates and their guests.

Thank you.

Prof. Kwang Hwan Choi, President
The Korean Solar Energy Society

Welcome of ISES

The International Solar Energy Society is pleased to welcome you to the ISES Solar World Congress in beautiful Daegu, Korea, 8-12 November, 2015. The Congress is hosted by the Korean Solar Energy Society. SWC 2015 continues a long tradition of connecting the renewable energy research and academic community with decision makers, financiers, and practitioners. The Congress will provide the most up-to-date information on renewable energy technology trends and breakthroughs, global and regional policies, and market opportunities. The Congress will feature a broad spectrum of technical presentations on the latest renewable energy developments, plenary and keynote addresses from global experts, workshops and discussion forums, and a variety of networking and social events.

ISES is committed to achieving the vision of 100% renewable energy for all, used efficiently and wisely. Achieving such a vision will require a transformation of our energy system, addressing technology developments, innovative financing, political will, and, most important, community acceptance of these transformative technologies. In addition, for this vision to become a reality, we must address gender engagement, community involvement, and public education. SWC 2015 offers many examples of progress in all of these areas, as well as addressing the challenges that remain.

I wish you a successful Solar World Congress 2015 and hope that you have a fruitful and enjoyable experience, and are able to meet old friends and colleagues and make many new important contacts to support your work.

Dr. David Renné, President
International Solar Energy Society

Committees

Co-Chairs

· Dave Renné	President ISES
· Kwang Hwan Choi	President KSES

International Organising Committee

· Dave Renné	President ISES
· Kwang Hwan Choi	President KSES
· Taebeom Seo	Former President KSES
· Manuel Romero	Vice-President ISES
· Jennifer McIntosh	Head of Secretariat ISES

Local Organising Committee

· Chair : Yongheack Kang	Director, Korea Institute of Energy Research
· Booseop Nam	CEO, Korea Energy News
· Sang-Yang Noh	President, New and Renewable Energy Center
· Hyungjin Kim	President, Green Energy Institute
· Changhyung Park	Associate President, Korea New and Renewable Energy Association
· Jajoong Kook	Associate President, Korea Photovoltaic Industry Association
· Wonyong Lee	Director, Korea Institute of Energy Research
· Jongdal Kim	Professor, Kyungpook National University
· Taebeom Seo	Professor, Inha University
· Doo Sam Song	Progessor, Sungkyunkwan University
· Seung Ho Yoo	Professor, Korea University
· Jun-Tae Kim	Professor, Kongju National University
· Gihwan Kang	Ph.D, korea Institute of Energy Research
· Donggun Lim	Professor, Korea National University of Transportation
· Hyun-Goo Kim	Ph.D, korea Institute of Energy Research
· Ju-Yeop Choi	Professor, KwangWoon University
· In Soo Cha	Professor, DongShin University
· Jeong-Bae Kim	Professor, Korea National University of Transportation
· Jae-Han Lim	Professor, Ewha Womans University
· Eung-Jik Lee	Professor, Semyung University
· Jung-Ha Hwang	Professor, Kyungpook national University
· Sun Jin Yun	Ph.D, Electronics and Telecommunications Research Institute

Scientific Committee

Co-Chairs

- Manuel Romero — Vice-President ISES
- Taebeom Seo — Former President KSES

Theme Chairs

- Solar Buildings and Architecture
  - Maria Wall — Lund University, Sweden
  - Haruki Sato — Keio University, Japan

- Resource Assessment and Energy Meteorology
  - John Boland — UNISA, Australia
  - Hyun-Goo Kim — Korea Institute of Energy Research, Korea

- Renewable Electricity Technologies: Photovoltaics
  - Nicola Romeo — University Parma, Italy
  - Jae-Ho Yun — Korea Institute of Energy Research, Korea

- Renewable Electricity Technologies: CSP, Biomass, Geothermal, Wind, Hydro, Ocean & Other
  - José González-Aguilar — IMDEA Energy, Spain
  - Zhifeng Wang — IEE Chinese Academy of Sciences, China

- Solar Heating and Cooling: Fundamentals & Applications
  - Andreas Häberle — Fraunhofer Chile Research Foundation, CSET, Chile
  - Jie Ji — University of Science and Technology of China, China

- Solar Energy and Society
  - Paulette Middleton — Panorama Pathways, USA
  - Guofeng Yuan — IEE Chinese Academy of Sciences, China

- Energy Storage
  - Luisa F. Cabeza — GREA, University of Lleida, Spain
  - Hong-Soo Kim — Korea Institute of Energy Research, Korea

- Renewable Energy Grid Integration & Distribution
  - Christof Wittwer — Fraunhofer Institute for Solar Energy Systems ISE, Germany
  - Yong-Hwan Chun — Hongik University, Korea

- Off-Grid & Rural Energy Access
  - Ajay Chandak — SSVPS BSD COE, India
  - Jangho Lee — Kunsan University, Korea

- Clean Transportation Technologies & Strategies
  - Scotte Elliot — Mid-Ohio Regional Planning Commission, USA
  - Xuhui Wen — IEE Chinese Academy of Sciences, China

Committee Members

· Arancibia-Bulnes Camilo	UNAM, Mexico
· Bai Fengwu	IEE-Academy of Sciences, China
· Bajare Diana	Riga Technical University, Latvia
· Barthelmie Rebecca	Cornell University, USA
· Bellan SelvanI	MDEA Energy, Spain
· Beltan Liliana	Texas A&M University, USA

Congress Themes and Topics

Theme 1: Solar Buildings and Architecture

Solar Architecture and Building Integration
Building Material and Components
Net Zero Energy Buildings
Advanced HVAC
Daylighting
Rational Use of Energy in Buildings
Other issues related to Solar Buildings

Theme 2 : Resource Assessment and Energy Meteorology

Solar Radiation Availability and Variability
Renewable Energy Resource Assessment
Theoretical, Technical and Economic Potentials
Resource Forecasting
Instrumentation and Tools
Other issues related to energy meteorology and resource assessment

Theme 3: Renewable Electricity Technologies: Photovoltaics

PV Cells, Materials and Components
Advanced Materials and Concepts
Design, Operation and Performance of PV Systems
Balance of Plant Components
Grid-integrated PV
Thin Film Solar Cells
Concentrating PV
Other issues related to PV fundamentals and technologies

Theme 4: Renewable Electricity Technologies: CSP, Biomass, Geothermal, Wind, Hydro, Ocean & Other

Solar concentration fundamentals and optical engineering heat transfer, materials and components
Solar Thermal Electricity Systems
Solar Detoxification and Photo-catalytic Processes
Biomass Energy, Geothermal & Other thermal Renewables
Wind Energy, Ocean Energy, Hydro and other direct conversion renewables
Other issues related to renewable thermal electricity
Solar Fuels and Chemicals

Theme 5: Solar Heating and Cooling: Fundamentals & Applications

Solar Collectors (including Thermal-PV collectors)
Testing, Certification and Quality Assessment, Simulation and Engineering Tools
Solar Domestic Hot Water and Combisystems
Solar District Heating and Cooling
Solar Heat for Industrial and Commercial Applications
Solar Distillation and Solar Thermal Desalination
Solar and Heat Pump Systems
Solar Cooling and Air Conditioning

Theme 6 : Solar Energy and Society

Strategies and Policies
International Renewable Energy Review
Solar Cities
Development of Community Renewable Energy Projects
Education and Training
Workforce Development
Gender and energy

Theme 7 : Energy Storage

Electrical Storage, Pumped Hydro and Mechanical Storage
High Temperature Thermal Energy Storage
Low-Medium Temperature Thermal Storage
Energy Storage in Buildings
Novel storage concepts

Theme 8 : Renewable Energy Grid Integration & Distribution

Grid integration of variable renewable energy systems
Automation and control
Smart Grids strategies including smart metering
Active Demand-Side Management
Communications & Data

Theme 9 : Off-Grid & Rural Energy Access

Electrical and Thermal Energy Supply
Small Wind and Small Hydro Power
Micro power and hybrid systems
Energy Access and Security
Expansion of RE in developing countries, off-grid systems
Solar Cooking and Clean Cook Stoves
Solar Food Processing, including crop drying

Theme 10 : Clean Transportation Technologies & Strategies

Renewable Energy in transport sector
Solar powered vehicles
Transport electrification and integration of Renewable Energy
Hydrogen vehicles
Policy, planning and economics

Evaluation of a Facade Integrated Concentrating Solar Collector System

Piratheepan Mahendran[1], and Timothy Anderson[1]

[1]Auckland University of Technology, Auckland, New Zealand

Abstract

The use of building integrated photovoltaic/thermal (BIPVT) collector modules is one of the most effective ways to harness the solar energy within the building environment. Using static reflectors along with BIPVT absorbers may be a cost effective way to utilize these in façade applications. In order to precisely predict the overall performance of such building integrated façade collectors it is crucial to develop a mathematical model that represents such systems. As such, a mathematical model was developed to describe the performance of a façade integrated BIPVT solar concentrator system and subsequently this was validated with a physical prototype.

Using the validated model, a sensitivity analysis was performed to determine the design parameters that significantly influence the efficiency of the collector. It was shown that key parameters such as tube spacing and thermal conductivity between the solar cell and the absorber have a significant effect on the overall efficiency while mass flow rate does not have any significant effect on the overall performance.

Keywords: *building integrated photovoltaic/thermal, façade, concentrator, BIPVT*

1. Introduction

Energy consumption in the built environment accounts for nearly one third of the global energy demand (IEA 2011). A significant portion of this could be met through onsite energy generation utilising solar energy, while intelligent building design practices and incorporating solar energy systems within the building envelope are two solutions that could reduce the long term energy costs and reduce environmental impacts. However, traditional solar energy systems such as photovoltaic panels or solar thermal collectors retrofitted onto buildings after they have been built may result in poor aesthetics and sub-optimal energy outputs. Therefore, integration of combined photovoltaic/solar thermal collectors into a buildings fabric could give greater opportunity for the use of renewable energy technologies in buildings.

Generating thermal and electrical energy simultaneously from solar irradiation using photovoltaic/thermal (PV/T) systems is an area of research that has received significant attention in recent years (Ibrahim et al. 2014, Fudholi et al. 2014, Tripanagnostopoulos 2012). However, there have been relatively few attempts to utilize such systems with low concentration ratio concentrating systems to increase the radiation incident on the PV/T absorber, and even fewer that incorporate such systems into the fabric of a building. A significant advantage of low concentration reflectors is that they do not need to track the sun making them ideal for integration into a building's facade, though by doing this they will have a lower acceptance angle range compared with tracking collectors (Rabl 1976). Despite this disadvantage, low concentration ratio collectors offer the advantage of collecting diffuse radiation as well as the beam component (Petter et al. 2012). This increases the possibility of using the traditional Si solar cells with less need for precise optics.

In 2002 Tripanagnostopoulos et al (2002) analysed PV/T combined collectors incorporating low concentration ratio booster reflectors with a view to achieving high combined efficiency. In a parallel study, (Tselepis and Tripanagnostopoulos 2002) performed a life cycle assessment of the combined collector and concluded that they were more cost competitive, had a shorter payback time and less environmental impact than that of standalone PV panels. As such, the combination of low concentration ratio reflective elements along with hybrid absorbers may further improve the cost competitiveness of the system by increasing the radiation on the absorber plate.

doi:10.18086/swc.2015.08.01 Available at http://proceedings.ises.org

Despite the work showing the benefits of using reflectors with PV/T absorbers, there are few studies that have investigated systems with a static reflector combined with a hybrid absorber plate for façade applications. A study by Gajbert, et al. (2007) found that low concentration ratio PV/T modules have advantages over traditional modules and proposed a PV/T collector with a parabolic reflector. However there appears to be few active attempts to utilise concentrating BIPVT systems, and a lack of detail in describing their combined thermal/electrical performances.

In light of this, this study examines the performance of a façade integrated solar collector that incorporates a flat reflective element with a view to increasing the radiation on a photovoltaic/thermal (PV/T) absorber plate, as shown in Figure 1.

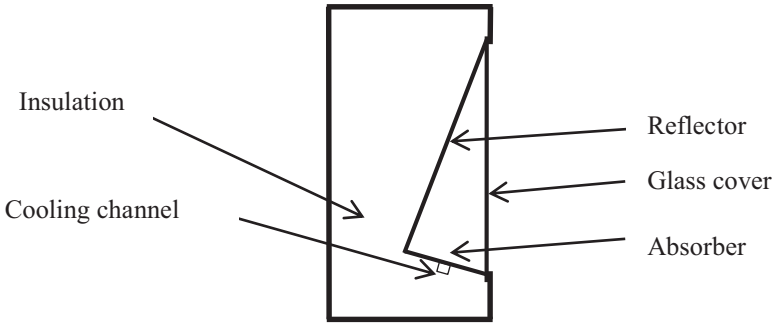

Fig. 1: Façade Integrated Concentrator

2. Mathematical model

In order analyse the performance of the proposed façade integrated collector, a one dimensional steady state thermal model was developed. A simplified thermal resistance network as shown in Figure 2 was used to undertake a heat balance of the absorber plate.

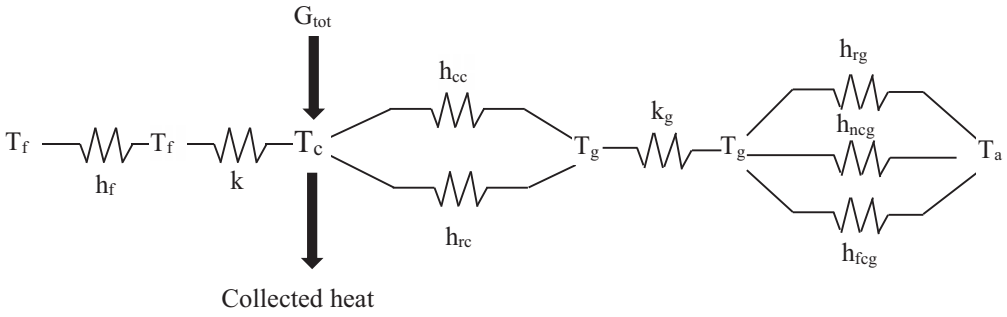

Fig. 2: Simple thermal network of the proposed module

For a typical solar thermal collector, the useful thermal energy gain Q can be determined from equation 1.

$$Q = AF_R[(\tau\alpha)_{PV}G - U_L(T_i - T_a)] \quad \text{(eq. 1)}$$

This equation can be further modified, as shown in equation 2, to incorporate the concentration ratio C of the proposed low concentration collector.

$$Q = AF_R[(\tau\alpha)_{PV}G.C - U_L(T_i - T_a)] \quad \text{(eq. 2)}$$

Here Q is given by a function of absorber area (A), heat removal factor (F_r), the transmittance-absorptance product for the photovoltaic absorber ($\tau\alpha_{PV}$), the solar radiation (G), the concentration ratio (C), the overall heat loss coefficient (U_L) and the temperature difference between inlet and the ambient temperature.

In practice it is not possible to cover the whole absorber module with photovoltaic cells, hence equation 2 can be further modified to include a packing factor (S) and the transmittance-absorptance product of the thermal absorber and the PV material, as shown in equation 3.

$$Q = S\left[AF_R[(\tau\alpha)_{PV}G.C - U_L(T_i - T_a)]\right] + (1-S)\left[AF_R[(\tau\alpha)_T G.C - U_L(T_i - T_a)]\right] \quad \text{(eq. 3)}$$

The ratio of the heat collected against the irradiation falling on the absorber plate gives the thermal efficiency of the collector as shown in equation 4

$$\eta_{thermal} = F_R[S(\tau\alpha)_{PV} + (1-S)(\tau\alpha)_T] - F_R U_L \frac{(T_i - T_a)}{GC} \quad \text{(eq. 4)}$$

Following on from this, to determine the optical concentration ratio in terms of the radiation reaching the absorber, equation 5 can be used (Kostic L et al. 2010).

$$C = {}^{G_{tot}}/_{G_{net}} \quad \text{(eq. 5)}$$

Where G_{tot} is the sum of the radiation directly falling on the absorber G_{dir} and the radiation from the reflector G_{ref} on the absorber, while G_{net} is the amount of radiation received by a horizontal absorber alone without the reflector. By incorporating the reflectance ρ_{Al} of the reflector, C can be expressed as equation 6

$$C = \frac{G_{dir} + \rho_{Al} G_{ref}}{G_{tot}} \quad \text{(eq. 6)}$$

Now from the work of Piratheepan and Anderson (2014), and basic geometry, the relationship for the average optical concentration ratio C for the proposed collector can then be expressed by equation 7. Where α is the elevation angle of the sun and the γ is the inclination angle of absorber relative to the horizontal.

$$\mathrm{C} = \begin{cases} \left[\frac{\cos(\alpha+\gamma)(\tan(\alpha+\gamma)+\tan\gamma)}{Sin\ \alpha}\right]\rho_{Al} + \frac{1}{\cos\gamma} & \alpha < (90-2\gamma) \\ \left[\frac{\cos(\alpha+\gamma)(3+\tan\gamma)}{Sin\ \alpha}\right]\rho_{Al} + \frac{1}{\cos\gamma} & (90-2\gamma) < \alpha < (90-\gamma) \\ \frac{sin(\alpha+\gamma)(1-3tan(\alpha+\gamma-90))(tan(\alpha-(90-\gamma)))}{sin\ \alpha} & (90-\gamma) < \alpha < 90 \end{cases} \quad \text{(eq. 7)}$$

Furthermore, the collector heat removal efficiency factor (F_r) can be expressed in terms of heat loss coefficient (U_L), mass flow rate (m) and the collector efficiency factor (F') as given by equation 8.

$$F_r = \frac{mC_p}{A}\left[1 - exp^{-\frac{AU_L F'}{mC_p}}\right] \quad \text{(eq. 8)}$$

The collector efficiency factor (F') can be calculated using equation 9 in terms of its fin efficiency factor F.

$$F' = \frac{1/U_L}{\left[\frac{1}{U_L[d+(w-d)F]} + \frac{1}{wh_{PVA}} + \frac{1}{\pi d h_{fl}}\right]} \quad \text{(eq. 9)}$$

Here h_{PVA} accounts for the bond resistance between the PV cell and the absorber plate as shown by (Zondag et al. 2002). The forced convection heat transfer coefficient (h_{fl}) in the cooling tube can be determined from equation 10.

$$h_{fl} = \frac{Nu * k_{fl}}{d} \quad \text{(eq. 10)}$$

Where k_{fl} is the conductivity of the fluid at the mean temperature and Nu is the Nusselt number that can be determined from any number of relationships for forced convective heat transfer in a tube, in this study the Gnielinski (Cengel 2007) correlation was used.

In order to calculate the fin efficiency factor F, it is necessary to calculate the coefficient (M) that accounts for the overall thermal conductivity and the thickness of the PV/T absorber plate as given by equation 11 in terms of overall thermal loss coefficient U_L.

$$M = \sqrt{\frac{U_L}{K_{abs}L_{abs} + K_{PV}L_{PV}}} \quad \text{(eq. 11)}$$

As such, the modified fin efficiency F can be calculated using equation 12, where w is the tube spacing and d is the hydraulic diameter of the tube.

$$F = \frac{tanh\left[\frac{M(w-d)}{2}\right]}{\frac{M(w-d)}{2}} \quad \text{(eq. 12)}$$

In the determination of M in equation 9, the overall thermal loss coefficient U_L is the sum of the heat losses via top, rear and edge of the collector as given by equation 13.

$$U_L = U_{top} + U_{rear} + U_{edge} \quad \text{(eq. 13)}$$

As the rear heat loss and edge losses are mainly through the insulation, the rear loss coefficient U_{rear} and the edge loss coefficient U_{edge} can be determined from Fouriers Law.

However, in the determination of the top losses the glazing on the proposed collector, as shown in Figure 1, is not parallel to the absorber plate. Recently though (Piratheepan et al. 2014) showed that the natural convection heat loss in an air filled enclosure such as this could be predicted by equation 14, where b is the breadth of the absorber and h is the height of the reflector.

$$Nu = 0.67Ra^{0.36}(b/h)^{1.75} \quad \text{(eq. 14)}$$

This can subsequently be rearranged to determine the value of the natural convection heat transfer coefficient h_{cc} inside the concentrator enclosure

To estimate the radiation heat transfer coefficient inside the concentrator h_{rc} the enclosure was assumed to be a two-surface enclosure consisting of the absorber plate and the glazing by assuming the reflector is adiabatic. Hence the expression of the h_{rc} can be written in terms of area of the absorber plate (A), area of the glazing (A_g), the view factor (F_{cg}) from the absorber to the glazing, and the emittance of absorber plate and the glazing ε_p and ε_g, as expressed in Equation 15.

$$h_{rc} = \frac{\sigma(T_{pm}^4 - T_g^4)}{\left(\frac{1-\varepsilon_c}{A\varepsilon_c}\right)+\left(\frac{1}{AF_{cg}}\right)+\left(\frac{1-\varepsilon_g}{A_g\varepsilon_g}\right)} \quad \text{(eq. 15)}$$

Where T_{pm} and T_g are the mean plate temperature and the internal glazing temperature of the collector respectively.

The view factor F_{cg} can be deduced from equation 16 in terms of enclosure dimensions

$$F_{cg} = \frac{2b}{b\left(1+\frac{1}{\sin\beta}\right)-h} \quad \text{(eq. 16)}$$

Subsequently, the heat loss through the glass cover can be calculated using the heat transfer coefficient of the glass k_g internal glazing temperature T_g and external glazing temperature T_g'.

Now, the external heat loss from the glazed cover is the sum of the radiation, natural and the forced convection heat losses. As majority of the collector faces the ambient environment, it was assumed that the glass cover radiated heat to the surroundings with an ambient temperature T_a. Hence, the radiation heat transfer coefficient from the glazing h_{rcg} can be expressed in terms of external glazing temperature T_g' and the ambient temperature T_a as shown in equation 17

$$h_{rcg} = \sigma\varepsilon_g(T_g'^2 + T_a^2)(T_g' + T_a) \quad \text{(eq. 17)}$$

Furthermore, the losses due to natural and forced convection also must be taken in to account. The forced convection heat transfer coefficient h_{fcg} will be a function of velocity of the wind, an approximation of which can be expressed by equation 18, where v is the wind velocity.

$$h_{fcg} = 4.214 + 3.575V \quad \text{(eq. 18)}$$

The natural heat transfer coefficient h_{ncg} can be expressed by equation 19

$$h_{ncg} = 1.78(T_{g'} - T_a)^{1/3} \quad \text{(eq. 19)}$$

Using this approximation it is possible to calculate the overall convection heat transfer coefficient h_c by

integrating both forced and natural heat transfer coefficient using equation 20 (Eicker 2006)

$$h_c = \left(h_{fcg}^3 + h_{ncg}^3\right)^{1/3} \quad \text{(eq. 20)}$$

In summary; the combination of heat losses and the total useful energy extracted, considering the energy balance of the collector, mean the thermal efficiency of the façade integrated collector can be established.

Now in examining the electrical performance of the system, one trade-off of using silicon solar cells under concentrated radiation is that their efficiency degrades with the temperature increase. Hence it is essential to express the electrical efficiency in terms of the temperature of the absorber plate.

The electrical efficiency of the solar cell can be determined by firstly determining the power generated by the cell at its maximum power point, as given by equation 21.

$$P = I_{mp} V_{mp} \quad \text{(eq. 21)}$$

This can also be expressed in terms of fill factor (*FF*) and the open circuit voltage V_{oc} and short circuit current I_{oc} as shown in equation 22.

$$P = FF\ I_{sc} V_{oc} \quad \text{(eq. 22)}$$

However, V_{oc} and *FF* decrease significantly with increased temperature, while short circuit current increases marginally with the temperature (Zondag 2008). Taking this into account using equation 23 (Dubey et al. 2013) gives a good approximation of the electrical efficiency of a photovoltaic cells under various temperatures given that the nominal operating cell temperature (*NOCT*) and the temperature coefficient (β) and the efficiency of the cell at *NOCT* conditions are known from the manufacturer's datasheet.

$$\eta_e = \eta_{NOCT}(1 - \beta(T_{pm} - NOCT)) \quad \text{(eq. 23)}$$

for typical crystalline Si modules β can be assumed as 0.004 (Notton et al. 2005).

When the packing factor *S* is taken in to account, the electrical efficiency of the collector on a relative area basis η_{elect} can be expressed by equation 24.

$$\eta_{elect} = \eta_{NOCT}\left(1 - \beta\left(T_{pm} - NOCT\right)\right) * S \quad \text{(eq. 24)}$$

By combining equation 4 and equation 2 the combined efficiency η_{tot} of the collector can be calculated from equation 25.

$$\eta_{tot} = \eta_{thermal} + \eta_{elect} \quad \text{(eq. 25)}$$

3. Experimental testing and results

In order to validate the mathematical model and findings derived from its use, it is necessary to compare the outcome with an experimental model. As there is no standard method for testing photovoltaic/thermal hybrid modules it was decided use a standard steady state test method similar to the one describing the thermal performance of glazed liquid heating collectors given in AS/NZS 2535.1 (2007). As such, an experimental testing system was constructed on the roof of Auckland University of Technology's School of Engineering building, facing true north. In doing this, T-type thermocouples were used to measure the inlet and the outlet of the coolant as well as the ambient temperature. A cup anemometer and a wind vane were mounted adjacent to the collector to measure the wind speed and direction. Finally, a Delta-T SPN1 type sunshine pyranometer was used to measure the beam and diffuse radiation. For the electrical output, the voltage and current were measured simultaneously while keeping the system loaded at maximum power point.

Now, fabrication of the façade collector involves three main parts; the PV/T absorber, the reflector and the insulation elements including the glass cover. For this work the finned tube absorber plate was fabricated from a 1.2 m length of 2 mm aluminium painted matte black, with two absorbers mounted in series. A 10 mm square aluminium tube was attached to the back of each absorber using a thermally conductive adhesive to act as the

cooling channel. Square tube was used as it provides a larger contact surface between the absorber plate and the cooling tube, thus improving the fin efficiency. Each absorber plate was then fitted with a custom made string of seven 150 mm crystalline solar cells connected in series and bonded to the absorber using a silicone conformal coating. This thin layer of clear conformal coating protects the cells under extreme environmental and climatic condition and insulates the rear wiring of the solar cells when the absorber is exposed to the concentrated radiation. Reflector was prepared by attaching a silver metalized film on an aluminum sheet.

Due to the practical issues associated with integrating the façade integrated collector into an actual building façade, two vertical "wall" sections were fabricated to mount the concentrators. Each wall was packed with mineral wool insulation (R2.8) to insulate the rear of the concentrator, and replicate a building façade, while the front surface was glazed using a low-iron glass cover. A schematic representation of the combined collector test system is shown in figure 3.

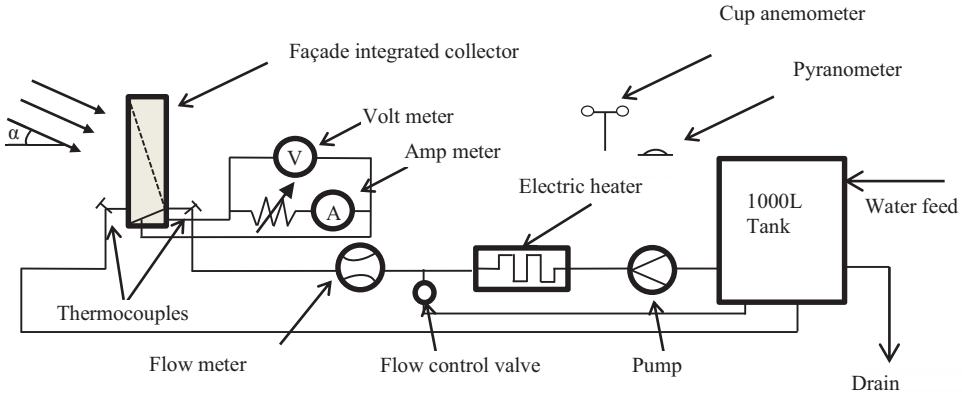

Fig. 3: Experimental test rig and the circuit diagram for electrical measurements

In summary, the design parameters of the prototype collector tested here are given in table 1.

Table. 1: Physical characteristics of experimental prototype

Parameter	Symbol	Value	Unit
System flow rate	m	$1.33X10^{-5}$	m^3/S
Collector length	L	2.4	m
Collector breath	b	0.2	m
Reflector height	h	0.6	m
Collector area	A	0.48	m^2
PV Transmit/apsorpt	$\tau\alpha_{PV}$	0.78 (De Vries 1998)	-
Thermal Transm/apsorpt	$\tau\alpha_T$	0.925 (Anderson et al. 2009)	-
Absorber thickness	L_{abs}	0.002	m
PV thickness	L_{PV}	0.0004	m
PV conductivity	K_{PV}	130	W/mK
Tube hydraulic diameter	d	0.0088	m
Tube spacing	w	0.2	m
Cell-absorber Quasi heat transfer coefficient	h_{PVA}	45	W/m^2K
Insulation conductance	k_{ins}	0.045	W/mK
Back insulation thickness	L_{ins}	0.1	m

Edge insulation thickness	L_{edge}	0.025	m
Absorber conductivity	K_{abs}	130	W/mK
Packing factor	S	0.7	-
Conductance of glass	k_g	0.9	W/mK
Reflectance of silver metalized film	ρ_{Al}	0.9	-

3.1 Experimental results and model validation

To validate the mathematical model several sets of readings were taken from the test rig under various solar elevation angles and input temperatures. These were taken when the sun was near solar noon, such that the effect of shading, due to the design of mounting enclosure, was minimised. As shown in figure 4 the mathematical model incorporating with new heat transfer relationships for the concentrator, as well as the concentration ratio, is capable of predicting the performance with good accuracy.

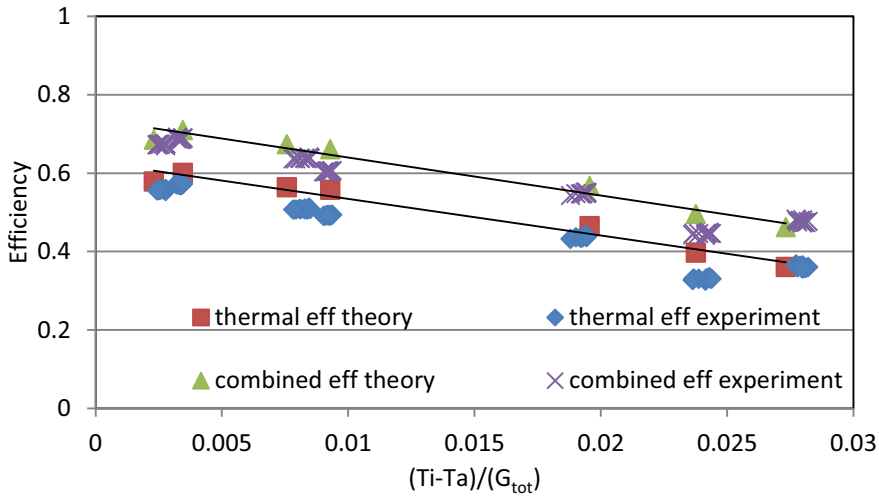

Fig. 4: Experimental and theoretical efficiencies of façade integrated collector

3.2 Modelling Results

Now in table 1, there are number parameters which can be modified to improve the performance of the collector. Hence, having validated the mathematical model it was used to perform a sensitivity analysis on the system. In this study, only one design variable was varied at a time and the effect of that particular parameter on the efficiency was observed. This allows us to determine the design variables that are critical in terms of efficiency of the system and its design.

In the concentrator it is likely that high temperatures will be achieved and so there is a need for improved cooling. Heat transfer in the cooling channel is a function of Reynold's number and thus varying the flow rate may have the effect on the overall efficiency of the collector. However as shown on figure 5, the efficiency of the collector does not significantly improve with the increased fluid flow rate. The slight increase in efficiency can be attributed to an increase in the turbulence in the system increasing the heat transfer marginally. Furthermore, a reduction in temperature will increase the electrical efficiency marginally though the pumping power required to achieve this may offset any gains by doing this.

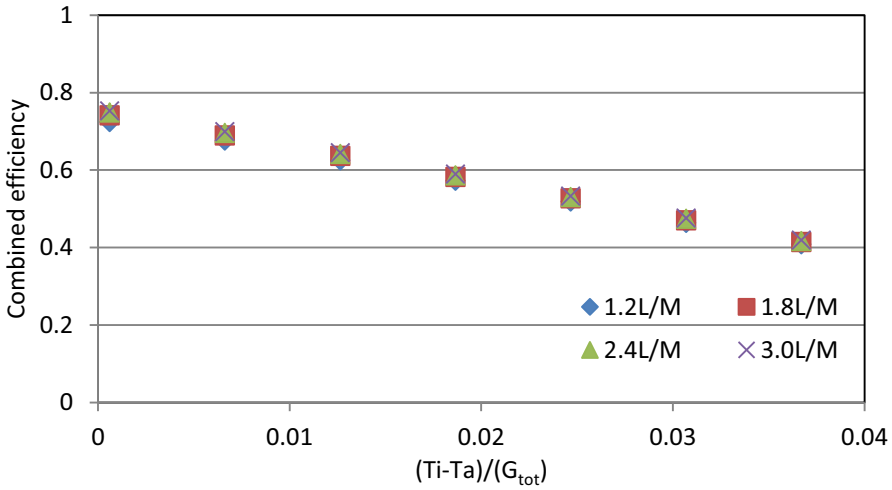

Fig. 5: Combined efficiency by varying flow rate

Another means of improving the efficiency could be to reduce the width of the absorber for a single tube, or by decreasing the spacing between adjacent tubes in systems with multiple cooling tubes. As shown in figure 6, this will increase the efficiency significantly. This can be explained by the fact that an increase in the number of tubes across the absorber plate improves the fin efficiency and thus increases the performance of the collector. However it can be seen that, at higher *(Ti-Ta)/G*C* values they tend to converge. This suggest that although decreasing the tube spacing increases the efficiency initially, there are other factors which will decrease the efficiency at higher *(Ti-Ta)/G*C*.

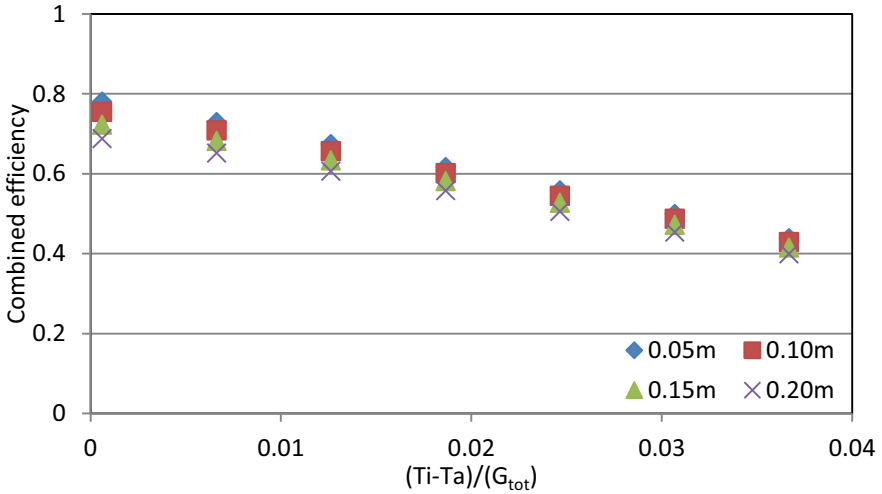

Fig. 6: Combined efficiency by varying tube spacing

Further, the combined efficiency of the collector could be also improved by improving the heat transfer coefficient between the solar cells and the thermal absorber. Unlike a thermal collector that has a bond resistance between the tube and absorber (Duffie and Beckman 2006), a "quasi" heat transfer coefficient, with a value of 45W/m^{2}K, between the PV cells and the absorber plate is used (Zondag et al. 2002). Based on this Anderson et al (2009) stated that this thermal conductance might be improved by means introducing a thermally conductive adhesive. Following on from this recommendation, it can be seen in figure 7, that when the heat transfer coefficient is doubled from 30W/m^{2}K to 60W/m^{2}K the efficiency is improved by approximately 10%.

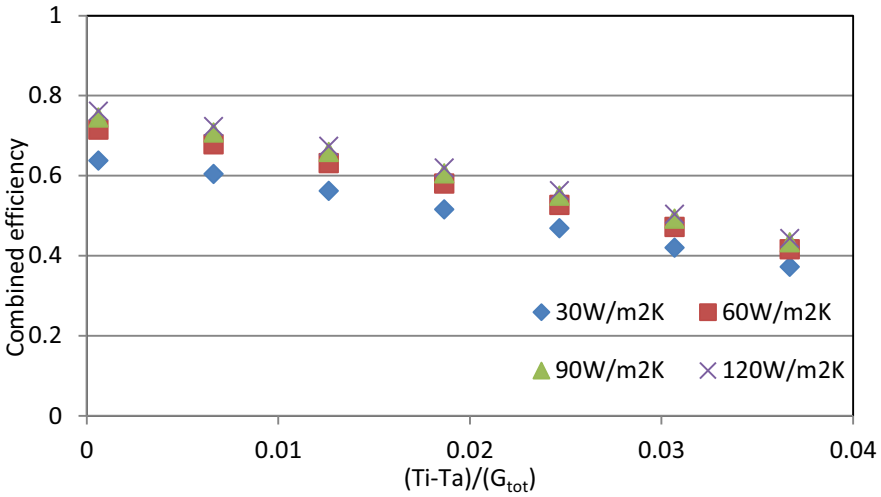

Fig. 7: Combined efficiency by varying cell to absorber heat transfer coefficient

4. Conclusion

From the results, it was shown that the mathematical model incorporated with the heat transfer empirical relationships presented in this paper was able to predict the performance of the particular system. Further, from the sensitivity analysis, there are number of conclusions that can be drawn. Firstly, increasing the flowrate in the cooling tubes appears to offer little benefit with respect to increasing the efficiency of the collector.

However, the combined efficiency of the collector can be improved by increasing the number of cooling channels across the absorber plate though this may not be economical. Hence increasing the number tubes has to be considered as a trade-off between the efficiency and the cost of the collector. Finally, improved thermal contact between the solar cells and the thermal absorber will increase the efficiency dramatically and appears to offer significant potential in improving the performance of the façade integrated BIPVT solar concentrator system.

Potential energy savings from a semi-transparent solar cell window system for code-compliant residential buildings in hot and humid climates

Sung Lok Do[1,*] and Juan-Carlos Baltazar [2]

[1] Department of Building and Plant Engineering, Hanbat National University, Daejeon, South Korea

[2] Department of Architecture, Texas A&M University, College Station, Texas, United States

Abstract

A semi-transparent solar cell window system is one of the most recent building integrated PV window technologies (i.e., BIPV window). This type of BIPV window systems can generate photovoltaic electric energy and can be designed to admit a specific amount of natural light and/or view to an indoor space. This study evaluates potential energy benefits of integrate semi-transparent solar cell windows on a 2009 International Energy Conservation Code (IECC) code-compliant residential building in a hot and humid climate. The energy analysis is based on a whole-building simulation model with a DOE-2.1e, which include a BIPV window module specially made for this study. The study analyzed peak demand, energy use, and electricity production from each orientation (east-, west-, south-, and north-facing). As a result, the south-facing window showed the greatest potential to generate electric power and to reduce building loads and system energy use. In comparison to the code-compliant base-case model, the BIPV windows provided noticeable energy savings about 12-21% in annual site energy use.

1. Introduction

Hot and humid climates demand significant electricity for cooling. In 2001, Texas implemented the Texas Emissions Reduction Plan (TERP) program that aims to diminish the pollution in the state by energy efficiency and renewable energy measures. To lower pollution to generate electricity from fossil fuels, Texas has been utilizing applications of renewable energy resources for both power plants and buildings.

As one of the efforts to reduce pollution, Texas has built renewable energy plants to generate electricity from eco-friendly fuel resources (e.g., mainly wind, solar, and biomass) (Haberl et al., 2014). Texas is one of the largest renewable energy producers in the United States (US), leading the nation in wind-powered generation capacity with over 14,000 megawatts (EIA, 2015; Haberl et al., 2015).

In addition to these efforts, other renewable energy applications to buildings (e.g., photovoltaic, PV, technology integrated into buildings) have been used to reduce the building's energy demands due to onsite power generation, and it resulted in reducing energy demands on power plant (Haberl et al., 2014; NREL, 2015). Recently, an interest in a semi-transparent solar cell window system (i.e., a building integrated photovoltaic (BIPV) window) has increased worldwide (bccResearch, 2011; DOE, 2015b; Kang et al., 2013; Sivanandan, 2009; SNE, 2011) because the these solar cell windows generate electricity without constructing additional PV structures on a building envelop and also provide natural light transmission (Kang et al., 2013; Lee et al., 2014; Li et al., 2009; Yoon et al., 2011). Due to these features, building designers and engineers may use the BIPV windows to generate electricity and to create unique daylighting features in building façades (e.g., window and sunroof), which at the same time reduce unwanted cooling load and glare associated with architectural glazing (Li et al., 2009).

In the US, a new residential construction must comply with a residential building energy code for its energy certificate. A number of residential building energy codes and standards (e.g., IECC, ASHRAE Standard 90.2, California Title 24, etc.) have been developed and adopted. In the US residential sector, the IECC is widely adopted as the state energy code in approximately 40 of the 50 US states (DOE, 2015c). Since January 2012, Texas has adopted the 2009 IECC (ICC, 2009) even though newer versions of IECC (i.e., 2012 and 2015 IECC) are available (DOE, 2015a; SECO, 2015). The aim of this study is to evaluate the potential effects of implementing semi-transparent solar cell windows on a residential building that complies with the adopted state energy conservation code (i.e., 2009 IECC) and is located in a hot and humid climate.

2. Semi-transparent solar cell windows

A semi-transparent solar cell window system (BIPV window) is one of many of the PV technology applications to buildings. The BIPV window system can generate photovoltaic electric energy, and can be designed to admit a specific amount of natural light and/or view to an indoor space (Yoon et al., 2011; DOE, 2015a, 2015c; SECO, 2015). In comparison to the conventional PV cells, it has several advantages: ease-to-manufacture due to no need for vacuum processes, capability to be colorable and transparent, applicability to flexible thin structure, and light weight (Miyazaki et al., 2005).

To calculate the electricity generation from the BIPV window, the PV efficiency (η) is determined as the fraction between the maximum power which a solar cell can convert from absorbed light to electrical energy (P_{max}) and the incident power (P_{in}). This study used Eq. (1) and Eq. (2) for the efficiency calculation, which are basic solar cell efficiency equations (Duffie and Beckman, 2013; Servaites et al., 2009; Sze and Ng, 2006). The degradation of the solar cell efficiency due to the increased cell temperature in operation was not considered in this study.

$$FF = \frac{V_{MP} \cdot I_{MP}}{V_{OC} \cdot I_{SC}} \quad \text{(eq. 1)}$$

$$\eta = \frac{P_{max}}{P_{in}} = \frac{V_{MP} \cdot I_{MP}}{P_{in}} = \frac{V_{OC} \cdot I_{SC} \cdot FF}{P_{in}} \quad \text{(eq. 2)}$$

where P_{max} is the maximum power (W), FF is the fill factor to determines the maximum power from a solar cell, V_{MP} is the maximum power voltage (V), I_{MP} is the maximum power current (A), V_{OC} is the open-circuit voltage (V), I_{SC} is the short-circuit current (A), η is the PV efficiency, and P_{in} is the incident power (W), which is based on 1 kW m^{-2} for the efficiency calculations. The BIPV window electric power generation is estimate using Eq. (3) (Chae et al., 2014; Corrao and Morini, 2012; Duffie and Beckman, 2013; Servaites et al., 2009; Sze and Ng, 2006).

$$P = \eta \cdot A \cdot G \quad \text{(eq. 3)}$$

where P is the generated electricity from a BIPV window (W), A is the BIPV window surface area (m^2), and G is the global irradiance on a BIPV window surface (W m^{-2}).

3. Semi-transparent solar cell windows

To evaluate the potential energy benefits from implementing the BIPV windows instead of conventional windows, this study simulates a 2009 IECC code-compliant residential building. The simulations are conducted under a hot and humid climate; this study selects the city of Houston, the Climate Zone 2 classified in IECC. The overall research methodology is briefly presented in Fig. 1.

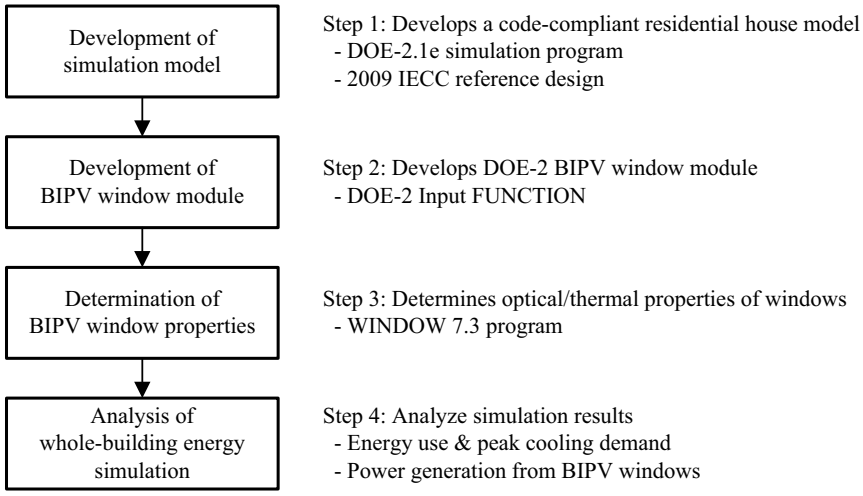

Fig. 1: Diagram of overall research methodology

In order to develop a code-compliant residential base-case simulation model, the requirements as defined in Chapter 4 of the 2009 IECC were referenced (ICC, 2009); the input parameter values such as envelope insulation, window area, and system efficiency were determined according to the code requirements (Do and Haberl, 2015). The developed base-case model (see Fig. 2) had a simplified structure with a rectangular geometry, flat roof, and

no attic space; they are a single-story, single-family, south-facing and detached house that has 232 m^2 of floor area and a 2.4 m floor-to-ceiling height without a plenum. For this study, the base-case model was modified to have five interior thermal zones, including east, west, south, north, and core. The base-case model used a double-pane window with a bronze-tinted glass. The window area on each exterior wall was determined using a 15% window-to-floor ratio (WFR), which was equivalent to a 23.4% window-to-wall ratio (WWR) for the base-case. In addition, this study used the Residential System (RESYS) in the DOE-2.1e program (DOE2, 2015) for a typical residential air-source heat pump system. The simulations for this study were performed using Typical Meteorological Year version 3 (TMY3) weather file.

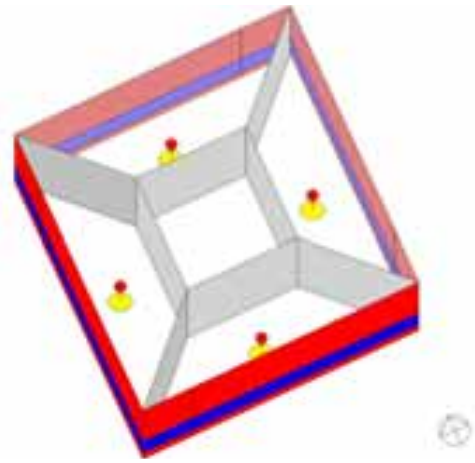

Fig. 2 (a)

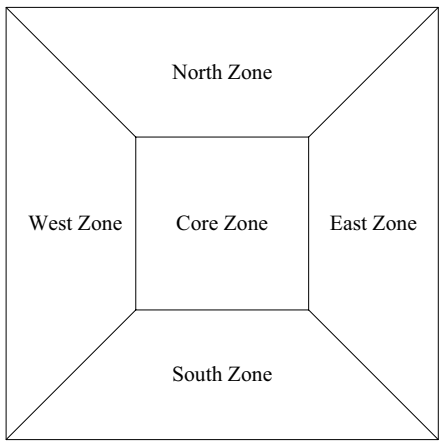

Fig. 2 (b)

Fig. 2: View of the base-case simulation model: (a) exterior 3D view; and (b) interior thermal zoning

In order to calculate the electricity power generated from BIPV windows on each exterior wall, the BIPV window module was developed using the DOE-2 input FUNCTION commands, which can be written in the Building Description Language (BDL) input file without debugging the DOE-2.1e program (LBL, 1993). The BIPV input FUNCTION commands collects the incident solar radiation on each outside window surface for each hour of the run period, and calculates hourly electric power generation from each BIPV window. The results of the calculated hourly electricity generation are separately saved as an output file.

In order to add the calculation of the BIPV window power generation into the DOE-2.1e calculation algorithm, the BIPV input FUNCTION commands were written in the LOADS section of the input BDL file. This study selected three types of the BIPV transparency: 40%, 20%, and 10%. The electrical performances of the selected BIPV types were obtained from the published data (Episolar, 2015). Table 1 presents the BIPV properties for the electrical performances.

Table 1. Electrical performance properties of the selected BIPVs

BIPV	Transparency (%)	Nominal Power (W)	Voc (V)	Isc (A)	Vmp (V)	Imp (A)	Pin (W)	Fill Factor -	Efficiency (%)
Type I	40	48	116	0.59	87	0.55	720	0.6992	6.65
Type II	20	64	116	0.78	87	0.73	720	0.7019	8.82
Type III	10	72	116	0.88	87	0.82	720	0.6989	9.91

The base-case window had a double-pane unit consisting of two layers of glasses, and the two layers were separated by an air gap. To evaluate the thermal performance of the window glass, three glass properties are required as the simulation input parameters: glass conductance (i.e., U-factor), shading coefficient (SC), and visible transmittance (T_{vis}). These input parameters were estimated using the WINDOW 7.3 program which is a windows and daylighting software developed by Lawrence Berkeley National Laboratory (LBNL) (LBNL, 2015). Using the glass library data in the WINDOW 7.3 program, the thermal and optical properties of the glasses used for the base-case and BIPV windows were determined. Table 2 presents the details of the window input parameter values used for performing DOE-2.1e building energy simulations.

Table 2. Defined window input parameters for simulations

DOE-2 Input Parameters	Base-Case	BIPV			Note
		Type I	TYPE II	Type III	
GLASS-CONDUCTANCE (W/m^{2}K)	2.699	2.603	2.412	2.308	Glass conductance
SHADING-COEF	0.574	0.422	0.253	0.182	Shading coefficient
VIS-TRANS	0.468	0.359	0.183	0.091	Visible transmittance

To implement a daylight-dimming system in simulations, this study used the existing daylighting calculation in DOE-2.1e. One reference point at which daylight illuminance levels were to be calculated was used for each exterior thermal zone (i.e., east, west, south, and north zones); it was assumed that a photocell controls the electric lighting system that responds to the light levels at the specified reference point. In simulations, the desired minimum lighting level (i.e., illuminance set point) was defined as 323 lux (30 fc), assuming a general ambient lighting level for a residential building. The lighting reference point was located at the middle of each space with 0.8 m (2.5 ft) height.

4. Semi-transparent solar cell windows

4.1. Power generation from BIPV windows

The electricity power generated from the BIPV window on each exterior wall was evaluated using the developed BIPV window module. Fig. 3 presents the estimation of the electric power generation from the BIPV Type II windows for different orientations.

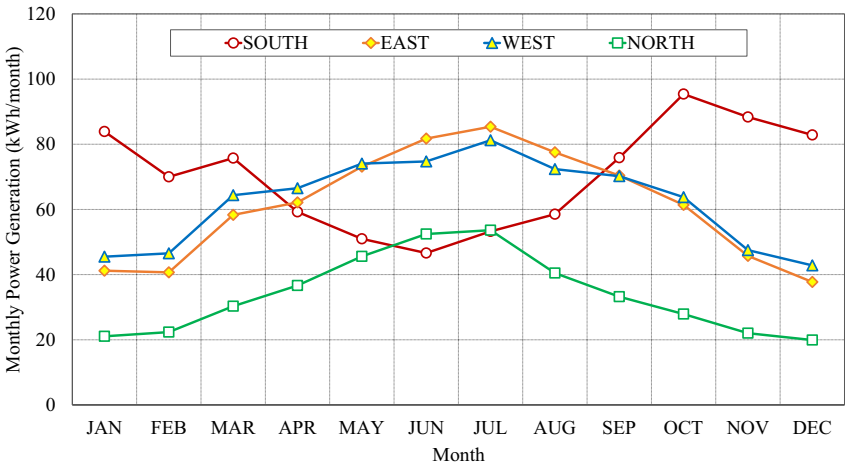

Fig. 3 (a)

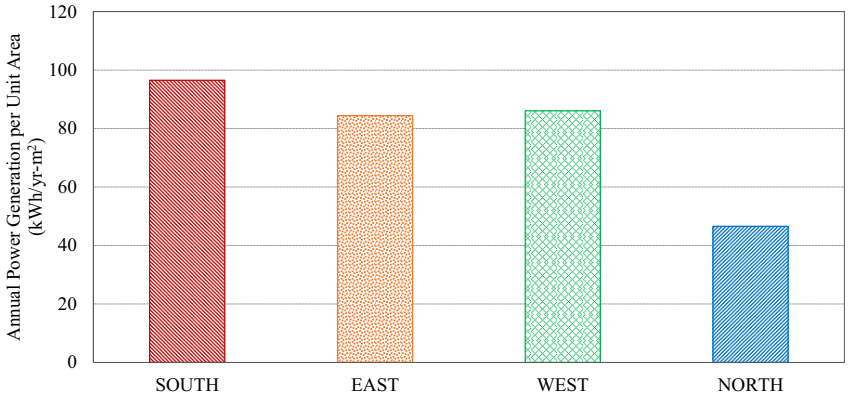

Fig. 3 (b)

Fig. 3: Electric power generation from BIPV II for different orientations: (a) monthly total; and (b) annual average power generation intensity

In general, the largest annual power generation was observed in the south-facing BIPV window whereas the smallest annual power generation was observed in the north-facing BIPV window. The east- and west-facing BIPV windows resulted in the similar amount of power generation. In addition, the east-, west-, and north-facing

BIPV windows generated more power during the summer period (May through August) than the winter period due to larger solar radiation and longer sunshine hours. On the other hand, the south-facing BIPV window generated less power during the summer period (especially in June) than the other periods due to the relation between the sun angle at a given time/location and a 90° exterior wall. That is, the projected area of the south-facing window during the summer period was relatively small to absorb solar radiation.

4.2. Building loads

The simulation results showed that the implementation of the BIPV window provided benefits in the annual building load reductions in comparison with the baseline case. This reductions came from the BIPV thermal performance that decreased shading coefficient in comparison with the base-case window (see Table 2). Fig. 4 presents the estimated distribution of the total annual building loads reduction from the implementation of the BIPV Type II windows in each of the orientations. The largest reductions occurred in the south-facing space; east- and west-facing spaces resulted in the similar annual reductions; and the north-facing space had the least reductions. This indicates that a south-facing space will be the most beneficial space in annual total building loads reduction from a BIPV window at a given location with a hot and humid climate.

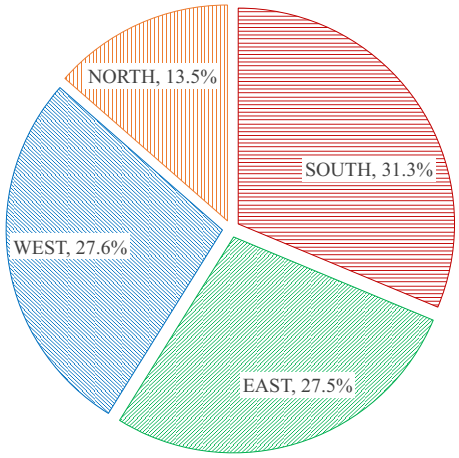

Fig. 4: Distribution of total annual building loads reductions for the implementation of BIPV type II windows according to the orientation

4.3. Cooling peak demands

The simulation results for the peak demands during the cooling season, including energy uses for cooling, lighting, others (i.e., miscellaneous equipment, heating, pumps, fan, and hot water), and for the generated BIPV power for the three BIPV types analyzed are presented below in Fig. 5.

	Basecase	Basecase + Dimming	BIPV I	BIPV I + Dimming	BIPV II	BIPV II + Dimming	BIPV III	BIPV III + Dimming
Total	4.92	4.67	4.23	4.06	3.86	3.77	3.68	3.63
Pumps & Fan	0.71	0.70	0.67	0.66	0.62	0.62	0.60	0.60
Area Lights	0.49	0.29	0.49	0.36	0.49	0.42	0.49	0.45
Misc Equipmt	0.66	0.66	0.66	0.66	0.66	0.66	0.66	0.66
Space Heat	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00
Space Cool	2.77	2.73	2.64	2.61	2.49	2.47	2.42	2.41
DHW	0.29	0.29	0.29	0.29	0.29	0.29	0.29	0.29
PV Power	0.00	0.00	-0.52	-0.52	-0.69	-0.69	-0.78	-0.78

Fig. 5: Comparison of peak demands during the cooling season

The BIPV type and daylight-dimming system reduced the peak demands in a range from 14.0% (0.69 kW) to

26.1% (1.29 kW), in comparison with the baseline case. When using a daylight-dimming system integrated with the BIPV window, the savings increased in both the cooling energy and the electrical lighting energy use. In general, the system's peak demands influences the determination of the system capacity, and thus the peak demands reductions indicate that there is a possibility for the cooling system to be downsized, which provides additional energy and cost savings due to lower compressor's power consumption.

4.4. Annual site energy use

As it has been presented above, the implementation of BIPV windows and daylight-dimming system influence the building energy performance: electricity power generation, decrease supplementary lighting, decrease building cooling loads, and decrease cooling peak demands. As a consequence, the BIPV window provided energy benefits in annual energy use of the building system. Fig. 6 presents the resultant annual energy use for the three analyzed window type, including cooling, heating, lighting, others (i.e., miscellaneous equipment, pumps, and hot water), and the BIPV power generation. In addition, Fig. 6 includes percent savings from the BIPV window in comparison with the code-compliant baseline which does not include a daylight-dimming system.

	Base-case	Base-case + Dimming	BIPV I	BIPV I + Dimming	BIPV II	BIPV II + Dimming	BIPV III	BIPV III + Dimming
Total	21,617	20,966	19,046	18,522	17,861	17,615	17,314	17,191
Cooling	6,186	6,060	5,541	5,425	4,862	4,820	4,585	4,550
Heating	2,155	2,157	2,288	2,290	2,454	2,455	2,521	2,522
Area Light	4,279	3,751	4,279	3,869	4,279	4,074	4,279	4,191
Others	8,997	8,997	8,997	8,997	8,997	8,997	8,997	8,997
BIPV Power	0	0	-2,059	-2,059	-2,731	-2,731	-3,069	-3,069

Fig. 6 (a)

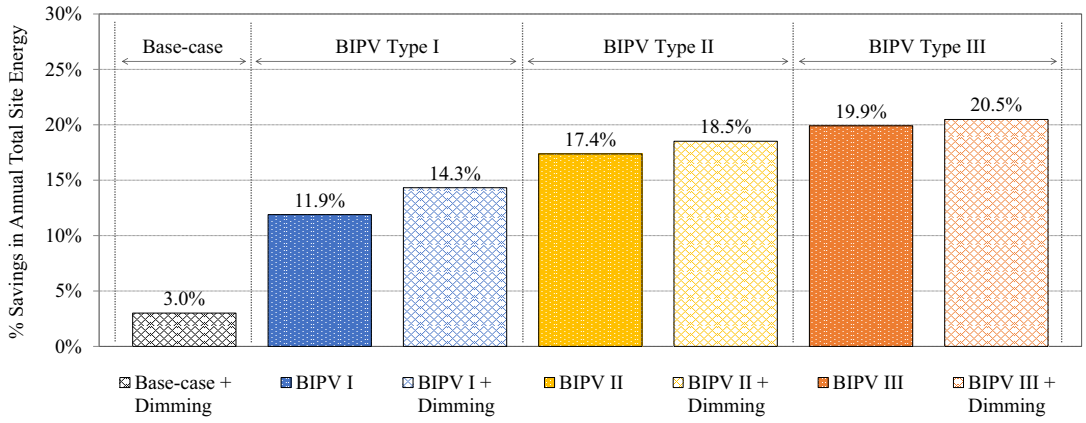

Fig. 6 (b)

Fig. 6: Comparison for annual site energy consumption: (a) annual energy use; and (b) percent savings against the base-case without a daylight-dimming system

The cooling energy use was significantly decreased with in a range from 10% (645 kWh/yr) for the BIPV type I to 26% (1,637 kWh/yr) for the BIPV type III. On the other hand, the heating energy use was increased from 6% (133 kWh/yr) for the BIPV type I to 17% (367 kWh/yr) for the BIPV type III. The increase/decrease amount of the cooling/heating energy use appeared to be caused by the BIPV window shading coefficient values (see Table 2); a low SHGC value led to a decrease in cooling energy use and an increase in heating energy use. In the simulations for a daylight-dimming system, the transparency value of the BIPV glazing appeared to influence on the electric lighting energy use; a higher transparency value resulted in bigger reduction in electric lighting energy use. Regarding the electric power generation, the higher electric power was generated from the BIPV type III because of the different BIPV's efficiency values (see Table 1).

In the calculation of the percent savings for the annual total site energy use, the generated electric power compensated the system's electricity consumption. The amount of the percent savings resulted from the BIPV window and a daylight-dimming system ranged from 11.9 to 20.5%. The BIPV type III resulted in the largest savings for the annual total site energy due to the significant cooling energy reduction and power generation. However, the daylight-dimming system using for the BIPV type III did not result in noticeable energy savings due to low transparency value. A cost analysis to evaluate economic benefits may be required to determine the optimal energy savings goals when using a daylight-dimming system for a BIPV window.

5. Summary and conclusions

To quantify the energy benefits of the BIPV window in hot and humid climates, a typical residential building was simulated in DOE-2.1e. A BIPV window module was developed for DOE 2.1e and implemented it into the 2009 IECC code-compliant residential building model. Based on the energy simulation results, potential energy benefits from utilization of the BIPV system were realized including: power generation, annual building loads, cooling peak demands, and annual total site energy use. Based on the analysis results completed in this study, the following conclusions can be made:

- The electric power generated from the BIPV window depends on its efficiency value, area, orientation, and incident solar radiation. The south-facing windows can produce the largest annual electricity, but the east- and west-facing windows present the highest potential to generate electricity during the summer period.
- Implementation of the BIPV window resulted in a reduction in the total annual building loads, ranged from 6 to 15%. In addition, the south-facing space was identified as the most beneficial space in reducing annual building loads. However, it should be noted that the BIPV power generation from the south-facing window was also reduced during the summer period when higher electricity power was consumed than the other periods. Therefore, the further study is required to optimize building loads reduction and BIPV power generation.
- The BIPV window and daylight-dimming system led to reductions in the peak cooling demands, from 14 to 26%. At the cooling peak day and time, the BIPV window significantly reduced the cooling energy use, and a daylight-dimming system resulted in additional savings in electrical lighting energy use. Therefore, the BIPV window has a potential to downsize the system due to the reduced peak demands; and it may result in additional energy savings due to lower compressor's power consumption.
- The BIPV windows provided electricity power generation, decreased electric lighting energy use, decreased annual building loads, and reduced he system's cooling peak demand. As a consequence, the percent savings in comparison with the base-case window were about 12 to 21%. This indicates that the BIPV window with the daylight-dimming system provide great energy benefits for a code-compliant residential building. However, a cost analysis to evaluate economic benefits may be required to determine the optimal energy savings goals when using a daylight-dimming system for a BIPV window.

Solar Constraints and Potential in Urban Residential Buildings

Chul Kim[1], Liliana Beltran[1]

[1] Texas A&M University, College Station (USA)

Abstract

Today, Asian cities have been full of high-rise and compact buildings with large population. In Seoul, Korean capital city where millions of people have lived, over 20 or 30 floors residential buildings are common sight. As a result, half of the Korean population is living in high-rise residential buildings like apartments. However, large residential buildings in cities have consumed huge energy provided from fossil fuels to support occupants' environmental convenience, and they are currently a major energy-consuming sector. To resolve this environmental and energy issues, solar systems are promising one of effective solutions to supplement energy demand for urban residential buildings. Therefore as fundamental approach this paper studies solar potential and constraints in high-rise residential buildings to understand unfavorable urban environment for solar energy based on diverse interferences from other urban factors. To maximize solar potential and to utilize effective renewable systems on the surface of buildings, this study analyses Korean typical multi-family housing buildings and also includes a case study to deal with an apartment complex to figure out the effective ways for solar energy. This result can be expected to be utilized for architects and engineers in their design process to plan low energy buildings.

Keywords: *Solar potential, High-rise buildings, Solar constraints, Building forms and arrangement*

1. Introduction

1.1. Backgrounds

Buildings, as a major energy consuming sector in the world, accounted for 21.2percent of total final energy consumption, consisting of 9.3percent and 13percent in commercial building and residential building respectively (Korean Energy Census, 2010). Building sector's share is still lower than transportation and industry sectors, but it will be expected to increase like other developed countries reported by IEA. They reported their residential buildings have averagely consumed about 27percent of total final energy consumption. In Korea, the Photovoltaic (PV) and Solar thermal (ST) market is consistently growing by government promotion projects since 2008, due to their green growth policy. Firstly, Korea Energy Management Corporation (KEMC), a public institution, has operated supply business projects for renewable energy systems such as PV and ST with financial packages. The budget are totally about 20 million won in 2015, and they have pursued green-village project that provides financial aid for owners to receive 35~50percent per total installation cost. However, unlike governmental support, major eight metropolitan cities in Korea just showed 8.3percent of renewable power production by region, and of that, the power portion by residential buildings is only 0.4percent in 2013 (Renewable Energy Dissemination of Statistics, 2013). Consequently, in Korea, to encourage solar system use is important strategy to improve energy efficiency of urban buildings. However, in the respect of building shape and arrangement, Korean high-rise residential buildings are unique and standardized unlike other countries' residential buildings. In a census on population and housing conducted Korean National Statistical Office (KNSO) in 2010, they also found that multi-family housing continuously has shown a growth from 53percent in 2005 to 59percent in 2010. Above all, over 75percent of total multi-family housing buildings is over ten stories buildings. Given this context, half of Korean today is closely connected to the life in high-rise residential buildings consuming lots of

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.08.03 Available at http://proceedings.ises.org

energy to stay their urban life. Therefore, to make environmentally-friendly urban space, successful energy efficient strategies for urban residential buildings are required such as renewable systems.
Also, in today's global society, many countries are worrying energy matters that fossil fuels will definitely be depleted in near future even though fossil fuels are still necessary in all fields of industries and public livelihood. According to a new UN Department of Economic and Social Affairs (DESA) report in 2015, the world population will reach 9.6 billions people until 2050 (UN database, 2015) and International Energy Outlook 2013 by IEA reported that world energy consumption will increase 56percent from 2010 to 2040 by world economic growth and specially, electric power demand will grow by 80percent between 2012 and 2040 (IEO 2013). Hence, as mass energy consuming sectors, future buildings should be considered to increased energy consumption by growing economy. For that, it is required to achieve better design and energy efficiency in all kinds of manufacturing industries and in all kinds of buildings. As the result of this movement for energy saving, many world nations are planning to go into effect on mandatory building codes to design low and zero energy buildings and to renovate existing buildings into high performance buildings. Along many European countries' plan which will reach zero energy building (ZEB) between 2015 and 2030, Korean government has also driven the policy to phase in ZEB as mandatory policy from 2008 to 2025. This means that many multi-family housing, so called apartments in Korea, will have to consider renewable energy systems to satisfy mandatory zero-energy efficiency because only plan for passive design and efficient HVAC systems cannot guarantee ZEB performance on site. Therefore, in order to maximize building energy performance and to design better green buildings in urban area, urban solar constraints and potential should be properly understood and settled by designers and engineers. For this, this research studies urban solar potential based on high-rise residential buildings in Korea and, depending on the features of their typical forms and arrangement, the study can be generalized and utilized for whole country.

1.2. Objective of the study

The research goal is to study solar potential in urban areas and to focus on high-rise multi-family buildings which have been very dominating in Korean housing market. The study has three major purposes; At first, multi-family housing in Korea has shown standardized forms and arrangements. This is due to the fact that forms of multi-family housing have been affected by governmental institutes and contractors for decades and sometimes, their principles for building arrangement have been guided by District Unit Planning by regional governments. As a result, multi-family housing complex have shaped the urban context in Korean cities. While they are not particularly good in urban scape design, it can be useful to generalize and to establish dissemination strategy for renewable energy. On the second purpose of this study, in architectural viewpoint, solar potential on building envelope can be easily affected by building physical features such as mass projection and curved mass design. Besides, in large multi-family housing complex, solar potential may be strongly influenced by adjacent building structures. Last but not least, the development in very densely urban areas usually requires high energy efficiency and performance following their enhanced building energy codes and for that, renewable systems should be optimized and effectively planned in the buildings. Given this, this study will be meaningful in the importance for practical experts. Therefore, this study investigates Korean high-rise residential buildings focusing on their forms and arrangement, and diagnoses solar potential in single building level. And then, the study analyses solar potential through case study of urban residential complex. By means of the result of this research, architects, engineers and building owners can more understand solar potential and effectively design green buildings reflected urban solar strategies.

1.3. Research process

This study analyses solar potential on residential building envelope and roof where can be used for PV and ST. In single building and urban scale, this study looks at urban solar limitations and solutions. This research is composed of three-step procedure:

(a) The first step is to do literature review on solar potential. Solar potential is usually used to explain a term for solar applicability or solar radiation that is calculated by a ratio of area on the building envelope. This paper deals with some research and their result of solar potential studied by other authors.

(b) On the second step, the research is to study solar potential and constraints in single building types. For this, this study looks into main residential types in Korea and simulates their solar performance by doing simulation tools. With this analysis, solar limitations and solutions are drawn.

(c) At the last step, case study in the single building complex is carried out to estimate actual solar potential on the building surface. Then, analyzing high-rise multi-family complex is done because this can explain how building direction and arrangement in the complex can affect solar potential in urban context. As the final outcome, solar potential and constraints are analyzed to draw solutions.

2. Literature review

Housing market in Korea has greatly changed for last several decades in their types and forms. In 1975, detached house occupied over 92 percent of total housing by total ground area. However, multi-family housing [1] and row house[2] had explosively grown over 10 times from 6 percent to 63 percent in total residential stock (Housing Census, 2010). Actually, plenty of new cities had been constructed since 1980s with multi-family housing buildings and consequently, housing supply ratio recorded from 86 percent in 1995 to 118 percent in 2014 in housing census by KNSO. In 2013, over 71 percent of existing multi-family housing has over 15th stories, which means most of multi-family housing is high-rise buildings (Apartment Housing Statistics, 2013). Therefore this study regarding solar potential in Korean high-rise residential buildings can have powerful influence for many apartments to become better energy efficient.

There are many ways to optimize building solar potential in preceding research. Many studies have already showed possible approaches to improve solar access on the surface, but still have a distance to explain urban solar limitations in residential buildings. Because residential building types in Korea are different from other countries in their residential types, density and patterns. Also, research in Korea mainly focused on the right of solar access (Changho Choi, 2007, Dosung choi 2009). Building's major design parameters (i.e. building aspect ratio, azimuth, site coverage, density and arrangement) are generally considered to assess solar potential in urban area because these are largely able to affect solar potential on the envelope of buildings. According to a study by Dapeng Li et al (2015), the research reported solar potential in urban residential buildings that can be raised when building aspect ratio increases, and thus they studied increased site coverage. Also, this study revealed that photovoltaic(PV) and solar thermal(ST) yield decreased up to 50% and 26% respectively by mutual shade in high-density scenario. However, it explained solar systems to be able to satisfy yearly electrical and thermal demands of residential buildings. Min-Hee Lee et al (2009) conducted a feasibility study to review business value on solar systems and assessed solar potential depended on urban structure. For applicability to urban buildings, the research describes that roughness affects solar potential. Such result is especially remarkable in high-rise and high-density buildings. Similarly, while high-rise buildings has lower solar potential than low-rise buildings, it is possible that solar systems harvest stable solar energy since probable areas for solar system installation are generally converged to particular upper floors in special buildings. However, M. Karteris et al (2013) reported that PVs in the urban environment may not be efficient than suppositions. This is due to the fact that urban obstacles, such as density, heights and shafts, often significantly lower valid surface areas above 50% on the roofs. This research reviewed the actual solar potential as developing a model for roof-top surfaces through a statistical analysis by using existing multifamily buildings in a general Greek city, Thessaloniki. Like above studies, at present, availability and limitation on urban solar potential are still in progress. On account of specificity in location, design and analytic condition, more research to be generalized and exploited should be studied for more solar energy use in Korean urban areas.

[1] The definition of apartment is an over 5floors permanent building to include many households, and each household can independently live in their apartment. (KNSO, www.kostat.go.kr)

[2] Row house is a permitted building as a row house by law and its height is limited below 4 floors. Also, several households can live in row houses. (KNSO)

3. Single building analysis

3.1. Korean multi-family housing

In 2007, Ministry of Land, Transport and Maritime Affairs in Korea reported that residential buildings took up the largest portion in national cities and were occupying 68percent of all building stock. Among all cities, Seoul and Kyunggi-do have formed the largest metropolitan area where 43percent of Korean population has lived and the greatest number of residential buildings have been built. However, regardless locations, Korean multi-family apartment have typical patterns in their forms. Doosung Choi and Jinseok Do (2009)[1] surveyed 74 multi-family housing complex and 919 multi-family housing buildings built after 2007 to classify multi-family housing category. Consequently, it informed that flat-type and tower-type occupied 57percent and 43percent respectively among investigated building types. Building size depends on the number of units and it can be changed following building conditions. Classified single building types of multi-family housing are as below table.1. Types of multi-family housing have significance on analysis of solar potential because their building forms restrict surface areas that can get solar energy and be installed for renewable energy. Hence, as first step this research studied solar performance in single buildings.

Tab. 1: Dominative Multi-family Housing Types in Korea (Doosung Choi 2009)

Flat-type			Tower-type		
— type	Bending-type	L-type	L-type	Y-type	Single-wing type
68.1%	17.6%	14.3	30.9%	22.1%	21.5%

3.2. Solar potential analysis

The aims to solar potential in this study are to understand cause and effect of urban solar limitations in the scale of single building and urban complex. In general, the forms and envelope designs of multi-family housing are primary factors to affect solar potential on the building surface. Severe building shade can also reduce solar potential on the surface by adjacent buildings that usually causes shading through its high density or mass projection. Moreover, Korean residential building has an unique character that it relatively has broad surface area per volume to get more solar radiation due to general Korean resident's preference of sunshine. However, in the analysis of an independent building, there is no interference from adjacent urban environment and buildings. This being so, there is no solar influence caused by density or height that these factors can be possible in complex level. Therefore, assessment in building types focuses on the amount of solar radiation, orientation, seasonal changes and restrictions by building design.

Tab. 2: Multi-Family Residential Buildings for Single Building Analysis

	Flat-type			Tower-type		
	— type	Bending-type	L-type	L-type	Y-type	Single-wing type
Floor plan						Units	6	5	4	3	3	4
Floor height (m)	2.8	2.8	2.8	2.8	2.8	2.8
Area (㎡)	571	404	827	569	523	694
Tilt (deg. E/W/S/N)*	90/90/0/0	90/50/0/0	90/90/0/0	90/90/0/0	76/120/166/76	90/141/0/51

* Horizon is 0 degree and counterclockwise rotation

For this, building height are decided to 16 stories that is one of standards to define Korean tower types, and also in single building analysis, building height don't affect building solar radiation and changes. This study simulated single buildings by utilizing IES-VE Apache and Sun-cast that can have ability to review solar radiation and building shade through their modules to estimate quantitative performance on the envelope.

[1] Doosung Choi (2009) defined a term of tower-type that ratio between long and short sides doesn't exceed 4:1 and by using one elevator and stairs, people can directly enter into their apartment units, and it is 16 and more stories with reference to Article 29.3.1 in Seoul Architecture Regulation. Also, Euntae Park (2007) gave tower-type a definition that ratio between long and short sides is under 4:1 on the authority of Article 86 for solar access right in the Building Code.

Building location is set on Seoul and Seoul weather data is extracted from ASHRAE design weather database v5.0, and the location is latitude 37.57N°, longitude 126.97E°, Altitude 86m and standard meridian 135.0E. Analysis duration is from January 1st to December 31th and their daylighting hours are based on monthly solar altitudes in Seoul calculated by VE-SunCast.

(1) Solar potential

In general, building forms in solar access, significantly affect solar gain and building shading to itself. Solar potential in each building type considered in aspect of annual average value, directional and seasonal effect to solar radiation. The longest, max and min solar gain sides on each direction side are reviewed of solar potential because diverse and tilted sides on the same direction show different solar potential due to different azimuth and projection by building designs. As a result of simulation analysis, solar radiation on the roof is the same as 105.2 W/㎡ hr because building roof has no shading by building itself. According to types, Flat-types basically have an advantage that long sides are commonly arranged to face south and can thus get more solar radiation in the amount of total solar potential. Hence, if Flat ㅡ type can face south, its most units can have an optimal direction for solar access. Values of simulation reported that annual solar radiation on long sides in typical floor by directions is that east, west, south and north are sequentially 65.2, 61.3, 81.8, 39.8 W/㎡ hr. Although Flat bending-type has partial refraction on the building mass, generally it can be exposed to originally arranged, because even though a bending side takes different azimuth, bending angle is less than 45 degree. Its each directional solar potential represents that east, west, south and north are 62.3, 49.6, 81.7, 39.3 W/㎡ hr in a row. Flat L-type has a form that its mass is perpendicular crossing which makes two continuing sides have completely dissimilar directions when they receive solar energy. At the same time, two perpendicular inner sides are relatively weak to gain solar energy due to be shaded by building mass itself. Its directional solar potential is 65.3, 62.0, 78.3, 39.9 W/㎡ hr in a row from east to west south and north. According to solar radiation data in passive design guideline (PCAP, 2012), average solar radiation* by directions in Seoul is that east, west, south and north on the vertical side are 65.9, 88.4, 96.5, 19.9 W/㎡ hr. Comparing solar potential to average solar radiation by building types in Seoul, there are some different ranges; on the east side, 94.5~99.0%, on the south side, 81.1~84.7%, on the west side, 56.1~70.2%, on the north side, 197.5~200.3%. Some values under average show that each type can have a weak-point on less solar potential sides. For example, Flat-bending is vulnerable to west and south sides.

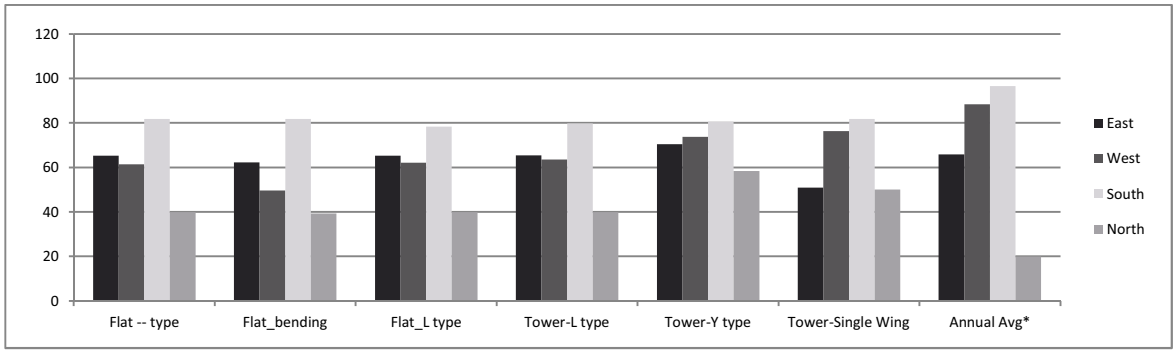

Fig. 1 Annual solar potential on the external walls (unit : W/㎡ hr)

Also, solar potential on long side by Tower L-type is that east, west, south and north are 64.5, 63.6, 79.8, 39.9 W/㎡ hr in a row, and solar potential in Tower Y-type is also 70.4, 73.7, 80.6 and 58.4 W/㎡ hr. Tower single-wing-type is 50.9, 76.4, 81.7 and 50.0 W/㎡ hr. On comparing these data to Seoul's average solar radiation, east side has 77.2~106.8% difference, west, south and north separately show 71.9~86.4%, 82.7~84.7% and 200.3~293.3% difference in solar radiation on the surface. One of causes is azimuth difference at each side on the building envelope and building itself shades its surfaces due to its roughness and projected mass, such as Tower single-wing type is delicate on east side. Actually, while optimal orientation in Seoul is east-south or south (135~210 degree), Tower types are comparatively exposed to unfavorable directions since their building forms preferentially decide their orientations before their building

arrangement. Consequently, even if all buildings face to the same direction on their placement, surface azimuth and area size on each side can be different owing to their types and forms have large effects on the amount of solar gain.

(2) Seasonal changes

On the other side, seasonal changes in Korea make considerable influence on solar potential by altering solar altitude, azimuth and daytime hours. Seoul's solar altitude is that spring and fall equinox are 52.4°, summer solstice is 75.9°, and winter solstice is 28.9° depended on Latitude 37° 34′. According to seasonal changes in Fig.2, east and north sides get the annual highest solar radiation on summer solstice and fall equinox. West pattern is similar with south in aspect that it takes large solar radiation on fall equinox. Besides, single building types and seasonal changes have a little correlation on their solar gain per the unit area even though they have azimuth difference on external surface. Hence, in respect of seasonal changes, influence on solar potential by single building types is insignificant.

* Length/Width (L/W) ratio on a typical plan, ** Existing only one side on a particular direction

(3) Building constraints

So far, this study analysed directional and seasonal solar potential by single building types of multi-family housing. On the independent building level, solar limitations are as the following; 1) building itself shade, 2) solar potential changes on surface affected by seasonal changes on solar azimuth and altitude. On account of seasonal solar changes are natural, solar potential and limitations by building forms are studied in this part. Generally, building shape, which is able to alter building exposure to external environment, is reviewed in the design stage to reduce energy consumption and to increase energy efficiency. On the design planning, to examine building mass, some indicators such as Surface/Volume (S/V) ratio, Length/Width (L/W) ratio and POP ratio can be used. Therefore, to find limitations in the independent building level, building types are diagnosed through such indicators. Table 3 demonstrates POP and L/W in case building types. Applied POP equation is like this;

$$POP = 2\frac{\sqrt{\pi \times A_b}}{P_b} \times 100(\%) \qquad \text{(eq.1)}$$

In the equation from Passive Design Guideline (2012), A_b = building area, P_b = perimeter length. High POP building commonly has a benefit in building heat gain or loss, whereas low POP ratio building has a weak-point in building heat gain or loss. This is because low POP ratio indicates that the building has relatively lots of protruded parts on its envelope, and if its weak-point is not revised on building arrangement, self-shade can largely reduce solar potential. Among building types, Flat L-type has the lowest POP value and other buildings are almost alike. In the table.3, weak point of Flat L-type shows a probable problem in low POP ratio buildings. To improve solar potential, low POP ratio building should consider dented parts on the surface and have an optimal placement to avoid perpetual shade. L/W ratio is also normally optimized on 1.5:1 which can affect annual heating and cooling loads by changing heat gain area by solar radiation and shaded heat loss area. Flat-types have L/W ratio that is almost 1:5 or more. However, Tower-types take around 1:0 in L/W ratio, which means that they have a weak spot on the surface by their shapes. Given this, preferably, wider building surface on Tower types should be more exposed to optimal direction to have better solar potential and reduce building loads.

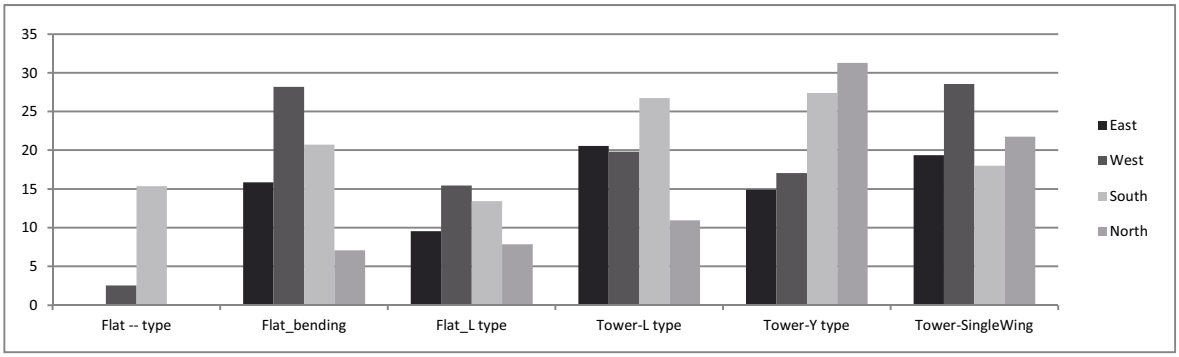

Fig. 3 Solar potential difference between max and min values on the same orientation (unit : W/㎡ hr)

Single buildings' self-shade presents another limitation. It makes solar potential difference and degradation on the same direction. Fig.3 reports how much self-shade by mass projection aggravates solar potential. Flat –type and Flat bending-type are almost even in their forms because it is merely 18 degree different on mass bending. On the contrary, in solar radiation on the same orientation, the bending makes large solar performance difference between the max and min values. Furthermore, Tower types reveal larger dynamic dispersion range than Flat types, which indicates Tower types in urban area are disadvantageous on solar potential and inevitable to have lower solar availability due to their structural problems. Accordingly, in order to solve these limitations in urban space, simplification on sun-exposed envelope and optimal arrangement to direction should be far outweighed.

4. Residential complex analysis

4.1. Arrangement of residential complex

Building arrangement methods have been developed following national building codes and the demands of social trends. Primary features of arrangement as follows: Since 1941, practice in fields of construction and design dominated by governmental institutes and construction contractors has generally used typical building drawings, which have affected current residential complex forms and urban context (Booseong Kang et al., 1999). After 1998, residential complex planning in Korea has a new trend that is remarkable changes of building forms. Some residential complex is consisted by only tower-type buildings, but most complexes of them have combination of flat-type and tower-type buildings. Also, the frequency of residential complex applied by diagonal line was increasing. The background of this is the result of chronological changes by preference of diversity, views and direction of urban scape planning. Moreover, wall area in flat-type-dominant residential complex is mainly larger than that in tower-type-dominant residential complex (Byeongho Lee et al., 2010). Also, all Korean residential buildings should meet governmental standard for solar access right in accordance with the provision of Article 53 in the National Building Code and Article 86 of the its Enforcement Ordinance. Thus every building that faces other buildings has to have 0.8 times distance between buildings based on due south (Yoonbok Seong et al., 2004). In this context, the solar limitation of case residential complex can have direct implication to improve solar potential in residential complex planning.

Tab. 4: Residential Complex (47BL) Information

Project : 47BL Dontan-2 District, Hwasung
Type : National sales and rental housing
Location : the whole region around Seoku-dong, Bansong-dong and Dongtan-myeon, Hwaseong-si, Gyeonggi-do located to 40km South from Seoul
Lot area (㎡) : 56,353
Floor area ratio (%) : 180 or less
Units : 930 households
Number of stories : 9F~23F
Building types : total 12 buildings (Flat – type, Flat-bending-type, Flat-L-type, Tower single-wing-type)

4.2. Solar performance

(1) Case information

This case study is to analyze solar performance of a residential complex in order to figure out the influence of building shade on the solar potential. The case complex is a design planning of a prize winner in 47 Block in Dongtan-2 District, Hwasung and it is currently under construction following this design. Above all, this project is a governmental project to distribute affordable houses to general people and the number of unit is around 930 households. Building size is diverse from 9 floors to 23 floors and east-southern located buildings are comparatively lower than west-northern located buildings due to satisfy a solar access code and get more sun shine that is preferred by many Koreans. IES-VE Apache and Sun-cast modules are used to analyze changes of solar potential and building shade on building surface. Weather data is Suwon, a neighboring city nearby Hwasung, of ASHRAE design weather database v5.0.

(2) Solar potential analysis

On the result of analysis, due to adjacent building's shades, gradation of solar potential is very different in vertical building surface. Solar potential on the surface in 20F is maximum value reflected by little influence of other buildings, and solar potential difference from 1F to 20F is the extent of building intervention that worsen urban solar potential and mainly become one of urban limitations for renewable use. In the table 5, the middle part located buildings in residential complex (702, 712) are Flat-bending-type (701) and Flat – type (712) that their forms are generally favorable performance to get solar energy than tower-types. However, in this complex, they are easily exposed by surrounding buildings which deteriorate solar potential on their different vertical stories, especially difference between 1F and 20F is obvious. For example, in 701 building, east side-solar potential shows about 3 times gap between 1F and 20F and if there is no interference

from other buildings, solar potential in each story by floor is the same as already confirmed in chapter 3. This means that in urban area, neighboring buildings can cause severe influence on solar potential and give rise to lower solar potential for use of renewable system.

On the east part in the complex, buildings (702, 710, 711) are Flat-bending-type (702, 710) and Flat-L-type (711) buildings. They represent that these buildings obtain almost same solar potential regardless their different stories and it signifies that the effect of adjacent buildings is small because the buildings are exposed to open space on the east side and there are only a few buildings along solar path. On the south side, buildings (708, 709) are Flat-L-type (708) and Tower single-wing-type (709). 708 building has a pattern that regardless of their floors, they show good efficiency due to open space in front of the buildings. Whereas east side of 709 building is influenced by 710 Buildings and its 1F solar potential is nearly one-third of 20F. On the west side are Flat-L-type (706, 707). Their solar potential gap by height is from 8.5 to 24.9 W/㎡ hr. Buildings located on the north are Flat – type (703) and Flat-L-type (704, 705). Their solar potential gap by height is from 0 to 25.1 W/㎡ hr. Also, comparing differences on the 1st floor, east, south, west and north side gap (max-min) are 48.8 W/㎡ hr, 26.2 W/㎡ hr, 52.1 W/㎡ hr and 14.2 W/㎡ hr respectively. East and west sides are relatively heavily affected by neighboring buildings. Therefore, in order to improve urban solar potential, the number of building in the middle part of complex should be relatively reduced or secure long distance from adjacent east and south buildings to make better solar potential.

Tab. 5 Solar Potential by Height and Direction (Unit: W/㎡ hr)

Bldg No.	EAST			SOUTH			WEST			NORTH			Note

(3) Urban solar limitations

Urban solar limitation in the complex is mainly building shades between adjacent buildings. Building interference significantly deteriorates solar potential on middle and lower floors (Tab.5). The approach to improve solar potential in arrangement level is two way; (1) building density planning, (2) distance and angle between adjacent buildings. Building density can be decided on the basis of principles of solar access. In this case study, residential building pattern, in density aspect, is that east and south-east located buildings are relatively lower than west and north-west located buildings. This is due to the fact that optimal direction for solar potential in Korea is south or south-east, and with optimal arrangement, lower front located buildings can have an advantage to reduce building interference to adjacent the back or the left other buildings. Therefore, building density planning based on optimal arrangement is one of better ways to settle urban solar limitation.

Fig. 4 Density and arrangement in a case high-residential complex

Another obstruction to solar potential is distance and angle between the front and the rear adjacent buildings. Below Fig.5 is an example of triangle interference. In general, residential complex is designed to have short distances between buildings to maximize using the floor area ratio. In Fig.5, the back building of the two front buildings is easily shaded by the front buildings, especially, in the middle and lower floors which is crucial one of urban limitations. Hence, to minimize building shaded area on the surface, suitable distance is secured from the front buildings or wider angle among two front located buildings is needed. Given this context, high-rise residential housing in Korea has particular points in parts of building forms and arrangement. Therefore, in order to maximize solar potential in urban area and to exploit it for renewable energy system, above-mentioned points should be considered in the design stages.

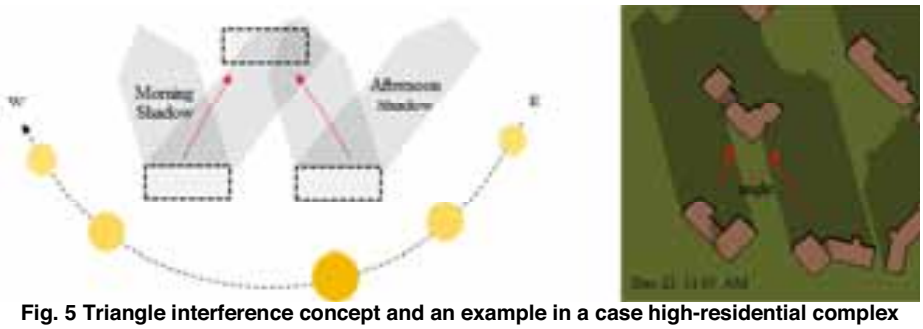

Fig. 5 Triangle interference concept and an example in a case high-residential complex

5. Conclusions

This study reviewed urban solar potential in high-rise residential buildings which are the most universal housing type in Korea. This study can be summarized as follows. In the single building level, surface azimuth and area size on each side can have large effect on the amount of solar gain. Also, building shapes can significantly affect solar potential because they can make self-shade on their surface which worsen vertical solar potential in urban areas. For instance, Flat-bending is weak to west and south side, and Tower single-wing type is feeble on east side when they face due south. Also, Tower types report larger dispersion range on the vertical solar potential than Flat types, which means Tower types in urban area are unfavorable on solar potential and inevitable to show lower solar availability because of such structural problems. On the other hand, high-rise residential building is disadvantageous for solar energy use. However, in urban environment, it is inevitable to avoid interference on solar potential between neighboring buildings due to high density. Therefore, high-rise residential building cannot help but consider effective mass design and arrangement to maximize solar potential and to use solar systems on upper floors or specific orientation. In triangle interference, in order to improve solar performance in lower and middle floors, proper distance is secured from the front buildings or larger angle among buildings is required. This study regarding building types and complex case can be valuable to understand urban solar potential in Korea. This result is expected to contribute, as a fundamental, for architect and engineers to create designs for low energy building.

Design and layout optimisation of a pair of buildings regarding their solar potential

Marko Bizjak and Niko Lukač

University of Maribor, Faculty of Electrical Engineering and Computer Science, Smetanova ulica 17, SI-2000 Maribor, Slovenia

Abstract

Urban planners are often faced with the formulation of plans for multiple buildings, where they need to consider the available solar energy. Presented work tackles this problem using an evolution-based algorithm in combination with modelling of buildings within a real environment that was captured with laser-based LiDAR (Light Detection And Ranging) technology in order to optimise the design and layout of a pair of buildings regarding their solar potential. To solve the constrained optimisation problem the self-adaptive differential evolution (DE) is considered. The method was tested with a pair of rectangular buildings on a hilly LiDAR dataset, where the influence of shadowing between buildings and additional design parameters (the distance between buildings and orientation of the building pair) was analysed.

Keywords: *Solar potential, LiDAR, Buildings, Differential evolution*

1. Introduction

Solar energy has an important role for the development of sustainable urban areas. Buildings are accounted for 40% of total European energy consumption and a considerable amount of carbon emissions (Parliament, 2010). With appropriate utilisation of solar energy and effective solar building design we can significantly reduce carbon emissions and maximise passive solar heating as well as electricity production. Hence, the layout of buildings within urban areas needs to be planned with the available solar energy in mind. This can be difficult for urban planners, especially when designing layouts of buildings in a real environment, where the availability of solar energy can be affected by many factors, such as shadowing from surroundings (e.g. man-made objects, vegetation or terrain), local climate and terrain topography. Difficulty increases with the number of buildings planned to be build. Before we can optimise more buildings, it is imperative to know how to optimise a single building regarding its solar potential.

In the past few years, several approaches have been developed for the optimisation of a solar building (Bizjak et al., 2015; Hachem et al., 2011a; Ouarghi and Krarti, 2006). When another building is considered, further factors need to be considered, such as mutual shadowing and relative position. Various studies have focused on optimising the design of residential neighbourhoods regarding the availability of solar energy at the urban scale. Some (Hachem et al., 2013, 2012, 2011b; Kanters and Horvat, 2012) manually inspected parameter space using predefined values, whilst others (Kämpf and Robinson, 2009; Kämpf et al., 2010) used automatic approach. None of them considered actual environment from real locations or focused on the layout of a pair of buildings.

Hachem et al. (Hachem et al., 2011b) developed a methodology for the investigation of the influence of two-storey housing units design parameters and neighbourhood patterns on the received solar irradiance. They investigated straight and curved roads as site layouts. Later they (Hachem et al., 2012) investigated solar

doi:10.18086/swc.2015.08.04 Available at http://proceedings.ises.org

potential and energy demand for heating and cooling of housing units. Their work continued in 2013 (Hachem et al., 2013) where previously developed methodologies were used to perform a parametric study to develop a design methodology for solar residential neighbourhoods based on an evaluation system that uses weighted objectives method. Kanters and Horvat (Kanters and Horvat, 2012) studied the impact of geometry form of urban blocks regarding the solar potential. Kampf and Robinson (Kämpf and Robinson, 2009) proposed a novel evolutionary approach for optimising the placement of buildings regarding the availability of solar irradiation. However, buildings' design was not considered. Kampf et al. (Kämpf et al., 2010) developed a multi-objective optimisation algorithm to optimise geometric parameters of building design on a range of urban typologies.

In this work we present a novel optimisation of the design and layout of a pair of buildings within LiDAR data and investigate the influence of geometrical design parameters of a pair of buildings on the received solar irradiance. To our knowledge, this is the first method for the optimisation of a pair of buildings to consider environment of real locations. Real environment is provided by LiDAR (Light Detection And Ranging) data. LiDAR is an active remote sensing technology that scans surface topographies and is normally mounted on an aircraft. The result of such scanning is an unstructured point cloud. As manual inspection of parameter space is exhausting, an evolutionary approach is used to perform the optimisation based on the methodology used in (Bizjak et al., 2015). The proposed method is therefore performed in two stages. In the first stage, user provides the footprint of a building model, which is then used as a base model for both buildings modelled within LiDAR data. During the second stage the pair of buildings is optimised with a modified self-adaptive differential evolution (DE) (Brest et al., 2006). The optimisation criterion is the cumulative estimation of solar potential (Lukač et al., 2013) of both buildings. Next to the design parameters of a single building model we consider the following optimisation parameters: the distance between the pair of buildings and orientation of the pair.

The paper is structured into four sections. The next section describes the proposed method. The third section presents the results and the last section concludes this paper.

2. Design and layout optimization of a pair of buildings

The following subsections describe the proposed method in detail. Subsection 2.1 details the method for the optimisation of a solar building, which is the base for the proposed method. The next subsection describes the design and layout optimisation of a pair of buildings.

2.1. Basic method for the optimisation of a solar building

The basic method's input is a classified LiDAR (Light Detection And Ranging) point cloud (see Fig 1a) that is arranged into a regular 2.5D grid, where each cell is defined by the height and classification of the highest point in the cell (Bizjak et al., 2015). The empty cells are interpolated with inverse distance weighting (IDW) method (Shepard, 1968). Points are classified as either building, ground or vegetation. The utilisation of LiDAR data enables us the optimisation within a real environment, where the influence of the local climate, terrain topography and shadowing from buildings and terrain are considered. Buildings are then modelled on the 2.5D grid, where the following design parameters are considered: position, rotation, facades' height, roof's height and roof's slope, as shown in Figure 1b. Buildings' position is bounded by an area of interest, which is defined as a user selected polygonal area on the grid. When modelling is completed, the building is rasterised into the 2.5D grid (see Figure 1c), where the highest point of the roof over each covered cell is considered. The cells of the rasterised building represent the input to the method for solar potential estimation (Bizjak et al., 2015), which is the considered optimisation criterion. An evolutionary approach is considered for the optimisation of a building model regarding the received solar potential, based on methodology used in (Bizjak et al., 2015). Evolutionary algorithms are inspired by biological evolution (Brest et al., 2006). One of them is differential evolution (DE) which is a direct parallel search method developed by Price and Storn (Storn and Price, 1997) that operates with P n-dimensional vectors $x_{i,G}; i = 1, \dots, P$ as a population throughout the optimisation for each generation G. Each vector goes through mutation, crossover and selection operations in a single generation G. During the mutation and crossover new candidates are generated, while selection regulates which vector survives the current generation. The decision regarding which candidate is selected is

based on the estimation of solar potential which is described in the next section.

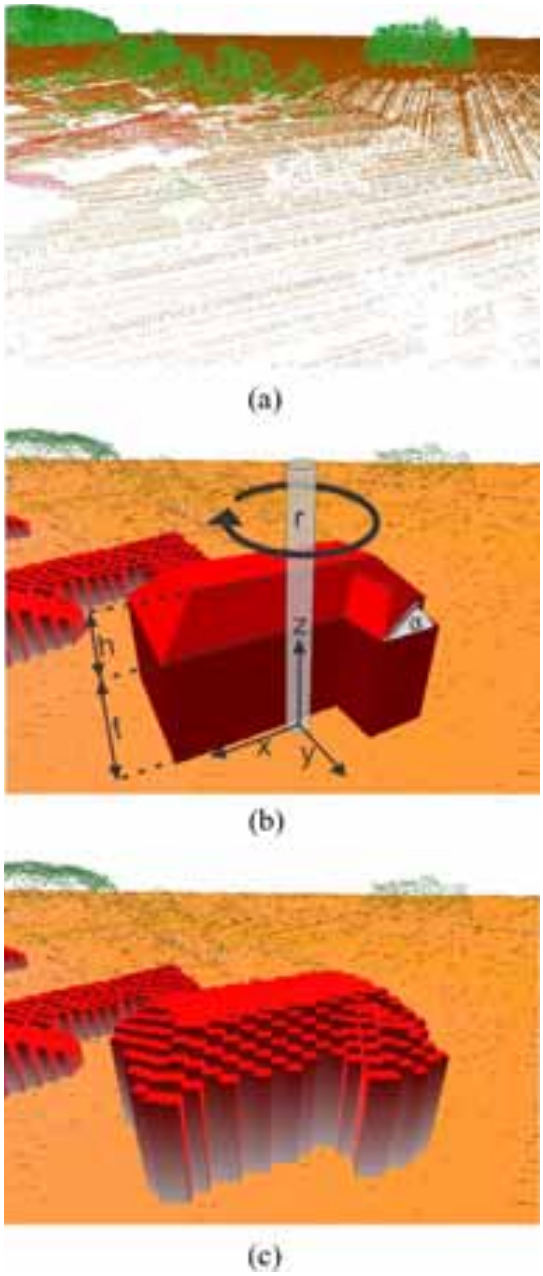

Figure 1: (a) Classified LiDAR point cloud; Building model on a 2.5D grid with the following building design parameters: r- rotation axis, f – facades' height, α – roof's slope and h – roof's height; (c) Cells of the rasterised building (Bizjak et al., 2015).

2.2. Building pair's solar potential maximisation

The optimisation method in (Bizjak et al., 2015) focuses only on the design of a single building, which is why this paper proposes a novel extension to the method's capabilities to assess the optimal design and layout of a pair of buildings. With an additional building, the influence of shadowing between buildings and the placement of a pair of buildings on a user defined area of interest can be estimated, in order to maximise the received solar irradiance. This is performed by introducing additional design parameters: the orientation γ of the pair of buildings and the distance d between the pair. The pair of identical buildings is parallel for any orientation angle. Two types of layouts of a building pair are considered. For the first layout type, the buildings lie on two parallel lines (see Figure 2a and equation 2) and for the other the buildings lie on the same line (see Figure 2b and equation 1). The lines for the layouts are defined as follows:

$$y = \tan(\gamma)\, x + \, y_P - \tan(\gamma)\, x_P \qquad \text{(eq. 1)}$$

$$y = \tan(\gamma)\, x + \; y_P - \tan(\gamma)\, x_P \pm \frac{\left(\frac{d+w}{2}\right)}{\cos\gamma} \qquad \text{(eq. 2)},$$

where $P(x_P, y_P)$ is the center point of the area of interest and w is the width of the building. Moreover, buildings can be mirrored over y-axis before rotated.

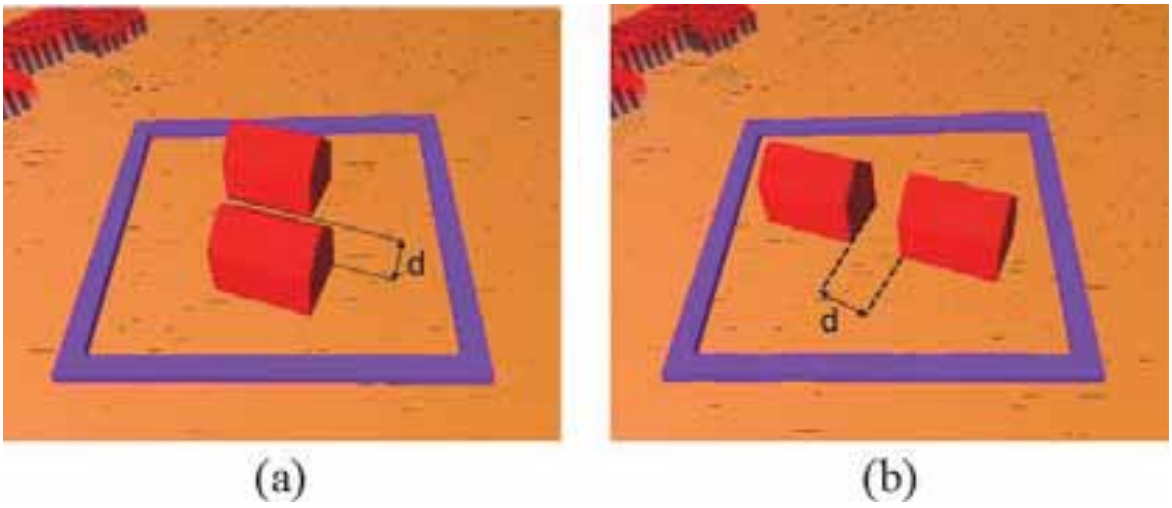

Figure 2: Two types of layout with orientation angle at 20°, where (a) buildings lie on two parallel lines and (b) buildings lie on the same line. The distance between buildings is defined by *d*.

The final model of the pair of buildings is rasterized into 2.5D grid by the rasterization of each individual building (see Figure 1c). The cells of both buildings are considered as input to the method for solar potential estimation (Lukač et al., 2013), that operates with the 2.5D grid that was generated with LiDAR data. Solar potential is roughly calculated as follows:

- Calculation of a normal vector for each building's cell.
- Time and location dependent terrestrial irradiance is calculated using cell's aspect and slope angles (Duffie and Beckman, 2006) together with long-term on-site diffuse and global solar irradiance measurements.
- The solar potential of a cell at a given time is defined as:

  $$I_c = \; I_{c_b}(1 - S_c) + I_{c_d} \left[\frac{\text{kWh}}{\text{m}^2}\right], \qquad \text{(eq. 3)}$$

  where I_{c_b} and I_{c_d} are the terrestrial direct and diffuse irradiances of a given cell, whilst $S_c \in [0,1]$ is the shadowing coefficient that affects the direct irradiance.
- I_c is considered between sunrise T_{sr} and sunset T_{ss} with the fixed time-step to estimate the daily solar insolation:

  $$J_c = \int_{T_{sr}}^{T_{ss}} I_c(t)dt \left[\frac{\text{kWh}}{\text{m}^2}\right]. \qquad \text{(eq. 4)}$$

- The solar potential is defined as an average daily insolation throughout the year (Lukač et al., 2013).
- The average amount of the daily solar energy the pair of buildings receives is the result of the fitness function. It is calculated as the sum of the solar potential of the pair's cells.

During the optimisation the initial population is not randomly generated over the parameter space only for the roof slope and the pair of building's orientation parameters. For these two parameters a simple heuristic is used, where the initial population is generated in Gaussian distribution with its peak at the expected value (Bizjak et al., 2015). Optimal roof slope is expected to be approximately at the location's latitude, whilst for the orientation most roof surfaces of the pair are assumed to be oriented towards equator. Figure 3 presents the workflow of the upgraded method.

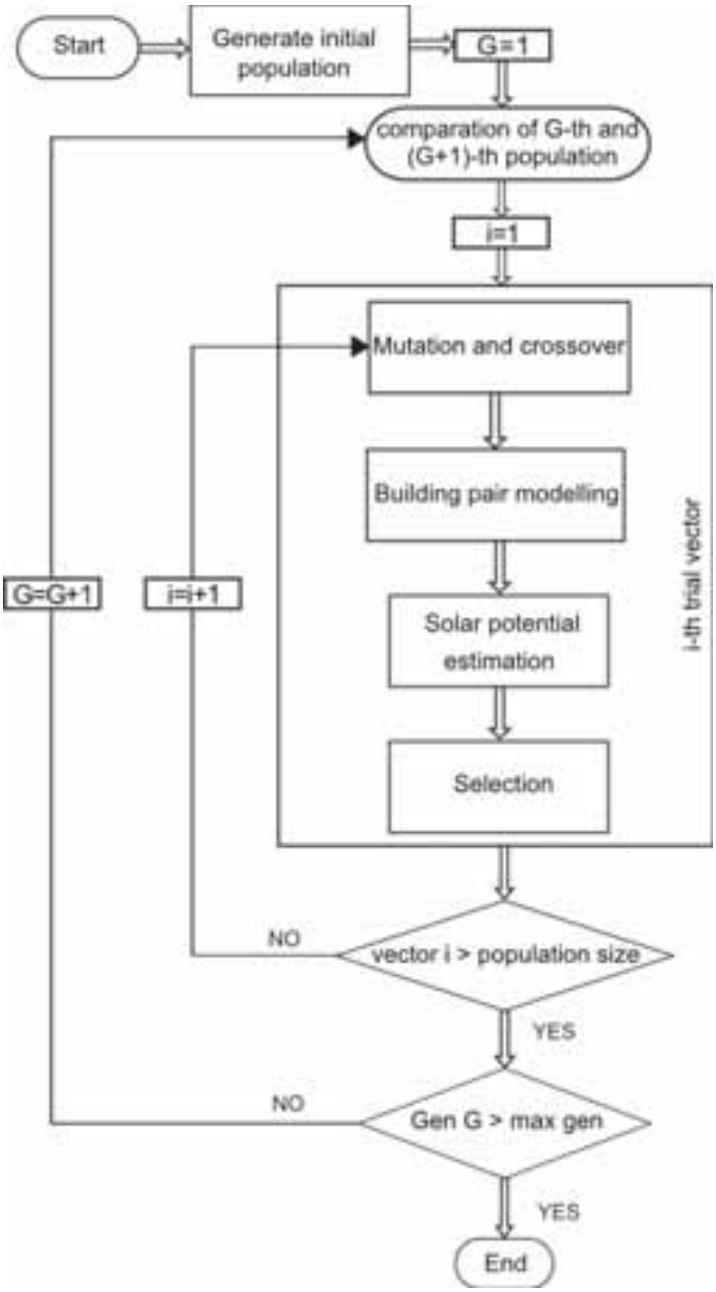

Figure 3: Workflow of the proposed method.

3. Results and discussion

The experiments were performed on two LiDAR datasets, one that represents a hilly landscape (located at 46° 37' 0.61" N, 15° 52' 37.59" E) and the other a flat landscape (46° 35' 59.43" N, 16° 13' 25.89" E) as can be seen in Figure 4. Testing was performed at a specified location on each dataset using a building in rectangular or L shape as a base for the optimisation of the pair. For the calculation of terrestrial irradiance of each pair of buildings candidate the average measurements from the closest meteorological station over the previous decade were used. The population size P for DE was set to 80 and the *DE/best/1/bin* strategy was considered, as proposed in (Bizjak et al., 2015).

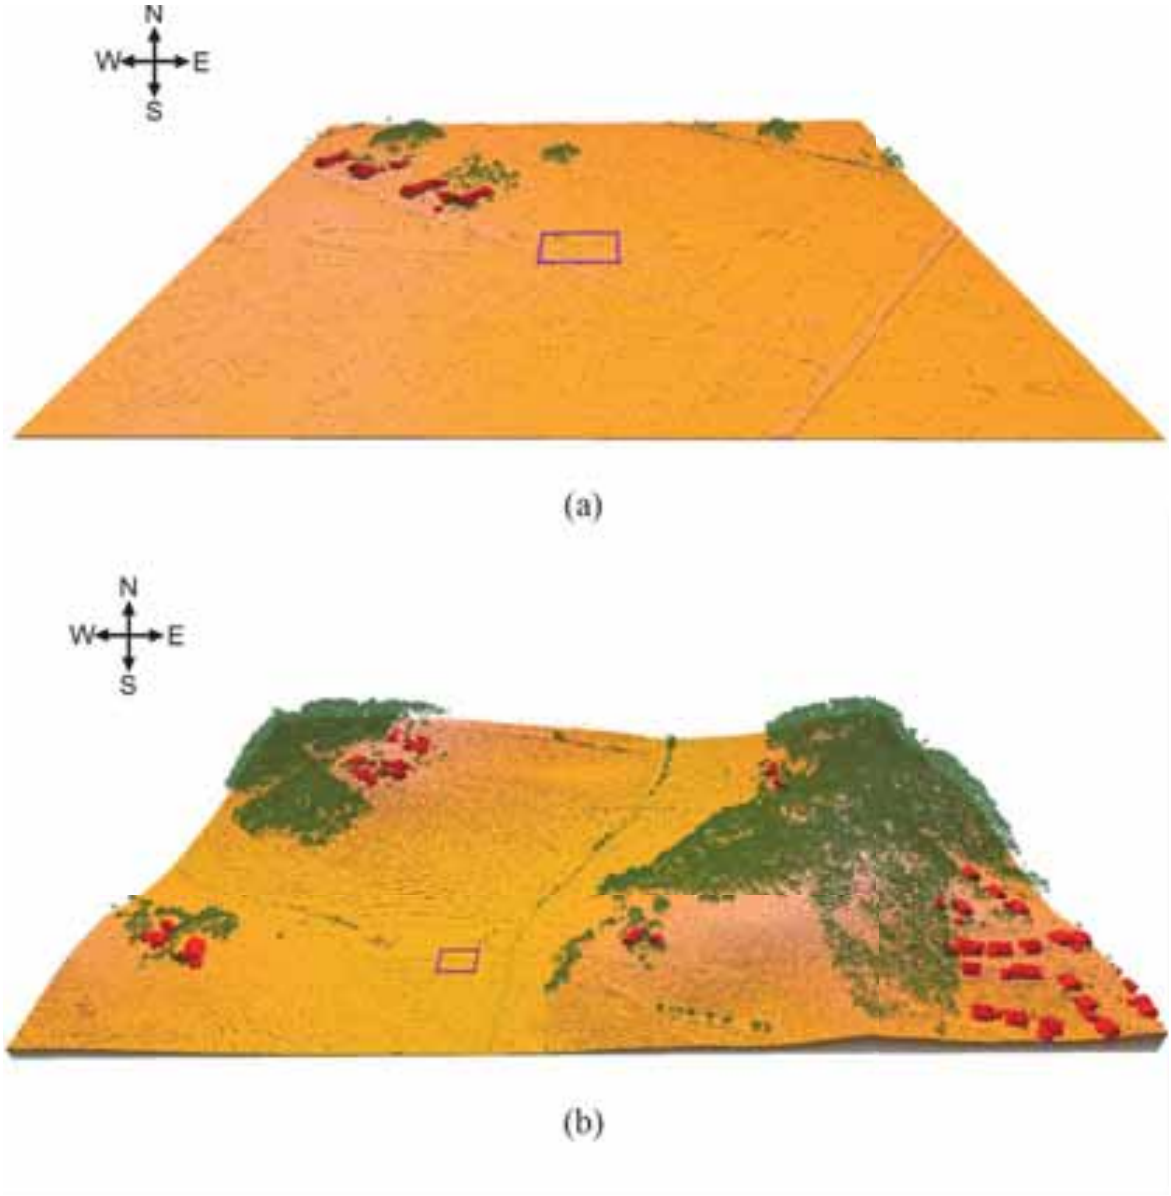

Figure 4: Flat (a) and hilly (b) LiDAR datasets with designated area of interest (purple rectangle).

The results of the optimisation for all combinations of layouts and datasets are presented in Figures 5 and 6. Figure 5 shows the optimised pairs of buildings on the flat LiDAR dataset. The buildings' roofs were sloped on average at 46° (±2°). Buildings' height varied for each pair, which is caused by the lack of shadowing from surroundings. The optimal orientation of both layouts for all pairs of buildings was on an east-west axis, where the most exposed roof surfaces were facing equator. The distance between the buildings was the maximum possible distance within the considered area for both layouts. This is a natural consequence of decreased shadowing between buildings as the distance increases.

Figure 6 presents the optimised pairs of buildings on the hilly LiDAR dataset. The buildings' roofs were sloped on average at 45° (±1°). The difference in slope is caused by different topography and geographic location of each dataset. Buildings' height was maximal, which is a consequence of shadowing from the hill. Higher building means lower shadowing and therefore better fitness. The optimal orientation of building pairs was on an east-west axis for all cases except for L-buildings on the same line (see figure 6c). The building pair was oriented 2° from the east-west axis. This occurred due to internal shadowing, which happens when a building's cell is shadowed by another cell from the building. The distance between buildings was maximum on this dataset as well.

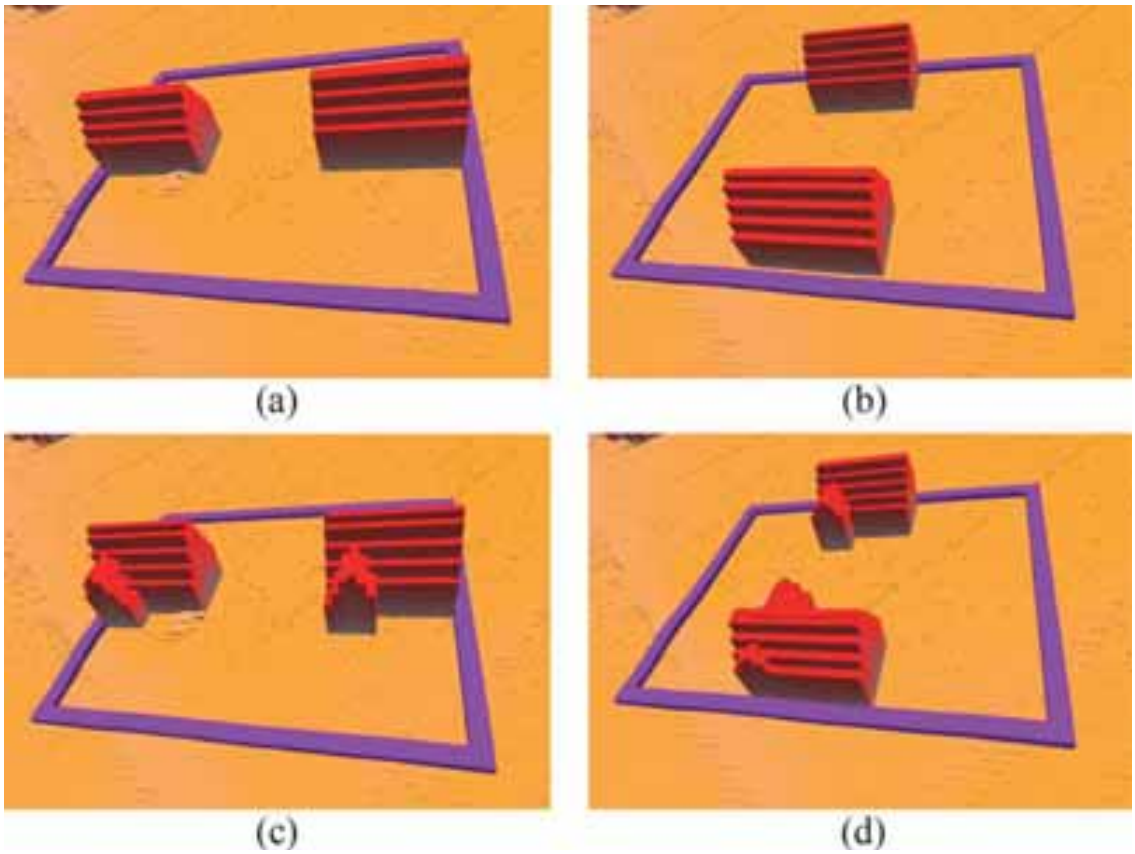

Figure 5: Results of the optimisation for buildings on the same line (a,c) and buildings on two parallel lines (b,d). Area of interest is located at a 2.5D grid generated from the flat LiDAR dataset (see Figure 4a).

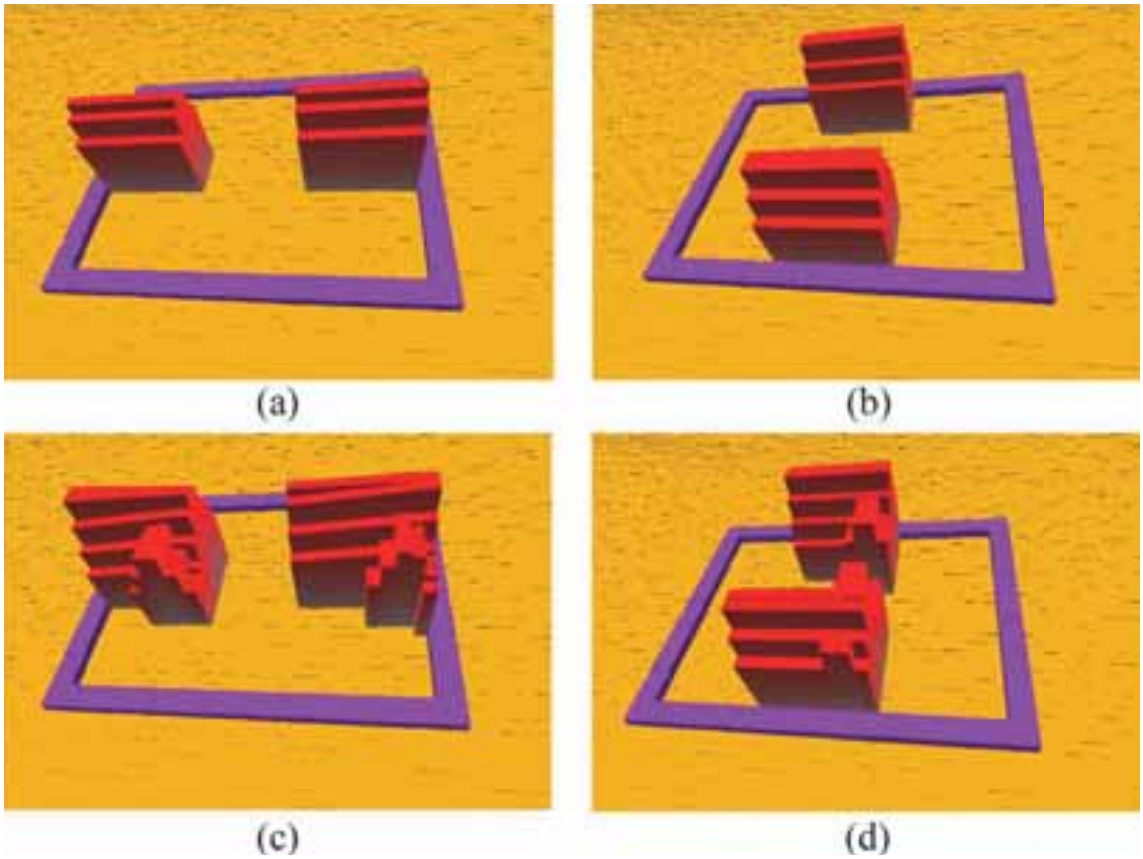

Figure 6: Results of the optimisation for buildings on the same line (a,c) and buildings on two parallel lines (b,d). Area of interest is located at a 2.5D grid generated from the hilly LiDAR dataset (see Figure 4b).

4. Conclusion

This paper presented a novel method for the design and layout optimisation of a pair of buildings regarding the received solar potential. The optimisation was achieved with a modified self-adaptive differential evolution. For each candidate, a pair of buildings was modelled and assessed regarding solar potential. The solar potential estimation considers shadowing from surrounding obstacles within real data and local climate. The results suggest, that the method successfully optimises a pair of buildings, where the distance between the buildings is maximal. To our knowledge, this is the first method that tackles the optimisation of two buildings within LiDAR data regarding solar potential.

[3] Escuela Superior Politécnica del Litoral, Guayaquil (Ecuador)

Abstract

During the design and construction of house walls, certain factors such as building materials and external climatic conditions, which are essentials and influence in human comfort, are generally ignored. The rice husk is one of the most common organic wastes generated around the word, and in Ecuador this is not an exception. The aim of this work is to study the feasibility of using a mortar which contains rice husk crushed (RHC). To show this feasibility, experiments have been conducted with mortar samples of different proportions of water, cement, sand, and crushed rice husk. The variables tested in this work include several parameters such as: analysis of flow, compressive strength, curing time, and adhesivity. As part of this project, this particular mortar is used during the construction of the housing walls in prototype houses located in one city of the Ecuadorian coastline.

Keywords: *Mortar, fluidity, compressive strength, curing time, adhesivity*.

1. Introduction

The raising of the world population and consequently their food consumption, result in the increment of organic and inorganic wastes. The overabundance of residual wastes causes a hard impact over the environment, and therefore can produce irreversible environmental issues to solve for the future generations. There are different initiatives to reduce the environmental impacts caused by the population´s consumption. For example, the waste recycling process to reuse this material during the manufacture of other products can be mentioned. Previous studies (Mahvi et al., 2004) mention the rice husk as one of the most common organic wastes generated around the world. Nowadays, it is found in large quantities in husking machines of rice; which is often burned, and in some occasions is thrown into rivers and estuaries, causing pollution and obstruction (Ganesan et al., 2008).

Finding a suitable utility of the rice husk in building construction will help not only to decrease the amount of this waste in the ambient, but it also improves the physical and thermal characteristics of the materials involved in the wall fabrication (Barzola et al., 2015).

The purpose of this work is to reduce the pollution generated for the husk rice wasted, using this organic waste during the manufacturing process of the housing wall mortar. According to its use, mortars in civil constructions can be classified in different ways according to its binding and use (Simba, 2007). In the present work, an innovative mortar for building applications that requires lower strengths like masonry and plastering is taken into account. Based on the mentioned characteristic, the weight ratio of the components is considered. However, the economic aspects of this alternative mortar with RHC was not considered during this study. It has been suggested as the next phase of this research.

The mortar must meet with certain characteristics; one of them is not displaying segregation in both fresh and hardened states; at inner and outer walls of a building. For this purpose, all mortar must follow technical

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.08.05 Available at http://proceedings.ises.org

processes and quality control in the laboratory, by reaching an optimal ratio among the constituent (Givi et al., 2010). The tests carried out over the mortars correspond to fluidity, compressive strength, curing time, and adhesion. Thus, the durability of mortar on the walls can be ensured, and it certainly will be complemented with the maintenance performed.

The rest of this paper is divided as follows: in Section 2, a detailed information about the materials and methods used to manufacture each sample is given. Section 3 is focused on the presentation of the results and discussions. Finally, the conclusions are given in Section 4.

2. Materials and methods

Along this section, information about the materials involved in the brick fabrication is given. The methodology followed and the composition for each sample mortar are presented.

2.1. Materials and mixture

Mortars are the result of a mixture of different materials, which in this work were added in different proportions. Among the materials used during the manufacture of the mortars are cement, rice husk crushed and other aggregates. Amount specification and characteristics about all of these materials are given in the following sub-sections.

2.1.1. Cement

The main constitutive element of the mortar is the cement. Ordinary Portland Cement (OPC) obtained from Holcim Cement Manufacturing Company of Ecuador conforming to ASTM-C1157 standard was used.

2.1.2. Rice husk crushed (RHC)

The rice husk was obtained from rice mill. Then, this waste was ground using mill for 30 minutes. Table 1 shows sieve analysis of the RHC conforming to ASTM-C33 standard.

Tab. 1: Sieve analysis of the RHC used in the samples

Sieve size	Cumulative Gram Retained	Cumulative % Retained	% Passing	ASTM – C33
3/8”				100
No. 4				95-100
No. 8	0.4	0.03	99.97	80-100
No. 16				50-85
No. 30	179.7	64.36	35.64	25-60
No. 50	119.6	73.94	26.06	10-30
No. 100	122.9	83.79	16.21	2-10
PAN	202.3	100	0	0

2.1.3. Aggregates

Graded river sand passing through 0.425 mm sieve with a fineness modulus of 2.01, and specific gravity of 2.58 was used as fine aggregate.

2.1.4. Mixture proportioning

A total of four series of mixtures were prepared in the laboratory trials. MSC0 series mixture which has traditional proportions of cement, sand and water were prepared as control specimens. MCA1, MCA2, MCA3 and MCA4 series mixture were prepared with different proportions of RHC and water.

Table 2 presents the amount and proportions used for the different samples. The amount of water is not affected because the container of the mixer is aluminum, and there is no absorption issue. (Mas i Barberà, 2006).

Tab. 2: Amount of the different elements in the sample mortars and water/cement ratio

Mortar	Cement (g)	Sand (g)	Rice Husk (g)	Water (g)	Water / cement
MCA1	233	700	23.3	200	0.86
MCA2	233	700	23.3	215	0.92
MCA3	233	700	46.6	220	0.94
MCA4	233	700	46.6	250	1.07

According to the information presented in Table 2, it is important to mention that each sample mortar has the same amount of cement and sand. The variable that has been subjected to change is the corresponding to the rice husk and water. The samples were prepared with two different amounts of rice husk, and four different quantities of water. The last column of Table 2 presents the ratio between the water and cement for each sample analyzed.

2.2. Preparation of test specimens

MCA1, MCA2, MCA3 and MCA4 series mixture were prepared by mixing the fine aggregate and powder materials (cement and RHC) in a laboratory mortar mixer. They were mixed in dry condition for 3 min followed by another 4 min after adding the water. The powder material in MSC0 series mixtures was only cement.

2.3. Mortar flow

Fluidity is the physical property of a material that shows the ability to flow. Considering that each sample is built from materials in different proportions, different values of fluidity are expected. Mortar flow is most sensitive to water content and air content. Once prepared, mortar samples were placed immediately at the flow table test in order to observe its workability. The test was done in accordance with the ASTM C 1437, the Standard Test Method for Flow of Hydraulic-Cement Mortar.

2.3. Compressive strength

Mortar strength is very important because it reflects the mortar's ability to carry intended loads. In our case, the adhesion force between the masonry and mortar in the wall. For all samples, cube specimens of size 50 X 50 X 50 mm were used for the compressive strength test of mortar. They were tested at the age of 7, 14 and 28 days. The test was done in accordance with the ASTM C 109, the Standard Test Method for Compressive Strength of Hydraulic-Cement Mortar.

2.4. Curing time

Another important property to analyze during the mortar fabrication is the hardening time, water retention and curing start. The mortar samples should be cured with the normal OPC hardening. The test was done in accordance with the ASTM C 191, the Standard Test Method for Time of Setting of Hydraulic-Cement by Vicat Needle.

2.5. Adherence

Adherence is a property that must maintain both fresh and hardened mortar. The test was done in accordance with the ASTM C 780, the Standard Test Method for Preconstruction and Construction Evaluation of Mortars for Plain and Reinforced Unit Masonry.

Additionally, sclerometer method is applied in housing prototypes built in order to test this mortar. This instrument measures compression strength in Q units, which can be converted in MPa units through of a curve supplied by the manufacturer. For each point to evaluate, ten measurements were made. Then, the median Q values are determined. These measurements are carried out in each both outer and inner walls, during the September 14, 2014; September 28, 2014 and May 23, 2015.

3. Analysis and discussion of results

3.1. Fluidity

Figure 1 shows the percentages of fluidity obtained during the measurements to the samples, i.e., MCA1, MCA2, MCA3 and MCA4, each one presenting different fluidity. The results are contrasted with a traditional pattern named MSC0, which does not contain crushed rice husk. Among the four samples of mortar with

crushed rice husk, results show that the MCA3 sample has better fluidity. This is as expected, because of the higher amount of water. This reduces the resistance to compression.

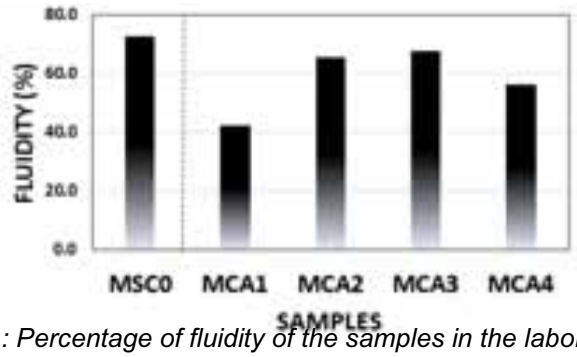

Fig. 1: Percentage of fluidity of the samples in the laboratory

3.2. Compressive strength

Figure 2 shows compression-resistance ratio. It is noticed that when W/C ratio increases, compressive strength decreases. Laboratory tests were performed on the day 7, 14 and 28. MCA1 shows a better performance in compressive strength, and therefore this sample was selected for being used in the construction of the walls in the prototypes.

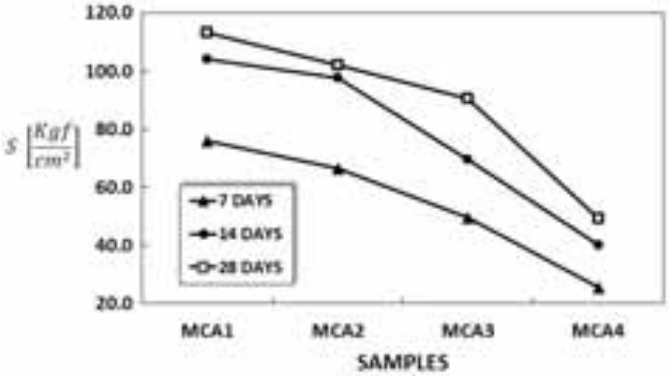

Fig. 2: Behavior of the compressive strength of the samples according ASTM C 109

Figure 3 presents a contrast between traditional mortar MSC0 and MCA1 selected. The traditional mortar always has a higher strength compared to mortar MCA1. In addition, on average MCA1 has a lower resistance compared to traditional mortar, since crushed rice husk also absorbs water; however, as discussed later, it has good adhesion.

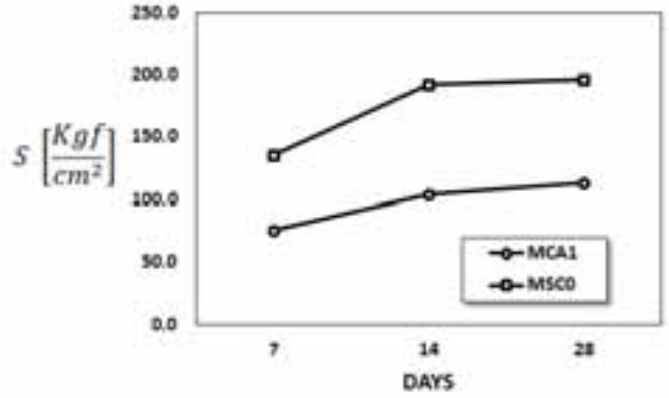

Fig. 3. Comparison of the Compressive Strength between the traditional mortar and mortar MCA1 selected.

3.3. Curing time

Figure 4 shows the Vicat needle experimental penetration behavior applied to the sample MCA1, the data were obtained every 15 minutes, according with the ASTM C 191, the Standard Test Method for Time of Setting of Hydraulic-Cement by Vicat Needle. The result presents a very good approximation between the experimental and the corrected (theoretical) curve. When 25 mm height is reached, the hardening of cement in the mortar is achieved, which corresponds to about 4 hours (243.3 minutes) of curing time. This was a reference value to consider for the curing stage of the mortars during their utilization in housing prototypes.

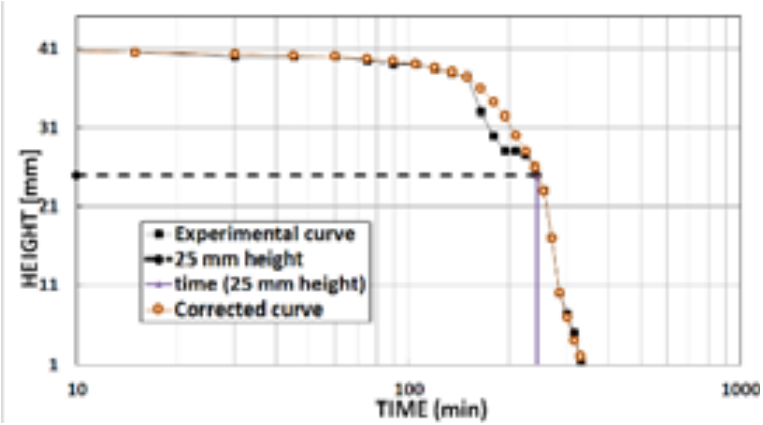

Fig. 4: Penetration curves Vicat needle applied to mortar MCA1

3.4. Adherence

Figure 5 depicts prototypes plastered with MSC0 and MCA1 mortars, the results showed good adhesion (Barzola et al., 2015). All the prototypes have the same dimensions (2.8 m by side) and characteristics. In order to improve the thermal isolation between the inner and outer ambient of the prototypes, windows and doors were treated. Special isolation treatment on the roof was applied.

Fig. 5: From left to right: Prototypes plastered A (MSC0), B (MCA1) and C (MCA1) in Atahualpa parishes.

Figures 6 - 8 show the sclerometer measurements which corroborated the resistance and adhesion of the mortars in each wall. For each point to evaluate ten measurements with the sclerometer were performed, and with these values the median was determined. This instrument measures compression strength in Q units, which can be converted in MPa units by using a curve supplied by the manufacturer. This process is carried out in each outer and inner wall of each module. The dates considered for analysis of the evolution of resistance were 14, 28 September 2014 and 23 May 2015.

Radar charts summarize the results of the medians of the data obtained from the external walls. These walls were labeled counter-clockwise, starting with the front wall, E1; right side, E2; posterior and left side are labeled as E3 and E4, respectively. Each colored line depicts the measurements of a particular date according to the legend box. It can be noted that the resistance at these test points has been increasing chronologically.

The results of applying sclerometer method evidences that the best compressive strength a short term is obtained with MSC0 mortar in Prototype A. However, the MCA1 mortar used to build the prototype C showed better median values compared with Prototype B. Note that Prototype C was built with brick block, unlike Prototype A and B with concrete block.

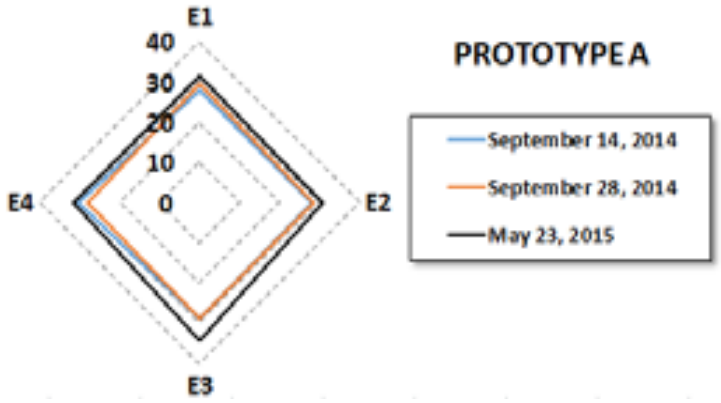

Fig. 6: Resistance performance at external walls prototype A

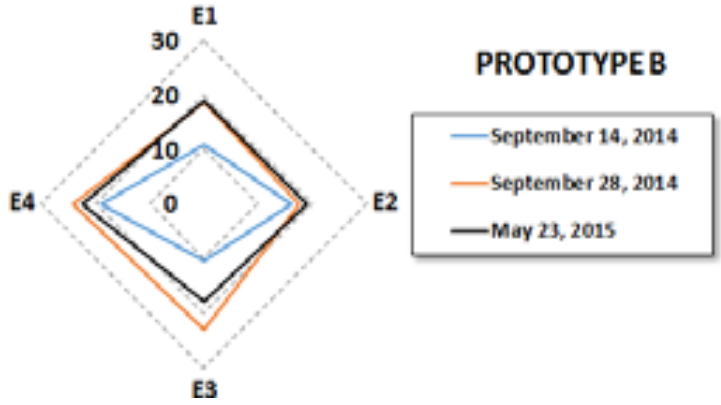

Fig. 7: Resistance performance at external walls prototype B

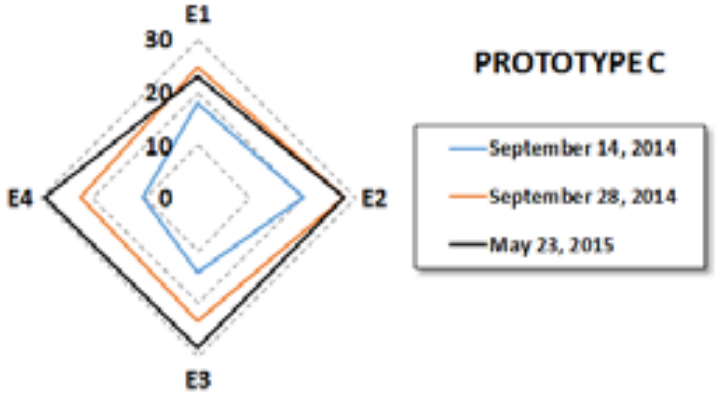

Fig. 8: Resistance performance at external walls prototype C

4. Conclusions

An innovative mortar, which contains RHC was tested. Although MCA1 mortar has lower compression strength compared to the traditional mortar, its feasibility for masonry and plastering due to both fluidity and adhesion performances is demonstrated.

In (Barzola et al., 2015), field test results of the MCA1 are shown. Two different geographical locations of the Ecuadorian coast were considered for this study, which have different weather conditions. The field test results show a thermal behavior similar to the expected if traditional mortar with OPC is used.

Finally, this study suggests that the mortar made of RHC represents a viable alternative to being used in wall constructions. At the same time using this type of mortar, the environmental impact of the overproduction of organic wastes is reduced.

Estimating feasibility of regenerating PCM and Desiccant in room interior wall surfaces using pre-dried air through an external desiccant bed

Edson Manyumbu[1]

[1] Chinhoyi University of Technology, Chinhoyi, Zimbabwe

Abstract

Buildings account for a significant fraction of energy use. Reduction of energy use in buildings has been the subject of research for quite a while to date. Passive means for comfort provision is one way of energy use reduction in buildings. A passive humidity and temperature control requires regeneration of the participating building envelope materials at some point in order for the buffering to be possible when needed. The present work focuses on investigating the potential for regenerating interior building envelope materials of an office that have been enhanced with a desiccant (for moisture buffering) and a PCM (for temperature buffering). The simulation study reveals that with an appropriate design the regeneration of both PCM and desiccant is possible. In winter, the cooling of the PCM takes place at a faster rate because the outdoor air temperatures are highly subdued during the night. The significantly low temperatures, however, are not favorable for the silica gel regeneration but moisture content of as low as 0.04kg/kg is achieved at the fourth hour of regeneration while beyond this hour the moisture content starts to increase. Temperatures are on a decrease towards minimum as dawn approaches. In summer, it is possible to reach about 0.07kg/kg and at the same time being able to freeze PCM that to dispatch about 470W of cooling power for a 10-hour period.

Keywords: *Regeneration, Phase Change Material, Desiccant, Passive Humidity and Temperature Control*

1. Introduction

Buildings account for a significant percentage of national energy consumption and HVAC systems contribute a significant portion of the buildings' energy demand (Shilei et al., 2007). Research into passive cooling through the application of PCM has received a lot of attention (Shilei et al., 2007, Cabeza et al., 2007, Baetens et al., 2010, 2012, Karim et al., 2014). Key comfort parameters include humidity in addition to the commonly focused on parameter, temperature. While some interior finishes can offer some moisture buffering, it is usually not enough to render the expected comfort. Efforts towards the application of desiccants to interior building envelope materials as a means to enhance the moisture buffering capacity has been limited; one known investigation towards this end is that of Rudd (1994). Potential regeneration for interior surfaces laden with a desiccant at a constant temperature was investigated through spreadsheet simulation (Manyumbu and Martin, 2013). The investigation did not look into the regeneration of the PCM; the assumption was that there is a constant phase change temperature of the PCM always. In the current study, the investigation looks into the feasibility of regenerating both the desiccant as well as PCM.

2. Methods

2.1. The Regeneration Concept

The concept involves a solar channel that has a desiccant bed forming its absorber surface during day-time operation, fig. 1. At night the channel operate as an air dryer, fig. 2, drying ventilation air passing through into the room. While the air is dried in the process, it gets heated up since the process is exothermic (it

doi:10.18086/swc.2015.08.06 Available at http://proceedings.ises.org

release heat of adsorption). The slightly warmer dry air is then responsible for the regeneration of the interior wall surfaces that are laden with a PCM and a desiccant (silica gel).

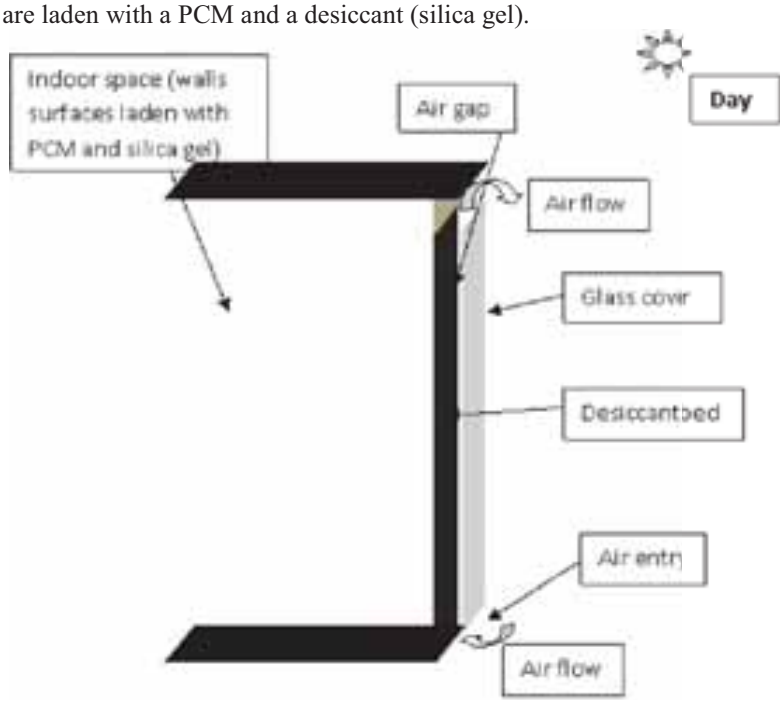

Fig. 1: Proposed Passive Regeneration Strategy for Exterior Desiccant

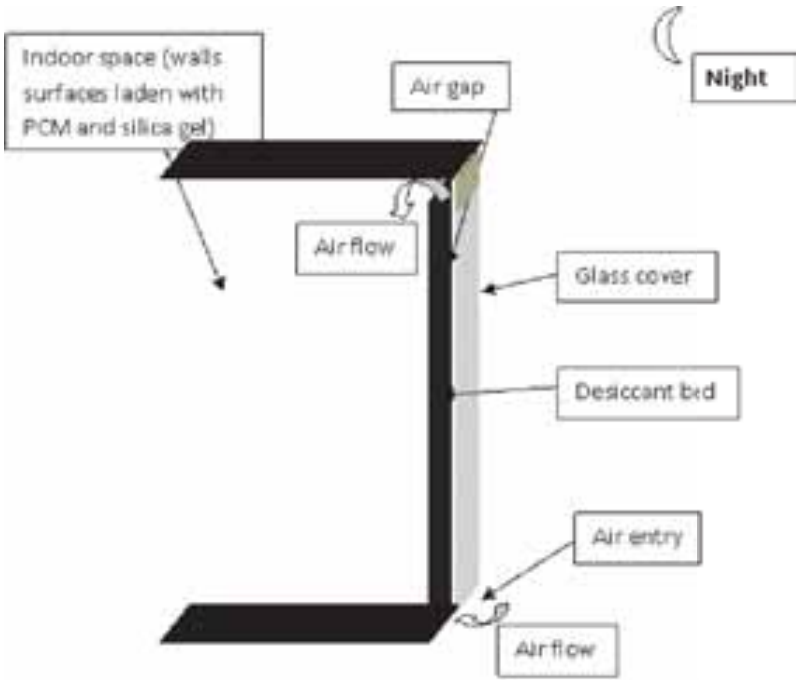

Fig. 2: Proposed Passive Regeneration Strategy for Interior Surfaces

2.2. Passive Ventilation _ Airflow

The air flow rate is based on the simulated results of Manyumbu et al. (2014). A PCM channel is expected to get charged during the day and then provide heating that then result in air flow in the channel at night time. According to Manyumbu et al (2014) the average velocity of air through the channel during charging and discharging is given by eq. 1.

$$u = \left(\frac{C_v g \beta L^2 b Nuk h_g}{24 \mu c_p} \right) \left(\frac{T_{pcm} - T_{in}}{Nuk / b + h_g} \right) \quad \text{(eq. 1)}$$

A ventilation flow rate of circa 1ach was obtained in the simulations and this is used as input in the current study.

2.3. Mathematical Formulations and Assumptions

Mathematical modeling and spreadsheet simulation are employed in this study. The mathematical modeling is based on the mass and energy principles while applying appropriate boundary and initial conditions. A Quasi-steady state and uniform assumptions are used in modeling the external silica bed processes. Parameters of importance are evaluated, these include exit air temperature and humidity. Energy balance equation for the external silica gel bed system during bed regeneration using solar energy including sorption heat can be generally represented by the following eq. 2.

$$T_f = T_a + \frac{\eta I A_c + Q_s}{2 \dot{m}_a c_p} \quad \text{(eq. 2)}$$

In eq.1, T_a is the environmental air temperature, η is the efficiency of converting solar radiation to useful thermal regenerating energy, I is the normal solar radiation received by the channel, c_p is specific heat capacity of air and Q_s is the sorption heat of silica gel. During the night, outdoor air temperature is dried as it passes through the channel whose absorber surface is the silica gel bed. Air conditions (temperature and humidity) are obtained based on the following eq. 3 and eq.4.

$$Q_{sorp,t-1} = m_a C_a \left(T_f - T_a \right) + m C_{sg} \left(T_{sg,t} - T_{sg,t-1} \right) \quad \text{(eq. 3)}$$

$$X_{ao} = \min \left(\left(X_{ai} + \frac{1 \times 10^{-4} m}{\dot{m}_a (1 + X)} \left(X - X_e \right) \right); 0.003732 e^{0.062T} \right) \quad \text{(eq. 4)}$$

Based on the obtained conditions of the bed and air, the humidity of the exit air is then obtained. The drying power of the silica gel bed depends on the initial dry state and this together with the ambient air conditions determines the extent to which the internal surfaces can be regenerated. Air leaving the bed is expected to be drier and warmer than the night outdoor air, but must still be cool enough to effect PCM regeneration. While elevated temperatures are favorable for the desiccant regeneration, PCM regeneration requires low temperatures. This conflict is somehow compensated by the heat of desorption since the process is endothermic.

2.4. External Bed Regeneration and Air Drying

Regeneration of the external silica gel bed is dependent on the condition of the bed, the conditions of the drying air and the amount of air that is responsible for the drying process. One limiting (or boundary) condition is the combination of the drying capacity of the air and the flow rate. If the air gets saturated it means it cannot absorb any more moisture. The amount of moisture removed from the silica gel bed is the function of moisture uptake by the drying air and its flow rate.

2.5. Internal Surface Regeneration

The condition of the air leaving the external silica gel bed determines the rate and extent of regeneration achievable. While it cannot be disputed that heating air improves its drying capacity, it must be noted that air humidity plays a significant role in the process. If air is saturated it does not matter at what temperature it is, it will not take up moisture. Low-temperature regeneration is possible if the regenerating air is pre-dried to low enough humidity levels. According to Ondier et al. (2010), it is clear that the relative humidity plays a significant role in the moisture exchange process. The temperature affects the rate of drying, but the relative humidity determines the extent of drying at the end of the process determined by the equilibrium moisture content. While saturated vapor pressure of moist air exponentially increase with temperature, Buck (1981), which trend is also followed by the reduction in moist air relative humidity, drying can sufficiently be achieved with relative humidity reduction in low temperature situations. Janssen (2011) concluded that the claim that thermal diffusion has a significant impact on vapor transport in porous media was flawed. According to Dalton's Law, moisture flux at a surface is given by;

$$\dot{m}_w = k\left(X_{sat} - X\right) \quad \text{(eq. 5)}$$

In eq.5 k is a constant that characterize the moisture exchange, X_{sat} is the saturation (equilibrium) moisture content while X is the moisture content, the difference of the two becomes the driving force. The surface vapor pressure is dependent on the moisture condition of the silica gel. X_{sat} and X are evaluated at the previous and current time steps respectively.

2.5.1. Silica Gel Regeneration

The relative humidity of the air leaving the external silica gel bed determines the rate and extent of silica gel regeneration achievable. The relative humidity is a function of both temperature and the specific humidity. The external silica gel bed dries the air and at the same time raises its temperature as the process is exothermic. The sorption heat generated during air drying will raise the temperature of the bed as well as that of the air being dried. Both drying and temperature increase lower the relative humidity, and this is desirable for the internal silica gel regeneration. However, it needs to be noted that the increase in temperature is not favorable for PCM regeneration. The specific humidity of air leaving the room is estimated based on eq. 6 below.

$$X_{ao} = \max\left(\left(X_{ai} + \frac{6\times10^{-5} m}{\dot{m}_a\left(1+X\right)}\left(X - X_e\right)\right); 0.0061X^{0.4329}e^{0.062T}\right) \quad \text{(eq. 6)}$$

In eq. 6 X_{ao} is the specific humidity of air leaving the room, X_{ai} is the specific humidity of air entering the room, X is the moisture content of silica gel, X_e is the equilibrium moisture content of silica gel, m mass of silica gel, $\dot{m}_a$ mass flow arte of air and is the temperaure of air in the room. Room air temperature is estimated using eq. 7 below assuming the relationship of a vertical surface and the air interaction with it convectionally (Paul and Alzwayi, 2010).

$$T_{room} = T_{PCM} + 0.38\left(T_{ai} - T_{PCM}\right) \quad \text{(eq. 7)}$$

In eq. 7, T_{room} is room air temperature, T_{PCM} is the PCM laden wall surface temperature and T_{ai} is the temperature of air entering the room from the external silica gel bed.

2.5.2. PCM Regeneration

PCM regeneration is a process of heat removal thereby freezing the PCM. The process, therefore, requires regenerating air that is at a lower temperature than the phase change temperature. The greater the temperature difference between the PCM and the regenerating air the improved the rate of regeneration and the regeneration extend that can then be achieved within the given regeneration period. The increase in air temperature during drying is therefore not desirable for PCM regeneration process. The night outdoor temperatures are highly subdued hence despite the increase of temperature because of the sorption heat during drying, the temperatures are still lower than the phase change temperature of around 26^{o}C. The heat transfer coefficient h at the wall surface is given by eq. 8 below. The heat transfer q is then denoted by the subsequent eq. 9.

$$h = 4.31\Delta T^{0.293} \quad \text{(eq. 8)}$$

$$q = 4.31\Delta T^{1.293} \quad \text{(eq. 9)}$$

PCM conduction has been ignored considering that the plaster/PCM mix will result in thermal bridges that are assumed to render the rate of conduction higher than the convective heat transfer rate. According to Amin et al (2009) for PCM of thickness less than 5mm, the heat flow resistance can be considered to be negligible. The heat transfer between the wall is, therefore, dependent on the difference between the wall and room air temperatures.

3. Results and Discussions

The simulations were carried out using a simple spreadsheet program based on the equations presented in the preceding sections. The results presented here are based on channel depth (air gap) of 0.02m, channel height

and width of 3m with 5kg of silica gel bed. While there are conflicting requirements in terms of conditions favorable for the regeneration of PCM and desiccant a compromise can be reached that result in desirable regeneration for both. The mass of silica gel in the external bed must be simulated in relation to other conditions such as the initial bed temperature and the desired temperature for the dried air meant for internal surfaces regeneration. The complexity of the processes involved requires a careful analysis in order to predict feasibility. The preliminary predicted regeneration conditions are; silica gel dryness of circa 0.07kg/kg and circa120 kg of PCM frozen if the phase change heat of fusion of 200kJ/kg is assumed. During summer the contribution of the desorption heat towards PCM regeneration is around 11% while in winter it is just 4% when the silica gel has reached the lowest best regeneration level.

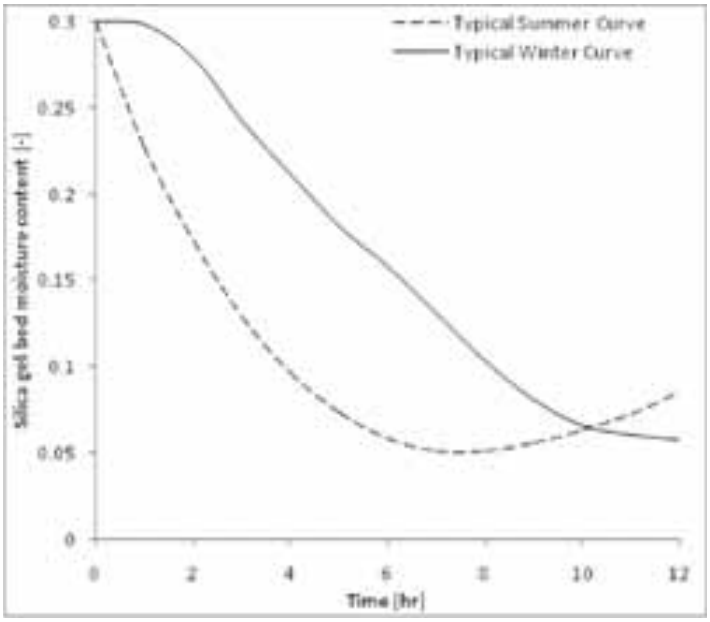

Fig. 3: The extent of external bed regeneration for a west-facing channel (January and June 1999 data)

From fig. 3, it is clear that it is possible to bring down the moisture content of silica gel bed within a solar channel from 0.3kg/kg to about 0.05kg/kg. It must be noted however that during summer, the regenerating process result in an increase of the moisture content of the bed beyond 8hours of regeneration. If the process is allowed to carry on up to 12hours the moisture content of the bed will approach 0.1kg/kg. In winter moisture content of around 0.05kg/kg is reached around the 12th hour of the regeneration process.

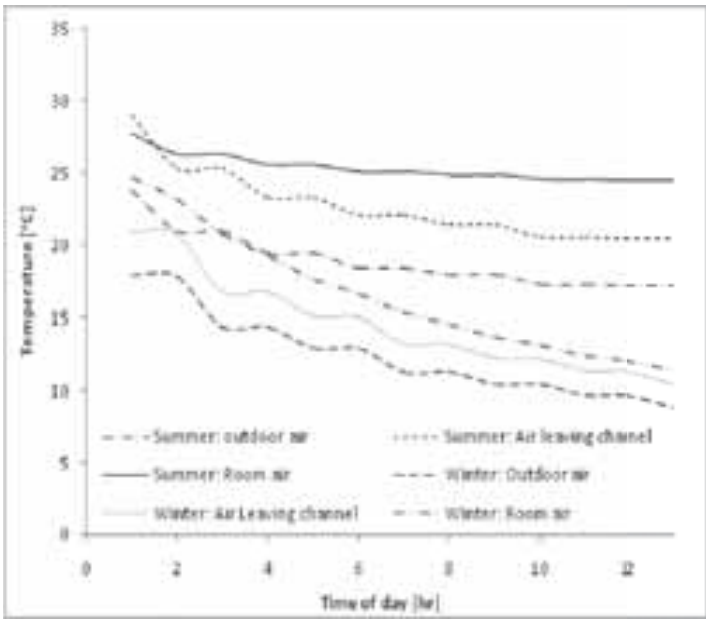

Fig. 4: Air conditions entering and leaving the external silica gel bed (based on January and June 1999 data)

Fig. 4 shows the outdoor temperatures, the simulated temperatures for air leaving the external silica gel bed as well as the room temperatures (estimated from a correlation between PCM surface temperature and natural convective air temperature of Paul and Alzwayi, 2010). The room air temperatures are generally quite low around due to very low outdoor temperatures. Low temperatures coupled with the fact that the drying effect of the external bed becomes less with time, continuing the regenerating process will instead result in an undesirable effect of increasing the moisture content of the interior surfaces. In summer, the effect is less due to generally higher temperatures. It is, therefore, important to have different regenerating time periods for the two seasons.

Fig. 5 below shows the simulated regeneration curves for both silica gel and PCM for the winter season. The moisture content of the silica gel of about 0.08kg/kg is possible. Beyond 6hours of the regeneration process, the moisture content approaches 0.1kg/kg (which is less effective during humidity buffering), hence it becomes advisable to stop the regeneration process since adequate PCM regeneration is already attained. For summer, the regeneration process must go all the stretch to get high PCM regeneration percentage, fig. 6.

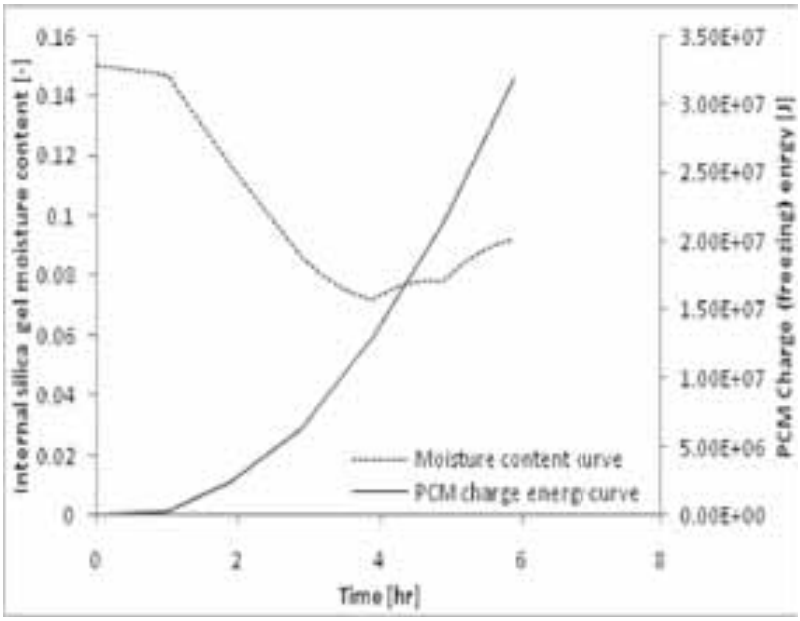

Fig. 5: The extent of internal surfaces regeneration (winter)

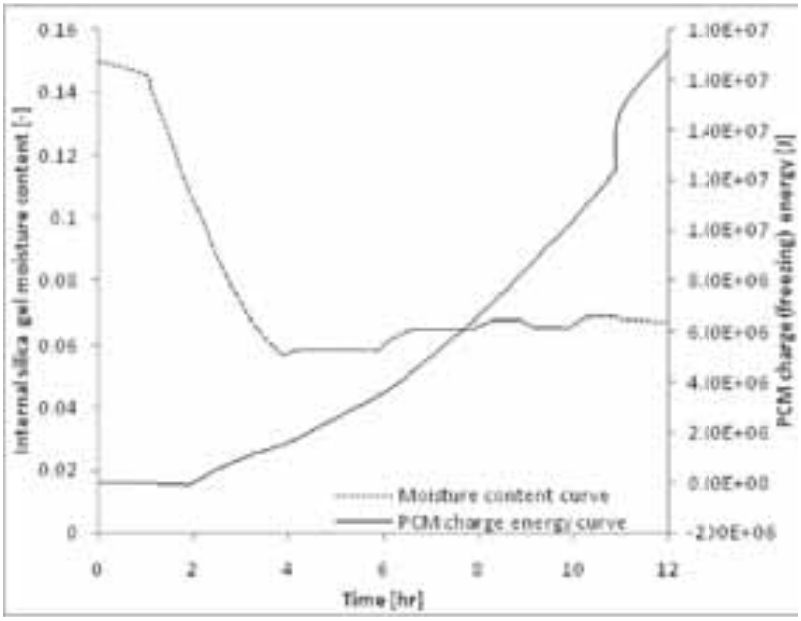

Fig. 6: Internal surface regeneration (summer)

An evaluation of the effectiveness of both the regenerated silica gel and PCM is shown in fig. 7 and fig. 8 below. Fig. 7 is indicating the effectiveness during winter with PCM phase change temperature being set at 27°C with varying mass of silica gel in the interior surfaces. PCM mass is assumed to be matching the available coolness from the regenerating air. A mass of 8kg of silica gel result in the highest performance of humidity buffering effectiveness (considering a 10% relative humidity change) of about 90%, and this correspond to a cooling effectiveness of 122%. This implies that there is possible over cooling of 22%.

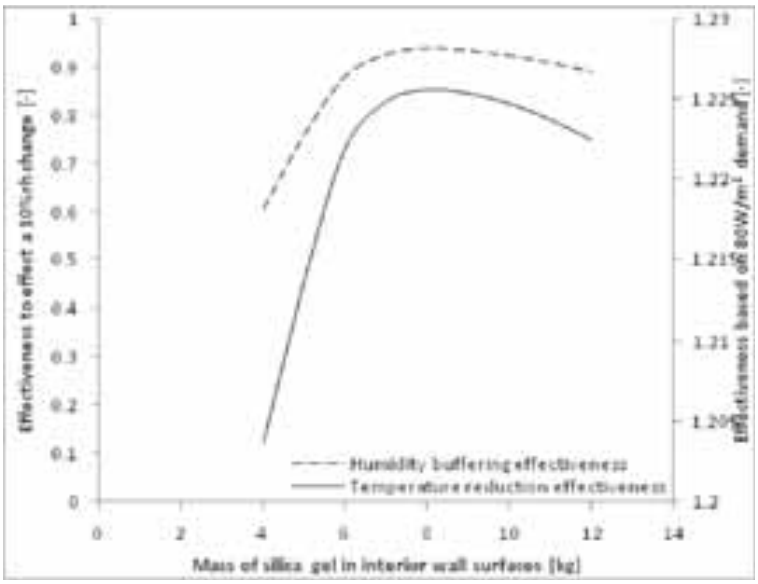

Fig. 7: Variation of the buffering effectiveness with varying silica gel mass within the interior walls for winter season (PCM phase change is set at 27°C), room volume is 27m³

Fig. 8 indicates the estimated humidity and temperature buffering effectiveness of the interior surfaces at varying masses of silica gel within the surfaces for the summer season. Evaluations were carried out at two PCM phase change temperatures of 27°C and 28°C. Improved buffering effectiveness is noted for both humidity and temperature, more so on the later. Elevated PCM phase change temperature results in increased temperature difference and hence improved regeneration. Similarly elevated temperatures have the effect of improving the drying effect of the room air and thus improved regeneration. It is clear that while silica gel regeneration is good, PCM regeneration is somewhat low because of the temperatures of the regenerating air which are fairly high.

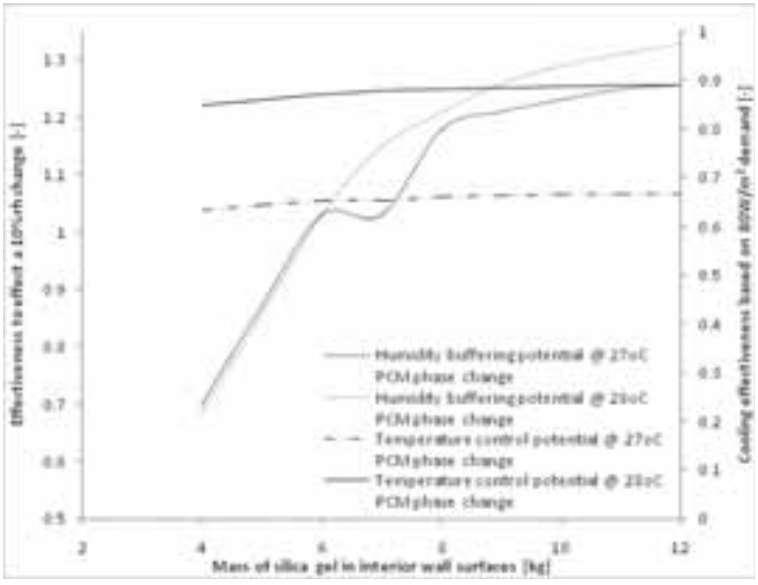

Fig. 8: Variation of the buffering effectiveness with varying silica gel mass within the interior walls for the summer season (PCM phase change is set at 27°C and 28°C), room volume is 27m³

4. Conclusions

The possibility for regenerating both the PCM and Silica Gel for temperature and moisture buffering in an office during daytime occupancy is demonstrated. Using simple mathematical transient models which were implemented in an excel spreadsheet the regeneration of both PCM and Silica Gel in interior wall surfaces could be predicted. Due to high parameter sensitivities and the rudimentary approach applied, it is imperative to conduct an experimental validation in order to firmly establish the feasibility. With further analyses and developments it is possible to have a feasible regeneration strategy that provides adequate humidity and temperature buffering passively for an office space for certain climates.

CONCEPT 22/26, A HIGH PERFORMANCE OFFICE BUILDING WITHOUT ACTIVE HEATING, COOLING AND VENTILATION SYSTEMS

Lars P. Junghans[1]

[1] University of Michigan, Ann Arbor (USA)

Abstract

The introduced building concept goes beyond the conventional high performance building discussion by introducing an office building without any active systems for heating, cooling and ventilation. The building is accomplished in July 2013 and is located in the cold climate of Austria. The intelligent control of the building façade is the heart of the innovative building energy concept. It controls automated natural ventilation openings by using demand optimized automation strategies. Results of the first two years of building operation are demonstrating that the comfort level is acceptable in all seasons and that there are no complaints from beside the occupants. The exemplary realized building project demonstrates how innovative building automation technology can be used to reduce the total energy demand for building operation in a cold climate. Its technology can be used in other climate regions as an innovative hybrid ventilation concept.

Keywords: *Zero Net Energy Building, High Performance Building, Hybrid Ventilation, Solar Architecture*

1. Introduction

The introduced building concept goes beyond the conventional high performance building discussion by introducing an office building without any active systems for heating, cooling and ventilation. The building is accomplished in July 2013 and is located in the cold climate of Austria. The intelligent control of the building façade is the heart of the innovative building energy concept. It controls automated natural ventilation openings by using demand optimized automation strategies. Results of the first two years of building operation are demonstrating that the comfort level is acceptable in all seasons and that there are no complaints from beside the occupants. The exemplary realized building project demonstrates how innovative building automation technology can be used to reduce the total energy demand for building operation in a cold climate. Its technology can be used in other climate regions as an innovative hybrid ventilation concept.

Architects and engineers are in the agreement regarding the goal in net zero energy building design - to improve the building envelope so that the energy demand not met by passive systems could be covered by on-site energy harvesting systems (Torcellini,2006). Most researchers agree that this goals cannot be met in a building without active systems (Sartori,2012,Lu,2015).

Office buildings have relatively high internal heat gains from occupants, electrical appliances, artificial lighting and computer server stations. High internal heat gains result in generally higher room temperatures throughout the year. These higher room temperatures are helpful to reduce the heating energy demand in the winter but can increase the cooling energy demand in the summer. The right balance between heat gain and heat loss must be found to meet the thermal demands in all seasons.

The technical system of the “Concept 22/26” takes a different road then the conventional zero net energy building. An office building without any conventional active systems for heating, cooling and ventilation. The “Concept 2226” was realized in July 2013 and is located in the cold climate of Austria. The name Concept 2226 reflects the technical goal of operating a building in the highest thermal comfort levels at an internal temperature range between 22 and 26 C without any active systems. The thinking behind the Concept 22/26 system departs radically from conventional approaches.

doi:10.18086/swc.2015.08.07 Available at http://proceedings.ises.org

Two methods have been applied to achieve the goal of the Concept 22/26 building. First, the building envelope has been improved so that the internal heat release is able to cover the heating energy demand in the heating season. Then, an innovative building automation system has been developed to control the natural ventilation openings based on the internal carbon dioxide concentration, temperature levels, and occupant demands. The challenge is to ensure comfortable room conditions and indoor air quality without using conventional heating or cooling devices. The room temperature of a building is defined by the factors heat gains, heat loss and internal thermal heat storage effects. To reduce the energy demand for building operation, we must control these three factors in a way that the room temperatures are in or close to the thermal comfort field. In other words, the room temperatures must be relatively low in the summer time and relatively high in the wintertime.

The outline of this paper is as follows: First, the methodology of the technical concept are explained in section 2. Section 3 presents the results of the measurements and the occupant surveys. Section 4 presents the conclusions and implications.

Fig. 1: The realized office building Concept 2226 (Photo: E. Hueber)

2.1. Building Envelope

To meet the goal for the heating season, the "Concept 22/26" building is designred with a building envelope with an extremely low heat transfer and with a high thermal capacity. The huge time delay of the heat flow resulting from the 72 cm external wall construction helps to maintain comfortable conditions even in extreme cold time periods (Tay et al.,1974, Shaviv, 2001). The building has a triple glazing with a U-value of 0.6 W/m^2K and an SHGC value of 0.5. A blower door test was done after completion oft he building. The infiltration was measured to have an average air change rate of 0.08 1/h. The deep structured facade design with a huge dimension of the overhang and wingwall deals as a fixed shading device. No active shading devices is added to the building. The building has an uncovered concrete slab of 20 cm . It is used as an internal thermal mass.

Architects and engineers are in the agreement regarding the goal in net zero energy building design - to improve the building envelope so that the energy demand not met by passive systems could be covered by on-site energy harvesting systems (Torcellini,2006). Most researchers agree that this goals cannot be met in a building without active systems (Sartori,2012,Lu,2015).

2.2. Building Automation

The goal of the building automation design is to operate the natural ventilation openings in a way so that maximal comfort and indoor air quality can be achieved without the use of conventional HVAC units. A balance must be found to (1) ventilate the amount of fresh air that needs to be supplied to achieve indoor air quality requirements, and (2) conserved heat in the room in the heating season. A conflict arises in the transition period and the winter season when natural ventilation is used as the fresh air supply source and the external air temperature is below the minimal comfort indoor air temperature (Heisselberg and Tjelflaat, 2006). Fresh air supply is needed to insure an appropriate indoor air quality by removing internal pollutants like CO_2. However, natural ventilation in the heating season is a heat sink and the time period for natural ventilation should be as short as possible.

To avoid too cool temperatures even in extreme situations, a new building automation system controls natural ventilation openings individually for each room, depending on the user demand and the weather condition. It uses predictive control strategies to use renewable energy sources and sustainable grid energy in a more efficient way. To maximize the performance of the automated natural ventilation openings, a control logic was developed and tested in a simulation model. It uses an on-off controller with death band, DB, (also known as hysteresis controllers) to actuate natural ventilation openings, mechanical ventilation, and heating and cooling

devices. A night ventilation strategy is used to cool the internal thermal mass in the summer time (Haase and Amato, 2009).

The novel hybrid building automation uses automated window openers as the main part of the innovative building energy concept. It controls the natural ventilation openings based on the internal carbon dioxide concentration, temperature levels and the occupant demands to ensure comfortable room conditions in all seasons (El Mankibi and Michel, 2009). The hybrid control logic is extended by the control parameters of external humidity level and artificial lighting for the use in Building 22/26. It ensures that the internal thermal comfort limit for relative humidity will not be exceeded and considers the internal humidity emission of occupants. The control of the artificial lighting ensures that the illuminance value will meet the required threshold value of 500 Lux at occupied working spaces. It will also provide additional internal heat gains in extremely cold situations in the heating season. Figure 2 shows the flow plan of the building automation in a simplified form.

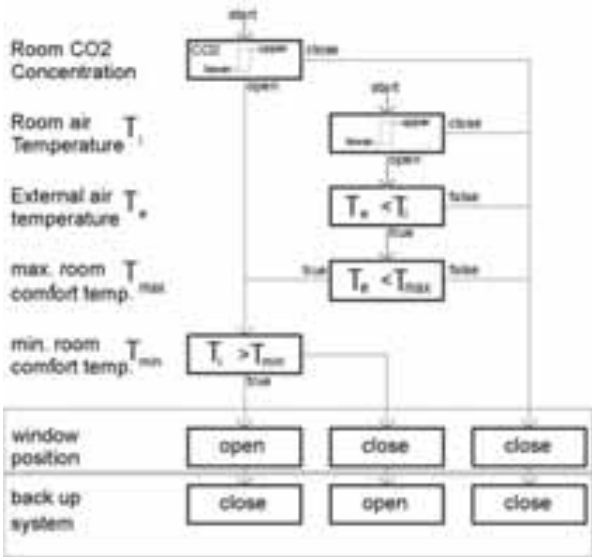

Fig. 2: Simplified illustration of the building automation

A simple predictive control strategy is integrated into the control strategy for the natural ventilation. The goal of the predictive control is to support the novel building automation system in operating the building in the winter or summer "mode". Predictive control is particularly important in the Concept 22/26 to avoid too cold temperatures caused by night ventilation. The operation mode is defined by the external temperature. The system predicts too cold temperatures when the external temperature undergoes a predefined treshold value for a given time period. It is the goal to use an advanced prdictive control logic in the future that involves single zone simulation tools.

The building control concept includes a back up operation to ensure comfortable room conditions in extreme cold weather situations. Additional internal gains are used for back up heating in time periods where extreme cold temperatures are expected in the morning hours. The artificial lighting is going to be used as additional heating to increase the surface temperature of the internal thermal mass. The back up system is controlled by the predictive control logic.

2.3. Measurement Device

Each room is equipped with an air temperature, humidity and a CO_2 concentration sensor. The sensors are located at the inside wall at a height of 1.1 m. The temperature, humidity and CO_2 concentration sensor is a GIRA SK01. The producer provides an accuracy of 0.3 K fort he temperature, 3 % fort he humidity and 50 ppm fort he CO_2 concentration. The room temperature, humidity and CO_2 concentration is measured for each room in the building since August 2013.

2.4. Occupant Survey

An occupant survey is done in March 2015 to validate the occupant satisfaction for the termal comfort and the internal air quality. The survey contains questions about the satisfaction in the winter and summer season in general . It also includes questions about the most extreme time periods in each season.
The questions are similar to the method introduced by Fanger (Fanger), where the occupant has 7 options to

evaluate the condition for much too warm, too warm, slightly warm, OK, slightly cold, too cold and much too cold. For the indoor air quality, the occupants have had five options: good, OK, acceptable, poor, very poor. Additional questions are asking for the gender, the typical type of clothing and the discomfort caused by air drag effects.

2. Results

3.1. Room Temperatures

Results for the first 1.5 years of operation are illustrating that the room temperatures are in the comfort level the winter season in all rooms of the building. The room air temperatures in the north oriented office space are 0.5 K below these of the south oriented office space. The internal surface temperatures are at an average of 22 C.

In the summer, the temperatures are in the comfort level in most of the time. There are a few hours with temperatures above the comfort standard in the west oriented office space. However, the temperatures are in the comfort field for 95% of the summer time.

Fig. 3 and Fig. 4 show the measured temperature in the west oriented office room at the most extreme weather periods in the winter (fig.3) and in the summer (fig.4). The west oriented open space office room has the highest challenge to be operated without mechanical systems because it does not have solar gains in the winter and does have extreme solar gains in the summer time. The room is occupied by maximal 8 people and each working space is equipped with a computer (180-230 W).

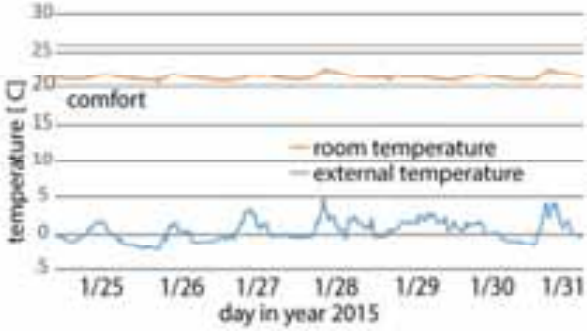

Fig. 3: External and room temperature for the west oriented office space in the coldest week in 2015

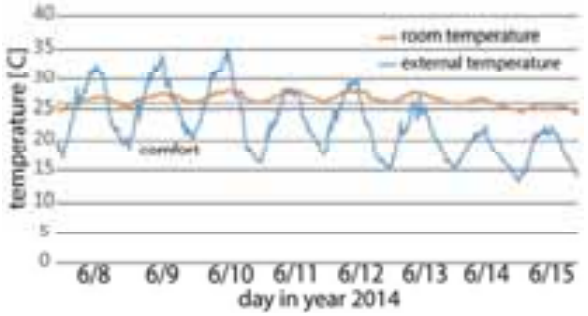

Fig. 4: External and room temperature for the west oriented office space in the warmest week in 2015

For the winter, the internal air temperature drops at time periods where the ventilation openings are open for fresh air supply. However, the temperature never goes below the comfort limit of 20 C.

The measured data for the hottest week in the summer time illustrates that the room temperature rise to as much as 3 K above the temperature goal of 26 C. It also illustrates that the night ventilation effect is not always sufficient to cool the internal thermal mass to an appropriate level (Haase et al.,2009). However, the time period with temperatures above the static comfort limit of 26 C is relatively short. The majority of occupants do accept higher temperatures when the external temperature is high (section 3.4).

3.2. CO_2 Concentration

Figure 5 shows the result of the CO_2 concentration for the west oriented office space. The measurement is done in the same time period in the winter like the temperature measurement in figure 3. It illustrates that the CO_2 concentration does not exceed the limit for the good indoor air quality of 1000 ppm. The automated natural ventilation opening is activated three to four times a day. A comparison between the room temperature (fig. 3) and the CO_2 concentration shows that the room temperature does not drop below the comfort limit at time periods where the ventilation opening are open.

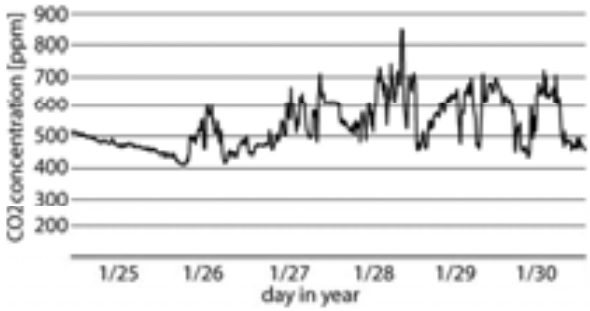

Fig. 5: CO_2 concentration in the west oriented office space in the coldest week in 2015

3.3. Relative Humidity

Figure 6 shows the internal relative humidity in the west oriented office space. The measurements show that the relative humidity is below 40%. It is above the recommended comfort limit of 30% and is therefore sufficient to meet the thermal comfort expectations (ISO norm). The constant relative humidity in the room is partly produced by the occupants. In the summer, the relative humidity is between 40 and 50%. It meets the comfort limit of 60%.

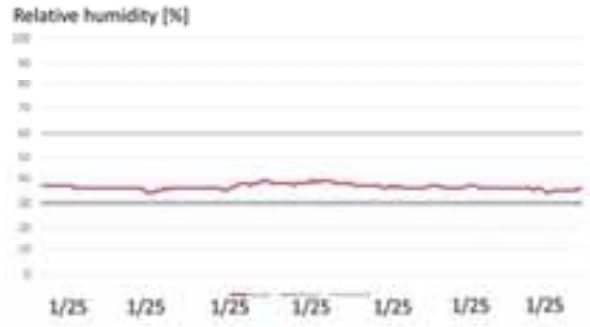

Fig. 6: Relative Humidity in the west oriented office space in the coldest week in 2015

3.4. Occupant Survey

Fig. 7 and fig. 8 shows the results of the occupant survey for the heating and the cooling season. It shows that the majority of the occupants are generally satisfied by the human comfort in both seasons.

Fig. 9 and Fig. 10 show the evaluation of the indoor air quality. The results are demonstrating that the occupants are satisfied with the indoor air quality in all seasons. None of the occupants evaluated the indoor air quality as to be only “acceptable”.

Fig. 11 shows the evaluation of the human comfort at the coldest period. It shows that the majority of the occupants are satisfied with the comfort in the extreme period. One female occupant describes the room temperature as to be too cold. However, there is a larger group of occupants evaluating it as to be slightly too warm.

Fig. 12 shows the comfort evaluation for the warmest time period. Like in the figures before, it illustrates that the majority of the occupants are satisfied with the thermal comfort in the warmest season. The diagram shows that there is a group of four occupants which are evaluating the thermal comfort as to be too warm. These four occupants are located in the west oriented office space.

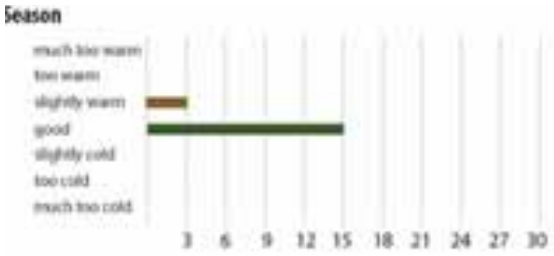

Fig. 7: Results of the occupant survey for the winter

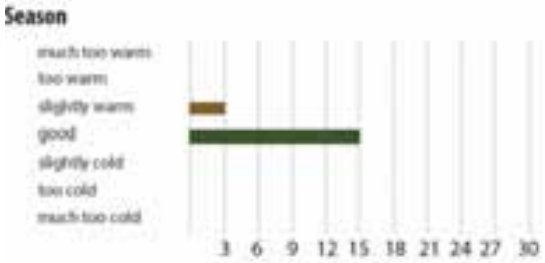

Fig. 8: Results of the occupant survey for the summer

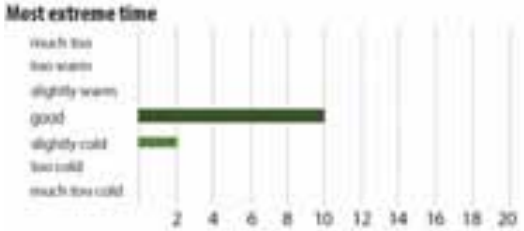

Fig. 9: Results of the occupant survey for the coldest time period in winter 2015

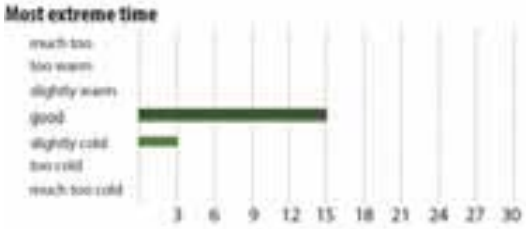

Fig. 10: Results of the occupant survey for the warmest time period in summer 2015

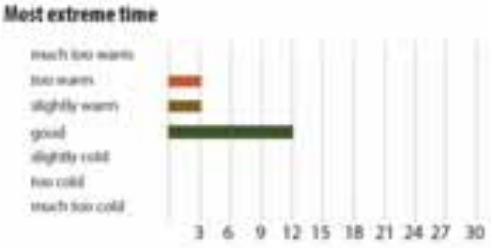

Fig. 11: Results of the occupant survey for the indoor air quality for the coldest time period in winter 2015

Fig. 12: Results of the occupant survey for the indoor air quality for the coldest time period in winter 2015

Notice: the occupants in the west oriented office space are mainly complaining about the temperatures with overheating in the time period from June 11 to June 13. The room temperatures in this time periods are above the comfort field even when the external temperature is relatively low. This illustrates that the adaptive comfort model introduced by Brager and DeDear (2008) is applicable in the controlled natural ventilation environment in this study.

None of the occupants have had any discomfort caused by the cold air drag effect at the ventilation openings or at the large windows. The occupants do not use additional local heating or cooling devices like resistance heaters to control the temperatures at the working space.

3.5. Indoor Air Quality

The Indoor air quality have been evaluated for the building at operation by a professional company. The concentration of the most critical components and pollutants have been measured. Also the VOC and germ concentration is measured. Their results are showing that the natural ventilation provides excellent indoor air quality conditions even in time periods where the ventilation openings are closed. Further tests will follow in the future. The results are showing that the pollution concentration is comparable like for a building with mechanical ventilation (Chou et al.2006).

3.6. Energy Demand

The total use energy demand for building operation including artificial lighting and electrical devices is measured for the Concept 22/26 for all time periods after completion of the project. The average specific use energy demand of the building is 38 kWh/m^2 year (measurement time period 9/1/2013 to 8/30/2014). The office space has a specific use energy demand of 42 kWh/m^2. The owner of the building operates the building with electricity that is produced with renewable energy sources (photovoltaic, hydropower). This type of primary energy source ensures that the building can be operated almost without greenhouse gas emission. The data shows that the use energy demand of the Concept 22/26 is 30% below comparable high performance buildings.

3.7. Improvements in Building Operation

Like every prototype, minor improvements needed to be done on the building control logic. (1) It was planned to operate only two ventilation openings per room to provide night ventilation. The operation logic have been changed to have 5 ventilation openings available for the night ventilation. (2) Some of the windows are now equipped with curtains to avoid radiation asymmetry in the summer time.

4. Conclusion

The measurement results for the Concept 22/26 building demonstrates that a building can be operated without conventional heating, cooling and ventilation systems in a cold climate when innovative building automation technology is paired with a well designed building envelope. It also illustrates that the demand controlled natural ventilation technology can significantly reduce the overall energy demand of an office building.

As indicated in the results section, measured room temperatures have been shown to be at least 21 C for all occupied hours in the year and in all rooms of the building. A small number of hours with overheating problems have been counted in the west oriented office space. However, the results demonstrate that the number of hours with overheating problems never exceed 3% of the total operation time of the building. Furthermore, the results of the occupant survey are illustrate that the higher temperatures are accepted when the external temperature is high.

In general, the automation concept of the Concept 22/26 is very effective in a building with hybrid ventilation to increase the number of hours where no mechanical heating or cooling is needed. The results are promising to be effective as a natural ventilation control in a hybrid ventilation system in even more challenging climate regions.

The results of the occupant survey illustrate that the controlled natural ventilation concept provides comfortable conditions for the majority of occupants in most of the operation time. It shows also that there is a minority of occupants, which are not satisfied in most extreme time periods with very cold or hot weather. Localized active solutions might be a good solution for these very short time periods.

On the basis of these results, we believe that the Concept 22/26 can be effectively applied into hybrid-ventilated office buildings suiltable for a wide range of climate regions.

Appendix: **UNITS AND SYMBOLS IN SOLAR ENERGY**

In 1977, a committee of ISES developed a set of recommended nomenclature for papers appearing in *Solar Energy.* This is a condensed and revised version

Volume
Volumes are measured in m^3 or litres (1 litre = 10^{-3} m^3). Abbreviations should not be used for the litre.

Flow

Temperature
The S.I. unit is the degree Kelvin (K). However, it is also permissible to express temperatures in the degree Celsius (°C). Temperature differences are best expressed in Kelvin (K).
When compound units involving temperature are used, they should be expressed in terms of Kelvin, e.g. specific heat J kg^{-1} K^{-1}.

2. NOMENCLATURE AND SYMBOLS

Tables 1-5 list recommended symbols for physical quantities. Obviously, historical usage is of considerable importance in the choice of names and symbols and attempts have been made to reflect this fact in the tables. But conflicts do arise between lists that are derived from different disciplines. Generally, a firm recommendation has been made for each quantity, except for radiation where two options are given in Table 5.
In the recommendations for *material properties* (see Table 1), the emission, absorption, reflection, and transmission of radiation by materials have been described in terms of quantities with suffixes 'ance' rather than 'ivity', which is also sometimes used, depending on the discipline. It is recommended that the suffix 'ance' be used for the following four quantities:

$$\text{emittance} \varepsilon = \frac{E}{E_b}\left(or \frac{M_s}{M_{sb}} \right)$$

$$\text{absorptance } \alpha = \frac{\Phi}{\Phi_i}$$

$$\text{reflectance } \rho = \frac{\Phi}{\Phi_i}$$

$$\text{transmittance } \tau = \frac{\Phi}{\Phi_i}$$

where E and ϕ is the radiant flux density that is involved in the particular process. The double use of α for both absorptance and thermal diffusivity is usual, as is the double use of ρ for both reflectance and density. Neither double use should give much concern in practice.

Table 1: Recommended symbols for materials properties

Retrofitting Electrically Heated Single-Family Houses to Net-Zero Energy

Ricardo Bernardo[1], Henrik Davidsson[1]

[1] Division of Energy and Building Design, Lund University, Lund (Sweden)

Abstract

Only in Sweden, single-family houses account for approximately 30% of energy use in all buildings and a large part uses only electricity for heating. The potential for improvements on energy efficiency in these houses is large. This study theoretically investigates retrofitting of electrically heated Swedish single-family houses by using an air-source heat pump for both space heating and domestic hot water. Combination with solar collectors and solar cells were also theoretically investigated. Since this solution is an add-on to the existing heating system the investment cost can be reduced compared with a new heat pump installation for domestic hot water. The total annual energy reduction for domestic hot water and space heating in a Swedish single-family house when using the combined heat pump and solar thermal collectors was estimated to be roughly 70%. The remaining electricity demand for electric appliances can be covered by approximately 10 kWp solar cells therefore reaching net-zero energy level.

Keywords: *retrofit, net-zero energy houses, solar thermal, heat pump, single-family houses.*

1. Introduction (SWC_Heading1)

In order to meet the current energy and climate targets for 2020 and 2050 in EU countries, the existing building stock needs to be addressed. A construction boom was experienced across Europe after the Second World War and there is now a need for renovation. Since such houses have high levels of energy consumption, this is a good opportunity to also perform an energy renovation. For example in Sweden, single-family houses account for about 30% of energy use in all buildings and a large part, around 500 000, uses only electricity for heating (Swedish Energy Agency, 2013). The potential for improvements on energy efficiency in these houses is large. A typical Swedish single-family house uses in average 12200 kWh/y for space heating, 4500 kWh/y for domestic hot water (DHW) and 5000 kWh for household electricity (Swedish Energy Agency, 2015). It is common to upgrade the space heating system, for example by installing an air-to-air heat pump. Commonly, this decreases the space heating demand to levels close to the energy used for domestic hot water, shown later in Fig. 3. However, simple and cost-effective renovation solutions for reducing the energy consumption for domestic hot water production are not wide spread today.

This study investigates theoretically the retrofitting of electrically heated Swedish single-family houses by using an air-source heat pump for both space heating and domestic hot water. The heat pump not only heats the indoor air but is also connected directly to the existing hot water heater (boiler). The investigation addresses the system configuration, comfort level, control strategies and energy savings. Combination with solar collectors and solar cells were also theoretically investigated. Since this solution is an add-on to the existing heating system no large changes are needed which has the potential to significantly reduce the investment cost in comparison with a new heat pump installation for domestic hot water.

At this stage the investigation excludes some of the practical challenges and assumes that existing air heat pumps reach desirable temperatures for domestic hot water. The focus is instead on evaluating whether a conventional air heat pump can alternate on providing heat for space heating and domestic hot water and still reach comfort on both. This is the ground for any further investigation. A short discussion on possible practical problems and future work is addressed under the discussion chapter.

2. Method

A model was built in TRNSYS in order to theoretically assess the potential for energy savings and possible challenges of using an air-source heat pump for both space heating and domestic hot water in a Swedish single-family house. The goal is to model a hybrid heat pump that alternates between providing lower temperature heat to space heating and higher temperature heat for domestic hot water. This thought to achieve high system efficiency. A sketch of the system is shown below in Fig. 1.

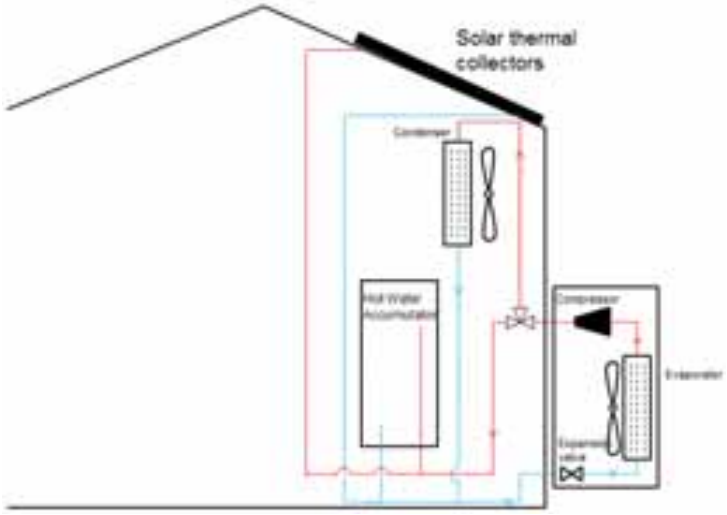

Fig. 1: Simplified sketch of the energy flow in the modelled system.

Since there is no standard TRNSYS model describing such a hybrid heat pump, the model was built by using two separate heat pump models: one air-to-air heat pump, Type922 Tess library (2015), and one air-to-water heat pump, Type941 Tess library (2015). For this purpose it was assumed that each of these heat pumps are common heat pumps in today's market and that they have conventional performance parameters such as described in the respective technical data sheets. In reality, a hybrid heat pump that delivers heat for both DHW and space heating at different temperatures may have different parameters and this is therefore a limitation of the investigation.

The operation of these two heat pumps was set in order to only allow one of them working at the time since the goal is to model one single heat pump. In this case, the air-to-water heat pump for DHW was prioritized. Hence, both the DHW storage and the house will work as heat "batteries" with only one heat source. These two heat "batteries" are charged alternately at different temperature levels and therefore at different efficiencies. In case there is deficit energy for space heating the existing direct electric heating was also modelled and is used as a backup heater. The heat pump starts at 20 °C and the direct electric heating at 18 °C. The solar collectors are used to preheat the incoming cold water to the air-to-water heat pump. When possible, during the summer period, the solar collectors alone will provide heat to DHW.

The model was used to estimate the comfort level, control strategies and energy performance. An overview of the modeled system in TRNSYS, the used components and the most relevant assumed parameters are illustrated in Fig. 2 and Tab. 1.

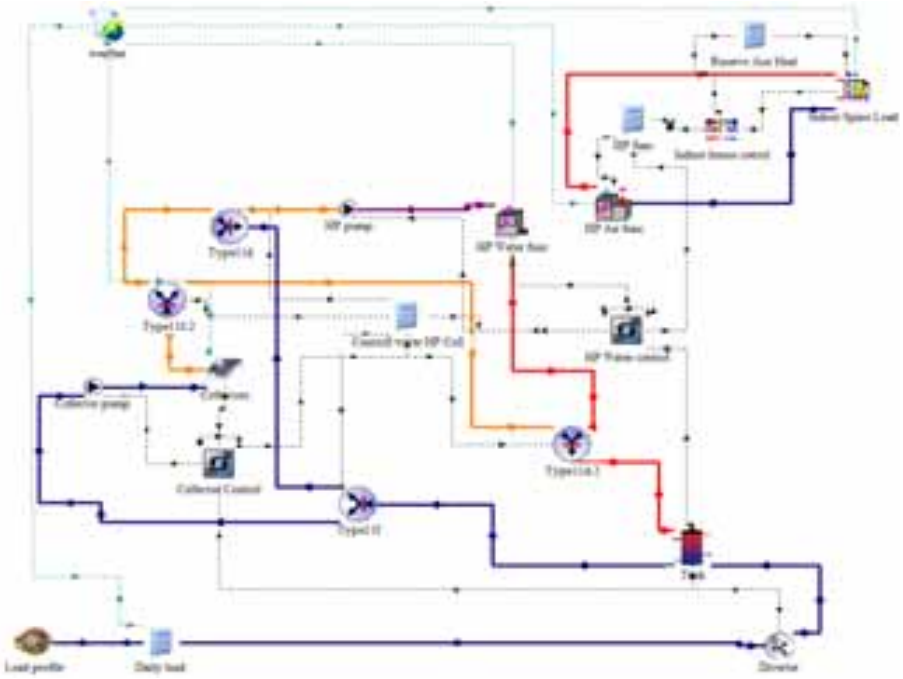

Fig. 2: Overview of the TRNSYS model.

Tab. 1: Parameters and TRNSYS types used in the simulation tool.

Type 12, house	The building has an average UA-value of 142 W/K. The internal gains were assumed to be approximately 900 W. Temperature setting 20 °C for the heat pump and 18 °C for the direct electric heating with a power of 7 kW.
Type 15, weather data	The weather data is data from Stockholm, Sweden.
Type922, air-to-air heat pump	The inputs are based in the heat pump model Thermia Aura (Thermia, 2015). This heat pump can work at two power levels: rated heating capacity 1,4-6 kW and rated heating power 0,3-1,7 kW.
Type941, air-to-water heat pump	The inputs are based in the heat pump model Nibe F2030 (NIBE, 2015) with a rated heating capacity 7 kW and rated heating power 1,8 kW
Type 1, flat-plate solar collectors	Collector area 6 m^2, zero-loss efficiency 0,8, efficiency slope 3,6 $W/m^2/K$, efficiency curvature 0,05 $W/m^2/K^2$ and first order incidence angle modifier 0,2.
Type 4, storage tank	Tank volume 0,3 m^3, 8 nodes, height of nodes 0,2m, U-value 1,15 $W/m^2/K$. No auxiliary heater is used, all the heat is provided by the air-to-water heat pump. The connections are fixed and placed at the top and bottom of the storage.

3. Results

The simulation results show that, in total, the heating energy (DHW plus space heating) was reduced from approximately 16760 kWh/y to 5170 kWh/y (69% decrease) without solar collectors and to 4790 kWh/y (71% decrease) with solar collectors (Tab. 2 and Fig. 3). The annual energy need for space heating was reduced from 12280 kWh/y to 4178 kWh/y. The heat pump in combination with solar collectors reduced the annual energy need for domestic hot water from 4480 kWh/y to 620 kWh/y.

Tab. 2: Energy use for DHW and space heating before and after the heat pump installation; with and without solar collectors.

	Before the heat pump installation (kWh/y)	After the heat pump installation without collectors (kWh/y)	After the heat pump installation with collectors (kWh/y)
Space heating	12280	4178	4178
DHW	4475	989	616
TOTAL	16755	5167	4794

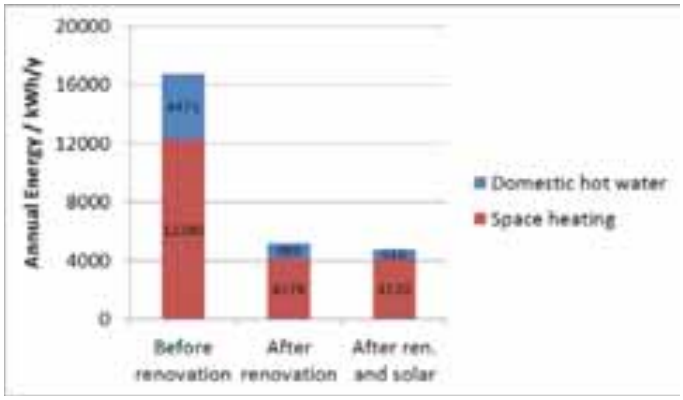

Fig. 3: Annual energy use before and after the heat pump installation, with and without solar collectors.

During the coldest winter months the heat pump was in fact not sufficient to provide all the required heat for space heating in order to keep the indoor temperature above 18 °C. To keep the indoor temperature above 18 °C during this period the existing direct electric heating system was used as an auxiliary heater. This situation corresponds to reality where standard air-to-air heat pumps also need support from a direct electric heater during the peak of the winter in Sweden. The comfort level reach for the indoor ambient and DHW is illustrated in Fig. 4.

Fig. 5 illustrates the energy load and production. In Tab. 3 the space heating energy is divided in two parts: the part covered by the heat pump (3667 kWh/y) and the remaining part covered by the existing direct electric heating system (511 kWh/y). If one excludes the direct electric heating and the use of solar collectors, the SCOP of the air-to-air heat pump is equal to 3,2 ($\frac{space\ heating\ load - direct\ electric\ heating}{heat\ pump\ energy\ for\ space\ heating - without\ direct\ electric\ heating} = \frac{12280-511}{4178-511}$). The SCOP of the air-to-water heat pump without solar collectors is equal to 4,5 ($\frac{DHW\ load}{heat\ pump\ energy\ for\ DHW}$).

It is roughly estimated that 10 kWp solar cells (67 m^2 solar photovoltaic modules at 15% efficiency) should be installed in order to cover the total annual electricity demand of roughly 5000 kWh/y for space heating and domestic hot water and additionally 5000 kWh that are estimated to be the average use of household electricity. Hence, net-zero energy level can be achieved.

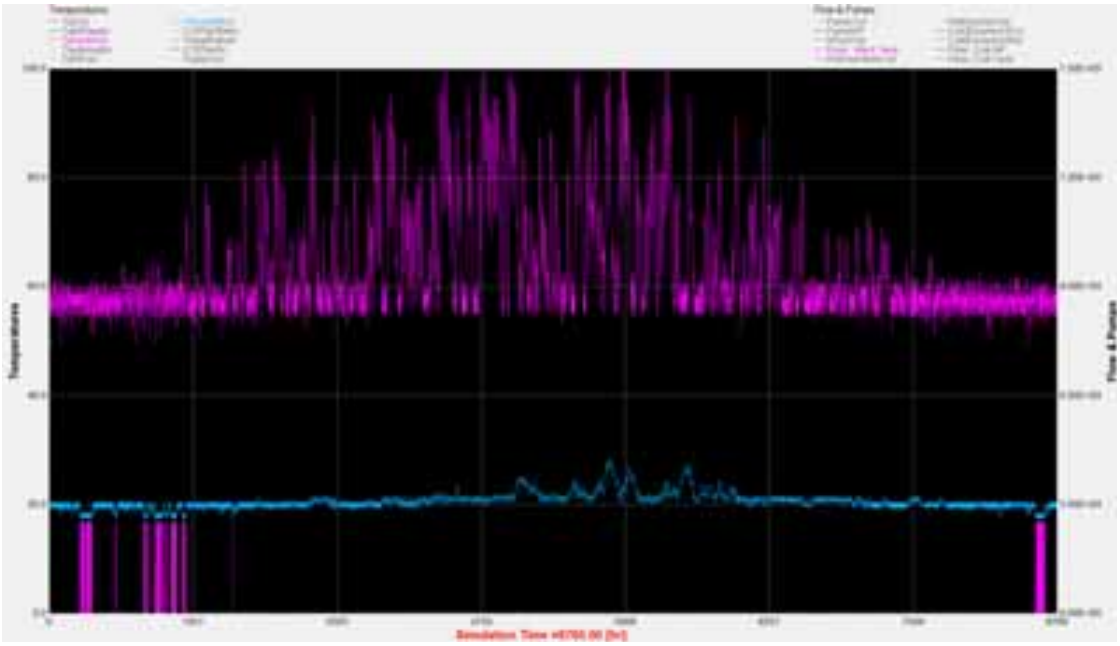

Fig. 4: Comfort analysis with heat pump and solar collectors: the upper curve shows the temperature at the top of the storage tank; the middle curve shows the indoor temperature of the house and the lower curve shows the use of the auxiliary direct electric heating system.

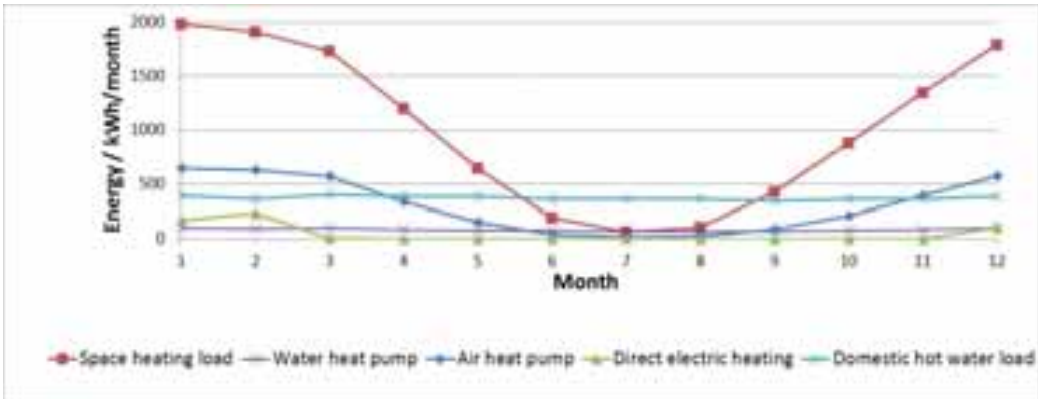

Fig. 5: Estimated monthly energy load and production.

Tab. 3: Space heating energy consumption divided in the part that is covered by the heat pump and the remaining covered by the existing direct electric heating system.

	Heat pump only used for space heating (kWh/y)	Heat pump also used for DHW (kWh/y)	Variation (kWh/y)	Relative variation (%)
Air heat pump	3740	3667	-73	-2
Direct electric heating	361	511	+150	+42
TOTAL space heating	4101	4178	+77	+2

4. Discussion

One practical challenge in retrofitting existing hot water storages is the fact that, in reality, these lack available connections to other heat sources such has heat pumps or solar collectors. This has been previously investigated and shown that the two available connections can be also used by for example solar collectors without a decrease in the system performance (Bernardo, 2013). This was kept outside of the scope of this

study.

The SCOP of the air-to-water heat pump is higher than expected and probably overestimated, especially when compared with the SCOP of the air-to-air heat pump that works at a lower temperature. The reason for this is the fact that the model did not include COP data for the desired temperature intervals and this was therefore extrapolated and probably overestimated. Improvements regarding this data are needed in future studies. This overestimation is thought to influence mostly the level of energy savings for DHW while the other results are thought not to change significantly.

The fact that the air-to-air heat pump is also used to provide energy for DHW showed almost no change on the annual energy spend for space heating. However, the contribution of the heat pump for space heating was decreased by 2% (73 kWh/y) which was compensated by a 42% increase (150 kWh/y) of the direct electric heating in the peak of the winter. This decrease in performance is largely compensated by energy savings on the DHW of approximately 3500 kWh/y.

The solar collector add-on does not provide a significant energy reduction since most of the energy is already saved by the heat pump. Since the SCOP of the air-to-water heat pump is 4,5, in order to save 1 kWh electricity to the heat pump the collectors need to produce in average 4,5 kWh of heat. Also, the existing hot water storage presents low levels of temperature stratification which also contributes significantly to the low output of the solar collectors.

Existing air-to-air heat pumps may not be able to reach the desired temperature for domestic hot water heating (approximately 55-60°C). This is a crucial limitation for the retrofitting and that needs further investigation. One possible solution is to install an extra small compressor as shown on the left hand-side in Fig. 6. Nonetheless, retrofitting can be complicated due to several factors such as complicated installation, different type of heat pump configurations in the market, problems with warrantee and insurances, low profitability, etc. Therefore, it might be more realistic to consider this concept for new heat pump installations instead. In that case a heat exchanger for the DHW can be installed as one of the multi-splits units as shown in the right-hand side in Fig. 6. The main competitive advantage of this new hybrid heat pump compared with a regular air-to-air heat pump is the large energy savings for DHW production. Depending on the eventual extra costs of using a stronger compressor that reaches 55-60°C, the extra investment may be compensated by such large energy savings. This needs further investigation that also includes costs.

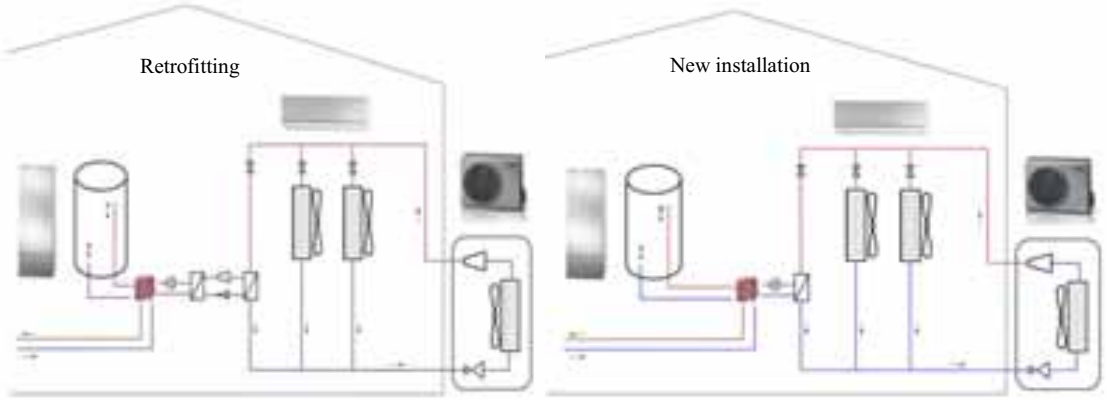

Fig. 6: Sketch of the hybrid heat pump for retrofitting (left-hand side) and new installations (right-hand side).

5. Conclusion

A model was built for assessing energy savings of retrofitting a common air-to-air heat pump for providing heat not only for space heating but also for domestic hot water (DHW). The heat pump was controlled in such a way to alternate the heat deliver between DHW and space heating at different temperatures and

therefore at different efficiencies. The DHW production was prioritized. Combining solar collectors into the system was also investigated.

The simulation results show that the total annual heating demand (DHW plus space heating) was reduced from 16755 kWh/y to 5167 kWh/y (69% decrease) without solar collectors and 4794 kWh/y (71% decrease) with 6 m^2 solar collectors. The annual energy need for space heating was reduced from 12280 kWh/y to 4180 kWh/y while the annual energy need for domestic hot water was reduced from 4480 kWh/y to 620 kWh/y. The remaining electricity demand for heating and electric appliances can be covered by approximately 10 kWp solar cells and therefore reaching net-zero energy level. The energy provided by 6 m^2 solar collectors was only 370 kWh/y which confirms that this is not profitable combination. This is explained by the combination with a high efficient heat pump and due to low levels of temperature stratification in the hot water storage.

The comfort analysis showed that in order to prevent the indoor temperature to fall below 18 °C in the peak of the Swedish winter the existing direct electric heating system had to use around 510 kWh/y. The rest was provided by the heat pump. The temperature in the hot water storage did not drop below 50 °C indicating a good comfort level.

Results indicate that this concept has potential for large energy savings but the implementation in retrofitting (and upgrading) existing air-to-air heat pumps can be significantly complicated and compromise therefore the cost-efficiency. It seems more realistic to apply the same concept at new installations where the heat pump can be chosen from the beginning to reach higher temperatures. Such extra cost needs to be compensated by the energy savings for domestic hot water production.

Design Proposal for Low Energy Buildings using Energy Simulation Program

Goopyo Hong[1], Hye Jin Kim[1] and Byungseon Sean Kim[1]

[1] Yonsei University, Seoul (Korea)

Abstract

The use of energy performance software will become a necessity in the early design stages to quantitatively verify the energy consumption of buildings. In this research, a simulation tool was used in designing a zero energy senior community center for an apartment complex. After comparing and evaluating case 1 (code) and case 2 (current design trend), each load element was analyzed to derive the low energy design for case 3. For case 3, the thermal performance of the insulation and windows as well as the lighting efficiency improved. In addition, photovoltaic solar power was considered as the renewable energy. For heating, the percentage of heat loss from opaque surfaces is 52%, while that from infiltration is 31% and that from window systems is 17%, demonstrating that the envelope has a significant effect on heat loss. For cooling, the percentage of heat gain due to window systems is 43%, while that due to lighting is 33%, that due to people is 17%, and that due to equipment is 7%, demonstrating that the internal and solar heat gain account for most of the energy loss, while the envelope has an insignificant effect. Photovoltaic solar panels were included as a source of renewable energy for the low energy design of case 3 to offset the heating and cooling energy consumption. It was found that using renewable energy would result in an energy surplus of 3,438kWh/year.

Keywords: *energy performance software, early design stage, zero energy design, renewable energy, PV*

1. Introduction

Buildings with improved energy consumption in Korea are being designed and constructed according to the Building Energy Conservation Design Standards (BECDS). The BECDS is categorized into sectors including construction, machinery, electricity, and renewable energy, and is applied to insulation, windows, high-efficiency mechanical and electric equipment, and renewable energy systems. Although the use of these materials is regarded as energy saving, it is difficult to quantify the amount of energy consumption. Thus, the standards are prescriptive requirements, not performance requirements. Also, the Korean government announced its goal to achieve the passive house standard by 2017 and zero energy standard by 2025. Likewise, Europe's target year for achieving zero energy houses is 2020 and that of the U.S. is 2025. In the future, building regulations will become more stringent in order to achieve low energy or zero energy buildings, and this will be a challenge for designers. As a result, architectural designers have focused on building geometry and envelope when designing low energy or zero energy buildings (Shady Attia et al., 2012).

In practice, a high level of expertise is required to apply passive and active techniques in the early design stages, since verifying energy performance is difficult, complex, and time consuming. The use of energy performance software will become a necessity in the early design stages of buildings in order to quantitatively verify energy consumption. In this research, EnergyPlus (Version 8.2) was used in designing a zero energy senior community center for an apartment complex. The energy consumption for designs adhering to the Korean government regulations and current design trends was verified. The purpose of this research is to analyze the technical elements used and determine the effects of energy demand. The findings

doi:10.18086/swc.2015.08.09 Available at http://proceedings.ises.org

could be considered and applied to future designs for low energy buildings.

2. Methods

Utilizing the senior community center as the subject building, EnergyPlus was used in this research to analyze and compare case 1 (code), which complied with the building code, and case 2 (design), which followed the current design trend. The elements affecting energy in case 1 were verified.

After evaluating and comparing case 1 and case 2, each load element was analyzed to derive the low energy design for case 3. Case 3 showed improved thermal performance of the insulation and windows. The only renewable energy source considered was solar power generation.

2.1 Case study

The subject building for this research is the senior community center within an apartment complex. Figure 1 shows the floor plan of the community center, with the living room, grandfather's room (Room 1), grandmother's room (Room 2), restrooms, kitchen, and storage rooms.

The heating system is floor heating via district heating. The cooling system consists of four air conditioners fitted to the ceilings in the living room, kitchen, and Rooms 1 and 2.

2.2 Energy Simulation Program - EnergyPlus

Developed by the U.S. Department of Energy, EnergyPlus is a program that uses climatological data for load calculation and analysis of energy consumption characteristics. It combines the advantages of DOE-2 and BLAST and has several new functions. It is a simulation to have input and output text files. Users can set a

time-step to calculate the loads of a building. EnergyPlus then calculates the heating and cooling system and the requirements of the plant, and predicts the accurate space temperature and humidity as well as occupant comfort (Crawley et al. 2008).

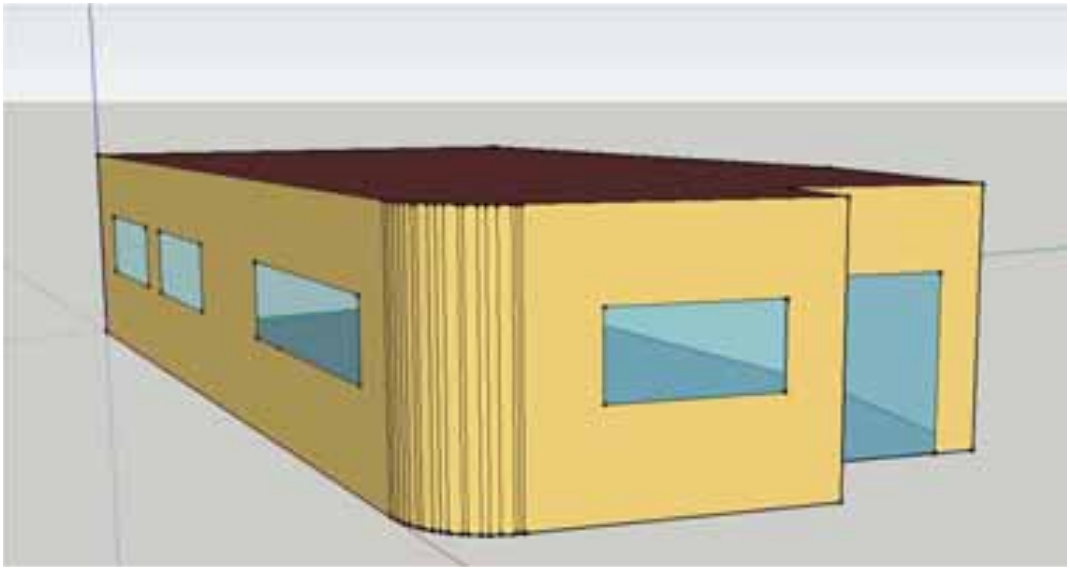

Fig. 2: Modelling using Sketchup

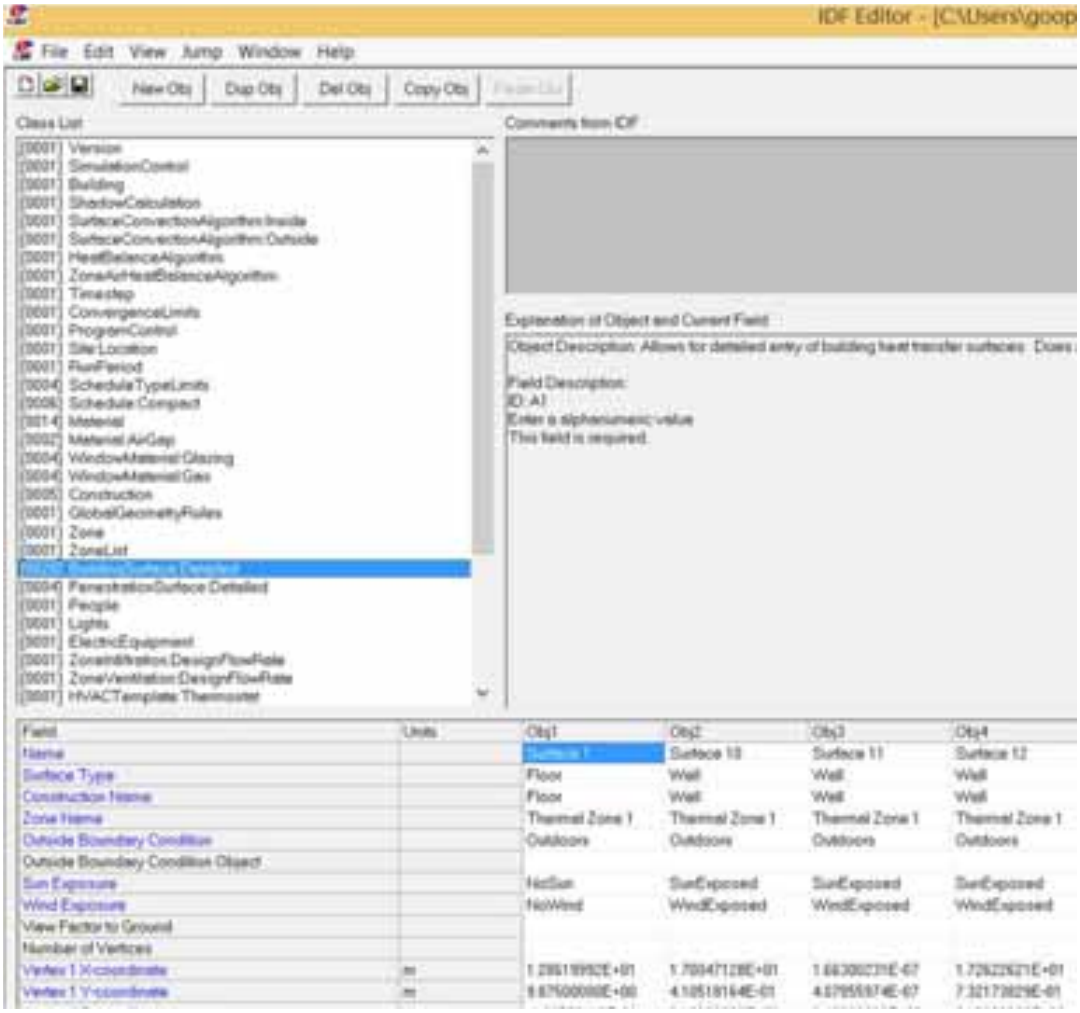

Fig. 3: Image of the EnergyPlus Input data

2.3 Model Conditions

Sketchup was used to model the subject building, as shown in Figure 2, and the model's data was entered into EnergyPlus. Figure 3 shows the values entered into the modeling wall of EnergyPlus. One zone was designated for the heating and cooling for the entire senior community center.

Table 1 shows the necessary elements for the building energy analysis of case 1 and case 2. The BECDS values from the middle region of Korea are shown in case 1. The data for case 2 reflect the values that are commonly used during construction. For the architectural sector, the thermal conductance of the roof, walls, floor, and window systems were calculated and entered. This was then repeated for the lighting, ventilation devices, and household appliances of the electrical sector. For the equipment sector, the district heating system installed was assumed to consist of an individual heating system, while the cooling system was assumed to consist of four air conditioners, each installed in the four main rooms. The number of occupants was 17, while the set point temperature for heating and cooling was set to 23℃ and 26℃, respectively. The amount of infiltration was presumed to be 0.1 h-1(ACH) and the ventilation was designed to be 0.5 h-1 (ACH).

Tab. 1: Condition of the case 1 & case 2

Contents		Case 1	Case 2
U-value (W/㎡ K)	Roof	0.29	0.23
	Wall	0.48	0.32
	Floor	0.34	0.29
	Window	2.70 (SHGC : 0.75)	1.76 (SHGC : 0.52)
	Door	3.70	3.26
Electric	Light	10W/㎡	
	Ventilation	0.5 ACH	
	Misc.	Equipment-television, refrigerator	
System	Boiler	Efficiency : 90%	
	System Air Condition	Capacity : 23kW	
Etc.	Occupants	17 people (0.1 person / ㎡)	
	Infiltration	0.1 ACH	

2.4 Schedule

A major factor in determining the energy consumption of a building is scheduling. It is important to set a reasonable schedule that considers occupant time, lighting, running time of household electric appliances, and the hours of operation of the building's systems for weekdays, weekends, and holidays. The time period set for this research was one year, starting on January 1st and ending on December 31st, with hours of occupation set from 7:00 AM to 9:00 PM. The contents of the schedule are shown in Table 2.

Tab. 2: Schedules

Content	Total / Week	Total/ Year
Occupancy	98 hours	5,096 hours
Appliances	98 hours	5,096 hours
Lighting	84 hours	4,368 hours
Ventilation	84 hours	4,368 hours

3. Results

3.1 Comparing case 1 and case 2

A simulation was used to verify the energy consumption for case 1 and case 2, with a focus on heating and cooling. Figure 4 shows the monthly heating and cooling energy consumption for case 1 and case 2.

The heating energy consumption of case 1 was 5,861kWh/year and that of case 2 was 4,722 kWh/year, which is 20% less than case 1. The use of improved materials that complied with the thermal conductance code for both insulation and windows system, led to approximately a 24% and 35% reduction in thermal performance, respectively. The cooling energy consumption of case 1 was 6,367 kWh and that of case 2 was 6,086 kWh, which is about 4% less than case 1. Therefore, enhancing the thermal performance of the insulation and window systems has a significant impact on heating energy consumption, but a minimal impact on cooling energy consumption.

According to the simulation results, case 2, which follows the current design trends in Korea, consumes 12% less heating and cooling energy than buildings that follow the BECDS (case1).

(a) Monthly Heating Energy **(b) Monthly Cooling Energy**

Fig. 4: Comparison of case 1 and case 2

3.2 Low Energy Design Elements

Figure 5 quantitatively shows the heating and cooling elements of case 1 according to load ratio. The heat loss through opaque surfaces was 52%, infiltration 31%, and window system 17%. This shows that the envelope has a significant effect on heat loss.

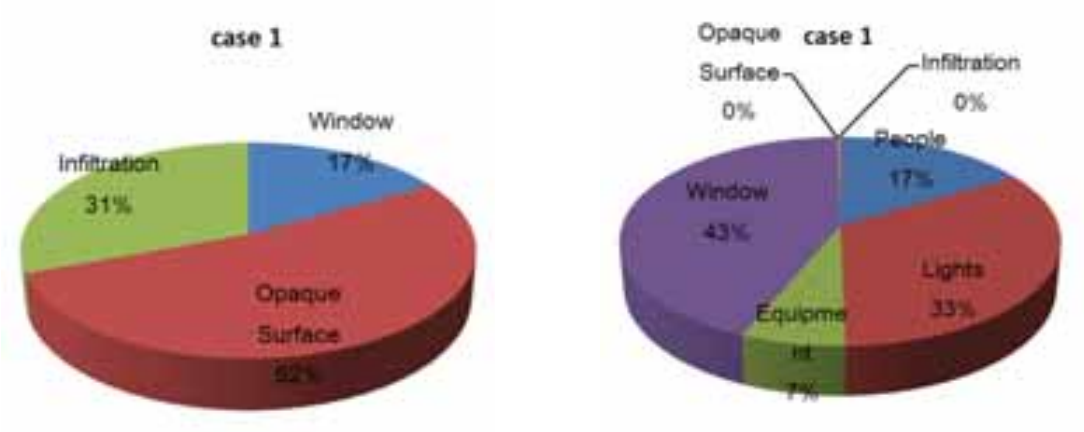
For cooling, heat gain due to window systems is 43%, lighting 33%, people 17%, and equipment (household electric appliances) 7%, which shows that the opaque surface has a minimal effect However, the window system, which is a major factor in solar heat gain, and other factors contributing to internal heat gain including people, lighting, and equipment, have a significant effect on the overall heat gain. It follows that the slight reduction of 4% in cooling energy consumption from case 1 to case 2 is due to the lack of change in the factors for internal heat gain.

The analysis shows that in order to reduce the heating load, the insulation for the walls, roof, and flooring must be improved. Infiltration is also a significant factor; insulation tape will thus be used during construction to reduce heat loss.

In order to reduce the cooling load, the solar heat gain through the window systems must be reduced by installing glazing with a low solar heat gain coefficient (SHGC). The internal heat gain factors such as people and equipment (household electric appliances) cannot be changed so it is more important to have highly efficient lighting.

Each factor for the load categories of case 1 was analyzed to reduce the energy consumption for the senior community center's design. The important objectives were to reduce the heating energy by enhancing the thermal conductance of the walls and window systems and to reduce the cooling energy by installing

windows with low SHGC glass and by installing LEDs.



(a) Heat loss (b) Heat gain

Fig. 5: Analysis of the load elements

Table 3 shows the factors contributing to the low energy design for case 3. Compared to case 1, the thermal conductance for insulation decreased by 57%, while the thermal performance for window systems significantly improved by 60%, with a drastic decrease in the SHGC value and a 20% decrease in light density. In addition, solar panels were added to the plans for a zero energy design with renewable energy.

Tab 3. Condition of the case 1 & case 3

Contents		Case 1	Case 3
U-value (W/㎡ K)	Roof	0.29	0.17
	Wall	0.48	0.11
	Floor	0.34	0.16
	Window	2.70 (SHGC : 0.75)	1.03 (SHGC : 0.13)
	Door	3.70	2.1
Electric	Light	10W/㎡	8W/㎡
Renewable	PV system	-	8kW x 4hr/day

3.3 Energy Consumption-case 3

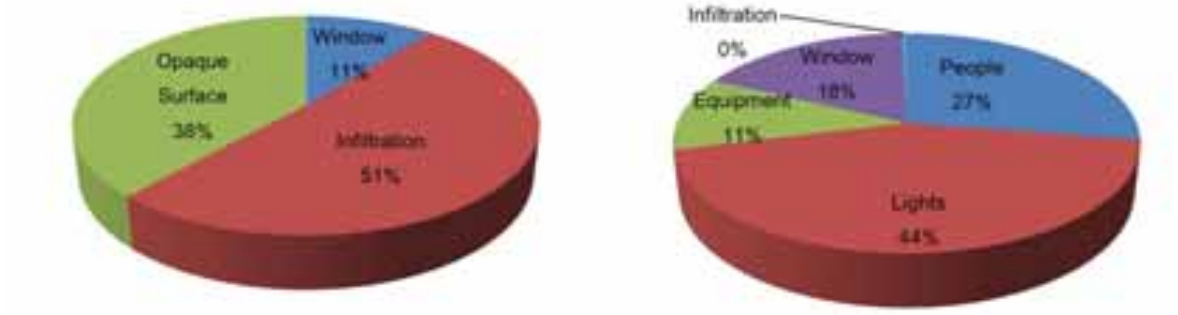
Figure 6 compares the heating and cooling energy consumption of case 1 and case 3. The heating energy consumption of case 3 was calculated to be 3,929kWh/year, which is 33% less than case 1, while the cooling energy consumption of case 3 was 4,313kWh/year, which is 31% less than case 1.

It was determined that the 33% reduction in heating energy consumption was due to the increase in the insulation of the wall and in the thermal conductance of the window systems. The cooling energy consumption was reduced by 31% by utilizing glass with an SHGC value of 0.134 for glazing, achieving a light density of 8w/㎡, and using LED lighting wherever possible.

To further reduce the energy consumption of case 3, the case 3 load ratios were analyzed, as shown in Figure 7. For heating, the infiltration was reduced and the insulation for the wall was improved. For cooling, the lighting density was reduced. However, since reducing light density can increase the heating load, it is necessary to calculate the lowest light density that does not fall below the recommended level of indoor illuminance.

(a) Heating Energy (b) Cooling Energy

Fig. 6: Comparison of case 1 and case 3



(a) Heat loss (b) Heat gain

Fig. 8: Analysis of the load elements in case 3

3.4 Photovoltaic using of renewable energy

Photovoltaic solar cells were included in case 3 to meet the need for renewable energy in a zero energy design. Figure 10 shows that the combined heating and cooling energy consumption is 8,242 kWh/year, while the solar panels produce 11,600 kWh/year. Therefore, by using renewable energy, the zero energy design is feasible and can result in a surplus of 3,438kWh/year.

4. Conclusions

An energy simulation was conducted to design a zero energy building accommodating a senior community center within apartment complexes in Korea. Case 1 was designed according to the Building Energy Conservation Design Standards (BECDS) and case 2 reflected the common designs of Korean construction companies. By analyzing the factors that affect heating and cooling in case 1, low energy design factors were derived to calculate the energy consumption for case 3, as shown below.

- Heating energy consumption was 5,861kWh/year for case 1, 4,722 kWh/year for case 2, and 3,929 kWh/year for case 3. Compared to case 1, case 2 and case 3 showed a 20% and 33% reduction, respectively.
- Cooling energy consumption was 6,367kWh/year for case 1, 6,086 kWh/year for case 2, and 4,313 kWh/year for case 3. Compared to case 1, case 2 and case 3 showed a 4% and 31% reduction, respectively.
- Analyzing the factors that affect heating and cooling for case 1 shows that 1) for heating, opaque surfaces are responsible for 52%, infiltration is responsible for 31%, and window systems are responsible for 17% of heat loss, which shows that the envelope has a significant effect on heat loss; 2) for cooling, window systems are responsible for 43% of the heat gain, lighting is responsible for 33%, people are responsible for 17%, and equipment is responsible for 7%, which shows that internal and solar heat gain account for most of the energy loss, while the envelope has an insignificant effect.
- Photovoltaic solar panels were included in the design as a source of renewable energy to offset the heating and cooling energy consumption of the low energy design of case 3. Using renewable energy would result in an energy surplus of 3,438kWh/year.

Heat Loss for a Run-Around Hybrid Ventilation System with Heat Recovery

Henrik Davidsson[1] and Ricardo Bernardo[1]

[1] Lund University, Lund (Sweden)

Abstract

The heat recovery system for ventilation is of major importance when low energy buildings are built. One alternative to the mechanical ventilation systems with heat recovery is to use a brine based run-around system that allows for heat recovery in for instance hybrid ventilated buildings. This type of heat recovery system has the potential to lower the need for electricity for the fans. Also, the installation has the potential to be simpler when pipes transporting the brine replace traditional air ducts. However, pipes needed to transport the brine will suffer from thermal losses. This will lower the efficiency of the heat recovery system. High losses could in practice make the system unusable. In order to estimate how much this affects the annual heat recovery a simulation tool was developed using TRNSYS. The result from the investigation shows that the losses for a system with 40 m pipes in total are approximately 300 kWh annually. This corresponds to approximately 9% of the energy savings from the ventilation heat recovery system. Insulating the pipes can reduce this heat loss by approximately 250 kWh annually.

Keywords: *Hybrid ventilation, Heat recovery,*

1. Introduction

One advantage with using hybrid ventilation is the reduced need for electricity consumed by the fans in a conventional mechanical ventilation heat recovery system. The importance for this becomes apparent when considering the following example: A typical single-family house in Sweden consumes approximately 4000 kWh to heat the incoming ventilation air. If a mechanical ventilation system with 75% heat recovery rate is used it means that 3000 kWh is saved on an annual basis. However, if we include the 456 kWh of electricity Swedish Energy Agency (2010) which corresponds to about 1370 kWh of primary energy (energy factor 3), the annual recovery rate is reduced to about 40%.

One alternative to this is to use natural or hybrid ventilation. However, hybrid ventilation systems normally lack the possibility to recover any of the energy that disappears with the outgoing ventilation air. This will lead to high energy consumption for heating and it could also result in a poor comfort in cold climates due to cold draught from the incoming ventilation air. One possibility could be to install hybrid ventilation systems with heat recovery. Recent development concerning heat exchangers with very low pressure drop has made these types of systems possible, Hviid and Svendsen (2011), and Davidsson et al. (2013a). These types of heat exchangers can be used in run-around heat recovery systems, Davidsson et al. (2013b). A typical run-around system equipped with a heat recovery system is shown in Fig. 1. The incoming air is heat exchanged in the water/air heat exchanger at the bottom of the building. The brine is then pumped to the top of the building where it is used to recover heat from the outgoing ventilation air. The heat is pumped to the bottom of the building and the circle is completed. The temperatures in the figure are used as an example to illustrate the heat recovery process.

However, in this type of system there will be losses from the indoor air to the brine. This means that heat will flow from the indoor air to the brine. In the end this means that the heat recovery rate for the system will be reduced. There are three effects that should be kept in mind regarding this heat loss:

doi:10.18086/swc.2015.08.10 Available at http://proceedings.ises.org

1. Heat will be lost from the room to the brine.

2. The increased brine temperature will reduce the heat transfer rate in the heat exchanger at the top of the house from the air to the brine.

3. The increased brine temperature will increase the heat transfer in the heat exchanger at the bottom of the house from the brine to the air.

This rather complex behavior makes it more difficult to estimate the heat loss effect from the system over a full year. Further complication arises when a full building is included in the energy system and therefore a dynamic simulation model is needed to quantify the above listed behavior.

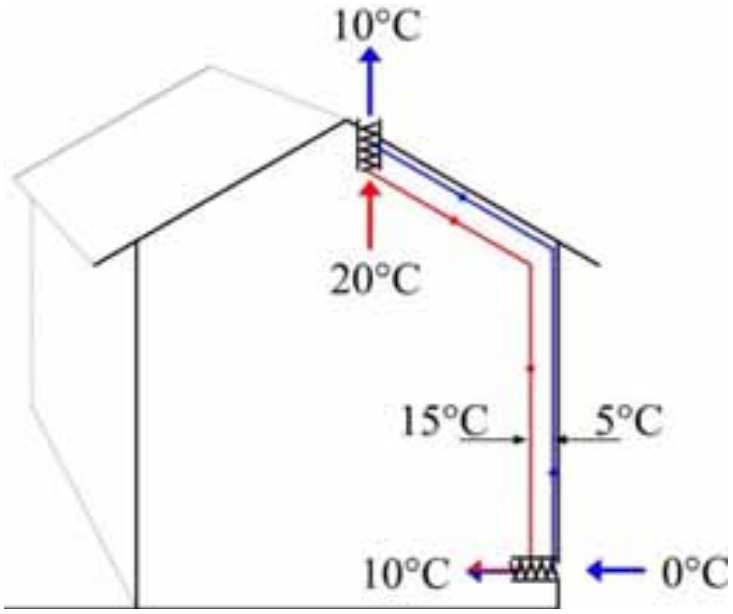

Fig. 1: Run-around heat recovery system suitable for hybrid ventilation.

2. Method

In order to investigate the consequences of heat losses in the pipes a TRNSYS simulation model was developed. The simulations do not include effects from dirt on the heat exchangers or air leakage. Nor does it include uneven consumption of electricity in the building or cooling during hours with overheating. The included TRNSYS components and the most important parameters are described in Table 1. The internal gains, window gains and thermal losses for the building are all included in the simulation in order to give a realistic surrounding for the ventilation system.

Tab. 1: Parameters and TRNSYS types used in the simulation tool.

Building, TRNSYS type 88	The building has an average U-value of 0.5 W/m²K. The thermal capacitance of the buildings was set to 40 MJ/K. This corresponds to approximately 100 m² concrete floor, 100 m² brick wall and it includes interior material and the roof.
Internal gains	Windows facing south (6.5 m² glazing area), west (6.5 m²), north (4 m²) and east (4 m²) with a g-value of 55% were installed in the building. This gives a glazing to floor area ratio of approximately 14 %, which is a typical value. The transmitted solar radiation was treated as internal gains of the building. The gain from people and electricity was set to 500 W continuously.
Weather data	The weather data is data from Malmoe in the south of Sweden. The weather data was obtained from Meteonorm (Meteonorm).

Ventilation: Heat exchangers, TRNSYS type 5b	The ventilation flow rate for all cases was set to 234 kg/h which is approximately equal to an air change rate of 0.5 changes per hour. This value was chosen in order to meet the requirements in the Swedish Building code BBR (2011). The brine in the ventilation circuit was assumed to be water. The temperature efficiency was set to 75%.
Pipes: type 31	The pipes for the run-around ventilation system were assumed to have an inner diameter of 12 mm and a total length of 20 meter for both flow directions, i.e. to the roof heat exchanger and to the bottom heat exchanger. The heat loss coefficient for the uninsulated and the insulated pipes are given in Table 2.

The heat resistance and thus the U-value of the pipes, uninsulated and insulated, where calculated using the program IsoDim from Isover (IsoDim). The values used in the different simulations can be seen in Table 2. The calculated values only includes the pipes. Connections and diverters are not included.

Tab. 2: Heat transfer rate for pipes with various insulation thickness.

Insulation thickness / mm	U-value / (W/m²K)
0	7.7
20	0.68
40	0.31
60	0.19
80	0.13
100	0.10

3. Result

This building was calculated to use 15000 kWh annually for space heating and heat for the ventilation. If the building is equipped with a heat recovery system, shown in Fig. 1, for the ventilation air the annual heating need is reduced to 11350 kWh per year. This assumes a temperature heat recovery efficiency of 75%. However, this simulation does not include any heat losses to the water piping system. If this is included the heating need is increased to 11660 kWh annually. This assumes a total piping length of 2·20 meters with heat loss rate for the water pipes assumed to be 7.7 W/(m²·K). The effects of insulating the pipes are shown in Fig. 2 and Fig 3. The first of the two figures shows the annual heating for buildings equipped with a run around ventilation system with heat recovery. The results show that not including any losses in the calculations for the ventilation system will result in an overestimate of its performance by approximately 300 kWh annually. However, insulating the pipes heavily will reduce this effect considerably resulting in only 50-100 kWh losses annually.

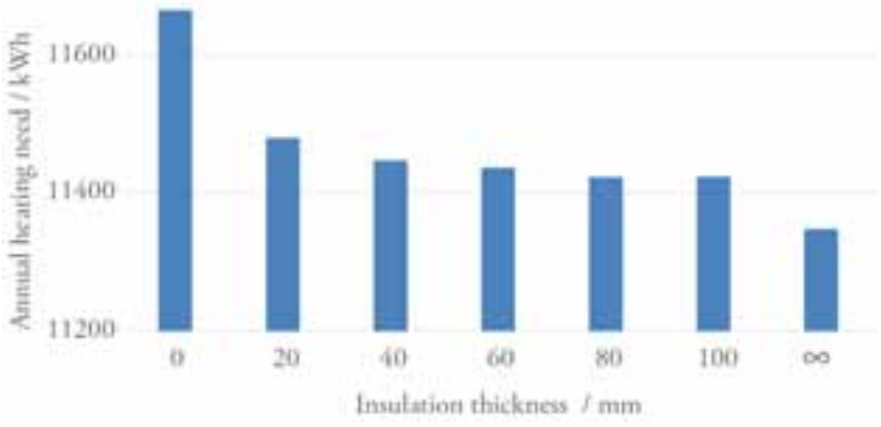

Fig. 2: The annual heating need for buildings with ventilation systems with different pipe insulation. Note the broken y-axis.

Fig 3 shows with red bars that the heat transfer in the Bottom HX increases as the losses are included. This happens since the air inside the building will heat the brine going to the Bottom HX. This is not beneficial for the total energy performance for the building since the heat comes from the building itself. At the same time the energy transferred in the roof HX will decrease. This is shown with blue bars. This happens since the brine is already heated and less energy can be transferred from the air to the brine. The phenomena can be described as a partly short circuited system. The losses in the pipes going from the bottom to the roof are indicated with black arrows and the losses for the pipes going roof to the bottom is indicated with grey arrows. The losses in the system matches the difference in energy transfer rate between the Bottom HX and the Roof HX. Note that both diagrams have broken y-axis.

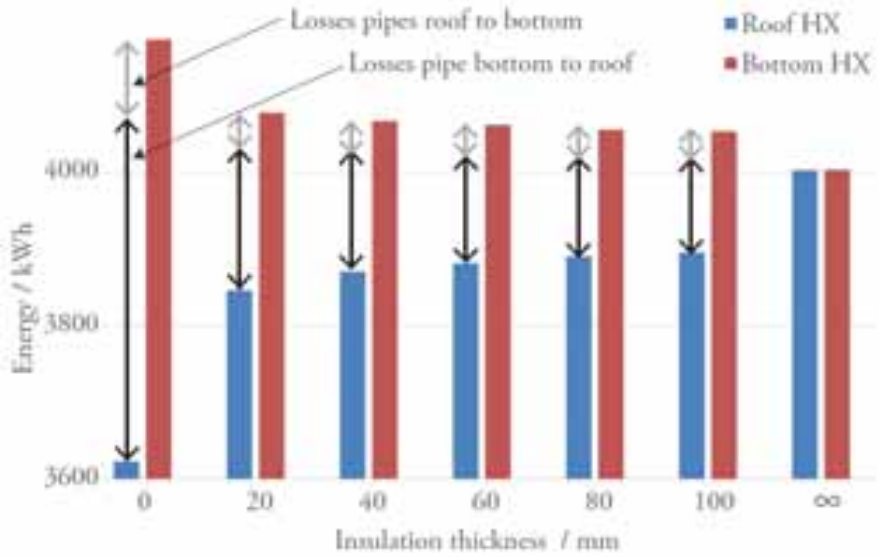

Fig. 3: Blue and red bars shows the heat transfer in the Roof HX (heat exchanger) and the Bottom HX. The black and the grey arrows indicate the thermal losses in the brine pipes. The black arrow is for the pipe going from the Bottom HX to the Roof HX and the grey arrow shows the losses related to the brine pipes going from the Roof HX to the Bottom HX. Note the broken y-axis.

Another consequence of the heat losses from the indoor air to the brine is that the heat exchanger at the bottom of the building will have slightly warmer incoming brine compared to a case with uninsulated pipes. The incoming air will therefore also be warmer. Simulations show that the incoming air is approximately 0.5°C higher for the case with uninsulated pipes compared to pipes without any heat losses.

4. Conclusion

Not insulating the pipes in a run-around heat recovery system will result in increased heating need. A typical one family house with a total of 40 m piping for the ventilation system will suffer from approximately 300 kWh higher energy need due to the pipe losses. However, insulating the pipes has the potential to lower the energy losses to approximately 50 kWh. It's also apparent that the losses from the pipe is heavily suppressed already by 20 to 40 mm insulation. Further insulation has limited impact.

Using uninsulated pipes will lead to a higher temperature for the incoming air due to heat losses from the indoor air to the brine. However, these losses only lead to a 0.5°C temperature rise for uninsulated pipes compared to pipes with no losses. This difference will not be significant for the performance of the ventilation system. A 1 kW_p PV module tilted in 40 ° placed in Lund in the south of Sweden produces approximately 1 000 kWh/year. That means that a 250 W_p module would produce approximately the same amount of electricity as the above discussed insulation saves for the ventilation system.

5. Discussion

Since the brine in the pipes can be considerably colder than the indoor temperature there is a large risk of having condensation on the pipes. This is not bad only for the energy performance. It can also cause humidity

related problems where the pipes are placed. If the pipes are insulated there will be less humidity from the indoor air that condense on the pipes.

One of the main advantages with a run around heat recovery system for retrofitting of ventilation systems in old building is the fact that the pipes needed for this system is in most cases easier to install than ducts are in a traditional balanced mechanical ventilation system. This is not discussed in this article even though it is well worth to mention.

The total savings of insulating the pipes in the ventilation system approximately corresponds to the annual electricity production from a 250 W_p PV module. However, it should be taken into account that the electricity from the PV panels could be used to run a heat pump therefore producing more that the needed 250 kWh.

LIGHTING PERFROMANCE IN OFFICE BUILDINGS WITH BIPV FACADES: VISUAL AND NON-VISUAL EFFECTS

Xin Zhang[1] and Jiangtao Du[2]

[1] School of Architecture, Tsinghua University, Beijing (China)

[2] Department of Architecture and Civil Engineering, University of Bath, Bath (UK)

Abstract

BIPV facades (integrated with opaque or transparent PV panels) have been accepted as an innovative strategy to provide electricity, reduce peak electrical and cooling demands, improve daylighting utilization, and achieve energy efficiency in buildings. This study presents a preliminary simulation study of impact of BIPV façades on visual and non-visual effects of daylight in an office building. DAYSIM and EVALGLARE, two advanced packages, were used to evaluate daylighting and visual performances. In general lighting and visual conditions can be expressed by the calculated Daylight Autonomy (DA) across the working plane and Daylight Glare Probability (DGP) at vertical planes of specific positions. The non-visual effect of lighting was indicated by the vertical DA at the same vertical positions. It has been found that BIPV facade configurations obviously affect both visual and non-visual performances of daylight. A balance of proper daylighting conditions and visual comfort should be a critical issue in the process of an office façade design.

Keywords: *BIPV façades, Lighting, Visual Performance, Non-visual Effects, Office Buildings*

1. Introduction

Building Integrated Photovoltaics (BIPV) has been generally adopted as one important solution to directly utilize solar energy in buildings, especially for the systems installed at building facades (Farkas et al., 2013). With respect to studies during the last ten years, the BIPV facades (with opaque or transparent PV panels) can provide electricity, reduce peak electrical and cooling demands, improve daylighting utilization, and achieve energy efficiency in buildings (Quesada et al., 2012). A case study in two modern buildings showed that PV facade systems significantly benefit fossil energy savings and the reduction of CO2 emission in a hot and highly luminous climate (Alnaser et al., 2008). According to simulations in northern, central and southern Europe, urban factors (obstruction and orientation) would impact the energy performance of opaque PV façade and determine its optimal configurations composed of glazing and solid wall (Yun and Steemers, 2009). However, semi-transparent PV has actually received more attentions from designers and engineers for the modern façade systems. In Hong Kong such a transparent PV facade was investigated in an office building (Li et al., 2009), which has been proved to produce a clear decrease of electrical lighting and cooling energy consumption. Another study in a cold climate also expressed that semi-transparent PV façade has a large potential to improve overall energy efficiency than opaque façade due to its ability to utilize daylighting (Robinson and Athienitis, 2009). A German simulation enhanced the fact that lighting, heating and cooling loads in an office with semi-transparent PV glazing façade could be partially displaced through the electricity produced by the PV systems (Mende et al., 2011). In contrast to this study, a Brazil research found that a PV window works more efficiently in terms of artificial lighting and cooling loads under a tropical climate than the central European climate (Didone and Wagner, 2013). Recently, a more complicated façade design integrated with PV panels has occurred at the locations with warm climates. Two studies of PV facade in a sub-tropical climate presented that a ventilated double-skin structure could improve both PV performance and indoor thermal comfort in summer (Chow et al., 2009; Han et al., 2013). The

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.08.11 Available at http://proceedings.ises.org

combination of shading devices and PV panels has been regarded as another interesting research topic. A movable shading device integrated with PV panels was proved as an efficient way to achieve the largest potential of energy savings for cooling and lighting use under central and southern European climates (Janak and Kainberger, 2009), while a similar result has been found in a study of fixed shading device at a Mediterranean location (Mandalaki et al., 2014).

Visual performance is also a crucial research focus of the PV façade in office buildings. An earlier investigation has preliminarily studied the visual amenity (glare, view, contrast and lighting model) and aesthetic quality of indoor spaces with various transparent PV windows at a Scandinavian location (Lien and Hestnes, 2000). The assessment of visual performance in this study was basically focused on qualitative aspects. Later, one study implemented under a similar climate has adopted quantitative methods including lighting measurements and subjective survey to evaluate lighting performance and visual comfort in a room with various transparent PV glazing facades (Markvart et al., 2012). It has been concluded that the integration of transparent thin-film PV in glazed facades could significantly influence occupants' perception of daylight in the room and the view to the outside. Based on a complicated simulation method, the impact of solar cell density of PV facade on indoor visual comfort was analyzed in an office building (Mende et al., 2011). The finding showed that the transparent solar cells in glazing façade might have a limited effect to keep a proper visual comfort and a supplement shading device might still be required.

Apart from the visual aspects, the non-visual effects of daylight (e.g. psychological and physiological issues) in an office have actually become a new research trend due to an increasing requirement for a healthy indoor working environment (Boyce et al., 2003). Even though daylight availability is generally accepted as a standard to justify a proper design, it is still necessary to implement more investigations in an office with various facades since there are still many unknown areas of human behavior related to daylighting (Aries et al., 2015).

Thus, it can be found that energy performance is only one of important issues in office buildings with PV facades. Directly and significantly influenced by the indoor lighting, occupants' health, well-being and work productivities in such a space could be more critical. This article therefore aims to study the visual and non-visual performances of daylight in an office building with various PV façade systems. A dynamic lighting and visual simulation was completed in an office at two locations of Beijing (China) and London (UK).

2. Methods

This section presents locations and climates, office and façade models, as well as simulation settings.

2.1 Locations and Climates

The simulation study was based on two locations with different climatic conditions: Beijing (39.9167° N, 116.3833° E) and London (51.5072° N, 0.1275° W). Beijing has a continent climate with cold winter and hot summer, while a typical temperate climate dominates at London. The annual sunshine hours for Beijing and London are 2707 and 1460 respectively (of a possible number 4383) (Database of World Climate & Temperature, 2015). Beijing has clearly 29% more sunny days than London.

2.2 Office and Façade Models

In this study a single office room has been chosen as a typical model (Fig.1), with a dimension of 5.4×3.6×2.85m (depth, width and height). The office room has one fully-glazed window facade, which the PV panels were integrated with. The window façade has a south-facing orientation. Five various façade configurations were studied as follows: bare window (no PV panels), façades with opaque PV panels (small and large areas), façade with semi-transparent PV panels (small and large areas). For the facades with bath types of PV panel, the large PV area means the ratio of glazing area to wall area is 30% (PV area: 70%), while the value for the small PV area is around 60% (PV area: 40%) (Fig.1). The surface reflectances of each room element are: 0.8 (ceiling), 0.6 (wall), 0.3 (floor) and 0.1 (glazing). The visual transmittance of façade glazing is 0.72 (clear float glass). The part of PV façade is made of the glass laminate thin film PV units with two outer layers (clear float glass, thickness 4mm, visual transmittance 0.9) and one middle layer (PV encapsulation panel, 0.8mm). The opaque PV encapsulation panel has a diffuse reflectance 0.1 whilst a

diffuse transmittance 0.3 was set for the semi-transparent PV encapsulation panel. An average diffuse transmittance of semi-transparent PV panel could be around 0.24.

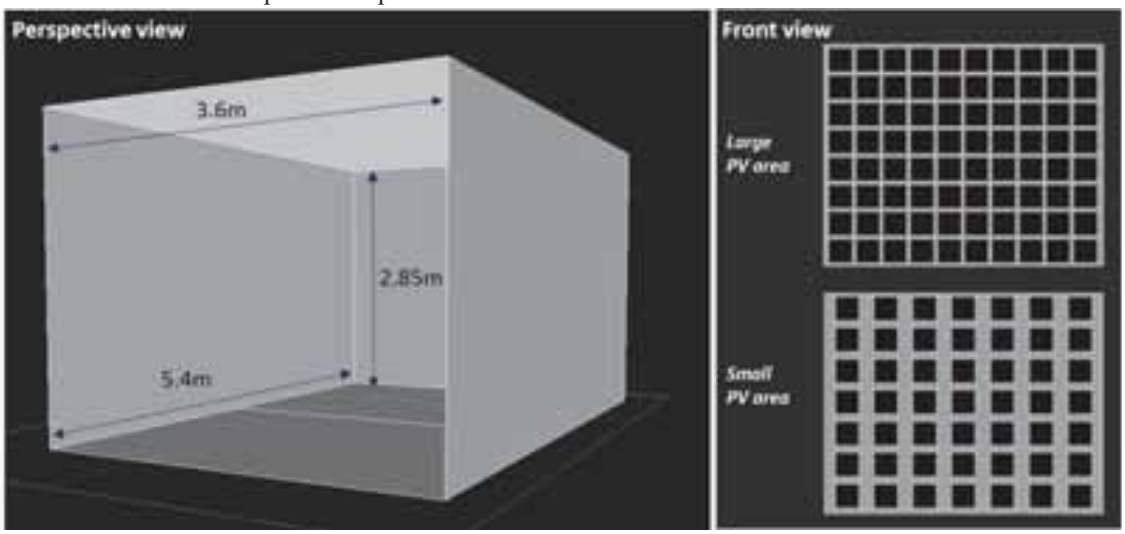

Fig. 1: Dimensions of office model (left: perspective) and configurations of two PV facades (right: front view).

2.3 Simulations

As for the basic daylight availability in this office, Daylight Autonomy (DA) and Daylight Factor (DF) across horizontal working plane (0.8m above floor) were calculated using a climate-based dynamic daylighting modelling tool DAYSIM (Reinhart and Herkel, 2000). A calculation grid with a 0.5m distance between two adjacent positions was used to get an average value of DA or DF. Also, eight positions were selected along the centre line of room from window to back wall, with a distance to window as follows: No.1-8 (0.51m, 1.18m, 1.86m, 2.53m, 3.21m, 3.88m, 4.56m and 5.23m). The design illuminance for DA assessment at the working plane is 500lux within a daily time period from 8am to 17pm.

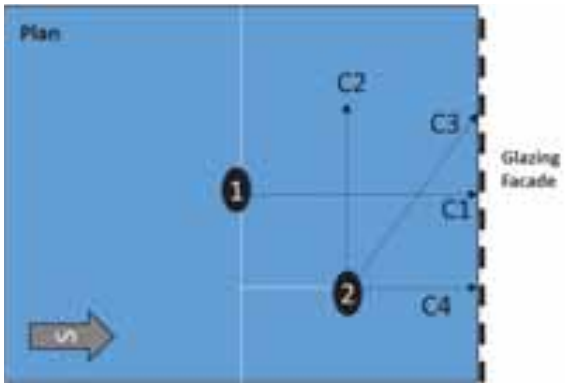

Fig. 2: Two positions and four view directions studied in this office (plan view).

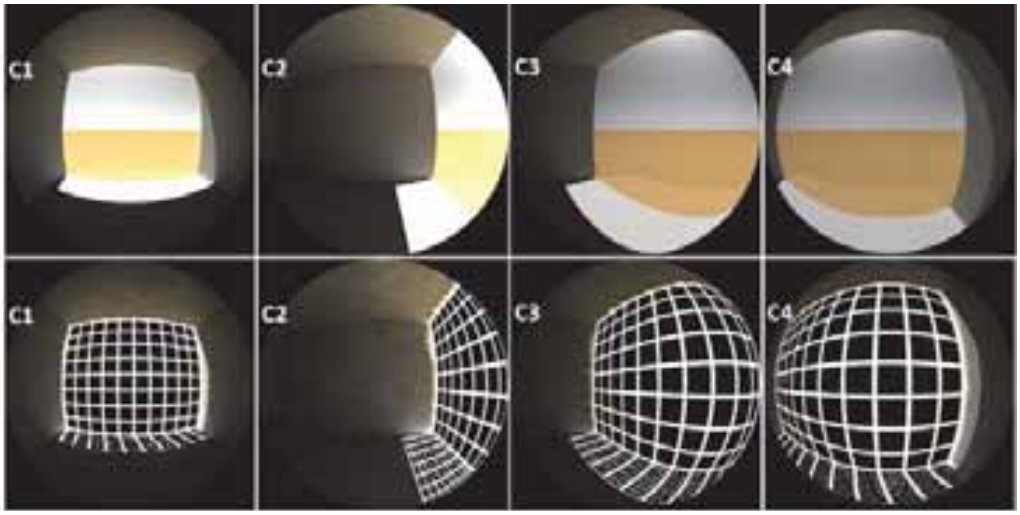

Fig. 3: Examples of rendering fish-eye images of four various views (up: glazing façade; bottom: PV façade).

In addition, two positions in the office were studied in terms of visual and non-visual lighting performances: No.1 & 2 (Fig.2). Position No.1 is exactly located at the room centre. Position No.2 is at the area near window, which could be regarded as a common place for a working station. The distances of position No.2 to window and side wall are 1.35m and 0.9m respectively. Four view directions were also defined at the two positions: C1 (at No.1, facing south), C2 (at No.2, facing east), C3 (at No.2, facing south east) and C4 (at No.2, facing south). C1 and C2 were the main views in this study. According to previous studies (Aries et al., 2015; Borisuit et al., 2014), the non-visual effect of daylight could be evaluated by the vertical illuminance received at the eyes of occupants. Thus, the daylighting availability at the two positions and along the four view directions has been assessed to indirectly indicate the effect. Similarly, two vertical DA values (illuminance threshold: 1000lux and 2000lux) were calculated at a height 1.2m (normal eye level of a sitting human being) using the DAYSIM for each view. In order to achieve a comprehensive visual performance of PV façade, a more complicated analysis was carried out in terms of Daylight Glare Probability (DGP) (Wienold and Christoffersen, 2006). Different from a conventional model Daylight Glare Index (DGI), DGP could be more suitable for assessing visual comfort in a real daylit space, especially for the window with a non-uniform surface luminance. Based on fish-eye images rendered by Radiance (Fig.3), DGP values were calculated at each view in a software package EVALGLARE (Wienold and Christoffersen, 2006). The glare metrics of DGP method are: DGP < 35%, imperceptible; 35% < DPP < 40%, perceptible; 40% <DGP < 45%, disturbing; DGP > 45%, intolerable. The dates for visual comfort evaluation were: spring equinox 20/03/2015; autumn equinox 23/09/2015; summer solstice 21/06/2015; winter solstice 22/12/2015. For each date, also, only three times 9am, 12pm and 15pm were analyzed.

Following a method to model PV glazing system (Didone and Wagner, 2013), BSDF (Bidirectional Scattering Distribution Function) of PV façades in this study was achieved according to various materials used for each layer. A software OPTICS (version 6.0) and International Glazing Database (version 29.0) from Lawrence Berkeley National Lab were the tools to produce Radiance material files used in all simulations.

3. Results and Discussions

This section includes a preliminary analysis of daylighting performance across the working plane, visual and non-visual performances in the office model with various PV façade systems. The five façade systems are named as: BW (bare window), LOP (large opaque PV facade), LTP (large semi-transparent PV facade), SOP (small opaque PV facade) and STP (small semi-transparent PV facade).

3.1. Daylight performance at the working plane

The daylighting level at the working plane is generally adopted to show a basic daylighting condition. Table 1 presents average DF and DA values at the working plane in various models. DF is a daylight metric to show a basic daylighting condition under CIE standard overcast sky condition.

Tab. 1: Average Daylight Factor and Daylight Autonomy in the office with various façade systems.

	BW	LOP	LTP	SOP	STP
DF (%)	9.49	2.2	4.06	5.26	6.32
DA (%): Beijing	86.96	43.64	64.34	72.87	78.04
DA (%): London	78.74	42.18	61.73	68.4	71.98

The façade with a large PV area normally gives rise to the minimum average DF, while the highest average value is found with the bare window. Taking the average DF of bare window as reference, the percentage DF differences of other façade systems are the following: -76.8% (LOP), -57.2% (LTP), -44.6% (SOP) and -

33.4% (STP). Interestingly, small opaque PV façade would still bring in more diffuse daylighting than the large semi-transparent PV facade. Based on the climate-based daylight modelling, nevertheless, DA is used to assess the daylighting availability taking into account locations and climates. Clearly, a higher average DA of Beijing can be found for each façade system than London, due to a better sky condition for daylight utilization. In response to the DF analysis, large opaque PV facades at both locations receive the lowest DA at the working plane, whilst small opaque PV facades would still lead to a relatively higher DA than large transparent PV facades. Reducing PV transmittance or increasing PV size would significantly lower the average DA in the office. Similarly, taking the DA of bare window as reference, the relative DA differences of PV facades are: LOP (Beijing: -49.82%; London: -46.43%), LTP (Beijing: -26%; London: -21.6%), SOP (Beijing: -16.2%; London: -13.13%) and STP (Beijing: -10.25%; London: -8.59%). Compared with London, Beijing sees a slightly [illegible] rally, a 43% decrease in PV size would reduce th [illegible] or 15% for transparent PV panels. However, a 0 [illegible] would lead to a reduction of relative DA differenc [illegible]

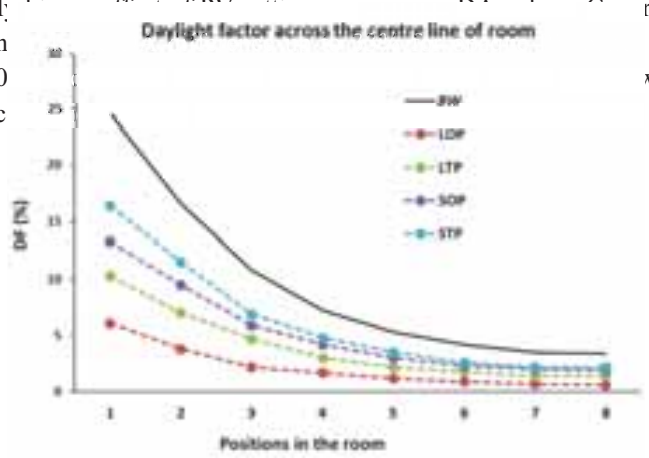

Fig. 4: Daylight Factors at the eight positions in the office with various façade systems.

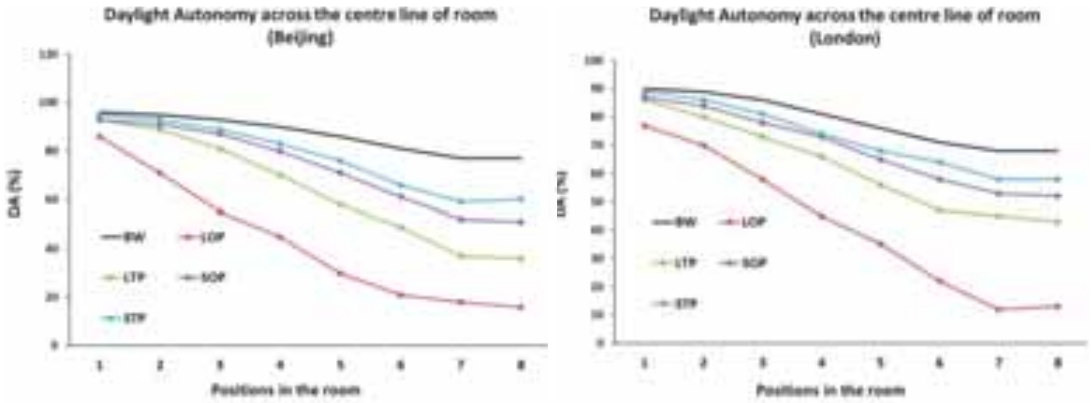

Fig. 5: Daylight Autonomy at the eight positions in the office with various façade systems (Beijing and London).

Fig 4 indicates variations of DF along centre line of the room with the five façade systems. An exponential decay of DF could be found for each façade system. With PV panels in the glazing facade, DF values have been clearly reduced along the room centre, especially for the area near window (distance to window < 2.7m). Normally, small PV size and transparent PV panel will give rise to a higher DF value than large PV and opaque panel from the window to back wall. The average DF values of the eight positions are: 9.49% (BW), 2.2% (LOP), 4.06% (LTP), 5.26% (SOP) and 6.32% (STP). In general, a 43% decrease in PV size would get an over doubled DF value for opaque panel and a 56% higher DF value for transparent panel, whilst a 0.24 increase in absolute transmittance value of PV panels would increase 100% and 20% DF value for large and small PV panels respectively. Similarly, variations of DA along the centre line of room have been displayed in Fig 5. Compared with other PV façade systems, large opaque PV façade has a much lower DA at both locations and only the perimeter area (No.1-3) has a DA >50%. Except for large opaque facade,

however, the first position No.1 (with a distance 0.51m to window) sees a similar DA value between bare window, while a DA divergence increases with the position moving towards back wall. For both Beijing and London, small PV facades could keep a DA > 50% at each centre position. Similar to average DA, the relative differences of DA between PV facades and bare window along centre line are smaller at London than Beijing.

Regards as the analysis above, a diffuse incident skylight under overcast sky could be heavily blocked by the large opaque PV panels. However, changing the size of semi-transparent PV panels would not bring in the difference as big as the opaque PV panels, due to a fact that the increased transmittance could significantly supplement one part of blocked diffuse daylight. For the DA analysis, nevertheless, the direct sunlight would be more difficult to block than the diffuse skylight by the application of PV panels in facades.

3.2. Visual performance of various facades

This section discusses the visual performance along four view directions in the office model with various façade systems at Beijing and London. The DGP was evaluated under a clear sky at the locations in order to investigate the worst visual condition with direct sunlight.

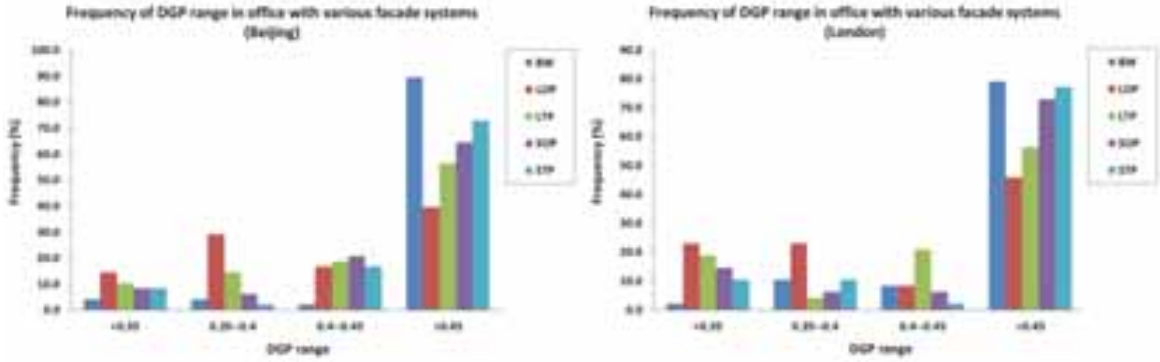

Fig. 6: Frequency distribution of four DGP ranges in the office with various façade systems

(Left: Beijing; Right – London).

First, a general visual performance has been discussed through a statistical analysis. Fig 6 shows the frequency distributions of four DGP ranges (see section 2.3) on four dates (20/03/2015; 21/06/2015; 23/09/2015; 22/12/2015) and three typical times (9am, 12pm and 15pm). The frequency was averagely analyzed with all four views (C1, C2, C3 and C4). Clearly, the biggest frequencies occur at DGP>0.45 (intolerable glare). DGP metrics show 0.4 is the threshold to justify visual comfort in a space (Wienold and Christoffersen, 2006). For the DGP>0.4 (visual discomfort), however, various façades have an occurrence frequency: Beijing – 91.7% (BW), 56.3% (LOP), 75% (LTP), 85.4% (SOP) and 89.6% (STP); London – 87.5% (BW), 54.2% (LOP), 77.1% (LTP), 78.4% (SOP) and 79.3% (STP). Accordingly, the potential to bring in a comfort visual environment in the office follows an order of lowest to highest as: BW>STP>SOP>LTP>LOP. In addition, the absolute differences of the frequency (DGP>0.4) between Beijing and London are: 4.17% (BW), 2.08% (LOP), -4.16% (LTP), 6.25% (SOP) and 10.41% (STP). Thus, Beijing office sees a relatively higher potential of visual discomfort than London office with bare window, large opaque PV and two small PV facades, whereas the large transparent PV façade would lead to a bit higher possibility to get visual discomfort in London office.

Second, as a main view facing outside, C1 has been specifically assessed with respect to visual comfort (DGP variations) in the model with five various façade systems (Fig 7 and 8) as below.

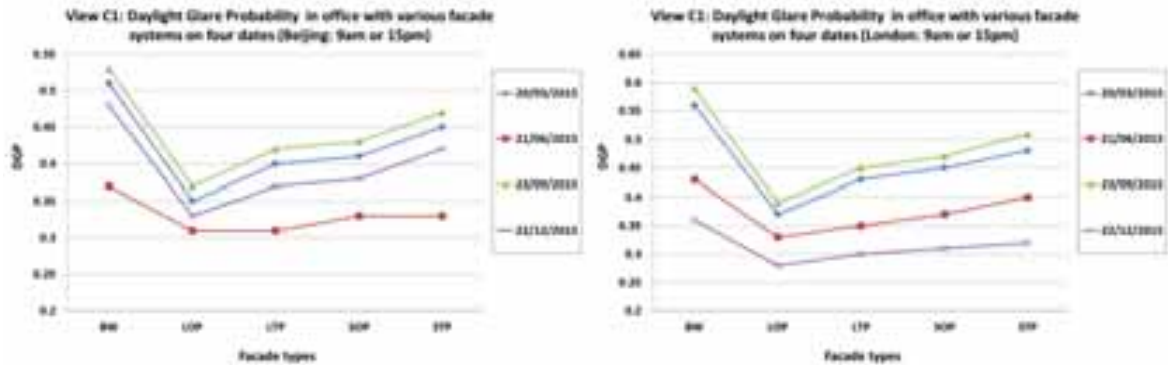

Fig. 7: Variations of Daylight Glare Probability in the office with various façade systems at 9am or 15pm (C1; Beijing: left; London: right).

Fig 7 displays varying DGP values of various facades in the morning (9am) or in the afternoon (15pm). Normally, a similar variation could be found on spring and autumn equinoxes: only large opaque PV façade could keep an acceptable visual environment; other façade systems would just bring in visual discomfort. Apparently, lower DGP values can be found on winter and summer solstices. All façade systems at Beijing office see a proper visual condition (DGP<0.4) on summer solstice, while a similar trend at London can be only found on winter solstice. Except for the bare window and small transparent PV façade at Beijing, other three facades have a DGP<0.4 on winter solstice. Interestingly, the summer solstice gives rise to an acceptable visual performance in the London office on the condition of using large opaque, large transparent and small opaque PV facades.

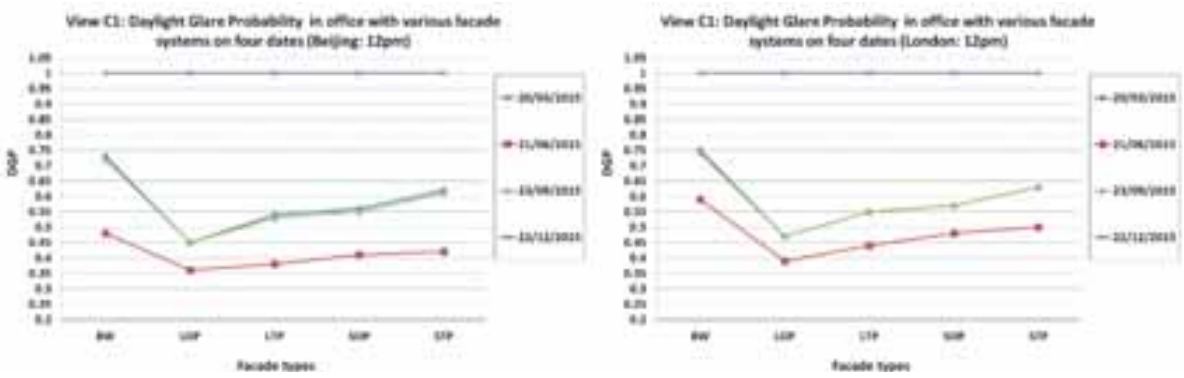

Fig. 8: Variations of Daylight Glare Probability in the office with various façade systems at 12pm (C1; Beijing: left; London: right).

The varying DGP values of various facades at noon (12pm) can be found in Fig 8. In general, it could be very hard to achieve a comfort visual environment in the office through the integration of PV panels in the glazing façade at Beijing and London. Even though the large opaque PV can block a lot of direct sunlight, DGP of LOP façade is still kept in a range of 0.35 — 0.4 (glare: perceptible). Beijing and London have a similar DGP varying trend: the highest value is found on winter solstice while summer solstice sees the lowest value; spring and autumn equinoxes have a middle value in between.

Third, view direction C2 (facing east) is commonly found in a typical office. The DGP assessment along this view is displayed in Fig 9, 10 and 11.

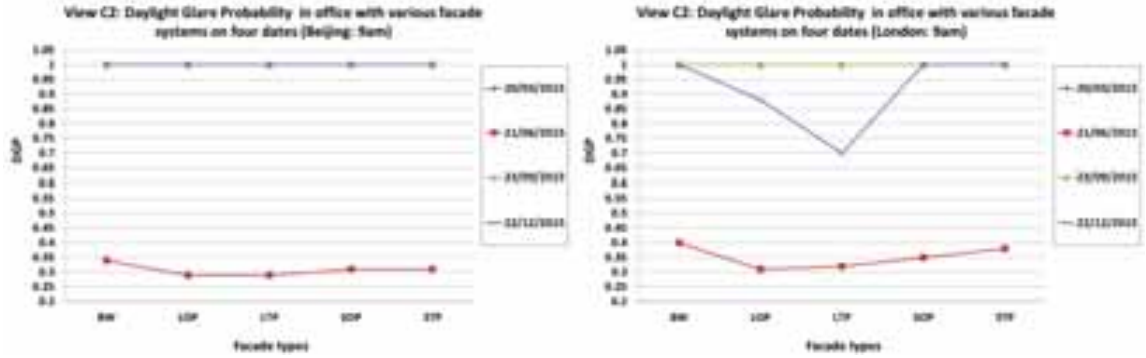

Fig. 9: Variations of Daylight Glare Probability in the office with various façade systems at 9am (C2; Beijing: left; London: right).

At time 9am in the morning (Fig 9), all façade systems could bring in a proper visual comfort (DGP<0.4) on summer solstice while a high possibility to be seriously disturbed by glare are found on other three dates. Two large PV facades would produce a good daylighting condition according to visual comfort

(DGP< 0.35; 'imperceptible' glare). For the time at noon (12pm), however, a more complicated DGP variation has been given regarding the Fig 10: the lowest DGP can be found on summer solstice at Beijing and on winter solstice at London, whereas both Beijing and London see the highest DGP on spring equinox. At Beijing, a proper visual condition (DGP<0.4) only occurs on summer solstice for PV facades. Also, the winter solstice and autumn equinox have a similar DGP performance. At London, large opaque façade can help achieve the lowest DGP and proper visual comfort (DGP≤0.4) on each date. With PV panels (both opaque and transparent), also, a very good visual environment is found on winter solstice (DGP≤0.35) at London office. Generally, London office has a relatively lower DGP value than Beijing office. In the afternoon (15pm, Fig 11), DGP variations of various façade systems are similar to those at noon (12pm, Fig 10). Spring equinox has the worst visual condition, whilst Beijing and London offices see the best visual comfort on summer solstice and winter solstice respectively. Besides, large opaque PV panel would bring in a proper visual comfort (DGP≤0.4) on all dates and at both locations. The use of PV panels (both opaque and transparent) could ensure the basic visual comfort (DGP<0.4) on winter and summer solstices at London office. However, a similar effect can be only found on summer solstice at Beijing. In terms of the analysis of three times 9am, 12pm and 15pm, an order of the potential to achieve visual comfort for all PV facades from highest to lowest is: LOP, LTP, SOP, and STP.

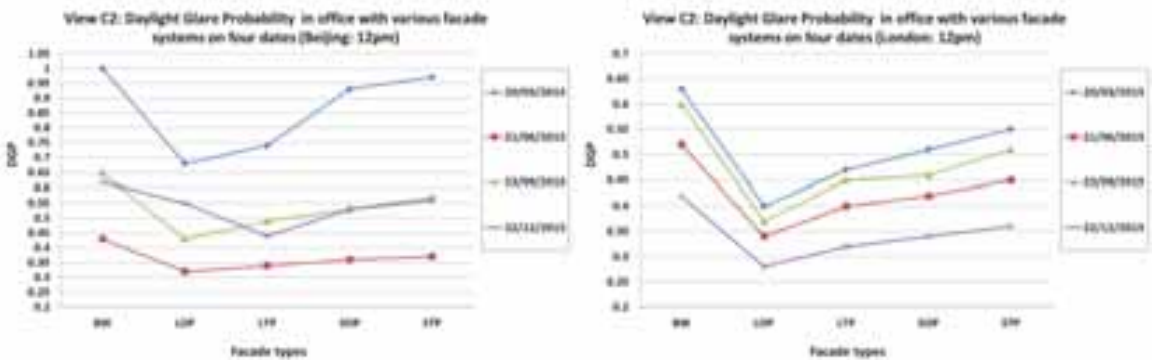

Fig. 10: Variations of Daylight Glare Probability in the office with various façade systems at 12pm (C2; Beijing: left; London: right).

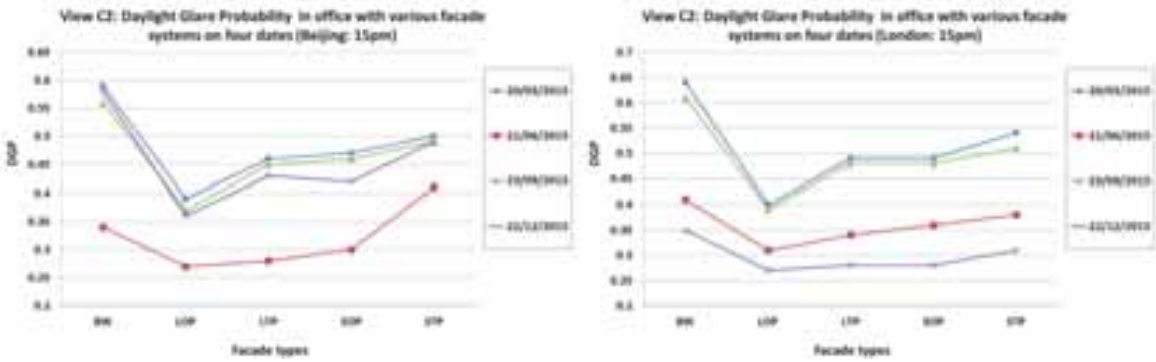

Fig. 11: Variations of Daylight Glare Probability in the office with various façade systems at 15pm (C2; Beijing: left; London: right).

From the analysis above, DGP variations could be explained by the combined effect of solar geometry and façade configurations. Compared with small PV panels, the large panels could block more direct sunlight that gives rise to a higher potential of visual discomfort. For the view facing south (C1), a higher solar altitude of summer solstice at noon results in a smaller daylighting level at the vertical surface of glazing façade, whereas the vertical daylighting level will go up with a lower solar altitude in winter. These could directly decide if a proper visual condition is achieved. When sunlight arrives from the side (9am or 15pm) on spring or autumn equinox, the lower solar altitude would lead to a higher daylighting level at the opposite side wall, which would make the wall brighter. Following this way, the view facing east (C2) will get a

similar visual performance at 9am and 12pm as the south-facing view at noon and in the afternoon respectively.

3.3 Non-visual performance of various facades

As mentioned in section 2.3, Daylight Autonomy (threshold: 1000lux and 2000lux) at four vertical positions was used to expressed the non-visual effects of daylighting with the occurrence of various façade systems. Tab 2&3 give the calculated DA values at the offices of Beijing and London. The larger is the DA, the higher is the possibility to active a positive non-visual effect of daylight.

Tab. 2: Daylight Autonomy at four vertical positions in an office with various façade systems (Beijing)

Daylight Autonomy (%) - Beijing						
Vertical Illuminance Threshold	**View**	**BW**	**LOP**	**LTP**	**SOP**	**STP**
1000lux	**C1**	91	45	75	81	82
	C2	89	36	65	76	79
	C3	94	64	84	88	89
	C4	94	72	86	90	90
2000lux	**C1**	77	17	44	53	61
	C2	71	12	35	45	54
	C3	87	26	60	71	77
	C4	89	38	65	75	80

Similar to the general daylighting performance at working plane, vertical DA values (1000lux and 2000lux) at the four positions of Beijing office in Table 2 follow a trend: LOP < LTP < SOP < STP < BW. Taking the bare window as reference, four PV facades have average percentage differences of vertical DA (threshold: 1000lux) as: -41% (LOP), -15.8% (LTP), -8.96% (SOP), -7.6% (STP) and vertical DA (threshold: 2000lux) as: -71.3% (LOP), -37% (LTP), -24.7% (SOP), -16.1% (STP). Increasing PV size would significantly reduce the vertical DA, especially for the large vertical illuminance 2000lux. For opaque PV panels, a 75% increase in PV size (from 40% to 70% wall area) would cause a fivefold percentage DA difference with 1000lux and a tripled percentage DA difference with 2000lux. However, transparent PV panels see a lower impact of the size change: a 75% increase in PV size will just get a doubled percentage DA difference for both thresholds. Normally, facing east (C2) receives the lowest vertical DA values with each façade system. With the small vertical illuminance 1000lux only the two positions (C1 and C2) with large opaque PV have a vertical DA < 50%, whereas more lower DA values can be found with the large vertical illuminance 2000lux: all positions (LOP), C1 & C2 (LTP), C2 (SOP).

Tab. 3: Daylight Autonomy at four vertical positions in an office with various façade systems (London)

Daylight Autonomy (%) - London						
Vertical Illuminance Threshold	**View**	**BW**	**LOP**	**LTP**	**SOP**	**STP**
1000lux	**C1**	80	48	67	71	75
	C2	76	40	58	65	69
	C3	85	58	73	78	80
	C4	86	65	77	80	83
	C1	68	21	47	53	60
	C2	62	9	36	48	52

2000lux	**C3**	76	36	56	64	68
	C4	78	43	61	68	72

Tab. 3 shows the vertical DA values in London office. A similar varying trend as Beijing office could be found here. The average percentage differences of vertical DA of PV facades to the bare window are as follows: for threshold 1000lux, -35.5% (LOP), -15.9% (LTP), -10.1% (SOP), -6.12% (STP); for threshold 2000lux, -61.6% (LOP), -29.6% (LTP), -18% (SOP), -11.3% (STP). With a 75% increase in PV size, the large opaque PV panel sees a 3.5 times percentage DA difference of small opaque panel, whereas the large transparent panel has a value slightly higher than the doubled percentage difference of small transparent panel. The large PV would give rise to a lower vertical DA (<50%), in particular for the vertical illuminance 2000lux or at the position facing east. Compared with Beijing office, it could be found that London office receives a smaller impact of PV panels on the vertical DA.

4. Conclusions

This simulation study was completed in an office with various PV façade systems, which focused on the impact of indoor daylighting on visual and non-visual performances of occupants. Several findings are given as follows:

(1) In modern office buildings, the energy efficiency could not be the only core issue considered by the BIPV façade designers and engineers. It would be necessary to implement a comprehensive daylight design in such buildings in terms of visual and non-visual effects.

(2) It could be possible to adopt a proper BIPV façade as a feasible design strategy in office buildings to achieve energy efficiency, a good general daylighting performance at the working plane, as well as an acceptable vertical daylighting level relating to non-visual performance at typical working stations.

(3) For a glazing façade with uniformly distributed PV units, size and transmittance of PV cells could be critical in terms of visual and non-visual daylighting design in office buildings. When considering opaque PV cells, it could be still possible to produce a relatively worse daylighting performance (visual and non-visual aspects), even with the occurrence of large glazing (e.g. 30% wall area).

(4) It would be difficult to keep a proper visual comfort at typical working times in office buildings with the vertical BIPV façade system. Extra shading devices (e.g. venetian blind, overhang, louvre, ect) would be strongly recommended in order to avoid glare and complete a normal office work in day time.

(5) For the vertical BIPV system integrated with building fenestrations, it could be possible to achieve a higher indoor daylighting performance at both horizontal and vertical planes, which are used to indicate a basic daylighting condition and a potential to active non-visual effect. However, a proper balance between horizontal and vertical daylight levels and visual comfort would be a big challenge.

Limitations: this study was based on a preliminary simulation with simple office and BIPV models. More complicated building spaces and façade systems will be studied in the next stage.

Demonstration of An Office Powered By Solar PV System

Bin-JuineHuang, Po-Chien Hsu, Y.H. Wang, J.H. Tsai, Leo Chen, Kang Li, KY Lee
Department of Mechanical Engineering, National Taiwan University, Taipei, Taiwan.

Abstract

The purpose of the present study is to demonstrate the concept of peak-suppression by energy saving and replacement of peak load by solar PV energy supply to replace nuclear power. An office with 150m^2 floor area and 14 employees was chosen as the demonstration site. The results show that retrofit for energy-saving reduces 65% energy and the solar PV system supplies 20%. The total energy reduction is 85%. The total investment of the solar PV system and the retrofit of energy-saving devices is around USD30,000. The net total energy saving in 20 years is USD 80,000, including M&O cost. The system has been run about one year. The measured average total power consumption of the office is reduced from 10.2 kW to 3.6 kW (after retrofit) in which solar PV supplies about half.

Keywords: solar PV energy, distributed solar system, solar energy office

1. Introduction

Grid power demand during peak load is caused mainly by energy consumption of air conditioning systems. Solar PV system is the best solution for peak-shaving. In addition, the utilization of solar PV power system should be for self-consumption, rather than feeding back to grid and causing transmission problem when solar PV is widely adopted. That is, solar PV distributed system will be one of the future major energy supplies in the world.

Since Taiwan is located in subtropical area, there is a peak load around 13:00 during summer around 34GW. From a long-term study, the power consumption of air conditoning contributes about 9 GW. Energy saving of air conditioning systems is thus most important.

Taiwan Government has set up a energy-efficiency classification for all air conditioners since 2010. Five categories are defined according to the energy efficiency ratio (EER) (W/W) and cooling capacity. See Table 1. However, EER of majority of air conditioners in the market or ever installed is below 3.5 (Category 3~5) . In 2010, 70% of air conditoners belongs to Category 5. Large potential of energy saving is feasible since the EER of the most advanced air conditioner in the market is higher than 5.6.

Table 1: Category of air conditioners

Type	Cooling capacity, kW	EER (W/W)				
Category		1	2	3	4	5
Integral-type	<2.2 2.2~4.0 4.0~7.1 7.1~10	>3.4	3.25~3.4	3.1~3.25	2.95~3.1	< 2.95
Split-type	<4.0	>4.17	3.93~4.17	3.69~3.93	3.45~3.69	<3.45
	4.0~7.1	>3.87	3.65~3.87	3.42~3.65	3.2~3.42	<3.20
	>7.1	>3.81	3.59~3.81	3.37~3.59	3.15~3.37	<3.15

Besides, lighting consumes about 10~15% energy in Taiwan. It is known that LED (light-emitting-diode) can save more than 50% lighting energy. Thus, lighting energy saving using LED is also feasible.
The cost of solar PV energy is reduced dramatically recently to bring the grid-parity age to come. Energy from solar PV is equal or cheaper than from the grid. High-efficiency air conditioning, LED lighting, and low-cost solar PV are all technically mature and available in the market for energy saving.

doi:10.18086/swc.2015.08.12 Available at http://proceedings.ises.org

The purpose of the present study is to demonstrate the concept of peak-suppression by energy saving first and then replacement of peak load by solar PV energy supply. This may be able to completely abandon nuclear power in Taiwan, as shown in Fig.1. An office in a 7-floor building located in Taipei with 150m^2 floor area and 14 employees was chosen as the demonstration site.

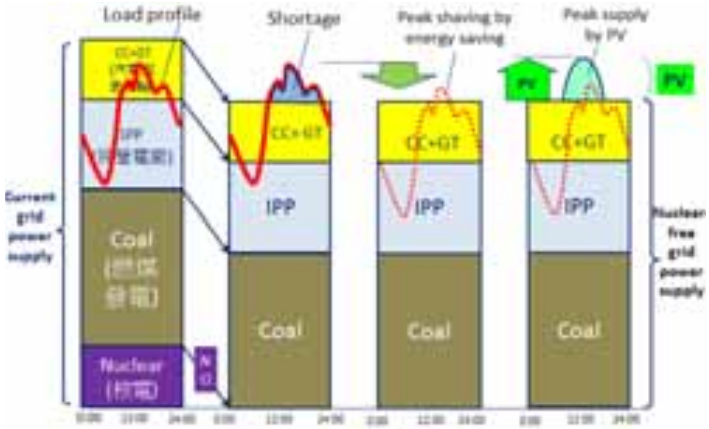

Fig. 1: The concept of nuclear power abandon by energy saving and using solar PV energy.

2. Retrofit of energy equipment and solar PV supply

2.1. Retrofit for energy saving

1. Energy consumption before energy-saving retrofit

The office of the Department of Mechanical Engineering, National Taiwan University, with 150m^2 floor area and occupied by 15 employees, was chosen as the demonstration site (D-1). The major energy consumption of the office comes from air conditoning, lighting, and PC. The power and daily energy consumption of air conditioners, lighting, and laptop PC was calculated and listed in Table 2. It is seen that the total power consumption for air conditioners, lighting, and PC reaches 10.16 kW and the daily total energy consumption reaches 81.3 kWh. 64% energy is consumed by air conditioners.

Table 2: Energy consumption before retrofit.

Daily consumption @8 h/day	Power input, kW	Daily energy, kWh/day
(1)Air conditioning		
Room 1: One split-type MW3299 BFR: cooling 7.3kW, COP 2.92	2.5	20
One window-type : cooling 5.8 kW, COP 2.9	2	16
Room 2: One window-type MW550BR: cooling 5.8kW, COP 2.9.	2	16
Energy consumption	6.5	52
(2)Lighting		
Room 1: Recessed fluorescent (47W)26 sets	1.222	9.8
Room 2: Recessed fluorescent (47W) 4 sets	0.188	1.5
Energy consumption	1.41	11.3
(3) PC		
Room 1: 13 laptop PC, 150W each	1.95	15.6
Room 2: 2 laptop PC, 150W each	0.3	2.4
Energy consumption	2.25	18
Total energy consumption (air conditioners, lighting, PC)	10.16	81.3

2. Energy-saving retrofit and energy consumption

To reduce energy consumption, four retrofitting was carried out: (1)air conditioning system is renewed with high-efficiency split-type air conditioner (Hitachi RAC-22NB) with COP 5.6; (2)lighting is retrofitted with LED luminaire with 100 Lm/W; (3)all lap-top computers are changed into notebook PC; (4)the window glass

is covered with low-E film to block IR part of solar radiation penetrating into the office. The above four retrofits results in 65% energy saving as shown in Table 3, at average power 3.6 kW (from 10.2 kW) and daily energy consumption 28.6 kWh/day (from 81.3 kWh/day).

Table 3: Energy consumption before retrofit.

2.2. Solar PV system design

A 6 kWp hybrid solar PV system is installed to replace another 20% energy. That is, 85% energy consumption is reduced in total.

The solar PV system is an isolated-type hybrid solar PV system (HyPV) which operates in Stand-alone PV Mode or Grid Mode, automatically. Fig.2 No solar PV energy is fed back to grid. When solar power generation and battery storage is sufficient, it operates in Stand-alone PV Mode and the load is powered completely by solar energy. When solar power generation and battery storage is not sufficient, it will switch to Grid Mode and the load is supplied completely by grid. The intelligent controller (MCU) performs optimal switching control between Stand-alone PV Mode and Grid Mode to reduce cycling of battery and ATS. The microprocessor-based MCU also carries out solar charging and system protection control, etc.

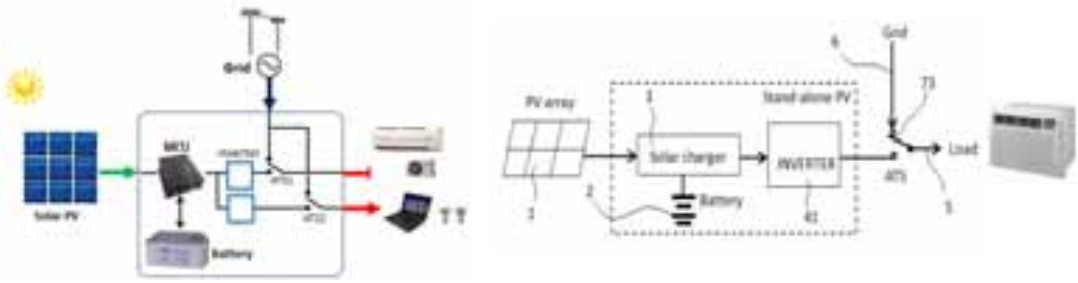

Fig. 2: Hybrid solar PV system (HyPV)

The HyPV utilizes nMPPO (near maximum-power-point operation) system design (Huang *et al*, 2006) to eliminate the conventional MPPT (maximum-power-point tracking control) but still keep optimal performance. This reduces MPPT energy loss and hardware cost and increases the reliability. The HyPV also utilizes direct PV charging control technique for battery to avoid energy loss and malfunction of conventional charger. This reduces cost and increases reliability. Fig.3 shows the installation of HyPV on roof-top for energy supply of the office.

Fig. 3: Hybrid solar PV system for office energy supply.

The design of 5.88 kWp solar PV system is shown in Table 4. To increase power generation, 1A-3P (one-axis 3-position) sun tracker is used to mount PV panels. The energy generation will be increased by 25% in Taipei (Huang *et al,* 2007). The solar PV system is divided into two 2.94 kWp subsystems. No.1 supplies 4 air conditioners (220VAC). No.2 supplies power to drive 2 air conditioners (220VAC) and LED lighting and PC's (110VAC) (Fig. 3). The installation is as shown in Fig. 4.

Table 4: PV system design.

Solar PV system:	
(1)energy generation capability, kWh/kWp-yr	900
(2)PV installed capacity, kWp	5.88
(3)system loss	10%

3. Test results

The installation of HyPV system including measuring system was completed in July 2014. The performance was monitored continuously from August, 2014. Fig. 5 shows the 5-month operation for No.1 unit which is used to supply 4 air conditioners. According to statistical data from the government monitoring network around Taiwan, the daily PV energy generation per unit PV installation is 2.47 kWh/kWp per day (900 kWh/kWp-yr). Fig. 6 shows that the 5-month performance of No.1 obtains 2.17 kWh/kWp per day in average which is 12% lower than the statistical data. This is due to low load energy consumption in fall season while air conditioner is not frequently used.

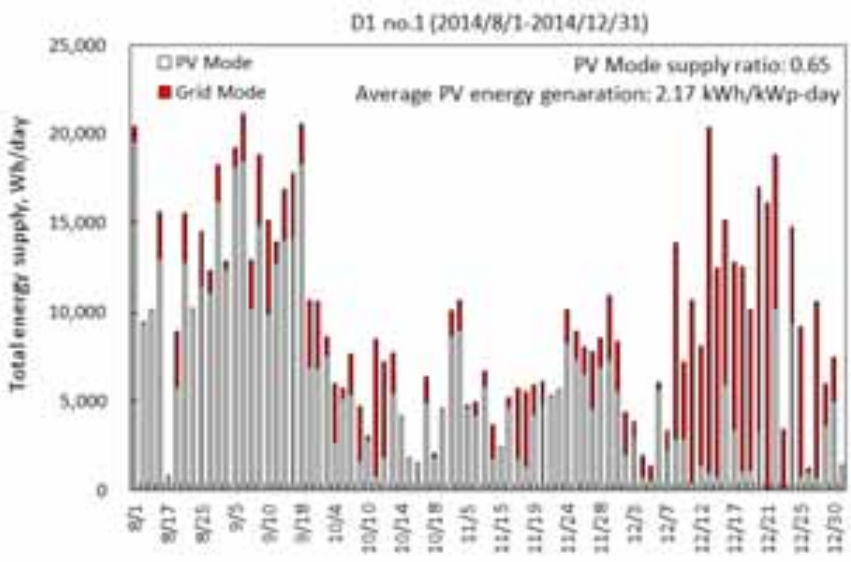

Fig 5: Long-term performance in No.1 unit.

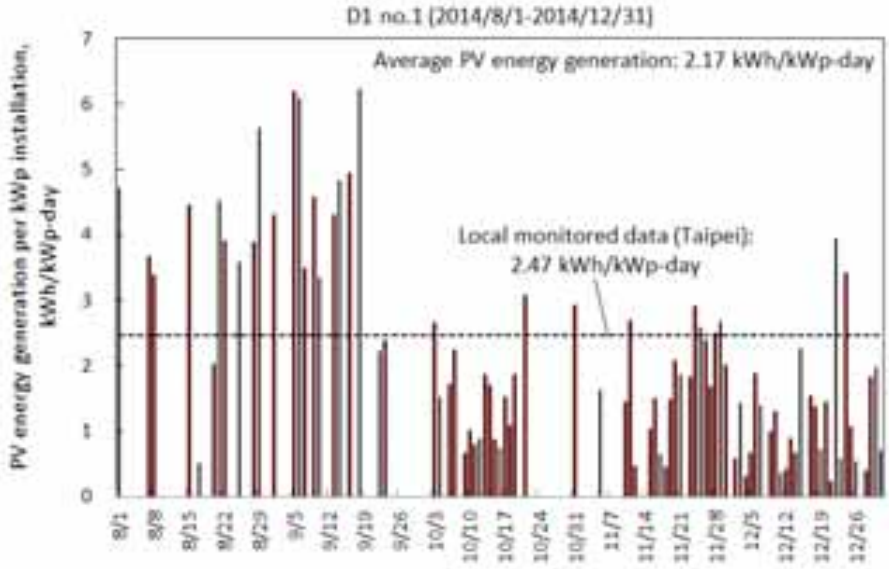

Fig 6: PV generation per kWp installed in No.1 unit.

The daily total energy supply (PV-Mode and Grid-Mode) of No.2 unit is shown in Fig 7. It reaches 2.67 kWh/kWp per day, 8.1% higher than the statistical result. This is due to the fact that the load energy of LED lighting and NB is supplied by No.2 unit which is not changed all year round.

Table 5 is the long-term results in PV energy generation and solar fraction. It shows that the PV energy generation per PV installed reaches 2.42 kWh/kWp per day (Fig.8), approaching the statistical result (2.47). This means that no PV energy generation loss for the whole D-1 system, even it is operated only in weekdays and at low load condition in fall season.

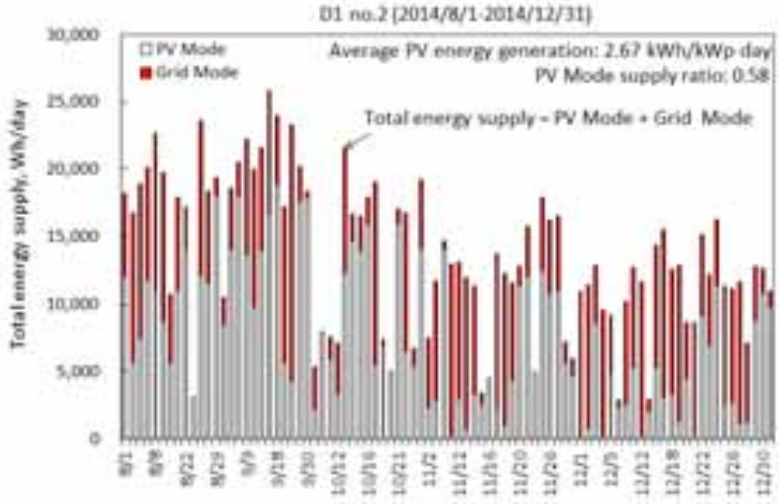

Fig 7: Long-term performance of No.2 unit.

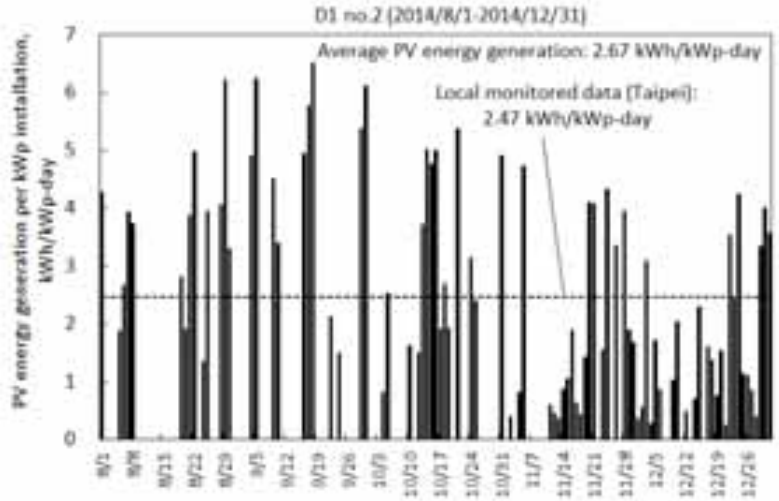

Fig 8: PV generation per kWp installed of No.2 unit.

Table 5: Performance of D-1 system in 2014.

D-1	No.1		No.2		No.1 PV generation loss, %	No.1+No.2	
	PV generation per kWp installation, kWh/kWp-day	Solar fraction	PV generation per kWp installation, kWh/kWp-day	Solar fraction		PV generation per kWp installation, kWh/kWp-day	Solar fraction
2014/8	3.71	0.88	3.5	0.61	-	3.61	0.745
2014/9	4.4	0.87	4.67	0.68	8.6	4.54	0.775
2014/10	1.59	0.75	3.7	0.7	52.7	2.65	0.725
2014/11	1.77	0.73	2.15	0.48	17.7	1.96	0.605
2014/12	1.21	0.29	1.95	0.4	33.3	1.58	0.345
Average	2.17	0.65	2.67	0.58	18.8	2.42	0.615

Fig 9 shows that the 7-month total energy supply (load) of D-1 in 2015 is lower than the estimation (28.6 kWh/day), except in summer. The PV-Mode supply ratio is 0.75. The load demand in March is quite low which increases the PV generation loss. However, the PV energy generation reaches 20.94 kWh/day in summer (June and July), 28% higher than average prediction. Fig.10.

The design of D-1 system is based on the concept of PV energy for self-consumption and small battery storage to reduce cost. The battery is used as a buffer to stabilize the instantaneous load only. The long-term test results for a year shows that the PV energy generation loss is low.

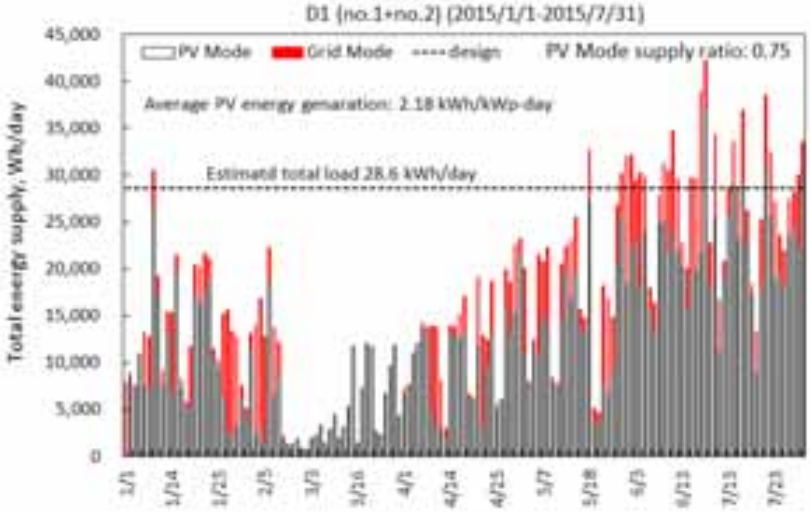

Fig 9: Total energy supply (load) of D-1 in 2015.

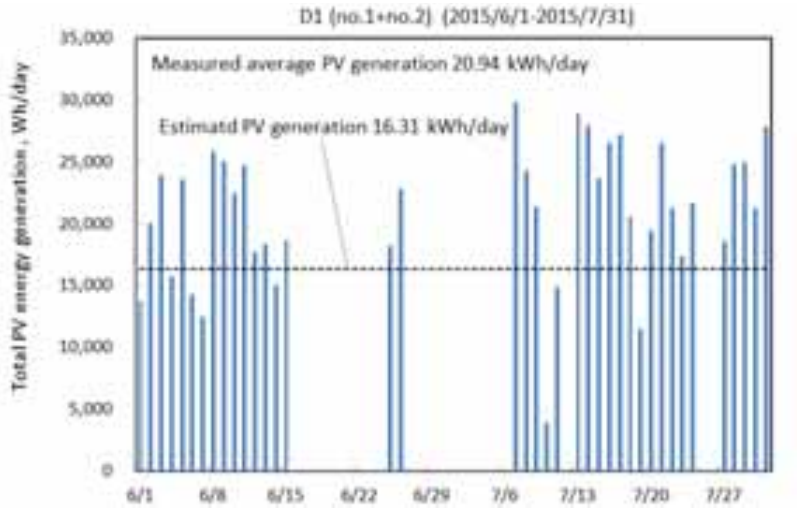

Fig 10: Overall performance of D-1 in 2015.

4. Economic Feasibility

The total investment of the solar PV system and the retrofit of air conditioning system, lighting devices, window insulation etc. is around USD30,000. The net total energy saving in 20 years is USD 80,000, including M&O cost. The system has been run about one year. The measured total power consumption of the office is reduced from 10.2 kW to 3.6 kW (after retrofit), about 65%. The solar PV system supplies about half of the rest of energy demand of the office. That is, 85% energy reduction in total.

The economic analysis (Table 5) shows that the total energy saving through retrofit and PV installation reaches 85% in Taipei (poor solar area) and 96% in Tainan (rich solar area). This indicates that the present demonstration system (D-1) can approach zero-energy office if installed in a solar rich area. The payback time is 8 yr in Taipei and 7.5 yr in Tainan.

5. Conclusions

The present study shows that, performing energy saving retrofit then utilizing solar PV energy to supply the remaining load demand in grid can solve the energy shortage problem, if nuclear power was abandoned in Taiwan. An office located in Taipei with 150m^2 floor area and 14 employees was chosen as the demonstration site (D-1). Four energy-saving retrofitting on air conditioning, lighting, PC, and anti-IR film on window glass results in 65% energy saving. A 6 kWp solar PV system is further installed to replace additional 20% energy. That is, 85% energy is saved in total. The solar PV system is an isolated-type hybrid solar PV system (HyPV) which operates under Stand-alone PV Mode or Grid Mode, automatically, by a

power controller. No solar PV energy is fed back to grid. The total investment for the solar PV system and the retrofit for energy saving is around USD30,000. The net total energy saving in 20 years is USD80,000, including M&O cost. System D-1 has been run more than one year. The solar PV system supplies about 60% final energy demand of the office.

If energy-saving in air conditioning and lighting can reach 60% as D-1 did in the whole country, the nuclear power (18%) can be abandomed by using solar PV installation to supply the remaining load demand with proper energy storage.

Abstract

In Korea, energy consumption information for existing building is provided to primary energy consumption by fuel types (electric, gas, and district heating) from energy service utilities. To be more effective building energy management nationally, it should be to manage building energy consumption by end use. For this, it is the best approach to collect direct end-use metering data for all buildings but in practically very difficult because of expense and long time. Moreover, it is not appropriate only the application of the building energy simulation based on model to derive energy consumption by end use due to error with energy consumption of actual building.

Therefore LBNL has been developed algorithm to estimate energy end use since 1980, the results are EnergyIQ based on web service. The final goal of this research is to develop algorithm to estimate energy end use with real state of Korea, so by selecting the reference buildings to meet the statistical significance level, it is necessary to collect on-site metered data.

In this study, the end-use sub-metering of office building in Seoul is ongoing hourly into cooling, heating, ventilation, domestic hot water, lighting, office equipment, elevator, miscellaneous since 1 March 2015. Weather conditions are not a crucial factor for lighting energy consumption in existing office building. So based on this sub-metering data, first we carried out an analysis of lighting energy use profile to utilize basic data in lighting energy consumption estimation.

Keywords: *Office building, Lighting energy use, End-use sub-metering, Estimation of energy end-use consumption*

1. Introduction

The South Korean government is managing the monthly energy consumption of electricity, city gas (LNG), and district heating system used by its existing buildings through the integrated building energy management system. This information about energy consumption by source of energy may be useful for the management of the national energy supply and demand policy, but there is not enough detailed information about energy consumption to lead occupants to participate in effective and practical energy saving activities. Therefore, the energy consumption of buildings needs to be controlled depending on end-use energy. For example, the energy consumption of residential buildings should be divided according to end-use such as heating, cooling, hot water supply, lighting, ventilation, electric appliances, cooking, etc., while the energy use of office buildings should be segmented into heating, cooling, hot water supply, lighting, ventilation(air movement), electric appliances, vertical transportation(elevators/escalators), city water supply, etc.

Here, the approach methods to acquire energy consumption by end-use can be divided into building simulation, direct end-use metering, and end-use disaggregation. Building simulation is a very common method, but its shortcoming is the lack of reality, given that there is a significant difference between the building assumption conditions and the actual building characteristics. The direct end-use metering method requires high costs and cannot draw general conclusions due to a limited number of sample buildings for measurement. The end-use disaggregation method provides disaggregated data about energy consumption of end-use by adjusting the building simulation based on the measurement data and collected information of a sample building, and it is worthwhile to apply the method to domestic buildings. In order to apply the end-use disaggregation method, it requires developing a disaggregation algorithm fit to a domestic condition. According to H. Akbari (1995), in order to develop a disaggregation algorithm, it requires selecting sample buildings for measuring and collecting measurement data by end-use energy, paying on-site surveys to gather information about equipment inventories,

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.08.13 Available at http://proceedings.ises.org

operation schedules, and the characteristics of buildings, and establishing a database of end-use energy after conducting an analysis of collected data, including regional climate characteristics. These databases are united through a statistical adjustment into a single database, based on which an end-use disaggregation algorithm will be developed.

We selected sample buildings for office building in Seoul and plans to install the measurement system to a total of 85 buildings to disaggregate end-use energy for a period of three years. The final purpose of this study is to develop disaggregation algorithm by identifying the characteristics of end-use through analysis of the above data for influential factors. This paper aimed to identify the characteristics of lighting energy use and to induce major influential factors through analysis of measurement data, which accounted for a relatively high-energy consumption ratio among non-HVAC energy in office buildings, and to use them as basic data in order to supplement and verify the end-use energy estimation equation.

2. Methodology

According to prEN 15193 (2006), the calculated method and the metered method are suggested as ways to determine the lighting energy use. The calculated method is once again classified into the comprehensive method and the quick method. The comprehensive method is to calculate an equation based on the actual building operation data (annual/monthly/hourly), and its shortcoming is that it cannot consider the energy consumption of some lighting control devices. In contrast, the quick method is to calculate an equation based on the standard data (annual), and although it can reduce the required time, it has its own limitation that it cannot consider the actual building conditions. The metered method is to measure energy consumption using electronic watt hour meters to the circuits in the low-voltage distribution panel, and provide the highest level of accuracy, but it is hard to be implemented due to cost and time.

Therefore, it is reasonable to develop an estimation equation of lighting energy use based on the monthly electricity bill data and the user input data. The basic input information to disaggregate lighting energy use from the total energy consumption through the estimation algorithm includes electricity bill information, building information, system information, operation information, and regional climate information (Fig. 1). To induce the required information, the influential factors in energy use need be taken into consideration by diving them into building factors, system factors, user factors, and weather factors. The building factors include the floor area (FLA), conditioned floor area (CFLA), number of floors (FLN), ceiling height (CLH), orientation (ORN), window-wall ratio (WWR), visible light transmittance (VLT), building age (BLAG), etc. The system factors include the type, power consumption and efficiency of lighting equipment(LTQ), lighting power density(LPD), interior illuminance(ILU), shading system(SHS), lighting control devices (manual, on-off, dimming, etc.)(LTCN). The user factors include operating time(OPHR), occupant density(OCD), behavioral patterns of occupants(OCS), and ownership(OWN), while the weather factors are the daylight factor(DAL), etc.(Fig. 2). The estimation equation of lighting energy based on these influential factors can be summarized as seen in Equation (1). This study will draw major influential factors through analysis of the measurement data of the sample buildings and will incrementally complement and verify the estimation equation.

3. Case study

3.1 Description of the building

The target building for the measurement is summarized as seen in Tab. 1; it was located in the central district of Seoul(with a climate zone of the central region), and its construction was completed in 1990; it has total floor area of 1,265.1 ㎡ and has one underground floor and five ground floors. The use purpose, floor area, occupancy information, and lighting power density of each office floor can be seen in Tab. 2. The ceiling down-type fluorescent lights (FL) and electronic luminescence (EL) were used for office lighting, and the average indoor illuminance was 300lx; no lighting control systems were applied, while the indoor blinds were installed.

Tab. 1: Overview of case study building

The target office spaces for the measurement of lighting energy consumption were office spaces on the 2F-5F (Fig. 3) and the electronic watt hour meters mounted with the zigbee-type wireless transmission devices were installed to office lighting circuits in the distribution panel of each floor. The accumulated electricity consumption was measured by the hour starting from March 1, 2015 (Tab. 3) and the data measurement period for the analysis lasted until the end of July. After calculating the total electricity consumption of each floor, the

lighting energy use was computed, which can be summarized and seen in the following Equation (2).

3.2 Results and discussion

3.2.1 Hourly lighting energy use

The monthly average of lighting energy use during the weekdays by month was recorded as 79.7Wh/㎡ in March, 80.8Wh/㎡ in April, 73.8Wh/㎡ in May, 74.5Wh/㎡ in June, and 73.3Wh/㎡ in July, while that during the weekends by month were estimated at 6.8Wh/㎡ in March, 5.1Wh/㎡ in April, 6.7Wh/㎡ in May, 5.4Wh/㎡ in June, and 15.2Wh/㎡ in July.(Fig 4) The highest hourly average of lighting energy consumption by month was recorded at 4.7kWh at 17 pm on March 12, 5.1kWh at 17 pm on April 23, 5.3kWh at 16 pm on May 8, 4.5kWh at 12 pm on June 8, and 5.0kWh at 10 am on July 15, and the morning hours showed a higher

occurrence ratio of monthly average peaks of lighting energy consumption.

Fig. 4: average hourly lighting energy use

According to a study by Xin Zhou et al. (2015), the 24 hours of the weekdays can be divided into a total of 6 time zones: the morning communing hours, the morning working hours, the lunch hour, the afternoon working hours, the closing hours, and the night hours (Fig. 5), but the total period time can vary depending on time zones. The morning commuting hours (3 hrs.) ranging from 6 am to 9 am showed a sharp increase in lighting energy use, which remained at a constant level during the morning working hours (3 hrs.) spanning from 9 am to 12 pm. The lighting energy use during the lunch hour from 12 pm to 13 pm was reduced by 1.6-6.8% compared to the morning working hours. Although the light energy use during the afternoon working hours (4 hrs.) from 13 pm to 17 pm showed a relatively constant level but displayed a greater deviation compared to the morning working hours. The hourly lighting energy consumption declined over the lapse of the closing hours (4 hrs.) from 17 pm to 21 pm, which displayed a more steady incline than the morning working hours. The night hours zone from 21 pm to 6 am of the next day (9 hrs.) showed an almost flat incline, but displayed a much wider deviation depending on the presence and absence of overtime work. The weekends showed a similar deviation in lighting energy consumption like the night hours zone.

According to the monthly lighting energy consumption rate of each time zone, the afternoon working hours took up the highest percentage at 28.5%, followed by the morning working hours (21.5%), the closing hours (15.4%), the lunch hour (13.8%), the morning commuting hours (9.8%), and the night hours (7.6%), and the weekends & holidays (3.3%).(Fig. 6)

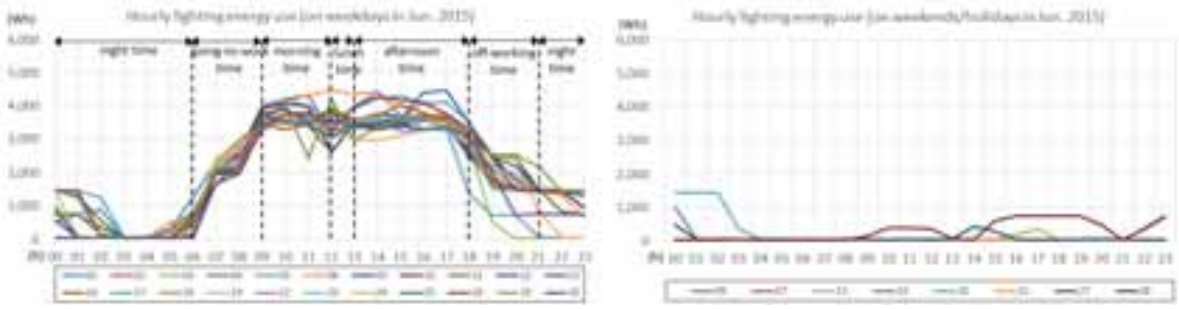

Fig. 5: hourly lighting energy use during 24 hours (L: weekday, R: weekend)

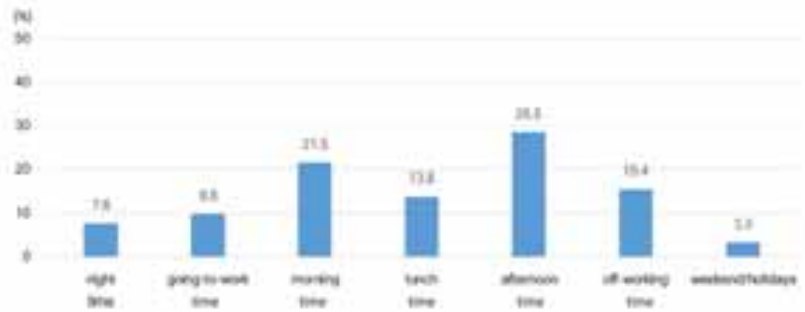

Fig. 6: The ratios of lighting consumption by time zone to lighting energy use per month

The hourly-based energy consumption of office lighting was recorded at 10Wh for the 3-5F offices, while that of the 2F office displayed a remarkably higher level of 20Wh. This was due to a high ratio of electronics lamps installed on the 2F office, almost 2 times that of the other office floors, as they were believed to consume more standby power than fluorescent lamps. (Tab. 4)

3.2.2 Daily lighting energy use

The ratios of the monthly average lighting energy consumption during the weekdays were recorded at 97.2% in March, 98.4% in April, 94.9% in May, 98.1% in June, and 95.1% in July, while those during the weekends 2.8% in March, 1.6% in April, 5.1% in May, 1.9% in June, and 4.9% in July. The average energy consumption ratio of the weekdays was estimated at 96.7%, while that of the weekends were at 3.3%.(Tab. 5)

Tab. 5: The ratios of monthly lighting energy use for weekday vs weekday/holiday

weekend/holiday(%)	2.8	1.6	5.1	1.9	4.9	3.3	1.7

3.2.3 Monthly lighting energy use

The ratio of lighting energy use against the total energy consumption by month was recorded at 15.4% in March, 19.0% in April, 16.2% in May, 12.6% in June, and 10.1% in July. The monthly average lighting energy consumption was within 1,100~1,200kWh. The lighting energy consumption was relatively lower in May, as the working hours of the month were reduced by the increased number of holidays, which was 1.8 times more than the other months. As the air-conditioning operation started from June, the energy consumption surged, while the percentage of lighting energy use against the total energy consumption showed a declining tendency (Tab. 6).

Tab. 6: The ratios of energy use to whole building electricity consumption per month

3.2.4 Correlation between lighting energy use and influential factors

As useful information was collected for the correlation analysis between lighting energy use of each office floor (2F~5F) of the case-study building and influential factors, the air-conditioned floor area was selected as a building factor, the lighting density and indoor illumination as system factors, and the number of occupants and use time as user factors can be seen in Tab. 7. According the results of the correlation analysis between the influential factors and light energy use, the correlation between the number of occupants and the use time revealed the highest coefficient of 0.95 in average, followed by the air-conditioned floor area, indoor illumination, and lighting density. The influential factors which belong to the user factors showed higher levels of correlation, but this was believed to be due to the design of the building to provide similar levels of lighting density to offices within the same building. Further studies need to be carried out in the future in order to conform the correlation between user factors and lighting energy use by comparing it with several different buildings.

4. Summary and Conclusions

In order to develop an estimation equation of lighting energy use of office building to be suitable to domestic situations, we analyzed the measurement data collected from the case-study building, identified the characteristics of lighting energy use, and drew major influential factors to be used as basic data to supplement and verify the estimation equation.

The major study results are as follows;

(1) For estimation of lighting energy use, this study examined the influential factors in energy consumption by classifying them into the building factors, system factors, user factors, and weather factors;

(2) The monthly average of lighting energy use of office building during the weekdays by month was recorded at 79.7Wh/㎡ in March, 80.8Wh/㎡ in April, 73.8Wh/㎡ in May, 74.5Wh/㎡ in June, and 73.3Wh/㎡ in July, while that during the weekends by month were estimated at 6.8Wh/㎡ in March, 5.1Wh/㎡ in April, 6.7Wh/㎡ in May, 5.4Wh/㎡ in June, and 15.2Wh/㎡ in July, and the morning hours showed a higher occurrence ratio of the monthly average peaks of lighting energy consumption;

(3) According to the monthly lighting energy consumption rate of each time zone, the afternoon working hours took up the highest percentage at 28.5%, followed by the morning working hours (21.5%), the closing hours (15.4%), the lunch hour (13.8%), the morning commuting hours (9.8%), and the night hours (7.6%), and the weekends & holidays (3.3%);

(4) This was due to a high ratio of electronic lamps installed on the 2F office, almost 2 times that of the other office floors, as they were believed to consume more standby power than fluorescent lamps;

(5) The ratios of the monthly average lighting energy consumption during the weekdays were recorded at 97.2% in March, 98.4% in April, 94.9% in May, 98.1% in June, and 95.1% in July, while those during the weekends 2.8% in March, 1.6% in April, 5.1% in May, 1.9% in June, and 4.9% in July. The average energy consumption ratio of the weekdays was estimated at 96.7%, while that of the weekends were at 3.3%;

(6) According the correlation between lighting energy consumption of each office floor within the case study target building and influential factors, the correlation with the number of occupants and use time showed the highest coefficients, followed by the conditioned floor area, indoor illumination, and lighting density.

Future studies need to conduct a comparative analysis by targeting numerous sample buildings in order to identi fy and confirm various possible correlations between lighting energy consumption and influential factors.

Abstract

To contribute in reducing the electricity consumption rate and the harmful impacts of fossil fuels, a Solar Water Heating (SWH) technology is recommended to cover around 50% of hot water demand in hospitals in Saudi Arabia. The paper studies the techno-economic viability of two types of SWH collectors in five different cities of Saudi Arabia. Findings indicate that Najran and Tabuk are the most attractive places because they have the highest annual life cycle saving, the highest benefit to cost ratio, and the lowest payback period, while, in contrast, Jeddah is the lowest attractive city to use SWH. Moreover, the economic analysis shows the advantage of using glazed flat plate collector over evacuated tubes because it has shorter payback periods and higher annual life cycle savings.

Keywords: *Solar Water Heating, Evacuated tubes, glazed flat plate collector, Hospital, Saudi Arabia*

1. Introduction

The rapidly increasing demand of electricity and global warming are factors that have brought interests to find an environmental and efficient source of energy. Solar energy is the most abundant source of energy and it will be the future source of energy for countries that receive high amount of solar radiation such as Saudi Arabia. The conventional electric water heating technology is used in Saudi Arabia to meet the demand of the hot water. The process of water heating by electricity in a hospital with 200 beds consumes annually around 450 MWh and, therefore, employment of solar water heating (SWH) systems is recommended.

Oil is the main source of energy in Saudi Arabia, however, the enormous potential of solar energy has brought the government attention in 1980s and, therefore, different solar technologies were developed and tested [Huraib, 1996]. Saudi Arabia receives high intensities of solar radiation in most of its regions that makes it an attractive place for implementing solar energy systems. A study was conducted to assess the daily solar radiation for ten different cities in Saudi Arabia and it was reported that the daily solar radiation varied from 4.73 to 6.94 kWh per m^2 [Bahel, 1986]. Another study selected four different climatic zones in Saudi Arabia and found similar results [Zuhairy, 1995].

In the past decade, attention has been concentrated in optimizing energy consumption in large buildings such as hospitals. Around 5% of the energy consumed in hospitals is for water heating [Čongradac, 2012] with almost constant consumption of 9 GJ per bed throughout the year [Bujak, 2010]. Some studies have developed different technologies to enhance the use of renewable energy in hospitals, such as solar energy in combination with thermal aquifer energy storage [Paksoy, 2000], hybrid plant using solar thermal, photovoltaic, and phosphoric acid fuel cell systems [Bizzarri, 2006].

Solar water heating technology have been widely used for domestic applications. [Kablan, 2004] reported that a continuous rise of solar collector installations in the period 1970 to 1995 was observed in Jordan. Techno-economic evaluation for SWH system of glazed flat plate collectors in Oman was presented by [Gastli, 2011]In a different study, [Hafiz and Al-Sulaiman, 2014] reported the techno-economic evaluation for glazed and evacuated tube collectors for water heating of residential buildings for different cities in Saudi Arabia.

The demands for water heating in hospitals are huge and, therefore, there is a need to seek a cost effective solution based on solar thermal energy. This study evaluates the techno-economic feasibility of using two SWH systems for a hospital with 200 beds at different locations in Saudi Arabia. The findings will help decision makers and engineers to determine the technical and financial viability of potential renewable energy projects in hospitals in Saudi Arabia or other countries that have similar operating and weather conditions. A Solar Water Heating (SWH)

doi:10.18086/swc.2015.08.14 Available at http://proceedings.ises.org

technology is recommended to cover around 50% of hot water demand in hospitals in Saudi Arabia. This percentage is selected because the sun is available only on the daytime and it is a visible solution to use this percentage; otherwise, using a larger percentage means, a larger solar collector should be installed, which is not practical due to space limitation.

2. Metrological data and simulation

This study is performed to cover a large area of Saudi Arabia, which is situated between latitudes of 17.5°N and 31°N, and longitudes of 36.6°E and 50°E. The findings will also be useful to other locations that have similar weather conditions in other countries. In this study, five different cities were selected to cover different coordinates, which are Tabuk (north), Dhahran (east), Riyadh (center), Jeddah (west), and Najran (south). The metrological data of the five cities selected have been listed in Tab. 1 [NASA RETscreen, Renewable Resource Atlas].

Tab. 1: Climate data for the selected cities.

Location	Jeddah	Riyadh	Dhahran	Najran	Tabuk
Average daily solar radiation (kWh/m^2/d)	5.95	6.2	5.83	6.77	6.33
Air Temp (°C)	30.7	28.6	27.8	26.5	23.4
Earth Temp (°C)	29.8	29.2	28.1	26.7	24
Latitudes (ø)	21.7	24.9	26.3	17.6	28.4
Longitude	39.2	46.7	50.2	44.4	36.6
Elevation (m)	17	614	17	1212	768
Wind speed (m/s)	3.3	2.9	2	2.1	2.8
Relative humidity (%)	56.7	24.9	49.6	22.2	31.7

The metrological data for these cities, including air temperature, average daily solar radiation, atmospheric pressure, wind speed, and relative humidity were imported from NASA database. These data were further crosschecked with the experimentally recorded data by K.A.CARE [Renewable Resource Atlas, 2015] and the data for Tabuk city was corrected. Figure 1 illustrates the daily solar radiation data for a horizontal surface where Tabuk has the highest solar radiation during the summer months whereas, Najran has the highest radiation during the winter months. It also shows that, on average throughout the year, Najran has the highest solar radiation while Dhahran has the lowest solar radiation, which can also be noticed in Tab. 1.

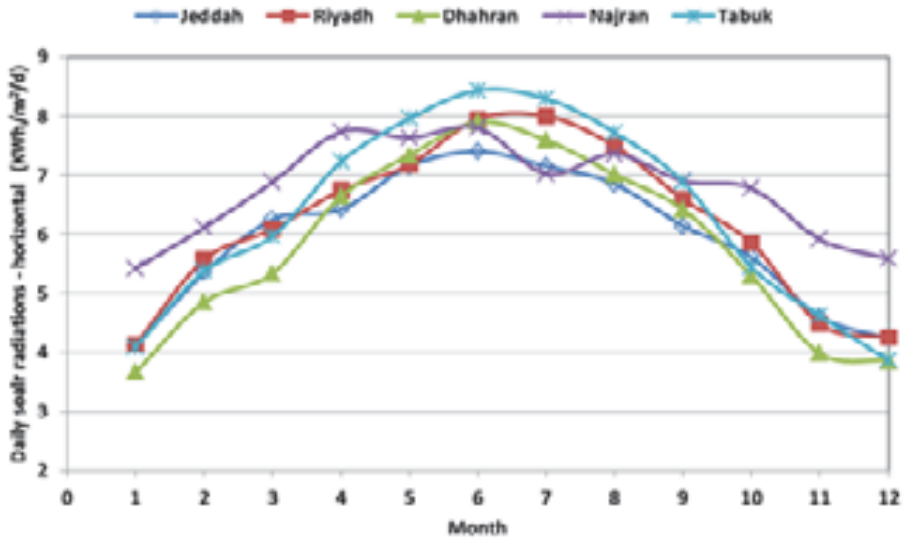

Fig. 1: Monthly variation of daily solar radiations on horizontal surface.

To get the best configuration for the collector, the study evaluated the SHW under two slopes. The first one is tilted at a slope equal to the latitude angle of the city selected, which represents the optimum value of the slope for a system to be used constantly throughout the year, while the other setting is for a horizontal surface. The findings have been shown in Fig. 2, which reveal the difference between the two settings.

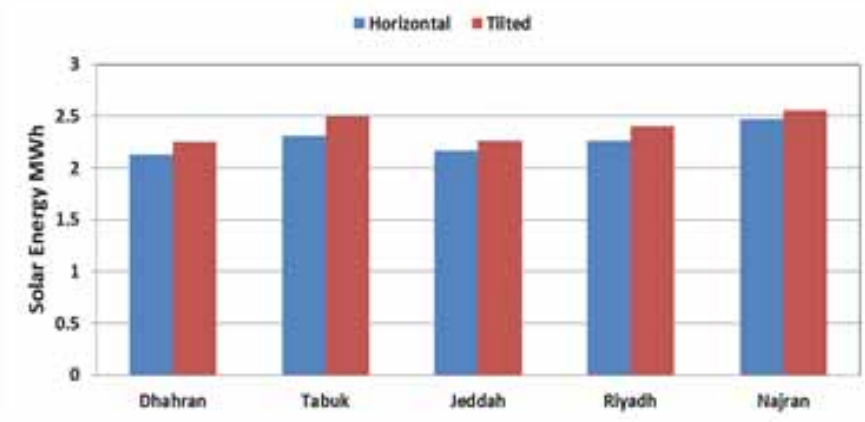

Fig. 2: Annual Solar Energy for horizontal and titled collectors.

There are three commonly used SWH technologies which are evacuated tube, glazed, and unglazed flat plate collectors. The temperature required for hot water in hospitals is between 50 and 60 °C and, therefore, only glazed flat plate collectors and evacuated tube collectors were selected to obtain the required temperature, meanwhile obtaining the required solar fraction with relatively a low aperture area [International Energy Agency, 2012]. Simulations were conducted for both technologies and the input data has been listed in Tab. 2 [Gastli, 2011, Abd-ur-Rehman and Al-Sulaiman, 2014]. Simulations were performed for evacuated tube collector to cover 50% solar fraction of the 200 beds hospital in Tabuk. Results indicate that the desired solar fraction can be achieved by using 21 collectors of evacuated tube type in Tabuk, which was used as a reference to analyze other four cities selected Similarly, simulations were performed for flat plate collectors under the same prevailing conditions and comparative analysis was conducted to obtain the optimum number of the collectors to be used for hospitals under different climatic conditions of Saudi Arabia. The technical and financial characteristics for both collector types have been listed in Tab. 3 [RETscreen].

Tab. 2: Input parameters for the evacuated tube collectors.

Parameter	Value
Number of beds	200
Occupancy rate (%)	80
Daily hot water usage estimate (L/day)	31,500
Hot water temperature (°C)	60
Operating days per week	7
Collector slope	Location latitude
Miscellaneous losses (%)	5
Storage capacity per square meter (L/m^2)	75
Conventional fuel type	Electricity
Seasonable efficacy (%)	90
Electricity rate ($/kWh)	0.03
Initial contingencies (labor, transportation etc.) (%)	5
Annual cost (O & M) (%)	5
GHG emission factor (tCO_2/MWh)	0.737
Fuel cost escalation rate (%)	2
Inflation rate (%)	2.5
Project life (years)	20

Tab. 3: Specifications for the evacuated and glazed collectors.

Solar Collector Type	Evacuated Tube	Glazed
Gross area per solar collector (m^2)	12.22	10.7
Aperture area per solar collector (m^2)	9.02	9.52
Fr (tau alpha) coefficient	0.53	0.63
Fr UL coefficient (W/m^2)/°C	1.42	3.88
Number of collectors	21	24
Capacity (kW)	132.5	160
Initial cost (US$)	77000	58500

3. Result and Discussion (results and discussion)

Evaluation and comparisons in terms of performance and economic viability have been conducted for both collector types. The solar fraction is defined as the percentage of the annual energy needs that the SWH system will cover. This value is set for Tabuk to be 50% for both flat plate and evacuated tube SWH systems. This means that the SWH system will cover half of the energy consumption and the rest of the energy requirements are met by a conventional heating system, which is electricity in our case. The findings, as shown in figure 3, demonstrate that the solar fraction varies from 49% to 55%, where Najran has the highest fraction and Dhahran has the lowest fraction. The variations of the solar fraction among the selected cities are relatively small which reflect the viability of using SWH in these cities.

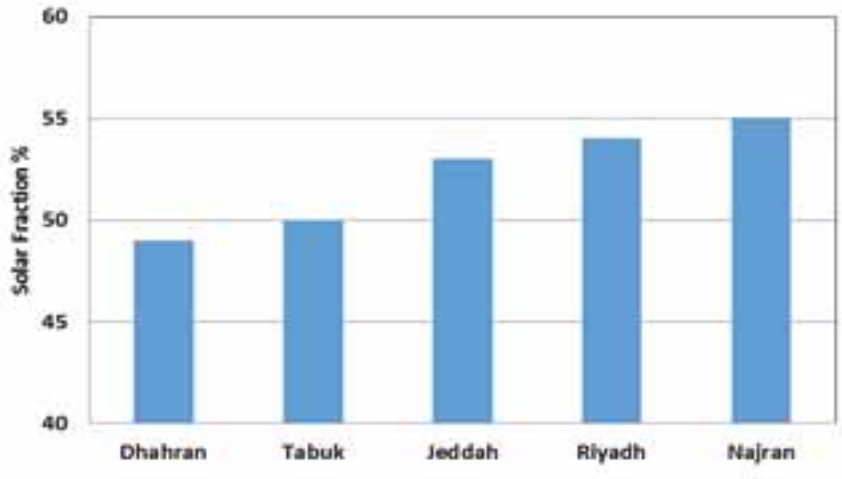

Fig. 3: Solar fraction of the annual energy needs covered by SWH.

The process of water heating to specific temperature by electricity consumes relatively a huge amount of energy, which is also function of input temperature to the system. Another evaluating term for a SHW technology is the electricity saving potential per year, which is the amount of energy that will be saved after using a solar heating system. It is directly proportional to the solar fraction, for example Tabuk has 50% solar fraction and it is expected to save 271 MWh annually, as shown in Fig. 3. Therefore, the conventional heating system will cover the rest of the total consumption, which is 271 MWh per year. Fig. 4 illustrates the annual electricity saving potential for each city on the left y-axis and the potential savings for whole project life on the right y-axis. The average electricity saving potential per year for all cities is 229 MWh and the average saving during the twenty years project life time is 4588 MWh.

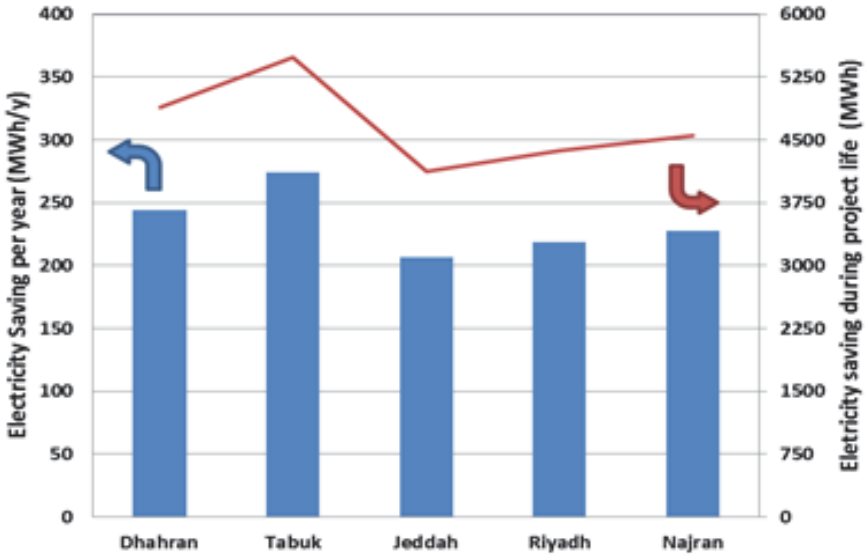

Fig. 4: Electricity saving potential.

The environmental advantages of using the SHW systems were also assessed. The study reports the amount of greenhouse gas (GHG) emissions that will be reduced after installing the environmentally friendly SWH system. Fig. 5 shows the annually expected GHG emissions reduction on the left y-axis while the total reduction of the emissions during the life-time of the project are shown on the right y-axis. It is shown that the highest amount of GHG emissions will be avoided in the cities of Tabuk and Najran, which reach 200 tons of annual CO_2 emissions. In addition, the cumulative reduction over the project life-time for these two cities is expected to be 4000 tons of CO_2 emissions.

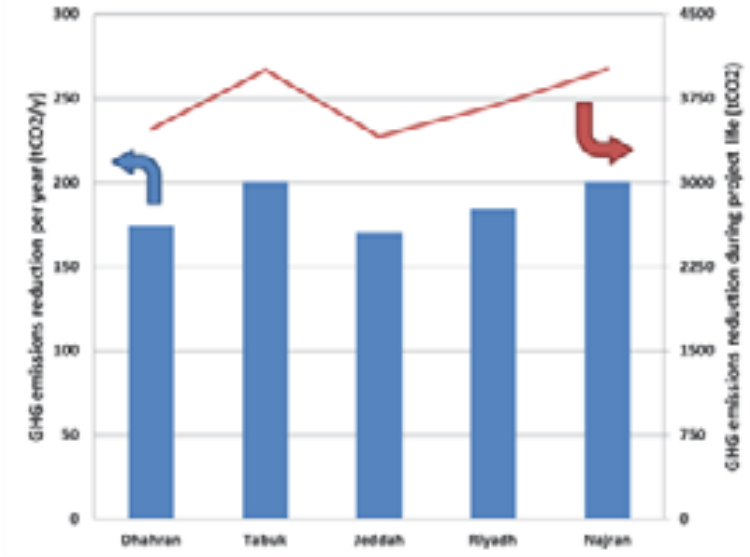

Fig. 5: GHG Emissions Reduction Potential.

After discussing the performance of the SWH technology, the economic viability of the system will be discussed next. It should be noticed the difference between the performance analysis where we have equivalent outputs for both evacuated and glazed collectors; the financial analysis will vary between the two technologies according to the initial cost and the annual saving of the project.

The payback period is the time for an investment to recoup its own initial cost from the savings it generates; the less time it takes the more desirable the project is. Fig. 6 presents the payback period of the project for both collector types. For the evacuated tube system, Najran and Tabuk have the shortest period of 8.9 years while the other cities have slightly longer periods, in which the maximum period takes place in Jeddah. Selecting flat plate collectors reveal better economic option because it recovers the initial cost faster for all the cities selected. The findings show that Najran and Tabuk, in terms of payback period, are the most attractive cities with flat plate

collectors at which they recover their initial cost in less than seven years.

Fig. 6: Payback Period.

Another economic evaluation parameter is the annual life cycle savings that would present the yearly cost saved and together with the solar fraction, a project can be evaluated economically. The annual savings for the evacuated tube system varies between $2054 and $3429 for Jeddah and Najran respectively, as shown in Fig. 7. The figure also shows the advantage of the flat plate type where its annual savings varies between $3389 and $5048 for Jeddah and Tabuk respectively.

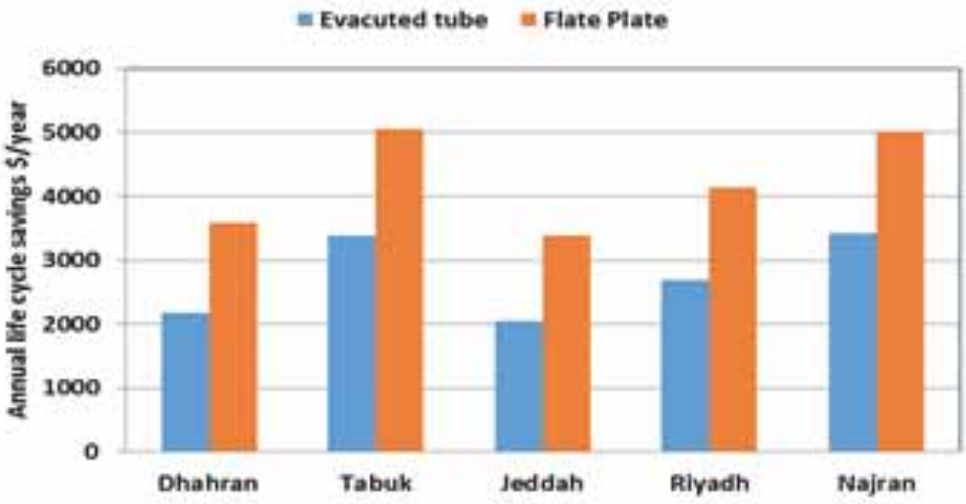

Fig. 7. Annual life cycle savings.

4. Conclusion

The study discussed the techno-economic feasibility of using SWH systems for five different cities in Saudi Arabia. The conclusions obtained from this study are:

- For the same number of collectors, the difference of solar fraction between the selected cities is relatively small which indicates viability of all regions in Saudi Arabia to adopt SWH technology.
- For all cities, the electricity saving potential is high and can reach up to 5400 MWh for project life time of 20 years. This also leads to high reduction in GHG emissions.
- For the same solar fraction in both evacuated tube and glazed SWH technologies, the economic analysis shows the advantage of using glazed flat plate collector because it has shorter payback periods and higher annual life cycle savings.
- Based on techno-economic evaluation, Najran and Tabuk are the most attractive places followed by Riyadh and Dhahran. Jeddah is the least attractive city among the five selected cities due to higher payback period and lower annual life cycle savings.

Abstract

This study evaluates experimentally the thermal behavior of architectural elements of insulate roofs, including semi-insulation material with overlaid green elements on vertical and horizontal planes, also known as green roofs, for temperate climates. The results of the study showed that the flux of heat transfer on the roof was reduced and provide a better controlled temperature in the interiors all the yearlong. Difference between the outside and inside temperature up to 4 Celsius degrees were observed frequently specially in the early and late hours of the days, which generate a steady comfort.

Keywords: *Building integrated green roof, Climatic Year Type, Thermal performance*

1. Introduction

Hot and humid climates demand significant electricity for cooling. In 2001, Texas implemented the Texas Emissions Reduction Plan (TERP) program that aims to diminish the pollution in the state by energy efficiency

The use of green architectural elements started to have presence in some types of buildings in Mexico, specifically the residential architecture is beginning to see some examples in general without a definite specific purpose, such as a fashion phenomenon in its alleged desire of being "sustainable", though these elements do not consider relevant aspects regarding the structural behavior of the decks, and less its thermal effects or behavior.

This study present a preliminary analysis of the recorded results from an example of this type of solution built it in order to identify the possible advantages and disadvantages that can be identified specifically in the overall thermal behavior in external conditions and interiors.

The Mexican housing type has been subordinated to the economic system, and consequently to prevailing economic conditions. In general, since beginning of the twenty century, it has widely avoid using insulating material and misuses the climate advantage of the region, being more marked in the country central region. This phenomenon primarily identified by change of more economic construction systems, but with fewer advantages in climate use. In earlier times, the constructive system comprised materials such as stone and adobe and more complete solutions based on those systems, which unfortunately with the pass of the time were disappearing. Because of the area climatic conditions, this phenomenon did not represent major problem, the differences between external and internal temperature have minimal variations as it will be shown in this study.

2. Methods

There are several concepts for defining the green roofs covers on buildings. Two categories are very well recognized, the ones called extensive, comprising covers where the plant substrate is not exceeding 0.1 m, also called by some "ecological cover", characterized by small plants and some grasses, and the intensive ones with distinguished thicknesses greater than 0.2 m., where it is possible to plant some type of trees. There is some ones in an intermediate case they have been called semi-intensive, employing features of both. The latter classification is the case analyzed in this study.

Another concept used to define this field of study is "Urban Naturalization", which includes the concept of "green roofs" employed by several research groups including the compilation by Spanish Society for the Promotion of Urban and Rural Naturalization (PRONATUR).

doi:10.18086/swc.2015.08.15 Available at http://proceedings.ises.org

The base of this study is the work done by Minke on reference to "Green roofs" research in Germany, a country to which he is regarded as one of the fastest developing and implementing these elements. Since 1974, Minke; has conducted research and development in the field of green buildings, affordable housing and especially in the field of earth constructions His works are not only in Europe but also in South America, Central America and India. Minke stated that in areas with cold climates, in winter the ground is frozen and kept for long periods at 0°C, even when the outside temperature is considerably lower. With a temperature of + 20°C inside and -20°C outside and soil temperature 0°C decreases the transmission heat loss of the roof (Minke 2004: 16).

According with the Minke´s hypothesis, in a climate with more solar radiation green roofs would have major advantages (Minke 2004: 17), however global climate conditions are contrasting, since in most places with solar radiation normally does not have conditions as those in cold areas and insulating characteristics therefore are not the same. Since in cold climates where water freezing functions as insulation, in temperate zones hardly water will freeze the rooftop. Therefore these benefits will not be capitalized.

The study arises from the following stages:

a) A green roof 6.5 m long and 3.1 m wide is implemented, with a slab based partly insulated panel "W" supported with metal light beams and with a concrete compression layer 0.7m thick, which together with the panel does not exceed 0.18 m.

b) On the cover a membrane is placed as insulation of the humidity of the vegetable substrate placed over the cover with a thickness of 0.12 m; in the peripheral region of the substrate a fraction of gravel is set and between the gravel and the “tezontle” substrate, in order to filter out excess water without eroding the vegetable substrate. In a secondary zone of the cover with an area of 2.2 m long and 1.82 m wide the depth of the plant substrate has a minimum thickness of 0.12 m to a maximum rate of 0.55 m.

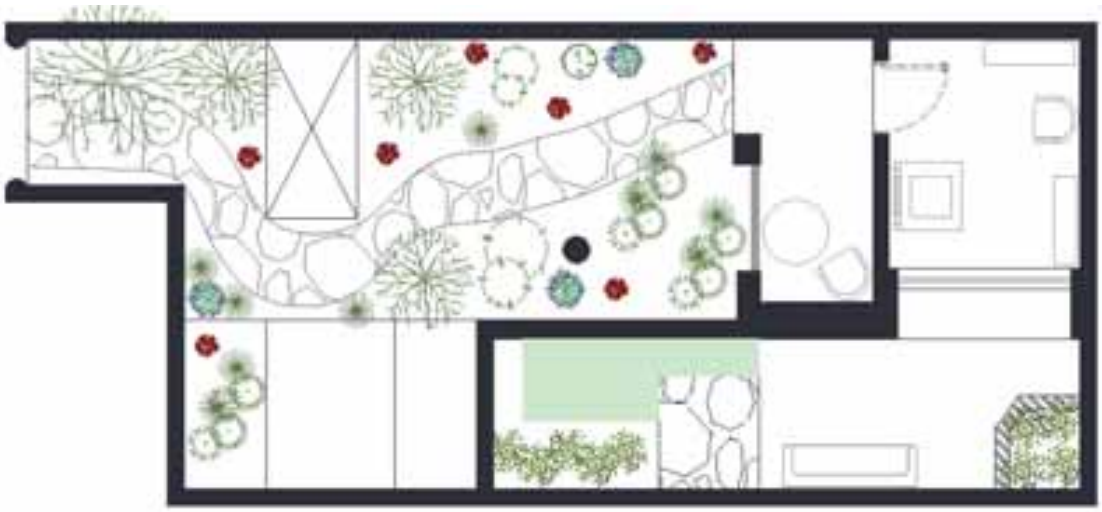

Fig 1: Plan view of the green roof.

The images below show some of the construction stages of the green roof:

Cover construction process

Cover basis completed

Implementation of vegetation cover

Integration of plant elements

Actual state of green roof

Fig. 2: Construction stages of the green roof

c) The plants used are native to the region, which has the characteristics of a semi-arid area. Specimens of mesquite (*Prosopis laevigata*), some specimens of huizache (*farnesiana Acacia, Acacia schaffneri*), a specimen of oak (*chihuahuensis Quercus*), a specimen of pine (*Pinus cembroides Zucc*.), a specimen of Garambullo (*Myrtillocactus geometrizans*), some specimens of Nopal (*Opuntia ficus-indica*), a couple sets of barrel cactus (*Echinocactus*), two specimens of rosemary (*Rosmarinus officinalis*), Evergreen (*Sedum praealtum*), Aranto (*Bryophyllum daigremontianum*) and wild grass.

d) For measuring some of the thermals performance a U30 HOBO weather station was installed where the outside and inside temperature is recorded, some case sensors are placed on the ground directly under the green roof cover, another in the upper part at 2.8 m and other at 1.65 meters high in the interior zone.

The Mexican normalization and certification organization for the construction, on reference to the decks in the

Mexican standard NMX-C-460-ONNCCE 2009 states that for Mexican thermal zones 1 and 2, the total thermal resistance of the enveloped must be at least 1.4 m^2K/W, and 2.1 m2K /W to achieve comfort and greater than 2.65 m^2K/W to save energy. Similarly, for 3A, 3B and 3C zones the values should be 1.4 m^2K/W, 2.30 m^2K/W to and 2.80 m^2K/W respectively. Regarding the indoor environment the NMX-AA-164-SCFI-2013 standard concerning sustainable building criteria and minimum requirements, it states that thermal comfort must be between reach between 18 and 25 °C.

With these benchmarks, the characteristics of the local microclimate are discussed from time records for a period longer than 50 years about 5 solar cycles, the comfort zone is determined by the model of Wakely which includes the definition of the scope comfort zone unlike other models, allowing you to adapt to different climatic zones, (Wakely,1979 in Tudela, 1982: 35-36), in this model the neutral temperature (*Tn*) it is called comfort center temperature *Tcc*, and is defined as follows: $Tcc = Tm/4 + 17.2$, where *Tm* is the annual average temperature. After the *Tcc* is determined, the temperature swing is identified from finding the range of the mean maximum and minimum extremes temperatures and from them the amplitude of the comfort zone.

The comfort zone, based on the period of the maximum and minimum temperature of 1959-2013 (for the city of Leon, Mexico), is determined to be 18.7 °C to 24.2 °C; next the Type Climatic Years are defined; for Maximum Activity (CYT-max) and for the Minimum Activity (CYT-min).

Figures 3 and 4 shows respectively the climatic years type for Maximum Activity (CYT-Max) and for Minimum Activity (CYT-Min) for the city of Leon, Mexico, for the period 1959-2013, comprising about 5 solar cycles.

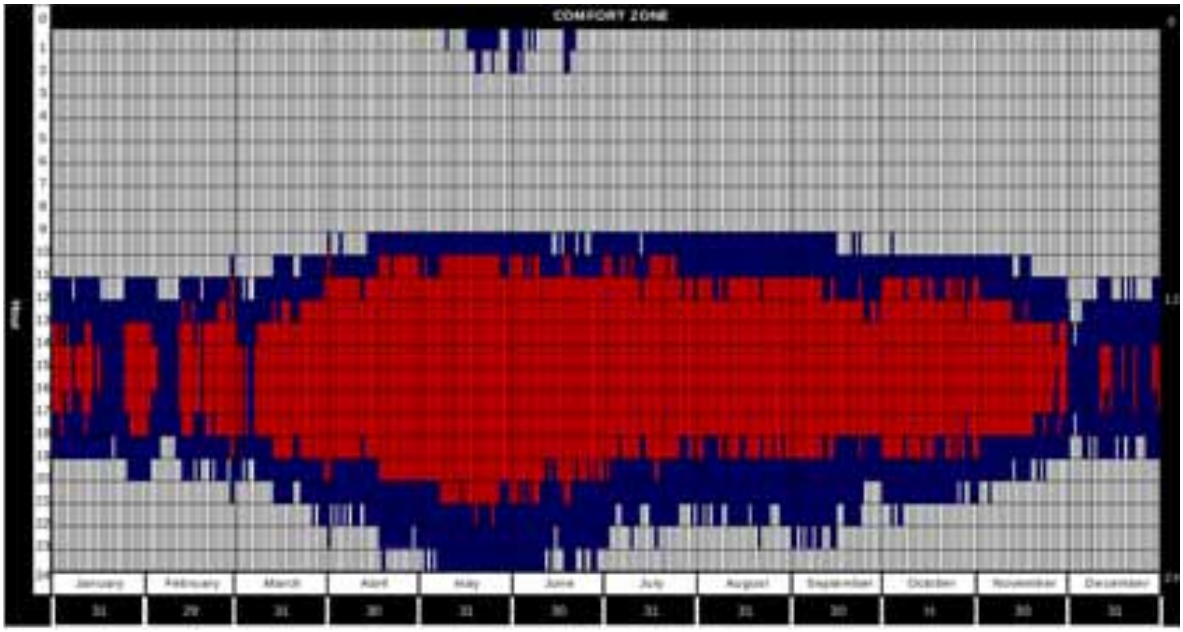

Fig. 3: Climatic Year Type for Maximum Activity (CYT-Max) for the Period 1959-2013. (Colors Represent Temperature Ranges: Greater Than 24.225 °C in Red, Between 18.725 and 24.225 °C in Blue, and Lower Than 18.725 in White)

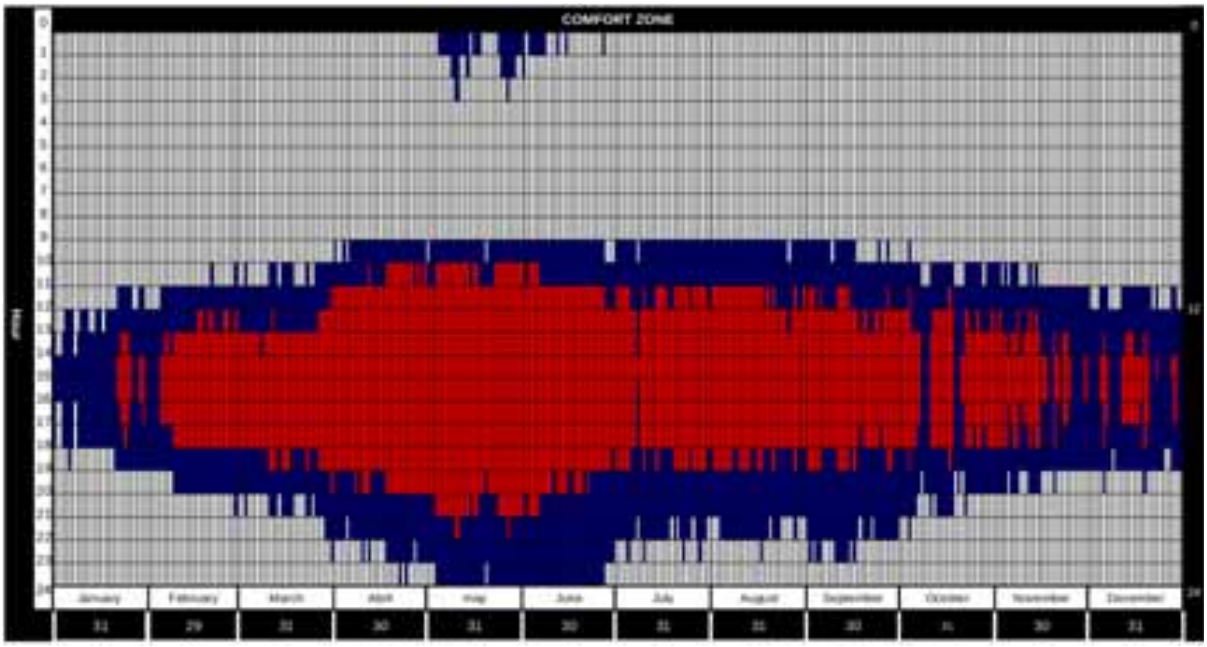

Fig. 4. Climatic Year Type for Minimum Activity (CYT-Min) for the Period 1959-2013. (Colors Represent Temperature Ranges: Greater Than 24.225 °C in Red, Between 18.725 and 24.225 °C in Blue, and Lower Than 18.725 in White)

3. Results

From the determination of the reference climate years types for major and minor solar activity considered from solar cycles of solar cycle number 19 to number 23, which covers the period of daily temperature of 1959-2013 and determining from this period CYT-MIN and CYT-MAX for the city of Leon Guanajuato. Based on these periods the behavior of the external temperature of the green roof cover is analyzed, and represented in a similar way to those of climate years as shown in the following figure.

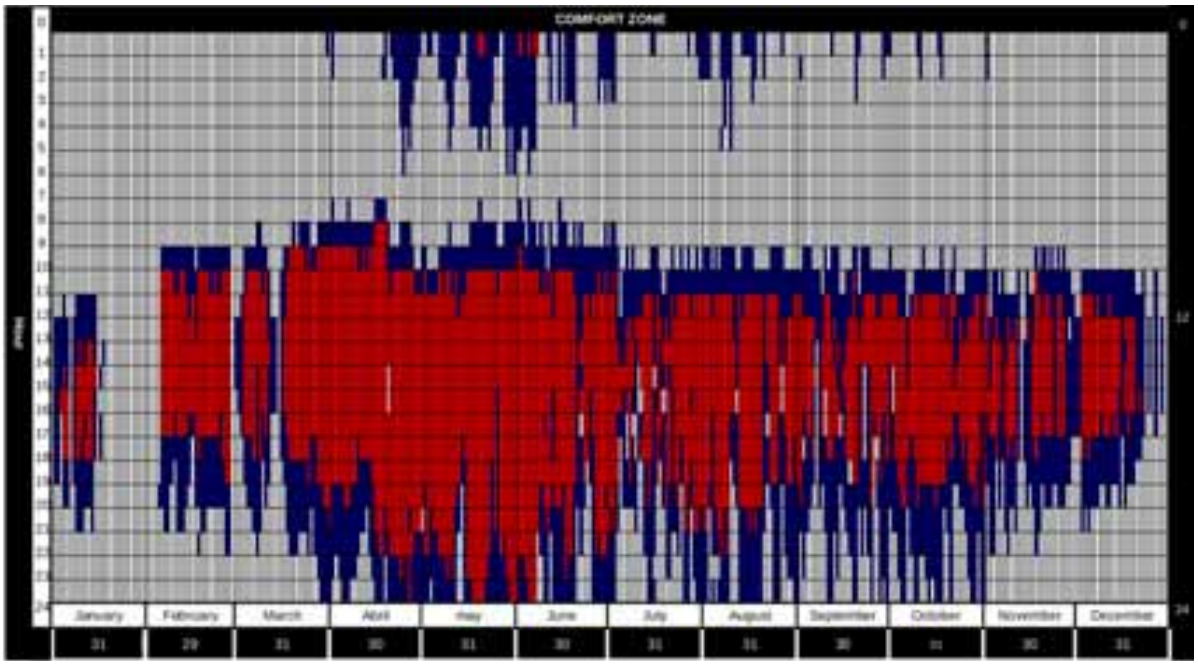

Fig. 5: Representation for the Comfort Zone with data for Outdoor Temperature over the Green Cover. (Colors Represent Temperature Ranges: Greater Than 24.225 °C in Red, Between 18.725 and 24.225 °C in Blue, and Lower Than 18.725 in White)

As for the results of the internal temperature in the two different positions of location sensors and 2.8 m and 1.65 m the results are presented in the figures below.

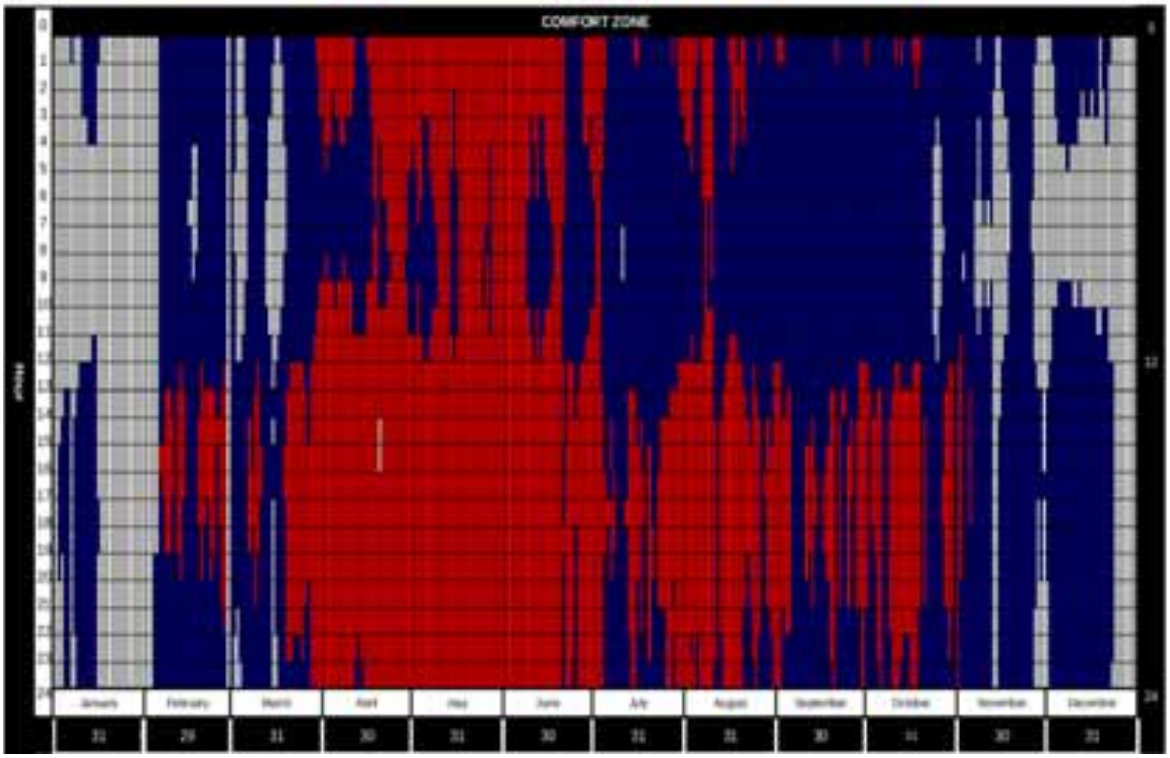

Fig. 6: Hourly Indoor Zone Temperature at 2.8 m Position. (Colors Represent Temperature Ranges: Greater Than 24.225 °C in Red, Between 18.725 and 24.225 °C in Blue, and Lower Than 18.725 in White)

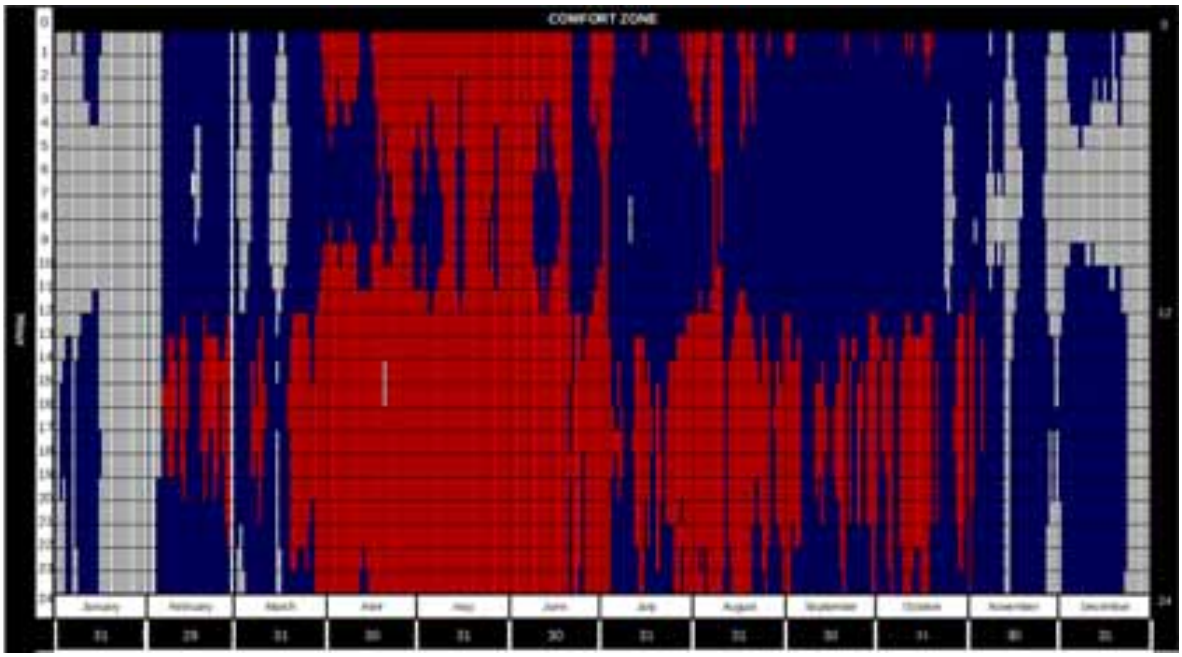

Fig. 7: Hourly Indoor Mid Zone Temperature at 1.65 m Position (Colors Represent Temperature Ranges: Greater Than 24.225 °C in Red, Between 18.725 and 24.225 °C in Blue, and Lower Than 18.725 in White)

In relation to the cover based on the Mexican standard NMX-C-460-ONNCCE-2009 and the method for estimating the thermal resistance of the envelope it was obtained a value of 2.16 m^2K/W, which is an equivalent to a global heat transfer coefficient of 0.464 W/ m^2K that when compared with those established by the standard for thermal zones the resulting value is in the range of comfort, Zones 1 and 2 are the zones defined for most of the areas comprising the center of the Mexico.

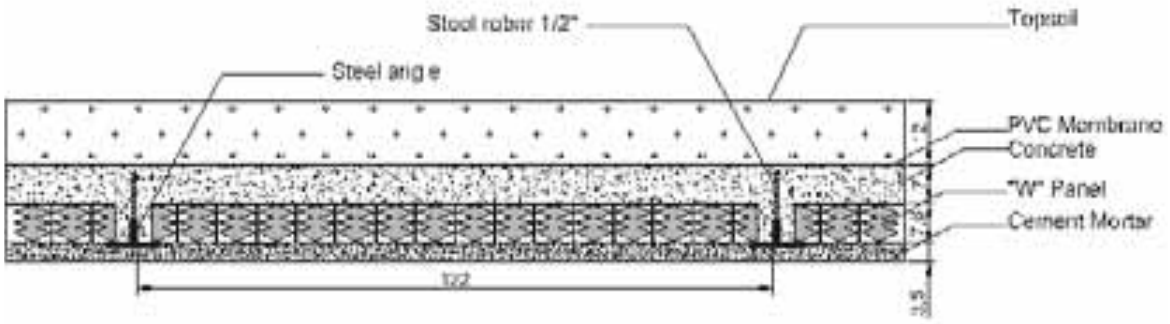

Fig. 8: Section of the deck structure

As for the overall analysis of the behavior of the temperature outside on the green cover and its correlation with the interior temperature shown in the graphs above; it can be seen that the overall difference is not significant, accounting for a difference between temperatures of approximately 2.6 °C and 2.5 °C, and presenting a difference between the exterior and interior extreme maximums within 5.2 °C and difference of 5.4 °C between high and medium internal sensors.

The analysis of historical temperature with reference to temperature measured on the green roof, it does not exceed 1.2 °C, yet if this historical temperature is analyzed with respect to the inner temperature the difference is even more significant of approximately 3.9 °C and a maximum temperature extreme of 6.8 °C.

Table 1: Daily behavior Historical Temperature for the period 1959-2013 and the outdoor temperature recorded over the green cover and indoor temperature for two different heights 2.8mts and 1.65 meters.

Higher Temperature Difference			Average Degree °C	Uncertainty relative	Standard deviation	%	Dispersion	Uncertainty random effects 90%	Uncertainty random effects 95%	Total Uncertainty 99.5%

Minimum	1.6 °C	**Historical Temperature TCY-MIN**	19.4	0.2	2.7	18.2	4.4	5.8	9.0	30.5

4. Conclusions

Building systems in Europe and higher latitudes are different to tropical latitudes, as the ones covered in Mexico. In non-tropical latitudes the insulation is more stringent, while some tropical areas this is not critical; most of those regions is not considered at all.

The variations of the outside temperature to inside are not extreme so insulate buildings, and it is impractical and more costly to the general population. Mexican norms for housing construction begin to be more favorable especially in the minimum characteristics residences that could stress the need for climate protection conditions.

The overall average temperature decrease inside is not very high with reference to the outside temperature not exceeding globally 2.6 °C. Greater differences are found considering the historical temperature on climate year type for maximum activity, a difference of 3.9 °C.

The wall insulation process in the tropics is not rigorous, presenting significant infiltrations but they are not responsible of the changes on the outside temperature.

Solutions with green roofs called extensive, are intended to insulate the constructions of external weather conditions and care of the same is performed by the user; maintenance is secondary. Yet, the professional practice to implement green roofs are too expensive for widespread use, The thermal performance perhaps is not significant on temperate climates but there are other relevant aspects of their environmental use, that may have a greater impact and benefit for the environment, as the case of rainwater harvesting and soapy water recycling.

A Multilinear Model for Estimating the Monthly Global Solar Radiation in Qassim, Saudi Arabia

A. H. Maghrabi; M.H. Almalki

National Centre For Applied and Physics, King Abdulaziz City For Science and Technology, P.O. Box 6086 Riyadh 11442, Saudi Arabia

Abstract

Information on the global solar radiation is essential for many solar energy applications. Because of the cost of the measuring equipment, data on global radiation are not always available in most places, especially in developing countries. To overcome this difficulty, several attempts have been made to estimate solar radiation components from easy-to-measure atmospheric and/or geographical variables. In this study, monthly mean global solar radiation data for Qassim City, Saudi Arabia for the period from 1971 to 1998 were modelled using three meteorological variables: relative humidity, air temperature and atmospheric pressure. The predictability of the model was superior to the experimental data, showing a correlation coefficient (R) of 0.988. The mean percentage error (MPE) was less than 1%, the root mean square error (RMSE) was 0.02 and the mean bias error (MBE) was -1.1×10^{-4}. The performance model was validated using an independent data set for the period between 2003 and 2005. The statistical results were optimal and showed the ability of the model to predict the monthly global solar radiation for Qassim City for any period of time with less error. The predictability of some of the previously proposed models, which differed from each other in terms of the variables that they used and the number of variables contained, were tested to estimate monthly global solar radiation. The performances of these models were different in terms of predicting the experimental data.

Keywords: *Global radiation, Qassim, relative humidity, temperature, atmospheric pressure, Saudi Arabia*

1. Introduction

Solar radiation and its components are the most important and renewable energy source, affecting global climate and energy budget studies; hence the accessibility of solar radiation data is essential for the research community. Global radiation data are essentially required for different applications such as the architectural design of solar energy systems. Information on global solar radiation is not only needed at specific locations but by the worldwide community, Li and Lam (2000); Lu , et al. (1998); Zekai (2008); El-Sebaii et al. (2010)

The measurement of solar radiation requires equipment such as pyranometers, which need regular maintenance and calibration, Chineke (2008). For many developing countries such costly equipment is not usually available; hence elaboration of an alternative method using the available meteorological data to calculate and model the global radiation data is a common practice. Several empirical and semi-empirical models have been parameterized using available meteorological and geographical parameters to calculate solar radiation. These include sunshine hours, air temperature, latitude, and water vapor, El-Sebaii et al., (2010); Alvaro et al. (2013); Maghrabi (2009); Maghrabi et al. (2008); Antonio et al. (2015); Bulent, et al. (2015); Trabea and Shaltout (2000); Li, et al.(2013).

In this work, data on atmospheric pressure, relative humidity (RH) and air temperature have been used to

doi:10.18086/swc.2015.07.01 Available at http://proceedings.ises.org

model the monthly average daily global radiation for Qassim City, central Saudi Arabia.

2. Experimental Data and Validation Methods

Mean monthly global solar radiation data on a horizontal surface (H) were obtained from the Saudi Arabian Solar Radiation Atlas, published by the Saudi King Abdulaziz City for Science and Technology (KACST). The atlas has two versions. The first contains data collected by the Ministry of Agriculture and Water from 1971 to 1980 compiled by KACST; the second measurements of the global horizontal radiation between 1994 and 1996 obtained from KACST's solar radiation network, KACST (1999). Meteorological information for the two periods was obtained from the Presidency of Meteorology and the Environment (PME). Clear sky data were only considered in this study.The monthly averages of the extraterrestrial global radiation (Ho) were calculated for the given periods using the procedures (Duffie and Beckman 1991) as follows.

$$Ho = (1/\pi)IscE0(\cos\lambda \cos\delta \sin ws + (\pi/180)\sin\lambda \sin\delta ws) \quad \text{(eq. 1)}$$

Isc is the solar constant 1376 Wm^{-2} ,Eo is the correction factor of the Earth's orbi calculated by:

$$E0 = 1.00011 + 0.034221\cos\alpha + 0.00128\sin\alpha + 0.000719\cos(2\alpha) + 0.000077\sin(2\alpha) \quad \text{(eq. 2)}$$

α is the day angle, obtained from:

$$\alpha = 2\pi(nday - 1)/365 \quad \text{(eq. 3)}$$

δ is the solar declination (in degrees),

$$\delta = (180/\pi).(0.006918 - 0.399912\cos\alpha + 0.070257\sin\alpha - 0.006758\cos(2\alpha) + 0.000907\sin 2\alpha - 0.002697\cos 3\alpha + 0.00148\sin(3\alpha)) \quad \text{(eq. 4)}$$

and the hour angle of the Sun *ws* (in degrees) is calculated as:

$$ws = \cos{-1}\,[-\sin\lambda\sin\delta/(\cos\lambda\sin\delta)] \quad \text{(eq. 5)}$$

We first developed and tested the performance of the several models using regression methods. The calculation procedures began with simple correlation between the clearance index H/Ho (ratio of the measured global radiations to the average daily extraterrestrial radiation) and each meteorological parameter individually; then multiple regression analysis, using two and three parameters, was carried out. The best performing model was validated using an independent set of global radiation measurements for the period between 2003 and 2005. Finally, we selected several models, with different parameters, from the literature and tested their predictability against the measured global radiation.

The calculated H/Ho values were assessed in terms of mean percentage error (MPE), mean bias error (MBE), and root mean square error (RMSE), calculated as:

$$MPE = \frac{1}{N}\sum_{i=1}^{N}\left(\frac{V_{imeas} - V_{ical}}{H_{imeas}} \times 100\right) \quad \text{(eq. 6)}$$

$$MBE = \frac{1}{N}\sum_{i=1}^{N}(V_{imeas} - V_{ical}) \quad \text{(eq. 7)}$$

$$RMSE = \frac{1}{N}\sum_{i=1}^{N}\sqrt{(V_{imeas} - V_{ical})}^{2} \ , \quad \text{(eq. 8)}$$

where V_{imes} and V_{ical}, are the measured and calculated (H/Ho) values respectively, and N is the number of the measurements The significance of the proposed model was tested using t-statistics calculated according to Stone (1993), as:

$$t - stat = \sqrt{\frac{(n-1)MBE^2}{RMSE^2 - MBE^2}} \quad \text{(eq. 9)}$$

3. Results and Discussions

3.1 Model parameterisation

Table (1) presents the regression equations between the measured clear sky index and single, two, and three meteorological parameters. The statistical results of these equations are also given. It can be seen that the statistical parameters vary from one model to another. All the models presented an MPE below 2%, which can be considered an excellent performance. Additionally, all the models were significant according to their t-values, which were smaller than the critical value (3.106).

The three-variable models (eq. 16) presented the lowest RMSE and MBE and the highest correlation coefficient. The correlation coefficient of this equation was 0.98, and the MPE, RMSE and MBE were, respectively, 0.15%, 0.02, and -1.1×10^{-4}. The two-variable models showed improvements in their

correlation coefficients; their MBE, RMSE and MPE values were not as good as those of the one-variable models. Models with air pressure (as either single or second variable) gave a poorer performance than those use the air temperatures.

Table 1: Results of the regression analysis of the clearance index, H/Ho (ratio of the measured global radiations to the average daily extra-terrestrial radiation) and meteorological parameters.

Equation	R	MBE	RMSE	MPE	t
$\frac{H}{Ho} = 0.004T + 0.491$ (eq. 10)	0.85	0.0009	0.021	0.3340	0.183
$\frac{H}{Ho} = 0.0023RH + 0.6556$ (eq. 11)	0.86	-0.003	0.023	-0.38	0.455
$\frac{H}{Ho} = -0.0084P + 8.50$ (eq. 12)	0.88	-0.008	0.020	0.0349	0.078
$\frac{H}{Ho} = 0.649 - 0.0021RH + 0.00016T$ (eq. 13)	0.80	-0.002	0.024	-0.261	0.351

Fig.1 shows the monthly variations of the measured and the calculated global solar radiation values obtained from (a) single and (b) two-variable models. It is obvious that the pressure-based model always overestimated the measured values. On the other hand, the RH-based and T-based models slightly overestimated the measured values in the months September, November and December and underestimated the measurements in the remaining months. Two-variable models showed the same behavior as the single T- and H-based models. All the models highly overestimated the global radiation measurements in April and May. This can be explained by the effect of the pre-monsoon dust events which are very frequent during these two months.

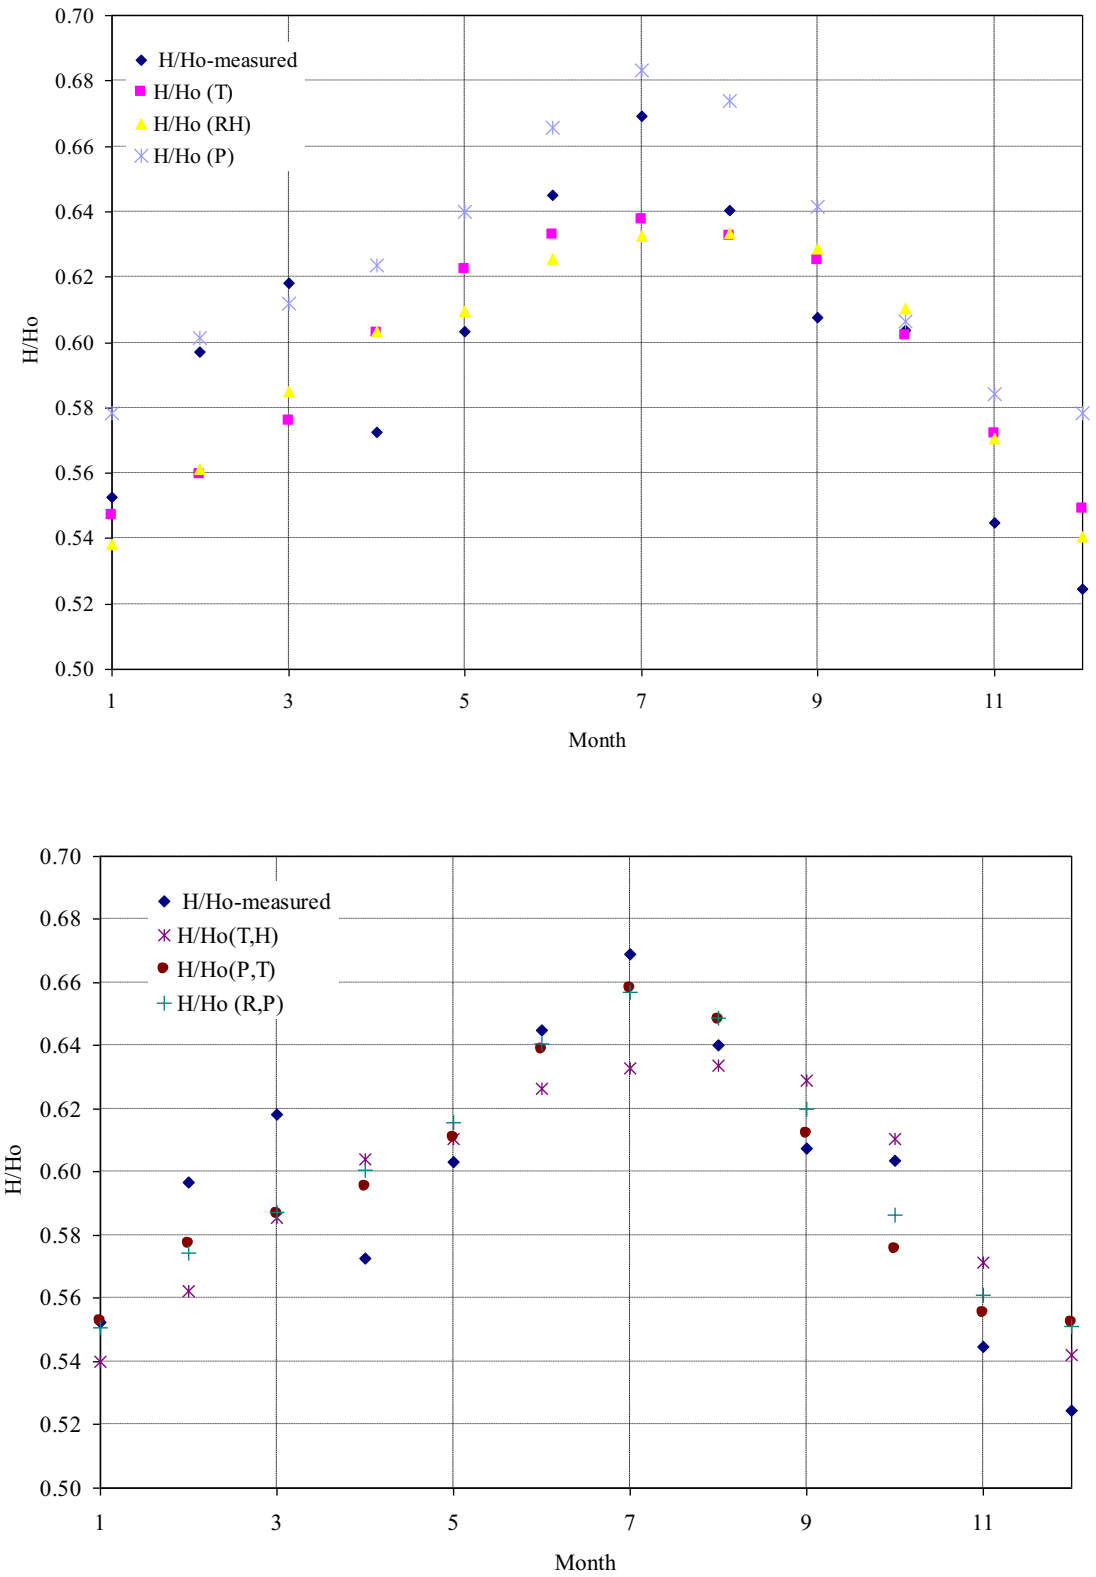

Fig 1. Monthly measured and predicted H/Ho from (a) single and (b) two-variable models.

Fig.2 displays the monthly measured and the calculated radiation from equation (16) (the model contains all three variables). Fig.3 is the scatter plot for the predicted and measured values. It is very evident that the three-variable model showed less deviation from the measured values and predicted with high accuracy. The data closely lie in the vicinity of the 1:1 line. The regression equation for the measured and predicted values has a slope of 0.98 (nearly equal to one) and an intercept of 0.01 (nearly equal to zero). This indicates a distinct relationship between the predicted and measured global radiation and rationalizes the excellent predictability of the model. Student's t-tests for this linear relationship at a significance level of $\alpha = 0.01$ were carried out and showed a t-value of 0.32, which is less than the critical value (3.106). This indicates the significance of the developed model in predicting the measured global solar radiation in Qassim.

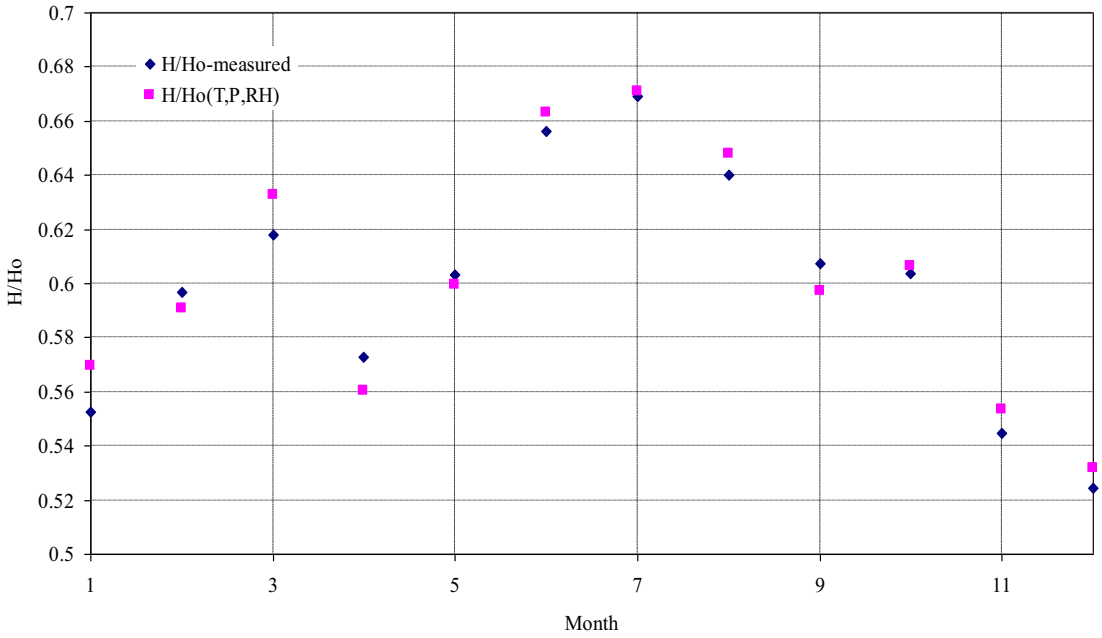

Fig.2. As in Fig.1, the measured data were compared with the predicted values calculated using equation (16).The dashed line is the 1:1 line and the straight line is the regression line.

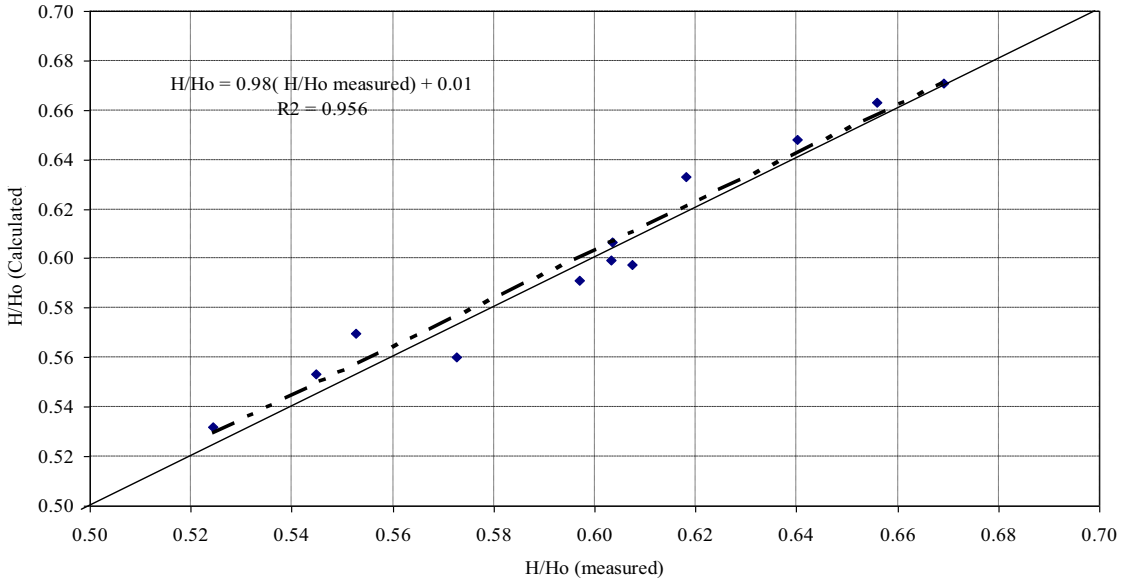

Fig.3. The measured H/Ho plotted against predicted values using equation (16). The straight line is the 1:1 line and te dashed line is the regression line between the two values.

3.2 Model Validation

The prediction of the proposed model (equation 16) for the global radiation in Qassim was tested using an independent data set. These data contain the mean monthly data on global solar radiation and the corresponding meteorological parameters for the period between 2003 and 2005. These data were obtained from the Saudi Presidency of Meteorology and the Environment.

Fig.4 indicates the monthly measured clearance index and the calculated values obtained from the model for the period between 2003 and 2005. The calculated H/Ho gives MPE =2.3 %, MBE -0.003, RMSE = 0.034, and t value =0.0921. These statistical results indicate an adequate performance of the model for this data set.

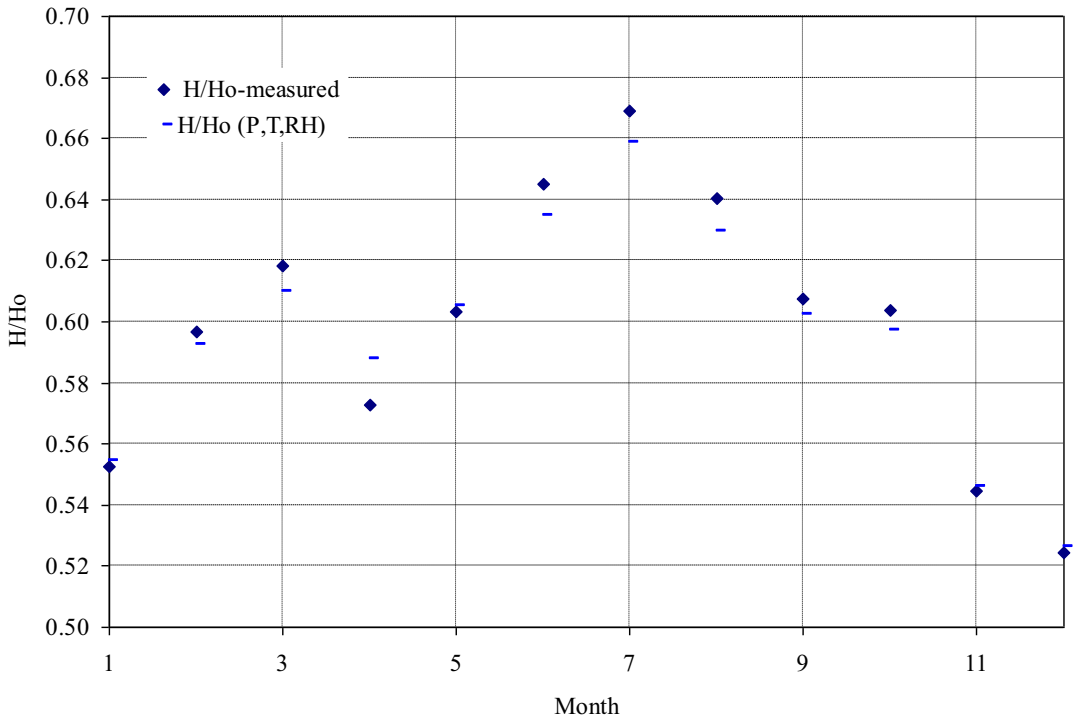

Fig.4. Monthly measured data for the period between 2003 and 2005 compared with their predicted values using the proposed model.

Fig.5 demonstrates the relationship between the measured and the predicted values of the clearance index for these data. The results show a close distribution of the data points around the 1:1 line, which verifies the ability of the model to predict global solar radiation in Qassim using independent measurements. The slope of the regression results for the measured and predicted values was 0.89 and the intercept was 0.052.

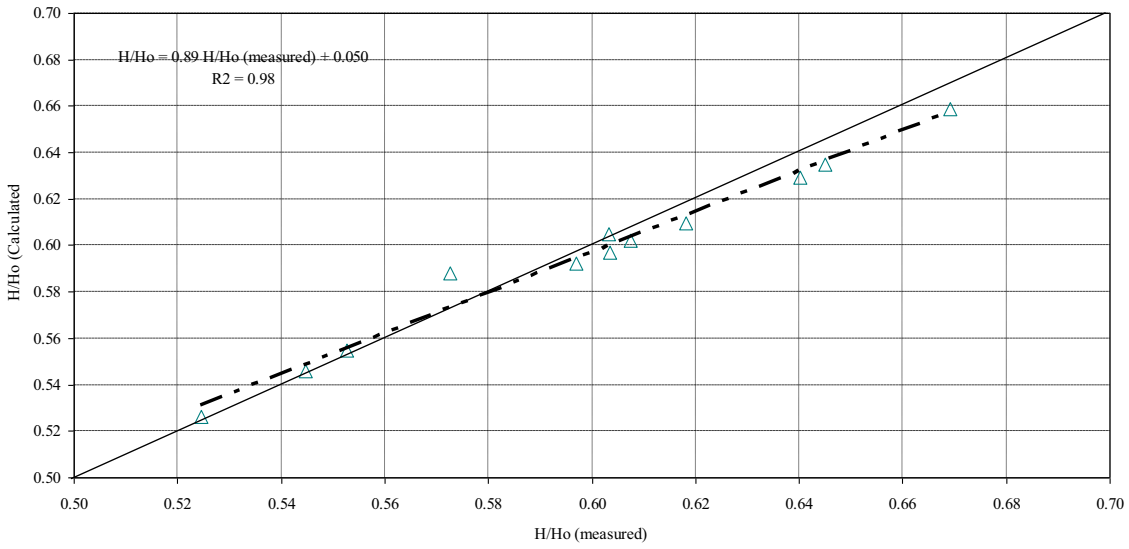

Fig. 5. As in Fig. 3, the figure plots the measured global solar radiation against the calculated values but for data between 2003 and 2005.

3.3 Comparisons with Other Models

Several models for predicting global radiation using meteorological parameters have been developed using data from different places around the world. In this study nine models were selected and their performances in predicting the measured global radiation data for Qassim for the period 1971 to 1996 were tested. Table (2) presents the functional form for the selected models and their statistical indicators. It can be seen that each model performed differently from the others. The RMSE values for all the models ranged between 0.27 and 0.069, MBE between 0.043 and 0.18. Apart from Bristow-Champbell model, all the models showed MPE values of less than 10%. Li et al.(2013) model was the best followed by the Adaramola (2012) model in predicting the measured data in Qassim. These two models contain three variables on them. Contrary, Bristow-Champbell (1984), Hargreaves et al. (1985), and Li et al. (2013) models showed the highest errors in estimating the measured data. According to the statistical tests all the models have poorer prediction in comparison with the proposed model in this study (equation 16) or even the single and multiple models.

Table 2: Functional of some of the selected models from the literature to calculate the measured H/Ho values for Qassim. The statistical results (MBE, RMSE, and MPE) for their predications are given.

	Form	MBE	RMSE	MPE(%)
Li et al (2013)	$\frac{H}{Ho}$ =0.064-1.1130T	0.132	0.231	5.43
Li et al (2013)	$\frac{H}{Ho}$ =1.025-0.879RH	0.143	0.272	8.620
Chen et al. (2004)	$\frac{H}{Ho} = 0.08 + 0.21(T_{max} - T_{\min})$	0.125	0.212	6.751
Adaramola (2012)	$\frac{H}{Ho}$ =1.419-1.1973(Tmin/Tmax)	0.161	0.201	5.820
Hargreaves etal 1985	$\frac{H}{Ho} = 0.153(T_{\max} - T_{\min})^{0.5} - 0.033$	0.146	0.261	9.351
Adaramola (2012)	$\frac{H}{Ho}$ =0.77-0.4656(RH/100) (Tmin/Tmax)	0.102	0.0749	4.793
Adaramola (2012)	$\frac{H}{Ho} = 0.845 - 0.464$(RH/100)	0.071	0.086	5.721
Bristow-Champbell (1984)	$\frac{H}{Ho} = 14.35[1 - \exp(-0.009(Tmx - T\min))^{0.549}$	0.183	0.136	10.457
Li et al (2013)	$\frac{H}{Ho}$ =-1.315+0.138(Tmax-Tmin)+0.8244RH	0.093	0.069	4.940

4. Conclusion

Solar radiation data are of great importance in many applications such as the design of solar energy systems and energy budget studies. In this study, monthly average daily global radiation on horizontal surface measurements between 1971 and 1998 were correlated with three meteorological parameters to develop an empirical model to estimate the global radiation for Qassim city, Saudi Arabia. These parameters are the air pressure, the mean air temperature and the relative humidity. The estimated radiation from the model presented excellent agreement with the measured data. The model has a correlation coefficient of 0.988, RMSE = 0.02, MBE = -1.1×10^{-4} and MPE less than 1 %. The model demonstrated an accurate estimation for the global radiation for Qassim using an independent data set for the period between 2003-2005. The performances of some models from the literature were conducted against the measured data for the period 1971-1998. The performances of these models were different in terms of predicting the experimental data

Acknowledgments

The authors thank the Saudi Presidency of Meteorology and Environment (PME) for kindly providing the surface climate data. The authors would also like to thank King Abdulaziz City for Science and Technology (KACST) for supporting this work.

Abstract

Well geographically distributed high temporal resolution solar irradiance data is scarce, resulting in many studies using mean hourly irradiance time-series as an input. This research demonstrates that by taking readily available mean hourly meteorological observations of okta, wind speed, cloud height and atmospheric pressure; 1-minute resolution irradiance time-series that vary on a spatial dimension can be produced. The synthetic time-series temporally validates against observed 1-minute UK irradiance data with 99% K-S test confidence levels across 3 metrics of variability indices, ramp-rate occurrences and irradiance frequency. A new methodology is applied to existing research that produces two-dimensional cloud cover using a vector approach to add spatial correlation to irradiance time-series, as well as improvements to the clear-sky index calculations. The methodology is applied to a hypothetical configuration to demonstrate its capabilities.

Keywords: *irradiance generation, minute resolution, resource modelling, cloud edge enhancement.*

1. Introduction

Solar irradiance fluctuates on a 1-minute time scale or less (Sayeef et al., 2012) and is driven by the transport of atmospheric pollutants (Vindel and Polo, 2014), atmospheric losses, and cloud dynamics (Calinoiu, 2014). Large irradiance fluctuations can cause ramps in solar energy power generation outputs (Hummon et al., 2012), these power fluctuations can result in electrical problems and supply/demand issues such as over voltages in PV laden distribution grids (Widén et al., 2011). Furthermore, irradiance is dependent on geography, irradiance at locations across 1 km are affected by different optical losses as they can be obscured at different times. It is important, therefore, to utilise a solar irradiance data input that can capture these problematic fluctuations and spatial variations when theoretically considering power reliability and impacts on a high frequency time scale. Averaging solar irradiance data over different temporal frequencies results in loss of detail of the irradiance fluctuations. Figure 1 demonstrates how averaging irradiance data across different time-scales significantly underemphasises the actual incident irradiance fluctuations, as well as underestimating peak irradiance values.

Calibrated 1-min irradiance datasets are usually the output of isolated research projects and are often limited in duration, consistent measurement techniques, and geographic distribution. Sources of 1-min resolution irradiance data exist such as the World Radiation Monitoring Centre's Baseline Surface Radiation Network (BSRN), which will be used in a validation, however it is lacking in coarse geographical distribution. 1-hour resolution weather data, however, is widely collected and made available through national meteorological offices. This hourly data fails to capture the intermittent nature of solar irradiance (Sayeef et al., 2012); some solar irradiance models, therefore, use hourly datasets to artificially generate minutely irradiance time-series. Examples of such have been reviewed previously (Gueymard, 2012), with more notable methodologies using utilising a sun obscured type approach (Morf, 1998, 2011, 2013) and (Ehnberg and Bollen, 2005).

This paper presents a novel methodology that takes readily available mean hourly meteorological observation data of okta, wind speed, cloud height and atmospheric pressure; 1-minute resolution irradiance time-series that vary on a spatial dimension can be produced, which validate temporally against observed 1-minute UK irradiance data.

doi:10.18086/swc.2015.07.02 Available at http://proceedings.ises.org

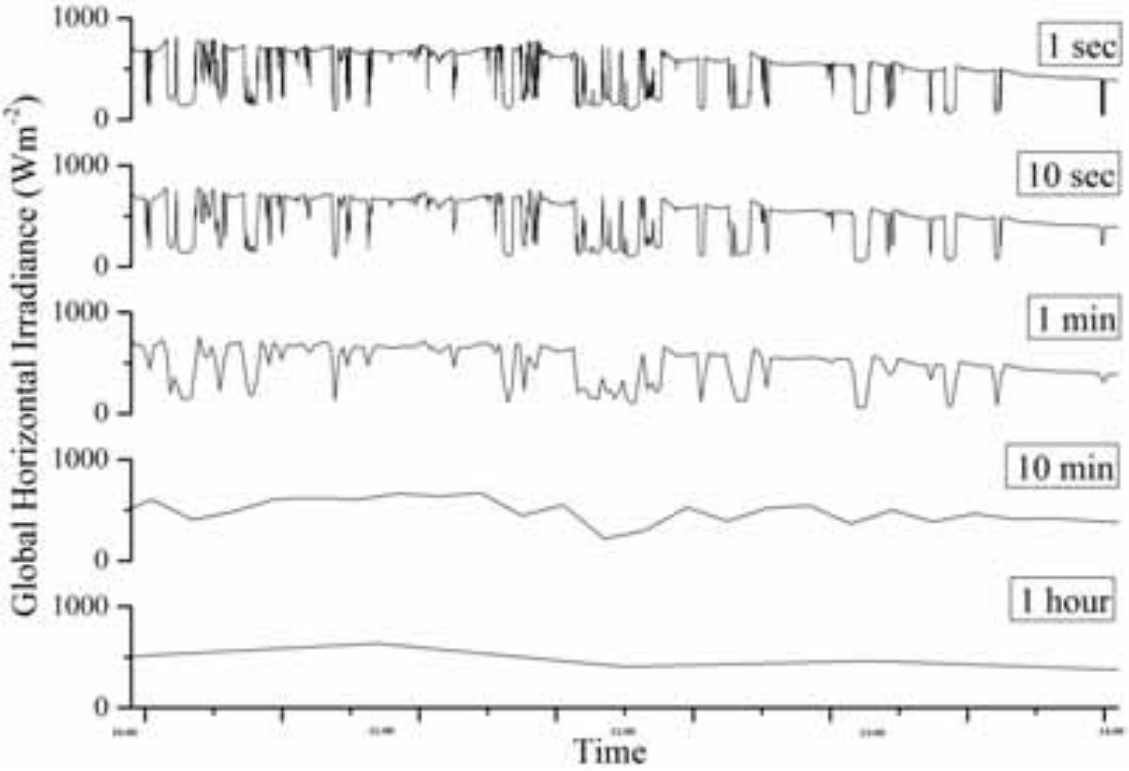

Fig. 1: Global horizontal incident irradiance in Leeds, UK on 25/06/2015 between the hours of 10:00 and 14:00. The data was logged using a horizontally-mounted silicon photodiode (BPW20) in short-circuit current mode with a linear current response converted to voltage with a transconductance amplifier, logged at 10 Hz using a 10-bit DAC. The data has been averaged across the timescales of, from top to bottom: 1 second, 10 seconds, 1 minute, 10 minutes and 1 hour.

2. Methodology

This work is an extension of the methodology by Bright et al. (2015) that demonstrated the success of taking mean hourly weather observation data to generate 1-min temporal resolution irradiance time-series. The original methodology has six distinct sections: cloud cover samples production, where descriptions of an hour of cloud are made; Markov chain production, produced through analysis of 12 years of mean hourly weather observation data to capture the patterns of transitions of each variable; the stochastic selection of variables, using probabilistic application of the variables guided by the Markov chains; calculation of global clear-sky irradiance, using standard irradiance modelling considering geography to determine the background irradiance; calculation of clear-sky index for each location, using statistics of optical losses derived as a function of the okta value; and finally calculation of incident irradiance upon an arbitrary plane, using methodologies from literature. For greater detail, the reader is referred to the work by Bright et al., (2015).

Significant developments have been made to the cloud cover samples production section and the calculation of clear-sky indices sections that allow for a spatial element to the previous temporal-only methodology. This section will discuss the production of cloud cover samples and their application in producing spatially correlating sun obscured time-series, and the updates to calculating the clear-sky indices and subsequent irradiance.

2.1 Cloud Cover Sample Production

Cloud cover samples are a description of an hour's cloud cover. The methodology is a sun-obscured type, which means that during periods when the sun is obscured, as indicated by the cloud cover sample, a clear-sky index value is applied to the global clear-sky irradiance. The clear-sky index is a fractional representation of the incident global horizontal irradiance from the available clear sky irradiance. Previously, the cloud cover samples were represented by a binary, single dimension vector describing each minute that

an arbitrary plane as obscured or unobscured, signified using 1s and 0s respectively. A new methodology is proposed that considers an area of sky with a randomly set number of clouds within it, as this will be moving across a static cluster with points of interest i.e. residential PV installations within a low voltage grid, each sample of cloud cover must represent the entire hour defined by the stochastic selection of the weather variables: cloud speed, u, and okta. The size of the area of sky is therefore a function of distance and time, 1.5km-by-u*3600, where 3600 is the number of seconds in an hour.

The cloud cover samples are lists of x and y coordinates for the centres of each cloud, and also includes their radii. The clouds are assumed to be circular with radii size adhering to the horizontal cloud length single power-law distribution (Wood and Field, 2011). The clouds' associated clear-sky indices are represented as optical thicknesses applied to all areas across the circle using a distribution that ranges from typical clear-sky indices lows of ~0.1, to highs of ~1.1, the implication of this is that across the circular cloud there will be sections above a clear-sky index of 1, indicating wispy or insignificant levels of cloud, whilst other areas indicate thicker sections, and therefore the clouds are not actually circular in application, instead the circle defines an area which cloud is allowed to form. In order to produce multiple samples, random numbers of clouds are selected, which are then given random x-y coordinates and radii drawn by the aforementioned distribution. The cloud cover fraction of each sample is analysed to determine the okta value, and is then sorted and stored appropriately in a larger matrix. Samples are then selected using an indexing based on the conditions stochastically selected through a Markovian process within the model simulation.

2.2 Clear-sky Fluctuations

Clear-sky indices fluctuate across different timescales. The cumulative probability distributions functions (CDF) for the frequency of occurrence of absolute step size changes for different time scales are shown in Lave et al. (2012). It is shown that 1-min and 1-hour data have very different statistics. To capture these fluctuations, the CDF profiles for the different time scales are applied to the clear-sky indices. Two vectors of fluctuations following the CDF profiles are drawn, one for clear periods, $\boldsymbol{F_0}$, the other for obscured periods, $\boldsymbol{F_1}$. For moments of obscured sky, the step changes are equally step downs as well as step ups.

To create $\boldsymbol{F_0}$ and $\boldsymbol{F_1}$, a step size change is selected following the appropriate cumulative distribution function, this increase is then linearly applied across the hour/10-min/minute, before being smoothed using a spline technique (using inbuilt Matlab functions (Matlab, 2012)) and can be represented for both as

$$\mathbf{F}_{(\mathbf{0}or\mathbf{1})}(t_0 : t_1) = \left(\mathbf{F}_{(\mathbf{0}or\mathbf{1}),t0} : T : 1 \pm s\right) \qquad \text{(eq. 1)}$$

$$s = \frac{\sum CDF_T < r}{100} \qquad \text{(eq. 2)}$$

where t_0 and t_1 are index references in minutes of current and future location within $\boldsymbol{F_{0or1}}$, T refers to the number of minutes within the operating frequency (when performing fluctuations on a 1-h period, T=60), $\boldsymbol{F_{t0}}$ refers to the fluctuation value at the previous index. The use of the colon, **:**, in the format $(t_0 : t_1)$ refers to the space within $\boldsymbol{F}$ between t_0 and t_1, and in the format $(x : n : y)$ refers to a linearly spaced vector starting at x and ending at y with n number of intervals. CDF_T refers to the appropriate cumulative probability distribution function, r is a random variate evenly distributed between 0 and 1, and finally s is the step size magnitude randomly extracted from the CDF.

2.3 Cloud Movement and Clear-sky Indices

Once the cloud cover samples are selected for each hour of the simulation, the samples are simulated to pass across the stationary targets within the spatial domain. To simulate the cloud direction, the locations are rotated in accordance with the cloud direction using rotational matrices as demonstrated in equation 3

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \begin{bmatrix} \cos\vartheta & -\sin\vartheta \\ \sin\vartheta & \cos\vartheta \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} \qquad \text{(eq. 3)}$$

where x and y denote the coordinates of the initial locations within the spatial domain, and x' and y' are the rotated coordinates by angle ϑ. The angle by which to rotate is determined using a normally distributed random walk, with standard deviation equal to 10, around a mean set to the previous cloud direction, this allows for gradual changes in direction. The cloud speed is determined stochastically (Bright et al., 2015) and so the cloud movements in relation to the locations of interest within the spatial domain are known.

The simulation works iteratively, progressing by one time-step at a time. Whilst the calculations are in a vectorised format, it is simplest to imagine a static rectangle with the locations of interest marked, being overlapped by a rectangle containing the clouds; at each moment it is determined whether or not a location is obscured by the cloud. For each iteration, the distance from the location of interest to the centre of each cloud within the sample is calculated. Firstly, let the length of the spatial domain be X_l and the length of the cloud sample be X_c, the coordinates of the location of interest and each cloud are (x_l', y_l') and (x_c, y_c) respectively. The distance from the location to the edge of the domain is

$$\partial x_l = X_l - x_l' \qquad \text{(eq. 4)}$$

while the distance from the cloud to the edge of the cloud environment is given by x_c. The overlap of domains is defined as the number of iterations, i, multiplied by the temporal resolution that the simulation is operating at, t. Therefore the distance in the x-direction from the location to the cloud, dx, is given by

$$\partial x = \partial x_l + x_c - it \qquad \text{(eq. 5)}$$

the distance along the y-axis from the location to the cloud is given by

$$\partial y = y_c - y_l' \qquad \text{(eq. 6)}$$

the horizontal distance from the location to the centre of the cloud is therefore calculated using Pythagoras' theorem as

$$d = \sqrt{\partial x^2 + \partial y^2} \qquad \text{(eq. 7)}$$

To produce a clear-sky indices vector for each location, the simulation enters an loop which cycles through each time step for the desired duration, and for each location. At each loop the locations are rotated according to the cloud movement direction as shown in equation 3, the x-y coordinates of each cloud sample are updated according to the cloud movement speed and time step before working through equations 4-7. At each loop it is determined if the location is covered by cloud. To do so, a logical *if* statement is applied, querying d against the radius of the cloud, r, such that

$$r > d \rightarrow B = 1 \text{ else } B = 0 \qquad \text{(eq. 8)}$$

where B is a Boolean matrix indicating the presence of cloud, and $\rightarrow$ denotes the use of a logical *if* statement. The iteration moves on until the end of the cloud sample. If a location moves beyond the sample

as it passes, the next sample is loaded and queried against using the same methodology.

B is used as a binary indicator for sun obscured. During periods of *B=1* when the cloud is present, a clear-sky index, k_c, is generated for each cloud present using distributions of clear-sky indices as a function of the okta number (Bright et al., 2015).

$$k_{ci} = f(okta) \quad \text{(eq. 9)}$$

The clear-sky index for overlapping clouds is found as the mean of the overlapping clear-sky indices

$$k_{ci}(\mathbf{B}=1) = \frac{1}{c}\sum_{n=1}^{c} k_{c,n} \quad \text{(eq. 10)}$$

Where subscript *i* is the current iteration, k_c***(B=1)*** are the clear-sky indices during moments of cloud, $k_{c,n}$ is the k_c value for the n^{th} term, and c is the total number of overlapping clouds index.

The clear sky indices vector, $\boldsymbol{k_c}$, for each property is calculated at each iteration, *i*. This iteration, *i,* must undergo a correction as a function of *x'* and *u* to account for spatial variability, where *u* is the cloud speed; $\boldsymbol{k_c}$ is therefore calculated as

$$i = i + \frac{x'}{u} \quad \text{(eq. 11)}$$

$$\mathbf{k}_{ci}(B=1) = kc_i \times \mathbf{F_1} \quad \text{(eq. 12)}$$

$$\mathbf{k}_{ci}(B=0) = kc_i \times \mathbf{F_0} \quad \text{(eq.13)}$$

Multiple irradiance time-series can now be drawn from any *x-y-z* location within a 1.5 km by 3600*u* km area, each with different arbitrary plane orientations and tilts, such as the different tilts and rotations of residential PV installations within a low voltage grid. Irradiance is calculated for each location using the methodology outlined in Bright et al. (2015), and the corresponding clear-sky indices, $\boldsymbol{k_c}$, are applied.

2.4 Cloud Edge Enhancement

Cloud edge enhancement, CEE, describes events whereby a point on the surface receives a larger amount of incident irradiance than is available in the clear-sky irradiance, the events are attributed to irradiance reflecting from the edge of cloud. The typical behavior of irradiance in the 60 sec leading up to, and after the largest 1 sec ramps is detailed by Lave et al. (2012). This behavior is applied to periods of transitions from clear to clouded moments.

The CEE behavior is normalised to 1 to form a correctional factor for both ramp up, CEE_{up}, and ramp down, CEE_{down} as a function of a magnitude, *M*. The magnitudes of the CEE ramps are determined through analysis of 1-min data from the BSRN against the corresponding mean hourly weather observational data from the same location. The frequency and magnitude of ramp events attributed to CEE correlate with the okta number, CEE events were defined as >25% of the clear-sky irradiance. CDF profiles of the magnitude for each okta were made allowing for random extraction following the appropriate distribution. The normalised

CEE correction factors are further corrected as a function of M, which is itself a function of okta, as detailed in equations 14-16

$$M = f(okta, CDF) \quad \text{(eq. 14)}$$

$$CEE_{up} = CEE_{up} \times (1 + M) \quad \text{(eq. 15)}$$

$$CEE_{down} = CEE_{down} \times (1 - M) \quad \text{(eq.16)}$$

The application of the CEE is performed using the Boolean matrix of cloud presence, B. Iterating through k_c and using a logical if statement that queries whether B undergoes a ramp on account of cloud cover, the appropriate M adjusted CEE correction factor, CEE_{up} or CEE_{down}, are applied to the time before and after the ramp as shown in equations 17 and 18

$$B_{i=1} = 0 \;\&\; B_i = 1 \rightarrow k_c(i-60 : i+60) = CEE_{down} \quad \text{(eq. 17)}$$

$$B_{i=1} = 1 \;\&\; B_i = 0 \rightarrow k_c(i-60 : i+60) = CEE_{up} \quad \text{(eq. 18)}$$

3. Application and Discussion

To illustrate how the output could be used, the model is applied to a hypothetical configuration for the location of Cambourne, UK. Cambourne is selected as there is a BADC 1-min resolution irradiance data set (BADC, 2013) which will allow a temporal validation; figure 2 depicts the configuration.

Table 1 shows the physical parameter inputs required for each of the locations within the simulation. The x and y coordinates are noted in reference to the centre of the spatial domain, C,1 defined as (750,750). The azimuth angles are defined as -180° to 180° East to West, with South being an angle of 0°.

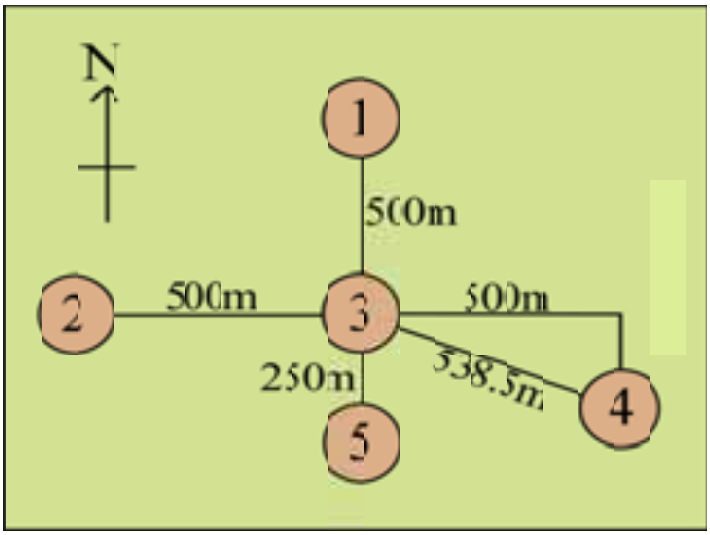

Fig. 2: A theoretical setup used to demonstrate the functionality of the model. The numbers indicate 5 different locations set in Cambourne, UK, of which spatio-temporally correlating irradiance time-series will be generated.

Tab. 1: Input physical parameters for the 5 locations as shown in figure 2. Note that the letter C denotes the centre of the spatial domain which represents *(750,750)*.

	1	2	3	4	5
x (m)	C	C - 500	C	C + 500	C
y (m)	C + 500	C	C	C - 200	C – 250
Azimuth *(°)*	0	0	0	0	0
Pitch *(°)*	0	0	0	0	0
Elevation *(m)*	87	87	87	87	87

The model is functional for all azimuth and tilts with reference to the input longitude and latitude, in this instance however the locations are assumed flat so that irradiance is reported in terms of global horizontal irradiance, the purpose of this is for comparison with the global horizontal observation irradiance data. The weather station in Cambourne, UK is at a longitude of -5.32656^{o} and latitude of 50.2178^{o}, with an elevation of 87 m above sea level.

The temporal resolution of 1 minute has a spatial granularity defined as the smallest distance between locations where a difference in irradiance can be observed. This is determined using the temporal resolution of *60 s* and the minimum and upper cloud speeds of *1* ms^{-1} and *~20* ms^{-1} to give a granularity of *60* to *~1200* $m.min^{-1}$. The average cloud speed is *10* ms^{-1} which gives typical granularity around *600* $m.min^{-1}$. The scenario depicted in figure 2 shows that the locations are separated by at least *250-1020* m and will therefore show appropriate differences. In order to observe spatially varying irradiance time-series for locations closer together, a decreased granularity would be required. This is achieved by increasing the temporal resolution e.g. from *60* s down towards *1* s.

Figure 3 displays a typical output from the model using inputs from table 1. The profile is typical of a clear day in mid-January for the location of Cambourne, UK. Typical patterns can be observed associated with the spatial correlation. Most notably around 700 minutes, there is a gradual ramp down in output at location 1 a few minutes before the other 4 locations undergo a similar ramp down, this is attributed to the wind speed and direction at the time, the clouds were travelling approximately north to south. At ~860 minutes, location 2 is the only location to undergo a large ramp down event.

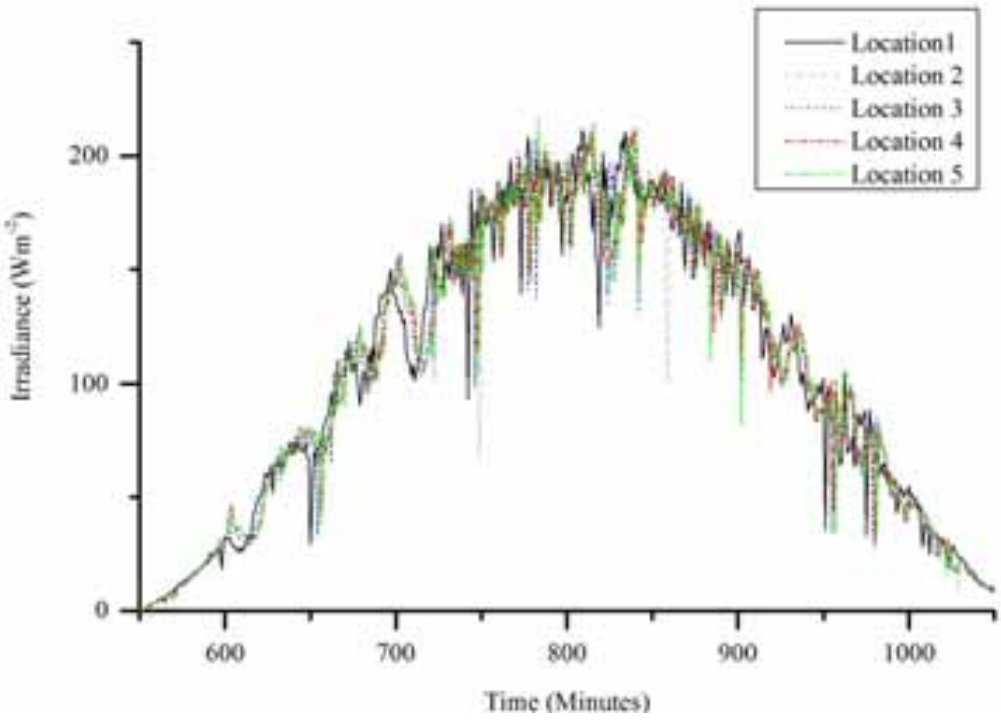

Fig. 3: Synthetic irradiance profiles across 5 locations on the 10th Jan using the described methodology for Cambourne, UK.

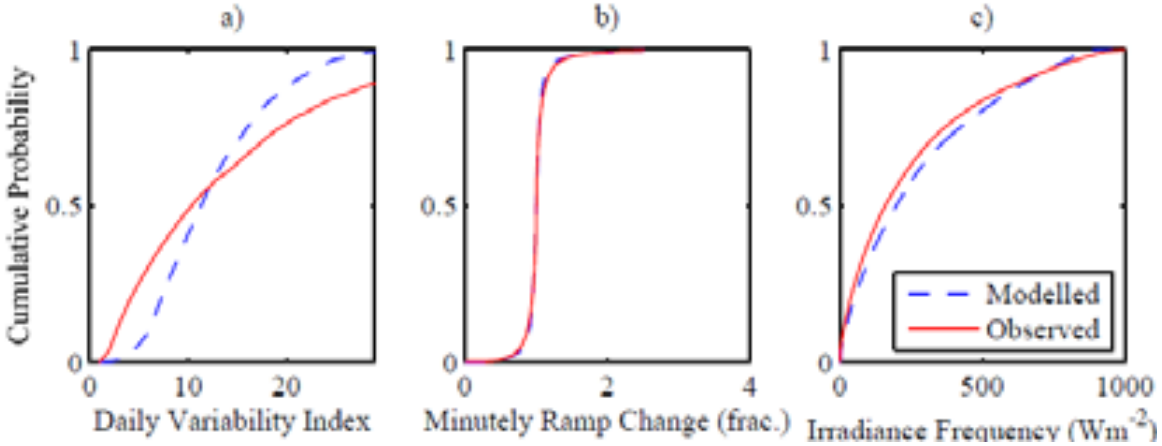

Fig. 4: Cumulative probability distribution plots of the (a) daily variability index, (b) the minutely irradiance ramp-up and ramp-down occurrences, and the (c) minutely global horizontal irradiance frequencies for both the modelled data and the measured data from Cambourne, UK.

4. Validation

Validation to date has focussed on a temporal basis only. All data processing was performed using the commercial software package Matlab r2012a (Matlab, 2012). Hourly weather observational data are taken from the BADC (BADC, 2013). As monitoring stations are occasionally taken off-line for repairs or upgrades for months at a time, 12 years of data are used to allow at least 10 years data for each variable that require a Markov chain to be created.

The simulation is run as detailed in the Application and Discussion section, and compared against the statistics obtained from the World Radiation Monitoring Centre – Baseline Surface Radiation Network (WRMC-BSRN, 2014) from BSRN station number 50, located in Cambourne, Cornwall, UK. Missing data points were ignored and deemed to not significantly impact the distributions for comparison.

Three metrics are used to validate the temporal nature of the model output, the variability index (Stein et al., 2012) cumulative probability function (CDF), the irradiance frequency CDF and the ramp rate CDF, denoted as VI, IF and RR respectively. The 2-sample Kolmogorov-Smirnov (K-S) test was carried out for each metric for each day of the year. When comparing the entire data sets against one another, the K-S validation technique is not appropriate due to the size. The subsets for comparison must be relatively small to gain any significant findings from the K-S test. For this reason the subset of each K-S test consisted of 7 of the same day's minutely data. For example, 7 modelled samples of the 1st January represent one subset, which is compared against a subset made from 7 samples of the same day from observational data.

The K-S test results are displayed in table 2 and comparative CDF profiles in figure 4. The RRs are captured well correlating with R^2=0.9998, and that 99.5% of days with the K-S test reject the null hypothesis that the modelled and observed minutely datasets are not from the same dataset with a confidence of 99%. The implications of this are that for each day of the year, only 0.5% of the days modelled did not produce statistically representative ramp rate data to a confidence of 99%. This means that for application of PV integration into the LV grid for example, the ramp rates seen in the synthetic irradiance time-series would be statistically accurate and allow for a good comprehensive study of how ramp rates impact upon the grid to a 1-min resolution. The daily VI CDF correlates with R^2=0.9777, and K-S at 95.9%. When comparing 1-min VI values for the whole datasets against one another in a frequency plot, the R^2 value is 0.9980 implying that throughout the year, the VI is captured, figure 4a however demonstrates that there is a more localised dependency with room for improvement. The daily VI value is the mean VI value recorded for that day. It can be seen that there is a slight overestimation of days with a VI between 7-15 and an underestimation of stable days between VI=0 to 7 and unstable days with VI >15, the implication of this is that the lower and higher daily variability extremes, where the variability is sustained over a lower time resolution, are slightly

Tab. 2: The percentage of days that reject the null hypothesis when performing the 2-sample Kolmogorov-Smirnov test on 7 of the same day of modelled and observational CDF profiles of 3 metrics.

K-S test significance Level	**90%**	**92.5%**	**95%**	**97.5%**	**99%**
Variability index	97.5%	97.5%	97.3%	96.4%	95.9%
Ramp rate occurrence	99.7%	99.7%	99.7%	99.7%	99.5%
Irradiance frequency	99.7%	99.7%	99.7%	99.7%	98.9%

less frequent than in reality. The VI is still captured at a satisfactory rate with K-S of 95.9% with only 4.1% of days accepting the null hypothesis that the observational and synthetic datasets are not the same, importantly of these 4.1% of days, there was no bias as to what time of the year these days occur, suggesting that there was no seasonal bias within the model. Potential reasoning is that within the observational data, a particular day for each of the 7 different years coincidentally had an overcast day each time, which when compared with a clear day generated by the model, would be dramatically unfavourably compared. The IF CDF correlates well with R^2=0.9980, and K-S at 98.9%. Figure 4c indicates a marginal overestimation in the lower range of irradiance magnitudes and a marginal underestimation in the extreme values of 900-1000 Wm^{-2}. The more extreme values within the models are functions of the clear-sky fluctuations and the cloud edge enhancements. It is possible that because the cloud edge enhancement correction described in section 2.4 only bands across 1-min before and after the CEE event, when in fact this 1-min is an average of all the events recorded within the study, it is entirely possible that a CEE event would span across 2 or more minutes depending on the speed of passing cloud, and so there is scope to make the correction a function of the cloud speed. Otherwise the validation is very strong and the magnitudes are captured well with only 1.1% of days accepting the null hypothesis with the K-S test.

5. Conclusion

This work has developed meaningful high temporal resolution irradiance time-series with a spatial correlation that temporally validates well. The irradiance time-series correlate spatially as a function of location, cloud speed and direction. The variability index, ramp rate occurrence and irradiance frequency metrics perform well using the 2-sample K-S test with a confidence level of 99%. The daily variability indices do tend towards midrange values, however the 1-minute variability index correlates excellently. The ramps present within the simulation have an excellent correlation to observation data with 99.5% of all days passing a 99% significance level K-S test.

Future work opportunities include further development of the temporal resolution as the nature of the methodology would allow it to be increased. This methodology would allow for theoretical high resolution simulations and studies of the impacts of solar variability and intermittency derived from readily available inputs of mean hourly weather observational data. The temporal methodology and Matlab script files are made freely available through download so that it can be adopted for any other application, and adapted to further the study (Bright et al., 2015).

Intermittence forecasting of the solar resource in Corsica

Pierrick Haurant, Auline Rodler, Ghjuvan-Antone Faggianelli , Marc Muselli, Philippe Poggi

University of Corsica, UMR SPE CNRS 6134, F-20000 Ajaccio, France

Abstract

Island electrical small-scale grids are sensitive to variations in power production. In case of important integration of solar power in the energy mix, the solar resource intermittency becomes a high risk to the grid's stability. That is why a good knowledge of the variations is the first step to the massive optimized PV integration in the energy mix. This paper focuses on the forecasting of the solar resource variability. First, the solar resource variability characterization will be presented. It is based on a typological classification method that relies on variability scales which enable to distinguish the different dynamics. Afterwards, the predictability of variations is studied through forecasting models as a simple persistence, the k-Nearest Neighbors and Artificial Neural Networks (ANN). In this regard, time series of intervals classified according to their dynamics of variations have been generated and the forecasting performance, for different horizons and with different models were compared.

Keywords: Solar resource, variations, classification, forecasting, k-Nearest Neighbors, Artificial Neural Networks

1. Introduction

Island electrical grids are typical: they are small-scale and sensitive to variations in power production. In case of important integration of solar power in the energy production mix, the solar resource intermittency becomes a high risk to the grid's stability. This is the reason why, in France, it is considered that no more than 30% of the production power must be supplied by power plants using intermittent renewable energy sources. In Corsica Island, this threshold has already been reached in 2012, as a large amount of PV plants have been connected to the grid. This threshold is a constraint to the development of renewable energies on the island. Therefore, the aim would be to overpass this threshold without destabilizing the electrical grid.

A good understanding of the solar resource in Corsica, its variability, its territorial mitigation and forecasting are important challenges for the electrical grid's manager to overpass this threshold. The optimization of the territorial mitigation may present an opportunity to the development of renewable energies and their integration to a small electrical grid which is not connected to the mainland power grid. We can anticipate that the smoothing of the electrical photovoltaic power production by the compensation of the territorial mitigation will be insufficient to stabilize the grid. Finally, it seems essential to compensate the solar variability using other means of production or storage solutions.

The level of solar variation has to be forecasted so that the electrical grid manager can anticipate and can choose a control strategy concerning all the means of power production. In this context, the solar resource intermittence characterization in Corsica, the use of the territorial mitigation and the forecasting of variations are challenges to the grid's manager. For this, a new method of typological classification of variations has been developed and will be introduced.

2. Typological classification of the radiation

Indicators such as the clearness index k_t, the air-mass-corrected clearness index k'_t or the clear-sky index k_{Cls} give information on the sky's clearness or cloudiness. A segmentation of these indexes domains into two

doi:10.18086/swc.2015.07.03 Available at http://proceedings.ises.org

or three intervals are the result of a first classification. In the literature, we can find numerous segmentations of daily k_t values that have succeeded to different classifications (De Miguel et al., 2001; Li and Lam, 2001; Mefti et al., 2008; Notton et al., 2004; Rigollier et al., 2004). This first classification method has the advantage to be easy but has the disadvantage to be static: fluctuations of irradiations and the cloudy dynamic are smoothen by a daily mean and cannot be considered. Consequently, a changeable weather day can have the same daily clearness index as an invariably cloudy one. Other typological methods can consider the clouds dynamics by completing the discrimination indexes of the different types of radiation. Muselli et al. (2000) have used a set of discriminating parameters derived from k_t hourly and daily values in order to characterize three types of days (clear sky, overcast sky, cloudy sky), using classification method of Ward. Daily dynamic of the sunshine has been considered by a parameter entitled "Integral of the squared second derivative of hourly clearness index profile". Other typological methods consider cloudy dynamic : the mean clearness index segmentation is completed by the segmentation of mathematical quantities that quantify the signals roughness such as the fractal dimensions (Maafi and Harrouni, 2003) or using Dirichtlet decompositions (Soubdhan et al., 2009) or even the wavelet decompositions (Woyte et al., 2007).

All these new methods present the limit of discriminating by days, while in a single day we can have different weather dynamics. That is why these classifications unable an energy manager to anticipate the variability of the production: the knowledge of the category of a day to come does not allow knowing precisely the irradiation profile. It seems valuable to consider days as successions of irradiation profiles that can be subject to a classification.

3. Methodology: Variation scales

Irradiance dynamic regimes distinguish themselves by the variations form observed that can be characterized by two criteria: their duration and amplitude. The aim of this work is to set up a classification method of these regimes depending on these characteristics.

The variation scales dt are defined as the time interval for which relative variations of solar irradiance $G(t)$ are calculated. In this study, we are interested in the relative absolute variation $dG(t)$ between two successive moments separated by a time dt, neglecting existing variations in the interval $[t - dt\,;t]$ and following this relation:

$$dG(t) = \left|\frac{G(t)-G(t-dt)}{G(t-dt)}\right| \qquad \text{(eq. 1)}$$

3.1. Variations categories

Variation scales allow discriminating different variation dynamics. Indeed, variations which are too slow to be perceptible for a value of dt can be revealed for a superior value.

A typology can be built on scale variation following this procedure: considering a given variations scale, the issue will be to calculate and compare variations at a variability threshold noted S_{var}. Variations higher than this threshold will integrate the equivalent class that could be described as the class of the «perceptible variations at this scale ». Then, for example, two different variations scales dt_1 and dt_2 lead to three classifications, from the close to zero variations set to high variations one. It is convenient to choose the scales separated by larger orders of magnitudes, in order to discriminate completely different variation profiles.

3.2. Intervals delimitation

In a majority of cases, even in a very dynamic cloudy regime, variations are only punctually above the fixed threshold. Then, the classification conditions generate a large number of intervals of different classes following themselves. Two thresholds have been introduced in this optic. The first threshold called intra-interval threshold and noted S_{intra}, represents a maximal duration between two variations so that they can be grouped in the same interval. The other threshold is called inter-interval threshold and noted S_{inter}. It is comparable to a minimal duration of intervals.

The use of these two thresholds gives birth to a sequential procedure of interval determination following

three non-commutative steps:

1. The instability instants set t_{inst} are defined as a set of instants for which variations exceed the variability threshold S_{var};
2. All the instants between two variations separated by the inferior laps time of the intra-interval threshold S_{intra} are considered fluctuant : it is the grouping inter-interval step or homogenization step;
3. The intervals considered too short integrate adjacent intervals: it is the inter-interval grouping. If adjacent intervals to the studied one are of different classes, the inter-intervals grouping is done under a condition: if the interval is of maximal class, it will be concatenated to the adjacent one of nearest inferior class, else it will integrate automatically to the nearest interval of the superior class. These conditions are coherent with the electric network managers' point of view: it is convenient to outrank marginal events in order to consider in the worst case to limit the risks and to upgrade marginal events. However, in the first case where the over-classification is impossible, we consider that the oddness or the short variation duration takes over their intensity, the interval is downgraded.
4. The classification method and the variability interval definition and sunshine regimes need the determination of four specific parameters:
   - A variability threshold S_{var} above which we consider that there is instability; it has been fixed to 10 % in our study.
   - Scale variation values dt for the discrimination of the different sunshine regimes; it seems better to use different order of magnitudes in order to distinguish different dynamics. The magnitudes of a few seconds can find out strong and narrowed variations while those of a few minutes find strong variations and also slower and stronger ones. Thus, considering these observations, it seems appropriate to have two scales: $dt_1 = 1$ s and $dt_2 = 300$ s leading to a partition in three classes:
     - Class 0 (noted C_0): the variations of this class are perceptible neither for $dt = 1$ s, nor for $dt = 300$ s. There are no or very few variations ;
     - Class 1 (C_1): variations are perceptible only for $dt = 300$ s. These variations are slow and not very intense ;
     - Class 2 (C_2): variations are perceptible for $dt = 1$ s and $dt = 300$ s. They are narrowed and deep.
   - Intra- and inter- grouping interval thresholds (S_{intra} and S_{inter}), which we can evaluate the limits of the intervals. No objective criterion has been found for the thresholds determination. It is the reason why these thresholds are determined depending on the application we want to do with the intervals and the temporal resolution necessary to this application. The smaller the thresholds' values are, the smaller and more numerous will be the resulting intervals.

Figure 1 is an example of days separated into intervals ranked for $S_{var} = 0.1$; $dt_1 = 1$ s and $dt_2 = 300$ s and $S_{inter} = S_{intra} = 900$ s.

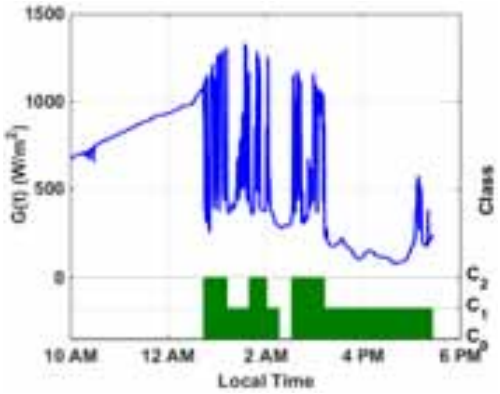

Figure 1 : An example of a daily irradiance curve and the variability classes associated

4. Forecasting of solar irradiance variation

In literature we can find a large amount of forecasting models to predict solar irradiance at different horizons (Kemmoku et al., 1999 ; Sözen et al., 2005 ; Mellit et al., 2005 ; Cao and Cao, 2006 ; Hocaoglu et al., 2008 ; Zervas et al., 2008 ; Chaabene et Ben Ammar, 2008 ; Paoli et al., 2010 ; Voyant et al., 2011 ; Marquez and Coimbra, 2011). These forecast concerns punctual irradiance values or the solar irradiance between two moments. For these two configurations no information is available on the short solar variations. Ideally, the aim would be to forecast for different small horizons in the range of the minute, on different lags at the same time. The shortest developed horizons until know are of 5 minutes on a single lag (Voyant, 2011). On the one hand, such a horizon does not seem sufficiently close to evaluate fast variations. On the other hand, a single lag does not allow to know a variation tendency (except if we refer us to past measures). Finally, this prediction does not leave the time to the grid manager to act on the system when a fluctuating regime is recognized. The ranks forecast seem interesting as it means that the variations of a future interval would be forecasted. The forecast methods which we have chosen are statistical based on:

- The k-Nearest Neighbor (k-NN): it is a technique following the philosophy that a succession of events of the same nature will lead always to a same consequence. Here k is the number of sequences. The principle of the k-NN consists to look for in a set of data identical events to the last observed. Then it is supposed that the future event will be the most often observed one after equivalent sequences observed in the historic.
- The Artificial Neural Network (ANN) is a learning algorithm inspired by biological neural networks. It represents a collection of neurons which are mathematical and computer representations of biological neurons. The mathematical representation is like an algebraic function which evaluates a weighted sum of the inputs matched to a bias, which is independent with the inputs.

Either the model has predicted the correct class or it has forecasted the wrong one, so that the performance of these models will be based on the percentage of times the class forecasted was the correct one. The models results will be compared to a primitive model, named the persistence. This model tends to reproduce the present event to the studied horizons.

4.1 Set of data

The classified irradiance data used in this study to test the different forecasting models were measured in 11 sites dispatched in Corsica Island (Fig. 2) during 2 years. The measurements are sampled at 1 s and synchronized. As a first step, the data collected in all sites have been concatenated in a same set in order to make a large sample as it is necessary for forecasting.

Figure 2 : Lucciana (42° 39' 49" ; 9° 25'28" ; 60) - 2 Oletta (42° 39' 36" ; 9° 19' 45" ; 52) - 3 Calvi (42° 33' 38" ; 8° 44' 48"; 31) - 4 Corte (42° 18' 04" ; 9° 09' 57" ; 381) - 5 Piana (41° 16' 03" ; 8° 41' 37" 12) - 6 Cargèse (42° 08' 40" ; 8° 35' 58" ; 30) ; 7 Ghisonaccia (42° 03' 54" ; 9° 22' 14" ; 65) - 8 Ajaccio (41° 55' 49" ; 8° 45' 23" ; 2) - 9 Sainte Lucie (41° 41' 59" ; 9° 20' 12" ; 66) - 10 Propriano (41° 39' 43" ; 8° 55' 02" 17) - 11 Bonifacio (41° 22' 17" ; 9° 12' 10" ; 46)

The variations classes have been determined according to the method previously introduced, using a variation threshold of 10 % and variations scales of 60 s and 300 s. The predictions realized in this study are based on time series defined as a sequence of observations for regular time steps. These observations are done based on identical acquisition methods and data processing. In our case, the observed days need to be

divided into constant time intervals for which we attribute fluctuation rank. Each measure has to be ranked using the method defined above. Then each time interval composed by ranked measures will get the mostly present fluctuation rank. The time series time step will be chosen based on the forecast demand in terms of temporal resolution and horizons.

80 % of the set of ranked intervals were used for the learning phase and 20 % were used for the assessments models performance.

4.2 Forecast with a persistence model

The persistence model is a simple model which considers that the event x_t at time t is repeated at time $t + h$, where h represents the horizon of the forecast:

$$\hat{x}_{t+h} = x_t \qquad \text{(eq. 2)}$$

This model has been implemented for ranked intervals of 15 min, 30 min and one hour. The model has been used to forecast horizons from 15min to maximum 6 hours. Figure 3 presents performance of the persistence model applied to these three types of intervals for the entire horizons predicted. First of all, we observe that whatever the size of the used ranked intervals, the predictions performance decrease when more lags are used. Above a number of lag the performance will not change much. For an interval of 15 min, we have a performance which changes from 83.3 % for lag 1, to 50.1 % for lag 6 to 33.3 % for lag 16. The performance does not change much and reach 32.9 % at lag 24. In the same way, the performance of the predictions for 30 min intervals changes from 72 % at lag 1 to 39.1 % for lag 6, decreasing then slightly. Finally, the correct forecast for a one hour interval will change between 66.9 % at lag 1 to 42.9 % at lag 6.

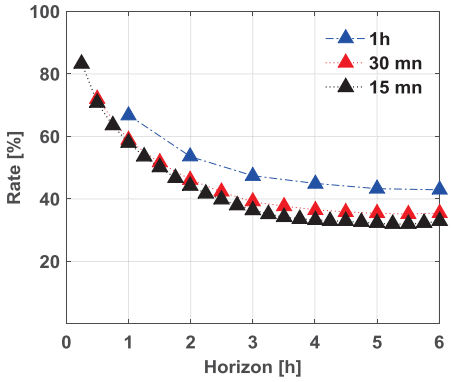

Figure 3 : Correct prediction rates obtained with a persistence as a function of horizons, using ranked intervals of 15 mn, 30 mn and 1 h.

For a same horizon we notice that longer (in terms of time) ranked intervals allow always better predictions for all the cases: for a horizon of 30 min the predictions with 30 min intervals (at lag 1) are better than with 15 min intervals (at lag 2). We have performance of 72 % for 30 min intervals and of 70.7 % for 15 min intervals. In the same way, one hour interval allow better predictions than with 30 and 15 min intervals, giving respectively 66.9 %, 58.8 % and 58 % of performance.

4.2. K-NN Forecast method

The k-NN method developed here is based on a historic of the successions of variation classes. The method consists in finding similar sequences of the k last past events in this historic. Then, the prediction at horizon h corresponds to the most frequently observed class that follows the sequences at lag h.

The optimization of the k-NN passes by the determination of the sequences size $k \in [1\,;8]$ and of the time series time step used as input. As the tests realized with the persistence model the intervals of 15 min, 30 min and one hour have been tested. The first results have shown that it is convenient to choose a k-NN model with k = 4:

- For a time step of 15 minutes (Fig. 4), the existence of forecast impossible for $k \in [5\,;8]$ puts into question their usability. Some sequences preceding the class to be predicted have not been found in the

historic so no class forecast has been possible. Taking k = 4 allowed all the predictions and give better results for h ∈ [1 ; 4]. It gave close results to the best results of the other horizons.

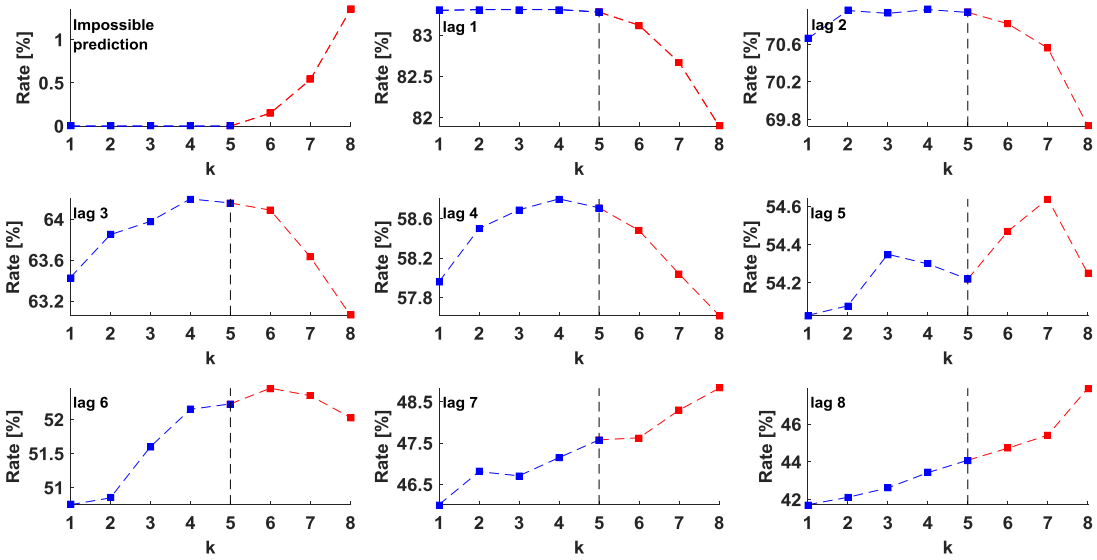

Figure 4 : Correct prediction rate as a function of the sequence size of the k-NN for different horizons, using 15 mn intervals

- For 30 minutes intervals (Fig. 5), the existence of impossible forecast for k ∈ [4 ; 8] show that these models are not reliable. The most performant model whatever the lag is 4-NN.

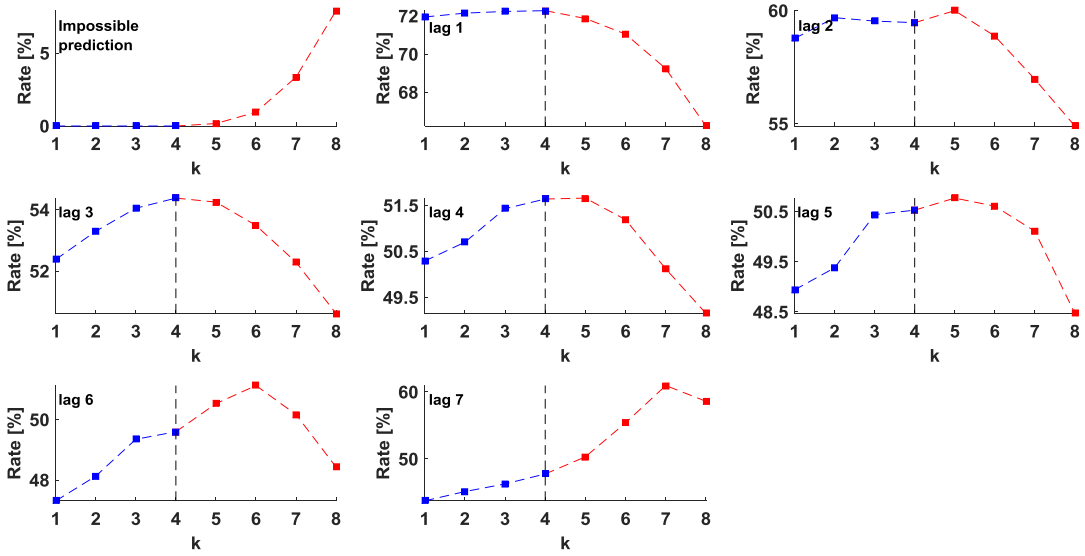

Figure 5 : Correct prediction rate as a function of the sequence size of the k-NN for different horizons, using 30 mn intervals

- Concerning the one hour interval (Fig. 6), impossible forecasts for k ∈ [5 ; 8] exist, so that we do not consider them. Then, the best forecasts are always reached with k = 3 or k = 4. We can notice that the performance of the 4-NN model are always higher than of the 3-NN for lags 1, 2 and 4 with small differences between 0.1-0.3 points. The 4-NN model has much better performance than model 3-NN for lags 3, 5 and 6 for differences between 0.5 and 7.2 points. In general, the 4-NN model presents the best results.

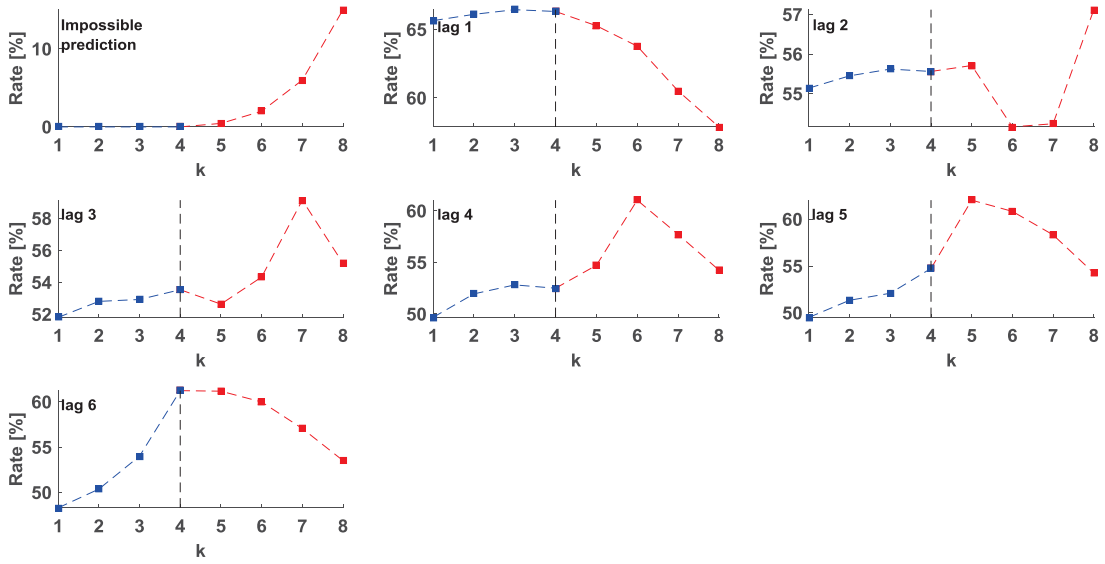

Figure 6: Correct prediction rate as a function of the sequence size of the k-NN for different horizons, using 1 h intervals

Finally, the performance of the 4-NN for the three ranked intervals studied are summed up on figure 7.

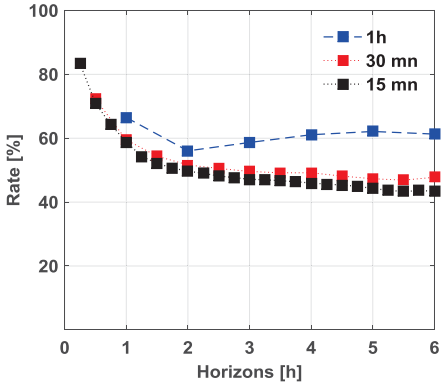

Figure 7 : Correct prediction rate obtained with a k-NN (k = 4) as a function of horizons, using ranked intervals of 15 mn, 30 mn and 1 h.

As the persistence, the longest ranked intervals give better results for distant horizons:

- The 15 minutes intervals allow 71.0 % of correct forecasts for 30 min horizons (at lag 2) while we have 72.3 % of good predictions, for the same horizon, with 30min intervals (à lag 1).
- The 15 minutes intervals give 58.8 % of correct predictions at one hour horizon (at lag 4), against 59.5 % with 30 minutes intervals (at lag 2) and 66.3 % with one hour intervals (at lag 1).

5. Artificial Neural Networks Forecast method

ANN have been applied to the time series representing the classes of variations. These classes are forecasted for different sizes of intervals and different horizons. In all the cases, only 6 lags have been forecasted in order to limit the complexity of the studied models.

The optimization of the ANN parameters is a major stake. Therefore, we have focused on the study of the number and the type of inputs as well as the number of hidden neurons N_c, conserving the rest of the ANN's structure (architecture, activation function, number of hidden layer, etc.). The optimization has been done by fixing one of these two parameters (i.e. the number and natures of the inputs or the number of hidden neurons) and varying the other one, following the method developed by Voyant et al. (2011). To start with, the inputs are defined and then the numbers of neurons of the unique layer hidden N_c are defined. The inputs have been optimized following two axes fixing $N_c = 1$:

1. The nature of the inputs, associating to the endogenous inputs exogenous inputs. The exogenous inputs used in this study are spatiotemporal indices: the measured instants of the events are detailed and are geographically located, since the historic is composed of measures done on 11 different sites on a period above one year and presenting discontinuities. Some successions of events can be linked to the site of measure and a temporality of the phenomenon can exist: some events successions are seasonal or daily. Three types of indexes have been studied independently each one from another :
   - A time index I_{tps} resuming the hour, the day, the month and the year of the event ;
   - A spatial index I_{geo} represented by the altitude of the measures site. This index is more representative than the geographic coordinates as the sites are very close to each other so that the coordinates would not be representative ;
   - A spatiotemporal index I_{Gcls} : the global radiation for clear sky daily conditions : Gcls, simulated by the ESRA model (Rigollier et al., 2000). The radiation depends on the position and the instant.
2. The number of inputs: we try to limit the number of inputs in order to reduce the complexity of the model. An iterative procedure has been set up to eliminate the unnecessary inputs. If we consider eight endogenous inputs and as many exogenous inputs a neural network is generated. The performance of the neural network is calculated and the weights between the inputs and the hidden units are examined. The input associated to the weakest weight is eliminated as it is considered unnecessary. This procedure is repeated until we have only one input. The model kept will be the one which maximizes the number of correct predictions.

We obtain from these optimizations different input choices according to the sizes of intervals. The model choice is difficult since their ranks are different from a lag to another: a model can be the best for prediction at a lag whereas it is the worst for predictions at another lag. A mean of the forecast on the six lags has been chosen to discriminate the different models. Only I_{tps} and I_{Gcls} indexes improve the ANN performance for 15 min classed intervals and lags higher than 1 (Fig. 8). The models using I_{tps} give the best results for lag 3 and 4 whereas I_{Gcls} increase the success rate for lag 2, lag 5 and lag 6, giving close results to the best ones for the other lags. These models need respectively 14 and 9 inputs. In this way, according to the Okham razor principle, it seems more interesting to keep the model with I_{Gcls} index for most cases. Only forecasts at lag 1 need endogenous data.

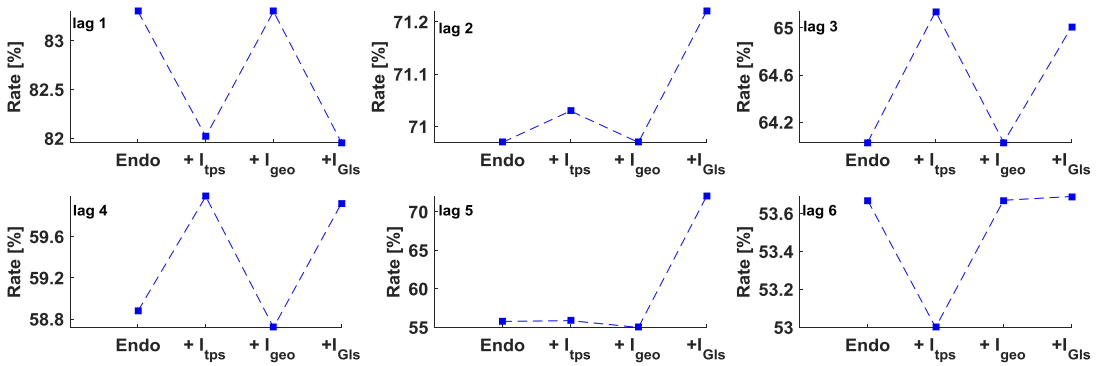

Figure 8: Correct prediction rate as a function of the type of ANN inputs for different horizons, using 15 mn intervals

For 30 minutes intervals, the indices tend to damage the models performance (Fig. 9). In this way the model using two endogenous inputs present the best performance for all the lags except for lag 3. This model will be put forward especially as it needs few inputs.

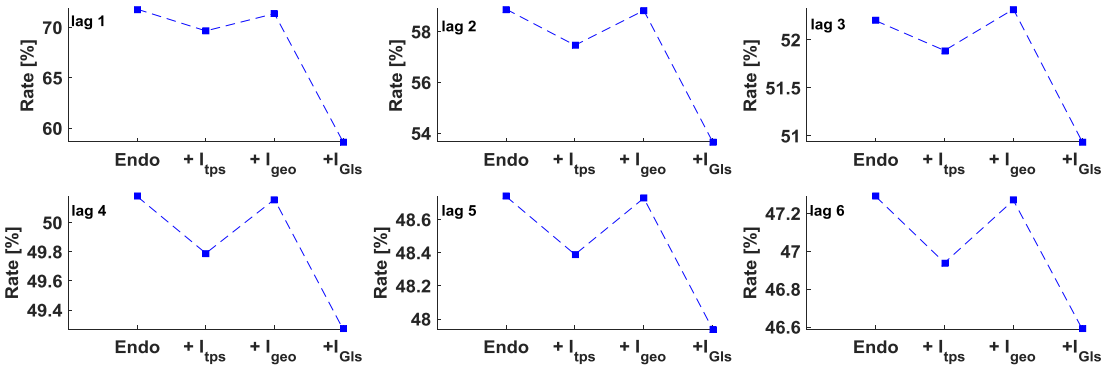

Figure 9: Correct prediction rate as a function of the type of ANN inputs for different horizons, using 30 mn intervals

Finally, concerning one hour intervals, the model using three endogenous inputs is the most promising. It allows better statistics for all the lags forecasted and needs few inputs.

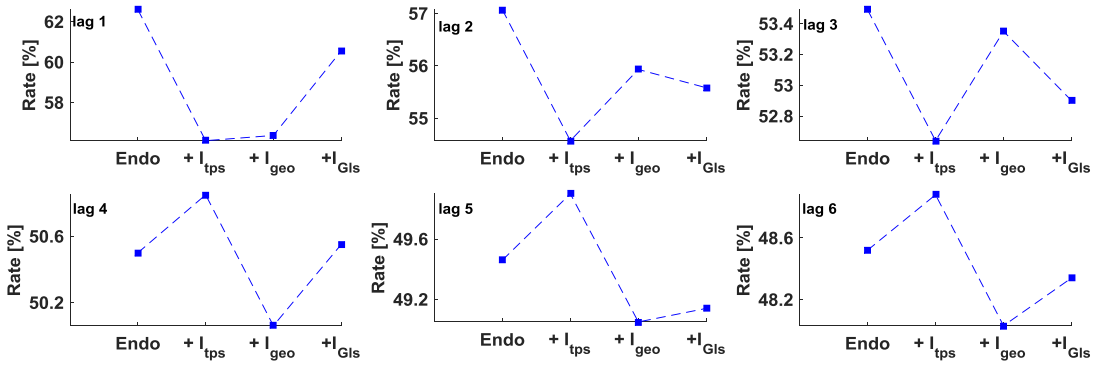

Figure 10: Correct prediction rate as a function of the type of ANN inputs for different horizons, using 1 h intervals

Concerning the number of hidden units in the unique layer, we must note that the number of parameters to evaluate for a ANN strongly increases with the number of hidden units: for a hidden layer with N_c neurons, N_e inputs and N_s outputs, the ANN will count $N_w = N_c(N_e + N_s)$ weights and N_c bias, a total $N_{tot} = N_c(N_e + N_s + 1)$ of parameters. It is important to limit at most N_c.

$N_c \in [1\,;8]$ have been tested for 15 min ranked intervals. We had slightly best performance for the three first lag with $N_c = 6$, $N_c = 7$ and $N_c = 5$ and the three following lags are a bit better forecasted with $N_c = 3$ and $N_c = 2$. But the small enhancements of the performance have to be relativized as the models are more complex so that $N_c = 1$ can be privileged since it is less complex and its performance are near the best more complex models.

For intervals of 30 minutes, 3 or 4 hidden neurons are needed to maximize the performance of the ANN at lag 1, lag 2 and lag 3 and that $N_c = 1$ shows the best results for predictions at lag 4, lag 5 and lag 6. $N_c = 1$ can be privileged: this model, which is the less complex, shows the best compromise between performance and complexity.

In the same way and for the same reasons, the ANN with $N_c = 1$ is preferred among $N_c \in [1\,;5]$ for one hour intervals.

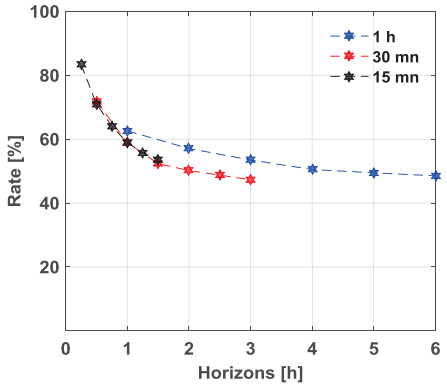

Figure 11 : Correct prediction rates obtained with an ANN as a function of horizons, using ranked intervals of 15 mn, 30 mn and 1 h.

6. Conclusions

The correct prediction rates for the studied horizons obtained with the optimized models are summed up in figure 12.

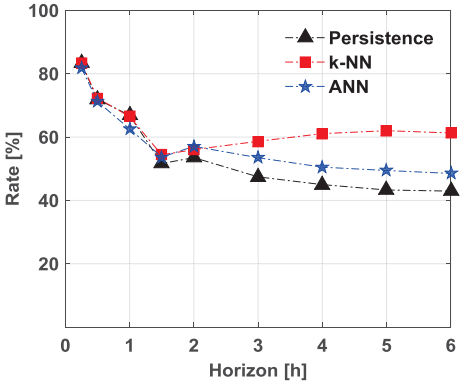

Figure 12: Correct prediction rate of the best model of each category as a function of horizons

We can see that whatever the model (persistence, k-NN or ANN), it is necessary to implement classified intervals of different durations as input to forecast variability classes at more or less far horizons:

1. for horizons above 1 hour, we can use classified intervals of 15 or 30 minutes. These inputs give close results whatever the model. However, it is interesting to input 15 minutes intervals for a best time resolution;

2. for horizons over 1 hour, it is necessary to input 1 hour intervals.

Besides, we can observe that for predictions at close horizon (between 15 minutes and 1 hour), the three studied models give quite similar results. For these horizons the persistence must be preferred to respect the Okham razor principle. For horizons between 1 hour and 2 hours, ANN gives best results and must be favored. Finally for horizons over 2 hours, the k-NN offers best performance and must be used. Thus an hybridation of these models should achieve better performance for prediction at all horizons.

In future works, Markow chains could be considered since it is possible to evaluate probability of transition from a class to another.

Enhancing satellite derived irradiance data for taking into account sub-pixel structures relevant for solar energy system analysis – current practice and future options

Hans Georg Beyer

Institute of Engineering. University of Agder, Grimstad (Norway)

Abstract

Satellite derived irradiance information currently approaches the status of a standard source for irradiance data used in solar energy system analysis. Due to intrinsic limitations in both spatial and temporal resolution, these data fail to give information of the full dynamics of the irradiance field in space and time. The analysis of systems comprising a sensibility to details of the temporal evolution of the irradiance field (i.e. systems comprising short-term storage elements) and of systems with sensibility to the spatial inhomogeneity of the irradiance field (i.e. large photovoltaic- or CSP-power plants) require knowledge of the "fine-structure of the irradiance field. Thus, methods for a respective enhancement of the satellite derived data are needed. This contribution presents various approaches discussed for setting up fine scale input data for the study of solar energy systems.

Keywords: fine scale irradiance data, irradiance field, temporal and spatial structure

1. Introduction

With the increasing availability of satellite derived irradiance information, this type of data set is more and more in use for the design and operation of solar energy systems, most notably PV- and CSP-systems. By this, the need for data measured on-site is reduced. However, due to basic limitations of the satellite-derived data, several requirements put by the intended application cannot be coped with this data type directly.

Grid integration studies and studies for systems involving either short-term storage devices (batteries) or show a sensibility to large power gradients, require data on the generated power - and thus on the irradiance - with a time resolution as short as one minute or even one seconds. With respect to spatial resolution, for a reliable modeling of both small and large solar installations, which can cover area from a few square meters up to square kilometers, respectively, information on the evolution of the area averages of the irradiance as well as on the inhomogeneity of this field is required. In this regard, the satellite-derived data are currently confined to a temporal sampling of - at best - a 10-15 min resolution. The spatial resolution is at best in the kilometer scale (depending on satellite type and data set), presenting spatially averaged information for the respective area, i.e. the pixel). Thus, in view of the requirements mentioned, the raw satellite information has to be enhanced in both space and time resolution by additional information to be fully applicable for all aspects of the system modeling.

2. Approaches

2.1 Enhancing the temporal resolution of irradiance information

The most direct approach concentrates on the temporal information, with the aim to paste synthesized high-resolution data into the low-resolution original sets. Pre-requisite is an appropriate model for temporal structure extracted from respective measurements. The models are mostly based on information directly

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.07.04 Available at http://proceedings.ises.org

extracted from ground measured data. Basic work in this field was done by Skarveit and Olseth 92 by a detailed analysis of statistical properties of short term (here: down to 1 minute) values of the clears sky index. Models to describe the probability density function (PDF) and the autocorrelation characteristics of the sets are identified. Based on this, universally applicable tools to generate appropriate short term time series of global and diffuse irradiances with pre-described hourly averages have been developed, see e.g. Remund and Müller 2011. An alternative approach presented by Bright et al. 2015 is based on first describing the temporal evolution of the cloud cover given in octa and handling the distribution of clear sky index in dependence of the cloud cover. The temporal evolution of the cloud cover is modelled by a Markov approach (which could be extended to a spatial field). Fig. 1 gives examples for the resulting time series.

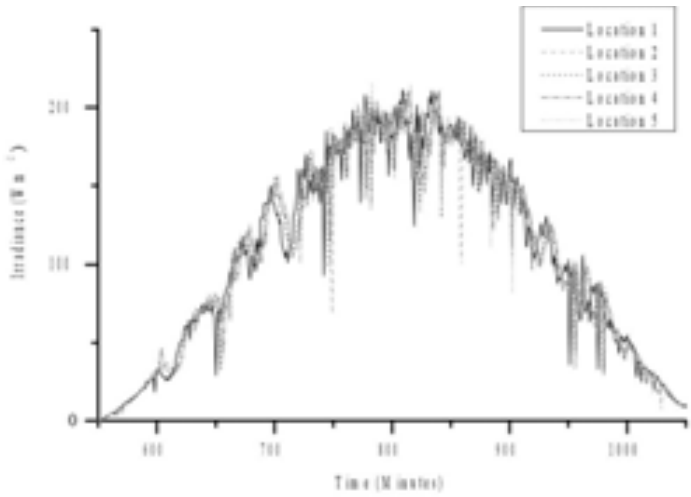

Fig. 1: Examples for daily time series of irradiances at different locations generated by the Bright et all 2015 model (taken from Bright et al. 2015). The mutual correlation of the series is up to now not tested.

Other more direct derivatives of the Olseth and Skartveit 1992 approach developed to cope with the direct normal irradiance as well are given by e.g. Beyer et al. 2010, Polo et al. 2011 and Fernández-Peruchena et al. 2015. Fig.2 gives examples for respective daily evolutions of the 1 min. global and direct normal irradiances.

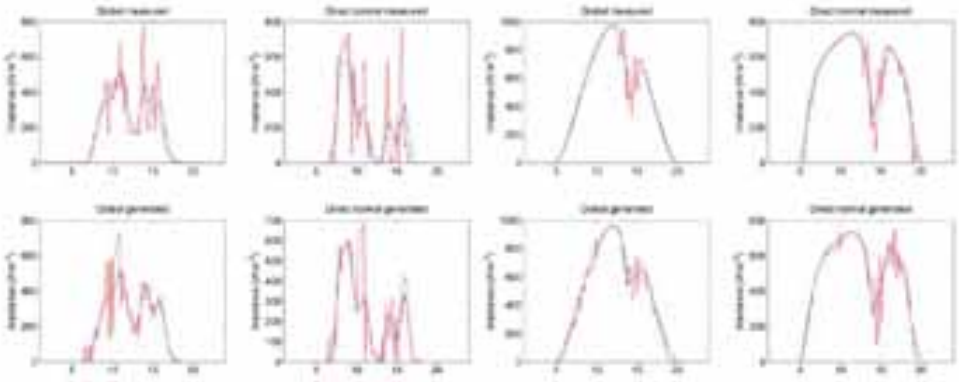

Fig. 2 Examples of daily evolution of global and direct normal irradiance with low (blue) and high (red) time resolution, Upper row presents measured data, data with high time resolution in lower row are synthetic (taken from Polo et al. 2009).

Validation of these schemes can be done by comparing simulations of the performance of solar energy systems for real and synthetic input data (see e.g. Beyer et al. 2010). When applying this approach to spatially distributed systems e.g. CSP-systems limitations are given by the fact, that it has to be assumed that the system is affected by a homogeneous irradiance field – which in general is not the case. This calls for additional information on the spatial statistics of the irradiance field.

2.1 Analysis of the spatial structure of the irradiance field based on fleets of point measurements

To gain the information on the time and space structure of the irradiance, dedicated measuring campaigns had been set up. Early examples as e.g. given by Beyer et al. 1993 and 1994 investigating the space/time structure of the irradiance field on scales of 100m and 1s respectively. More actual examples are e.g.

reported by Kuszamaul et al. 2010, Sengupta and Andreas 2010, Madhavan et al. 2015. Luger et al 2013 and Öchsner et al. report on a campaign analyzing both, the small scale structure of the irradiance field covering a MW scale PV system as measured by fleet of irradiance sensors and the reaction of the PV system. Based on the set of irradiance data, Luger et al. 2013 propose a method for the reconstruction of the field cased on the time series of the point measurements and (see figs. 3,4).

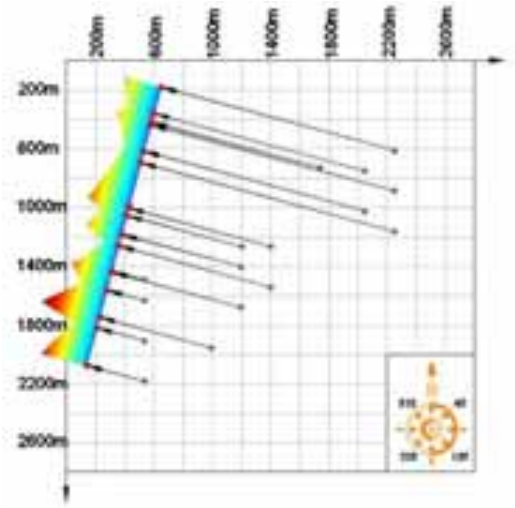

Fig. 3: Generating an irradiance field driven by measurements of a fleet of irradiance sensors. From the cross-correlation structure of the point data a cloud drift vector is derived. Assuming rigid clouds and an appropriate interpolation techniquwtime coherent irradiance bands can be constructed (taken from Luger et al. 2013).

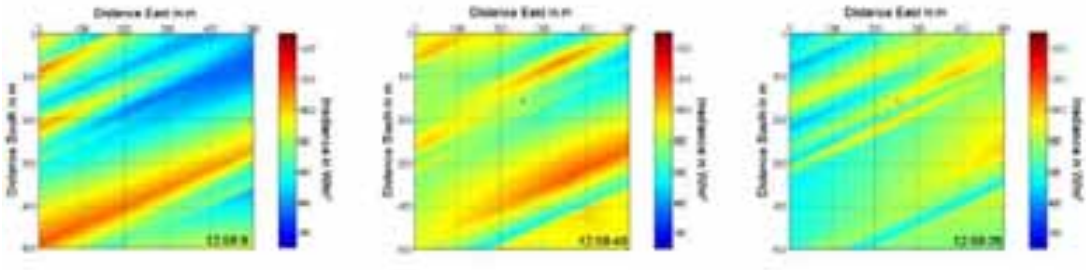

Fig. 4: Consecutive irradiance field situations generated by the method presented by Luger et al. 2013 (taken from Luger et al. 2013).

The procedure makes use of the assumption that the temporal evolution of a highly fluctuating irradiance the field is governed by the movement of shadow casting clouds, and is thus linked to the spatial structure of the cloud field and its displacement over time.

2.2 Analysis of the space/time structure of the irradiance field based on sky image analyses and models for the synthetizations of irradiance fields derived

As the structure of the irradiance field is governed by the evolution of the cloud field, the explicit analysis of cloud field geometry comes into the focus. With information on cloud field geometry and dynamics, the modulation of the irradiance by this field can be modelled with space and time resolution according to the resolution of the spatial cloud features.

As data source, ground based cameras proved useful. Fig.5 gives an example for raw and processed sky images presented by Nitche et al. 2014. The processing used here aimed at the separation of the pixels containing clouds. This cloud image offers the basis for an analysis of the clouds as two dimensions spatial structure.

As tool for the structural analysis, the description of the clouds as fractal object proved helpful. The fractal characterization of the cloud circumference was applied by e.g. Beyer et al. 1996. Based on the fractal dimension of the cloud circumference for a cumulous cloud field a scheme for the generation of a synthetic field with similar characteristics was set up. Fig. 6 shows a synthetic cloud shadow band. By assuming a

cloud drift speed, the shift over a (Generator-) area of interest can be modelled, resulting in a cloud modified irradiance time series at each point at the ground effected by the cloud field (see Fig. 7 for a single point series). It could be shown, that the resulting irradiance field can reflect statistical properties of the ground measured irradiance field (Beyer et al., Hammer and Stolzenburg 1993).

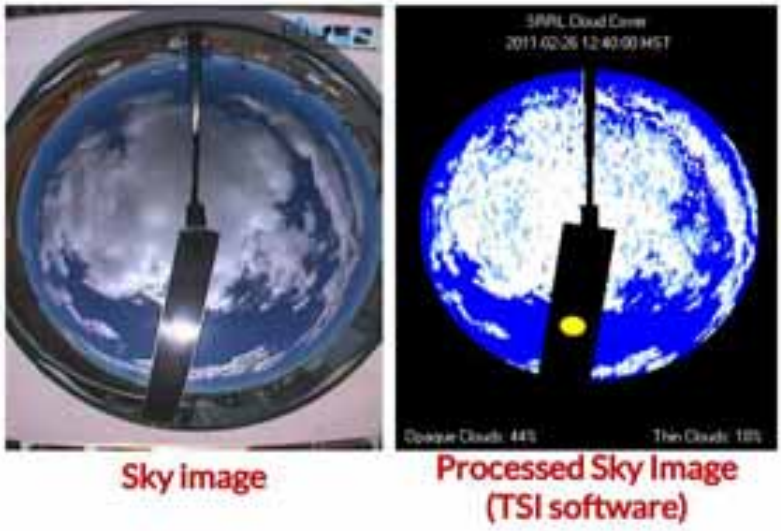

Fig. 5: Photographs taken by a sky imager. The image on the right is processed for cloud/clear sky separation. (taken from Nitsche et al. 2013).

Fig. 6: 2D Cloud band generated according to a fractal dimension of the cloud circumference (taken from Beyer et al. 1993).

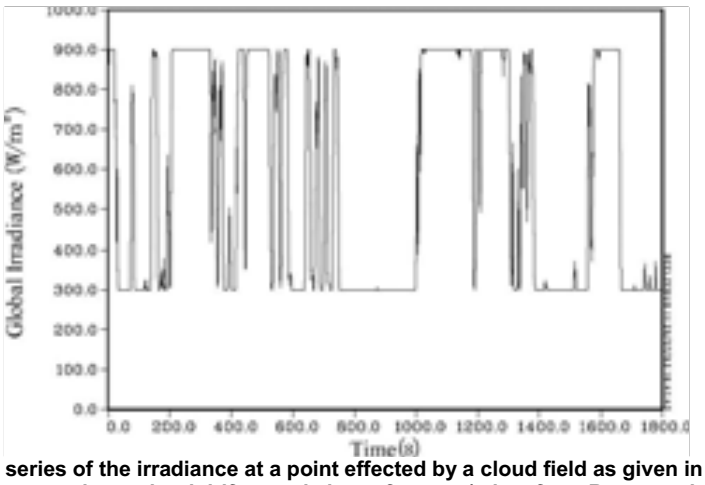

Figure 7: Time series of the irradiance at a point effected by a cloud field as given in Fig. 6. , drifted across assuming a cloud drift speed circumference (taken from Beyer et al. 1993).

This approach has been taken up by Cai 2014. An irradiance field modulated by a fractal cloud field generated similar to the abovementioned approach is shifted over a housing area area with high PV penetration of aprox 2*2 km^2 extension. Fig.8 gives an example for the cloud band and the resulting shadow pattern generated here. Fig.8 gives an example for the for the system reaction concerning the PV effected power at the substation and the voltage reaction of the grid.

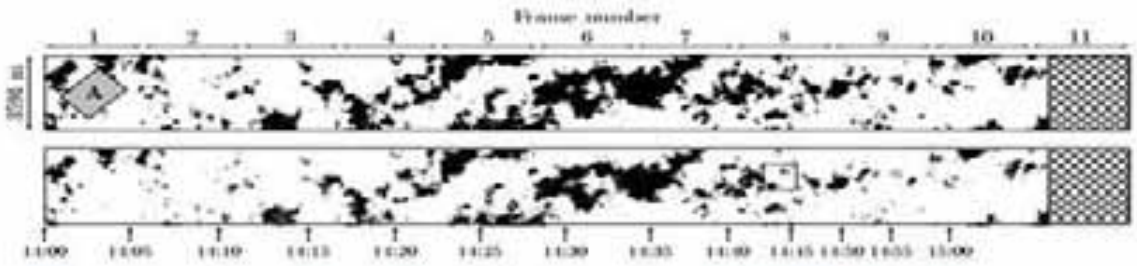

Fig. 8: A cloud band and resulting shadow pattern a given by Cai 2014. The time marks at the bottom are linked to the cloud drift speed assumed. The study area is marked by A (taken from Cai 2014).

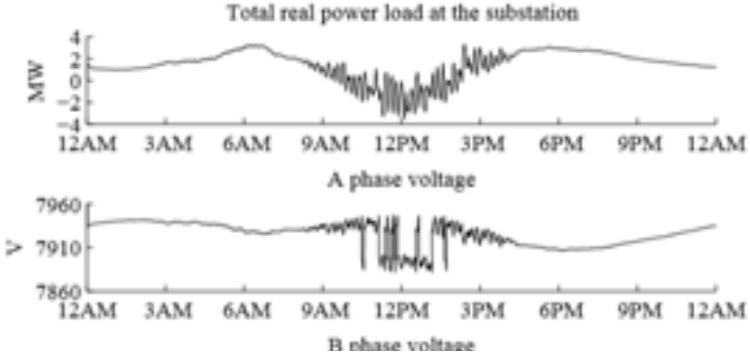

Fig. 9: Grid reaction to the passing cloud field. The upper graph the time pattern of the load of the substation effected by the PV generation, the lower graph gives the respective voltage response (the sharp transitions are caused by actions of transformer tap changes (taken from Cai 2014).

2.2 Other Methods for cloud field generation stemming

Another scheme for the generation of 2D cloud fields is based on information on cloud fraction, cloud and gap cords applying of cellular automata is suggested by Alexandow et al.2010. These automata give a procedure to populate a prescribed mesh with clouds according to the selected distribution properties and can be applied on various spatial scales. This procedure can be performed in steps of consecutive resolutions. Fig. 10 shows the result of such process.

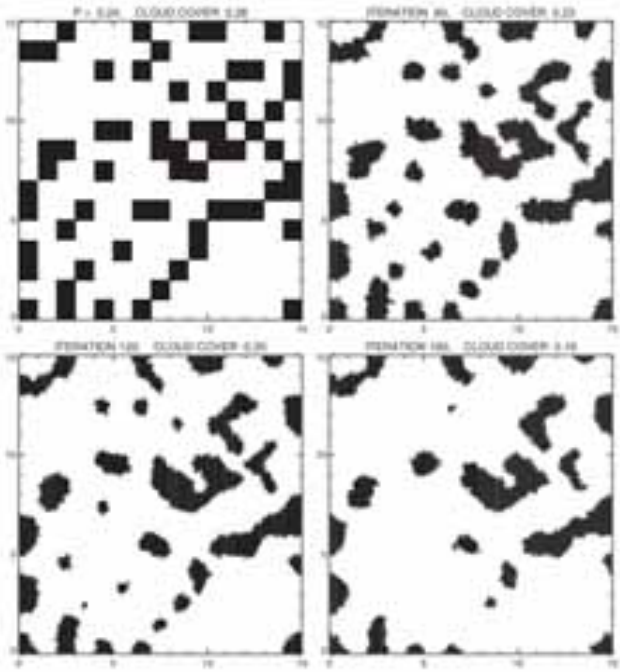

Fig. 10: The generation of a cloud field by a cellular automata scheme as given by Alexandrov et al. 2010. The resolution of the field increase with iteration (from top left to top right to bottom left to bottom right) (taken from Alexandrov et al. 2010

2.3 Methods for the synthetization of 3D cloud fields based on detailed distribution of cloud constituents

Based on detailed information of the structure of cloud fields, as e.g. liquid and ice water content derived from radar observations the 3D spatial structure of the respective fields can be extracted and be used for the generation of respective synthetic fields. Kew 2003 has set up a scheme for the generation of cirrus cloud fields. The model is based on 3D presentation of the spatial power spectral densities of the parameters inspected. The spectra form the basis of an inverse Fourier transform, which by randomly selected phases results in a stochastic filed. Fig. 10 shows an example for a 3D field of the ice water content covering 200km*200km with a resolution of 1km. This field generated according to desired large scale properties can form the basis for detatailed radiative transfer calculations giving a pattern of the irradiance at ground level.

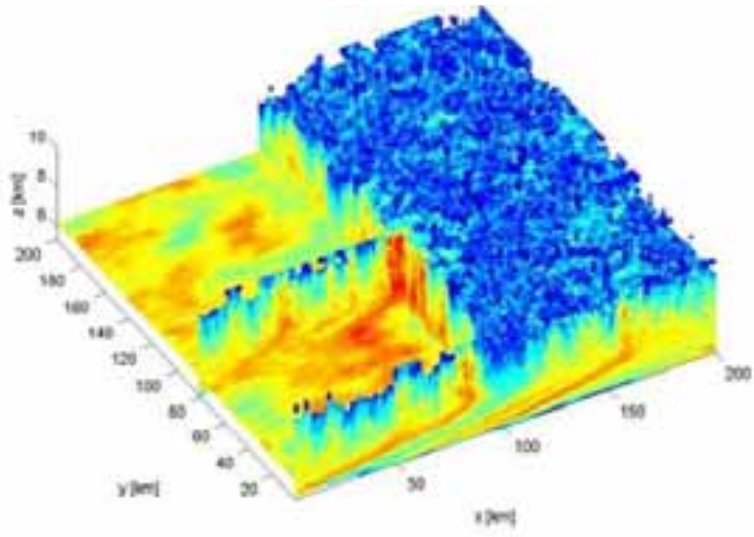

Fig. 10: Presentation of a synthetic 3D field of the ice water content (IWC). For demonstration a section is cut away (taken from Kew 2003).

2,4 A general procedure for the generation of cloud fields with arbitrary optimization goals

A more general scheme for construction of 3D clouds, that can handle various goal values for the statistical properties of the field is given by Venema 2005. It uses evolutionary algorithms to iteratively modified an initial field until is statistical properties approach the goal characteristics (e.g. power spectra). In fig.11 two examples for the outcome of this procedure are given, concerning a 2D field of cloud water content generated based on 1D measured power spectrum. The panel on the right shows the evolution of a cloud, constructed based on selected measured statistical cloud properties.

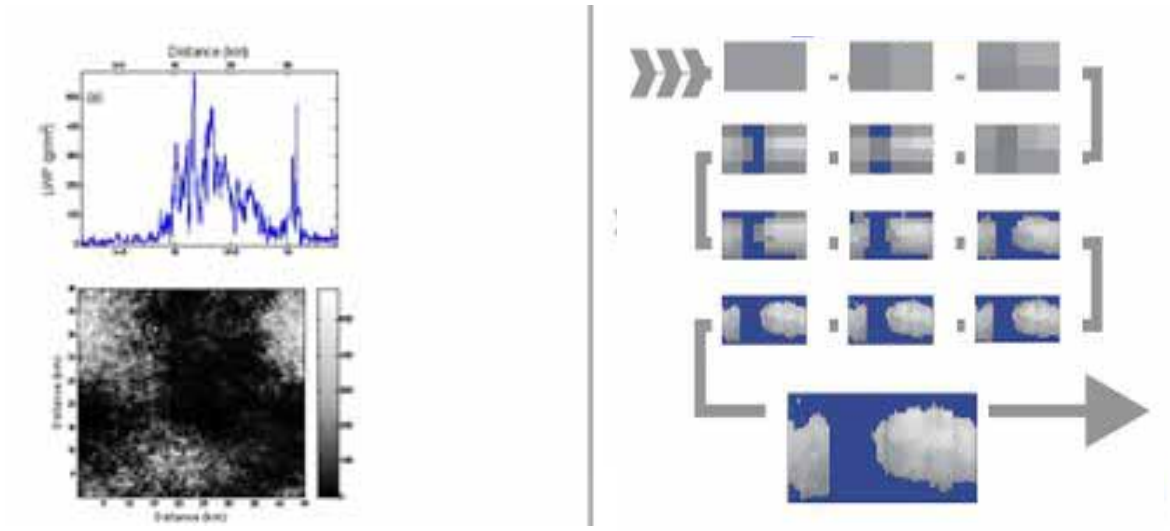

Fig. 11: Outcomes of a procedure of Venema 2005 to modify initial fields iteratively to present prescribed statistical characteristics. In the left panel a 2D field of cloud water content generated on the basis of a 1D spectrum is given. The right panel presents the evolution of a 3 D cloud structure by consecutive refining (starting upper lef) aimed to present selected measured statistical properties (taken from Venema 2005).

3 Conclusion

Over the years a variety of procedures had been developed to generate synthetic high-resolution (e.g. showing minutely resolution) irradiance time series that can be merged in sets with lower resolution (e.g. the seies derived from satellite information). For the generation of respective 2D fields, additional information on the spatial statistics have to be added. For this task most work is done be approaching the spatial structure of the irradiance field via the analysis of the spatial structure of the cloud field causing the statistical disturbance of the irradiance field. Various schemes for the generation of 2D cloud fields showing statistical properties close to the cloud characteristics derived from e.g. sky images. For application key parameters of the cloud field e.g. the average cloud cover ration must be extractable from the large scale information. New developments from basic meteorological research more directly tied to the modelling of the cloud physics offer new ways for an extension to the handling of 3D fields and the application of radiative transfer calculations to derive detailed spatial information of the irradiance field and, with information on spatial cloud dynamics (drift), detailed temporal information.

Assessment of the quality of satellite derived irradiance data for Rwanda by comparison with data from a fleet of automated ground stations

Fabien Habyarimana[1], Hans Georg Beyer[2]

[1]Department of Physic, College of Science and Technology, University of Rwanda, BP3900, Kigali, Rwanda

[2]Institute of Engineering. University of Agder, Grimstad (Norway)

Abstract

Satellite data is a worldwide available data source, quality in regions with dense networks (eg. Europe, North America) well known as less data for comparison for central Africa.
Here, analysis of Satellite data source enhanced ground data now offered by Rwanda Environment Management authority (REMA) network.
REMA has installed around 22 Automatic Weather Stations (AWS) in Rwanda (surface area of Rwanda ~26000 km^2). Solar irradiance data are available since end 2013 with a time resolution of 5min. After passing through a quality check, a first analysis of this data base is done by the investigation of the applicability of standard models of both, their probability distribution and autocorrelation characteristics performed for temporal resolutions of 1day, 1h and 15min. As currently time synchronous ground and satellite derived data sets are missing these data are used here for but a first qualitative comparison to the Satellite derived data available
Keywords: Solar *irradiance, Satellite derived data, Automatic Weather station*

1. Introduction

To support planning concerning solar energy application in Rwanda, the quality of local solar resources is on important decisive. The spatial and temporal distribution of solar radiation resources are needed to be analyzed. Due to the limitation of available local measurement data of global solar irradiance in some regions of Rwanda, this problem is sort out by exploitation of the empirical model tools (Museruka and Mutabazi, 2007; Safari and Gasore, 2009) with daily means monthly results, and indirect measurement data sets from meteorological satellites (PVGIS, 2015) which covering 20 years with a temporal resolution of 15min. Currently, radiation data from several web services which offer irradiance information for Africa and Rwanda (PVGIS, 2015; GeoModel, 2013; NASA, 2015). However, each has its own limitation in space-time and accuracy level for the inspected region is no well-known. In this study, satellite derived irradiance from Photovoltaic Geographical Information System (PVGIS) has been used. PVGIS gives the hourly pattern of the average day of the month from the HelioClim-3 database with a temporal resolution of up to every15min and spatial (approx. 5 km) observations. Due to its excellent help and its integration of geographical database of solar radiation model, PVGIS has been exploited as interactive web for estimating the potential for solar energy in Rwanda and offers a long time series with daily monthly means of global horizontal irradiance values that cover the period 1985-2004. As complement, the daily global solar energy with 15-time resolution data supplied by GeoModel solar, Slovakia (GeoModel, 2013) is available from 2007 to 2012 for Kigali location and was also analyzed here. Currently, the new data set of solar irradiance at some particular location in wide variety of real operating environmental condition in Rwanda has been given by Rwanda Environment Management Authority (REMA), the global solar irradiance data with a high temporal resolution of 5min (Meteo Rwanda, 2014) in 17 districts of Rwanda where 22 automatic weather stations has been installed and operated since end of 2013. As the ground data measurement tool, these new automated weather station data has been analyzed for being a new source for technical assessment of solar energy potential in Rwanda and its

doi:10.18086/swc.2015.07.05 Available at http://proceedings.ises.org

quality is been investigated by a qualitative comparison with the existing satellite derived irradiance data model. Due to this problem we have propose to explore the similarity between the available global solar data from AWS and satellite derived irradiance data for Rwanda.

The objective of this paper is thus to give a first comparison of local irradiance provided by automated ground station data (AWS) versus satellite derived irradiance data for Rwanda

2. Solar radiation components at the ground level

The presented analysis of satellite derived data is based upon the global horizontal irradiance estimated at inclination of 15° degrees as tilted angle of inclination, fixed at azimuth 0^0(north) for both PVGIS and GeoModel**.** This global solar irradiance (G) received at ground level is taken as a sum of direct irradiance G_b, diffuse irradiance G_d and ground reflected irradiance G_r.
The ground measured data of global tilted radiation used, has been offered by the automatic weather station installed across the country and they are received from Meteo Rwanda. Due to the incoherent space and time resolution for these 3 sources data (PVGIS, GeoModel and AWS), the conversion for common resolution has been done, especially from 5 minutes (AWS data) to 15 minutes (Satellite derived data). In this study, the correlation for both set data (ground measurement and satellite derived data) was statistically tested by mean percentage error (MPE %), mean bias error (MBE) and root mean bias error (RMSE) as it is defined by Indira et al. (2012).

3. Data acquisition of global solar radiation in Rwanda

3.1 Satellite information

Global solar irradiance can be derived from weather satellites measurements. There are many sources of the global solar irradiance for Africa and including Rwanda such as NASA, NREL/SWERA, PVGIS/HelioClim and Solar GIS for free or by payment (PV magazine, 2014). The data sources here apply different versions of the Heliosat method (Hammer et al., 2003; PVGIS, 2015; GeoModel, 2013).

Figure 1 illustrates a map for annual irradiance sum over Rwanda, as given by PVGIS. This map refers to the average for the years 1994 to 2010.

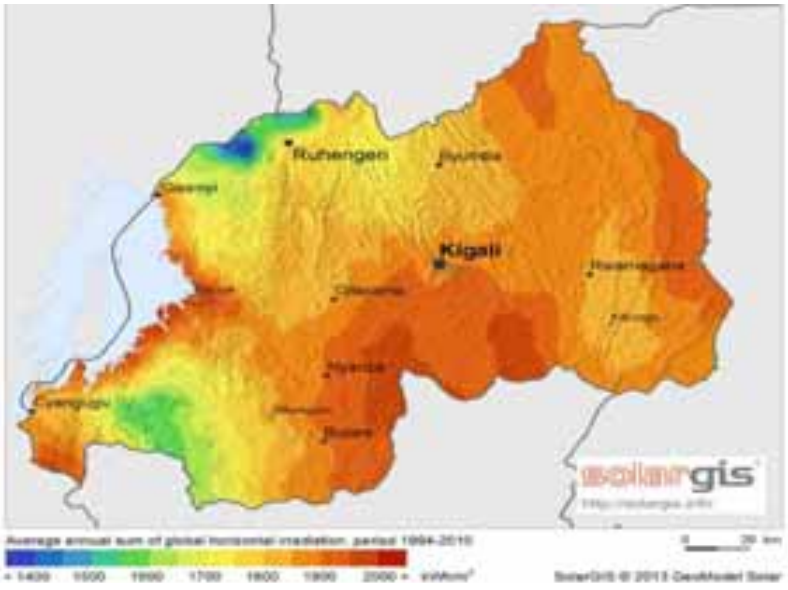

Fig.1: Average annual sum of global horizontal irradiation in Rwanda (GeoModel, 2013).

3.2 Surface observation

In 2013, Rwanda Environment Management Authority (REMA) has installed 22 automatic weather stations with 7 Automatic Weather Station for Hydro-meteorological (AWS-H) Observation located close to water bodies and 15 Automatic Weather Station (AWS-S) for synoptic observation installed on land (Meteo Rwanda, 2014). As an advantage, some of them are web-based and can be accessed online through Meteo Rwanda`s

authorization. Nowadays, in Rwanda, meteorological data are manually and automatically collected from weather countywide. The figure 2 represents some positioning of automatic weather station in Rwanda.

Fig. 2: Automatic weather station (AWS) in Rwanda (Meteo Rwanda, 2014).

The AWS offers local weather data (global solar irradiance) with 5 minutes of temporal resolution. These parameters are often needed for prediction of performance of solar system application. Additionally, each station for AWS is equipped the weather sensors, for monitoring data that can be used in assessment of current climate. The some AWS data bases are already containing the information monitored data from October 2013 until today, but some data are missing or incomplete for some AWS.

4. Checking the similarity of satellite derived datan and automated ground station data

4.1 Comparison of annual and monthly means

At country wide scale, due to the small extension of the country, here should be distinctive latitudinal gradient of global solar radiation on the territorial surface of Rwanda as represented on figure 1 from PVGIS. But as at local scale, terrain is the major factor characterizing the spatial distribution of global solar radiation. The trend of spatial distribution of solar irradiation is characterized by its continuous positive gradient from West to East region and from North to South region of Rwanda which is corresponding to the negative gradient of relief in Rwanda. The annual average of global solar radiation has been estimated for some locations from PVGIS and AWS; the results are represented on the figure 3.

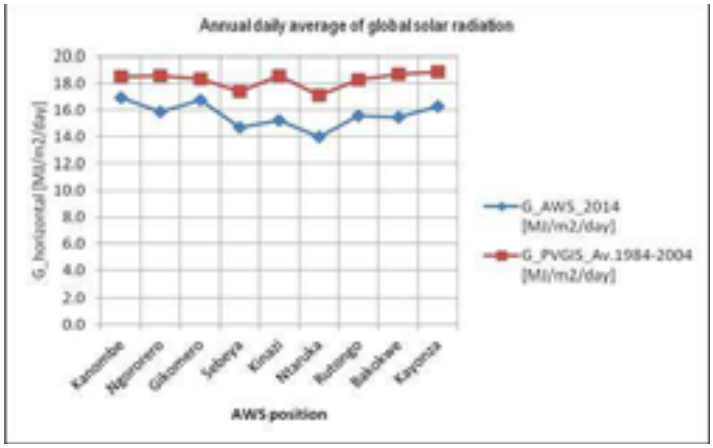

Fig.3: Annual daily average of global solar radiation from PVGIS (several years) and AWS (2014)

The annual average of the daily global solar radiation sum shows but small differences from station to station from both sets. It is remarkable that – by showing a similar station to station pattern – the satellite data give higher values throughout. This difference has to be traced back to be either a result from year to year variations or from an overestimation error in the satellite data. Table 1 gives the mean absolute MBE and percentage MPE deviation for various sites.

Table 1: Spatial variation of MPE, MBE and RMSE for data derived satellite (average 1984-2004) and automated ground station data 2014

Location	MBE[MJ/m2/day]	MPE[%]	RMSE [MJ/m2/day]
Kanombe	1.7	-10.2	2.8
Ngororero	2.6	-17.2	3.7
Gikomero	1.6	-9.9	2.7
Sebeya	2.7	-19.1	3.2
Kinazi	3.4	-23.8	4.4
Ntaruka	3.2	-23.8	3.9
Rutongo	2.7	-18.1	3.6
Bakokwe	3.2	-21.3	3.8
Kayonza	2.6	-15.9	3.2
Average	2.6	-17.7	3.5

Looking at the month-to month deviations of ground and satellite derived data (table 2, fig.4) it can be remarked, that the deviations are mostly pronounced in the May to August period. This may give an indication for a problem in the satellite derived data due to faulty assumptions on the monthly atmospheric turbidity.

Table 2: Monthly values of MPE, MBE and RMSE for satellite derived (multi year average) and automated ground station data (single year)

Month	MBE [MJ/m2/day]	MPE [%]	RMSE [MJ/m2/Day]
Jan	0.7	-4.9	0.3
Feb	3.0	-21.0	2.7
Mar	2.1	-14.4	1.7
Apr	2.6	-17.0	2.2
May	3.4	-23.7	3.4
Jun	5.3	-36.5	8.1
Jul	5.3	-32.4	8.1
Aug	5.9	-40.8	10.0
Sep	3.4	-22.0	3.4
Oct	0.0	-0.5	0.3
Nov	1.2	-8.4	0.5
Dec	-0.9	5.1	0.6

Looking at the analysis of results of table 2 shows that one only month of December the MPE is 5.1 (greater than 0), means that the data monitored from AWS is greater than data estimated from PVGIS. October presents a good agreement data for both set of data.

Analyzing the other satellite derived set, which allows for looking at year to year variations gives the same qualitative result of a positive Bias of the satellite data, being highest in the Mai to September period. The general overestimation for the satellite derived data again indicates a necessary adjustment of the assumptions of atmospheric turbidity used by the models.

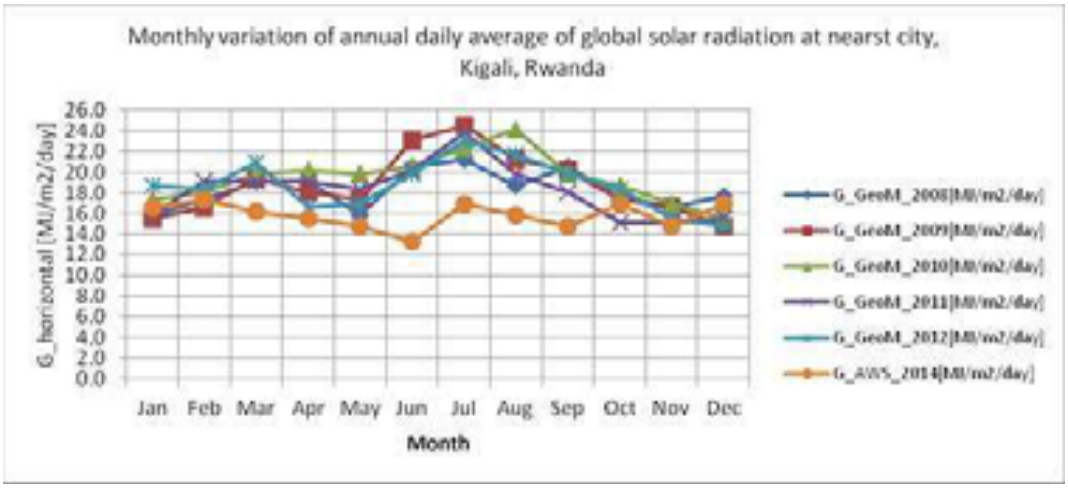

Fig. 4: Comparison of GeoModel and AWS global horizontal irradiance data on a monthly basis.

4.2. Comparison of cumulative distribution functions.

Based on 15 minutes of resolution available in the GeoModel and the ground station sets the similarity of the distribution functions of the 15min irradiances can be analyzed

The annual cumulative distributions for one site - Rutongo - is given in figure 11, shown here in the higher than presentation. The distributions refer to the 2014 ground data set and GeoModel sets for individual days.

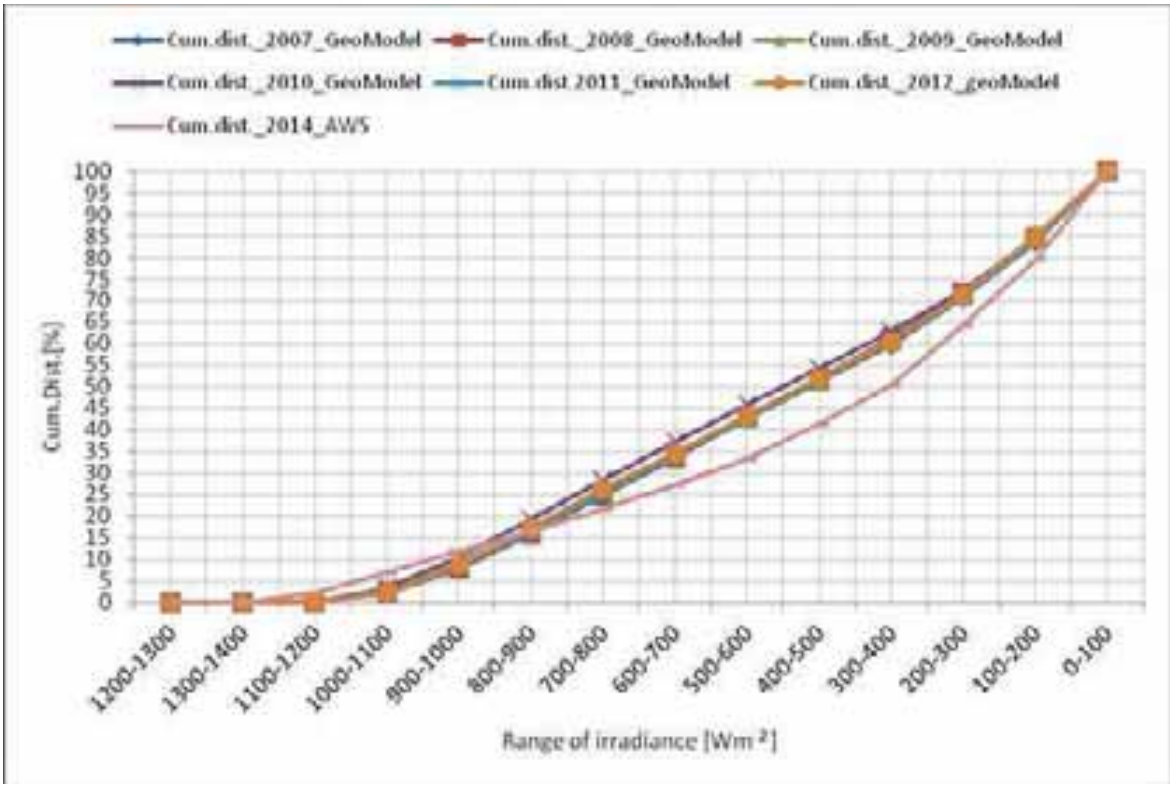

Fig.5: Cumulative distribution of global solar irradiance from multiple years GeoModel and 2014 AWS sets (shown here in the higher-than presentation.

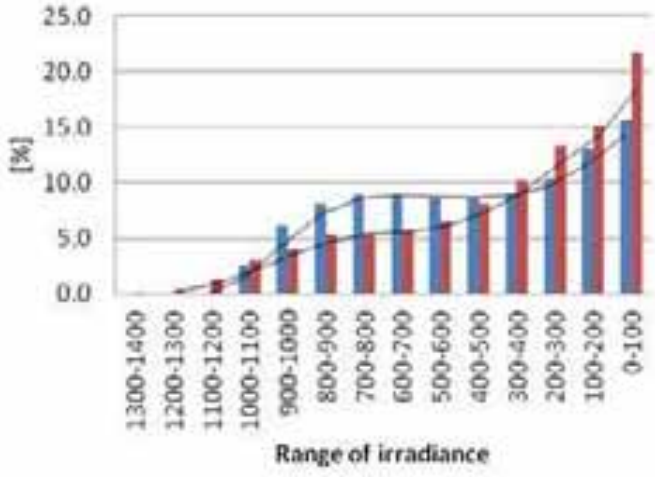

Fig.13: Histrgram of the 15min irradiances fo the 2014 ground data set (red) and the 2008-2014 satellite derived set (blue).

4.1 Conclusions on data similarity

Whereas the data confirm, that the basic spatial and temporal distribution of the ground measured irradiance can be reflected by the satellite derived sets, even from this problematic case of not time parallel data sets it has to be stated, that the quality of the satellite derived data needs improvement. From the error pattern it may be stated, that that a better representation of the atmospheric turbidity can lead to substantial improvements here.

5. Conclusions

In this paper a preliminary analysis of the quality of satellite derived irradiance data by using a set of newly installed ground stations in Rwanda is performed. Within the limitations enforced by the missing of time parallel data sets a need for the improvement of schemes for the derivation could be pointed out. However, this proves the value that should be given to this kind of in-situ measurements of the solar resource.

Optimal Weighting of Parameters for Constructing Typical Meteorological Year Datasets for Photovoltaic Power Stations Operated under Hot Dry Maritime Climates

Arttu Tuomiranta and Hosni Ghedira

Masdar Institute, Research Center for Renewable Energy Mapping and Assessment, Abu Dhabi, United Arab Emirates

Abstract

The objective of this study is to find an optimal set of the weights of different typical meteorological year (TMY) parameters for photovoltaic (PV) power plants operated under hot dry maritime climates. The TMY datasets are generated for a maximum period of six years, for which there are power output data available from a PV power station located in Abu Dhabi, United Arab Emirates and equipped with both polycrystalline silicon and cadmium telluride modules. After determining the typical yield year (TYY) i.e. the months with the plant yields closest to the long-term averages, the parameter weights that result in the closest month combination are found. In total, 19 TMY parameters are considered in the study. The TYY-based TMY parameter weighting approach proposed in this paper reduces the deviations of TMY-based yield estimates from the multiannual monthly averages as compared to the previously proposed TMY weighting sets. The resulting locally determined weight sets place approximately two third of the weight on irradiance variables and one third on parameters that are correlated with plant yield but not with irradiance. On an annual scale, no major benefit is derived from using the proposed TYY-based approach as compared to the previously proposed TMY weighting sets. In accordance with the objective, the weighting sets proposed in this study are expected to suit best the regions characterised by hot dry maritime climates such as the areas around the Persian Gulf and the Red Sea as well as the coastal regions of Egypt and Libya.

Keywords: *typical meteorological year, parameter weighting, photovoltaic power stations, hot dry maritime climate*

1. Introduction

Typical meteorological year (TMY) datasets are widely used to reduce the computation time and storage requirements when determining the optimal designs for photovoltaic (PV) power stations. In principle, the TMY datasets for PV plant projects should be constructed based on all the temporally variable parameters that have an impact on plant performance at the plant site. In addition, the parameters should be individually weighted based on their order of importance. As the relative differences in the importance of the parameters are highly location-specific, also the weights applied would ideally be adjusted based on the location.

Due to their abundant solar resource and proximity to major centres of electricity demand, the areas around the Persian Gulf and the Red Sea as well as the coastal regions of Egypt and Libya possess a large economic potential for PV power generation (Beták et al., 2012). These regions are characterised by a hot dry maritime climate and, therefore, significantly differ from the temperate climate regions that account for most of the world's installed PV capacity. The most important differences are related to operating cell temperatures, atmospheric aerosol loading, and humidity levels. Due to the high ambient air temperature levels typical of hot dry climates, the output power-weighted average operating cell temperature is exceptionally high. The highly variable aerosol loading of desert conditions contributes to the variation in dust deposition as well as the variability of the incident solar spectrum together with atmospheric water vapour. Consequently, the commonly used PV performance modelling methodology may not appropriately address the regional conditions. This is the case with the TMY construction methods as well.

doi:10.18086/swc.2015.07.06 Available at http://proceedings.ises.org

In order to adjust the weights of different TMY parameters to suit the hot dry maritime climate type, the present study aims to determine an optimal set of weights based on five to six years of data on the power output of a 10 MWp PV power station located in Abu Dhabi, United Arab Emirates and equipped with polycrystalline silicon (pc-Si) wafer-based and cadmium telluride (CdTe) thin-film modules mounted at a fixed, roughly polar-aligned tilt. In addition, the weights previously proposed by Marion and Urban (1995), Stoffel et al. (2010), Kalogirou (2003), and Cebecauer and Šúri (2015) are evaluated with the same data. Abu Dhabi has a typical hot dry maritime climate, therefore, supporting the generalisation of the results to other regions characterised by the same climate type.

2. Methodology

2.1 Plant Yield Data Processing

A TMY dataset constructed for a PV power station should be designed to represent conditions under which the yield of the station is equal to the long-term average yield. Normally, TMY datasets are constructed based on the time series of those individual months whose statistics are in the best accordance with the long-term monthly statistics. That is why in this study, the first step is to find the individual months, during which the considered PV power station generated the yield closest to the long-term monthly average yield.

The power station's central inverters have measured output power since May 2009. The inverter-specific measurements are summed up for power blocks equipped with each module type resulting in two time series. At the beginning of a PV plant's operating life, down-time periods are frequent because the plant's operation and maintenance (O&M) plan is still under development and defective components are being detected and replaced. Hence, the plant output data recorded during this initial phase are not considered in the analysis. The included data cover a six-year period from October 2009 until September 2015 for the pc-Si module time series and a five-year period from October 2010 until September 2015 for the CdTe module time series.

The raw output data are corrected for outage losses in order not to bias the long-term average calculation. The outage losses have been quantified by the plant's operator and given in the annual plant performance reports. As TMY construction is only dependent on the ambient conditions at the plant's site, not on the plant's age, the data are also corrected for time-dependent degradation. In accordance with Jordan et al.'s (2012) findings, the time-dependent degradation rates are assumed to be one per cent per year for both sections of the plant. Finally, the long-term monthly average yields are calculated based on the five (CdTe) or six (pc-Si) monthly values corresponding to each year of the available power output data. The set of the individual months, during which the considered PV power station generated the yield closest to the long-term monthly average yield, can be considered as the typical yield year (TYY).

2.2 Ambient Data Processing

The dataset of ambient parameters is generated for the same period and scale as the TYY dataset. The considered ambient parameters are measured in the close vicinity of the power station and comprise global horizontal irradiance (GHI), beam normal irradiance (BNI), diffuse horizontal irradiance (DHI), ambient air i.e. dry-bulb temperature (T), wind speed (WS), wind direction (WD), and relative humidity (RH). The original data consist of average values over intervals of five and ten minutes. Dew point temperature (T_{dp}) values are estimated based on T and RH measurements using the August-Roche-Magnus approximation (Alduchov and Eskridge, 1996). The final dataset of ambient parameters consists of time series of 19 monthly statistics specified in Tab. 1.

Tab. 1: Monthly statistics used in TMY dataset construction.

Statistic	GHI	BNI	DHI	T	WS	WD	RH	T_{dp}
average	✓	✓	✓	✓	✓	✓	✓	✓
maximum				✓	✓		✓	✓
minimum				✓	✓		✓	✓
range				✓	✓		✓	

According to the best practice, a TMY dataset should be based on 15 years or more of source data (Cebecauer and Šúri, 2015). In this case however, the objective is not to generate a dataset that is a good representative of long-term climatic conditions but rather a test bed for different parameter weights. In order to assess how well different weight combinations predict the actual plant performance, the time frame of the TMY dataset needs to be the same as that of the plant output data.

2.3 Evaluation of Parameter Weight Sets

The method proposed by Cebecauer and Šúri (2015) is used to construct TMY datasets in the present study. Drawing on the past work on TMY dataset construction, Cebecauer and Šúri base their method on the concatenation of continuous multivariate time series spanning those individual months that are found to provide the best agreement with long-term monthly statistics. The different TMY parameter weight sets proposed by other authors or developed here are integrated in Cebecauer and Šúri's methodology. The previously proposed weight sets under consideration are presented in Tab. 2.

Tab. 2: Previously proposed TMY parameter weight sets under consideration.

Variable	Statistic	TMY2	TMY3	Kalogirou	SGIS-PV	SGIS-CSP
GHI	**average**	12/24	5/20	8/32	0.75	0.23
BNI	**average**		5/20	8/32		0.7
DHI	**average**				0.2	0.03
T	**average**	2/24	2/20	2/32	0.05	0.04
	maximum	1/24	1/20	1/32		
	minimum	1/24	1/20	1/32		
	range			1/32		
WS	**average**	2/24	1/20	2/32		
	maximum	2/24	1/20	1/32		
	minimum			1/32		
	range			1/32		
WD	**average**			1/32		
RH	**average**			2/32		
	maximum			1/32		
	minimum			1/32		
	range			1/32		
T_{dp}	**average**	2/24	2/20			
	maximum	1/24	1/20			
	minimum	1/24	1/20			
	CDF	0.2	0.2	0.2	0.2	0.2

TMY2 (Marion and Urban, 1995), TMY3 (Stoffel et al., 2010), Kalogirou (2003), SGIS-PV (Cebecauer and Šúri, 2015), SGIS-CSP (Cebecauer and Šúri, 2015)

In order to determine the TMY months, Cebecauer and Šúri (2015) deploy two approaches used in parallel: comparison of single monthly statistics with their long-term counterparts and comparison of monthly empirical cumulative distribution functions (CDF) with their long-term counterparts. In this study, the most appropriate weights also for these two TMY determination approaches (11 possible combinations with

intervals of 0.1) are found based on the plant output data. When evaluating the previously proposed parameter weight sets however, the same TMY determination approach weights as used by Cebecauer and Šúri are adopted: 0.8 for single monthly statistics and 0.2 for monthly empirical CDFs.

3. Results and Discussion

The importance of correct weighting of TMY variables increases with the inter-annual variability of monthly plant yield levels. Fig. 1 presents this variability considering outage-corrected yield. It reaches its maximum in December with ranges of 17 and 21 per cent of the 5-year means with the pc-Si and CdTe modules, respectively. In the case of both module types, the months from May to October are characterised by a lower variability than the months from November to April. The variability of annual yield levels, in turn, is within a range of four per cent with the plant's pc-Si section and six per cent with the CdTe section.

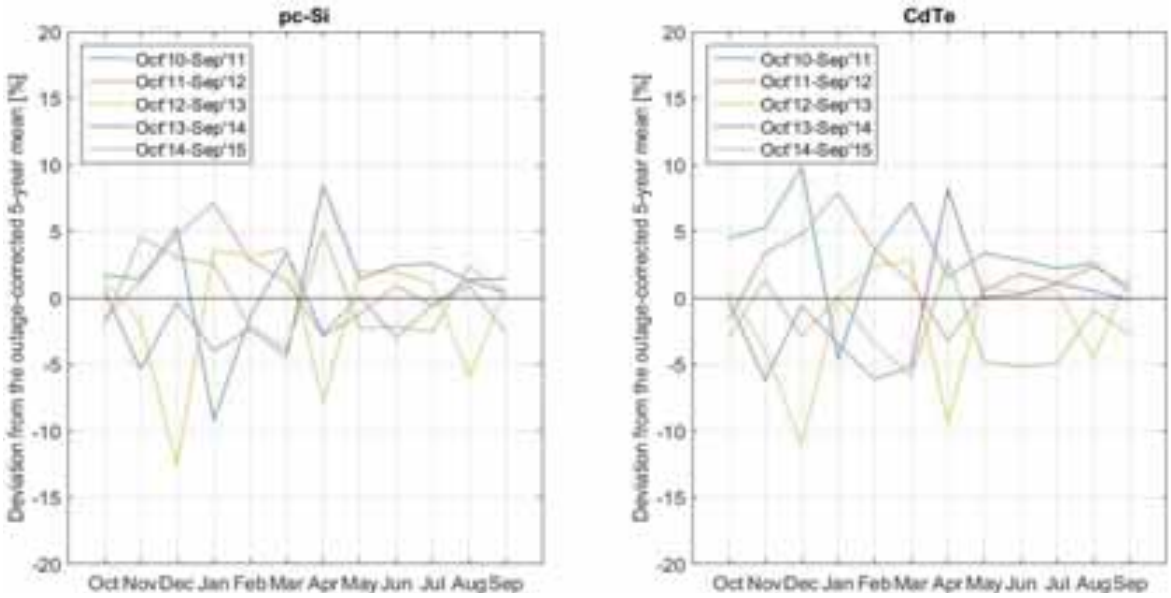

Fig. 1: Inter-annual variability of the outage-corrected monthly yields of the plant under consideration.

When determining the TYY months, outage-corrected plant yield data are further corrected for the assumed time-dependent degradation. The TYY months are found to be sensitive to the assumed rate of time-dependent degradation and therefore, a locally conducted degradation analysis is required to further improve the accuracy of the TYY month selection.

Fig. 2 compares the corrected TYY yields with the monthly mean yields. As can be seen from the figure, the monthly TYY yields are within a range from -2 to 2 per cent of the monthly means in all months apart from April and December in the case of the pc-Si modules and November in the case of CdTe modules. In both cases, the use of the TYY months results in the overestimation of the annual yield compared to the multiannual mean: by 0.9 per cent with the pc-Si modules and by 0.2 per cent with the CdTe modules.

The TMY dataset construction methods proposed by Marion and Urban (1995), Stoffel et al. (2010), and Kalogirou (2003) have not been designed for any specific solar energy technology. They consider a wide variety of different meteorological parameters and give half of the weight to irradiance variables. The two methods proposed by Cebecauer and Šúri (2015) for modelling the performance of PV and solar thermal power stations involve only three or four weighted TMY variables and place a 95 or 96 per cent weight on irradiance parameters, respectively.

After iterating through tens of thousands of different weighting sets for both sections of the power station, the sets resulting in TMY months with the greatest overlap with TYY are selected for further comparison. The respective weighting sets are presented in Tab. 3. With both module types, the combined weight of irradiance variables is 64 per cent. The remaining 36 per cent is placed on *T*'s monthly range in the case of the plant's pc-Si power blocks and on monthly average WS and minimum RH in the case of the CdTe

blocks. It is not clear why the use of these meteorological statistics resulted in the best agreement between the TMY and TYY months. The monthly average *T* was initially expected to exist in the optimal weighting sets together with irradiance parameters due to the significant impact of *T* on solar cell temperature. One reason for the somewhat surprising outcome may be the strong positive correlation between *T* and irradiance variables and the consequent positive correlation between *T* and plant yield. *T* range and average WS are also positively correlated with plant yield but exhibit low correlation with irradiance parameters. Thus, they may better capture the actual negative impact of *T* on plant yield. The TMY determination approach through CDFs is emphasised over individual statistics with a weight of 0.7 in both cases.

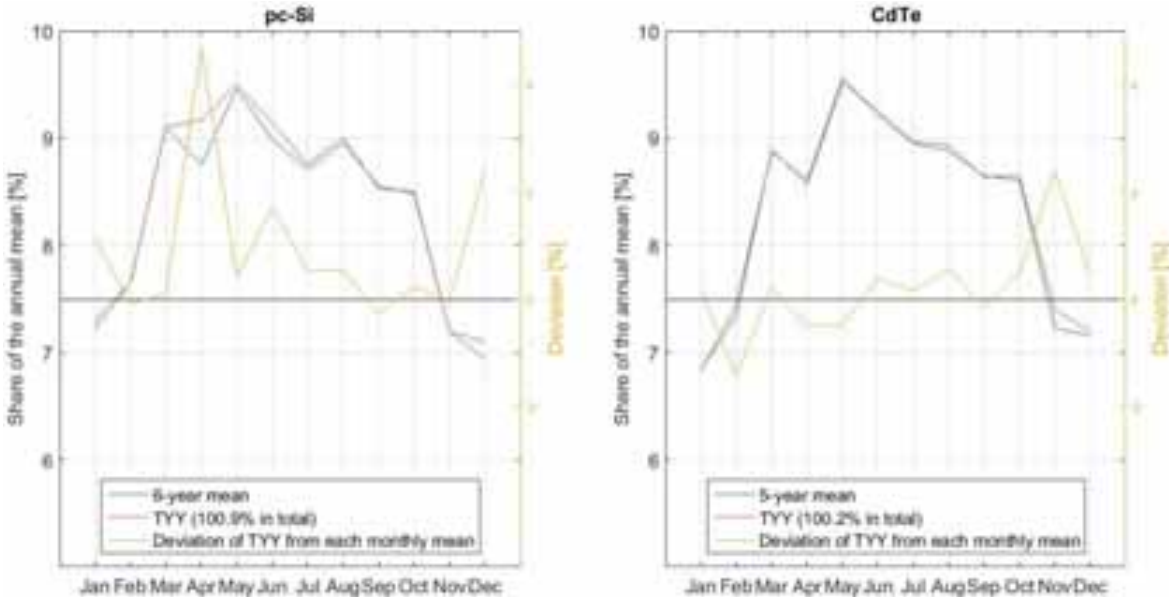

Fig. 2: Deviation of outage and time-dependent degradation-corrected TYY yields from monthly means.

Tab. 3: Weighting sets resulting in TMY months with the greatest overlap with TYY for both module types

Module type	GHI average	BNI average	DHI average	*T* range	WS average	RH minimum	CDF
pc-Si	0.11	0.23	0.30	0.36			0.7
CdTe	0.45	0.19			0.35	0.01	0.7

Fig. 3 compares the monthly yields estimated based on the different TMY weighting sets to the multiannual monthly mean yields. As can be seen from the figure, the monthly deviations are reduced in most cases when using the TYY-based weighting set (AD) as compared to the previously proposed sets. Fig. 4 shows the performance of the different sets in terms of root mean square error (RMSE) and bias. The improvement in RMSE is more significant with the CdTe section due to the better agreement of its TYY months with the multiannual monthly means. In both cases, RMSE is reduced, however. While RMSE measures the monthly average deviation, bias can be considered as the annually aggregated error. As implied by the bias bar graph of Fig. 4, the AD sets do not perform better than the previously proposed sets on an annual scale. In fact, the AD set for the pc-Si section results in the highest bias amongst all the sets. As this is due to the overestimating TYY yields, the bias can be reduced by using longer time series as the basis for TYY determination. The findings presented in Fig. 4 imply, however, that on an annual scale, the choice of the TMY parameter weighting set does not have a major impact on the estimated yield levels if the set is selected amongst the previously proposed sets.

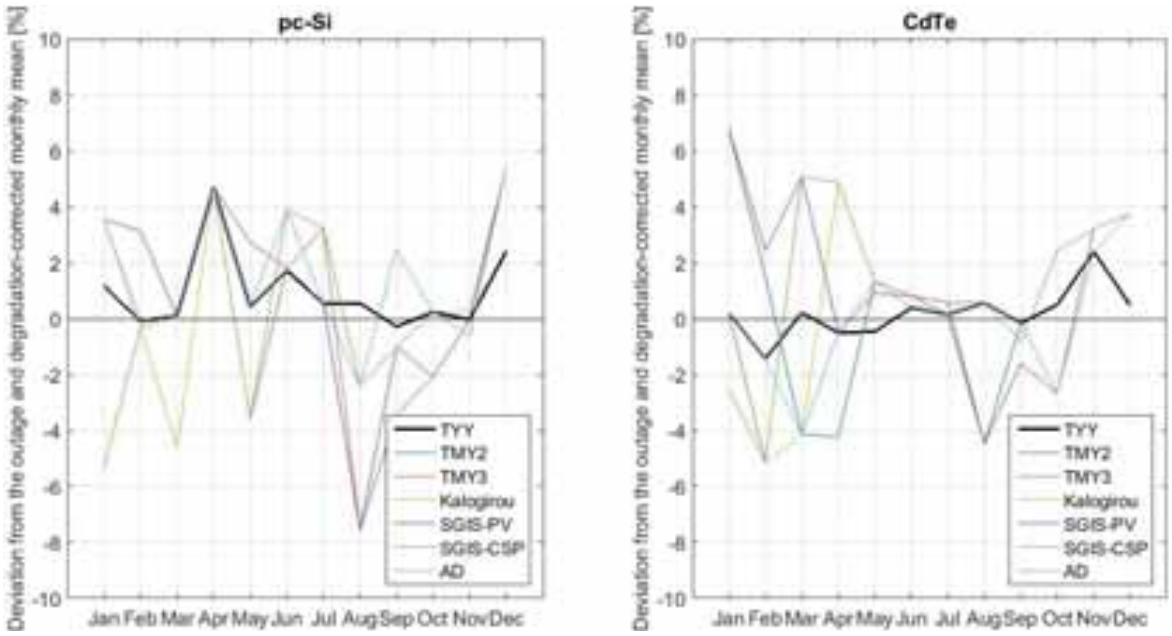

Fig. 3: Deviation of yield estimates based on different TMY variable weighting sets from the multiannual monthly mean yields (AD = weighting set optimised for the power station of interest)

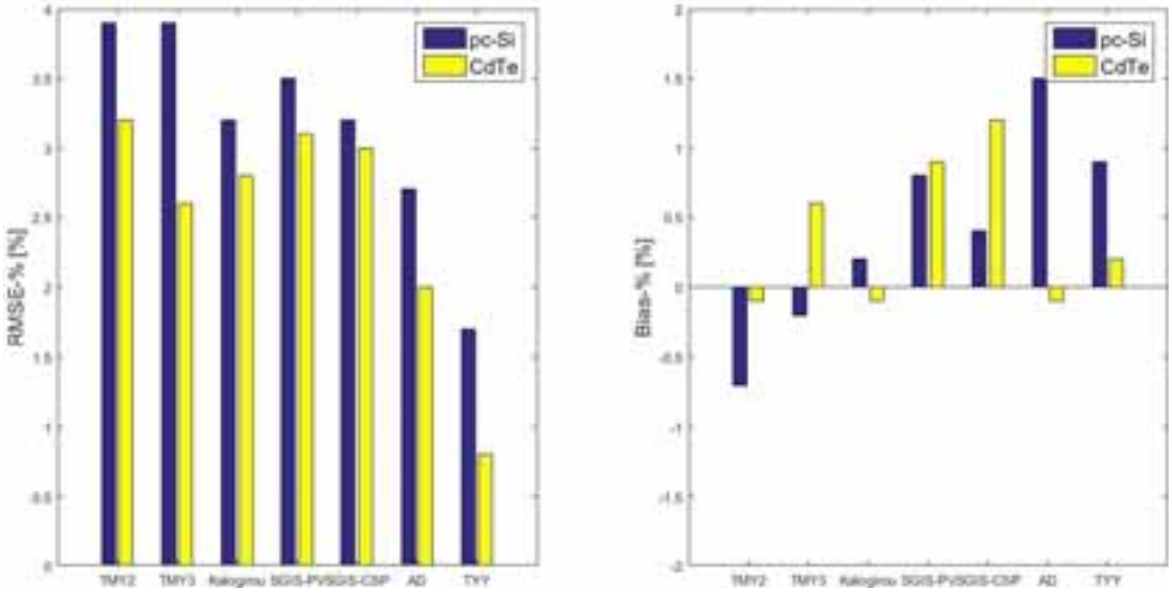

Fig. 4: Performance of different TMY variable weighting sets when compared to the multiannual monthly mean yields

4. Conclusion

In this study, weights of different TMY parameters are adjusted to suit PV plant performance assessment under the hot dry maritime climate type of Abu Dhabi. The results are expected to be generalizable to other regions characterised by the same climate type. The use of an appropriate weight set is the more important, the higher is the inter-annual variability of monthly yield levels. The variability is found to exhibit both seasonal dependence characterised by higher levels during winter months and technological dependence with higher levels for the CdTe module-equipped power blocks. In December, which is the month with the highest inter-annual yield variability, the difference in yield between the best and worst years can be more than 20 per cent of the multiannual mean yield.

The TYY-based TMY parameter weighting approach proposed in this paper reduces the deviations of TMY-based yield estimates from the multiannual monthly means as compared to the previously proposed TMY

weighting sets. The resulting locally determined weight sets place approximately two third of the weight on irradiance variables and one third on parameters that are correlated with plant yield but not with irradiance, *T* range and WS in specific. The performance of the proposed approach is highly dependent on the accuracy of TYY on a yearly scale and therefore, further improvement can be achieved by using longer yield time series and deploying locally identified rates of time-dependent degradation. On an annual scale, no major benefit is derived from using the TYY-based approach as compared to the previously proposed TMY weighting sets.

QATAR DYNAMIC SOLAR ATLAS AND SOLAR RESOURCE ASSESSMENT

Yasir Mohieldeen, Luis Pomares, Daniel Perez-Astudillo, Dunia Bachour, Saiyed Wahadj

Qatar Environment and Energy Research Institute(QEERI), HBKU, Qatar Foundation, Doha, (Qatar).

Abstract:

Solar resource assessment is key preliminary to any successful solar energy production project. This study presents the solar resource assessment and mapping efforts that are currently being carried out at the Qatar Environment and Energy Research Institute (QEERI) in Qatar, to create a dynamic solar atlas for Qatar, showing solar irradiation, across the country, every 15 minutes. These data are essential for the successful harnessing and utilization of solar energy.

Rigorous analysis of solar irradiation components measured through ground monitoring stations combined with data derived from satellite imagery has made it possible to generate the dynamic atlas. The developed maps will help identify areas and locations with high solar energy generation potentials. Direct Normal Irradiance (DNI), Diffused Horizontal Irradiation (DHI) and Global Horizontal Irradiation (GHI) will be calculated from the satellite images and calibrated and validated with their corresponding ground measured values. The time series of these valuable maps will enable solar energy short-term forecasting and will contribute to the successful operation of solar energy production facilities in the country. The generated datasets will be available through a solar geo-portal on the World Wide Web.

Keywords: Solar atlas, solar irradiation, network optimization, METEOSAT MSG, solar monitoring stations, solar modeling, neural network, Heliosat, and solar forecasting.

1. Introduction:

The primary objective of this paper is to present the solar atlas development programme at Qatar Environment and Energy Research Institute (QEERI), a member of Qatar Foundation. The study will present the framework and the plan to achieve these goals. Achievements so far and the status of the solar atlas as it stands now (at the time of presenting this paper) are also included, along with the next/future steps.

The paper is structured as follows: First, a brief overview is given about Qatar and its electricity demand in the background section. Second, the need for the solar atlas and its importance to Qatar's solar energy plan is highlighted. The framework for the atlas development is described in section 2. Section 3 presents some concluding comments.

1.1 Background

The State of Qatar wants to generate 20% of its electricity requirement from solar power by 2020. This policy aims to meet the increasing electricity demand induced by increasing population and the associated urbanization with its energy-hungry life-style while adopting at the same time environmental-friendly renewable energy. Qatar's population has increased almost five times from 0.37 million to 1.74 million between 1986 and 2010, and six times between 1986 and 2014, as shown in Fig. 1.

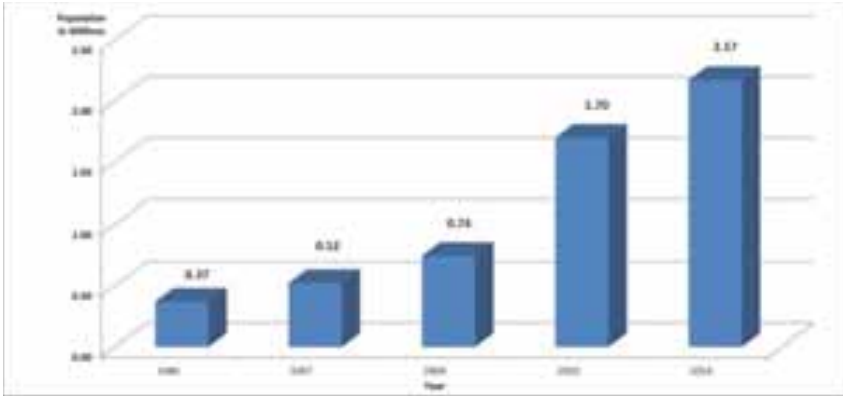

Fig. 1: Population growth in Qatar in millions

Source: (QSA, 2013; PC, 2006; TE, (2014)

The electricity and water company in Qatar KAHRAMAA has reported an increase in the maximum network load from 941 MW in 1988 to 3,990 MW in 2008 and reached 6255 MW in 2012 (KAHRAMAA, 2013). The number of customers increased from 132,429 in 1998 to 293,604 in 2013 (ibid, 2013)

This increase in demand is triggered also by changes in life-style, indicated by electricity per capita consumption figures. The per capita consumption grew from 12.963 KW in 1998 to 17.774 KW in 2007 (ibid, 2013).

To meet this increasing demand for electricity, and as a dry country with no hydro-power resources, Qatar has increased the number of gas-generated electricity plants in the 2000s from 3 to 8 plants. Electricity production over the last few years is shown in Fig. 2.

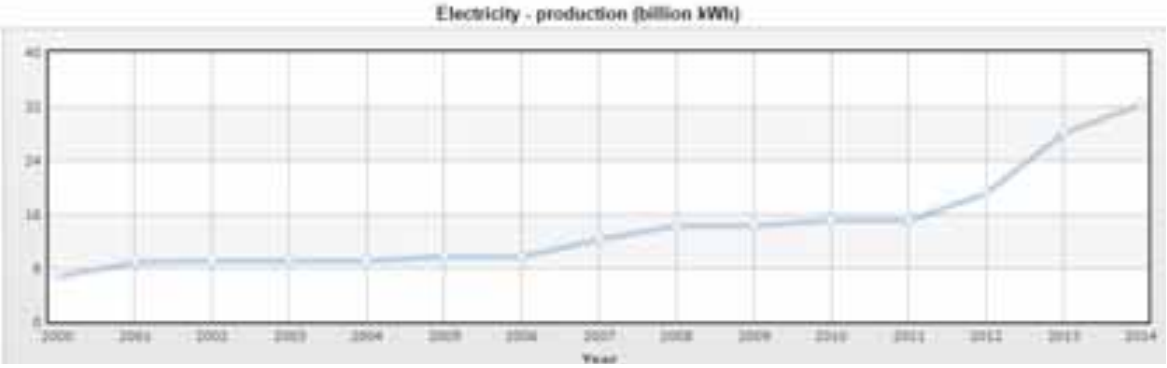

Fig. 2: Electricity Production in Qatar 2000-2014

Source: CIA World Factbook

Qatar is ranked as having the second-highest per capita ecological footprint among 150 countries, down from being the highest in 2012, according to the WWF's Living Planet Report (WWF, 2014). This report is published every two years. With these environmental concerns and the unstable oil prices in mind Qatar has decided to introduce clean renewable energy to produce electricity as opposed to non-renewable environmentally un-friendly natural gas.

Solar energy is arguably the most effective way to meet the increasing energy demand of Qatar and the region, for the following reasons: firstly, solar energy is renewable as opposed to the non-renewable gas and oil which are finite resources. Secondly, solar energy is clean and limits the emissions of Greenhouse Gases. Thirdly, using solar energy lengthens the life of oil and natural gas resources, and reserves them for future generations. .

A preliminary analysis of solar energy potentials carried out using historical data collected by Qatar Meteorological Department (QMD), reveals that there is a high potential of solar energy in Qatar. The ground-measured yearly average Global Horizontal Irradiation (GHI) for Qatar is 2113 kWh/m2/year (Bachour et al, 2013). GHI is suitable for the Photovoltaic (PV) method of converting solar energy into

direct current electricity.

Another analysis carried out by QEERI (Perez-Astudillo *et al*, 2013) using data from a ground solar station installed at QEERI, collecting Direct Normal Irradiance (DNI), Diffused Horizontal Irradiance (DHI) and GHI, confirms the solar energy potentials in Doha.

1.2 Why the Dynamic Solar Atlas

The Solar Atlas and solar mapping is key to successful implementation of any solar energy production program in Qatar. The Atlas helps identify areas and locations with high solar energy generation potentials. It helps in the identification of the optimum locations for solar panels. Qatar is a small country but the spatial variability in solar irradiation is variable because of the existence of micro-climates related to different land-covers and effects of the sea on inland climate. The atlas helps a wide range of professionals to better understand the spatial and temporal distribution of the solar irradiation in the country.

The dynamic atlas provides near-real time solar maps every 15 minutes of solar data including DNI, DHI and GHI. These datasets are accessible online through the World Wide Web. The atlas also provides now-casting and forecasting of solar irradiation data that can be used for solar energy production management.

The maps are produced through rigorous analysis of solar irradiation components measured through ground monitoring stations combined with data derived from satellite imagery. Solar information produced from satellite images are calibrated and validated with their corresponding ground measured values.

2. Method & Framework:

This section describes the plan adopted to develop the dynamic solar atlas. The steps that were undertaken and future plans are also highlighted. These steps could be summarized as: data collection; and modeling of solar irradiation.

2.1 Data collection

The collection of high quality solar irradiation data is a key to the development of the atlas of solar resources of Qatar. It is necessary to install two kinds of equipment: a METEOSAT satellite ground receiving station and a number of solar monitoring stations.

2.1.1 Satellite data:

Data from METEOSAT satellite EUMETSAT program has been used in the study. A METEOSAT Second Generation (MSG) ground receiving station has been procured and installed at the QEERI premises in Doha. The MSG is a geostationary meteorological satellite collects weather information all over the globe. The sensor onboard the satellite, known formally as the Spinning Enhanced Visible and Infrared Imager (SEVIRI), observes the full disk of the Earth with a repeat cycle of 15 minutes. It captures images in 12 spectral wavelength regions or channels. Many parameters related to solar irradiation are recorded by these channels. The Water vapour, Infra-Red (IR), and the visible channels of the satellite are the main channels that are utilized here for modeling and mapping solar irradiation. Atmospheric Motion Vectors (AMV) products are received every hour. AMVs show cloud speed and direction and are used for atmospheric and solar irradiation forecasting. Fig. 3 below shows the satellite ground receiving station installed at the QEERI premises.

(a) (b)

Fig. 3: The METEOSAT MSG ground receiving station installed at QEERI in Doha. (a) The 2 meter antenna on the roof-top at QEERI's premises. (b) The receiving and processing servers of the MSG data in the GIS lab.

The raw data captured by the antenna (Fig. 3a) are processed and modeled/converted to solar irradiation values by combining them with ground measurements recorded at the ground Solar Monitoring Stations (SMS). These ground measurements and SMS are discussed in the following section.

2.1.2 Ground measurements:

High quality ground solar irradiation components measurements in selected locations are needed to model, verify and calibrate the satellite data to produce accurate estimates of solar radiation for the whole country. To determine the locations and the number of stations needed in Qatar, existing solar data collected by the Qatar Meteorological Department (QMD) was obtained and analyzed. The QMD network consists of 12 stations, designed to measure meteorological data. Global Horizontal Irradiation is the only solar component that is measured by QMD network.

A collaboration agreement with QMD has enabled QEERI to use QMD's network to install solar equipment on selected stations.

To determine which stations in the QMD network to use for solar installation, a network optimization study was carried out on the network. The network optimization study also determines potential gaps in the network for solar measurements.

2.1.2.1 Solar Monitoring Stations (SMS) Network optimization:

Different techniques and methods have been developed by scientists and meteorologists to address the optimum site selection task (Singh et al, 2013; Mohajeri, 2010; Pardo-Igúzquiza, 1998).

The network was optimized first, by determining the maximum distance from a station that maintains acceptable relative variation in magnitude of solar irradiation. Second, by determining potential gaps in the network and cover them by new stations.

To determine the maximum distance with acceptable variability, the GHI data from the QMD network was analyzed. The QMD network of 12 stations is shown in Fig. 4 below.

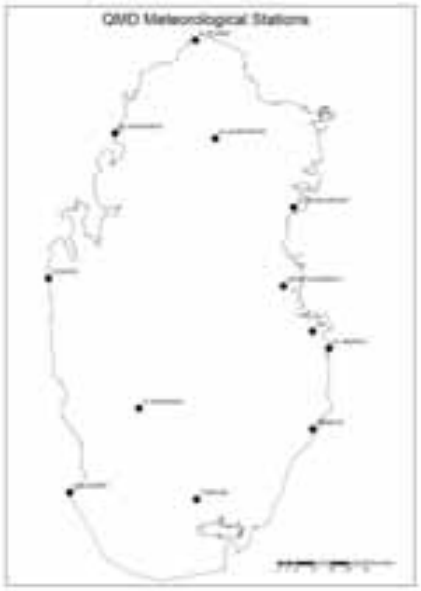

Fig. 4: Locations of the 12 solar monitoring stations operated by QMD.

GHI values were analyzed relative to the distances between the station sites. Daily and monthly GHI averages from QMD's stations were analyzed, along with corresponding GHI values derived from satellite images by Masdar Institute of Science and Technology (MIST)- the United Arab Emirates (MIST, 2015). Fig. 5 shows the relative variations, as a function of distance, of daily (red line) and monthly (blue) averages of GHI as measured at ground level by the 12 QMD stations. The (green) line is for monthly averages from satellite. The distances in the Figure are grouped in bins of 10 km, centered at 5, 15, 25 km intervals up to 160 km. For example the point at a distance of 65 km represents all pairs of stations with separation between 60 and 70 km. The relative variations of GHI are the averages for all pairs in each distance bin.

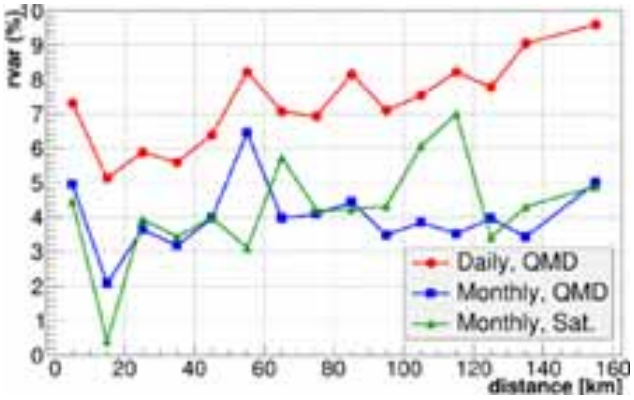

Fig. 5: Relative variations of GHI values as a function of distance between stations

Data Source: QMD, 2015

Fig. 5 shows that the selected stations less than 30km apart experienced 6% relative variation in their daily GHI measurements. Counter intuitively, a higher relative variation (7%) is found at the lesser distance of 5km, and this is attributed to stations being located in and around Doha City where various micro-climates are induced by variation in aerosol loads across the city. The authors consider 6% variation in daily GHI values of adjacent stations to be an acceptable variation.

In addition to the analysis of interstation solar radiation variability using QMD data, satellite imageries were also analyzed for network optimization. A 2010 average GHI image produced by Masdar Institute of Science and Technology derived from satellite data is analyzed using Moran's I index spatial statistics method.

The Moran's I index compares the differences between neighboring pixels and the mean to provide a measure of local homogeneity. The value range is between +1 and -1, where:

+1 = strong positive spatial autocorrelation, 0 = spatially uncorrelated, -1 = strong negative autocorrelation.

Results of the Moran's I index analysis are shown in Fig. 6.

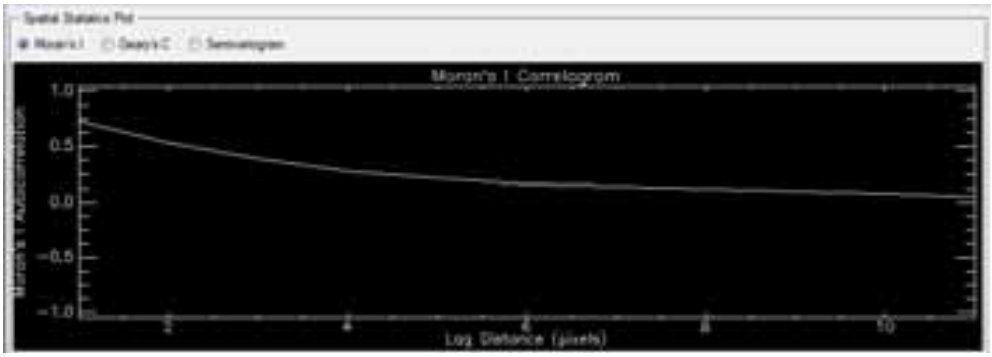

Fig. 6: Moran's I analysis on 2010 GHI pixel values.

Results of Moran's I analysis shows that the spatial correlation of the 2010 GHI values was strong within neighboring pixels. The index value did not start from the value of 1 as one would expect since neighboring pixel values should have exhibited high autocorrelation. This discrepancy was due to micro-climate and satellite model errors. The spatial autocorrelation decreases as the distance between the measurements increases, and is nearly lost (that is close to 0 Moran's index) when it reaches 8 pixels apart. Since the pixel size is 3 km, this distance is equivalent to 24 km. The analysis further confirms the results obtained from QMD data analysis. Generally, 30 km distance between ground stations is considered as appropriate for good spatial coverage (Perez et al., 1997).

The results above imply that GHI measurements taken at one location could be considered as representative of up to 25-30 km away from that location. That is to say, a solar station measurement could be considered representative of the local irradiation status within a 25km radius from that station. For the sake of accuracy and achieving an adequate research quality data a 20km radius is used here. Fig. 7 below shows a 20km radius buffer that is covered by individual station in the QMD network of SMS. The red circles represent gaps that need to be covered.

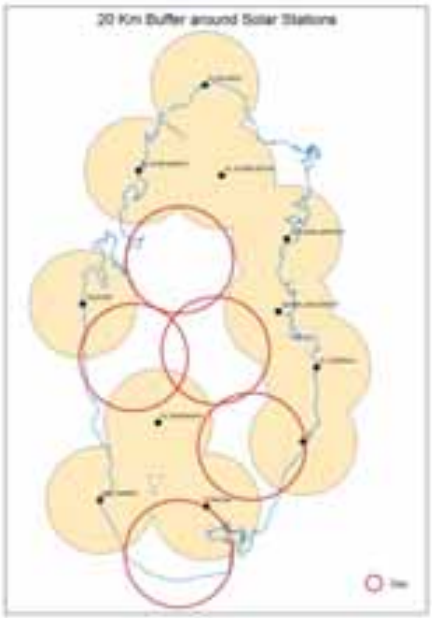

Fig. 7: Map of the coverage achieved with buffer zones of 20 km radius around QMD stations. The red circles show the locations of additional stations needed to cover the gaps.

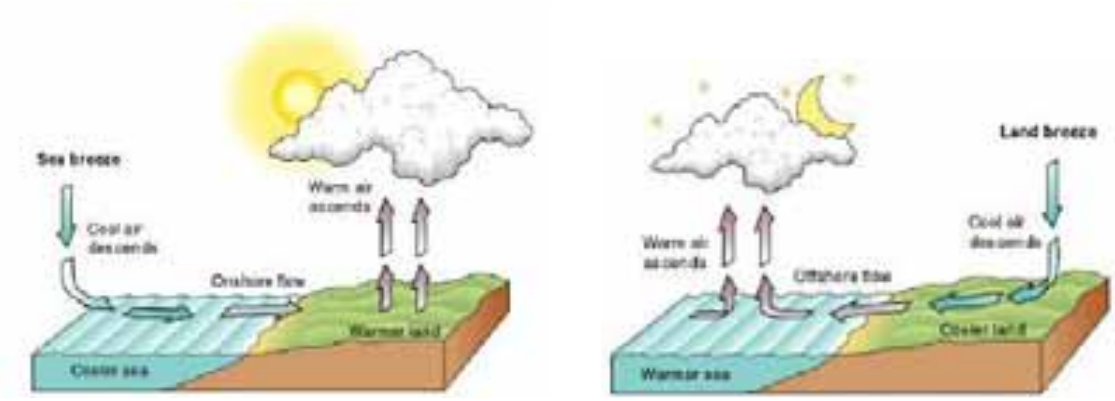
Site visits were conducted to all existing and proposed stations for sites verification. Fig. 8 below shows a photo of one QMD stations during a site visit.

Fig. 8: Location of one of the QMD stations, south west of Doha.

2.1.2.2 Land see-breeze effect:

In order to ensure representative sampling of the solar irradiation, many factors that influence the spatial distribution of solar irradiation have to be taken into account in the site selection for stations. As Qatar is a peninsula, it was necessary to study the influence of the sea on Qatar solar resources. The two main sea phenomena that might have influence on solar radiation and are considered here are land-sea breeze phenomenon, and the mixed land-sea satellite pixel.

The influence of land-sea breeze on aerosols concentration and transportation in the atmosphere along coastal areas has been investigated by numerous studies (Tsai et al, 2011; Kolev et al, 1998). The land-sea breeze (Fig. 9) arises because of differential temperature between land and water surfaces. During the day winds develop over water near land due to differences in air pressure created by their different heat capacities, as solar radiation heats the land more quickly than the water, causing sea breeze (Fig. 9a). At night, water's high heat capacity prevents rapid loss in water temperature and therefore remains warmer than land causing the winds to reverse direction (from land to sea, causing land breeze (Fig. 9b).



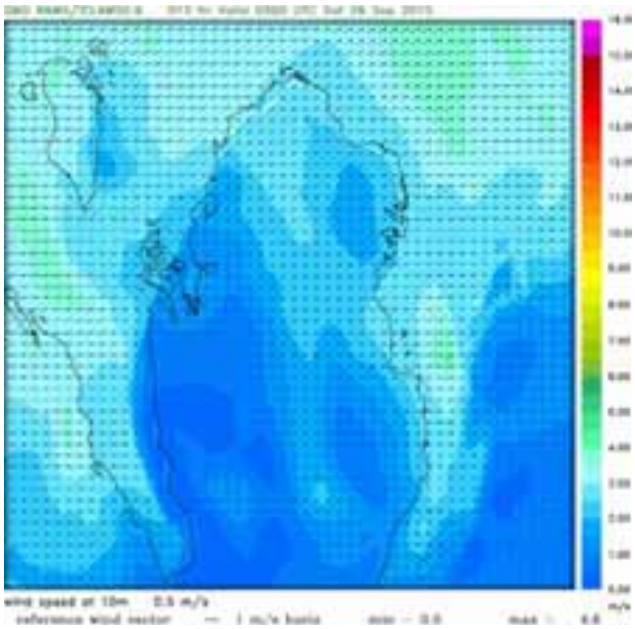
(a) Sea breeze **(b) Land breeze**

Fig. 9: Land-sea breeze phenomena.

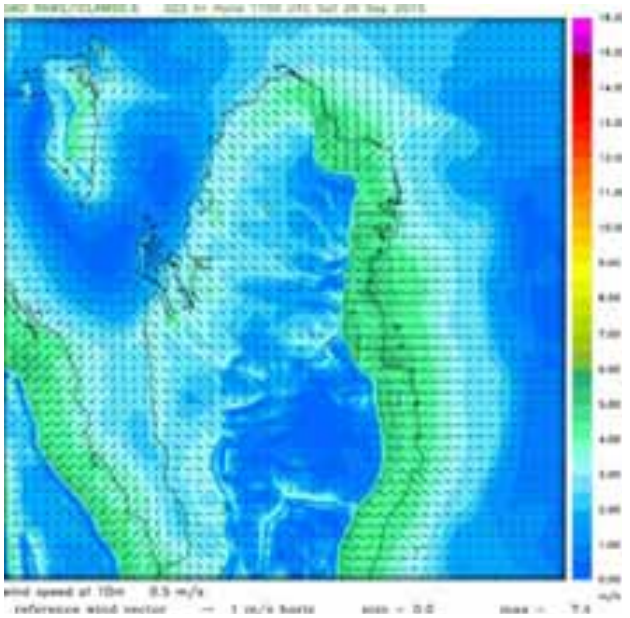
These studies of land-sea breeze have shown that these phenomena lead to high concentration of aerosols in coastal areas and result in aerosol circulation (between land and water) along the coastal line This high concentration is due to the accumulation and the forward and backward movements of the aerosols between land and water, leading to aerosol entrapment around the coast. All pollution sent from land to the sea at night and early morning, returns back to the coast during the day. The high aerosol concentration leads to high diffusion of solar irradiation.

As for Qatar, the land-sea phenomena could be observed by the RAMS/ICLAMS model applied by the QMD for wind monitoring as shown in Fig. 10, on the 26th Sept 2015. Land breeze is shown in Fig. 10a (at 03:00

AM UTC time) early in the morning when the sea is warmer than the land, whereas see breeze is shown in Fig. 10b (at 11:00 AM UTC time) when the land started to heat up a clear reverse of wind direction took place from the Arabian Gulf into the eastern coast of Qatar.



(a) Land breeze



(b) Sea breeze

Fig. 10: A normal day Land-Sea Breeze sequence in Qatar, 26th Sep 2015.

Source: QMD, 2015

It should be noted that nine out of twelve of QMD stations are coastal stations, and located in areas most affected by the land-sea breeze phenomena and hence by aerosols. This means that the existing sampling structure/regime is biased and is not necessarily optimum for solar mapping.

To optimize the sampling of the solar monitoring stations network, more inland stations have been introduced by shifting some coastal stations to inland sites (Al Rwais, Qatar University, Doha Airport & Umsaid); and by introducing/proposing new inland station sites (Ghasham Farm, Jumailiah, Um Wishah, Suda-nithail, Camel Racing court). The final optimized SMS network is shown in Fig. 11 below.

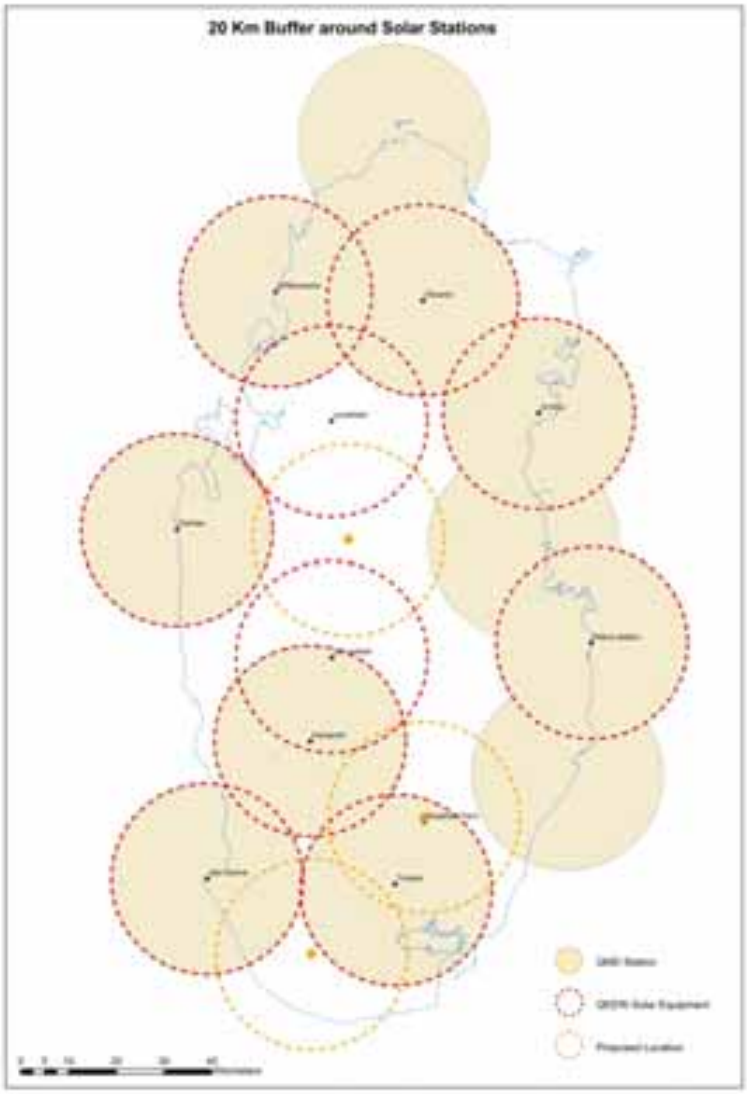


Fig. 11: Optimized Solar Monitoring Stations Network, with existing and proposed stations indicated.

Another reason for minimizing the number of coastal stations is to reduce the impact of the satellite "mixed-pixel" issue in the analysis when combining ground measurements with METEOSAT satellite images in the modeling. As the pixel size of these images is 3km, coastal station measurements might be analyzed with a pixel that partially covers land and water (mixed), and that could introduce in-accuracies to the model.

Based on the above optimized network, thirteen solar monitoring stations have been procured and are in the process of being installed in their respective sites. The next section discusses the processing of the data captured by the METEOSAT receiving station (Section 2.1.1) and the optimized SMS network (Section 2.1.2).

2.2. Data processing and solar modeling

This section describes how the satellite data collected by satellite ground receiving station and the ground measurements collected by the 13 monitoring stations are combined to create the atlas.

The SEVIRI satellite data are converted to solar irradiation estimates. Two methods are adopted to compare results. The first is to use existing empirical/physical models, in this case Heliosat model, and use local ground measurements data to adjust the model to Qatar climatic conditions.

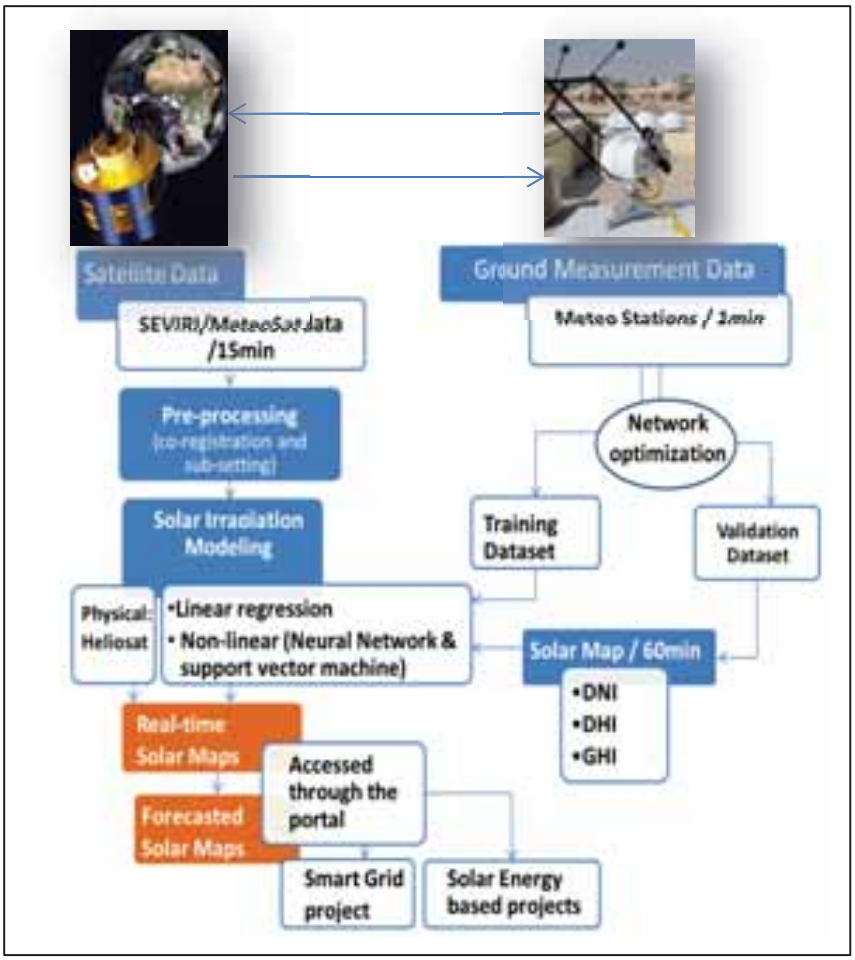

Fig. 12: The dynamic solar atlas framework

The main principle of the Heliosat method is the construction of a Cloud Index (CI) by comparing what is observed in the pixel by the sensor to what should be observed over that pixel if the sky were clear, which is related to the "clearness" of the atmosphere (Rigollier *et al*, 2002).

The CI is derived from the Meteosat 15 minutes satellite images. The CI is then used to calculate the atmospheric Clearness Index (Kc) values. First the Clear Sky solar radiation component is derived using Linke Turbidity values obtained from MACC II. Then the Kc is combined with CS solar radiation to produce all-sky solar radiation estimates from the satellite. The schematic diagram of this physical model is shown in Fig. 13 below.

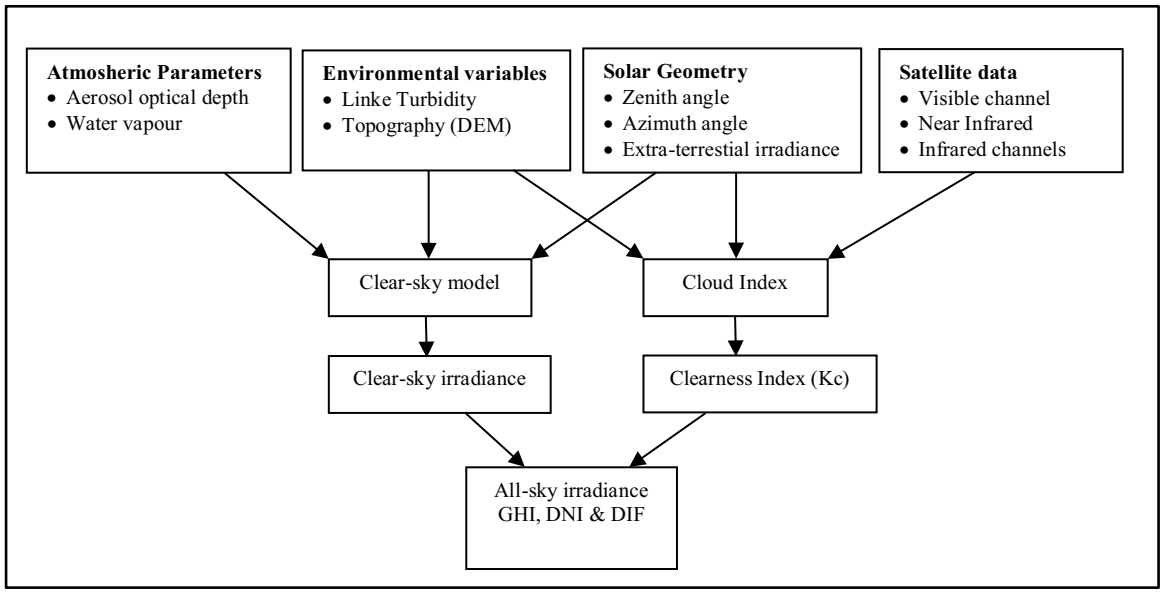

Fig. 13: Schematic diagram of the adopted Heliosat semi-physical all-sky solar radiation model

The satellite data used in the model and derived inputs to the model is listed in Table 1 below:

Model Input	Data source	Coverage period	Time step	Spatial Resolution
Cloud Index	Meteosat MSG Visible, NIR & IR channels	2005 to present	15 minutes	5 km
Atmospheric Optical Depth (AOD)	MACC II	2003 to present	Daily	125 km
Linke Turbidity	MACC II	2003 to present	Daily	125 km
Clearness Index	ESRA model	2005 to present	15 minutes	5 km
Water vapour	MACC II	2003 to present	Daily	125 km
Topography (DEM)	SRTM	Present	-	1km

Table 1: Input data to the satellite model

Ground measurements of daily GHI from nine QMD stations, with available measurements between2003-2013, were used to validate the satellite model results. The validation results and the uncertainty parameters of these daily GHI estimates are shown in Table 2 below. The mean relative RMSD for the stations was 11.5%. A relatively high coefficient of determination R^2 of 0.92 was depicted.

Station	MBD (Wh/m^2 day)	RMSD (Wh/m^2 day)	KSI	rMBD (%)	rRMSD (%)	KSI (%)	R^2
Dukhan	449.43	776.12	431.62	7.97	13.77	123.36	0.92
Turayna	63.96	601.34	17.88	1.09	10.21	5.11	0.92

AlShehaimiya	10.60	481.65	68.84	0.18	7.96	19.68	0.96
Ummsaid	235.28	708.94	336.36	4.12	12.41	96.13	0.91
Qatar University	204.33	595.18	269.30	3.50	10.20	76.97	0.94
AlKhor	95.75	697.08	195.80	1.62	11.80	55.96	0.91
AlKaranaah	238.81	690.89	283.94	4.06	11.75	81.15	0.91
AbuSamra	169.88	745.44	155.11	2.91	12.78	44.33	0.88
AlWakrah	126.68	727.61	132.80	2.17	12.48	37.96	0.89
Mean	**177.19**	**669.36**	**210.18**	**3.07**	**11.48**	**60.07**	**0.92**

Table 2: Validation results and the uncertainty parameters for the satellite-derived daily GHI

The resulted annual average GHI map for Qatar for the period 2003 to 2013, from the model, is shown in Fig. 14 below.

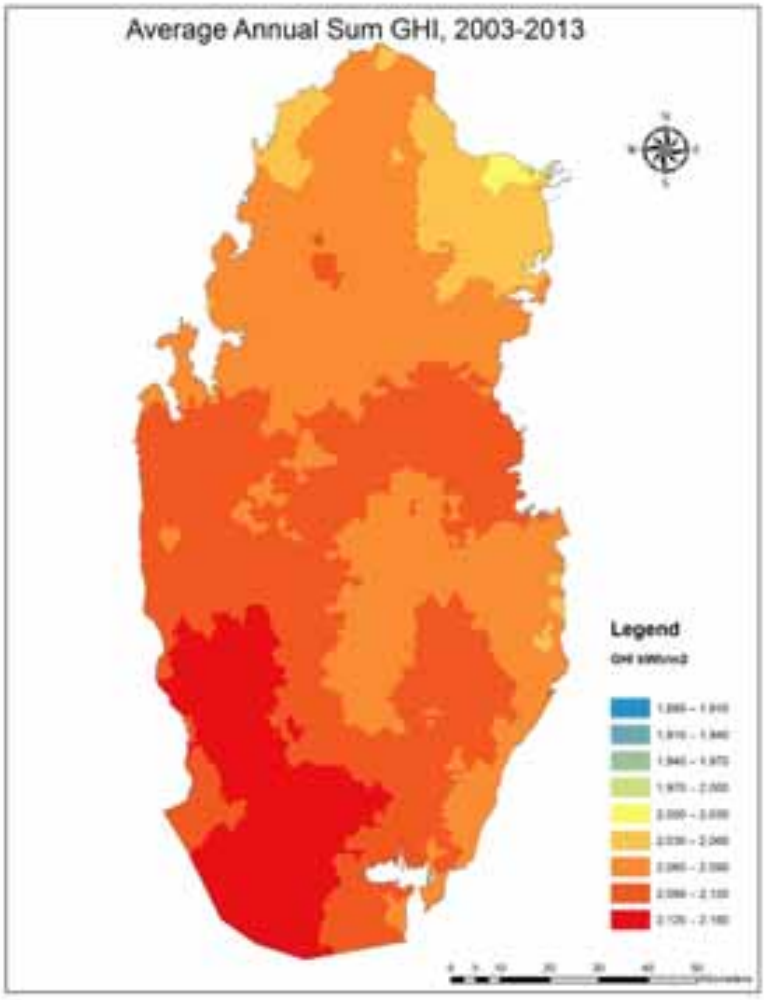

Fig. 14: Average Annual Sum GHI (kWh/m^2) for Qatar, 2003-2013

The second modeling method, that will be implemented, is a statistical model, regression analysis (linear,

and non-linear such as neural network). In this method the satellite data will be regressed with the ground measurement from the 13 monitoring stations to derive accurate estimates of solar irradiation from the satellite imageries. The data processing methods are shown in Fig. 12 above.

Output from the models and the data processing and analysis are near-real time (every 15 minutes) solar maps show the spatial distribution of the solar irradiation parameters in the country. These results are used for solar forecasting and now-casting of irradiation, as shown in Fig. 12 above. Statistical models and weather prediction models will be used for forecasting. The generated datasets would be used for instance for smart grid management and any other solar-energy based projects. These datasets are stored and organized in a data-portal and disseminated online through the World Wide Web. The data-portal is highlighted in the next section.

2.3 Results dissemination and data-portal:

The solar datasets produced by the modeling are organized by a data-portal. The portal is a database and an application that enable the dissemination and querying of geospatial data. The data-portal application is built on ESRI ArcGis Server, Java scripting, and python programing. A snapshot of the on-line Qatar solar atlas is shown in Fig. 13. Point, line and polygons geometries could be used to query the solar maps and to extract statistics and values from them.

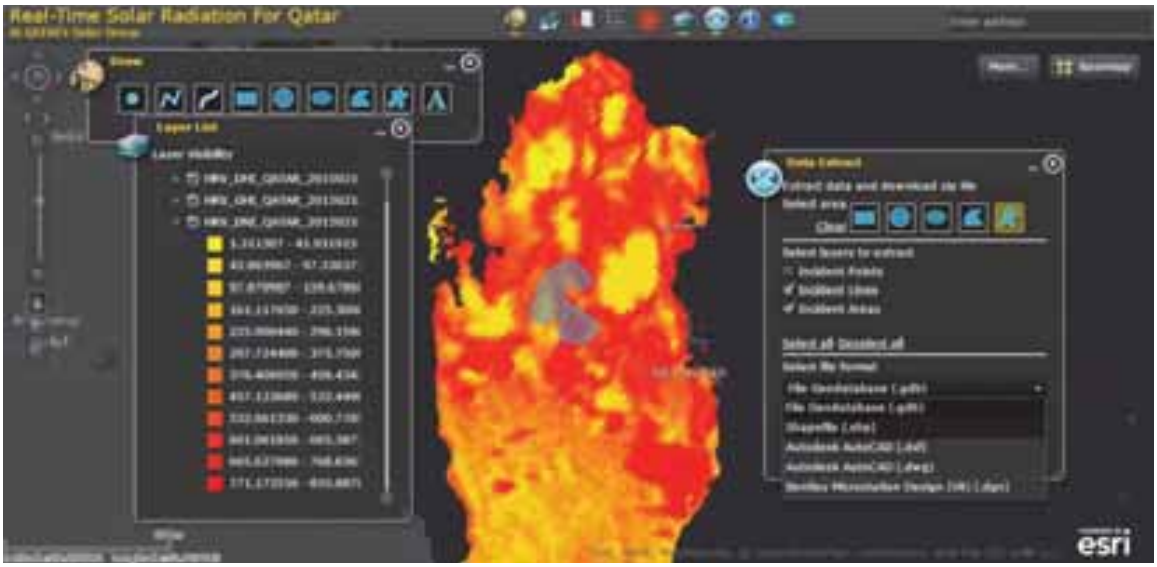

Fig. 13: A snapshot of the solar atlas geo-portal

3. Conclusion

The State of Qatar aims to generate 20% of its electricity requirement from solar power by 2020. This is to meet the increasing electricity demand caused by increasing population and to reduce the high ecological footprint resulted from dependency on oil and gas in generating electricity. Mapping the solar resources in Qatar and creating a solar atlas is key preliminary to the successful implementation of any solar energy project in the country.

This paper presented the solar resource assessment and mapping efforts that are currently being carried out at the Qatar Environment and Energy Research Institute (QEERI) in Qatar. A solar atlas for Qatar will be generated which will show solar irradiation, across the country, every 15 minutes. These data are essential for the effective harnessing and utilization of solar energy in the country.

Data collected by METEOSAT MSG satellite and by ground measurements have been combined and analyzed. The network of the ground measurement stations has been optimized in order to capture high quality data. The optimization was carried out based on rigorous analysis of daily GHI data collected by 12

QMD meteorological stations. The sea-breeze effect on solar energy, and the land-water mixed pixel issue were also taken into account in the optimization, by shifting some coastal stations to inland sites. The resulted average annual sum GHI map, derived from the Heliosat model, shows high potentials of solar energy generation using PV technologies. The time series of the 15 minutes GHI maps will also enable solar energy short-term forecasting and will contribute to the successful operation of solar energy production facilities in the country. The generated datasets will be made available and accessible through a solar geo-portal on the World Wide Web.

Abstract

A locally-adapted model to predict irradiance in the United Arab Emirates (UAE) has been developed. It is based on the McClear model and the HelioClim database, and it utilizes aerosol optical depth measurements from AERONET network, and high-precision measurements of irradiance collected at Madinat Zayed, UAE. The clear-sky part of the model consists of McClear model operated with ground-corrected Aerosol Optical Depth (AOD) as inputs. The all-sky part is made of HelioClim-3, recalculated with the AOD-corrected McClear as inputs, and then calibrated using irradiance measurements at one station. The locally-adapted model accurately estimates the global and direct irradiances. The estimated irradiances have been validated against measurements collected from 7 Rotating Shadowband Irradiometers distributed over the UAE. The obtained root mean square errors on the hourly means of irradiance are 4% for Global Horizontal Irradiance (GHI), 10% for Direct Normal Irradiance (DNI) in cloudless skies and 8% for GHI, 26% for DNI in cloudy skies.

Keywords: *solar resource, irradiance, aerosol optical depth, UAE*

1. Introduction

In many regions, the available solar resource data do not meet the requirements for solar plant simulation and feasibility studies. On the one hand, the satellite-based models that are used for long-term irradiance estimation are often not adapted to the potential sites of interest. Additionally, the measurements collected in ground-based stations are often not well processed and/or produced by not well maintained and calibrated stations. This is especially true for the regions where limited efforts have been made so far on the solar resource estimation, like in the Middle East. The research program Predisol aims to develop a locally-adapted tool to predict downwelling irradiances in desert environments in order to support present and future solar investments in the Middle East where the interest in solar power is rapidly increasing. The United Arab Emirates (UAE) have set a target to cover 7% of its electricity demand from renewable energy sources by 2020. As part of this effort, a 100 MW CSP plant, Shams-1, one of the largest plants of the World is operating in the middle of the UAE desert.

This paper presents the result of a joint effort between two research institutes and two private companies to improve the estimate of the solar resource in the Middle East region. State-of-the-art satellite-based models and irradiance measurement techniques have been used to improve the assessment of solar resource potential in the region. The high performance of McClear model (Lefèvre et al. 2014) in estimating the clear-sky

doi:10.18086/swc.2015.07.08 Available at http://proceedings.ises.org

irradiance in the UAE has already been demonstrated by Eissa et al. (2015). In this work, this performance has been enhanced thanks to a local adaptation with measurements of aerosol optical depth (AOD). The locally-adapted McClear is combined with the HelioClim-3 irradiance database (Blanc et al. 2011). The resulting model was then calibrated with high-precision measurements of irradiance collected from a ground station (AD1) located close to the Shams Power plant at Madinat Zayed, UAE.

2. Method

2.1. Background

- McClear model

McClear (Lefèvre et al. 2013) is a fully physical model that exploits the atmospheric properties provided by the EU-funded MACC (Monitoring Atmospheric Composition and Climate) project to estimate the surface downwelling solar irradiances in cloud-free conditions. McClear is based on the radiative transfer libRadtran (Mayer and Kylling, 2005) and uses a Look-Up-Table approach to enable routine calculations in real-time. The clearness indices –ratio between irradiance at the ground and irradiance at the top of the atmosphere– obtained by running libRadtran are stored in the abaci. The values that contain the abaci are called node points. Interpolation functions are used to interpolate between these node points. An optimization was made for the selection of the node points and interpolation functions in order to (1) minimize the number of node points to keep abaci as small as possible, (2) interpolate/extrapolate functions as fast as possible, and (3) obtain low differences with libRadtran outcomes: bias less than 3 Wm^{-2}, and 95% of the differences less than 20 Wm^{-2}.

The comparison between McClear irradiances and measurements from the Baseline Solar Radiation Network (BSRN) on various climates has shown that McClear offers similar or better performances (Lefèvre et al. 2013). In addition, Eissa et al. (2015) performed validations of the McClear model in the United Arab Emirates, and compared McClear's performances against the performance of two other models in the literature. They concluded that McClear was better in capturing the temporal variability of the DNI and similar performances were obtained for the GHI retrieval in this desert climate. They also observed an underestimation in estimating the DNI, which was explained by the overestimation of the AOD in the MACC data and the not accounting for the circumsolar radiation in McClear model.

- Helioclim-3 database

The HelioClim-3 (Blanc et al. 2011) surface solar radiation database is based on the irradiances retrieved from Meteosat Second Generation satellite images. This satellite-based method used to estimate the irradiances is named Heliosat-2. The principle of Heliosat-2 (Rigollier et al. 2004) is that the attenuation of the downwelling shortwave irradiance by the atmosphere over a pixel is determined by the magnitude of change between the reflectance that should be observed under a very clear sky and the currently observed one. The HelioClim-3 database covers Europe, Africa, the Mediterranean Basin, the Atlantic Ocean and part of the Indian Ocean with a spatial resolution of approximately 5 km and a temporal resolution up to 15 minutes and contains irradiance estimates from February 2004 onwards. The HelioClim databases are commercialized by Transvalor and are available, with other solar related web-services, at www.soda-is.com.

Qu et al. (2014) demonstrated the advantage of replacing the clear-sky model in HelioClim-3 with McClear. They obtained an improvement of HelioClim-3 in most cases, and with no degradation in the others.

2.2. Scheme

The all-sky irradiance is computed as a product between clear-sky (or cloud-free sky) irradiance and a clear-sky index (Oumbe et al., 2014). The following two ratios, Kc and Kcb, are called clear-sky indices (Beyer et al., 1996):

$$Kc = GHI / GHI_{clear\text{-}sky} \qquad \text{(eq. 1)}$$

$$Kcb = DNI / DNI_{clear\text{-}sky}$$

The estimation of irradiance under clear-sky condition is based on the McClear model. It has been observed

that the error on MACC AOD estimations leads to important deviations on the clear-sky irradiances in the region: up to 20% on DNI if the deviation is expressed as a root mean square deviation (Oumbe et al. 2013). The MACC AODs have been therefore calibrated using AOD measured by AERONET (Aerosol Robotic Network) stations in the UAE before being used as input for irradiance calculation in the region.

The clear-sky index, Kc_{HC3}, was extracted from HelioClim-3 database. The obtained all-sky irradiances are then locally adapted using the measurements collected at AD1. The probability density function of the difference Kc_{HC3} - Kc_{AD1} is estimated by a model which is then applied to all locations and periods to correct the Kc_{HC3}. Eventually, the $GHI_{estimated}$ and $DNI_{estimated}$ are derived (Figure 1).

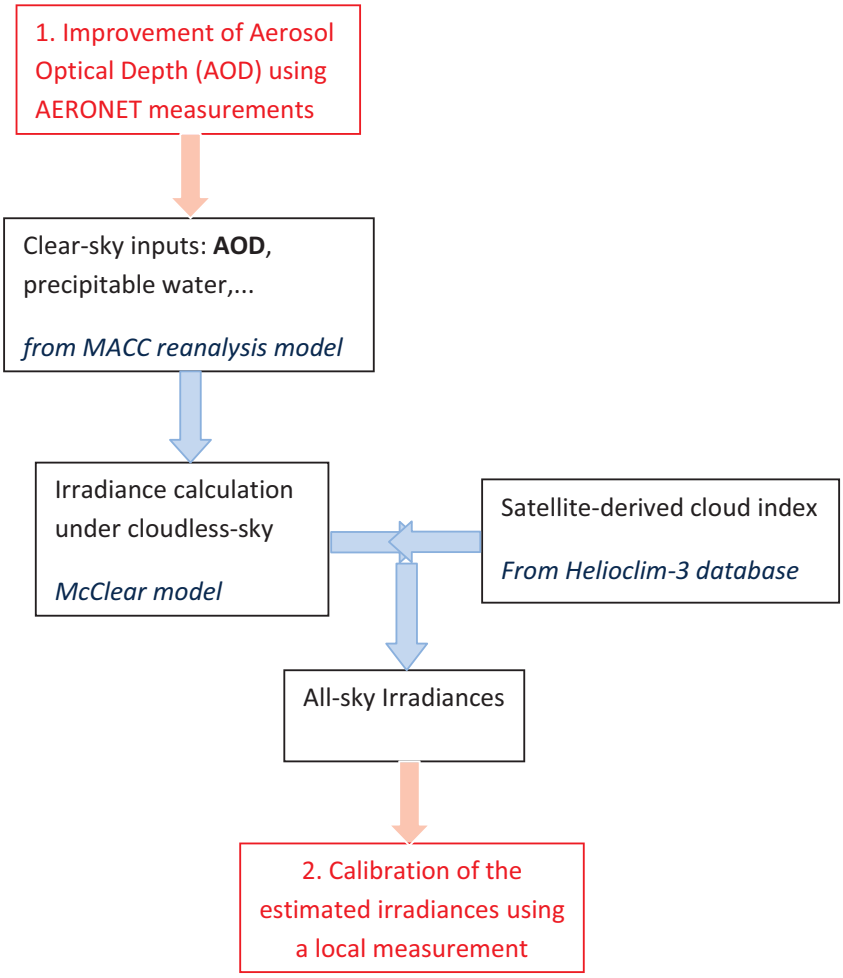

Fig. 1. Scheme of the Predisol model

The location map of the stations used in calibration and validation is shown in Figure 2.

2.3. AOD data and calibration

The AOD is a particularly critical input for irradiance estimation in desert region given its less-frequent cloud coverage and its dusty atmosphere. MACC re-analysis model provides partial and total AODs in reduced Gaussian Grid resolution: 1.125° in latitude, 1° to 20° in longitude from equator to pole (Benedetti et al., 2009). Every day at 0h, MACC predicts AODs at 0h, 3h, 6h, 9h, 12h, 15h, 18h and 21h (daily forecasting). Predicted quantities are total AOD at 550 nm, total AOD at 1240 nm, AOD of organic matter at 550 nm, AOD of black carbon at 550 nm, AOD of sea salt at 550 nm, AOD of dust at 550 nm and AOD of sulphate at 550 nm. The total AOD is the sum of all these individual AODs. The relative contribution of each aerosol species is used to determine the aerosol type, which is another input to McClear .

The NASA-operated AERONET program performs ground-based CIMEL CE-318 Sun photometer measurements, and converts them into estimates of aerosol optical properties. It provides a valuable validation data for satellite retrievals of aerosol optical properties. Datasets are available at

http://aeronet.gsfc.nasa.gov and contain AOD measurements at 16 different wavelengths as well as solar zenith angles, total water vapor column measurements and several inversion coefficients. Measurements at some AERONET stations correspond to a time-limited campaign performed over a short period of time. In 2004 the United Arab Emirates Aerosol Experiment took place contributing to a remarkable increase in AERONET data availability in the Middle East. Therefore, the bulk of measurements in the Middle East correspond to 2004. Only 5 of the 16 stations in the UAE have more than one year of measurements. The AOD at 550 nm ($AOD_{\lambda=550nm}$) is derived from AERONET AOD at 440 nm and AOD at 870 nm. AERONET level 2 - "cloud screened and quality assured" data were used in this study.

The comparison between MACC and AERONET AODs shows large deviations, partly due to the coarse spatial resolution of MACC. The MACC AOD product overestimates the AOD by 26% in the UAE. The relative root mean square deviation (RMSD) on the estimated AOD reaches 47%, but the correlation coefficient was around 0.8 showing that MACC reproduces the temporal variability of AOD in the region relatively well. No daily variation of deviation is observed, though significant monthly changes were observed in the deviation. The highest bias of 0.16 is reached in July, corresponding to the highest mean AOD where the lowest bias (0.04) was obtained in November. Overall, the accuracy of MACC decreases when the AOD increases. These deviations lead to significant error in the estimation of irradiances. Over all the AERONET stations, the deviation – by the means of root mean square error (RMSE) – between irradiances estimated (using the radiative transfer model libRadtran) with MACC aerosols and irradiances estimated with AERONET is 5% for GHI and 20% for DNI. The general overestimation of AOD leads to underestimation of GHI and DNI. The differences between measured and AERONET derived irradiances notably increases with the distance, due to the modification of aerosol loading. When the AERONET and pyranometric stations are 100 km away, the standard deviation reaches 7% for GHI and 18% for DNI. This gives important information about the spatial variability of AOD in the UAE desert, and shows the limitation of using aerosol properties that are measured (or estimated) on locations or grid cells that are more than 100 km away. (Oumbe et al. 2012).

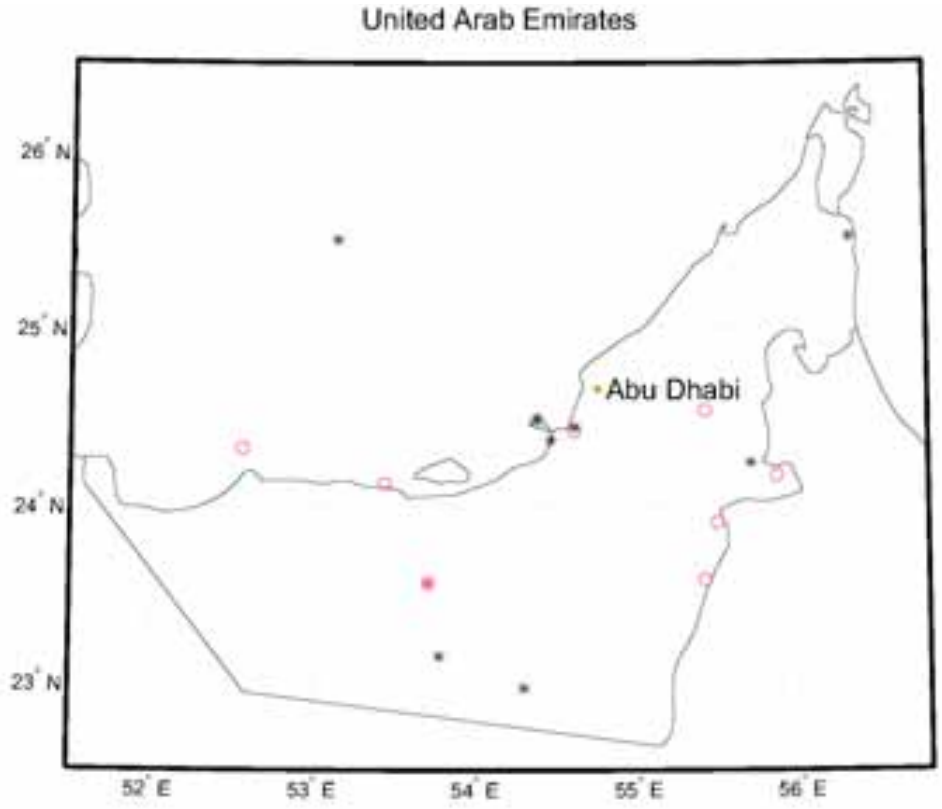

Fig. 2. Location of the Irradiance measuring stations (in red) and aerosol measuring stations (AERONET) (in black) in the UAE. The stars are stations used to calibrate the model (all AERONET and AD1) and the circles are stations used for model validation.

Since the spatial resolution of MACC aerosol database is greater than 100 km (1.125°), a local correction is necessary to properly reflect this actual spatial variability of the AOD. A correction function for MACC AOD was derived for each AERONET station. Then a global correction of MACC is AOD in the UAE was generated. This correction has improved the accuracy of AOD estimation at each AERONET station. The table 1 shows the performance of this correction: significant decrease of bias, noticeable decrease of RMSD, and no change in correlation coefficient.

	Original AOD	**Corrected AOD**
Bias	26% *(0.10)*	-2% *(-0.01)*
RMSE	47% *(0.17)*	36% *(0.13)*
Correlation coefficient	0.797	0.797

Table 1. Comparison between the original and the corrected MACC AOD and AERONET AOD. RMSE stands for root mean square error.

The Predisol clear-sky model was made of McClear operated with the MACC corrected AOD.

2.4. Irradiance measurement and calibration

The AD1 measuring station was specifically designed and commissioned for the Predisol project. It has been installed at Madinat Zayed near the Shams CSP plant. AD1 has provided high quality irradiance measurements with high temporal resolution. The station comprises the following instruments:

- a SOLYS 2 suntracker (Kipp & Zonen) supporting the radiative sensors and allowing for sun tracking and DHI (Diffuse Horizontal Irradiance) sensor shading,
- a CHP1 first class pyrheliometer (Kipp & Zonen) for measurement of the DNI component of irradiance. This sensor is equipped with a temperature probe in order to allow for temperature shift according to the sensor calibration curve,
- two secondary reference CMP11 Pyranometers (Kipp & Zonen), one being unshaded for GHI measurement, the other being shaded by a shadow ball for DHI measurement,
- a meteorological mast equipped with wind measurement (Vaisala WMT520), temperature and HR measurements (Vaisala HMP155), atmospheric barometer (Vaisala BARO-1),
- a data acquisition module (Vaisala QML201) with storage capacity and modem for data transmission, and a 24V autonomous power supply (2x90 W peak PV panels + 2x 12 V/130 Ah batteries).

Datasets are reported in a 1-min average (DNI, GHI, DHI) or a 10-min average (Temperature, Relative humidity, Atmospheric Pressure, Wind speed, Wind direction). Within the measurement period we noticed some meteorological events that could affect the quality of solar data:

- Morning condensation during fall/winter, characterized by droplets condensing on sensors.
- Sand storms during spring/summer, characterized by sudden drop of GHI and DNI, the latter falling to zero.
- Large temperature excursions in summer. During these periods, the outside temperature exceeds 47°C during at least one hour a day.

The quality of the data was monitored based on the three component test (Roesch et al., 2011):

$GHI / (DNI*\cos(SZA)+DHI) = 1.0\pm8\%$ for $GLOB1 > 50 Wm^{-2}$, $SZA < 75$ (eq. 2)

$GHI / (BNI*\cos(SZA)+DHI) = 1.0\pm15\%$ for $GLOB1 > 50 W^{-2}$, $75 < SZA < 93$

where SZA is the Sun Zenith Angle.

Routine maintenances (mainly cleaning and verification of alignment of the instruments) of the station were

found critical to maintain the quality of the measurements. Figure 3 illustrates the correlation between the number of maintenance operations in a month and the percentage of data passing the three component test over the period from April 2012 to December 2013. August 2012 clearly appears as a "bad month" with only 6 maintenance operations and a poor fraction of good data (65%). The poor result of October 2013 is due to the lack of DHI signal. Basically, in a desert region, at least one maintenance operation per day is needed for the high-precision station. TEMP1 is DNI*cos(SZA)+DHI.

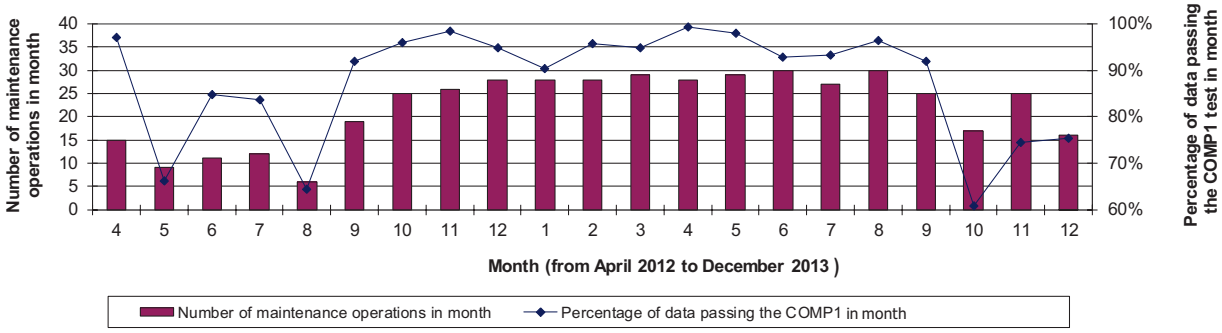

Fig. 3: Correlation between maintenance frequency and fraction of good solar data

The Predisol clear-sky model is proposed to replace the clear-sky model in the Middle East region of the HelioClim-3 database. This new database is calibrated with the quality-checked AD1 irradiance measurements. This calibration corrects systematic errors of the HelioClim-3 database in the region. E.g. we have noticed a clear under-estimation for the first hours in mornings, except in winter. After investigation, this almost systematic underestimation of GHI in the morning was found to be caused by the specular reflectance from the ground when the satellite observation direction is opposite to the sun direction, for high longitude. This under-estimation artifact due to high longitude implies a large global under-estimation of the non-calibrated GHI. The graphs presented in Figure 4 show the time series of the non-calibrated GHI and that of calibrated estimated GHI. With the calibration, the bias and RMSE drop respectively from 14% and 22% to 0% and 10%. The calibrated database is the Predisol irradiance database.

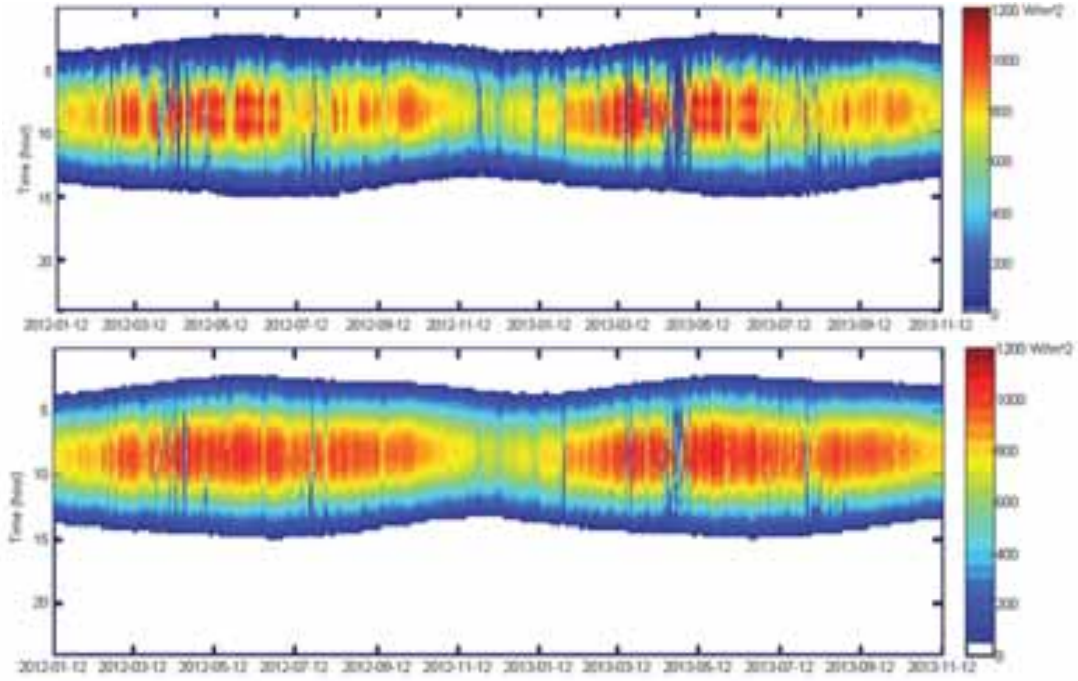

Figure 4: Timeseries of non-calibrated estimated GHI (at top) and of AD1 calibrated estimated GHI (at bottom) at AD1 station. Time is in UTC

A local transposition function has been then used to derive DNI from GHI.

3. Validation

The estimated irradiances have been validated against high-quality measurements taken by 7 Rotating Shadowband Irradiometers (RSI) managed by Masdar Company and maintained by CSP Services. The RSI is a silicon photodiode, the LI-COR LI-200 Pyranometer, integrated with a rotating shadowband. When the shadowband is stationary below the horizon of the photodiode, the GHI is measured. The DHI is measured when the shadowband masks the entire solar disc from the pyranometer. The DNI is then derived from the GHI and DHI measurements. The shadowband rotates once per minute. The irradiances are averaged and delivered in a 10-minute time step. The locations of the RSI stations used for validation are shown by the red circles in Figure 2.

The 10-min measurements of RSIs, and the 15-min estimates of Predisol were averaged hourly irradiances. Each hour corresponds to the end of integration period (h for]h-1, h]). The daily and monthly irradiation time-series were then computed. Deviations were computed by subtracting the measurements from the corresponding Predisol estimate. They were summarized by the bias, the standard deviation, the RMSE, and the Pearson correlation coefficient. Relative values are expressed with respect to the mean of the used measurements. See Table 2.

	HOURLY MEANS (26229 hours)				**DAILY MEANS (2331 days)**				**MONTHLY MEANS (68 months)**			
	Mean	*Bias*	*RMSE*	*CC*	*Mean*	*Bias*	*RMSE*	*CC*	*Mean*	*Bias*	*RMSE*	*CC*
DNI	**458 W/m^2**	**0%**	**26%**	**0.880**	**5051 Wh/m^2**	**0%**	**20%**	**0.797**	**154.1 kWh/m^2**	**-1%**	**10%**	**0.805**
GHI	**552 W/m^2**	**2%**	**8%**	**0.988**	**6107 Wh/m^2**	**2%**	**6%**	**0.966**	**188.7 kWh/m^2**	**2%**	**4%**	**0.990**

Table 2. Validation of global and direct irradiances. Measurements from all stations are combined. "Mean" is the mean of the measurements. CC stands for correlation coefficient. Bias and RMSE are expressed relative to "Mean".

Validation of the hourly means of irradiance show high coefficients of determination: 0.88 on DNI and 0.99 on GHI. The relative biases are close to zero: 0% on DNI and 2% on GHI and the relative root mean square error (RMSE) are low: 8% on GHI and 26% on DNI. Lower deviations are obtained on daily and monthly means of irradiance. There are still rooms for improvements on the DNI. These performances are better than those currently reported in the literature for the UAE (Eissa et al., 2012; Alobaidi et al., 2014; Gherboudj and Ghedira 2015).

The uncertainties of E-ANN (Eissa et al., 2013) for hourly irradiances in all-sky situations are similar for RMSE on DNI and higher for the bias on DNI and bias and RMSE on GHI. The relative bias and RMSE of E-ANN are respectively 6% and 26% for DNI and 3% and 12% for GHI. But the E-ANN validation is presented only on two stations. The ensemble artificial neural network (E-ANN) model, is a statistical model utilizing the Meteosat Second Generation images for irradiance prediction specifically over the region of the UAE. It requires a training beforehand. The E-ANN model was trained using reference data from three ground measurement stations for the full year of 2010 and validated over two independent stations for the full year of 2009.

The cloud-free situations represent 60 to 80% in the region. The performance of McClear and E-ANN models for cloud-free situations, taken from Eissa et al (2015), are compared to those of the new method – named Predisol (see Table 3). The enhancement of MACC AOD significantly reduces the bias on DNI estimation in cloud-free situations, leading Predisol to have less bias on DNI than McClear. The rest of performances of McClear and Predisol are close. McClear and Predisol perform better and E-ANN.

	Model	Bias	RMSE	CC
DNI (mean of measurements: 670 W/m²)	E-ANN	-9%	19%	0.607
	McClear	-4%	11%	0.837
	Predisol	**-0.6%**	**10%**	**0.894**
GHI (mean of measurements: 600 W/m²)	E-ANN	-6%	11%	0.947
	McClear	+2%	5%	0.982
	Predisol	**+3%**	**5%**	**0.995**

Table 3. Validations of cloud-free hourly DNI and GHI by ANN, McClear and Predisol

4. Conclusion

The calibration method exhibit very satisfactory results on GHI and DNI estimations over the UAE, even though it was based only on one year of irradiance measurement at one site. The obtained accuracy was better than those reported in the literature for the UAE. The generated irradiance database -resolutions: 3km and 15 minutes, period: 2004 to 2013- is therefore a reliable inputs data for feasibility studies and performance simulation of Solar Power Plant in the region. There is room for improvement of the DNI retrieval accuracy. It is expected that a higher resolution of AOD as inputs and /or a direct estimation of DNI, instead of transposition from GHI, would improve the model accuracy.

ISES SWC2015 –THE STATE OF SOLAR ENERGY RESOURCE ASSESSMENT IN COSTA RICA

Natalia Alvarado[1], Rodrigo A. Escobar[2], John Boland[3], and Evelyn Quiros[4]

4 Instituto Costarricense de Electricidad, Costa Rica.

Abstract

It is traditionally assumed in Costa Rica that given its geographical location there must be a large potential for electricity generation from solar energy. However, this potential has not been properly assessed with measurements of high quality up to modern standards, and therefore the country still lacks the information needed to either establish public policies to promote solar energy utilization or support the development of commercial projects. The current trend of increasing energy consumption in the country and the existing interest on increasing solar energy utilization require an updated analysis of the available solar resource in order to generate meaningful data that can be used by government and private parties.

Costa Rica has been measuring global horizontal irradiation for over 20 years in several stations distributed throughout the country, although in most cases the measurements have been conducted without quality control checks and postprocessing. This network of radiometric measurement stations was set out to identify regions with adequate levels of average daily sunlight in order to define regions in which solar energy systems could find engineering applications.

Currently the measurement network is operated for the ICE group (Costa Rican Institute of Electricity), and consists of Second Class Pyranometers CHP3 and First Class Normal Incidence Pyrheliometer CHP1, both from Kipp and Zonen brand. The information is stored as minute-averages and spans a period of four years. No locally developed and validated satellite estimation models have yet been reported, and instead the country relies on commercial data. There are no measurements of either diffuse or direct normal irradiance. A more complete climatological characterization of the solar resource is possible by using the measured data of global horizontal irradiance coupled with the existing diffuse fraction models such as (Boland, Lauret, & Ridley, 2010) and (Jing, Boland, & Ridley, 2012), which allow decomposing the Global horizontal into its direct and diffuse components. This represents a significant improvement in the amount and quality of solar information that is available for solar engineering applications in Costa Rica and can be published for public access.

key-words: solar data, irradiance, radiation, solar energy, resource assessment & climate, solar potential, Central America

1. Introduction

Costa Rica is located in the southern part of Central America, between the coordinates 8° 15’ – 11° 00’ North and 83° 30’ – 86° 00’ West. This area is located within the tropical belt of the Northern Hemisphere. To the

doi:10.18086/swc.2015.07.09 Available at http://proceedings.ises.org

north, the country borders with Nicaragua, and in the south with Panama. To the east and west the country is surrounded by the Caribbean Sea and the Pacific Ocean, respectively. The country has a rich geography that is associated with higher levels of precipitations, humidity and temperature. Costa Rica has a surface area of 51,100 km² and a population of approximately 4.3 million people.

More than 60 % of the population lives around the capital San José, which is located in the center of the country. This area is called the "Gran Área Metropolitana" (GAM) in Spanish also called Central Valley. The area is surrounded by mountains and it concentrates most of Costa Rica´s industry. The rest of the country consists mainly of natural reserves and agricultural land.

Energy Consumption

Costa Rica has a 98.6% electrification rate, which is the highest in Central America, and a per capita power consumption of about a 1,611 kWh/year. On average, a middle-income Costa Rican family's electric bill takes up 2% of its income—one of the lowest rates in the region, thanks to Costa Rica's higher per capita income and lower power prices owing to the large utilization of hydropower for electricity generation that reaches 91% of the total installed capacity, making it very dependent and vulnerable to weather variability. Today it is known that climate and climate variability (such as for example events like El Niño Southern Oscillation ENSO) can cause unusual atmospheric patterns in the country thus affecting the energy generation and increasing use the energy from fossil fuels.

Electricity demand presents a clear pattern with growing consumption during the morning and two daily peaks, one in the early afternoon and the second at dusk. The forecasted demand growth rate for the next few years is 4% annually. Solar energy is considered as an important potential source to meet the growing energy demand of Costa Rica.

As of now, there have been several different reports trying to characterize the solar resource in the country including the following documents: *Non-Conventional Energy Sources* (Electrowatt Engineering Services ltd, 1983), *Radiación solar global de Costa Rica* (Castro, 1987), *Mapas de radiación solar en Costa Rica* (Wright, 2002), *Map of solar resource of SolarGIS from satellite data* (Weigl, 2014), *Determinación del potencial de energía solar para generación eléctrica en Costa Rica*. (ICE, 2014).

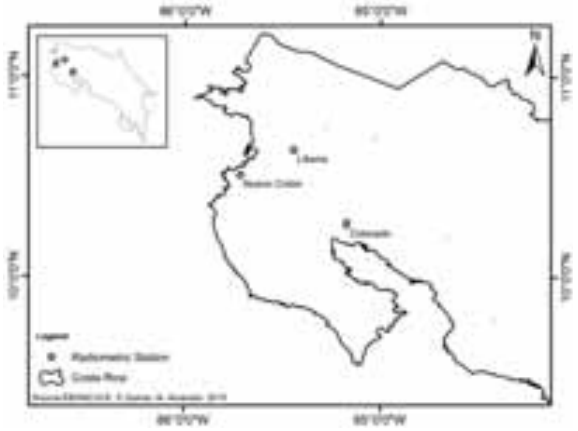
Some of these reports were performed the ground data, but with low quality, because had a systematic errors. Due to this low quality of the data arises the need for modeling as a method of quality control and analysis of solar resource available in the country for its subsequent use as an energy source. In the Electrowatt document the information considered included 22 actinographs and 26 heliometers with data previous to 1982. The results indicated that the majority of the irradiation data was affected by systematic and random errors due to poor sensor operation and maintenence. Castro´s work (1987) reviewed all actinography and heliometer data available in the country and achieved similar conclusions, that the uncertainty levels on average of 10% with maximum of 25%. Wright´s work (2002) concluded that the density of measurement points was adequate although the data quality was low as it displays high uncertainty, short measurement periods, uncalibrated sensors, and substandard maintenance. Considering this, it is clear that a larger effort must be made to properly evaluate the available solar resource in Costa Rica.

2. Available Data

The data we choose to use with a model is data from three locations over same climate region, the north pacific region in Costa Rica (Liberia, Colorado and Nueva Colon). These data were collected as a response of campaign of measurement the national electricity company in Costa Rica.

Each station was equipped with a pyranometer (CMP3) and a pyrheliometer (CHP1) manufactured by Kipp and Zonen with Campbell-Stokes datalogger. The measurements include globaland direct normal irradiance values with sampling rate and minutal averaged storing rate. Every dataset has been reviewed using a quality control (QC) procedure based on the BSRN guidelines (McArthur, 2005).

Liberia and Colorado locations used have time series of measured irradiance since a 2009.In the following analysis only a full year of data (2014) is considered. Figure 1 present the location of the three stations considered here. These radiometric stations have similar geographical and climatological characteristics as the elevation and climate of the stations differ from 85 m to less 1000 m. These three stations are located in relative proximity as it was previously determined that the region has a large potential for solar energy utilization.



Station	Lat (deg.)	Lon (deg.)	Elev. (m)
Liberia	10.6	-85.4	990.7
Colorado	10.3	-85.2	999.2
Nuevo Colón	10.5	-85.7	85.0

Figure 1: Measurement stations location

3. The Boland-Ridley-Lauret (BRL) Model

However, for this paper, we have global and direct radiation is measured, for modelling solar energy applications, the amount of radiation on a surface is needed. Different models for estimating the diffuse fraction and correlating it to the clearness index, such as Orgill and Hollands, Erbs et al, Reindl et al (Duffie & Beckman, 1980). Also, Boland et al. (2010) presented a model based on predictors for finding the diffuse fraction from GHI data. The model utilizes the hourly clearness index, solar altitude, apparent solar time and a measure of persistence of global radiation level as predictors and allows estimating the diffuse fraction for measured datasets. The diffuse fraction is defined as the ratio between diffuse horizontal irradiation and global horizontal irradiation:

$$d = \frac{I_{diffuse}}{I_{global}} \tag{1}$$

According to Boland et al (2010), the diffuse fration can be also represented as:

$$d = \frac{1}{1 + e^{-5.38 + 6.63 k_t + 0.006 AST - 0.007 \alpha + 1.75 K_t + 1.31 \psi}} \tag{2}$$

Where k_t is hourly clearness index, AST the solar time, α the solar angle in degrees, K_t the daily clearness index, and ψ is the persistence.

4. Methodology

For this paper, it had been used at hourly data from 365 days of Liberia Station, 398 days of Colorado Station and 88 days of Nueva Colon Station.

The information obtained from the model (BRL), is compared with the diffuse fraction from the Orgill and

Hollands model (Duffie & Beckman, 1980) and the diffuse fraction obtained from DNI data. The diffuse fraction of the Orgill and Hollands model is:

$$d = \begin{cases} 1.0 - 2.49k_t & for\ k_t < 0.35 \\ 1.557 - 1.84k_t & for\ 0.35 \leq k_t \leq 0.75 \\ 0.177 & for\ k_t > 0.75 \end{cases} \quad (3)$$

For this work the minutal data was initially to convert to hourly data. With the calculated of k_t-hourly clearness index we applies an Orgill and Hollands model, the equation 3.

For the BRL model, equation 2, first step it to calculate the parameters is hourly clearness index, *AST* the solar time, the solar angle in degrees, K_t the daily clearness index, and ψ is the persistence detailed is in Boland et al. (2010)

Finally to determine the diffuse fraction from the minutes variables of GHI and DNI, it calculated the hourly averages, diffuse radiation is determined with the differential of the global radiation (GHI) and the horizontal component of direct radiation (DNI cos (θ_z)), the diffuse fraction was determined by applying the equation 1.

After include the information, we obtained the next figures 2 to figure 4.

5. Results

The diffuse fraction was obtained by a BRL model, have a right behavior curves expected by a data in the three locations. These patterns we associate with a good performance of this model in a north pacific Costa Rica region.

After a graphical comparison for the three points of data of the fit of the BRL model overlaid against Orgill and Holland model is shown in Figure 2 and Figure 4 where we can observe a very good fit to most of that data set of Liberia and Colorado. We observe seems to fit the data reasonably well but does not fit enough into the high clearness index region.

In a case of a Nuevo Colón, Figure 4 shows the fit between the two models where we see that both does not extend fit enough into the high clearness to low diffuse values, but this station has less quantity of data.

We need move onto formal error analysis, because we need to know if BRL model is performing better than other models.

Besides in a Figure 2 to 4, the result of used DNI fraction to calculate diffuse, but the result show very complex patterns, in the three points if possible that we have errors resulting from the operational problems, easily noticed by this type of plot. We recognized that any serious departure of data from the normally expected value is thus identified.

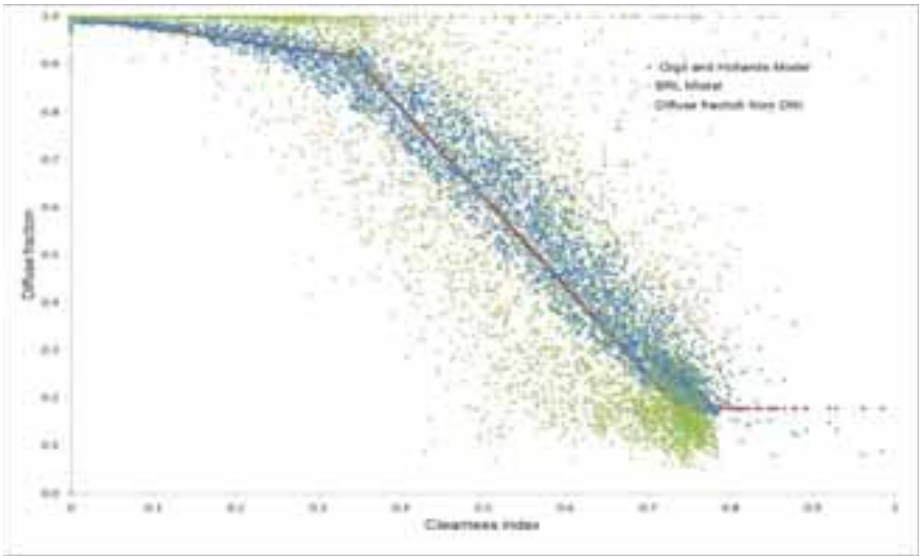


Figure 2. Liberia Data with BRL model, Orgill and Hollands model and Diffuse Fraction from DNI

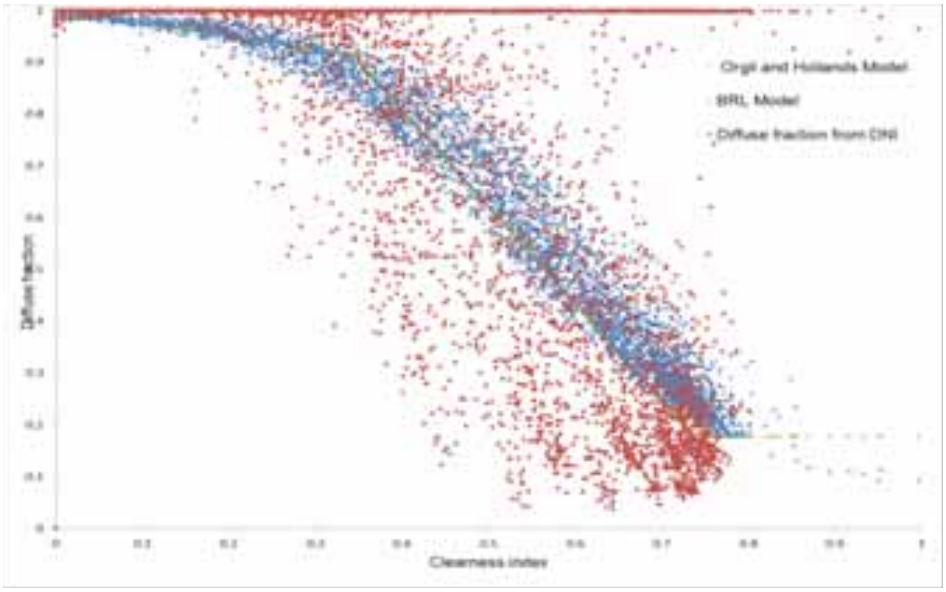

Figure 3. Colorado Data with BRL model, Orgill and Hollands model and Diffuse Fraction from DNI

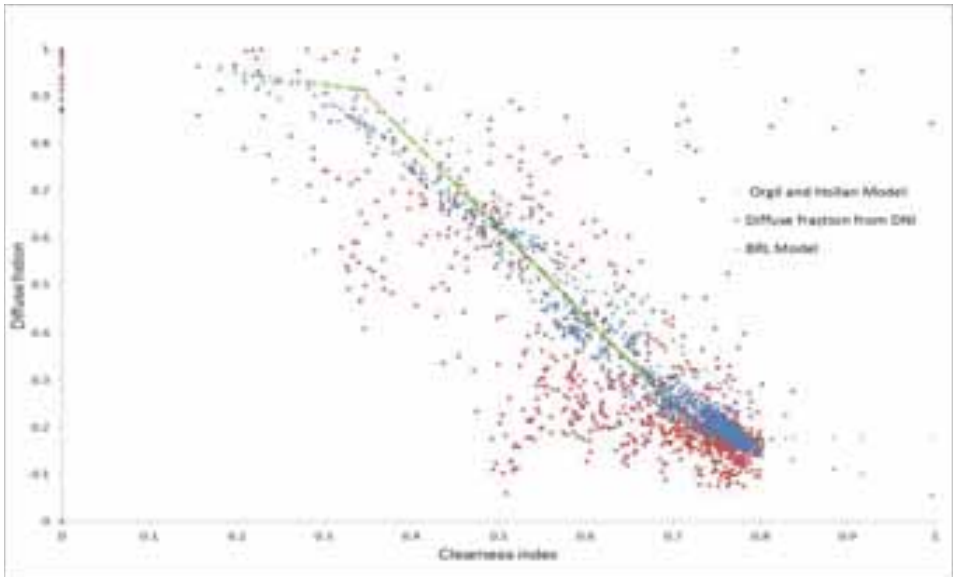

Figure 4. Nueva Colon Data with BRL model, Orgill and Hollands model and Diffuse Fraction from DNI

The points in the top right of the graphic can be caused for misalignment of the sensor CHP1, the data modeled with BRL and as obtained from measured data present conglomerate with low fraction of diffuse, so the DNI component is significant.

La información disponible actual es insuficiente, para su comparación con diferentes modelos. Adicionalmente, permitirá analizar la afectación de los patrones atmosféricos de la región ante el recurso solare. Costa rica debe generar bases de dato de calidad, que genere información requerida para su comparación con diferentes modelos

The available information is insufficient for comparison with various models applied. In addition, it did not allow analyzing the affectation of the weather patterns of the region on the solar resource.

6. Conclusions

The all figure we observe that BRL model and Orgill and Hollands models have the right behavior curves but the information from de DNI presents an involute acceptable some data out of it. Some reason of this because the measures have many errors.

We need move onto formal error analysis, because we need to know if BRL model is performing better than other models.

Costa Rica must generate reliable and high quality databases, with sufficient information for the use and verification of different solar models in order to determinate of the solar resource and its subsequent conversion to energy.

SPANISH RENEWABLE ENERGY GENERATION SHORT-TERM FORECAST

Nicolas Perez-Mora[1,2], Victor Martinez-Moll[2] and Vincent Canals [2]

[1] SAMPOL Ingeniería y Obras, Palma of Majorca (Spain)

[2] University of Balearic Islands, Palma of Majorca (Spain)

Abstract

This work presents and compare four short-term forecasting methods for one day-ahead hourly values of Spanish solar and wind energy generation. From the four models analyzed, two are based on ARIMAX statistical methods and the other two are based on computational intelligence methods as Non-linear Autoregressive eXogenous Neural Networks (NARX). Both forecasting methodologies use the same numerical weather prediction data (NWP), consisting for solar energy, on solar irradiation and for wind power, on wind speed. The NWP data is combined in the model with the installed power of the different generation technologies in Spain. In addition to the NWP data, the models are fed with the aggregated solar and wind energy generation in hourly steps provided by the Spanish Transport System Operator (TSO).

The obtained results by the forecasting methods and by the different energy generation technologies are compared using different error metrics such as: MBE, RMSE, MAE, MAPE and MADPE.

Keywords: *Forecasting, Solar Irradiation, Solar Forecasting, Wind Forecasting, Energy Market, ARIMAX, Neural Networks, NARX, Time Series*

1. Introduction

A huge number of renewable energy power plants have been installed in the previous decade. This was due the subsidies promoting the construction of green power plants (Monteiro et al., 2013b) and the increase in the price of fossil fuels. These factors became a huge boost for the renewable energy generation, being the installation of renewables a profitable business (Monteiro et al., 2013a). Such expansion and the policies adopted by many countries to integrate renewables into the energy generation mix has brought a rearrangement of the energy market (Rubin and Babcock, 2013).

The integration of energy generated by green power plants into electric power system is priority, meaning that this power is fed into the system in preferential order within the energy mix. Although the volatility and variability of the renewable resource makes the integration in the grid difficult taking into account that the supply and load of electric power must be balanced at every instant.

In the Spanish Energy Market or Pool the total electricity power production is balanced in hour step with the demand. The electricity is traded in different markets: the main market "daily" (D) and the 6 regulation markets "intra-daily" (ID). In the daily market the producers release their bids at 12:00 for next day's hourly generation. The intra daily markets take place: at 17:00 for ID1, at 21:00 for ID2, at 01:00 for ID3, at 04:00 for ID4, at 08:00 for ID5, at 12:00 for ID6; the generators can release their bids covering each hour from a few hour after the auction time till the end of the auctioned day, as long as that bid modifies a previous bid placed in the daily market.

The energy mix is the result of the counter clockwise auctions where the demand and the cheapest combination of generation energies matches. The retribution for all the accepted generators in an hour will be the same and equal to the last and highest accepted bid in the auction. In order to always ensure the renewable energy

doi:10.18086/swc.2015.07.10 Available at http://proceedings.ises.org

acceptance into the generation mix the green energies place their bids at the legal minimum, 0€/MWh and its retribution would be calculated as the sum of the final auction price times the generated energy plus the generation subsidy stipulated by the government. Such situation brings variations on energy generation prices. Energy generators can increase their profit by matching their production with the high price hours (Perez-Mora et al., 2016). On the other hand, the grid operator may penalize the generator in case that the energy generation is different than the offered in the auction by charging the cost of the deviated energy.

A major drawback for technologies harvesting electricity out from volatile resources is the non-continuous availability of the resource. Solar energy depends critically on the variability of irradiance (Y. Gala et al., 2014), typically cloud cover cause rapid changes in the irradiance during the day (Chen et al., 2011) which brings along generation fluctuations. In the same way, wind energy generation depends on the wind direction, speed and its variations (Cassola and Burlando, 2012). This dependence on weather conditions may lead to wrong or inaccurate bids from the generators in the energy auction and therefore into a penalties from the grid operator. An accurate bid would therefore minimize the penalties. Wind and solar generators might pursue low penalties by relying on energy forecasts (Lange and Focken, 2006; Mahoney et al., 2012; Yang et al., 2012).

This paper presents two different approaches to forecasting for each technology. The first method is based on AutoRegressive Integrated Moving Average (ARIMA) supported with eXplanatory variable (ARIMAX) and other is based on Artificial Neural Networks (ANN), in particular, based on Nonlinear AutoRegressive models with eXogenous Neural Network (NARX). Both methods are proved to provide accurate energy resource forecasts, either through computational models as in ANN (Li and Shi, 2010; Qazi et al., 2015; Reikard, 2009) or using autoregressive models such as ARIMA (Erdem and Shi, 2011; Huang et al., 2012; Paulescu et al., 2013).

This paper is organized as follows: Next section provides an overview of the problem to approach. Section 3 describes the obtained data to use. In Section 4 the methodology used to approach the problem is explained. Section 5 presents the result obtained from the methodology and the conclusions from those is given in Section 6.

2. Problem description

The aim of this work is to propose a comparison between two sets of methods forecasting solar and wind power. Both of the methods are improved with a valid explanatory variable obtained from a Numerical Weather Prediction method (NWP). This comparison is carried out within a specific boundaries conditions such as Spanish Energy market abovementioned, in particular, the forecasts focus on the daily market being the forecast horizon from +12h to +36h in hourly step.

The importance on forecasting green energy generation lies in the variability along the time and markedly different generation potential between stations and different months of the year. In case of solar power it changes from a 540 MW minimum power peak in winter to a 5.6 GW maximum power peak in summer which implies the 12% of the total generation power injected into the grid. For wind power it varies from a minimum of 120 MW to a maximum of 16.9 GW reaching peaks of production which implies the 69.4% of the total injected power into the grid. Wind power does not necessarily follow the seasons per se, but it is possible to see an annual trend line. In 2014 wind power was the resource with the biggest share in the energy mix, 20.9%. The maximum injection power achieved by solar and wind into the grid reached a total of 19.4 GW.

It is important to bear in mind that the solar electricity generation in Spain includes two technologies: photovoltaic with an installed capacity of 4.16GW; and solar thermal power stations with an installed capacity of 2.3GW, additionally these power plants may have with a storage system.

Regarding wind power the main difficulty is the lack of information on wind farm layouts impeding the use of wind direction to estimate the power decrease due shadowing between wind turbines.

A common approach to the forecast problem over a wide region is to calculate individual forecast and sum the results up (Mellit and Pavan, 2010), and it is expectable that individual errors to partially cancel out when summing up the forecasts and thus, obtaining a more accurate prediction (Y. Gala et al., 2014). An aggregated forecast approach for a country like Spain it is an extremely complicated proceeding due the large amount of

installations, the variety of technologies and the lack of historical generation information from each generator. Thereby, the approach given in this paper is forecasting the aggregated power for the Spanish peninsular market for each technology. To do so, the forecast methods are supported with a valid explanatory variable which comprises a time series of hourly values.

The mentioned explanatory variables are obtained developing a NWP method. This method provides the cloudiness index and the wind speed for a certain location. In the case of wind power, the wind speed is presumed to be a sufficient and valid explanatory variable. In the other hand solar power, is related with irradiation on the collector surface, thus cloudiness index is inversely correlated with the solar generation. The cloudiness index is a useful information that helps modeling solar irradiation. A model has been developed based on the extraterrestrial radiation modified by the cloudiness index of each location. The obtained value is expected to have a high correlation to the actual irradiation of a given location (Biga and Rosa, 1980; Lorenz et al., 2009).

2.1. Forecasted Irradiation

In order to obtain the irradiation with the developed method it is required to calculate the extraterrestrial hourly radiation (G_0) for a given point (Duffie and Beckman, 2013).This calculation depends upon the location of the plant, the time of the year and the slope of the solar collectors. The radiation (G_0) is calculated according to (eq. 1):

$$G_0 = G_{SC}\left(1 + 0.033\, cos\frac{360n}{365}\right) cos\,\theta_z \qquad \text{(eq. 1)}$$

Where G_{SC} is a solar constant (1367 W/m^2), n is the day number of the year, θ_z is the zenith angle calculated in (eq. 2):

$$cos\,\theta_z = cos(\emptyset - \alpha)\, cos\,\delta\, cos\,\omega + sin(\emptyset - \alpha)\, sin\,\delta \qquad \text{(eq. 2)}$$

The latitude of the location is denoted by ∅, a is the slope of the collecting surface, δ is the declination or angular position of the sun calculated in (eq. 3) and ω is the hour angle or the angle of displacement of the sun calculated in (eq. 4).

$$\delta = 23.45\, sin\left(360\frac{284+n}{365}\right) \qquad \text{(eq. 3)}$$

$$\omega = (h_s - 12)\cdot 15 \qquad \text{(eq. 4)}$$

The solar time is denoted by h_s. The difference between the solar time and the standard time is calculated through the formula (eq. 5) and the result is given in minutes:

$$Solar\ time - standard\ time = 4(L_{st} - L_{loc}) + E + DLS \qquad \text{(eq. 5)}$$

Where L_{st} and L_{loc} are the longitudes for the standard meridian and the location, DLS references the possibility of having Day Light Savings and E is a value calculated through (eq. 6):

$$E = 229.2(0.000075 + 0.001868\cdot cos(B) - 0.032077\cdot sin(B) - 0.014615\, cos(2B) - 0.04089\cdot sin(2B)) \qquad \text{(eq. 6)}$$

And finally, B is calculated according (eq. 7):

$$B = (n-1)\frac{360}{365} \qquad \text{(eq. 7)}$$

The intensity of the solar resource that reaches the surface of the earth decreases with increasing values of cloudiness index or sky cover (Sharma et al., 2011). Taking this hypothesis as valid the method forecasts the irradiation (I_f) for a given location as dependent on the extraterrestrial hourly radiation (G_0) and the symmetrical of the forecasted cloudiness measured in 0 to 1 range (N_f). The values are calculated hourly according to (eq. 8):

$$I_f = G_0\cdot(1 - N_f) \qquad \text{(eq. 8)}$$

A similar model was presented by (Zhang et al., 2014), where global irradiance is obtained adding to the model the clouds transmissivity.

2.2. Forecasted wind speed

As mentioned before the wind speed and direction are directly related with the availability of a wind turbine to generate power. In the case of wind direction it could be useful to understand how the wind turbines shadow each other on a wind farm (Astariz et al., 2015; Sørensen et al., 2002), in order to improve the calculation of the explanatory variable. To do so, the wind farms turbine distribution is required, unfortunately this information is not easily accessible. Therefore the only contribution to the explanatory variable is the wind speed in the location. In (eq. 9) the power delivered by a wind turbine is given by (eq. 9):

$$P = \frac{1}{2} \cdot \rho \cdot A \cdot v^3 \qquad \text{(eq. 9)}$$

Where ρ is the air density, A is the area swept by the rotor and v is the wind speed through the blades.

2.3. Weighted explanatory variable

The value of the weighted explanatory variable used for Spain is calculated taking into account the forecasted time series, either irradiation or wind speed, in the measured places and the installed powers in those places. Spain irradiation (I_E) values are calculated according to (eq. 10):

$$I_E = \frac{1}{P_S} \sum_{n=1}^{50} I_{fn} \cdot P_{sn} \qquad \text{(eq. 10)}$$

Where I_{fn} is the forecasted irradiation on the n location, P_{sn} is the installed solar power for a given location, Ps is the total solar power accumulated in Spain and is calculated using (eq. 11).

$$P_S = \sum_{n=1}^{50} P_{sn} \qquad \text{(eq. 11)}$$

Spain wind speed (v_E) values are calculated according to (eq. 12):

$$v_E = \frac{1}{P_w} \sum_{n=1}^{50} v_{fn} \cdot P_{wn} \qquad \text{(eq. 12)}$$

Where v_{fn} is the forecasted wind speed on the n location, P_{wn} is the installed wind power for a given location, P_w is the total wind power accumulated in Spain and is calculated using (eq. 13).

$$P_w = \sum_{n=1}^{50} P_{wn} \qquad \text{(eq. 13)}$$

3. Data acquisition

The required data for both forecasting methods comprises two related time series, the aggregated energy generation and the explanatory variable. The historical data is obtained from the Spanish TSO, *Red Eléctrica de España* (REE). This solar generation data is available from 24/7/2013 and provides the time series of the national solar production in 10min step. In the other hand, wind generation is available from 1/1/2012 and provides the time series of national wind production in 10min step.

The installed power for solar and wind technologies is given by the Ministry of Industry. Detailed information of the installations, such as, location, technology, power and whether or not is connected to grid is provided. This information is processed and clustered according to the province division in Spain. In this way 50 aggregated installed powers are obtained. In the case of solar power, photovoltaic and solar thermal technologies are summed up in each region.

The NWP is based on an algorithm that analyses satellite images and predicts the climatic data (Zhang et al., 2014). The NWP data comprises three days ahead time span. The cloudiness and wind speed database starts

on 8/9/2014. In order to have a homogeneous database in the area of Spain, one station per province is used; those stations are located, mainly, in the province's main city, therefore 50 stations are selected for Spain. Stations are marked with black dots in Fig.1.

Fig. 1. Weather Stations Localizations

3.1. Possible source of errors

The variable grid used that takes as unit the provinces may lead into errors since the obtained NWP value is given for a point and it is used in the whole area regardless of either station or the power plant location. The asymmetry in the location of weather stations and the different shapes and sizes of the provinces avoid the possibility of spatial averaging of the NWP data used in (Lorenz et al., 2009) and only the aggregation of the weighted data in the whole country is carried out in this study.

The sum of photovoltaic and solar thermal power plants regardless of the different technologies comprising this categories may lead to errors while forecasting the final output.

The shadowing effect within wind farms due the location of the wind turbines in the land and the wind direction may bring power decreases in the local wind generation and thus affecting the aggregated generation.

For the extraterrestrial hourly radiation calculation a value of slope (α) is estimated, this value is fixed for all the solar power plants and during the year. The most common slope value for Spain is fixed at the average latitude value, 40º. The optimum yearly slope value for an installation could have been taken as the same as the latitude where it is located (Benghanem, 2011).

3.2. Time series correlation

The resulting acquired data gives two pairs of time series, one for solar forecasting and the other for wind forecasting. In order to study the rightness of the abovementioned suppositions two correlation studies have been carried out on the time series, Pearson correlation study and R^2 correlation study.

The results for solar, where irradiation and national solar generation are taken into consideration shows a good correlation (Fig.2a), with a Pearson factor of 0.90 and $R^2 = 0.816$.

The results for wind, where wind speed and national wind generation are taken into consideration shows a correlation (Fig.2b), with a Pearson factor of 0.79 and $R^2 = 0.63$. In the wind speed case the same study is made for wind speed to the power of three (cubic wind speed, v^3) since as seen in (eq. 9) it is related with wind

power. This study gives as Pearson factor a result of 0.73 and $R^2 = 0.54$; which is lower than the previous one and thus, simple wind speed is used to forecast.

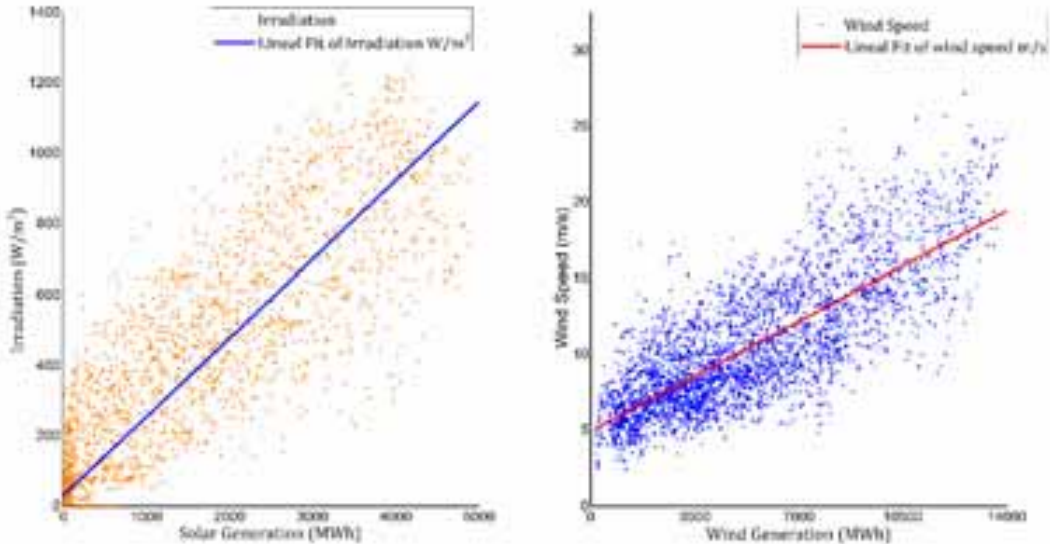

Fig. 2. Variables relation for (a) Solar Generation Vs Irradiation and (b) Wind Generation Vs Wind Speed.

4. Methodology

The relations between the explanatory variables and the generations are reasons to think that the likeness between the time series would be sufficient to calculate the aggregated energy generation (Fig. 3). Nevertheless the relation is not perfect, and in the case of wind is far to be close to 1, adding this to the variability and differences between the various installed power plants, technologies and performances precludes a reliable analytical model. Therefore a statistical forecasting method needs to be developed to obtain the aggregated power hourly generated in Spain.

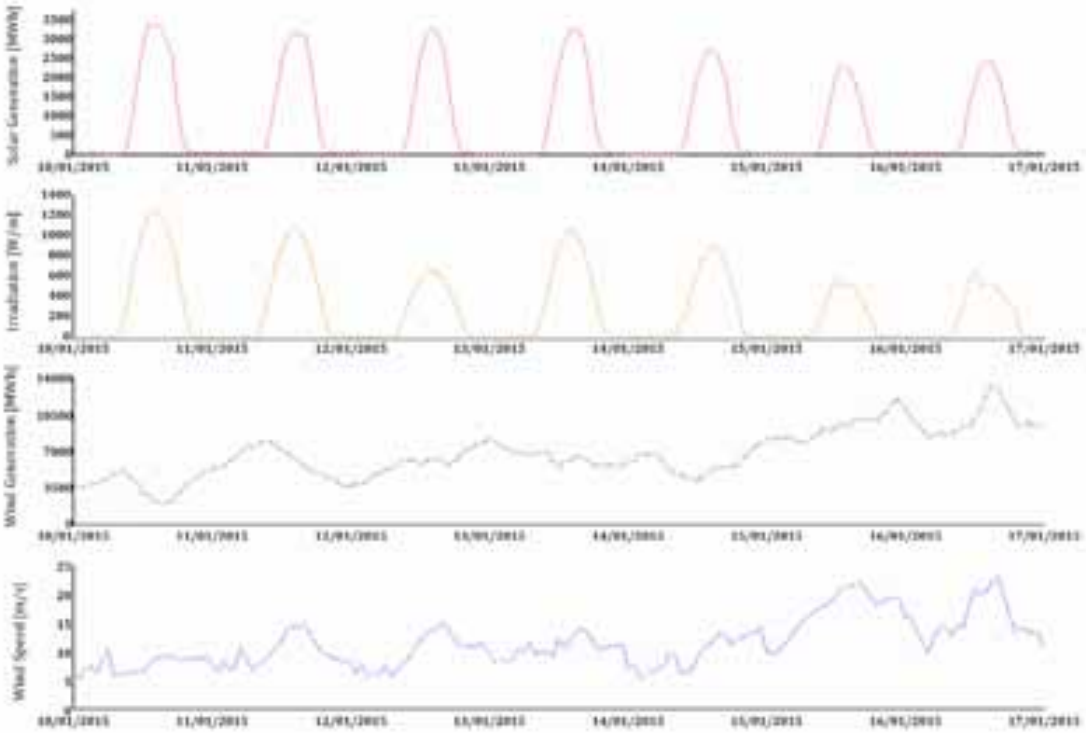

Fig. 3. Generation and proposed explanatory variables

This statistical model is fitted to time series data in order to forecast an extra time series to understand better and predict future values of the main time series. It is composed by an autoregressive model (p), moving average model (q) and differencing degree (D). Mathematically, it can be expressed as: ARIMA (p, D, q).

An approach to the forecast problem is given by the ARIMAX model. This model has been commonly used for forecasting renewable energy resources. Total irradiation is forecasted in (Dong et al., 2013; Reikard, 2009) and wind speed is forecasted in (Erdem and Shi, 2011; Liu et al., 2013).

The other proposed approach to the problem is using neural networks, these are found to outperform the regressions models when it comes to high resolutions (Reikard, 2009). Since the late 1990s ANN have been applied in energy forecasting using climatological variables as inputs to an ANN to predict generation values (Sulaiman et al., 2009). There are several ANN models that approach forecasting, in this work a NARX model is selected since they outperform other ANN models as MLP (Perez-Mora et al., 2015).

NARX model relates the current value of a time series to current and past values of the exogenous series influencing, therefore the series of interest (Da Silva Fonseca et al., 2012). This approach based on ANN which allow to find next values in a time series using past measurements of aggregated power and explanatory variable used as inputs to an autoregressive model with exogenous input (ARX) building therefore a NARX recurrent neural networks.

5. Results

Several combinations and configurations of ARIMAX and NARX models have been tried out to obtain the most accurate results. The configuration of each model is different for each energy source. Nevertheless the length of the time series is the same for both sources, starting on 8/9/14 and finishing on the forecasted days, 17/1/15. The days selected to forecast are a week in January which is the end of the available data set and has changes on weather conditions (cloud cover and wind speed) to evaluate the goodness of the obtained results. The parameters that achieve the best set of results are shown in this section.

For ARIMA forecasting the data is split in training set, 95%; and result comparison set, 5%. The length of the vector in the best performing configurations are shown in Tab. 1; where “MA”, stands for vector of non-seasonal moving average coefficients; “SMA”, stands for vector of seasonal moving average coefficients corresponding to an invertible polynomial; “AR”, stands for vector of non-seasonal autoregressive coefficients; “SAR”, stands for vector of seasonal autoregressive coefficients corresponding to a stable polynomial; and “D”, stands for integer indicating the degree of the non-seasonal differencing in the time series.

Tab. 1. ARIMA Configurations & Models

NN Method	MA	SMA	AR	SAR	D	Explanatory Variable
ARIMA Solar	3	0	5	0	0	Irradiation
ARIMA Wind	12	5	7	6	0	Wind speed

For NARX forecasting and in order to avoid over fitting, the data is split in training, 70%; validation, 15%; and result comparison and testing, 15%. The training method used in both cases is Levenberg-Marquardt back-propagation algorithm. The results obtained with the configurations are evaluated using the error measurements explain in this chapter. The best performing methods and neural network configurations are shown in Tab. 2; where “L”, stands for Linear; “ST”, stands for Sigmoid Tangent and “I” stands for Input layer.

Tab. 2. NARX Configurations & Models

NN Method	Number of layers	Neurons in each layer	Activation function	Explanatory Variable
NARX Solar	3	48-24-1	I-ST-L	Irradiation
NARX Wind	3	48-24-1	I-ST-L	Wind speed

The obtained results with the abovementioned methods are presented as an hourly time series of 168 values (equivalent to one week) in Fig. 4 and compared with the real generation.

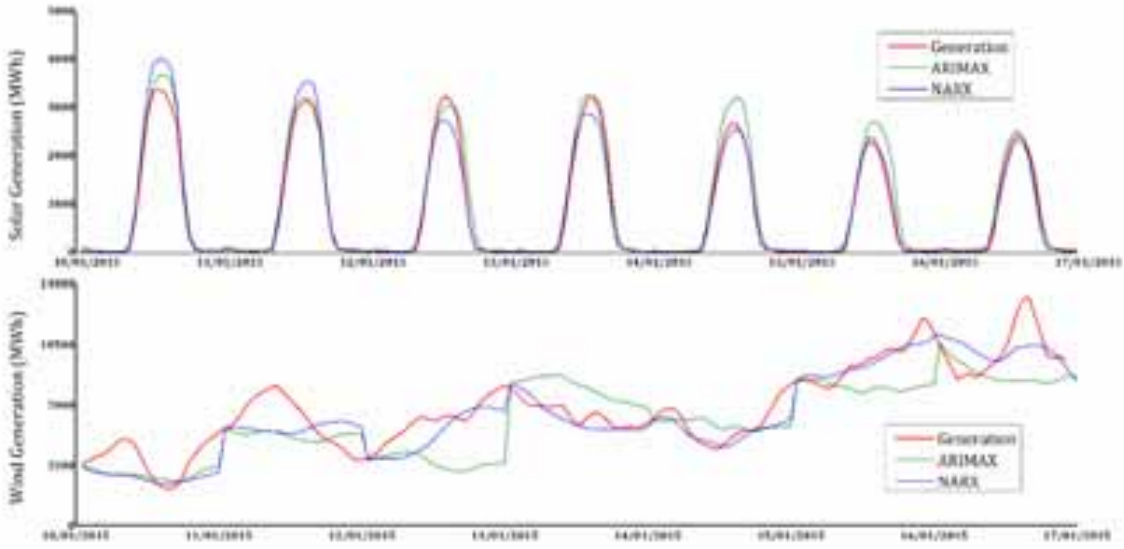

Fig. 4. Different forecast methods results comparison

In order to measure the accuracy of the predictions, the error between the forecasted values and real data is analyzed in this section. To validate the forecast methods in this work, the following calculations are used:

- Mean Bias Error (MBE), shows the deviation of the forecast divided by the installed power. This gives a perception of how the forecasted values are greater or lower than the real ones in percentage (eq. 14).
- Root Mean Square Error (RMSE), shows the deviation of the forecast divided by the installed power. With this error is possible to understand the deviation of the forecast in percentage (eq. 15).
- Mean Absolute Error (MAE), shows the absolute deviation of the forecast divided by the installed power. This gives a perception of the accuracy of the method in terms of percentage (eq. 16), this method is particularly useful for market deviations.
- Mean Absolute Percentage Error (MAPE), shows the same error divided by hourly generation; representing a percentage (eq. 17) (Tseng et al., 2002). This figure is useful to understand the accuracy of the forecast method. The percentage of error escalates when the value of generation is close to zero.
- Mean Daily Absolute Percentage Error (MADPE), the sum of the daily MAE is divided by the sum of the daily generation; thus represents a relative daily error (eq. 18). This figure is useful to understand the accuracy of the method in daily basis, solving MAPE's drawback when generation is close to zero.

$$MBE = \frac{100}{P_{ins}} \frac{1}{n} \sum_{t=1}^{n} S_{(t)} - F_{(t)} \qquad [\%] \qquad \text{(eq. 14)}$$

$$RMSE = \frac{100}{P_{ins}} \sqrt{\frac{1}{n} \sum_{t=1}^{n} \left(S_{(t)} - F_{(t)}\right)^2} \qquad [\%] \qquad \text{(eq. 15)}$$

$$MAE = \frac{100}{P_{ins}} \frac{1}{n} \sum_{t=1}^{n} \left| S_{(t)} - F_{(t)} \right| \quad [\%] \quad \text{(eq. 16)}$$

$$MAPE = \frac{100}{n} \sum_{t=1}^{n} \left| \frac{S_{(t)} - F_{(t)}}{S_{(t)}} \right| \quad [\%] \quad \text{(eq. 17)}$$

$$MADPE = \frac{100}{n} \sum_{d=1}^{n} \frac{\sum_{t=1}^{24} |S_{(t)} - F_{(t)}|}{\sum_{t=1}^{24} |S_{(t)}|} \quad [\%] \quad \text{(eq. 18)}$$

As presented before an ARIMA and NARX models for solar and wind energy generation for one day-ahead forecast have been developed. Both of the proposed models accepts as inputs either the hourly irradiation or the wind speed. The output are 24 hourly values of, either, the solar generation or the wind generation in Spain. After several simulations for the four proposed methods the best configuration found gives the results shown in Tab. 3 for the representative weeks evaluated (10/1/15 – 17/1/15).

Tab. 3: Results for ARIMA and NARX models forecasting solar and wind energy generation

	Error	10/1/15	11/1/15	12/1/15	13/1/15	14/1/15	15/1/15	16/1/15	Mean

6. Conclusions

In this work an ARIMAX and NARX models for solar and wind energy generation forecasting have been developed. The model is developed to obtain hourly results for one day-ahead or main market, from +12 to +36h. Both of the proposed models accept as inputs the time series to forecast and explanatory time series to improve the accuracy of the results. In the case of solar power the explanatory variable used is the irradiation; for wind power the explanatory variable used is the wind speed.

Once the forecasts are compared with the error figures, the results point out that the proposed NARX method outperform ARIMAX for both generation forecasts. It also points out that solar forecasts are more accurate that wind forecasts.

Nevertheless, the solar generation results are very tight for ARIMAX and NARX methods. RMSE, MAE and MAPE values are practically the same and it only differs slightly for MADPE when NARX method (13.51%) outperforms ARIMAX method (15.98%). This indicator is the most reliable for generations which fall off to values close to 0MWh as the solar generation does during the night.

For wind generation the results are much clearer. NARX method outperforms ARIMAX in every single error figure. In terms of MAPE, the result for NARX is 13.62% and ARIMAX reaches 21.67%. MADPE values are similar to MAPE in this case.

The results of performance achieved with NARX method for solar and wind forecasts in terms of MADPE are very similar; 13.51% in solar and 14.12% in wind. On the other hand the results obtained with the ARIMAX method in terms of MADPE differ for solar and wind forecasts; while in solar forecast the result is similar to the achieved in NARX, 15.98%; the results in wind generation are much worse reaching 22.77%, which is the worst result obtained for any of the proposed forecasting methods.

MBE figure shows the trend of the error in forecasting, if it is either overestimated or it is a lower value of energy generation. When averaging this figure on weekly basis the absolute value tends to decrease since the errors cancel themselves.

Abstract

In this work, we assess the performance of statistical models for intra-hour solar forecasting. More precisely, a linear recursive model and a nonlinear model are used for generating solar irradiance forecasts at temporal resolutions of a few minutes and over multiple horizons. Our approach is applied to forecasting solar irradiance at single sites using the sole historical ground observations of solar irradiance. The benchmarking of the forecasting methods is made at four sites that exhibit different sky conditions.

Keywords: *intra-hour solar forecasting, statistical models*

1. Introduction

The availability of accurate solar forecasts is of great importance for an efficient integration of large shares of solar energy into the electricity grid (Lorenz and Heinemann, 2012). To ensure reliable grid operation, utilities require accurate forecasts at different granularities and different forecasting time horizons (Kostylev and Pavloski, 2011). Depending on the forecast horizon, different input data and forecasting models are appropriate. Statistical models with on-site measured irradiance are adequate for the very short-term time scale ranging from 5 minutes up to 6 hours (Lorenz and Heinemann, 2012).

Today, solar forecasts are essentially produced on an hourly basis. However, there is a broad consensus among energy experts, electric utilities and regulatory authorities on the future need for intra-hour forecasts in order to accommodate the increasing share of photovoltaic power in power systems.

In this work, the focus is placed on lead times from 10 minutes to 3 hours ahead with a granularity of 10 minutes. Consequently, we assess the performance of two statistical models: a linear recursive model ARMA.rls (Ljung and Söderström, 1983) and a nonlinear model ν-SVM based on support vector machine (Smola and Schölkopf, 2004) for intra-hour solar forecasting. The benchmarking of the two methods is made at four sites that exhibit different sky conditions.

2. Data

Four sites are used to evaluate the performance of the forecasting methods. Three of these sites are island sites: Saint-Pierre and Le Tampon (Reunion island), Oahu-Hawaii (Wilcox and Andreas, 2010). The fourth one is located in Las Vegas (Andreas and Stoffel, 2006). The choice of the aforementioned sites aims at testing the different forecasting techniques for different sky conditions. Table 1 gives the details related to the four locations. The data (two years) used to build the models are Global Horizontal Irradiances (GHI) measured at the four stations. Contrary to the ARMA.rls method, the machine learning technique ν-SVM investigated in this work is a supervised learning method, which consists in learning input-output mappings from empirical data (the training dataset). Consequently, data have been divided into training and test datasets. The test dataset (one year) is used to evaluate the performance of the forecasting techniques. Table 1 gives also the mean GHI of the test year used to compute the relative error metrics (see section 5).

3. Data processing

The Bird clear sky model (Bird and Huldstrom, 1981) is used to remove the daily and annual seasonalities in the global horizontal solar irradiance (GHI) time series then leading to the definition and use of the clear sky index:

$$k^* = G/G_{clsk} \qquad \text{(eq. 1)}$$

where G is the measured global irradiance and G_{clsk} is the output of the Bird clear sky model. With this methodology, the models designed in this work are dedicated to the stochastic part of the global radiation due to cloud cover, leaving the geometric and the deterministic part to be modeled by the clear sky model.

It is also a common practice to filter out the data in order to remove night hours. This choice is justified because during these periods there is obviously no significant solar radiation to generate electricity (i.e. low potential overnight). We chose to apply a filtering criterion based on the solar zenith angle (θ_Z): solar radiation data for which the solar zenith angle is greater than 80° have been removed. In addition, this filtering process allows to discard data with less precision as measurement uncertainties associated with pyranometers are typically much higher than ± 3.0% for SZA > 80°. Notice also that for the sunrise and sunset, the prediction is also very difficult (mainly in mountainous areas) owing to the geographical shield.

4. Forecasting methods

The performance of the linear ARMA.rls and nonlinear ν-SVM models are appraised against two reference models namely persistence and climatologic mean models.

4.1 Reference models

We propose to test our forecasting methods against reference models like persistence and climatology.

The persistence model is expressed as follows:

$$\widehat{k^*}(t+h) = k^*(t) \qquad \text{(eq. 2)}$$

This model assumes that the clear sky index for each forecasting time horizon h only depends on the previous value, which means that the sky conditions remain invariant between time t and time $t+h$.

We also propose the climatological mean model, which is independent of the forecast time horizon (Lorenz

and Heinemann, 2012). More precisely, this model performs a constant forecast of the clear sky index that corresponds to its mean historical value:

$$\widehat{k^*}(t+h) = mean\,(k^*(t))_{training\ period} \qquad \text{(eq. 3)}$$

4.2 ARMA.rls model

The Auto Regressive Moving Average (ARMA) model is a popular technique in the realm of solar forecasting. In particular, it has been extensively studied in renewable energy forecasting and, owing to its parsimony, it has turned out to be a very tough competitor to beat. Applications include, among others forecasting of wind power generation (Pinson, P., 2012), online power forecasting (Bacher et al., 2009) and wave energy flux (Pinson et al., 2012).

An ARMA(p,q) model with p AR terms and q MA terms is defined as follows:

$$\widehat{k^*}(t+h) = \theta_0 + \sum_{i=1}^{p} \theta_i k^*(t-i+1) + \varepsilon(t) + \sum_{j=1}^{q} \phi_j \epsilon(t—j) \qquad \text{(eq. 4)}$$

$\epsilon(t)$ is an independent and identically distributed random variable with a zero mean. The vector $\Theta = \left(\theta_0, \theta_1, \cdots, \theta_p, \Phi_{1,}, \cdots, \Phi_q\right)$ contains the set of parameters to be estimated. A classic setting based on a least-squares method and training data can be used to estimate the set of parameters (Chatfield, 2004).

However, in this work, to estimate the model's parameters, we chose a variation of the least squares method, namely the Recursive Least Square (RLS) method (see Ljung and Söderström, 1983 for details of implementation). This method offers the advantage of reducing the computational cost for estimating the model's parameters. In addition, the parameters are updated in real-time as new data become available (no training set is necessary here). This contrasts with more intensive estimation methods operating on a sliding window where the estimation process is being carried out at each time step. Hence, the RLS method is particularly well suited in an operational context where forecasts have to be timely delivered.

Regarding the structure of the ARMA model, the use of the classical ACF (Auto Correlation Function) and PACF (Partial Auto Correlation Function) techniques (Chatfield, 2004) led to the selection of the following orders $p = 6$ and $q = 2$.

4.3 ν-SVM model

The support vector machine (SVM) is part of the kernel based machine learning techniques used in classification tasks and regression problems (Smola and Schölkopf, 2004). The forecasted clear sky index for time horizon h is given by Eq. (5):

$$\hat{k}^*(t+h) = \sum_{i=1}^{n} \alpha_i\, k_{rbf}(\mathbf{x}_i, \mathbf{x}_*) + b \qquad \text{(eq. 5)}$$

k_{rbf} denotes the kernel radial basis function $k_{rbf}(x_p, x_q) = \exp\left[-\gamma\left|(x_p - x_q)\right|\right]$ with hyperparameter γ and b a bias parameter. SVM models are generally stated as a kernel-based method. Indeed, it can be shown that, given n training samples, the prediction for an input test vector $\mathbf{x}_*$ can be seen in terms of a linear combination of n kernel functions; each one centered on a training point $\mathbf{x}_i$. Notice that $\mathbf{x}_i$ and $\mathbf{x}_*$ are vectors that contain the p past values of the clear sky index. A variant of the SVM algorithm called ν-SVM allows controlling the amount of kernel functions used in the regression.

The parameter b (or bias parameter) is derived from the preceding equation and some specific conditions (see Smola and Schölkopf, 2004 for details). The coefficients α_i are related to the difference of two Lagrange multipliers, which are the solutions of a quadratic programming (QP) problem (Smola and Schölkopf, 2004).

Unlike artificial neural networks, which are confronted with the problem of local minima, here the problem is strictly convex and the QP problem has a unique solution. In addition, it must be stressed that not all the training patterns participate in the preceding relationship. Indeed, a convenient choice of a cost function i.e. Vapnik's ε-insensitive function (Smola and Schölkopf, 2004) in the QP problem enables to obtain a sparse solution. The latter means that only some of the coefficients α_i will be nonzero. The examples that come with non-vanishing coefficients are called Support Vectors.

The parameters related to the SVM optimization process are a parameter C that controls the trade-off between overfitting and generalization capability of the algorithm, a parameter ν that controls the amount of support vectors used in the regression and the parameter γ of the covariance function that controls the smoothness of the covariance function (Fonseca Junior et al., 2013). These parameters have been optimized through the use of a k-fold cross-validation procedure (Fonseca Junior et al., 2013). In the present study, regarding the implementation of the support vector regression, we used the LibSVM library (Chang et al., 2011).

5. Results

In the realm of the solar forecasting community, the commonly used error metrics are: the Root Mean Square Error (RMSE), Mean Absolute Error (MAE) and Mean Bias Error (MBE). Relative counterparts (rRMSE, rMBE and rMAE) are obtained by normalization with the mean GHI of the test period (see Table 1). The interested reader is referred to Lorenz and Heinemann (2012) for the definition of these error metrics.

In this work, a special focus is placed on the rRMSE. This error metric tends (unlike the rMAE) to be influenced by some extreme events or outliers. Nonetheless, most utility users find this metric suitable as large forecast error results in high financial losses (Lorenz and Heinemann, 2012).

Tables 2, 3 and 4 list respectively the rRMSE, rMBE and rMAE for each forecasting time horizon and for each location. As shown by these tables, one can a priori state that the performances of the different models depend heavily on the sky conditions experienced by each site. The persistence model is a good indicator of the type of climate experienced by a particular site. As seen, it seems that the Las Vegas location experiences high occurrences of clear sky situations while the insular sites (particularly Le Tampon and Oahu) exhibit more variable sky conditions.

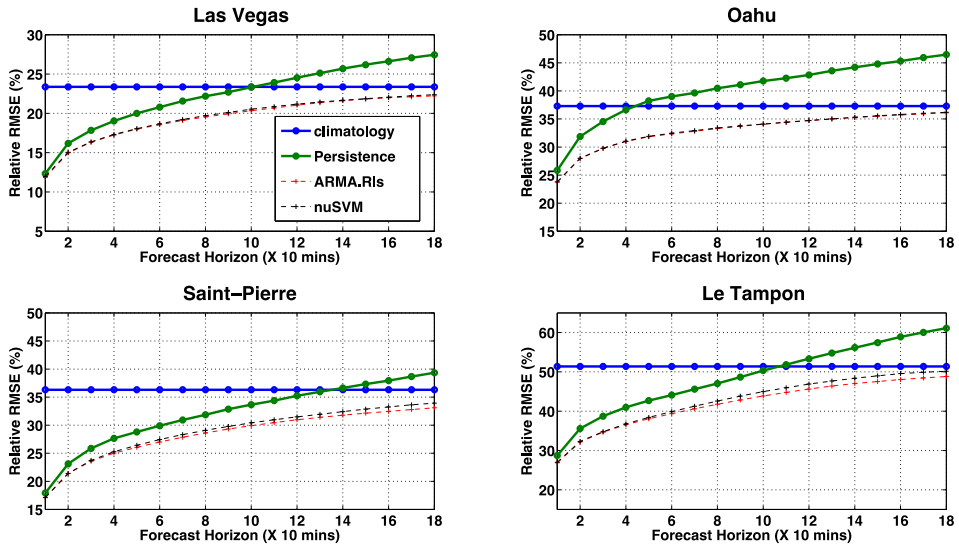

Fig. 1: Accuracy of intra-hour solar forecasting

Fig. 1 plots the rRMSE of the different methods for forecast horizon ranging from 10 minutes to 180 minutes. Fig.1 demonstrates the better performance of the SVM method (ν-SVM) and ARMA.rls model over the persistence model when the forecast horizon increases. As shown by Fig.1, the linear recursive model ARMA.rls performs equally well than the nonlinear SVM model. It even produces slightly better forecasts in the case of Saint-Pierre and Le Tampon. Further, the improvement is more pronounced as the forecast horizon increases. One may notice also that the performances of the linear and nonlinear models tend

towards that of the climatological mean. This behavior is consistent, as these methods tend to asymptotically model the mean of the data.

Overall, contrary to the ν-SVM model, it appears that the ARMA.rls method produces less biased forecasts (see Table 3). Regarding the rMAE metric, except for Las Vegas, the ARMA technique performs better than the SVM method.

Tab. 2: Relative RMSE in % for each location and for each forecast horizon. Pers, RLS and SVM correspond respectively for Persistence, ARMA.rls and ν-SVM models.

6. Conclusion

This work proposes a benchmarking of techniques for intra-hour solar forecasting. A machine learning technique such as support vector machine was evaluated against a recursive linear model and reference models like persistence and climatological mean. It was shown that a linear recursive technique like ARMA.rls performs equally well or slightly better than a non-linear method such as support vector machine.

As a conclusion, it appears that a simple technique like ARMA.rls could be a viable solution to predict solar radiation at high resolutions. In addition, the recursive estimation of the model's parameters makes the method very well suited to online forecasting.

Abstract

Production of electricity from solar energy is gaining a tremendous significance. The integration of all solar energy power to the electricity grid challenges new horizons. Mainly, the prediction of short-term power generation to optimise its management, avoid situations of load reduction and anticipate supplying problems.

This paper presents a methodology to forecast hourly global horizontal solar irradiance (GHI) and direct normal irradiance (DNI) using global forecast system (GFS) model from NOAA and MACC model from ECMWF. Three clear sky models are tested to increase temporal resolution of GFS model from 3 hours to 1 hour. The forecasting horizon of the predictions is six days. The model has been validated using a ground radiometric station in Qatar with data from 2014 to 2015. The errors of the best model tested are 19% in terms of relative RMSD and -1.68% regarding relative bias for GHI. In the case of DNI, relative RMSD is 48.43%, and relative bias is -3.40%.

Keywords: *solar radiation forecasting, AOD forecasting, DNI prediction, Atmospheric aerosols*

1. Introduction

Solar energy is gaining an enormous significance due to the unsustainable current energetic model. In the case of solar power, technology to produce electricity, the integration of all these power to the electricity grid challenges new horizons. The most important are the estimation of short range power generation to optimise its management, avoid situations of load reduction and anticipate supplying problems (Pelland, Remund, Kleissl, Oozeki, & De Brabandere, 2013).

In this study, we present a methodology to forecast hourly global horizontal solar irradiance (GHI) and direct normal irradiance (DNI) using cloudiness from global forecast system (GFS) model from NOAA and AOD and water vapour predictions from MACC model from ECMWF. The forecasting horizon of the predictions is six days. The model has been validated using a ground radiometric station in Qatar with data from 2013 to 2015.

2. Experimental Solar Radiation Dataset

The radiometric data employed in this study for the validation is located in the Middle East. The instruments in the station are Kipp & Zonen high precision and measurements are available at the end of November 2012. The station is equipped with a Solys2 sun tracker with sun sensor kit for improved tracking accuracy and shading ball assembly for diffuse measurements. Mounted on the sun tracker are one CHP1 pyrheliometer for measuring DNI and two CMP11 pyranometers (one of them shaded) for GHI and DHI measurements; both pyranometers are fitted with CVF 3 ventilation units. Data from the monitoring station are collected as minute

doi:10.18086/swc.2015.07.12 Available at http://proceedings.ises.org

by minute averages in W/m^2. Maintenance and checks are conducted on a daily basis and consist of cleaning all sensors and tests on the tracking and alignment of the sensors and shadow ball as well as visual checks on the collected data (Bachour & Perez-Astudillo, 2014; Perez-Astudillo & Bachour, 2014). Two type of quality filters has been applied to the data. The first group of filters is based on physical limits of solar radiation. We have removed from the comparison values lower than zero and higher than extraterrestrial solar radiation. The second group of filters is more restrictive and is based on BSRN quality filters (Long & Dutton, 2002).

3. Methodology

The model developed uses 3-hourly solar radiation predictions from GFS model to obtain hourly values using a statistical downscaling model and a clear sky model.

The Global Forecast System (GFS) is a global numerical weather prediction model from NOAA. The GFS model covers the entire globe at a base horizontal resolution of 28 kilometres between grid points, which is used by the operational forecasters who predict weather out to 16 days in the future. In this work, we obtain hourly predictions for six days ahead.

The predictions of hourly GHI are calculated using directly the output variable DSWRF at a surface level from GFS model. The nearest grid output point of GFS model to each station is used as the basic predictions. Afterwards, 3-hourly values from GFS model are calculated as hourly values with the interpolation of k_c which is the quotient between measured global solar radiation and clear sky solar radiation. Clear sky solar radiation is calculated with three different models as they behave better than others depending on the climatic conditions of the sites. ESRA (Rigollier, Bauer, & Wald, 2000), SOLIS (Ineichen, 2008) and REST2 (Gueymard, 2008) clear sky models have been tested. Hourly atmospheric parameters of AOD at 550nm and water vapour column are obtained from MACC-II model (Monitoring Atmospheric Composition & Climate from ECMWF) for clear sky models. The spatial resolution of MACC-II model is 1.125ºx1.125º. MACC-II uses a comprehensive global monitoring and forecasting system that estimates the state of the atmosphere on a daily basis, combining information from models and observations, and it provides a daily 5-day forecast.

Once GHI hourly predictions are calculated, DNI hourly predictions are obtained using DirIndex model (Perez, P.Ineichen, E.Maxwell, R.Seals, & A.Zelenka, 1992).

An algorithm to detect clear sky days has been applied (Zarzalejo, Polo, Martín, Ramírez, & Espinar, 2009) to calculate to clear sky conditions. In such a case, the prediction for the next day for GHI and DNI components are made using the clear sky model. Fig 1. shows the schema of the methodology employed to obtain hourly predictions of GHI and DNI for six days ahead.

4. Results

The parameters to calculate the errors of the models are mean bias deviation (MBD), root mean squared deviation (RMSD) and its relative value as rMBD and rRMSD. The relative expressions are obtained using the following equations:

$$\mathrm{rMBD} = \frac{1}{N}\sum_{i=1}^{N}\left(\hat{x}_i - x_i\right) \qquad \text{(eq. 1)}$$

$$\mathrm{rRMSD} = \frac{\sqrt{\sum_{i=1}^{n}(x_i - \hat{x}_i)^2 / n}}{\overline{x}} \qquad \text{(eq. 2)}$$

where N is the population size, x is the observed value, $\overline{x}$ is the mean of observed values and $\hat{x}$ is the predicted value.

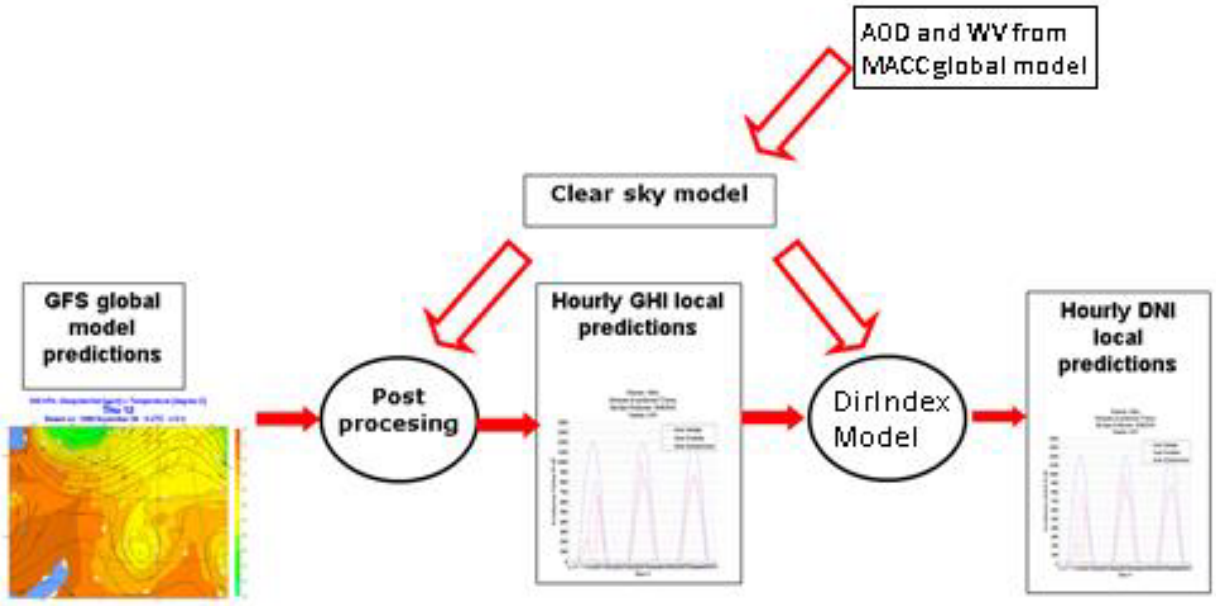

Fig. 1. Schema of the methodology used to obtain hourly predictions of GHI and DNI

Last parameters are often insufficient to establish a complete, coherent comparison for benchmarking. Due to this, additional measures for model quality based on the analysis of cumulative distribution function (CDF) are used. A comprehensive approach to analyse the deviations of measured and predicted data is applied. It is based on the Kolmogorov-Smirnov (KS) test and defines new parameters to quantify the similarity of the two CDFs. Although there are several statistical tests and ways of evaluating the goodness of a model, the KS test has the advantage of making no assumption about the data distribution and is thus a non-parametric, distribution-free test. The KS test determines if two datasets differ significantly. The test consists of comparing the distribution of a dataset to a reference distribution. It can be done by converting the list of data points to an unbiased estimator $S(x_i)$ of the CDF, $i = 1..N$, N is the population size. The KS statistic D is defined as the maximum value of the absolute difference between the two CDFs:

$$D = \max \left| S(\mathrm{x}_i) - \mathrm{R}\left(x_i\right) \right| \qquad \text{(eq. 3)}$$

where $R(x_i)$ is the CDF of the reference dataset. Thus, if the D statistic is lower than the threshold value VC, the null hypothesis that the two datasets come from the same distribution cannot be rejected. The critical value depends on N and is calculated for a 99% level of confidence as:

$$V_c = \frac{1.63}{\sqrt{N}}, \quad N \geq 35 \qquad \text{(eq. 4)}$$

This test detects smaller deviations in cumulative distributions than the $\chi 2$ test does. However, instead of using the original one, an extended KS test is used, in which the distances between the CDFs are calculated over the whole range of the variable x, i.e. the solar radiation. A discretization in $n = 1 \ldots m$ levels is applied here. In the following $m = 100$ intervals as a reasonable choice are used. Greater order of magnitude for$m$ is not recommended since it implies more computational cost for no improvement in the accuracy of the result. The interval distance p is thus defined as:

$$p = \frac{x_{\max} - x_{\min}}{m}, \quad m = 100 \qquad \text{(eq. 5)}$$

where x_{max} and x_{min} are the extreme values of the independent variable. Then, the distances between the CDFs are defined, for each interval, as:

$$D_n = \left| S\left(x_j\right) - R\left(x_j\right) \right|, \quad x_j \in \left[x_{\min} + \left(n-1\right) p, x_{\min} + np \right] \qquad \text{(eq. 6)}$$

The representation of the values D_n, along with the critical value, gives the complete testing behaviour of the CDF on the reference over the whole range. However, although application of the KS test contributes valuable information, it only materialises in the acceptance or rejection of the null hypothesis. In the next paragraphs, new parameters are proposed, which, based on the estimation of the distance between the two CDFs for the sets compared, define quantitative measures that can be used to rank models (Espinar et al., 2009).

The KSI parameter (Kolmogorov-Smirnov test Integral) is defined as the integral of the area between the CDFs for the two sets. The unit of this index is the same for the corresponding magnitude, the value of which depends on it. The KSI is defined as the integral:

$$KSI = \int_{x\min}^{x\max} D_n dx \qquad \text{(eq. 6)}$$

As D_n is a discrete variable and the number of integration intervals is identical in all cases, trapezoidal integration is possible over the whole range of the independent variable x. A percentage of KSI is obtained by normalising the critical area, $a_{critical}$:

$$KSI\% = \frac{\int_{x\min}^{x\max} D_n dx}{a_{critical}} * 100 \qquad \text{(eq. 6)}$$

where $a_{critical}$ is calculated as:

$$a_{critical} = V_c * (x_{max} - x_{min})$$

where V_c is the critical value for the level of confidence selected and (x_{max}, x_{min}) are the extreme values of the independent variable. Normalisation to the key area enables the comparison of different KSI values from various tests. The minimum value of the KSI Index is zero, in which case, it can be said that the CDFs of the two sets compared are the same.

Over, Over %, KSE and RIO parameters are also used to calculate the error of the models. More information about them can be found in (Espinar et al., 2009).

The assessment of the models proposed is performed with hourly ground radiometric data (GHI and DNI) for the period from 1st of January 2014 to 28th of February 2015. In the validation, only values for solar zenithal angle higher than 85 degrees are considered.

4.1 Results for ESRA clear sky model

In this section, the results for ESRA clear sky model is presented. The next graphics show the scatter plot for predicted and measured hourly GHI and DNI.

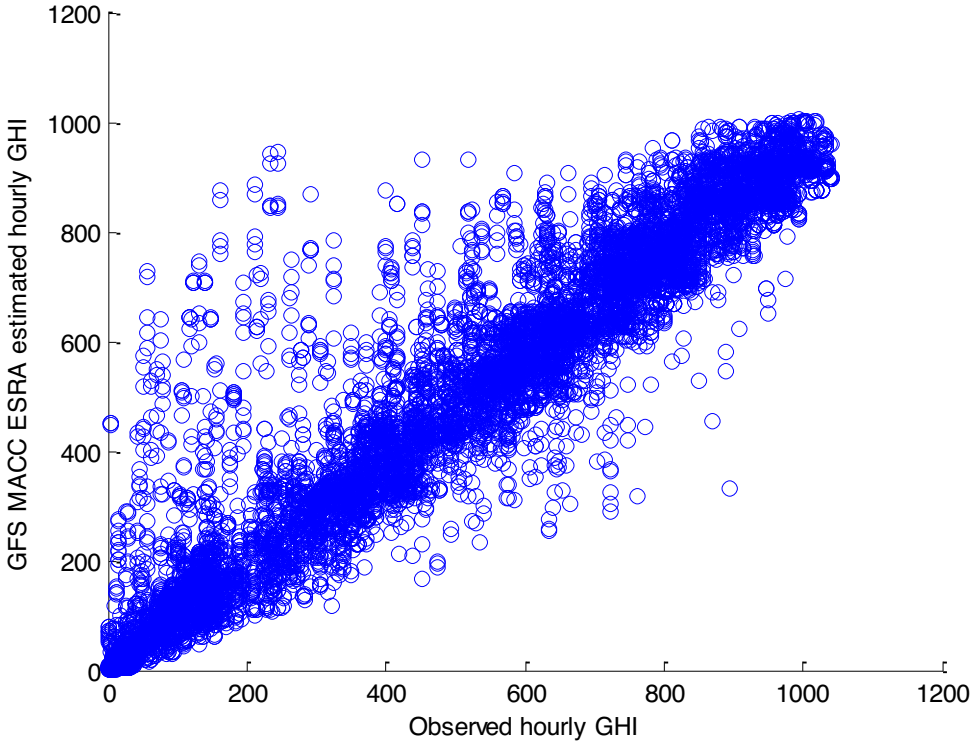

Fig. 2: Scattering plot of GFS ESRA clear sky model predictions and measurements of GHI for the next six days.

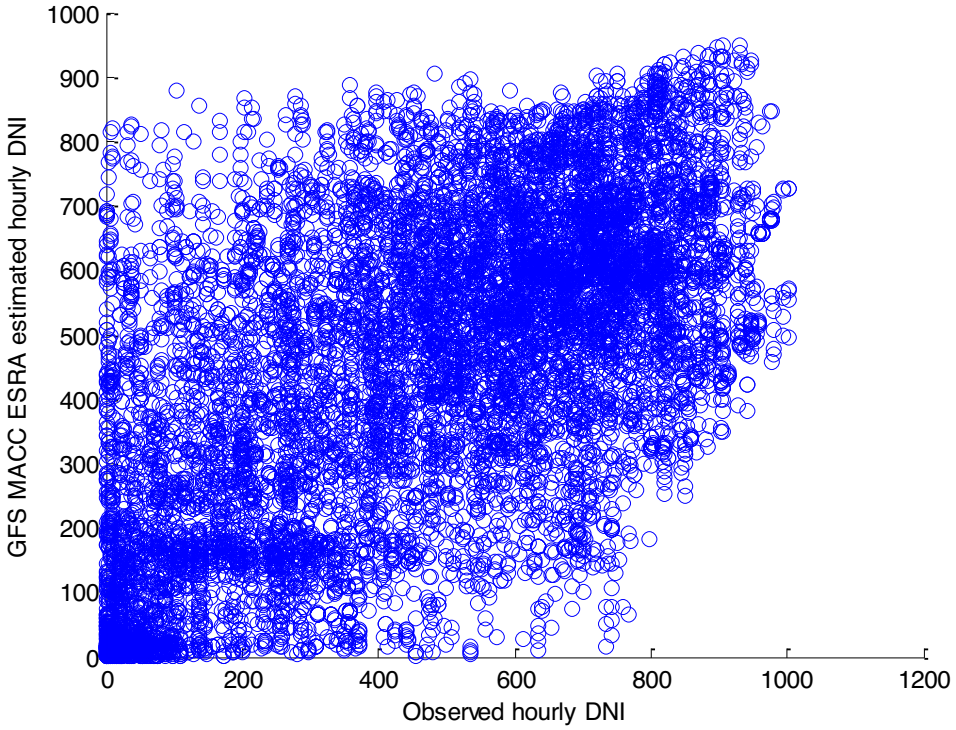

Fig. 3: Scattering plot of GFS ESRA clear sky model predictions and measurements of DNI for the next six days.

As can be seen in the last scatter plots, predictions of GHI are much better correlated than DNI predictions.

Next figures present forecasts (in blue colour) and measurements (in green colour) of hourly GHI and DNI and extraterrestrial solar irradiance (in red colour) in true solar time temporal reference for date 01/01/2014 for six days of prediction ahead as an example of the results of the model.

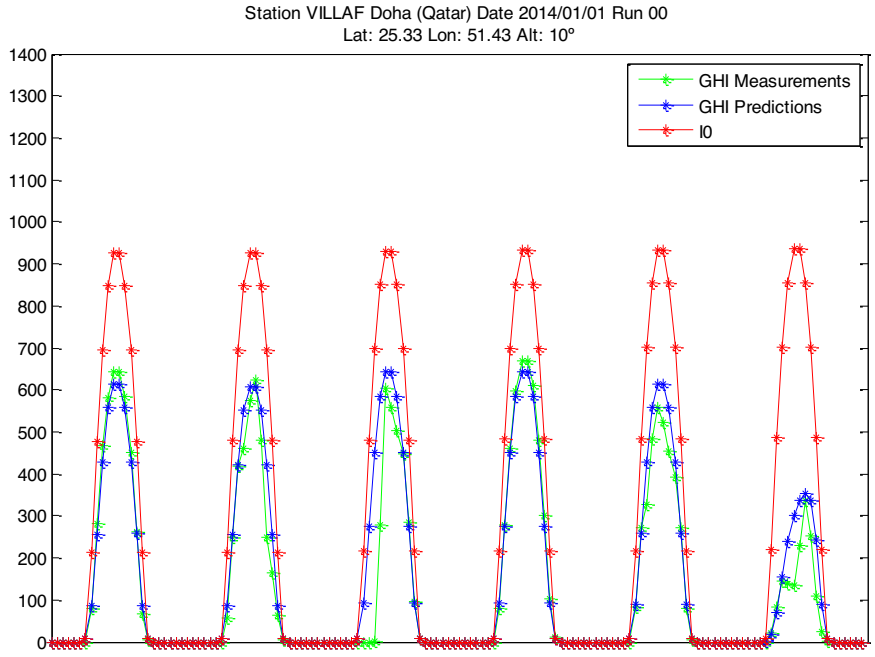

Fig. 4: GFS ESRA clear sky model predictions and measurements of hourly GHI for the next six days.

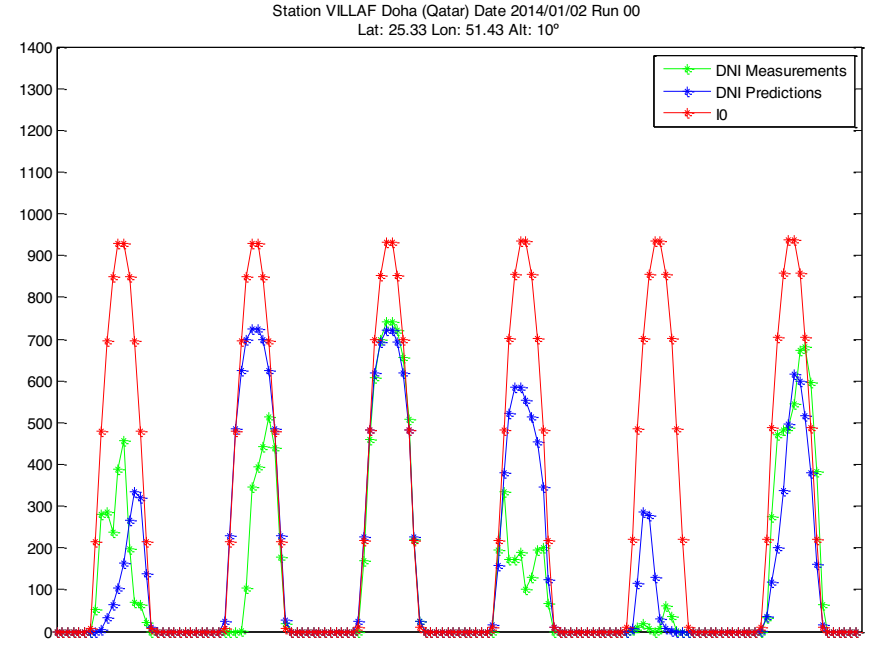

Fig. 5: GFS ESRA clear sky model predictions and measurements of hourly DNI for the next six days.

The next tables show MBD, RMSD, rMBD, rRMSD and R for GHI and DNI, for each day ahead of prediction from 1 to 6 and total errors of the models.

Tab. 1: Statistical errors of hourly GHI predictions validated with ground measurements. ERSA clear sky model

Day ahead	MBD (Wh/m2)	RMSD(Wh/m2)	rMBD (%)	rRMSD (%)	R
1	-11.39	87.54	-2.32	17.82	0.96
2	-8.36	94.34	-1.70	19.23	0.95
3	-8.61	94.88	-1.75	19.27	0.95
4	5.37	98.17	-1.08	19.80	0.95
5	-9.86	89.15	-1.98	17.87	0.96
6	-6.37	98.90	-1.28	19.91	0.95
TOTAL	**-8.32**	**93.93**	**-1.68**	**19.00**	**0.95**

Tab. 2: Statistical errors of hourly DNI predictions validated with ground measurements. ERSA clear sky model

Day ahead	MBD (Wh/m2)	RMSD(Wh/m2)	rMBD (%)	rRMSD (%)	R
1	-19.17	215.17	-4.17	46.78	0.67
2	-14.23	226.91	-3.10	49.41	0.62
3	-15.72	225.30	-3.42	48.96	0.63
4	-12.96	229.82	-2.78	49.33	0.61
5	-16.53	222.18	-3.56	47.77	0.63
6	-15.67	222.72	-3.39	48.25	0.64
TOTAL	**-15.71**	**223.73**	**-3.40**	**48.43**	**0.63**

GHI predictions are almost unbiased, and rRMSD is reasonably small. The value of rMBD decreases as the temporal horizon of prediction increases. On the contrary, the value of rRMSD increases as the horizon of prediction increases. The predictions are well correlated as the total mean value of R is 0.95.

DNI predictions have a small bias of around 3%. rRMSD is big in the case of DNI. The value of rMBD decreases as the temporal horizon of prediction increases. On the contrary, the value of rRMSD increases as the horizon of prediction increases. The predictions are relatively well correlated as the total mean value of R is 0.63.

Next, we present tables with MBD, RMSD, rMBD and rRMSD for GHI and DNI, for each hour ahead forecasted in true solar time (TST) within the first day of prediction.

In the case of GHI, rRMSD is lower in the central hours of the day and considerably high during sunrise and sunset. |The predictions are biased during the first hours of the day, most probably due to some walls near the station which hide the horizon when the sun is appearing in the sky. During the rest of the day, the model presents unbiased results with a considerable value in the last two hours of the day.

In the case of DNI, we have almost the same analysis. rRMSD is lower in the central hours of the day and considerably high during sunrise and sunset. |In this case, the predictions of DNI are not biased during the first

hours of the day because there is no wall between the pyrheliometer and the sun disk. During the rest of the day, the model presents unbiased results with a considerable value in the last two hours of the day.

Tab. 3: Statistical errors for each hour of the first day of prediction. Hourly GHI predictions validated with ground measurements. ERSA clear sky model

Hour ahead in TST	MBD (Wh/m2)	RMSD(Wh/m2)	rMBD (%)	rRMSD (%)

The next graphics show the Kolmogorov-Smirnov test (D_n) for hourly GHI and DNI. The black dotted line represents the critical limit, V_c, calculated for the number of values available.

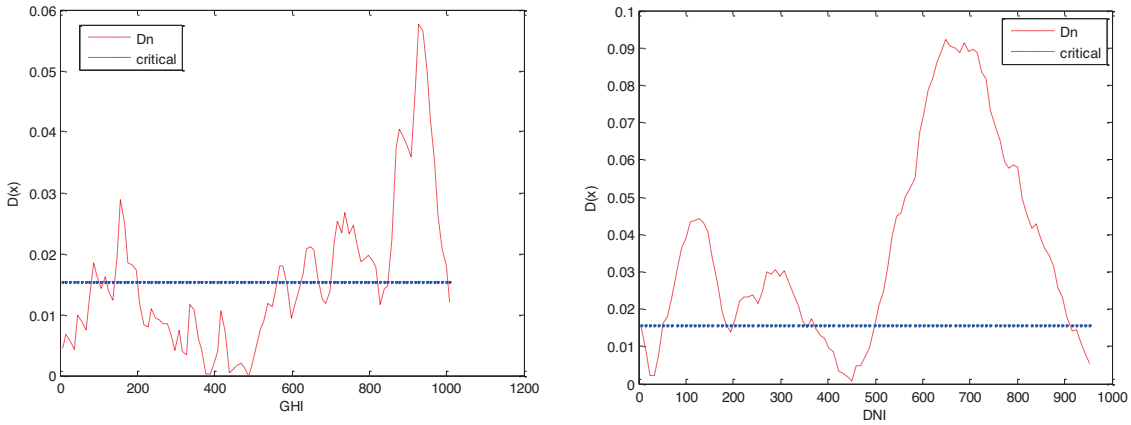

Fig. 6: Kolmogorov-Smirnov test for hourly GFS predictions and ground measurements of GHI and DNI (Wh/m^2) for Doha.

As we can see from the last graphics, there is a notorious difference in GHI predictions and measurements for high values. In the case of DNI, the difference is notorious for low and high values.

Next graphics show the distribution of hourly measurements (red line) and predictions (blue line) for GHI and DNI. The frequency of the range of values from 0 to 1000 Wh/m^2 for intervals of 100 Wh/m^2 is presented.

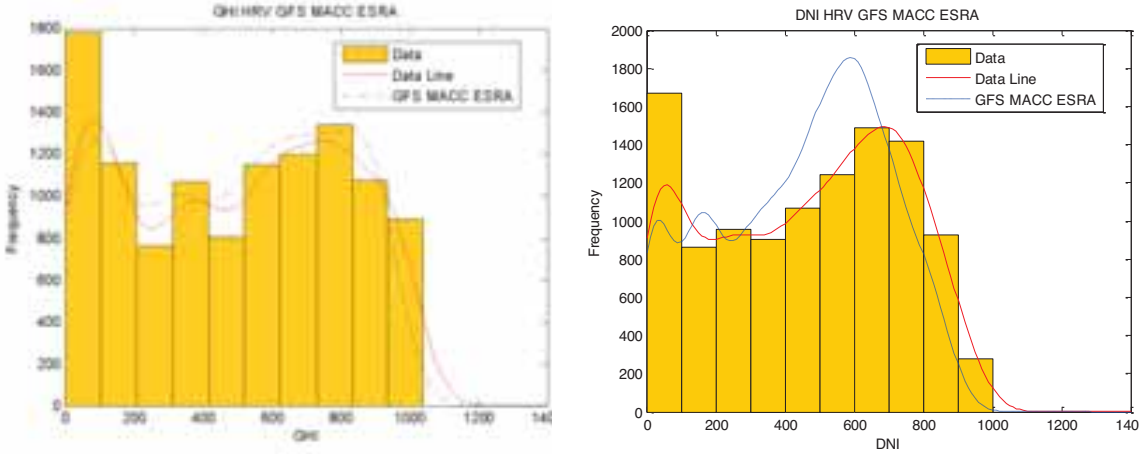

Fig. 7: Cumulative distribution function of hourly GHI and DNI predictions in DOHA.

Next graphics show the Cumulative Distribution Function of hourly GHI and DNI:

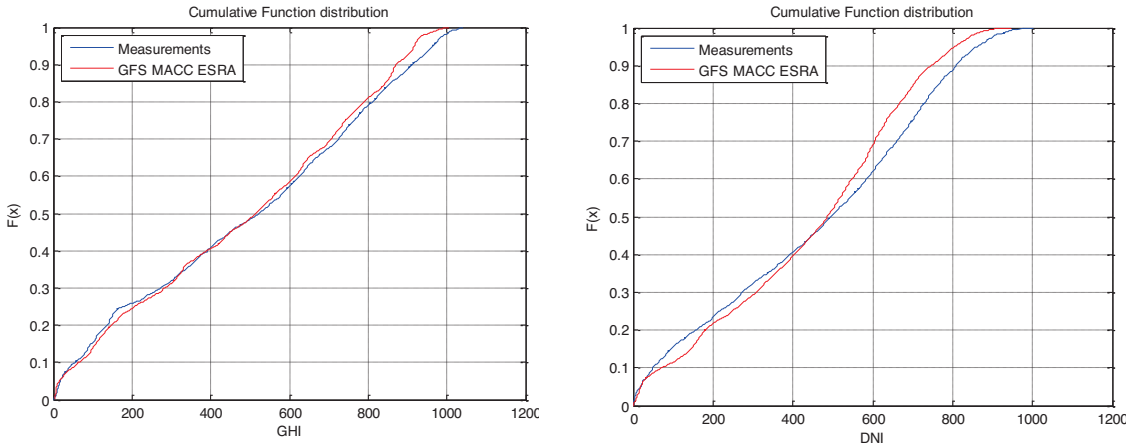

Fig. 8: Cumulative distribution function of hourly GHI and DNI GFS predictions and measurements in DOHA.

Finally, IKS, IKS %, Over, Over %, KSE and RIO for hourly GHI and DNI is presented:

Tab. 5: Errors for hourly GHI and DNI predictions in DOHA. ESRA clear sky model

Variable	IKS	IKS %	Over	Over %	KSE	RIO
GHI	15.98	102.95	4.77	30.73	133.69	76.34
DNI	34.68	232.24	21.48	143.86	376.10	212.26

As main conclusions for ESRA clear sky model, the results for GHI presents acceptable magnitude of the error regarding rRMSD. However, DNI is considerable high. One of the reasons could be that the model used to transform from GHI to DNI has been developed in the climatology of the USA and is not valid for the Gulf climate.

4.1 Results for SOLIS and REST2 clear sky models

In this section, we present the results for SOLIS and REST2 clear sky models. The next tables show MBD, RMSD, rMBD, rRMSD and R for GHI and DNI, for each day ahead of prediction from 1 to 6 and total errors of the models.

Tab. 6: Statistical errors of hourly GHI predictions validated with ground measurements. SOLIS clear sky model

Day ahead	MBD (Wh/m2)	RMSD(Wh/m2)	rMBD (%)	rRMSD (%)	R
1	-71.39	131.61	-16.62	30.64	0.92
2	-67.78	133.61	-15.70	30.95	0.91
3	-67.57	135.86	-15.56	31.27	0.91
4	-63.39	139.55	-14.52	31.97	0.89
5	-62.91	137.31	-14.51	31.67	0.90
6	-63.63	139.75	-14.56	31.97	0.90
TOTAL	**-66.10**	**136.32**	**-15.24**	**31.42**	**0.90**

Tab. 7: Statistical errors of hourly DNI predictions validated with ground measurements. SOLIS clear sky model

Day ahead	MBD (Wh/m2)	RMSD(Wh/m2)	rMBD (%)	rRMSD (%)	R
1	-62.43	243.11	-13.60	52.95	0.62
2	-51.26	249.78	-11.10	54.10	0.58
3	-49.12	246.56	-10.61	53.28	0.59
4	-37.23	250.16	-7.99	53.73	0.56
5	-42.23	242.86	-9.20	52.94	0.60
6	-42.47	249.98	-9.10	53.55	0.57
TOTAL	**-47.45**	**247.10**	**-10.26**	**53.43**	**0.59**

Tab. 8: Statistical errors of hourly GHI predictions validated with ground measurements. REST2 clear sky model

Day ahead	MBD (Wh/m2)	RMSD(Wh/m2)	rMBD (%)	rRMSD (%)	R
1	-17.82	91.73	-4.15	21.36	0.94
2	-12.31	91.10	-2.85	21.10	0.94
3	-12.22	97.02	-2.81	22.33	0.94
4	-4.09	97.69	-0.93	22.35	0.94
5	-3.98	105.38	-0.92	24.25	0.92
6	-2.71	106.47	-0.62	24.33	0.92
TOTAL	**-8.84**	**98.43**	**-2.04**	**22.67**	**0.93**

Tab. 9: Statistical errors of hourly DNI predictions validated with ground measurements. REST2 clear sky model

Day ahead	MBD (Wh/m2)	RMSD(Wh/m2)	rMBD (%)	rRMSD (%)	R
1	-71.92	240.23	-15.79	52.74	0.64
2	-61.99	247.43	-13.61	54.33	0.60
3	-61.74	242.45	-13.53	53.13	0.62
4	-47.69	245.26	-10.39	53.45	0.60
5	-52.53	239.70	-11.61	52.96	0.62
6	-52.22	246.62	-11.34	53.55	0.60
TOTAL	**-57.99**	**243.64**	**-12.70**	**53.36**	**0.61**

Conclusions for these clear sky models are similar as for ESRA model. Errors for SOLIS clear sky model are considerable high in term of rRMSD. The GFS-SOLIS models also present a substantial underestimation.

In the case of REST2 model, the errors regarding rRMSD are not so high for GHI. In the case of DNI, rRMSD is great and the value underestimated.

3.3 Data filtered with BSRN standards

In this section, we present the errors for ESRA clear sky model compared with ground measurements filtered with more restrictive BSRN quality filters. The next tables show MBD, RMSD, rMBD, rRMSD and R for GHI and DNI, for each day ahead of prediction from 1 to 6 and total errors of the models.

Tab. 10: Statistical errors of hourly GHI predictions validated with filtered ground measurements. ESRA clear sky model

Day ahead	MBD (Wh/m2)	RMSD(Wh/m2)	rMBD (%)	rRMSD (%)	R
1	-23.44	82.29	-3.62	12.71	0.94
2	-22.42	86.03	-3.46	13.27	0.94
3	-22.78	83.76	-3.51	12.91	0.94
4	-20.55	79.14	-3.15	12.15	0.95
5	-22.06	81.00	-3.39	12.43	0.94
6	-23.02	80.78	-3.52	12.37	0.94
TOTAL	**-22.37**	**82.19**	**-3.44**	**12.64**	**0.94**

Tab. 11: Statistical errors of hourly DNI predictions validated with ground measurements. ERSA clear sky model

Day ahead	MBD (Wh/m2)	RMSD(Wh/m2)	rMBD (%)	rRMSD (%)	R
1	-34.77	225.37	-6.08	39.44	0.41
2	-31.80	233.09	-5.57	40.82	0.36
3	-31.36	233.02	-5.49	40.76	0.37
4	-29.12	231.41	-5.05	40.13	0.34
5	-32.07	227.08	-5.59	39.60	0.37
6	-35.26	223.64	-6.15	39.00	0.40
TOTAL	**-32.39**	**228.95**	**-5.65**	**39.96**	**0.38**

The conclusions are similar as for ESRA model presented in section 4.1. There is a considerable decrease of the magnitude of rRMSD for GHI and DNI. It is because there are some reflections due to walls near to the station. This effect affects primarily to GHI. We have also detected a temporal deviation in the clock of around 2 to 5 minutes. When the deviation is corrected, rRMSD improves around 1% in the case of GHI.

5. Conclusion

The results show that the combination of the predictions of cloudiness from GFS and AOD and Water vapour from MACC and ESRA clear sky model provide good results for hourly GHI. In the case of DNI, the results are not so good. Bias can be removed using MOS, NN or correction with k_t and solar zenith angle matrix. We expect this model to have poor results regarding performance predicting variability of solar radiation due to coarse resolution of GFS model which is 3 hours. This last result has been presented recently in Task 46 of IEA. In the future, we are going to step up a mesoscale model customised for Qatar. The results in this paper will be used as a reference to improve prediction of solar radiation.

Abstract

Detailed knowledge of the solar resource is important for its possible applications in solar use, design of buildings and biological effects, among others. In this paper, we present an algorithm for the calculation of global solar irradiance based on a parametric model, which allows us to obtain global solar irradiance, at any geographical location and time of day. Also, we present a new algorithm using the derivative. Results were compared with measurements taken with a solar radiometer, supporting our arguments. We found percentage of discrepancy of 1.6% to 6.8% in days of May, 2007). Another very useful application of the algorithm is to determine the threshold levels of solar irradiance for Rosario and Concepción del Uruguay, Argentina. The algorithm produces an alert signal that is transmitted when an error happens. We present applications of the algorithm, which allow modifying the incorrect measurements in near real time, giving more confidence to the published data.

Keywords: *algorithm, model, solar radiation, data control*

Introduction

At the global level, there are few stations of measurement of solar radiation, and less still with the necessary maintenance. For example, Gaztelumendi (2003) reported that in 2002, 160 error warnings were registered in the Automatic Weather Stations (AWS) network of the Basque Country, Spain. These include 5% failure in communication, 5% failure of the booster station, 20% general failure of the station and 70% detected errors in the measurement of meteorological variables (of which there were 8% in the sun irradiation), i.e. the errors in the sun irradiation were 5.6% of the total error warnings. Thus, it is imperative to use the automatic control method for counting the data.

Data analysis makes it possible to identify factors that produce errors or systematic deviations. In the latter case, along with the hardware maintenance, it is necessary to take into account the location of the weather station (WMO, 1996).

The measurements recorder with instruments exposed to the elements are subject to a large number of possible failures/errors, which can be due to internal and external causes. Among the former the measurement of negative values may be mentioned: sensor or protective cover deterioration, peak voltage (Cede, 2004), time mismatch in the computer or acquisition system with respect to the real time. Some of the external causes for failures/errors are depositions of matter that obstruct the entry of radiation in the exterior dome, and the extreme winds that modify the tilt of the instruments.

The basic idea is to perform data control detecting the suspected values produced by an abnormal solar radiation distribution. If the data have an error then the program must send a signal about the failure to the support staff, and do the automatic correction.

The main issue, in relationship to the data provided by instruments exposed to the elements, is constant checking and verification. Consequently, the present work proposes the development of a methodology, supported by efficient algorithms, which would allow a constant systematic verification. This will significantly reduce the frequent data problems of external sensors.

doi:10.18086/swc.2015.07.13 Available at http://proceedings.ises.org

1.1 Analysis of data errors

An antecedent to this work, is the one realized by the Basque Service of Meteorology (BSM) which has more than 25 pyranometers (model CM11), complementing the measurements of atmospheric variables with its net of Automatic Weather Stations (AWSs) (Hernandez et al., 2003a, 2003b; Gaztelumendi et al., 2003). The AWSs of the BSM is a net located in about a 100 places of the Basque country in Spain and its validation procedure of values was based on a series of rules (Hernández et al., 2003a).
The validation rules are:
1- Data must be consistent with the technical specifications defined by the pyranometer.
2- Data must be consistent, i.e. they must satisfy the physics laws of the variable. Therefore

→ No solar irradiance during the night;

→ Daily evolution of solar irradiance under clear skies is characteristic, its graph being very similar to the Gaussian bell, symmetric with respect to the solar noon;

→ Solar irradiance values can exceed a certain percentage of the solar irradiance for clear sky conditions.

It is important to emphasize that the BSM considers the consistency of the solar irradiance essential for the meteorological variables (the graph must show the cloud progress; under clear sky conditions, the temperature develops in correlation with the solar radiation, although with a temporal delay).
3- Data must be coherent with the information of the nearest stations.
The most common data failures/errors are:

a- *Station failure*: when the station´s normal functioning has been interrupted (see Figure 1);

b- *Transmission failure*: communication problems;

c- *Storage failure*: the data disc or storage capacity is full;

d- Data failure: the station and the computer it connects to, communicate, but they are not synchronized (time and date) and the assigned data have incorrect time.

e- Zero positive shifts: when the sensor does not absorb the solar radiation (wavelengths in the spectral range of the instrument) it must indicate zero voltage. This error appears with positive values during the darkness periods, or during the day as well. There is a minimum threshold to be considered in the interpretation of the records. Some authors think that these values should be corrected to zero for night values and taken off for the diurnal values. Grossi Gallegos (2009) claims that the parasitic signal received (f.ex. artificial lighting, radio station or electric generator) in the sensor, or in the connecting cable, should be detected. In the case of a constant signal it is possible to correct the records only eliminating the false nocturnal values.

f- *Zero negative shifts:* this error is normally present when the internal dome has a different temperature to the cold connections of the sensor. For more data about this phenomenon, see the Kipp&Zonen web site (2007).

h- Sensor fail: since the sensor is outside, it could sometimes measure incorrectly during the day and due to other effects. The most common failures are moisture in the dome interior, lightning striking the sensor, problems in cabling and pyranometer break down.

i- Fault in calibration of the sensor: if the calibration factor is wrong, the signal is multiplied by a constant that does not belong to the sensor. These data will be higher or lower than they should be.

j- Wrong location of the sensor: the environment can produce shadows on the pyranometer (vegetation, buildings, its own station, etc.) (see Figure 1).

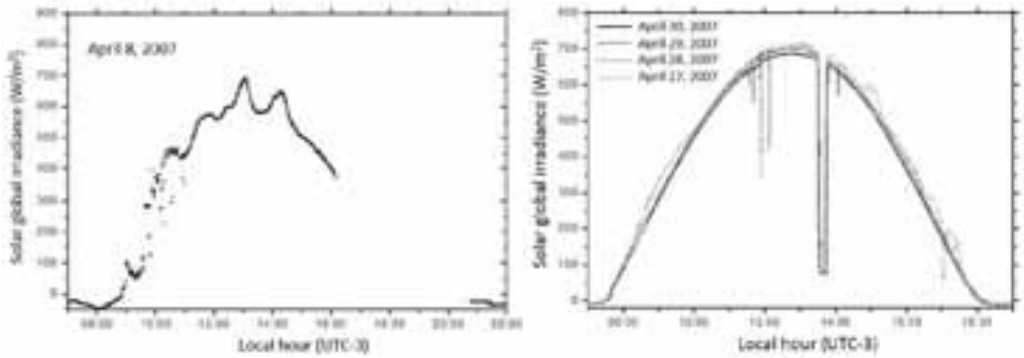

Fig.1. Solar data with failures in solar irradiance acquisition in Concepción del Uruguay, Argentina, in 2007. Left: Loss of data due to electrical failure in the station. Right: Wrong location of the sensor causing shadow from a water pipe.

k- Cosine error: the incident radiation on a horizontal plane has a value proportional to the cosine of incidence radiation at the zenith.
The errors listed above can occur randomly and simultaneously. According to Rudel (2003), the new stations, recording data simultaneously, do not generally verify their proper functioning.

1.2 Significant atmospheric events

Significant atmospheric events are exceptional manifestations of nature with significantly different values of the atmospheric variables from the average values. They usually are not caused by failures of the measuring system, and require more data and complementary equipment to evaluate the correct values. An example is the enhancement caused by the *edge effect* in the cloud, where the solar irradiance is similar or superior to the solar irradiance at top of the atmosphere (solar constant). This phenomenon was registered in Puna in the Atacama Desert and in the city of Recife (Brazil) by Piacentini et al. (2003 and 2010).
Furthermore, cloud effects, like the attenuation or increase of the radiation, are considered significant atmospheric events.
One of the rules when measuring solar radiation is that the value must be greater than the expected minimum under prevailing cloud cover (Hernández et al., 2003a). For the development of the present algorithm, the case of solar radiation values greater the extraterrestrial radiation has been taken into consideration. These values are not considered as errors as they could have been caused by some significant event like *cloud border effect* or *multiple scattering* in the cloud plane.

1.3 Solar radiation models

There are several models of total solar (or global) radiation: models based on meteorological data (Gul et al., 1998), cloud observations (Ehngerg and Bollen, 2005), isotropic sky models, with or without considering horizon brightening (Loutzenhiser, 2007), among others.
Usually, modelling of the radiative transfer is performed in different ways:
a) An integro-differential equation that describes the incidents of the direct and diffuse components at a given point, or
b) by using parametric semi-analytical models that are based on algebraic functions obtained by adjusting the solutions of the radiative transfer equations and mathematical formulae for these parameters.
Iqbal (1983) proposed three models (A, B and C), chosen for their simplicity and accuracy. For the present algorithm, we use the model C of Iqbal, based on studies by Bird and Hulstrom (1980) that developed a transmittance expression for the different attenuation processes in the atmosphere. The model needs three input parameters: water vapor column, broadband aerosol optical depth, and ozone and carbon dioxide column values.
When solar radiation enters the atmosphere, a portion of the incident energy is removed through scattering and absorption. Both considerably influence the spectrum, modifying the extraterrestrial spectral energy that passes through the atmosphere. The scattered radiation is called *diffuse radiation*. A portion of this scattered radiation goes back into space and a portion reaches the Earth's surface. The radiation that hits the Earth's surface in a straight line from the solar disk is called *direct radiation* (Iqbal, 1983).

1.4 Developed algorithm

The implemented algorithm has two important parts: A- the implementation of the C model; and B- the analysis of the dataset. The first part should determine the theoretical values of solar irradiation (at all times): global, direct and diffuse. In addition, it calculates the times of sunrise, noon and sunset. These values are obtained by implementing the C model for the entry parameters. The second part implies the reading of the text file and the searching of the real values (noontime, sunrise and sunset, and the values outside the range). Figure 2 describes the algorithm flow diagram.

1.4.1 Implementation of the C model

Input values must be read before the calculations. These values are:
A- The latitude, longitude and difference to the GMT. The algorithm calculates the sunrise, noon and sunset times.
B- The date, latitude, total ozone and carbon dioxide columns, precipitable water, atmospheric pressure, visibility, albedo and single scattering albedo. The algorithm calculates the solar irradiance values for each minute.

One advantage of this model is the possibility to count the total, direct and diffuse components, for posterior analysis.

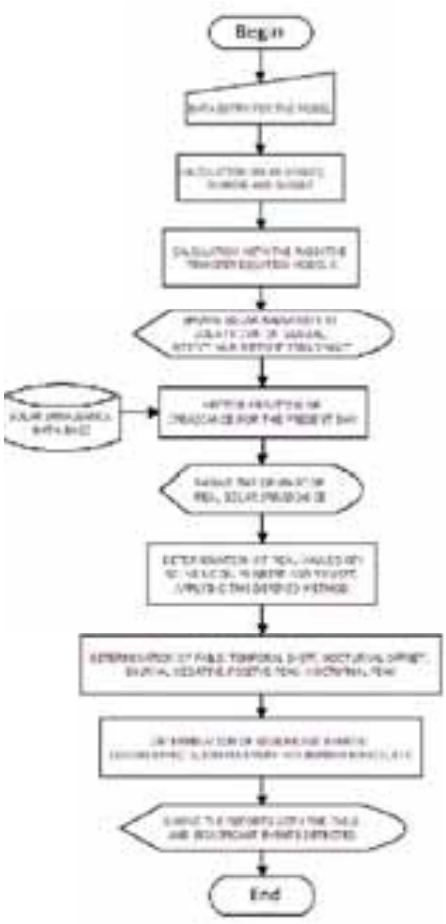

Fig. 2. Detection algorithm.

1.4.2 Search of real values

Once the data file has been copied as a vector, the present algorithm looks for the solar noon applying the derivative method.

The derivative method (proposed here) consistsin the calculation of the slope for the global solar irradiance, data by data, as follows:

$$slope\ (i) = \left[\frac{data(i) - data(i-1)}{\Delta t}\right] \qquad \text{(eq. 1)}$$

where Δt=1 minute. For this reason, the slope is just the difference between the current data and the previous data.

As can be seen in Figure 3, when midday occurs (maximum value of solar global irradiance, in red), the slope values pass from positive to negative (blue line).

Once noontime is found, the algorithm uses the theoretical data of the hours of sunshine for calculating the sunrise and sunset. From then on, the *derivative method* will be used for searching slopes steeper than the normal bell's slope.

In Figure 3, the global solar radiation data measured with the indicated pyranometer under clear skies (red line) and its slope (blue line) are drawn showing the signals, but not to scale. In Figure 4, the representation of some solar global irradiance data and the corresponding slope can be seen. There is a peak (see (i) in fig.4) of the solar global irradiance data and therefore a slope with positive data and negative in the case of (i +1), returning then to the value of the slope if there are no peaks.

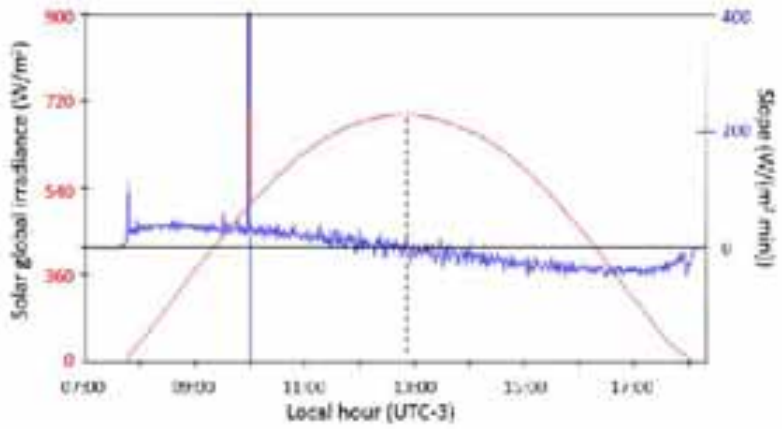

Fig. 3. Graph of example of solar global irradiance measured with a Kipp&Zonen pyranometer (red line) as a function of the local hour and superimposed the variation of the slope, data to data (blue line) (adapted from Salum et al., 2008).

The factor used to detect positive and negative peaks was found experimentally after working on several global solar radiation records. To find the peak this factor must be at least 1.3, i.e. the current data are 30% larger than the previous one.

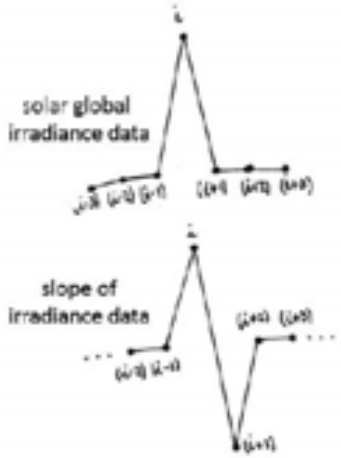

Fig. 4. Top: Scheme of positive peak in solar global irradiance. Bottom: Scheme of the slope (data to data) resulting from these values.

1.4.3 Detection of failures/errors

The software checks for failures/errors:

- *Systematic search for a nocturnal nonzero (or offset) value*

The algorithm searches nonzero values overnight, which is defined as the period from the end of twilight (about 45 minutes after sunset) until the beginning of the dawn (about 45 minutes before the sunrise). These values are averaged and shown in the report on the output screen.

- *Search for values that exceed the normal values*

This search consists in finding a threshold value above which the value is anomalous. The value chosen was 1528 W/m^2, which is one of the maximum values recorded and published internationally up to the present. This value was measured with a precision pyranometer at the peak of Tres Cruces, at 3900 m above sea level, in the high altitude intertropical desert of Puna de Atacama, in December 1997 (Piacentini et al., 2003).

- *Search for abnormal diurnal positive/negative peaks*

With the irradiance and slope data, the algorithm performs the scanning in compliance with the following rules:
a) The value of the current data must exceed the previous data value multiplied by a certain factor, and then returned to the previous value,
b) the current value of the slope is to be positive,
c) the posterior value of the slope must be negative, and
d) the phenomenon last less than three minutes (corresponding to three data) (see Figure 4).
If complying to these rules, the data is labeled a positive diurnal peak.
There are similar rules for negative peaks, but the slope is first negative and then positive.

- *Time shift*

The delta parameter (time shift) is calculated as the difference between the *actual solar noon time* and the *theoretical one*. The time shift is calculated and then the algorithm alerts this value. Furthermore, it automatically corrects the data and stores them in a data file (corrected solar radiation).

1.4.4 Combination of theoretical and real values

First, the algorithm applies the model C to the calculation of solar total irradiance, minute by minute. In figure 5, the graph of the real data (red line) and the model data (white line) is seen.

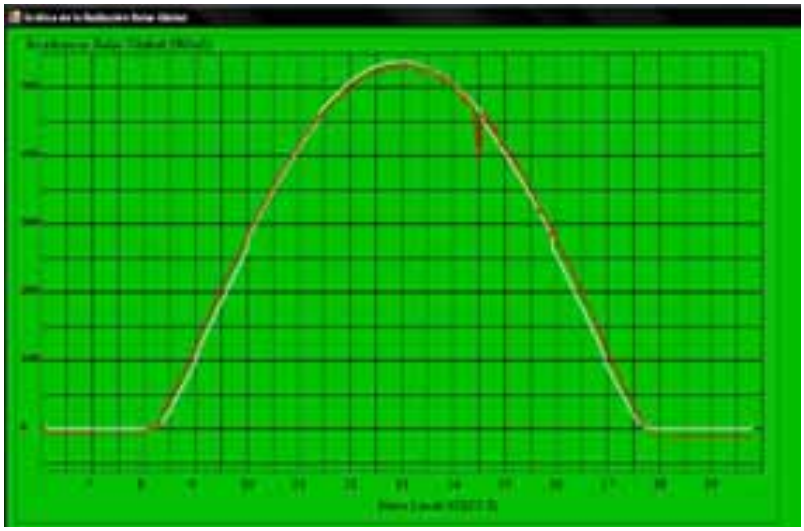

Fig. 5. Sample of the screen that shows the graph of the real data (red line) and the model data (white line).

3. Results

To implement the detection of daily features (solar noontime, the rising and setting of the Sun - dusk and dawn) and the positive and negative peaks of the acquired data, calculate the derivative, data by data, for the whole day

Figure 6 shows the first screen shot of the developed software for May 8, 2007. Here, the user enters the necessary parameters for the algorithm of the solar model for clear sky. Furthermore, it shows the solar radiation at noontime: total radiation is 629.99 W/m^2, the diffuse one is 239.21 W/m^2, and direct solar one is 580.64 W/m^2. The real value of the total solar irradiance at local noon is 640 W/m^2, resulting in a percentual difference (or percentage of discrepancy) for this day of 1.6%.

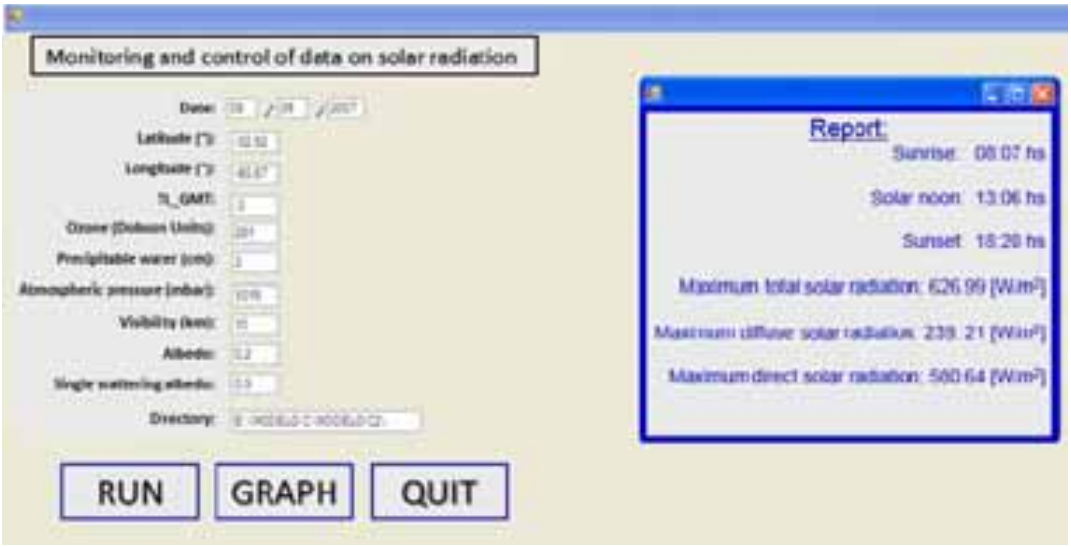

Fig. 6. Example of the initial screen and model results report for May 8, 2007.

On the left in Figure 7 below is the screenhot of the real data acquired (top) and the report of failures and significant events for May 8, 2007 (at the bottom). There was a peak at 10:00 am local hour, which was added to the real set of data (fictitious value of 900 W/m^2) in order to evaluate the algorithm. This peak turned out to be adequate. The data has a nocturnal offset (see fig.7) of -8.42 W/m^2. In addition, Figure 7 shows a time drift of 9.46 minutes.

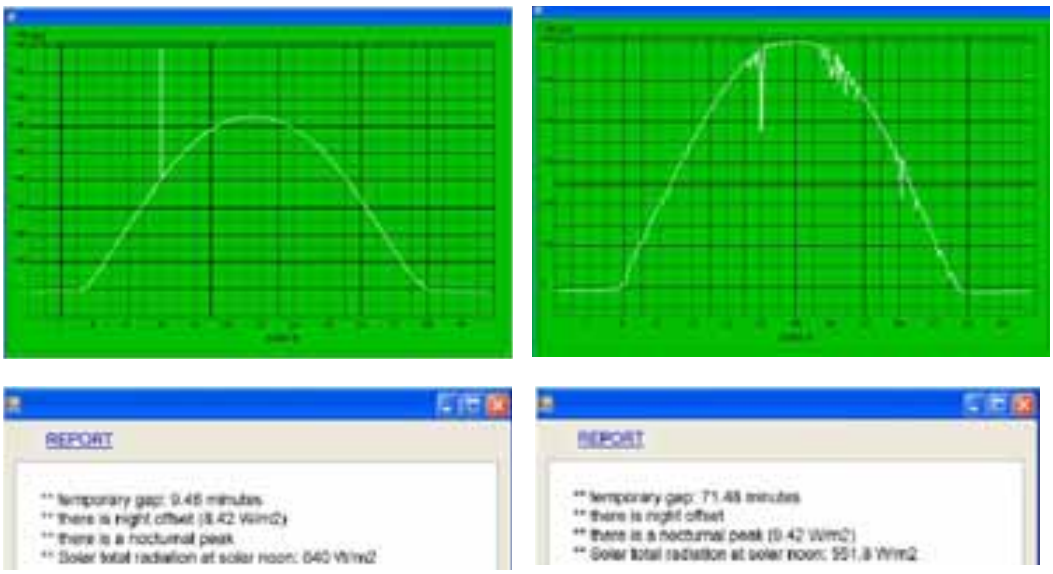

Fig. 7. Top: Graph of the real solar radiation data for: May 8, 2007 (left) and May 17, 2007 (right). Bottom: Reports corresponding to the days above.

For May 17, 2007, the software calculated the theoretical solar noon radiation at 592.13 W/m^2, diffuse radiation: 233.66 W/m^2, and direct radiation: 561.29 W/m^2. The real values of solar total irradiance at local noon was 551.8 W/m^2, resulting a porcentual difference of 6.8%. In Figure 7 Right, there are the graph screen of the real data acquired and the report of fails and significant events for this day. In the graph of data it was seen that and some of nocturnal offset. The report says that the nocturnal offset was of -9.41 W/m^2.

For May 18, 2007, the model solar noon values were 588.62 W/m^2, 233.08 W/m^2, and 559.27 W/m^2, for total,

diffuse and direct radiation respectively. The real values of solar total irradiance at local noon is 575.8 W/m^2, resulting a porcentual difference of 2.2%.

For May 19, 2007 the model solar noon values were 585.18 W/m^2, 232.51 W/m^2, and 557.29 W/m^2 for total, diffuse and direct radiation respectively. The real value of total solar irradiance at local noon was 551.8 W/m^2, resulting in a percentual difference of 5.7%. Figure 8 (left) is screenshot of the real data acquired and it shows the failures and significant events for this day. We can see a fictitious peak in the afternoon, which was added to the real set of data (of 9000 W/m^2). The search for the peak was successful. It shows a day without clouds and the nocturnal offset. The report says that the nocturnal offset was -8.70 W/m^2 and a time drift of 4.48 minutes.

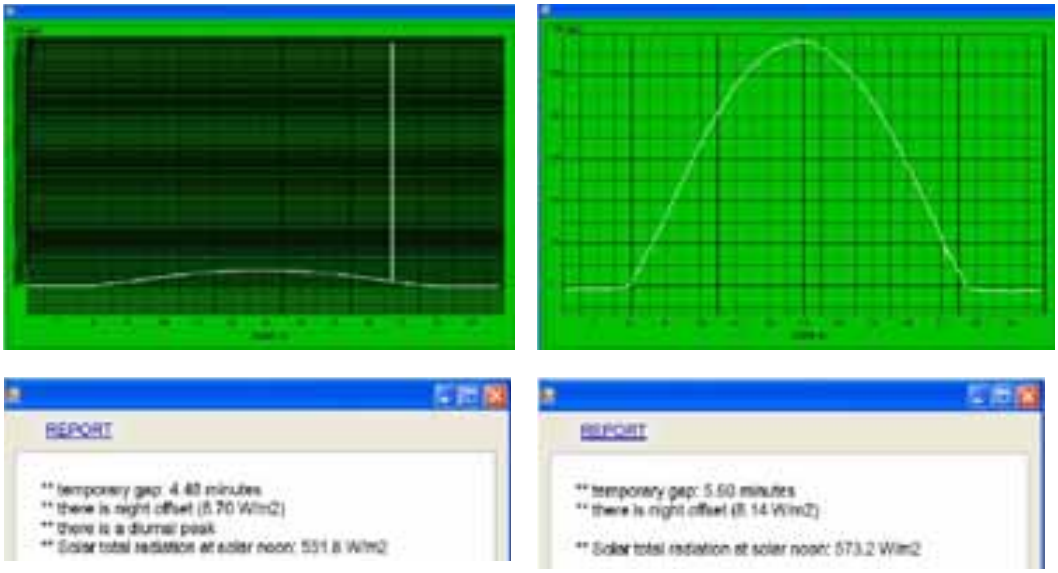

Fig. 8. Top: Graph of the real solar radiation data for May 19, 2007 (left) and May 25, 2007 (right). Bottom: Reports corresponding to the days above.

For May 25, 2007 the model solar noon values were 566.35 W/m^2, 229.33 W/m^2, and 546.19 W/m^2 for total, diffuse and direct radiation respectively. The real value of solar total irradiance at local noon is 573.2 W/m^2, resulting a porcentual difference of 1.2%. In the right of figure 8, there is a screenshot of the real data acquired and the failures and significant events for this day. The algorithm reports that the nocturnal offset was of -8.14 W/m^2 and a time drift of 5.60 minutes.

3. Conclusions and future perspectives

Data transmission, data storage, zero positive shifts, sensor failures, fault in calibration of sensor, wrong location of the sensor and cosine error are some of the failures that can be detected with the present algorithm. It proves that it is reliable for solar radiation data validation, resulting in a percentage of discrepancy values (percentual difference) of 1.6%, 6.8%, 2.2%, 5.7% and 1.2% for the total irradiance at local noon May 8, May 17, May 18, May 19 and May 25, 2007, respectively. For the days with peaks (diurnal and nocturnal), the detection was successful, as well as those for the time shift and the night offsets.

Some future perspectives are the extension of the algorithm (for solar radiation data) to other types of data that need a continuous monitoring of meteorological and air quality data.

Abstract

This paper investigates the realizable potential for photovoltaic (PV) systems in Swedish agriculture. Marginal lands and available building areas for PV systems are quantified, and factors limiting the potential are analyzed. It is shown that the potential for PV in Swedish agriculture is high, but what is fully realizable is limited by the capacity of the rural power grid. A case study in the rural municipality of Herrljunga was conducted and scaled to national level. The study shows that the risk of surges in the medium voltage grid (10 kV) in rural areas are small in case where all roof surfaces with an annual solar irradiance of over 950 kWh/m^2 are used for solar power. The total electricity production from the Swedish agriculture, if all roof areas with this irradiance level were used, is estimated to 4 TWh annually. With solar power on all roof surfaces with an annual irradiance of at least 900 kWh per m^2 problems with voltage rise and overloads in the electricity grid might occur. The electrical grid capacities thus substantially limit how much solar power can be installed. Our results also show that the profitability limits the potential to 0.2 TWh on a national level, but that it could increase if more optimistic economic conditions are assumed.

Keywords: *PV potential, grid integration, agriculture, business models*

1. Introduction

Agriculture is a sector with a seemingly high potential for photovoltaic (PV) power generation. The abundance of land and different types of farm buildings provide several options for installing PV systems. At the same time, previous studies have shown that rural distribution grids are the grid types that are most sensitive to high PV power injections (Walla et al., 2012), which may limit the achievable generation capacity.

Previous studies of the potential solar power generation in Sweden has mainly been based on building statistics combined with assumptions about key parameters such as building dimensions. For example, Kjellsson (1999, 2000) estimated the building areas in agriculture that were available for solar power generation to 150 km^2. An important task for new studies in this field is to improve the estimates of the total potential by using more refined methods, and to determine the limiting factors in realizing this potential.

The aim of this paper is to quantify the realizable potential for PV power generation in Swedish agriculture, both on land and on buildings. Realizable potential is defined here to be the technical potential (PV capacity on available areas) reduced by constraints in the power grid and by what is economically profitable. The study combines analyses of GIS (geographic information system) data with power flow simulations of power grids. A case study is performed on the rural municipality of Herrljunga in western Sweden. These results are then combined with national statistics to estimate the realizable potential for the whole Swedish agricultural sector. Details on the findings in this paper can be found in the full project report (Norberg et al., 2015).

The paper is structured as follows. The methodology for determining the realizable potential is described in Section 2, the results are presented in Section 3, and a concluding discussion is included in Section 4.

2. Methodology

2.1. Available land and buildings

It is assumed that the lands primarily considered for PV installations are marginal lands, i.e. lands that are not profitable for agricultural use. The availability of marginal lands is determined from national statistics (Johnsson, 2008). However, all available land in the statistics cannot be used for PV, since the distance from the grid is too large, the land is shaded, difficult to build on or not accessible.

Available building roof areas are analyzed based on LiDAR (Light Detection And Ranging) data and property maps in ArcGIS (ESRI, 2015) for the municipality of Herrljunga, Sweden. Every building is linked to the low voltage (LV) grid connection node within the same property, determined from data provided by the local distribution grid operator (DSO), Herrljunga Elektriska AB. If there are no connections within the property the closest connection within a radius of 200 meters is linked to the building (see Fig. 1). The radius was set to 200 m based on the recommended cost for connection to the LV grid according to the Swedish Energy Market Inspectorate (Energimarknadsinspektionen, 2013a). This radius is of course not universally valid but depends on the profitability of each individual case.

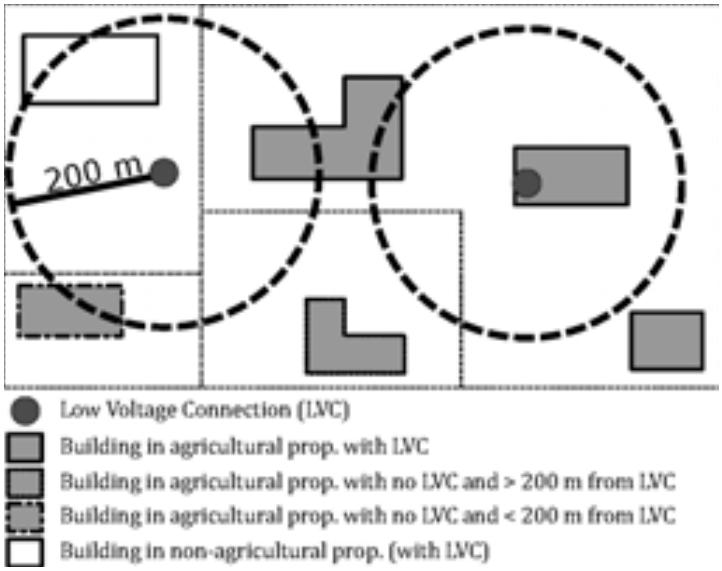

Fig. 1: Methodology for identifying agricultural buildings (grey) with potential for PV installation. Buildings within an agricultural property with a low voltage connection (LVC) or < 200 meter from any LVC are included in the analysis. In this example the south middle building will not be included.

2.2 Solar energy calculations

The solar resource potential on the building areas is quantified using the built-in tool *Solar Area Radiation* in ArcGIS, allowing both internal shading and shading from surrounding terrain, vegetation and buildings to be taken into account (Fu and Rich, 1999). Different thresholds for annual irradiance availability are studied (minimum level for installing PV), for instance 700 kWh/m^2/year meaning that only roof segments having at least 700 kWh/m^2/year are considered for PV installation. For generating data to the detailed grid simulations, PV systems on the available areas were simulated in the modeling environment Matlab using standard models for available solar irradiance and PV output power (Duffie et al., 1994). The following assumptions about losses were made:

(1) 15% of the available roof area was not considered due to obstacles such as chimneys etc. (Kjellsson, 1999).

(2) Shading from surrounding buildings, trees etc. was represented by a general removal of the beam component of the irradiance for solar angles ($\cos(\theta_i) < 0.2$).

(3) 15% efficiency of the PV cells assumed at standard test conditions. Overall PV system efficiency was assumed to be 85%.

(4) 19% of the total potential was excluded corresponding to the share of roofs not in sufficiently good condition for PV installation (Riksantikvarieämbetet, 2004).

2.3 Distribution grid simulations

Access to a very detailed database of grid data from the local DSO for both the medium voltage (MV) and low voltage (LV) grids in the studied area has made it possible to make detailed power flow simulations of the whole distribution grid. Hourly load data are available for all customers and also line-impedances of all connections in the grids. Only active load data were available, thus a constant load factor of 0.95 was assumed to derive the reactive load (Thomson and Infield, 2007). Balanced three-phase power flow for the whole grid was solved using Raphson-Newton's method implemented in Matlab. According to current Swedish regulations, short-term voltage fluctuations deviating 10% from nominal are allowed in the MV grid (Energimarknadsinspektionen, 2013b). To allow further voltage fluctuation in the LV grid, voltage fluctuations are limited to 5% in the MV grid. Furthermore, the maximal current allowed is specified for each line. The maximum PV penetration is thus limited by an overvoltage limit of 5% above nominal voltage or 1.05 p.u. and the specified load of current for each line.

2.4 Profitability limitations

The cost of PV systems has dropped considerably in the last decade. For Sweden the mean price was 13 SEK/W_p for systems larger than 20 kW_p (Lindahl, 2015). This should be compared to the avoided cost of electricity when self-consuming the PV electricity, which in our calculations is set to 0.45 SEK/kWh in the agricultural sector, which pay very low energy tax, whereas the corresponding figure for other businesses is 0.75 SEK/kWh. The excess share of the electricity generated is sold, with an expected price of 0.25 SEK/kWh, according to mean Nordpool spot prices, and additional incomes of 0.05 SEK/kWh from the grid owner and 0.18 SEK/kWh for electricity certificates. From 2015 it is also possible to get 0.60 SEK/kWh as a tax rebate, given annual net consumption, a fuse of $\leq$ 100 A, and a maximum of 30 MWh fed into the grid. Besides this it also possibly to be granted an investment subsidy of 30% for companies and 20% for others. The application rate is high and it has more been seen as a bonus, as the uncertainty of being granted the subsidy have been high. However, the Swedish government has in the last budget bill proposed significantly more funds the coming years (Brolund, 2015).

When estimating the profitability we therefore assume a maximal production of 60 MWh, of which 50% is fed into the grid. This gives a mean compensation for sold electricity of 0.38 SEK/kWh without tax rebate and 0.68 SEK/kWh including the tax rebate (see Tab. 1).

Tab. 1: Cases for the profitability assessment

	Investment [SEK/kW_p]	Discount rate	Self-consumption	Value of self-consumed electricity* [SEK/kWh]
Base case, agricultural	13 000	6%	50%	0.38
Base case, agricultural incl. tax rebate	13 000	6%	50%	0.68
Base case, other	13 000	6%	50%	0.40
Base case, other incl. tax rebate	13 000	6%	50%	0.70

*Also additional incomes from electricity certificates of about 0.15 SEK/kWh for 15 years.

It is however difficult to find profitability in the cases presented in Tab. 1. Therefore we examined some possible cases were profitability would increase. These are presented in Tab. 2. In the first case (1) a discussed investment subsidy within the agricultural program of Sweden is implemented. In (2) the compensation offered by some electricity suppliers for selling the electricity to the grid is higher than Nordpool spot prices, here assumed as 1.25 SEK/kWh. For how long this generous compensation will last is highly uncertain. In (3) we assume that the farmer has own capital to invest, and thereby lowering the discount rate. In (4) we assume the farmer to install the PV system, and thereby reduce the investment cost. Lastly in (5) we assume a large scale PV system (1 MW_p), for which own capital is used and all generated electricity is fed directly into the MV grid. We assume a distance of 500 meter from the PV field to the MV grid, which means a connection cost of 550 000 SEK (Svensk Energi, 2011).

Tab. 2: Cases for increasing profitability.

	Investment [SEK/kW_p]	Discount rate	Self-consumption	Value of self-consumed electricity* [SEK/kWh]
(1) Investment subsidy 40%, incl. tax rebate	7 800	6%	50%	0.68
(2) Higher sell rate, incl. tax rebate	13 000	6%	50%	1.18
(3) Own capital, incl. tax rebate	13 000	3%	50%	0.68
(4) Self-installed, incl. tax rebate	11 000	6%	50%	0.68
(5) Large-scale (1 MW_p), own capital, investment subsidy, 40%	6 000	3%	0%	0.30

*Also additional incomes from electricity certificates of about 0.15 SEK/kWh for 15 years.

2.5 Scaling to national level

It is difficult to make a fair scaling of the results in the case study in Herrljunga to national level. In Herrljunga there are 591 agricultural properties which can be compared to 350 000 nationally. A previous inventory of agricultural buildings in 10 different regions in Sweden showed that there were on average 6.5 buildings in each agricultural property (Riksantikvarieämbetet, 2004). This can be compared with 5.4 buildings per property in Herrljunga, which is at least in the same range as the previous study.

The solar resource availability varies significantly over Sweden. Therefore the available global annual solar resource was scaled for each county *c* compared to Herrljunga as;

$$G_c = \frac{\bar{G}_c}{\bar{G}_{hl}} G_{hl}, \qquad \text{(eq. 1)}$$

where $\bar{G}_c$ and $\bar{G}_{hl}$ are the mean annual global solar irradiance for 1979-2012 of county *c* and Herrljunga (*hl*) respectively and G_{hl} is the available solar resource on the roofs of Herrljunga derived from ArcGIS *Solar Area Radiation.* The hourly PV production $E_{c,h}$ depends on the incident solar angle $\theta_i^{c,h}$ as;

$$E_{c,h} = \begin{cases} G_{c,h}\eta & \text{if } \cos\left(\theta_i^{c,h}\right) > 0.2 \\ D_{c,h}\eta & \text{if } \cos\left(\theta_i^{c,h}\right) < 0.2 \end{cases}, \qquad \text{(eq. 2)}$$

where the G_h is the global irradiance and D_h is the diffuse irradiance at hour *h* and η is the fraction of the energy than can be extracted from the total incident solar irradiance and can be expressed as;

$$\eta = \eta_{PV}\eta_{sys}\eta_{obs}\eta_r, \qquad \text{(eq. 3)}$$

where $\eta_{PV} = 0.15$ is the module efficiency, $\eta_{sys} = 0.85$ is the PV system efficiency, $\eta_{obs} = 0.85$ is due to obstacles on the roof and $\eta_r = 0.81$ is due to available roofs of sufficiently good condition for PV installations (see section 2.2). The annual total power that can be extracted from the solar resource is thus;

$$E_c = \frac{N_c}{N_{hl}} \sum_{h=1}^{8760} E_{h,c}, \qquad \text{(eq. 4)}$$

where N_c and N_{hl} are the numbers of agricultural properties in county c and Herrljunga respectively.

3. Results

3.1. Potential PV generation capacity

The available marginal lands are found to be large (the Swedish average is in the order of 1 ha per agricultural property) and are therefore not considered to be limiting for the total PV capacity in the case study. Moreover, a total building roof area of 0.8 km^2 is available in the case study, corresponding to a total installed capacity of 120 MW. The results of allowing different irradiance thresholds for PV on these buildings in Herrljunga are shown in Fig. 2, indicating the total technical potential for PV (at 15% assumed efficiency).

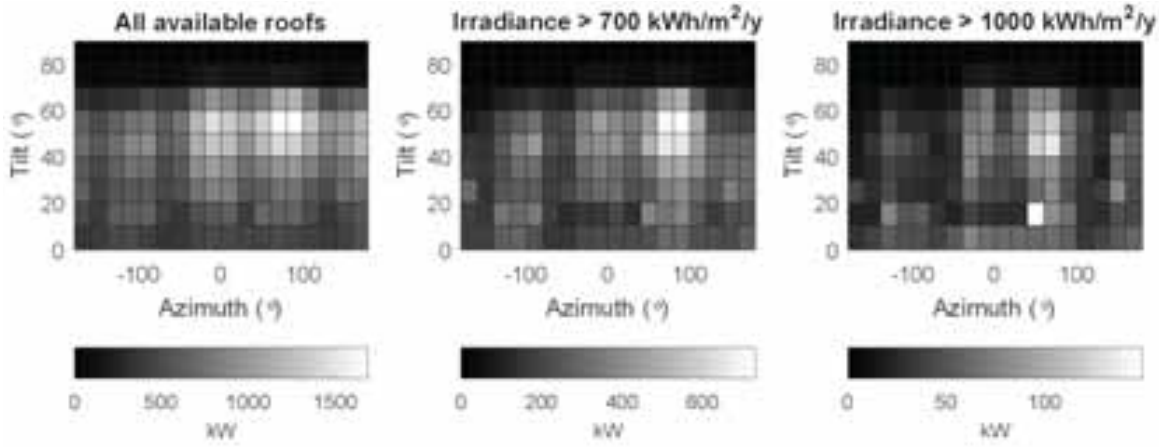

Fig. 2: Potential PV generation capacity on agricultural building roofs in the studied municipality, with three different requirements on annual irradiance. Note that the scale of the color bar differs between the subfigures.

The total potential as function of solar irradiance level is presented in Fig. 3. The total numbers of buildings having at least one roof segment of the solar irradiance level is included, as well as the total roof area and power production. In Tab. 3 key figures of an average agricultural property in Herrljunga are presented for three different solar irradiance levels. If scaling to national levels, following eq. 1-4, the total annual PV production would be 35.7, 13.5 and 2.5 TWh for the solar irradiance levels > 0, > 700 and > 1000 kWh/m^2 respectively.

Tab. 3: Key figures for an average agricultural property in the Herrljunga distribution grid for three different levels of annual solar irradiance; > 0 kWh/m^2 (all roofs), > 700 kWh/m^2, > 1000 kWh/m^2.

Key figures	All roofs	> 700 kWh/m^2	> 1000 kWh/m^2
Roof area (m^2)	1100	410	70
Solar irradiance (MWh/year)	940	360	62
PV capacity (kW)	170	62	10
PV power production (MWh/year)	128	48	8.3

3.2. Hosting capacity of rural distribution grids

In an early stage it was clear that the maximum accepted current in the lines would not be reached as Fig. 4 shows. The figure only displays line currents from the northern part of the grid but power flow simulations for the southern part gave similar results. Resulting histograms for MV grid voltages are shown in Fig. 5 together with the probability for voltage rise outside the allowed ±5% limits. All building areas with more than 950 kWh/m^2 annual irradiation (B) can be utilized without problems, but if building areas in the other categories (C and D) are used, there is a probability for overvoltage. However this risk is small, 0.13 % for C (> 900 kWh/m^2/year).

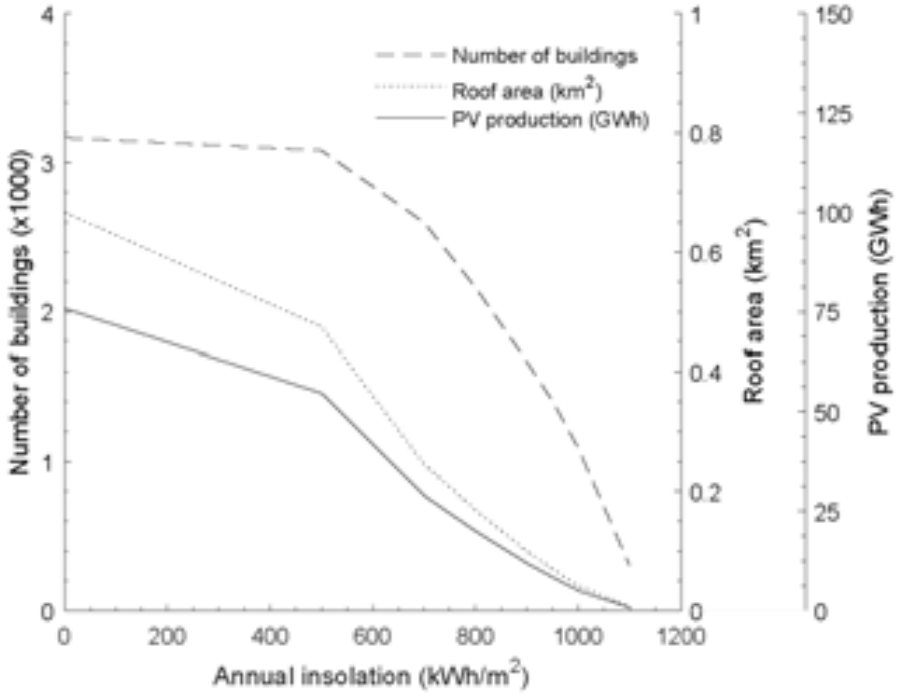

Fig. 3: Total potential for agricultural properties in Herrljunga.

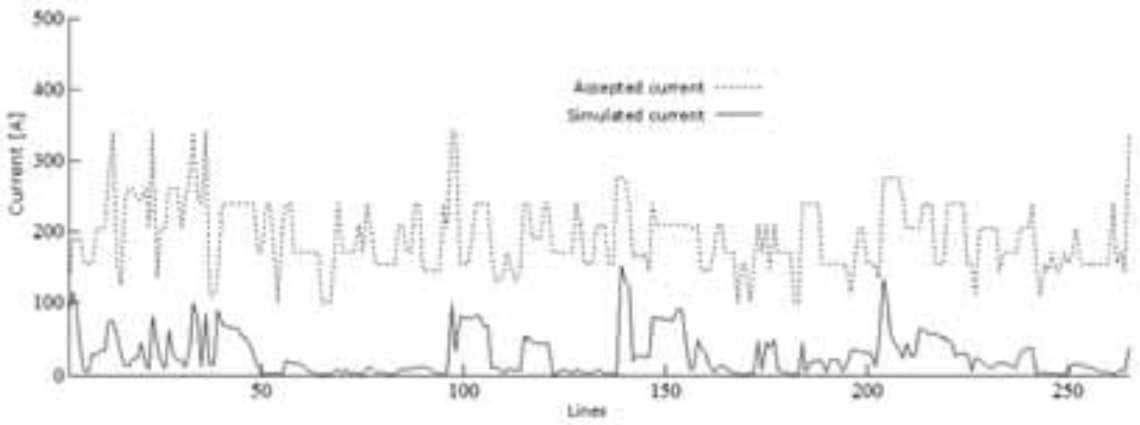

Fig. 4: Accepted current (dashed) and simulated current (solid) for each line in the northern part of the grid. In this figure the solar irradiance level was > 1000 kWh/m^2/year.

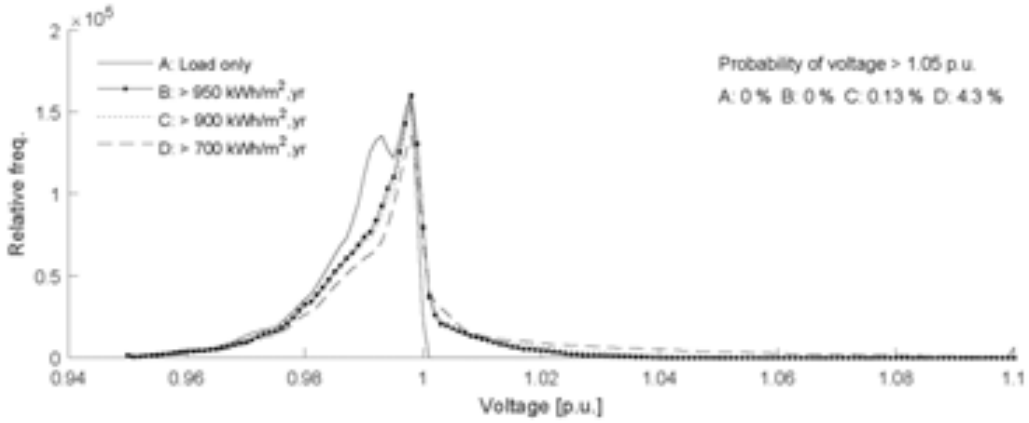

Fig. 5: Histogram of voltage in the medium voltage nodes for some different solar irradiance levels and for load only. All hours and nodes of the northern part of the grid are included. Also the probability for exceeding the overvoltage limit of 1.05 p.u. is presented in the upper right for the different cases.

3.3 Profitability of PV in agricultural sector

Following the assumptions in Section 2.4 it is not profitable to invest in PV without tax rebate. If tax rebate is included it is only profitable on the very best roofs, > 1 150 kWh/m^2/year. In Herrljunga there are almost no buildings with those conditions, scaled to national level only 0.2 TWh. In Tab. 4 an estimation of the annual yield and the scaled national potential is presented. As can be seen the national potential is low for profitable PV systems.

When it comes to the cases of improved profitability as presented in Tab. 2 there is a significant potential since locations with lower solar irradiance will become profitable (see Tab. 5). If own capital is used, giving a discount rate of 3% and a 40% subsidy on the investment is granted it is profitable to deploy large-scale PV fields of 1 MW$_p$, resulting in a total annual generation of 281 TWh, which is about twice as much as the Swedish electricity consumption. It should be noted that this is profitable from the farmers' perspective and only if the subsidies would be sufficient for all PV fields. Still, the potential will be limited by the overvoltage limit in the rural distribution grids of 4 TWh (see Section 3.2).

Tab. 4: Calculated income for a roof mounted PV system and the national potential at different solar irradiance levels.

Solar irradiance [kWh/m^2/year]	Annual yield on investment		National potential [TWh/year]	
	With tax rebate	Without tax rebate	Unlimited tax rebate	< 30 MWh tax rebate
700	0,0%	1,7%	14	11
800	0,0%	2,8%	10	8
900	0,0%	3,8%	7	5
1000	0,7%	4,7%	3	3
1100	1,4%	5,6%	0,5	0,5
1200	2,1%	6,4%	0	0

Tab. 5: Potential for cases with increased profitability

Case	Profitable solar irradiance level [kWh/m^2]	National potential [TWh/year]	
		Unlimited tax rebate	> 30 MWh tax rebate
Investment subsidy 40%	700	14	15
Higher sell rate	700	14	15
Own capital	850	9	8
Self-installed	1000	-	21
PV field, own capital, investment subsidy 40%	800	281*	

*All electricity from the PV field is assumed to be sold direct to the grid, with no tax rebate.

4. Concluding discussion

The results indicate that there is a considerable theoretical PV potential in the Swedish agricultural sector, but what is realizable is limited by the profitability, which at the current market situation is low, around 0.2 TWh on a national level. However, when including more or less optimistic scenarios, the profitability is no longer limiting; instead the hosting capacity of the rural distribution grid sets the limit to about 4 TWh/year. In this case the hosting capacity could be increased by different means, like curtailment, storage, grid enforcements or as previously shown for the same grid through smart allocation, where PV is only deployed at the strongest nodes (Lingfors et al., 2015).

The accuracy of the scaling to national level from the case study done for the distribution grid in Herrljunga is of course highly uncertain. Herrljunga only represents less than 2 ‰ of the agricultural sector of Sweden and it is not clear if Herrljunga is representative in terms of kind of farming or the condition of the grid. The difference in solar resource has been accounted for as described in Section 2.5, which means that no PV should be installed approximately from the 60th latitude northbound if the current level of solar irradiance of >1150 kWh/m^2/year were to be used.

2 National Renewable Energy Laboratory, Golden, CO (U.S.)

Abstract

Evaluating photovoltaic (PV) cells, modules, arrays and systems performance of solar energy relies on accurate measurement of the available solar radiation resources. Solar radiation resources are measured using radiometers such as pyranometers (global horizontal irradiance) and pyrheliometers (direct normal irradiance).

The accuracy of solar radiation data measured by radiometers depends not only on the specification of the instrument but also on a) the calibration procedure, b) the measurement conditions and maintenance, and c) the environmental conditions. Therefore, statements about the overall measurement uncertainty can only be made on an individual basis, taking all relevant factors into account. This paper provides guidelines and recommended procedures for estimating the uncertainty in measurements by radiometers using the Guide to the Expression of Uncertainty (GUM) Method.

Special attention is paid to the concept of data availability and its link to uncertainty evaluation.

Keywords: *uncertainty evaluation, pyranometer, pyrheliometer, measurement, data availability*

1. Introduction

Within the American Society for Testing and Materials (ASTM) International Subcommittee G03.09 on Radiometry, a standard is developed that provides guidance and best practices for evaluating uncertainties when calibrating and performing outdoor measurements with pyranometers and pyrheliometers. The standard will describe a procedure that follows the guidelines in the Guide to the Expression of Uncertainty in Measurement, the GUM (JCGM 100, 2008). This method has been successfully applied to uncertainty evaluations of calibrations of and measurements with pyranometers and pyrheliometers (Habte et al., 2014; Reda et al., 2008; Reda, 2011).

The use of the GUM has become an accepted method to perform uncertainty evaluation, and for example the Baseline Surface Radiation Network (BSRN) recommends that all uncertainty calculations follow the procedure of the guide (McArthur, 2005). Within BSRN, a working group on uncertainty is established with the goal to calculate the uncertainty of BSRN data.

To illustrate the individual steps in the process of uncertainty evaluation, and to clarify the choices made, we present a worked example using real world data. We selected one day of pyranometer data from the National Renewable Energy Laboratory (NREL) Baseline Measurement System, located in Golden, CO, U.S; the 8th of June 2015 (Andreas and Stoffel, 1981). We assume that the pyranometer used to take these measurements is a secondary standard pyranometer with specifications that exactly match the requirements of its category. State of the art pyranometers have specifications that exceed the requirements of the ISO secondary standard category, and can reach lower uncertainties than presented here.

We go through both the formulation stage and the calculation stage in detail. We analyse the relative importance of the different uncertainty contributions, and make the link between uncertainty evaluation and the concept of data availability. Data availability is a new concept, which will be defined in chapter 4.

2. Formulation stage: development of measurement model

We define the output quantity, or measurand, E as the one-minute average of global horizontal irradiance in W m^{-2}.

In the most basic pyranometer measurement model, the irradiance depends on two input quantities only:

- *V*, the pyranometer voltage output, measured in V
- *S*, the sensitivity of the pyranometer in V W^{-1} m^2

The measurement model is straightforward

$$E = \frac{V}{S} \qquad \text{(eq. 1)}$$

Other, more complicated, measurement models for pyranometers are in use that include corrections for systematic dependencies; i.e. temperature response, directional response, or response to net longwave radiation (zero off-set a). The process of uncertainty evaluation does not change, although the mathematics become more involved. For the scope of this paper, we limit ourselves to the basic measurement model.

With the measurement model established, the next step is to come up with factors that affect the uncertainty of the measurement. All factors are attributed to a specific quantity. The GUM only allows for uncertainty sources that apply to the input parameters. We present an approach where we also allow uncertainty sources to apply directly to the output parameter. The reasoning behind this is that certain pyranometer and pyrheliometer characteristics are stated explicitly in W m^{-2}, and are therefore best applied to the irradiance.

The GUM states that all knowledge of the (input) quantities is inferred from either repeated indication values (Type A evaluation of uncertainty) or scientific judgement (Type B evaluation of uncertainty). In high end meteorological networks such as the BSRN, it is considered best practice to take readings at a frequency of 1 Hz and store data as one-minute averages, together with the one-minute standard deviation, minimum and maximum value. However, irradiance is never constant; the 60 readings within a minute are not truly repeated observations. The variation within the minute can be caused by instrumental variation, but just as well by atmospheric variations on short timescales. Therefore, we argue that the standard deviation should not be taken into account when calculating the measurement uncertainty of a pyranometer or pyrheliometer measurement.

Without any Type A contributions present, all contributions are treated as Type B. For a Type B evaluation of uncertainty, often the only available information is that the quantity lies in a specified interval [*a*, *b*]. In these cases, the GUM recommends to use a rectangular or uniform probability distribution with limits *a* and *b*.

The judgement of which uncertainty sources to include or exclude has to be made on an individual basis for every application, and is fundamental to the process of uncertainty evaluation. We present a set of possible sources per uncertainty source, discuss the relevance, and assign specification limits.

3.1 Uncertainty contributions to the pyranometer voltage output

The voltage output of the pyranometer is measured with a device called a data logger: a voltmeter with the ability to store measurements. The manufacturer of the data logger normally specifies the measurement accuracy. In our scenario, we use a data logger with a specified accuracy of 10 µV, and treat this accuracy as a symmetric specification limit.

3.2 Uncertainty contributions to the sensitivity of the pyranometer

For the sensitivity S, we use the value as given by the manufacturer as 15.00 µV W^{-1} m^2 ± 0.15 µV W^{-1} m^2 where the number following the ± symbol is the expanded uncertainty with a coverage factor k = 2.

Calibration reference conditions are given as 20 °C instrument temperature, normal incidence solar radiation, horizontal mounting and an irradiance level of 500 W m^{-2}. This calibration is a single point calibration, which is different from the traditional meteorological calibration which results in an average sensitivity valid for a range of temperatures, angles of incidence and irradiance levels.

The term 'reference conditions' should be understood as the operating conditions under which the specified instrumental measurement uncertainty is the smallest possible (JCGM 200, 2012). In the theoretical case where all measurements would take place under these reference conditions, the calibration uncertainty as given by the manufacturer would suffice as the only contribution to the input quantity *S*. In practice, because all data points deviate from the reference conditions, the instrument characteristics have to be included in the uncertainty budget as well.

The most common set of characteristics is the list defined in ISO 9060 (ISO 9060, 1990) and most pyranometer and pyrheliometer manufacturers specify their instruments accordingly. These characteristics are defined both for pyranometers and pyrheliometers.

Of that list, the following apply to the input quantity sensitivity *S*.

- non-stability, the percentage change in sensitivity per year, relevant if the instrument has not been recalibrated recently. For our pyranometer, the secondary standard specification limit of 0.8 % per year applies. As the most recent calibration is about one year ago, we will use 0.8 % as a specification limit. ISO 9060 lists non-stability as a symmetric source, but we treat this uncertainty source as one-sided: the most common source of non-stability in thermal pyranometers is degradation of the black coating that absorbs the solar radiation. The coating can become less black over time, leading to a reduction in sensitivity. We use specification limits of [-0.8 %, 0 %].
- non-linearity, the change in sensitivity of the instrument for irradiance levels other than the reference condition (500 W m^{-2}) between 100 and 1000 W m^{-2}. We use the secondary standard specification limit of ± 0.5 % and apply it to the full measurement range.
- temperature response, the change in sensitivity of the instrument for temperatures other than the reference condition (20 °C). ISO 9060 states a limit of 2 % percentage deviation due to change in ambient temperature within an interval of 50 °C. In our scenario, the range of ambient temperatures is smaller than 50 °C, but we will use a specification limit of ± 1 % as a conservative estimate.
- tilt response, the change in sensitivity of the instrument for mounting orientations other than the reference condition (horizontal). In our example, we do not include the tilt response characteristic, because we are measuring global horizontal irradiance. When we measure tilted solar radiation with a pyranometer (for example in a plane-of-array setup) or direct solar radiation with a pyrheliometer, we do have to include tilt response in the uncertainty budget.

The ISO 9060 list of characteristics is not exhaustive; other effects can be considered as well. For our scenario, we will include an uncertainty contribution related to the level of maintenance. Pyranometer domes are subject to fouling. Fouling can be a continuous process, a slowly building layer of dust, or appear in bursts, for example due to sandstorms. The severity depends on the local conditions. For our scenario, clean air and daily cleaning, we estimate a maximum contribution of 0.5 %. This estimate is not based on any documented numbers, but is based on experience with and general knowledge of the behaviour of the instrument. In the GUM framework, this is allowed under the general header of 'scientific judgement'.

3.3 Uncertainty contributions to the global horizontal irradiance

We include three uncertainty sources that apply directly to the output quantity, the irradiance

- zero off-set a, the response to net thermal radiation. The pyranometer domes exchange radiation with the cold clear sky, cooling them down. This results in a negative offset in the irradiance. ISO 9060 specifies a limit of 7 W m^{-2} for 200 W m^{-2} thermal exchange. The thermal exchange, or net longwave radiation, varies with atmospheric conditions and altitude. 200 W m^{-2} is typical for very clear sky conditions at altitude, which fits nicely for our scenario. The offset is negative only, we use specification limits of [-7 W m^{-2}, 0 W m^{-2}]
- zero off-set b, the response to temperature gradients. As the ambient temperature increases and decreases, different parts of the instrument can be out of thermal equilibrium. ISO 9060 specifies a maximum value off-set of ± 2 W m^{-2} for a gradient of 5 °C per hour. We will use this value.
- directional response, the error caused by assuming the sensitivity to a normal incidence beam of irradiance is valid when measuring beams coming from any direction. ISO 9060 uses a specification limit of 10 W m^{-2} for a beam whose normal irradiance is 1000 W m^{-2}. In practice, this means that the relative specification limit is different with the position of the sun in the sky. With the sun in zenith (normal

incidence) the 10 W m^{-2} error on the normal incidence beam of 1000 W m^{-2} leads to a specification limit of 10 W m^{-2}/1000 W m^{-2} = 1 %. With the sun at 60 ° from zenith, the same normal incidence beam of 1000 W m^{-2} contributes cos(60 °)·1000 W m^{-2} = 500 W m^{-2}. The specification limit due to the 10 W m^{-2} error is then 10 W m^{-2}/500 W m^{-2} = 2 %.

In our example, we have a separate measurement of direct irradiance E_{direct} available, so we can apply the error to the direct component of the global horizontal irradiance only

$$a = \frac{10\ \text{W m}^{-2}}{E_{\text{direct}} \cos \Theta z} \qquad \text{(eq. 2)}$$

with Θ_z the zenith angle.

When no separate measurement of direct irradiance is available, a decent estimate of the specification limit of the directional response can be found by replacing E_{direct} in equation 2 by the global horizontal irradiance E itself.

The uncertainty sources are summarized in table 1.

Tab. 1: Summary of uncertainty contributions

Uncertainty source	Parameter	Specification limit *a*	Type	Distribution	Shape
data logger accuracy	*V*	10 µV	B	rectangular	symmetric
calibration uncertainty	*S*	1.5 %	B	normal (k = 2)	symmetric
non-stability	*S*	0.8 %	B	rectangular	one-sided (negative)
non-linearity	*S*	0.5 %	B	rectangular	symmetric
temperature response	*S*	1 %	B	rectangular	symmetric
maintenance	*S*	0.5 %	B	rectangular	symmetric
zero off-set a	*E*	7 W m^{-2}	B	rectangular	one-sided (negative)
zero off-set b	*E*	2 W m^{-2}	B	rectangular	symmetric
directional response	*E*	$\frac{10\ \text{W m}^{-2}}{E_{\text{direct}} \cos \Theta z}$	B	rectangular	symmetric

With the measurement mode developed and all quantities characterized, the measurand *E* is fully specified in terms of this information. The rest is applying the algorithms as laid out in the GUM, but involves no further judgement or decisions.

3. Calculation stage: propagation of distributions and summary of expanded uncertainty

The GUM uncertainty framework uses the values of the input quantities, their standard uncertainties and the sensitivity coefficients to form an estimate of the output quantity and the associated combined standard uncertainty.

The standard uncertainty of a quantity is the square root of the sum of the squares of all uncertainty sources that apply to that parameter

$$u(X) = \sum_j u_j \qquad \text{(eq. 3)}$$

where *j* sums over all uncertainty sources that apply to the input quantity *X*.

The introduction of one-sided uncertainty sources should lead to asymmetric uncertainty distribution of the measurement. Our current method is not yet suited to handle this. We choose to halve the one-sided

specification limits and treat them as symmetric. Future work should aim to improve on this, and allow asymmetric uncertainty distributions of the measurements.

We do not consider correlations between uncertainty sources in this method. Some uncertainty sources are clearly uncorrelated, such as data logger accuracy and non-stability, but others certainly have some level of correlation. Correlations, including correlations over time scales, are the subject of current research.

In table 2, the standard uncertainty of all quantities is calculated for the single data point at 11:45, with a pyranometer voltage output V of 15384 µV and a solar zenith angle Θ_z of 17.2°.

Tab. 2: Calculation of standard uncertainty of voltage output, sensitivity and irradiance for one data point

(Input) Quantity	Uncertainty source	u_i	Standard uncertainty
V = 15384 µV			
	data logger accuracy	10 µV	
			$u(V)$ = 10 µV
S = 15.00 µV W^{-1} m²			
	calibration uncertainty	0.08 µV W^{-1} m²	
	non-stability	0.03 µV W^{-1} m²	
	non-linearity	0.04 µV W^{-1} m²	
	temperature response	0.09 µV W^{-1} m²	
	maintenance	0.04 µV W^{-1} m²	
			$u(S)$ = 0.13 µV W^{-1} m²
E = 1025.6 W m^{-2}			
	zero off-set a	2.02 W m^{-2}	
	zero off-set b	1.15 W m^{-2}	
	directional response	5.92 W m^{-2}	
			$u(E)$ = 6.36 W m^{-2}

Note that the standard uncertainty of the irradiance u(E) is not the final result. The standard uncertainties in table 2 have to be combined to reach the so-called 'combined standard uncertainty' of the measurand $u_c(E)$. This is done using the law of propagation of uncertainty.

$$u_c(E) = \sqrt{c_V^2 u^2(V) + c_S^2 u^2(S) + c_E^2 u^2(E)} \quad \text{(eq. 4)}$$

where c_V, c_S, c_E are the 'sensitivity coefficients' of quantities V, S and E respectively.

The sensitivity coefficient of a quantity is the partial derivative of the output quantity with respect to that quantity. GUM defines this only for input quantities, but the definition can be extended to the output quantity to give a sensitivity coefficient equal to one (eq. 7). For our measurement model, the sensitivity coefficients are

$$c_V = \frac{\partial E}{\partial V} = \frac{1}{S} \quad \text{(eq. 5)}$$

$$c_S = \frac{\partial E}{\partial S} = -\frac{V}{S^2} \quad \text{(eq. 6)}$$

$$c_E = \frac{\partial E}{\partial E} = 1 \quad \text{(eq. 7)}$$

For the single data point we used as an example above, the combined standard uncertainty of the irradiance becomes

$$c_V = \frac{\partial E}{\partial V} = \frac{1}{S} = 0.07 \text{ µV}^{-1}\text{Wm}^{-2} \quad \text{(eq. 8)}$$

$$c_S = \frac{\partial E}{\partial S} = -\frac{V}{S^2} = -68.37\ \mu V^{-1} W^2 m^{-4} \quad \text{(eq. 9)}$$

$$c_E = 1 \quad \text{(eq. 10)}$$

$$u_c(E) = \sqrt{c_V^2 u^2(V) + c_S^2 u^2(S) + c_E^2 u^2(E)} = 11.2\ \mathrm{Wm^{-2}} \quad \text{(eq. 11)}$$

The combined standard uncertainty can be universally used to express the uncertainty of a measurement result, but it is preferable to define an interval about the measurement result that is expected to encompass a certain fraction of reasonable results for the measurand. This is achieved by multiplying the combined standard uncertainty with a coverage factor *k* to find the expanded uncertainty *U*. In practice, the coverage factor is chosen to reach a level of confidence of 95 %. The expanded uncertainty is then written with a subscript 95 to reflect this.

$$U_{95} = k u_c \quad \text{(eq. 12)}$$

This approach has the advantage of taking the abstract concept of uncertainty and applying a physical meaning. An irradiance reading of 1000 W m^{-2} with a symmetric expanded uncertainty U_{95} of 10 W m^{-2} can be understood to mean that if you would repeat that measurement 100 times, 95 times you would get a reading between 990 and 1010 W m^{-2}. This is a useful way of thinking when performing a risk analysis based on irradiance readings.

Choosing the right coverage factor is a complicated procedure, and is detailed in Annex G of the GUM (JCGM 100:2008). A simple approach is often adequate in measurement situations where the probability distribution is approximately normal and there is a significant number of effective degrees of freedom. When this is the case, one can use $k = 2$ to produce an interval having a level of confidence of 95 %, and $k = 3$ to produce an interval having a level of confidence of 99 %.

We introduced uncertainty sources with a rectangular probability distribution and although the effective degrees of freedom is significant (with a measurement rate of 1 Hz, we have 60 readings in the one-minute average), it is not infinite. However, we argue that using a coverage factor of 2 is a conservative and simple approach when analysing pyranometer of pyrheliometer measurements.

For the single data point, the final result is

$$U_{95}(E) = 2u_c(E) = 22.4\ \mathrm{Wm^{-2}} \quad \text{(eq. 13)}$$

The GUM recommends to report this measurement result as follows

"E = (1025.6 ± 22.4) W m^{-2}, where the number following the ± symbol is the numerical value of $U = ku_c$, with U determined from u_c = 11.2 W m^{-2} and k = 2 based on the normal distribution, and defines and interval estimated to have a level of confidence of 95 percent."

This result is valid for a single data point, but the analysis can be repeated for every data point. In this example, the only parameter that changes is the voltage output *V*, and therefore also the magnitude of the measurand *E*. When you perform this analysis over a full day, it can be seen that the expanded uncertainty varies over time.

In figure 1 the global horizontal irradiance is plotted with the expanded uncertainty drawn as error bars. As the irradiance increases, the absolute value of the expanded uncertainty increases as well, even as the relative value of the expanded uncertainty decreases.

Fig. 1: Measured global horizontal irradiance as a function of time, red bars give the expanded uncertainty values that correspond with a level of confidence of 95 %.

4.1 Analysis of relative importance per uncertainty source

It is possible to calculate the relative contribution of each uncertainty source to the expanded uncertainty. This way, it is possible to judge which uncertainty sources are dominant for this application. This information can be useful for purchasing decisions, product development and/or help to decide which systematic errors should be corrected for.

To calculate the relative contribution of an uncertainty source, first calculate the relative importance of all quantities as the ratio of the standard uncertainty of the quantity to the sum of the standard uncertainty of all quantities, weighed by their sensitivity coefficients.

For a quantity *X* this is

$$\frac{u(X)}{\sum_l c_l u(l)} \qquad \text{(eq. 14)}$$

where *l* sums over all quantities

The relative importance of one uncertainty source within a quantity is found directly from the ratio of the standard uncertainty to the sum of the standard uncertainties of all sources that apply to that specific quantity.

For an uncertainty source *i* this is

$$\frac{u_i}{\sum_m u_m} \qquad \text{(eq. 15)}$$

where *m* sums over all uncertainty sources that apply to the same quantity as *i*.

Multiply the two ratios to find the final contribution.

We work this out for three sources explicitly, and present the contributions of all sources in table 3, for the same single data point.

$$\frac{u_{\text{data logger accuracy}}}{\sum_{i=\text{data logger accuracy}} u_i} \cdot \frac{u(V)}{c_V u(V)+c_S u(S)+c_E u(E)} = 4.1\ \% \qquad \text{(eq. 16)}$$

$$\frac{u_{\text{non-linearity}}}{\sum_{i=\text{calibration uncertainty, non-stability, non-linearity, temperature response, maintenance}} u_i} \cdot \frac{u(S)}{c_V u(V)+c_S u(S)+c_E u(E)} = 8.7\ \% \qquad \text{(eq. 17)}$$

$$\frac{u_{\text{zero off-set b}}}{\sum_{i=\text{zero off-set a, zero off-set b, directional response}} u_i} \cdot \frac{u(E)}{c_V u(V)+c_S u(S)+c_E u(E)} = 5.0\ \% \qquad \text{(eq. 18)}$$

Tab.3: Calculation of relative contribution to the expanded uncertainty per uncertainty source for one data point

Input quantity	Uncertainty source	Relative importance per input parameter	Relative importance per uncertainty source
V = 15384 µV			
	data logger accuracy		4.1 %
		4.1 %	
S = 15.00 µV W^{-1} m^2			
	calibration uncertainty		15.0 %
	non-stability		6.9 %
	non-linearity		8.7 %
	temperature response		17.4 %
	maintenance		8.7 %
		56.7 %	
E = 1025.6 W m^{-2}			
	zero off-set a		8.7 %
	zero off-set b		5.0 %
	directional response		25.5 %
		39.2 %	

This procedure can be repeated for all data points. In figure 2, the expanded uncertainty is plotted as function of time, split per uncertainty source in a stacked area chart. Figure 2 a) gives the expanded uncertainty in W m^{-2}, figure 2 b) in percentage. For low irradiances, the uncertainty expressed in percentages becomes very high.

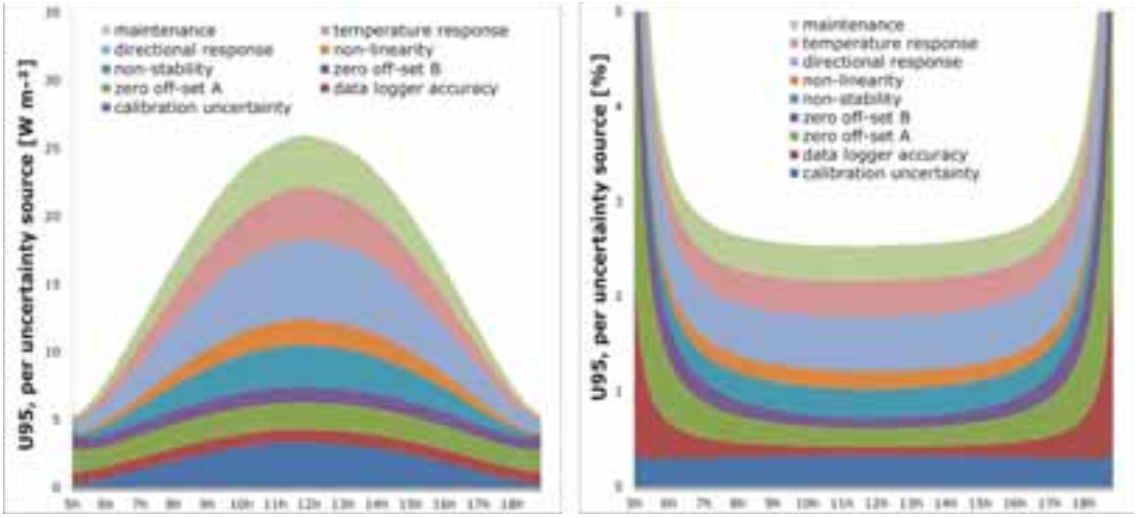

Fig. 2: Expanded uncertainty as function of time, split per uncertainty source.
The expanded uncertainty is expressed in a) absolute values in W m^{-2}, b) relative values in %.

In figure 3 we plot the relative contribution of each uncertainty source as a function of irradiance. Here it becomes clear that at low irradiance levels, the zero off-set a, dominates together with the zero off-set b and data logger accuracy. At higher irradiance levels, the directional response dominates, and the importance of the zero off-sets and data logger accuracy diminishes.

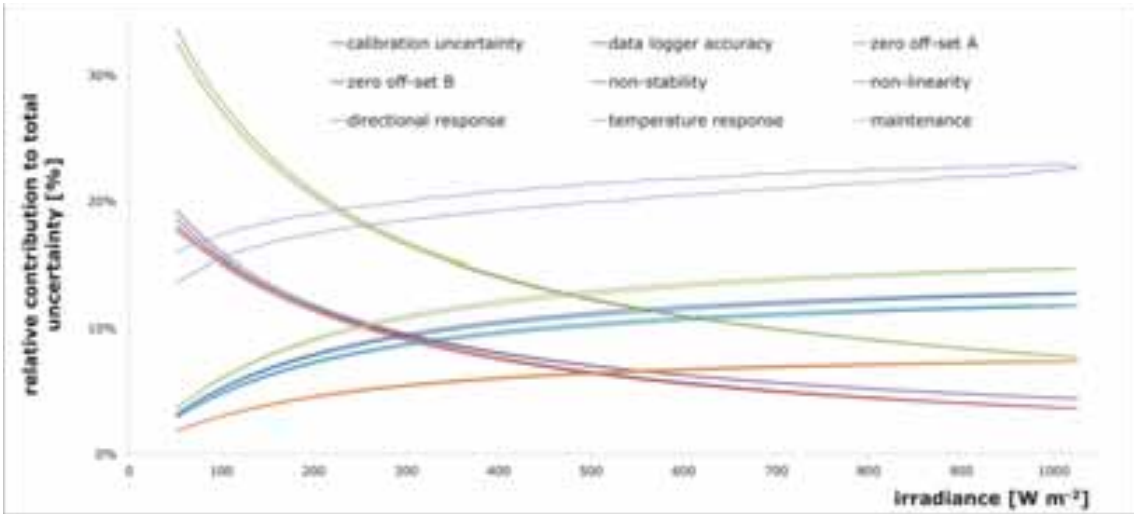

Fig. 3: Relative importance of each uncertainty source as a function of irradiance.

4. Data availability

The 'rated operating conditions' are defined as conditions that must be fulfilled during measurement in order that a measuring instrument performs as designed (JCGM 200:2012). For pyranometers and pyrheliometers, the condition that the optics (domes, windows) of the instrument are clean is a critical rated operating condition. Snowfall can obstruct the domes to no longer transmit solar radiation, leading to an underestimation. Rain droplets on a pyranometer can focus the incoming solar radiation, leading to an overestimation. Figure 4 gives visual examples of situations where the optics of the instrument are not clean.

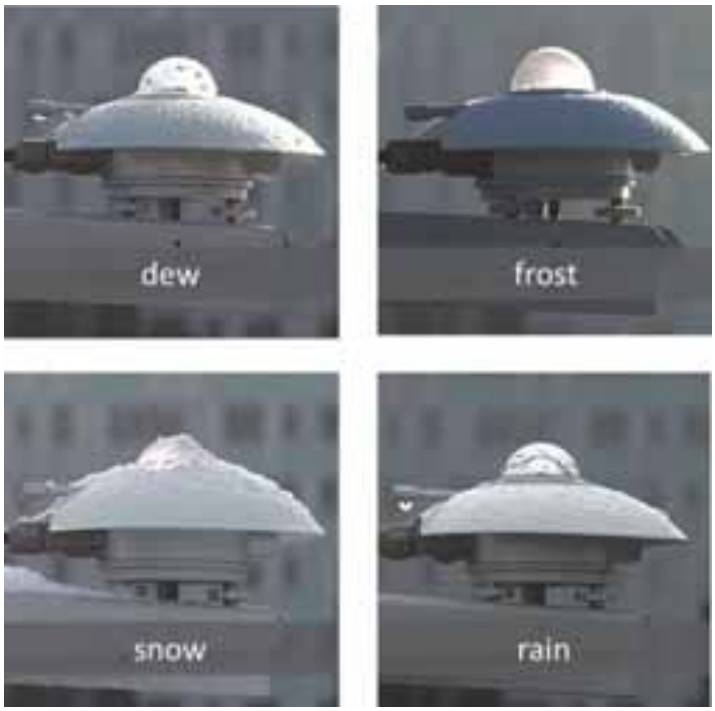

Fig. 4: Examples of pyranometers with domes that are not clean. These measurements cannot be assigned a meaningful measurement uncertainty.

In these situations, it is not possible to assign a meaningful measurement uncertainty to the instrument reading. Data points that fall outside the rated operating conditions should be flagged accordingly and considered as not available. This provides a definition of the concept of 'data availability': the percentage of data points over a certain time period that fall within the rated operating conditions of the instrument, and can be assigned a meaningful measurement uncertainty.

Data availability can be used as a requirement during site assessment, and can be useful for purchasing decisions or when determining the required level of maintenance during operation.

A trained user can recognize 'false' data point from a visual interpretation of the measurement data, but other methods are available that provide a more solid process of flagging data points. The BSRN uses a set of recommended Quality Control tests that compare measurement data with physically possible limits and extremely rare limits (Long 2012). A strong method is to combine separate measurements of global, diffuse and direct irradiance and compare the ratios between measured direct irradiance and the direct irradiance back-calculated from measurements of global and diffuse irradiance.

$$E_{\text{direct}} = E_{\text{global}} \cos \Theta z + E_{\text{diffuse}} \quad \text{(eq. 19)}$$

When measurements of direct radiation are not available, which is often the case in solar energy applications, it can be helpful to monitor the pyranometers, for example using webcam images. A study using webcam images in Delft, the Netherlands, over 26 days in the spring of 2015, found that without any measures to improve data availability, an average 80 minutes of data per day was lost due to early morning dew.

Ways to improve the data availability of pyranometers and pyrheliometers include the use of forced ventilation (using purpose built ventilation units) and direct heating of the instrument optics to keep the optics above dew point temperature and free of frost and snow. Both methods can be effective, and in the study above were able to increase data availability to 100 %. Figure 5 shows the visual difference between a heated and unheated pyranometer during frost.

Fig. 5: Visual difference between a heated (left) and unheated (right) pyranometer during frost. Data points measured with the left pyranometer can be assigned a meaningful uncertainty, data points measured with the right pyranometer have to flagged as not available.

Both methods can also induce off-sets on the thermal instruments. These off-sets will have to be included as an uncertainty source, and can become dominant for instruments that were not designed for use with ventilation or heating. Especially in environments with extreme conditions, the user will have to find a balance between data availability and measurement uncertainty.

Instruments that are specifically designed for use with ventilation or direct heating in mind will often include ventilation or heating off-sets in the data sheet.

For example, the left pyranometer in figure 5 uses a combination of a sapphire outer dome with 1.5 W internal heating and specifies a heating off-set of 0 to -1.5 W m^{-2} (Hukseflux 2015). This uncertainty source should be applied directly to the irradiance, with a specification limit of 1.5 W m^{-2} and be treated as a Type B uncertainty with a one-sided (negative) rectangular distribution.

5. Results and discussion

We presented a worked example of the uncertainty evaluation of one clear sky day of global horizontal irradiance measured with a pyranometer specified as a secondary standard pyranometer.

We used a method based on the GUM, according to the procedures and guidelines that are written into a standard that is in development within the ASTM International Subcommittee G03.09 on Radiometry. In the formulation stage, we developed the measurement model and defined the relevant sources of uncertainty. In

the calculation stage, we combined this information to find the expanded uncertainty of the measurement. As a separate analysis, we calculated the relative importance per uncertainty source.

We find an expanded uncertainty U95 of 2.2 % (k = 2) for a data point around solar noon, and we find the three dominant contributions to the measurement uncertainty; the directional response, the temperature response and the initial calibration uncertainty. For conditions with lower levels of irradiance, the zero off-sets and data logger accuracy become dominant.

Users have to adapt the analysis shown here to their own situation. In practice, this means they have to update the formulation stage with sources and specification limits for their own situation. The calculation stage does not change. Spreadsheets are available from the authors on request that can assist in this process.

The procedure presented is not capable of producing asymmetric confidence intervals, and does not incorporate correlations between different uncertainty sources, or correlations over time. Future work should improve on these matters.

We introduced the concept of data availability, and made a specific link of this concept with the process of uncertainty evaluation. Data availability can be a useful tool for site assessment, determining a maintenance schedule, purchasing decisions or product development.

ASSESSMENT OF DAILY ATMOSPHERIC TURBIDITY DATABASES USING AEROSOL OPTICAL DEPTH AND DIRECT NORMAL IRRADIANCE MEASUREMENTS

Luis Martin-Pomares[1], Jesus Polo[2], Daniel Perez-Astudillo[1] and Dunia A. Bachour[1]

Abstract

This study presents the validation of atmospheric turbidity databases. It is divided into two parts. The first part shows the validation of three Aerosol Optical Depth (AOD) databases with worldwide coverage. AOD at 550nm estimates from MISR, MODIS-L3 satellites and MACC model and water vapour from NCEP are compared against measurements from 865 AERONET stations as ground-truth data for more than one year in each location.

The second part addresses the limitation that ground measurements of AOD are not always available. An alternative methodology is presented here to evaluate the AOD databases. It consists of comparing the daily Linke Turbidity Index (TL) obtained from the databases to the corresponding TL derived from DNI measurements.

All databases show a significant overestimation of AOD and errors in terms of rRMSD are between 85 and 118% in total for the AERONET stations validated.

Keywords: *Atmospheric aerosols, turbidity, solar radiation, AOD, TL*

1. Introduction

Aerosol Optical Depth (AOD) is the degree to which aerosols prevent the transmission of light by absorption or scattering of light and is defined as the integrated extinction coefficient over a vertical column of the unit cross-section (Albrecht, 1989).

AOD is a fundamental parameter for the modelling of solar radiation. It is mainly needed for clear sky models (Gueymard, 2008; Ineichen, 2008; Rigollier, Bauer, & Wald, 2000).The clear sky models are an essential component of many methods of solar radiation estimation from satellite images (Polo, Antonanzas-Torres, Vindel, & Ramirez, 2014; Rigollier & Wald, 1999). The measurements of AOD are scarce in the world due to the high cost of installing and running a station to measure this variable. Because of this scarcity, AOD estimated from satellite images or chemical transport models are widely used.

Another index to quantify turbidity is the Linke Turbidity (TL) index (Ineichen & Perez, 2002; Kasten, 1996; Linke, 1922) which establishes a relationship between the real and theoretical optical depth of the atmosphere and represents the degree of transparency of the atmosphere. It is an adequate approximation when quantifying the effects of absorption and dispersion of solar radiation when traversing the atmosphere. TL can be obtained directly from solar radiation ground measurements; however, due to the unavailability of ground data, it is derived from empirical adjustments (Kasten, 1980).

doi:10.18086/swc.2015.07.16 Available at http://proceedings.ises.org

Several validations of AOD databases in a regional scale have been presented previously (Antonanzas-Torres et al., 2014; Eissa et al., 2015; Ruiz-Arias, Dudhia, Gueymard, & Pozo-Vázquez, 2013; Zhong & Kleissl, 2015), but a global validation has not been done yet. In this study, we present first results of a comprehensive validation of three AOD databases (MODIS, MACC and MISR).

Besides, as in most of the locations, AOD measurements are not available, we present a methodology to estimate turbidity from solar radiation measurements. The turbidity of two sites obtained using Linke TL from Direct Normal Irradiance (DNI) ground measurements is presented to show the capabilities of this methodology.

2. Experimental Datasets

In this section, we present the experimental data used in this study.

2.1 Aeronet ground measurements

Field measurements from the NASA AERONET (AErosol RObotic NETwork) program are available all around the Globe. We have used in this study 865 stations from the AERONET network. The measurements were collected during different periods. For each AERONET station, the measurements of the CIMEL CE-318 Sun photometer were converted into aerosol optical properties and are available for public access (http://aeronet.gsfc.nasa.gov). The data sets include the aerosol optical depth (AOD) at eight different wavelengths, as well as the solar zenith angle and the total column content in water vapour (PW). The AERONET Level 2.0 products (cloud-screened and quality assured) are compared in Section 4 to the daily AOD at 550 nm from MODIS, MISR and MACC. Daily PW is compared with NCEP model.

2.2 Radiometric measurements

The radiometric data used in this study for the validation is located in China and South of Spain. DNI is measured with first class pyrheliometer. Global Horizontal Irradiance (GHI) and Diffuse Horizontal Irradiance (DHI) were also available from secondary standard pyranometers. Both stations have solar trackers and shading ball for DHI. Data is registered every 10 minutes in both stations, and hourly averages were calculated. BSRN quality checks (Long & Dutton, 2002) are applied to remove suspicious wrong data.

2.3 Aerosol and Atmospheric databases

The atmospheric and aerosol datasets, compared in this study, come from different sources. Daily values of AOD at 550nm from satellite and models are the following:

- MODIS-L3: daily values of AOD with a spatial resolution of 1ºx1º for the period from the year 2004 to the present.
- MACC (Monitoring Atmospheric Composition & Climate from ECMWF): daily values of AOD with a spatial resolution of 1.125ºx1.125º for the period from 2003 to the present.
- MISR (Multi-angle Imaging SpectroRadiometer): daily values of AOD with a spatial resolution of 0.5ºx0.5º for the period from 2001 to the present.

Daily PW from AERONET stations is validated with NCEP (National Centers for Environmental Prediction) for the temporal period coincident. The spatial resolution of NCEP data is 1ºx1º.

3. Methodology

The parameters to validate daily AOD at 550 nm and PW from different databases with AERNET stations are mean bias deviation (MBD), root mean squared deviation (RMSD) and its relative value as rMBD and rRMSD. The relative expressions are obtained using the following equations:

$$\mathrm{rMBD} = \frac{1}{N}\sum_{i=1}^{N}\left(\hat{x}_i - x_i\right) \qquad \text{(eq. 1)}$$

$$\mathrm{rRMSD} = \frac{\sqrt{\sum_{i=1}^{n}(x_i - \hat{x}_i)^2 / n}}{\bar{x}} \qquad \text{(eq. 2)}$$

where N is the population size, x is the observed value, $\bar{x}$ is the mean of observed values, and $\hat{x}$ is the predicted value.

The following parameters have also been calculated (Espinar et al., 2009). The correlation coefficient (R), Kolmogorov–Smirnov test Integral (KSI), and its relative magnitude (KSI (%)), the critical limit from the original Kolmogorov–Smirnov test (Over), and its relative (Over(%)), the evaluation parameter based on KSI and Over (KSE) and RIO, combination of the three most representative parameters: OVER (%), KSI (%), and RMSD (%).

3.1 Turbidity from DNI measurements

Besides, when AOD measurements are not available, we have used DNI measurements to validate the satellite and model estimates. We have extracted turbidity from DNI measurements after identifying clear sky conditions which can be done automatically or manually by visual inspection. We have used the last option. The values of TL are obtained using the inverse of a clear sky model for clear sky days at solar noon (Ineichen & Perez, 2002).

AOD at 550 nm from MODIS, MISR and MACC are converted to TL values using Ineichen correlation (Pierre, 2008) and daily PW from NCEP.

4. Results

In this section, we present the primary results.

4.1 Validation of Aerosol Optical Depth (AOD) from satellite and models

The next tables show the results for MBD, RMSD, rMBD, rRMSD, R, KSI, KSI (%), Over, Over(%), and RIO, (Espinar et al., 2009) for daily PW from NCEP model compared with AERONET measurements:

Tab. 1: Statistical errors of daily water vapour column from NCEP model compared with AERONET stations

MODEL	MBD	RMSD	rMBD (%)	rRMSD (%)	R
NCEP	0.17	0.65	16.87	42.66	0.72

Tab. 2: Errors for daily water vapour column from NCEP model compared with AERONET stations

MODEL	IKS	IKS %	Over	Over %	KSE	RIO
NCEP	0.27	94.03	0.11	47.25	141.28	91.89

As we can see from the results, NCEP database presents a considerable overestimation and rRMSD is considerably high.

The next tables show MBD, RMSD, rMBD, rRMSD, R, IKS, IKS(%), Over, Over(%), KSE and RIO for AOD at 550 nm for MODIS and MISR satellites and MACC model:

Tab. 3: Statistical errors of daily Aerosols Optical Depth (AOD) at 550 nm from MODIS and MISR satellite and MACC model compared with AERONET stations

SATELLITE/MODEL	MBD	RMSD	rMBD (%)	rRMSD (%)	R
MODIS	0.03	0.20	40.58	118.10	0.48
MISR	-0.02	0.17	6.66	85.60	0.29
MACC	0.02	0.18	32.07	101.86	0.33

Tab. 4: Errors for daily Aerosols Optical Depth (AOD) at 550 nm from MODIS and MISR satellite and MACC model compared with AERONET stations

SATELLITE MODEL	IKS	IKS %	Over	Over %	KSE	RIO
MODIS	0.06	56.77	0.02	25.25	82.02	99.46
MISR	0.05	96.66	0.02	46.69	143.35	114.52
MACC	0.06	87.38	0.02	46.28	133.66	117.75

All databases show overestimation which is considerably high in the case of MODIS and MACC. It has a direct effect on clear sky models output and solar radiation derived satellite from a satellite which will be underestimated in the case of using raw AOD values from these databases. MISR satellite presents better results globally in terms of rMBD and rRMSD, maybe due to its higher spatial resolution.

4.2 Validation of Aerosol Optical Depth (AOD)

The hourly values of DNI for a clear sky day selected manually for a location in Spain are shown in the next figures for several days. In the plots, measured clear sky DNI (blue), modelled clear-sky DNI (green), DNI estimated from satellite MODIS TL and DirIndex model (pink) and DNI estimated from satellite MODIS TL and Louche model (red). In the figure, we also show the values of daily TL estimated from MODIS satellite and calculated from measurements for all hourly values and two hours during the day at noon time (11:00 and 12:00 UTC). The values of TL are calculated from measurement at noon hours because there are some days which have clear sky conditions in most of the times of the day but not in all.

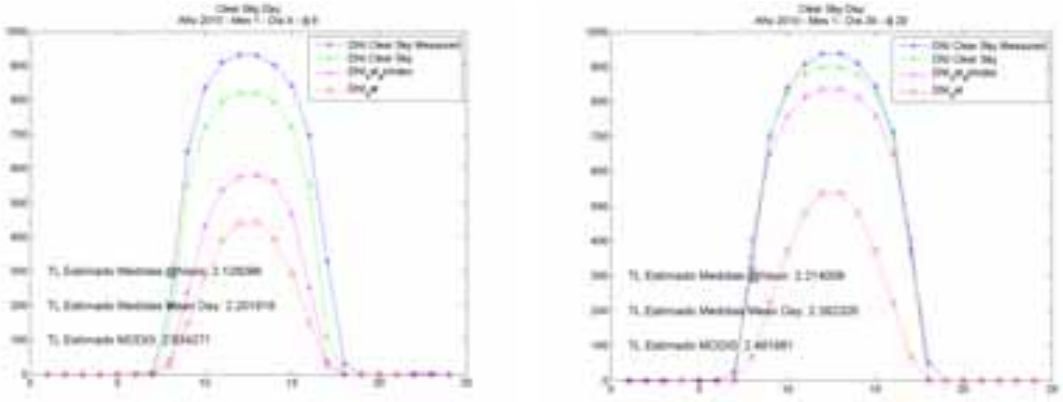

Fig. 1: TL estimated from MODIS and measurements of DNI for a clear sky day. 09/01/2010 and 29/01/2010 in Spain.

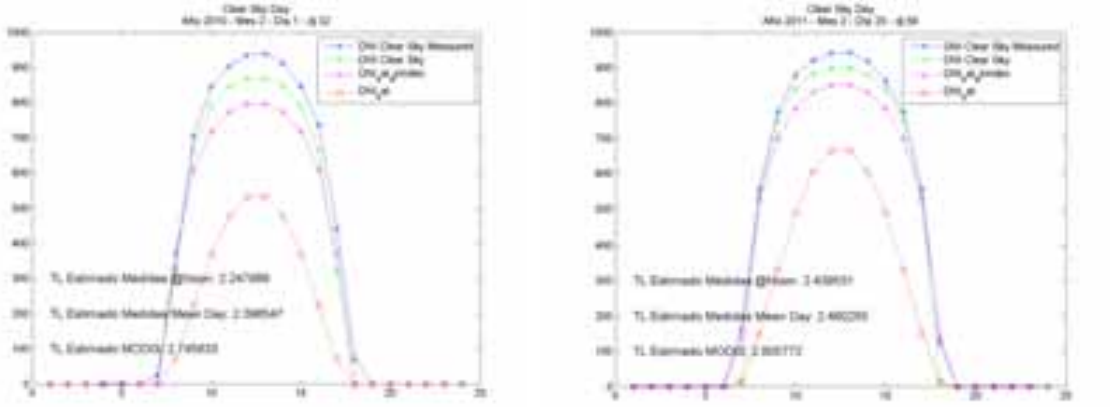

Fig. 2: TL estimated from MODIS and measurements of DNI for a clear sky day. 01/02/2010 and 25/02/2011 in Spain.

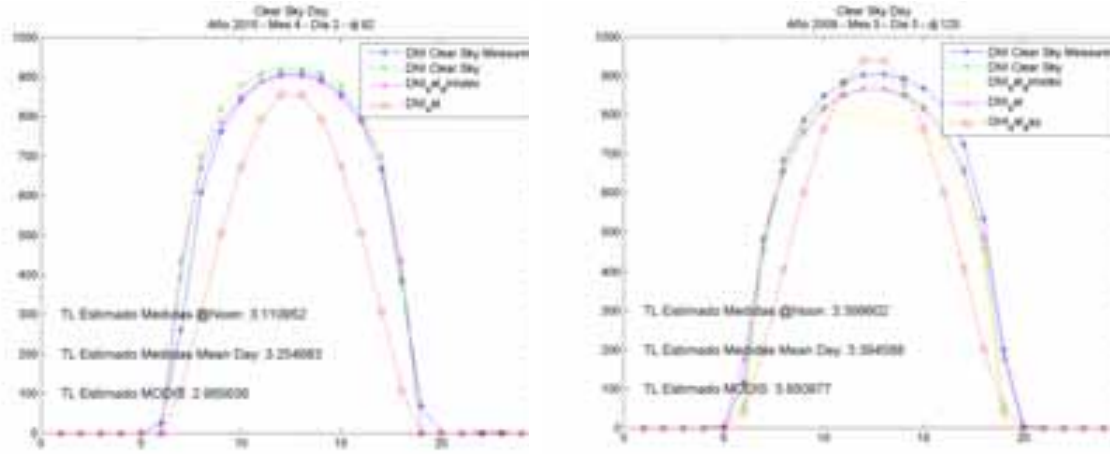

Fig. 3: TL estimated from MODIS and measurements of DNI for a clear sky day. 02/04/2010 and 05/05/2009 in Spain.

The next figures represent the same information as in the last ones but for cloudy conditions.

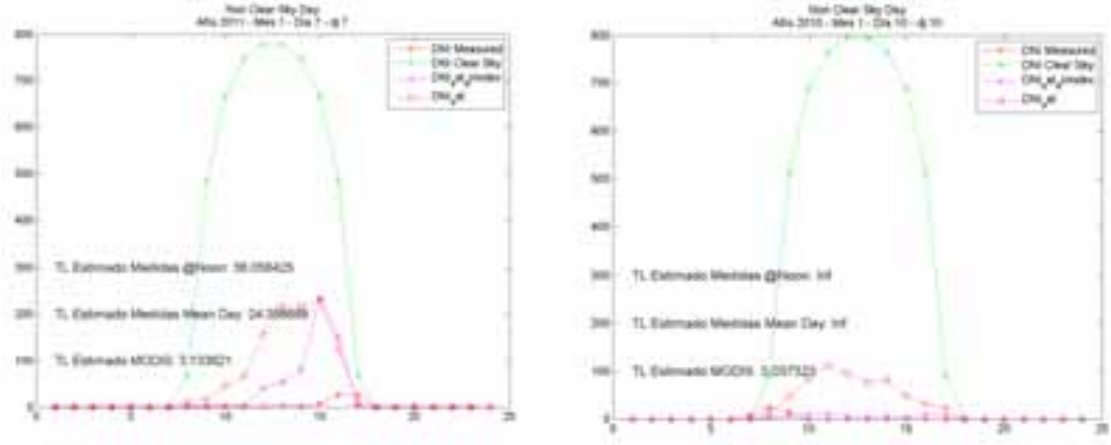

Fig. 4: TL estimated from MODIS and measurements of DNI for a cloudy sky day. 07/01/2011. 10/01/2010 in Spain.

With the values calculated from the daily selection, we have obtained daily time series of TL. The next figures show some examples of the relationship between daily Linke Turbidity (TL) estimated from MODIS satellite (red line) and estimated from measurements (blue line) with clear sky days for several months in the location in Spain. TL is obtained from several years of measurements:

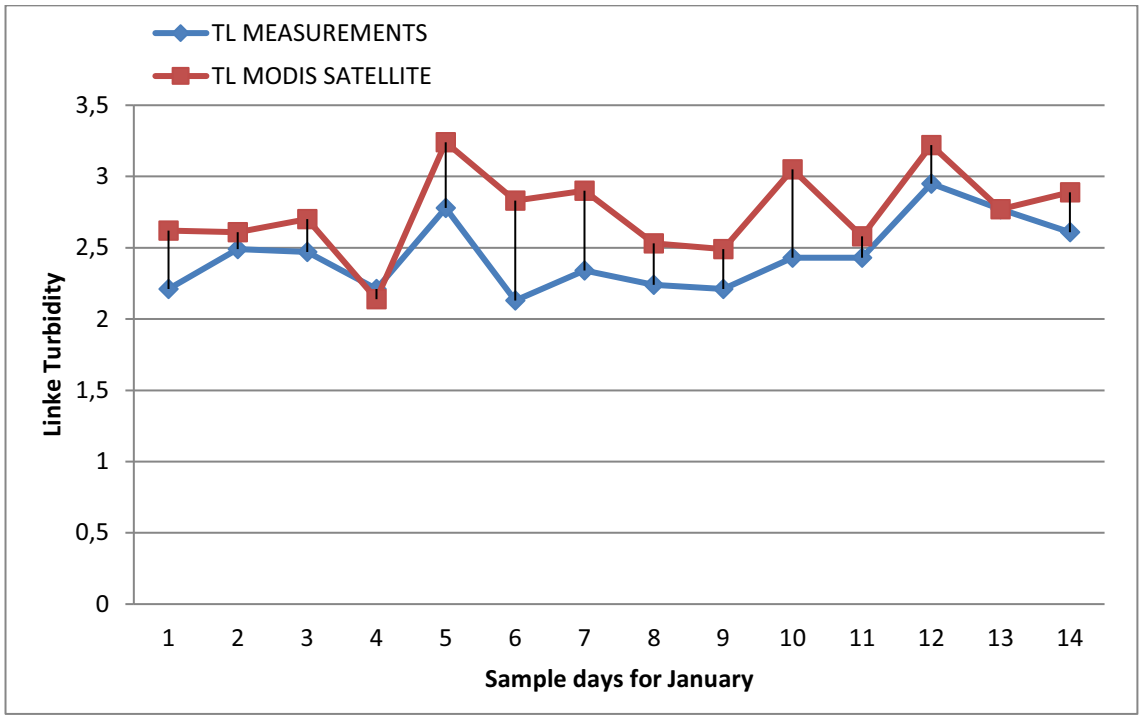

Fig. 5: Daily values of TL estimated from MODIS and measurements with clear sky days in January

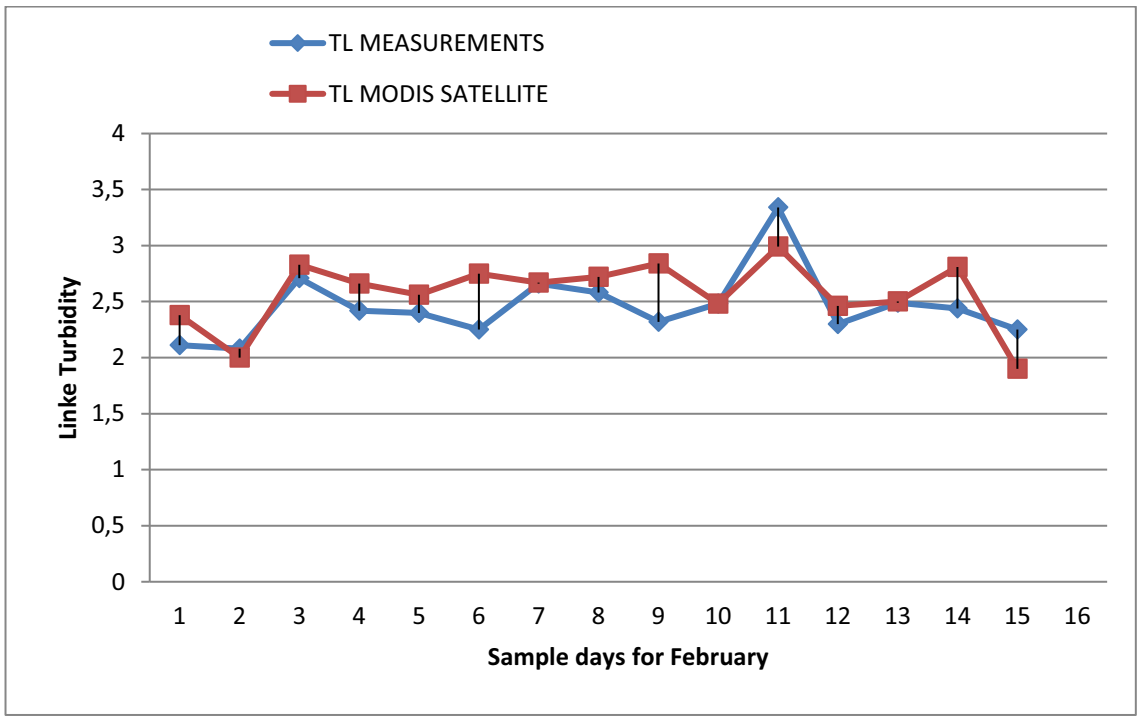

Fig. 6: Daily values of TL estimated from MODIS and measurements with clear sky days in February

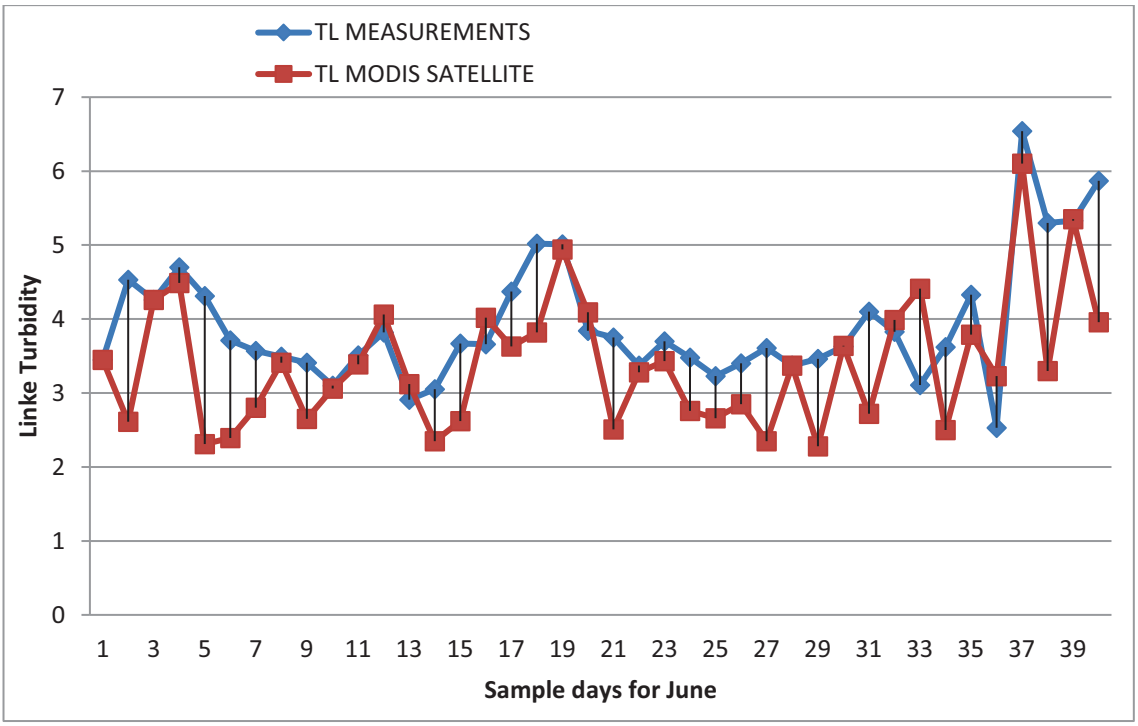

Fig. 7: Daily values of TL estimated from MODIS and measurements with clear sky days in June

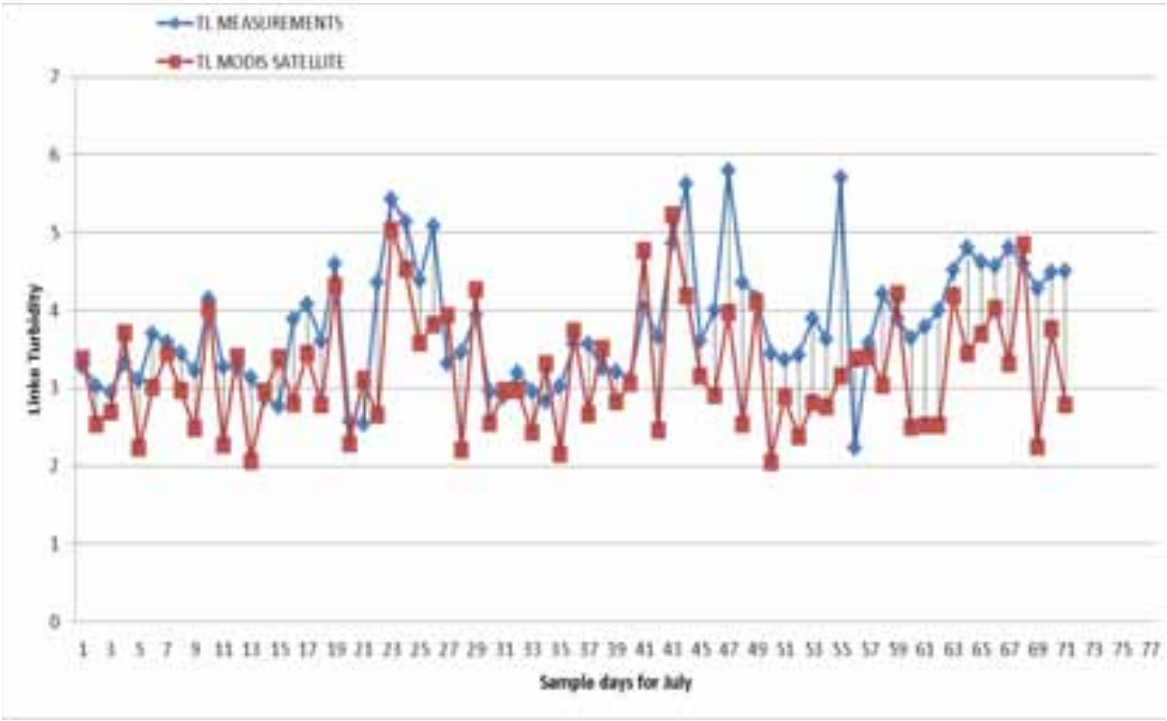

Fig. 8: Daily values of TL estimated from MODIS and measurements with clear sky days in July

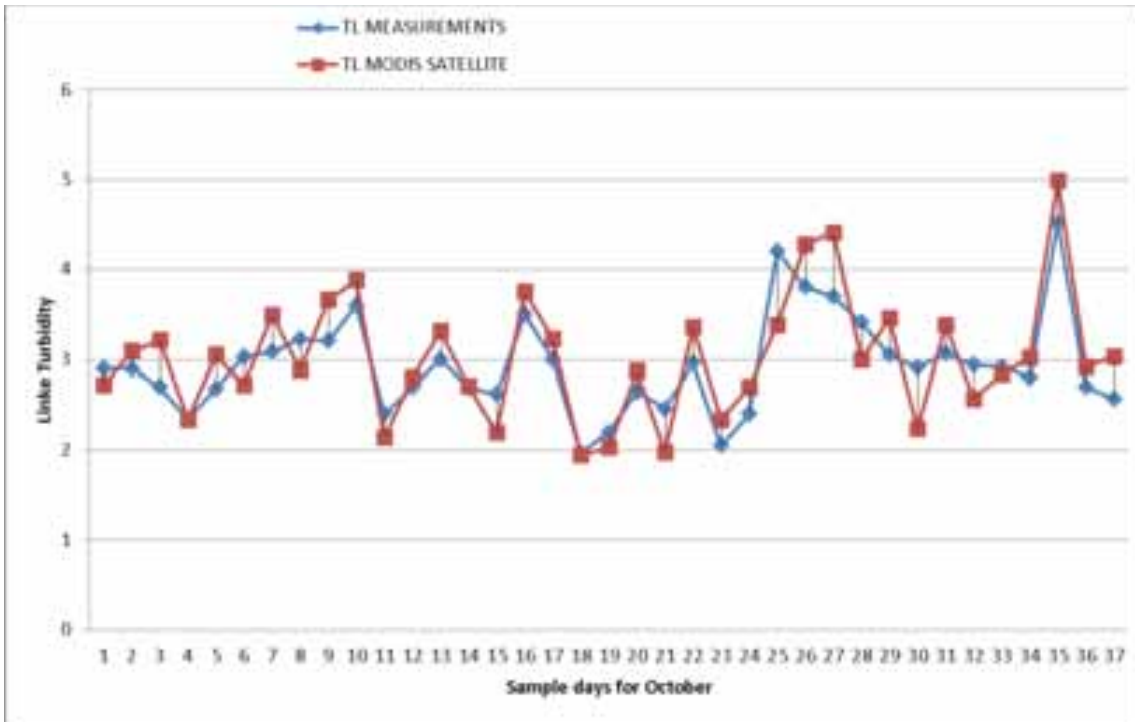

Fig. 9: Daily values of TL estimated from MODIS and measurements with clear sky days in October

As can be seen from last figures, MODIS database represents well turbidity for this location in Spain. The different observed between MODIS and TL derived from DNI measurement are due to deviations of clear sky models and raw spatial resolution of MODIS data.

Figure 10 presents the results of applying the same methodology to a location in south-west China at an altitude of 3000 meters. Monthly TL derived from DNI measurements (purple line) is compared with TL from MISR (red line), MACC (blue line) and Meteotest databases (red line). MODIS values have not been included in this graphic as the database only had values from June to September for this location. Most probably because MODIS have difficulties estimating AOD over high reflectivity land surfaces and in winter months, due to the altitude of the site, most likely this site is entirely covered by snow. It works better over the ocean/sea.

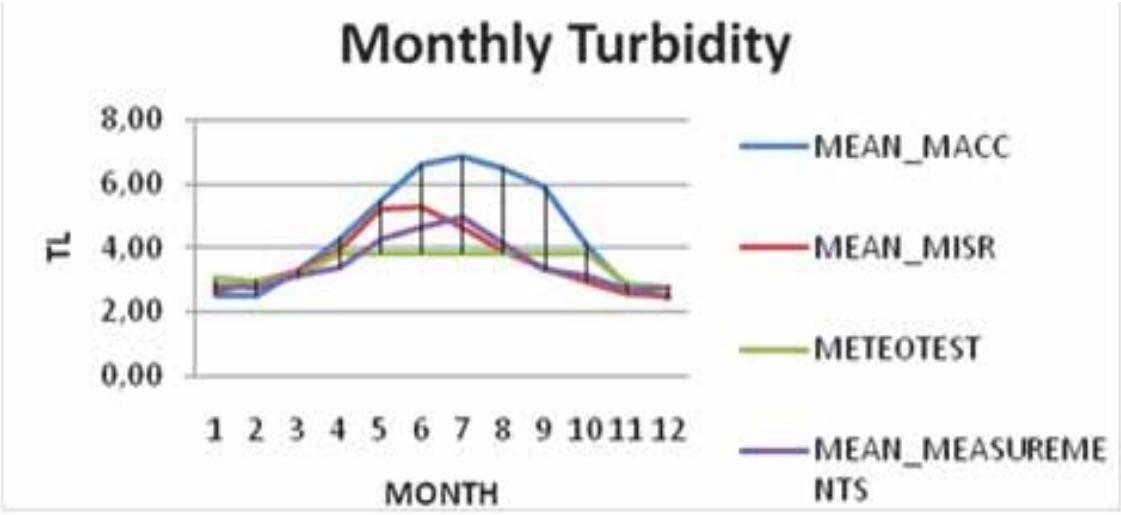

Fig. 10: Mean monthly Linke Turbidity values from DNI measurements, MACC, MISR and Meteotest database for a location in south-west of China

In this location, as can be seen in the last graphic, MACC presents a big overestimation. This resulted in obtaining yearly DNI estimations from satellite images around 30% less than ground measurements. MISR TL (AOD 550nm) estimations are the nearest to TL obtained from DNI measurements. Meteotest values don't follow the monthly dynamic of the turbidity.

The deviations between TL from databases (MODIS, MISR and MACC) and TL derived from DNI measurements can be corrected using different statistical methods (linear/non-linear). This process can be done to improve the calculations of clear sky models before the estimation/processing of solar radiation from satellite images

5. Conclusion

MODIS, MISR and MACC daily AOD at 550nm and daily PW from NCEP were compared against AERONET measurements for 865 locations. All databases show overestimation which is considerably high in the case of MODIS and MACC. This has a direct effect on clear sky models output and solar radiation derived satellite from a satellite which will be underestimated in case raw AOD values from these databases is used. MISR satellite presents better results globally in terms of rMBD and rRMSD, maybe due to its higher spatial resolution. Additionally, the difference in the quality between MISR and MODIS may also be induced by the different algorithms used to estimate the aerosols (not only the resolution). A methodology to estimate TL from DNI measurements was introduced. This can be used to correct turbidity in the databases before using it in models to derive solar radiation from satellite images.

In future works, we will create global uncertainty maps and a fusion daily AOD at 550nm and PW database combining AERONET data and corrected MODIS, MISR and MACC data using kriging techniques.

Effect of Day-ahead Forecasts on Curtailment Planning of PV Power in Japan

Joao Gari da Silva Fonseca Junior[1], Yusuke Udagawa[1], Tetsuo Saito[1], Takashi Oozeki[2], Kazuhiko Ogimoto[1]

[1] The University of Tokyo, Institute of Industrial Science, Tokyo (Japan)

[2] National Institute of Advanced Industrial Science and Technology, Tsukuba (Japan)

Abstract

The objective of this study is to evaluate the effect that the accuracy of day-ahead forecasts of photovoltaic, PV, power generation has on forecast based curtailment of PV power. Two main regions of Japan were targeted, Kanto, which has a high potential for installations of roof-top PV systems; and Kyushu, which already has high levels of PV power penetration. To provide a qualitative measure of the importance of accurate PV forecasts with different levels of PV power generation, for each region, 2 penetration scenarios were assumed. One year of regional and day-ahead forecasts of PV power were done using numerical weather prediction data, support vector regression, and measured PV power generation data. The PV power generation data comes from to a set of 52 PV systems in Kyushu and to a set of 62 PV systems located in Kanto. The curtailment of PV power was planned one day ahead of time, using the PV power forecasts and a method based on residual loads. The results show that with current day-ahead forecasts it is possible to correctly predict the hours when curtailment will occur most of the time. For example, for Kyushu, curtailment was properly detected 83.1% of the time in a scenario of 8.64 GW of PV installed. For Kanto the values were between 73% and 80.5%. Regarding the effect of the forecast error, we found that it annualy represents near to 35% of the amount curtailed, indicating the importance of improvement of day-ahead forecasts in the curtaiment problem. Finally, the study shows that the relation between the months and hours of curtailment with the period of high forecast errors is crutial to the efficient use of the forecasts, and must be considered before using the forecasts to plan curtailment.

Keywords: *photovoltaic power generation, day-ahead regional forecasts, curtailment planning, support vector regression.*

1. Introduction

In Japan, since the enactment of a new feed-in tariff plan for renewable energy in June of 2012, the number of installations of photovoltaic, PV, power had a 4-fold increase, reaching 25 GW in February of 2015 (METI, 2015a). Such rapid growth is cause of concern, as Japan`s power systems are not prepared to deal with high levels of PV power penetration. In Kyushu region for example, the penetration of PV power has already reached particularly high levels, with 4.5 GW of installed capacity and other 4.1 GW authorized and waiting for grid connection as of December of 2014. Considering that the region has a minimum annual demand of power near to 7 GW, to keep the balance between demand and supply of power throughout the year became a difficult task for Kyushu's power utility. Problems derived from the inadequacy of current power systems to deal with high penetration of PV power are also affecting other regions in Japan, although at different levels.

Measures such as power market liberalization, increase of power transmission capacity between different power balacing areas, demand response systems, and power storage solution, can mitigate such problems.

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.07.17 Available at http://proceedings.ises.org

Nevertheless, their implementation requires time and significant resources. Thus, while these measures are being considered and implemented, a short-term solution to deal with the current situation is necessary. In this regard, curtailment of PV power is seen a key measure to guarantee the stable operation of power systems without restricting the growth of PV systems installations.

Japanese power utilities will start to integrate renewable energy curtailment planning in their power systems and grid operation scheduling from 2016. The curtailment will be based on regional forecasts of PV power done at different forecast horizons, and with different levels of accuracy. As the forecast have variable accuracy throughout the year, it is crutial to know the impact that such variable accuracy will have on curtailment of PV power.

Although there is a variety of studies on methods to forecast power generation of renewable energy systems such as (Lorenz et al., 2012), (Diagne et al., 2012), (Paulescu et al., 2012), (Lauret et al., 2015), studies on their application to or of their impact on curtailment of PV power are scarce. On the other hand, available studies about curtailment, usually are focused on estimates of the total amount curtailed per country (Lew et al., 2013), local practices regarding curtailment (Rogers et al., 2010), or estimates of required curtailment given scenarios of renewable energy penetration (Garrigle et al., 2013), for example.

In this initial study we evaluate the impact of day-ahead regional forecasts of PV power generation on its curtailment plan. The study focus on two regions in Japan, the Kyushu region, which already has high levels of PV power penetration, and the Kanto region, which has the highest potential for roof-top PV installations in the country. For each region, data of 2010 was used; but the levels of PV power penetration were based on values of 2014. The forecasts of PV power were done one day ahead of time, in regional scale, and regarding current penetration of PV power in each prefecture within the regions. For each target day and PV power scenario, we compare curtailment based on regional PV power forecasts with the actual curtailment that would be necessary to avoid excess of PV power generation, and analyze the effects that the forecast errors will have on the curtailment plan.

2. Methods and Data

To plan curtailment for a day and region, first the corresponding regional PV power generation was forecasted. This section contains the description of the forecast method, curtailment method, data used and PV power penetration scenarios studied.

2.1. Forecast Method

To forecast regional PV power generation we used a method that employed support vector regression and numerical weather prediction, NWP, data. The support vector regression used was the ν support vector regression (Schölkopf et al., 1998), implemented on the LibSVM library (Chang et al., 2001). The NWP data included cloudiness, temperature and relative humidity; they came from the meso-scale model (5 km by 5 km of spatial resolution) of the Japan Meteorological Agency (Saito et al., 2006), released at 12h of the day preceding the target day. The forecasts were done hourly from 6h to 19h of each target day. This method was developed in previous studies, where further details are available (Fonseca et al., 2015).

The regional forecasts were calculated from sets of point forecasts for single PV systems installed in different locations within each region. Given the location of a single PV system, and for a given hour, the corresponding predictions of cloudiness, temperature and relative humidity, as well as the calculated extraterrestrial insolation are entered in a trained support vector regression algorithm, which then returns the corresponding amount of PV power generation. For each day of forecasts, we trained the algorithm before using it. The training used input data and PV power generation data of the 60 days preceding the target day. Thus, one forecast model was set for each day of forecasts. Once the point forecasts were done, the regional yield was calculated using a upscaling procedure described in Eq. 1 and Eq. 2.

$$|P_{pf}| = \frac{1}{P_{rt,pf}} \sum_{i=1}^{n} P_i \quad (1)$$

$$P_{reg} = P_{rt,reg} * \sum_{pf=1}^{m} |P_{pf}| * \alpha_{pf} \quad (2)$$

As Japan is geopolitically divided in prefectures, in Eq. 1 $|P_{pf}|$ is the normalized PV power generation per prefecture inside the target region. The PV power generation of each system i inside a prefecture is P_i (in kW), and $P_{rt,\mathrm{pf}}$ (in kW) is the total rated power of the PV systems inside the same prefecture. In Eq. 2, P_{ref} (in kW) is the regional yield, $P_{rt,pf}$ (in kW) is the regional installed capacity scenario, and α_{pf} is the ratio between the PV rated power in each prefecture by the total regional rated power.

2.2. Curtailment Method

To calculate the total amount of PV power to be curtailed in a target day we used a methodology based on the base and residual loads. The base load was regarded as the minimum amount of power demand that has to be supplied by power systems using conventional and non-renewable energy. This amount was assumed to be the minimal regional power demand value in a year. Any power demand higher than the base load is regarded as residual load. The residual load can be supplied by conventional power system or by PV power, if available. Nevertheless, PV power generation cannot exceed the residual load: if it does, curtailment happens. It should be noted that this method to identify when curtailment occurs does not consider wind power generation, optimized unit commitment planning, dispatch to other regions, or other ways to control excess of PV power. In spite of that, this method provide good reference values and it is a simplified version of the method suggested to power utilities by the Ministry of Economy Trade and Industry of Japan, when calculating acceptable levels of renewable energy penetration and estimating amounts of PV power to be curtailed (METI, 2015b), [13]. An example of forecast based curtailment plan and the required one, using this methodology, is in Fig. 1. The example shows the load curve for a few days of May of 2010, Kanto region, and a PV power penetration scenario of 14 GW.

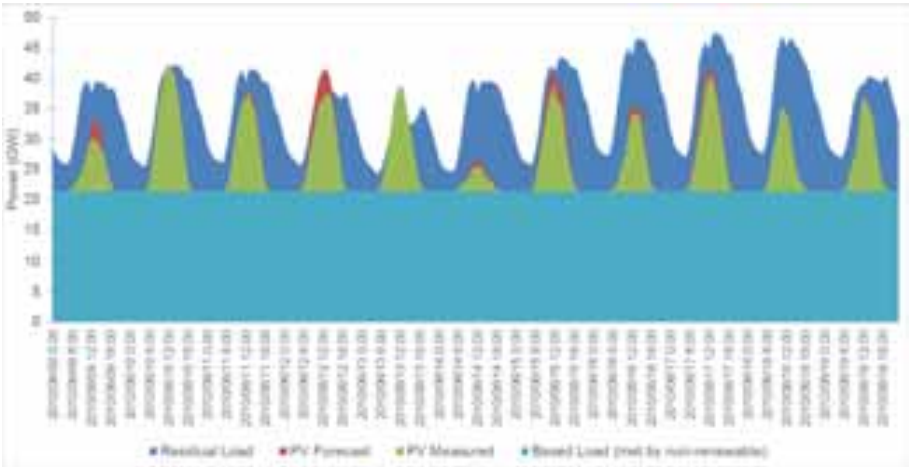

Fig. 1:Examples of planned versus required curtailment of PV power with the curtailment method used.

Following the proposed curtailment plan, on 2010/06/09, 2010/06/10, and 2010/06/17 in Fig. 1, there are forecast errors, but as the total PV power generated and forecasted are lower than the residual demand no curtailment is applied. On the other hand, on 2010/06/12, the forecast of PV power indicated that no curtailment would be required but in fact, as the PV power generated was higher than what was forecasted, curtailment was in reality required.

2.3. Target Regions' Data

To calculate the regional forecasts of power from single PV systems, data from systems installed in Kanto and Kyushu areas were used. The sets of PV systems and their power generation data are part of the Field Test Project sponsored by the New Energy and Industrial Technology Development Organization, NEDO. For Kanto region the set included 62 PV systems and for Kyushu, 52 PV systems. Both sets of PV systems are fairly dispersed within the regions so that they provide a good estimate of the regional yield normalized by the corresponding PV rated power. The sets included only PV systems for which there were complete power generation data of the period studied. In spite of that, due to the availability of power demand data, for Kyushu only 9 months of curtailment plan was done, from April 2010 to December 2010.

In addition to the PV power and power demand data for each region, current PV power penetration scenarios by region and prefecture were necessary to perform the analysis. Kyushu region is already facing a high penetration scenario, with 4.5 GW of PV power installed and another 4.1 waiting for grid connection as of December of 2014 (METI, 2015b). Therefore, for Kyushu both values were used in the scenarios studied. To calculate the equivalent penetration of PV power in 2010, both the PV power penetration values were divided by the peak demand of power in December of 2014. These ratios then were applied to the peak demand of power in Kyushu in December of 2010. To compare Kanto and Kyushu, the equivalent PV power penetration scenario for 2010 power demand in Kanto was calculated using the same logic. Thus PV power penetration ratios of Kyushu were applied to the power demand of Kanto in 2010. The PV rated power for both regions in 2 scenarios are presented in Tab. 1.

Tab. 1: PV rated power for Kanto and Kyushu and two penetration scenarios in 2010.

	Kanto Region	Kyushu Region
Scenario 1	14.93 GW	4.55 GW
Scenario 2	28.44 GW	8.64 GW

Finally, to calculate the regional PV power measured and forecasted in each scenario it is necessary information about the ratio between the PV rated power of each prefecture and the total regional rated power (α in Eq. 2). These ratios are also based on the real PV power installed in Kanto and Kyushu as of December of 2014. The same ratios were used for the scenarios of 2010; their values are in Tab. 2.

Tab. 2: Prefecture's PV rated power by the regional one (Kanto and Kyushu, December of 2014 [1]).

Kanto	Gumma	Tokyo	Chiba	Tochigi	Saitama	Ibaraki	Kanagawa
% of the regional value	0.1380	0.0782	0.1895	0.1467	0.1573	0.198	0.0923
Kyushu*	Saga	Oita	Miyasaki	Kumamoto	Fukuoka	Nagasaki	Kagoshima
	0.078	0.1253	0.1228	0.1482	0.2542	0.093	0.1785

*Okinawa although it is geopolitically part of Kyushu, it is out of the power balacing area of Kyushu power utility.

3. Error and Evaluation Parameters

The effect of the accuracy of the regional forecasts of PV power were evaluated in two ways: from the point of view of the error of the amount curtailed, and from the point of view of the detection error of the hours when curtailment should be applied. The performance of the forecasts and their impact on curtailment from the first point of view is evaluated using the annual mean bias error, MBE, and the mean absolute error, MAE. Both errors of the curtailment planning were calculated using the forecasts of PV power and the required curtailment. The MAE and MBE are calculated in GW as showed in Eq. 3 and Eq. 4.

$$MAE = \frac{1}{n}\sum_{i=1}^{n}\left|Cr_{pln} - Cr_{req}\right|_i \quad (3)$$

$$MBE = \frac{1}{n}\sum_{i=1}^{n} Cr_{pln} - Cr_{req\,i} \quad (3)$$

In Eq. 3 and Eq. 4 Cr_{pln} , for each target hour *i*, is the amount of curtailment of PV power planned, in GW, and Cr_{req} is the amount of curtailment that was actually required, in GW. Both errors were calculated with all the *n* hours of the target periods excluding night periods when forecasts were not made.

To analyze the impact of the forecasts' accuracy on curtailment plan from the point of view of required curtailment detection, a confusion matrix or contingency table as showed in Tab. 3 was used. From the confusion matrix several performance parameters can be inferred. However, in this study the main parameter used is the precision (also showed in Tab. 3) of the curtailment plan based on the forecasts: it shows in how many of all planned curtailment hours, curtailment was actually required. The precision in this case provides

information of how reliable the detection of required curtailment hours is when day-ahead regional forecasts of PV power are used. The calculation of the precision variable was done using data of all target period excluding night hours (the period outside the interval from 5 h to 19 h).

Tab. 3: Confusion matrix used to evaluate the PV power forecast based curtailment plan in Kyushu and Kanto.

		Required Curtailment		
		YES	NO	
Planned Curtailment	YES	A	B	Precision = A/(A+B)
	NO	C	D	

4. Results

As the analyses included 1 year of data of Kanto and 9 months of Kyushu, first, in subsection 4.1 we present the complete results for Kanto. In the subsection 4.2 the results for Kyushu are presented and compared with the results of the same period in Kanto.

4.1. Forecast based Curtailment for Kanto Area

For Kanto, with a minimum annual power demand of 21.4 GW, two PV power penetration scenarios were studied, 14.93 GW and 28.44 GW. For each penetration scenario day-ahead regional forecasts of PV power were made and used to decide when curtailment should be applied. Figures 2(A) and 2(B) contain the matrix confusion resulting from the comparison between forecast based and required curtailment for both scenarios.

(A) 14.93 of PV Power

Curtailment		Required: yes	Required: no	Precision
Forecast based	yes	58	17	77.3%
	no	13	5840	

(B) 28.44 of PV Power

B Curtailment		Required: yes	Required: no	Precision
Forecast based	yes	369	78	82.6%
	no	66	5840	

Fig. 2: Confusion matrix for the curtailment of PV power based on day-ahead regional forecasts for Kanto in two scenarios of PV power penetration 14.93 GW (A) and 28.44 GW (B) (values in hours).

The results in Fig. 2 show that in Kanto with a scenario of 14.93 GW of PV power, during one year, only 71 hours curtailment of PV are required. Of those hours the forecast based curtailment plan was able to detect 58 hours, and issued false alarms in 17 hours, yielding a precision of 77.3%. For a scenario of 28.44 GW, curtailment PV power becomes more common, being required on 435 hours. In spite of the increase of the hours in which PV must be curtailed, and therefore increasing the probability that the curtailment planning will include more forecast errors, the precision of curtailment plan based on forecasts of PV did not decrease. In fact, the precision was better reaching 82.6%.

This behavior is explained by the fact that in a scenario where PV power curtailment is seldom such as the one of 14.93 GW of PV rated power, throughout the year curtailment will happen mostly in peak hours of PV power generation (11h to 13h for example). These are also the hours where is more likely that large forecast error occur simply because of the magnitude of PV power generated. As high forecast errors imply in misdetection of required curtailment hours, occurrence of required curtailment exactly in the hours when large forecast errors can occur will result in a low detection of required curtailment. Once PV rated power is increased and curtailment becomes frequent in off-peak hours, the detection of required curtailment is improved because these hours will contain in average lower forecast errors. Increasing even further the PV rated power will cause not only the required curtailment related hours to increase but also the amount curtailed. In this situation, the detection of required curtailment with forecast based plan should decrease again, as even small forecast errors will become cause for misdetection of required curtailment.

The results in Fig. 3(A) and 3(B) show the performance of the forecast based curtailment regarding the error

in the amount curtailed. The errors were calculated using the required curtailment (based on a perfect forecast) as reference and, as in the case of Fig. 2, just for the hours within 5h and 19h.

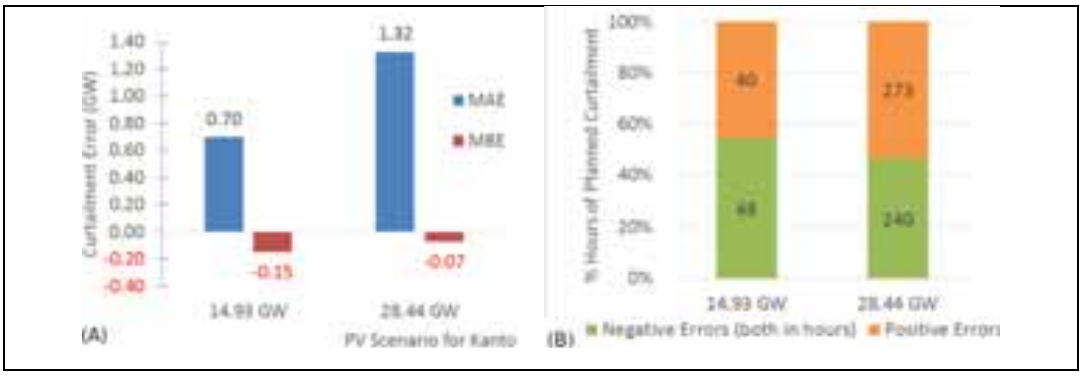

Fig. 3: Curtailment error with day-ahead regional forecasts for Kanto in two scenarios of PV power penetration (A), and frequency of curtailment errors according to their sign (B).

Both Fig. 3(A) and 3(B) show that increasing the number of hours when PV power is curtailed had a strong effect on the behavior of the error of the curtailment plan. When curtailment happens only in a few hours, it will happen mostly in peak hours. Forecast errors on these hours will be mainly related with underestimations of the real PV power generated. Thus, such errors will cause required curtailment not to be detected, or they will underestimate the amount of required curtailment. Once PV power penetration increases hours of required curtailment will be dispersed and both underestimations and overestimations of the real PV power generation will affect the curtailment plan. The general effect will be a balanced distribution of curtailment errors related with the accuracy of PV forecasts. This behavior is clear in the MBE of Fig. 3(A) and on the frequency of errors in Fig. 3(B).

Another issue that must be noted is regarding the importance of sign of the curtailment errors. If the error is positive more PV power was curtailed than necessary. The direct effect of this kind error is economic as PV systems owners may loose income of the selling of the amount curtailment in the case it is not compensated. Contrasting with that, if the curtailment error is negative, an insufficient amount of PV was curtailed. The result is excess of PV power on the grid, which may cause balancing and operation problems in the corresponding balancing area. Tab. 4 shows the mean positive and negative errors of the forecast based curtailment. In the same Tab. 4 the average amount of required curtailment in year is showed to provide a measure of the magnitude of the errors in relation to the amount usually curtailed.

Tab. 4:Mean positive and negative curtailment errors and average required curtailment (per hour of curtailment) in Kanto, 2010.

PV rated Power	Mean Positive Curtailment Error (GW)	Mean Negative Curtailment Error (GW)	Annual Average Curtailment Required (GW)
14.93 GW	0.604	-0.772	1.76
28.44 GW	1.17	-1.49	3.96

The results in Tab. 4, Fig. 2 and Fig. 3 show that for Kanto, 14.93 GW was a relatively low penetration scenario. Moreover, this scenario yielded more and higher negative curtailment errors than positive ones. Increasing the the PV rate power to 28.44 GW partially reversed such trend.

4.2. Forecast based Curtailment for Kyushu Area

For Kyushu area, the 2 PV power penetration scenarios were 4.55 GW and 8.64 GW. The first scenario is already realized and the second one should be reached in near future as another 4.1 GW are waiting for grid connection. Considering that Kyushu's minimum annual demand is 7.1 GW, both scenarios are of high penetration of PV power. In these cases, the required number of curtailment hours with the forecast based curtailment plan, for 9 months of data, was 207 hours and 644 hours. Both numbers are considerably higher than the corresponding values for Kanto region. The precision, calculated as showed in Tab 3, of the forecast

based curtailment plan compared with Kanto, and for the same period, is in Fig. 4.

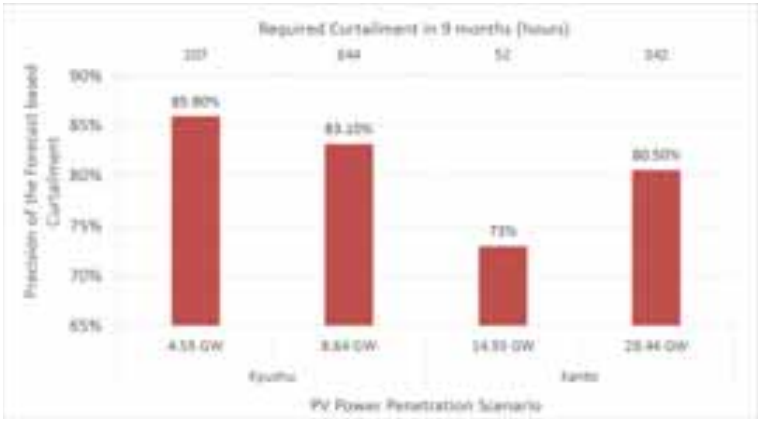

Fig. 4: Precision of required curtailment detection with a forecast based curtailment for Kyushu and Kanto in two PV power penetration scenarios.

Due to difference of power demand in both regions, Kyushu is clearly more sensitive to penetration of PV power than Kanto. In Fig. 4, the required curtailment hours in Kyushu for a PV rated power of 4.55 GW reached 207 hours. Doubling the PV rated power increased 3 times the required curtailment. For Kanto the situation was different, as even with 28.44 GW required curtailment hours were just slightly higher than half the number obtained with the highest PV power penetration scenario in Kyushu. This variation in the numbers of required curtailment hours affected signficantly the precision of the forecast based curtailment plan. This variation of the precision in detecting required curtailment hour is related with the PV forecast error magnitude and the period of the year when curtailment is required. To understand these relations, Fig. 5(A) and Fig. 5(B) show the normalized error of the PV power forecast throughout the year and the months and hours where curtailment was required.

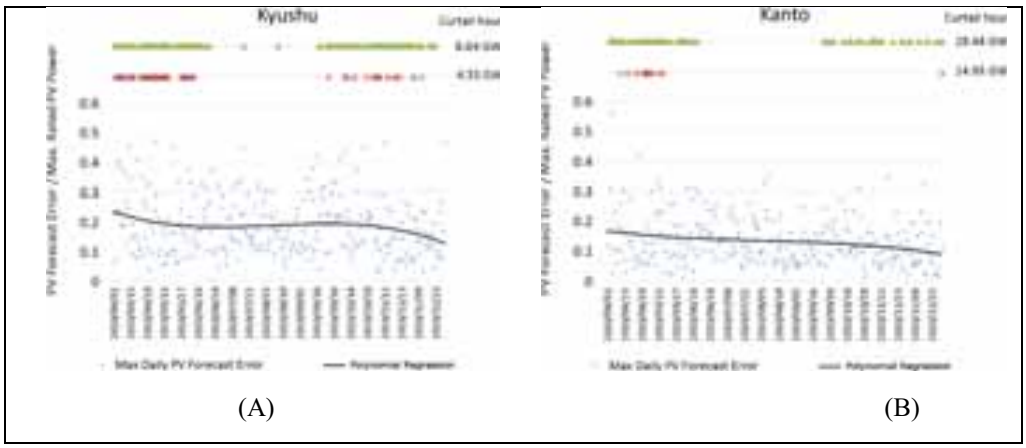

Fig. 5:Occurrence of required curtailment and maximum daily value of the PV forecast errors throughout the year for Kyushu (A) and Kanto (B).

Starting with Kyushu, the results show that even with 4.55 GW of PV power, curtailment is happening in most of the 9 months studied with the exception of the months of July to August, when it is summer in Japan and the power demand is high enough to use all PV power generation. Increasing further the PV rated power to 8.64 GW, causes further curtailment and some occurrences of it now in July and August. Looking at the behavior of forecast error of PV power, curtailment is happening in situations where the forecast error is high and when is low in an uniform fashion, regardless the scenario. Thus, the precision in detecting required curtailment presented low variation.

Focusing now in Kanto, with the lowest PV power scenario, curtailment is seldom and it is happening in April to May, where there is occurrence of high PV forecast errors. Increasing the requirement of curtailment to other months and hours, yield the use of forecasts with lower errors improving the precision of the forecast

based curtailment from 73% to 80% as showed in Fig. 4.

The results in Fig. 6 show the variation of the effect that the forecast error of PV power has on curtailment planned using these forecasts.

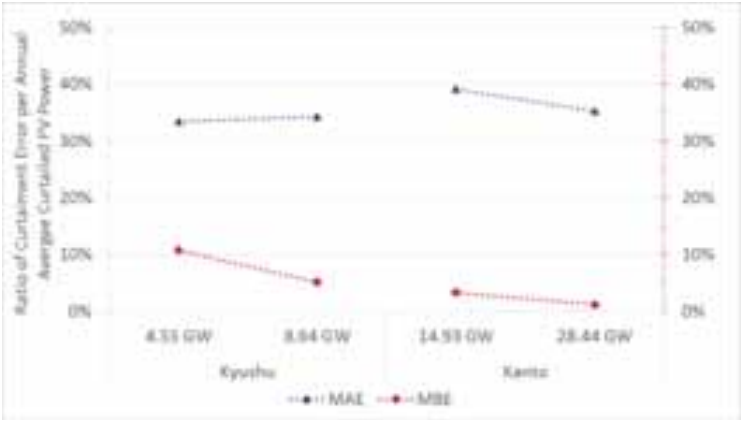

Fig. 6: Effect of the forecast error of day-ahead regional PV forecasts on curtailment planning according to the region and PV penetration scenario.

In this case a similar trend can be noted, increasing the amount of hour curtailed in Kanto caused the use of more forecasts with low errors. This yields lower errors on the execution of curtailment. For Kyushu, there was a slight increase of MAE, but the MBE was significantly reduced with the increase of PV power installed similarly to what happened in Kanto.

5. Conclusions

The objective of this study was to verify the impact that the accuracy of day-ahead regional forecasts of PV power has on a curtailment plan based on such forecasts. Two regions of Japan were analyzed, Kyushu where high penetration of PV power is already a reality, and Kanto, which has a high potential for roof-top installations of PV system. The impact of the accuracy of the forecasts was evaluated from the point of view of properly detecting the hours of required curtailment, and from the point of view of the error in the amount curtailed with a forecasts based curtailment plan.

The results showed that when required curtailment hours are few, the precision in detecting them was near to 70%. Increasing the number of hours of curtailment yielded the use of forecasts with a variety of errors, improving the precision parameter to near 80%. These results mean that in at least 70% of the time, a forecast based curtailment plan correctly determined the hours that curtailment is necessary. This means that, in the worst case, 30% of the curtailment hours will have to be located with intra-day forecasts or with improvements of day-ahead forecasts.

Regarding the effect of the forecast accuracy on the amount of PV power curtailed, the results show that annualy the curtailment error represented near to 35% of the average amount of PV power curtailed. The effect was strong as excessive curtailment yield financial losses to PV systems owners. However, considering the possibility of intra-day corrections on the curtailment plan, balacing area interconnections, storage solution and an optimized unit commitement plan, the effect of the forecast error can be significantly mitigated.

Finally, comparing both regions, it is clear that Kyushu, due to its low power demand, is already facing problems with high PV penetration. Even with 4.55 GW, curtailment was required in 207 hours of 9 months. In Kanto, the high demand of power (minimum annual value of 21 GW) yields a more confortable situation, as even with 14.93 GW of PV rated power only 70 hours in a year required curtailment. In spite of that, the required curtailment in this scenario happened exactly in months where high errors of PV forecasts occur, decreasing the forecasts usefulness. The obtention of these values provide important information about the efficacy of the forecast of PV power and about how they should be used. Moreover, they can be used to guide the use of forecasts and improvements of their accuracies. A limitation of this initial study is the use of base

load and residual demand related assumptions to characterize when cutailment happens. In following studies, these simplifications will be removed, and the analysis of the forecast error on curtailment of PV power will be further advanced by considering optimal unit commitement planning.

Estimation of greenhouse gas emission factors for natural gas in Bangladesh

H M Enamul Haque and Himangshu Ranjan Ghosh

Institute of Energy, Dhaka University, Dhaka-1000, Bangladesh

Abstract

Anthropogenic greenhouse gas emissions from fossil fuel burnings are strongly affected by fuel properties, operation procedure, emission control etc. Production of indigenous natural gas is around 23 billion metric tons/year from 120 wells of 19 fields in Bangladesh. At the production sites mole percent of methane in the natural gas varies from 93.50 to 98.00. Gas chromatography study on a sample from a natural gas based electric power station at Ashuganj shows that the fuel have lower heating value of 34.9389MJ/m^3, 96.60 mole percent CH_4, 0.54 mole percent N_2, 0.10 mole percent CO_2 and the rest other hydrocarbons. The average transmission and distribution losses of natural gas over the country is 1.77% and the estimated emission factors for main greenhouse gases are 55.52 gCO_2/MJ, 0.35 gCH_4/MJ and 0.17 gN_2O/MJ. Considering global warming potentials of Intergovernmental Panel on Climate Change 2007 report the equivalent CO2 emission factor for natural gas in Bangladesh is 115.04 gCO_2e/MJ.

Keywords: *Fossil Fuel, Greenhouse gases(GHG), GHG emission factors*

1. Introduction

Energy is a basic requirement for the existence and development of human life. The major percentage of the commercial demand of energy is generally supplied from the fossil fuels (coal, oil and natural gas). The demand for energy is growing at an alarming rate year after year.

Every year Greenhouse gases add to the carbon already present in atmosphere .The power sector is major source of carbon dioxide (CO_2) emission and accounts for about 36 % of the total CO2 emission in the world, 45 % in Asia and 40 % in Bangladesh. The power sector CO_2 emission has been increased at an average annual rate of 8.5 % from 1990 to 2004 in Asia as a whole (Shrestha et al. 2009). Because carbon dioxide is a good absorber of heat radiation coming from the Earth's surface, increased carbon dioxide acts like a blanket over the surface, keeping it warmer than it would otherwise be. With the increased temperature the amount of water vapour in the atmosphere also increases, providing more blanketing and causing it to be even warmer (Houghton, 2009). Due to heat trapping our earth is warming. Earth's average temperature has risen by 1.4°F over the past century, and is projected to rise another 2 to 11.5°F over the next hundred years (USEP online, 2015). The amount of CO_2 emission depends on carbon content of fossil fuel.

CO_2 emissions can be estimated fairly accurately based on the total amount of fuels combusted and the averaged carbon content of the fuels. However, emission factors for methane and nitrous oxide depend on the combustion technology and operating conditions and vary significantly, both between individual combustion installations and over time. Due to this variability, use of averaged emission factors for these gases, that must account for a large variability in technological conditions, will introduce relatively large uncertainties.

2. Methodology

The The IPCC Guidelines (2006) for estimating emissions from fossil fuel combustion estimate carbon emissions in terms of the species which are emitted. During the combustion process, most carbon is immediately emitted as CO_2. However, some carbon is released as carbon monoxide (CO), methane (CH_4) or

doi:10.18086/swc.2015.07.18 Available at http://proceedings.ises.org

non-methane volatile organic compounds (NMVOCs). Most of the carbon emitted as these non-CO_2 species eventually oxidizes to CO_2 in the atmosphere. The Reference Approach of IPCC 2006 can be used as an independent check of the sectoral approach and to produce a first-order estimate of national greenhouse gas emissions.

The Greenhouse Gas Emissions from stationary combustion can be found from the following equation 1

$$\text{Emission}_{GHG,fuel} = \text{Fuel Consumption}_{fuel} \times \text{Emission Factor}_{GHG,fuel} \quad \text{(equ. 1)}$$

Where:

$\text{Emissions}_{GHG,fuel}$ = emissions of a given GHG by type of fuel (kg GHG)

$\text{Fuel Consumption}_{fuel}$ = amount of fuel combusted (TJ)

To calculate the total emissions by gas from the source category, the emissions as calculated in Equation 1 are summed over all fuels:

$$\text{Emission}_{GHG,fuel} = \sum_{fuels} \text{Emissions}_{GHG,fuel} \quad \text{(equ. 2)}$$

The estimation of GHG emission factor from a fossil fuel burning is determined stepwise by estimating the consumption of fuels by fuel/product type, converting the fuel data to a common energy unit (TJ), selecting the carbon emission factors for each fuel/product type to estimate the total carbon content of the fuels, estimating the amount of carbon stores in products for long time, accounting for carbon not oxidized during combustion, converting emissions of carbon to full molecular weight of CO_2 and finally dividing the total estimated CO_2 by the total consumed fossil fuel.

3. Fuel sample collection and testing

Bangladesh produces gas from several different fields, and much of it is merged at the Ashuganj gas metering station (AGMS) before distribution via major trunk lines, some power plant customers, such as those of Jalalabad GasTransmission & Distribution System Ltd., receive gas from upstream of AGMS. Meanwhile,some gas fields feed their supply directly into the gas transmission grid downstream of AGMS. For this reason, the chemical composition, calorific value or other properties available from AGMS,would be more or less precisely for all natural gas combusted in Bangladesh.

On April 29, 2014,one sample of natural gas from Bakhrabad Gas Distribution Company Limited (BGDCL) at Ashuganj Power Station Company Limited (APSCL) has been analyzed at a gas cromotography system at Petroleum and MineralResources Engineering (PMRE) laboratory of the Bangladesh University of Engineering and Technology. The report showed that the sample had a Lower Heating Value (LHV) of 34.9389 MJ/m3Higher Heating Value (HHV) of 38.7536 MJ/m3(with a ideal gas density of 0.0442lb/ft3) as shown in Table 1.

Tab. 1: Chemical composition of Natural gas from BGDCL at APSCL

Gas	Composition	% Volume
Nitrogen	N_2	0.536
Carbon di-oxide	CO_2	0.090
Methane	CH_4	96.603
Ethane	C_2H_6	1.904
Propane	C_3H_8	0.378
i-Butane	C_4H_{10}	0.121
n-Butane	C_4H_{10}	0.085
i-Pentane	C_5H_{12}	0.053
n-Pentane	C_5H_{12}	0.037
Hexane	C_6H_{14}	0.095

Heptane	C_7H_{16}	0.072
Octane	C_8H_{18}	0.027
Nonane	C_9H_{20}	-
Decane	$C_{10}H_{22}$	-
Total		100.00

4. Estimation of GHG emission factor

Carbon dioxide (CO_2) emissions from natural gas combustion result from the release of carbon during combustion. The amount of carbon dioxide (CO_2) emissions are calculatedthrough the combustion Equation 3 of alkanes $C_nH_{(2n+2)}$.

$$C_nH_{(2n+2)} + \frac{3n+1}{2}(O_2 + 3.76\ N_2) \rightarrow n\ CO_2 + (n+1)\ H_2O + \frac{3n+1}{2}\ 3.76\ N_2 \qquad \text{(equ. 3)}$$

During combustion process, most carbon is emitted as CO_2immediately. CO_2emission factors for fossil fuel combustion will depend upon the carbon content of the fuel that is inherently chemical property and does not depend upon the combustion process or conditions. In case of perfect and complete combustion, nitrogen can be neglected as there is no NOx creation and no carbon monoxide as well. The GHG is computed in Table 2.

Tab. 2: GHG emission during combustion

Gas	Composition	Amount (g in one mole)	C content (in g)	H content (in g)	N content (in g)	O content (in g)	g CO_2	g N_2O
Nitrogen	N_2	0.090	-	-	0.090	-	-	0.141
Carbon di-oxide	CO_2	0.015	0.004	-	-	0.011	0.015	
Methane	CH_4	16.218	12.164	4.055	-	-	44.600	
Ethane	C_2H_6	0.320	0.256	0.064	-	-	0.938	
Propane	C_3H_8	0.063	0.052	0.012	-	-	0.190

For each greenhouse gas, a Global Warming Potential (GWP) has been calculated to reflect how long it remains in the atmosphere, on average, and how strongly it absorbs energy. Gases with a higher GWP absorb more energy, per pound, than gases with a lower GWP, and thus contribute more to warming Earth. The global warming potentials of Intergovernmental Panel on Climate Change (IPCC, 2007) are given in Table 3.

Tab. 3: Global Warming Potentials

GHG	GWP
Carbon dioxide	1

Methene	25
Nitrous oxide	298

The average transmission and distribution losses of natural gas over the country is 1.77% (Tital, 2013-2014). Estimated volume of 1 mole Natural Gas is 0.024 m^3 and Heating value of Natural Gas (as per test report) is 0.919 MJ. The estimated emission factors for main greenhouse gases are 55.52 gCO_2/MJ, 0.35 gCH_4/MJ and 0.17 gN_2O/MJ. Considering global warming potentials of IPCC 2007 report the equivalent CO2 emission factor for natural gas in Bangladesh is 115.04 gCO_2e/MJ.

5. Conclusion

Greenhouse gas emission factors for natual gas in Bangladesh are 55.52 gCO_2/MJ, 0.35 gCH_4/MJ, 0.17 gN_2O/MJ and equivalent CO_2 emission factor is 115.04 gCO_2e/MJ.

A NOVEL METHOD FOR CALIBRATION OF AEROSOL DATABASES WITH LIDAR-CEILOMETER MEASUREMENTS

D. Bachour, D. Perez-Astudillo, L. Martin-Pomares

Qatar Environment & Energy Research Institute, Qatar Foundation, HBKU, Doha, Qatar

Abstract

Satellite observations and chemical transport models used for the derivation of Aerosol Optical Depth (AOD) values have an extensive coverage worldwide and are widely used when ground-measured AOD is not available. However, satellite and modelled values present high uncertainties and cannot be always considered reliable especially at the level needed for solar radiation modelling. This work presents a methodology for calibrating existing AOD databases, which are commonly used as inputs to clear sky models for estimating clear-sky solar irradiances. This methodology makes use of ground-measured direct normal irradiance (*Hb*), integrated backscatter profiles of a lidar-ceilometer device, and *Hb* calculated from clear sky models with different AOD databases.

Keywords: *AOD, lidar, ceilometer, aerosol loads, DNI*

1. Introduction

In clear skies, aerosols are the main atmospheric component absorbing and scattering solar radiation. Their atmospheric extinction is generally described in terms of Aerosol Optical Depth (AOD), a useful parameter for the calculation of clear-sky solar irradiances. AOD can be directly measured by ground-based sun-photometers [Holben et al, 1998], or derived from satellite images such as MISR [Keller et al, 2007] and MODIS [Kosmopoulos et al, 2008] and from chemical transport models such as MACC [Cebecauer and Suri, 2010]. The direct measurements are the best option for determining AOD, but they have limited coverage. The indirect sources have wider coverage, but provide AOD data with lower temporal and spatial resolutions, and exhibit high uncertainties particularly in regions of high aerosol loads [Cebecauer et al, 2011; Gueymard, 2012].

Lidar-ceilometers measure atmospheric backscatter profiles as a function of time and height in the atmosphere. These profiles are normally used for the determination of the boundary layer height and cloud base height [Munkel, 2006]. However, they can also be used to extract aerosol information that can be used as an alternative to the AOD parameter in the modelling of solar radiation; indeed, a good correlation was found between lidar-ceilometer measurements and direct normal irradiance ground measurements in [Bachour and Perez-Astudillo, 2014].

2. Instrumentation and data used

The experimental data used here consist of clear days in the time interval 10 am to 1 pm, collected over a period of 12 months from December 2012 to November 2013. 214 clear days were selected for the analysis presented in this paper. The Vaisala ceilometer CL51 was used for the recording of the range-corrected atmospheric backscatter profiles. It uses a 910 nm pulsed diode laser. The reported backscattered signal has a vertical resolution of 10 m, with 15 km as maximum range. For more details about the CL51 instrument, the reader can refer to [Vaisala, 2015]. A CHP1 pyrheliometer [CHP1, 2015] mounted on a high precision Kipp and Zonen solar radiation monitoring station was used for the measurements of the direct normal irradiance as one-minute averages in W/m^2.

The clear-sky irradiation values used here were derived from the McClear and REST2 models. McClear estimates the solar radiation at ground level under clear sky conditions by using the abaci approach and interpolation functions. It uses mainly inputs from the MACC project. Aerosol information used by the McClear model consists of aerosol optical depth at 550 nm, Angström coefficient, and aerosol type from the MACC database. The model has been validated at several BSRN stations and gives good results [Lefèvre, 2013]. REST2 is a high-performance radiative model used to predict clear-sky broadband irradiances. It uses the Angström turbidity coefficient, the Angström wavelength exponent and aerosol single-scattering albedo as aerosol inputs to the model [Gueymard, 2008]. It is possible to use any AOD data with this model. For the irradiation data presented here, the aerosol information used with the REST2 model is extracted from the MISR and MACC databases.

doi:10.18086/swc.2015.07.19 Available at http://proceedings.ises.org

3. Methodology

The backscattered intensity profiles recorded by the CL51 during a clear day depend on the aerosol constituents of the atmosphere and provide information on their height as a function of time. Of interest for this analysis, are the atmospheric backscatter coefficients recorded as a two-dimensional dataset values, reported every 36 s, in 10-m steps up to 15 km height. From these measured backscatter coefficients, the hourly-averaged backscatter coefficients were obtained for each height step and summed thereafter up to 5 km height in the atmosphere. The 5 km height limit in the atmosphere was found to be representative of the dynamicity of the atmosphere in the studied location. The obtained integrated backscatter coefficient, named hereby the beta coefficient, is the starting point of the calibration method using lidar-ceilometer measurements as suggested here.

This high-resolution local aerosol information is used to validate indirectly the aerosol databases by measuring the performance of a clear-sky model through the hereby-called 'performance ratio':

$$Kp\_cs = Hb\_cs / Hb\_m, \qquad \text{(eq. 1)}$$

Where *Hb_m* is the ground-measured value of the hourly beam irradiance (also called DNI, direct normal irradiance) obtained from the quality-controlled 1-minute values of measured direct normal irradiance. The applied quality control checks follow the BSRN standards [Long and Dutton, 2002]. *Hb_cs* is the corresponding modelled clear-sky value, derived from a clear-sky model. This ratio measures the performance of the used clear-sky model. The calculated performance is then correlated to the corresponding measured integrated backscatter, the beta coefficient, and the resulting correlation is used in order to correct the DNI values derived from the clear-sky model. This way, aerosol information used as input to the clear-sky model is indirectly calibrated.

4. Results and discussion

Fig.1 shows the ratio of the DNI derived from the clear sky model McClear versus the ground-measured DNI, as a function of the integrated backscatter lidar-ceilometer signal. Fig.2 and Fig.3 show the performance ratio of the REST2 model using aerosol information from MISR and from MACC, respectively, as a function of the integrated backscatter lidar-ceilometer sigmal.

It can be seen that up to a certain value of the beta coefficient, the clear-sky models performs reasonably well; for higher values of the integrated backscatter coefficient, i.e., high aerosol loads, the performance of the clear-sky models degrades and leads to an overestimation of the direct normal irradiance, most likely related to an underestimation of aerosols in the used databases, as has been also shown by [Jiang et al, 2007] and [Polo and Estalayo, 2015].

The overestimation in DNI can be correlated with the integrated backscatter measurements derived from the lidar-ceilometer. The correlation will be used to calibrate the clear-sky models for high aerosol loads.

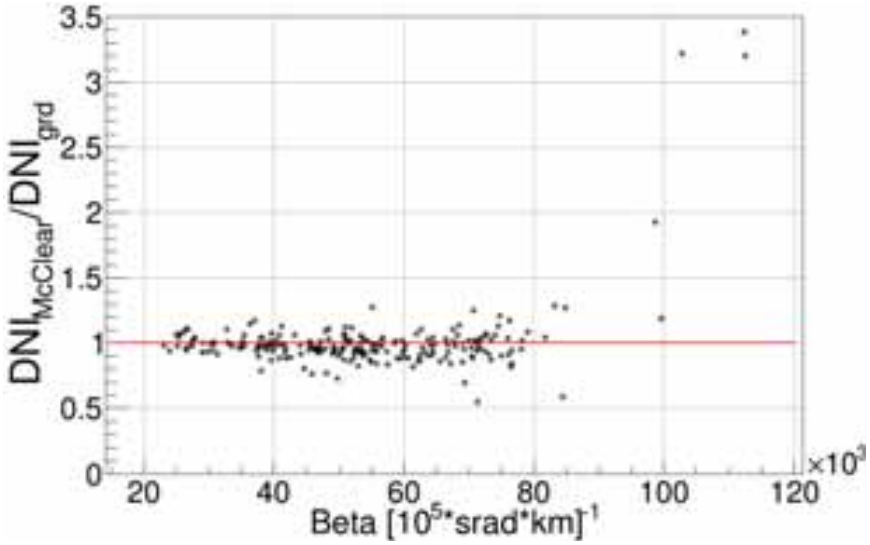

Fig. 1: Performance of the McClear model-derived beam irradiance vs. the integrated backscatter coefficient, at the hour from 11 am to 12 pm.

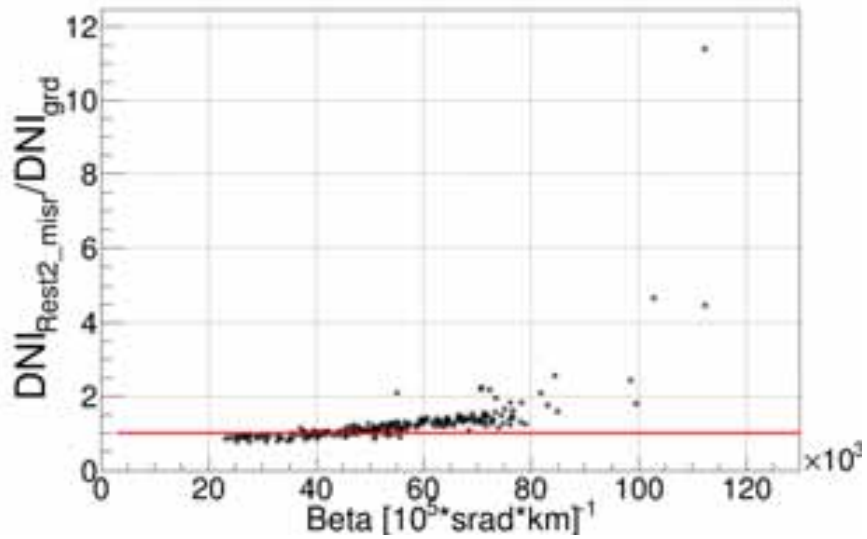

Fig. 2: Performance of the REST2 model-derived beam irradiance using aerosol from MISR vs. the integrated backscatter coefficient, at the hour from 11 am to 12 pm.

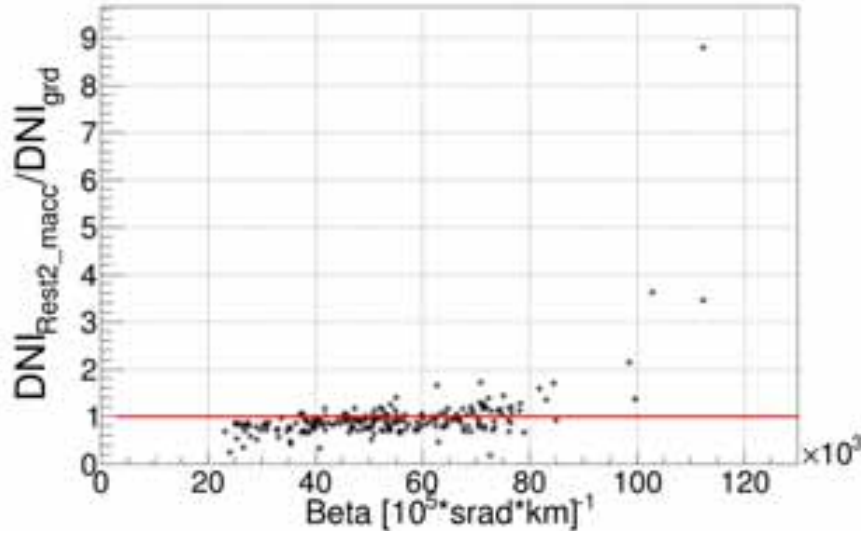

Fig. 3: Performance of the REST2 model-derived beam irradiance using aerosol from MACC vs. the integrated backscatter coefficient, at the hour from 11 am to 12 pm.

The decrease in performance at high beta values was quantified using an exponential function fitted to the ratios corresponding to beta values around 70000×10^5 $[srad.km]^{-1}$ and higher, where poor performance of the clear-sky models can be seen. The equation of the fit is the following:

$$Hb\_cs / Hb\_m = CF = \exp(slope * Beta + const), \quad \text{(eq. 2)}$$

Where Beta is the sum up to 5 km of the hourly-averaged backscatter lidar signals, *Hb_cs* is the hourly DNI derived from the clear-sky model, *Hb_m* is the hourly DNI derived from the ground measurements. *CF* stands for calibration function, and *slope* and *const* are parameters obtained from the applied fit.

The fitted function can then be used to correct the DNI values derived from the clear sky models for Beta values higher than the used Beta limit. The correction can be written as follows:

$$Hb\_cs,corr = Hb\_cs / CF, \quad \text{(eq. 3)}$$

where *Hb_cs,corr* is the corrected value of *Hb_cs*.

By using Eq.3 to calibrate the clear-sky model, the aerosol information used as input to the model is indirectly calibrated as a function of the lidar-ceilometer measurements.

Fig. 4 shows the performance of the corrected McClear model, after applying the function in Eq.3. The effectiveness of the calibration method as applied to the McClear model is noticeable on the data points corresponding to high beta values, i.e., high aerosol loads. The calibration of the REST2 model using MISR and MACC databases (not shown here) confirms the same.

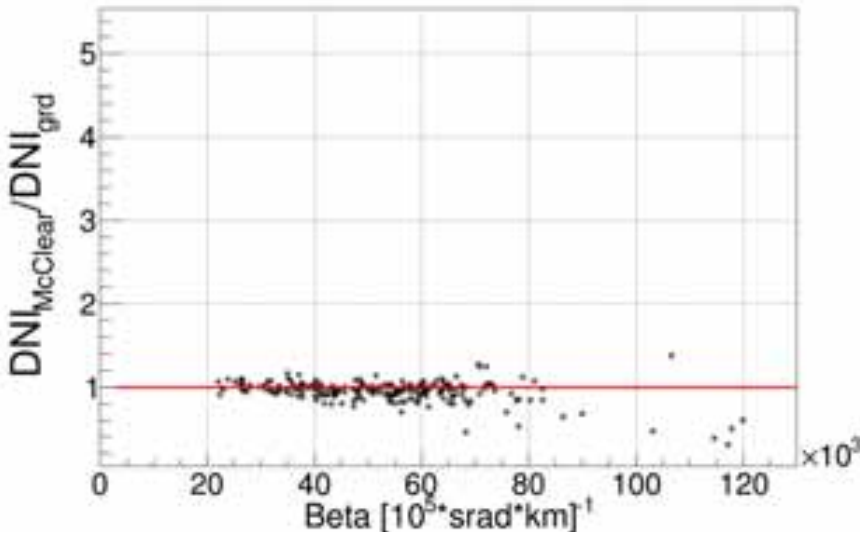

Fig. 4: Performance after calibration of the McClear model-derived beam irradiance vs. the integrated backscatter coefficient, at the hour from 11 am to 12 pm.

The effect of the suggested method on the calibration of the McClear model was evaluated using the relative mean bias error (MBE) and root-mean-square error (RMSE) of the performance ratios before and after calibration for different periods of time. The results for the hour 11 and 13 are listed in Table 1 and Table 2, respectively.

Tab. 1: Statistical indicators of the comparison of clear-sky model against clear-sky calibrated model using the beta coefficient, for the hour 10 to 11. rMBE and rRMSE are in %.

Model	rMBE	rRMSE
BEFORE CALIBRATION		
McClear	-1.05	24.16
REST2 with MISR	24.71	93.51
REST2 with MACC	-6.86	69.41
AFTER CALIBRATION		
McClear	-5.11	14.2
REST2 with MISR	8.36	25.16
REST2 with MACC	-14.64	29.67

Tab. 2: Statistical indicators of the comparison of clear-sky model against clear-sky calibrated model using the beta coefficient, for the hour 12 to 13. rMBE and rRMSE are in %.

Model	rMBE	rRMSE
BEFORE CALIBRATION		
McClear	1.96	29.22
REST2 with MISR	31.48	107.33
REST2 with MACC	-0.25	79.63
AFTER CALIBRATION		
McClear	-5.09	15.53
REST2 with MISR	5.5	23.98
REST2 with MACC	-13.18	27.37

Table 1 and Table 2 show that the calibrated dataset has lower rRMSE values for all the clear sky models as compared to the original clear-sky datasets. The rMBE value for the calibrated REST2 model with MISR database is also lower than the relative bias of the uncalibrated model, but higher for the calibrated clear-sky models using the MACC database. Since the calibration was only applied to the points with high beta values, the rMBE of the calibrated models shown in the tables are now dominated by the bias of the points with lower beta values; this discrepancy can be easily reduced and will provide smaller relative bias values when calibrating the DNI using all Beta values in the fit to obtain *CF*.

The noticeable decrease in the relative errors, when comparing the results before and after applying the suggested calibration method on the clear-sky models, shows the effectiveness of using the lidar ceilometer measurements as local aerosol information, which can be ultimately used as a reliable tool to correct the existing aerosol databases.

Analysis of the Silicon Dioxide Passivation and Forming Gas Annealing in Silicon Solar Cells

Izete Zanesco and Adriano Moehlecke

Solar Energy Technology Nucleus (NT-Solar), Faculty of Physics,

Pontifical Catholic University of Rio Grande do Sul (PUCRS), Porto Alegre (Brazil)

Abstract

The passivation of silicon solar cells by the deposition of SiN_x anti-reflection coating is usual in the industry. However, materials such as SiO_2, TiO_2 and Al_2O_3 may be a cost-effective alternative and its analysis is mainly reported in silicon wafers. The goal of this paper is to present the development and analysis of silicon solar cells passivated with a thin layer of SiO_2 as well as the evaluation of the effectiveness of the annealing step in forming gas. The dry oxidation was performed before the TiO_2 anti-reflection coating deposition and the annealing in forming gas was performed in the same furnace. The temperature and time of the oxidation and the annealing step were experimentally optimized. The efficiency of 15.9 %was achieved. The highest average efficiency was found in the oxidation temperature range from 750 ºC to 800 ºC, during 7 minutes, caused by the increasing of open circuit voltage and fill factor. At short wavelengths, the internal quantum efficiency decreases slightly with the increasing of the oxidation temperature. The minority carrier diffusion length (L_D) of the solar cells processed with the oxidation temperature of 800 °C was around 1890 μm. The open circuit voltage shows a slight trend of increasing with the oxidation time. The annealing step in forming gas did not improve the average efficiency of the solar cells. Solar cells processed with oxidation and annealing presented higher internal quantum efficiency at short wavelengths than cells with only annealing.

Keywords: silicon solar cells, passivation, silicon oxide

1. Introduction

The industry of silicon solar cells is mainly based on conventional screen printing metallization and passivation of the phosphorus emitter with silicon nitride anti-reflection (AR) coating. The passivation reduces the recombination of minority charge carriers in the surface of the solar cells. The surface passivation with silicon nitride using plasma-enhanced chemical vapor deposition (PECVD) at low temperature (< 450 ºC) results in low surface recombination velocity on both p-type and n-type c-Si, as well as low absorption at short wavelengths (Aberle, 2001). Silicon nitride passivation for n^+ emitter provides positive interface charges, causing a field effect passivation (Rahman and Khan, 2012). Low surface recombination velocity of 1.6 cm/s on p-type c-Si with passivation by SiN_x deposited at 290 ºC was achieved (Wan et al., 2013).

The passivation with Al_2O_3 is also under investigation. The aluminum oxide has advantages over SiN_x when used to passivate the p^+ emitter, because Al_2O_3 presents a high density of fixed negative charges (Pawlik et al., 2014; Saynova et al., 2013). Surface recombination velocities below 2.9 cm/s and low interface state density were achieved with Al_2O_3 layers, performed by atomic layer deposition (ALD) (Werner et al., 2011). The surface recombination velocity of 90 cm/s was reported with Al_2O_3 as rear surface dielectric layer and this value was similar to that achieved with thermally grown SiO_2 (Schmidt et al., 2008). Duttagupta et al. (2013) reported that good passivation can be obtained with the AlO_x/SiN_x dielectric stack, deposited by PECVD and an AlO_x thickness of 5 nm is sufficient.

Thermally grown SiO_2 is the most effective c-Si surface passivation technique, but silicon dioxide has a low

doi:10.18086/swc.2015.05.01 Available at http://proceedings.ises.org

refractive index and, consequently, it is not good to form the anti-reflection coating. In this way, silicon dioxide is usually complemented by other dielectric layers. The interface defect density may be low after the growth of a thermal SiO_2 film on c-Si and a subsequent annealing in forming gas. The surface passivation behavior has also been investigated for SiO_2/SiN_x stack and the surface recombination velocity of 2.4 cm/s was found in n-type Cz silicon wafers passivated by SiO_2 thermally grown (Ye et al., 2010). Low dark current densities of <20 fA/cm^2 on textured n-type FZ silicon wafers were found. In this substrate, both surfaces were phosphorus doped and the sheet resistance was of 140Ω/□ (van Erven et al., 2008). In the frontal surface field solar cells with very low surface phosphorous concentrations, the passivation with a SiO_2/SiN_x stack demonstrated an increase in cell efficiency of around 0.5 % (absolute), compared to the standard PECVD-SiN_x passivation. For instance, n-type CZ-Si solar cell passivated by the SiO_2/SiN_x stack achieved the efficiency of 19.4% (Book et al., 2011). Another technique investigated was a stack of hydrogenated amorphous silicon and SiO_x deposited by PECVD and the surface recombination velocity of 120 cm/s on p-type FZ-Si substrate was achieved (Hofmann et al., 2008).

Titanium oxide may not provide efficient surface passivation, but it is used to form the AR coating, because presents low absorption in short wavelengths and has a high refractive index. This material is more suitable to passivate boron doped surfaces, but the technique used to deposit the layer influences the passivation. A layer of TiO_2 performed by atmospheric pressure chemical vapor deposition leads to a surface recombination velocity less than 30 cm/s, on a 200-Ω/□ boron emitter (Thomson and McIntosh, 2012). On the other hand, titanium oxide films performed by thermal atomic layer deposition provide the surface recombination velocity of 2.8 cm/s and 8.3 cm/s on n-type and p-type FZ-Si substrate, respectively (Liao et al., 2014).

As presented above, surface velocity recombination can be reduced by passivation using a dielectric film and by performing a surface electric field that repels the minority charge carriers. In this way, Bonilla and Wilshaw (2014) developed a technique using positively charged alkali ions (Na or K) embedded in a silicon oxide grown in a dry dichloroethylene (DCE) environment. Surface recombination velocities in the range of 6–15 cm/s were obtained in n-type FZ-Si.

Many studies were reported on the surface velocity recombination in Si-wafers, but the experimental analysis of the passivation on the performance of Si solar cells needs more investigation. Otherwise, the passivation with a thin layer of silicon dioxide, growth at temperature below 800 °C and combined with the TiO_2 AR coating, may be an alternative to the silicon solar cell industry. The goal of this paper is to present the development and analysis of the surface passivation with a thin layer of SiO_2, with and without annealing in forming gas, on the electrical parameters of silicon solar cells. The AR coating was formed with TiO_2 deposited by e-beam evaporation.

2. Solar cell processing and characterization

Solar cells were developed in p-type CZ-Si solar grade wafers with thickness of 200 μm and base resistivity from 1 Ω.cm to 20 Ω.cm. The process sequence to produce solar cells consists of the following steps: texture etching, RCA cleaning, phosphorus diffusion, phosphorus silicate glass (PSG) etching and RCA cleaning, dry oxidation and forming gas annealing, anti-reflection coating deposition, screen printing metallization on the frontal and rear face, firing of the metal pastes and laser edge isolation.

The n^+ layer was performed by phosphorus diffusion at 845 ºC using $POCl_3$ as source, resulting in the sheet resistance around 60 Ω/□. The thermal oxidation was carried out in a specific quartz tube furnace and the forming gas annealing was performed in the same furnace. The thickness of the TiO_2 anti-reflection coating, deposited by the e-beam technique, was of 60 nm. The depth of aluminum back surface field (Al-BSF) of around (5 ± 1) μm was estimated taking into account the peak temperature firing of 840 °C and the Al paste surface density of about 3.5 mg/cm^2 (Zanesco et al., 2014).

The temperature during thermal oxidation was ranged from 650 ºC to 900 °C and the short time of the oxidation was from 4 to 15 minutes, resulting in a thin layer of silicon dioxide of around 10 nm. The forming gas annealing temperature was ranged from 350 °C to 450°C and the processes were performed during 20 and 30 minutes.

Solar cells were characterized under standard conditions (100 mW/cm^2, AM1.5G and 25°C) in a solar simulator calibrated with a solar cell previously measured at CalLab - FhG-ISE (*Fraunhofer-Institut für Solare Energiesysteme*), Germany. The two-dimensional distribution of minority carrier lifetime and diffusion length was measured using the WT-2000PV device of Semilab, by μ-PCD (microwave induced photoconductivity decay) and LBIC (light beam induced current) technique, respectively. The minority carrier lifetime was measured after the thermal oxidation and with a SiO_2 layer in order to compare the passivation. The internal quantum efficiency was calculated starting from the measured external quantum efficiency and reflectance.

3. Results and analysis

3.1. Influence of the oxidation temperature

Tab. 1 presents the average values of the open circuit voltage (V_{oc}), short-circuit current density (J_{sc}), fill factor (FF) and efficiency (η) of the solar cells processed with different oxidation temperature (T_{oxi}), during 7 minutes. The highest average efficiency was found in solar cells processed with the oxidation temperature range from 750 ºC to 800 ºC. Comparing solar cells with and without passivation in Tab.1, we observe that the average efficiency increases from (14.3 ± 0.3)% to (15.6 ± 0.1)%, due to the SiO_2 passivation. The increasing of the efficiency of 1.3 % (absolute) is caused by the behavior of V_{oc} and FF. Moreover, Tab. 1 and Fig. 1-d show that the optimization of the SiO_2 passivation reduced also the standard deviation.

The electrical parameters of the best solar cells are reported in Tab. 2. The highest efficiency of 15.9 % was achieved in a solar cell processed at the oxidation temperature of 800 °C, due to mainly the increasing of the V_{oc} and FF, caused by the passivation.

Tab. 1: Average electrical characteristics of the silicon solar cells as a function of oxidation temperature (T_{oxi}).

T_{oxi} (°C)	Nº of Cells	V_{oc} (mV)	J_{sc} (mA/cm^2)	FF	η (%)
Without oxidation	18	586.9 ± 2.3	33.85 ± 0.06	0.719 ± 0.013	14.3 ± 0.3
650	18	592.3 ± 1.9	33.80 ± 0.11	0.754 ± 0.012	15.1 ± 0.3
750	18	593.4 ± 0.9	33.81 ± 0.07	0.785 ± 0.006	15.6 ± 0.1
800	18	593.9 ± 0.3	33.85 ± 0.08	0.770 ± 0.007	15.4 ± 0.2
850	17	592.2 ± 1.4	33.8 ± 0.4	0.73 ±0.04	14.6 ± 0.9
900	18	579 ± 6	33.83 ± 0.09	0.749 ± 0.019	14.7 ± 0.5

Tab. 2: Electrical characteristics of the silicon solar cells with higher efficiency as a function of oxidation temperature.

T_{oxi} (°C)	V_{oc} (mV)	J_{sc} (mA/cm^2)	FF	η (%)
Without oxidation	589.3	33.8	0.75	15.0
650	593.0	33.7	0.76	15.5
750	595.0	33.8	0.79	15.6
800	593.3	33.9	0.78	15.9
850	593.4	33.8	0.76	15.2
900	582.7	33.9	0.76	14.7

The Fig. 1 (a) and (b) show that higher values of open circuit voltage and fill factor were achieved at temperature oxidation of 800 °C and 750 °C, respectively. The V_{oc} increased about 7 mV when passivation step was implemented. The passivation affects also the fill factor. This parameter augments from 0.72 to 0.78 with the oxidation at temperature of 750 ºC – 800 ºC. The oxide growth at 900 °C reduces the V_{oc}, when compared to the results without oxidation. This temperature may cause a degradation of the substrate. Fig. 1 (c) indicates that the J_{sc} was not affected by the oxidation temperature and the SiO_2 passivation, because of the efficient aluminum back surface field (Al-BSF). Consequently, the higher efficiencies occur at the oxidation temperature of 750 °C and 800 °C, as Fig.1 (d) confirms.

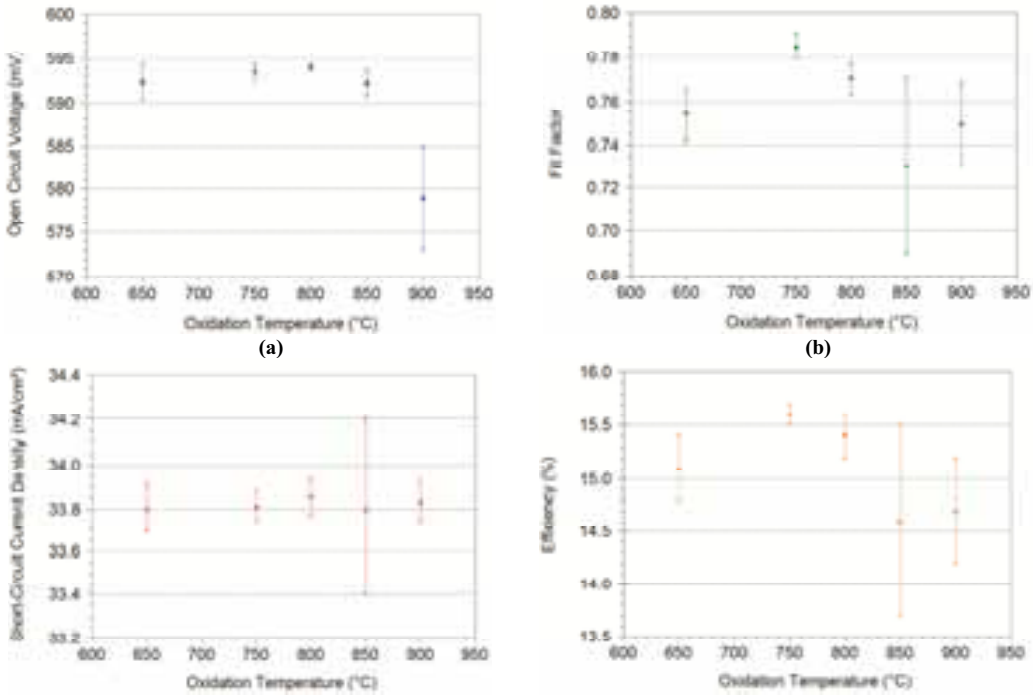

Fig. 1: (a) Open circuit voltage, (b) fill factor, (c) short-circuit current density and (d) efficiency of the solar cells as a function of temperature oxidation.

The Fig. 2 indicates that at short wavelengths, the internal quantum efficiency (IQE) decreases slightly with the increasing of the oxidation temperature because the SiO_2 passivation is less effective. With the increase of the oxidation temperature from 850 °C to 900 °C, the surface recombination velocity enhances of about two orders of magnitude, indicating that the SiO_2 passivation is worst.

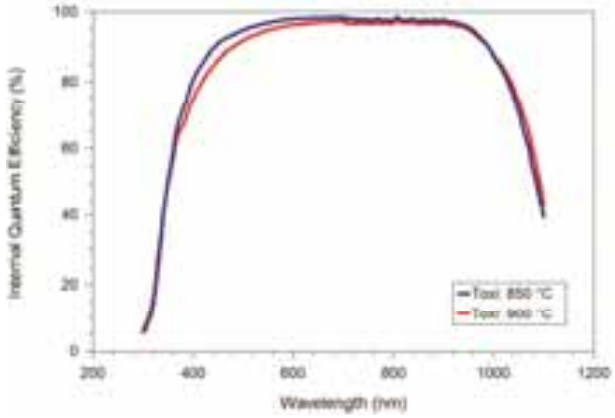

Fig. 2: Internal quantum efficiency of the silicon solar cells with the highest efficiency and processed at temperature oxidation of 850 °C and 900 ºC.

The effective minority carrier lifetime (τ_{eff}) was low for the oxidation temperatures evaluated and depends on the oxidation temperature, as Fig. 3 shows. The highest average values of 40 μs - 50 μs were found at temperature oxidation from 750 °C to 850 °C.

It's worth mentioning that the average initial minority carrier lifetime measured in 60 solar grade silicon wafers was of 39 μs and the final effective value takes into account the double pn junction formed by phosphorus diffusion, passivated with SiO_2 growth at different temperatures. Then, the process to fabricate the solar cells with the oxidation temperature range of 750 - 850 °C leads to the minority carrier lifetime slightly higher than the initial value. Fig. 3 shows also that low values of the minority carrier lifetime occur in the center of the wafers. For the range of oxidation temperature from 750 °C to 850 °C, the highest values of the lifetimes are of around 110 μs.

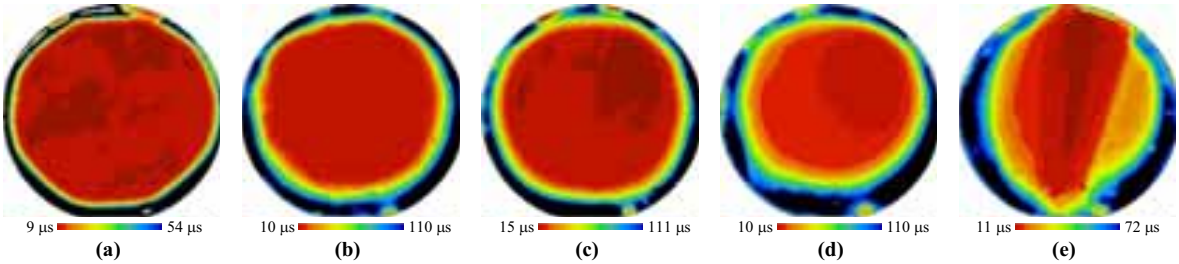

Fig. 3: The two-dimensional distribution of the minority carrier lifetimes measured by µ-PCD technique afterwards the oxidation during 7 minutes and temperature of (a) 650 ºC (τ_{eff} = 21 µs), (b) 750 ºC (τ_{eff} = 42 µs), (c) 800 °C (τ_{eff} = 43 µs) (d) 850 °C (τ_{eff} = 49 µs) and (e) 900 °C (τ_{eff} = 33 µs).

The Fig. 4 shows the comparison of the minority carrier diffusion length (L_D) of the solar cells processed with the oxidation temperature of 800 °C and 900 °C and without oxidation. The average L_D of the solar cells without oxidation step is around 1380 µm and this parameter enhances to 1890 µm, when the oxidation is performed at 800 °C. However, when the oxidation temperature is of 900 °C, the average minority carrier diffusion length decreased to 960 µm, indicating that the substrate was degraded during the oxidation process.

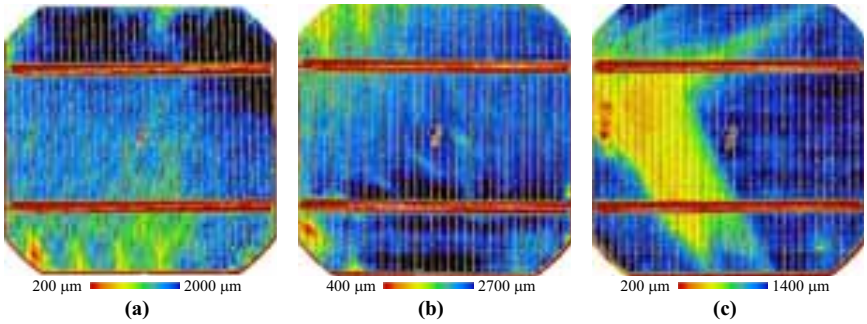

Fig. 4. The two-dimensional distribution of the minority carrier diffusion length of solar cells processed (a) without oxidation (L_D = 1380 µm) and (b) with oxidation temperature of 800 °C (L_D = 1890 µm) and (c) of 900 °C (L_D = 960 µm).

3.2. Influence of the oxidation time

The electrical characteristics of the solar cells processed by the oxidation time from 4 minutes to 15 minutes at the temperature of 800 ºC are presented in Tab.3. The highest average efficiency was found when cells were thermally oxidated during 7 minutes. The V_{oc} shows a slight trend of increasing with the oxidation time. Nevertheless, the J_{sc} decreases slightly when the oxidation time is increased, as Tab. 4 confirms. The Tab. 4 indicates that the highest efficiency of 15.9 % is obtained in solar cells processed at the oxidation temperature of 800 °C during 7 minutes.

Tab. 3: Average electrical characteristics of the silicon solar cells as a function of oxidation time (t_{oxi}).

t_{oxi} (min)	Nº of Cells	V_{oc} (mV)	J_{sc} (mA/cm^2)	FF	η (%)
4	17	593.2 ± 1.0	33.88 ± 0.11	0.751 ± 0.011	15.0 ± 0.3

Tab. 4: Electrical characteristics of the fabricated silicon solar cells with the highest efficiency as a function of oxidation time.

t_{oxi} (min)	V_{oc} (mV)	J_{sc} (mA/cm^2)	FF	η (%)
4	593.9	34.0	0.76	15.3
7	593.3	33.9	0.78	15.9
15	594.0	33.7	0.77	15.4

3.3 Analysis of the annealing step

Batches of solar cells were processed at temperature oxidation of 800 °C during 7 minutes and the annealing temperature and time were ranged. Starting from the results summarized in Tab.5, we observe that the annealing in forming gas at 400 °C did not improve the average efficiency of solar cells when compared to the results presented in Tab. 1. Moreover, the annealing temperature of 350 °C and 450 °C lead to lower efficiencies than that presented in Tab. 1 for the oxidation temperature of 800 °C, indicating that the annealing process at these temperatures did not improve the efficiency of the solar cells.

The open circuit voltage tends to increase with long annealing time. For annealing temperature of 400 °C and 450 °C, the V_{oc} increased about 2.5 – 3.0 mV, when the annealing time was increased from 20 minutes to 30 minutes. This result is confirmed in Tab. 6 that reports the electrical characteristics of the solar cells with the highest efficiency. For the best cells, the V_{oc} was improved up to 3 mV when the annealing time is augmented of 10 minutes.

With the annealing without the previous oxidation, an average efficiency of (15.3 ± 0.2) % was achieved, as shown in Tab. 5. This value is only 0.3 % (absolute) lower than the value obtained in devices with oxidation and annealing in forming gas and the reduction of the efficiency was caused by the decrease of V_{oc}, J_{sc} and FF.

Tab. 5: Average electrical characteristics of the solar cells processed with different parameters of forming gas annealing.

T_{An} (°C)	t_{An} (min)	Nº of Cells	V_{oc} (mV)	J_{sc} (mA/cm^2)	FF	η (%)
350	20	7	591.2 ± 1.3	33.84 ± 0.09	0.756 ± 0.017	15.0 ± 0.3
400	20*	6	590.7 ± 0.4*	33.73 ± 0.06*	0.774 ± 0.003*	15.3 ± 0.2*
	20	3	593.8 ± 0.8	33.88 ± 0.10	0.782 ± 0.007	15.6 ± 0.1
	30	2	596.7 ± 1.1	33.81 ± 0.11	0.800 ± 0.004	15.6 ± 0.1
450	20	5	591.5 ± 1.4	33.75 ± 0.10	0.766 ± 0.008	15.1 ± 0.3

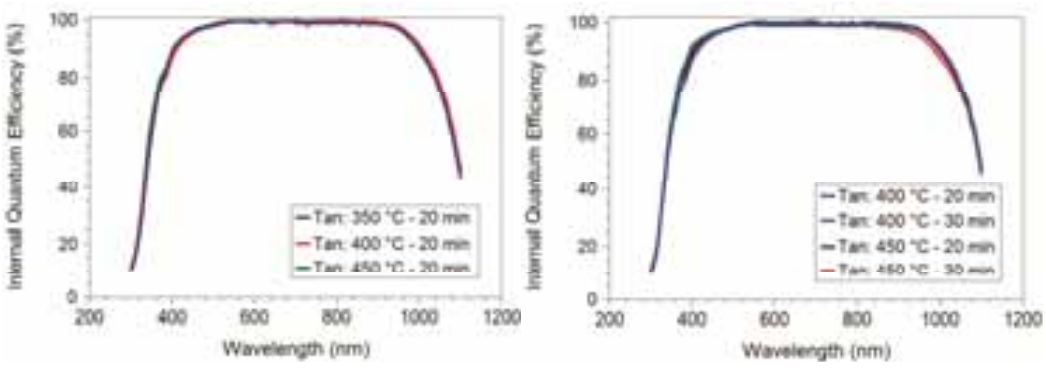
	30	594.4	33.9	0.77	15.4

* with annealing and without previous oxidation

The short-circuit current density is slightly affected by the annealing process, as Tab. 5 reports. The annealing temperature and time do not influence the J_{sc} and this conclusion is confirmed in Fig. 5 that compares the internal quantum efficiency of the best processed solar cells as a function of annealing temperature and time. Otherwise, the oxidation step improves the passivation, as shown in Fig 6. In this figure, the internal quantum efficiency of the solar cell processed at 400 °C during 20 minutes with oxidation and annealing steps is compared to the IQE of the cell processed with annealing and without oxidation. At short wavelengths, the IQE of cells with SiO_2 passivation is higher, indicating the effectiveness of the passivation. When the oxidation is implemented, the surface recombination velocity was reduced of about one order of magnitude.



(a) (b)

Fig. 5: Internal quantum efficiency of the silicon solar cell with the highest efficiency as a function of (a) annealing temperature and processed during 20 minutes and (b) annealing time at the temperature of 400 °C and 450 °C.

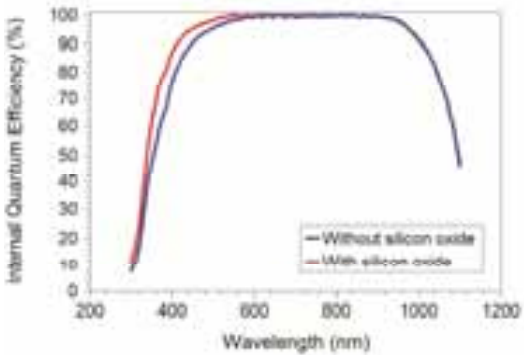


Fig. 6: Internal quantum efficiency of the silicon solar cell processed with and without oxidation step and annealing at the temperature of 400 °C during 20 minutes.

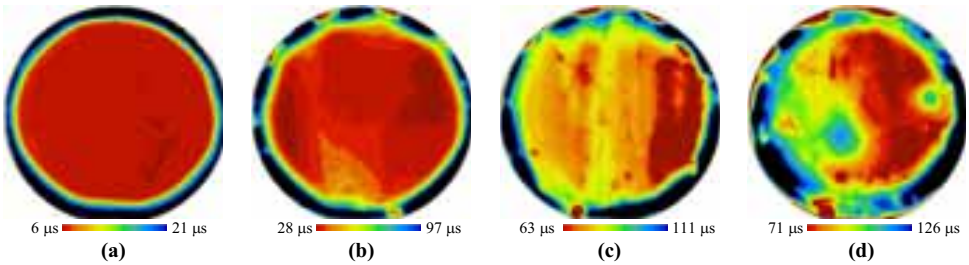
The Fig. 7 illustrates the two-dimensional distribution of the minority carrier lifetimes after the oxidation at the temperature of 800 °C during 7 minutes and annealing step during 20 minutes with different temperatures. In the sample without oxidation (see Fig. 8-a), but with annealing step, the average value of τ_{eff} was of 10 μs. This result confirms that oxidation at 800 °C improves the minority carrier lifetime, as Fig. 7 (c) shows. Values of the average effective minority carrier lifetime of around 80 μs – 95 μs were measured in samples processed at 400 °C and 450 °C. In this annealing temperature range, values of the τ_{eff} up to 125 μs were measured. Again, we can observe that the low values of the effective minority carrier lifetime occur in the center of the sample. Moreover, comparing Fig 3-c (τ_{eff} = 43 μs) to Fig. 7-c (τ_{eff} = 82 μs) and Fig. 7-d (τ_{eff} = 95 μs), we can notice that the average effective minority carrier lifetime may be increased if the annealing step is implemented.



(a) (b) (c) (d)

Fig. 7: The two-dimensional distribution of the minority carrier lifetimes afterwards the oxidation at temperature of 800 °C during 7 minutes and annealing step during 20 minutes and temperature of (a) 400 °C (without oxidation) (τ_{eff} = 10 μs), (b) 350 °C (τ_{eff} = 48 μs), (c) 400 °C (τ_{eff} = 82 μs) and (d) 450 °C (τ_{eff} = 95 μs).

4. Conclusion

The passivation of silicon solar cells with a thin SiO_2 layer were experimentally optimized and analyzed. The

efficiency of 15.9 % was achieved in solar cells processed at the oxidation temperature of 800 ºC, during 7 minutes. The better average efficiencies were obtained in the oxidation temperature range from 750 °C to 800 °C, caused by the increasing of the open circuit voltage and fill factor. This result is related to the highest effective minority carrier lifetime, of 40 μs - 50 μs, measured in wafers processed in this oxidation temperature range. The short-circuit current was not affected by oxidation temperature, but the internal quantum efficiency decreases slightly with the increasing of the oxidation temperature. The minority carrier diffusion length of the solar cells processed with the oxidation temperature of 800 °C was around 1890 μm and decreased to 960 μm with the increasing of the oxidation temperature to 900 °C. The open circuit voltage shows a slight trend of increasing with the oxidation time, but the fill factor decreases. The annealing step in forming gas did not improve the average efficiency of solar cells and the open circuit voltage tends to grow with the increasing of the annealing time. The annealing temperature and time did not affect the short-circuit current density. The highest values of the average effective minority carrier lifetime of around 80 and 100 μs were measured in samples processed at annealing temperature of 400 °C and 450 °C, respectively. Solar cells processed with oxidation and annealing presented higher internal quantum efficiency at short wavelengths than cells with only annealing step.

Abstract

In this article, we have used boric acid source to form the boron emitter in a selective way. And, the conditions of boron diffusion process were investigated. It was found that for 5% boric acid in DI water, the spinning of 3000 rpm for 15 sec and dry out process at 200°C are the most appropriate conditions.

Also, in this study, by using boric acid source, a selective doping method was developed. Therefore, it can be possible to have both light and heavy (under contacts) dopings on different areas of the wafer but without any extra masking layer (e.g. silicon dioxide) and undergoing only one drive-in process.

Keywords: *Boric acid, Emitter formation, Solar cell*

1. Introduction

Solar cells based on n-type c-Si wafers have raised growing interest since they feature clear advantages compared to the standard p-type Si; because of having lower sensitivity to metallic impurities and not degraded by the boron-oxygen pairs [1, 2].

Recently, there has been a remarkable increase in investigating spin-on or spray-on dopant (SOD) sources particularly in solar cell research and production. Low cost and neither toxic nor pyrophoric are advantages of these sources [3, 4]. Boron diffusion using BBr_3 is toxic and needs an additional etching step in order to diffuse either on one side of the sample or on specific areas. Since diffusion processes using Boron SOD films are common, we have used and developed a SOD process applying boric acid source to have boron emitter formation. By controlling the boric acid concentration in the solutions, temperature and the diffusion time, we have obtained a wide range of sheet resistances and doping profiles for solar cell applications. In this paper, the conditions of boron diffusion process, which includes the appropriate rotation (spinning speed) and temperature to drive out the excess solvents, were investigated. The output parameters such as carrier lifetime, sheet resistance and diffusion profile have also been measured. Finally, using this method, we were able to produce samples with selective diffusion areas without any extra masking layer, which can be used as the selective emitter for solar cell applications.

2. Experimental

doi:10.18086/swc.2015.05.02 Available at http://proceedings.ises.org

In order to achieve the desired properties of the boron emitter, n-type Cz <100>-oriented wafers of 1-3 Ωcm were used as the substrates. After standard Piranha cleaning, the solution of boric acid, known as H_3BO_3 (orthoboric acid), was spin-coated on the samples. Later, all samples were dried in the oven to remove the solvent. Subsequently, boron diffusion process was performed in a quartz tube furnace at different temperatures in the range of 950-1050 °C. The borosilicate glass (BSG) is removed in a HF solution after the furnace diffusion. Next, a thorough characterization of the process was performed using various techniques. The sheet resistance and the minority carrier lifetimes were measured respectively using four point probes and μ-PCD method. Electrochemical capacitance voltage profiler (ECVP) was applied to investigate the emitter surface doping concentration and the dopant profiles.

3. Result and Discussion

a. Boron Diffusion

The boric acid which exists in the crystalline phase was used as the solid source in this study. H_3BO_3 solutions with various concentrations can be prepared by dissolving different amounts of boric acid in DI water. The solubility in DI water at most at room temperature reaches up to 5wt% [1]. The formed anhydrous boric oxide (boron oxide) begins to soften at 325 °C [1]. The boron oxide then reacts with silicon to form SiO_2 and B, which then diffuses into the silicon by manipulating the temperature. After boric acid was dissolved in DI water, the samples were placed on a spinner and the SODs were drop-coated on the center of the sample. The required SOD solution (boric acid/DI water) for 1cm×1cm samples was 100 μl. In order to choose the appropriate layer deposition, we have first investigated various speeds and times. Then, the coated samples were baked at several different temperatures for 15 min to drive out the excess solvent (also called pre-deposition). Afterward, the samples were loaded in the diffusion furnace for 14 min consisting of N_2 gas as the ambient gas (drive-in step). Fig. 1 shows the optical microscope images of samples primarily dispersed by 5% boric acid solution after diffusion and BSG layer removal for different spinning speeds. It can be seen that 3000 rpm for 15 sec is appropriate for conformal coating. The process was also optimized for the appropriate temperature to drive out the excess solvents. It was examined at 50, 100, 150 and 200°C to check which gives the best uniformity of the final layer. It found that 200°C can result in the optimum layer (shown in Fig. 2).

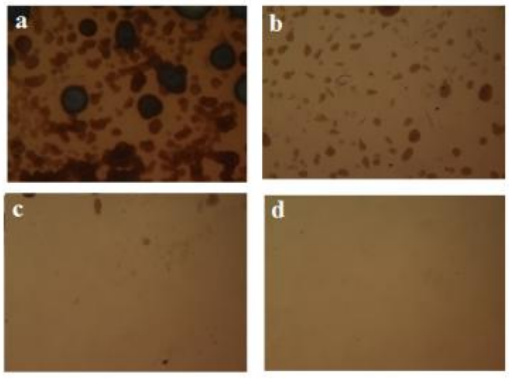

Fig. 1: Optical Microscopy image for different spin coat speed (a: 500 rpm, b: 1000 rpm, c: 2000 rpm, d: 3000 rpm) after drive-in step: 1050°C and 5% boric acid/DI water concentration.

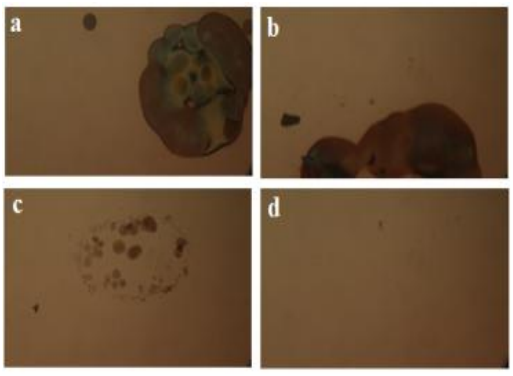

Fig. 2: Optical Microscopy image for different predep temprature (a: 50°C, b: 100°C, c: 150°C, d: 200 °C) after drive-in step: 1050°C and 5% boric acid/DI water concentration.

In addition, the effects of different concentrations of acid boric in DI water (1-5%) and different drive-in temperatures (950-1050°C) on the sheet resistance and the lifetime were studied and the results are shown in Table I & II. It can be seen that when the boric acid concentration or drive-in temperature increases, the sheet resistance decreases. On the other hand, the carrier lifetime unfortunately decreases as well. This results in an increase in the probability of contamination, and this is the reason. Fig. 3 shows the boron profile for different concentrations of boric acid solution, measured using ECVP. The surface concentration was assumed to the concentration at 10 nm deep inside the bulk and was found to be increasing in the range of 5.71-19.8×10^{19} cm^{-3} for different solutions used in the study. The junction depth was estimated to be in the range of 0.32-0.65 μm. The effects of different drive-in temperatures (950-1050°C) on the sheet resistance and the lifetime were also studied. The results are shown in Table II. According to this table, when the drive-in temperature increases, both sheet resistance and carrier lifetime will be decreased.

According to a previous report [5], two mechanisms of contamination and generation of dislocations due to a high B doping using this solid source are the reasons why the lifetime decreases. Fig. 4 shows the boron doping profiles at different temperatures, showing that we can have a good control on the depth of the profile (the both shallow and deep boron profiles) using boric acid as a diffusion source.

Table I: Sheet resistance and lifetime from different concentration of acid boric: pre-deposition time:15 min, drive-in time: 14 min, drive-in temp:1050°C.

Boric acid concentration (%)	Rsh (Ω/□)	τ (μs)
1	47.7	3.81
2	40.6	2.78
3	35.1	2.62
4	30.1	1.85
5	17.5	1.6

Table II: Sheet resistance and lifetime at different drive-in temperatures: pre-deposition time:15 min, drive-in time: 14 min, boric acid concentration:5%.

Temperature (°C)	Rsh (Ω/□)	τ (μs)
950	386.6	4.93
975	148.8	2.27
1000	58.8	2.01
1025	25.4	1.75
1050	17.5	1.6

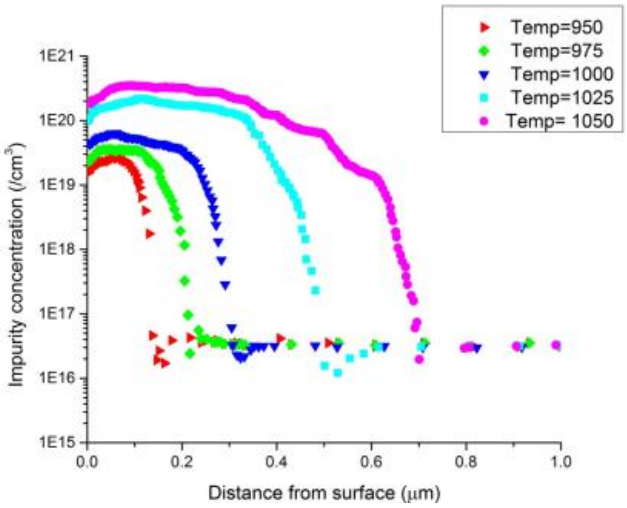

Fig. 4: Depth profile of boron in samples shown in Table II (Temp=°C).

b. Selective B Diffusion

The most interesting feature of this process compared to normal diffusion process is the ability to have a selective diffusion without having additional etching process. At first, photolithography was used to define windows in which the diffusion must be performed (shown Fig 5 b and c). After developing and post baking the resist, 200µl of 5% acid boric/DI water solution was applied on the patterned sample using spin-coating (see Fig. 5 d). Then, the sample was placed in an oven at 100°C for 15 min to drive out the solvent. Afterwards, the over-photoresist part of the boric acid was removed by lift off using acetone followed by DI water (Fig. 5 e). Finally, the sample was placed in the diffusion furnace in N_2 gas environment for 15 min at 1050°C.

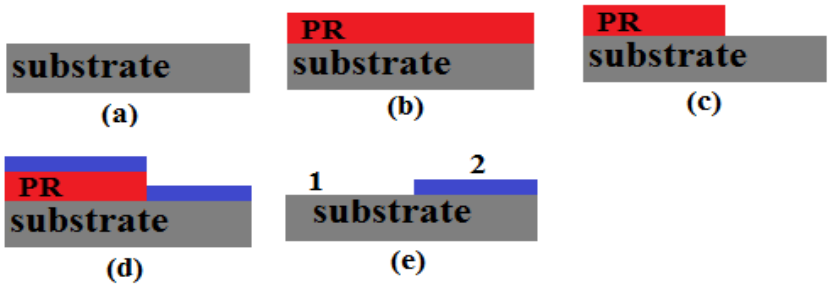

Fig. 5: Selective diffusion process with boric acid/DI water source. a) sample cleaning, b) photoresist spin coat, c) lithography, d) SOD & baking, e) photoresist (PR) lift off.

The ECVP measurements on these samples (shown in fig 6) show a remarkable difference in the surface concentration as a result of this selective process.

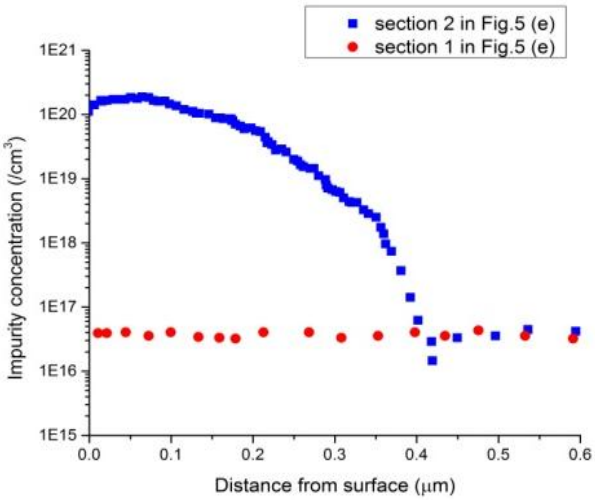

Fig.6: Depth profile of boron on a sample prepared as mentioned in Fig. 5. Section 1 and 2 are shown in Fig. e. Temperature: 1050°C, drive-in time 14 min.

In order to study the selective diffusion effect on the lifetime and sheet resistance, another experiment was designed. Therefore, after SODs were formed on the samples (100µl, 3000rpm and 15 sec), the coated samples were baked at different temps (50, 100, 150 and 200°C) to drive out the excess solvent. Next, samples were placed on the hotplate stirrer containing DI water in at 90°C for 3h so that the layer would be removed. Then, the samples dried and were loaded in diffusion furnace for 14 min with 4slm flow of N_2 gas.

The results of lifetime and sheet resistance are shown in Table III and Table IV respectively.

Table III: lifetime results at different pre-deposition temperatures: pre-deposition time:15 min, drive-in time: 14 min, boric acid concentration:5%.

Pre-dep Temp (°C)	τ (µs) : after 3h in the DI water	τ (µs): after drive-in diffusion
50	1.293	2.994
100	1.206	2.914
150	1.114	2.272
200	0.942	2.189

Table IV: sheet resistance results at different pre-deposition temperatures: pre-deposition time:15 min, drive-in time: 14 min, boric acid concentration:5%.

Pre-dep Temp(°C)	R_{sh} before process	R_{ah} after Dry	R_{sh} (Ω/□): after 3h in the DI water	R_{sh} (Ω/□): after drive-in diffusion

200	87.2	80.1	83.8	14.8

These tables clearly show that hot DI water can dissolve the solid layer formed on the samples and can be used as the potential etchant for this material. The ECVP measurements on the sample with and without etching with hot DI water are shown in Fig.7. This figure illustrates a remarkable difference in the surface concentration. In the other words, we have both light and heavy dopings in different areas of the wafer.

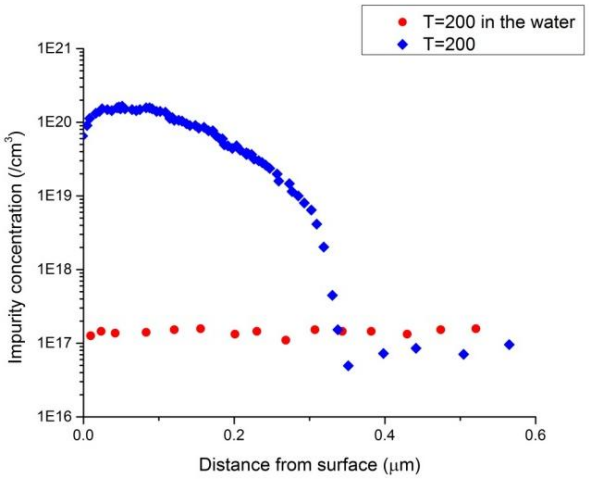

Fig.7: Depth profile of boron diffusion. Temprature:1050°C, drive-in time 14 min.

4. Conclusion

In this paper, we used boric acid source to formed boron emitter selectively on the n-type substrates. A thorough investigation of the effective parameters was performed to obtain the optimum conditions of boron diffusion process. It was found that spinning speed of 3000 rpm for 15 sec and 200°C drive-out bake result in a uniform dopant seed layer for the diffusion. The depth profile can be carefully controlled by monitoring the

boric acid solution concentration and the drive-in temperature. For selective cases, patterning can be done either by optical lithography and etching the unwanted parts using hot DI water or lift-off process. ECV measurements after selective process showed that the pre-deposition step (SOD) will not change the doping unless samples undergo a high temperature drive-in process.

Abstract

We present results of spectral solar irradiance measured by a high quality doble-monocromator spectroradiometer in different seasons at the Astronomical Observatory of Rosario, Argentina. Since measures were done in the UV and visible ranges, we extended the measurements using the SMARTS model. Also, the model is applied to extend the analysis of spectral solar irradiance for Recife (Brazil) and Urcuquí (Ecuador). The maximum photovoltaic current for different solar cells (monolayer and multilayer) was derived using spectral irradiance associated to quantum efficiency of the PV cells. At 5th May 2013, the calculated photovoltaic currents were: 33.47 mA/cm^2 (mono-Si); 25.42 mA/cm^2 (poly-Si); 18.52 mA/cm^2 (CdTe); 12.28 mA/cm^2 (multilayer cell). The sensitivity of each cell technology to different atmospheric components (e.g., aerosols, water vapour, ozone) is also shown.

Keywords: *spectral, solar irradiance, photovoltaic cells, quantum efficiency*

1. Introduction

Solar spectral irradiance is one of the variables most difficult to be measured due to the requirement of high quality instruments (spectrorradiometers) with a periodic calibration and to the modification of the atmospheric components (gases and suspended particles, aerosols and clouds) that can vary rapidly. Even the Sun position changes more than1º in only some minutes. Consequently, special care needs to be taken in order to measure solar spectral irradiances in outdoor conditions. In the present work we present these measurements done in the Astronomical Observatory of Rosario, Argentina (32.95º S, 60.68ºW, 25 m asl) in different months of the year, with an OL756 portable UV-Vis spectroradiometer Optronics, a double monocromator, in the 280-400 nm and 400-750 nm (UV and visible) ranges.

We are mainly interested in the correlation of these spectral data with the photovoltaic (PV) current produced by (mono- and multi-) layer solar cells. Since usually these cells have quantum efficiencies that go up to the IR wavelength range, we used an extension of the data considering the SMARTS (Gueymard, 1995) algorithm. Currents (per unit area of the incident radiation) in the range of 10.02-38.3 mA/cm^2 can be obtained, depending on the maximum efficiency, the place and the spectral range of the considered cell. Theoretical analysis of the maximum limiting efficiencies has been obtained by Araújo and Martí (1994) with values of 40.8% for optimum single gap devices and of 86.8% for infinite number of gaps.

The significance of solar photovoltaic as a renewable energy source has been highlighted by Razykov et al. (2011) indicating that the PV market is growing at an annual rate of 35-40 %. Also the reduction to around 1 year in the time at which the solar cells equals the energy consumed for its production to the generated energy

doi:10.18086/swc.2015.05.03 Available at http://proceedings.ises.org

and the minimization of the environmental impact of a solar power plant has been discussed by Piacentini et al. (2013).

2. Results and discussions

2.1 Spectral solar irradiances

It was measured spectral solar irradiances at the Rosario Astronomical Observatory, Argentina, from 290 to 420 nm during clear sky days (with cloud coverage ≤ 25%) on horizontal plane, employing an Optronics OL756 spectroradiometer of the Institute of Physics Rosario (CONICET-National University of Rosario). This high quality instrument is a double monocromator (eliminating in this way the straylight effect that produces false signal at wavelength less than about 300 nm) with calibration lamp. In order to extend the wavelength range in the visible and infrared (IR) parts of the spectrum, we employed the SMARTS algorithm (Gueymard, 1995) for the model calculation of the solar spectral irradiance corresponding to the same day and hour of measurement.

The solar spectral global irradiance was modelled through SMARTS model using satellite data. The air temperature at 10 m, relative humidiy, total column precipitable water and surface albedo were obtained from the SSE/NASA, the ozone total column with OMI/NASA and AOD_{550m} (aerosol optical depth to 550 nm) with MODIS-Aqua Deep Blue.

The ozone and aerosol components were modified in order to have a very good match between model calculation and spectral measurements in the UV range. In order to adjust the model to measurement was used as a criterion "the area adjusted". This means, to find a small percentage difference between the areas of the irradiances. For May 03, 2013, the percentage difference was 0.12% and in the case of December 28, 2011 was 0.54%. In Fig. 1, it can seen the measurement superimposed to modelling.

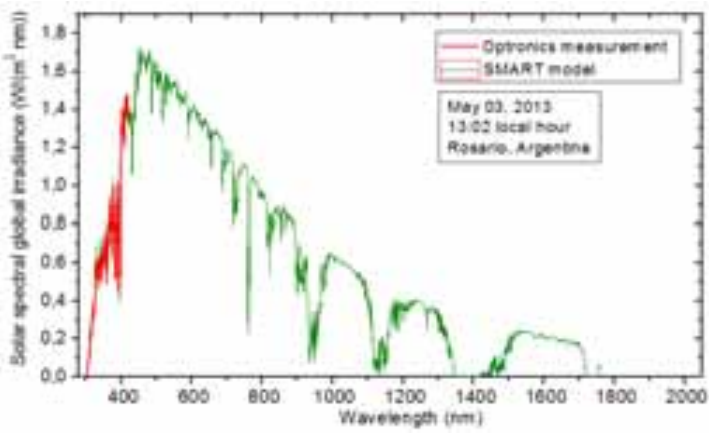

Figure 1: Solar spectral global irradiance incident on a horizontal surface for Rosario, Argentina, in May 03, 2013. The red line represents the Optronics measurement and the green line represents the SMART model result.

In Figure 2 (left), we display the solar spectral global irradiance for the days: December 28, 2011 at 13:03 local hour (=UT - 3); and May 05, 2013 at 13:02 local hour. The irradiances displayed in Figure 2 show the typical behavior of sun radiation in the UV-visible-IR ranges (see for example the reference spectrum of Gueymard, 1995), with strong absorption at certain particular wavelengths due to atmospheric gases.

In the Urcuqui case, since a lack of measurements, it was modelled the solar spectral global irradiance through SMARTS model using the same satellite data bases.

The selected days were: September 24 and July 21 because they are the days with the minimum (1.1°) and

maximum (80.6°) solar zenital angle respectively for the place, see Fig.2 (middle). The reason for the election site is based in the altitude of the Urcuquí, since this place is located at 2320 masl (meters above the sea level). Also, Urcuquí has a low aerosol optical depth (0.046 in September and 0.137 in July). The middle of Figure 2, we shows the solar spectral global irradiance calculated with the SMARTS for Urcuquí.

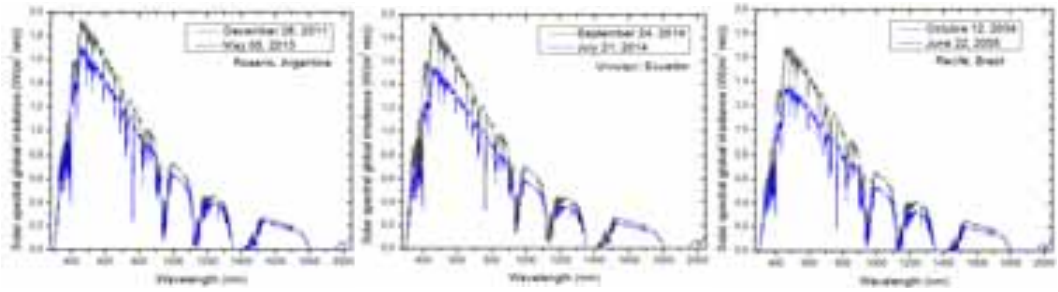

Figure 2: Solar spectral global irradiance incident on a horizontal surface for Rosario, Argentina (left), Urcuquí, Ecuador (middle) and Recife, Brazil (right). In the case of Rosario, the model was used to extrapolate the measurements and in the cases of Urcuqui and Recife all data was modeling.

Also, for Recife there is a lack of calibrated measurements, then it was modelled the solar spectral global irradiances for two day through SMARTS model using the same satellite data base. It was modeled the following days: June 22, 2005 and October 12, 2004 (see Fig.2, right).

2.2 Spectral quantum efficiency

The figure 3 shows the quantum efficiency for different types of solar cells. Quantum efficiency refers to the efficiency with which photons that reaches the cell is able to generate collectable carriers. It depends on the absorption characteristics of the solar cell. The upper limit wavelength for each type of cell is determined by the energy gap of the materials that composes the solar cell. Photons with energy lower than this limit is not absorbed.

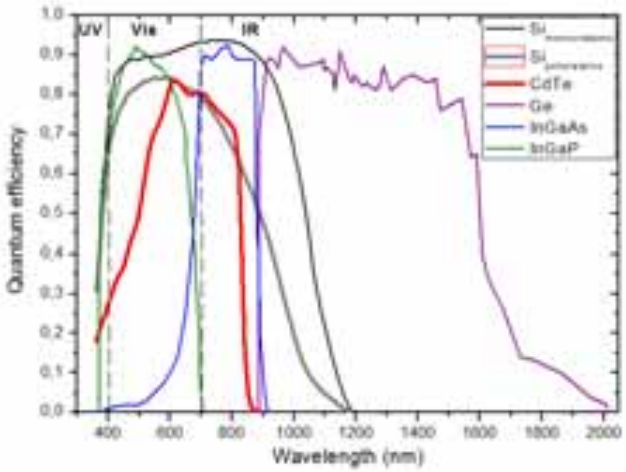

Figure 3: External quantum efficiency of different solar cells as function of wavelength.

The quantum efficiency of InGaAs, InGaP and Ge presented in Fig. 3 were obtained directly from the datasheet of a manufacturer of multijunction solar cells. The curves presented for the other materials (Fig. 3) were obtained using the relationship between quantum efficiency (QE) and spectral response (SR), presented by Field (1997) in equation (1).

$$QE = \frac{hc}{\lambda q} SR \qquad \text{(eq. 1)}$$

were q is the absolute value of electron charge, λ is the wavelenght, h is the Planck constant, and c the the speed of light in vacuum.

3. 2.3 Spectral and total surface density photovoltaic current

The photovoltaic current (per unit area) is produced in the solar cell by the interaction of solar photons with the material exposed to the Sun. This can be described mathematically through the following equations (2 to 4):

$$I_{FV,A} = \int_{\lambda_2}^{\lambda_1} \varphi . \varepsilon_\lambda . \Delta\lambda \quad \text{(eq. 2)}$$

$$\varphi = \frac{I(\lambda,t)}{E_f} . e^- \quad \text{(eq. 3)}$$

$$E_f = \frac{h.c}{\lambda} \quad \text{(eq. 4)}$$

being φ the maximum spectral surface density photovoltaic current, e^-= the electron charge, h = Planck´s constant, ε_λ the solar cell external quantum efficiency, $\Delta\lambda = \lambda_2 - \lambda_1$ the wavelength interval which is defined from the external quantum efficiency wavelength range of each solar cell, and E_f is a photon energy.

One of the purposes of studying the photogenerated current is the possibility to analyze the efficiency of the solar cell to capture solar radiation in different regions of South America. For example, Hau-Vei et al. (2014) presented a hybrid design of the GaAs combined with colloidal quantum dots, achieving a power conversion efficiency as high as 24.65% compared with traditional GaAs-based devices and current densities until approximately 23 mA/cm^2. Also, Mohammed et al (2013) presented a model for simulation of the enhancement of the photogenerated current por PN silicon photodetectors with impurities.

Figure 4 shows the maximum spectral surface density photovoltaic current, the particular quantum efficiency and the weighted value with external quantum efficiency for different solar cells for a typical clear sky day (May 5, 2012 in Rosario) around solar noon. We also indicate in the same figure the integral value of this weighted value ($\varphi.\varepsilon_\lambda$). The corresponding values of the surface density photovoltaic current are summarized in Table 1 showing that the maximum current corresponds to the mono-Si and the minimum one to InGaAs, in all cases.

Table 1: Integrated weighted surface density photovoltaic current (iFV,A) for different days of the year and for monolayer and polylayer solar cells. Also, the ratio between the maximum and minimum current values and the mean (with its standard deviation) values are included.

		$i_{FV,A}$ (mA/cm^2) for different solar cells							
Date (local hour = UT-3)	Place	InGaP	InGaAs	Ge	mono-Si	poly-Si	CdTe	Ratio max/min	Mean value (standard deviation)
28/12/2011 (13:02)	Rosario Argentina	17.09	13.97	18.68	38.30	29.04	21.15	2.13	23.7 (8.4)
05/05/2012 (13:02)	Rosario Argentina	14.82	12.28	17.86	33.47	25.42	18.52	2.73	21.9 (11.1)
24/09/2014 (13:00)	Urcuquí Ecuador	16.81	13.67	18.8	37.61	28.49	20.68	2.75	22.7 (8.8)
21/07/2014 (13:00)	Urcuquí Ecuador	13.68	11.33	15.70	30.96	23.96	17.01	2.73	18.8 (7.3)
22/06/2005 (11:30)	Recife Brazil	12.10	10.02	12.91	27.13	20.59	15.10	2.71	16.3 (6.4)
12/10/2005 (11:20)	Recife Brazil	15.03	12.48	16.54	33.87	25.67	18.75	2.71	20.4 (8.0)

Araújo and Martí (1994) obtained an optimum photogenerated current of 56.09 mA/cm^2 with their model, while Razykov et al. (2011) determined a short-circuit current density of 42.2 mA/cm2, with an efficiency of 24.7%. Steudel et al. (2012) presented a short-circuit current density of 17.94 mA/cm^2 in a CdTe solar cell for an air mass of 1.5. As it can be seen in Table 1, our calculations gave a range of 15.10 to 21.15 mA/cm^2 for the same type of solar cells with air mass between 1 and 1.54

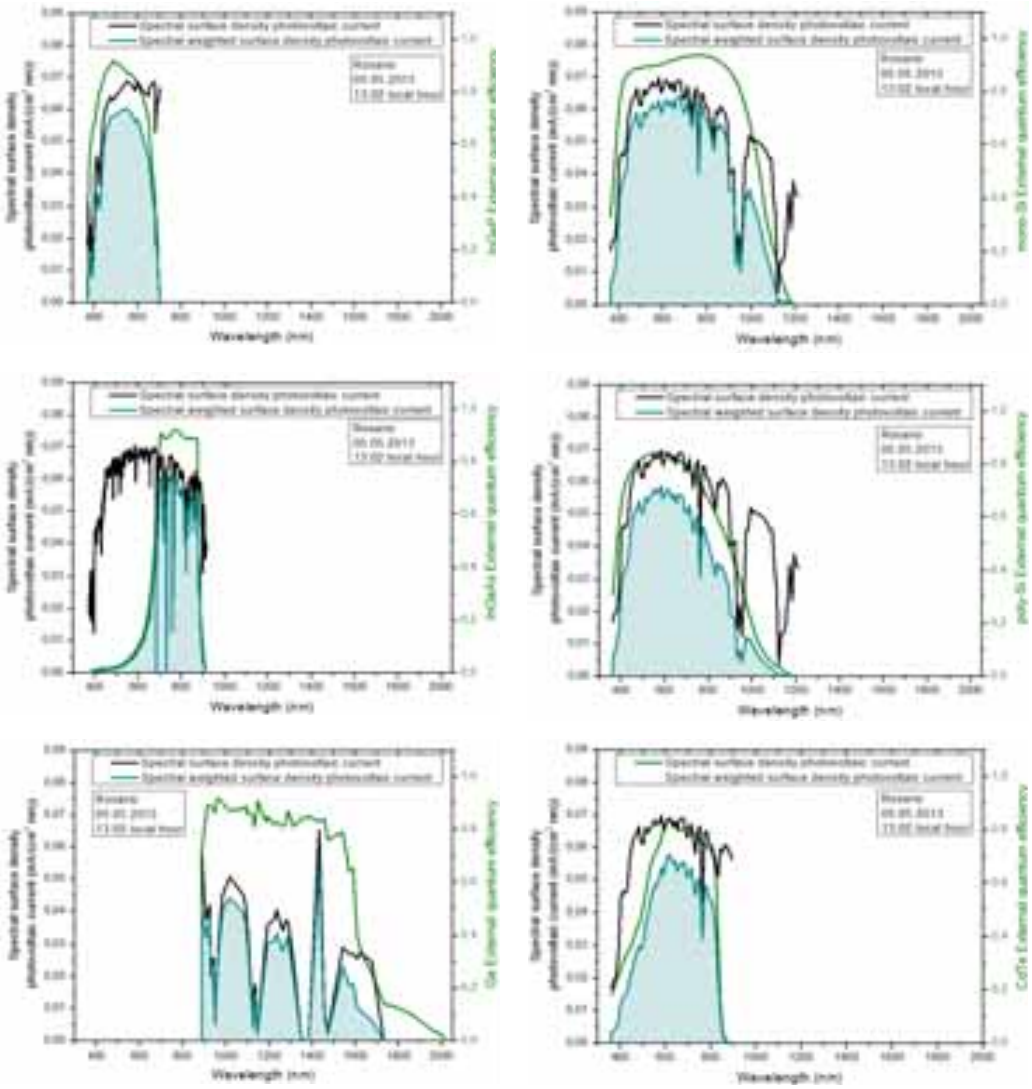

Figure 4: Spectral surface density photovoltaic current (black line) and weighted (cyan shading area) with external quantum efficiency (green line) for different solar cells determined for solar spectral irradiance measured the day May 5, 2013 at 13:02 local hour at the Astronomical Observatory of Rosario, Argentina. The integrated weighted surface density photovoltaic current is also given.

4. 2.4 Sensibility analysis

As a general criteria for the analysis of the influence of each atmospheric component on the surface density photovoltaic current, first it was analyzed if there is a significant wavelength superposition of the external quantum efficiencies and the atmospheric transmittance of given gases or aerosol. From Figure 5 and considering the criteria described before, it can be deduced qualitatively that the water vapor amount in the atmosphere influences meanly in the Ge solar cell. The total column ozone and the aerosols have more impact over the InGaP cells while they have less impact on Ge cells.

It was calculated the sensibility for three different parameters with the data of Rosario in December 28, 2011. The corresponding results of the sensitivity of the different atmospheric component variation on surface density photovoltaic current ($i_{FV,A}$) is given in Table 2. They confirm the initial hypothesis. To build the Table 2, each parameter (ozone, aerosol and water precipitation) were changed in ten percent and it was calculated the percentage change of the resulting surface density photovoltaic current.

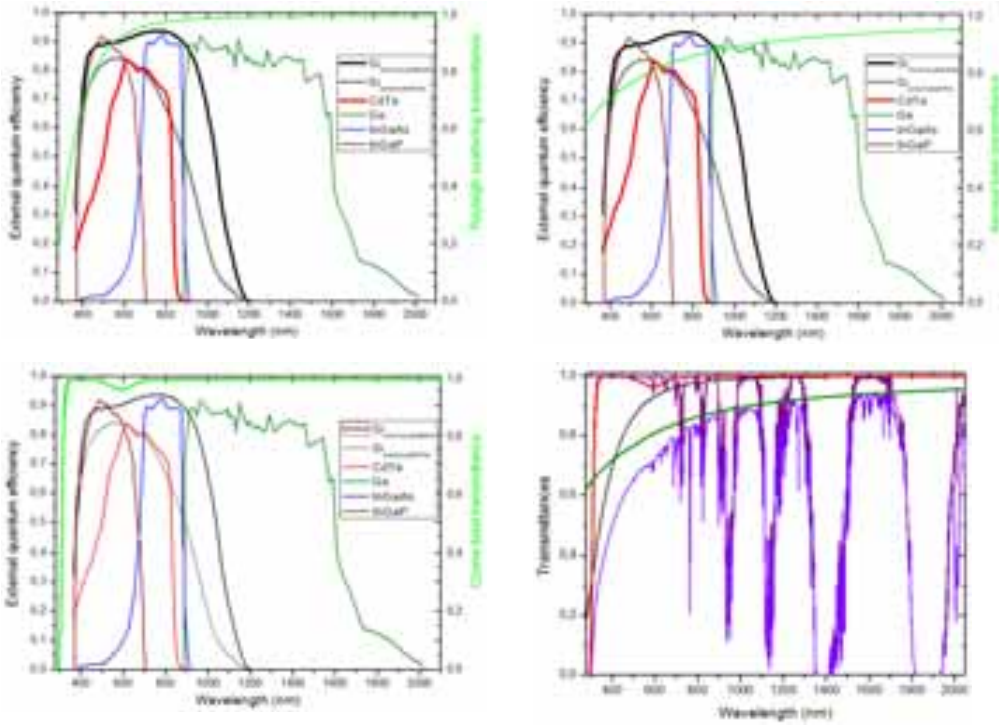

Figure 5: Transmittances and its relationship with the different external quantum efficiency of solar cells. Top left: Rayleigh scattering transmittance. Top Right: aerosol total transmittance. Bottom left: ozone total transmittance. Bottom right: All transmittance at December 28, 2011 in Rosario: ozone total (red line), Rayleigh scattering (black line), aerosol (green line), water vapor (purple line) and total (violet line) transmittances.

Table 2: Analysis of the sensitivity ($\Delta i_{FV,A}$ %) of atmospheric component variation on surface density photovoltaic current ($_{iFV,A}$) for Rosario in December 28, 2011. Top: with change of total column ozone. Middle: with change of AOD_{550nm}. Bottom: with change of precipitable water.

Parameters		$i_{FV,A}$ (mA/cm^2) for different solar cells					
		InGaP	InGaAs	Ge	mono-Si	poly-Si	CdTe
Total column ozone (DU)	265.5	17.09	13.97	18.68	38.30	29.04	21.15
	292.05	17.06	13.96	18.68	38.26	29.00	21.12
$\Delta i_{FV,A}$ %	10	0.176	0.071	0	0.104	0.138	0.142

Parameters		$i_{FV,A}$ (mA/cm^2) for different solar cells					
		InGaP	InGaAs	Ge	mono-Si	poly-Si	CdTe
AOD_{550nm}	0.2325	17.09	13.97	18.68	38.30	29.04	21.15
	0.25575	17.02	13.94	18.65	38.19	28.95	21.09
$\Delta i_{FV,A}$ %	10	0.410	0.215	0.161	0.287	0.310	0.284

Parameters	$i_{FV,A}$ (mA/cm^2) for different solar cells					
	InGaP	InGaAs	Ge	mono-Si	poly-Si	CdTe

Precipitable water (cm)	2.71	17.09	13.97	18.68	38.30	29.04	21.15
	2.98	17.09	13.97	18.68	38.30	29.04	21.15
$\Delta i_{FV,A}$ %	10	0	0	0	0	0	0

In the last case, a change of ten percentage in the precipitable water value did not produce a change in the surface density photovoltaic current.

5. 3. Conclusions and future perspectives

The main results and conclusions are:

-Spectral solar irradiance has been measured and modelled for Rosario (Argentina), Urcuquí (Ecuador) and Recife (Brazil), at different seasons permitting to have a wide wavelength range, in order to calculate photovoltaic current.

-Spectral and total surface density photovoltaic current shows a range between 10.02mA/cm^2 (for June 22, 2005, in Recife) and 38.3mA/cm^2 (for December 28, 2011, in Rosario).

-Sensibility analysis of atmospheric components of the total surface density photovoltaic current, shows that a change of ten percentage of the total column ozone and the same change in the AOD_{550nm} produces the largest decrease in the current solar cells of InGaP, in both cases, and smallest in the Ge solar cells. A change of ten percent in the precipitable water do not produce a change in a current of any solar cell.

Express – analysis of Local Current Density Distribution Over the Area of PV Cells Using Thermovision Systems

Leonid D. Saginov

Russian Research Institute for Electrification of Agriculture, Moscow (Russia)

Abstract

The current density distribution over the area of photovoltaic cell is an important characteristic for at least two reasons. The first one - the homogeneity of the current density distribution characterizes the quality of solar cell production and second - the heterogeneity of the photocurrent distribution leads to local overheating of the solar cell and consequently decrease in its lifespan. The paper describes the methodology and experimental results of current density distribution research over the area of PV cell by thermovision-thermographic method. Silicon solar cells of different design where researched. Over the area of investigated samples, the spots of local Joule overheating are observed due to higher current density in these localities. The study of these spots by Laser Beam Induced Current (LBIC) method showed the presence of leakage current through p-n junction.

Keywords: *photovoltaic cell, thermal imaging system, infrared (IR) region of spectrum, forward- and back-biased diode, local leakage current, vertical multijunction solar cells, IR thermovision picture*

1. Introduction

The total peak power of photovoltaic (PV) stations is increasing annually by more than 20%. However, this power station lifespan remains twice less than those of atomic or thermal power station. The efficiency degradation of cells (and modules) is one of the main reasons of this. It is evident, that heterogeneity of the photocurrent distribution over the area of PV cell accelerates this degradation because of additional local overheating in spots with high current density.

Production of solar cells requires rapid and effective technology and function control of PV cells. Measurement of photovoltaic characteristics at the output of the production line is an integral feature of the functioning and technology. This measurement does not reflect the details of technology and in particular the important characteristics of the process uniformity for the plate area, which is important when increasing the area of the plates. The purpose of this paper is to identify the heterogeneity parameters of photoelectric conversion on the solar cell area by thermovision - thermographic method.

The method is based on the fact that any body with the temperature above absolute zero, in accordance with Planck's law, emits a continuous spectrum of electromagnetic waves. Infrared imager, sensing infrared region of the spectrum, forms the image. As the average temperature resolution of thermal imaging currently reaches 0.1 K (Weinreich, 2009), the presence of even small overheating will be shown in the infrared image.

2. Methodology of measurements

Si-monocrystal PV cell structure (and, accordingly, the built-in potential) was usual: on one side of p-type plate a diffused p-n junction was formed, on the other - a layer of p^+ for contacts. Photoelectric effect in PV cell is characterized by the current flow, arising from the absorption of solar radiation, through the PV cell built-in potential (if the load is connected to it). It is evident from PV cell equivalent model (Fig.1), PV cell heating is determined by R_{sh} ,R_{ser} resistances distribution over the area of the cell. Shunt resistance R_{sh} is connected in parallel with diode and characterizes the leakage currents of p-n junction, which should be minimal for high efficiency PV cell, i.e. resistance R_{sh} should be maximum. Series resistance R_{ser} is determined by metal - semiconductor contact resistance, n-layer distributed resistance and metallization routings resistance. It is important that all these parameters are distributed through plate area and completely depend

doi:10.18086/swc.2015.05.04 Available at http://proceedings.ises.org

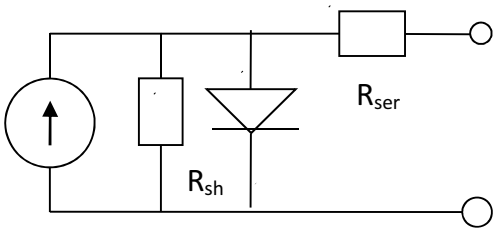

Fig.1: PV cell equivalent model

on the level and quality of photovoltaic production technology. Direct study of PV cell by thermovision system when illuminated by solar radiation or simulator is a complex task. The reason for this is the need to get rid of distracting reflections in infrared (IR) region of the spectrum that distort the IR image of the cell. In addition, silicon has high reflectance in IR region and hence low emissivity. Thus, it is necessary to ensure the flow of current through the PV cell in the absence of light illumination. This is achieved by applying voltage to the PV cell, provided that the contacts are ohmic. However, special measures should be taken to maximize the thermal contrast (Sviridov, 2002), including reflectionless arrangement. When the ratio R_{sh} / R_{ser} of order $10^2 – 10^3$ for usual PV cell and infinite generator resistance, the forward – biased (with respect to p-n junction) current will heat series resistance but reverse – biased will heat shunt resistance.

3. Research of ordinary PV cells

Si-monocrystal bifacial PV cell size (125x125) mm was selected for research. We used infrared NEC thermovision instrument TN5100 (HgCdTe time delay and integration detector, spectral range 8-12 mkm, minimum temperature sensitivity 0,05 K, field of view 20x30 °, working distance approximately 0,5 m).

Fig. 2-4 and Fig. 5-7 show IR thermovision pictures (TVP) of the mentioned above PV cell with current

Fig.2: TVP, *I*=0

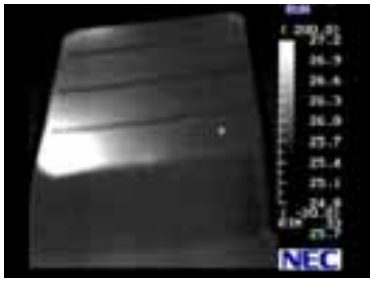

Fig.3: TVP, *I*= - 0,2A

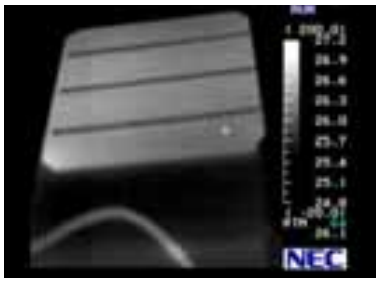

Fig.4: TVP, *I*= +1,4A

$I = 0$, forward (+) and reverse (-) directions with respect to the p-n junction. Fig. 2-4 show thermovision picture of p-n plate side. Comparison of IR pictures shows that the uniform temperature background when $I = 0$ (Fig.2) changes significantly at the current $I = - 0,2$ A (Fig.3). There are three different degrees of heating. The greatest overheating occurs in the left front corner of the plate, weaker heating in the left rear corner and the weakest - in the right rear corner. Local current density in Fig.3 is determined by the differential resistance of back-biased diode in this particular place. Obviously, the overheating of the place is due to the increase in leakage current through the R_{sh} in these areas. In this case, according to the degree of heating, the strongest current flows in the left front corner, smaller current in the left far corner and the weakest in the right rear corner of the cell image. In the case of forward biased photodiode (Fig.4, $I = +1,4$ A), the heating picture, determined by R_{ser} as mentioned above, is more uniform. Only left front spot picks out. It can be assumed that here the shunt resistance R_{sh} is comparable to series resistance R_{ser} , which is caused by shot on the end face of the p-n junction. In addition, in the Fig.4 three dark metallization routings are clearly visible, the emission of which is due to the metallization significantly lower than that of silicon.

The p^+ side TVP of the same cell (sample inverted to the right) is represented by Fig.5-7. The same three

Fig.5: TVP, *I*=0

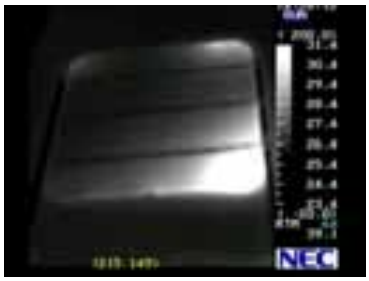

Fig.6: TVP, *I*= - 0,4A

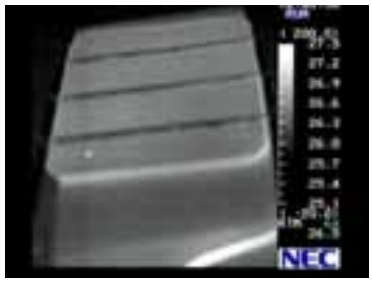

Fig.7: TVP, *I*= +1,8°

leakage areas through shunt resistance are observed with back bias (Fig.6), but to obtain the same temperature contrast picture, as in Figure 2, it is necessary to increase the current by two times (I = - 0,4 A). It confirms the fact that the source of the heating is on the lower (i.e. p-n) side of the cell. p^+ side of the cell, as would be expected, is heated uniformly with direct current (Fig.7), however, to get image contrast as in Fig. 4, the current must be increased (I = +1,8 A). In this case lower (p-n) side of the cell is warmer, as indicated by a significant reflection of the infrared light from the table in Fig.7. Note that the metallization routing on p^+ side is less clear than on p-n side (Fig.4); which may be caused by lower quality of contacts (e.g. non-ohmic) on the p^+ side of the cell.

These results confirm the use of thermovision system for PV cell technology analysis. Indeed, if in the technology process non-uniformity takes place in any area of Si-plate, heterogeneity arises (in p-n junction or tunneling in the metal-semiconductor contact due to, for example, pollution), the local current density at this point will change and it will lead to changes in temperature (Joule heat). Resulting local temperature inhomogeneities are fixed by thermovision system.

4. Comparative study of PV cell by thermovision system and LBIC

IR thermovision and LBIC methods are used for comparative study of 100 mm diameter cell with low efficiency of PV conversion (some less than 12%). Fig.8 shows TVP of this cell. The increase of temperature by 5 degrees corresponds to the transition from blue to raspberry color. The highest temperature is white color.

Fig.8: TVP 100mm cell

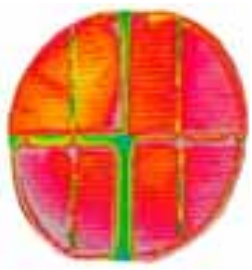

Fig.9: TVP catted cell

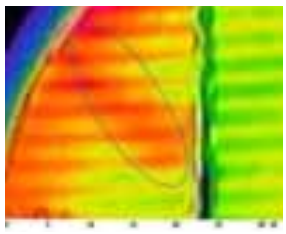

Fig. 10: TVP of upper left quarter

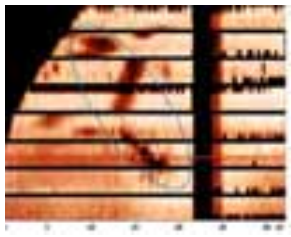

Fig.11: LBIC scan of upper left quarter

The characteristic features of the picture are: temperature increase is observed around the perimeter of the specimen, i.e. junction leakage currents increase from the center to the edges of the plate; there are local areas of high currents, for example, area 1; evident temperature non-uniformity of metallization routings.

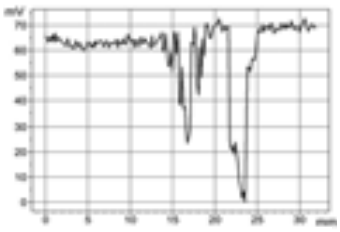

Fig.12: LBIC current along Fig. 9 red line

This PV cell was cut into four pieces for LBIC investigation. The corresponding TVPs are shown in Fig.9. The comparison of images in Fig.8 and Fig.9 shows that all the features of thermovision images remain. Upper left quarter of the cell with local inhomogeneity marked number 1 (Fig.9) was chosen for LBIC investigation using NT-MDT instrument «Spectrum». The field of scanning is ~ 20x35 mm. Fig.10 and Fig.11 show upper left quarter of cell and LBIC scan image of this area. In Fig.11 LBIC current reduction under laser illumination corresponds to the darkening of the picture. It is an evident coincidence of temperature increasing area (Fig.10) and low LBIC current (Fig.11), due to an increase in leakage current in

the last case. Fig.12 shows LBIC current along red line on Fig.11. There is correspondence to Fig.11: the right line (21-25mm) is in keeping with highway and left (15-20 mm) conforms to the darkening (leakage current increasing).

5. Thermovision pictures of Vertical Multijunction Solar Cell

TVP of silicon Vertical Multijunction Solar Cells (VMSC) were also researched in IR region 3-5 mkm. VMSC are made by connection (soldering) in series of ordinary PV cells with continuous metallization on p- and n-sides of the Si-plate and consequent cutting of the pile perpendicular to the p-n junction plane (Strebkov, 2010). When illuminated, the light front is perpendicular to the plane of p-n junction but is not parallel as for ordinary planar PV cell. The main advantage of VMSC (production by usual planar Si-processing) is high voltage with density more than 15 V/cm.

In our experiments we research VMSC with 25 microelements in series on facial side of the cell. Methodology of image getting is subtraction of the picture without bias out of the picture with forward or reverse bias. Fig.13 shows TVP of VMSC with reverse bias and Fig.14 - TVP of VMSC with forward bias. Comparison

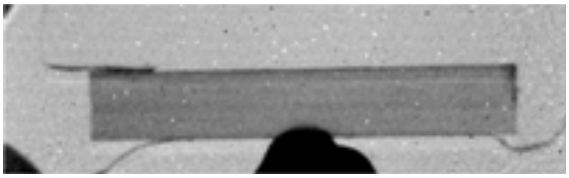

Fig.13: TVP of VMSC with reverse bias, V= - 30V, I= 10mA

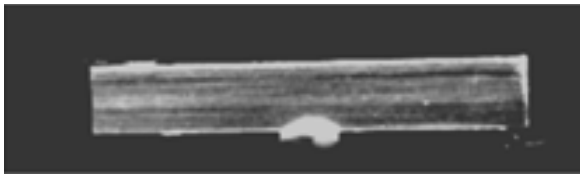

Fig.14: TVP of VMSC with forward bias, V= + 10V, I= 100mA

of these pictures leads to the conclusion about the inversion of temperature pattern. The reasons of this inversion require more detailed research. However, if we assume that the composition of the sample consists of microelements with different indices of ideality in the exponential diode characteristics, the ratio of the differential resistance will be inverted with forward and reverse bias. Accordingly, temperature pattern will also be inverted.

6. Conclusions

1. Thermovision-thermographic method is useful in inspection of PV cells quality and its production technology. Also, the functioning of solar power station in field conditions may be controlled to identify the faulty elements in the modules, substandard wiring and terminal connections, etc.

2. In the above procedure tests a lot of attention should be paid to the exclusion of side illumination, reflections, etc.

New recycling process was attempted to recover copper substrate and to remove coating layer consisting of tin (Sn) and lead (Pb) of photovoltaic ribbon in spent solar module by means of oxidation using water vapor generated by waste heat. The oxidation behavior of the photovoltaic ribbon was studied under two different conditions of dry and moist atmosphere. The rate of oxidation was compared at 500°C in given conditions and the oxidized coating layer consisting of lead of 68.99wt% and tin of 31.21wt% was taken off from the substrate at room temperature. The chemical composition of copper ribbon after oxidation was analyzed using ICP-MS (Inductively Coupled Plasma Mass Spectrometry) and the purity of copper obtained was found to be about 99.5wt%. Further process using zone-melting furnace was consequently carried out fabricate high-purity copper and 4N grade of copper (≥ 99.99%) was finally obtained. The component of coating layer was safely stabilized as oxide forms of PbO and SnO.

1. Introduction

The increased energy consumption of recent industrial advancements has further increased the use of fossil energy, resulting in serious environmental problems and a growing concern over energy depletion. A great deal of research has been devoted to the development of new and renewable energy sources to solve these problems. In particular, the solar energy industry has prompted rapid growth of photovoltaic energy research.[1)] Unlike fossil fuels, photovoltaic cells are ecofriendly, powered by a renewable energy source, and have a lifetime of 15 years or more; as a result of these traits, their development is rapidly growing on the national and global scales.[2)]

With the growth of the solar energy industry, the volume of spent photovoltaic modules has continued to increase, with its cumulative volume estimated to reach about 130,000tons by the year of 2030. However, over 90% of the end-of-lifetime photovoltaic modules can be recycled, despite currently being buried in general landfills or completely neglected.[3)4)] For this reason, various studies have been carried out on the recovery and recycling of precious resources from spent photovoltaic modules, but in particular there have been very few attempts at recovering the copper in the photovoltaic modules.[5)]

Existing copper recovery methods involve oxidizing the copper ribbon electrode at high temperatures of 800°C or more in order to separate the oxidized coating layer from the base material. However, in this study a water oxidation method at a lower temperature of 500°C is used for oxidation, and a ball milling process is subsequently carried out in order to separate the oxidized coating layer from the base material. The recovered copper base is analyzed by ICP-MS (inductively coupled plasma mass spectrometry), and the oxidized coating layer is analyzed using XRF (X-ray fluorescence) and XRD (X-ray diffraction).

2. Methods and Materials

2.1 Experimental Setup

Figure 1 shows the experimental setup used in this study, which includes an electric furnace, a thermocouple and a heater, as well as a tube that connects a flask containing distilled water and the electric furnace for the injection of H_2O. To prevent the water vapor from condensing in the tube, the tube was wound with heating tape.

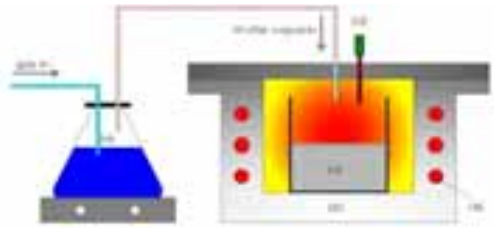

Fig. 1 Schematic of H_2O oxidation process (a: distilled water, b: furnace, c: photovoltaic ribbon, d: thermocouple, e: heater)

Figure 2 is an image of the ball milling equipment, which was used to oxidize the copper ribbon during the H_2O oxidation process and to separate the copper base from the oxidized coating layer, as well as an image of the milling balls used in the test.

Fig. 2 Ball milling equipment and used milling balls

Three 30mm diameter balls and 15 0.7mm diameter balls were used in the test.

Table 1. Chemical composition of photovoltaic ribbon analyzed by ICP-MS

Element	Weight, %
Cu	87.752
Pb	5.247
Sn	6.150
Nb	0.063
Ag	0.046

2.2 Test Materials

The chemical composition of the photovoltaic ribbon of KOSBON Co. used as the test material is given in Table 1. Based on the ICP-MS results, the ribbon contained 87.752% copper, 5.427% lead, 6.150% tin and trace amounts of niobium and silver.

3. Results

The spent photovoltaic module was heat treated under air condition at 500°C for 2h to recover the copper ribbon electrode from the module. The coating layer was then oxidized to separate and recover the copper base and the scale under the following reactions.

$2Cu + O_2(g) \rightarrow 2CuO$ (eq. 1)
$2Pb + O_2(g) \rightarrow 2PbO$ (eq. 2)
$2Sn + O_2(g) \rightarrow 2SnO$ (eq. 3)

Table 2 shows the thermodynamic properties for the oxidation reactions of copper, lead and tin, the main components of the copper ribbon electrode, as determined by HSC Chemistry[5.1].
Copper, lead and tin underwent forward reactions because their ΔG values were less than 0, as shown in the Table 2, confirming activated oxidation reactions.

The chemical equations for the reactions of copper, lead and tin with oxygen and H_2O are shown below, and the thermodynamic properties of these reactions (as determined using HSC chemistry) are shown in Table 3.

$2Cu + 2O_2(g) + 4H_2O(g) \rightarrow 2Cu(OH)_2 + O_2(g) + 2H_2O(g)$ (eq. 4)

$2Pb + 2O_2(g) + 4H_2O(g) \rightarrow 2Pb(OH)_2 + O_2(g) + 2H_2O(g)$ (eq. 5)

$2Sn + 2O_2(g) + 4H_2O(g) \rightarrow 2Sn(OH)_2 + O_2(g) + 2H_2O(g)$ (eq. 6)

The copper, lead and tin that reacted with oxygen and H_2O also showed forward reactions because their ΔG values were less than 0, as shown in Table 3, confirming activated oxidation reactions. Based on these theoretical values, the oxidation test temperature was set to 500°C.

First, to oxidize the coating layer through the use of water vapor, distilled water is placed in the flask connected to the furnace and boiled. In order to facilitate the injection of water vapor into the furnace, argon gas was injected into the flask at 100 cc/min After inserting the heat-treated copper ribbon into a furnace for 2h, the ribbon was heat treated at 500°C in order to facilitate the oxidation test. The original copper ribbon sample used in the test weighed 15g, and the H_2O oxidation tests were carried out at time intervals of 1, 3, 5 and 10 hrs. The oxidized copper was analyzed by SEM (scanning electron microscopy) to analyze the oxidized layer. Figure 3 shows images of the oxidized copper ribbons for each reaction time.

Afterwards, the copper base was recovered by ball milling at 90rpm for 1h and was analyzed by ICP-MS, and the oxidized coating layer was analyzed by XRF and XRD.

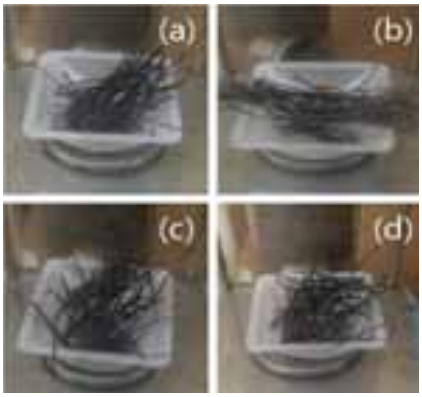

Fig. 3 H_2O oxidized photovoltaic ribbons(a: 1 h; b: 3 h, c: 5 h, d: 10 h)

4. Discussion

Rather than using the existing high temperature oxidation approach under atmospheric conditions at 800°C to recover copper from the copper ribbon electrode in the spent photovoltaic module, an H_2O oxidation approach was carried out at 500 °C for 1 h, 3h, 5h, and 10h. The weight of the oxidized copper ribbon increased by 0.32g after 1h H_2O oxidation, by 0.53g after 3h oxidation, by 0.98g after 5h oxidation, and by 1.20g after 10h oxidation. The amounts of distilled water consumed were 551.17g, 891.52g, 1673.24g, and 3172.48g, respectively. To compare the weight change between the air and H_2O oxidation tests under atmospheric conditions, an air oxidation test was carried out under atmospheric conditions, similar to the H_2O oxidation test, and the copper ribbon was heat treated for 1h, 3h, 5h, and 10h at 500 °C. The weight of the copper ribbon increased by 0.054g after 1h heat treatment, by 0.16g after 3h heat treatment, by 0.36g after 5h heat treatment, and by 0.38g after 10h heat treatment. Figure 4 shows the comparison of weight increases between the H_2O atmosphere oxidation and air atmosphere oxidation methods. As the graph shows, the weight increases from the H_2O method were much greater than those of the air atmosphere method, with the oxidized amount sharply increasing after 3h.

Figure 5 shows the SEM results of the coating layer of the H_2O oxidized copper ribbon. The left-most photo shows the coating layer of the copper ribbon before the oxidation test, where the lead and tin coating layers have thicknesses of 20μm and the thickness of the coating layer of the copper ribbon is 50μm after 1h H_2O oxidation, 160μm after 3h H_2O oxidation, 155 μm after 5h H_2O oxidation, and 146μm after 10h H_2O oxidation. These results confirm rapid oxidation after 1h of oxidation, which greatly increased the thickness of the oxidized coating layer. After 5h, the copper base and the oxidized coating layer were separated. The oxidized copper ribbon electrode was separated into the copper base and oxidized coating layer by ball milling.

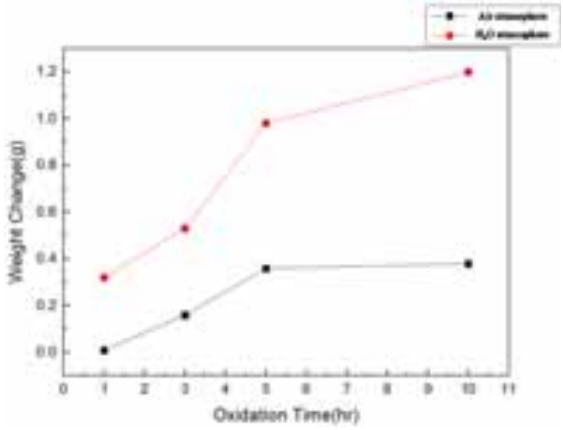

Fig. 4 Weight increases of air atmosphere and H_2O atmosphere oxidation conditions.

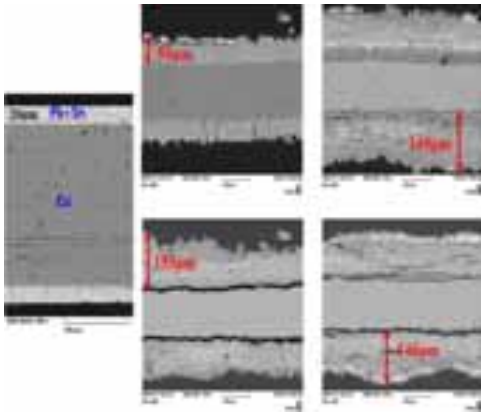

Fig. 5 Coated layer of oxidized photovoltaic ribbon sample analyzed by SEM

Table 4. Weight increase after H_2O oxidation and recovered oxide scale weight after ball milling process

Oxidation time, hr	Weight increase	Recovered oxide scale weight
1	0.32 g	0.35 g
3	0.53 g	1.53 g
5	0.98 g	5.94 g
10	1.20 g	6.54 g

Table 5. The recovered copper ribbon analyzed by ICP-MS

500 °C – 5 hours		800 °C - 30 mins	
Element	weight %	Element	weight %

Cu	98.106	Cu	99.554
Pb	0.992	Pb	0.027
Sn	0.716	Sn	0.297
Nb	0.065	Nb	0.071
Ag	0.003	Ag	0.009

Figure 6 shows the copper base and oxidized coating layer separated by ball milling, and Table 4 shows the weight increase after H_2O oxidation and the weight of the oxidized scale recovered by the ball milling process for each oxidation time. As shown in the table, 0.35g, 1.53g, 5.94g, 6.54g of

Fig. 6 The recovered copper ribbon and the oxide scale (a: 1 h; b: 3 h, c: 5 h, d: 10 h)

oxide scale were recovered at oxidation times of 1h, 3h, 5h, and 10h, respectively, and the amount of recovered oxide scale greatly increased after 5 h of oxidation time, indicating oxidation of most of the copper coating layer in the copper ribbon electrode at this point, allowing for good separation of the copper base and the copper coating layer. ICP-MS analysis of the recovered copper base showed that 98.106% pure copper could be obtained, and this result is compared to that of the 800 °C oxidized copper base in Table 5. The recovered oxide scale was analyzed by XRF and XRD and the results are shown in Table 6 and Fig. 7.

Table. 6 XRF data from the recovered oxide scale

500 °C – 5 h		**500 °C – 10 h**

Si	0.47	Si	0.21
Al	0.16	Al	0.08

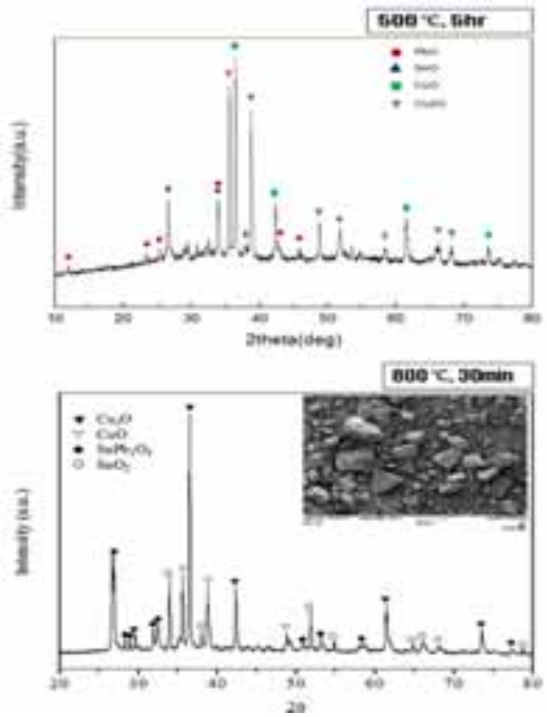

Fig. 7 The recovered oxide scale analyzed by XRD

5. Conclusions

Rather than using the existing high temperature oxidation method at 800°C in atmospheric conditions to oxidize copper ribbon electrodes for the separation of the base material from the oxide coating layer, this study used a H_2O oxidation method at 500°C, and the oxidized copper ribbon electrode was ball-milled to separate the base material from the oxide coating layer. The following results were obtained from the separation test:

(1) Based on the SEM results of the copper ribbon oxidized using the H_2O method at 500°C, the thickness of the coating layer of the copper ribbon was 50 μm after 1 h H_2O oxidation, 160 μm after 3h H_2O oxidation, 155μm after 5h H_2O oxidation, and 146 μm after 10h H_2O oxidation, with the oxidation proceeding more rapidly after 1h to greatly increase the thickness of the oxide coating layer, resulting in the separation of the copper base from the oxide coating layer after 5 h.

(2) Based on comparisons of the weight increase between H_2O oxidation and air atmosphere

oxidation at 500°C, the weight increase of the H_2O oxidized copper ribbon was about 3 times that of the copper ribbon oxidized by air atmosphere oxidation, confirming that more efficient oxidation is achieved with the water vapor method.

(3) After ball-milling to separate the copper base from the oxide coating layer, the weight of the recovered oxide scale was measured. 0.35g, 1.53 g, 5.94g and 6.5g of oxide scale could be recovered after oxidation times of 1h, 3h, 5h, and 10h, respectively.

(4) The ICP-MS analysis results of the recovered copper base after ball-milling showed that the purity of the recovered copper base was 98.106%, which was similar to that of the recovered copper base oxidized at 800°C.

(5) XRF and XRD analysis revealed that the recovered oxide scale contained 68.21% copper, 17.72% tin and 10.01% lead, all existing as oxides.

Abstract

We examine the role of structural and chemical properties of Hydrogenated polymorphous Silicon, *Pm-Si:H,* thin films on the optoelectronic characteristics and the level of stability under prolonged white light exposure at 100 mw/cm^2 (AM1.5 condition), for applications in solar cells. These thin films were grown by Plasma Enhance Chemical Vapor Deposition (PECVD) using diclhorolsilane (SiH_2Cl_2), instead of silane (SiH_4) as precursor gas, at different hydrogen dilutions (D_H). The nano-structural properties were confirmed by Raman measurements. The films compositions were determined by XPS measurements. From FTIR analysis we notice bonding configurations associated to photo-stability. Light soaking experiments during 250h show important behaviors on the electronic transport properties measurements to different levels of incorporated oxygen.

Keywords: Polymorphous Silicon, Solar Cell, Photoconductivity.

1. Introduction.

During the last decades extensive efforts have been made to overcome the light-induced degradation in amorphous silicon films. Currently huge interest has been drawn towards the use of nanocrystalline silicon as the intrinsic layer of a solar cell. At the same time, numerous works have been carried out to clarify the growth mechanism of amorphous, microcrystalline and polycrystalline silicon (a-Si:H, mc-Si:H and poly-Si) thin films [1]. Plasma-enhanced chemical vapor deposition (PECVD) using highly diluted silane (as precursor gas) in hydrogen mixtures allows the production of a wide range of silicon thin films with varying degrees of disorder [2]–[4]. The optimization of plasma conditions used for the growth of amorphous and microcrystalline silicon thin films has led to obtain different silicon crystalline phases (nanocrystals, microcrystals, etc.) embedded in an hydrogenated amorphous silicon, material called Hydrogenated polymorphous silicon (pm-Si:H) [4], [5]. Due to its specific nanostructure pm-Si:H is a suitable candidate for application in silicon-based thin film solar cells because, despite being heterogeneous, it exhibits improved electronic transport and stability properties after light-soaking compared to those of a-Si:H [4]. Normally, pm-Si films have been deposited by PECVD using highly diluted silane in hydrogen mixtures. However, the use of high hydrogen dilutions can contribute to an excessive incorporation of weak Si–H bonds into the pm-Si:H, obtaining in light-induced degradation of efficiency due to the so called Staebler–Wronski effect, resulting unsuitable for thin-film photovoltaic applications [6]. Alternative passivating atoms with higher mass and lower diffusion coefficient than hydrogen, such as chlorine, are being investigated. Consequently, Chlorinated silanes, i.e., SiH_2Cl_2, $SiHCl_3$ and $SiCl_4$ have been used aiming at the improvement of material properties [1]. The use of chlorine in PECVD processes

doi:10.18086/swc.2015.05.06 Available at http://proceedings.ises.org

has shows, i) increases crystallization process, ii) pos thermal annealing are no necessaries and iii) minor incorporation of weak Si-H bonds [4]. Recently, using dichlorosilane (SiH_2Cl_2) we have obtained different crystalline silicon formations (nc-Si to μc-Si) inside of the amorphous matrix, depending on the deposition conditions [3], [7], [8]. However, more extensive studies about the effects of chlorine chemistry in plasma systems are needed. In this work we had examined the role of structural and chemical properties of material to determine the optoelectronic characteristics of the material and, therefore, the level of stability under prolonged light exposure. We analyze the correlations between photoconductivity measurements and chemical composition, oxidation level, crystalline volume fractions, mean grain size and optical band gap.

2. Experimental.

Pm-Si thin films were grown in a conventional PECVD system with parallel plates of 150 cm^2 and 1.5 cm apart, activated by a RF signal of 13.56 MHz. Depositions were performed at pressures of 250 and 500 mTorr and hydrogen dilutions ratio, $R_H = H_2/(SiH_2Cl_2+H_2)$, of 83.3, 90.9, 93.8 and 95.2, keeping the other deposition parameters constant. Growth conditions are summarized in Table 1. Nano-structural analysis was performed using a Raman equipment model T64000 with Horiba Jobin-Yvon triple monochromator. The excitation source was an Ar+ Lexcel laser of 514.5 nm. All measurements were performed at room temperature in air. The samples were irradiated at a power of 20 mW in a spot size around 1 mm^2 to prevent laser-induced crystallization. The measuring range was between 400 and 600 cm^{-1}, the integration time of measurements was 1 min and the Raman signal was acquired by a cooled CCD detector. The atomic compositions were obtained by X- ray Photoelectron Spectroscopy (XPS) analysis in a VG Microtech Multilab ESCA 2000 system, equipped with a hemispherical-multichannel detector CLAM4-MDC, in which we determined the presence of Cl and O in the samples. Fourier transform infrared (FTIR) spectra of the films were recorded in absorbance mode using a Nicolet-210 FTIR spectrometer in the range 400–4000 cm^{-1} on thin-film samples deposited on polished crystalline silicon substrates. Optical properties were investigated by means of optical band gap, which was deduced from the absorption spectrum between 1 and 3.0 eV by a JASCO V630 spectrometer UV-VIS, using the Tauc Model, where the films thicknesses were obtained by typical profilometry. Variation of photoconductivity of all these films was investigated under a light intensity of 100mW/cm^2 for 250h of light soaking by measuring the current and voltage. The light soaking treatment was realized in homemade equipment under AM 1.5 spectrum and the temperature was controlled at 25ºC by heat dissipation.

3. Results and discussion.

3.1. STRUCTURAL PROPERTIES BY RAMAN.

Each spectrum obtained by Raman measurements was deconvoluted at the best fit corresponding to amorphous, nanocrystalline and microcrystalline phases [4], [9]. The peaks of the amorphous and microcrystalline phases are fixed at 480 cm^{-1} and 520 cm^{-1}, respectively [3], [10]–[12]. The third peak, associated to the nanocrystalline phase, is located at the best fit between 500 and 519 cm^{-1} [4], [12]. Each spectrum was deconvoluted following the next criteria: two Lorentzian curves, corresponding to nano and microcrystalline contributions, and a Gaussian curve corresponding to the amorphous phase [4]. We obtained the crystalline volume fraction, X_C, using relation 1 [4], [11], [13]. The area of the curves are designated as I_A, I_N, and I_C, for the peaks of amorphous, nanocrystalline and microcrystalline phases, respectively.

$$X_C = \frac{I_N + I_C}{I_N + I_C + I_A} \qquad \text{(eq.1)}$$

while the mean grain size, D_R, is calculated using relation 2 which is based on the quantum confinement model where $\Delta\nu$ is the frequency peak shift of the nanocrystalline phase with respect to 520 cm^{-1} [4], [11]. At the same table 1, values of both properties are also presented.

$$D_R = 2\pi\sqrt{2.24/\Delta\nu} \qquad \text{(eq.2)}$$

Table. 1 shows results of both X_C and D_R, as a function of dilution of hydrogen for both pressures. To detect the behavior of these parameters with better accuracy, the uncertainty of each data using standard deviation of three different deconvoluciones made to each spectrum was obtained.

Table 1. Growth conditions of *pm-Si:H* thin films deposited by PECVD, structural and optoelectronic Results as a function of dilution of hydrogen for both pressures.

RF Power = 150 W, flows: Ar = 50 sccm and SiH_2Cl_2 = 5 sccm. $T_{sustrato}$ = 200°C. Time of Growth 30 min			Structural Parameters		Effective Optical Band Gap	Photoconductivity % Degradation or improvement
Dilution D_H [%]	Thickness [nm]	Growth rate (nm/min)	X_C [%]	D_R [nm]	[eV]	$\left(\frac{\sigma_{p_1} - \sigma_{p_2}}{\sigma_{p_1}}\right)$
Pressure of 250 mTorr						
83.3	268	9.1	70 ± 18	2.7 ± 0.3	1.75 ± 0.09	**34%**
90.9	291	10.8	83 ± 14	2.4 ± 0.2	1.66 ± 0.09	**34%**
93.8	235	10.1	69 ± 7	3.2 ± 0.5	1.36 ± 0.03	**-15%**
95.2	284	11.8	94 ± 15	4.2 ± 0.4	1.18 ± 0.09	**-68%**
Pressure of 500 mTorr						
83.3	214	7.8	92 ± 12	2.8 ± 0.3	1.75 ± 0.04	**65%**
90.9	223	8.2	65 ± 16	3.1 ± 0.3	2.12 ± 0.03	**-92%**
93.8	245	9.4	95 ± 19	3.3 ± 0.2	1.15 ± 0.06	**-191%**
95.2	111	10.4	94 ± 16	3.4 ± 0.4	1.57 ± 0.05	**-16%**

Table 1 shows that for all samples the average of the nanocrystals size not greater than 5 nm in diameter, from which it follows that the optical properties of the films must be influenced by quantum confinement, which in turn will influenced by the density of these nanocrystals and their distribution within the matrix of amorphous silicon [8].

As seen from the table, for both pressures is observed that D_R tends to increase with hydrogen dilution. In the system SiH_2Cl_2 when SiH_xCl_y species (x + y <3) hit the surface of growth, both the hydrogen and chlorine are preferentially extracted as HCl. Exothermic reaction of atomic hydrogen with chlorine emit a considerable amount of energy sufficient to promote the local crystallization [3]. So by increasing the hydrogen dilution, more nanocrystals are formed in the films of pm-Si:H with increasing size. While the increased pressure the mean free path of the gas species decreases, decreasing the extraction of hydrogen and chlorine, and exothermic reactions thereby increasing the local crystallization of the material.

3.2. CHEMICAL PROPERTIES.

3.2.1. X-ray photoelectron spectroscopy, XPS.

Figure 1 shows the chemical composition profiles of all samples to different depths probed by sputtering the surface with argon ions for different erosion times in vacuum. The atomic percent corresponding to Cl, O and Si are reported, because hydrogen is not detectable by this technique.

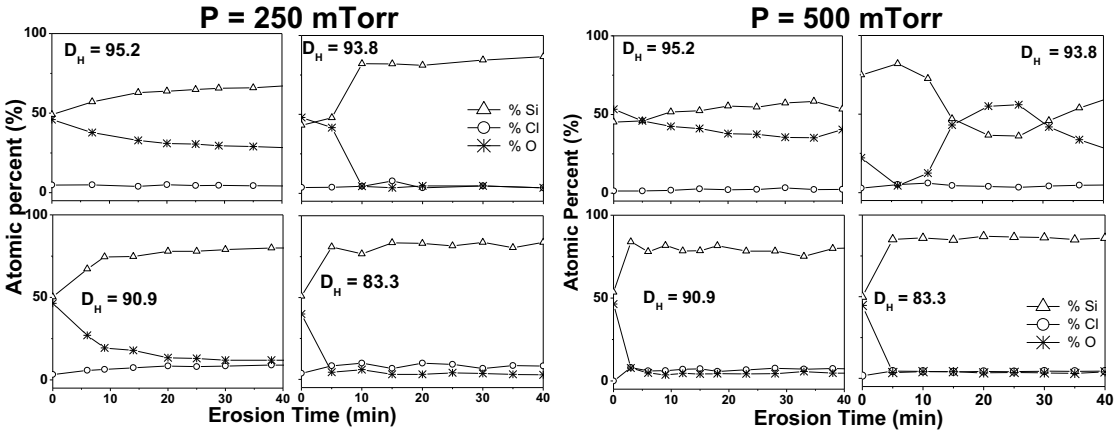

Fig. 1. Composition profiles of pm-Si:H thin films including atomic percents from Cl 2p, O 1s and Si 2p peaks for different argon ion erosion times.

Fig 1. Shows how the films are mainly composed by silicon (triangles). However, important concentrations of oxygen (asterisk) are detected in some samples. The amount of chlorine (circles) is always lower than 10%. It is possible to observe that in some cases Si and O concentrations changed with erosion time. In the film surface oxygen concentrations around 50% are detected in all samples. This value decreases to less than 15% with erosion time, except in some samples with elevated D_H where oxygen concentration remains above 25% for all erosion times. The appearance of O in some samples is the result of porous and less dense in the grain boundary regions, which facilitates absorption of oxygen on the surface of micro-voids, when the films are in ambient. Some studies have been noted that by introducing small amounts of oxygen introduced to the μc-network further decreased the optical absorption and conductivity [14]; these effects are discussed below.

These results suggest that the films deposited at D_H of 83.3 and 90.9 have qualitatively better measure of the density and compact structure compare to films deposited at D_H of 93.8 and 95.2, for both pressure. The high D_H values of our films can attributed to a more porous structure, possibly caused by the nucleation of nano-sized crystallites in the amorphous network.

3.2.2. Fourier transform infrared spectroscopy, FTIR.

Figure 2 shows the spectra of FTIR transmission curves in the wave number range 550–800 and 1900-2400 cm^{-1} for the most representative samples deposited at different D_H for pressures of 250 mTorr.

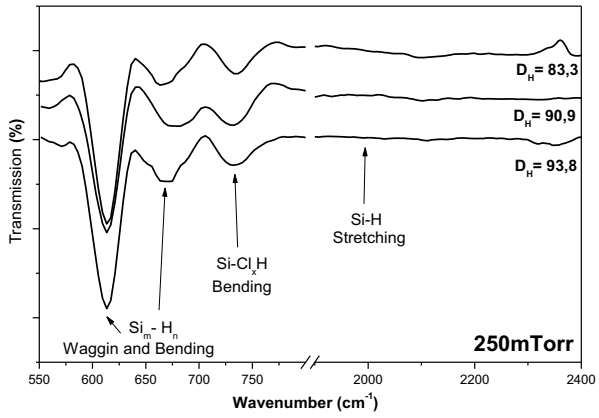

Fig 2. Infrared spectra of pm-Si:H films deposited at 250 mTorr showing the absorbance peaks, for three different hydrogen dilutions.

Fig. 2 exhibit that the Si-H stretching mode around 1900-2100 cm^{-1} cannot be distinguished in our samples.

This band is generally associated to silicon hydrides incorporated into the amorphous matrix which are related with weak hydrogen bonds that are prone to generate light induced degradation of the material [4], [11], [15]. Instead, the Si_mH_n wagging mode around 620-640 cm^{-1} and $SiCl_xH$ bending mode at 744–775 cm^{-1} is present in all cases [11] [16]. The Si_mH_n wagging mode has been correlated mainly with surface passivation of silicon nanocrystals in these type of pm-Si films [4], [10], [14]. Whereas $SiCl_xH$ bending mode is associated to the small amount of incorporated chlorine in the films (less than 10 at.%, agree with the XPS analysis) [16], [17]. Based in results of XPS the FTIR transmission spectra should show signature of the Si–O peak near 1000–1100 cm^{-1}, which also cant be distinguished.

From the perspective of application of these films as photovoltaic materials, having a high fraction crystalline in as grown films with low hydrides content in the amorphous matrix, is adequate for their utilization in silicon thin film solar cells.

3.3. OPTOELECTRONIC CHARACTERISTICS.

3.3.1. *Optical Band gap, E_g^{op} .*

Optical properties of our thin films were investigated from UV–VIS spectroscopy. Fig. 3 shows the variation of the effective optical band gap, E_g^{op} as a function of the structural properties through of D_R and X_C, for samples grown at 250 and 500 mTorr of pressure, respectively. The optical band gap energy E_g^{op} was obtained by the Tauc plot $(\alpha h\upsilon)^{1/2}$ vs. $(h\upsilon - E_g^{op})$ where α is the absorbance, ν is the frequency and h is the Planck constant. Tauc's plot is an effective method to determine the energy bandgap in amorphous thin film materials [18] [19].

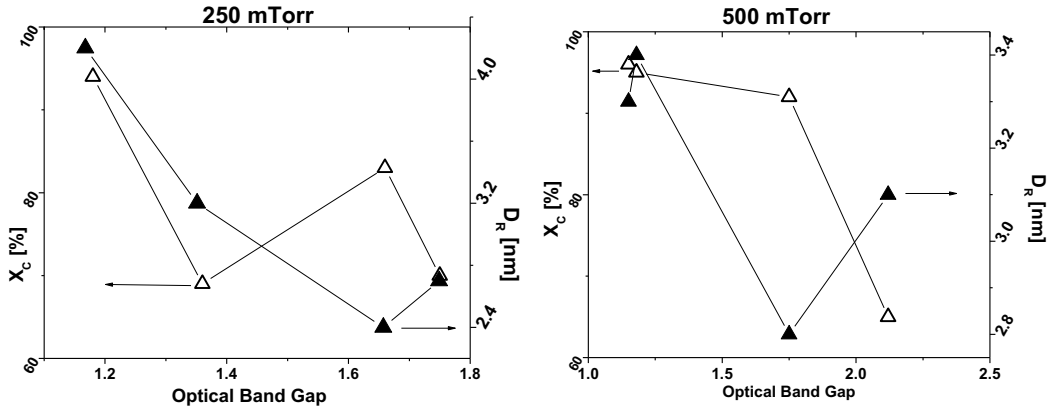

Fig. 3. crystalline volume fraction, X_C,(open triangle) and mean grain size, D_R,(solid triangle) as a function of Optical band Gap, E_g^{op}, to pressures of 250 and 500 mTorr.

We can see in fig. 3 is how E_g^{op} is modified by the structural parameters X_C and D_R and we found a tunable band gap in function of D_R. As seen from the figure, the E_g^{op} of films increases from 1.18 to 1.75 eV when D_R is decreased from 4.2 to 2.7 nm for samples grown at 250 mTorr, while for films 500mTorr it is difficult to comment this behavior due to the estimated values of D_R are almost a constant ($\Delta D_R <$ 1nm, see Table 1). However, it is too possible to note that E_g^{op} tends to decrease as X_C increase for both pressures. Accordingly, in the case of a mixed phase of crystalline and amorphous, i.e. nanocrystalline phase, the band gap should lie between amorphous and crystalline silicon. The typical value of the band gap of hydrogenated amorphous silicon (a-Si:H) is about 1.6 eV [19]. The higher band gap in pm-Si:H thin films in the present case may be due to the quantum size effect [8], [14], [19], [20]. So the behavior in E_g^{op} support the influence of quantum confinement as $E_g^{op} \approx E_g + \frac{\hbar^2 \pi^2}{2\mu D_R^{\,2}}$ where E_g^{op} is the bulk material gap and μ It is the reduced mass of electron-hole pair [8], [20]. Then E_g^{op} tends to decrease with the increase in D_R of embedded nanoclusters and randomly

distributed in the amorphous network of pm-Si:H thin films. One may argue that the increased band gap of the films is due to the presence of oxygen in these films. However the FTIR transmission of the films, taken immediately after the deposition, do not show the presence of Si–O bonds (near 1000–1100 cm^{-1}), though the feature appeared in some of the films when these are stored for a couple of week at room temperature.

3.3.1. *Photoconductivity, σ_p.*

Photoconductivity measurement of the samples, using white light illumination of 100mW/cm^2, during continuous light 250h were performed. We observe important behaviors in Photoconductivity for samples with high and low D_H and Pressure, as can be seen in fig 4. The results and D_R and X_C values obtained by Raman are mentioned in Fig. 4 and also in Tables 1.

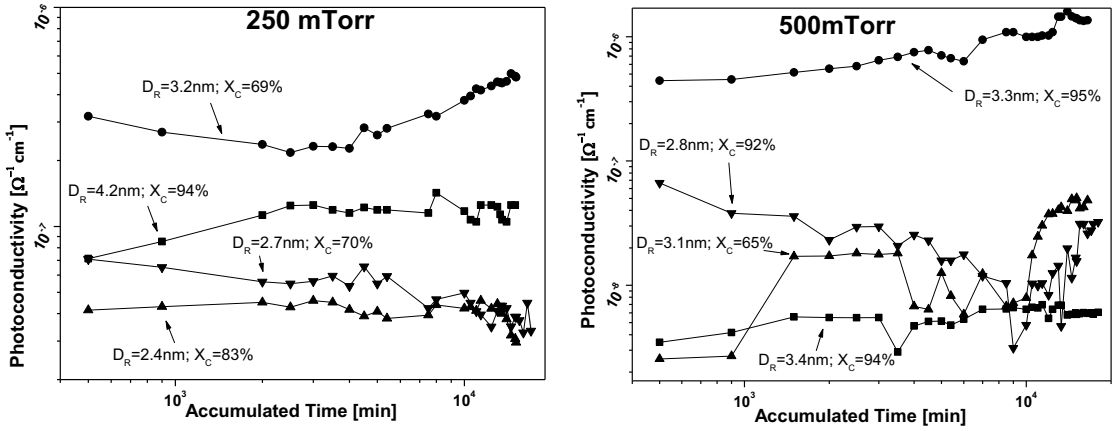

Fig. 4. Photoconductivity versus illumination time for pm-Si:H thin films

It is observed from Fig. 4 can not be distinguished stability in photoconductivity, instead we can see tendency to degrade over the time of light soaking in most films. We calculated different degradation rates of σ_p which are shown in Table 1 as $(\sigma_{pi} - \sigma_{pf})/\sigma_{pi}$, where σ_{pi} and σ_{pf} are inicial and final photoconductivity, respectively. If these values of degradation are negative then we call them improvement, so we could see improvement in the films whit high D_R and D_H for both pressures. This behavior could be due to improved pasivation process; sinse on the one hand, is closely related to the fact that the Si-O bond is stronger than the Si-Si bond and the Si-H bond. And the other, transport can be influenced by change in mobility due to the space charge between the crystalline and amorphous interfaces, by the incorporation of oxygen as a terminal bond.

4. Conclusion.

We have shown that optoelectronics characteristics of pm-Si:H thin films can be modulated by structural and chemical properties which depend of grown conditions is PECVD system using diclhorolsilane. The chlorine chemistry introduced by the silicon precursor favors the formation of nanocrystalline inclusions. Raman measurements confirm that our films are nanocrystalline, with crystal average size on the range 2–3.5 nm. We found by XPS measurements, films deposited with high D_H present a considerable amount of oxidation evidence. Since on the other hand, From Fourier transform infrared spectroscopy analysis we notice that weak silicon hydride (Si-H) bonds were not detected while bonding configurations associated to the silicon nanocrystal surface (Si_mH_n) were clearly observed. This result is largely related to possible photostability of our samples. By UV-Vis measurements we found a tunable band gap in function of D_R, with a behavior that support the influence of quantum confinement, while for the photoconductivity do not show stability in the samples, instead we obtained improvement of photoconductivity in the films whit high D_R and D_H for both pressures. Understanding structural and chemical properties of pm-Si:H thin films is key towards optimizing their electrical and optical properties for applications in solar cells.

Study on amorphous Silicon single junction p-i-n PV cell

Al-Rajib Bhuiyan and Himangshu Ranjan Ghosh

Institute of Energy, University of Dhaka, Dhaka-1000, Bangladesh

Abstract

The performance of solar PV cells depends on its design, material properties and fabrication technology. In this study design and analysis on thin film single junction hydrogenated amorphous silicon (aSi:H) has showed that the efficiency of a single junction PV cell can be achieved upto 9.823% for with optimized window layer bandgap of 1.85eV. For this the current density is 13.827 mA/cm2, open circuit voltage is 0.987 volts and fill factor is 0.719. Moreover different interface recombination velocities are applied to investigate the impacts on short-circuit current density (Jsc), open-circuit voltage (Voc), fill factor (FF) and efficiency ( ). Higher recombination velocity of front and back contact give a detrimental impact on Jsc& . Jsc and drastically decline in the range where surface recombination speed are greater than 104 cm/s. it would be possible to yield efficiency more than 10% by reducing surface recombination speed from 107 cm/s to 104cm/s. The Quantum Efficiency (QE) curve has revealed that the cell has good spectral response in the wavelength range 0.4 µm – 0.65 µm which means that it would be a good candidate as a top cell of double junction/ micromorph solar cell configuration and as a middle cell in triple junction structure. The research has been carried out with AMPS-1D modelling and computer simulation program.

Keywords: *Thin film solar cell, Amorphous silicon solar cell*

1. Introduction

Amorphous silicon (aSi:H) technology was up to now the only thin film concept, that has entered into large scale production plants in turning out about 5MW/y. But already now aSi:H modules are sold at lower prices than wafer based crystalline silicon modules. However, compared to crystalline silicon the efficiency of commercially available aSi:H solar cell module suffer still from relative low efficiency. While in the research laboratory stabilized efficiencies over 13% have been demonstrated for small size cells. There is a gap between this record test cells and the translation into commercial modules. It is interesting to look into the various individual factors that cause efficiency losses for aSi:H technology between laboratory records cell and industrial production (Fonash, 2010).

The performance of solar photovoltaic cells depends on its design, material properties, and fabrication technology. Photovoltaic (PV) researchers present improved cells over the period of time, although the overall process is quite complex, expensive, and time consuming. Numerical simulation is the best approach for solar cell researchers, which help to find out an optimized structure with good fitted parameters. As a result fabrication complexity, costs, and time reduce significantly. The major objectives of numerical modeling and simulation in solar cell research are testing the validity of proposed physical structures, geometry on cell performance, and fitting of modeling output to experimental results. The numerical modeling has become indispensable tools for designing a high-efficiency solar cell. Numerical modeling is increasingly used to obtain insight into the details of the physical operation of thin-film solar cells. Over the years, several modeling tools specific to thin-film PV devices have been developed. A number of these tools have been reached in a mature status and are available to the PV community. In this study AMPS-1D simulation software (AMPS 1D 2015) has been used.

2. Methodology

AMPS can simulate an extremely general semiconductor device structure. In the electrical part of the model, three coupled differential equations: the Poisson's equation and the two carrier continuity equation are solved simultaneously under non-equilibrium steady state conditions (i.e., under the effect of voltage or light bias, or both) by using the method of finite differences and Newton-Raphson technique, directly from the first principles (Belfar et al. 2011). The equations used are:

Poisson's Equation:

$$\frac{\partial^2 \psi(x)}{\partial^2 x} = \frac{\rho(x)}{\varepsilon} \qquad \text{(eq. 1)}$$

Hole Continuity equation:

$$G(x) - R(p(x), n(x)) - \frac{1}{q}\frac{\partial J_p(x)}{\partial x} = 0 \qquad \text{(eq. 2)}$$

Electron Continuity equation

$$G(x) - R(p(x), n(x)) + \frac{1}{q}\frac{\partial J_n(x)}{\partial x} = 0 \qquad \text{(eq. 3)}$$

Where $\rho(x)$ is the charge density

$$\rho(x) = q[p(x) - n(x) + p_T(x) - n_T(x) + N^+_{net}] \qquad \text{(eq. 4)}$$

And the electric field

$$E = \frac{\partial \psi(x)}{\partial x} \qquad \text{(eq. 5)}$$

where, ε is the dielectric constant,
E the electrostatic field, represents the position in energy of the local vacuum level,
x the position in the device,
p and n the valence-band hole density and the conduction band electron density, respectively,
q the electronic charge,
R the recombination rate,
p_T and n_T the trapped hole and electron population density, respectively,
N^+_{net} the net doping density, if any,
G the electron-hole pair generation rate,
$J_p$andJ_n the hole and electron current density respectively and
E_{FP} and E_F,, the hole and electron quasi Fermi levels.

In this study, the three state variables that completely define the state of a device have been taken to be the local vacuum level, ψ and the quasi-Fermi levels E_{FP} and E_{Fn}. Once these three dependent variables are known as a function of x, all other information about the system can be determined as functions of position. In thermodynamic equilibrium, the Fermi level is a constant as a function of position and hence the three Equation (1-3) essentially reduce to only one equation viz., the Poisson's equation. Therefore, the local vacuum level $\psi(x)$ is the only unknown to be solved for in thermodynamic equilibrium.

In the non-thermodynamic equilibrium steady-state, a system of three coupled non-linear second order differential equations in the tree unknown (ψ, E_{Fn}, E_{Fp}) are obtained, In order to solve these equations for state variables (ψ, E_{Fn}, E_{Fp}), we need six boundary conditions, two for each dependent variable. The first

two boundary conditions are modified versions of the ones used for solving Poisson's equation in thermodynamic equilibrium:

$$\psi(0) = 0 - \chi(L) - \varphi_{bL} + \varphi_{bO} - \chi(0) - V \qquad \text{(eq. 6)}$$

And

$$\psi(L) = 0 \qquad \text{(eq. 7)}$$

Where, L is length of the device,

$\chi(0), \chi(L)$ are the electron affinities at x = 0 and x = L, respectively and

V is the applied voltage.

The zero of $\psi = \psi(x)$ is generally chosen to be the position in energy of the vacuum level at the boundary point x = L. The boundary conditions for the Poisson's equations in thermodynamic equilibrium are Equation 6 with the applied voltage V term absent and Equation 7. The four other boundary conditions are obtained from imposing constraints on the currents at the boundaries at x = 0 and x =L. These constraints force the mathematics to acknowledge the fact that the currents must cross at x = 0 and x = L (the contact positions) by either thermo ionic emission or interface recombination. Expressed mathematically, we obtain the following:

$$J_n(0) = qS_{n0}[n(0)-n_0(0)] \qquad \text{(eq. 8)}$$
$$J_p(0) = qS_{p0}[p(0)-p_0(0)] \qquad \text{(eq. 9)}$$
$$J_n(L) = qS_{nL}[n(L)-n_0(L)] \qquad \text{(eq. 10)}$$
$$J_p(L) = qS_{pL}[p(L)-p_0(L)] \qquad \text{(eq. 11)}$$

Where, S_{n0}, S_{p0} are surface recombination velocities for electrons and holes respectively at the x = 0 interface and quantities

S_{nL}, S_{pL} are the corresponding velocities at the x = L interface.

The largest Value the can have is $\approx 10^7$ cm sec^{-1} dictated by thermionic emission. Here, n(0) (p(0)) are the electron (hole) density at x =0, n(L) (p(L)) are the same at x = L.

$N_0(0)$ ($p_0(0)$), $n_0(L)$ ($p_0(L)$) are the electron (hole) density in the thermodynamic equilibrium at x = 0 and x = L, respectively. With the help of the boundary conditioned stated above; the three Eq. 1 to 3 can be solved simultaneously for $\psi = \psi(x)$, $E_{fn} = E_{fp}$ (x) and $E_{Fp} = E_{Fp}(x)$. For this, the different terms in the equations are to be calculated first. The gape states and two Gaussian distribution functions to simulate the dangling bond states. The generation term in the continuity equations has been calculated using a semi empirical model (Leblanc et al., 1994) that has been integrated into the modelling programme. Both specular interference effects and diffused reflectance and transmittances due to interface roughness were taken into account.

3. Data and Result

Figure 1 gives the dark and light J-V characteristics of simulated aSi:H (p-i-n) single junction solar cell as calculated on the basis of model AMPS-1D. The calculated light J-V characteristics of the cell yield the following results:

Short circuit current density of Jsc= 13.827 mA/cm2,
Open circuit voltage Voc = 0.987 volt,
Fill-factorFF = 0.719,
Efficiency = 9.823 %.

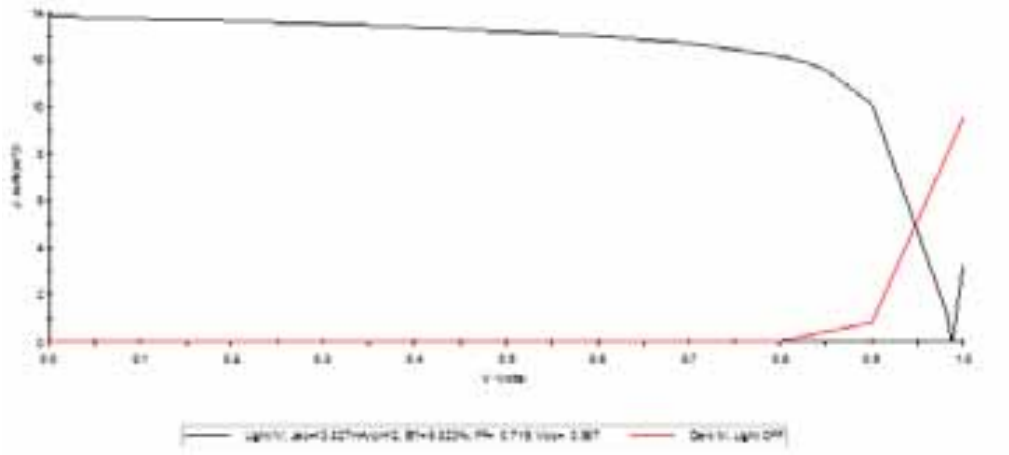

Fig. 1: Simulated J-V Characteristics curve of single junction (pin) aSi:H solar cell

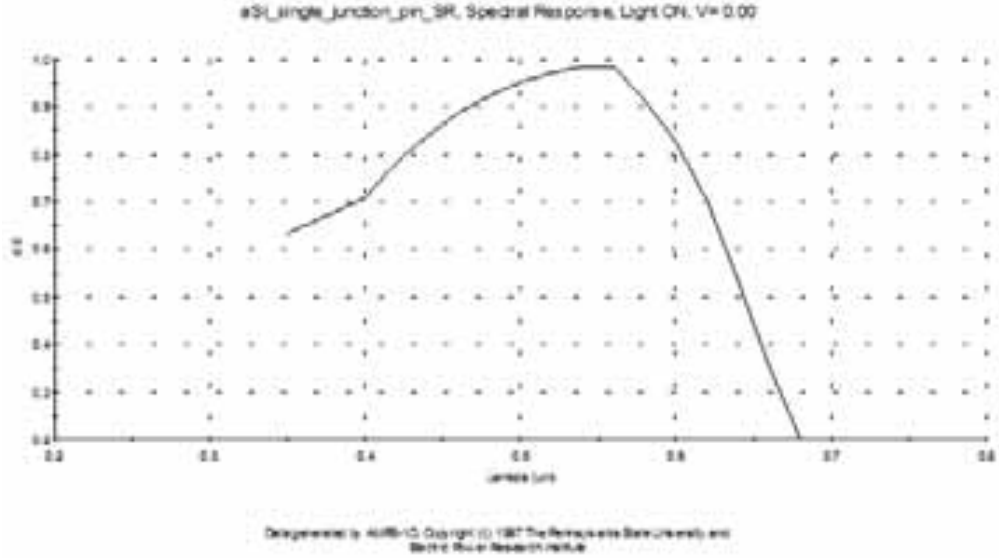

Fig. 2: Spectral response curve of single junction (pin) aSi:H solar cell

Figure 2 shows the quantum efficiency (QE) under AM1.5 illumination at 0 volts. From this SR curve it is clear that due to higher bandgap of aSi:H silicon, it has spectral response only below wavelength of 700nm. With respect to a band gap of 1.85 eV theband gap utilization is relatively low dueto the high levels of SRH recombination andthe relative broad valence and conduction-band tails.

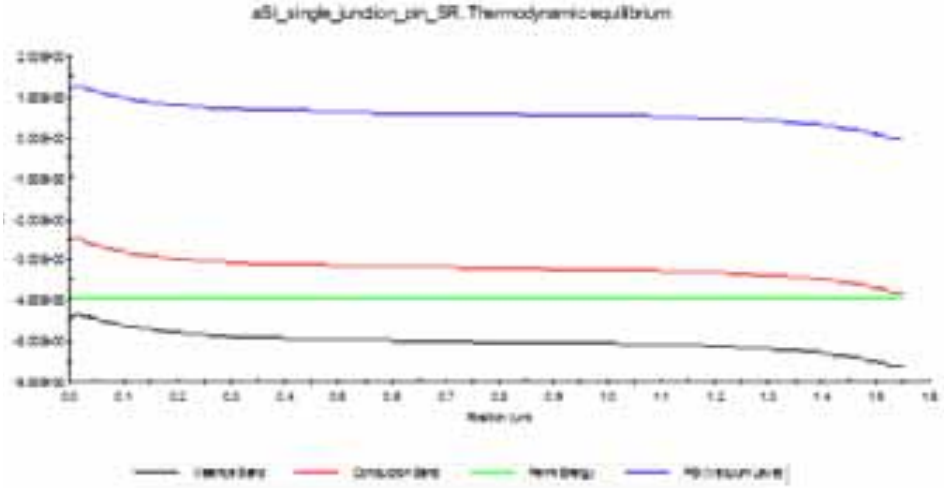

Fig. 3:Thermal equilibrium band diagram of aSi:H single junction solar cell

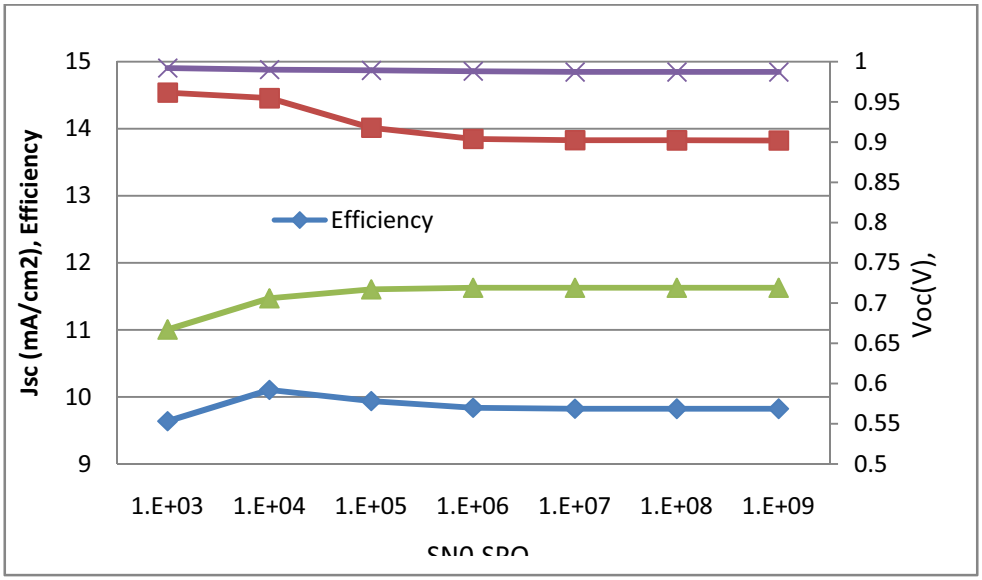

Fig. 4: Impacts on Voc, Jsc, FF& Eff come from the interface recombination speed

Interface recombination is one of the important recombination models. Different interface recombination velocities were applied to investigate the impacts on short-circuit current density (J_{sc}), open-circuit voltage (V_{oc}), fill factor (FF) and efficiency (Eff). The results are shown in Figure 5. In this simulation, the Rs mainly depends on thematerial properties, such as the interface recombination velocity, and whether the defects exist or not. Assume that the square of this solar cell is unity square centimeter. From Figure 4, it can be seen that Jsc and Eff drastically decline in the range where SNO and SPO are greater than 10^4 cm/s. The reason is that the increase in interface recombination velocity reduces the number of holes and electrons collected by the electrodes so that the short-circuit current reduces. Experimentally, the SNO, SPO, should be controlled into small value by optimizing the conditions of material growth in order to improve the conversion efficiency.

	1.8	1.85	1.9	1.95	2	2.05	2.1
Efficiency	9.175	9.487	9.757	9.842	9.623	9.171	8.633
Jsc	14.153	13.97	13.857	13.798	13.779	13.778	13.784
FF	0.715	0.719	0.721	0.715	0.696	0.627	0.653
Voc (Volt)	0.906	0.944	0.997	0.998	1.003	0.991	0.958

Fig. 5: Impacts on Voc, Jsc, FF& Eff come from the Window layer bandgap

Figure 5 gives the impacts on V_{oc}, J_{sc}, FF & Efficiency come from the window layer bandgap. From this figure it can be seen that the maximum efficiency of 9.82% has been achieved for window layer bandgap at 1.95 eV. Before and after the bandgap of 1.95 eV the efficiency decreases sharply due to decrease of photoconductivity and photosensitivity.

4. Conclusion

Win AMPS-1D simulation software, the best efficiency of this numerically designed single junction aSi:H solar cell is 9.823% with intrinsic layer thickness of 1200 nm and optimum window layer bandgap of 1.85eV. The obtained results show that the interface recombination speeds of front and back contact is crucial to short circuit current density and efficiency of aSi:H solar cell. Therefore one can increase the performance of aSi:H solar cell by minimizing the surface recombination speed of transparent conducting oxide. The Quantum Efficiency (QE) curve shows that the cell has good spectral response in the wavelength range 0.4 µm – 0.65 µm which means that it would be a good candidate as a top cell of double junction/ micromorph solar cell configuration and as a middle cell in triple junction structure.

Abstract

Inkjet printing technique is a material-conserving technique, which can greatly reduce the production cost by reducing the wastage of materials during the deposition. Additionally, this method can be easily adapted to Roll-to-Roll processing for large-scale application. The most challenging issues that remain open for multi-component system such as $Cu_2ZnSn(S_xSe_{1-x})_4$ (CZTSSe) are: (1) Formulation of long-term stability raw material ink and (2) Optimization of electronic and electrical properties for high efficiency solar cell. We developed two different methods for ink formulation. The first one is based on preparation of nanoparticles such as ZnS, SnS and Cu_3SnS_4. The second method consists of metal salt precursors dissolved in organic solvents. We use metal salt solutions containing Cu, Sn, Zn and S precursors dissolved in dimethyl sulfoxide (DMSO) to prepare the ink. We used two deposition techniques (spin coating, inkjet printing) for the preparation of absorber layers. Both method lead to the production of kesterite films. However the metal salt based ink is well adapted to inkjet printing and the resulting solar cells with glass/Mo/CZTSSe/CdS/ZnO structure show total area (0.5 cm^2) efficiency of 6.4 %.

Keywords: *Inkjet printing, kesterite, thin film solar cell*

1. Introduction

Kesterite $Cu_2ZnSn(S,Se)_4$ (CZTSSe) has emerged as a promising candidate for solar energy conversion. The optical band gap of this material can be tuned between 1.0 eV and 1.5 eV by changing [S]/([S]+[Se]) ratio. Wang et al., have developed a solar cell with record efficiency of 12.6% obtained for CZTSSe absorbers from hydrazine-based solution [1]. However the fabrication process suffers from certain safety hazards due to the use of explosive and toxic hydrazine solvent. Previously, we have shown that CZTSSe thin film absorbers can be formed by annealing spin coated in-house formulated ZnS, SnS and Cu_3SnS_4 (CTS) nanoparticle (NP) inks [2-5]. Cao et al. have fabricated CZTSSe based solar cells with efficiency up to 8.5 % by using a similar binary and ternary chalcogenide nanoparticle as precursors to prepared CZTSSe absorber [6]. Another way is to use CZTS quaternary nanoparticles as precursors to fabricated CZTSSe thin films [7, 8]. This approach has led to an efficiency of 9.0 %. However, the nanoparticle (NP) synthesis process is time consuming and requires complicated steps. Moreover, long chain organic ligand is required to prevent the agglomeration of the nanoparticles during the synthesized process, which is difficult to be removed after thin film processing. Therefore, a ligand-exchange process to minimize the amount of carbon in the layers may be needed. Although the ligand exchange can reduce the carbon content in the layers, the resulting absorbers

doi:10.18086/swc.2015.05.08 Available at http://proceedings.ises.org

still containing large amount of carbon left near the back contact after the annealing step, which limit the performance of the solar cell device. A simple alternative approach developed by Ki et al., is based on Cu, Zn, and Sn precursors dissolved in DMSO leads to efficiency of 11.8% obtained by annealing the spin-coated Cu-Zn-Sn-DMSO solution [9, 10]. It has been reported that sodium has a positive influence on the morphology as well as electronic properties of CZTSSe absorbers, thereby enhancing the solar cell performance [11].

2. Experimental

2.1. Sample preparation

NP inks were prepared from ZnS, SnS and Cu_3SnS_4 (CTS) NP precursors in certain ratio mixed with oleylamine (solvent) and 1-dodecanethiol (capping agent) [5]. This mixture was heated to 130^{o}C with 10 ^{o}C/min and held at this temperature for 30 minutes. Thereafter, the mixture was further heated to higher temperature (200 °C-250°C) and stayed at this temperature for certain time to allow the growth of the NP. After cooling room temperature, the NP were precipitated by addition of excessive ethanol or acetone followed by centrifugation. The precipitated NP was dispersed in toluene or 1-hexanthiol to formulate the ink. Thin films were deposited by spin coating of using the NP inks. The residual solvents and organic surfactants surrounding the NP were removed by heating at 170 $^{\circ}$C and 350 $^{\circ}$C respectively for 2 minutes. It should be noted that a ligand exchange process is carried out with 0.04 M $(NH_4)_2S$ methanol solution for the sample cooled to RT from 170 °C. Thick films are obtained by repeating the spin coating and intermediate annealing at 350 °C. The processed CZTS NP film is further annealed at 580 °C for 25 minutes in Se atmosphere to form CZTSSe absorbers. The chemical composition of the absorber layer can be tuned by adjusting the ratio of NP precursors. It is also reported that the CZTSSe based SC performance is strongly dependent on the ratios of Cu/(Zn+Sn) and Zn/Sn [5]. The chemical reaction leading to the formation of CZTSSe can be represented as,

$$CTS+SnS+ZnS \xrightarrow{Se,\Delta} CZTSSe \text{ [5]}$$

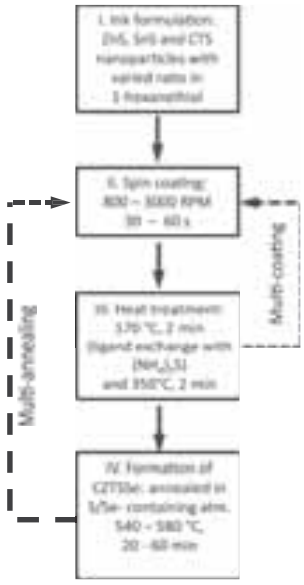

Figure 1: Preparation process of NP based CZTSSe absober layers[5]

Metal salt based CZTS ink were prepared by mixing Copper chloride, zinc acetate dihydrate, tin chloride dehydrate, thiourea and sodium fluoride in 12 mL DMSO with stirring overnight. The metal ratios of the ink precursor were Cu/(Zn+Sn) =0.73 and Zn/Sn = 1.02. NaF was directly introduced in the Cu-Zn-Sn-S ink with a concentration of 0.14 M. The resulting ink is well adapted for inkjet printing as revealed by the measurement of the contact angle. The best inkjet printing condition was found by adjusting the printing parameters (droplet volume less than 20 pl., printing speed set to 4.8 to 7.2 m/min). The resolutions in both

the X and Y directions for the printing were 400 dpi. With such conditions, the volume of ink needed for each printing on an 25.4 mm x 25.4 mm substrate is calculated to be less than 4 µL. Figure 2 shows the prepared ink and operating principle of inkjet printing. The as-deposited Cu-Zn-Sn-S precursor layers after printing were baked to remove the residual solvent on a pre-heated hot plate at 300 °C for 2 min. A second annealing in selenium containing atmosphere at 560 °C for 20 min allow the formation of well crystallized CZTSSe thin film absorbers.

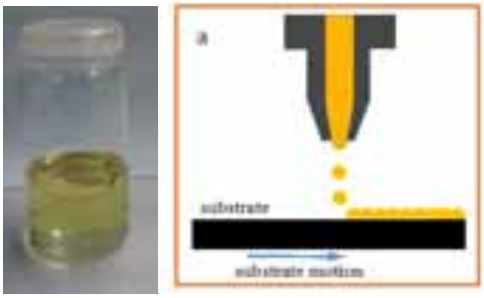

Figure 2: Formulated ink and operation principle of inkjet printing.

2.2 Fabrication of solar cells

Solar cells were fabricated by chemical bath deposition of a CdS buffer layer, and subsequently by sputtering of i-ZnO and aluminum doped ZnO window layers. A Ni/Al upper contact electrode was deposited by evaporation using a shadow mask. Finally solar cells with an area of 0.5 cm^2 were defined by mechanical scribing. The fabricated Solar cells with Mo/CZTSSe/CdS/i-ZnO/ZnO:Al/Ni:Al grids were studied for their photon conversion efficiency.

2.3. Characterization

X-ray diffraction (XRD) was used to verify the crystalline structure of NP and metal salt based CZTSSe absorber layers. Bruker D8-Advance X-Ray diffractometer was used with Cu K_α radiation in a step size of 0.02° and a step time of 5s. The contact angle was measured by using "contact angle system OCA" from data physics Instruments GmbH, Germany. The SEM image was recorded in a LEO 1530 GEMINI SEM of Zeiss at an acceleration voltage of 10 kV. Solar cell efficiency was calculated from J-V curves under 1.5 AM, 100 mW cm^{-2} illumination by using an in-house class A sun simulator.

3. Results and Discussion

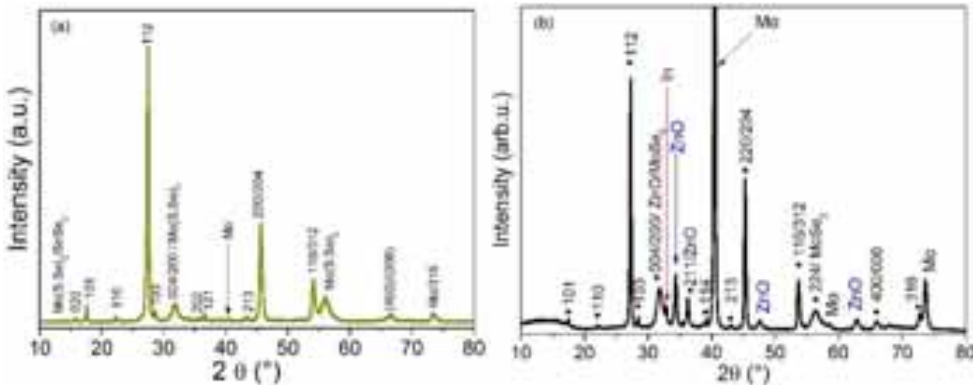

Figure 3: XRD patterns of (a) a NP based CZTSSe thin film and (b) metal salt based CZTSSe device.

XRD pattern in figure 3 (a) shows tetragonal structure for NP based CZTSSe sample. There are peaks from the Mo substrates as well. Peaks corresponding to $Mo(S,Se)_2$ are also observed. Usually Zn(S,Se) and CTS crystallographic peaks overlap with CZTSSe peaks, and it is difficult to identify the exact phase. It has been verified that there is no separate phase such as ZnS and CTS exist in CZTSSe using Raman spectroscopy (data is not shown here). Figure (3) (b) displays the XRD pattern of the metal salt based CZTSSe completed

device. Peaks assigned to CZTSSe are indexed as shown in the Figure. Since the measurement was performed on complete device, peaks related to window layer of ZnO and Mo substrate were also detected.

Figure 4 shows the contact angle of DMSO before (Figure 4a, 21.6°) and after adding Cu, Zn, and Sn metal salts (Figure 4b, 42.4°), which conform with the increase of the viscosity with increasing metal salts concentration. For the metal ratio used in this study (Cu/(Zn+Sn)=0.73 and Zn/Sn=1.02), the contact angle still below 90° suggesting the feasibility for the formation of a homogeneous film on Mo substrate by inkjet printing [12].

Figure 4: Contact angle of (a) DMSO and (b) formulated ink containing Cu-Zn-Sn-S precursor on Mo coated glass substrate.

Figure 5a shows the cross sectional scanning electron microscopy (SEM) image of NP based CZTSSe with a thickness of around 4.5 µm. It is a four layered structure with fine grain/large grain/fine grain/large grain arrangement on top of Mo layer. Device geometry is not shown here. The SEM image in Fig. 5b shows a complete metal salt route based CZTSSe device. Crack free compact CZTSSe is synthesized as shown in Fig.5b [12]. A layer of $MoSe_2$ is formed in-between the Mo layer and CZTSSe absorber layer due to the reaction between Mo and chalcogen Se (during selenisation). Generally, a thin $MoSe_2$ layer is helpful in adhesion and provides an Ohmic contact for the $Cu(In,Ga)Se_2$ (CIGS) solar cells [13]. These findings could be also applied to CZTSSe solar cells due to the similar properties between CZTS and CIGS. However, an excessively thick $MoSe_2$ layer may have adversely effect on the performance of CZTSSe solar cells because of the high resistance of lead to a high series resistance of $MoSe_2$ layer (in the range of 10^1 to 10^4 Ω.cm [14]).

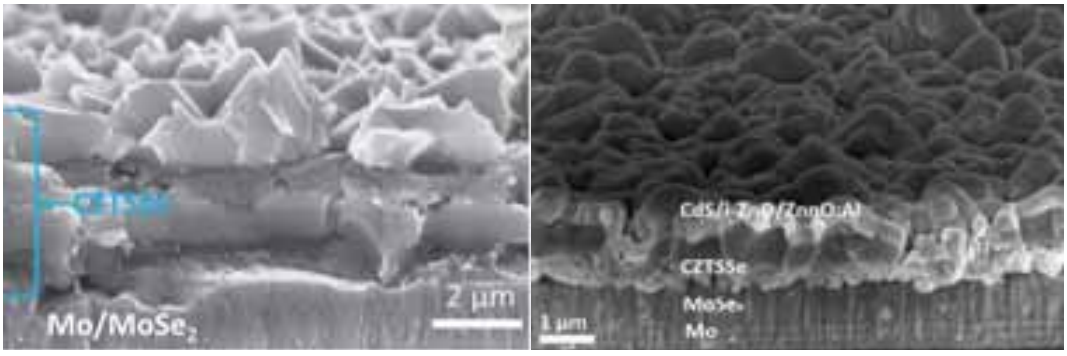

Figure 5: Cross-sectional scanning electron micrograph of NP based CZTSSe thin films (left) and the complete solar cell based on metal based CZTSSe (right).

The corresponding I-V characteristics measured in the dark and under AM 1.5 conditions are shown in Figure 6. The curves in blue show typical J-V curves of NP based CZTSSe solar cell under dark and illumination. Conversion efficiency of 3.0 % was achieved with an open circuit voltage (V_{OC}) of 306.5 mV, short circuit current density (J_{SC}) of 27.5 mA/cm^2, and fill factor (FF) of 35.0 %.

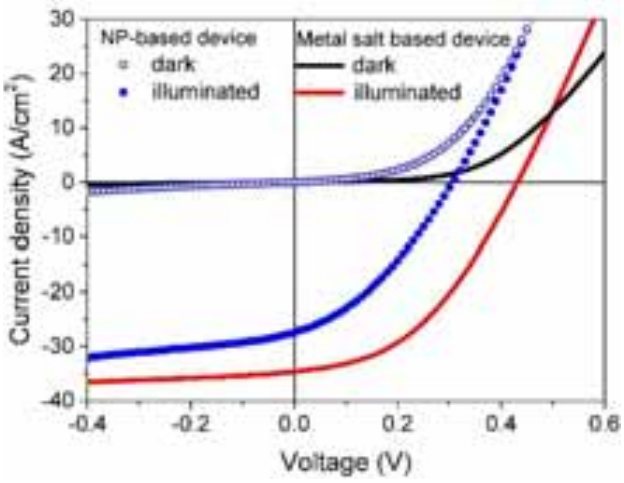

Figure 6: J-V characteristics in the dark and under illumination measured under AM 1.5 conditions for NP based CZTSSe device and metal salt based CZTSSe device. The area of the device is 0.5 cm^2.

Compared to spin coating method where most of the ink dropped on to spin coater substrates are spun away during rotation, inkjet printing method allows a uniform deposition with a negligible material waste due to the drop on demand properties. This reduces the material waste and cost of the solar cell. For example, in one of our studies, 20 µl ink is enough for the deposition of 1 µm thick absorber film in an inch^2 area [12]. Moreover, solar cells prepared with 0.5 cm^2 area in a glass/Mo/CZTSSe/CdS/ZnO structure demonstrated a power conversion efficiency of 6.4% (J-V curve in red in Figure 6). The V_{OC} was 431 mV, J_{SC} was 34.6 mAcm^{-2}, and fill factor FF was 42.8%. The series resistance, shunt resistance, and diode quality were found to be 5.7, 1230 Ω cm^2, and 2.3, respectively, by fitting the dark $J - V$ curve using one diode model.

The device performance is mainly limited by the low fill factor, which could be due to the high series resistance. Several factors may contribute to the high series resistance. One of the reason could be the thick $MoSe_2$ at the back contact. Another reason could be the fine grain layers near the back contact. We do not have a direct proof for that at the moment. Further studies are needed. The defect level studies on the CZTSSe thin films by photoluminescence (PL) and surface photovoltage spectroscopy (SPV) shows an increased $(Zn_{Cu})^+$, $[Zn_{Sn}+Cu_{Zn}]$ defect states and a dominating quasi donor-acceptor pair recombination in the recombination process [15]. We know the samples studied are Cu poor and Zn rich and the Cu and Zn disorder is already observed in the neutron diffraction studies as well [16]. This could also be a reason affecting the performance of the solar cell.

4. Conclusion and Outlook

Nanoparticle inks are affected by stability issues which is due to the agglomeration of NPs after certain time. To avoid this agglomeration long chain organic-ligand is used during the formation of ink. However, it is difficult to remove the long chain organic ligand which stabilizes the NPs completely from the thin films. A combination of ligand exchange and non-ligand exchange processes result a crack free CZTSSe absorber film. Selenisation lead to a layered structure with unwanted carbon in the grains. The carbon serves as a barrier for the growth of NP, however gives an efficiency around 1-3% [5]. we explored DMSO as solvent for the formulation of stable Cu-Zn-Sn-S precursor ink and by varying the concentration of Cu, Zn, and Sn metal salts, the viscosity can be controlled. The resulting ink is well adapted for inkjet printing as revealed by the measurement of the contact angle. Inkjet printing is more effective than the spin coating in terms of raw material utilization. Solar cells with glass/Mo/CZTSSe/CdS/ZnO structure with total area (0.5 cm^2) power conversion efficiency of 6.4% are demonstrated from thin film absorbers processed by inkjet printing technology of Cu-Zn-Sn-S precursor ink followed by selenisation. Inkjet printing allows the development of

Micro concentrator solar cell concept, which allows enhancing the efficiency of PV devices while reducing the material consumption. Furthermore, the adaptation and integration of micro-lenses for optimal concentration of light on micrometer size solar cell is a promising area of interest which can use micro-CPV with integrated optics without the need of tracking system.

Abstract

Solar cell developers should have the theoretical knowledge how to best manipulate the solar cell properties in order to improve in a most effective way the solar cell efficiency. Such knowledge can be obtained by the simulation of the solar cells efficiency. Here a validated analytical model is used in order to simulate the model efficiency of the hybrid p-i-n solar cell in a multidimensional property space. The analytical model is based on a self-consistent stationary quantum simulation of the charge carrier generation and is established on the drift diffusion and the Poisson equations. The model simplifies the numerical simulation of the carrier generation as a function of the penetration deepness of the solar radiation, where the total charge generation is obtained by integration of local generated charges over the whole absorber layer thickness. Recombination currents at the p and n transport layers are considered as a function of (i) the diffusion coefficients of the free charges, (ii) the excess and the moderation of charges at the front and the back of solar cell, (iii) the effective surface recombination velocities of these charges and the (v) the solar cells built-in voltage. By use of a sensitivity analysis, it is shown how the properties of an ideal perovskite cell should be manipulated in order to improve its efficiency.

Keywords: *Perovskite Solar Cell (PSC), Analytical PSC Model, Sensitivity Analysis.*

1. Introduction

Whereas photovoltaic power plants based on the widely used silicon solar cells are already economically viable without subsidies in several countries [1] in residential applications and on the industrial scale, climate change problems demand the usage of renewable energy sources in very large scale [2], which stresses large investments. In order to reduce this investment cost photovoltaic modules should be available at lower costs in the future. Such an demand may be accomplished with the hybrid perovskite solar cells, as it combines potentially a low manufacturing cost with very high efficiency values in a multiple junction cell structure [10]. As discussed in [10] a triple junction solar cell combined with a crystalline silicon cell would lead to a cell efficiency of up to 50 %, which will result to the efficiency of photovoltaic modules of approximately 40 %. The first commercially available hybrid photovoltaic modules are based on Dye Sensitized Solar Cells (DSSC) [3], and they are commercially available by the company Solaronix[1]. In 2010, the photovoltaic effect of the hybrid Perovskite material was unveiled [4], which lead at the state of the art to much higher solar cell efficiencies than the one obtained by dye sensitized solar cells. Remarkable in the research with the

doi:10.18086/swc.2015.05.09 Available at http://proceedings.ises.org

Perovskite solar cell is the unprecedented and strong tendency to high efficiency values within the short time frame of the research with this cell[1]. Due to its recent discovery it seams that the efficiency of these cells degrades over time. However a very promissing way in order to improve the stability of the perovskite solar cell efficiency over time is the encapsulation of the perovskite layer with a metal-oxide layer in order to protect it from the humidity of the air [11]. As shown by these authors such a protection result to an initial degradation of 10 % of the PCE, which stabilize after approximating 30 days. The use of standardized module encapsulation should further reduce the degradation of this solar cell, if used in a solar module.

At the state of the art the improvement of the efficiencies of the hybrid solar cells is mostly based on the exhaustive cell prototyping and measurements of the efficiency values of the cells manufactured in laboratories. However the potential benefits from mathematical modelling of the solar cell efficiency, as shown in [5, 6], should be more exploited in order to foster the velocity of their development. By having a mathematical model at hand, which expresses most accurately the solar cell efficiency as a function of its material properties and other engineering parameters, it can be analyzed theoretically which of the parameters or properties do lead to the most significant improvement of the solar cell efficiency. Therefore a multidimensional sensitivity analysis of the model variables of a perovskite p-i-n solar cell is here accomplished based on the analytical model elaborated in [5].

2. Tuneability of the properties of the perovskite cell

Whereas the organic component of the hybrid perovskite material provides the viability of its deposition in a solution, which permits the printing of the cell in a roll to roll process, the inorganic component of the perovskite solar cell forms an extended framework of strong covalent interactions, ionic interactions, or both of them, which permits the advanced engineering of the cell properties. As stated in [9], the optical and electronic properties of the perovskite material can be tuned to a great extend by replacing the halide ion, the metal ion or the organic cation. Furthermore the perovskite material has an excellent tuneability of its band gap by adjustment of the relation of its chemical composition [10], making it therefore fit for the optimization of its efficiency in single, double or multiple junction cells. The details highlight the remarkable tuneability of the perovskite cell properties, which show its high potential for further improvement of its efficiency in the near future.

3. Model description of the perovskite p-i-n solar cell

Using as reference the results obtained by a detailed numerical simulation, the authors Sun et al. [5] elaborated a simplified analytical model for four different types of perovskite solar cells considering a fixed band gap. For the present analyses only the p-i-n solar cell is analyzed in more detail based on its analytical model as this cell resulted in [5] to the highest measured and modelled efficiency values of 15.7 %. The p-i-n solar cell consists of a p-type and a n-type charge conduction layer, an absorber layer, also denominated as intrinsic i-type layer, a transparent front electrode layer and a reflecting the back contact layer. As it is considered that the excitons are principally generated within the charge neutral depletion zone, the enlargement of this zone by use of the undoped intrinsic layer, constituted by the perovskite material, does improve the probability of the generation of the free charges by means of the solar radiation. Whereas the majority carriers account for the generation of the free charges, the minority carrier's results to the recombination effect under explosion to light. The electron and the hole transport layers of n-type and p-type are considered as perfect conductors for the majority carriers and as imperfect blocking layers for the minority carriers. Whereas the p-layer conducts the majority holes to the cathode and blocks the minority flux of electrons to this electrode, the n-layer conducts the majority electrons to the anode and blocks the minority flux of holes to this second electrode.

4. Initial parameter configuration based on measured results

Sun et al., 2015 [5] defined by use of the Optical Transfer Matrix method first the fundamental optical parameter of the analyzed cell, which are (i) the generation of free charges G_{max} = 1.4356 x 10^{23} $cm^{-2}s^{-1}$ (qG_{max} = 23 mA/cm²), and (ii) the average optical decay length λ_{ave} = 100 nm for the presented p-i-n solar cell. Wereas G_{max} gives the charge generation rate at the surface of the solar cell as function of the band gap λ_{ave} gives a measure of how the radiation intensity decays as it pentrates into the solar cell. Then, in order that the p-i-n model UI curves at AM1.5 irradiation $J_{light}(U)$ and in the dark $J_{dark}(U)$ fit to the measured UI curves, these obtained optical parameters and the measured ambient temperature T_a = 27.41 °C, were used in a regression using the algorithm 'lscurvefitt' of the Mablab™ program. This algorithm minimizes the sum of the least square deviations in-between the measured and the modeled UI curves and leads to the perovskite material properties considering a fixed solar cell thickness. Then, using the obtained model specification the cell efficiency for different absorber layer thicknesses was modeled in a unidimensional optimization process. The optimized cell was manufactured and its efficiency was validated with the optimized model efficiency. The authors obtained the following model properties: Diffusion coefficient of charges $D_n = D_p \approx$ 0.05 cm^2/s, front and back surface recombination velocities of charges s_f = 2 x 10^2 cm/s, s_b = 19.2 cm/s, number of charges participating at the recombination process Δn = 8.426 x 10^6 cm^{-3}, Δp = 1.3003 x 10^8 cm^{-3}, front and back surface recombination currents J_{f0} = 2.7 x 10^{-13} mA/cm^2, J_{b0} = 4.0 x 10^{-13} mA/cm^2, built-in voltage V_{bi} = 0.78 V, absorber layer thickness of t_0 = 450 nm, average optical decay length λ_{ave} = 100 nm. This optimization resulted to an cell efficiency of η = 15. 7% [5].

5. Results and discussion

As graphically shown in [5], the efficiency is a function of the recombination velocities of charges trough the front and the back transport layers s_f and s_b and the absorber layer thickness t_0. A reduction of s_f and s_b , and principally the front surface recombination velocity s_f , would improve the cell efficiency also by approximately 3 % (figure 4 in [5]). However, as given from the model equations the cell efficiency is sensible to more than those three variables. Therefore, in the present sensitivity analysis the efficiency is shown as a function of an increased number of model variables. The following material properties are considered as additional variables of which the efficiency is a function: (i) the average optical decay length (λ_{ave}) in context with the thickness of the intrinsic absorber layer (t_0), (ii) the diffusion coefficients of electrons and holes D_f and D_b, the built-in voltage V_{bi} .

Whereas the cell thickness seems to be the main factors in order to improve the cell efficiencies (see figure 3 is [5]), the melioration of the average optical decay length seems to be insignificant leading to an improvement of only 0.05…0.1 %, if a fixed optical decay length is considered. However, showing these two variables in a bi-dimensional space, while the other variables are are being fixed to the values in item 4, it can be seen that the efficiency can be considerably improved if it would be possible to reduce the optical decay length (Figure 1). As shown by the vertex line in this figure, the active layer thickness t_0 has to be adjusted as a function of the average optical decay length λ_{ave} in order to obtain the best efficiency values. In the best case this results to the augmentation of the efficiency from 15.7 % to around 17 % (Figure 1). Further improvement of the efficiency values can be obtained by manipulation of the diffusion coefficients and principally the diffusion coefficient of the holes D_p , which lead to an improvement of up to approximately 3 % of the efficiency (Figure 2). The variation of the built-in voltage resulted to an increase of the efficiency of approximately 1.8 % at V_{bi} of 1.4 eV. As to see from the Shockely-Quaisser efficiency curve the a band gap adjustment would improve the efficiency by less then 2 %.

Recommendations for the improvement of the efficiency of the p-i-n perovsktite cells

The perovskite material with the lowest average optical decay length λ_{ave} should be selected as this results to the conversion of the solar irradiance by use of smaller values of the cell thickness t_0 . The cell thickness t_0 should be adjusted as a function of the attained average optical decay length of the synthesized Perovskite absorber layer as shown by the blue vertex line in Figure 8, which shows the highest solar cell efficiency values within this function space. The perovskite material should be modified in order that the diffusion coefficients of the electrons and holes D_n and D_p are coming as high as possible. Especially high improvements can be obtained by the improvement of D_p , if D_n is at least higher than approximately 0.3 m²/s (Figure 2). The perovkite material and the organic conduction layer material should be selected in order to obtain the highest possible built-in voltage V_{bi} .

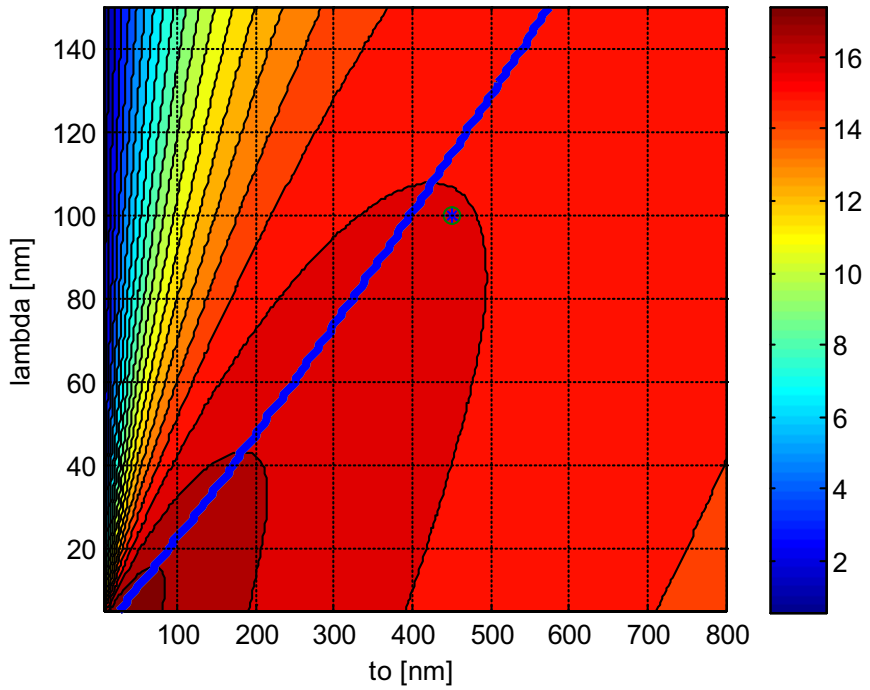

Figure 1: Modeled efficiency for a current generation of q x G_{max} = 23 mA / cm² as a function of the thickness of the absorber layer t_0 and the average optical decay length λ_{ave} with a vertex line of the maximal efficiency points (blue line) and the measured efficiency obtained in [5] (blue star surrounded by a circle).

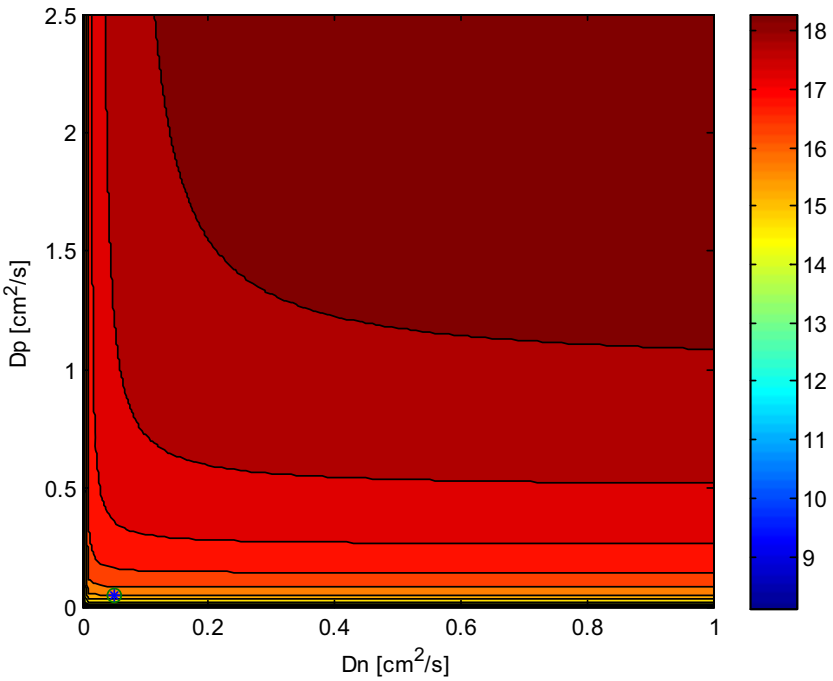

Figure 2: Cell efficiency for a current generation of q x Gmax = 23 mA / cm² as a function of the diffusion coefficient of holes D_p and diffusion coefficient of electrons D_n with maximum value of the efficiency of 18.8 % within the upper right part of the presented graphic and the measured efficiency in [5] (blue star surrounded by an circle).

6. Conclusions

In the present publication the perovskite cell efficiency is shown as a function of an extended variable space determined by the cell properties and manufacture parameters. The obtained results lead to a better understanding on how the efficiency of the p-i-n perovskite solar cell can be improved and results into recommendations to show how to modify these variables, in order to increase most successfully the solar cell efficiency. Whereas the melioration of each one of the single variables lead to a lower improvement of the efficiency the interplay or interdependence of the model variables in an nonlinear space lead to more substantial improvements, which are much higher than the improvements obtained by single variable variations.

Abstract

a-SiGe:H thin film solar cells with a light-abosrbing layer having differently graded Ge-compostion (C_{Ge})-profiles were fabricated to investigate the effect of C_{Ge}-profiling on the cell performance and light-induced degradation (LID). The C_{Ge}-profiles were linear normal profiling, nonlinear normal profilings, nonlinear reverse profiling, and nonlinear U-shape profiling. The cells with these C_{Ge}-profiles were compared to the cells with a constant $C_{Ge.}$ Among the samples, the cells with normal profilings showed better performances than the others. The efficiencies of the cells with linear and nonlinear normal profilings were 6.31 and 6.10%, respectively. Compared to the cells with constant-C_{Ge}, the efficiency of the cells with normal profiling was increased mainly due to the increase in the fill factor, which could be induced by the enhancement of internal field. The light-soaking experiment also showed that C_{Ge}-profilings can reduce LID. In this work, the use of a light-absorbing layer with graded C_{Ge}-profiling could improve the cell performance in terms of both efficiency and LID.

Keywords: *substrate-type solar cell, a-SiGe:H, Ge-composition profiling, light-induced degradation, internal field*

1. Introduction

Thin film photovoltaic devices based on hydrogenated amorphous silicon (a-Si:H) have been extensievley investigated in efforts to achieve high conversion efficiency and low-cost production. One of the most effective approaches used to achieve high efficiency is the fabrication of multi-junction (MJ) solar cells. The nip-type MJ cells on opaque and flexible substrates such as metal sheets or plastic films have also attracted much attention due to their promising applications including building- and device-integrated solar cells. Si-based MJ solar cells usually consist of a wide bandgap a-Si:H top cell (the optical bandgap energy, E_g = 1.7 –

1.8 eV) and narrow bandgap sub-cells. Hydrogenated microcrystalline Si (μc-Si:H) and hydrogenated amorphous silicon germanium (a-SiGe:H) are good candidates for the narrow bandgap materials because the E_g of μc-Si:H is approximately 1.1 eV (Kondo and Matsuda, 2001) and that of a-SiGe:H can be varied in the range of 1.1 – 1.8 eV by controlling the Ge-fraction (Xu et al., 1996). However, μc-Si:H film have a low deposition rate and low light absorption coefficient, which are drawbacks in view of productivity because the μc-Si:H films need to be thicker than 1.5 μm to sufficiently absorb incident sunlight (Vetterl et al., 2000; Guo et al., 1998). Therefore, a-SiGe:H films, which have high deposition rates and a high light absorption coefficient can be good alternatives for improving the productivity of MJ solar cells.

The E_g of an a-SiGe:H film can be lowered and the light absorbance in the long-wavelength region ~~is~~ can be increased by increasing the amount of the Ge-fraction. However, the defect density of a-SiGe:H films increases with Ge-content (Stutzmann et al., 1989; Beyer, 2010), and many defects at n-Si:H/i-SiGe:H and p-Si:H/i-SiGe:H interfaces are generated by band-gap discontinuities (Lundszien et al., 2002). Therefore, the incorporation of Ge adversely affects the collection of photo-generated carriers due to the decrease of drift length and the increase of recombination centers, and causes the deterioration of cell performance. Earlier studies investigating methods to reduce the bandgap discontinuity and defect density have focused on the insertion of buffer layers or Ge-composition grading at the p/i- and n/i-interface regions (Zimmer et al., 1998; Arya et al., 1989). We previously reported the effect of a-SiGe:H with linearly graded Ge-composition on solar cell performance in the relatively low Ge-composition ranging from 0 to 16% (Yun et al., 2012). The light-induced degradation (LID) effect has also been studied for a-SiGe:H thin film solar cells because LID is more severe in a-SiGe:H than a-Si:H thin film solar cells (Shima et al., 2005). The study on LID effect is very important because it is closely related to the long-term stability of the a-SiGe:H thin film solar cell module.

In the present work, the Ge-composition of a light-absorbing layer was graded throughout rather than the p/i- or n/i-interface regions, and the Ge-content was varied in the range of 0 - 33%. A Ge-content of 33% is significantly higher than the commonly used Ge-content in a-SiGe:H solar cells because the performance of cells having a Ge-content exceeding 20% has been reported to be deteriorated by defects (Jones et al., 1993). The purpose of the Ge-grading in this work is to utilize the advantage of a high Ge-content region for absorbing a wide solar spectrum and to reduce the disadvantage of defective Ge-rich region in the light-absorbing layer. The enhanced internal field which can improve the carrier collection would be caused by the Ge-composition grading throughout light-absorbing layer. We also explored the optimum Ge-grading profile to achieve high conversion efficiency of nip-type a-SiGe:H thin film solar cells, and the most effective Ge-profiling was suggested for obtaining high efficiency and long-term stability.

2. Experimental details

The nip-type a-SiGe:H single junction cells were fabricated in a single chamber plasma enhanced chemical vapor deposition (PECVD) system. The schematic structure of the a-SiGe:H solar cell is illustrated in Fig .1. Ga-doped ZnO (ZnO:Ga) layers deposited by an rf-magnetron sputtering technique were used as transparent electrodes. Ag films coated with 200 nm ZnO:Ga were used as back-reflectors. Intrinsic SiGe:H layers with a thickness of 200 nm were deposited on the n-Si:H layer at 200 ^{o}C using SiH_4 (100%), GeH_4 (1.5%, diluted in H_2) and H_2 (100%) as source gases. a-SiGe:H films with graded Ge-composition profiles were prepared by gradually varying GeH_4 flow rate from 0 to 100 sccm (normal profiling) or 100 to 0 sccm (reverse profiling). The 20 nm-thick n-Si:H and 25 nm-thick p-Si:H layers were deposited using PH_3 (1.5%, diluted in H_2) and B_2H_6 (0.5%, diluted in H_2) as doping gases. An Al grid was formed on the ZnO:Ga top electrode using an e-beam evaporation process. The cell area defined by the top electrode was 0.2 cm^2. The solar cells were characterized by solar simulator under AM 1.5G spectrum and 100 mW/cm^2 illumination intensity at room temperature. External quantum efficiency (EQE) measurement was also carried out to investigate the light-absorbing behavior of a-SiGe:H layers having different Ge-profiles. To estimate the LID, the a-SiGe:H thin film solar cells were light-soaked under 1sun at 25^{o}C for 140 h.

The Ge-composition (C_{Ge}) profiles of the a-SiGe:H films were analyzed using Auger electron spectroscopy (AES). UV-Vis spectroscopy was utilized to measure the absorbance of the a-SiGe:H films, and the E_g was determined by Tauc's plot utilizing the absorbance data.

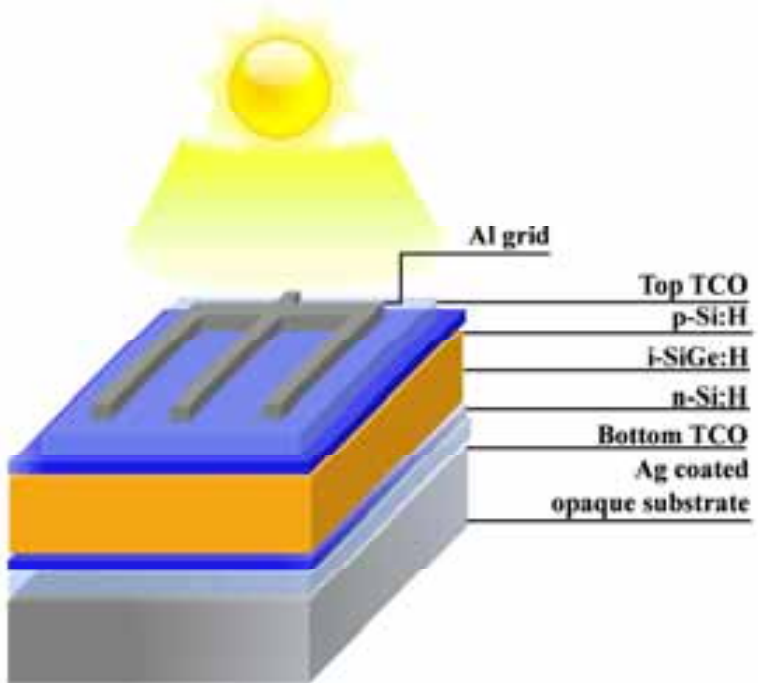

Fig. 1: Structure of the substrate-type a-SiGe:H thin film solar cells with Ge-composition profiled light-abosrbing layer.

3. Results and Discussions

First, thin film solar cells having a-SiGe:H light-absorbing layers with four different C_{Ge} profiles were fabricated to investigate the effect of Ge-profiling on cell performance. In this work, two different methods of C_{Ge}-grading were used; linear and nonlinear profilings. Cells with constant C_{Ge} in the a-SiGe:H light-absorbing layers were also fabricated to compare with the cells that had C_{Ge}-gradings.

The AES depth profiles of a-SiGe:H films with constant C_{Ge} and linear normal profiling are presented in Fig. 2(a), and those with nonlinear normal and reverse profilings are shown in Fig. 2(b). The thickness of the a-SiGe:H layer was 200 nm for all samples. The AES data in Fig. 2(a) shows that the C_{Ge} of the film deposited with GeH_4 100 sccm was approximately 33.0%, and that the Ge was uniformly distributed in the a-SiGe:H. Fig. 2(a) also shows that the C_{Ge} of the linear normal profiling sample changed linearly from approximately 33 to 0% and the average C_{Ge} in the film was 16.5%. The depth profiles of the nonlinear profilings are presented in Fig. 2(b). The C_{Ge} of the films with normal and reverse profiling decreased nonlinearly from approximately 33 to 0%, and increased from 0 to 33% in the depth direction, respectively. For the nonlinear C_{Ge}-profiled a-SiGe:H films, the average C_{Ge} was approximately 11.0% which is 5.5% smaller than that of the linear C_{Ge}-profiled film. To determine the bandgap energy (E_g) depending on the C_{Ge} of a-SiGe:H, the absorption coefficient of the films was obtained using UV-Vis spectroscopy. The E_g values of the films with C_{Ge} = 33, 16, and 0%, estimated by Tauc's plot, were 1.55, 1.66, and 1.75 eV, respectively, which were linearly decreased with respect to C_{Ge}. Then, the C_{Ge}-graded profiles correspond inversely to the E_g-graded profiles.

As briefly explained in the introduction section, the purpose of C_{Ge}-grading is to absorb a wide solar spectrum and to reduce the disadvantage of a Ge-rich region. However, to obtaining high efficiency, it is also very important that the C_{Ge}, i.e., E_g should be profiled to effectively collect carriers.

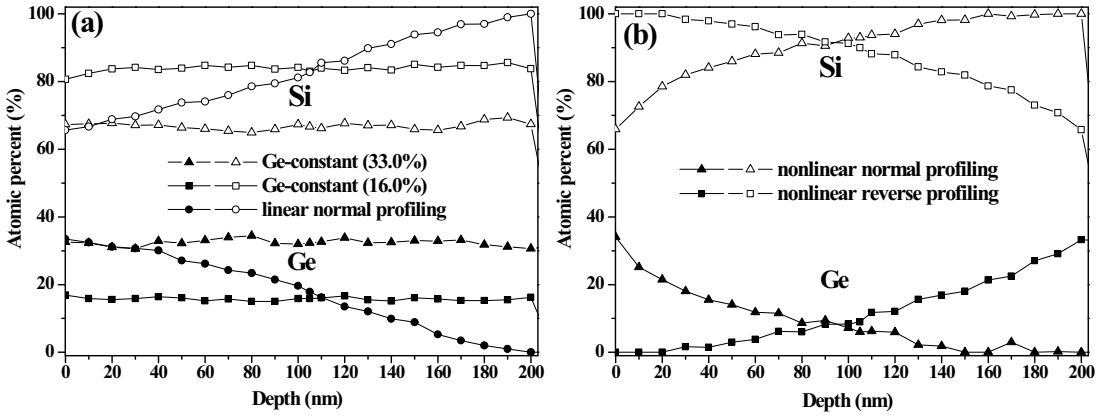

Fig. 2: AES depth profiles of a-SiGe:H films of (a) constant (33 and 16 %) and linearly graded C_{Ge} (33 - 0%) and (b) nonlinearly graded C_{Ge}-profiles (0-33 % or 33-0 %).

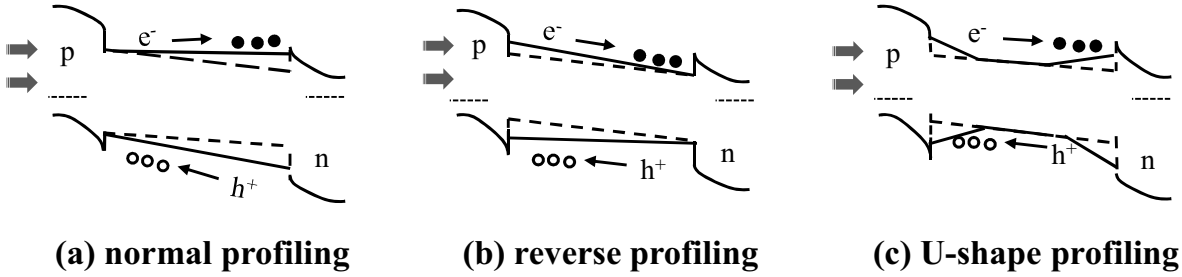
Figure 3 shows the schematic band-diagrams of thin film solar cells having a light-absorbing layer with E_g-profiles. As denoted by the arrows in the band-diagrams, the photo-generated holes and electrons are collected through p- and n-layers, respectively. The internal field in the light-absorbing layer with the E_g-profile could be enhanced either in view of hole or electron drift (Zambrano et al., 2004). The band-diagram of Fig. 3(a) shows that normal profiling can strengthen the internal field toward the p-layer and this allows holes to transport effectively from the n-side to the p-side in comparison to that of the E_g-constant light-absorbing layer denoted by the dotted line. On the other hand, the reverse profiling of Fig. 3(b) can enhance the internal field in the opposite direction to hole collection. With U-shape profiling, which is the complex structure of (a) and (b) as shown in Fig. 3(c), the additional internal field generates in the opposite direction to the carrier collections at both the p/i- and n/i-interface regions.



(a) normal profiling **(b) reverse profiling** **(c) U-shape profiling**

Fig. 3: Energy band-diagrams of the nip-type a-SiGe:H solar cells with (a) normal profiling, (b) reverse profiling, and (c) U-shape profiling; the dotted lines indicate the band-diagram of the cell with Ge-constant (33%).

For a-SiGe:H thin film solar cells, it has been reported that efficiency is limited by the collection of holes because the lifetime of holes is much shorter than electrons. Therefore, among the profilings shown in Fig. 3, the normal profiling is expected to be the most advantageous for the collection of holes in the nip-type a-SiGe:H solar cells fabricated in the present work.

To investigate which profiling is effective for obtaining high efficiency in practical a-SiGe:H thin film solar cells, single junction a-SiGe:H solar cells having different C_{Ge}-profiles were fabricated on opaque substrates. The cell performances are summarized in Table 1. The cell with linear normal profiling (Cell C) showed the highest conversion efficiency (η) of 6.30%. The η was approximately 20 and 29% higher than the cells with C_{Ge} = 33.0% (Cell A) and 16.0% (Cell B), respectively. The improvement of η was mainly attributed to the increase of fill factor (FF) which was induced by the improved shunt resistance. Normally, a strengthened internal field causes an increase in shunt resistance. It also has been generally known that the short-circuit current density (J_{SC}) of a-SiGe:H is considerably increased with increasing C_{Ge} (Agarwal et al., 2002). However, the Jsc of Cell C (15. 65 mA/cm^2) was a little higher than Cell A (15.43 mA/cm^2) although the average C_{Ge} of Cell C (16.5%) was much lower than that of Cell A (33.0%). In the case of Cell D with nonlinear normal profiling and an average C_{Ge} = 11.0%, the η was 6.10% and the J_{SC} was only 2.3% lower than that of Cell A.

The cells with reverse profiling (Cell E) and U-shape profiling (Cell F) showed an increased V_{OC} of 0.697V. The U-shape profiling consisted of 50 nm reverse profiling, 100 nm C_{Ge}-constant (C_{Ge} = 33.0%), and 50 nm normal profiling regions. The increased V_{OC} in both Cell E and Cell F could be explained that the wide bandgap region (C_{Ge} = 0%) of the a-SiGe:H layer was interfaced to the p-layer, as illustrated in Figs. 3(b) and (c). On the other hand, the J_{SC} of Cell E was significantly lower than that of Cell A. This might be because the C_{Ge} of Cell E was much smaller than that of Cell A and it was also difficult to collect holes due to the enhanced internal field in the opposite direction, as illustrated in Fig. 3(b). The generation of additional internal field in Cell E could be indirectly supported by the increase of shunt resistance compared to Cell A and Cell B with constant C_{Ge}, as shown in Table 1. In contrast to Cell C, Cell D, and Cell E with C_{Ge}-gradings, the shunt resistance of Cell F was rather decreased due to the additional internal field generated in the p/i- and n/i-interface regions in the opposite direction.

Table 1: Performance of the a-SiGe:H solar cell with different C_{Ge}-profiles

i-SiGeH layer (graded C_{Ge} from p- to n-side)		Cell ID	V_{OC} (V)	J_{SC} (mA/cm^2)	FF (%)	η (%)	R_{Sh} (Ω)	R_S (Ω)
Constant	C_{Ge} = 33.0%	A	0.669	15.43	50.8	5.24	1000	41
	C_{Ge} = 16.0%	B	0.703	13.83	50.2	4.89	1000	48
Linear normal profiling (from 33.0 to 0%) (average C_{Ge} = 16.5%)		C	0.679	15.65	59.3	6.31	2000	34
Nonlinear normal profiling (from 33.0 to 0%) (average C_{Ge} = 11.0%)		D	0.670	15.08	60.4	6.10	2100	31
Nonlinear reverse profiling (from 0 to 33.0 %) (average C_{Ge} = 11.0%)		E	0.697	10.43	58.9	4.28	1900	38
Nonlinear U-shape profiling (from 0% (p-side) to 33.0% (50 nm), constant 33.0% (100 nm) and 33.0 - 0% (n-side) (50 nm)) (average C_{Ge} = 22.0%)		F	0.697	13.15	42.3	3.87	890	57

The influence of C_{Ge}-grading on the the light-absorbing behavior was also examined by EQE measurement. Fig. 4 shows the EQE curves of the cells whose performances are listed in Table 1. The EQE curves of the cells with linear normal profiling (Cell C), nonlinear normal profiling (Cell D), and constant C_{Ge} (Cell A (33.0%) and Cell B (16.0%)) are presented in Fig. 4(a). The EQE values of Cell C and Cell D were larger than that of Cell A and Cell B in the wavelength region (500 – 730 nm) due to the enhancement of the internal field. In the long-wavelength region (730 – 850 nm), Cell C (16.5%) and Cell D (11.0%) showed smaller EQE values than Cell A (33.0%), but the EQE values of the Cell C and Cell D were significantly larger than that of Cell B (16.0%). The result clearly showed that the EQE values of Cell C (average C_{Ge} = 16.5%) and Cell D (average C_{Ge} = 11.0%) with graded C_{Ge}-profiles greatly increased compared to that with constant C_{Ge} (Cell B, C_{Ge} = 16.0%) especially in the long-wavelength region where the light-absorption is belived to depend

on the C_{Ge}, i.e. E_g. The EQE gain of Cell C and Cell D in the long-wavelength might be attributed to the presence of high C_{Ge} (> 16.0%) regions in the light-absorbing layer as well as the strenghtened internal field beneficially to hole collection.

In Fig. 4(b), the EQE curve of Cell D with the nonlinear normal C_{Ge}-profile is compared to the cells with different types of nonlinear profilings. In the case of the cell with reverse profiling (Cell E), which has the same average C_{Ge} as the Cell D, the EQE value was considerably smaller than Cell D in the wavelength region longer than 500 nm. It is thought to be owing to the internal field enhanced in the opposite direction to hole collection for the Cell E. The EQE value of the cell with U-shape profiling (Cell F) was also samller than that of Cell D in the wavelength region (500 - 730 nm). But, in the wavelength longer than 730 nm, the light-absorption of Cell F (average C_{Ge} = 22.0%) was larger than that of Cell D due to its much larger C_{Ge}.

The results shown in Fig. 4 and Table 1, clearly demonstrate that the normal profiling is the most advantageous for improving cell performance owing to the E_g-grading in the way beneficial to hole collection as well as the advantage to utilize a wide solar spectrum although the cell performance obtained using the single-chamber PECVD in this work was relatively low compared to reported performances of nip-type a-Si:H or a-SiGe:H thin film solar cells fabricated with multi-chamber systems (Cho et al., 2011; Li et al., 2006).

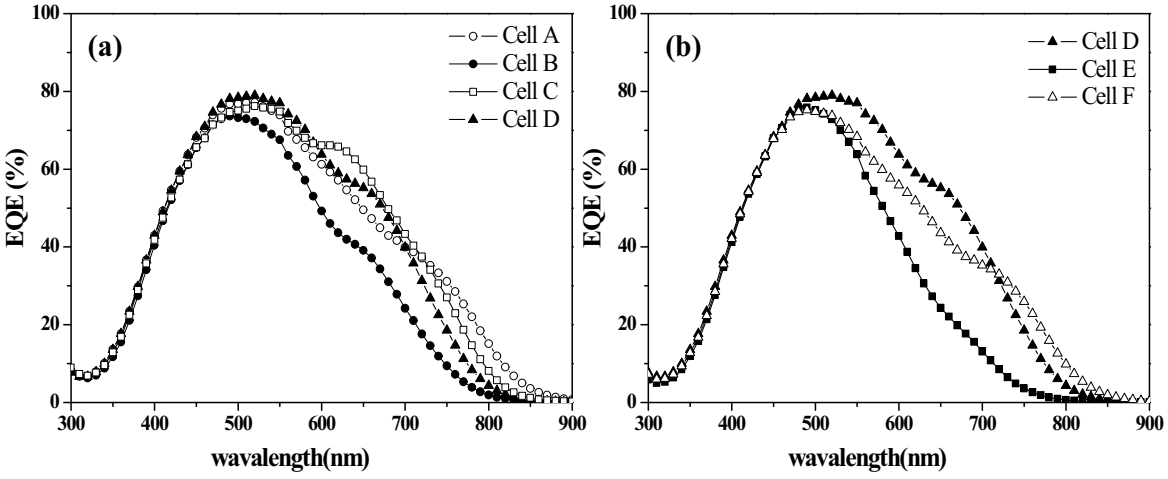


Fig. 4: EQE data of a-SiGe:H thin film solar cells listed in Table 1.

In order to consider the influence of C_{Ge}-grading on LID, the cells with C_{Ge}-constant (33.0%) (Cell A), linear normal profiling (Cell C), nonlinear normal profiling (Cell D), and nonlinear reverse profiling (Cell E) were light-soaked under 1sun at 25°C for 140 h. Fig. 5 shows the normalized FF and η as a function of light-soaking time. While there were not big differences between the cells in the V_{OC} and J_{SC} degradation behavior, the FF of Cell A was significantly decreased compared to the cells with C_{Ge}-graded profiling (Cell C, Cell D, and Cell E). Then, the η decrease of Cell A was approximately 40% while the η decrease of Cell C, Cell D, and

Cell E was approximately 25% by 140 h light-soaking. Especially, Cell C shows mostly the same LID behavior as Cell D and Cell E although the average C_{Ge} (16.5%) was considerably higher than the average C_{Ge} (11.0%) of Cell D and Cell E. The results obtained in this LID experiment clearly show that the C_{Ge}-grading in the light-absorbing layer of a-SiGe:H thin film solar cells is also advantageous for reducing LID, which has been considered to be a drawback of adding Ge in the light-absorbing layer.

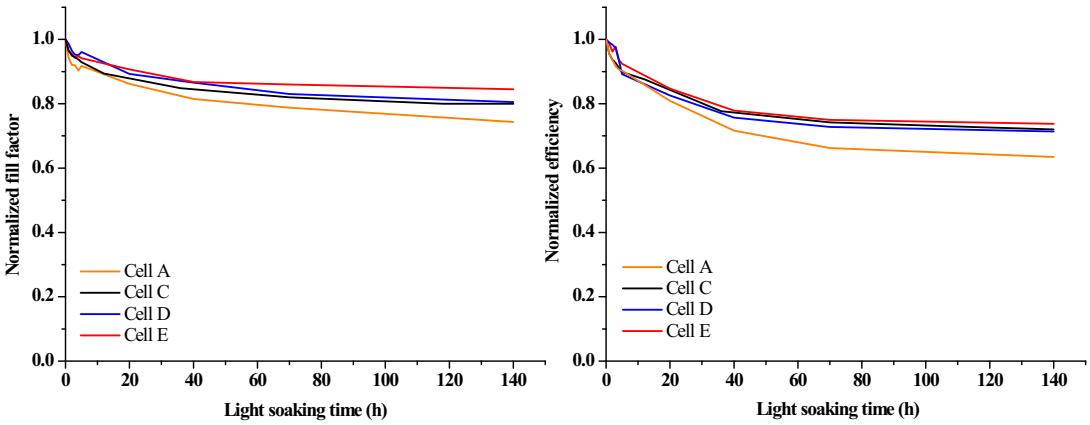

Fig. 5: Normalized FF and η of nip-type a-SiGe:H solar cells having graded C_{Ge}-profiles or constant C_{Ge} (33.0%) as a function of light-soaking time.

4. Conclusion

The influence of C_{Ge}-profiles on cell performance and LID was investigated for substrate-type a-SiGe:H thin film solar cells fabricated on opaque substrates. In this work, the cells with different C_{Ge}-profiles, such as linear normal, nonlinear normal, nonlinear reverse, and nonlinear U-shape profilings, were evaluated in comparison to that of constant C_{Ge}. The efficiency of cell with linear normal grading (average C_{Ge} = 16.5%) was 6.31% while the cells with constant C_{Ge} (16.0 and 33.0%) showed the efficiency of 4.89 and 5.24%, respectively. Among the C_{Ge}-profiles, normal profiling was found to be advantageous for enhancing light-absorption in the middle wavelength region because the E_g-grading was beneficial to hole collection. The LID experiment showed that the C_{Ge}-grading in the light-absorbing layer of a-SiGe:H thin film solar cells ~~is~~ was also advantageous for reducing LID. The use of C_{Ge}-profiling clearly shows that for nip-type a-SiGe:H solar cells, a light-absorbing layer with linear normal C_{Ge}-profiling is the most useful for obtaining high efficiency and long-term stability. The present work could suggest very useful C_{Ge}-profiling method for improving the performance of the a-SiGe:H single junction or a-Si:H/a-SiGe:H multi-junction solar cells.

Simulation and Optimization of Single Silicon Nanowire Solar Cell with Radial Junctions

Ali Alimardani, Ebrahim Asl-Soleimani and Ali Afzali-Kusha

School of Electrical and Computer Engineering, University of Tehran, Tehran, Iran

Abstract

In recent years, both solar cell research and nanowire research have become popular topics in design and fabrication of semiconductor devices. The need for higher solar cell efficiencies at lower cost has been the main concern of scientists and engineers. Nanowire solar cell is one candidate for decreasing the cost of solar cell fabrication. The nanowire geometry has many advantages over planar bulk and thin-film solar cells in processes of photoconversion. They reduce the quantity and quality of material necessary to obtain the limits, which leads to lower cost. In addition, complex single-crystalline nanowires are able to be fabricated directly on low-cost substrates and electrodes. In this work, we simulate single vertical nanowire solar cell made from silicon with radial junction, in order to examine the influence of the different parameters of the cell structure on efficiency. Length and diameter of the cell, thicknesses of regions, dopant type and concentration are these parameters. The simulations enable one to find the optimized structure and predict the fabrication process.

Keywords: *: Nanowire solar cell, Core-shell nanowire, Radial junction, N-p structure, N-i-p structure.*

1. Introduction

Solar energy harvest has attracted much attention in the previous decades. The need for higher solar cell efficiencies at lower cost has become apparent, and at the same time synthetic control in nanoscience has improved such that high-performance electronic devices are becoming possible (Cao et al., 2010; Gunawan et al., 2008; Ford et al., 2009). In recent years, Nanowire solar cells have been investigated for improving optical absorption (Adachi et al., 2010; Li et al., 2009; Lin and Povinelli, 2011; Sivakov et al., 2009; Tsakalakos et al., 2007;) , collection efficiency (Garnett and Yang, 2010; Law et al., 2005) and some other potential benefits over traditional wafer-based or thin-film devices related to optical, electrical, and strain relaxation effects. Bottom up grown nanowires, usually by the vapor-liquid-solid (VLS) method, offer a simple and large area compatible method for synthesizing a dense array of silicon nanowires on low cost glass substrates (Adachi et al., 2013). Ordered arrays of vertical nanowires with radial junctions take advantage of all mentioned effects, although solar cells made using axial junctions or random arrays can still have some benefits over planar cells (Garnett et al., 2011). Nanowire photovoltaic devices have been fabricated using variety of materials including silicon, germanium, zinc oxide, zinc sulfide, cadmium telluride, cadmium selenide, copper oxide, titanium oxide, gallium nitride, indium gallium nitride, gallium arsenide, indium arsenide, and many polymer/nanowire combinations (Fan et al., 2009; Greene et al., 2007; Varghese et al., 2009; Wang et al., 2011; Wei et al., 2009; Yuhas et al., 2009; Williams et al., 2008)

In this paper, we simulate a radial junction silicon nanowire in order to investigate the effects of length and diameter, doping type and concentration and thickness of each region, on output parameters. At first step, we study the influence of length and diameter of the nanowire cell. Secondly, the thickness of each region in p-n junction and p-i-n are taken into consideration. The thicknesses of p-type, n-type and intrinsic layers have impacts on charge separation and consequently on photoconversion due to difference in electric field distribution. The type of dopants for core and shell of the cell and also the concentration of them affect the diffusion length and amount of the charge reach the contacts. All these effects can be compared by examining the short circuit current, open circuit voltage and efficiency of the simulated cell.

2. The Structure of Nanowire Solar Cell

A TCAD device simulator is exploited to analyze the influences of design parameters like doping concentrations and types, and thicknesses under AM1.5 solar spectrum. The structure of simulated cell is defined as a p-n or p-i-n radial junction with transparent contacts on top and bottom. Outside of the cell is coated and passivated by a silicon nitride layer. Fig 1. shows the defined structure for p-i-n junction cell.

Inner active layer and outer active layer can be either p-type or n-type silicon, with different doping concentrations and different thicknesses. The layer between them is an intrinsic layer which is eliminated in some cases to compare the effects of its existence and thickness with other cases. Numerical solutions are obtained by discretizing the cell structure in grid points whose spacing has to be short enough to follow microscopic variations of geometrical and electrical parameters. Once the geometries of the cell have been defined, material electrical properties, minority carriers recombination, doping concentrations, etc. are set to perform the simulations.

Fig. 1: The structure of nanowire solar cell

3. Simulation Results and Discussion

3.1. Effect of Nanowire Length

In first step, we simulate the nanowire structure for different lengths of the cell. By assuming constant diameter of 200nm and n-p junction with same thicknesses and doping concentration of $5\times10^{17}cm^{-3}$, the influence of cell length is taken into consideration. Open circuit voltage, short circuit current and the efficiency of the nanowire cell for different lengths are as in Table.1.

Table 1. Open circuit voltage, short circuit current and the efficiency of the nanowire cell for different lengths

Length (μm)	0.5	1	2	3	4
V_{OC} (V)	0.409	0.416	0.417	0.414	0.410
I_{SC} (pA)	2.44	3.64	5.02	5.88	6.50
Efficiency (%)	2.35	3.51	4.74	5.43	5.87

Increasing the length, results in more generation along the cell and due to improved collection efficiency of nanowires, short circuit current get higher values. Open circuit voltage is changed a little by changing the length, therefore maximum power of the cells almost occur in same voltages. In consequence, output power and the efficiency of the cell improve in longer cells.

3.2. Effect of Nanowire Diameter and Dopant Types

In order to study the impact of core and shell dopant types, we simulate the structure in four forms, and with different diameters to consider the thicknesses. N-type core, p-type shell and vice versa without intrinsic layer, and with intrinsic layer are these forms of structure. We assume that the layers in each case have the same thickness. For examining the influence of nanowire diameter on output parameters, the cell with four mentioned forms is simulated in different diameters. Fig.2 shows the efficiency of these four forms with different cell diameters.

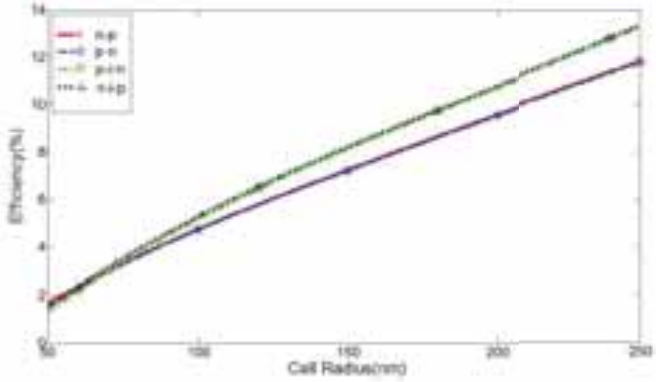

Fig. 2. The efficiency of different structure forms of nanowire solar cell with different lengths

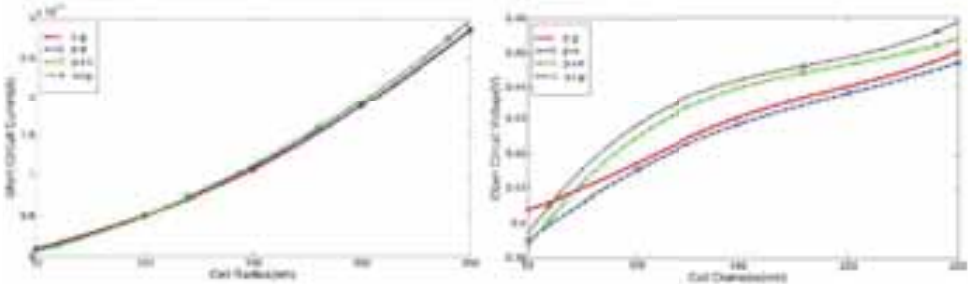

Fig. 3. (a) Short circuit current (b) Open circuit voltage, of different structure forms with different cell diameters.

It can be seen that in all cases, increasing the diameter improves the efficiency of the cell. These diameters are below the mean free path of the carriers, therefore almost all the generated carriers participate in the cell current. By increasing the area projected to solar light output power is increased due to higher level of photogenerated current and higher voltage. Fig.3.a and Fig.3.b show the short circuit current and open circuit voltage versus cell diameter.

It is shown that short circuit current changes almost proportionally to the area of the cells. But, longer diameter leads to higher open circuit and it will result in higher output power.

Another important phenomenon that should be taken into consideration is the difference between core and shell dopant type. Fig.2 shows that n-p junction (n-type core and p-type shell) has better efficiency than p-n junction cell. This improvement is not considerable and is due to difference in resistivity of the core and shell which also results in difference in open circuit voltage. This is also true for n-i-p in comparison with p-i-n structure.

Including an intrinsic layer in cell structure enhances the cell efficiency because electric field distributes in more positions across the nanowire and leads to higher voltages in constant diameters in comparison with structure with no intrinsic layer. Thus, open circuit voltage is also improves. Electric field distribution across the cell is shown in Fig.4.a and Fig.4.b for n-p and n-i-p structure.

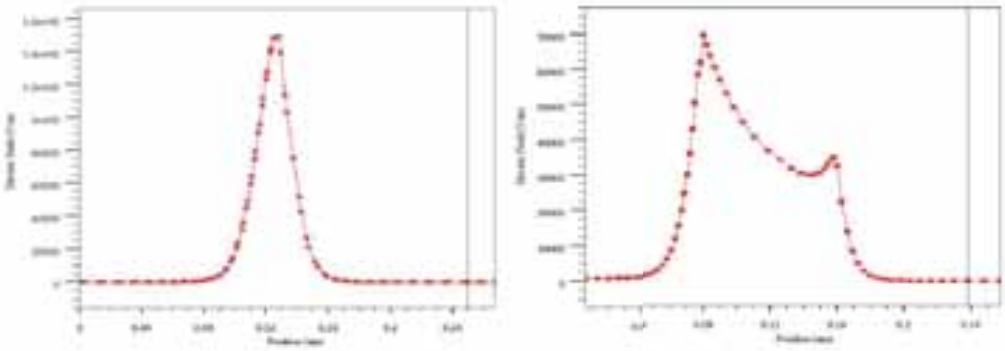

Fig. 4. Electric field along the radius of the cell, (a) p-n structure (b) p-i-n Structure

3.3. Effect of Active Layer Thicknesses

For next step, n-p and n-i-p junction cells are simulated with different active layer thicknesses. First, the n-p cell with radius of 100nm and then the n-i-p cell with radius of 120nm are studied. Fig.5.a and Fig.5.b show the efficiency of these structures respectively. In n-p cell the core radius is changed from 12.5nm to 87.5nm. In n-i-p cell, for three intrinsic thicknesses, the radius of the core is changed to investigate the efficiency.

It is depicted that by increasing the ratio of core thickness to cell thickness up to 0.6, the efficiency improves, but it reduces in higher ratios. This reduction is negligible in n-p structure. The thickness of intrinsic layer has different impacts on efficiency by changing the ratio. Thicker intrinsic layer raise the efficiency of the cell in middle ratios. But it causes reduction in efficiency in high and low ratios.

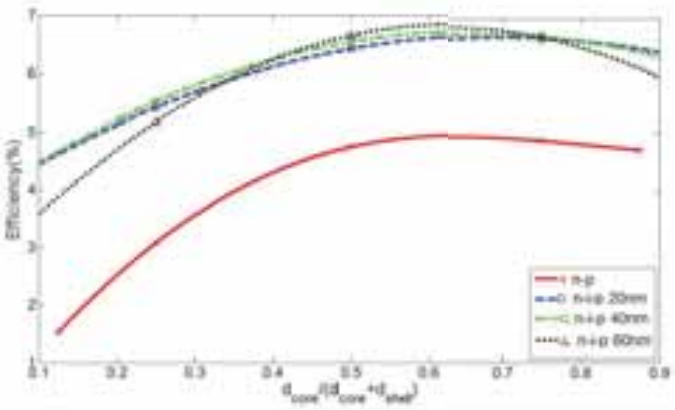

Fig. 5. The efficiency of n-p structure and n-i-p with different thicknesses of active layers

Fig.6.a shows the short circuit currents of both structures with variant core, shell and intrinsic layers' thicknesses and Fig.6.b shows their open circuit voltages.

It is seen that short circuit current increases when the ratio get higher values. The rate of this rise is higher in cell with thicker intrinsic layer. This is different for n-p structure in higher ratios. The intrinsic layer enhances the short circuit current in higher ratios. The open circuit voltage is determined by two parameters, the value of the electric field and the distance it distributes. In thinner intrinsic layer, in middle ratios, the value of electric field is higher and results in higher voltages. But while the ratio goes higher or lower, the distribution of electric field becomes the dominant parameter.

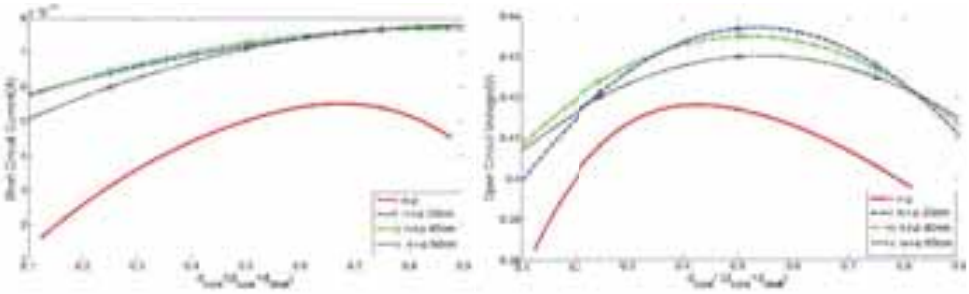

Fig. 6. (a) Short circuit current (b) Open circuit voltage of n-p structure and n-i-p with different thicknesses of active layers

3.4. Effect of Doping Concentration

Finally, the n-i-p structure with 40nm intrinsic layer, 20nm core and 60nm shell is simulated. The doping concentrations of both core and shell are changed in order to examine the efficiency, short circuit current and open circuit voltage. Fig.7 and Fig.8.a and Fig.8.b show these parameters.

It can be seen in Fig.7 that by increasing the doping concentration of both core and shell region, efficiency get higher values. The rate of increment reduces in higher concentrations. Short circuit current decreases because of more recombination in nanowire cell when doping concentration rises. But it enhances due to higher electric field especially near the junctions, thus different behaviors can be seen by changing the doping concentration in core and shell. Voltage changes by changing the electric field and in consequence it improves in higher levels of doping. By examining the Fig.8 it is confirmed that the efficiency in higher concentration of doping is higher because the voltage improves and the current does not change a lot. But in other concentration either current or voltage reduces considerably.

4. Conclusion

In this paper effective parameters of silicon nanowire solar cells' structure on efficiency are investigated by means of TCAD simulator. Length and diameter of the cell, thickness, type and doping concentration of p-type and n-type regions are studied. Longer and thicker cells have higher output powers and efficiencies.

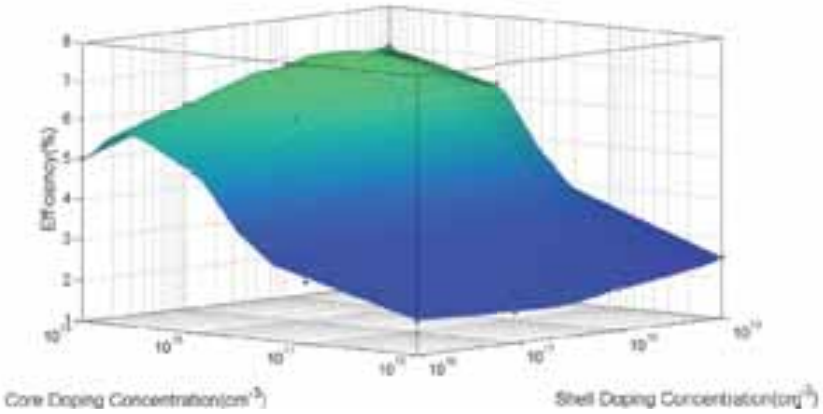

Fig. 7. The efficiency of the cell in different core and shell doping concentrations

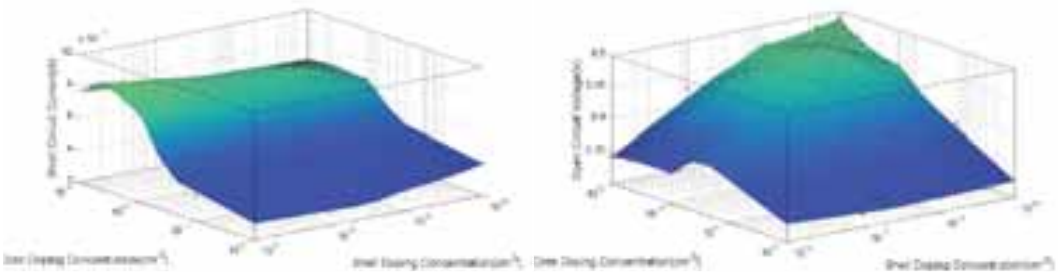

Fig. 8. (a) Short circuit current (b) Open circuit voltage of the cell with different core and shell doping concentrations

It is seen that n-p and n-i-p structures show better performance in comparison with p-n and p-i-n. Including an intrinsic layer in cell structure enhance the efficiency and in consequence, n-i-p structure shows the highest efficiency among the structures. For optimizing the thicknesses and doping concentrations different simulations are done. In different thicknesses the optimized structure is varied, it can be said that the efficiency of the cell with thicker intrinsic layer and core region got higher values. Increasing the doping concentration of the cell regions improve the efficiency. These analyzes will help one to optimize the structure of silicon nanowire solar cells before fabrication. By simulating all effects, generalizing and obtaining analytic relations from fitted curves, exact rules can be reached for predicting the optimized structures.

Simulation of the Properties of Nano-Grooved Back Reflectors for Increasing the Efficiency of Solar Cells

Ali Alimardani, Ali Afzali-Kusha, Mahmoud Shahabadi and Ebrahim Asl-Soleimani

School of Electrical and Computer Engineering, University of Tehran, Tehran, Iran

Abstract

In recent years, both solar cell research and nanostructure research have become popular topics in design and fabrication of semiconductor devices. The need for higher solar cell efficiencies at lower cost has been the main concern of scientists and engineers. By improving synthetic control in nanoscience high-performance electronic devices are becoming possible. The reflectors that are high-conductivity metals used as back contact in solar cells. Nano-grooved back reflectors can increase the efficiency of solar cells by improving the light–matter interaction near the mirror surface. In this work, we simulate and investigate the electrical and optical properties of these reflectors and their effects on solar cell efficiency. For this purpose, the properties of the back reflector in different wavelengths are examined and output parameters of a GaAs cell with a back reflector optimized for visible wavelengths are considered to find the appropriate absorber thickness.

Keywords: Mirrors, Back reflectors, Nano-grooves, GaAs Solar cell

1. Introduction

Mirrors are key components in optical systems and currently used as back reflectors in a wide range of optoelectronic devices. These reflectors are usually metals with high-conductivity and used as back contact in solar cells. When the planar mirrors are used, the phase reversal that occurs when light is reflected from a metallic mirror produces a standing wave with reduced intensity near the reflective surface. This results in efficiency degradation in solar cells because the magnitude of the local electric field strength is suppressed near the mirror surface and leads to decreased light–matter interaction. This problem shows its importance particularly in thin film devices with sub wavelength active layers. In order to overcome this issue magnetic mirrors are exploit to cause an electric field with its highest value right at the surface of the mirrors (Schwanecke, 2007). Using these mirrors, the direction of magnetic field of an incident light wave is changed instead of the electric field, and as a result overall intensity in active layer will not be reduced. As back-reflectors they can control the reflection phase of the incident light waves and therefore manipulate the field distribution and optical resonances. The idea of incorporation of such mirrors to enhance the light absorption in sub wavelength devices is used in some recent works (Genevet, et al., 2012; Dotan, et al., 2013). Variety of metallic structures have been used for designing nanostructure surfaces (Fedotov et al., 2005; Kildishev, et al., 2012). In (Esfandyarpour, et al., 2014) a nanoscale groove array is patterned into a conventional metallic mirror to make magnetic mirrors. The phase and magnitude of the reflected wave can be controlled by choosing the dimensions of these nano-grooves.

In this work we simulate a GaAs solar cell with nano-grooved back reflector using FDTD method. The array of sub wavelength grooves in silver mirror filled with ZnO can be designed in a way that reflects the incident light with desired phases and magnitudes, therefore the light intensity can be manipulated in distances near the surface of the reflector. As a result one can optimize the absorber layer for defined back reflector structure. For this purpose, first we examine the properties of the back reflector in different wavelengths, especially in visible range, by changing the depth and width of the grooves. This helps to determine the dimensions of the grooves according to the wavelengths of solar radiation that generate more carriers. This is done by simulating the nano-grooved arrays with different dimensions in different wavelengths. Then, the electrical properties of optimized absorber which is determined by reflector design are studied in sunlight

doi:10.18086/swc.2015.05.12 Available at http://proceedings.ises.org

spectrum and compared with conventional cells with planar reflector.

2. Cell Structure and Simulation

A TCAD device simulator is exploited to analyze the influences of design parameters like groove depth and absorber thickness and examine the output parameters including absorption, optical field, voltage and current.

The cell is made of a back reflector, an absorber layer and transparent top contact. The back reflector is an array of sub wavelength grooves in silver mirror filled with ZnO that also can be serves as back contact. Absorber is an ultrathin GaAs layer that deposited on mirror surface.

Fig. 1b and Fig. 1c show the back reflector and compares the field distribution of it with planar back mirror (Fig. 1a). They show how the reflection of normally incident, 800 nm light from a conventional, silver mirror results in a standing wave with a suppressed electric field near its surface. A very similar field profile results when a reflector with a periodic groove array is illuminated with transverse electric (TE-polarized) light (Fig. 1c). The result changes when the grooved mirror is illuminated with transverse magnetic (TM-polarized) light (Fig. 1c). For this polarization the field profile shifts by a quarter wavelength and a standing wave with a maximum electric field near the surface of the mirror is produced.

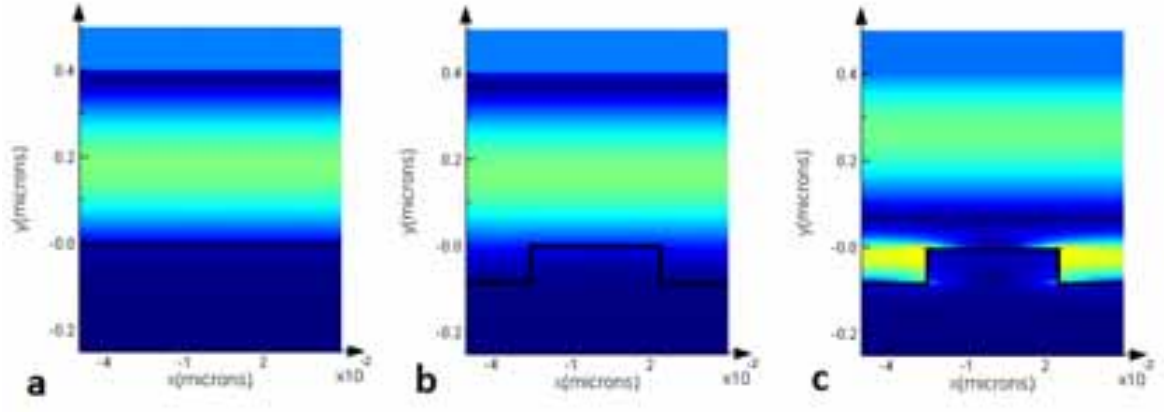

Fig. 1: Electric field distribution in a- Planar back reflector. b- Unit cell of nano-groove back reflector with TE polarization of incident light. c- Unit cell of nano-groove back reflector with TM polarization of incident light

3. Results and Discussion

In planar metallic mirrors, the reflection phase of incident light is related to the penetration and energy storage inside the metal which are fixed at each wavelength for a given metal. But in mirrors made by implementing periodic nano-grooves in silver back contact, by changing the dimensions of the grooves, different phases and magnitudes of reflected light wave in each wavelength can be reached. Fig. 2. shows $|E|^2$ which represents the light intensity, from the surface of mirror in Y-direction in three wavelengths of incident light with three groove depths and compare it with planar mirror.

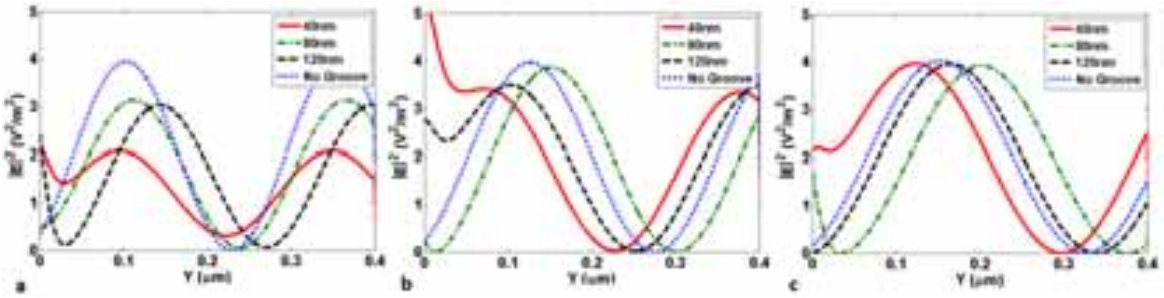

Fig2: $|E|^2$ distribution from the surface of mirror in Y-direction with incident wavelengths of a- 500nm, b- 600nm and c- 700nm with three groove depths and planar mirror.

It is seen that near the surface of planar mirror light intensity is about zero as it is predicted, but by implementing the nano-grooves and changing the reflection phase the light intensity has different value near the surface. The groove depths determine the intensity of light at the mirror surface and distances from that. In each wavelength, according to the light intensity profile which depends on groove depths, different absorber thicknesses may be optimal. In other words, if the thickness of absorber layer varies, the depth of the groove that causes the maximum absorption may differ. For example, for incident light of 500nm, if the absorber layer is about 30nm thick, groove depth of 40nm will make more absorption in cell than the other depths. But if the thickness of absorber layer is assumed to be about 120nm, the optimum groove depth will be 80nm.

In different wavelengths, also the influence of groove depth is different. For instance, it can be seen that the intensity of light wavelength of 600nm has higher value at the surface of the mirror with 80nm groove depth than 120nm. But this is opposite, in wavelength of 700nm. These figures show that absorber thickness, wavelength and groove depth are the key parameters for designing the solar cell with nano-groove back contact (by assuming fixed period of nano-grooves). Implementing the absorber layer changes the profile of electric field because of the reflection in interfaces of the layer and its absorption. Fig. 3. shows this profile for the cell with 100nm absorber thickness, incident light wavelength of 600nm and three groove depths.

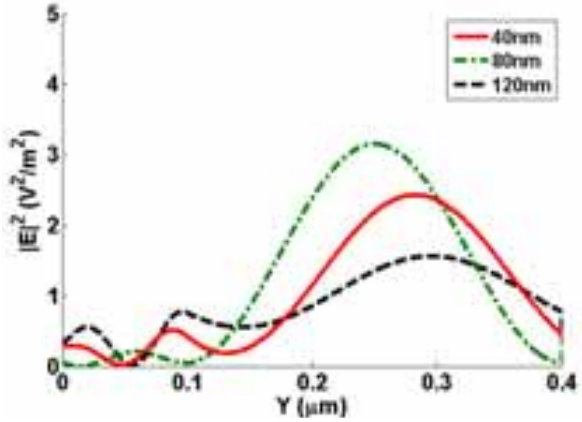

Fig. 3: $|E|^2$ distribution from the surface of the nano-grooved back reflector with existence of GaAs absorber layer and incident light of 600nm.

It is shown that light intensity has different profiles with changing the groove depth, thus, the thickness of the absorber layer which located on the surface of the mirror define the total absorption of the cell. For instance, if we assume that the absorber thickness is 100nm, it can be concluded that implementing 120nm groove depth in back reflector will result in more absorption than the other groove depths in this wavelength.

The electric field in absorber layer determines the absorption and in consequence, photogeneration in the cell. Fig. 4. shows the absorption of the cell in three wavelengths (500nm, 600nm and 700nm) with different groove depths and absorber thicknesses.

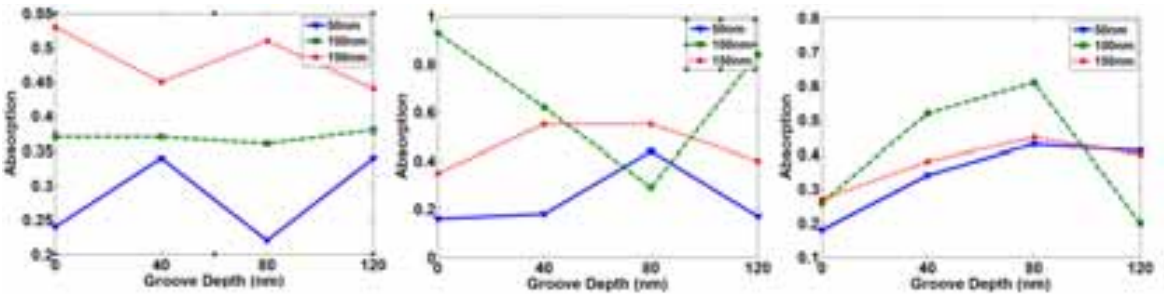

Fig. 4: Absorption of the cell with no groove and three groove depths, three absorber thicknesses and with incident wavelength of a- 500nm b- 600nm c- 700nm.

With incident wavelength of 500nm, increasing the absorber thickness results in more absorption, but groove depth has different effects in each thickness. The groove depth of 40nm in 50nm absorber thickness causes more absorption than the other but this is 80nm for thickness of 150nm. With two other wavelength of incident light wave, it is seen that absorber with 100nm thickness may have more absorption than 150nm thickness which is completely related to electric field distribution in this layer. Some groove depths in all wavelengths may cause less absorption in the cell than planar mirror. But total absorption in all wavelengths of solar radiation with consideration of absorber thickness will determine the absorbed power of the cell.

The absorption of the devices shows the available current they can produce in each wavelength. This analysis is necessary for all photodetectors, but is not enough for solar cells. In solar cells, the total absorption in all wavelengths of solar radiation should be considered. Thus, calculating the optimum thickness of absorber layer and groove depth is differ from single wavelength and the simulation results of light wavelengths in visible range that generate more carriers, can be a guideline to design better structures.

In solar cells, in addition to optical parameters including absorption and light intensity, electrical parameters should be taken into consideration. Therefore, semiconductors' equations also solved for the cell structure assuming a p-n junction in absorber area, and conventional output parameters of solar cells like short circuit current, open circuit voltage and efficiency are extracted. Fig. 5. Shows these parameters for three structures with different groove depths and compare them with a structure with conventional planar mirror.

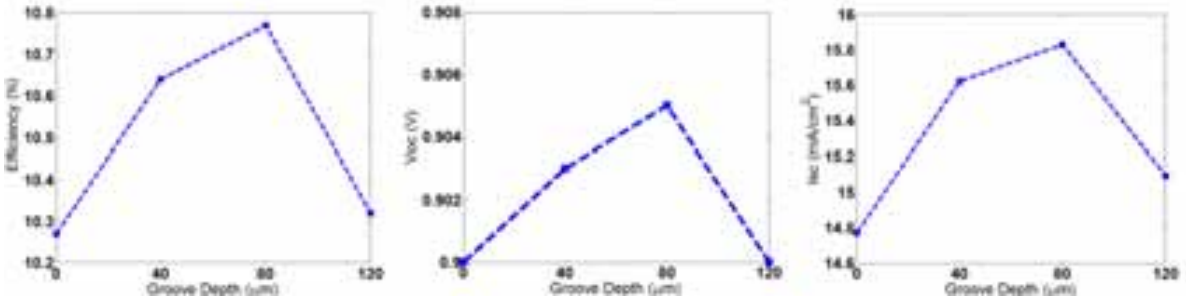

Fig. 5: a- Efficiency b- Voc and c- Isc for solar cell structure with no groove and three groove depths and absorber thickness of 100nm

It is depicted that patterning the nano-grooves in back reflector, can increase the photogenerated current and thus the efficiency of the solar cell. Open circuit voltage is changed slightly because it is strongly depends on the properties of absorber layer. Photogenerated current has logarithmic effect on this voltage. In different thicknesses of absorber layer, implementing the nano-grooves may result in different improvement and the optimum depth of groove may also change. In the simulated structure with absorber layer of 100nm, the optimum depth is 80nm.

4. Conclusion

In this work, the idea of patterning nano-grooves in back reflector of ultrathin solar cells is investigated. These grooves will make the reflector act similar to magnetic mirror which can increase the light intensity near the surface of the mirror. This improves the absorption and thus photogeneration in absorber layer and is considerable, especially in very thin solar cells. In order to examine the properties of these mirrors and finding the guidelines to design them for higher efficiency, the structure with different dimensions, incident wavelengths and in exposure of solar radiation is simulated and analyzed. Design of optimum structure depends on the constituent materials, absorber thickness and grooves' depth. Therefore, for a cell with given materials and absorber thickness, the groove thickness can be optimized by simulations. Engineering the shape and dimensions of these types of mirrors as reflectors in solar cells may lead to fabrication of new kind of ultrathin solar cells.

Abstract

This paper centers on the development of a micro-scale combustion-driven thermophotovoltaic (TPV) power generation system. The Micro-TPV system is a direct energy conversion device. It does not have any moving parts, and it converts the thermal power to electrical power directly. In this thesis, the first task is to design a combustor as an emitter for TPV power system. The characteristics of the combustor are to use catalyst tube with specific configuration and fuel/air mixture deployments to overcome the shortcomings of combustion instability and radical termination in a small-scale confined channel. Backward-facing step and perforated platinum tube are employed in a small-scale combustor to enhance flame stabilization and extend stable flammability. The stable operating range of the proposed tubular combustor is also verified.

Keywords: *thermophotovoltaic, platinum, emitter, combustion-driven.*

1. Introduction

Thermophotovoltaic (TPV) is a direct heat to electricity conversion approach, and the TPV conversion concept is straightforward. Thermal or infrared radiation is converted by a photovoltaic (PV) cell into electricity, and it is analogous to solar radiation converted by a PV cell into electricity. Compared to solar PV, TPV has two advantages. One is that TPV conversion is applicable to any high temperature heat source including the solar, combustion, nuclear and waste heat sources. Accordingly, using combustion to generate thermal radiation is considered as combustion-driven TPV system. The second benefit is that the efficiency can be enhanced by the control of the absorbed spectrum in the PV cell compared to solar PV. Nevertheless, combustion-driven TPV power generator is one of promising approaches to simultaneously harvest electric power and heat output. Because it does not involve any moving parts, its fabrication and assembly are relatively simple and easy. Research interest in combustion-driven TPV power generator has received intensive attention recently. Chou *et al.* (2014) designed a small-scale combustor with SiC porous medium and engaged in TPV system with the benefit of uniform thermal radiation. Li *et al.* (2010, 2011a, 2011b) attempted to convert flame radiation into electrical output via photovoltaic cells, to add iron pentacarbonyl into liquid hydrocarbon fuels for enhancing flame radiation and to coat metal oxide layer on a quartz tube for improving radiant efficiency. Li *et al.* (2009) and Yang *et al.* (2002) proposed a hydrogen-fueled micro-TPV combustor, and used backward facing step as flame stabilization mechanism. Besides, Yang *et al.* (2005) tested different emitting materials for enhancing radiant efficiency. Ferrari *et al.* (2014) outlined the current state-of-the-art of TPV system, and assessed the energy conversion of each component in TPV system.

Undoubtedly, the high surface-to-volume ratio of a small-scale combustor could lead to increasing heat loss to the surroundings and the possibility of radical termination on the wall. These effects may greatly reduce flame stability and fuel conversion efficiency in a small-scale combustor. In order to extend the stable

doi:10.18086/swc.2015.05.13 Available at http://proceedings.ises.org

operating range of a small-scale combustor, the utilization of quenching-resistant fuel, such as hydrogen (Zarvandi *et al.*, 2012), and catalytic materials (Li *et al.*, 2012), such as noble metals, in a small-scale TPV system has been considered as a promising manner to alleviate the above mentioned shortcomings. Since catalytic material is an important reaction enhancer for small-scale combustor, a novel concept is proposed here to use platinum, a noble metal, as the catalyst and the emitter for the small-scale TPV system. Besides, platinum is not only a catalytic material, but also a selective material (Yang *et al.*, 2005). The spectrum of illumination from platinum is prone to congregate in shorter wavelength region due to its larger emissivity in this region. Furthermore, it is much easier to manufacture a platinum emitter than the other selective emitters such as micro-machining tungsten and rare-earth oxide. For the quenching-resistant property, hydrogen is a promising fuel candidate for small-scale TPV power system due to its inherent large thermal diffusivity and high sticking coefficient to catalyst. Furthermore, hydrogen is a high-energy-density and quenching-resistant fuel. Therefore, hydrogen is a candidate for applying in micro-TPV power system. Platinum tubes are often used as a catalyst for hydrogen-fueled small-scale combustors [Volchko *et al.*, 2006]. However, the low volumetric energy density of hydrogen leads to the small-scale combustor that has to be operated at high fuel mass flow throughout. The high mass flowrate would further reduce the residence time for flame stability and complete combustion. Therefore, the flame-stabilizing mechanism is a pivotal consideration in small-scale combustor design.

In a small-scale channel, the mechanism of flame stabilization is strongly related to combustion efficiency and operational range. Akram and Kumar (2011) experimentally investigated combustion behaviors of methane-air mixture in meso-scale diverging channels, which showed an enhancement of flame blow-off limit compared to the plain channel. Wan *et al.,* (2015) implemented a wall cavity in a micro channel to extend the flame blow-off limit of H_2-air combustion. Li *et al.* (2012) applied the cavity flame holder to micro-channels with segmented catalyst on the inner walls. Nonetheless, non-uniform illumination of the emitter and reduced overall efficiency of TPV system are usually related to using improper flame stabilizers in a micro channel. Therefore, in the present study, a novel combustion chamber design is originated from the concept of our previous study with regard to segmented catalyst with cavity in a channel. In order to apply this concept to combustion-driven TPV system, a platinum tube with perforated-hole array is proposed and used as catalyst, emitter, and flame stabilizer to overcome the critical heat loss and to improve the flame instability. Concept, design, and demonstration of the small-scale tubular platinum combustor with perforated-hole array for future application in a small TPV power generation system are addressed and discussed in this paper.

2. Conception of the small-scale combustor

In our previous paper (Li *et al.*, 2012), applying segmented catalysts with cavities in a channel can integrate advantages of homogeneous and heterogeneous reactions, and enhance fuel conversion. The heterogeneous reaction in a prior catalyst segment produces chemical radicals and catalytically induced exothermicity, and homogeneous reaction can be subsequently ignited and anchored in the following cavity. The presence of cavities appreciably extends the stable operational range of the micro-reactor for a wide range of inlet flow velocities. To demonstrate and verify the above mentioned concept that is feasible in a small-scale TPV combustor, a preliminary numerical simulation is performed prior to experiments. A commercial code, CFD-ACE+, is modified to incorporate the detailed gas-phase and surface reaction mechanisms in CHEMKIN formats for the simulation. For simplicity, the small-scale combustor is modeled as a two-dimensional system. The platinum tube has two segments, 4.5 mm and 24.5 mm long, respectively, as shown in Fig. 1. The distance between segmented tubes is 1 mm. The dimension of segmented platinum tube is 5.3 mm in inner diameter and 6 mm in outer diameter, and the dimension of quartz tube is 8 mm in inner diameter and 10 mm in outer diameter. Accordingly, the area of cross section for inner tube and annular tube are approximate. The total length of the reaction channel is 30 mm long. The inner and outer equivalence ratios of the hydrogen-air mixtures are 0.3 and 0.6, respectively. The inlet temperature is 300 K. A uniform velocity profile is specified at the inlet and the flow velocity is fixed at 20 m/s for the platinum tube with and without segmentation. At the exit, pressure is specified with a constant ambient pressure of 101 kPa and an extrapolation scheme is used for species and temperature.

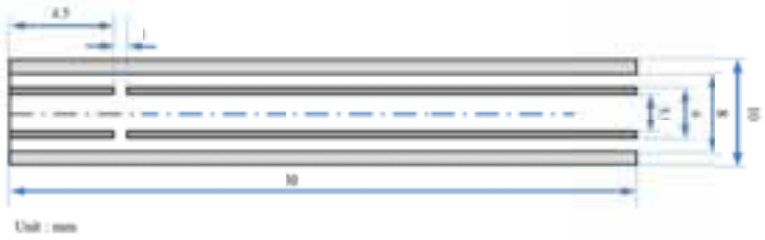

Fig. 1: Schematic diagram of segmented platinum tube for numerical simulation.

Chemical reaction mechanisms are used in the gas phase as well as on the catalyst surface. The homogeneous reaction mechanism of hydrogen-air combustion composes of 9 species and 19 reaction steps; these are adopted from the mechanism proposed by Miller and Bowman [1989]. The surface reaction mechanism is compiled primarily from that proposed by Deutschmann et al. [1996]. These reaction mechanisms have been used in previous studies and the comparisons with experimental results are satisfactory [Chen *et al.*, 2006].

Figure 2 compares the computed H_2 and OH mass fractions in both catalyst configurations. As to the conventional plain platinum tube, H_2 at the inner surface is initially reacted heterogeneously and provides catalytically induced exothermicity to assist hydrogen conversion at the outer surface, as seen in lower panel of Fig. 2. The overall fuel conversion rate of the conventional plain platinum tube is 83.8%. According to the computed OH mass fraction, the catalytically induced combustion is anchored on the outer catalyst surface. However, the anchoring position of gas-phase reaction is strongly related to the inlet condition in a conventional plain platinum tube. As to the segmented platinum tube, the distance for completion of hydrogen conversion is shorter than that in a conventional plain platinum tube. The overall fuel conversion rate of the segmented platinum tube is 95.2%. The gas-phase reaction is anchored on the gap between two tubes, as seen in the upper panel of Fig. 2. It appears that the gap between two tubes can enhance the flame stabilization by means of providing a low-velocity zone as well as collecting heat and chemical radicals from both sides. Consequently, the distribution of different equivalence ratios of fuel/air mixtures along both sides of catalyst surface can mutually assist heterogeneous and homogeneous reactions in a confined space, and hence prevent heat loss to the tube wall. The preliminary computation confirms that the proposed concept is applicable to a small-scale perforated-platinum combustor.

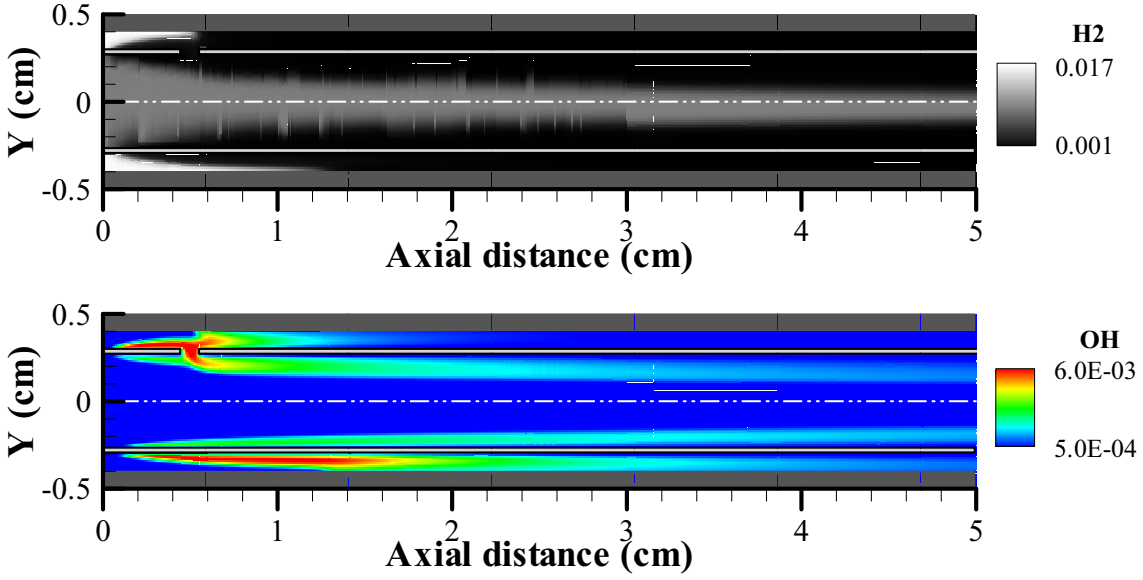

Fig. 2: Comparison of the computed contours of H_2 and OH mass fractions for the platinum tube with and without segmentation. The inner and outer equivalence ratios are 0.3 and 0.6, respectively, with the inlet velocity fixed at 20 m/sec.

3. Experimental apparatus

In order to realize the concept of segmented platinum tube in a confined channel, a small-scale platinum tube with perforated-hole array is designed in this study. The function of perforated-hole array is to simulate the gap between two platinum tubes. Figure 3 shows the schematic diagram of the proposed platinum combustion chamber with perforated-hole array and its corresponding pipes. The dimension of the platinum tube is 5.3 mm in ID, 6 mm in OD, and 30 mm in length with six perforated holes (1 mm in diameter) equidistantly placed around the tube at 5 mm away from the bottom of the platinum tube. The platinum tube is connected with a stainless steel tube with 1 mm in ID and 2 mm in OD. It makes a backward-facing step, which of length is 5mm, in the connection section. The platinum tube is confined in the quartz tube, which has a diameter of 8 mm in ID and 10 mm in OD. Hydrogen, utilized as fuel, and air are metered with electronic flowmeter (Brooks, 5850E) and calibrated in the range of 0-20 standard l/min. The pre-chamber filled with steel wool can provide a space to mix the fuel/air, as shown in the right hand-side of Fig. 3. Well premixed fuel/air mixtures with different equivalence ratios are separately delivered to the inner and outer tubes. The Reynolds number ranges from 377 to 1258 in the experiments. Therefore, the flow is assumed to be in laminar regime. In this study, two different platinum tubes, the conventional plain and perforated platinum tubes, are employed in the experiments to investigate the effects of fuel/air distribution and inlet flow velocity on the performance of the small-scale combustor. Figure 4 shows the experimental setup. A digital camera is used to record the combustion phenomenon in the combustor. For the irradiance measurement, the platinum combustor has to place inside the integrating sphere and the resulting radiant intensity is measured by the spectrum meter (Oceanoptic, USB2000+XR1), which has a uniform quantum efficiency ranging from ultraviolet (200 nm) to near-infrared (1050 nm) wavelength region. Various fuel/air mixtures are separately deployed and delivered to outside and inside of the tube, and the combustion phenomena of two platinum tubes are individually recorded via a digital camera. For monitoring temperature distribution and radiant intensity of two platinum tubes, an infrared thermal camera and a radiometer are used and recorded via a computer.

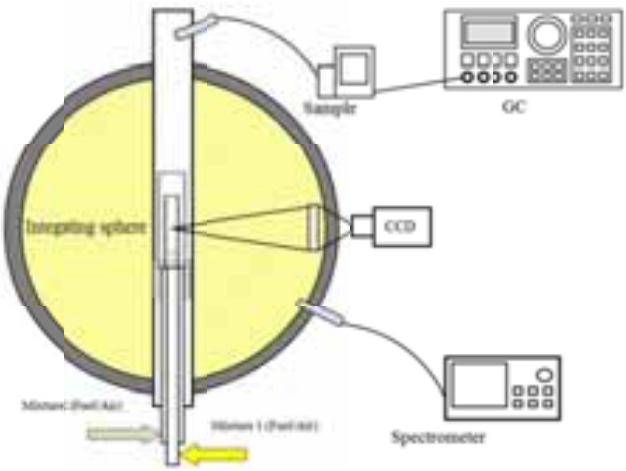

Figure 4: Schematic diagram of the experimental setup.

4. Results and discussion

Figure 5 shows the photograph of combustion phenomenon for two combustor cases under fixed fuel/air equivalence ratios and various inlet velocities (V = 5 and 10 m/s). The stream of ER = 0.6 mixtures is prone to induce both heterogeneous and homogenous reactions, while the ER = 0.3 stream induces only heterogeneous reaction. When ER_{in} = 0.3 and ER_{out} = 0.6, there is only heterogeneous reaction on the conventional plain platinum tubular combustor due to heat loss and the lack of flame stabilization mechanism, as shown in Fig. 5a. With the perforated-holes, the catalytically holding combustion can be seen on the tube (Fig. 5b). When the inlet velocity is increased to 10 m/s, the radiation from the two tubes becomes much brighter than the previous cases (Figs. 5a and 5b). This is due to that catalytically holding combustion can be induced and stabilized inside the combustion chamber under the flammable fuel/air condition. It is noted that there are bright illumination regions congregated in the downstream part of the conventional plain platinum tube under the condition of ER_{in} = 0.3 and ER_{out} = 0.6 (Fig. 5c). In principal, extensive hydrogen reaction on the outer surface of the catalyst can release large amount of catalytically induced exothermicity, which can sufficiently compensate the heat losses. Besides, when the inlet flow rate is further increased, the residual hydrogen can induce gas-phase reaction in the downstream of the platinum tubular combustor. As to the perforated platinum tubular combustor, it can be seen from Fig. 5d that flame is anchored on the perforated holes of the platinum tube. The presence of flame not only accelerates fuel conversion, but also heats up the platinum tube to become a bright emitter. Figure 6 displays the measured surface temperatures along the platinum tubes for the case of ER_{in} = 0.3, ER_{out} = 0.6 and V=10 m/s. The surface temperatures of the perforated-hole platinum tubular combustor are much higher than those of the conventional plain platinum tubular combustor. This is because that both heterogeneous and homogeneous reactions occur in the perforated platinum tubular combustor, but only heterogeneous reaction takes place in the plain platinum tubular combustor.

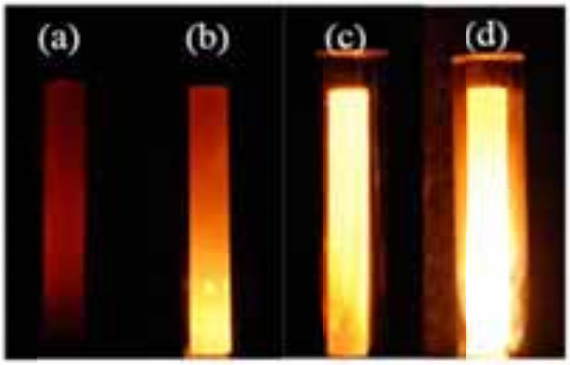

Figure 5. Photograph of combustion phenomenon for the cases: a conventional plain (a,c) and perforated platinum (b)(d) tubular combustor under the condition of ER_{in}=0.3 and ER_{out}=0.6 and various V=5 m/s (cases of a and b) and 10 m/s (cases of c and d). (The exposure time of photograph is fixed in 1/200 sec.)

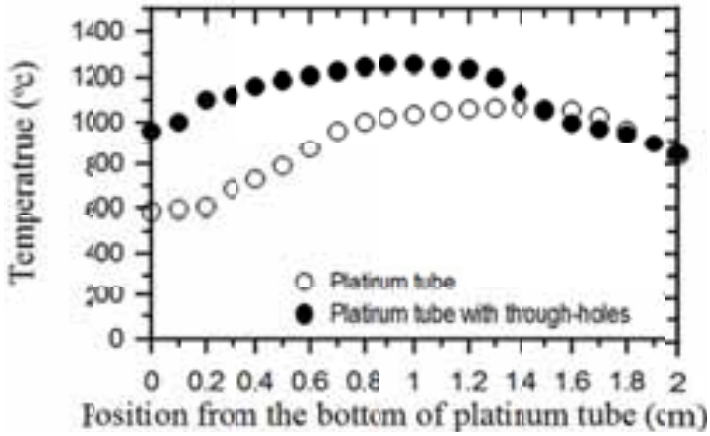

Figure 6. The measured surface temperatures along the plain and perforated platinum tubular combustors for the case of ER_{in} = 0.3, ER_{out} = 0.6 and V=10 m/s.

Figures 7 shows the operating range of the plain and the perforated platinum tubular combustors, respectively, with various fuel-air distributions under V = 10 m/s. Four distinct combustion phenomena, i.e., no illumination, heterogeneous reaction with dim red illumination, hetero- and homogeneous reaction with moderate illumination, and the combined hetero-/homo-geneous reaction with bright illumination, are identified by image observations and wall temperature measurements. For the plain platinum tubular combustor, conditions for bright incandescent illumination congregate in the higher inner and outer equivalence ratios (see Fig. 7a). The bright incandescent region is congregated in larger inner and outer equivalence ratios. The presence of backward-facing step in the conventional plain platinum tubular combustor primarily stabilizes the flame inside the tube, and heat loss from the tube can be reduced by means of heat release from catalytic induced exothermicity on the surface. Consequently, excessive fuel consumption in one side is necessary to sustain catalytically stabilized thermal combustion in the other side. Comparison of Figs. 7a and 7b indicates that the operating range with bright incandescent illumination for the perforated tubular combustor is much larger than that for the plain tubular combustor under the conditions of larger outer equivalence ratio. This is attributed to the presence of perforated holes for flame stabilization. The operating range of bright incandescent illumination for the perforated platinum tubular combustor is remarkably extended, especially for lower inner equivalence ratios. Regarding to the irradiance, the plain and perforated platinum tubular combustors are placed inside the integrating sphere connecting to spectrometer under the fixed equivalence ratios (ER_{in} = 0.3, ER_{out} = 0.6) and flow velocity (V=10 m/s). The measured irradiances are 18,052 W/m^2 for the conventional plain platinum tubular combustor and 19,858 W/m^2 for the perforated platinum tubular combustor.

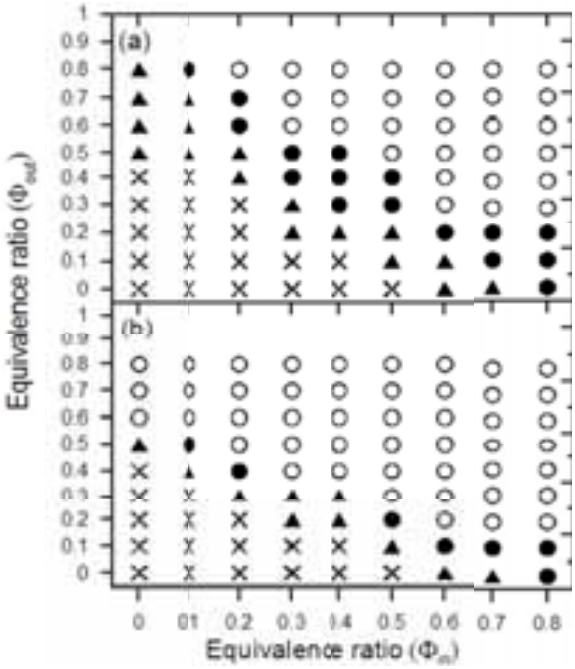

Figure 7. Operating range of a (a) plain and (b) perforated platinum tube under the condition of inlet flow velocity of 10 m/s. Symbols: (×) no illumination, (▲) heterogeneous reaction with dim red illumination, (●) combined hetero-/ homo-geneous reaction with illumination, and (○) hetero- and homogeneous reaction with bright illumination.

5. Conclusions

The result of a simplified simulation supports the concept of sustaining catalytic combustion on a platinum wall with a gap, and flames anchoring on the wall can contribute to efficiently heat up the wall temperature. For testifying the concept of our proposed micro-TPV combustor, an experimental study on the performance of the proposed perforated-platinum combustion chamber is made under various equivalence ratios and inlet velocities. Results demonstrate that the perforated-platinum tubular combustor can sustain the heterogeneous and homogeneous reactions, extend the operating range of the combustor, and enhance the incandescent illumination of the platinum tube. Besides, delivering fuel/air mixtures into two sides of platinum tube can reduce the heat loss from the chamber wall, and a perforated-hole can sustain flames anchoring on the wall in various flow velocities. These two novel approaches realize the application of simultaneously flame stability in a small-scale system and high illumination on the chamber wall. Therefore, the perforated-platinum

tubular combustor can serve as an effective emitter for the small-scale TPV power generation system as compared to the plain platinum tube. These facts suggest that future application of the proposed concept and design of the perforated-platinum combustor to a small-scale TPV power system is feasible.

Electrical PV Array Reconfiguration Strategy against Partial Shading

Robert Alfie S. Peña[1,2], Erees Queen B. Macabebe[1] and Davide Del Col[2]

[1] Department of Electronics, Computer, and Communications Engineering, School of Science and Engineering, Ateneo de Manila University, Quezon City 1108, Philippines

Abstract

Partial shading presents a huge problem for photovoltaic (PV) arrays because of mismatch losses. One way to maximize power output is to make the arrays dynamic. These dynamic PV arrays change configuration depending on shading pattern and strength. This work evaluates the electrical PV array reconfiguration (EAR) strategy in dynamic arrays that use total-cross tied topology through modeling and simulation. The approach searches for the optimum configuration which has the most equal row irradiance averages. A static 3×3 PV array model and a dynamic PV array model, which uses the EAR algorithm, were developed. The models were tested for binary- and random-irradiance shading. Results show that the EAR strategy suits some shading patterns and that the irradiance distribution affects improvement in power output. The simulations performed demonstrate both the limitations and benefits of using the EAR strategy in PV array reconfiguration.

Keywords: *electrical PV array reconfiguration, dynamic PV array, partial shading, simulation*

1. Introduction

Partial shading in photovoltaic (PV) arrays causes losses in power output. The different irradiance levels produce different current values. Thus, when modules exposed to different irradiance levels are connected in series, the total current is limited by the module with the lowest generated current. This mismatch in current can be reduced when other array topologies are used such as total cross-tied configuration (TCT). However, even with such change, different values for row currents still produce mismatch. Thus, dynamic PV arrays are introduced.

This paper explores dynamic reconfiguration in PV arrays with a view toward its use in smart PV systems that dynamically respond to partial shading. Companies like Trina Solar, SolarEdge, Enphase Energy, and Optistring already offer smart PV modules that mitigate mismatch due to nonuniform irradiance. These solutions are based on a hybrid power conversion architecture, where each PV module has either a power optimizer or a microinverter to obtain the maximum power from a partially shaded array (Burger et al., 2010; La Manna et al., 2014; MacAlpine et al., 2013). While these commercial, smart PV modules compete with dynamic PV arrays at the array level, these technologies can complement one another if reconfiguration is applied at the PV cell level to create a dynamically reconfigurable PV module. A power optimizer or a microinverter can then be attached to the module for coupling at the array level to reduce mismatch to a minimum.

The focus of this work is on a strategy for reconfiguration known as the electrical PV array reconfiguration strategy (EAR). The average improvement in power output is estimated and comparison of power output of static and dynamic arrays to determine power output improvement using the EAR strategy is accomplished through simulation using the popular one-diode PV model.

2. Photovoltaic array model

2.1 One-diode PV cell model

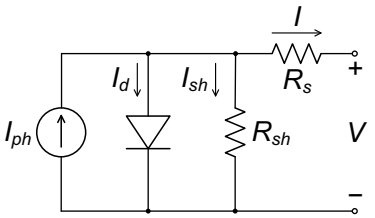

Fig. 1: Circuit representation of the one-diode PV model

One of the popular models that describes a PV cell is the one-diode model. The equivalent circuit of the model is shown in Fig. 1. It is composed of a current source representing the cell's photo-generated current I_{ph}, a single diode connected in parallel, a shunt resistance R_{sh} also connected in parallel and a series resistance R_s (Villalva et al., 2009). A two-diode model is more accurate, but accuracy is obtained at the expense of additional computation. Also, for crystalline silicon PV modules, the one-diode model is sufficient.

The equation describing the model is an expression for the current produced by the PV cell. Looking at the circuit in Fig. 1, the cell current I is just the algebraic sum of the currents of the upper node. Eq. 1 is called the characteristic or the I-V equation of the PV cell:

$$I = I_{ph} - I_{sat}\left(\exp\left(\frac{q(V+IR_s)}{n_d kT}\right)-1\right)-\frac{V+IR_s}{R_{sh}} \qquad \text{(Eq. 1)}$$

where I_{sat} is the diode's reverse saturation current, q is the elementary charge constant, n_d is the diode's ideality factor, k is the Boltzmann constant and T (K) is the absolute temperature of the cell p-n junction. The three terms correspond to the three currents that comprise the cell current: I_{ph}, I_d and I_{sh}. The second term is Shockley's equation for the diode current I_d, where the diode voltage $V_d = V + IR_s$. The third term represents leakage current due to junction defects as represented by the shunt resistance, I_{sh}, obtained by the application of Ohm's law.

2.2 Improved one-diode PV cell model

A serious problem that the classical one-diode model presents, at least for the purposes of this study, is its inadequacy in modeling what happens when a PV cell or module is reverse-biased. This happens when a module or an array is partially shaded. In a series-connected array, the PV module operating in the worst conditions dictates the performance of the whole array (La Manna et al., 2014). A PV cell or module breaks down when the reverse-bias voltage reaches the breakdown voltage (V_{br}) (Alonso-García et al., 2006). To resolve this, the model is modified to account for the avalanche breakdown phenomenon by describing the breakdown phenomenon in the expression for I_{sh} (Orozco-Gutierrez et al., 2014, 2013).

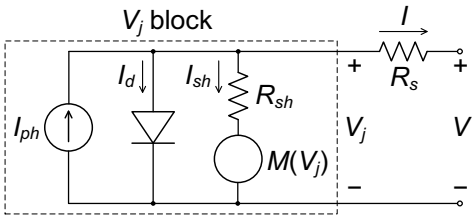

Fig. 2: Circuit representation of the modified one-diode PV model that considers behavior of PV cells in reverse bias

Fig. 2 shows the modified one-diode model equivalent circuit used in this study. Circuit components which are in parallel were lumped into a junction block. This junction block has V_j as its voltage which is equal to V_d. The component $M(V_j)$ represents the modification to the model which takes into account avalanche breakdown in PV cells or modules in reverse bias such that $I_{sh} = V_j M(V_j)/R_{sh}$ (Bishop, 1988). It considers the current through the shunt resistance as mainly the one affected by avalanche breakdown. While the primary

currents are the ones carrying the avalanche effects in other models for cells in reverse bias and parameters were sometimes meaningless or out of range as predicted by theory, the simplicity, wide use and the good fit with actual measurements of this model were instead considered here (Alonso-García and Ruíz, 2006). The modified cell model is:

$$I = I_{ph} - I_{sat}\left(\exp\left(\frac{qV_j}{n_d kT}\right) - 1\right) - \frac{V_j}{R_{sh}}\left(1 + \alpha\left(1 - \frac{V_j}{V_{br}}\right)^{-m}\right) \quad \text{(Eq. 2)}$$

where the additional variables included are α which is the fraction of ohmic current involved in avalanche breakdown exponent, V_{br} which is the junction breakdown voltage when a cell or module is reverse-biased and m which is the avalanche breakdown exponent (Bishop, 1988; Orozco-Gutierrez et al., 2014).

To complete the model, expressions for the other parameters must also be found. What has been described so far is the general characteristic *I-V* equation of a PV module. This equation depends on two parameters: I_{ph} and I_{sat}. Eqs. 3 and 4 are the formulas for I_{ph}:

$$I_{ph,STC} = \frac{R_s + R_{sh}}{R_{sh}} I_{sc,STC} \quad \text{(Eq. 3)}$$

$$I_{ph} = \left(I_{ph,STC} + K_I \Delta T\right)\frac{G}{G_{STC}} \quad \text{(Eq. 4)}$$

where I_{sc} (A) is the module's short-circuit current, K_I (A K^{-1}) is the temperature coefficient of the short-circuit current and G (W m^{-2}) is the irradiance that the module receives. The formulas for I_{sat}, on the other hand is Eq. 5 (Mäki and Valkealahti, 2012):

$$I_{sat} = \frac{I_{ph} - \dfrac{V_{oc,STC} + K_V \Delta T}{R_{sh}}}{\exp\left(\dfrac{V_{oc,STC} + K_V \Delta T}{n_d V_t}\right) - 1} \quad \text{(Eq. 5)}$$

where V_{oc} (V) is the module's open-circuit voltage and K_V (V K^{-1}) is the temperature coefficient of the open-circuit voltage (Villalva et al., 2009). The STC in the subscripts of some of the variables refers to the standard testing conditions which specify that junction temperature should be 25 °C, irradiance, 1,000 W m^{-2} and air mass AM 1.5 when measurements are made.

2.3 3×3 PV array with bypass diodes model

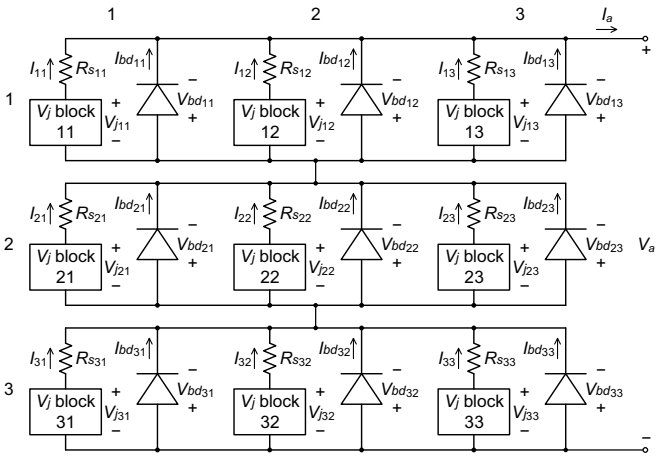

Fig. 3: Circuit representation of the PV array model

To demonstrate the construction of the PV array model, a 3×3 PV array is considered and is shown in Fig. 3. The modules are named according to their position in the array. For example, the module in the second row,

first column of the array is referred to as module 21. In general, for an $M\times N$ array, a module mn has $m \in \{1,2,3,\ldots,M\}$ as its row position and $n \in \{1,2,3,\ldots,N\}$ as its column position. The voltages, currents and resistances are numbered following the designation of the module e.g. V_{11}, V_{j11}, I_{11}, R_{s11} for module 11. Every module has a bypass diode attached to it in antiparallel position. The bypass diodes' voltages and currents also follow the designation of the module it is paired to e.g. V_{bd11}, I_{bd11} for module 11. The array circuit has 18 unique components consisting of nine modules and nine bypass diodes. Thus, the solution requires 18 voltage variables. These variables are stored in a vector called **x**. In general, for an $M\times N$ array, $\mathbf{x} = [V_{j11} V_{bd11} V_{j12} V_{bd12} \cdots V_{jMN}\ V_{bdMN}]^{\mathrm{T}}$, which contains MN variables.

To create the system of equations that describes the 3×3 PV array in Eq. 6, Kirchhoff's voltage and current laws (KVL and KCL) are applied to the circuit in Fig. 3. The 18 variables require that the system of equations consist of 18 equations. There are three rows in the array, so the system of equations can be split into three divisions, one division for each row, each division containing six equations. Each division has the same form, except for the last one. For the first division, the procedure is to first apply KVL to the five meshes in the array's first row. The convention chosen is such that meshes follow the clockwise direction. For the first mesh, $V_{j11} - I_{11}(V_{j11})R_{s11} + V_{bd11} = 0$. The same steps are done for the remaining four meshes. To obtain the last equation in the division, KCL is applied to the node connecting the array's first and second rows. The convention is chosen such that currents leaving the node are positive. The converse is true for currents entering the node. Thus, $\sum_{n=1}^{N}\left[I_{1n}\left(V_{j_{1n}}\right)+I_{bd_{1n}}\left(V_{bd_{1n}}\right)\right]-\sum_{n=1}^{N}\left[I_{2n}\left(V_{j_{2n}}\right)+I_{bd_{2n}}\left(V_{bd_{2n}}\right)\right]=0$. The same procedure was followed for the other divisions. However, the last equation of the third division differs because it is the application of KVL to the big mesh containing the array voltage V_a.

$$\mathbf{F}(\mathbf{x})=\begin{cases} V_{j_{11}}-I_{11}\left(V_{j_{11}}\right)R_{s_{11}}+V_{bd_{11}}=0 \\ -V_{bd_{11}}-V_{j_{12}}+I_{12}\left(V_{j_{12}}\right)R_{s_{12}}=0 \\ V_{j_{12}}-I_{12}\left(V_{j_{12}}\right)R_{s_{12}}+V_{bd_{12}}=0 \\ -V_{bd_{12}}-V_{j_{13}}+I_{13}\left(V_{j_{13}}\right)R_{s_{13}}=0 \\ V_{j_{13}}-I_{13}\left(V_{j_{13}}\right)R_{s_{13}}+V_{bd_{13}}=0 \\ \sum_{n=1}^{N}\left[I_{1n}\left(V_{j_{1n}}\right)+I_{bd_{1n}}\left(V_{bd_{1n}}\right)\right]-\sum_{n=1}^{N}\left[I_{2n}\left(V_{j_{2n}}\right)+I_{bd_{2n}}\left(V_{bd_{2n}}\right)\right]=0 \\ V_{j_{21}}-I_{21}\left(V_{j_{21}}\right)R_{s_{21}}+V_{bd_{21}}=0 \\ -V_{bd_{21}}-V_{j_{22}}+I_{22}\left(V_{j_{22}}\right)R_{s_{22}}=0 \\ V_{j_{22}}-I_{22}\left(V_{j_{22}}\right)R_{s_{22}}+V_{bd_{22}}=0 \\ -V_{bd_{22}}-V_{j_{23}}+I_{23}\left(V_{j_{23}}\right)R_{s_{23}}=0 \\ V_{j_{23}}-I_{23}\left(V_{j_{23}}\right)R_{s_{23}}+V_{bd_{23}}=0 \\ \sum_{n=1}^{N}\left[I_{2n}\left(V_{j_{2n}}\right)+I_{bd_{2n}}\left(V_{bd_{2n}}\right)\right]-\sum_{n=1}^{N}\left[I_{3n}\left(V_{j_{3n}}\right)+I_{bd_{3n}}\left(V_{bd_{3n}}\right)\right]=0 \\ V_{j_{31}}-I_{31}\left(V_{j_{31}}\right)R_{s_{31}}+V_{bd_{31}}=0 \\ -V_{bd_{31}}-V_{j_{32}}+I_{32}\left(V_{j_{32}}\right)R_{s_{32}}=0 \\ V_{j_{32}}-I_{32}\left(V_{j_{32}}\right)R_{s_{32}}+V_{bd_{32}}=0 \\ -V_{bd_{32}}-V_{j_{33}}+I_{33}\left(V_{j_{33}}\right)R_{s_{33}}=0 \\ V_{j_{33}}-I_{33}\left(V_{j_{33}}\right)R_{s_{33}}+V_{bd_{33}}=0 \\ -V_{bd_{13}}-V_{bd_{23}}-V_{bd_{33}}-V_a=0 \end{cases} \quad \text{(Eq. 6)}$$

Eq. 2, the characteristic *I-V* equation, was used to compute for values of $I_{mn}(V_{jmn})$ in the system of equations. On the other hand, the Shockley diode equation in Eq. 7 was used to compute for values of $I_{bd}(V_{bdmn})$ in the system of equations:

$$I = I_{sat,bd}\left(\exp\left(\frac{qV_{bd}}{n_{bd}kT}\right)-1\right) \quad \text{(Eq. 7)}$$

The mesh used to obtain the last equation in the system is especially chosen to create the Jacobian matrix **J**

of the vectorial function **F** with a diagonal containing nonzero elements. The Jacobian matrix is needed to use Newton's method for systems of nonlinear equations. In Newton's method, the equation $\mathbf{J}(\mathbf{x}_i)\Delta\mathbf{x} = -\mathbf{F}(\mathbf{x}_i)$ is solved for $\Delta\mathbf{x}$. Then, this vector is substituted in $\mathbf{x}_{i+1} = \mathbf{x}_i + \Delta\mathbf{x}$ for the new value **x**. There is an initial guess $\mathbf{x}_0$ that serves as the initial value of **x**. The two steps are repeated until convergence. In theory however, a convergent Newton's method is reached only after an infinite number of iterations. In practice, a tolerance that is small enough for one's purpose is set (Quarteroni and Saleri, 2006).

One important step in Newton's method is the choice of the initial approximation $\mathbf{x}_0$. The convergence of the method depends on it. The choice of $\mathbf{x}_0$ must be sufficiently close to the actual solution for Newton's method to converge (Quarteroni and Saleri, 2006). As stated earlier, V_a is swept from V_{oc} to zero. The actual value of the array's V_{oc} is unknown, so an approximate value for the modules' V_{oc}, solved using Eq. 8, is used (Orozco-Gutierrez et al., 2014):

$$V_{oc,init} = V_t n_d \ln\left(1 + \frac{I_{ph}}{I_{sat}}\right) \qquad \text{(Eq. 8)}$$

Assuming that the modules in the array have the same material properties and are under the same conditions, the array's V_{oc} is just a module's V_{oc} multiplied by the number of rows m. Another use of Eq. 8 is in populating the initial approximation $\mathbf{x}_0$. Because of the parallel connection, a module and the bypass diode connected to it always have the same voltage. So, $\mathbf{x}_0 = [V_{oc,init} V_{oc,init} \cdots V_{oc,init}]^T$.

2.4 3×3 PV array with bypass diodes program

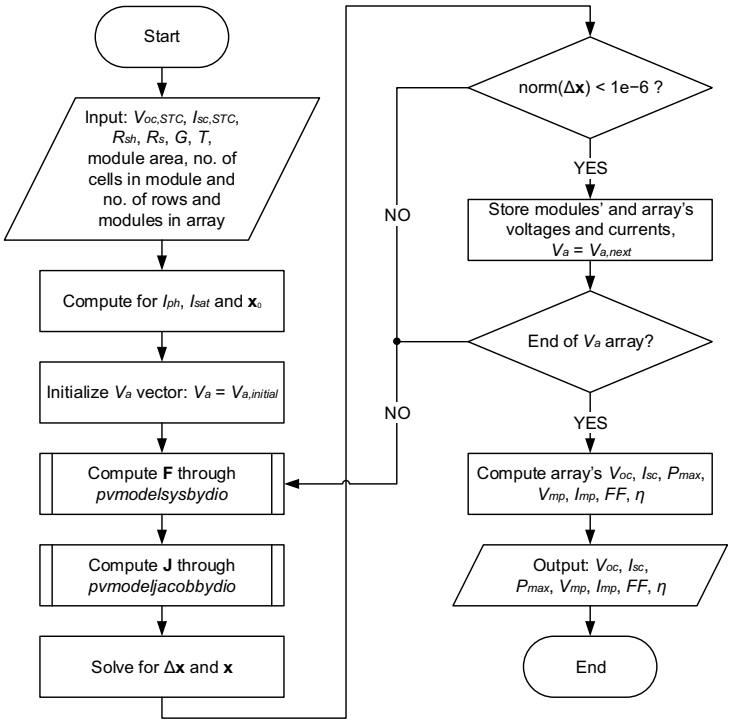

Fig. 4: Flowchart of the MATLAB function *pvmodelbydio*

The equations and the model described in the previous sections were programmed in MATLAB. They were incorporated into the function *pvmodelbydio*, shown in Fig. 4. The function takes G, the module's surface area and the number of rows and modules in the array as inputs or arguments. On the other hand, the outputs are the array's V_{oc}, I_{sc}, P_{max}, V_{mp}, I_{mp}, fill factor (FF) and efficiency (η) under given conditions. The conditions are dictated by the irradiance G that each module receives and the temperature of the module T. In the function, however, only G is an input. Module temperatures were set at 35, 45 and 55 °C. When the function is called, the program computes for I_{ph} and I_{sat} of all the modules in the array using Eqs. 4 and 5. $V_{oc,init}$ is also computed using Eq. 8 and is used to populate the initial approximation $\mathbf{x}_0$. Eq. 8 is also used to initialize the MATLAB vector for V_a from its approximate V_{oc} value to zero. Newton's method is applied

starting with the first element of the vector. It is repeated until a condition is reached that causes termination of Newton's method. In this case, termination is set when the norm of $\Delta\mathbf{x}$ reaches a tolerance of 1×10^{-6}. Thus, the system is solved for the first value of V_a. The steps are repeated for the next values of the array voltage. The whole process is akin to setting the array voltage at a specific level, and finding out the values of all the parameters of interest. To completely characterize the system then is to sweep the voltage from its open-circuit value down to zero and solving the resulting systems of equations.

3. Reconfiguration strategies and their simulation

Velasco-Quesada et al. proposed a scheme for the reconfiguration of PV arrays to minimize mismatch and therefore maximize power output (Velasco-Quesada et al., 2009). They called this the electrical array reconfiguration or EAR strategy. It is based on the principle of irradiance equalization that their group earlier explored (Velasco et al., 2005).

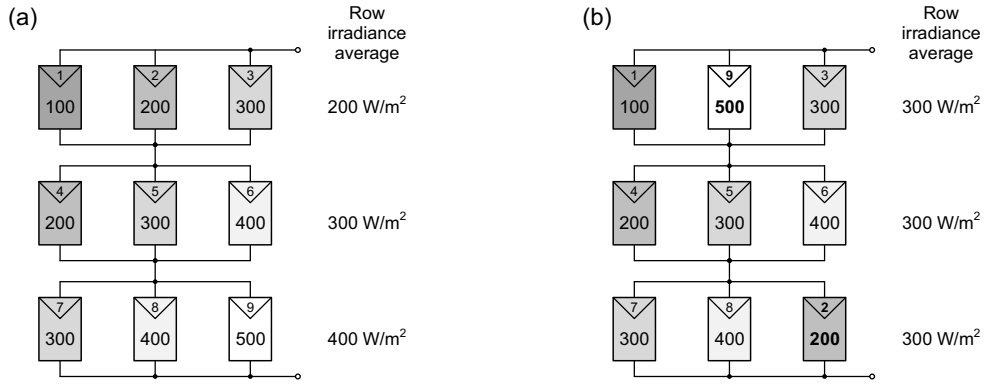

Fig. 5: Principle of irradiance equalization for dynamic PV arrays: (a) original configuration and (b) new configuration where modules 2 and 9 were interchanged

Irradiance equalization serves as a framework for the reconfiguration strategy for PV arrays in TCT configuration tested in this work. It works by configuring PV arrays in such a way that each row's average irradiance is as close as possible to the average irradiances of the other rows. The principle is illustrated with an idealized example in Fig. 5. Fig. 5(a) is the original configuration. In irradiance equalization, the configuration that minimizes the difference among the average row irradiances becomes the new configuration. Fig. 5(b) is such a configuration. The connections of modules 2 and 9 were interchanged resulting in equal average row irradiances.

Irradiance equalization works because it reduces the current mismatch among the rows which are connected in series. Even though the rows have different shading profiles, they will still produce currents which are close in value to one another because they have close average row irradiances. Previous studies show that cross-tied configurations such as TCT and bridge-link arrays do not only produce more power in the face of partially shadowed conditions but are also more reliable in terms of operational lifetimes as compared to serial-parallel (SP) arrays (Gautam and Kaushika, 2002; Kaushika and Gautam, 2003). The effect of a change in irradiance is mostly seen in the current produced by a PV module. The effect on voltage is minimal (Velasco-Quesada et al., 2009). This makes the parallel connection of modules possible with minimal effect on the current produced by a row. Mismatch still happens, but at the level of the series connection of rows. The array current is limited by the row that produces the lowest current. As already said for modules connected in series, the module in the worst operating conditions dictate the performance of the whole array. By employing irradiance equalization through array reconfiguration, current mismatch is reduced.

3.1 Electrical PV array reconfiguration strategy

As can be observed in the topology of TCT arrays, there are permutations which are equivalent in terms of power production. Cases of two interchanged parallel modules are redundant. Also redundant are interchanged rows in series. Computing for these irrelevant cases is just a waste of time. The EAR strategy discards these redundancies when considering the total number of configurations of interest (COIs) (Velasco-Quesada et al., 2009). For an $M\times N$ array, the number of configurations of interest is:

$$N_{coi} = \frac{(MN)!}{M!(N!)^m} \qquad \text{(Eq. 9)}$$

For a 3×3 array where $M = N = 3$, the total number of permutations possible is 9! = 362,880 while the number of COIs given by Eq. 9 is 280. Based on these numbers, it can be seen that considering only the COIs greatly reduces the number of configurations that the EAR algorithm has to consider.

The following are the steps that describe the algorithm to implement the EAR strategy:

1. The COIs are computed based on the size of the PV array.
2. The irradiance of each module in the array is estimated using the voltage and current values of individual modules.
3. For a COI, irradiance values of the modules in each row are averaged. Each row of the COI then has an associated average row irradiance. The same is done for the other COIs.
4. For a COI, an "irradiance equalization index" is computed for based on the average row irradiances. This index is just the difference between the maximum and minimum values among the average row irradiances. The same is done for the other COIs so each has an associated index. The COI with the lowest index becomes the target for the reconfiguration.
5. In case of COIs with equal indices, the tie is broken by computing for the number of module relocations needed to arrive there from the current configuration. The COI with the lowest number of relocations then becomes the target for the reconfiguration.

Table 1: Array sizes and number of configurations

Array size	Total number of configurations	Number of configurations of interest
3×3	362,880	280
4×4	2.09×10^{13}	2,627,625
5×5	1.55×10^{25}	5.19×10^{12}

A problem emerges when scaling is considered. Table 1 shows different array sizes and the corresponding total number of configurations and number of COIs. For a 3×3 array, only 280 COIs have to be considered and for square arrays larger than 3×3, implementation of the EAR strategy becomes harder because of the exponential jump in the number of COIs. This issue is fundamental in the EAR strategy as COIs are the framework for the scheme.

3.2 Simulation and performance tests of the strategies

The EAR algorithm was also implemented in MATLAB. Two models were constructed: a static array and a dynamic array using the EAR strategy. Also, two tests were conducted for the static and dynamic PV array models: binary- and random-irradiance shading. For the binary-irradiance test, 511 shading patterns containing all combinations of shaded modules were generated for each irradiance level. Random-irradiance shading, on the other hand, involved random irradiance values which follow uniform and normal distributions. 1,000 random shading patterns were prepared for both distributions. The simulations were run on desktop PCs with Intel Core i5-3450 (at 3.10 GHz) processors.

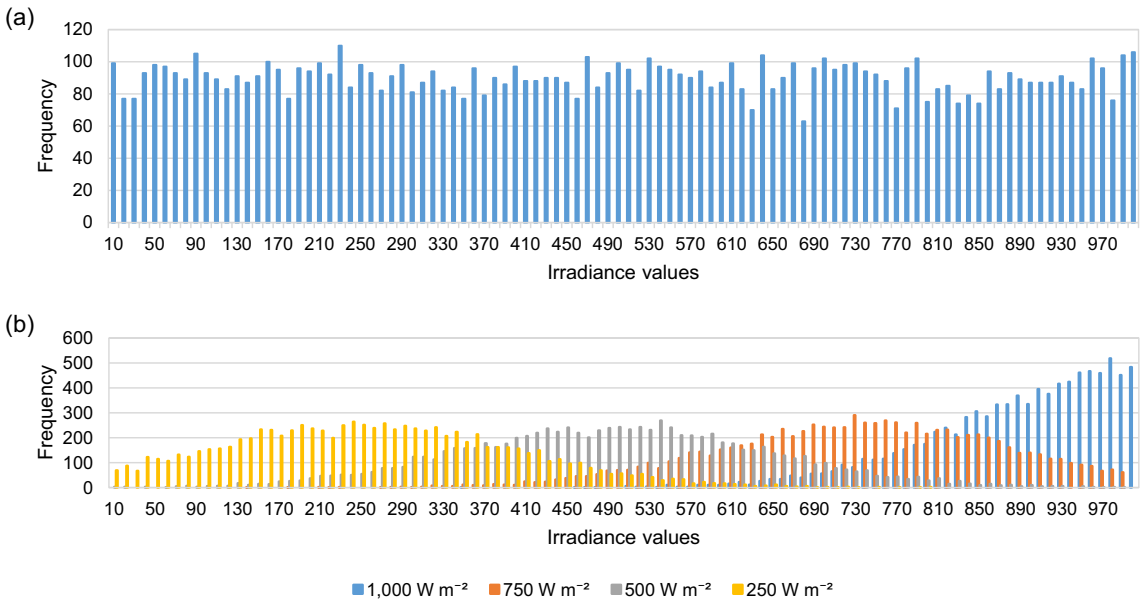

Fig. 6: Histogram of the random irradiance distributions: (a) uniform distribution and (b) normal distributions with different means and σ = 150 W m^{-2}

The histograms for the two random irradiance shading tests are shown in Fig. 6. The uniform distribution in Fig. 6(a) simulates a condition for a PV array where the change in irradiance of each PV module over time is drastic. The normal distribution, on the other hand, simulates a condition where the change in irradiance over time is more moderated or more concentrated within an irradiance range as seen in Fig. 6(b). In actual conditions, it could resemble different levels of cloudy conditions. The different levels are simulated as the means (μ) of the normal distribution: 1,000, 750, 500 and 250 W m^{-2}. A standard deviation (σ) of 150 W m^{-2} was chosen for the distributions. To give an idea of the range of irradiance values this σ brings, for a mean of 500 W m^{-2}, 95% of the values are within 2σ or within the range 200–800 W m^{-2}. 68% of the values are within a σ or within the range 350–650 W m^{-2}. Other values for the standard deviation could also be tested, but the results here are for σ = 150 W m^{-2}. The range of irradiance values was limited to 0–1,000 W m^{-2}.

Table 2: Parameters of the PV module and bypass diode used in the model

Parameter	Value	Parameter	Value
V_{oc}	21.7 V	R_s	1.4 Ω
I_{sc}	0.61 A	R_{sh}	2.31×10^4 Ω
V_{mp}	17.3 V	V_{br}	−15 V
I_{mp}	0.58 A	M	3
P_{max}	10 W	A	0.002
K_V	−0.0708 V K^{-1}	n_d	1.3
K_I	0.0034 A K^{-1}	n_{bd}	1.5
N_s	36	$I_{sat,bd}$	5.6×10^{-6} A

Table 2 gives the parameters used in the model for the PV module and bypass diode. The PV model used in this study is the GP010PA PV module by Alexan Commercial. K_V and K_I were obtained from outdoor experiments characterizing and measuring the performance of the modules. The values for the resistances R_s and R_{sh}, on the other hand, were obtained following the procedure for the modeling of PV modules (Villalva et al., 2009).

4. Results and discussion

The two tests were performed for both the static and dynamic PV arrays to compare their power outputs and ultimately to assess whether using the EAR strategy for dynamic arrays improves power output.

4.1 Binary-irradiance test results

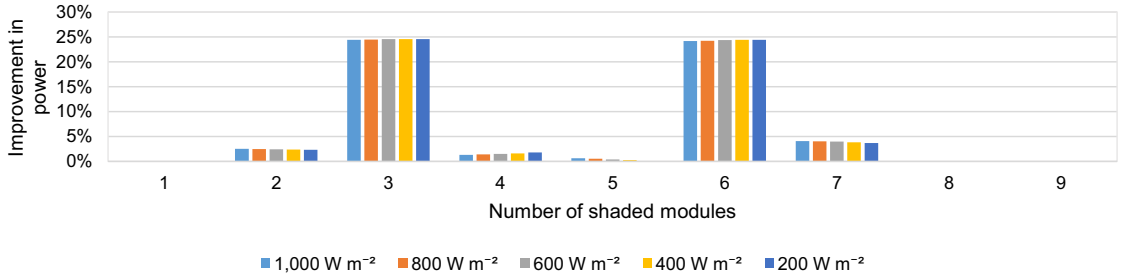

Fig. 7: Average percent improvement in power output of the 3×3 dynamic over the static PV array model in binary-irradiance shading at 35 °C; irradiance of shaded modules is 5% of unshaded level

Fig. 7 shows the results for the binary-irradiance shading test where each PV module in the array can either be shaded or unshaded. Both the static and EAR-based model were run 511 times for each irradiance and shading level. This is based on the total number of combinations possible for shaded and unshaded modules in the array. The unshaded irradiance level in a run can have a value of 1,000, 800, 600, 400 or 200 W m^{-2}, while the shaded irradiance level is 5% of the unshaded level. It can be seen that when a module is shaded and when only one module is unshaded (eight modules are shaded), using a dynamic array based on the EAR strategy does not improve power output. The principle on which the strategy is based, irradiance equalization, cannot optimize these cases. Otherwise, using dynamic arrays improved power output for other cases when the number of shaded modules is not one or eight.

Table 3: Percentage of shading patterns with decreased and increased power output due to the EAR strategy for 1,000 W m^{-2} unshaded irradiance level at 35 °C

No. of shaded modules	Total no. of shading patterns	Patterns with decreased power	Patterns with the same power	Patterns with increased power
1	9	0%	100%	0%
2	36	0%	75%	25%
3	84	0%	32.14%	67.86%
4	126	35.71%	21.43%	42.86%
5	126	47.62%	16.67%	35.71%
6	84	0%	32.14%	67.86%
7	36	0%	75%	25%
8	9	0%	100%	0%

From the results in Fig. 7, it can be observed that the EAR algorithm performs best when the number of shaded modules equals the number of columns in the array or is a multiple of it, as in the case when three and six modules are shaded. It was able to relocate the shaded modules into columns such that each row has the same number of shaded modules as the other rows. Average improvement in power when three modules are shaded (24.39%) in the case of 1,000 W m^{-2} is as much as nine times better than when two modules are shaded (2.53%).

The effect of using the EAR strategy in dynamic arrays on the number of patterns with decreased or increased power output is summarized in Table 3. Percent differences whose absolute value is less than 0.01 were taken to show no difference in power output between the static and dynamic arrays. The table also shows that the decrease in power is only seen when four or five modules are shaded. The case when five

modules are shaded serves as another illustrative example of the limitation of the EAR strategy. For instance, at an array temperature of 35 °C and unshaded irradiance level of 1,000 W m^{-2}, the dynamic array in 47.62% of the 126 shading patterns possible produced a decrease, instead of an increase, in power. This means that for these numbers, the EAR strategy is unable to optimize the power for some shading patterns.

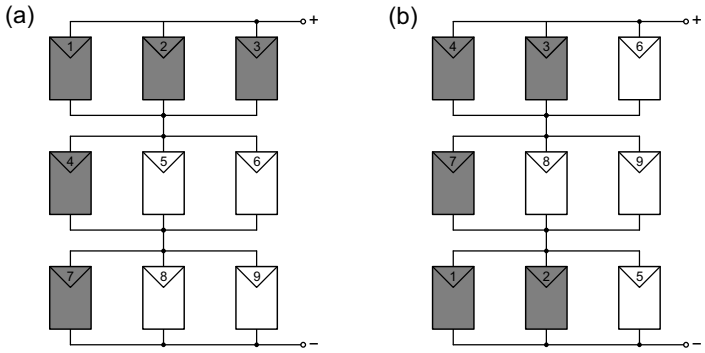

Fig. 8: Third case when five modules are shaded at 35 °C and unshaded irradiance level of 1,000 W m^{-2}: (a) original shading pattern and (b) shading pattern after reconfiguration using the EAR strategy

Fig. 8 shows a sample case of five shaded modules where the EAR strategy failed. The third shading pattern for five shaded modules at 35 °C and unshaded irradiance level of 1,000 W m^{-2} is shown in Fig. 8(a). This original configuration produced a power of 40.06 W. The resulting shading pattern after reconfiguration through the EAR strategy is shown in Fig. 8(b). It has a power of 35.29 W. Fig. 8 is a case of the reconfiguration strategy not being able to optimize a shading pattern. As the power outputs show, applying the EAR strategy reduced the power output instead of improving it. In Fig. 8(a), the whole of the first row is shaded. However, the bypass diodes connected to every panel served as an alternative path for the array current. In effect, the configuration actually has balanced currents. On the other hand, Fig. 8(b) has unbalanced row currents. The second row of this configuration has two unshaded modules, unlike the first and the third rows. The row currents are mismatched resulting in a lower power output as compared to the original configuration in Fig. 8(a).

4.2 Random uniformly distributed irradiance shading test results

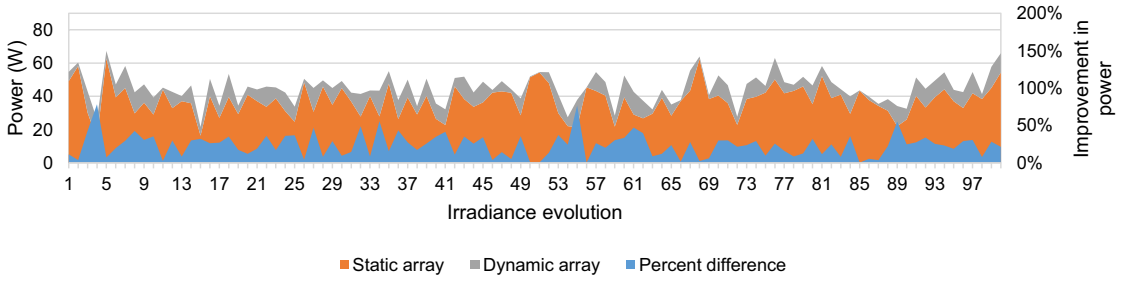

Fig. 9: Power output of 3×3 static and dynamic photovoltaic array models in random-irradiance shading (first 100 shading patterns) with uniformly distributed irradiance at 35 °C

For the first random-irradiance shading test, uniformly distributed shading patterns were generated. The simulation of the models was executed with each pattern as input. Fig. 9 shows the irradiance evolution and the output power for both static and dynamic arrays at 35 °C. The model was run 1,000 times for each distribution because there were 1,000 shading patterns generated for each distribution.

Table 4: Percent improvement in power of the dynamic arrays over the static array with uniformly distributed shading patterns

Improvement at 35 °C	Improvement at 45 °C	Improvement at 55 °C
21.12%	20.87%	20.61%

Table 4 shows the average improvement in power of the EAR-based dynamic over the static array when the irradiances in the shading pattern is uniformly distributed. With uniformly distributed shading patterns, improvements of above 20% can be expected. Percent improvement decreases with an increase in temperature, but the effect of temperature on the percent improvement is very minimal.

4.3 Random normally distributed irradiance shading test results

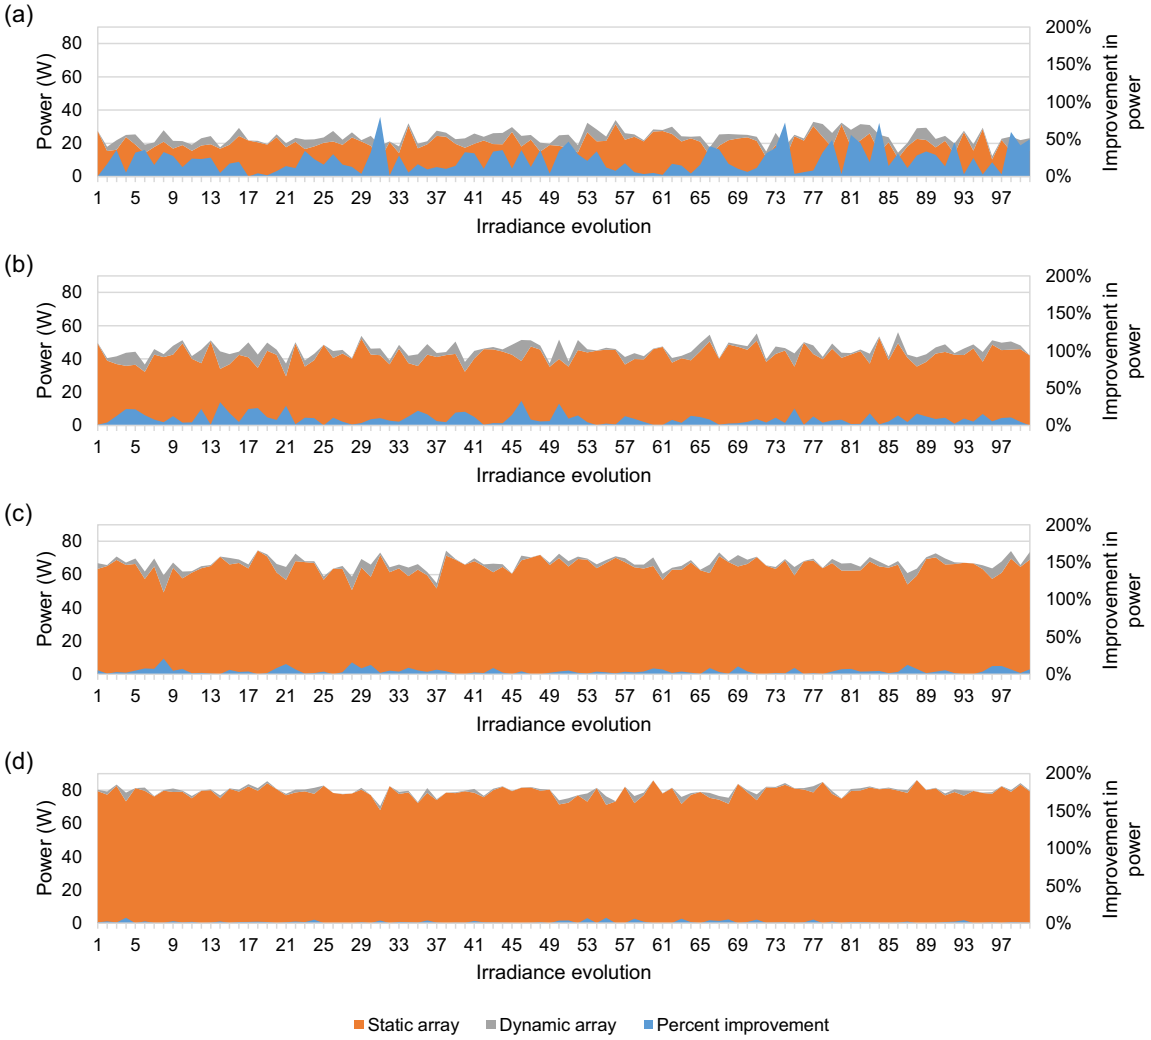

Fig. 10: Power output of 3×3 static and dynamic photovoltaic array models in random-irradiance shading (first 100 shading patterns) at 35 °C with normally distributed irradiance (σ = 150 W m^{-2}): (a) μ = 250 W m^{-2}, (b) μ = 500 W m^{-2}, (c) μ = 750 W m^{-2} and (d) μ = 1,000 W m^{-2}

Fig. 10 shows the results for the second random irradiance shading test with the distributions centered at different irradiances at 35 °C. The irradiance level at 1,000 W m^{-2} was taken as the maximum possible irradiance so the distribution centered at this value is only a half-normal distribution, as in Fig. 6. As seen in Figs. 10(a)–(d), the percent improvement of the dynamic over the static array is small for the irradiance distributions centered at 750 and 1,000 W m^{-2}. The percent improvement increases as the mean of the distribution decreases.

Table 5: Percent improvement in power of the dynamic arrays over the static array with normally distributed shading patterns

Irradiance distribution mean (W m^{-2})	Improvement at 35 °C	Improvement at 45 °C	Improvement at 55 °C
250	20.62%	20.35%	20.06%
500	9.63%	9.37%	9.09%
750	4.13%	3.96%	3.79%
1,000	1.52%	1.43%	1.35%

Table 5 summarizes the results of the random irradiance shading test. The values confirm that as the mean of the distribution increases, the percent improvement decreases. The values for the distribution centered at 250 W m^{-2} almost match those obtained for uniformly distributed irradiances. However, for the other distributions, percent improvement is much less than half that of the uniform distributions. It shows that as the irradiance distribution becomes more spread, the dynamic array becomes more effective in recovering power which is otherwise lost due to partial shading.

It must be noted however, that while the percent improvement is high for lower irradiances, actual deployment of a dynamically reconfigurable array will depend on the power requirements of the system versus the recoverable power, as estimated here. Table 5 also shows the effect of temperature on the percent improvement. As in the uniform distributions, percent improvement minimally increases as the temperature decreases.

5. Conclusion

This work demonstrates some of the limitations and benefits in using the EAR strategy in dynamic PV arrays through modeling and simulation. The binary-irradiance shading test showed that the algorithm works best for particular configurations. Specifically, irradiance equalization works best when the number of shaded modules equals the number of columns. On the other hand, the random-irradiance shading test revealed how the irradiance distribution affects power output improvement when a dynamic array is used. Dynamic reconfiguration is most effective when the distribution of irradiance each module receives is more uniformly spread. Thus, shading profiles must also be studied if dynamic reconfiguration is to be implemented. The two tests employed here can serve as platforms for evaluating dynamic reconfiguration strategies for PV systems. PV system designers benefit by considering these results that inform when and where to use the EAR strategy in dynamic PV arrays.

AN OUTDOOR PLATFORM FOR PV AGEING STUDIES: ELECTRICAL PARAMETERS EXTRACTION FROM IV CURVES

Ghjuvan Antone Faggianelli, Pierrick Haurant, Auline Rodler and Philippe Poggi

University of Corsica, UMR SPE CNRS 6134, Ajaccio (France)

Abstract

Accurate models for solar technologies are essential to evaluate the lifetime, ageing and degradation modes of these devices, depending on local climatic constraints. In this context, the DURASOL project aims to provide more sophisticated tools and methods for solar industries, based on studies in multi-site facilities with indoor and outdoor platforms under diverse and complementary climates. For solar cells and modules, simple diode modelling allows to determine several electrical parameters from IV curves: the series and shunt resistances, the photocurrent, the reverse saturation current of diode and the diode ideality factor. These parameters can be used for various applications such as analyze of performance losses, quality control and devices improvements. In this paper, we focus on their extraction through a Particle Swarm Optimization algorithm. Three approaches are compared, based on a direct optimization of the five electrical parameters and on the use of the short-circuit current I_{sc} and the open-circuit voltage V_{oc}. The tests realized on a synthetic IV curve show that the use of V_{oc} leads to a more robust and accurate model with both exact and noisy data.

Keywords: *Photovoltaic, Simple diode model, IV curve, Parameters extraction, Particle Swarm Optimization*

1. Introduction

The markets of solar technologies as photovoltaic (PV) are rapidly growing. However, long term performance and reliability remain major issues to provide warranties, develop insurance and subsidy programs, evaluate a long term investment risk or help the customer to choose between manufacturers. Therefore, methods for evaluating the lifetime, ageing and degradation modes of these technologies are necessary. Most of the time, simple assumptions of a constant and linear degradation rate performance per year are made for PV modules (Vázquez and Rey-Stolle, 2008). The impacts of non-linear and non-uniform degradations as well as their sources require further studies.

Environmental conditions and local climate have an important impact on PV energy efficiency and its evolution over time (Jordan et al., 2012; Jordan and Kurtz, 2013). Even well qualified modules can degrade more than expected when exposed to outdoor conditions (Sharma and Chandel, 2013). These degradations can be correlated to various stresses affecting solar modules lifetime such as temperature (heat, freezing, night-day cycles…), mechanical stresses (wind, snow load, hail…), atmosphere (salt mist, dust, sand, pollution…) and humidity (rain, dew, frost, fog…). Moreover, it must also be considered that each stress may show up some singular ageing effect as well as it can combine with other stresses. As an example, Mekhilef et al. (2012) focus on some environmental factors (dust, humidity and air velocity) and show that they should not be studied separately as their effects are linked up and each of them impacts the other two. Skoczek et al. (2009) also present the results of electrical performance measurements of hundreds crystalline silicon photovoltaic modules, following long-term continuous outdoor exposure. An important outcome is that visual inspection is generally not enough to track the module degradation and by no means answer the question of module lifetime. Advanced diagnostic tools are thus required to measure the degradations, quantify them and also explain the phenomena.

For PV technologies, some electrical parameters allow to analyze performance losses and lead to more

doi:10.18086/swc.2015.05.15 Available at http://proceedings.ises.org

accurate models and simulations. The extraction and interpretation of these parameters has a variety of important applications. They can, for example, be used for quality control during production or to provide insights into the operation of the devices, thereby leading to improvements in devices (Gottschalg et al., 1999). In this paper, we will focus on the series and shunt resistances R_s and R_{sh}, the photocurrent I_{ph}, the reverse saturation current of diode I_0 and the diode ideality factor n which can be obtained from IV curves through the monitoring of solar cells and modules. The variation of these parameters over time can be correlated to specific degradations (delamination, discoloration…) and thus allow to assess the ageing effects and the impact of environment. In their review of photovoltaic degradation rate methodologies, Phinikarides et al. (2014) present a list of possible sources of performance losses and their impact on some of these parameters. For example, the series resistance has a significant effect on both the fill factor and the conversion efficiency. The shunt resistance is crucial to photovoltaic system performance, especially at reduced irradiance levels (Priyanka et al., 2007). Inaccurate determination will provide a misleading interpretation on the impact of each parameter and lead either to an overestimation or underestimation of the degradation. The main difficulty of this type of study is thus to define measurement and extraction methods with a sufficient robustness and precision.

For this purpose, the DURASOL project aims to provide more sophisticated tools and methods for the PV, ST and CSP industries. This project, supported by the French National Research Agency as an "Invest for Future, EQUIPEX", relies on multi-site facilities with several indoor and outdoor platforms under various and complementary climates. It aims to compare analysis of indoor and outdoor ageing, determine accelerating ageing factors depending on climatic constraints and develop analysis methods for degradation mechanisms. On the medium term, it will provide deeper insight and understanding of degradation mechanisms allowing to design and manufacture new components with longer life-time and higher performances. As a first step, we focus on this paper on the extraction of electrical parameters through simple diode modelling.

2. IV curves processing

2.1. Measurement protocol

In order to get reliable information on a solar device, it is required to set up a robust measurement protocol. Depending on the method used for the calculation of electrical parameters, an important accuracy will be needed. As an example, curve fitting method needs to calculate the differential value dV/dI from the experimental data, which requires a very smooth IV curve (Zhang et al., 2011).

According to Gottschalg et al. (1999), there are three standard measurement strategies for measuring the IV characteristics of PV solar devices. One can apply the voltage in regularly distributed steps, control the current in regularly distributed steps or measure with a variable resistance load. Comparing the different measurement strategies clearly shows that it is better to measure devices with constant voltage steps. In the context of DURASOL project, we have opted for a measurement method based on the application of a voltage with a specific step. This is done with a test bench for PV characterisation through current-voltage measurements. This IV bench is connected to photovoltaic modules, on an outdoor platform which is being installed at the SPE Laboratory UMR CNRS, University of Corsica, France (Fig. 1). The site is located in a coastal zone (distance from the sea of less than 400 m) with a Mediterranean climate and exposed to salty sea spray. In addition to the current and voltage measurements, each module is also equipped with a temperature sensor (PT100) and the surrounding conditions (ambient temperature, solar radiations, wind speed and direction…) are measured on the platform. This facility allows to plot and back up the modules IV curves with a 5 minutes time step and at least 100 points per curve for a given temperature and irradiance. These parameters can be changed depending on the accuracy needed and the aim of the study. The only limitation here is to ensure that the computation time for each IV curve is not too high (of about 1s) in order to avoid variations of surrounding conditions during measurement.

Fig. 1: DURASOL platform at SPE Laboratory, University of Corsica

2.2. Single diode model

To study solar cells and modules, it is common to represent them with an electrical analogy. For electrical engineering applications, simple diode models are usually suitable (Askarzadeh and Rezazadeh, 2012; de Blas et al., 2002). This type of model allows extracting several electrical parameters: the series and shunt resistances R_s and R_{sh}, the photocurrent I_{ph}, the reverse saturation current of diode I_0 and the diode ideality factor n. These parameters influence the behavior of the IV characteristics and give information on solar device performance. Fig. 2 shows an equivalent circuit of a solar module based on a simple diode model.

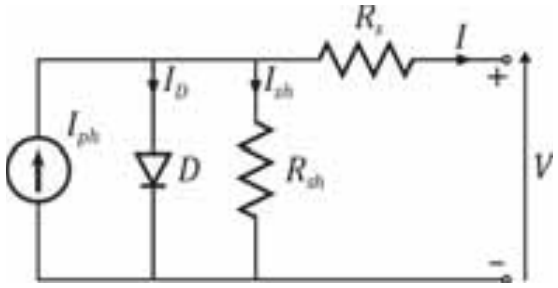

Fig. 2: Equivalent circuit of a solar module (simple diode model)

In this circuit, the current I can be simply expressed as:

$$I = I_{ph} - I_D - I_{sh} \quad \text{(eq. 1)}$$

With:

$$I_D = I_0 \left(e^{\frac{q(V+IR_s)}{nkT}} - 1 \right) \quad \text{(eq. 2)}$$

$$I_{sh} = \frac{V + IR_s}{R_{sh}} \quad \text{(eq. 3)}$$

Which leads to the transcendental equation:

$$I = I_{ph} - I_0 \left(e^{\frac{q(V+IR_s)}{nkT}} - 1 \right) - \frac{V + IR_s}{R_{sh}} \quad \text{(eq. 4)}$$

This equation is then resolved by an exact explicit method based on the Lambert W-function $W(z)$ (Jain, 2004):

$$I = \frac{R_{sh}(I_{ph} + I_0)}{(R_s + R_{sh})} - \frac{nkT}{qR_s} W(z) - \frac{V}{R_{sh}} \quad \text{(eq. 5)}$$

With:

$$z = \frac{qI_0}{nkT} \frac{R_s R_{sh}}{(R_s + R_{sh})} e^{\left(\frac{R_{sh}}{(R_s+R_{sh})} \frac{q[V+R_s(I_{ph}+I_0)]}{nkT}\right)} \quad \text{(eq. 6)}$$

The solution of this equation is obtained by the algorithm proposed by Fritsch et al. (1973). This method allows to express the current as a function of the voltage, the temperature and the five electrical parameters that we need to determine.

3. Parameters extraction methodology

From the experimental equipment presented in the previous section, it remains five unknown parameters that appear in (eq. 5). Their accuracy will depend on both the precision of the experimental data and the robustness of the method used for their determination. In addition to the measurement protocol, the main part of this work is thus to establish and validate a robust method for parameters extraction.

In the last decades, this problem has been treated frequently in literature with different methods which can be classified into three categories: analytic, iterative and evolutionary computational methods. Among these methods, we will focus in evolutionary algorithms which are the best suited with varying weather conditions (Tamrakar and Gupta, 2015). For this problem, we observe a large variety of algorithms such as Genetic (Jervase et al., 2001), Pattern Search (AlRashidi et al., 2011), Differential Evolution (Ishaque and Salam, 2011), Penalty-based Differential Evolution (Ishaque et al., 2012), Harmony Search (Askarzadeh and Rezazadeh, 2012), Simulated Annealing (El-Naggar et al., 2012) or Chaotic Asexual Reproduction Optimization (Yuan et al., 2014). In this paper, we propose the use of a Particle Swarm Optimization (PSO) algorithm which has been validated by several authors (Macabebe et al., 2011; Qin and Kimball, 2011; Sandrolini et al., 2010; Ye et al., 2009). According to Ye et al. (2009), this technique is accurate, fast, and easily applicable for the parameter extraction of solar cells from illuminated IV characteristics. Moreover, it does not particularly necessitate initial guesses as close as possible to the solutions, which is an important point as we can study a large amount of different PV solar devices. The interest of PSO algorithms for applications in power systems has also been demonstrated by Del Valle et al. (2008).

3.1. PSO configuration

The Particle Swarm Optimization is a metaheuristic which is trying to improve a candidate solution by successive iterations. It is inspired by social behaviour of living organisms such as bird flocking. The members of the population, the particles, are initially dispersed in the search area with random coordinates (position and velocity). At each iteration, the fitness of each particle is evaluated. The algorithm keeps in memory the best solution of each particle and the best solution obtained so far by any particle in the population. This information is then used to update the velocities and positions of all particles to improve the solution. Indeed, the choice of the PSO parameters will have a large impact on optimization performance (calculation time and accuracy). However, PSO algorithms use less parameters compared to other methods such as artificial neural networks and basic principles allow to define some of them more easily. Since 2006, the Standard Particle Swarm Optimization (SPSO) gathers these principles (Maurice Clerc, 2012; Zambrano-Bigiarini et al, 2013). Here, we use the following configuration for standard optimizations:

- Number of iterations: *variable;*
- Number of particles in swarm: 40;
- Cognitive acceleration coefficient: 2.8;
- Social acceleration coefficient: 1.3.

These parameters can always been modified depending on the problem and expectations. As an example, a compromise can be found between calculation time and accuracy by changing the number of iterations and particles.

3.2. Methods

According to the approach chosen in this paper, the most direct method would be to extract the five electrical parameters from (eq. 5) using a PSO algorithm. However, it is known that some of these parameters are interrelated or correlated to other parameters such as the short-circuit current I_{sc} or the open-circuit voltage V_{oc}. The advantage of these two variables is that they can also be obtained by measurements.

If we set the current to 0 in (eq. 4), the voltage takes the value of the open-circuit voltage V_{oc}:

$$I_{ph} - I_0\left(e^{\frac{qV_{oc}}{nkT}} - 1\right) - \frac{V_{oc}}{R_{sh}} = 0 \quad \text{(eq. 7)}$$

If we set the voltage to 0 in (eq. 4), the current takes the value of the short-circuit current I_{sc}:

$$I_{ph} - I_0\left(e^{\frac{qI_{sc}R_s}{nkT}} - 1\right) - \frac{I_{sc}R_s}{R_{sh}} = I_{sc} \quad \text{(eq. 8)}$$

From these two equations, it is possible, for example, to express n in terms of V_{oc} or I_{sc}:

$$n = \frac{qV_{oc}}{kT\ ln\left(\frac{-V_{oc}}{I_0R_{sh}} + \frac{I_{ph}}{I_0} + 1\right)} \quad \text{(eq. 9)}$$

$$n = \frac{qR_sI_{sc}}{kT\ ln\left(\frac{-I_{sc}R_s}{I_0R_{sh}} + \frac{I_{ph} - I_{sc}}{I_0} + 1\right)} \quad \text{(eq. 10)}$$

This approach allows to extract only four parameters with the PSO algorithm and to determine the fifth with (eq. 9) or (eq. 10). Moreover, it should increase the robustness of the optimization if we have reliable data for V_{oc} or I_{sc}.

4. Application

4.1. Comparison with a synthetic IV curve

In order to test the methods proposed in this paper, it is interesting to work with a synthetic IV curve. This approach presents many interests. First, this type of curve corresponds to perfect curve (without measurement noise) and allows to assess the maximum accuracy which can be reach by the model. As we know the exact value of all the parameters it is also possible to evaluate the accuracy of each of them and their impact on overall model performance.

Here, we use a set of parameters representative of a silicon solar cell (at $T = 306\ K$) and reported in several literatures (Ye et al., 2009):

- $I_{ph} = 0.7608\ A$;
- $I_0 = 3.223 \times 10^{-7}\ A$;
- $n = 1.4837$;
- $R_s = 0.0364\ \Omega$;
- $R_{sh} = 53.76\ \Omega$.

It is also required to determine V_{oc} and I_{sc}, which are used in this method. The exact value of I_{sc} can be directly calculated from (eq. 5) using the Lambert W-function. From this equation, it is also possible to extract the value of V_{oc} using a numerical solver such as *fsolve* function in MATLAB environment.

To determine the best approach, we compare the three possibilities presented in 3.2. The first consists in the application of a PSO algorithm to extract the five parameters from the IV curve. The other two are based on the same PSO algorithm but use V_{oc} and I_{sc} for the calculation of the diode ideality factor n with (eq. 9) or (eq. 10). In each case, we set the same initial values and boundaries:

- $I_{ph} = \max(I) \in [\max(I) ; 1.02 \max(I)]\ A$;
- $I_0 = 1 \times 10^{-6}\ A \in \left[1 \times 10^{-10} ; 1 \times 10^{-4}\right] A$;
- $n = 1.5 \in [1 ; 2]$ (not used when calculated with V_{oc} or I_{sc});
- $R_s = 1\ \Omega \in \left[1 \times 10^{-5} ;\ 1 \times 10^{2}\right] \Omega$;
- $R_{sh} = 1\ \Omega \in \left[1 \times 10^{-3} ;\ 1 \times 10^{5}\right] \Omega$.

The initial values are quite far from the researched parameters and the boundaries are large enough to match different types of solar cells.

To compare these methods, we run 10 simulations with 1000 iterations and 40 particles in each case. First, we focus on the error made on the current I by calculating the Mean Absolute Error (MAE) for each simulation. All the results are presented in Fig. 3 and show important variations between the three methods.

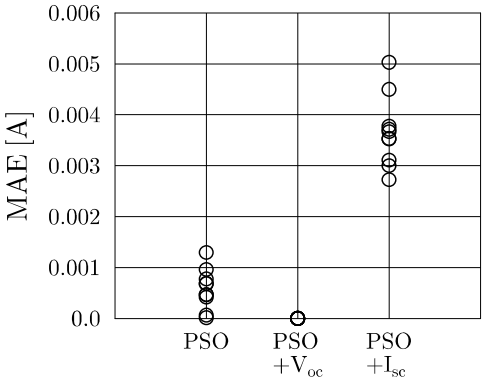

Fig. 3: Performance of the three methods on 10 simulations

The use of the PSO to extract the five parameters provides a MAE between 1.45×10^{-5} and $1.29 \times 10^{-3}\ A$. Even if these errors seem quite low, their differences show that the method is not particularly robust. Moreover, these errors still have an important impact on the electrical parameters, as seen in Fig. 4. As an example, the most impacted parameter, I_0, has a relative error varying between 1.80% and 244%. If we need a very high precision on parameters (relative error lower than 2% for each parameter), only one simulation in ten fulfilled this condition here. To ensure this precision each time, it will thus be necessary to run many simulations which will be time consuming if we apply this method on several solar modules with a low time step. It should also be noted that we did not observe any effect of error compensation between parameters. In each case, the lowest error on current is obtained when each parameter is the closest to its real value. We thus clearly observe that the optimization of this method to further reduce the error is not meaningless and will lead to a better extraction of parameters.

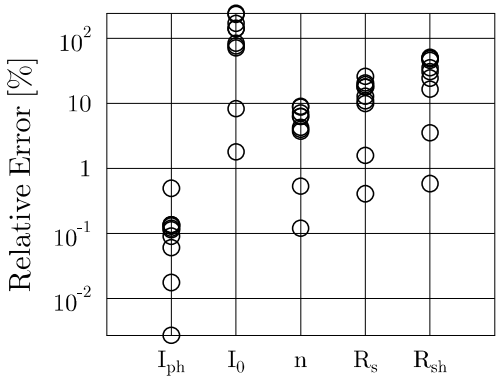

Fig. 4: Relative error of electrical parameters extracted by PSO on 10 simulations

As shown in Fig. 3, the addition of (eq. 9) with V_{oc} calculation significantly improves the performance of the optimization. We observe that all simulations tend to the exact solution, with a MAE of about $1.45 \times$

$10^{-17}\ A$, leading to a perfect extraction of all electrical parameters. This method is thus more robust and could be further improved by determining the best algorithm complexity (number of particles and iterations) while maintaining a high precision. The Fig. 5 also shows that much less iterations are necessary to reach a satisfying result. If we are looking for a MAE of about $10^{-5}\ A$, which corresponds to a near perfect extraction of parameters, we observe that 150 iterations are enough when we use the PSO combined with (eq. 9). If necessary, this result allows to bring an important decrease of calculation time.

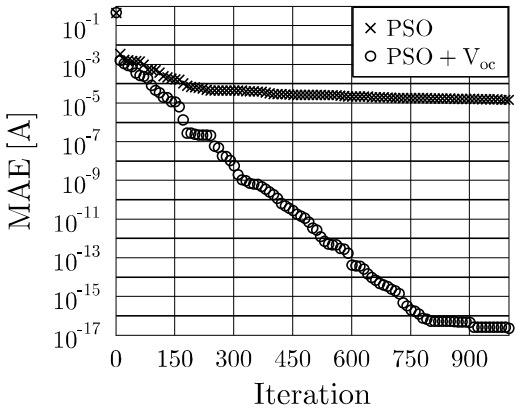

Fig. 5: Evolution of MAE depending on number of iterations

The third case, based on the addition of (eq. 10) with I_{sc} calculation, does not share the same results. Even if the approach is similar, the MAE is varying here between 2.72×10^{-3} and $5.03 \times 10^{-3}\ A$. This precision is thus not satisfying compared to the other methods and does not allow to obtain a reliable extraction of parameters. This difference comes from a stability problem due to the use of (eq. 10). In order to solve this equation, it is necessary to have a positive logarithm and thus:

$$\frac{-I_{sc}R_s}{I_0 R_{sh}} + \frac{I_{ph} - I_{sc}}{I_0} + 1 > 1 \qquad \text{(eq. 11)}$$

Which leads to:

$$\frac{1}{I_0}\left(I_{ph} - I_{sc}\left(1 + \frac{R_s}{R_{sh}}\right)\right) > 0 \qquad \text{(eq. 12)}$$

As I_{ph} is known to be very close to I_{sc}, this equation will often lead to a negative result and thus to an impossible solution during the optimization, decreasing its performance. To improve this method, it is possible to define more efficiently the boundaries and the initialization of the PSO algorithm. However, these conditions will change depending on the technologies studied and this lack of robustness is not suitable for this type of model. Here, the use of V_{oc} appears to be a more robust and reliable method.

4.2. Impact of uncertainties

In the application proposed in the previous section, we used a synthetic IV curve which has allowed to determine the exact value of all parameters. In a real case, even with high accuracy measurements, we have to deal with uncertainties. Here, we want to assess the impact of V_{oc} uncertainties on current and thus on electrical parameters extraction. As the ideality factor n is calculated from V_{oc}, the uncertainties on this parameter necessarily induce a loss of precision. In Fig. 6, we present this impact on the optimization (MAE on current I). In each case, 10 simulations have been run with a percentage error x such as $V_{oc,er} = V_{oc} \pm x(\%)V_{oc}$. We still observe the robustness of the method as all simulations tend to the same result for a given error x. However, it should be noted that a very high precision on V_{oc} is required to obtain reliable results. Indeed, this parameter appears to be very sensitive as we observe an almost linear relationship between the errors on V_{oc} and I.

The applicability of this method thus highly depends on both the precision of measurements and the precision desired for electrical parameters. For our application, we estimate that a MAE of about $10^{-4}\ A$ is more than enough to obtain a reliable extraction of electrical parameters. Here, it allows to extract all

parameters with the following relative errors: 5.03×10^{-3} % for I_{ph}, 6.65 % for I_0, 0.42 % for n, 1.58 % for R_s and 0.57 % for R_{sh}. However, it still requires an error of less than 0.1 % on V_{oc}, which may be difficult to achieve.

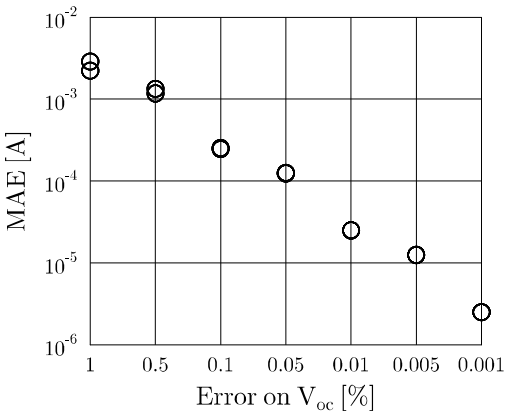

Fig. 6: MAE on current I depending on the error on V_{oc}

With higher error on this parameter, the standard method (direct optimization of all electrical parameters by PSO) could lead to a decrease of overall uncertainty. It is thus needed to compare also these two methods with more realistic IV curves, which may be subjected to measurement noise. For this purpose, it is possible to add a noise in current to assess its impact on parameters extraction. Here, we add a white Gaussian noise with a variance of 0.01, as presented in Fig. 7.

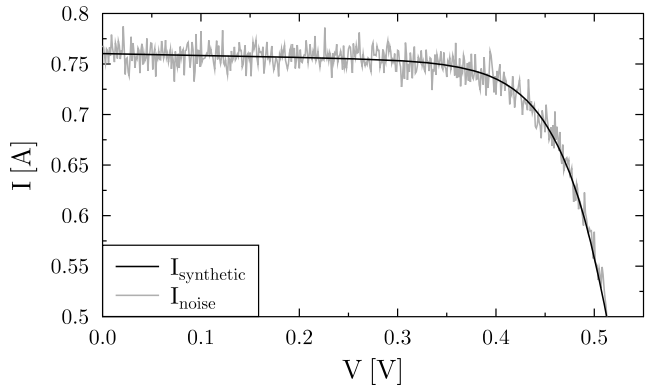

Fig. 7: Synthetic and noisy IV curves (zoom between 0.5 and 0.8 *A*)

In this case, it seems necessary to modify the boundaries of I_{ph}, as $\max(I)$ is no more an accurate value to rely on. We now use the following boundaries: $I_{ph} \in [0.95 \max(I) ; 1.05 \max(I)]$ A, which are broader than the previous ones. For the noisy IV curve, the two methods present an identical error on current I, with a minimal MAE of about 7.67×10^{-3} A on ten simulations. However, as in the previous cases, we still obtain a better robustness of the optimization by using the V_{oc}. Moreover, the electrical parameters are also more accurate with this method, as presented in Tab. 1. The only exception is observed for I_{ph} but the error remains low and the difference is not significant.

Even with noisy IV curves, the method proposed in this paper, based on the use of V_{oc}, still appears to be the best choice to extract the electrical parameters. These results could be probably improved with data processing such as filtering and smoothing which is a perspective of this work and will be assessed on real IV curves.

Tab. 1: Comparison of the two methods on a noisy IV curve

	Real values	PSO	PSO + V_{oc}	Relative Errors (%)	
				PSO	PSO + V_{oc}
I_{ph}	$0.7608\ A$	$0.7600\ A$	$0.7619\ A$	0.11	0.14
I_0	$3.223 \times 10^{-7}\ A$	$7.597 \times 10^{-7}\ A$	$2.464 \times 10^{-7}\ A$	135.71	23.54
n	1.4837	1.5737	1.4574	6.06	1.78
R_s	0.0364 Ω	0.0298 Ω	0.0372 Ω	18.13	2.07
R_{sh}	53.76 Ω	83.55 Ω	42.73 Ω	55.42	20.51

5. Conclusion

In this paper we proposed an alternative method to extract the electrical parameters from IV curves with a single diode model. The calculation of the diode ideality factor based on the open-circuit voltage allows to improve the parameters extraction with a Particle Swarm Optimization algorithm. In comparison with a direct optimization of all parameters, which is often used, this method provides much more accurate results. With a synthetic IV curve, it is possible to reach a MAE on current of about $10^{-17}\ A$, leading to a perfect extraction of parameters. This method is also more robust, as we reach similar precision for each simulation with less iterations. Even if a high accuracy on the open-circuit voltage is needed to obtain such results, we observed that it is still applicable for noisy IV curves which are more representative of real measurements.

In the framework of DURASOL project, this study will be applied on real IV curves from different solar PV devices. The next step of this work will thus focus on the real data processing (filtering and smoothing) and on their interpretation. The main contribution will concern the use of this valuable information in order to assess correlations between PV degradations and environmental conditions.

6. Nomenclature

Name	Symbol	Units
Temperature	T	K

Multi-objective genetic algorithm for the optimization of a PV system arrangement

Freitas, S.[1], Serra, F.[1], Brito, M.C.[1]

[1] Instituto Dom Luiz (IDL) - Faculdade de Ciências, Universidade de Lisboa (FCUL), Campo Grande, 1749-016 Lisboa, Portugal

Abstract

Urban landscapes feature complex topographies and many shadow casting elements, which can jeopardize the energy yield of building integrated photovoltaic (BIPV) systems. Phenomena like partial shading have a significant impact in the electric performance of PV modules, mostly when systems are deployed in conventional arrangements regardless of surrounding obstructions. The goal of this assessment is to test a multi-objective genetic algorithm (MOGA) in order to find one optimal string sizing and tiling, considering two different scenarios: a west facing building facade and a south facing rooftop, both located in Lisbon, Portugal. Relevant loss mechanisms are considered, such as hourly solar irradiance changes caused by shadow events, high incidence angles and module temperature. Optimization processes allow a reduction of around 24% and 23% in the cost of energy for the rooftop and the facade, respectively, when compared to a scenario that considers individual modules with micro-inverters.

Keywords: *Photovoltaic, partial shading, genetic algorithm, multi-objective optimization*

1. Introduction

Planning a PV system often relies on software-based approaches that employ averages of solar radiation and ambient temperature for the desired location. When non-obstructed areas are under consideration, such simplistic methodologies might be reliable as a means to estimate energy yields. However, when there is complex dynamic shadow casting (typical in urban environments), the incident solar radiation can vary dramatically throughout the day, requiring a more detailed system sizing procedure: as the connection between solar cells and modules is done in series (PV strings), partial shadow on one of the modules significantly impacts the production of the whole string.

Shadow patterns cast on surfaces make this a non-trivial problem for systems optimization. These problems cannot be fully represented and solved through well-defined mathematical expressions, since they deal with continuously changing and entangled variables. When a problem has neither a unique and obvious solution or the search space is overly large, or even if the problem has more than one objective, Genetic Algorithms (GA) (Goldberg, 1989) are numerical modelling procedures that can be used to reach one possible optimal solution. GA rely on the replication of the behavior of natural evolution of species in nature, and for that purpose populations of individuals are created, which are then subject to selection, recombination and mutation operators.

A different approach would be to avoid numerical optimization and invest in micro inverters as an alternative to conventional string based systems (Kurokawa et al., 1997). Micro inverters are immune to output power drop when a module is partially shaded thus avoid mismatch losses. Nevertheless, their installed power cost is higher and maintenance can be costly and hard to perform in urban environments, such as in vertical mounted systems.

The goal of the present assessment is to address two different surfaces to test a multi-objective GA aiming at maximizing the PV production of the system and minimizing system costs (wiring, module and inverter costs). The relevant losses to the system are considered together with solar radiation changes caused by shadow events. The solutions obtained are compared with micro inverter scenarios.

2. Methodology

In order to estimate the PV production of a system, solar radiation data is mandatory. However, while solar radiation long-term measurements in the horizontal plane are somewhat common, measurements on the tilted plane are rare, which demands the employment of a solar potential algorithm adapted to a 3D environment. The SOL model was used (Redweik et al.,2013) to calculate annual solar irradiance in a 3x6m^2 south facing rooftop

doi:10.18086/swc.2015.05.16 Available at http://proceedings.ises.org

and a 7x5m^2 west facing building façade (Fig. 1), obtained from a digital surface model (DSM) of the district of Campo Pequeno, in Lisbon, Portugal (38.74N, 9.15W), with 1m^2 resolution. A local typical meteorological year (TMY) data set allows hourly irradiation calculations for any point of the DSM, taking into account mutual shading between buildings and other urban elements.

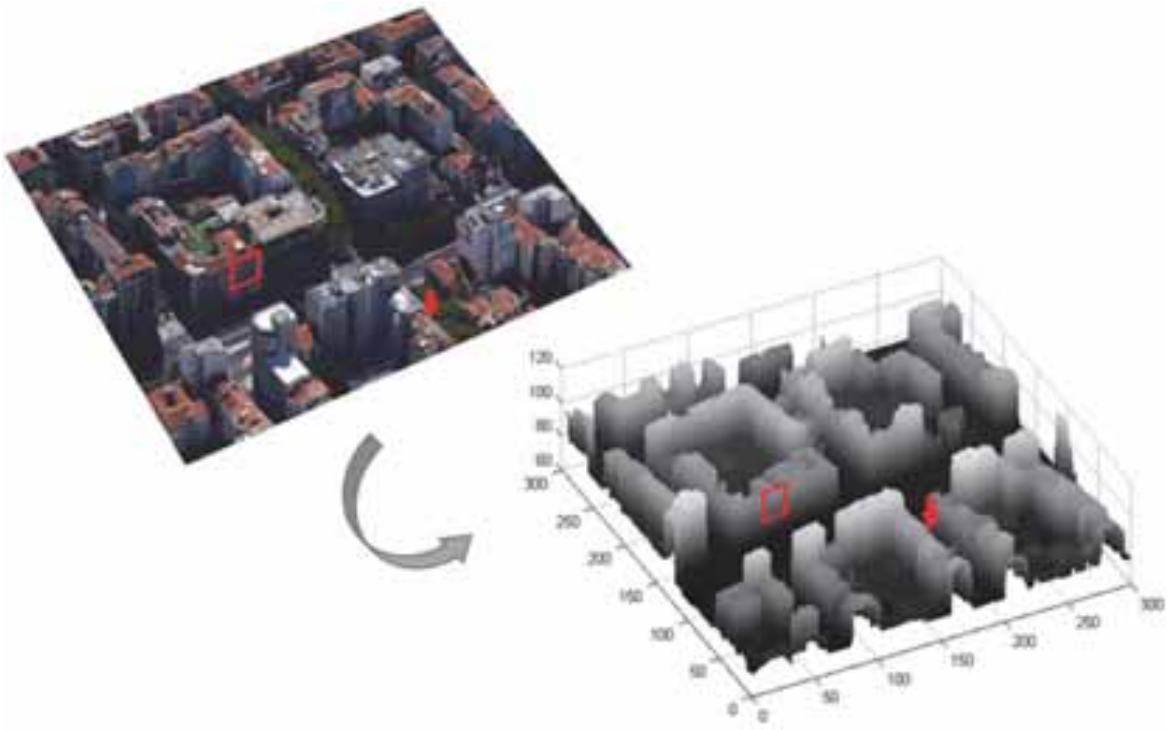

Figure 1 – Bird's eye perspective for the area under analysis and the respective digital surface model (DSM). The rooftop and façade case-studies are indicated in red.

The electricity production estimate considering relevant losses to the PV system typical 1m^2 PV module characteristics were considered and employed in the following equations (Marion, 2002):

$$T_{m,p,t} = T_{a,t} + \frac{T_{NOCT} - 20\ ^{o}C}{800\ W m^{-2}} G_{p,t} \quad \text{(eq. 1)}$$

where T_a is the ambient temperature in °C, NOCT is the Nominal Operating Cell Temperature, G is the Global irradiation on the tilted plane in Wh/m^2, the index *m* identifies one module, the index *p* identifies a position on the layout and *t* is the time index.

The effect of the temperature on the efficiency of each PV module can be estimated through (eq. 2) while the expected angular losses due to the angle of incidence in the panels is given by (eq. 3):

$$\eta_{m,p,t} = \eta_{ref}\left[1 + \Delta\eta(T_{m,p,t} - 25)\right] \quad \text{(eq. 2)}$$

$$AL_{\alpha,t} = \frac{\left(1 - e^{-\cos\alpha,t/a_r}\right)}{\left(1 - e^{-1/a_r}\right)} \quad \text{(eq. 3)}$$

where α is the irradiance angle of incidence and a_r the angular losses coefficient (Martin et al., 2001).

Then, as PV modules are connected in series in a string, by knowing the positions of the modules that belong to each string in the surface, the hourly expected energy yield in Wh of all PV strings can be estimated by:

$$E_{s,t} = min\left(G_{p,t}\eta_{m,p,t}AL_{\alpha,t}\right) n_{m,s} A \eta_{i,s} \quad \text{(eq. 4)}$$

where the index *s* identifies a PV string, the index *p* identifies the positions of the modules belonging to string *s*, $n_{m,s}$ is the total number of modules in string *s*, A = 1m^2 is the module area, and $\eta_{i,s}$ = 0.95 denotes an average

efficiency of the inverter *i* connected to string *s*. The *min*() function reflects the fact that the current in a string is determined by the lowest module current in that string.

The PV production function of a system layout with n_s strings can be defined by adding the hourly PV yield of all strings throughout the year:

$$E_{syst} = \sum_{s=1}^{n_s} \sum_{t=1}^{n_t} E_{s,t} \quad \text{(eq. 5)}$$

The total systems cost of a certain PV layout is assumed to cover three components: the cost of the modules plus the copper wiring required to connect the modules in series and the inverters needed to the conversion of the output current from DC into AC. Since the purpose of the optimization is the selection of the layout but not the full financial project evaluation of the project, no maintenance or operating costs nor discount rates were taken into account in the system costs function[1], which is defined by:

$$C_{syst} = C_m \sum_{s=1}^{n_s} n_{m,s} + \sum_{s=1}^{n_s} L_s C_s + \sum_{i=1}^{n_i} C_i \quad \text{(eq. 6)}$$

where L_s,and C_s are the length and wire costs for string *s*, respectively, and C_i is the cost of each of the chosen inverters for the PV system. A module price C_m= 150€/m^2 was considered. Thus, the first summation refers to the modules' costs, the second summation to the wiring costs and the third one to the inverters' costs.

The typical constraint of 3% for the maximum voltage drop allowed on a PV string was assumed. Regarding the inverters, in order to distribute the PV strings to a set of inverters, two main constraints must be calculated to prevent unfeasible solutions: $N_{m,i}$ the maximum number of modules connected in a string (eq. 7) and $N_{s,i}$ he maximum number of strings connected to a certain inverter *i* (eq. 8).

$$N_{m,i} \leq \frac{min\left(V_{s\_max}, V_{DC\ max,i}\right)}{V_{oc}[1 + \beta(-10 - 25)]} \quad \text{(eq. 7)}$$

$$N_{s,i} \leq \frac{I_{DC\ max,i}}{1.25 I_{sc}} \quad \text{(eq. 8)}$$

The relevant properties of 13 inverter models were considered (Table 1), including the maximum values allowed for the DC input current I_{DCmax}, the DC input voltage V_{DCmax},and the DC input power P_{DCmax}, as well as prices.

Table 1 – List of 12 inverter and 1 micro-inverter models.

Model	Pnom [kW]	Average price [€][2]	Vcc_max [V]	Icc_max [A]	Pcc_max [kW]
SMA micro	0.24	150	45	8.5	0.24
Fronius 1.5-1	1.5	893	420	13.3	1.5
Fronius 2.0-1	2	916	420	17.8	2

IG 40	3.5	1568	500	29.4	5.5
Plus 60-V1	6	1474	600	27.5	6.32
Plus 70-V2	6.5	1579	600	30.0	6.88
Plus 80-V3	7	1678	600	32.0	7.36
Plus 100-V3	8	1693	600	37.1	8.43
Plus 120-V3	10	1885	600	46.2	10.59

[1] Thus assuming that the O&M costs are independent of the layout connection of the strings, which is an optimistic approach regarding the micro-inverter solution.

[2]Prices retrieved between December 2014 and August 2015 from (SMA, 2015), (CCL, 2014), (Energy Matters, 2014), (MG, 2014)

3. Results

The developed GA, fully described in Freitas et al., 2015, has achieved optimal solutions for the case-studies analysed in this paper with 23% and 24% lower costs of energy, and helped finding one possible solution to give the best trade-off between cost and energy yield.

Rooftop

The optimization process encompassed 50 individuals per generation, with 3% mutation rate, 10% elitism reinsertion rate and a maximum of 500 generations. The best individual in each generation has the lowest cost of energy (C_{syst}/E_{syst}) over a lifetime period of 25 years. In Fig. 2 the optimal layout for the partially obstructed rooftop under study shows 0.22€/kWh, with 5 clustered strings in the most sunlit areas and two places that have no modules (string number 0), while 0.29€/kWh corresponds to individual modules with micro-inverters.

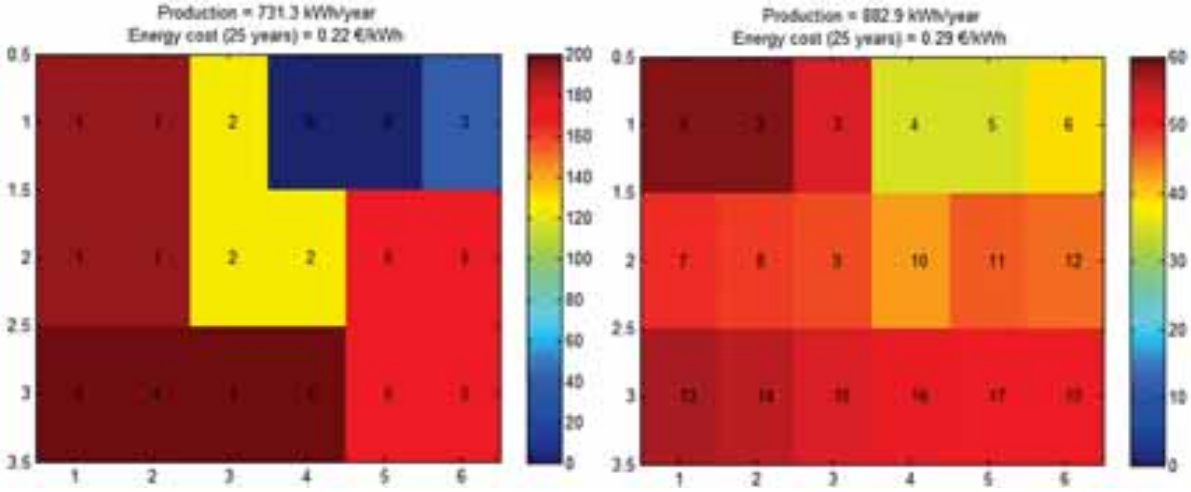

Figure 2 – On the plane perspective of the yearly total and per string PV production [kWh/year] of the optimized distribution of strings (left) and the micro-inverter scenario (right) for the rooftop case-study. Note the differences in the color scale values.

The overview of all individuals throughout the optimization process (Fig.3) reveals that 250 generations could have allowed for a decent optimal layout; however slight improvements were produced after. As all solutions are compared among each other based on their fitness, although some of the individuals with the best cost of energy are eliminated.

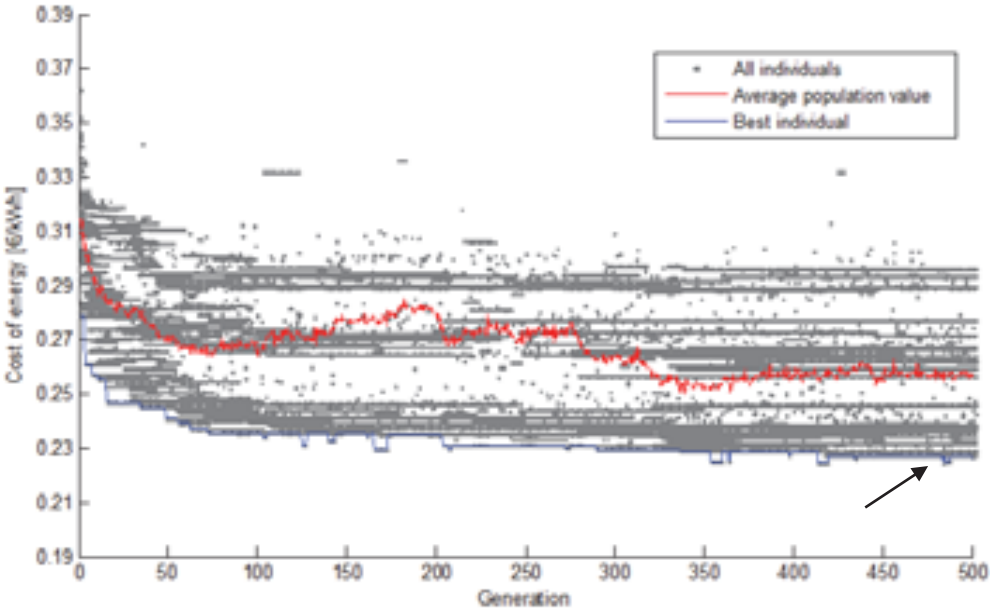

Figure 3 – Chart with the overview of the Cost of Energy in the course of the optimization process for the rooftop case-study.

All solutions in a generation can be organized in Pareto fronts (Fig. 4), i.e. groups of solutions which optimize both objectives (C_{syst} and E_{syst}) and that are compared among each other. The best fitted individuals belong to the highest Pareto front (red dots) and dominate all the other fronts. Looking specifically at the Pareto fronts

from the initial population and the last, the convergence of solutions throughout the generations is evident. Higher higher yielding solutions, at higher cost, are located in the right end of the front, while more affordable arrangements, but featuring lower electricity production, can be found in the left. The layout with micro-inverters is placed on the top right, achieving high yields but requiring very high investment, thus being far from the optimal solution (€/kWh).

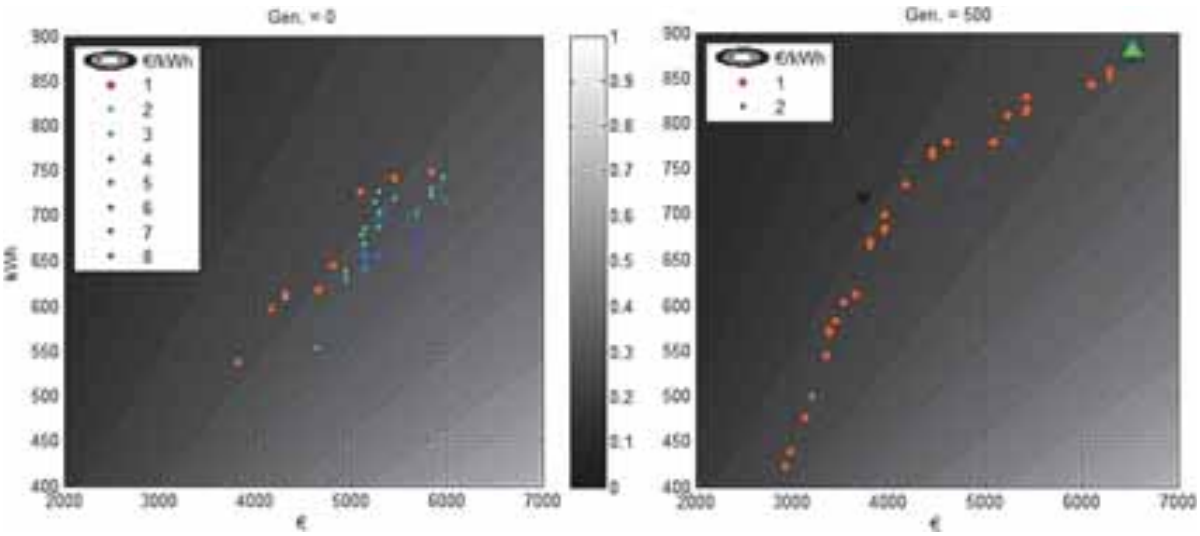

Figure 4 - Comparison between the Pareto fronts from the initial (left) and 500th (right) generations. The arrow points the individual with minimum €/kWh in 25 years of system lifetime (i.e. 0.22 €/kW h and 731 kW h/year) and the green triangle marks the location of the micro-inverter scenario.

Facade

The building facade case-study optimization followed the same procedure. In Figure 5 the optimal layout reveals that a west facing and also partially obstructed facade is able to match PV production of a rooftop in non-optimal conditions (0.30 vs 0.22 €/kWh). It is worth mentioning that this facade layout accounts for blanks that represent prohibited locations for modules, in this case due to windows or balconies.

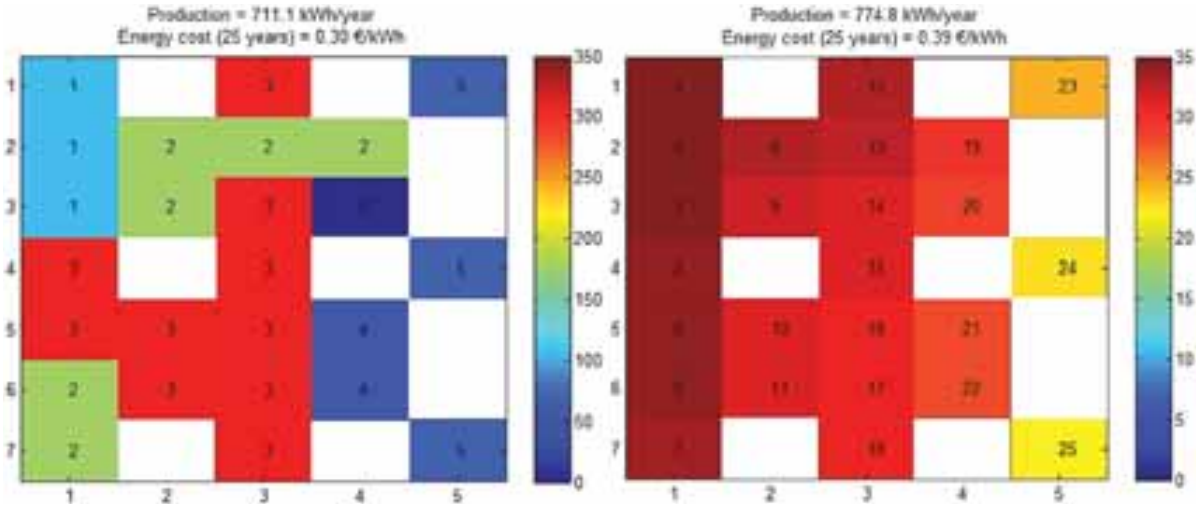

Figure 5 – On the plane perspective of the yearly total and per string PV production [kWh/year] of the optimized distribution of strings (left) and the micro-inverter scenario (right) for the facade case-study. Note the differences in the color scale values.

Again, optimization proves to be more cost-worthy than installing micro-inverters for all individual modules. The Pareto fronts of the initial population and 500th generation (Fig.6) also corroborate conclusions taken from the rooftop assessment.

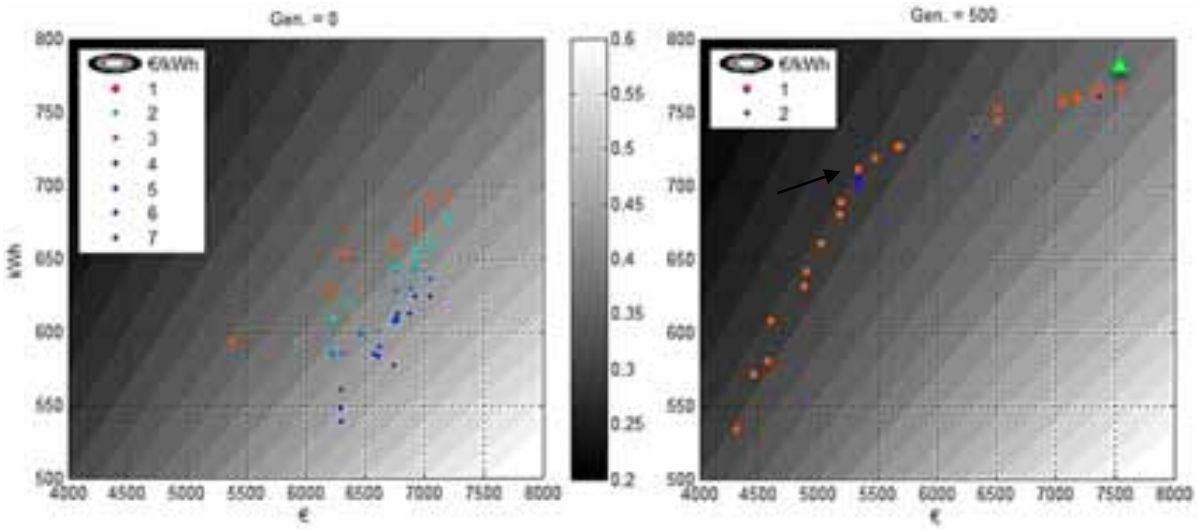

Figure 6 - Comparison between the Pareto fronts from the initial (left) and 500th (right) generations. The arrow points the individual with minimum €/kWh in 25 years of system lifetime (i.e. 0.30 €/kW h and 711 kW h/year) and the green triangle marks the location of the micro-inverter scenario.

4. Conclusions

A partially obstructed south facing rooftop and a west facing building facade were subject to a PV system sizing optimization using a multi-objective genetic algorithm (MOGA). This study aimed at the maximization of yearly energy yield, based on hourly solar radiation profiles obtained from a 3D urban-oriented solar potential model, and the minimization of wiring, modules and inverter costs, and the comparison with a micro-inverter scenario. Results show which PV string tiling strategies are more adequate in case the end-user has financial limitations or aims at the highest possible yield. By examining the arrangements with minimum cost of energy €/kWh, it is suggested that higher number of PV strings formed by individual modules using micro-inverters achieves the highest electricity yields, but the costs double those of the layouts with longer and clustered strings in the more sunlit areas. An improvement of 23% and 24% in the cost of energy is observed from the micro-inverter scenarios to the MOGA solutions.

Abstract

One of the world's largest solar mini-grids was installed for the community of Bamiyan in central Afghanistan in 2013. The 1 MWp photovoltaic/diesel hybrid mini-grid was installed by a partnership led by Sustainable Energy Services International (SESI) for the Government of New Zealand as part of international donor infrastructure development for the country. This paper details system design, operation, and lessons learned.

Keywords: *Mini-grids, photovoltaics, Afghanistan*

1.0 Introduction

Bamiyan formed part of the ancient Silk Road in central Afghanistan and lies 230 km northwest of Kabul at an altitude of >2,500 meters. The ancient history of Bamiyan is witness to the invasions of Genghis Khan in 1221, who massacred every person and living thing in Bamiyan at the still desolate "City of Screams." Marco Polo visited Bamiyan in1271 and wrote of its splendor and famed Buddha statues (sadly destroyed by the Taliban in 2001). Today the community is largely comprised of the Hazara ethnic group, and is a relatively peaceful haven designated as a UNESCO World Heritage Site (Rakotozonia, 2011). Bamiyan is also the gateway to Afghanistan's first national park at the beautiful Band-e Amir Lakes.

Due to its remote location and rugged terrain, Bamiyan has never been connected to the national electric grid, and only a modest diesel plant was used to supply power to the main bazaar area. Prior to the arrival of the solar mini-grid in Bamiyan in late 2013, some of the 20,000 villagers used small solar panels to provide some basic electric lights and communications for their homes. Some also used generators and rented out power to their nearby neighbors at an approximate cost of 300 Afs (~US$4.68) per bulb per month for four hours a day. This equates to around US$1.95 per kWh.. In the Mulah Ghulam neighborhood, the Afghan government through Ministry of Rural Rehabilitation and Development (MRRD) had also previously installed a diesel generator, but it did not operate for very long as with most diesel similar efforts in Afghanistan since diesel fuel was difficult to truck in and unaffordable for the residents. The absence of power metering for billing purposes also adds to the inability for isolated systems to achieve financial sustainability.

The New Zealand Ministry of Foreign Affairs (MoFA) approved development of a one MW solar-diesel hybrid mini-grid system, called the Bamiyan Renewable Energy Project (BREP) in 2012. The system was divided into three smaller systems in order to reach a larger customer base. An additional smaller system was initially planned for connection to the generator for the Bamiyan Bazaar. This plan was later modified for technical reasons. The equipment allocated for this smaller 40 kW system was reallocated for a system to power a portion of the community in the nearby Folaadi Valley.

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.05.17 Available at http://proceedings.ises.org

The Bamiyan Renewable Energy Program (BREP) was contracted by the New Zealand Ministry of Foreign Affairs and Trade (MFAT) to provide power and built as a joint venture of Sustainable Energy Services International (SESI) and NetCon, both New Zealand registered companies. The BREP generation system provides high-quality, 230 V, 50 Hz electricity to about 1,800 households in several neighborhoods around the Bamyan City area. The installation began in August of 2012 with the system beginning operation in October, 2013. The total project cost was US$14.1 million, including all tranmission and distribution lines, capacity building and construction. After completion of construction, the system was given to Da Afghanistan Breshna Sherkat (DABS), the Afghan utility company who now wholly owns and operates the system. The BREP Project Developers included

- New Zealand Ministry of Foreign Affairs and Trade (MFAT)
- Sustainable Energy Services International: SESI (prime)
- DABS: Da Afghanistan Breshna Sherkat (national utility)
- NET Con (distribution)
- Stephenson & Turner Architects & Engineers
- Snowy Mountain Engineering Company: SMEC (review)

It should be noted that over the past four decades, several studies and falst starts have been made in Bamiyan to develop a small hydro-electric project. There exists sufficient hydro resource potential for developing a small ~750 to 1,000 kW hydro plant near Bamiyan in Topchi that could be implemented to help meet the growing energy needs of the community that will grow beyond the present solar mini-grid system. A complete feasibilty study and design for this proposed project was prepared by the USAID Afghanistan Clean Energy Program (ACEP) in 2010 by Winrock International (Winrock, 2010).

1.1 Initial Design Stages

The design of the system was definied and constrained by two factors. The first determination was the overall size of the community and the demand for energy. Secondly the budget available to meet the demand. The design of the system was undertaken by Sustainable Energy Services International. Primary considerations were:

- The average demand from each household, and time of day of consumption.
- The population size, and expectations of growth in population and power demand.
- Socioeconomic factors influencing system operation and management
- Environmental and human capacity factors impacting component selection

Average loads of 200 watts per household were allowed, and 1.5 kWh per household per day were estimated based on previous experience with rural electrification, and allowing some room for future growth in demand.

The system design expects either additional solar panels to be installed as the population and/or demand for power grows, or for the use of the diesel generator to increase to meet demand if additional investment in solar PV is not made.

The system is also designed to allow the solar PV and transmission/distribution network to be merged into the wider Afghan power network in future, with all components constructed to international standards.

Component selection was designed to allow for modular components for inverters that could survive the dust and heat of Afghanistan, and also be installed and maintained by semi-skilled staff. This led the designers to favour the AC bus architecture of SMA (Germany) equipment, coupled with the flooded lead acid technology of Crown Batteries (USA).

Key to the long term success of the project was for financial viability to be built into the project. Pre pay power meters were installed at each household, on the pole outside to reduce meter tampering and power theft. This has been successful. The tariff calculation was undertaken by DABS, and set at US$ 0.25 for domestic use and US$ 0.70 for commercial use. The contractor preferred a single flat tariff for all consumers

to avoid complication and more accurately reflect the cost of power for all consumers, but the split tariff was preferred by DABS.

To purchase power, consumers pay cash at the local bank into the DABS account, and then take the receipt to the DABS office who use an electronic dispensing unit to add power credits onto the consumer card. The consumer then takes the card back to their house and inserts the card into their meter to transfer the credit onto the meter. Consumers were required to purchase the prepay meter and consumer connection cable from DABS for the subsidised rate of US$30. DABS supplying the cable ensured that the correct cable quality was used. All household cables are buried, to reduce illegal temporary connections made to overhead lines.

2.0 Bamiyan Solar Mini-Grid Design and Components

The Bamiyan Renewable Energy Program (BREP) generation system provides 230 V, 50 Hz electricity to 2,400 households in several neighborhoods around the Bamyan City area. This 1,050 kW of power is divided between four generation sites: 400 kW at the Bamiyan New City site, 300 kW at the Hyderabad site, 300 kW at the Mullah-Gholam site and 50 kW at the Folaadi valley site. Each system has a main solar energy power plant and a backup diesel power plant. Each of the power generation sites is connected to a dedicated 20 kV transmission and 0.4 kV distribution system. These generation and distribution sites are not connected. The small site at Folaadi Valley connects directly to the distribution lines at 0.4 kV. A series of step down transformers reduces the voltages from the transmission lines and for supply into the distribution system. Each of the customer connections is 230 VAC and has a digital prepay electricity meter.

These provide energy to consumers 24 hours a day. For most of the year the solar energy system provides all of the power to the loads during the day while charging the batteries. During nighttime and times of poor solar insulation a diesel generator on site will automatically start and charge the batteries.

2.1 Power Generation

The solar modules provide the primary generation source, with the diesel as secondary source, and batteries for energy storage. Figure 1 below provides a visual representation of the generation system topography.

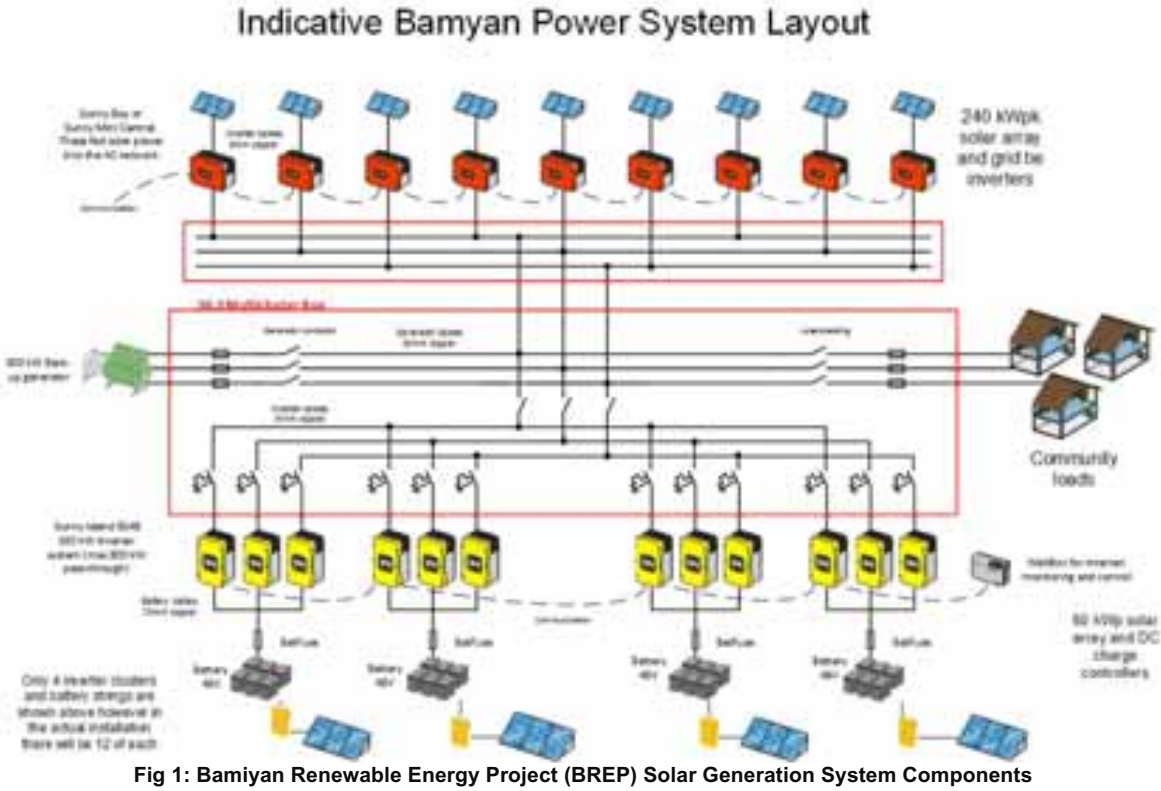

Fig 1: Bamiyan Renewable Energy Project (BREP) Solar Generation System Components

All components except for the solar modules, grid inverters, generator and transformer are contained within the powerhouse: an insulated, secured, weatherproof, and electrically grounded building on the grounds of the generation facility. All components are equipped with disconnects, allowing each component to be electrically isolated from any other component of the system. These disconnects variously include switches, fuses, relays and circuit breakers.

The primary power supply to the communities during daylight hours is directly from the solar arrays to the distribution network via the 3 phase AC inverters. Surplus power generation during the day is used to recharge the batteries, ready for use at night. The diesel generator is only used during bad weather or high demand periods.

2.2 Solar Modules and Inverters

Due to constraints of how much power can be sent to the batteries through the inverter/chargers, a small portion of the solar modules is directly connected to DC charge controller that uses the DC power to directly power the batteries. The battery inverters convert the DC power in the batteries to AC power that feeds to the grid. At the three large sites, the DC arrays consist of 288 modules; connected in arrays of 12 modules each to each charge controller. In total the system has 24 charge controllers, with two charge controllers each for the 12 battery banks. At Folaadi Valley, all 192 of the modules are connected to battery inverters. Each battery bank powers three battery inverters; with each of the three inverters providing one phase of power for the system. These 36 battery inverters all connect through the multicluster box that combines and controls power from the AC solar arrays, the diesel generator and also controls power fed back out to the grid.

The remaining solar modules are connected to the grid inverters. These are SMA three phase inverters installed at the site of the solar modules, and directly connected to the multicluster box. The site at Bamiyan New City has a slightly different configuration. It has 400kW of solar modules instead of the 300kW at Hyderabad and Mullah Gholam. This 100kW extra of solar modules is connected directly to the transformer. The Bamiyan New City generation site is connected to most of the high-power loads in Bamiyan City, including government buildings and large NGO offices. The design assumes that this portion of the city will experience higher day time loads from government offices and NGO's, thus the design is weighted towards higher day time power generation. The direct connection to the transformer bypasses the multicluster box and allows for the additional 100 kW of PV power to be supplied with minimal electrical losses.

The battery inverters are the "brains" of the power generation system. While all of the inverters are identical products, their software is configured differently to allow them to perform different functions. The 36 battery inverters are distributed into 12 clusters of three inverters each: one main cluster and 11 slave clusters. Each cluster has one master inverter and two slave inverters. The master inverter synchronizes the single-phase output of each inverter to create three-phase power output; controls the power draw from each of the two charge controllers for the cluster; and copies any changes in settings from itself to its two slave inverters. The main master inverter in the master cluster in turn controls these master inverters.

The master cluster has the same master-slave topography of the other clusters. However, it additionally controls the master inverter of each cluster. The main master inverter synchronizes the three-phase power output from each inverter; copies settings from itself to each of the main master inverters; and has the ability to start up or shut down the entire generation system. Not only does it control the master inverters, but it also controls some other elements of the system. These include the relays in the multicluster box for connecting and disconnecting the grid inverters, the battery inverters, the generator, and the transformer; a relay that remotely starts and stops the generator; and a relay that starts and stops the powerhouse ventilation fan.

Fig. 2: One of the Large BREP PV Arrays: 300 kWp at the Mullahghulam site

2.3 Diesel Generator

Each of the three large sites is equipped with a 275 kVA diesel generator made by FG Wilson. The diesel generator will automatically start when either the demand from the loads is more than the battery inverters and solar inverters combined can provide; or when the demand might cause the battery state of charge to drop to a low level. The generator is equipped with an external 3,000 liter fuel tank. The Folaadi valley site has a smaller 30 kW FG Wilson diesel generator. The main master inverter controls the autostart for the diesel generator at each site.

2.4 Battery Storage

The system uses flooded lead acid batteries manufactured by Crown (USA) for backup. Tab. 1 below gives the key parameters for the batteries used in the system.

Tab. 1. Battery Bank Parameters for the Bamiyan Solar Mini-Grid

Parameter	Value	Unit
Capacity	3750	Ah
Nominal Discharge Rate	20	hours
Nominal Operating Temperature	27	°C
Battery Voltage	8	V
Weight	860	kg
Cell voltage	2	V
Number of Cells	12	
Depth of Discharge	40	%
Cycle Life	3800-4000	Cycles
Batteries per Cluster	6	
Cluster Voltage	48	V
Batteries per Large Site	72	
Batteries at Folaadi Valley	12	
Total Batteries	228	

Each battery bank is charged and regulated by the two charge controllers in each cluster. As vented lead-acid batteries, the batteries must periodically have water added to the cells. To facilitate this process, each battery has a hose system connecting all of the cells. Each powerhouse is equipped with an automated battery watering system. This system consists of a water tank, a water deionizer and a battery-watering cart with a pump. This watering cart connects to the hose and automatically fills each cell to the appropriate level. The system is designed for a 40% depth of discharge. Under proper maintenance the battery bank should have a

lifetime of about 7 to 9 years of operation, or longer depending on how it is used and maintained. Figure 3 below shows the arrangement of the battery banks in the power house.

Fig. 3: Crown Battery Banks each at 48 V; 3,747 Ah at a C/20 Discharge Rate

2.5 Transmission and Distribution

The transmission and distribution system begins at the step up transformer at the generation site and ends at the customer connections. The three large systems produce 400V three-phase electricity at the generation site. A transformer at the generation site steps up the power from 400V to 20kV for transmission. At the interface between the transmission and distribution systems, another transformer steps down the 20kV three-phase electricity to 400V three-phase electricity. The network at Folaadi Valley has no 20kV portion due to the close proximity of the consumer loads, so no transformers are used.

Most of the loads in Bamiyan come from residential homes and hence are only single phase. Larger consumers, including government offices and businesses have a 3 phase supply and 3 phase meter. The distribution pole and lines used the original ACEP proposed distribution design for the Topchi hydro-power plant (Salinas, 2011). The transmission network was installed by NetCon, a New Zealand electrical lines company. The lines were built to New Zealand Standards and installed by professional NZ linesmen.

Each transmission and distribution network is equipped with a recloser that can automatically isolate the electrical lines from the generation source. In the case of faults on the line, the recloser will disconnect and reconnect the lines a few times to see if the fault opens. If the fault does not correct itself, the recloser will leave the lines disconnected until a technician can repair the problem.

Fig. 4: BREP electrical distribution system as installed by NetCon

Fig. 5: SMA Multi-cluster Hyderabad BREP Power House with Sunny Island Battery Charging Inverters

Fig. 6: SESI trained and utilized Afghan women technicians as part of the installation crew.

2.6 Interconnection Requirements

The generation system of the power planet produces 230 V electricity at 50 Hz. While this does match the power output of the rest of the Afghan grid, the system cannot connect with the rest of the Afghan electrical grid as currently configured. In order to connect, the Bamiyan system would have to synchronize to the grid signal. However, the battery inverters determine their own synchronization and are not able to synchronize to

an outside signal. If a utility operator would like to connect the Bamiyan system to an outside grid, the battery inverters and the batteries must be removed from the system. The grid inverters, however, can continue to be used after modifying the settings. This will allow the operator to reduce peak loads, but it will not allow them to store energy. As any outside system will likely have some manner of baseload power (e.g. hydro, gas) the system will not require the battery storage of the Bamiyan system. Ideally grid connection would occur before the lifetime of the batteries is completed. This will allow the solar modules to continue creating electricity without requiring the replacement of any energy storage equipment.

3.0 Community Development and System Operation

SESI maintained close contact with the community throughout the course of the project, soliciting their opinions and asking for support in construction and site monitoring. All of the local laborers were hired from communities nearby the power plant sites. In one community there was a problem with someone in the local community stealing grounding wires. The implementing partner worked with the local community to find the perpetrator and to prevent further theft in the future. Maintaining the support of the local community prevented members of the community from delaying the project or harassing the project staff.

The installation team encountered theft of system materials as a recurring problem. Specifically, some members of the local community would cut and steal the grounding cables used on the meter boxes in order to sell the copper for scrap. This problem persisted even when the issue was raised with the local leaders (shura). The project team was forced to delay livening the system in some communities for this reason. Operating the system is unsafe without proper grounding and so these communities had to wait until the theft stopped before they could be connected to the system. Most homes in Afghanistan on the national grid do not use grounding either and electrocution is a danger.

3.1 Metering and Tariffs

BREP uses a prepaid pay-as-you-go model for collecting revenue. This differs from the post-paid analog metered collection system common in the the rest of Afghanistan. Instead of the traditional analog electricity meter, each house is equipped with a digital meter that is charged by means of a charge card. The customer takes the card for their meter to the DABS office where they prepay for an amount of electricity. The DABS staff accepts their payment and adds value to their card by a dedicated charging machine housed in the office. The customer then takes this card back to the meter installed outside his or her home. They insert the card into the electrical meter, where the meter automatically subtracts the value from the card and adds it to it's own internal meter. The meter has a large backlit digital display that shows the current balance for the customer. When the balance reaches zero, the meter automatically disconnects the power.

Currently the electricity tariff is set at AFN 16 (USD $0.25) per kWh for residential customers and AFN 45 (USD $0.70) per kWh for government and business customers. However, the tariffs collected by DABS is not sufficient for the long term sustainable operation of the plant, which would require full depreciation of the batteries, solar PV and distribution lines to be deemed *fully sustainable*. This is actually much higher than the national tariff rate and represent as compromise. However, the cost of fuel alone for operating the plant on diesel backup is about 20 AFN (USD $0.30) per kWh. This means that any time the diesel generators are turned on, the plant is operating at a loss; even before taking into account costs other than diesel itself. The tariff should be high enough to pay for all of the fixed and variable operating costs of the plant as well as making extra money to replace equipment as it fails. The system currently covers all of its own operational and maintenance costs under the current tariff structure however as demands grow, and diesel consumption grows, the setting of the domestic tariff at a rate lower than recovery for diesel means that operating surpluses generated from running on solar PV will diminish over time.

There was some strong suggestions from development agencies to introduce load limiting systems in the supply to each household to *prevent households taking more than their fair share*. This was firmly rejected by SESI as it places a limit on growth, irresective of the willingness and ability to pay of consumers. Instead, our focus was on growing the system to meet demand and facilitate growth rather than the limiting of power and hence community development.

Gradually Bamiyan residents been signing up for the power system and willing to pay the interconnect fee. About 2,000 customers have signed up for BREP out of the 2,500 planned customers so far. Afghans often take a wait and see attitude to see if the system will work before signing up; they are also wary of the relatively high electric tariff as compared to their urban counterparts.

It is estimated that the system will be fully depreciated after 20 years, so the tariff would need to make, at least, 14 million dollars extra over the course of 20 years. As it stands, DABS are able to pay for variable costs of operation; including staff salaries, maintenance of equipment, tools and parts, but due to internal politics it heasitates to pay for fuel for the generators in winter. As of early 2015, DABS was requesting the government of New Zealand to still provide a diesel subsidy for the system operation and it has been shut down at times for lack of diesel fuel. Additionally, DABS must seek a capital injection or outside funding in order to replace equipment at the end of the equipment lifetime. This could be as early as 7 years from the date of installation in the case of the batteries. After parts start to fail, the entire system must be shut down until a new capital source is found.

3.2 System Operation and Maintenance

The largest capacity building need was educating the operator (DABS) about how to operate and maintain the plant. This including training DABS engineers and their participation in the installation of the system. In addition to the engineers, clerical and management staff was trained on how to properly manage an electrical system of this type, how to make customer connections, how to charge customer cards, and how to maintain an accurate accounting system. SESI-NetCon staff remained at the site to operate the system, allowing time to train DABS staff on the proper long-term maintenance of the system.

4.0 System Monitoring and Performance

Recognising the value of monitoring and evaluation to measuring long term project success or failure, Sustianable Energy Services International undertook on itself to perform detailed monitoring and evaluation activities with a professional social survey subcontractor to survey and record community attitudes and expectations on the project. These findings will be contrasted with a followup survey again to be undertaken by SESI and its subcontractor and a detailed report issued once 2 full years of operational data has been gathered.

Initial risks to public acceptance of the system related to the subsidy of other power networks elsewhere in Afghansitan, and the failure to use power meters on other smaller power networks in Bamyan prior to the BREP project. The lack of power metering and the reliance on the lightbuld basis of charging households for power menat that households were completely unaware of how much they actually paid for power. It was only with the introduction of power meters that they could compare their power costs with other cities, and then unfortunately they compared with subsidised power tariffs in cities like Kabul and Kandahar leading to incorrect perceptions that the people of Bamyan were being over-charged for power. This is despite the BREP solar installation reducing actual household power costs down from US$1.95 per kWh to US$0.25 per kWh. The willingness and ability to pay for power was clearly evident, and supported by the increasing demand for power measured over 2014/2015, however the public perception was based more on comparisons with other cities.

4.1 Online Monitoring

Each of the networks is monitored by a complete monitoring system that is web accesible via the local Bamyan cellphone network. The monitoring function allows online monitoring of error codes, power output, voltage and current, battery conditions and other core system parameters. This is extremely useful for troubleshooting and tuning the system to current needs, as well as additional support of DABS in the longer term. An example of the data gathered shown below in Fig. 1 below shows a typical operational period for the network in September 2015. The generator can be seen to have been required only once in this period, as shown by the green bars on the far left. The Total Multicluster Load Power (demand) can be seen shown by

the red line, and power output from the solar arrays by the blue line. The surplus power generated (kWh) is stored in the batteries and meets demand in the night hours.

Fig. 1: Example System Power Output and Load Demand

Expectations of power demand from the community have roughly met expectations, and power demand grew sharply in 2014 once the system was accepted by the community as being real and reliable. This is shown graphically in Fig. 2 below from monitoring from the installation at Hyderabad, one of the three large installations; which shows power demands from 2014 and 2015, and the average demand in bold.

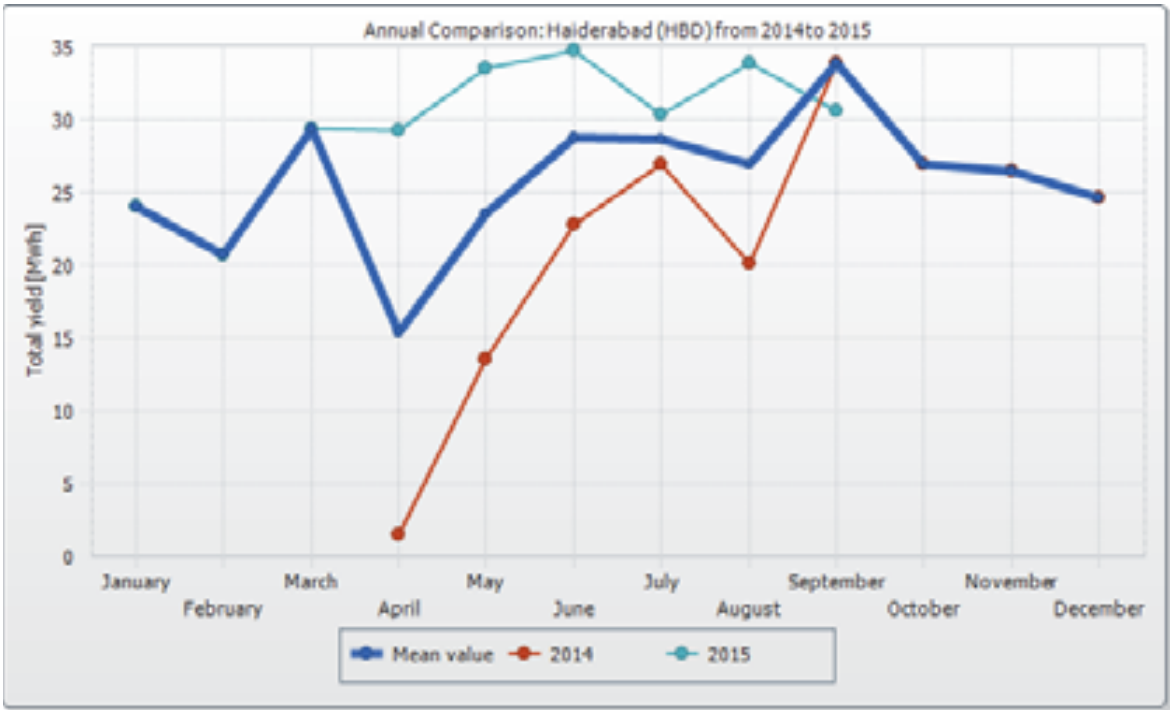

Fig. 2: Year to Year Energy Output Comparison at Hyderabad

5.0 Bamiyan Solar-Diesel 1 MW Mini-Grid LCOE Analysis

Markets currently serviced by diesel generators represent the largest potential market for many kinds of RE, especially solar energy which shares diesel's deployability across much of Afghanistan. To better understand the economics of solar-diesel mini-grids, an economic comparison between off-grid solar systems and diesel systems is considered for a real installed project in Afghanistan. This analysis compares the US $14 million (with T&D) 1 MW Bamiyan solar-diesel hybrid mini-grid energy system to an equivalent diesel only system. The diesel system considered is the same as the diesel backup generators powering the Bamiyan solar energy system, however they are operated more hours per day. The analysis assumes equal annual electricity sales for both systems.

5.1 Methodology and Assumptions

Two calculations are compared in this analysis. The first is the levelized cost of energy (LCOE) for both systems and the second is the net present value (NPV) for each system given an average sale price of the electricity generated. The LCOE calculation first considers the net present value of all costs associated with production of the system over its lifetime. This levelized cost is divided by the estimated energy production over the lifetime of the system, yielding the LCOE.

To assess the financial viability of the systems, a NPV calculation were performed. The profits for each year of the 20 year lifetime were calculated. Then all of these profits were discounted to present dollars, yielding the value of the system in today's dollars.

Electricity sold is considered instead of electricity generated because diesel generators often operate at only a proportion of their highest-efficiency loading. Because the solar system has battery backup, nearly all of the electricity produced can be sold. An exchange rate of 57 AFN per USD was used. A mid-range diesel price of 66 AFN per liter was used reflecting the Central Statistics Organization Q3 2014 data (however, current diesel prices in Bamiyan have recently come down to only 48 AFN per liter but can be expected to go back up in the future). DABS Bamyan currently offers a two-tiered tariff system: 16 AFN per kWh for residential consumers and 45 AFN per kWh for commercial consumers. This analysis assumes that 90% of the energy sold will be to residential customers, giving an average revenue of 17.9 AFN per kWh. Horizontal solar radiation was conservatively estimated at 5.0 kWh per square meter per day from a 2007 NREL estimates discussed in the solar resource section.

This analysis also assumes proper operation of the system. The battery depth of discharge is currently set at 40%, which the vendor (SESI) estimates will allow for a 12 year operational lifetime of the battery bank (depending on user operaiton and battery abuse, it could only be half of this lifetime). There will be some short-term incentive to set the depth of discharge lower (eg. 50%-80%). This will dramatically reduce the operational lifetime of the batteries and necessitate several replacements over the operational life of the system. A discount rate of 10% was assumed for the investments.

5.2 Life Cycle Cost of Energy (LCOE) Analysis

The table below shows key values determined by the analysis for both the solar and diesel systems. The LCOE of energy for the diesel only case was calculated at US$0.32 /kWh, while that for the solar diesel was calculated at US$0.46/kWh (about mid-range). The solar system may actually cost more depending on battery replacements. The LCOE for the solar system without batteries would be about half of this estimate.

Tab. 2. Bamiyan 1 MW Solar-Diesel Mini-Grid Analysis

Parameter	Diesel	Solar-Diesel
LCOE	$0.32	$0.46
NPV at Current Tariff	-$4,550,152.85	-$10,338,220.81
Average Tariff Needed for Profitability	AFN 48.4 (USD $0.61)	AFN 74.4 (USD $1.31)
NPV Sensitivity to Diesel Prices (Per dollar change)	$4.29 million	$0.26 million

Neither the solar-diesel nor the diesel only system is profitable at the 90% residential sales ratio. The solar system achieved a positive revenue flow, but was never able to make up for it's capital outlay if full cost recovery is desired. The diesel system never attained a positive cash flow. The solar system requires a somewhat higher tariff in order to reach profitability. It is likely that future projects similar to the Bamiyan project will be able to be completed with a lower capital outlay as PV prices continue to decline. The Bamiyan project was the first of it's kind in the region, and one of the top three largest solar-diesel mini-grids in the world. The solar system is much less susceptible to fluctuations in diesel prices. Because of the volatility of petroleum prices, this analysis assumed a constant price of diesel fuel as it is difficult to predict what the future costs will be. Such a scenario is unlikely and diesel prices will likely increase and decrease

over the 20-year analysis timeframe. The solar system will be much more able to maintain a long-term profitability in this respect. At current tariffs, DABS will have to subsidize future battery bank replacements for the DABS solar-diesel mini-grid if the wider national grid does not extend into Bamyan before the battery banks require replacement.

6.0 Key Success Factors

Three key factors contributing to the project's success are technical operation, safety, and long-term financial viability. Successful technical operation was completed after livening of the system, providing power to the customers, and demonstrating that the design goals of the system are met. Risks to the long-term successful operation of the system focus mainly on the technical capacity of DABS to operate the system and retain the trained staff needed to support it. This includes the need for DABS to invest in the system to cope with the inevitable growth in demand that can be expected with any commercial power supply network.

Success in safety will be partially determined by the proper operation and maintenance of the system. This could be jeopardized if the system is damaged, improperly maintained, or if public awareness and education about the system flags.

Future risks to the long term viability of the project in future include:

- Potential lack of access to qualified support staff, both commercially and inside DABS
- Potential lack of support from DABS Kabul to respond to needs of the local Bamyan DABS office
- Reduced consumer support if the system reliability is not maintained.
- Inability to perform scheduled maintenance and maintain an adequate depreciation account for future parts replacement and upgrade.
- Employee graft reducing financial viability of the system.
- Theft of system components.
- Over-subscription of electricity services inducing system failure.
- Encroachment of the ongoing conflict in Afghanistan to the area.

The long-term financial viability will determine if the system is operated adequately to arrive at the end of its useful design life. Proper financial management will play a key role in this success. This will include setting and maintaining proper electricity tariffs, preventing theft and fraud, as well as proper operation and maintenance to ensure correct system function long term.

Feasibility Study on Thermoelectric Conversion to Improve Photovoltaic Operation

Ma. Liwanag O. Montayre and Erees Queen B. Macabebe

Department of Electronics, Computer and Communications Engineering, School of Science and Engineering, Ateneo de Manila University, Quezon City 1108, Philippines

Abstract

Thermoelectrics (TE) is an emerging technology with a wide range of potential applications namely recapturing energy lost as wasted heat from burning fossil fuels as well as serving as a cooling agent. One viable application is to integrate thermoelectric devices with photovoltaic (PV) modules that suffer from performance issues because of heat. This study proposes a model where the TE device can help lower the temperature of the PV modules which will optimize its performance through an increase in generated output. The same device can also increase the total output power from the combined PV-TE system when the TE acts as a generator. The PV-TE system was simulated using Matlab software and results show that there is potential in using TE technology as coolant and generator improve the performance of the PV device. Experiments and actual deployment also reveal an improved output for the combined PV-TE system.

Keywords: *Thermoelectric cooling/generator, Photovoltaic module, conversion efficiency, PV-TE system, Seebeck coefficient, temperature difference*

1. Introduction

Fossil fuel energy has been constantly scrutinized for its negative impact on the environment. Not only does it harm the environment with its carbon emissions and depletion of natural resources that are running out fast, it is not as efficient as it seems. When power plants burn fossil fuel to produce electricity, only a fraction (roughly one-third) of it is converted to useful energy while the rest of it is lost as waste heat (Jones, 2012). Efforts have been made to recover this untapped source of energy and one of the best ways to achieve this is through thermoelectric technology.

Thermoelectrics (TE) uses a temperature gradient to generate electricity. This is made possible by two different semiconductor materials coupled together, arranged electrically in series and thermally in parallel (Rowe, 2006). When a temperature gradient is applied to it, current flows through the system resulting in a voltage difference. This phenomenon is called the Seebeck Effect. When voltage is applied instead, a temperature difference occurs which results in heating on one end and cooling on the other. This is called the Peltier Effect. A third phenomenon occurs called the Thomson Effect that plays a negligible role in the operation of practical thermoelectric modules (Tellurex, 2010).

Thermoelectrics is still a niche technology that is not widely used in the market due to the poor energy conversion efficiency of its devices. Given the right application however, its unique characteristics could prove beneficial. The most popular of these applications is cooling and refrigeration owing to its precise temperature control.

While thermoelectrics is not a well-known category in the field of renewable energy, photovoltaic (PV) technology is its most prominent. Unfortunately it is also susceptible to issues of conversion efficiency. Heating of the photovoltaic PV modules above standard conditions causes performance issues where the device suffers losses in performance efficiency due to high temperature due to high irradiance conditions which also lead to cell degradation (Najafi and Woodbury, 2012). Temperature affects the speed of electrons

doi:10.18086/swc.2015.05.18 Available at http://proceedings.ises.org

flowing through a circuit. The lower the temperature, the lower the resistance in the circuit, the better the performance (Teach Engineering, 2015). Increasing the temperature on the other hand will reduce the band gap of the semiconductors in the PV cells leading to more energy of the electrons which is not ideal in order to break the bond (PV Education, 2015). Cooling the solar cells allows them to function at a higher efficiency and produce more power. Increasing conversion efficiency of any alternative power generation system is crucial because conventional means of producing energy is cheaper.

A feasibility study on a photovoltaic-thermoelectric hybrid system was conducted by Van Sark where an idealized model was able to calculate the employment of present day thermoelectric materials that could lead to efficiency enhancements of up to 23% for roof integrated PV-TE modules. Instead of simple module cooling methods, the study proposed utilizing the thermal waste by attaching thermoelectric converters to the back of the PV modules resulting in a PV-TE hybrid module (Van Sark, 2011). A more comprehensive model of the combined system of the PVT-TEG was developed and simulated by Najafi and Woodbury (2013) where the TE Generator is also employed to convert the heat generated by photovoltaic or thermal collectors into electricity. The model illustrated a very detailed heat transfer process where the TE modules convert the temperature gradient to electricity and generate additional power from the excess heat which is an improvement to the overall performance of the system. Another approach by Park et al. (2013) focused on optimal hybridization between the PV and TE devices by using "full spectrum solar energy" by means of lossless coupling between the devices in hopes of reaching the ideal for efficient harnessing of solar energy. These studies have indicated that attaching a TE device to a PV device has improved the conversion efficiency and power output of the photovoltaic module.

The use of thermoelectric conversion as a strategy to mitigate the issue has been examined where a PV-TE hybrid utilizes thermal waste. Thermoelectric devices make ideal cooling agents because they are solid-state materials that are reliable, durable and compact, with zero maintenance, no noise and no mechanical parts (Teach Engineering, 2015). This paper proposes integrating TE devices, which actively use heat, to PV modules as its cooling mechanism. PV-TE systems have been explored in the past however the type of integration that is modeled in this study attempts to make use of the TE device's two functions albeit not in a simultaneous manner.

2. Designing theoretical models for feasibility testing

2.1. Visualized Model of Proposed PV-TE System

A layout of the design of the PV-TE model is shown in Fig.1 where a solar PV module was deployed. Data of the PV without any TE attachments was first collected and acted as the control. The data output was examined in contrast with PV data of the setup installed with TE devices.

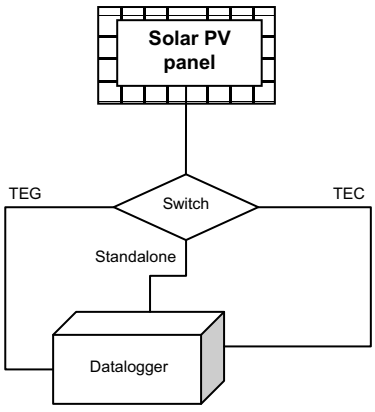

Fig. 1 Layout design of model to study the feasibility of the PV-TE System

The TE system alternated between energy harvesting mode and cooling mode as seen in Fig. 2. Data of the PV with TE attachments in generator or cooling mode were collected and compared with PV-only set of

data. Note that the TE device as a generator is an accepted form of cooling and has been an examined approach by many previous authors (Van Sark, 2011; Najafi and Woodbury, 2013; Park et al., 2013) as it absorbs heat from the PV modules so it can convert it to energy. This can be seen as a passive form of cooling, whereas when the TE device is in its actual cooling mode, this would be an active or forced form of cooling.

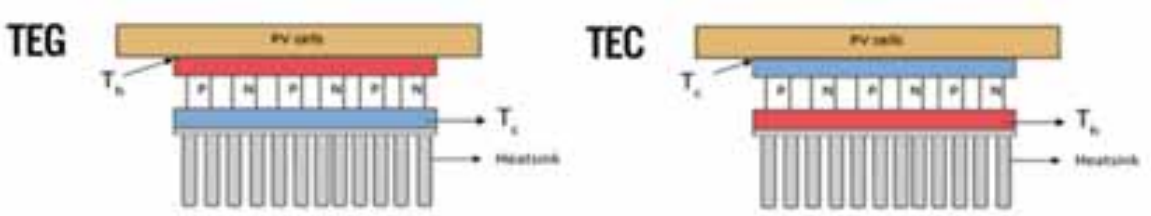

Fig. 2 Schematic of the PV-TE Section with (left diagram) in *generator* mode; and (right diagram) in *cooling* mode

As the TE system shifted from generator to coolant, the thermal equilibrium between the ambient air and PV was observed. The system remained a generator during parts of the day as it is judged to be more effective. It switched to a coolant during times it was seen more effective as such.

2.2. Mathematical Modeling

Typical TE module equations are described in existing literature (Diaconescu and Grigorescu, 2009) where the generator output voltage is given as follows:

$$V = S_M \Delta T = I\left(R_M R_L\right) \qquad \text{(Eq. 1)}$$

Where S_M is the device's Seebeck coefficient and $\Delta T = T_H - T_C$, I is the current through the load, R_M is the averaged module resistance and R_L is the load resistance. The current I through the load is given in Eq. (2) where N_S is the number of TE modules connected in series, and N_P is the number of TE modules connected in parallel.

$$I = \frac{N_S S_M \Delta T}{\left(\frac{N_S R_M}{N_P}\right) + R_L} \qquad \text{(Eq. 2)}$$

The general expression for generator output power P is typically given as the product of voltage V and current I but can also be calculated as seen in Eq. (3) derived from Eqs. (1-2) where N_T is the number of TE modules used and is calculated as $N_T = N_S \times N_P$.

$$P_{TE} = VI = R_L\left(\frac{S_M \Delta T}{R_M + R_L}\right)^2 = \left(\frac{N_T\left(S_M \Delta T\right)^2}{4R_M}\right) \qquad \text{(Eq. 3)}$$

The output power of the PV-TE system is the total of the power of the TE derived from Eq. (3) and output power of the PV derived from collected experimental data using the equation for power at the maximum point as given in Eq. (5) where E is the irradiance and A is the area of the PV module.

$$P_{PVTE} = P_{PV} + P_{TE} \qquad \text{(Eq. 4)}$$

$$P_{PV} = \frac{P_{\max}}{EA} \qquad \text{(Eq. 5)}$$

In thermoelectric cooling, precise temperature control is its strongest feature. The Peltier effect allows for a cold surface to cool to a temperature T_C and a hot surface to cool to a temperature T_H. This is made possible by the given equation described by Khattab et al. (2005):

$$V = S_M\left(T_H - T_C\right) + R_M I \qquad \text{(Eq. 6)}$$

3. Simulation and Hardware Design

3.1. Physical model and assumptions

The TE device used for the study is the commercially available TEC12706. The device is a single stage module that contains 127 pairs of thermoelectric p-type and n-type elements made of Bismuth Telluride with two terminals in dissimilar colors (black and red). This device has interchangeable polarity. The basic performance parameters of this TE device are listed in Table 1. (Ferrotec Corporation, 2014)

Table 1: Performance Parameters of the TEC12706

Parameter	Value
Dimensions	40mm x 40mm x 3.8mm
Maximum Operating Temperature, T_{max}	90 ~ 100 °C
Maximum Temperature Difference, ΔT_{max}	70 °C
Maximum Operating Voltage, V_{max}	15 V
Maximum Current, I_{max}	6 A
Maximum Cooling Power, Q_{max}	50 W
Resistance, R	1.98 Ω

Prior to performing simulations, the following assumptions are adopted to simplify the problem:

- The solar TEG is in steady-state.
- The configurations of the p-type and n-type elements are identical.
- The thermoelectric elements are connected electrically in series and thermally in parallel.
- The whole system is in a vacuum environment, so the heat loss due to heat convection is neglected. (Chen et al., 2013)
- The heat sink is not included in the computations, and the ambient temperature is assumed to be a constant specified by the weather report for that day.

The TE device is characterized by three parameters that are most vital in modeling its capabilities: namely, the module Seebeck coefficient, resistance and thermal conductivity. These properties can be approximated through manufacturer data. (Ferrotec Corporation, 2014)

Table 2: Performance Parameters of the GP005PA PV Module

Parameter	Value
Dimensions	190mm x 290mm x 15mm
Peak Power, P_{max}	5 W
Maximum Power Voltage, V_{mp}	18.29 V
Open Circuit Voltage, V_{oc}	22 V
Maximum Power Current, I_{mp}	0.273 A
Short Circuit Current, I_{sc}	0.3 A
Cell Efficiency	16.0 %

The PV device is a 5-Watt GP005PA acquired from local electronics retailer Alexan. It is a polycrystalline module with 36 cells connected in series in a 2x18 layout. The module has a voltage temperature coefficient of 0.32%. Table 2 presents the parameters of the solar PV module used in this study according to the device's datasheet.

3.2. Technical Feasibility Tests through Simulation

Simulation of the TE system's generator performance was accomplished through applying the mathematical

models in the matrix laboratory (MATLAB) software. The TE system was assumed to be installed to the backside of a PV module, where the latter acted as the former's heat source. Data gathered on PV performance—module temperature, irradiance, maximum power—together with corresponding meteorological data—average air temperature—available online (Weather Underground, 2014) as well as manufacturer data (Ferrotec Corporation, 2014) of the TE properties—module Seebeck coefficient, resistance, thermal conductivity—were utilized. Fig. 3 shows the general structure of how the software runs.

The same software technique was used to determine the total output power generated by a combined PV-TE system. This was compared with the output generated by a standalone PV system and analyzed.

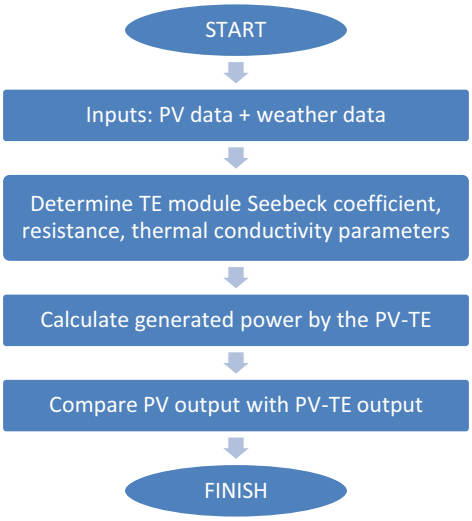

Fig. 3 Flow of the software program

Determining the thermal effect of the TE on the PV module was achieved through the relationship of the open circuit voltage (V_{OC}) of the PV with temperature. Among the attributes of the PV, the effect of temperature is most apparent to the V_{OC} (PV Education, 2015). A V_{OC} versus temperature profile of the GP005PA was used to model the thermal effects on the output of the PV:

$$V_{OC} = -0.0169T + 10.445 \qquad \text{(Eq. 7)}$$

Data results from the combined performances of the two simulations of TE as generator to PV and TE as coolant to PV were collected and evaluated against a PV-only model. Using Eq. (4) the study was able to determine the total output power of the system which is analyzed against the characteristics of a PV-only system.

3.3. Hardware Implementation

A simple hardware implementation was designed to test the proposed PV-TE system. A total of eight modules of the TEC12706 were fitted on the backside of the GP005PA and were connected in series. They were attached and distributed evenly to the backside of the PV module. Each TE device had heat sinks attached to the side not in contact with the PV. Thermal paste was used to ensure thermal contact between the components. Additional metal reinforcement was added to secure the components in place and to act as an extra heat sink to dissipate the heat. LM35 probes were inserted to log temperature data for analysis.

The PV-TE system was first deployed in a controlled environment indoors to determine the best parameters for use in outdoor conditions. A 500-Watt Tungsten Halogen lamp was chosen as a light source because its spectra matches closely to that of the sun. Experiments were carried out under a 110 W/m^2 rating for irradiance with a 2-hour duration. The current-voltage (I-V) curve tracer developed by Peña et al. (2013) was used in this study for the characterization of the PV modules.

Outdoor deployment was carried out on a rooftop with the devices propped on a metal stand. The duration for each collection of data took around 6-7 hours from morning until late afternoon. Data for all circuits were logged using Arduino software which were later processed in MATLAB and Microsoft Excel.

4. Results and Discussion

4.1. Device Characterization

The eight TEC12706 TE devices used in the study were characterized individually then in series by means of applying electrical current to them in increments. Fig. 4 shows the corresponding graph for the characterization of the TE devices in series. It shows the linearity of V versus ΔT curve. Thus, ΔT increases as voltage increases.

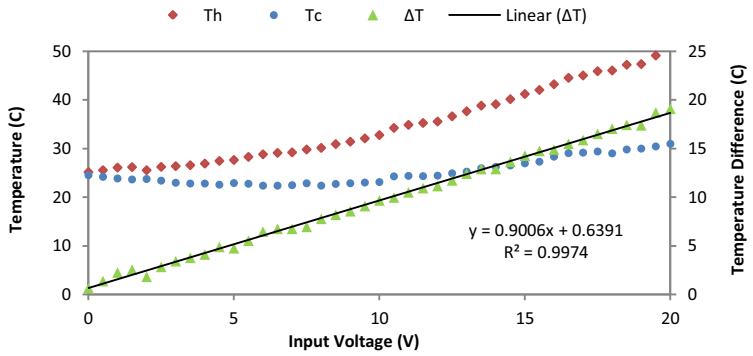

Fig. 4 Characterization of the TEC12706 in a series of 8 modules

The GP005PA PV device used in the study was characterized under outdoor conditions. The graphs in Fig. 5 exhibit the respective I-V and P-V curves with a solar irradiance of 919.8 W/m^2, temperature of 59.0 °C and a P_{max} of 5.802 W.

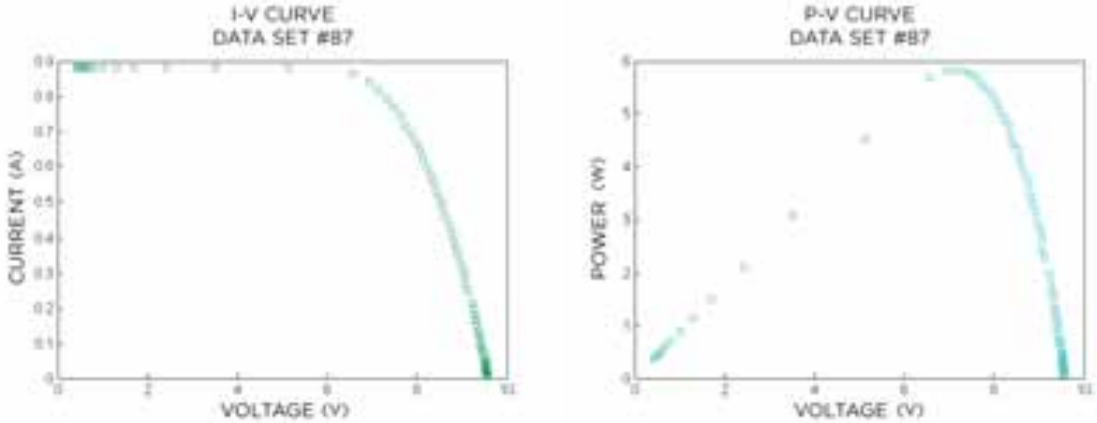

Fig. 5 I-V and P-V Curves of the GP005PA with the sun as the light source

4.2. Observations from Theoretical Modeling

One of the earlier TE models illustrated the attractive nature of the technology as a power generator in which a large output is possible given an equally large temperature gradient and with more modules used. For this model, the basis for maximum temperature is the highest estimated temperature for a solar PV module in conditions where irradiation is very high such as sometime around noon, which is 60 degrees Celsius. In ideal scenarios where the cooler side of the TE is dissipated well that it is at 0 °C, 60 °C in ΔT can be achieved. Fig. 6 shows the graphs of the TE output power versus temperature difference as a result of the simulation. In the figure, the maximum power (21 W) can be produced if 20 TE modules are placed at the backside of the solar PV module and ΔT = 60 °C. Even with ΔT = 30 °C, the TE can generate 5 W.

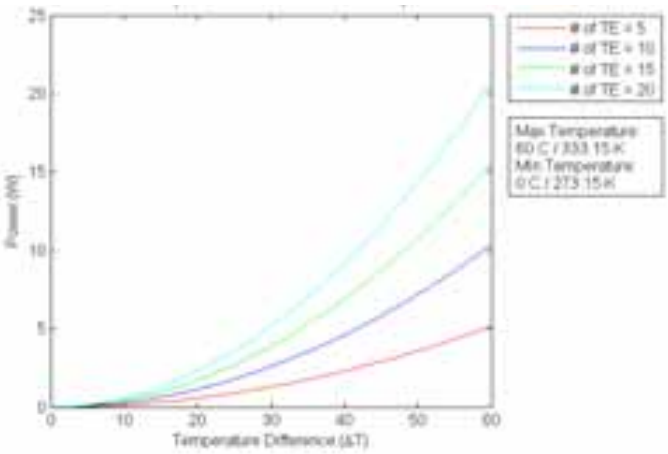

Fig. 6 Graph for TE output power versus temperature difference

The thermoelectric generation models used collected weather data (ie. irradiance, ambient air temperature) and PV data (ie. peak power, PV module temperature) from July 21, 2015, and TE attributes (ie. Seebeck coefficient, module resistance) to generate plots of TE and PV-TE system performances. Fig. 7 shows a comparison of the power output of the TE as a generator and the power output of the PV module, and the combined power output of the PV and TE. A comparison can be made of the power generated by the 5 W GP005PA PV device, an array of eight TEC12706 TE modules, and their combined output. It can be observed that solar irradiation and temperature have influence on the output power of the devices, while temperature levels appear proportional with the trend of the TE output. An average of 27.6% increase in PV output power was calculated when using the TE attachments compared to a PV-only setup.

The model to determine the thermal effect on the GP005PA PV device was designed using the parameters in Eqs. (6-7) and weather data from July 20, 2015. Variations in the temperature of solar PV modules greatly affect its open-circuit voltage V_{OC}. Thus, the V_{OC} parameter and its variations were investigated when the TE device was modeled as a coolant. Fig. 8 shows a comparison of the V_{OC} of the PV device with the TE device acting as a cooling mechanism, against the V_{OC} of the PV device alone. An average increase of 0.04% in the V_{OC} is noted.

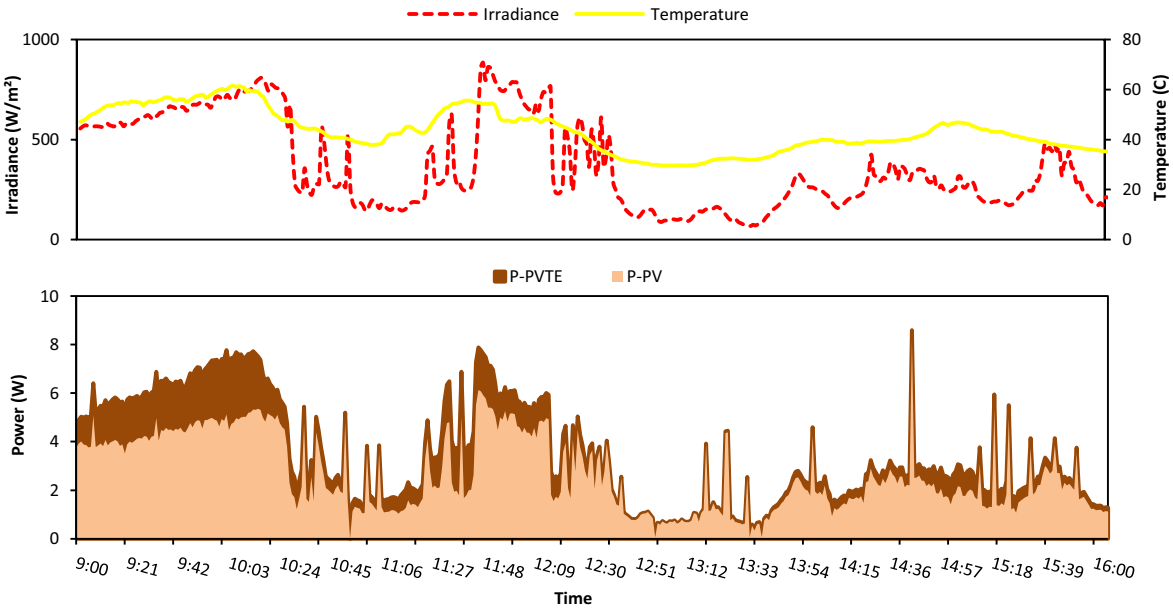

Fig. 7 Comparison of the theoretical power output of the 5W Polycrystalline PV device (*P*-PV), and its combined output power with the TEC12706 TE device (*P*-PVTE) as a *generator*

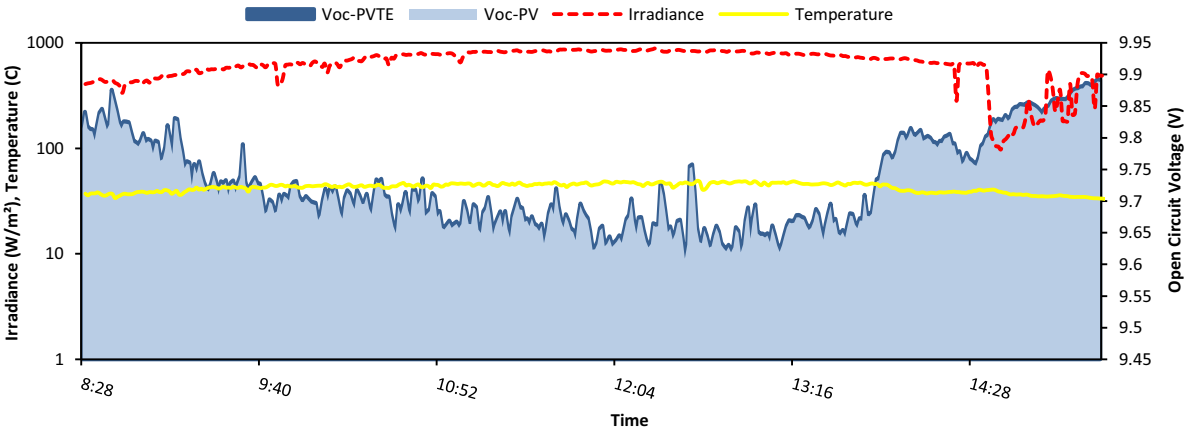

Fig. 8 **Comparison of the open circuit voltage output (V_{OC}-PV) of the 5W Polycrystalline PV device against the theoretical output V_{OC} of the PV with the TEC12706 TE device (V_{OC}-PVTE) as a *coolant***

4.3. TE as Generator

The results of the PV-TE prototype after it was deployed outdoors and observed for a number of days revealed a small but noticeable improvement compared to the standalone PV. Fig. 9 shows a comparison of the output power of the PV-TE system against the output power of the stand alone 5W PV module during outdoor deployment. An average increase of 1% in output power for the combined PV-TE was noted. Measurements were obtained on another day and an average increase of 1.9% in output power was observed. These however are not enough to match the projected increase in output power by the PV-TE model which theoretically indicated a 27.6% increase. It can be noted that similar to the model, the actual results showed that the trend of the output power followed irradiance levels, thus the current generated by the solar PV module dominated over the temperature variations and the effects on V_{OC}. The graph also revealed that the most noticeable improvement was in the morning when irradiance levels were observed to be high. This translates to high module temperature but lower ambient temperature, hence, greater ΔT.

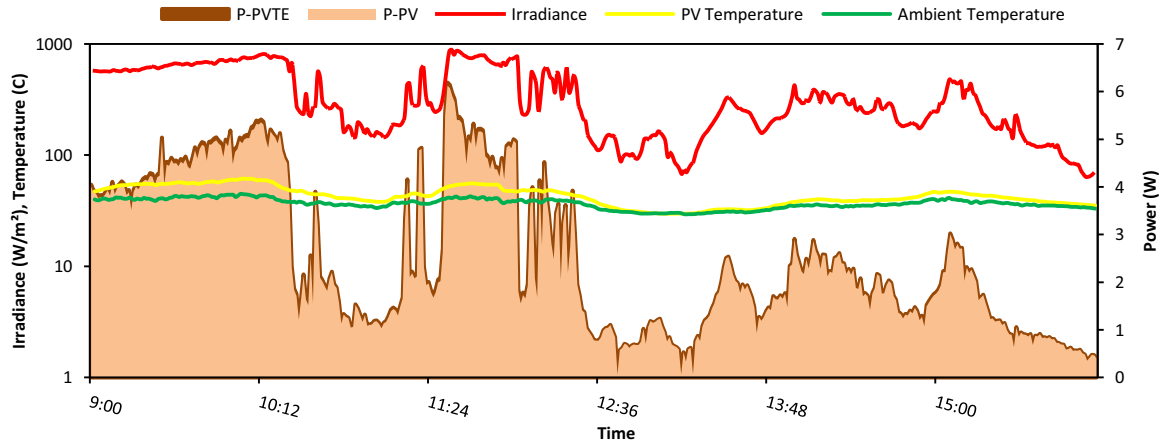

Fig. 9 **Comparison of the experimental output power of the PV-TE system (*P*-PVTE) with the TE as *generator* against the output power of the 5W PV alone (*P*-PV) after outdoor deployment**

4.4. TE as Coolant

Fig. 10 shows a general overview of the GP005PA PV device with TE attachments acting as a cooling mechanism to it. The 8V that was supplied to the TE array causing the cooling effect was determined in earlier lab tests where it showed the most promising results. It would seem that there is not much effect, in fact experimental results were less by an average of 3.7% from the simulated results. One noticeable observation is the ΔT indicative of cooling effectiveness when the difference is greater, which is apparent during the morning and late afternoon of the day. A zero to negative ΔT at midday around noon when PV temperature is hotter than the ambient, implies that the TE is not ideal as a coolant during this time.

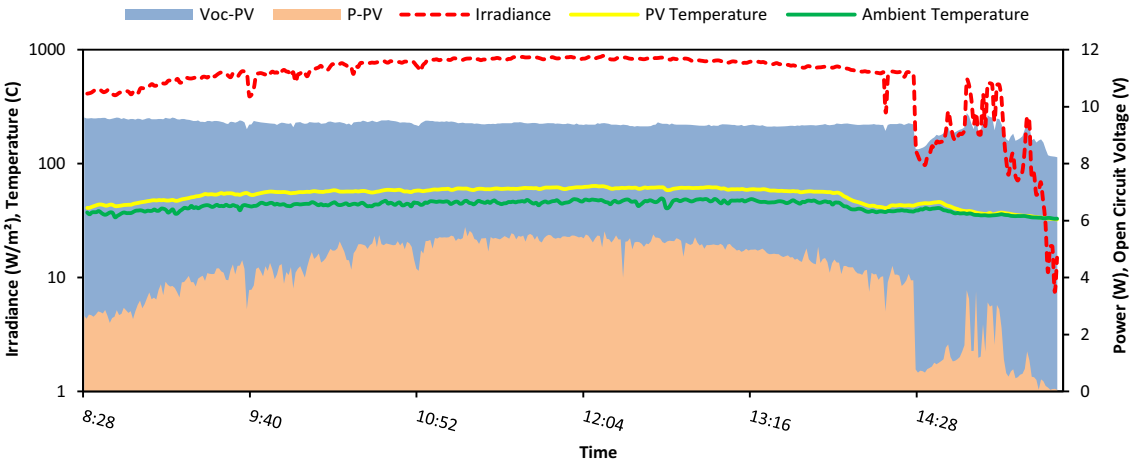

Fig. 10 Experimental effect of the TEC12706 TE devices as a *coolant* to the 5W PV device on its V_{OC} and P_{max} after outdoor deployment

The study also considered the relationship of irradiance to the performance parameters of the PV-TE and standalone PV systems by plotting irradiance versus output power for TE as generator (TEG) and irradiance versus V_{OC} for TE as coolant (TEC) from the data obtained in this study, which are shown in Fig. 11. Fig. 11a shows that the TEG has little effect on the power output though a small improvement in output power of the PV-TE system is observed. Fig. 11b shows that there is an improvement for PV performance with the TEC attachments. In general, at lower irradiance levels, the V_{OC} output of the PV-TE system is higher compared to a PV-only setup. This would indicate that at this range up to 600 W/m^2, it is when the TE cools the PV most effectively. This is supported by the Irradiance versus ΔT plot in Fig. 12 which shows that ΔT is negative (ie. hot side is cooler than the side emitting the cooling effect therefore ineffective) at high irradiance levels. Therefore, the TE devices are not recommended in cooling at high irradiance levels. On the average the difference is about 2% in V_{OC} in favour of the PV with TEC. Efficiency for this system taking into account the input needed by the TE calculated against the output of the PV is at 11.4%.

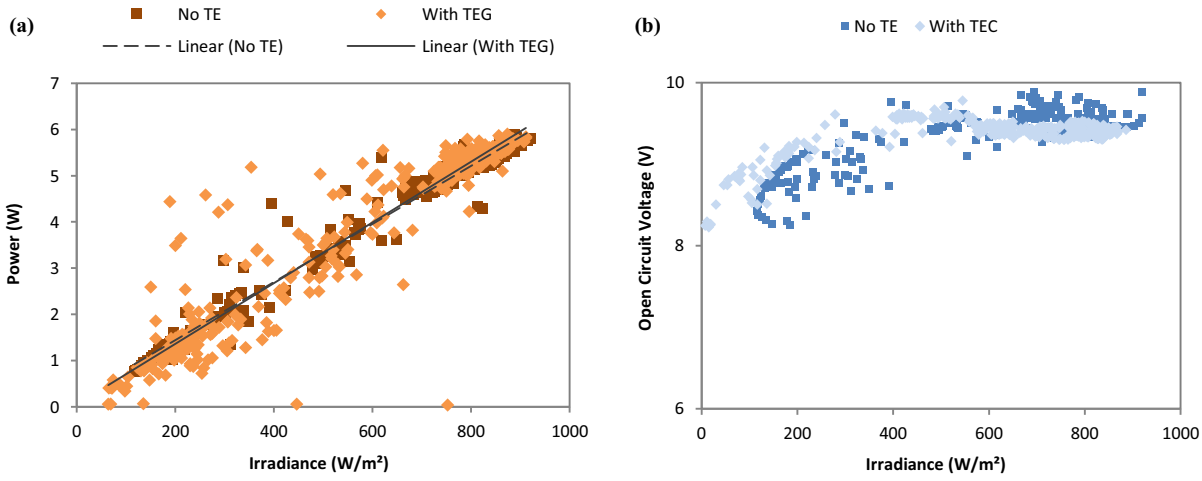

Fig. 11 Results of the performance parameters for PV-TE and PV-only measured against Irradiance: (a) output power for PV-TEG (as *generator*), and (b) open circuit voltage for PV-TEC (as *coolant*)

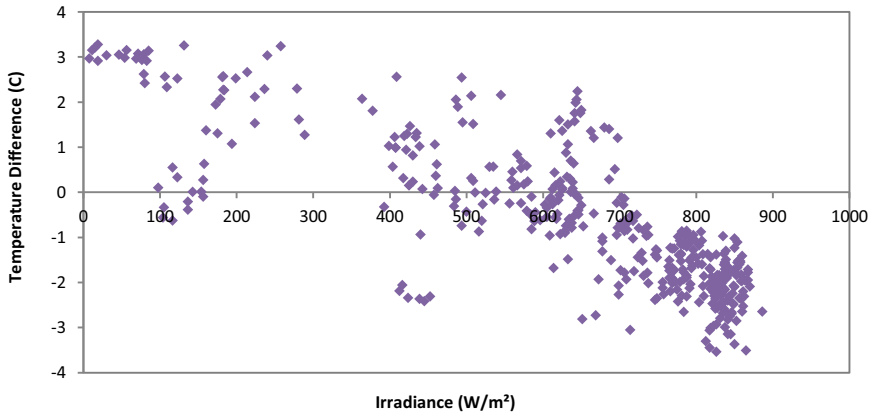

Fig. 12 Irradiance versus ΔT of the TEC in a PV-TE system

5. Conclusion

This study has shown that thermoelectric application has an effect on PV performance. In theory, the power generated by a PV-TE system with the TE in generator mode has a 27.6% improvement when compared to a standalone PV-only setup. Moreover, a 0.04% increase in the V_{OC} of the PV is also predicted when the TE acted as a cooling mechanism. After outdoor deployments were carried out to put the theory to the test, the increase in output power recorded for the PV-TE system with TEG was only about 1–1.9%. There was a noticeable improvement however on the TEC influence on the V_{OC} of the PV when it produced a 2% increase as compared to the standalone PV based on aggregated data. These results may be small but notable enough to indicate that the TE indeed does improve the power output of the solar PV module. Future research is strongly recommended with added features to the TE system such as better heat sink design and the utilization of boost converters that can potentially augment the effects of the TE on the PV module.

Designing an innovative secondary optics for parabolic trough

Daniela Fontani, Paola Sansoni, Franco. Francini, David Jafrancesco

CNR-INO National Institute of Optics,

Largo E. Fermi 6, Firenze (Italy)

Corresponding Author Email: daniela.fontani@ino.it

Abstract

A secondary optics for CPV parabolic troughs was developed to reduce the photovoltaic cells number. The proposed solution is a cylindrical Fresnel lens that transforms the focal line into a series of focal points. Its insertion inside the Concentrating PhotoVoltaic trough increases the solar concentration keeping unchanged the total collection efficiency of the system. The research includes optical design of the secondary collector and auxiliary analyses to control trough operation and to optimize trough collection efficiency.

Keywords: *secondary optics, optical design, trough, CPV, solar concentration*

1. Introduction

This paper describes a solution studied to reduce the number of photovoltaic cells in a linear parabolic trough (Bakos et al 2000, Kearney 2007, Kruger et al 2008, Prapas,et al 1987, Price et al 2002), which is used for the combined production of heat and electricity (Klapp et al 2007, Weiss and Rommel 2005). This solar trough combines photovoltaic and thermal systems: PV cells directly exploit the sunlight concentrated on them and their cooling system supplies thermal energy. Given that the linear concentrators act only in a direction that is normal to their length, consequently with a linear parabolic reflector the entire focal line must be covered by photovoltaic cells (Kearney 2007).

The secondary optical system examined in this study is interposed between the parabolic mirror and the linear row of photovoltaic cells. The sunlight collected by the parabolic reflector is intercepted by the secondary optics and concentrated, in portions, precisely in the direction where the concentrator may not work (along the longitudinal axis of the trough).

The working principle of the additional optical system appears evident placing a screen in the focal area: the secondary optics transforms the focal line into a series of focal points. Hence the proposed solution allows to reduce the number of PV cells while maintaining unchanged the total collection efficiency of the system because it simultaneously increases the concentration. In practice the production of electricity is not affected by the reduction of cells number, because it is balanced by an enhancement of solar concentration.

2. Positioning of the secondary optics in the solar trough

The starting point was an existing solar trough that combines photovoltaic and thermal systems (Bakos et al 2000, Klapp et al 2007, Kearney 2007 Kruger et al 2008, Prapas,et al 1987, Price et al 2002, Weiss and Rommel 2005). It concentrates the sunlight by means of a linear parabolic reflector over an articulated absorber. The focal image is a rectangle and it is focused on a row of squared photovoltaic cells. The cells are placed on a metallic tube of rectangular section, which acts as cooling system by means of a liquid flowing inside. The absorber is completed by an external protection tube in glass, enclosing cells and cooler. The photocells directly exploit the concentrated sunlight providing electricity, while the cooling system of the cells furnishes heat.

In this concentration geometry the secondary optical system must be located inside the first mirror (parabolic reflector) around and near the absorber, constituted by a glass tube enclosing a row of photovoltaic cells placed over a rectangular tube (cooler).

The parabolic reflector concentrates the solar rays in the direction transversal to the solar trough axis. Then the secondary optics intercepts these rays and it re-concentrates them also in direction of the trough axis. So the concentration is performed transversally by the trough; while it is performed transversally and longitudinally by the secondary lens. Hence the secondary optical system realises a concentration in the direction where the

doi:10.18086/swc.2015.05.19 Available at http://proceedings.ises.org

trough does not concentrate. In practice this secondary optics transforms the focal line into a series of focal points. This result can be easily visualized placing a screen in the focal area of the solar trough.

3. Design criteria for the secondary optics

The secondary concentrator (Giannuzzi et al 2010 Giannuzzi, et al 2011 , Giannuzzi, et al 2014, Jafrancesco et al 2010) was optically designed for an solar trough realized for the combined production of electricity and heat. It has a primary parabolic mirror that focuses the solar rays over a row of PV cells placed on a linear cooler. The aim is to decrease the number of required cells introducing a secondary optics that concentrates the light along the longitudinal direction of the trough.

The optical design of this secondary optics should be based on the characteristics of the existing solar trough and of the photovoltaic cells. The preliminary phase of the optical design is to simulate the optical system. Successively the solar trough parameters are analysed, to optimize the collection efficiency that maximised the obtainable energy. Finally the optical project of the secondary optics, in terms of geometrical parameters and optical characteristics (Winston et al 2005), is selected on the base of the analyses of the irradiance concentrated on the receiver (photovoltaic cells) (Güven and Bannerot 1986, Kandpal et al. 1985).

Auxiliary studies can assist in monitoring trough performance and in keeping high efficiency. Some examples of these additional analyses are summarised in Sect. 7: effects of collector deformation, axial defocusing, tracking errors and receiver alignment errors.

The proposed secondary optics is a lens, with cylindrical symmetry, which focuses in a point all the rays that arrive in a direction perpendicular to its surface, as shown in Fig. 1.

Considering that the rays coming from the parabolic reflector converge at the same point (the PV cell) is sufficient to design only a radial section of the lens that will be subsequently replicated on a cylindrical surface of radius R.

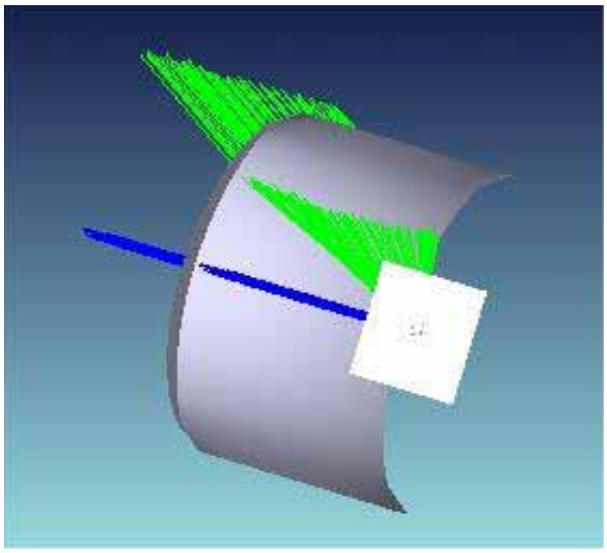

Fig. 1 - The secondary optics is a cylindrical Fresnel lens. It focuses in a point all the rays that arrive in a direction normal to its surface.

The criteria used to optically design the secondary cylindrical lens are summarised below.

1) The radius R of the cylinder depends on geometrical considerations linked to the size of the secondary optics and its position over the array of PV cells. There was a superior limit agreed with the optical manufacturers.

2) The transversal dimension Dt of the lens is determined by the f-number Fn = Dt / f, where f is the focal length of the lens, which must not be greater than R. Dt is chosen to have Fn <1, since it is known that the characteristics of an optical system are less critical for f-number less than 1.

3) Since the intention was to obtain a thin and weightless lens, it was established that his type had to be prismatic (Fresnel).

The result is a cylindrical Fresnel lens, whose profile is illustrated in Fig. 2. The figure shows the section of the lens, which contains 12 prisms that distribute the light on the PV cell. The total lens width L is composed of 12 prisms, each of which has width l, while the maximum height of the tooth is H. All the prisms in the central part have height equal to l, the width of each tooth.

The light intensity distribution on the PV cell obtained with the insertion of this secondary cylindrical Fresnel lens is presented and discussed in Section 5.

Fig. 2- The secondary optics is a cylindrical Fresnel lens with this profile.

4. Results of the optical design

The secondary optical system (Giannuzzi et al 2010, Giannuzzi, et al 2011, Giannuzzi, et al 2014, Jafrancesco et al 2010) was defined to be a cylindrical prismatic lens, of Fresnel type.

Figure 2 reports in detail the profile of the Fresnel lens with the characteristic angles αi of the individual prisms that define the optical design of the lens. The angle of prism surface inclination are symmetric, as the figure shows. From left to right of Fig. 2, the characteristic angles of the second face of each prism are: α1, α2, α3, α4, -α4, -α3, -α2, -α1, where a negative angle corresponds to a surface with the same inclination but in the opposite direction. The specific angles αi of each prism slope are calculated in the optical design simulation in order to optimise the light intensity distribution on the PV cell, balancing maximum obtainable power and maximum obtainable uniformity.

These data of the prismatic lens profile were used to generate the 3D cylindrical lens according to the criteria expressed in the previous section. This phase was executed using the Rhinoceros software, which allows to generate a three-dimensional file with IGES format. The screen output of the Rhinoceros software, reporting four different views of the secondary optics, is show in Fig. 3: the top-left image is a superior view, the top-right image is a perspective view, the bottom- left image is a frontal view, the bottom-right image is a lateral view from the right side.

As illustrated in Fig. 2, in the central part the upper surface of the prisms is almost flat: the angles α4 and -α4 approach zero.

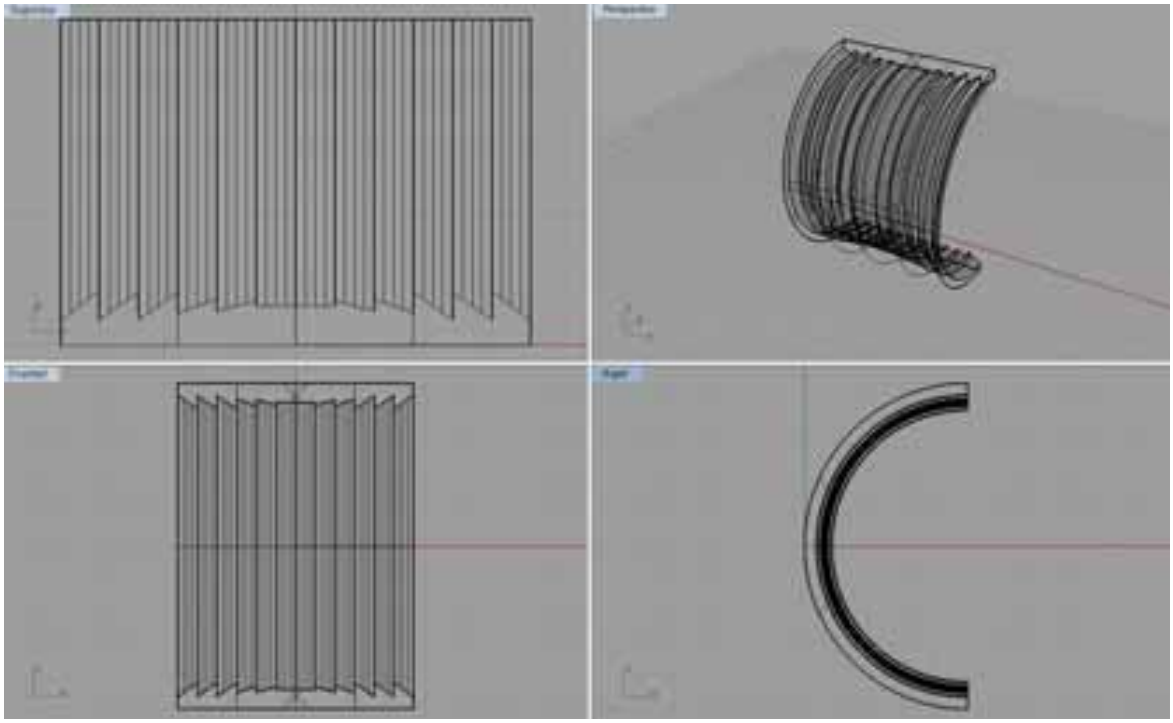

Fig. 3 - Rhinoceros drawings of the cylindrical Fresnel lens.

5. Behaviour of the prismatic lens in the parabolic trough

The prismatic lens is calculated for a photovoltaic cell of squared shape with dimensions 10mm x10mm, located at a distance d from the central flat face of the lens. The final cylindrical Fresnel lens has a diameter D, obtained from optical design simulations performed for a lens width L, with 12 prisms of size l.

The simulations were developed using a the specific ray-tracing software package Zemex-EE (by Radiant Zemax). One of their result, reported in Fig. 4, is the tri-dimensional rendering of the cylindrical Fresnel lens. The lens profile, corresponding to Fig. 2 is evidenced in orange in Fig. 4.

However the most significant result of the simulation is the irradiance light distribution over the photovoltaic cell, plotted in Fig. 5 in false colours. Figure 5 shows the irradiance distribution considering the prismatic lens inserted in the parabolic trough concentrator. The image frame is a square of 10mm x 10mm, which corresponds to the size of each PV cell.

The light focused by the secondary optics is quite uniformly distributed on the cell square. The great result is that the shape of the image is squared and it is illuminated almost with the same irradiance level. Only near the perimeter the irradiance has lower values. The uniformity of light distribution is a fundamental aspect when photovoltaic cells are employed, since they will work correctly only if they are uniformly illuminated. When the light is mostly focused on a portion of the PV cell, the cell converts light into electricity with a lower conversion factor. This loss of illumination uniformity can also affect (unbalancing the series of cells) the performance of the other PV cells.

The total collection efficiency is the product of the collection efficiency of the parabolic concentrator (95%) multiplied by the collection efficiency of the cylindrical Fresnel lens. Considering the entire solar spectrum was estimated a value of 75% for the total collection efficiency

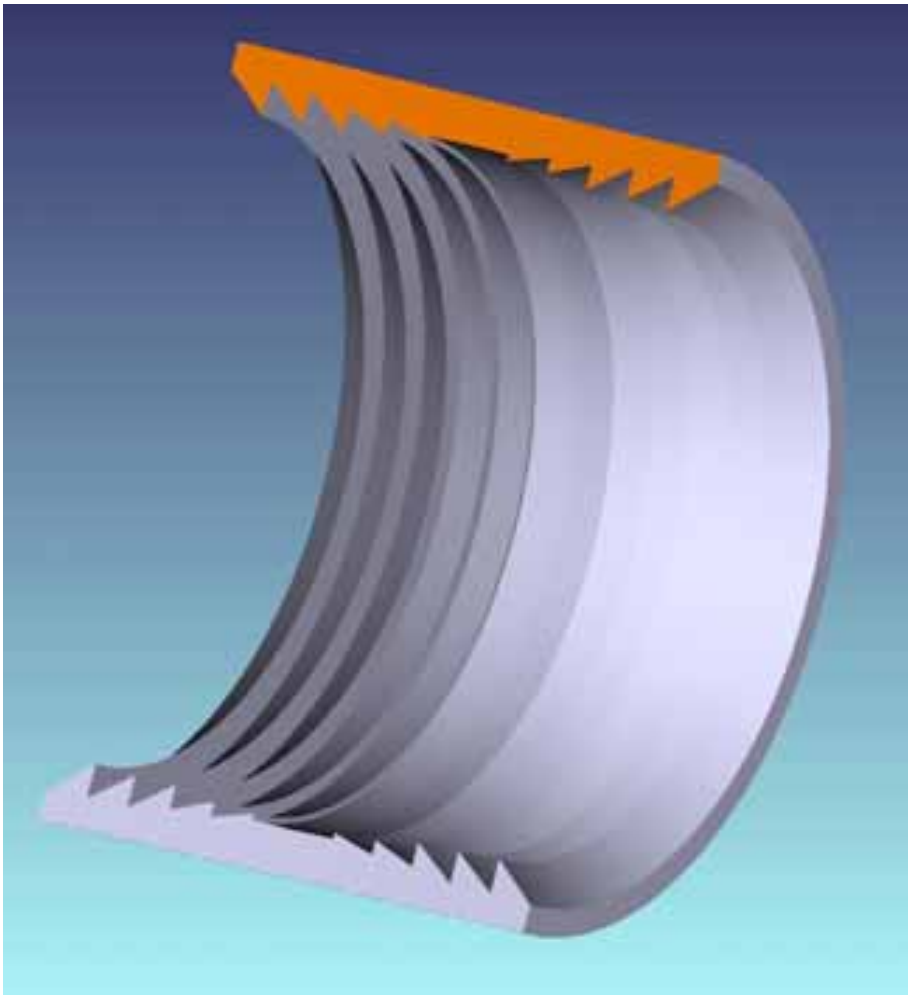

Fig. 4 – 3D rendering of the cylindrical Fresnel lens.

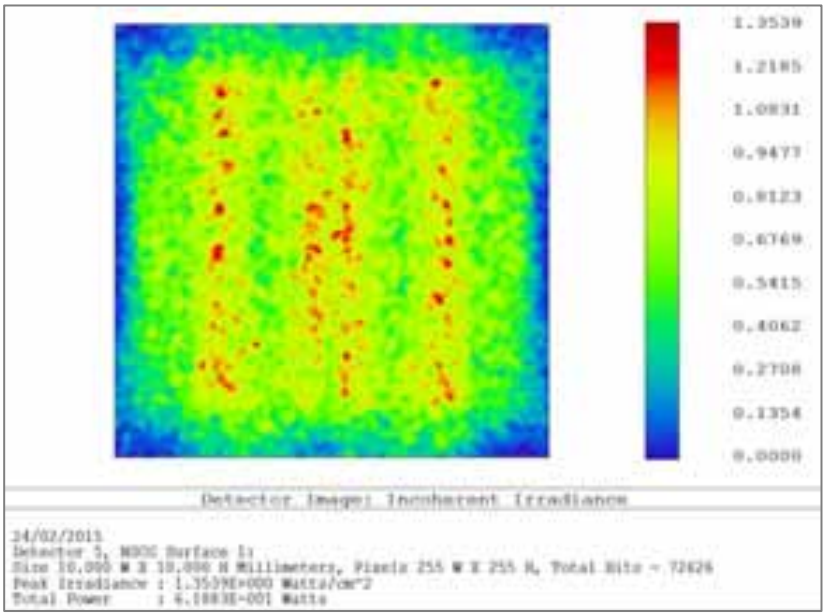

Fig. 5 – Image of the cylindrical Fresnel lens on the PV cell.

6. Simulations for the optical design

The optical design work (Güven and Bannerot 1986, Kandpal et al. 1985 , Sansoni et al. 2011, Winston et al

2005) consisted in simulating, analysing and optimising the optical configuration of the solar trough system. The optical simulations reproduced the system, whose main components are parabolic mirror (primary optics), cylindrical Fresnel lens (secondary optics) and photovoltaic cell (receiver). In particular the optical system was simulated in order to verify the optical behaviour in case of axial defocusing, tracking errors, alignment errors and deformations of the collector. For each of these cases were calculated:

• the collection efficiency of the system, that indicates how much of the power incident on the parabolic collector arrives at the receiver;

• the irradiance distribution on the receiver, that can give an idea of the uniformity of illumination of the receiver along a certain direction;

• the integrated power, that assesses the power collected by the receiver as a function of its width.

These analyses were exploited to define the optical parameters of the secondary optics; moreover they give fundamental information to optimise the solar trough performance. The results of the detailed studies are briefly discussed in Sect. 7.

The parabolic collector has a development of 1600 mm, a radius of curvature of 1600 mm and a focal length of 800 mm. The receiver, a PV cell of size 10mm x10 mm, is placed in the focal plane of the parabolic mirror. The Fresnel lens is placed at a distance d from the cell, on the side of the parabolic mirror.

For these simulations was considered only a small section of the parabola, of a width corresponding to that of the lens (L) and placed behind it. The reason is that it is this section that contributes to the collection efficiency; possible contributions from adjacent areas are compensated by the loss of light that impinges near the edges of the section.

The following list summarizes the parameters used in the simulations, subdivided for every principal optical component.

- Parabolic Concentrator: Parabolic Trough Concentrator (PTC) type; section width; curvature radius; total chord length; focal length; surface reflectance.

- Secondary Lens: cylindrical Fresnel lens type; dimensions; material; distance from the receiver; distance from parabolic mirror vertex.

- Screen: dimensions; distance from the receiver.

- Receiver 1 (for collection efficiency): dimensions; distance from parabolic mirror vertex.

- Receiver 2 (for irradiance profiles): dimensions; distance from parabolic mirror vertex.

- Source: plane with rectangular divergence; divergence angle; dimensions; distance from parabolic mirror vertex; power; wavelength (in these simulations the reference wavelength was 550nm).

- Number of rays (in these simulations 5 million rays were sufficient to have reproducible results).

The source projects on the parabolic reflector a homogeneous rectangular beam. The screen placed behind the receiver has the purpose of intercepting the rays emitted by the source in arrival on the receiver and on the secondary lens. In this way the obscuration effect of the tube is considered in the calculation of the collection efficiency of the whole optical system.

Receiver 1 and Receiver 2 are two detector planes of different size that are placed in the same position. They are used interchangeably for the calculation of collection efficiency (Receiver 1) and distribution of illumination irradiance (Receiver 2).

The z-axis is the optical axis, along which the propagation occurs rays; the x-axis is perpendicular to the drawing plane and is parallel to the longitudinal axis of the parabolic collector; the y-axis completes the right-handed triad. This reference system is used with all the objects (parabolic mirror, secondary lens and receiver).

The collection efficiency η of the whole optical system is defined as

$$\eta = \frac{P_{out}}{P_{in}} \qquad \text{(eq. 1)}$$

where Pout is the power that reaches the detector and Pin is the power that impinges on the section of the parabolic reflector.

7. Auxiliary investigations of trough performance

The study is completed with some analyses devoted to aspects essential for the correct functioning of the linear parabolic collector, assessing how to optimize the performance of the system (Diver and Moss 2007, Fontani et al. 2006, Fontani et al. 2011, Kandpal et al. 1985, Sansoni et al. 2011). These investigations examine in detail the consequences of axial defocusing of the receiver, deformations of the parabolic mirror, error in sun tracking, errors in aligning the optical components.

The axial defocusing (Sansoni et al. 2011) is an incorrect positioning of the receiver with respect to the focus of the parabola. It is studied by varying the distance of the receiver from the vertex of the parabola with displacement along the parabola's axis. The results are expressed using the trough collection efficiency η as a function of defocus, using the irradiance distribution on the receiver as a function of the distance from the centre varying the defocus and using the concentric integrals as a function of the cell width for various defocus values.

The collector deformations (Fontani et al. 2006) are the mechanical deformations of the primary parabolic mirror and they can be expressed by a variation of the conic constant K (K = 0 for perfect parabola). The results are expressed using the trough collection efficiency η as a function of K or as a function of the vertical displacement of the edge of the deformed collector.

The sun tracking errors (Fontani et al. 2011) occur when the sun's rays do not arrive perpendicularly to the entrance surface of the parabolic mirror because of an imperfect pointing. The effects of this tracking error are simulated by rotating the source around the x-axis and translating it in the y direction by an amount $A \cdot \tan\Phi$, where A is the source - parabola distance and Φ is the angle of rotation (tilt Φx); this is equivalent to the entire concentrator rotate about the longitudinal axis of the parabola. The results are expressed using the trough collection efficiency η as a function of tilt Φx, using the irradiance distribution on the receiver as a function of the distance from the centre for several tilt Φx values, using the concentric integrals as a function of the width of the cell varying the tilt Φx.

The errors of alignment (Diver, R.B., Moss, T.A, 2007) are the effects on the system performance due to any misalignment of the collector axis with respect to the North - South direction. In Parabolic Trough Collectors (PTC) without secondary lens the effect is a translation of the focal line along the linear receiver; in PTC with secondary lens the system collection efficiency may drop due to the small size of the PV cell. The situation is identical to the tracking errors but the source is rotated around the y-axis and translated along the x-axis. The results are expressed using the trough collection efficiency η as a function of tilt Φy.

The typical reference parameter for the system performance is the collection efficiency η of the whole solar trough (including primary parabolic mirror and secondary cylindrical Fresnel lens). The image focused by the secondary lens should concentrate the maximum power (maximise the trough collection efficiency η), but also uniformly illuminate the photovoltaic cell (maximise the receiver irradiance distribution, in Fig. 5).

8. Conclusion

The purpose was to develop a secondary optics for a solar CPV parabolic trough that increases the solar concentration and reduces the photovoltaic cells number keeping unchanged the total collection efficiency of the system. The solar trough is a Concentrating PhotoVoltaic system whose primary collector is a linear parabolic reflector. The proposed secondary concentrator is a cylindrical prismatic lens of Fresnel type. The primary parabolic mirror of the CPV trough concentrates the sunlight in a focal line, which is successively transformed by the cylindrical Fresnel lens into a series of focal points.

The research started with the optical design of the secondary component, selecting a configuration that optimizes collection efficiency of the whole system and uniformity of the PV cell illumination. The study proceeded with auxiliary analyses to optimize operative conditions and collection efficiency of the whole system. Finally specific simulations evaluated the possible future implementations.

The secondary optics was optically designed for an existing solar trough, already realized. This trough is used for the combined production of heat and electricity, with a parabolic mirror concentrating the sunlight over a line of photocells placed over a linear cooling system. The idea is to reduce the number of photovoltaic cells introducing a secondary optics to concentrate the light along the direction of the trough axis, where the trough does not concentrate.

The optical design of this secondary concentrator must take into account the characteristics of the existing trough and of the photovoltaic cells. The optical parameters of the secondary optics are principally determined by examining the irradiance distribution on the receiver. The study is completed by analyses and simulations of the effects due to collector deformation, axial defocusing, tracking errors and receiver alignment errors. The purpose of these auxiliary analyses is to maintain elevated performance of the solar trough in real working conditions.

Abstract

A simple, efficient and low-cost sun tracking method is presented: it is based on optical pointers used as "sun finders" and on a double guiding system. A passive tracker provides the preliminary orientation, then an active system with the sun finder realizes fine positioning and adjustments. Two optical sensors for solar pointing are proposed discussing working principle and applications. The two-axis pointer is appropriate for solar concentrators coupled to optical fibers or tiny photovoltaic cells; while the one-axis sensor is suitable for linear tracking collectors. They can be adapted to every specific application and to every solar collection device. The sensors were optically characterized indoor, under controlled and reproducible conditions, and outdoor in real working situations.

Keywords: *sun finder, optical sensor, solar energy, optical test, sun concentrator.*

1. Introduction

A device based on the concentration of sunlight needs to track the sun in its movement in order to improve the system performance (Armstrong and Hurley, 2005; Lee et al., 2009; Mousazadeh et al., 2009). Solar systems based on light concentration require the use of an optical pointer because they can work only with direct sunlight. In Concentrating Photovoltaic (CPV) systems the primary optics is a Fresnel lens or a parabolic concentrator and a secondary optics can be added to improve pointing precision and plant collection efficiency (Altera Technical Staff, 2009; Chong and Wong, 2009). The required pointing precision is higher than the tenth of degree, which is not obtainable by passive trackers, based on the ephemerides of the year (Chen et al, 2006; Huang et al., 2009). The reasons are plant orientation problems, difficulties in keeping a high mechanical stability, wind action and high precision required by the concentrator type. Hence the solar plants employ an active tracker, based on a device that supplies to the moving system the information to correct the concentrators' orientation to maintain the alignment (Mohammad and Karim, 2012; Roth et al., 2004; Sadyrbayev et al., 2013). These devices utilized to provide the error signal to the control electronics, are commonly called "sun finders" (Bopp, 2014; Salawu and Oduyemi, 1986).

A tracking technique, based on optical sensors used as "sun finders", is discussed with a specific attention to practical realization and application of the solar pointers. The proposed strategy for sun tracking includes a double guiding system that uses two complementary procedures. The first one provides the preliminary orientation, then the second realizes the fine positioning and adjustments. The first tracking system is of passive type and it drives the motors to correctly orient the collector every day of the year. The second tracker is of active type and it employs an optical pointing system. The passive preliminary orientation is necessary to track the sun position when the solar light does not reach the pointer (in case of cloud passage or sun absence). In this way when the sun illuminates again the pointer, the active system can take the control of the collector orientation. The advantage of the double driving technique is to confer flexibility to the tracking system, which automatically follows every weather variation in all environmental conditions. The solar pointer is the optical device constituting the active guiding system of the tracking methodology. To improve the pointing precision, it is suggested the use a device including two sections, with different Field Of View apertures (FOV), corresponding to different accuracies.

This double guiding procedure to perform solar tracking is simple and effective; the realized pointers are reliable and inexpensive. The core of the active tracking system is the solar pointer. Two types of pointing sensors are presented, illustrating working principle, components, optical characterization and validation. The two-axis sensor, with pinhole, is suitable for solar concentrators coupled to optical fibers or tiny photovoltaic (PV) cells. The one-axis pointer, with slit, is appropriate for linear tracking collectors. These pointers can be adapted to every specific application and to every solar collection device. Installation and alignment become

doi:10.18086/swc.2015.05.20 Available at http://proceedings.ises.org

more and more crucial as the tracking precision increases. In practice, first the solar collectors should be properly placed on the ground, then the pointer must be accurately mounted and oriented. If the sensor is precisely aligned with the collector, the information coming from the sun finder is useful to compensate possible errors in the placement of the solar collectors. All sensors were tested in laboratory, in a controlled and reproducible environment, to provide an optical characterization of the devices. To complete the experimentation, the pointing sensors were tested outdoor, assessing their performance in operative conditions.

During the last 15 years these pointing sensors have been experimented (Fontani et al., 2011) and applied with success in different versions in several research projects concerning thermal solar concentrators (Sansoni et al. 2011), concentrating photovoltaics (Fontani et al., 2007a), hybrid solar collection systems (Ciamberlini et al., 2003), lighting (Ciamberlini et al., 2003; Fontani el al., 2007b; Sansoni et al., 2008). As essential component of devices for solar energy exploitation, the optical sun trackers have been used to perform outdoor optical tests, to experiment collector prototypes or to develop researches in the field of sun light collection. In the past decade the CNR-INO Solar Collectors Laboratory has collaborated with the major Italian actors, private and public, in the energetic research field.

2. Sun pointers for high concentration tracking

In the last decade Concentrating Photovoltaic (CPV) systems have improved their diffusion and the related electronics and optical components have experienced great technological and scientific developments. Photovoltaic cells of the last generation require concentrations that can exceed 700 suns. Consequently the associated optical systems must have a quite high value of posterior numerical aperture and a very tiny Field Of View (FOV). These requirements impose a very high angular precision to the systems for sun tracking. For tracking sensors that guide high concentration systems the typical required resolution is at least 0.1°.

Optical solar trackers have been developed and experimented by CNR-INO since 1997, implementing mechanics, electronics and software to realize prototypes (Ciamberlini et al., 2003; Fontani et al., 2011). The proposed two-axis pointer is basically a “pinhole camera” without lenses, whose scheme is reported in Fig. 1. It performs sun tracking on two perpendicular axes.

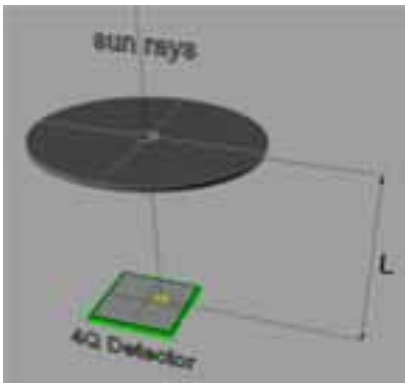

Fig. 1. A two-axis sun pointer, with pinhole.

A simplified version is represented by the one-axis pointing sensor, where the pinhole is replaced by a slit, as Fig. 2 shows. Pinhole or slit are coupled to a four quadrant photodetector. Two-axis sensors are suitable for fiber-coupled or CPV collectors. One-axis pointers are appropriate for solar troughs or linear lenses.

The working principle is illustrated in Fig. 1, which shows the main elements of the two-axis sensor: pinhole and four-quadrant detector (4Q-detector). The distance L, between pinhole and four-quadrant detector, determines the sensor Field Of View (FOV); L corresponds to the focal length of the collecting optics, hence the sun’s image moves on the photodetector with the same speed of the image on the PV cell. Sun’s image dimension and light intensity on the detector depend on the pinhole diameter d. The angular resolution of the sensor depends on detector dimensions, pinhole size and pinhole-detector distance. The lateral dimension s of the square photodetector is few millimeters.

The FOV aperture can be obtained as:

$$FOV = 2\,\mathrm{arctg}\frac{s}{2*L} \qquad \text{(eq. 1)}$$

For L = 50 mm and s = 5 mm, the total FOV aperture results 5.7°.

The one-axis pointer, in Fig. 2, is analogous to the two-axis sensor, but it mounts a slit over the photodetector. Consequently the four-quadrant detector can be substituted by a 2Q-detector.

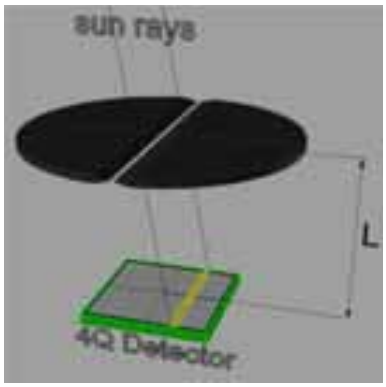

Fig. 2. A one-axis sun pointer, with slit.

3. Components and construction of the sensors

Detection configuration and light collection geometry were theoretically studied using ray tracing simulations, in particular referring to real solar plants involved in the CNR-INO research, briefly summarized in Section 1. Most of the detection geometries were obtained from ray tracing analyses of test prototypes or solar plants under development. The sensor realization evolved, customizing the pointer geometry and creating new detector typologies, on the basis of the experience in component production or driven by the extensive experimentation on the pointers.

Several versions of the described sun pointers were realized, optically characterized and practically applied on test installations and solar plants developed during 15 years of scientific experimental work (Ciamberlini et al., 2003; Fontani et al., 2007a, 2007b, 2011; Sansoni et al., 2008, 2011). Two-axis and one-axis sensors were implemented starting from the optical design, optimized in the study phase; and then suitable mechanics and electronics were developed. Two examples of two-axis pointer, with pinhole, are presented in Figures 3 and 4, showing the interior components.

Fig. 3. A two-axis sensor with narrow FOV and elevated precision.

Every sensor was previously tested in laboratory, in particular analyzing angular resolution and Field Of View aperture and then experimented in outdoor installations, testing functionality, performance and reliability. The optical characterization of the devices, performed indoor and outdoor, is summarized in Section 4, which also includes a validation by theoretical simulations; finally the assessment of the Field of View of the pointer is presented in Section 5.

Fig. 4. A two-axis sensor with large FOV.

The distance *L* can be adjusted, changing the FOV, to obtain the required precision. Figure 3 reports a version with elevated precision: *L* is 42 mm, so for detector side s = 5 mm the FOV is 7°. Figure 4 shows a two-axis sensor with *L* = 7 mm, whose FOV is 40° that corresponds to a lower precision with respect to the sun pointer in Fig. 3.

The dimensions of the four-quadrant detector was experimentally determined: typical values are 5 mm of squared detector side. The pinhole dimension depends on sensor and electronics and it was also experimentally defined. At the base of each well, forming the camera, there is a board mounting the four-quadrant detectors and their pre-amplifiers with gain adjustments.

As the sun pointer precision improves, the phases of sensor assembly and mounting on the solar collection plant become more critical: in particular it is essential to correctly and precisely place the detectors. Then the pointer must be mounted on the solar installation with the axis aligned to the collector axis. Sometimes the sensors are used in combination: for safety the solar pointer can contain two sections with different FOVs; the two sections are used in sequence, improving the precision, from the wide-angle section (low-precision section) to the narrow-angle section (high-precision section) (Sansoni et al., 2008).

The electronic system controlling the motor guide is of digital type. It employs an Input/Output DAQ device NI USB-6009 supplied by National Instrument. The I/O card is linked to a personal computer through a connection of USB type. The analogical inputs of the card are used to manage the photodetector with 2 or 4 quadrants of the solar pointer. The digital outputs are employed to guide the drivers of electric motors, which move the concentrators or the collectors' supports.

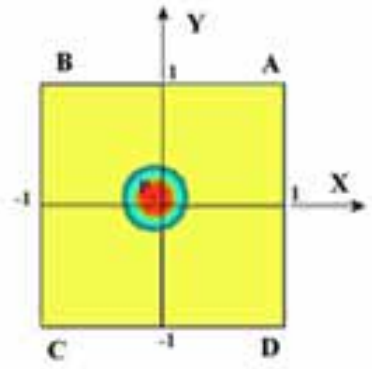

Fig. 5. Solar image on the four quadrant detector.

The position of the luminous spot is expressed by the coordinates of point $P(P_x;P_y)$, which is the barycenter of the solar image projected by the pinhole. P_x and P_y are the coordinates with respect to the reference axes of the detector surface (X;Y), indicated in Fig. 5. For the two-axis pointer they are:

$$P_X = \frac{(V_A + V_D) - (V_B + V_C)}{V_A + V_B + V_C + V_D} \qquad \text{(eq. 2)}$$

$$P_Y = \frac{(V_A + V_B) - (V_C + V_D)}{V_A + V_B + V_C + V_D} \qquad \text{(eq. 3)}$$

where V_A, V_B, V_C, V_D are the values (in Volts) of the output signals arriving from the four preamplifiers.

The elaboration procedure is analogous for the case of one-axis pointer, but considering only a single coordinate P_x .

4. Indoor and outdoor tests of the sensors

The sun pointers were optically characterized indoor and outdoor, preliminarily in laboratory with reproducible tests and successively with real measurements in direct exposure to the sun. This solar tracking methodology is based on an optical pointing system exploiting a two-axis sensor (or a one-axis sensor) as "sun finder". The two-axis sensor contains a photodetector coupled to a pinhole, while in the one-axis sensor it is coupled to a slit.

Suitable mechanics and electronics were realized for the prototypes of both pointers and to perform their optical characterization. The laboratory setup to test two-axis and one-axis sensors is illustrated in Fig. 6. A He-Ne laser beam is expanded to obtain a collimated beam. This light impinges on the pointer under test with different angles of incidence obtained by rotating the sensor. This experimentation has two purposes: the first is to test the angular sensitivity of the sun pointer; the second is to check the output voltage level. This latter must be sufficiently high with respect to the noise of the electronics; but at the same time the voltage level must guarantee a sufficient dynamic of the sensor.

Fig. 6. Optical system to tests the sun pointer in laboratory.

Afterward the sun tracking sensors were experimented with direct solar exposure, replicating the real installation in a solar plant. In these outdoor tests the optical tracking system was applied to different testing devices for sunlight collection: solar concentrators coupled to photovoltaic cells, optical fibers or linear metal pipes. To experiment the practical functionality and to measure the sensitivity of the solar pointers the technique described in Section 1 was simplified. Instead of employing the double guiding system the solar tracker used only a driving system of dynamic type based on the optical pointer.

Some exemplificative results of laboratory measurements and field experimentation on both sensors are presented in Figures 7-9. The plots report the position of the luminous spot on the detector versus angle of incidence of solar light: each measurement represents a characterization of the optical behavior of a sun pointer. Figures 7 and 8 compare the measurements performed in laboratory with the characterization obtained with direct exposure to the sun: Fig. 7 for two-axis pointer, with pinhole; Fig. 8 for one-axis pointer, with slit. Then Figure 9 reports the field measurements for both pointers: the comparison evidences a different slope of the curves that corresponds to a different sensitivity.

The two-axis sun pointer is the most precise one and it executes sun tracking in two directions achieving a very high sensitivity. It performs a sun tracking with an angular precision of 0.1° or higher. It is indicated for solar optical systems requiring high pointing precision, like collectors coupled to small PV cells or optical fibers, with dimensions (diameter/side) of few mm and sometimes inferior to 1 mm.

The one-axis sun pointer reaches the same precision of the two-axis pointer but only in one direction. Hence it can be applied to linear concentrators (like solar parabolic troughs or linear Fresnel lenses), in solar thermal plants or low concentration CPV systems.

The solar tracking system is effective and precise, mainly due to the simplicity of working principle and optical components. The sensors, which can be implemented with low costs, are reliable and adaptable to every solar plant. In case of sun shading or temporary sun absence, the control program provides a realignment of the collector in few seconds. The system is able to compensate possible errors in the positioning of the device, which should be correctly aligned to the Earth axis. The described optical pointers can track the sun's position with an angular precision of 0.1°, which is sufficient for the majority of solar plant.

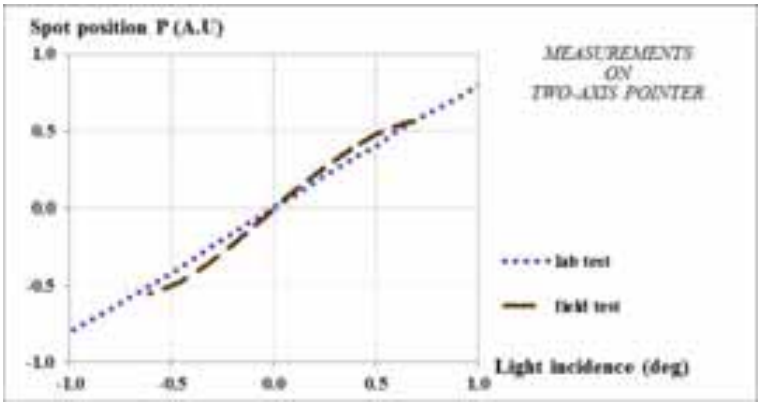

Fig. 7. Optical characterization of the sensor with pinhole.

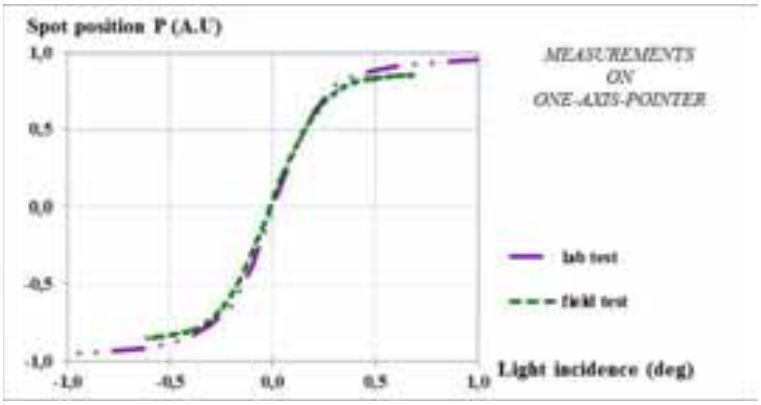

Fig. 8. Optical characterization of the sensor with slit.

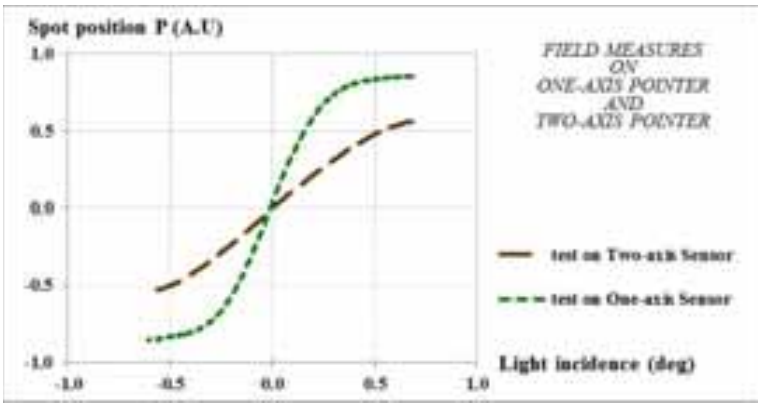

Fig. 9. Optical characterization of the sun pointers.

The validation of these experimental measurements was obtained by comparing the curves of Figures 7-9 with the theoretical data. For the curves in Fig. 7, the two-axis sun pointer was reproduced in a Zemax-EE optical simulation and the output signal was compared to the signal measured in indoor and outdoor tests. For the two-axis pointer, Figure 10 presents the comparison between the spot positions P obtained in the Zemax-EE simulation and corresponding values measured in the outdoor test. The position of the luminous spot projected on the detector is reported as a function of the incidence angle of the sunlight. The simulated curve is in fairly good agreement with the data measured in the field test.

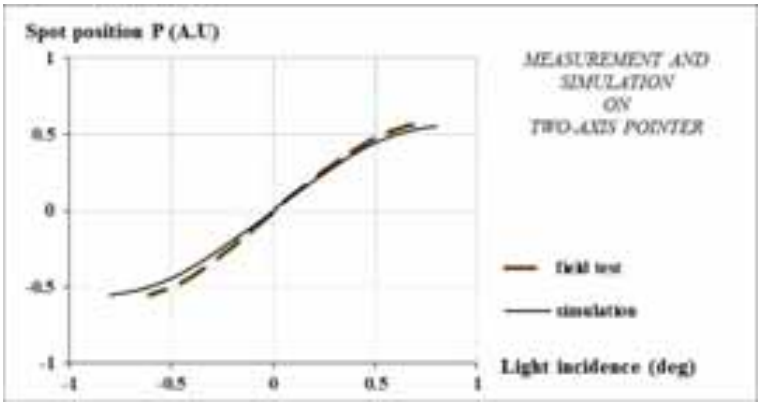

Fig. 10. Validation by ray tracing simulations for the two-axis pointer.

Each different realized sensor was examined indoor and experimented outdoor in order to assess detection characteristics and sun tracking precision. The optical characterization curves in Figures 7-9 were used to determine the zone of linear behavior of the pointers: this curve mathematically describes the working principle of each sensor and indicates its sensitivity. The validation in Fig. 10 confirms the accuracy of the experimental curves.

5. Measurement of the field of view of the sensors

Another fundamental parameter in the application of the pointers is the Field of View (FOV) aperture. The maximum sensitivity is obtained in the central part of the detector, while the total FOV aperture shows the extent of the range of operation of the sensor. The FOV aperture is obviously connected to the time in which the pointer is capable to re-track the sun in case of cloud passage or momentary absence of sunlight. The re-tracking time can be extended by using multiple sections with different FOV apertures or combining the active tracker with the passive tracker, based on the ephemerides of the year (discussed in Section 1).

Using the same set-up described in Fig. 6 it is possible to assess in laboratory the FOV of each sensor. The averaged data of these measurements are reported in Fig. 11: referring to Fig. 5, the plotted function is still the spot position P(Px;Py), given by Eq(2) and Eq(3). In practice this curve is the extension of the curves of Figures 7-9.

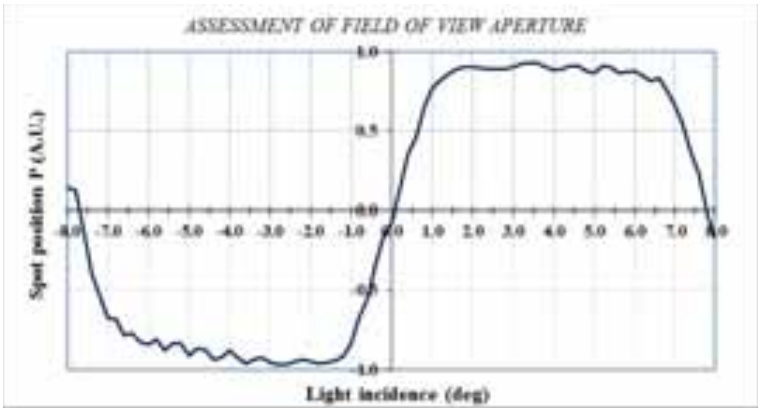

Fig. 11. Averaged measurements of the spot position P.

The spot position P remains approximately at the value of +1 (or -1) from the final angle of the linear zone to the edge of the detector. The measurement has been specifically carried from one detector border to the opposite one, even though usually the detector is mainly used in its central part. In the two lateral zones there is no more linearity between spot position P and angle of incidence, so the misalignment cannot be determined but it is however possible to try a re-alignment because the direction of the sun (in terms of up-down, left-right) is roughly known. Therefore it is useful to know the angular range within which the angular sensor still gives a valid signal in order to use it more completely. Figure 12 illustrates the two zones on the detector area: in the central zone (green in Fig. 12) P linearly depends on the incidence angle; while in the lateral zone (yellow in Fig. 12) P oscillates around +1 (or -1), and finally at the detector border the P value approaches 0.

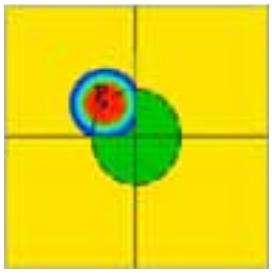

Fig. 12. Averaged measurements of the spot position P.

The determination of the FOV aperture is simply obtained from the complete plot of P values measured scanning the detector from one edge to the opposite one. In the example of Fig. 11, where the data are averaged on the measurements performed on a series of one-axis pointers, it is possible to use the sensor in a range between ± 7.5 degrees. Hence the total Field Of View aperture results 15 degrees. It is useful to remind that the FOV angle depends on the distance *L* between pinhole (or slit) and detector, which is chosen during the mounting of the device. Figures 3 and 4 show two pointers with different FOV: longer *L* gives narrower FOV and corresponds to higher angular precision (Fig. 3).

6. Conclusion

The proposed strategy for sun tracking includes a double guiding system that uses two complementary procedures: the first one provides a preliminary orientation, then the second realizes fine positioning and adjustments. The first tracking system is of passive type and it drives the motors to correctly orient the collector every day of the year. The second one is of active type and it employs an optical "sun finder". The double guiding system maintains the alignment in case of temporary sun absence or sun shading. The pointer perform an angular sensitivity higher than 0.1°, which is acceptable for many solar plants.

Two exemplificative optical pointing systems are proposed: the two-axis pointer that tracks on two perpendicular axes and the simplified one-axis pointer that tracks only in one direction. They can be adapted to every specific application and to every solar collection device. Installation and alignment become more and more crucial as the tracking precision increases. Solar installation placement, mounting and orientation of the sun pointer should be executed with particular attention to obtain an elevated tracking precision. If the sensor is precisely aligned with the collector, the information coming from the solar pointer is useful to compensate possible errors in the collector placement.

Sun pointing in one direction is required in linear collectors, solar trough collectors and linear Fresnel lenses. If the collector axis is parallel to the North-South direction, the tracking system must follow the sun in its daily excursion and the altitude of the sun over the horizon depends on Latitude and day of the year. If the collector axis is parallel to the East-West direction, the sun should not be tracked in its daily excursion. The proposed one-axis pointer can be applied to linear collectors for solar thermal plants or low concentration CPV systems.

Sun pointing in two directions is necessary to orient every concentrator with circular symmetry. In practice the tracking systems follows the sun position, which can be decomposed into two movements of single axis tracking. The combination of the two orientation adjustments gives the two-axis tracking. The proposed two-axis pointer performs solar tracking in two perpendicular directions with high sensitivity. It is indicated for solar optical systems requiring high pointing precision, like concentrators coupled to small PV cells or optical fibers.

In synthesis these optical pointing devices work as a pinhole camera without lenses. The working principle is simple, the device is adaptable and cheap, the pointer is effective and reliable.

COMPARATIVE STUDY ON TWO PHOTOVOLTAIC AND THERMAL SOLAR MODULEDS WITH POINT-FOCUS FRESNEL CONCENTRATOR

Ning Xu, Jie Ji, Wei Sun and Wenzhu Huang

Department of Thermal Science and Energy Engineering, University of Science and Technology of China, #96 Jinzhai Road, Hefei City, Anhui Province, People's Republic of China

Abstract

In this paper, the electrical and thermal performances of both Fresnel concentrator photovoltaic/thermal (FCPV/T) modules with thermal collector and FCPV modules with passive cooling heat-sinks are investigated in experimental method. Both types of modules are equipped with triple-junction solar cells. Their geometric concentrating ratio is as high as 1090×. Comparative analysis has been conducted based on experimental data. The experimental results have been analyzed from the viewpoint of thermodynamics. From the first law point of view, it is found that the overall efficiency of the FCPV/T modules can exceed 80% but it drops significantly as the coolant water is heated up. Meanwhile, the electrical efficiency of the two types of modules can reach up to 28.9%. While from the second law point of view, a highest exergetic efficiency of 33.9% and 28.9% can be produced by the FCPV/T modules and the FCPV modules, respectively. Water temperature is found to play an insignificant role on the exergetic efficiency and irradiation influences dominantly. Besides, the electrical outputs of the two types of modules are almost equal at the same time even if notable operating temperature difference between their cells exists. Thermal profile of the CPV/T receiver has been simulated on the basis of a 3D heat transfer model developed in the thermal analysis software Comsol. The influence of beam irradiance and cell temperature on electrical efficiency is further studied. The results indicate that electrical performance of these modules is affected mainly by beam irradiance, and it is influenced little by cell operating temperature, which greatly differs from flat-plate PV/T modules.

1. Introduction

A photovoltaic/thermal (PV/T) system is an integration of PV cells and solar thermal collectors which produces both electricity and heat simultaneously to increase its overall efficiency. The first investigation on PV/T system was presented by Martin Wolf (Wolf, 1976) in 1976. A large amount of experimental and theoretical studies on PV/T technology have been conducted during the decades (Amrizal, et al., 2013; Gang, et al., 2012; Tiwari, et al., 2009). Respect with the merit of a PV/T system lies in the reduction of demands on physical space and the equipment cost through the use of common frames and brackets as compared to the separated PV and solar thermal systems placed side by side, the cost of large area of photovoltaic cells is still higher than traditional power. Concentrator photovoltaic (CPV) system can reduce the area of solar cells by concentrating solar radiation onto small solar cells. If the cost of tracking assembly and concentrator is less than the cost of the saved solar cells, it could be an effective way to reduce the total cost of the system (Rabl, 1976). On the other hand, high efficient multi-junction solar cells are usually equipped in CPV systems to enhance the photovoltaic efficiency, which is rarely employed in systems without concentrator due to lack of economics. High efficient multi-junction solar cells have been developed and manufactured in both laboratories and factories. The efficiency of them is reported to be above 40% (Dimroth, et al., 2014; Green, et al., 2012; King, et al., 2012). On the CPV module level, photovoltaic efficiency over 35% have been reported (Ghosal, et al., 2014; Green, et al., 2015; Steiner, et al., 2015).

CPV systems can be generally classified as compound parabolic concentrator type (CPC) (Brogren, et al., 2001; Li, et al., 2014), parabolic trough type(Akbarzadeh and Wadowski, 1996; Coventry, 2005; Luque, et al., 1997), dish type (Chen, et al., 2014; Kribus, et al., 2006), linear Fresnel type (Liu, et al., 2014; Rosell, et al., 2005) and point-focus Fresnel type (Chengdong, et al., 2013; Wu, et al., 2012) according to the concentrator type. Among the CPV modules/systems, those with point-focus Fresnel lens recently have received more attention because of its advantages such as small volume, light-weight, mass production with low cost as well

doi:10.18086/swc.2015.05.21 Available at http://proceedings.ises.org

as effectively increasing the energy density. Xie et al. (Xie, et al., 2011) give a review on concentrated solar energy applications using Fresnel lenses in the last two decades, the highest photovoltaic conversion efficiency based on imaging Fresnel lens and non-imaging Fresnel lens is reported as over 30% and 31.5±1.7%, respectively. Amongst the existed point-focus Fresnel CPV systems, almost all the modules are passively cooled. Royne et al. (Royne, et al., 2005) believe that passive cooling could work well for single-cell geometries with flux level as high as 1000× suns, because there is large area available for heat sinking. However, for passively cooled CPV modules, the truth is that a large part of the already collected solar energy is dissipated as heat to the environment. Integrating the thermal collectors into a CPV module with point-focus Fresnel lens could be one of the potential solutions. Nevertheless, reports on point-focus Fresnel concentrator photovoltaic/thermal (FCPV/T) modules/systems are fragment. It is meaningful to investigate whether a FCPV/T system is better than a FCPV system whose cells are cooled passively, especially when they are close in manufacture cost.

In this study, an experimental rig containing two FCPV/T modules with thermal collector and two FCPV modules with passive cooling receivers were built. The modules are equipped with high-efficiency InGaP/GaAs/Ge triple-junction solar cells and the FCPV/T module was originally presented. The comparative investigation was conducted based on outdoor experimental data. The overall performance of these two types of modules were evaluated by energetic analysis and exergetic analysis. Thermal profile of the FCPV/T receiver was also analyzed with the employment of Comsol, a powerful thermal analysis software developed for various physics and engineering applications. The influence of beam irradiance and cell operating temperature on electrical efficiency is further studied on module level.

2. Description of the experimental setup

The photograph of the experimental setup is shown in Fig. 1. The experimental setup is built in Huainan (32.37 °N 116.59 °E), Anhui Province, China. It mainly consists of four parts, namely two FCPV/T modules and two FCPV modules, the two-axis tracking system, the water circulation system and the data acquisition system. The modules are equipped with high-efficiency InGaP/GaAs/Ge triple-junction solar cells whose photovoltaic efficiency is 31.4% (AM1.5D, 25 ^{o}C) under one sun. Two identical FCPV/T modules and two identical FCPV modules are mounted parallel in the same holder for comparison, as shown in Fig. 1. Each module consists of 15 receivers and 15 point-focus Fresnel lenses, mounting one for one in a 5×3 matrix. The area of each Fresnel lens is 330.2×330.2 mm^2, and the size of each solar cell is 10×10 mm^2, which means the geometric concentrating ratio of the modules is 1090×. For a single module, all the 15 solar cells are connected in series. The two FCPV/T modules are connected in series, so are the two FCPV modules. The electrical characteristics of the module are listed in Table 1, which is achieved by indoor testing under steady condition (DNI 900W/m^2, 20 ^{o}C, 4 m/s) and they are offered by the manufacturer. The two-axis tracking system maintains the modules tracking the sun automatically within a range of 0.3°.

Fig. 1: Photograph of the experimental rig

Tab. 1: Electrical characteristics of a module

Parameter	Variable	Value
Maximum power	P_{max}	402W±5%
Voltage@ P_{max}	V_{max}	38.3V
Current@ P_{max}	I_{max}	10.5A
Open circuit voltage	V_{OC}	45.2V
Short circuit current	I_{SC}	11.1A

The main difference between these two types of modules lies in their receivers. Both types of receiver consist of a solar cell and an aluminum heat-sink, as shown in Fig. 2. The solar cell is pasted at the center of front side of the heat-sink by thermal conductivity silica gel. The optical prism is pasted on the solar cell by optical silicone. A ceramic housing is arranged to surround the solar cell, which protects the solar cell against interference of unnecessary illumination. For the CPV/T receiver, an axial grooved tube is designed on the rear side of the heat-sink, through which water flows and takes heat away. The groove could increase the heat exchange area and it also enhances the convective heat transfer by disturbing the fluid. Therefore, the heat-sink of the CPV/T receiver serves as the thermal collector. Threads are made at both ends of the tube for pipe connection. As to the CPV receiver, large-area fins are employed to increase heat exchange area. Although the pipe connection increases the cost of FCPV/T module, the volume of its heat-sinks is smaller than the FCPV module's. Besides, there is no difference between the fabrication technologies for both types of receivers. As a consequence, the costs for the FCPV/T module and the FCPV module are almost the same.

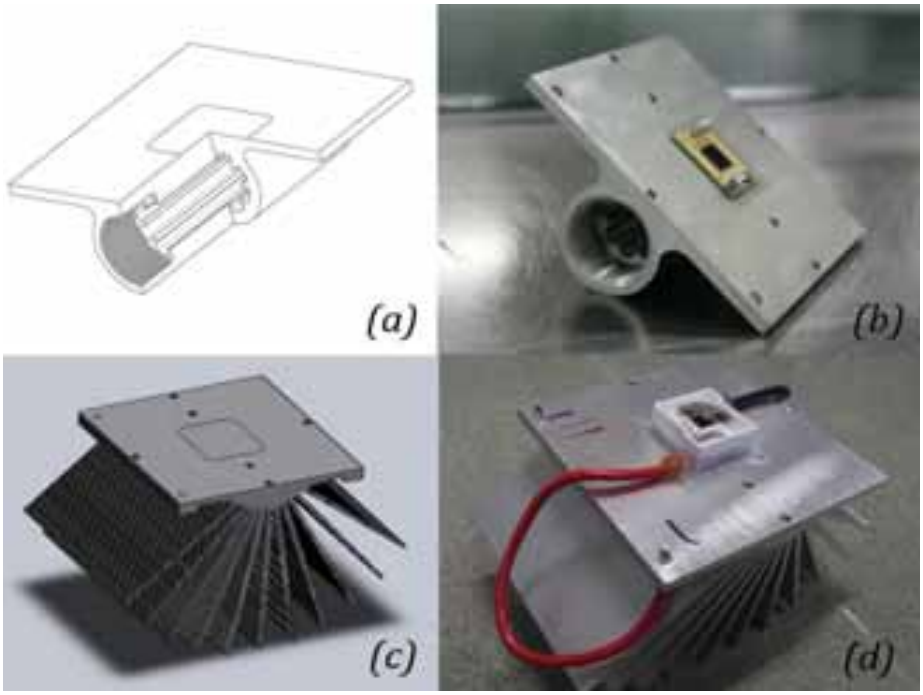

Fig. 2: Schematic and photograph of the FCPV/T and FCPV receiver

Fig. 3 shows the schematic of the water circulation in the FCPV/T system. Water is pumped from the bottom of the storage tank and flows through the tubes below the heat-sinks. Hot water flows back to the tank. The whole water circulation is a closed loop without secondary heat exchanger. Every 10 heat-sink tubes are connected in series by pipes. This arrangement divides the water circulation system into three branches and it also decreases the temperature difference on the water flow direction due to short flow distance, thus decreasing the impact on solar cells caused by water temperature gradient. At the inlet of each branch, a valve and a flow meter are installed to control and measure the water flow rate, respectively. Two pressure gauges are installed at the inlet and outlet of the main pipeline, respectively. All pipes and heat-sink tubes are insulated by insulation cotton with a thickness of 15mm. The volume of the tank in this system is 75L.

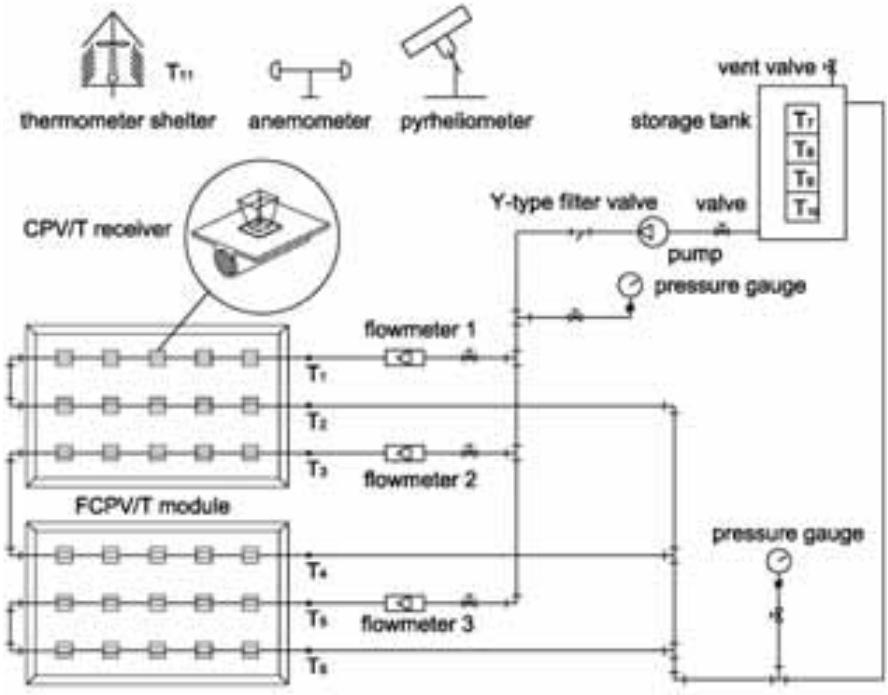

Fig. 3: Schematic of water circulation in FCPV/T system

The data acquisition system mainly consists of sensors and a data logger. The locations of sensors are also illustrated in Fig. 3. Inlet and outlet temperatures for each branch are measured by platinum resistances. The ambient temperature and the tank water temperatures are measured by T-type thermocouples. To eliminate the measurement error caused by temperature gradient in the tank, four equidistant temperature measuring points are arranged. The beam irradiance is measured by a pyrheliometer. Both temperature and beam irradiance are recorded by a data logger (Agilent 34970A) at an interval of 10s. Pressure and water flow rate are also recorded. A photovoltaic analyzer is used to measure and record the electrical output of the modules. The electrical data is recorded every 5 minutes. A thermal infrared imager is also employed to record the thermal profiles of the modules. Details of all the measurement instruments are listed in Table 2.

Tab. 2: Characteristics of sensors and measurement instruments

Device	Accuracy	Specification
Thermocouple	±0.2°C	T-type
Thermal resistance	±0.1°C	Pt 100
Pyrheliometer	2%	TBS 2-2
Data logger		Angilent 34970A
Flow meter	1%	Lmag_W800
Photovoltaic analyzer	1%	HT I-V400
Thermal infrared imager	±2°C	Fluke Ti400

3. Analysis methods

The overall performance of a PV/T system can be evaluated according to thermodynamics, economics, marketing and environmental implications, as demonstrated by Coventry and Lovegrove (Coventry and Lovegrove, 2003). Among the evaluation methods, the thermodynamic approach is popularly used in optimizing an engineering system that owe their thermodynamic imperfection to heat transfer, fluid flow and mass transfer irreversibility. Bosanac et al. (Bosanac, et al., 2003) believed that the economical and marketing approaches are affected by the political environment and are never universally valid. The thermodynamic approach based on energy and exergy analysis is more objective. Therefore, the analysis in this study is mainly from the viewpoint of thermodynamics.

3.1. First law efficiency of thermodynamics

From the first law of thermodynamics, the overall performance of a PV/T system can be evaluated by the energetic (first law) efficiency η_{PVT}. It is widely used in previous studies (Chow, et al., 2009; Ji, et al., 2007), which directly reflects the overall performance of a PV/T system. The first law efficiency is defined as follows:

$$\eta_{PVT} = \frac{E_t + E_{PV}}{A_F \int_{t_1}^{t_2} G_b dt} = \eta_t + \eta_{PV} \quad \text{(eq. 1)}$$

$$E_t = c_p m (T_2 - T_1) \quad \text{(eq. 2)}$$

$$E_{PV} = \int_{t_1}^{t_2} P_m dt \quad \text{(eq. 3)}$$

where E_t and E_{PV} are the thermal energy output and electrical output of a module, respectively. c_p is the specific heat of water, m is the mass of water in storage tank, and T_2 and T_1 represent the final and initial water temperature during the time period from t_1 to t_2, respectively. A_F is the area of Fresnel lens in a module and G_b is the beam irradiance measured by the pyrheliometer. η_t and η_{PV} are the thermal efficiency and the electrical efficiency of the module, respectively.

3.2. Second law efficiency of thermodynamics

Although the first law efficiency reveals the overall performance of a PV/T system intuitively, it ignores the difference between thermal energy output and electrical output produced by the modules in "quality", even if they are the same in "quantity" and measurable by the same physical unit. In fact, thermal energy cannot produce work until a temperature difference exists between a high temperature heat source and a low temperature heat-sink, while electrical energy can completely transform into work irrespective of the environment. In other words, the second law efficiency, namely the exergetic efficiency, offers a qualitative and standardized evaluation for the overall performance of a PV/T system. Exergy is simply the available energy obtained by subtracting the unavailable energy from the total energy, and is equivalent to the work transformable.

According to the work conducted by Fujisawa and Tani (Fujisawa and Tani, 1997), the second law efficiency of a PV/T system is expressed as eq. 4. This definition is on the basis of the assumption that the initial temperature of the fluid medium is equal to the ambient temperature.

$$\varepsilon_{PVT} = \varepsilon_t + \varepsilon_{PV} = (1 - \frac{T_a}{T_2})\eta_t + \eta_{PV} \quad \text{(eq. 4)}$$

where ε_t and ε_{PV} are the exergetic efficiency of solar cells and thermal collectors, respectively. T_a is the ambient temperature and T_2 is the final water temperature.

In eq. 4, the calculation of the exergy of solar radiation is not considered. Instead, the energy of radiation is taken as the exergy of radiation directly. Exergetic efficiency is the ratio of total exergy output to total exergy input (Hepbasli, 2008). Therefore, the exergetic efficiency can be defined as

$$\varepsilon_{PVT} = \frac{Ex_t + Ex_{PV}}{A_F \int_{t_1}^{t_2} \dot{E}x_{sun} dt} = \varepsilon_t + \varepsilon_{PV} \quad \text{(eq. 5)}$$

where Ex_t and Ex_{PV} are the thermal exergy output and electrical exergy output of a module, respectively. $\dot{E}x_{sun}$ is the exergy input of solar radiation. The exergy outputs are related to the energy outputs as follows:

$$Ex_t = (1 - \frac{T_a}{T_2})E_t \quad \text{(eq. 6)}$$

$$Ex_{PV} = E_{PV} \quad \text{(eq. 7)}$$

There are different methods to determine the exergy of radiation in evaluating the performance of PV/T system when using the exergy method. Among them, three most commonly used calculation methods are summarized by Chow, et al. , i.e.

$$\dot{E}x_{sun} = [1 + \frac{1}{3}(\frac{T_0}{T_{sun}})^4 - \frac{4T_0}{3T_{sun}}]G_b \quad \text{(eq. 8)}$$

$$\dot{E}x_{sun} = [1 - \frac{4T_0}{3T_{sun}}]G_b \quad \text{(eq. 9)}$$

$$\dot{E}x_{sun} = [1 - \frac{T_0}{T_{sun}}]G_b \quad \text{(eq. 10)}$$

where T_0 is the environment temperature and T_{sun} is the solar radiation temperature at 6000 K. Actually, the difference between results calculated by these three methods are less than 2%. In this study, eq. 10 was adopt.

3.3. Evaluation of thermal profile of the receiver

Cell operating temperature is believed to play a significant role in evaluation of performance of a PV/T system because it greatly influences the electrical output. However, it is difficult to measure cell temperature directly because of the lamination connection between solar cell and heat-sink. Fernandez et al. (Fernandez, et

al., 2014) proposed four methods to calculate the cell temperature of a high concentrator photovoltaic module, but they are either oversimplified (such as one-dimensional model) or required with adequate measurable data (such as ANN method). There is no doubt that a 3D thermal model can better describe the real thermal profile of the receivers. A number of thermal analysis software could be adopted to establish the 3D thermal model, and the core issues are providing the boundary conditions accurately. For the FCPV modules, their boundary conditions mainly include the beam irradiance, ambient temperature, and wind speed as well as wind direction. However, the wind direction is difficult to define because the modules always move. While for the FCPV/T modules, the boundary conditions primarily consist of beam irradiance, water temperature and ambient temperature. Fortunately, these parameters could be measured precisely. Therefore, the 3D thermal model of the CPV/T receiver could be solved in a more rational way by virtue of a thermal analysis software.

In this study, a powerful thermal analysis software Comsol is employed to simulate the thermal profile of the CPV/T receiver. Comsol is a finite element analysis, solver and simulation software for various physics and engineering applications, especially coupled phenomena or multiphysics. A 3D transient heat transfer model was developed as the simulation process described in Fig. 4. The 3D geometric model of the CPV/T receiver is firstly imported into the software, followed by mesh generation automatically. After defining the initial values and boundary conditions, the thermal profile of the receiver can be obtained by the solver. In this way, the thermal profile, especially cell temperature under a particular condition can be calculated. The cell temperature is treated as the average temperature of cell region on the CPV/T receiver.

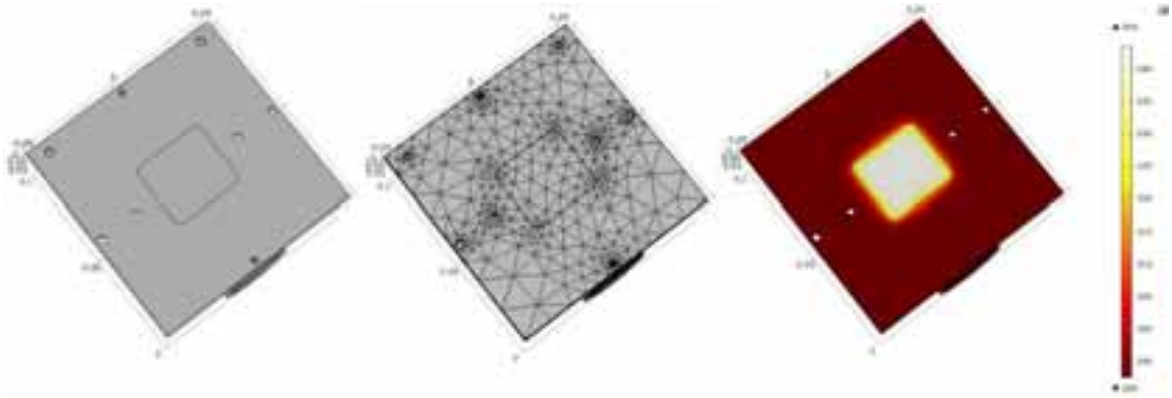

Fig. 4: Thermal analysis process by Comsol on a FCPV/T receiver

4. Results and discussion

A typical daily data in November 7th, 2014 is selected to show the results and followed by detailed discussions. Fig. 5 shows changes of measured weather data and temperature of water in storage tank from 10:00 am to 15:30 pm. As seen in Fig. 5, the ambient temperature changes in a small range between 15~17 °C, and the beam irradiance changes between 300~700W/m^2 with a steady stage from 11:00 am to 12:00 am. Water is heated from 25 °C to near 55 °C and water temperature drops a little after 14:30 pm. Wind speed in the daytime is always below 2m/s. Water flow rate of each branch is controlled at 0.33m^3/h which ensures water flows turbulently.

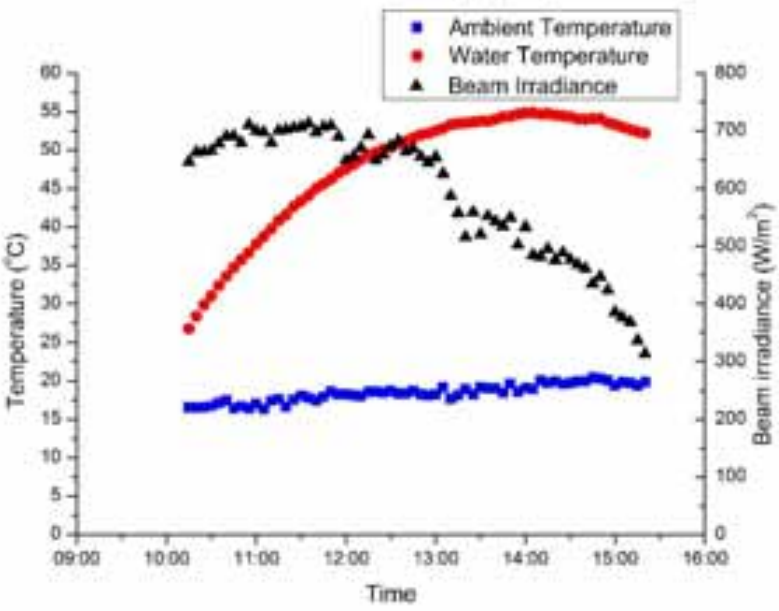

Fig. 5: Measured weather data and water temperature during experimental test

Electrical power yield of one FCPV/T module and one FCPV module are illustrated in Fig. 6. It is obvious that the higher beam irradiance is, the larger the power yield is. Power yield by both types of modules remain almost equal at the same time, regardless of how much irradiation they receive. Fig. 7 depicts the thermal profiles of the modules, which is captured by a thermal infrared imager. At the given moment, the temperature of CPV receiver is found to be higher than that of CPV/T receiver, as shown in Fig. 7. However, the corresponding power yields shows no difference. Considering the temperature difference between the two types of receivers, it can be deduced that cell operating temperature is not the dominant factor that influences the electrical performance of these modules. This feature is greatly different from flat-plate PV/T modules. Stated another way, the increase of water temperature would not lower the electrical efficiency of the FCPV/T modules significantly.

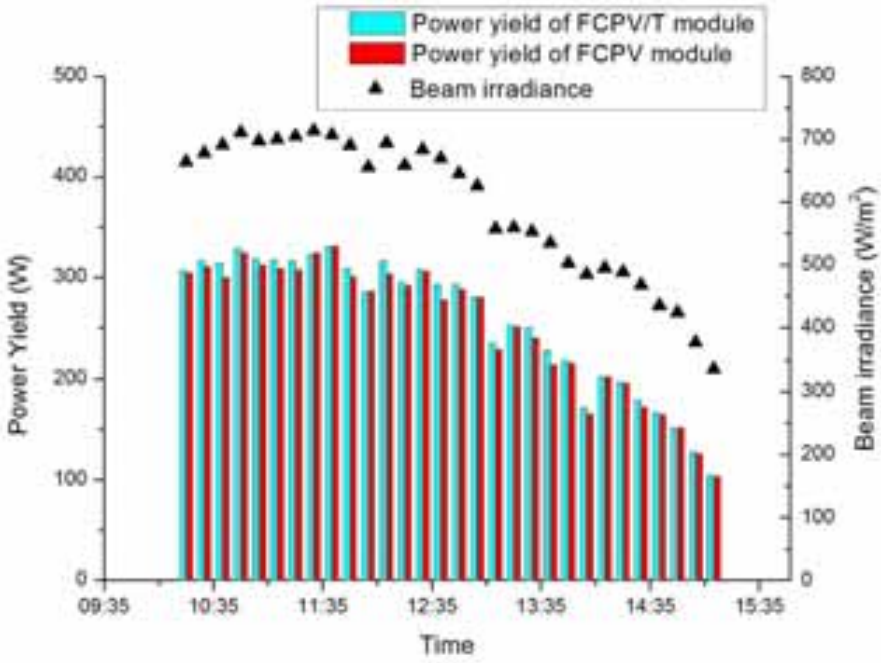

Fig. 6: Electrical power yield of FCPV/T module and FCPV module

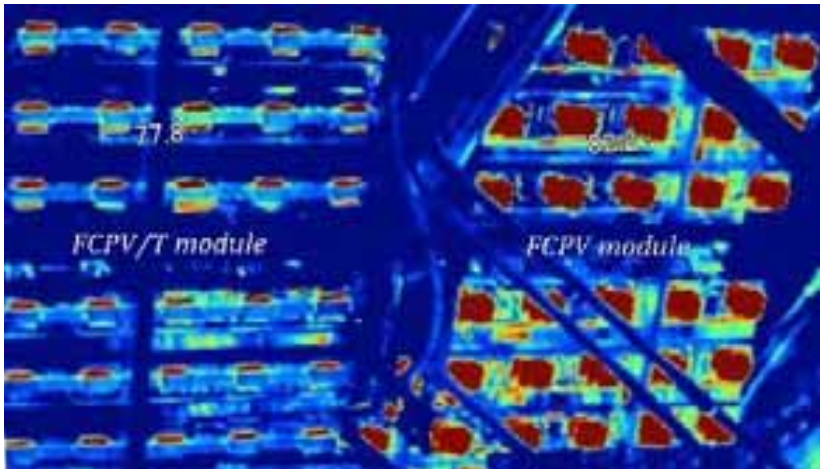

Fig. 7: Thermal profile of FCPV/T module and FCPV module

The variation of overall efficiency of the FCPV/T module and the FCPV module are shown in Fig. 8. From the viewpoint of the first law of thermodynamics, an overall efficiency of 80% can be obtained at the start of the experiment. It drops due to the decrease of thermal efficiency, which can be attributed to the descending irradiance and the decreasing temperature difference between cell temperature and water temperature. Besides, a highest electrical efficiency of 29.3% can be obtained and it changes with narrow fluctuation between 20.7% and 29.3%. On the other side, water temperature is found to play an insignificant role when the overall performance is viewed from the second law point. A highest exergetic efficiency of 33.9% and 28.9% can be produced by the FCPV/T module and the FCPV module, respectively. The exergetic efficiency is mainly affected by irradiance.

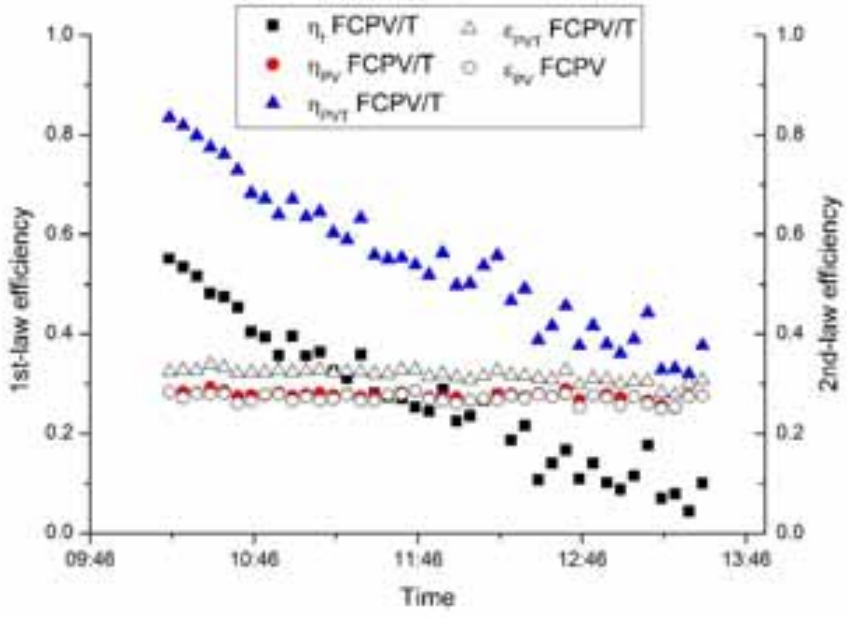

Fig. 8: Variation of overall efficiency of FCPV/T module and FCPV module

Fig. 9 depicts the variation of module electrical efficiency with beam irradiance and cell temperature. For better identification, the “beam irradiance-electrical efficiency” projection and the “cell temperature-electrical efficiency” projection are also marked in Fig. 9. Cell temperature is obtained by Comsol with the method proposed above, and the boundary conditions are based on experimental data. The calculation shows cell temperature changes between 60 °C and 90 °C, which is always lower than the design ceiling cell operating temperature of 100 °C. It can be seen that the electrical efficiency of the system is affected by cell temperature and beam irradiance together. Among the results, the highest electrical efficiency occurs under high irradiance

condition (where beam irradiance is near 700W/m^2) with a value of 29.3%. It decreases as the cell temperature increases within a narrow range. The electrical efficiency remains in a narrow range between 27% and 29% when beam irradiance is over 600W/m^2. However, the electrical efficiency drops steeply with the decrease of beam irradiance when beam irradiance is below 600W/m^2. This indicates beam irradiance has a dominated effect on module electrical efficiency, although cell temperature affects it as well.

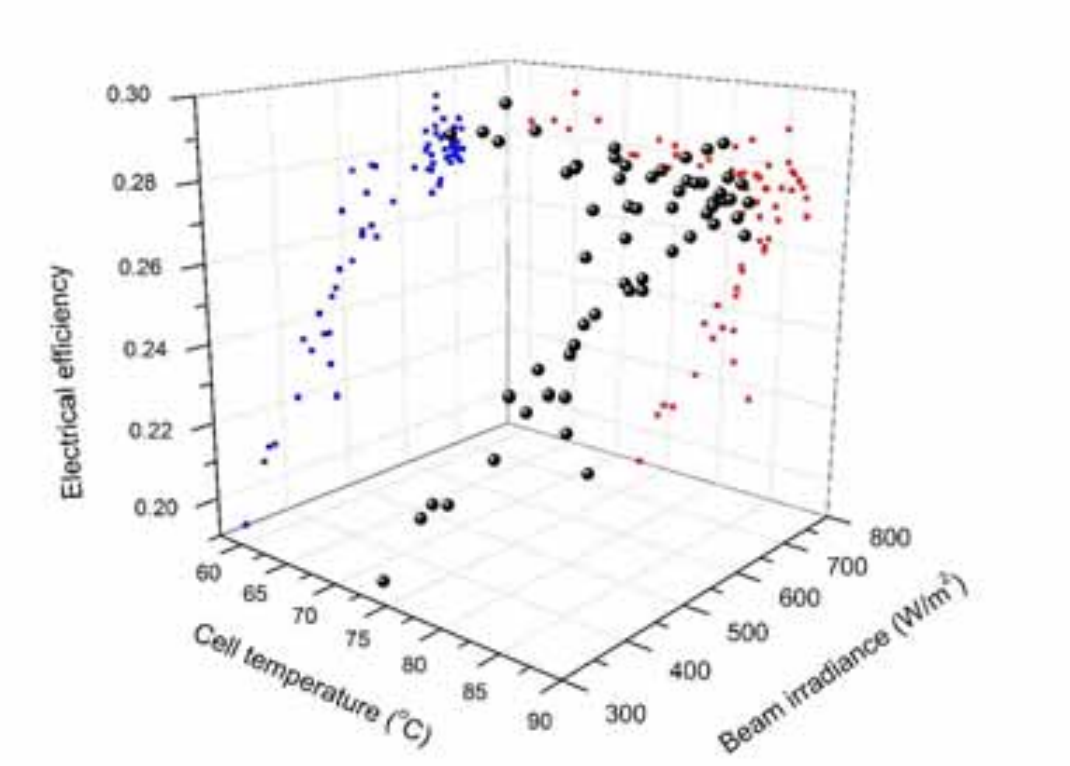

Fig. 9: Variation of electrical efficiency with irradiation and cell temperature

5. Conclusions

A comparative study on FCPV/T module with thermal collector and FCPV module with passive cooling heat-sinks were conducted. The overall performance of these two types of modules were evaluated by energetic analysis and exergetic analysis. The results show that the FCPV/T module can obtain an instantaneous electrical efficiency of 27% and a highest instantaneous thermal efficiency of 54%, which means its overall energetic efficiency can exceed 80%. From the second law point of view, a highest exergetic efficiency of 33.9% and 28.9% can be produced by the FCPV/T module and the FCPV module, respectively.

Electrical outputs of the two types of modules are found to be almost equal under the same environmental condition, even if distinct temperature difference between two kinds of module receivers exists. This indicates that cell temperature does not influence the electrical performance of the modules predominantly, which is greatly different from flat-plate PV/T modules.

Thermal profile of the CPV/T receiver has been simulated based on a 3D transient heat transfer model in Comsol. The boundary conditions of the model is acquired from experimental data. With the calculation, the influence of beam irradiance and cell temperature on electrical efficiency is further investigated. It can be concluded that beam irradiance has a dominated effect on the electrical efficiency of the modules, although cell temperature affects it as well. The electrical efficiency of the modules remains in a narrow range between 27% and 29% when beam irradiance is over 600W/m^2, but it drops steeply with the decrease of beam irradiance when beam irradiance is below 600W/m^2.

A New Tubular Photovoltaic Solar System with Low Sun Concentration

Claude Oiknine

Yuma SAS,Gargas, France

1. Summary

The Yuma project is to manufacture and commercialize a new photovoltaic (PV) energy solar system with leading partners. The tubular low sun concentration module, based on a disruptive design, provides a new optimized solution to produce green electricity in sandy or dusty environment. Originally developed and designed by a top-level research team, this system is protected by patents owned by the company.

The product successfully passed the prototype and preliminary performance tests. From early 2015, Yuma entered the industrialization and marketing phases with the ambition to be leader in the Sunbelt regions.

A short summary of photovoltaic market, based on outstanding analysis is given to show orders of magnitude of this market in the near future.

Keywords: *Photovoltaic, low sun concentration, one axis tracking, sun-belt market, grid parity, low LCOE*

2. The PV Market

2.1 Global PV market as of 2013

The global PV market progressed in 2013: after two years of approximately 30 GW of installations annually, the market reached 37 GW in 2013 and 40 GW in 2014. But the most important developments were the rapid development of PV in Asia, combined with a sharp drop of installations in Europe. As indicated in Global Market Outlook for photovoltaics, 2014-18:

"China became the top PV market in the world in 2013 and achieved the world's largest PV installation figure in one year with 11.8 GW connected to the grid, after Italy installed 9.3 GW in 2011 and Germany installed between 7.4 GW and 7.6 GW from 2010 to 2012. Japan scored 6.9 GW and took the second place in 2013, while the USA installed 4.8 GW."

2.2 Global PV market forecast by 2018

Previsions for the PV market in the near future are very encouraging: The same reference indicates:

"While European electricity demand is stagnating, this is not the case globally and PV growth will continue to be driven by local and global energy demand. The fastest PV growth is expected to continue in China and South-East Asia in general, with Latin America, the MENA countries and India following. The PV potential of the Sunbelt countries – where PV can already compete with diesel generators for peak power generation without financial support – could range from 60 to 250 GW by 2020, and from 260 to 1,100 GW in 2030. And with the faster than expected price decrease in PV technology that the industry experienced in recent years, even more countries will see PV as a competitive energy source before the end of this decade."

3. The Yuma Vision

3.1 The Yuma Vision

Yuma intends to provide a disruptive technology to unlock the Sunbelt PV potential

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.05.22 Available at http://proceedings.ises.org

3.2 The untapped Sunbelt potential

According to Global Market Outlook for photovoltaics, 2014-18 and EPIA and "Unlocking the Sunbelt potential of photovoltaics, October 2010, EPIA:

"The 66 Sunbelt countries account for 5 billion inhabitants representing respectively 95% of the Sunbelt and 75% of the world's population. Their 6.800 TWh electricity consumption represents respectively 97% of the Sunbelt and 38% of the world's electricity consumption"".

In the Company vision the huge potential of these sun-rich countries is a key parameter to make possible the introduction of a PV system whose design has been thought for the specific conditions of this market.

3.3 Technology limitation of PV flat panels

Increasing module efficiency is a major strategy for reducing per-watt module price. Consistent improvements in PV cell efficiency have been realized for virtually every PV technology (Fig.7), and module efficiency has followed this trend, albeit with a time and performance lag; this trend is projected to continue.

As single-junction PV technologies approach the theoretical (Shockley-Queisser) efficiency limit for their respective semiconductor materials, the extent to which further cost reduction may be attributable to efficiency gains will be reduced, and more substantial cost reductions will need to be realized via other ways.

CPV technologies offer high efficiency performance. However, at the module scale, HCPV has to deal with major technological challenges as high temperature management in the module, high tracking precision to target small and costly multi-junction cells. At this stage HCPV developers haven't found the solution to solve these issues at a low cost.

3.4 The dust problem

Dust and sand storms are prominent issues for PV installations in many sun-belt countries. (See Fig 1)

First, dust is deposited on solar surfaces every day of the year, and because of the absence of rain, it is not naturally washed from the panel. For example, deposition rate on solar surfaces has been measured at approximately 12.5 g / cm^2/ month in Saudi Arabia. This deposition rate will induce an efficiency drop of 8 to 15 % per month. This dust requires frequent cleaning involving significant manpower and water; it impacts heavily the O&M cost of the PV array. During the life time of a solar field, about 0.5 $/W additional cost to the initial price of the panel has to be paid.

The "dust problem" points out that flat solar panels, originally developed in Western Countries , are not the best fit for these conditions.

Integration of a Levelized Cost of Electricity (LCOE) have to be taken into consideration by developer in a long term vision

PV LCOE in Sunbelt Countries is expected to range from 5 to 12 c€/kWh by 2020 and 4 to 8 c€/KWh by 2030. In North Chile and South Morocco PV solar fields reach already grid parity as indicated by A.T Kearney National Renewable Energy Laboratory, National Technology Laboratory, EPIA Set for 2020, World Bank

Fig.1: sand storm in UAE

3. Yuma Project: An Alternative solution

4.1 The Yuma technology

4.1.1 Yuma's cylindrical LCPV sun receiver

The photovoltaic module consists of glass tubes including in their inner upper part a thin Fresnel lens. The lens concentrates the sun energy ten times along the bottom of the tube where a narrow strip of silicon cells is located (See Fig 2). Each tube, including dry air at atmospheric pressure, is permanently sealed and thanks to a simple rolling system tracks the sun from East to West.

Cells are manufactured out of quite ordinary wafers used for flat panels, however the two electrical contacts are both in the back of the cell allowing automatization of the stringing. Therefore the cost of these cells is close to one sun ordinary cells.

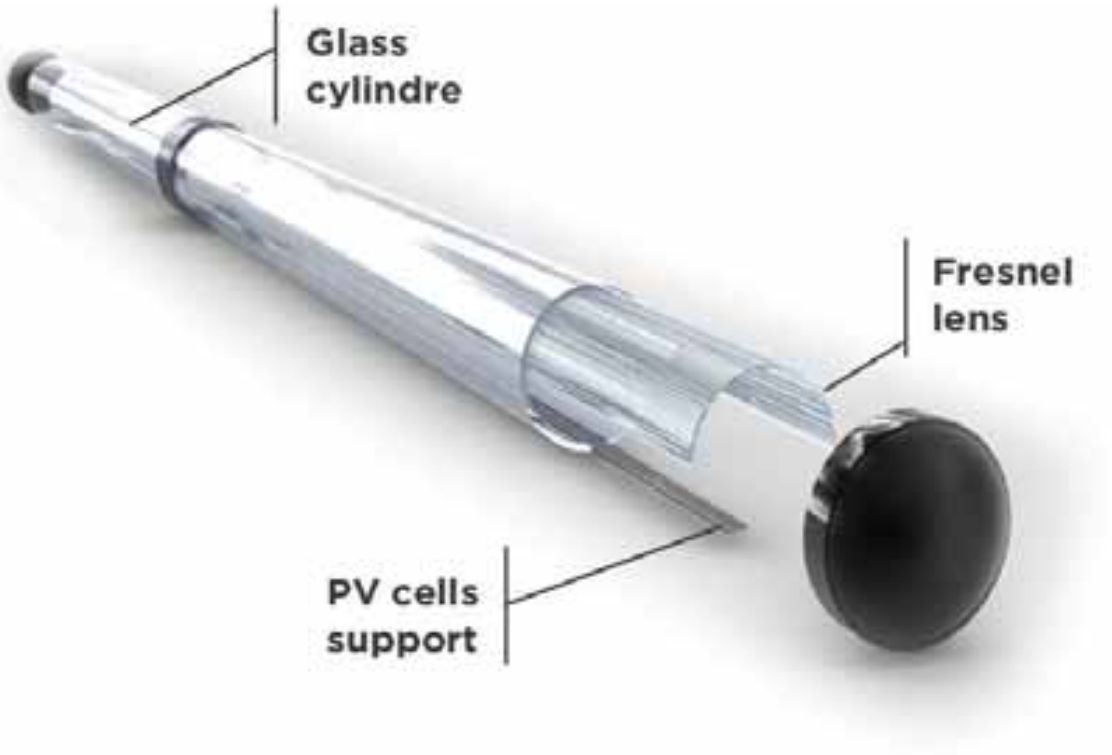

Fig.2: The Tenoga cylindrical LCPV module

Glass cylinder

A borosilicate glass tube with a 110 mm outside diameter and a 2000 mm length, both ends including a mechanical and electrical adaptor which allow a permanent closing of the tubes after assembly operations.
We chose standard tubes used for water heating in China where they are manufactured in huge quantity and at an affordable price. Borosilicate 3.3 was chosen for its good transparency and its proven resistance to UV and field conditions

Fresnel lens

A thin TPU film (around 100 µm thick) includes in one of its face a linear Fresnel Lens structure made of UV curing lacker; the TPU is slightly sticky on glass and the bond becomes very strong when heated. Moreover it has a good behavior when submitted to UV without yellowing.The Fresnel lens is located inside the glass tube on a 120° sector; its special design focused the solar irradiation linearly on a seven mm width-band, located on the low part of the tube.
The Fresnel Lens film was developed and manufactured by Film Optics specially for our application. The use of TPU allows a relative low cost and an easy integration in the glass tube. We chose Fresnel lens technology to avoid the use of big mirrors or sun concentrators.

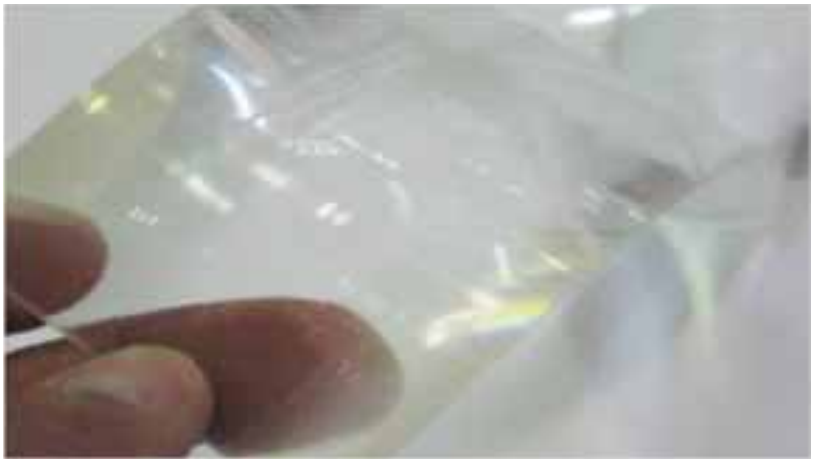

Fig. 3: Fresnel lens film

PV cells support

On a thin aluminum bar, located at the focal point of the Fresnel lens are connected in series forty MWT cSi photovoltaic cells with back contacts. This design allows to manufacture on the bar copper electrical contacts and to use an automatic process of pick and place to bond the cells on the bar. Bonding the cells must not introduce significant local electrical resistance; a special process using point soldering by laser was used.
Each tube will deliver around 25W.

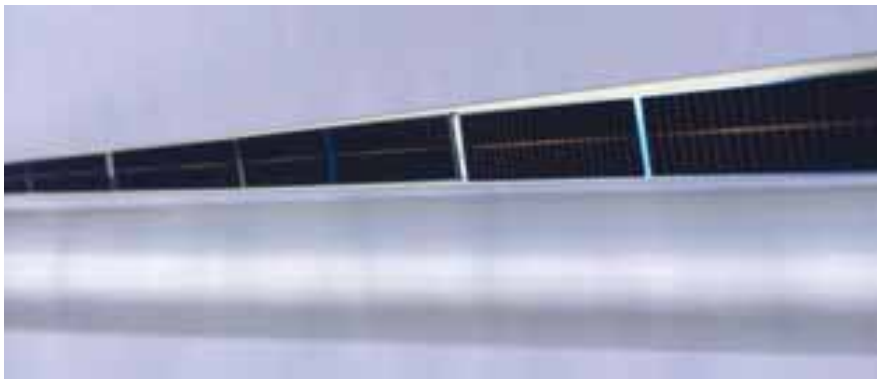

Fig. 4: PV cells support with back contact

Heat Sink

A Heat sink is made of a thin sheet of aluminum flattened by pre-stress against the inner wall of the tube; the bar with the solar cells is thermally bonded to the heat sink. The heat sink design is very important due to the large decrease of cells efficiency with temperature increase.

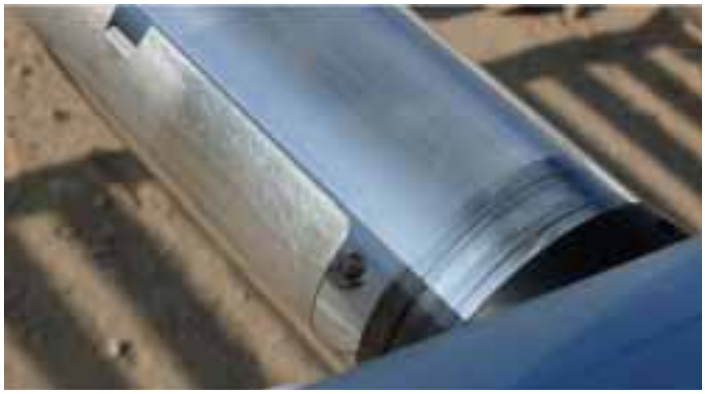

Fig 5: Heat sink

The thermal flux produced by the cells is quite small; therefore conduction through the heat sink and the glass tube occurs with a quite small loss of temperature. Radiation helps partly the cells to remain at a reasonable temperature. The area of the heat sink contributing to the cooling is about twice that existing on flat panel. Finally thermal flux is absorbed outside by natural or forced convection.
Laboratory simulations and site tests have confirmed that with a DNI of 1000 W/m^2 and with a wind speed of 0 km/hour, temperature elevation at the surface of the cells is no more than 30 °C above ambient temperature. With a 1 m/s wind this elevation will be 20 °C only.

So even with a sun concentration of ten, the design of the sun receiver and the efficiency of the heat sink avoid high temperature elevation of the cells.
Fig 23 shows a simulation of temperatures on the heat sink for a DNI of 1000 W/m^2 and without wind.

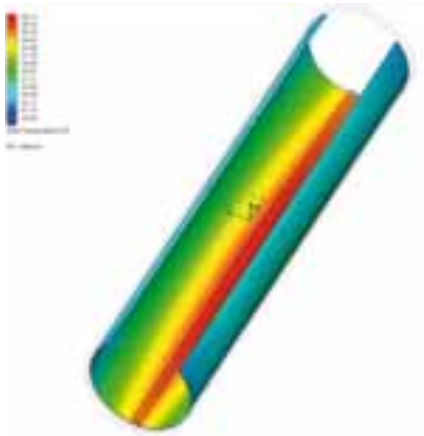

Fig. 6: Heat sink thermal simulation

4.1.2 Yuma's one axis tracking system

A one-axis tracking system enables each tube to rotate and to follow the sun in the East-West direction: hundreds of tubes can be rotated together driven by one small electrical motor.
The tracking system includes:

- A sun tracker with its control box
- A small electrical motor driving together a line of hundreds tubes
- A simple mechanism allowing the tube rotation without translation.

The whole mechanism with all electrical contacts is pre- installed in factory; it is protected against UV and dust inside Aluminum beams which are both support of the system and protection of components.

Fig. 7: Rolling mechanism stress tests

4.1.3 Ground installation

All cylindrical modules are mechanically and electrically «plug and play» connected to dedicated Aluminum beams. These beams include the electrical connections as well as the tube rotating mechanism and are ready to be installed on site.

The whole design enables a very easy and quick ground installation which *does not require any civil work.*

Moreover replacement of tube or of electrical motor does not require time nor special qualification.

Fig. 8: Pilot ground mounted installation

4.2 R&D

4.2.1 First Phase: Research

A first phase of R&D conducted in 2011-2013 focused on:

- Technical and economical feasibility studies
- Design of each component of the system including photovoltaic and mechanical items.
- Build pilot equipment and conduct laboratory tests and also tests in a desert environment in order to valid the system performances.

This first R&D phase has led Yuma to the installation of one prototype system tested in desert situation. This 500 W generator has strengthened the expected performance forecast of the future commercial product.

This first phase was supported by national institutions and private companies in particular Navallon Groupe.

Components developments:

Yuma uses basic components like standard borosilicate glass tubes and existing under-control technologies with a dedicated design for Yuma System, such as focusing optics developed by Film Optics in Great Britain and MWT cSi cells developed at Fraunhofer Institut in Germany.

Availability of components has always been a driver in the development of the Yuma technology.

4.2.2 Second Phase: Development

Supported by Institutional and financial partners as BPI (Banque Publique d'Investissement) , Midi Pyrenees Region in France and technological leaders as CEA, Fraunhofer lnstitut, Yuma has entered in a 2 years development phase leading to the construction of a 50 KW industrial pilot and the certification of the commercial product. (2016)

This phase includes additional components modification to fit industrial cost and time manufacture :

- *Lens:* Fresnel lens will use a 100 µm TPU substrate cheaper than PMMA and allowing a simple bonding process inside glass tube.
- *Cells:* Fraunhofer Institut tested successfully blue wafers produced by IrySolar in France. It will allow in the future production of MWT back contacts cells at competitive price
- *Electrical Connection:* Using technology Aluminum bars with copper electrical connections will enable to manufacture bars ready to include solar cells by a pick and place automatic bonding process.

5. Yuma system advantages:

Yuma PV solar system presents numerous advantages:

5.1 Price

The cost of a solar systems includes mainly the initial investment for the project, all hardware, ground preparation, financial cost, field installation, insurance, but also all the expenses during the life time of the array to allow a good installation efficiency (cleaning, new inverters).The energy produced during the life time of the PV generator depends on the sun irradiation and on the system efficiency. The LCOE which is the ratio of all costs divided by the total energy harvested in c$/kWh is a good integral indicator of the value of a solar field; today the lowest proposed LCOE is the key to win public tenders. Yuma, with a hardware cost around 0.5 $/W, a very low cost of installation and maintenance and a high level of irradiation, can reach LCOE less than 7c$/kWh.

5.2 Self cleaning

We showed that maintaining sun receivers clean is a main issue in order to maximalize the energy harvested. In our case the tubes are horizontal and separated by a small gap; therefore they collect much less dust and sand that flat surfaces. Moreover automatic dry cleaning, if necessary, is very easy and cheap.

5.3 Installation time

Is very small due to the facts that:

- There is no need of ground preparation and of concrete basis
- The forces due to wind are small and the system stays by its own weight
- Aluminum beams and supports come pre-integrated from factory
- Cylindrical sun receivers are put in place like Neon tubes

5.4 No danger of robbery

In several countries robbery of flat panels is quite usual because they can be used for TV; so the solar field has to be closed by fences and monitored by cameras. In our case it is very easy to rob a glass tube but there is no utility.

5.5 Flexibility

Future, more efficient, new cells can be incorporated in Yuma system very easily

5.6 Easy maintenance

Failure of a sun receiver or of an inverter will be automatically identified and replacement of the failed item is very quick and simple

6- Competition

Today more than 95% of solar fields are equipped with flat PV panels. Other technologies like thermal solar or PV with high sun concentration have not succeeded for the moment to gain a relevant part of the market:

the main reason is cost.
The idea to use PV with low concentration was tested some years ago [1], [2], [3] but without success; the main reason was the system design using big troughs leading to high cost.

7 Conclusions:

Yuma is building an industrial Pilot of 50 kW, based on a new tubular PV technology including low sun concentration and one axis tracking. This Pilot will be ready for real-life tests in desert conditions before the end of 2015. The maturity of this technology will allow us to market and manufacture Yuma systems before end 2016. . No other market solution provides comparable level of efficiency and competitiveness in sun-rich regions.

Abstract

The present paper reports the results of the BioCPV project, a venture of six universities conceived to develop a novel integrated renewable energy system for an autonomous electrical power generation for rural electrification. Concentrating Photovoltaics (CPV) is coupled to an Anaerobic Digestion Biogas system through a smart control mechanism to maximize the efficiency and to supply electricity uninterruptedly. The excess electricity generated during the day time is used to generate hydrogen, stored using metal hydride technologies and released during evening hours as input of an electricity generator. The waste heat of the CPV is recovered and used to accelerate the biogas production. The outcomes of the research on concentrating photovoltaic technologies are resumed: two high-concentrating systems have been developed, different thermal and electrical models have been proposed and the results of innovative researches on optics, building-integration and cooling have been presented.

Keywords: *Concentrating photovoltaics, rural electrification, integrated renewable energy system*

1. Introduction

Global energy consumption is constantly increasing, driven by the emerging economies. In 2013, renewable

doi:10.18086/swc.2015.05.23 Available at http://proceedings.ises.org

energies contributed to the 5.3% of global power generation, and accounted for more than half of the yearly global power capacity installed (Renewable Energy Policy Network for the 21st Century, 2014). Despite the grid requirement for a balanced and continuous power supply, the electricity generated by renewable sources is generally fluctuating both on short-term (seconds to hours) and long-term scales (months to years) (Weitemeyer et al., 2014). Hybrid power plants with different renewable technologies have already been identified as efficient, cheap and sustainable options for rural electrification (Bajpai and Dash, 2012). In this light, the BioCPV project aims to contribute to the optimization of hybrid renewable power generation systems and to the electrification of a rural village in the eastern part of India. The system under development integrates concentrating photovoltaic (CPV), anaerobic digestion (AD) and hydrogen storage systems. The present paper reports the latest progresses made in terms of scientific achievements on the development of innovative concentrating photovoltaic systems.

2. Concept and system's configuration

The BioCPV system is installed in the village of Kaligunj – Pearon Pally, adjacent to Visva-Bharati, Santiniketan, West Bengal, India, and supplies renewable energy to 14 household, one school, one community building and 50 street lights. In the early stage of the project, a survey has been carried out to estimate the energy need of the village (Mallick et al., 2013). During summer the peak load was found to be 5.8kW, whereas during winter it dropped to 5.5kW. Therefore, the system configuration has been designed in order to meet the necessities of the villagers. Taking into account the load profile, the peak energy demands and the weather conditions of the locality, a 10kW high concentrating photovoltaic (HCPV) system has been designed. The energy produced by the HCPV is mainly used to supply electricity to the village, whereas, during the low-load times, part of it is used by an electrolyzer to produced hydrogen. The hydrogen is stored and used through a generator during the peak-consumption times. The same generator uses the biogas produced by an anaerobic digestion system: the food waste and the local biomass are used to generate the biogas. In order to maximize the performance of the system, the waste heat generated by the HCPV system is recovered and used to support the anaerobic digestion.

The HCPV is expected to supply the electrical energy needed: the energy surplus is stored by producing hydrogen and used during the low-irradiance hours. It consists of four HCPV units with two axis tracking: each unit is made of two primary concentrators and two receivers. The electrolyzer requires 1kW in input from the HCPV and is designed to work for 7 hours a day. It has an efficiency of 60 % and it is expected to produce about 3 liters of hydrogen per minute. The hydrogen is stored in a metal hydride system, which has an efficiency of 90-95 % and can release about 300 liters of hydrogen for 4 hours. The digester for the AD system has been dimensioned to produce daily an adequate amount of biogas. A maximum of 15kW of thermal energy can be recovered by the HCPV (K. S. Reddy et al., 2014) and used to support the anaerobic digestion.

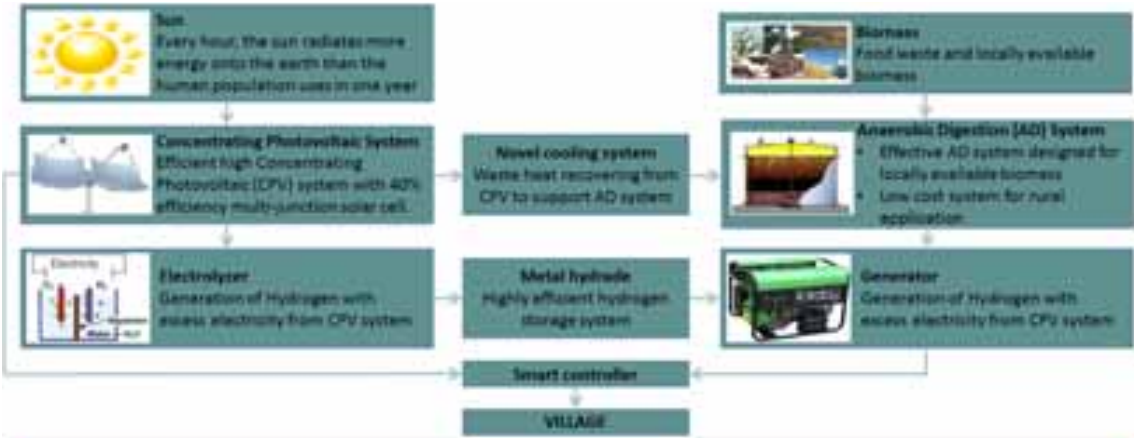

Fig. 1: Schematic of the BioCPV system.

The integrated renewable energy system designed for the BioCPV project has been demonstrated to be more beneficial than a single source system (Castellanos et al., 2015). A cost of $ 0.289 per kWh^{-1} was estimated

and is lower than that predicted for other technologies and scenarios ($ 0.335–1.332 per kWh^{-1}). According to the authors, the main reasons for this achievement are due to the synergy between the various production and storage elements at meeting the demanding load profile with a very high quality of supply.

2.1. Expected social and health benefits

The tribal communities residing in the villages of Kaligunj – Pearon Pally do not have access to the grid. These people are mostly dependent on leaf litters, forest wood, cow dung cakes for cooking and use kerosene lantern in the night time for education and other household activities, which is responsible for the indoor pollution as well. This lack of proper electrical/power facilities is deterrent for their development in terms of education, sanitation, health and entertainment. Electrification drive through renewable energy recourses like solar and biomass in the form of BioCPV system is conceived to face the problem of poverty, illiteracy, and lack of healthiness and also to ensure a clean and sustainable environment by reducing greenhouse gas emission thereby curbing indoor and outdoor pollution. Once implemented, the renewable energy harvesting system through AD/PV will generate employment opportunities among the tribals, make them self-sufficient and inculcate better competitiveness to take on the challenges of the rest of the world.

2.2. In-loco components installation

In the project site of Santiniketan, where the BioCPV system is being implemented, a control room has been built for housing different components of the system, such as the genset, the biogas engine or the inverter. Electrification works have been done for providing electricity to the designated households, school building, primary health center in the village. The Anaerobic Digester (Fig. 2) has been set up which will produce biogas (methane) with locally available aquatic weeds (such as water hyacinth and salvinia), kitchen waste, and cow dung as the source of inoculums. The biogas can be used for cooking purpose as well by the villagers and also used to generate electricity in the rainy season when the radiation is not enough to run the solar technologies at their highest capacity.

Fig. 2: Components of the AD system: gas chamber (a), main digester (b), predigester (c), chopper/grinder (d).

3. The concentrating photovoltaic systems

Concentrating Photovoltaic (CPV) systems make use of optical components which concentrate the incoming sunlight and focus it on solar cells. The concentrated light reaching the solar cell magnifies the production of energy several times. These optical components often referred to as concentrators, make use of reflective/ refractive principles of optics, individually or in combination for concentrating the sunlight.

3.1. 144-cell HCPV systems

A novel densely-packed HCPV system has been developed. The optics consists of a 125× primary and a 4× secondary optics that focus the sunlight onto a 144-cell receiver. The CPV system is equipped with two reflective geometries a square parabolic reflector as primary concentrator and 12 x 12 array of three-dimensional compound parabolic concentrators (CPCs) with optical homogenizer as secondary concentrator.

The geometrical concentration ratio for primary concentrator is 125× primary and secondary concentrator is 4×. The secondary concentrator integrated with CPV cell assembly and an active cooling system forms the complete CPV receiver. The incoming rays falling on the aperture of the parabolic dish will be reflected to CPCs. The CPCs will concentrate and redirects the rays towards the cell. The light rays which are parallel to the CPC's optical axis will not lose energy because it falls directly on the cell surface without any reflection, whereas the light rays entering the CPC within the acceptance angle will go multiple reflections in both CPC and homogenizer before reaching the cells. The homogenizer mounted on the exit aperture of the CPC will homogenize the flux distribution on the cell surface by multiple reflections. The irradiation distribution on one-fourth (6 x 6) of the 12x 12 CPV receiver is shown in Fig. 3 (S. Lokeswaran et al., 2015). The characteristics of the concentrators are resumed in Tab 1.

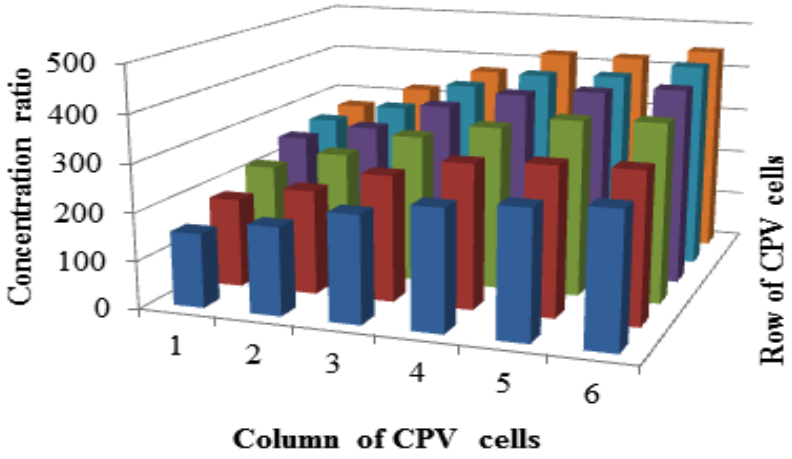

Fig. 3: Flux distribution for one-fourth of the array

Focal lenght	3.37m	Length of CPC	25mm
f/d ratio	0.794	Length of the homogenizer	10mm

The design of the receiver has been conceived to lower the costs and reduce the electrical losses (Micheli et al., 2015e). The receiver is built on an insulated metal substrate (IMS) that gives mechanical support to the receiver, collects the electrical energy produced by the cell and facilitates the removal of the waste heat. It was already known that IMS had a similar resistance to fatigue to that of the direct bonded copper (DBC) boards (Mabille et al., 2013), dominantly used to produce the HCPV receivers. Within the BioCPV project, IMS have been demonstrated to have a thermal behavior similar to that of DBC and more advantageous in terms of fabricability and costs (Micheli, 2015).

Each board allocates 144 1cm^2-sized 3C40 cells, supplied by Azurspace. The geometry of all the components has been designed to fit the requirements of the standards and to grant acceptable thermal management and electrical performance to the assembly. The shape of the electrically conductive layer has been conceived to minimize the electrical resistance. One Schottky diode per cell has been employed in the receiver to avoid damages to shaded cells and to reduce the power losses in case of current mismatch among different series-connected cells. Aluminum wires have been bonded to interconnect the cells and the conductive layers: they have been sized to safely work even in presence of overcurrents.

Fig. 4: A prototype of the HCPV system developed for the BioCPV project.

The HCPV systems are required to work for 20+ years in outdoor conditions, with minimum degradation. For this reason, the developed receiver has been mechanically and electrically tested (Micheli, 2015). At 500x, each cell is expected to work at a maximum power point power of 14.7W, achieving, under 1000W/m^2 DNI, an efficiency of 29.4%. A full scale prototype of the HCPV system has been installed (Fig. 4) and is being tested on the roof of the Institute of Technology Madras, in Chennai (India).

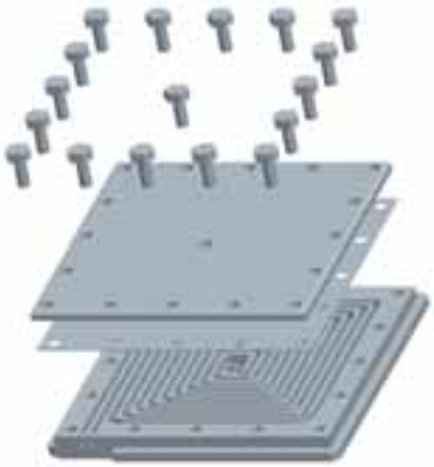

Fig. 5: Spiral Heat sink for CPV Cooling

The HCPV receiver is mounted on an active spiral mini channel heat sink, made of aluminum (S Lokeswaran et al., 2015). It consists of spiral flow mini channel heat sink with rectangular cross section channels where separate inflow and outflow paths with inlet and outlet ports were grooved as shown in Fig. 6 (K. Reddy et al., 2014). The base of the mini channel receives heat flux from the cells and the heat is transferred directly to the coolant by convection from the bottom surface and indirectly through the dividing wall. The large surface area of mini channel enables the coolant to take away large amounts of heat per unit time per unit area while maintaining a considerably low device temperature. Water is used as cooling fluid. The coolant enters the inlet port at ambient temperature and takes up the heat all the way through the flow path grooved in heat sink flowing clockwise towards the center. From the center the fluid flows anticlockwise towards outlet port through outflow channels located adjacent to the inflow channel. So, high heat fluxes can be dissipated at relatively low surface temperatures. The dimensions of the heat sink have been optimized to keep the HCPV module at a temperature of 80°C, with an overall pressure drop of 8.0 kPa. The solar radiation is concentrated on secondary reflector (CPC) which in turn concentrates onto the bottom surface of

the mini-channel spiral cooled receiver holding the 12 x 12 dense array of efficient triple junction PV cells.

3.2. Cassegrain Concentrator Photovoltaic System

Along with the large HCPV system, a cassegrain 500x HCPV module has been developed. The system consists of two reflective optics and a homogenizer, which concentrate the sunlight on a 1 cm^2-sized multijunction cell. The two-stage reflector configuration has been chosen to enhance the compactness of the module. The optics geometries (Tab 2) have been optimized to achieve an efficiency as high as 84.82% at normal incidence and limiting the losses in case of a ±1° tacking error (Shanks et al., 2014).

Tab 2: Specifications of the cassegrain concentrator optics.

Primary concentrator		Secondary concentrator		Homogeniser	
Geometric concentration ratio	125×	Geometric concentration ratio	3×	Geometric concentration ratio	9×
Aperture area	23cm×23cm	Aperture Area	5cm × 5cm	Aperture Area in	3cm × 3cm
Focal Length	27cm	Focal Length	7cm	Aperture Area out (Cell)	1cm 1 cm
Height of dish	2.8cm	Separation Distance from Primary	15.6cm	Length	7.5cm
Width of dish	23cm	Full system Height	20cm	f/d ratio	1.2

The surface roughness of the homogenizer can significantly affect the overall optical efficiency and to compensate for this inherent loss due to manufacturing processes, a new conjugate refractive reflective homogenizer (CRRH) was developed and proven capable of increasing the optical efficiency of the system by 6% (Shanks et al., 2015a). The new homogenizer was found to improve the optical efficiency by 3% at normal incidence (Fig. 6).

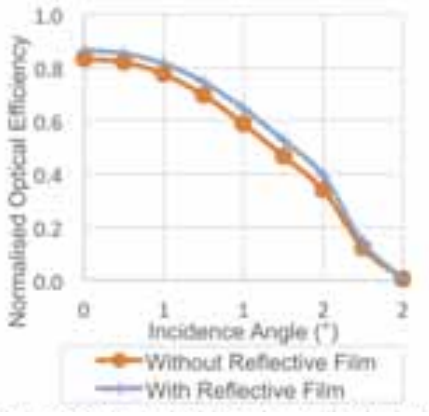

Fig. 6: Enhanced optical efficiency of the homogenizer due to the use of the reflective film (Shanks et al., 2015a).

The Cassegrain Concentrator Photovoltaic modules have been arranged in 3x3 arrays (Fig. 6) and are currently being outdoor tested in Spain and India.

Fig. 7: The 3x3 Cassegrain Concentrator Photovoltaic System a) top and b) side view.

3.3. Electrical and thermal modelling

Electrical and thermal modelling of HCPV is a fundamental research aim to optimize the design of the systems and the prediction of energy production. In this light, different studies on the electrical and thermal behavior of the HCPV systems have been presented and made available in literature (Almonacid et al., 2015; Fernández et al., 2015). A comparative studies demonstrated that the available models could predict the maximum power output of different HCPV systems with discrepancies lower than 5% (Soria-Moya et al., 2015). An integrated thermal-electrical model has been developed: it has been found that a 1cm^2-sized cell can be adequately cooled by an heat sink with a thermal resistance of 1.63 K/W or less (Theristis and Donovan, 2015).

3.4. Data logging and system integration

The data acquisition system produced for the BioCPV project differs from standard systems at it collects data from the off-grid system and stores them remotely, making them available through a real time interface (Calabria, 2015). Generally, the data recorded in a stand-alone system are stored in a “black box” that needs to be directly accessed in order for the data to be retrieved. On the other hand, biosciences data logging systems transmit the GPS coordinates to track the animal movements but the data is stored on the microprocessor directly and retrieved by following the GPS signal.

The system used in BioCPV has been programmed using LabVIEW, a software package developed by National Instruments (NI). The system, shown in Fig. 8, is composed of 5 independent units connected through a NI chassis. The NI controller is the cRIO-9024, a real time controller used for deterministic control, data logging and analysis. Three standard modules have been used for the acquisition of currents, voltages and temperatures. A communication module developed by the Science & Engineering Applications Datentechnik GmbH, based in Germany, has been configured to transfer the data through a M2M platform and has been connected to a GPS and a GSM positioning antennas

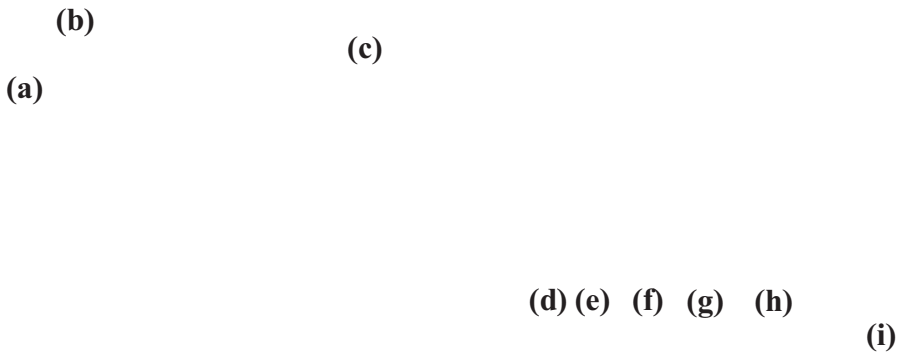

Fig. 8: The data logging system (Calabria, 2015): (a) GPS Antenna, (b) GSM Antenna, (c) NI 8-slot Chassis, (d)SEA 9721 3G Module, (e) Current Sensor (NI 9227), (f) Voltage Sensor (NI 9225), (g) Temperature Sensor (NI 9213), (h) CompactRIO 9024 microcontroller, (i) Power Supply

4. Scientific impacts on the future of HCPV

4.1. Future scenarios for HCPV optics

Shanks et al. (Shanks et al., 2015c) listed the main features of an ideal solar concentrating optical system which should be aimed for when designing a solar concentrator: 100% optical efficiency, uniform irradiance distribution, maximum acceptance angle, high optical tolerance, reliability and durability. Along with these characteristics, the optics should be cheap, easy to manufacture and to install as well as light in weight. In this light, the results of a multi-disciplinary work have been recently presented (Shanks et al., 2015b): the wings of white *Pieris* butterflies have been investigated to understand their applicability in HCPV. The white *Pieris* butterflies use their highly reflective white wings to increase their thorax (and hence flight muscles) temperature. To do this, they hold their wings in a v-shape, similar to a V-trough concentrator. It was found that, using the butterfly wings instead of a standard reflective film to concentrate the light on a 1cm multi-crystalline cell (Fig. 4), the electrical power output to weight ratio was enhanced by 17 times. Although the wings had a very high reflectance of >80%, this is not as high as reflective films available at present (>90%), however the wings have the advantage of being extremely lightweight. This lower weight and enhanced power to weight ratio would be a great benefit to CPV systems. HCPV systems in particular are often heavy and bulky due to the large optics used but developing a lighter reflective material could greatly expand their applications. In the research by Shanks et al., 2015b a single mono-layer of scale cells removed from the wings was able to perform as a high-reflective coating as well, enhancing its potential applicability in HPCV system as a new reflective coating or film material. The unique nanostructure of these wings is at present being investigated and replicated for a new reflective and lightweight material for CPV systems.

4.2. Building Integrated Concentrating Photovoltaics

The general principle of Building Integrated Photovoltaics (BIPV) is that PV modules are integrated into the building envelope, substituting standard glass and other cladding materials with glass/glass laminates encapsulating PV cells within. Incorporating the concentrating photovoltaics into any part of the building

architecture is referred to as Building Integrated Concentrating Photovoltaics (BICPV). These systems can be classified based on the type of concentrator used for achieving solar concentration. The systems may be classified primarily two type's (a) linear concentrators, (b) three-dimensional concentrators

An asymmetric design was applied to refractive based optics and a new generation of concentrator was developed for building integration. This system consisted of linear dielectric non-imaging concentrators with an asymmetric CPC and a geometric concentration ratio of 2.82. Three different systems were designed to have half acceptance angles of 0° and 55°, 0° and 66° and 0° and 77°. The optical analysis of these systems showed that the DiACPC-55 outperformed the other two designs. A prototype of the same was later reported (Sarmah et al., 2014). The indoor characterization of the system showed as maximum power ratio of 2.27 when compared to a similar non-concentrating counterpart. A detailed optical-thermal-electrical modelling procedure for such type of system was shown recently (Baig et al., 2013). Use of ray trace methods was made to carry out the optical analysis of the system. Based on the illumination profile found from the optical simulation, a coupled electrical and thermal simulation was carried out on the system. The impact of non-uniform illumination was also studied. A prototype was developed and tested for its electrical performance under 1000W/m^2. About 0.5% absolute drop in solar cell efficiency was observed due to non-uniformity at 5° incident angle.

The 3D concentrator principally concentrated the light from all the directions unlike the linear concentrators. One of the first designs proposed for building integration is the reflective 3D crossed compound parabolic concentrator (3DCCPC) for building integration (Mammo et al., 2012). The system consisted of an array of 3DCCPC placed over 1cm2 sized LGBC solar cells. The developed system was found to perform with optical efficiencies of 75 % experimentally for a 60° acceptance angle. An improved optical efficiency of 81% was achieved experimentally in the second prototype of the system. Based on the similar design a refractive based 3DCCPC was modeled and experimentally evaluated (Baig et al., 2014b). The refractive based system has higher acceptance angle as compared to the reflective type system. A detailed optical, electrical and thermal modelling of the system was carried out with experimental validation. A maximum power ratio of 2.67 and an acceptance angle of 80° were found when comparing the electrical output of the concentrator unit with the bare cell. The temperature was found to have a parasitic effect on the overall performance of the system bringing about 14.6% drop in the overall power production. A further enhancement to the above system was recently reported recently (Baig et al., 2014a), where light trapping was performed by applying a reflective film along the edges of the 3DCCPC concentrator. A maximum power ratio of 2.73 was observed at an incidence angle of 10°. The system optical efficiency improved, however this reduced the acceptance angle slightly. In another study, a 3D concentrator reported for the building integration is the Square Elliptical Hyperboloid (SEH) concentrator (Sellami and Mallick, 2013). Four different concentration ratios were investigated: 4×, 6×, 8× and 10×. Results showed that the 4× system gives higher optical efficiency compared to the other systems. A complete optical-electrical and thermal analysis of a 6×SEH based concentrator was studied under AM1.5G spectrum (Baig et al., 2015). A detailed analysis highlighting the illumination non-uniformity and its effect on the system performance has been presented (Baig et al., 2012).

4.3. Passive micro-cooling for HCPV systems

Heat removal is a non-negligible concern in HCPV: any photovoltaic cell is negatively affected by the increase in temperature. The HCPV cells are therefore particularly sensitive to this issue because of the high

amount of heat produced. The heat sinks used in HCPV are generally made of Al and can contribute to more than 60% of the module's weight of the system (Timò, 2014). A reduction in the heat sink weight is beneficial for both the system's efficiency and the emissions' drop. In this light, micro- and nano-technologies offer new perspectives for HCPV cooling. Among the several solutions reviewed, the micro-fins under natural convective conditions have been found to be one of the most suitable for HCPV applications, due to their intrinsic simplicity and high potentials (Micheli et al., 2013). In order to find out the best geometry for HCPV applications, the thermal behaviour of micro-fins have been experimentally investigated. In this light, the correlations among the performance and the fin geometry have been determined (Micheli et al., 2015c). Moreover, the micro-fins have been found to have higher heat dissipation per unit of mass than convectional heat sinks or flat plates (Micheli et al., 2015d). For the first time, the applicability of micro-fins for an effective passive cooling of CPV has been proved: the reduction of temperature obtained by using micro-fins compared to a flat heat sink can lead to an enhancement in cell electrical efficiency up to 1% (Micheli et al., 2015f).

4.4. Ultra-High CPV

In recent years, the interest in for systems working at concentrations higher than 1000 suns, generally called Ultra-High concentrating Photovoltaic (UHCPV), is increased (Algora and Rey-Stolle, 2012), because of the potential in cost and material usage reduction as well as in efficiency enhancement (Vossier et al., 2012). Handling the large amount of heat produced by a cell under ultra-high concentration is one of the main challenges for the development of this solution. For this reason, the use of optimized least-material heat sinks has been investigated (Micheli et al., 2015a, 2015b): they were found able to passively cool a UHCPV systems, with a normalized cost ranging between 0.10 and 0.18\$/W_p for concentrations from 1000x to 8000x.

5. Conclusions

The BioCPV project addresses the rural electrification of an off-grid village in the west of India, by using an innovative renewable energy power system. Concentrating photovoltaic, anaerobic digestion and hydrogen technologies are integrated to produce continuous and reliable electricity. The present paper focuses on the latest outcomes of the researches conducted on concentrating photovoltaics. A large 2.5kW_p receiver and a cassegrain concentrator system have been designed and are currently being tested: the novel designs and the fabrication processes have been made available in literature to contribute to the development of more-efficient and reliable HCPV systems. Moreover, new thermal and electrical models have been presented. The BioCPV project team has investigated new scenarios that can in future benefit the development of HCPV. The butterfly wings can represent an innovative, light-weight solution for HCPV concentrators, whereas micro-fins can be used for the cooling of cells under natural convection.

Acknowledgments

The BioCPV project is jointly funded by EPSRC, UK (Ref No: EP/J000345/1) and DST, India (Ref No: DST/SEED/INDO- UK/002/2011). Authors acknowledge both the funding agencies for the support.

PHOTOVOLTAIC ENERGY PREDICTION ANALYSIS CONSIDERING TILT AND AZIMUTHAL ORIENTATION IN BRAZIL

Gabriel Mendonça de Paiva[1], Sérgio Pires Pimentel[1], Enes Gonçalves Marra[1] and Bernardo Pinheiro de Alvarenga[1]

[1] Federal University of Goias, Goiânia (Brazil)

Abstract

This article is about the analysis of photovoltaic (PV) potential generation in the city of Goiania, Goias, Brazil. The main objectives of this work are to predict reliably the energy production considering tilt and azimuthal orientation in this location and analyze the energy behavior and system performance along a simulation process. With the use of PVsyst, an example system of 2.5kWp of polycrystalline silicon had been considered for simulations of 1387 possible tilt-orientation sets in 5° scale. The annual energy production and the system Performance Ratio were obtained. As a conclusion, 180 of the total configurations were considered acceptable for payback time projects. The optimal energy generation set found differs from typical slope equal to location's latitude and orientation to north and was in 25° tilt and -5° azimuth, still leading to over 8 years payback time considering. As energy behavior, the system sensibility for azimuthal deviation is higher as higher is its plane tilt.

Keywords: Energy prediction, PV systems, PVsyst.

1. Introduction

One of the main advantages of Distributed Generation based on PV technology is the possibility of building integration, therefore the energy is generated close to the load (Macêdo, 2006). The integration of PV modules over building's roofs hides two important factors in which PV generation depend: tilt and azimuth angles. PV energy production depends in fact on many parameters such as PV array peak power, solar irradiation on module plane, module temperature, inverter efficiency and size, maximum power point tracking losses and other losses (Notton et al., 2010).

In order to make reliable energy prediction considering all main factors which influence PV generation, a simulation process with reliable data is required. It is well known that different irradiation data results in different predictions. When multi-year time series are used as reference for radiation data, deviations of 1% were found to Typical Meteorological Year (TMY) values and over 3% to synthetic data series (Cabecauer et al., 2011). Those deviations in total irradiance are different depending on plane tilt and location.

Also, different time resolution data may lead to different prediction and design as well. Using hourly average data, some important irradiation peaks and its respective inverter losses due to power limiting may not be noticed compared to one minute or 10 seconds resolutions (Burger and Ruther, 2006).

This study analyses the behavior of annual energy production and annual performance ratio of an example grid-connected PV system related to the variation of tilt and azimuth angles in the location of Goiania, Brazil. The reason of particular interest on these annual parameters is because Brazil currently has a policy which makes it possible for consumers only to reduce its electricity bills and not to sell energy, known as net metering. However, if the energy produced during a month exceeds the load demand it could be accounted in further periods up to three years later, in terms of revenues. In this case, those annual parameters could be applied for designing grid-connected (or stand-alone) PV systems. The radiation data related to this paper is compared with other available radiation data for this location.

2. Simulation characteristics

A simulation model of a grid-connected PV System was created on PVsyst software. The chosen methodology of simulations on PVsyst can be described as a process of determination of the system output energy in periods of one hour along a year, based on the input parameters variation for each specific hour and mathematical models of the whole system.

The PV array is composed by series connection of 10 modules of 250Wp p-Si from YINGLI SOLAR (model YL-250P-29b). The solar inverter is a high frequency transformer (HFT) inverter from INGETEAM (model Ingecon Sun 2.5HF). Table 1 presents the main parameters for both module and inverter.

Tab. 1: Parameters of PV module and inverter of the simulated system.

PV Module	Solar Inverter
Yingli Solar YL250P-29b	Ingeteam Ingecon 2.5HF
P_{nom} = 250Wp	P_{nom} = 2500Wp (AC power)
I_{SC} = 8.831A	Min MPP Voltage = 130V
V_{OC} = 37.78V	Min Voltage for Pnom = 125V
I_{MP} = 8.263A	Max MPP Voltage = 450V
V_{MP} = 30.26V	Absolute Max PV Voltage = 550V
–	Power treshold = 20W

Other parameters defined on PVsyst were considered: 30m length of 2.5mm² cables in the DC side, resulting in 225.6mΩ of total cable resistance; standard PVsyst 1% MPPT loss; and 2.5% loss for voltage fixing. A fixed 5% loss due to soiling over the modules was also considered, independent of the module slope, although it tends to be higher in low inclination and lower in high inclination positions. This is because some estimations from some places result in average 5% soiling losses (Caron and Littman, 2013), even though measurements in the current location and for specific module inclination should be done for more realistic soiling evaluation. Losses of 0.5% were determined for system unavailability. The constant related to albedo irradiation estimation on tilted surface was defined as 0.2, a typical value used for urban areas.

The simulation process which estimate the PV annual energy generation had been done a synthetic hour data series based on monthly averaged values of irradiation data from NASA's satellite. The annual irradiation was compared to other available radiation data, like Project SWERA (Brazilian Atlas of Solar Energy SWERA), Meteonorm (available on PVsyst) and INMET (Institute of Meteorology of Brazil). Table 2 shows the equivalent irradiation on the horizontal plane over one year period from different radiation data.

Tab. 2: Annual Irradiation on the horizontal plane for different radiation databases.

Reference	I_{HOR} annual (kWh/m²)
Project SWERA(range)	1788 - 2044
NASA(average)	1927.5
Meteonorm(average)	1829.0
INMET(average)	1854.2
INMET(range)	1793 – 1926.1

The available data on PVsyst are average years from NASA (satellite) and Meteonorm (interpolation of solarimetric stations over the world). The data from INMET are measurements obtained from a solarimetric station with hourly measured values, installed in the city of Goiania, which leads to a range of annual incident irradiation on the horizontal plane from 1793 to 1926kWh/m², a variation of +3.8% or -3.3% from average value, considering a period of 12 consecutive years of measurements.

The available data from Project SWERA is a map of equivalent sun hours incident on the horizontal lpane of all regions of Brazil and it's obtained from interpolation of solarimetric stations over Brazil. The map of sun

hours lead to a range of annual incident irradiation on the horizontal plane from 1788 to 2044kWh/m² for the state of Goias, a variation of ±7% from the average value of 1916kWh/m².

The irradiation model used to determine irradiation in tilted planes was the Perez model (Duffie and Beckman, 2013), also available on PVsyst. The annual analysis is a result of hourly simulation of the complete system under synthetic hourly variation of climate data.

3. Simulation results

The system was simulated for all possible configurations in 5° scale of tilt and orientation variation, resulting in a map of 1387 possible sets of annual energy production and system Performance Ratio. During this process, the input parameters were fixed in the values determined in section 2.

Figure 1 shows the tilt angle or slope (β) and the surface azimuth angle (γ_s). As this case of study is related to a city of Brazil (South America), negative azimuth values mean that the module has rotated from north to east direction and positive values mean that it rotated to west direction.

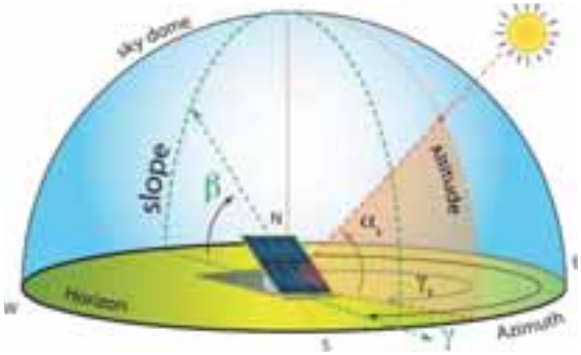

Fig. 1: Solar geometry defined for the energy prediction analysis.

The results analysis shows that the common sense (and traditional procedure) of tilting PV solar panels to a value equal to the location's latitude and 0° azimuth did not lead to optimal output. It was noticed that a maximum energy production for 5° scale of 3833kWh/year would occur when plane tilt = 25° and azimuth = -5° (or 5° to east direction). These conclusions were obtained mainly because of the albedo influence on total irradiation, which is calculated on PVsyst trough Equation 1. When the albedo constant ρ_g is omitted, the optimal generation gets closer to location's latitude (-16.7°).

$$I_{alb} = I\rho_g \left(\frac{1-cos\,\beta}{2}\right) \qquad \text{(eq. 1)}$$

In addition, 180 of the total possible configurations obtained less than 5% annual loss compared to the optimal set, meaning that there are many possible positions which lead to satisfactory energy production when only energy output or payback time are considered in the project.

Also from results analysis, it is possible to observe the system sensibility according to azimuth deviation considering fixed tilts. Figure 2 shows that the azimuth deviation of 180° in lowly tilted systems lead to low annual energy production losses, while in highly tilted systems, the annual loss increases.

Considering 15° of tilt inclination angle, the generation loss for 180° azimuthal deviation is around 15%, while in 90° tilt, the reduction from northbound is over 60%. Another interesting result concerning the azimuth deviation is that in highly tilted systems, the optimal energy generation was obtained in -55° azimuth, in east direction. The annual production was also higher in 55° azimuth than in 0°. This behavior was observed in module inclinations of 80° or higher for Goiania and this result could be verified to other locations.

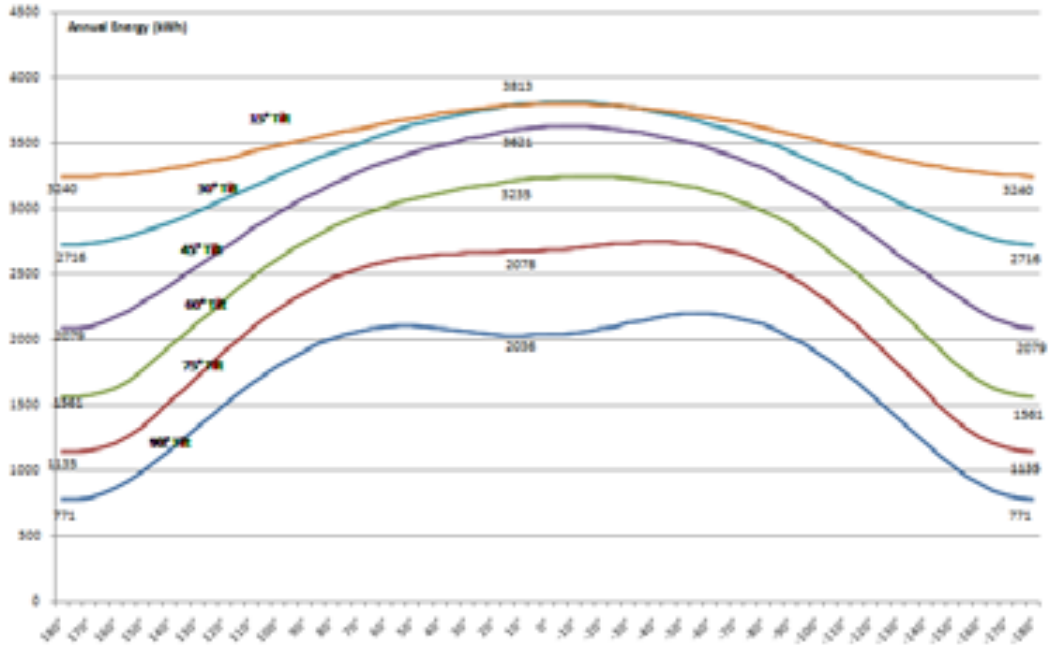

Fig. 2: Annual energy production in kWh/year as a function of azimuth for different tilt angles for the 2.5kWp system.

By now considering the Performance Ratio of the system observed during the simulations, it resulted in a range of values around 73 and 75% for most configurations and only reached lower values of 68% in extremely bad output configurations, when annual losses over 60% were obtained in respect to optimal. Figure 3 presents the PR behavior considering tilt and azimuth variations.

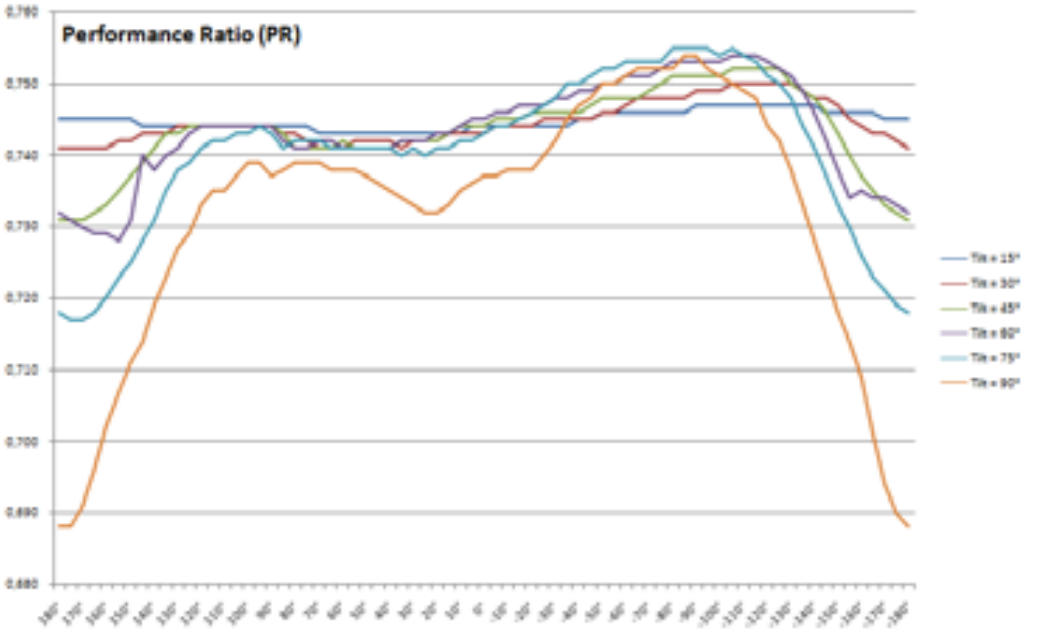

Figure 3: Annual Performance Ratio in % as a function of azimuth for different tilt angles for the 2.5kWp system.

Although the PR does not perform significant variations as function of module positioning, the factors that influence on it change significantly from optimal to minimal production configurations, like inverter efficiency losses, temperature losses in respect to Standard Test Conditions and incidence angle losses, due to light reflection. Inverter efficiency losses increase from 4% to 9%, losses from module temperature decrease from 11% to 4%, losses from incidence angle increase from 3% to 8% and from module efficiency due to low irradiance level increase from 0.5% to 7.5%.

4. Energy prediction analysis

If the irradiation incident in the module plane is compared to the global horizontal irradiation, the annual transposition factor could be obtained on PVsyst. Table 2 presents the transposition factors considering the use of Perez's model on PVsyst.

Tab. 2: Transposition Factors for different tilt and azimuth angles for Goiania obtained by Perez model on PVsyst.

Azimuth / Tilt	-90°	-75°	-60°	-45°	-30°	-15°	0°	15°	30°	45°	60°	75°	90°
90°	0.56	0.59	0.61	0.60	0.59	0.58	0.57	0.57	0.58	0.59	0.59	0.57	0.54
80°	0.64	0.68	0.70	0.71	0.70	0.70	0.69	0.69	0.69	0.69	0.68	0.66	0.62
70°	0.72	0.76	0.79	0.80	0.81	0.81	0.80	0.80	0.79	0.78	0.77	0.74	0.70
60°	0.79	0.84	0.87	0.89	0.90	0.90	0.90	0.90	0.88	0.87	0.84	0.81	0.77
50°	0.85	0.90	0.93	0.95	0.97	0.98	0.98	0.97	0.96	0.94	0.91	0.87	0.83
40°	0.91	0.95	0.98	1.01	1.02	1.03	1.03	1.03	1.01	0.99	0.96	0.93	0.89
30°	0.95	0.99	1.01	1.04	1.05	1.06	1.06	1.06	1.04	1.02	1.00	0.97	0.93
20°	0.98	1.01	1.03	1.05	1.06	1.07	1.07	1.06	1.05	1.04	1.02	1.00	0.97
10°	1.00	1.01	1.02	1.03	1.04	1.05	1.05	1.04	1.04	1.03	1.02	1.01	0.99
0°	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00

Comparing the annual energy generation to the transposition factor values, it can be concluded that there is a strong linear dependence of energy generation on irradiation incident on module's planes.

The amount of energy output from a grid-connected PV system can be estimated from Equation 2 (Pinho and Galdino, 2014), when P_{PV} is the generator nominal power at STC, PR the performance ratio and sun hours are the equivalent hours of 1000W/m² irradiation per day obtained for the module plane in the specific location.

$$E(kWh) = P_{PV}(Wp).PR.\text{sun hours}.365 \qquad \text{(eq. 2)}$$

From Equation 2, it is possible to explain the linear dependence of energy output as function of incident irradiation on the module's plane, but it is also the result of the product of irradiation (in the form of equivalent sun hours) and the performance ratio.

Equation 2 also shows that the energy production by the PV system during a full year may vary in the range of incident irradiation on the horizontal plane from 1788 to 2044kWh/m². Then, as the energy output has a linear dependence on the irradiation and the PR will probably be near the same results of Figure 3.

5. Conclusions

It can be concluded that there are several tilt-orientation configurations that lead to satisfactory energy production in PV generation for this specific location in Brazil, since a number of180 (from 1387 possible) sets of tilt-azimuth configurations result in less than 5% annual energy losses in respect to optimal configuration.

Additionally, it was found that considering the solar irradiance available in Brazil, the optimal tilt-azimuth set was 25° module inclination and -5° azimuth which is not the typical inclination angle equal to local's latitude and orientation equal to 0° north. This example project would still lead to over 8 years payback time considering energy costs and policy in 2015.

Other conclusion is related to annual power production from PV System. Specific to fixed tilts, the annual production becomes more sensible to azimuthal deviation as higher is its inclination. The Performance Ratio of a system is almost invariable for tilt and azimuth deviation and only becomes significantly lower for extremely low production configurations (in this case, over 60% annual losses in respect to optimal), positions that are almost unviable for payback time projects.

Considering the location in Brazil related to this study, the energy generation of a PV system is linearly

dependent on the irradiation, which means that a variation of ±7% from the prediction in this paper may be classified as acceptable relative to real variations for different year periods.

The reference PV power plant-based method

Zoltán Kapros

Szent István University, Gödöllő, (Hungary)

Abstract

A new method has been developed by small scale power plants were built in a closely related place to estimate the power generation an any given time and give a short term forecast. This is called the reference power plant-based method. The essence of the method is a few references plants is under continuous monitoring, so an accurate estimation could prepare for the entire closely PV area in any time. It is possible, this method will able to forecasting. This could help while the balancing and the trading activity in the low voltage network. Thus, network integration of photovoltaic systems could be significantly facilitated.

Keywords: *Small scale photovoltaic*, *aggregator forecastind methode, clouds variability factor,*

1. Introduction

It is common that the photovoltaic power plants for predicting the clouds build solar radiation monitoring network (Bilionis et al., 2014). The application of similar solutions for the urban environment relatively could be more expansive and less accurate. In Hungary, the solar panels installed on rooftops rationally would be cover approximately 22.5% of the annual residential electricity consumption. For larger institutional buildings this number is nearly 8%. The technical potential is significant value, although the buildings are still typically not able to produce more power than consumed. In the event that available potential by 2020 is only 5% considered this, the expected target could be 555 GWh/year in the residential sector. This is approximately ten times bigger the total 2014 small scale PV production. In Hungary, the electricity network is basically centralized and not yet flexible enough to provide high VRE ratio will be available. The present study aims to provide a reference power plant based method to help the integration with the small-scale photovoltaic systems.

The PV GRID program showed the main network problems caused by the small scale photovoltaic systems and summarized the possible proposals for solutions. These solutions can be divided into five main groups from another own specific perspective:

- The surplus electricity production compared to consumer demand could be converted heat losses in the grid;
- Restricted effective photovoltaic electricity generation from the PV system (eg reactive power production, switch-off from the grid); avoid to actual overproduction ;
- Use some energy storage system with acceptation of the storage losses;
- In addition to making possible reversal of the current paths transformation losses with efficiency reduction by the larger power plants.

The important thing is the produced but also really consumed electricity production. The performance ratio (PR), for example, typically does not take into account as a negative quantity the produced, but not utilized energy. A system oriented new performance ratio value (PR_{net}) could be useful by the development and the optimization:

$$PR_{net} = \frac{(E_{pr} - E_{grl} + E_{grw} - E_{ow} - E_{st} - E_{bl})}{E_{us}} \qquad \text{(eq. 1)}$$

Where the PR_{net} is the system oriented performance ratio, E_{pr} is the net photovoltaic production [kW h^{-1}], E_{grl} is the transformation, distribution and other losses in the grid from the photovoltaic electricity production, E_{grw} is the total avoided grid losses due to the decentralized system near to the consumption. $E_{\tilde{o}w}$ is the PV

doi:10.18086/swc.2015.05.25 Available at http://proceedings.ises.org

power system losses (the system's own losses). E_{st} is the storage losses, if the battery option is available. E_{bl} is the blocked photovoltaic electricity production by the producer with automatic shutdown, reactive energy conversion, so on. E_{us} is the useful (really consumed part) energy.

So there is a need for indicators to characterize by complex way the photovoltaic systems and their grid integration quality. According to an IEA study (Müller, S. et al, 2014), the electricity price with a conventional fossil power plant portfolio could be expected between 86 and 94 USD/MWh. In the case when VRE (variable renewable energies) ratio could reach the 45% the electricity price would be higher (between 97 and 119 USD/MWh) with considering the additional network charges. In 2014 the EU supported "PV Parity" project modeled until 2030 to build 480 GW new photovoltaic power plants (PV Parity, 2013). According to the program the transmission grid cost can grow from the current costs from 0.5 euro / MWh to 2.8 euro / MWh up, but the distribution grid connected needs cause 9 EUR / MWh.

So by the integration ability one key component by the small scale photovoltaic systems is the reduction the variability and uncertainty with more accurate forecast. By these systems there is currently no cost-effective best practice method. In addition the forecasting tasks are complex challenges which are significantly differentiated:

- Planning, optimization, network assessment, ost - benefit analysis, evaluation of alternatives, verification by supports.
- 15 minutes schedule giving an electricity trader.
- Clarification of the planned schedule before the beginning of the relevant period.
- Clarification of the planned schedule within the relevant 15 miuntes long period.
- Forecast for a very short periods (balancing) forecast, for example only 1 minute ahead.

My PhD research in progress examines the possibilities by the last two points. Those solutions as the „Wavelet Variability Model" (Dyreson et al, 2014), which for multi-megawatt power plants are acceptable even for small scale sizes often not cost effective.

The reference PV power plant-based method is based on simple idea. In a given urban setting the individual systems will receive the similar environmental impacts (for example smog, air pollution, temperatures, or spectral distribution. In some cases it can be useful for making forecast.

2. Basic model description

By a monitoring the following two main tasks are given:

- Making analytical forecast for every minute performances.
- Improving the accuracy of these forecasts very shortly in advance.

The energy output of PV systems depends on more special effects, which hard and expensive to measure and evaluate in time, for example the solar radiation intensity, temperature or solar spectrum (Farkas, Seres, 2008). The reference value is the difference the expected performance which based on analytical analysis and actual measured power. In order that this error (difference) can be used as a reference value, several conditions must be met:

- to be a relative number, because a comparison of different systems output is the target;
- to characterize the various systems by a comparable manner with simple transparency.

The equivalent peak load hours are characterized by the energy-generating capacity in a given moment. It means if same amount of power will produced in one year, the equivalent peak load hours is equal the traditional peak load hours (Sharma, Tiwari 2012):

$$h_{ekv} = \frac{\zeta_{real}}{I_P} \qquad \text{(eq. 2)}$$

where I_p is the current value of the global radiation intensity [kW/m^2] and ξ_{real} is the total amount of solar energy production unit [kWh/m^2]. If the performance is expressed as an equivalent number of hours, the expected value can be written as follows:

$$h_{ekv,t}(t) = \frac{(G_{PV}(t) \times \eta(t) \times A)}{I_P} \qquad \text{(eq. 3)}$$

Where G_{pv} is the amount of daily global radiation in [kWh/day], η is the reference efficiency [%] and A is the useful photovoltaic solar surface [m^2]. The equivalent peak load hours shows a reachable capacity at a given moment with dimension of the hour or kWh/kW. If the system is functioning at a given time at a specific equivalent peak load hours, then in an imagined year with equal continuous output power, same value would result for the peak load hours for that year. This value represents an actual capacity of the PV power plant, which is clear, meaningful and comparable.

During the measurement, therefore in different periods of time it were determined the expected and the measured equivalent peak load hours. The series thus produced error factor is adapted to be forecast and made suitable systems to estimate the combined capacity in the closely related place (the formerly analytical forecast could be more precise). Determination of the relative error factor can be seen in the next table (Table 1.):

Tab. 1: Determination of the relative error factor

t_0	Δt	$h^*_{equ,t0}$ (expected equivalent peak load hours)	$h^m_{equ,t0}$ (measured equivalent peak load hours)	$H_{t0} = \lvert (h^*-h^m) \rvert / h^*$ (error factor)	$h^{**}_t = f(h^*_t, r_{t-k}, r_{t-k+1}, ..., r_{t-k+n})$ (short time prediction)
t_1	$t_1 - t_0$	$h^*_{equ,t1}$	$h^m_{equ,t1}$	h_{t1}	h^{**}_{t1}
t_2	$t_1 - t_0 = t_2 - t_1$	$h^*_{equ,t2}$	$h^m_{equ,t2}$	h_{t2}	h^{**}_{t2}
t_3	$t_1 - t_0 = t_3 - t_2$	$h^*_{equ,t3}$	$h^m_{equ,t03}$	h_{t3}	h^{**}_{t3}
...	...	...	...	...	...
t_n	$t_1 - t_0 = t_n - t_{n-1}$	$h^*_{equ,tn}$	$h^m_{equ,tn}$	h_{tn}	h^{**}_{t4}
...	...	...	...	...	
t_m	$t_1 - t_0 = t_m - t_{m-1}$	$h^*_{equ,tm}$	$h^m_{equ,tm}$	h_{tm}	h^{**}_{t5}

Based on the analytical model and real values $r_{(t-k)}$, ... $r_{(t-k+1),}$ $r_{(-1)}$, $r_{(0)}$ error factors are added. Based on $r_{(t-k)}$, $r_{(t-k+1)}$, ..., $r_{(t-k+n)}$ error factors, and the results of the traditional analytical model forecast for the expected equivalent peak load hours in t time it could be improve h^*_t for h^{**}_t. So there are two main steps, first of all $h^*_{equ,t}$ have to be counted, than after a monitoring it could be improve sort time in advance.

Therefore it is necessary to determine solar geometric data, the expected value of global radiation, and the characteristics of direct and diffuse radiation conditions. By the effective component of direct radiation it should be also considered the orientation of the solar panels. The ISES Pocket book gives the main equitation (Martin, 2005):

$$H_{\alpha,\beta} = RB_\alpha + D\cos^2(\frac{\beta}{2}) + (D+B)\rho\sin^2(\frac{\beta}{2}) \qquad \text{(eq. 4)}$$

With the R factor in the equitation 3 (solar panel tilt factor) at each moment it can be determined the perpendicular portion of the solar direct radiation reaching the surface depending on the inclination of the solar cell. The module temperature of the solar cell is important to estimate the cell efficiency. By the cell temperature estimation it was applied an approximate curve, which is considered as a typical for the relevant period (Figure 1.).

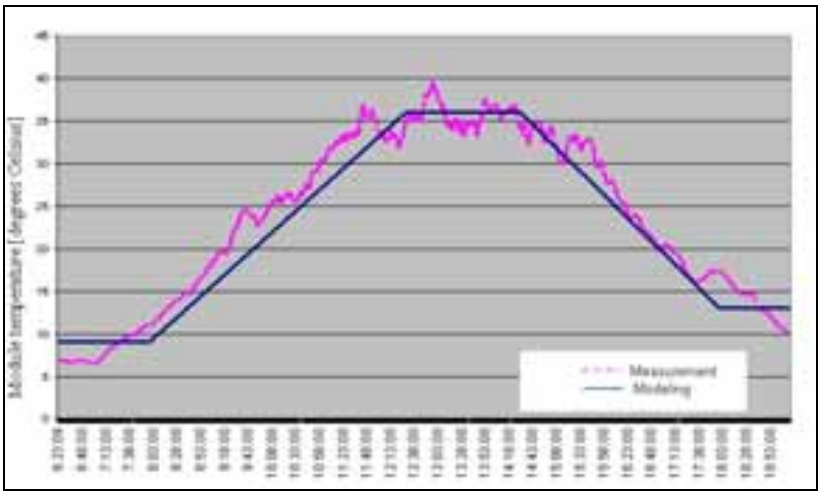

Fig. 1: Module temperature estimation

The other additional losses by determination of the electricity production were estimated according to the table. 2.

Tab. 2: The estimated electricity losses depending on the energy capacity of the effective part of the direct solar radiation

H [W m^{-1}]	Losses in DC system	Installation uncertain-ties	*Performance ratio of DC production*	Inverter losses	Other losses in AC system	Expected losses barring service function by Inverter	*Performance ratio*
>500	6%	2%	*92%*	5%	3%	0.5%	**84.46%**
240 – 499	9%	2%	*89%*	4%	3%	0.5%	**82.63%**
120 – 239	12%	2%	*86%*	6%	3%	0.5%	**77.43%**
< 119	15%	2%	*83%*	9%	3%	0.5%	**72.41%**

Thus, according to the above, I calculated totally 15.5 - 27.6% losses. Therefore in every minute it may be obtained to get the expected equivalent peak load hours:

$$h_{equ,AC}(t) = \frac{P_{AC}(t)[W]}{(P_p[kW]\times 1000)} \times 8760 \text{ , [h].} \qquad \text{(eq. 5)}$$

Where P_{DC} is the actual current PV performance to the grid and P_p is the nominal capacity of the PV system. From the differences between the observed (measured) and the expected equivalent peak load hours the error factors could be calculated according to the next equation:

$$H_{t-n} = \frac{(h^*_{t-n} - h^M{}_{t-n})}{h^*_{t-n}} \text{ , [\%].} \qquad \text{(eq. 6)}$$

It can be defined a specific series of error factors between t-n and t-m. From this the current characteristics of their changes (dH/dt) can be deduced:

$$\frac{dH}{dt} \approx \frac{\Delta H_{n-m}}{\Delta t_{n-m}} = \frac{(H_{t-n} - H_{t-n-1}) + (H_{t-n-1} - H_{t-n-2}) + ... + (H_{t-m+1} + H_{t-m})}{n-m} \text{ , [\% min}^{-1}\text{]}$$

(eq. 7)

where are true, that

$$t_{t-n} - t_{t-n-1} = t_{t-n-1} - t_{t-n-2} = ... = t_{t-m+1} - t_{t-m} \qquad \text{(eq. 8)}$$

Thus, the error factor prediction is described here:

$$H_t = H_{t-1} + (1+\frac{dH}{dt}) \approx H_{t-n} + (1+\frac{dH}{dt})^n \approx H_{t-n} \times (1+\frac{\Delta H_{n-m}}{\Delta t_{n-m}})^{0,4n}, [\%].$$

(eq. 9)

Under the average conditions the 0.4n exponent has formed to be approximately an optimal value during by measurements. View of the above the revised forecast comes according to next equation:

$$h_t^{**} = h_t^* + H_t \times h_t^* = h_t^* \times (1 + H_t), [\text{h}]. \qquad \text{(eq. 10)}$$

The parameters, which were used during the analysis and the measurements, are shown in Table 3.

Tab. 3: The main parameters of the tests

The duration of the predicted period	t_{t-n}-t_{t-n-1}	n	m
1 minutes	1 minutes	5 minutes	15 minutes

Therefore during the measurement and analysis the series of $h_{t,}^{**}$ was available in 5 minutes before time t. This gave the opportunity to give other forecast for the average performance in every full quarter-hour with 5 minutes before the end of the period. During the test the prediction for average performance (equivalent peak load hours) in 15 minutes periods based on 5 minutes measured data and 10 minutes predicted data with get from the presented method.. The method of determining is illustrated with nest equations.

$$h_{15\,\text{min}}^{m} = h_{t-14} + h_{t-13} + h_{t-12} + h_{t-11} + h_{t-10} \qquad \text{(eq. 11)}$$

$$h_{15\,\text{min}}^{\exp} = h_{t-9}^{**} + h_{t-8}^{**} + h_{t-7}^{**} + h_{t-6}^{**} + h_{t-5}^{**} + h_{t-4}^{**} + h_{t-3}^{**} + h_{t-2}^{**} + h_{t-1,}^{**} + h_t^{**} \qquad \text{(eq. 12)}$$

$$h_{t,15\,\text{min}}^{**} = \frac{h^{m}{}_{15\,\text{min}} + h^{\exp}{}_{15\,\text{min}}}{15} \qquad \text{(eq. 13)}$$

The significance of the error factor is stronger in these times when the radiation is more intensive, so the period between 10:00 – 16:00 were also separately analyzed.

3. The reference PV power plant model description

The reference PV power plant-method is based on the presented forecast which is extended to a whole photovoltaic plant area. Continuous monitoring system works only by the reference power plant and the basic data from others is known. There are two approaches are conceivable:

- forecast for balancing purpose;
- virtual smart grid group (aggregator) forecast for a 15 minute average performance.

So based on the analytical expected equivalent peak load hours ($h^*_{1,t}$) and these modified forecasts with the monitoring ($h^{**}_{1,t}$) for the reference power plant, as well as expectations for a second pv system ($h^*_{2,t}$) without monitoring the new modified values ($h^{**}_{2,t}$) also could it be estimated:

$$\frac{h_{1,t}^{**} - h_{1,t}^{*}}{h_{1,t}^{**}} \approx \frac{h_{2,t}^{**} - h_{2,t}^{*}}{h_{2,t}^{**}} = 1 - \frac{h_{2,t}^{*}}{h_{2,t}^{**}} \qquad \text{(eq. 14)}$$

Consequently $h^{**}_{2,t}$ could be counted with the next equation:

$$h_{2,t}^{**} \approx \frac{h_{2,t}^{*}}{1 - \frac{h_{1,t}^{**} - h_{1,t}^{*}}{h_{1,t}^{**}}} \qquad \text{(eq. 15)}$$

As noted above, in addition to the analysis of a reference power plant it also could be prepared the forecasts

for the 15 minute average performance ($h^{**}_{2,t,15m}$) by other nearby plants (which based on 5 minute measurement data from the reference system due to equation 13):

$$h^{**}_{2,t,15m} \approx \frac{h^{*}_{2,t,15m}}{1-\frac{h^{**}_{1,t,15m}-h^{*}_{1,t,15m}}{h^{**}_{1,t,15m}}} \qquad \text{(eq. 16)}$$

4. Data and methods

The research examined reference power plant owned by the Budapest District Heating Co. Ltd. (Főtáv Zrt.). The PV plant is located in the company' headquarter (Budapest, Kalotaszeg 31.) in the top of the 'D' building. The reference power plant was considered only one part of the whole (the one inverter part form the 8). With the same orientation and the same angle 19 panel units has a single inverter. The main data of the plant:

- Location: Latitude: 47.4584°, Longitude: 19.045°;
- PV module type: AS-60P 250 W ECO;
- Rated power of a panel: 250 W_p;
- The number of solar panels installed: 150;
- Position: +10.7 degrees (SSW) (as determined by measuring from map),
- Angle of inclination: 20 degrees
- Number of inverters: 8;
- The PV Power Plant nominal connection cpacity: 40 kW.

The main site of research is shown in Figures 2.

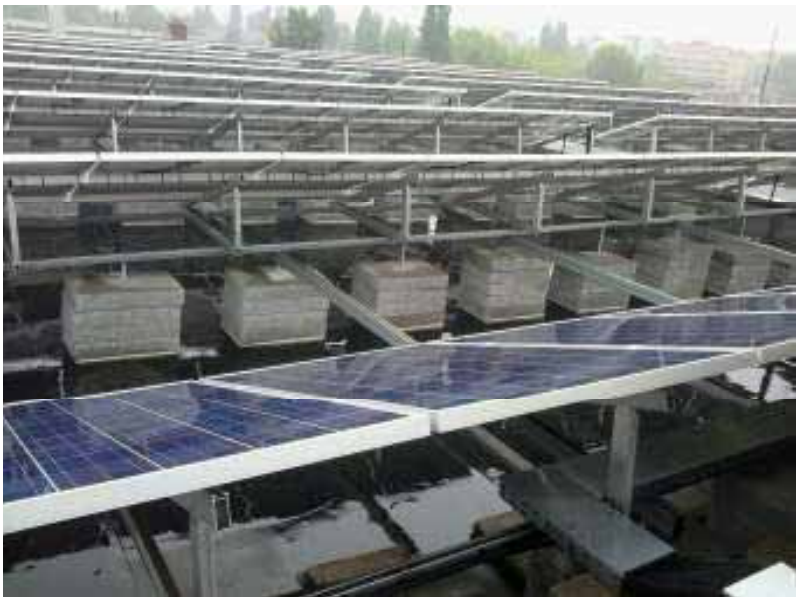

Fig. 2: The examined reference power plant

The eight independent inverters have enabled to forecast from one continuously measured inverter data to others, so the reference PV power plant model can be test in optimal situations (the systems are very close each others in the same position). This will be also tested another two system is located within a 10 km. The research analyzes data from seven different days which was randomly selected (Table 4. and Table 5.).

Tab. 4: The test days and characteristics

Number	Dates	The serial number of the day (d_n)	Sunrise (GT+1)	Sunset (GT+1)	Azimuth at sunrise (AZI_{SRT})	Azimuth at sunset (AZI_{SST})	Potential sunshine duration (N_0) [h]
1.	1 April 2014.	91	6:23:09	19:13:13	-97.58°	97.89°	12.84
2.	20 April 2014.	110	5:46:32	19:39:56	-108.07°	108.37°	13.89
3.	1 May 2014.	121	5:27:32	19:55:15	-113.55°	113.89°	14.16
4.	20 May 2014.	140	5:01:25	20:20:01	-121.36°	121.58°	15.31
5.	1 June 2014.	152	4:50:58	20:32:51	-124.80°	124.96°	15.69
6.	14 June 2014.	165	4:46:12	20:42:09	-126.86°	126.91°	15.93
7.	20. July 2014.	201	5:07:10	20:32:34	-122.58°	122.38°	15.42

Tab. 5: Characteristic of the analyzed days by the reference power plant

Dates	Throughout the day		Between 10:00 and 16: 00		Solar irradiation characteristics
	Average equivalent peak load hours	Maximum equivalent peak load hours	Average equivalent peak load hours	Maximum equivalent peak load hours	
	hour	hour	hour	hour	
1. 04. 2014.	3889	6766	5633	3427	sunny, slightly cloudy, stable light conditions
20. 04. 2014.	3047	9360	4245	1187	Cloudy volatile, rarely sunny
1. 05. 2014.	2604	8310	4609	1522	almost uniformly cloudy but periodically clear
20. 05. 2014.	4227	7679	6348	802	variably cloudy or clear sky, rapidly changing light conditions
1. 06. 2014.	2717	9528	4606	761	volatile cloudy typically, it is rarely sunny
14. 06. 2014.	4032	9089	5515	757	strong variably, cloudy or sunny wether
20. 07. 2014.	4252	7031	6261	1557	sunny, cloud drift infrequently, but otherwise stable

5. Validation results

To evaluate the reliability of the model it was introduced a special indicator that is able to characterize the variability of the particular days. This indicator is the variability factor, it signs with V. Determine of this value is deepen on the numbers of the bigger changes of the measured average AC power within one minute. The definition is shown with the equation 16 and 17 and is illustrated in the table 6 and 7. This indicator is unique in that the connected weight values larger when the sudden change is bigger.

So the variability factor for the all day:

$$V_{day} = 4a_1 + 3a_2 + 2a_3 + a_4 + 4b_1 + 3b_2 + 2b_3 + b_4 \qquad \text{(eq. 17)}$$

And for the period between 10:00 - 16:00:

$$V_{10-16} = 4a_{1'} + 3a_{2'} + 2a_{3'} + a_{4'} + 4b_{1'} + 3b_{2'} + 2b_{3'} + b_{4'} \qquad \text{(eq. 18)}$$

These factors in the investigated date are in the next: The confidence indicator correlates to the period considered as a unit specific value is shown in the table 8.

Tab. 6: Determination of variability factor for the measured days

Dates	Changes in average AC power within 1 minute								Variability factor V_{day} [unit/ day]
	Down				Up				
2014	Above 55%	Between 35%-55%	Between 15%-35%	Between 5%-15%	Above 55%	Between 35%-55%	Between 15%-35%	Between 5%-15%

Tab. 10: Fifteen-minute' forecast performance data between 10:00 and 16:00
(5 minutes before the end of the period)

	Absolute errors (equivalent peak load hour)				Relative errors				
	Average error	Above 200 hour	Between 100 and 200 hour	Under 100 hour	**Average error**	Above 15%	Between 10% and 15%	Between 5% and 10%	Under 5%
01. 04.	**87**	12,50%	25,00%	62,50%	**1,55%**	0,00%	0,00%	4,17%	95,83%
20. 04.	**302**	37,50%	16,67%	45,83%	**6,63%**	12,50%	0,00%	29,17%	58,33%
01. 05.	**256**	37,50%	29,17%	33,33%	**5,92%**	12,50%	8,33%	25,00%	54,17%
20. 05.	**260**	29,17%	8,33%	62,50%	**4,36%**	8,33%	8,33%	4,17%	79,17%
01. 05.	**397**	58,33%	20,83%	20,83%	**9,29%**	20,83%	12,50%	20,83%	45,83%
14. 06.	**694**	75,00%	8,33%	16,67%	**13,09%**	37,50%	12,50%	16,67%	33,33%
20. 07.	**56**	8,33%	4,17%	87,50%	**0,93%**	0,00%	0,00%	8,33%	91,67%

The average relative error examining the relationship between Specific variability factors Student's t-test were performed. The square of the correlation coefficient by the fifteen-minute' forecast performance was 0.9854 between 10:00 – 16:00, so this mens a strong linear relationship. The confidence intervals for this tested case are summarized in Table 11.

Tab. 11: The forecast errors' critical values in the 95% confidence level
(5 minutes earlier prediction before the end of the 15 minutes period)

Specific variability factors [unit/hour]	Average relative error [%]
23.65	5 ± 1.46 = [3.54; 6.46]
47.85	10 ± 1.47 = [8.53; 11.47]
23.65 ± 7.04 = [16.61; 30.69]	5
47.85 ± 7.28 = [40.57; 55.13]	10

So, using the developed forecasting methodology for a 15-minute average performance in five minutes earlier to predict between 10 and 16 hour, when a specific variation factors are met 23.65 unit/h, with 95% confidence level true that the relative error of the forecast between 3.54% and 6.46% in Hungary. Furthermore, if the specific peak loads variation is less, than 40.57 unit/hour, it can be sure with a 95% confidence that the mean relative error of the forecast is less than 10%. If specific variability factors are less, than 16.61 unit/hour, the average relative error is better than 5%. The average value of the indicator during the tests was 28.3 unit/hour. This is very close to the 23.65, so it could be estimated an annual average of between 5-7% accuracy available between 10:00 -16:00.

Further analyzes are still in progress, but it is already clear that in some cases from the monitoring by only the inverter 1. No. a good prediction could be made for example with a relative error of 1.6% of the full power (inverter 8) performance between 10 and 16 hour.

6. Conclusions

The reference power plant-based method seems to be suitable for simultaneous modeling of the whole electricity energy production of more pv system in a low-voltage distribution grid with a smart grid, for short-term predictive modeling (balancing activity) and for prediction to keep the 15 minute schedule (trading activity).

The main research results so far:

- To establish a new factor (indicator);
- Anew analysis of the accuracy of forecast
- Analysis of other systems for the accuracy of forecast

Abstract

An enhanced methodology for the assessment of energy economic potential for utility-scale photovoltaics is proposed in this paper. Independent methods are presented for the quantification of resource, technical, and economic potentials. The methodology is demonstrated through a case study focusing on the territory of the United Arab Emirates (UAE). The technical potential is computed by means of a locally validated PV plant performance model and the economic potential by estimating levelised cost of electricity (LCOE) based on detailed and spatially variable cost data. The results of the case study indicate a large potential for utility-scale photovoltaics in the UAE. At an electricity price of 0.07 USD per kWh, the economic potential is identified as approximately 10 EJ – 26-fold the country's electricity demand in 2013.

Keywords: solar photovoltaic, levelised cost of electricity, potential assessment

1. Introduction

Geospatial analysis based on geographic information systems (GIS) is a commonly used method for the site selection of solar photovoltaic (PV) power stations. The objective of such analysis is to identify the areas with the highest potential for PV power generation. The potential of a renewable energy source can be evaluated at three different levels: resource or theoretical potential (RP), technical potential (TP), and economic or energy economic potential (EP). Fig. 1 illustrates the potentials as three overlapping rectangles in two dimensions specified as surface area and unit-area-specific average energy content. RP assessment is a necessary first step when quantifying TP. TP, in turn, is the basis of EP assessment.

RP refers to the total amount of energy theoretically available in a renewable resource in the area of interest over a time period that is sufficiently long to cover most of the range of the resource's variability. Therefore, in the context of PV power generation, an appropriate definition of RP is the global normal irradiation (H_n) received in the area of interest during a typical meteorological year (TMY). There is a wide variety of scientifically validated models for geospatial solar resource assessment. Some of them are demonstrated by the International Renewable Energy Agency in their Global Atlas for Renewable Energy (International Renewable Energy Agency (IRENA), 2015). The maps visualising PV RP often show global horizontal irradiation (H) instead of H_n. Global horizontal irradiance (G) can be converted into global normal irradiance (G_n) by means of irradiance decomposition and transposition models. G and G_n are the first temporal derivatives of H and H_n, respectively.

TP is dependent on the energy conversion efficiency and land use-related limitations of the technology of interest. The power output of PV devices is reduced by loss mechanisms that are affected by ambient parameters. In accordance with RP, PV TP can be defined as the annual amount of electrical energy supplied by a group of PV power stations covering the entire technically suitable part of the area of interest. PV TP with and without territorial constraints has been evaluated by numerous authors for different parts of the

world (e.g. Beták et al., 2012; Domínguez Bravo et al., 2007; Lopez et al., 2012; Šúri et al., 2007). A widely used tool for the geospatial analysis of PV TP is PVGIS covering Europe, Africa, and Asia (European Commission, Joint Research Centre, Institute for Energy and Transport, 2014; Huld et al., 2005; Šúri et al., 2005).

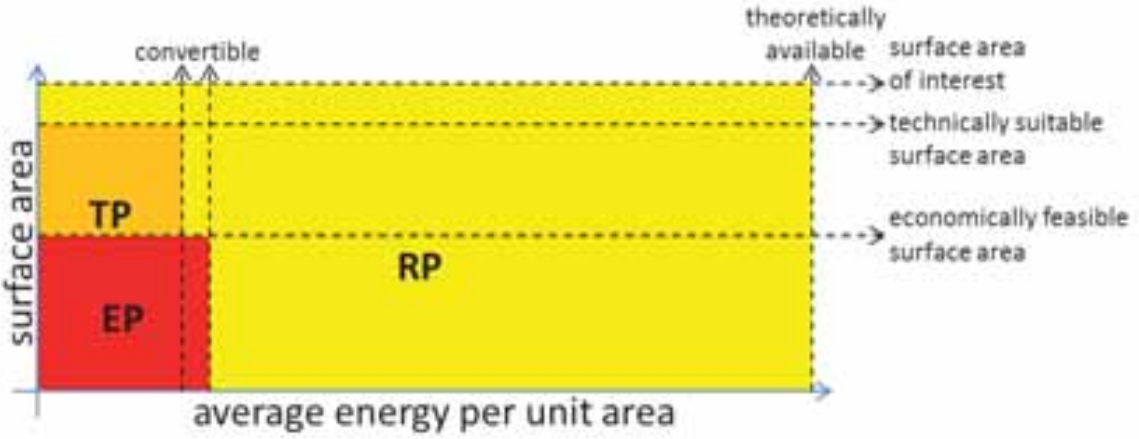

Fig. 1: The relation of renewable energy potentials to energy convertibility and site suitability

The economic viability of renewable energy-based power generation is primarily determined by its unit energy cost i.e. levelised cost of electricity (LCOE). Provided that consumers and policy makers do not have power source-specific preferences, there is no EP for a technology at a site where the competing technologies can generate electricity at a lower cost. Hence, in this paper, EP for a technology is defined as the amount of electrical energy that no other technology can supply at a lower cost in the area of interest. Due to the poor availability of component and infrastructure-related cost data, the quantification of EP is more difficult than that of TP. That is why when assessing PV EP, most authors have settled for fuzzy logic-based models which score sites based on their suitability for PV power generation rather than actually computing LCOE estimates. Suganthi et al. (2015) review studies applying fuzzy logic to PV EP assessment. While the LCOE-

based EP quantification is a common topic amongst the scholars of solar thermal technologies (starting from Broesamle et al., 2001), PV EP is found to be geospatially quantified based on LCOE estimates only in three published studies – by Sun et al. (2013) in Fujian, China and by Ossenbrink et al. (2013) and by Huld et al. (2014) by means of PVGIS in Europe.

In addition to the absolute level of PV EP, the focus of PV plant site zoning studies lies on the spatial variability of site suitability. Therefore, special attention should be paid to appropriately modelling the impact of spatially variable parameters, be they ambient variables or cost components. Sun et al. (2013) base their PV EP assessment on simplistic PV TP quantification assuming horizontally fixed PV array mounting and a performance ratio, which is constant in space. In other words, they assume the spatial variability of potential PV system output to be entirely dependent on the variability of H ignoring the impact of the other spatially variable ambient factors. Also, apart from the sites located near the Equator, PV arrays with fixed mount are usually tilted and therefore, irradiance incident on the plane of arrays (G_i) is the primary performance factor rather than G. By contrast, Ossenbrink et al. (2013) and Huld et al. (2014) consider G_i and vary PR in space addressing the nonlinear effects of T_a and G_i on module output power. Their performance ratio maps are based on a model proposed by Huld et al. (2011) for crystalline silicon wafer-based (c-Si) solar modules. Since Ossenbrink et al. (2013) and Huld et al. (2014) only analyse the LCOE of building-applied PV systems, it is justifiable to use a model that has been exclusively developed for c-Si modules as other module types are rarely used in such systems. As for the EP assessment of utility-scale photovoltaics however, it is important to also consider other module types. In addition to ambient parameters, some of the engineering, procurement and construction (EPC) as well as operation and maintenance (O&M)-related costs show spatial variation. The reviewed past PV EP assessment studies, however, assume all costs to be constant in space.

Previous work by Sun et al. (2013), Ossenbrink et al. (2013), and Huld et al. (2014) is enhanced by complementing PV EP quantification methodologies with more comprehensive PV performance modelling tools as well as more detailed and spatially variable cost data. This paper describes the modified methodology and presents the results of its application using five different PV plant configurations in the United Arab Emirates (UAE). Utility-scale photovoltaics in the UAE is an interesting subject for the case study due to the large potential indicated by previous studies (e.g. Beták et al., 2012; Mokri et al., 2013; Sgouridis et al., 2015) against the relatively modest installed capacity of 23 MWp (Abu Dhabi Future Energy Company PJSC, 2015; First Solar, Inc., 2015) and 340 MWp under development (Dubai Electricity & Water Authority, 2015; Middle East Solar Industry Association, 2015). In addition to proposing novel methods for PV EP assessment, this study aims to serve the various actors working on PV plant siting and zoning in the UAE by creating up-to-date high-resolution information about the spatial variability of PV EP in the country.

The proposed methodology is demonstrated at the hourly scale based on a database of irradiance and meteorological parameters for the year 2013. Spatial referencing is performed through an equal-area map projection with a resolution of 1000 metres. As each considered map pixel is assumed to be covered by the largest possible PV plant that can be fitted in the pixel, plant surface area does not show systematic spatial variability. However, due to the significance of latitude in optimal array inclination and row spacing, plant capacity does. Thus, capacity cannot be specified as a fixed PV plant configuration parameter.

The parameters of the five fixed plant configurations are specified in Tab. 1. The three commercially dominant PV materials are considered: monocrystalline silicon (mc-Si), polycrystalline silicon (pc-Si), and cadmium telluride (CdTe). The first three configurations are equipped with each of the three module types with fixed polar-aligned mounting. The two remaining configurations involve high-efficiency mc-Si wafer-based modules mounted on horizontal single axis or dual axis trackers. Inverters are sized based on an array-to-inverter loading ratio. The loading ratios given in Tab. 1 are approximate optimal loading ratios derived through plant design optimisation based on irradiance and meteorological observations made at a coastal (24.42 °N, 54.61 °E) and an inland site (23.90 °N, 55.50 °E) in the UAE over a three-year period from 2009 until 2011. The design optimisation is performed through maximising the simulated yield of each configuration in both locations by varying the loading ratio from 50 to 150 per cent at intervals of five per cent.

In the UAE, electricity is mostly generated by combined cycle power plants that use natural gas as the

primary fuel. Therefore, PV EP is calculated based on the price of natural gas under different market conditions. Drawing on the analysis of Sgouridis et al. (2015), resale prices at 6, 10, and 14 United States Dollars (USD) per million British thermal units (MBtu) are considered.

Tab. 1: PV power station configurations considered

Configuration identifier	Module type	Mounting method	Inclination	Array-to-inverter loading ratio
mc-Si-fm	mc-Si, N_c: 72, P_{stc}: 340 Wp	fixed mount	polar-aligned	115%
pc-Si-fm	pc-Si, N_c: 72, P_{stc}: 310 Wp	fixed mount	polar-aligned	115%
CdTe-fm	CdTe, N_c: 146, P_{stc}: 100 Wp	fixed mount	polar-aligned	110%
mc-Si-1t	mc-Si, N_c: 128, P_{stc}: 455 Wp	single axis tracking	horizontal	110%
mc-Si-2t	mc-Si, N_c: 128, P_{stc}: 455 Wp	tip-tilt dual axis tracking	-	105%

N_c: number of individual cells, P_{stc}: output power under standard test conditions (STC)

Sections 2-4 discuss each of the three levels of PV potential. All the three sections consist of two subsections. The first subsection describes the proposed methods while the second one specifies the case-specific inputs and shows the outcome of their application to utility-scale photovoltaics in the UAE. The case study follows the proposed methodology but due to limited data availability, simplifying assumptions are deployed.

2. Assessment of Resource Potential

2.1. Proposed Methodology

As explained in section 1, PV RP is defined as H_n in the territory of interest over a TMY. A TMY dataset is constructed instead of using the entire spatiotemporal database in order to reduce the computational requirements. Yearly average datasets are easier to generate but their usage is not recommended because they smoothen out natural variability and do not preserve persistence of temporal patterns and information related to the consistency and coevolution of different variables. This is problematic from the viewpoint of PV performance modelling as PV plant output is nonlinearly dependent on multiple ambient parameters. More information is preserved when using TMY dataset construction methods that are based on the concatenation of continuous multivariate time series spanning those individual months that are found to provide the best agreement with long-term monthly statistics (e.g. Cebecauer and Šúri, 2015; Kalogirou, 2003; Marion and Urban, 1995). How different variables are weighted when quantifying monthly representativeness depends on the application. Cebecauer and Šúri's (2015) proposal for the PV power generation-specific set of TMY variables is G, diffuse horizontal irradiance (G_d), and ambient air i.e. dry bulb temperature (T_a) with the respective weights of 0.75, 0.20, and 0.05. Thereby, T_a indirectly influences PV RP estimation. As for the source data, Cebecauer and Šúri (2015) recommend using time series of 15 years or more to establish a good representativeness of the long-term solar climate.

As H_n is an extensive physical property, an equal-area map projection (e.g. Mollweide projection or Lambert cylindrical equal-area projection) has to be applied to the TMY maps in order to avoid map pixel size-related bias in the pixel-specific H_n estimates. For example, when using the reference coordinate system of the Global Positioning System (WGS 84) with a spatial resolution of 0.02° and without an equal-area map projection, the pixel surface areas at 20 °N are approximately nine per cent greater than those at 30 °N.

H_n estimates are computed based on the equal-area projected TMY time series of maps of G, G_d, beam normal irradiance ($G_{b,n}$), solar zenith angle (θ_S), and solar azimuth angle (ϕ_S). In addition, a spatially constant time series of normal irradiance at the top of the Earth's atmosphere ($G_{toa,n}$) is required. An irradiance transposition model (e.g. Hay, 1979; Muneer, 1990; Perez et al., 1990; Reindl et al., 1990a) enables the conversion of these data into G_n maps. If not readily available, $G_{b,n}$ and G_d estimates can be derived from G

data by means of an irradiance separation i.e. decomposition model (e.g. Erbs et al., 1982; Perez et al., 1992; Reindl et al., 1990b). θ_S, ϕ_S, and $G_{toa,n}$, in turn, can be computed through a solar geometric algorithm (e.g. Blanc and Wald, 2012; Duffie and Beckman, 2006, pp. 12–16; Reda and Andreas, 2008). Finally, the resulting G_n maps are integrated over time into a single H_n map, which is further integrated over space to obtain a PV RP estimate for the territory of interest.

2.2. Resource Potential in the UAE

The spatiotemporal database of irradiance (G, $G_{b,n}$, and G_d) for the UAE is created by means of an artificial neural network-based model proposed by Eissa et al. (2013). The model uses satellite-based SEVIRI images as input data and has been developed based on ground observations from five monitoring stations in the UAE. The resulting irradiance maps cover the year 2013 with a temporal resolution of 15 minutes and a spatial resolution of 0.02° (in WGS 84). Minor discrepancies in the spatial resolutions of the source data are removed by resampling the anomalous maps through nearest-neighbour interpolation. Irradiance data gaps are filled by interpolating and extrapolating clear-sky indices calculated based on the McClear algorithm (Lefèvre et al., 2013). As the timeframe of the data used in this case study spans only one year, no TMY dataset is constructed. Hence, the results of the study cannot be generalised to other years.

The Mollweide equal-area projection is applied to the input data maps. When reprojecting the maps, their spatial resolution is converted from 0.02° to 1000 metres. As explained in section 2.1, solar position (θ_S, ϕ_S, and $G_{toa,n}$) has to be known in order to estimate G_n. The solar geometric parameters are computed by means of the Solar Geometry 2 (SG2) algorithm developed by Blanc and Wald (2012). The SG2 algorithm is selected because it is computationally efficient with an accuracy only slightly surpassed by Reda and Andreas's (2008) Sun Position Algorithm, which is commonly considered as the state of the art in terms of accuracy.

Transposition models, which convert G, $G_{b,n}$, G_d, and solar geometric data into G_i estimates, comprise transposition processes for $G_{b,n}$, diffuse sky irradiance, and ground-reflected irradiance. In the case of G_n, $G_{b,n}$ is not transposed as it is always normal to the receiving surface. Tuomiranta and Ghedira (2015) evaluate 18 sky diffuse and four ground-reflected irradiance transposition models under the conditions of the UAE. They find the best agreement with ground observations with the model proposed by Perez et al. (1990) for sky diffuse irradiance and the model proposed by Badescu (2002) for ground-reflected irradiance. Accordingly, the two models are used to generate the G_n maps in the present study.

Fig. 2 presents the findings of the PV RP assessment. The resulting H_n estimates translate into a PV RP of 872 EJ for the UAE. At the sites with the most abundant solar resource, H_n is estimated to be 17 per cent higher than at the least sunny sites, which are concentrated in the coastal areas.

3. Assessment of Technical Potential

3.1. Proposed Methodology

As discussed in section 1, PV TP is defined as the maximum amount of electrical energy that can be supplied from PV power stations to consumers in the territory of interest over a TMY. The geographic area considered in PV TP assessment is limited by technical suitability. In other words, any site whose utilisation is possible when cost-related criteria are not taken into consideration is assumed to have nonzero PV TP. The excluded sites include all areas that cannot be used for reasons other than economic, e.g. areas protected for their natural, cultural, or other public welfare-related value such as nature reserves, historical monuments, and areas under a restrictive urban planning code.

Prior to the actual plant performance simulation, PV plant system architecture needs to be determined for every site. Due to the definition of PV TP, the maximum surface area of each plant is the pixel area. Based on the desired loading ratio and row spacing requirements as well as the maximum number of modules in a string, the plant capacity and the other system configuration-related parameters are computed. In order to enable detailed PV EP assessment, it is recommended to calculate the numbers of at least those components, for which there are cost data available. The components, whose number is directly dependent on plant sizing, include solar modules, mounting structures, inverters, transformers, junction boxes, and cables.

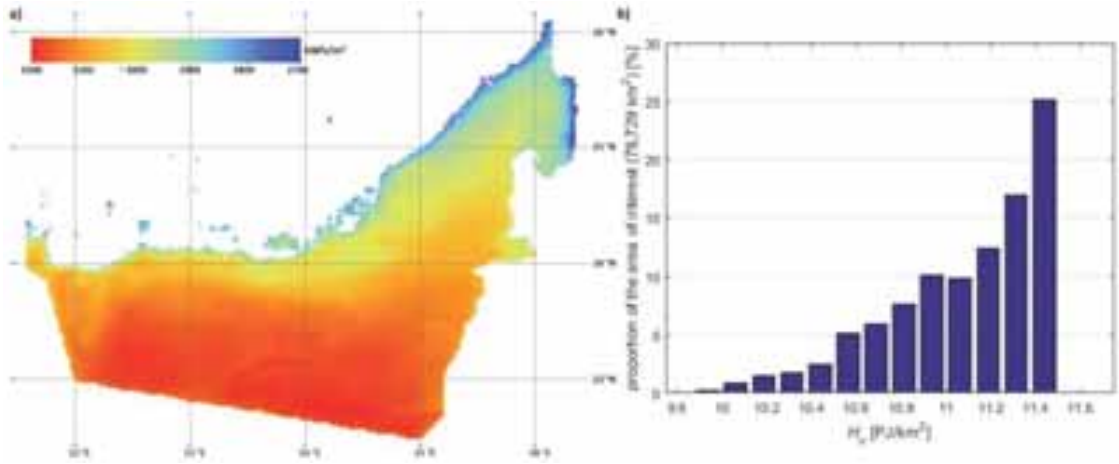

Fig. 2: PV RP in the UAE; a) map of H_n per m^2, b) histogram of H_n per km^2

The proportion of PV RP that can be converted into electricity depends on the ratio of G_i to G_n and PV system efficiency (η_s). While G_n stands for the theoretical maximum irradiance capable of being received by a solar module mounted on the Earth's surface, G_i refers to the irradiance actually incident on the module considering the mounting method and shading conditions. Geometric models (e.g. Duffie and Beckman, 2006, pp. 20–23; Marion and Dobos, 2013; Narvarte and Lorenzo, 2008) are used to compute the incidence angle of incoming irradiance (θ), which is input to a transposition model in order to obtain G_i in different plant configurations. Theoretically, a plant with dual axis tracking installed on a flat terrain with a very low ground coverage ratio can reach a unity G_i-G_n ratio.

By contrast, η_s cannot reach 100 per cent due to losses fundamentally associated with the operation of semiconductor-based solar cells: spectral mismatch and charge carrier recombination. In addition, utility-scale PV power conversion involves extrinsic optical losses, recombination via impurities, and parasitic losses. Each loss process is determined by both ambient and technological parameters. The ambient parameters of relevance include level, spectral distribution, and θ of incoming irradiance, T_a, sky temperature, wind speed (v_w), wind direction, and dust deposition. The technological parameters are subject to the selected module type and system architecture of each plant. Finally, the amount of electrical energy actually supplied to consumers is dependent on the losses of power transmission.

As illustrated in Fig. 3, the simulation of η_s is divided into three components: optical, thermal, and electrical modelling. Most of the models following this approach make use of the STC parameters that are commonly measured and available in module datasheets. Based on its STC parameters, a solar module's performance is known under a set of standard conditions to which the operating conditions can be compared.

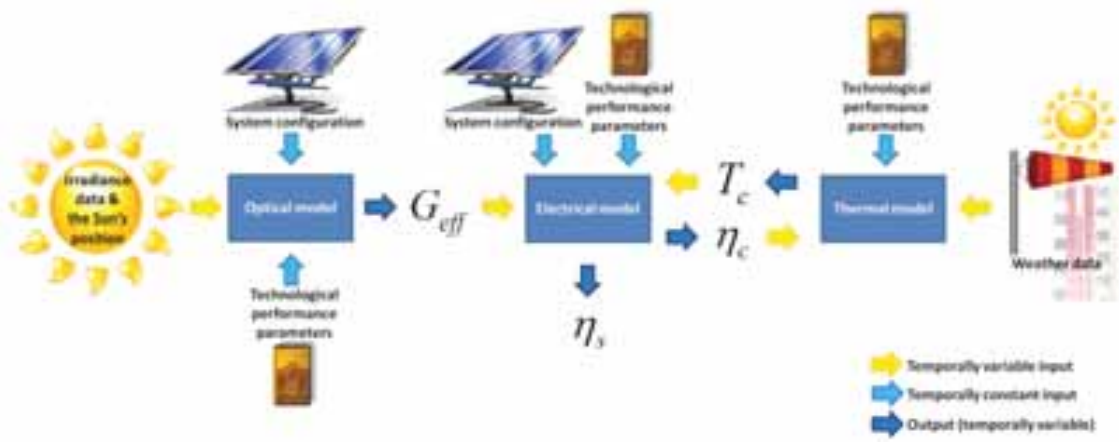

Fig. 3: Steps involved in modelling η_s

Under STC, a solar module receives irradiance that is normal to its surface and whose spectral distribution follows the standard spectrum at an air mass coefficient of 1.5 (G03 Committee, 2012). The purpose of an

optical model is to address the performance effects of the deviations of the spectrum and θ from STC. The additional attenuation due to dust deposition should be quantified. For this purpose, an optical model converts G_i and θ as well as dust deposition and spectral distribution-related data into effective irradiance (G_{eff}). G_{eff} is adapted from G_i such that a solar cell's short circuit current (I_{sc}) is always linearly dependent on it. In G_{eff}, the effects of changing spectrum, angular reflection losses, and dust deposition are isolated by normalising $G_{i,stc}$ (1000 W/m^2) by the ratio of I_{sc} to $I_{sc,stc}$. Thus, $G_{eff,stc}$ is equal to $G_{i,stc}$. I_{sc} is estimated by means of modifier equations for θ (e.g. Davis et al., 2002; Duffie and Beckman, 2006, p. 234; Souka and Safwat, 1966) and spectral distribution (e.g. Betts et al., 2004; King et al., 1998; Martín and Ruiz, 1999). The impact of dust deposition should be considered on its own (e.g. Kimber et al., 2006) as well as in association with θ and spectral modifiers (e.g. Martín and Ruiz, 2005).

The purpose of a thermal model is to simulate the temperature of a solar cell's photoactive layers (T_c), which is the primary effective variable involved in η_s modelling. The fundamental basis of the simulation of T_c is the heat transfer energy exchange of a solar cell's active components with the surrounding layers and ambient air. Therefore, T_c can be obtained through transient heat transfer modelling or by means of one of the numerous empirical and semi-empirical models and correlations (see e.g. Skoplaki and Palyvos, 2009a). The most significant ambient parameters are T_a, G_i, and v_w. Since the internal heating process within a solar cell depends on the efficiency at which the cell is converting radiation into electricity, most of the T_c modelling formulations also include cell efficiency (η_c) as an input variable.

The effective variables, G_{eff} and T_c, are converted into η_s by an electrical model with three components addressing power generation (e.g. De Soto et al., 2006; King et al., 2004; Mermoud and Lejeune, 2010; Sutterlueti et al., 2011), transmission, and conversion (e.g. Baumgartner et al., 2007; Driesse et al., 2008; King et al., 2007). A power generation model simulates all losses occurring inside solar cells. If T_c is simulated by means of a thermal model which is dependent on η_c, the thermal model and the electrical model for generation are coupled and, therefore, comprise a thermoelectrical model. The numerous empirical relationships (see e.g. Skoplaki and Palyvos, 2009b) between η_c and ambient and technological parameters are not recommended due to their weak generalizability across different locations and technologies. Nevertheless, the effects of time-dependent degradation (see e.g. Jordan et al., 2012) and performance mismatch between modules and arrays are generally considered through empirically determined, fixed loss percentages. Models for transmission and conversion address the losses occurring in conductors and power conditioning equipment, respectively. Power transmission losses are due to Joule heating and power conversion losses due to the conversion of direct current (DC) into alternating current (AC) in inverters and stepping up plant output voltage in transformers.

Furthermore, η_s is affected by a power station's auxiliary consumption. While inverter self-consumption during power conversion is considered by most inverter performance models, power losses due the consumption of trackers, air conditioning units, lighting, plant management equipment, and inverters' nocturnal standby operation have to be additionally quantified. The consumption levels of trackers and inverters are available in product datasheets. Air conditioning-related losses can be estimated by heat transfer modelling (e.g. International Organization for Standardization, 2008), which is also enabled by various software packages used for sizing air conditioning units.

The instantaneous PV plant output power can be computed as a product of G_i and η_s. As PV TP represents the amount of electricity supplied to consumers, the final step is the estimation of transmission losses for each site. Apart from the plants' own power consumption, all power demand is assumed to be concentrated on the urban areas excluded from the assessment. Transmission losses are computed for each site based on the weighted average distance to the nearest demand concentration areas using a reference high-voltage transmission line and increasing quadratically with plant output power. The transmitted power, when integrated over time and space, provides the PV TP of the territory of interest.

3.2. Technical Potential in the UAE

Area-wise, we exclude areas with conservation status as specified in the World Database on Protected Areas (International Union for Conservation of Nature and United Nations Environment Programme World Conservation Monitoring Centre, 2015) and urban status classified manually using open access geographical

information software. The excluded areas represent 21 and 2 per cent of the entire area of interest, respectively.

As explained above, PV TP assessment requires data on meteorological parameters in addition to irradiance – most importantly T_a and v_w. A locally calibrated global atmospheric model is used to retrieve the relevant data. Due to the optical and thermal models of choice, spectral data as well as data on sky temperature and wind direction are not needed.

Both the plant's system architecture and performance are simulated by means of a PV plant performance simulator (Tuomiranta, 2014). The simulator incorporates locally validated optical and thermal models and Sandia's electrical models for generation and conversion (King et al., 2007, 2004). The impact of soiling is addressed by a fixed loss percentage together with the dust deposition-dependent θ modifier model proposed by Martín and Ruiz (2005). This simplified approach is justified as PV arrays installed in the UAE can be assumed to be regularly cleaned. Therefore, dust deposition can be primarily considered as an O&M cost factor. Spectral correction is not applied due to the lack of models appropriately validated for desert climates characterised by severe aerosol loading. The thermal model found to provide the best agreement with local measurements is the one proposed by Schott (1985) (Tuomiranta et al., 2014). This semiempirical model predicts T_c based on T_a, G_{eff}, v_w, and η_c and is calibrated based on measurements made in Abu Dhabi (Tuomiranta et al., 2014).

As PV TP represents the maximum amount of electrical energy that can be supplied in a territory of interest, a single power station can be assumed to serve the entire territory rather than the areas in its proximity. Accordingly, transmission losses are estimated by means of an approximated power demand-weighted average distance to all urban areas where the country's entire demand for electricity is assumed to be concentrated. The electrical properties of transmission lines are based on the parameters published by Abu Dhabi Transmission & Despatch Company (2013).

The results of the PV TP assessment are illustrated in Fig. 4. Due to its comparatively high ground coverage ratio and average η_s, configuration mc-Si-fm provides the highest TP at all sites in the UAE. Therefore, the PV TP histogram presented in Fig. 4b is solely based on the transmitted yields of mc-Si-fm type of power stations. Out of the total PV TP of 51 EJ, 11 EJ (22 per cent) is represented by the protected areas and 94 PJ (2 per cent) by the urban areas. The maximum plant yield (mc-Si-fm, 23.22 °N, 52.60 °E, 681 TJ) is 183 per cent higher than the minimum yield (mc-Si-2t, 25.29 °N, 56.37 °E, 240 TJ).

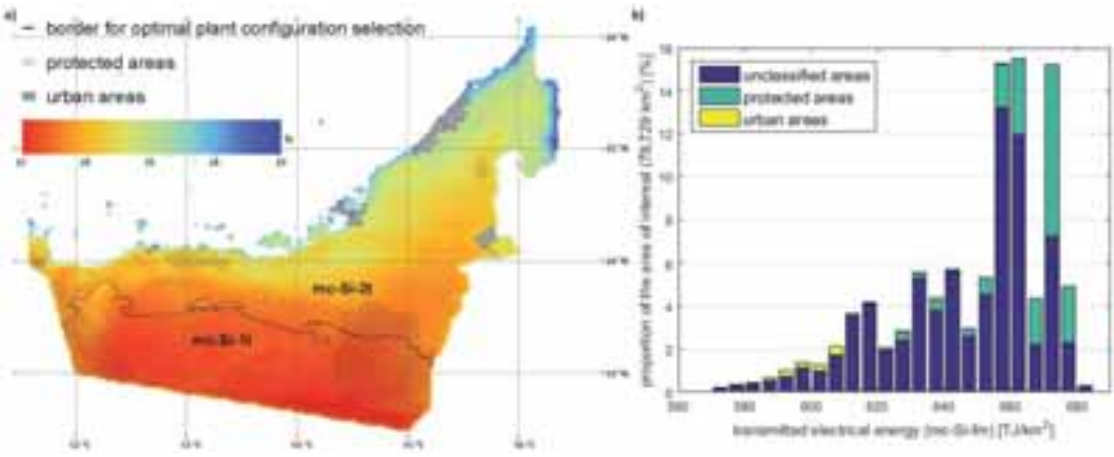

Fig. 4: PV TP in the UAE; a) map of CF and technically optimal plant configurations, b) histogram of transmitted electrical energy per km^2 separating the contributions of urban and protected areas

The map of Fig. 4a shows the spatial distribution of the highest simulated plant capacity factors (CF) considering transmitted electrical energy. Due to the high G_i-G_n ratio enabled by tracking, configurations mc-Si-1t and mc-Si-2t provide the highest CFs everywhere in the UAE. The G_i-weighted average T_c is lower in the case of configuration mc-Si-1t. Hence, configuration mc-Si-1t is the technically optimal choice for the southern part of the country, which experiences the highest G_i-weighted average T_a. The technically most appropriate site-configuration combination (mc-Si-1t, 23.69 °N, 53.23 °E, CF: 26.7%) provides 42 per cent

higher CF than the technically poorest combination (pc-Si-fm, 25.90 °N, 56.12 °E, CF: 18.9%). Amongst the fixed mount configurations, CdTe-fm power plants operate at the highest capacity factor (21% on average) at all sites.

4. Assessment of Energy Economic Potential

4.1. Proposed Methodology

PV EP assessment mainly involves the estimation of the level and spatial distribution of different cost components in order to appropriately capture the spatial dynamics of PV LCOE. In the present paper, PV LCOE refers to the cost of electricity supplied to consumers by a PV power station when considering the entire lifetime of the power project. LCOE is sensitive to numerous cost factors, some of which are difficult to be quantified accurately. Due to site-specific plant configuration and other spatial cost factors, most costs show spatial variability.

PV project-related cost data are often given in price per Wp of module capacity. When comparing different sites and technologies, this highly case-specific cost indicator can be regarded as excessively simplified. Therefore, Wp-based cost data are recommended to be converted into more appropriate cost component-tailored indicators, which enable the allocation of spatial cost factors more accurately to the components actually affected. Such a set of indicators is proposed in Tab. 2. In addition to cost categorisation, the table specifies the spatial factors influencing each of the cost components. These factors do not include plant configuration-related parameters (e.g. capacity, array area, cable volume), which are also varied spatially in the present analysis.

Accurate quantification of the cost factors specified in Tab. 2 requires access to data that are often non-existent or unavailable free of charge. However, through publicly accessible industry review studies and interviewing local industry experts, many of the factors can be approximated without costly data acquisition. Land values can be estimated by correlating point data from real estate market with relevant spatial data such as land use and population density. Earthworks cost can be estimated by multiplying publicly available cost estimates by cut and fill volumes calculated based on a digital elevation model. PV system design software can be used to convert Wp-based EPC costs to component unit-based costs. Estimates of the effects of land cover, wind load, and slope as well as project development, O&M, and road and grid connection costs for land and sea can be obtained from experts. A critical component of O&M is array cleaning if the area of interest is under severe dust loading. A three-dimensional chemistry transport model such as CHIMERE can be used to estimate the spatial variability of dust deposition. By means of published average soiling loss percentages, the dust deposition estimates can be correlated to the desired cleaning frequency.

4.2. Energy Economic Potential in the UAE

A detailed listing of the different cost data is presented in Appendix A. As shown in Fig. 5a, the spatial variability of LCOE is significantly higher than that of PV RP or TP. In fact, the LCOE levels in the country's mountainous areas are far higher than the maximum specified in the legend. The two most significant cost factors that can be identified based on Fig. 5a are cut and fill volume contributing to earthworks cost and soil consistency affecting the foundation EPC cost. The areas with LCOE levels higher than 0.10 USD per kWh are characterised by highly variable terrain elevation and consequently high earthworks costs. Most of the areas with LCOE levels ranging from 0.08 to 0.10 USD per kWh are either covered by loose sand causing inconsistency in the surface soil or located on islands with a poor access to supporting infrastructure. The minimum LCOE of 0.0657 USD per kWh is reached by configuration mc-Si-fm at the site coordinates of 24.00 °N and 52.50 °E.

The natural gas prices of 6, 10, and 14 USD per MBtu correspond to conventional power LCOE estimates of 0.06, 0.08, and 0.11 USD per kWh. As can be seen from the histogram of Fig. 5b, there is no PV EP anywhere in the UAE if natural gas price is 6 USD per MBtu. At the price of 10 USD per MBtu, 32 % (16 EJ) of the country's surface area provides conditions for economically feasible PV power generation. The proportion becomes as high as 96% (49 EJ) at the price of 14 USD per MBtu. Fig. 6 illustrates PV EP in the

UAE in case the LCOE of conventional power generation is 7 USD per kWh (natural gas at 8.1 USD per MBtu). The resulting entire PV EP is 11 EJ, out of which protected areas represent 10%.

Tab. 2: Proposed cost categorisation and the spatial cost factors under consideration

Cost category	Cost component	Cost unit	Spatial cost factors
Land	Land acquisition	USD/ha (plant area)	• land value
	Earthworks	USD/m^3	• cut and fill volume
EPC	Foundation	USD/m^2 (array area with fixed mount and single axis tracking) / USD/tracker (dual axis tracking)	• land cover • road distance to a cement factory/industrial area • slope
	Mounting structures	USD/m^2 (array area) / USD/tracker	• wind load • slope
	Solar modules	USD/Wp	
	Module cables	USD/module	• slope
	Solar cables / DC main cables	USD/m^3 (cable volume)	• slope
	Junction boxes	USD/junction box	• slope
	AC BOS	USD/MVA	• slope
	Civil works	USD/ha (plant area)	• slope
	Auxiliary systems	USD/Wp	• slope
Supporting infrastructure	Road connection	USD/km	• Euclidean distance to a road • slope
	Grid connection	USD/km	• Euclidean distance to a transmission line • land/marine connection • slope
	Substation	USD/substation	• slope
Intra-country transportation		USD/m^3/km	• road/Euclidean marine distance to a primary port
Project development		USD (% of total EPC)	
O&M	Arrays	USD/m^2/year (array area)	• dust deposition • slope
	Civil works	USD/ha/year (plant area)	• slope
	Power block	USD/power block/year	
	Plant management	USD/MWp/year	
	Utilities	USD/MWp/year	
	Road connection	USD/km/year	• Euclidean distance to a road • slope
	Grid connection	% of transmission line cost	

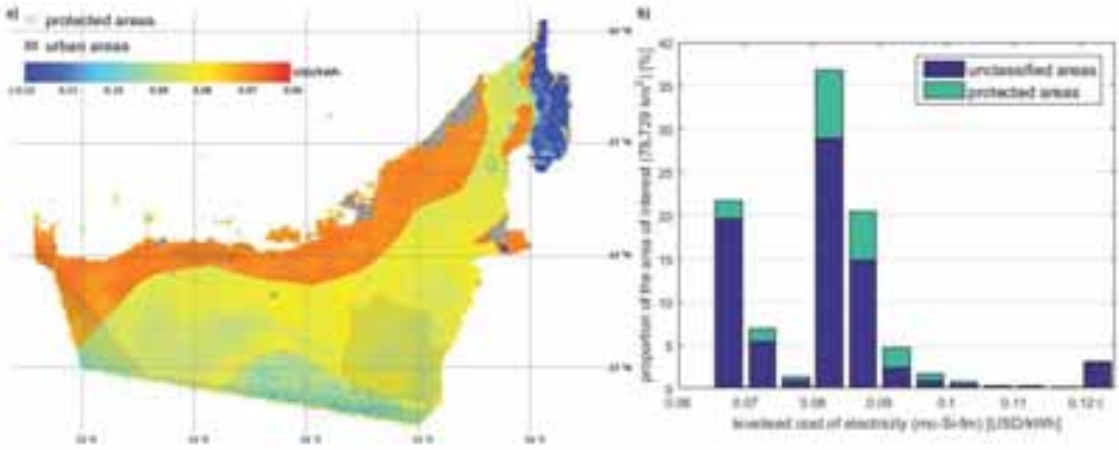

Fig. 5: PV LCOE in the UAE; a) map of minimum LCOE, b) histogram of the minimum LCOE estimates

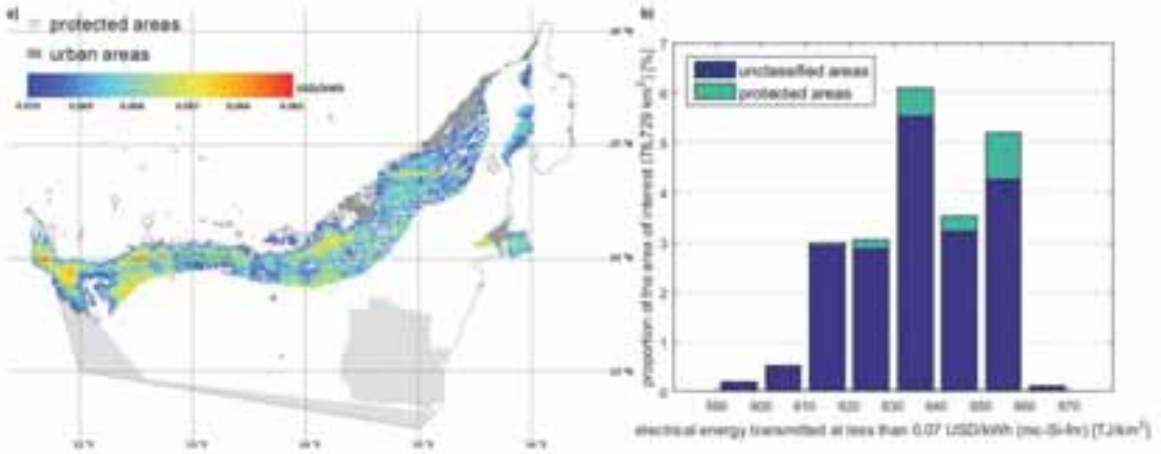

Fig. 6: PV EP in the UAE; a) map of LCOE in areas where PV competitive against natural gas at 8.1 USD/MBtu, b) histogram of transmitted electrical energy per km^2 from the highlighted area

In 2015, Dubai Electricity and Water Authority (DEWA) reached a financial close for a PV project of 200 MWp at a historically low price of 0.0598 USD per kWh (Dubai Electricity & Water Authority, 2015). This price is significantly less than the lowest LCOE level estimated in this study. It should be noted, however, that in this paper, PV potential is analysed from the governmental perspective. Thus, some cost components irrelevant for the companies bidding for DEWA's project need to be considered. These components are mainly related to land and supporting infrastructure. In addition, financial parameters such as debt-to-equity ratio have a great impact on LCOE but are highly company-specific. The presented analysis is based on financial parameter values typical of the industry.

5. Conclusion

This paper presents an enhanced methodology for the assessment of energy economic potential for utility-scale photovoltaics. It is shown that by only using publicly accessible literature and expert interviews, high-resolution information about the spatial variability of PV potential can be generated. The methodology can be further improved by using optical models that capture local spectral and dust deposition-related particularities and more refined cost parameters e.g. for foundation construction. Also, the power demand-driven cost factors should be taken into consideration when taking the high-level, systemic approach in future studies.

The presented case study confirms the UAE's tremendous PV potential indicated by previous studies by actually quantifying it for the entire country for the first time. Tab. 3 aggregates the findings and compares

them to the annual power demand in the UAE in 2013. As can be seen from the table, the PV EP is 26-fold the country's electricity demand when considering an electricity price of 0.07 USD/kWh. These findings together with the recent advances in further capacity building indicate a bright future for PV power generation in the UAE.

Tab. 3: Comparison of the different levels of PV potential to the UAE's annual electricity demand in 2013

Potential	Entire territory	% of annual electricity demand (0.4 EJ, 2013)	Unclassified territory	% of annual electricity demand (0.4 EJ, 2013)
PV RP	872 EJ	231,000%	670 EJ	177,000%
PV TP	51 EJ	13,500%	39 EJ	10,300%
PV EP (≤ 0.11 USD/kWh)	49 EJ	13,000%	37 EJ	9,900%
PV EP (≤ 0.08 USD/kWh)	16 EJ	4,200%	13 EJ	3,400%
PV EP (≤ 0.07 USD/kWh)	11 EJ	2,900%	10 EJ	2,600%

[2] Codesign Australia Pty. Ltd, Brisbane (Australia)

Abstract

The technological advancement in solar photovoltaic (PV) materials enabled system designers, engineers and end-users to select the best type of system for a given environment. This paper identifies and investigates the key environmental factors that affect the performance of two different PV technologies under the tropical climate; the thin-film copper indium gallium di-selenide (CIGS) and the conventional crystalline silicon (c-Si) systems. The annual Northern Australian climate consists of distinct wet and dry cycles and a cyclone-prone environment. The effects of real-world conditions on the panels were investigated experimentally. The measured performance of the PV systems showed a reduction of 19.6% and 9.2% for the maximum energy output and 34% and 22% reduction of the total daily energy production for the CIGS and c-Si systems respectively during the dry season period. The systems managed to regain their optimal efficiencies during the start of the wet season when the first rainfall occurred. This study highlighted the effects of soiling (dust accumulation), fauna droppings, shading and orientation on the PV system efficiencies in a tropical locale were presented. For the Northern Australian climate, CIGS and c-Si PV systems should be washed at least once during the dry season in order to maintain its original efficiencies. This paper concluded that real-world testing of PV technologies is crucial, and should complement the existing laboratory testing to accurately estimate the system's performance and behavior.

Keywords: *copper indium gallium di-selenide, crystalline silicon, environmental effects on PV, thin-film PV, CIGS, c-Si*

1. Introduction

The systems involved in the study presented in this paper are the thin-film copper indium gallium di-selenide (CIGS) and crystalline silicon (c-Si) panels. The thin-film systems are expected to perform well in slightly diffused light and their performance is not supposed to drop during hot days [1]. The following literature identifies the relevant studies on the thin-film CIGS and other conventional photovoltaic (PV) technologies in the tropical locale.

The most common effects studied on the performance of PV systems are the environmental effects. These effects are generally the effect of temperature, rainfall, humidity, cloud and wind speeds. Along with that, few external effects were also investigated, including the effect of shading, tilt angle and gradual degradation of the PV materials. However, what seems to be somehow ignored in the past studies is the effect of dust accumulation as it can be detrimental, specifically in the extended dry season locales in Northern Australia.

Dust particles can impinge on to the surface of a PV panel. The extent of dust accumulation mainly depends on wind, moisture, electrostatic charge, gravity and surface properties of the panels [2]. Jiang et al. carried out a controlled laboratory experiment to measure the effect of dust accumulation losses in different

doi:10.18086/swc.2015.05.27 Available at http://proceedings.ises.org

PV materials. The experimental results found that the PV output efficiency grew from 0% to 26% for dust deposition density increasing from 0 to 22g/m^2 [3]. However, the difference in reduction of efficiency due to cell types was not evident. On a different occasion, Kaldellis and Kapsali performed laboratory analysis and developed theoretical model to investigate the effect of dust in PV performance losses. However, they recommended performing real-life data analysis to map actual results [4]. Beattie et al. presented numerical and analytical models of dust accumulation that quantitatively coincide with a laboratory investigation of particle accumulation on a glass slide for PV in dry regions. Their study was laboratory based with controlled conditions and did not include real PV systems with environment data [5]. Also, Boyle et al. performed an experiment on dust accumulation on PV cover plates (not actual PV) and found 6% reduction in light transmission per g/m^2 of dust accumulation [6]. Study by Said and Walwil found 6% reduction after 5 weeks of exposure in Qatar [7].

The effect of soiling on PV panels in the Sahara region was investigated by Kalogirou et al. who suggested immediate washing after dust events [8]. Mohamed and Hasan observed gradual decrease of power from PV panels (type unknown) in Sahara environment of Libya due to the effect of dust accumulation. They suggested weekly washing during windy periods and at least a month for other months in order to maintain performance losses between 2 to 2.5% [9]. Piliougine et al., during an analysis of the dust losses in c-Si PV modules with different cover glasses in Malaga (Spain), found losses reached 15% in no rainfall period (> 2 months) and annually 6% losses due to dust accumulation [10]. Adinoyi and Saidfound 50% reduction in power of crystalline solar panels installed in Saudi Arabia which had not been cleaned for six months [11]. Various simulations and experiments to measure the effect of dust losses on PV systems were performed by Qasem et al. in the arid environment of Kuwait. They found that the worst angle for most non-uniform dust accumulation is 30^0 [2]. The PV materials experiencing the most losses due to dust shading are the wide band-gap materials. The materials could be categorized as c-Si, followed by Cadmium Telluride (CdTe) PV, whereas c-Si and CIGS PV systems were found to be less affected. The mean daily energy loss due to dust accumulation on the surface of PV was recorded 4.4% and could extend to 20% during no rainfall periods, as studied by Zorrilla-Casanova et al. [12]. This study was done in Spain with the author suggesting that the losses can vary depending on the location and angle of tilt at which the PV was installed. A study by Lorenzo et al. at their solar park dust investigation found detrimental aspects of homogenous dust accumulation which may also cause hot spot phenomenon, hence, a threat to the PV module lifetime [13].

Darwin, located in the Northern Territory (NT), has a unique climate with high monthly and annual solar radiation, distinct wet (humid and high rainfall) and dry (less humid and no rainfall) seasons, along with a highly cyclone-prone environment. This study, conducted at the Charles Darwin University's Outdoor Solar Facility as detailed in the following scripture, outlines actual quantified production loss figures over the dry and wet periods. In addition, this study also covers a unique tropical locale of Australia involving two often installed types of PV modules of different optical properties and attributes. A highly efficient inverter system was used to analyze the real production of the system.

2. System Description and Background

For experimental measurements, both systems were installed in the Casuarina Campus at the Charles Darwin University (CDU) (-12.37°S, 130.86°E). Fig. 1 shows the picture of the monitoring and evaluation solar

facility. The solar facility is an outdoor structure made of composite material, impregnated by thin-film CIGS PV material as roof sheeting, and fastened directly to the steel structure. The thin-film modules are bonded on the composite sheet away from the borders to avoid direct heat transfer from the steel structure. The modules are affixed using pressure sensitive adhesive to the Category 4 cyclone wind resistant glass reinforced composite backing of trapezoidal profile [14]. This 1.5kWp solar facility has local vegetation around and it is a home to numerous local birds and other fauna. Fig. 2 shows the c-Si PV system set up on one of the buildings adjacent to the CIGS setup. This 5.0kWp system was installed in the rooftop of the building, and similarly to the CIGS system, is grid-connected.

The two solar facilities were setup to monitor the influence and impact of environmental factors on the performance and production efficiency of both the systems. Incorporating the data from the Australian Bureau of Meteorology (BoM) weather station mounted at CDU, effects of real-world conditions on the panels such as dust, rainfall, fauna droppings, shading and orientation were investigated and discussed.

This study is in particular extremely interesting with the unique Northern Australian climate with high monthly and annual solar radiation, distinct annual wet (humid, high rainfall and cyclone-prone) and dry (less humid and virtually no rainfall). These two seasons highlight the natural effects of washing (due to rainfall) and soiling (dusts and fauna droppings build-up during the dry season) on the PV systems. The objective of this study is to complement the research of PV performance in the laboratory where the environmental parameters are often ignored in laboratory testings.

Fig. 2: The installed 5.0 kWp c-Si rooftop system (Auxin AXN-P6T275, Inverter: SunnyBoy SMA SB 5000TL-20)

3. Results and Discussions

3.1 PV power production

The power production for both the 1.5kWp CIGS and 5.0kWp c-Si systems were recorded, together with the rainfall data for the period from March 2014 to July 2015. The profile is shown in Fig. 3.

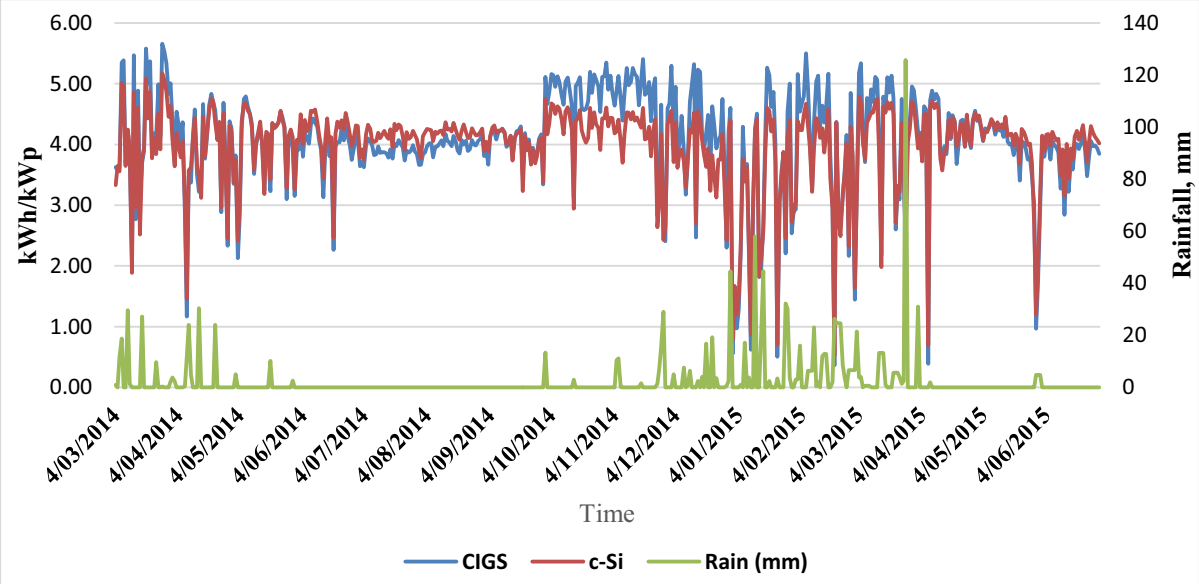

Fig. 3: Daily normalized power output and rainfall profile

From the plot, the power output for the two PV systems were fairly irregular during the annual wet season (March-May 2014 and November-April 2014/15). This was expected due to constant rainfalls, cloud cover and low radiation. During the dry season (June-October 2014 and March-June 2015), the power outputs were constant, which was expected due to clear skies and no rainfall.

The average power output recorded were higher during the wet season (although production was erratic), in the region of 5kWh/kWp for CIGS compared to 4kWh/kWp during the dry season. The c-Si system do not vary much, but similarly do have higher average compared to the dry season. Observing the period from March to June 2015 (start of the dry season), the average power outputs are slowly decreasing to the constant levels similar to the previous dry season (June-October 2014). This performance behaviour was expected. Overall the power output profiles were within the expected behaviour and both systems displayed similar qualitative relationship.

The power output increased significantly after the first recorded rainfall on the 30th of September 2014 for both systems. Taking a closer look at Fig. 3, the escalation in production after the first rainfall was observed to be much higher for the CIGS system as compared to c-Si system. There could be number of possible reasons for this increase in the power generation. One of the reasons is that the CIGS system has a rough surface material, which attracted more dust and accumulated a higher amount of dust particles compared to the much smoother surface of the c-Si system. Also, the efficiency of CIGS system does not drop in slightly diffuse light and on hot days compared to the c-Si system which are more sensitive to cloudy conditions and high temperatures [1].

The daily maximum energy output recorded for October showed a substantial increase of 19.6% and 9.2% (from the previous month, September) for the CIGS and c-Si systems respectively. This 'natural

washing' phenomena (due to rainfall) cleaned the surface of the panels, and thus contributes to this increase to the PV's original efficiency (as observed during the wet seasons). This phenomena is critical, especially for the Northern Australian climate, and highlighted to importance of washing during the dry seasons. These natural environmental effects are discussed in the next section.

3.2 Natural environmental effects - dust accumulation, fauna droppings and rainfall

Fig. 4 to 6 shows the amount of dust accumulation and fauna (birds and bats) droppings on the panel surface. This occurs mostly during the dry season, where no rainfalls were observed. The figures were obtained during the end of the dry season to highlight the dust and droppings accumulated over the period.

Fig. 4: c-Si panels, 26th August 2014

Fig. 5: CIGS panels, 22nd August 2014

Fig. 6: Fauna droppings on the panels - 1st August 2014

The increase in the power output, with increasing monthly solar exposure, is observed for the month of October. It is worth noting that the first rainfall recorded for this testing facility is on the 30th of September 2014. This natural washing of the panel surfaces by the rainfall had drastically improved the power output of

both the PV systems, as highlighted in the previous section. Fig. 7 shows the CIGS system after the first rainfall where the accumulated dust and soil are washed away.

Fig. 7: Naturally washed panels due to rainfall - 3rd October 2014

Fig. 8 shows the monthly normalized average and maximum production power for both of the PV systems and the maximum monthly solar irradiation. The maximum recorded power output for both systems are consistent with the Darwin climate; wet season (March-May 2014 and November-April 2014/15) and the dry season (June-October 2014 and March-June 2015). The maximum outputs recorded are lower for the dry seasons as compared to the wet seasons. The measured performance of the PV systems showed a reduction of 19.6% and 9.2% for the maximum energy output and 34% and 22% reduction of the total daily energy production for the CIGS and c-Si systems respectively for the dry season compared to the wet seasons. They are further discussed in the following sections

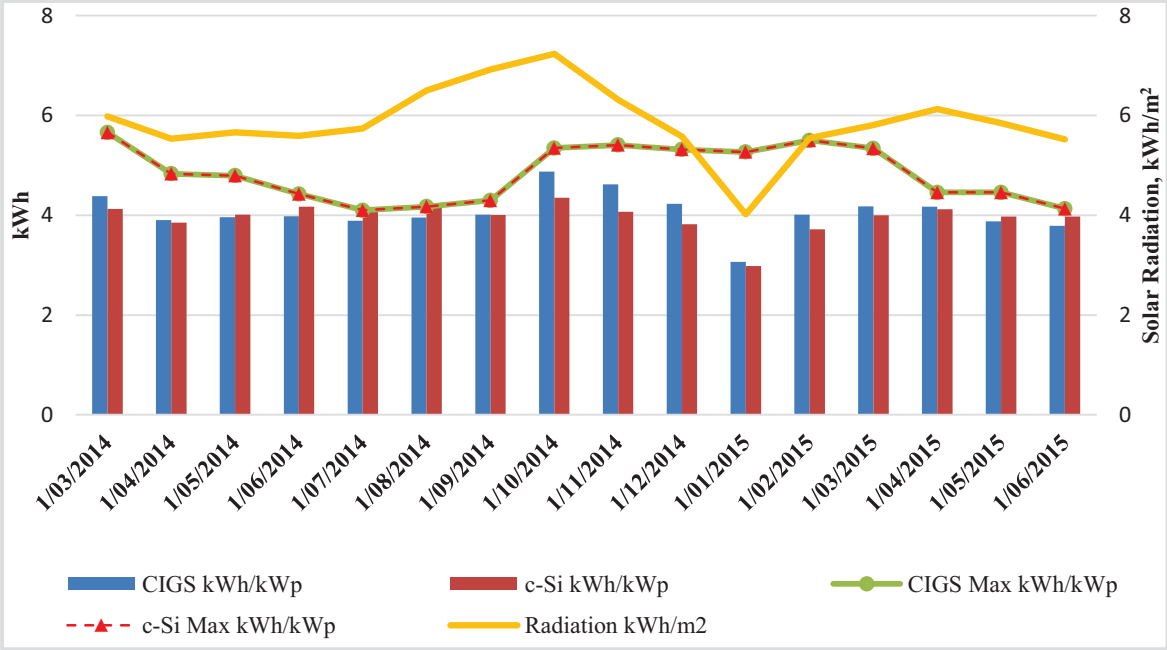

Fig. 8: Monthly normalized average and maximum kWh for CIGS and c-Si and maximum solar irradiation

3.2.1 Effects on the CIGS system

To further observe the role of rainfall on the system's performance efficiency, the maximum daily production was analysed against the rainfall and solar exposure data as shown in Fig. 8. For 2014, at the end of the wet

season (March-May), the maximum production power recorded was just over 7kWh/day. Entering to the dry season (May-October 2014), the maximum production power decreased steadily although the solar irradiation increases. The same profile (slowly reduced in efficiency) was observed in 2015 (April-June) during the start of the dry season.It was found that this level of production was not reached until it rained again on the 30th of September 2014. This rainfall washed away the accumulated dust from the surface of the panels. This observation further emphasized the critical effects of soiling and fauna dropppings on the surface of the CIGS panels.

The effect of soiling on the PV panels was investigated in the Sahara region by Kalogirou et al., where the authors suggested that panels to be cleaned after every dust event and once every 2 to 3 weeks during high dust seasons [8]. Mani and Pillai also suggested weekly cleaning during long dry spells [15]. The observations from this study concluded that CIGS systems installed in tropical Northern Australia should be washed at least once during the dry season to maintain its efficiency.

3.2.2 Effects on the c-Si system

The c-Si PV system was installed adjacent to the CIGS system within the same area, hence it experienced similar intensity and pattern of rainfall. Similarly to the CIGS, the increase in power production was observed after the first rainfall (30th of September 2014). The same hypothesis, may apply here that the rigorous natural washing (removing accumulated dust) of the solar panels by the rainfall is the reason for the increment in power generation. Furthermore, the weather conditions recorded from the closest weather stations (CDU and Darwin Airport) are very similar as well on both the days.

Similarly, in order to investigate the role of rainfall in system's performance efficiency, the maximum daily production was analysed against the rainfall and solar exposure data as shown in Fig. 8. For 2014, Darwin experienced its end of wet season rainfalls until May and the maximum power production recorded was about 23kWh/day. Analysing the data it is found that this level of production was not recorded until it rained on the 30th of September, removing the accumulated dust from the surface of the system. The same profile was observed in 2015 (April-June) during the start of the dry season. Similar to CIGS systems, it appears rational to suggest that c-Si PV systems installed in the tropical Darwin should also be washed at least once in between the dry season to maintain its original efficiency.

3.2.3 Performance comparison

The effect of dust accumulation in the case for c-Si system does not seem to affect the production performance to the same degree compared to the CIGS system. Physical observation of the two systems in this period shows that CIGS had attracted and accumulated more dust as compared to c-Si system.

In addition, the physique of the thin-film CIGS can be described as flexible, undulating with rough surface in contrast to a smoother surface of the conventional c-Si PV panels. Moreover, given the smooth surface of conventional panels would also have supported the removal of some dust through the regular moisture flow from the natural morning dew.

3.3 Effect of system orientation

As mentioned previously, both systems were installed in close proximity to each other (approximately 20m apart in the same area). However, the systems each has different orientations. The c-Si system was installed

on the east facing roof and the effect of this orientation can be seen in Fig. 9 (in the morning and late evening). The sudden drop in power generation after 3:30PM can be observed when the sun is located behind the building.

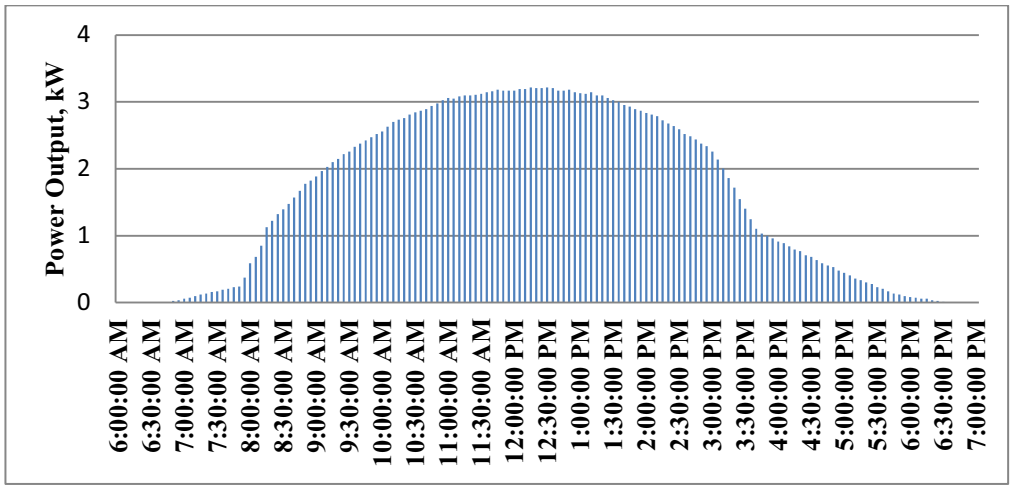

Fig. 9: Intraday power plot for the c-Si system on 17th September 2014

On the other hand, the CIGS system is installed facing north and the effect of this orientation can be seen in Fig. 10. The intraday power plot on the same day exhibits a smooth and uniform profile throughout the day, taking the maximum advantage of the sunshine hours, compared to the c-Si system. The CIGS system however, misses out on some sun time in the mornings and late afternoons. This was due to the fact that the experimental system is installed at a lower height over the ground and hence surrounded by tall trees around the area.

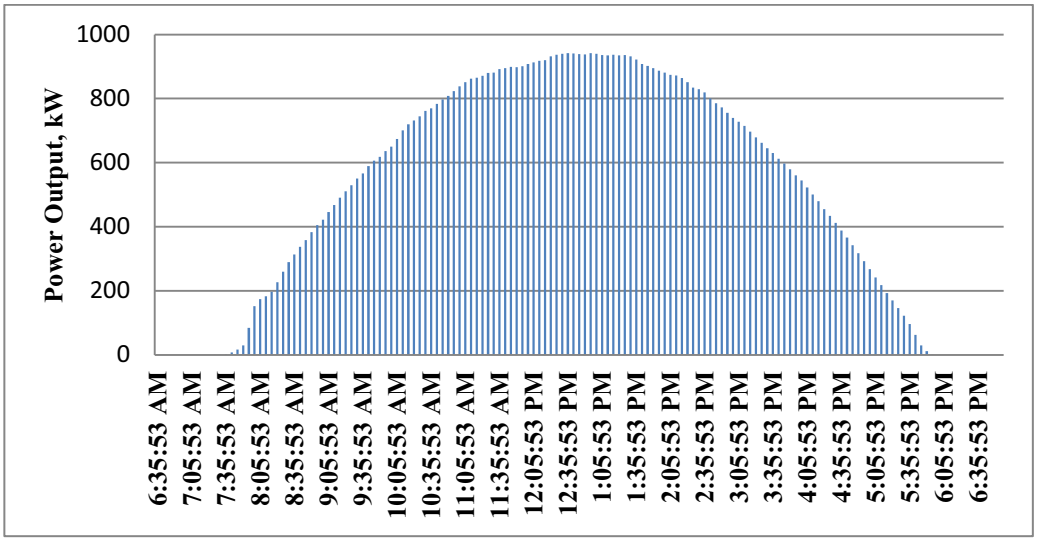

Fig. 10: Intraday power plot for the thin-film CIGS system on 17th September 2014

4. Summary and concluding remarks

This paper identifies and investigates the environmental factors that affect the performance of two different PV systems under the tropical climate; the thin-film CIGS and the traditional c-Si systems. For experimental measurements, both systems were installed in the Casuarina Campus at the CDU (-12.37°S, 130.86°E),

where the annual climate for Northern Territory, Australia consists of distinct wet and dry cycles and a cyclone-prone environment annually.

Utilizing the climate data obtained from the BoM, results showed the system performances under that the effect of dust, soiling and fauna droppings (on the respective panel surfaces), especially during the dry season, has significant affects on the power production of the systems. It was observed that during the dry season, such factors have the opportunity to collect on the respective panel surfaces.

The daily power output (Fig. 3) and the maximum monthly energy output (Fig. 8) recorded for both the CIGS and c-Si systems exhibited similar and expected behaviours; a constant decline in efficiency over the dry season, and the systems regain their original efficencies during the start of the wet season. When the first rainfall was recorded (end of September), the daily maximum energy output recorded for October showed a substantial increase of 19.6% and 9.2% for the CIGS and c-Si systems respectively. This 'natural washing' phenomena cleaned the surface of the panels, and thus contributes to this increase to the PV's original efficiency, and the effiencies were maintained over the season. In addition, the measured performance of the PV systems showed a 34% and 22% reduction of the total daily energy production for the CIGS and c-Si systems respectively for the dry season compared to the wet season. This was highlighted in Fig. 3 and 8, from October 2014 to March/April 2015. It was concluded that washing the panels once during the dry season is sufficient to maintain its orginal efficiencies.

The effect of shading and system orientation were also presented and discussed. Analysing the intraday power plot curve for both systems, it was concluded that the north-facing CIGS system exhibits a smoother profile compared to the east-facing c-Si system. However, the CIGS system was missing out on some amount of sun time during the early morning and in the late afternoon.

In conclusion, results showed a significant difference in the percentage increase in the power generation of the two different types of PV systems with same daily average solar exposure before and after the rainfall. There could be number of possible reasons for this difference of behaviour between the two systems. The two systems could have different response to diffuse sunlight/cloud cover, temperature and affinity for dust accumulation. Moreover, difference in the affinity for dust accumulation due to difference in surface material, smoothness, angle of tilt and height of system installed. Therefore, this finding makes a strong implication for further investigation of each system’s performance on an intra-day basis, also incorporating the necessary environmental factors of this tropical locale. This study highlighted that real-world testing of PV systems is crucial and important, and this should complement on the additional laboratory testings to accurately estimate the system performance and behaviour.

Energetic and exergetic analysis of monocrystalline and polycrystalline photovoltaic modules

Suellen C.S. Costa, Janaína de O.C. Silva, Cristiana B. Maia, and Antonia Sonia A.C. Diniz

Pontifical Catholic University of Minas Gerais (PUCMinas)/Graduate Mechanical Engineering Program/Group of Energy Studies (GREEN-IPUC), Belo Horizonte (Brazil)

Abstract

In this paper, the concepts of energy and exergy are used to estimate and compare the performances of monocrystalline (m-Si) and polycrystalline (p-Si) silicon photovoltaics (PV) modules. The energetic efficiency is the ratio of the energy output of the module to the incident light energy (product of solar radiation and the area of incidence or area of the module). The exergetic efficiency is derived from the electrical parameters, the operating temperature of the modules, and the specific weather conditions. The electrical parameters of the modules were evaluated by adjusting module (nameplate) specifications to the climate variables obtained for the city of Belo Horizonte, Brazil. The m-Si module (190W) had energetic and exergetic efficiencies around 20% and 14%, respectively. In comparison, the p-Si module (210W) had an expected lower energetic efficiency of approximately 18% and exergetic efficiency about 13%. The modeling and analysis conditions are described in detail.

Keywords: *Photovoltaic modules, performance, energetic efficiency, exergetic efficiency.*

1. Introduction

Growing demand for electricity and the predicted depletion of fossil fuels are among the important factors to enhance research and financial incentives to facilitate use of renewable sources. According to Dincer et al. (2010), the decline in the supply of fossil energy in the world, associated with increased energy consumption and the continuing indications of global climate change, have driven research, innovation and market deployment for the realization of a global economy based on clean, renewable energy. Solar energy has to potential to provide a significant portion of the global energy demand—especially that associated with electrical power generation.

Renewable-electricity generation sources have capacity factors and availability factors less than optimum values (intermittent, dispatchable power). Semi-regular, periodic, and stochastic changes in resource availability affect the performance of systems using renewable energies throughout their livespans. One way to better address the impacts of changes or interuptions in resource availability is to use a *typical meteorological year* (TMY), which represents the behavior of weather variables generated from a data bank much longer than a year in duration. The TMY pattern is a set of experimental data that represents a typical year for a given location—and is used as baseline indicator for analysis and assessment giving annual averages that are consistent with the long-term averages for the location in question. The default year applies the knowledge of local weather procedures for evaluation, design, planning and operation of power plants from renewable sources. PV systems are among the energy conversion systems that have performances that are significantly influenced (controlled) through non-ideal conditions. The main factors contributing to the reduced PVmodule performance in operating conditions are the meteorological variables, mainly the ambient temperature and the solar radiation.

The performance of photovoltaic modules can be evaluated by processes applying the First and Second Laws of Thermodynamics, called energetic and exergetic analysis, respectively. According to Dincer (2002), the

doi:10.18086/swc.2015.05.28 Available at http://proceedings.ises.org

exergy analysis is a tool for assessing the ensemble of environmental impacts on the use of any energy source. The exergy analysis technique provides pathways toward the operation of more efficient and higher performance energy sources. This methodology can provide a valuable tool in reducing the real encountered losses of existing energy systems. Pandey et al. (2013) recommend application of exergy analysis when a comprehensive analysis is required. The *energy efficiency* of photovoltaic modules is the ratio of the generated energy to the solar radiation energy, not including the direct influence of some factors, such as thermal properties (Sarhaddi et al. (2010)). The *exergetic efficiency* considers climatic parameters, geometric factors, and operation of the modules (including thermal properties) and provides more realistic insights into the energy conversion process for photovoltaic modules. Joshi et al. (2009) point out that the energy of a photovoltaic system has two primary components: electrical and thermal energy. The electrical exergy can is equal to the actual electricity generated by the photovoltaic system, since it is completely available to be converted into work. The thermal energy available from solar cells is not used to generate useful work (i.e., is not used by these devices to generate electricity) in operating PV systems, becoming heat lost into the environment.

The performance of a photovoltaic module depends on variables such as ambient temperature, solar radiation, incident angle, dirt accumulation, and the type or technology of the photovoltaic cell utilized. The temperature has an important influence on the efficiency of the modules and therefore the entire PV array. Sahin et al. (2007) investigated the thermodynamic characteristics of photovoltaic cells based on their energy and exergy efficiency. Results indicated that energy efficiency ranged between 7 and 12% during operation under available sunlight, while the exergetic efficiency varied between 2 and 8%. According Xydis (2013), exergy losses are related to the temperature correction factor due to the increase in module temperature, representing 1.3% losses in system performance. Colombo et al. (2014) presented a general thermoeconomic analysis to assess the economic and environmental effects of energy integration system, taking into account the life cycle and the effect of inefficiencies due to off-design operation of systems. The method was applied to a case study from a photovoltaic power plant and a standard commercial power plant gas turbine (without cogeneration) deriving the final cost of a kWh. The evaluation of the economic cost was accomplished through termoeconômicas techniques, while exergy costs were assessed using both Extended Exergy Accounting (EEA) and the Thermo-Ecological Cost (TEC) methods. The results showed that a purely monetary evaluation can lead to contrasting results, and that the EEA and TEC cost indicators can generate different rankings among the alternatives studied.

Many studies on the performance evaluation using the First and Second Law of Thermodynamics have been applied in photovoltaic/thermal (PV/T), where a single system generates electricity and heat. Ceylan and Gürel (2015) experimentally evaluated a new PV/T system design for cooling of the PV modules and using the extracted heat to warm water. This PV/T system is a forced circulation system without pump. The exergy analysis of PV/T system has accounts for thermal exergy of the PV module and the solar collector, as well as variations of electric exergy. The authors derived that for the temperature of 45°C that the exergetic efficiency was 17%, while at 55°C, the exergetic efficiency was 21%.

Yazdanpanahiet et al. (2015) used combined analytical and experimental analysis to evaluate the exergetic efficiency of a PV/T system. The operating parameters were obtained through the experimental setup, which recorded the intensity of solar radiation, wind speed, ambient temperature, temperature of photovoltaic cells, the flow and fluid input temperature, and fluid output temperature, open circuit voltage and short-circuit, and the voltage and current at the maximum power point. The numerical simulation used a three-dimensional model under a constant thermal load and a 4-parameter current-voltage model. The model was modified to account for the exergetic efficiency and exergy losses in the PV/T system components. The results of this numerical simulation were compared with their experimental measurements. Additionally, a comparison between the modified exergetic efficiency used in the study and one from the literature showed that the modified exergetic efficiency obtained in this approach avoids the shortcomings of exergetic efficiency from the literature, since it derives the loss of exergy in the system PV/T directly.

The First and Second Law of Thermodynamics can be used to determine and compare the efficiencies of different PV module technologies from a fundamental analysis approach, but this method has not been widely used. This approach has mainly been incorporated to evaluate PV/T technologies. This paper aims to

analyze the performance of photovoltaic modules of monocrystalline silicon (m-Si) and polycrystalline silicon (p-Si), applying the concepts of the First and Second Law of Thermodynamics. The energetic and exergetic efficiencies have been evaluated, expanding reported mathematical models to assess the influence of meteorological variables for the city of Belo Horizonte, Brazil. This analysis has provided direct evaluation and comparison of the two, most widely used commercial silicon PV technologies.

2. Methodology

Photovoltaic modules are composed of several solar cells connected in series and/or parallel configurations to provide the required voltage and current (power) for the given application. Currently there are several types of cell technologies, both in research and commercial stages. The most most prevalent in the market (about 90%) use silicon, because of cost and availability factors. Bulk silicon cells can be crystalline silicon, monocrystalline and polycrystalline, and these are the most common commercial technologies. Thin films, such as those using amorphous Si, are also used, but have a far lower manufacturing base and a much lower performance capability. According to Green et al (2015), the monocrystalline silicon modules have demonstrated manufacturing line efficiencies to 22.9%, due to the high degree of crystalline quality, low defect and impurity levels, and innovative device design. The polycrystalline silicon modules have comercial efficiencies to about 19%, while the amorphous silicon thin film approaches can achieve efficiencies in the 10%-12% range.

In the studies of this paper, we analyze the performances of the two major Si PV module technologies (m-Si and p-Si), through modeling and simulation of *energy and exergy efficiencies*. In this analysis, the estimated time meteorological data using models of Duffie and Beckman (2006) and Lorenzo (1994) are incorporated into the models. The weather conditions were for the city of Belo Horizonte, Brazil, with 19.93° S latitude and longitude 43.93° S. The inclination of the PV modules was set at 20°, the ground reflectivity index for the urban area (ρ) at 18%, and average monthly atmospheric transparency indices ($\overline{K_T}$) (as indicated in Table 1) were incorporated with minimum and daily maximum temperature data and wind speed at this location, provided by *Solar and Wind Energy Resource Assessment* project (SWERA). Weather conditions for Belo Horizonte were validated with data provided by the National Institute of Meteorology (INMET) and with the TMY information obtained through SWERA.

Guimarães (1995)

The simulations were performed using the Engineering Equation Solver (EES) software. The energetic and exergetic efficiencies were estimated hourly for the year studied and included the variation of meteorological parameters and operating parameters of the PV modules. To estimate electrical and thermal parameters of the PV modules for different operating conditions, the reference condition was chosen as the nameplate values of the operating parameters. The PV modules used were (1) monocrystalline Si: module of the 190Wp nameplate power output and (2) polycrystalline Si: module of the 210Wp. Table 2 presents the complete nameplate electrical specifications for each of these PV module technologies.

Tab. 2: Electrical characteristics of the PV modules

	Monocrystalline Module	Polycrystalline Module
Power	190 Wp	210 Wp
Open circuit voltage ($V_{oc,ref}$)	21.68 V	33.05 V
Short circuit current ($I_{sc,ref}$)	11.80 A	8.23 A

Module Length	0.808 m	0.990 m

3. Mathematical Model

The PV generator consists of a set of modules whose performance may be influenced by weather conditions (e.g., intensity of solar radiation, the ambient temperature, and wind speed). Performance can be evaluated by applying the First and Second Law of Thermodynamics for the assessment of the respective energy and exergetic efficiencies. Energy efficiency for the theoretical case is given by (Pandy et al., 2013):

$$\eta_{\text{energy}} = \frac{V_{oc} * I_{sc}}{G_T * A} \quad \text{(eq. 1)}$$

where A is the area of the photovoltaic module; G_T; the solar radiation; V_{oc} is the open-circuit voltage and I_{sc} is the short-circuit current. The open-circuit voltage and short-circuit current can be obtained by the model proposed by Chouder et al. (2012):

$$V_{oc} = V_{oc,ref} - \beta(T_{c,ref} - T_c) + A_f \ln\left(\frac{G_T}{G_{ref}}\right) \quad \text{(eq. 2)}$$

$$I_{sc} = I_{sc,ref}\left(\frac{G_T}{G_{ref}}\right) + \alpha(T_c - T_{c,ref}) \quad \text{(eq. 3)}$$

where T_c is the module temperature. Variables with subscribed ref indicate the parameters in reference (or namplate) condition. The parameters of reference used in this modeling were taken from the datasheet provided by the manufacturer of the PV modules evaluated, considering the standard test conditions (STC). The solar irradiance was set at 1000 W/m². The β and α are the temperature coefficients for the open-circuit voltage and short-circuit current, respectively. A_f is the modified ideality factor of the diode, defined by (Chouder et al., 2012.):

$$A_f = \frac{n\sigma T_c}{q} \quad \text{(eq. 4)}$$

where n is the diode ideality factor (and in this study was set n = 1), σ, the Boltzmann constant, and q is the electronic charge.

The module temperature (T_c) is defined from the data set to the nominal operating condition of the module, as proposed by Pandey et al. (2013):

$$T_c = T_a + \left(\frac{NOCT - 20\,°C}{800\ W/m^2}\right) G_T \quad \text{(eq. 5)}$$

where NOCT is the nominal operating temperature of the module and T_a is the ambient temperature. The ambient temperature (T_a) was estimated of according with the model proposed by Lorenzo (1994), which

depends on the hour angle (ω) relating the displacement of the sun from noon and accounting for a displacement of 15 ° every hour, and the angle the sunset (ω_s), the completion of the sunlight period (Duffie and Beckman, 2006):

For $-\pi < \omega < \omega_s$, T_a is calculated by:

$$T_a = T_{aM}(i-1) - \frac{T_{aM}(i-1) - T_{am}(i)}{2}\left[1 + +cos\left(\left(\frac{\pi}{\left(\frac{\pi}{6} - \omega_s - 2\pi\right)}\,\omega\right) + \left(-\frac{\pi}{\left(\frac{\pi}{6} - \omega_s - 2\pi\right)}\,\omega_s\right)\right)\right] \quad \text{(eq. 6)}$$

In Eq. (6), T_{aM} and T_{am} are the maximum ambient temperature and minimum along a day, respectively, and i is the day of the year.

For $\omega_s < \omega < \frac{\pi}{6}$, T_a is calculated by:

$$T_a = T_{am}(i) + \frac{T_{aM}(i) - T_{am}(i)}{2} * \left[1 + \cos\left(\left(\frac{\pi}{\left(\omega_s - \frac{\pi}{6}\right)}\omega\right) + \left(-\frac{\frac{\pi}{\left(\omega_s - \frac{\pi}{6}\right)}\pi}{6}\right)\right)\right] \quad \text{(eq. 7)}$$

And for $\frac{\pi}{6} < \omega < \pi$, T_a is calculated by:

$$T_a = T_{aM}(i) - \frac{T_{aM}(i) - T_{am}(i+1)}{2}\left[1 + +cos\left(\left(\frac{\pi}{\left(2\pi + \omega_s - \frac{\pi}{6}\right)}\,\omega\right) + \left(-\left(\pi + \frac{\frac{\pi}{\left(2\pi + \omega_s - \frac{\pi}{6}\right)}\pi}{6}\right)\right)\right)\right] \quad \text{(eq. 8)}$$

To estimate the solar radiation on the inclined photovoltaic module(G_T), we used the isotropic sky model from Duffie and Beckman (2006) that considers the sum of direct components, the isotropic diffuse and diffuse solar radiation reflected by the ground:

$$G_T = G_b R_b + G_d \frac{(1+cos\,\beta_{in})}{2} + G\,\rho\,\frac{(1-cos\,\beta_{in})}{2} \quad \text{(eq. 9)}$$

In Eq. (9), G_b and G_d are the direct and diffuse solar radiation, respectively; G is the total incident solar radiation on a horizontal plane; R_b is the ratio between the total radiation incident on an inclined surface and a horizontal surface; ρ is the ground reflectivity, and β_{in} is the tilt angle of module.

The exergetic efficiency of photovoltaic modules is given by the ratio between output exergy and input exergy.

$$\varepsilon = \frac{\text{Output exergy}}{\text{Input exergy}} = \frac{\text{Ex}_{\text{elet}} - \text{Ex}_{\text{therm}}}{\text{Ex}_{\text{solar}}} \quad \text{(eq. 10)}$$

The input exergy is from the solar radiation:

$$\text{Ex}_{\text{solar}} = \left(1 - \frac{\text{T}_\text{a}}{\text{T}_{\text{sol}}}\right)\,\text{G}_\text{T} * \text{A} \quad \text{(eq. 11)}$$

The output exergy of the photovoltaic module is the difference between the electrical exergy and thermal exergy defined by Pandey et al. (2013):

$$\text{Ex}_{\text{elet}} = \text{V}_{\text{oc}}\text{I}_{\text{sc}} - (\text{V}_{\text{oc}}\text{I}_{\text{sc}} - \text{V}_\text{m}\text{I}_\text{m}) \quad \text{(eq. 12)}$$

$$\text{Ex}_{\text{term}} = \left(1 - \frac{\text{T}_\text{a}}{\text{T}_\text{c}}\right)\text{U} * \text{A}(\text{T}_\text{c} - \text{T}_\text{a}) \quad \text{(eq. 13)}$$

where V_m and I_m are the voltage and current at the maximum power point defined by (Chouder et al., 2012):

$$I_m = I_{m,ref}\left(\frac{G_T}{G_{ref}}\right) \quad \text{(eq. 14)}$$

$$V_m = V_{m,ref} - \beta\left(T_{c,ref} - T_c\right) \quad \text{(eq. 15)}$$

In Eq. (14) and (15), $I_{m,ref}$ and $V_{m,ref}$ are the voltage and current at the maximum power point for a reference condition. In Eq. (12), the variable U is the heat transfer coefficient:

$$U = 5.7 + 3.8 * v \quad \text{(eq. 16)}$$

where v is the wind speed. Thus, the exergetic efficiency is the ratio between the difference of electrical and thermal exergy by solar exergy. The thermal exergy is subtracted from the electric exergy, because the heat generated in the process of conversion of solar radiation into electrical energy is rejected, and is not used as a useful product:

$$\varepsilon = \frac{\text{output exergy}}{\text{input exergy}} = \frac{V_m I_m - \left(1 - \frac{T_a}{T_c}\right) U * A(T_c - T_a)}{\left(1 - \frac{T_a}{T_{sol}}\right) G_T * A} \quad \text{(eq. 17)}$$

4. Results

The monthly average estimated for the incident solar radiation on a horizontal surface were compared with experimental average monthly data for the years 2011-2013 for the city of Belo Horizonte/Brazil (provided by INMET as shown in Figure 1).

Fig. 1: Comparison of monthly averages of solar radiation to Belo Horizonte, Brazil

When comparing the values of the solar radiation estimated by the model with standard (TMY) year values, differences of up to 15% are possible. However, the overall performance and average annual are quite close. The standard (TMY) year is defined for a given location. There may occur substantial actual variations from one year to another, as seen in experimental curves obtained for the years 2011, 2012 and 2013 in Fig. 1.

The ambient temperature obtained by the model is shown in Figure 2, and it is compared with the standard year and with experimental data for the years 2011-2013. It is noted that experimental data varied significantly among the analyzed years. When comparing the data obtained by Lorenzo model (1994) and standard year, the data are very close, with maximum differences below 3%.

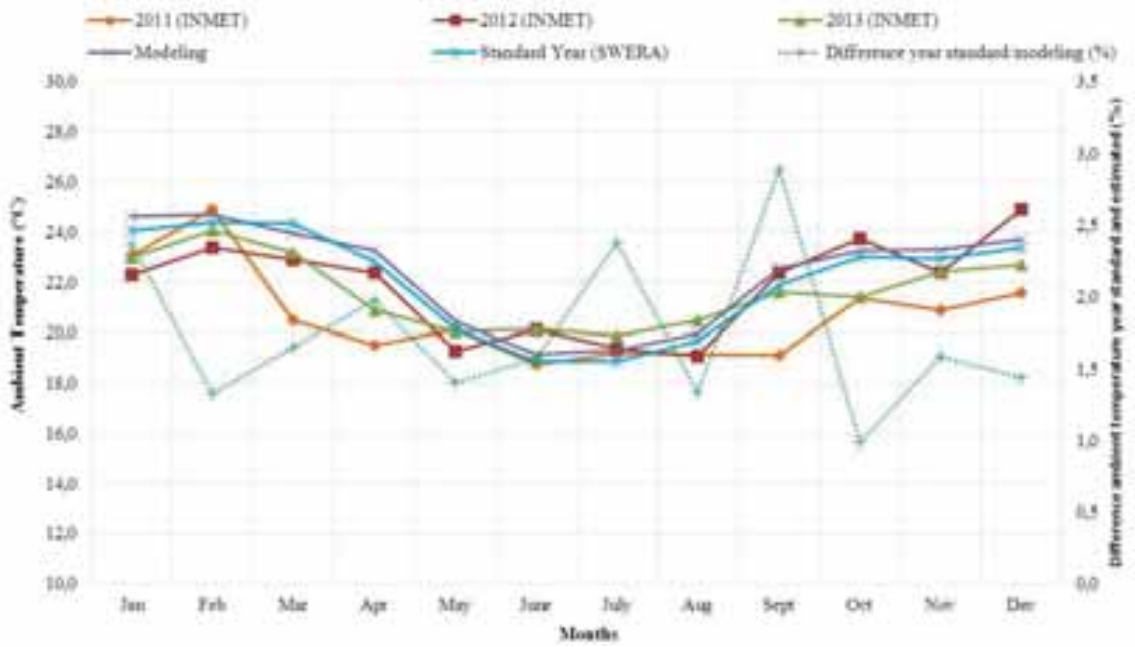

Fig. 2: Comparison of monthly averages of ambient temperature to Belo Horizonte, Brazil

Comparing the data obtained by this model with experimental data and data obtained by the TMY, it is concluded that the results are valid to estimate the performance of the solar radiation and ambient temperature for the city of Belo Horizonte, Brazil. Thus, these results were used as input data for estimating the radiation incident on the inclined photovoltaic modules (β_{in} =20°) and energy and exergy efficiency.

Figure 3 shows the monthly average values of ambient temperature and of solar radiation incident on the plane of the photovoltaic modules inclined (Belo Horizonte, Brazil).

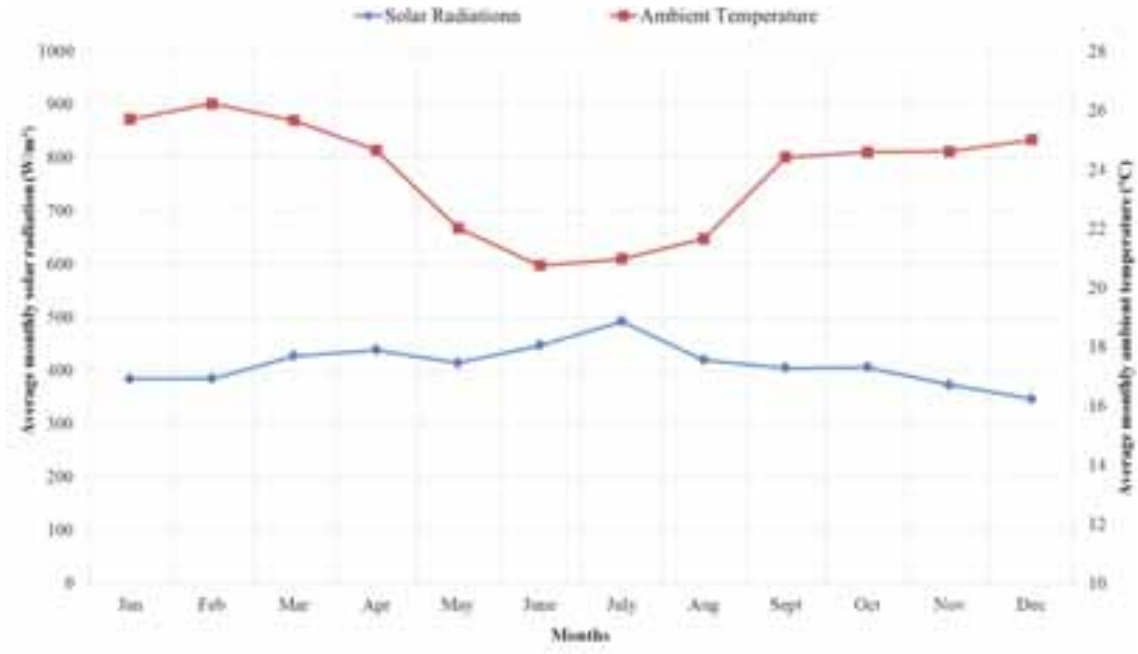

Fig. 3: Monthly average weather conditions for Belo Horizonte, Brazil

The months corresponding to winter in the southern hemisphere (June, July and August) have the lowest average monthly temperature indices—as expected. The months corresponding to summer in the southern hemisphere (December, January, February and March) have higher temperatures and lower values of solar radiation. This behavior can be attributed to both higher levels of atmospheric transparency that occurs in the

winter and the inclination of the modules fixed at 20°. Duffie and Bekman (2006) affirm that for maximize incident of solar radiation in winter, the solar equipment must have inclination equal to the local latitude module.

Figure 4 presents and compares the exergy efficiency of the photovoltaic modules m-Si (190Wp) and p-Si (210 Wp). The exergy due to solar radiation is the maximum work that can be used by the photovoltaic module. When comparing the values obtained for the m-Si and p-Si modules on a particular date, it is clear that the p-Si module presents higher values. The exergy due to solar radiation depends on the environmental parameters (ambient temperature, sun temperature and solar radiation) and the module area. As environmental parameters are the same for both modules, the higher values obtained by the p-Si (210Wp) can be attributed to its larger area. For this module, the temporal variation of exergy depends only on weather conditions. The value of solar exergy depends only of solar radiation and ambient temperature; while the rates of electrical and thermal exergy depend on solar radiation, ambient temperature and wind speed. As the month of July has the highest values of solar radiation, exergies were higher this month compared to the months of December or January.

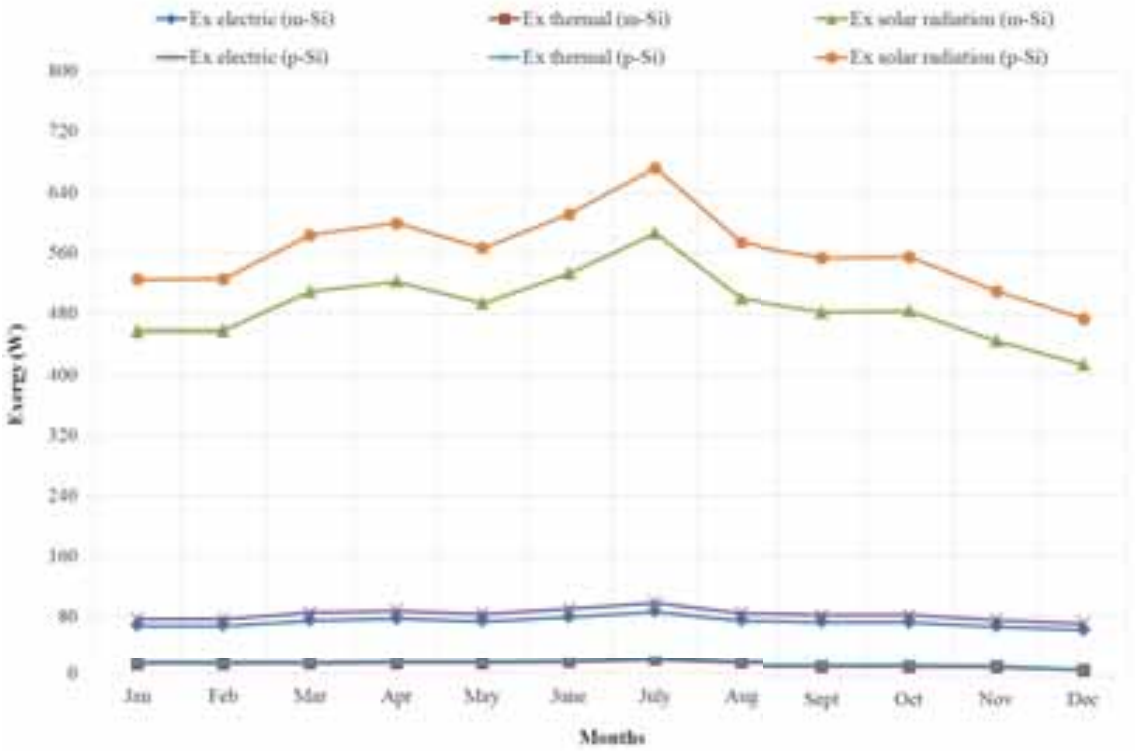

Fig. 4: Monthly averages of electrical and thermal exergias for m-Si and p-Si modules

The thermal exergy reduces the efficiency of the module. This loss can be reduced by minimizing two factors: the operating temperature of the cell and the heat transfer coefficient by convection. The electrical exergy depends on the electrical parameters of each cell and the particular technology. The electrical exergy of the PV modules can be maximized by reducing optical losses (e.g., using cells that absorb different portions oft he solar spectrum, and/or antireflection coatings to increase the photon absorption). Similarly, the value of solar exergy for the p-Si module (210Wp) were higher than m-Si module (190Wp), while the thermal exergy rates were approximately same for both technologies. In addition, the behavior throughout the year is similar for the three values of exergy, with highest values in July (Fig. 4).

The accumulation of dirt and dust are external environmental factors that can significantly affect the performance of photovoltaic modules. Piliougine et al (2013) evaluated the production of polycrystalline power modules with and without anti-soiling coatings. The authors report 12% loss in uncoated modules and 10% having the dust mitigting coating. According to the homogeneity of the distribution of the dust, these

losses can be even greater (e.g., shading can occur). Appels et al (2013) developed an experimental work on photovoltaic modules, and observed losses between 3-4% due to deposition of dirt, even with rain in the review period. The coating modules with non-stick (udst preventing) films contributes to the reduction of accumulation of dirt and minimize losses due to reflection.

Figure 5 shows the monthly average energy and exergy efficiencies for the m-Si module and p-Si module. The monthly average of the energy efficiencies of the m-Si module or the order of 20.0% and for the p-Si module this variation was 18.3%-18.6%. The results of the analysis of the exergetic efficiencies showed an average of 13.0% to 13.8% for the monocrystalline photovoltaic module, and between 12.5 and 13.3% for polycrystalline photovoltaic module (approximately).

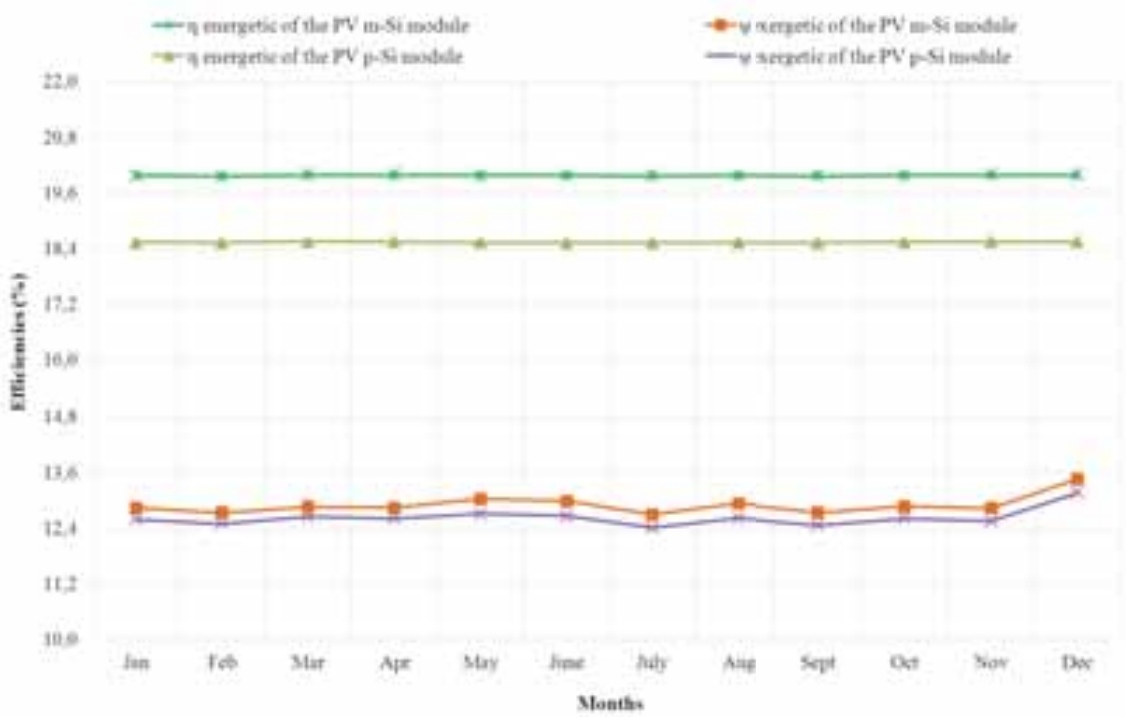

Fig. 5: Monthly averages of energetic and exergetic efficiencies for m-Si and p-Si modules

The polycrystalline module has higher measured power output compared with the monocrystalline module (Fig. 6). However, the area of p-Si module is larger, and has a lower energy efficiency values than the m-Si module. The behavior of the output power curves shown in Fig. 6, is a reflection of influence of the variation of the solar radiation on the output current of the modules These results show that although the input exergy and electrical exergy are higher in p-Si module compared to the m-Si, this is a consequence of the area and the nominal power (current and voltage) difference of the two types. Energy efficiencies and exergetic were higher for m-Si module. This is explained by inherent characteristics oft he m-Si technology that is characterized by less defective material and lower impurity levels than with the polycrystalline technologies. That is, a polycrystalline module would require greater area of the semiconductor for generate the equivalent power of a monocrystalline module because of its lower conversion capabilities.

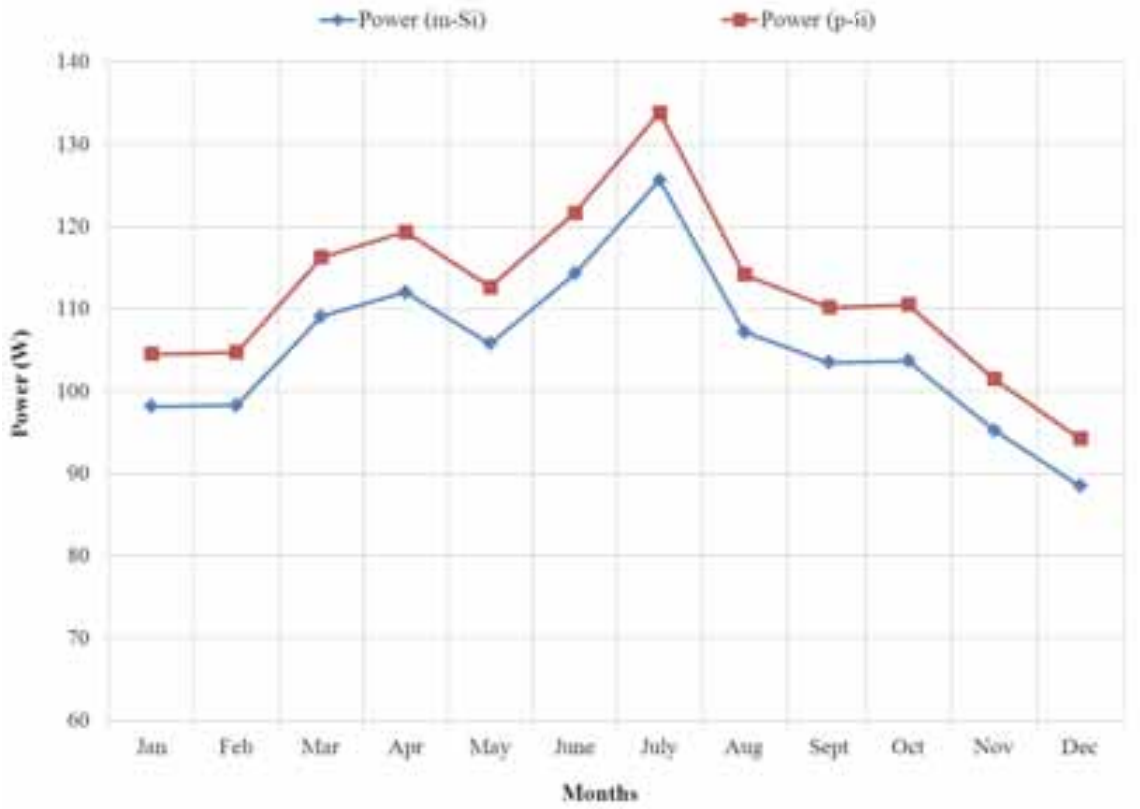

Fig. 6: Monthly average output power of the m-Si and p-Si modules

5. Conclusions

This study derives and uses a model incorporating TMY and PV module nameplate specifications to estimate and compare the energy and exergy efficiencies of photovoltaic of monocrystalline silicon and polycrystalline PV modules operating in the city of Belo Horizonte, Brazil. The module operating parameters were evaluated from mathematical models for solar radiation and temperature. The assessnent of efficiencies provides pathways to increase these values by reducing possible optical losses and the electrical conversion processes. The main losses related to photovoltaic technology are related to heat generation, which in this case is the heat rejected to the environment.

The m-Si module displayed higher values for average annual energy efficiency (19.9%) and exergy efficiency (13.3%). However, its exergy values were lower when compared to the p-Si module. These variations are explained by the energy and exergy differences in area between the module types and the inherent technology characteristics (i.e., the differences in crystalline quality and impurity levels).

Acknowledgments

The authors gratefully acknowledge the generous support of PUC Minas, FAPEMIG, CAPES and CNPq enabling us to perform this research. Also we thank L.L. Kazmerski, visiting research professor at PUC Minas, for his comments and suggestions for the analysis and presentation of this work.

Abstract

This study investigated the heat transfer between air flow and ceramic foam absorber in open air receiver system using dynamics simulation based on Modelica language and Dymola solver. The experimental platforms of air receiver were built to validate the model, and the comparison between the experimental data and the simulation results showed this model was reliable to predict the dynamic performance of the air receiver system and to help optimize this system. The methodology of the model development and the implementation of the experiment are presented in this paper. Relied on the validated air receiver model, the sensitivity studies had been done to explore the influence of the absorber geometric parameters (thickness, mean cell size and porosity) on the volumetric ceramic foam air receiver performances. In addition, the optimization of the foam air receiver with the thermal efficiency as the objective function had been carried out based on the air receiver model and the optimization tool in Dymola.

Keywords: *Air receiver, ceramic foam, dynamic simulation, experimental validation, sensitivity studies, optimization*

1. Introduction

Due to its high concentration ratio and high efficiency, solar thermal power tower (STPT) technology has gained the worldwide attention, which is being vigorously promoted all around the world. The heat transfer fluid (HTF) used in the solar power tower system can be water, molten salt, thermal oils and air (Pavlovic et al., 2012; Romero et al., 2002). Compared with others, air as the working fluid has several advantages, such as no pollution to the environment, no phase transition, high operating temperature, no need for preheating. In the air STPT system, the air receiver plays the most significant role, which converts the concentrated solar radiation into the thermal energy of the air (Behar et al., 2013; Kribus et al., 1998). USA pioneered the first development of air receiver, which is the tube one. Since 1980s, volumetric air receivers started to be researched in Europe. The concentrated radiation flux can penetrate deeper into the volumetric air receiver due to its porosity and large extinction volume, which makes this type of air receiver more flexible than tube receiver (Avila-Marin, 2011). Refer to the material of the absorber in volumetric receiver, metal and ceramic are considered as the most appropriate materials for the high porous structure, especially silicon carbide ceramic, has large surface area, high-temperature capability, low density, and good mechanical strength, which is more suitable to be used in the high temperatures environment (Becker et al., 2006; Chavez and Chaza, 1991; Fend et al., 2004).

A lot of researches have been done numerically to study the silicon carbide ceramic foam using as the absorber in the air receiver. Some studiers focus on the macroscopic properties of the absorber based on certain simplifying assumptions. The influences brought by the air inlet velocity, the absorber porosity, the absorber thickness and mean cell size on the heat transfer performance of the receiver have been researched (Bai, 2010; Wu et al., 2011; Xu et al., 2011). Some other researchers proceed from the microscopic perspectives of the ceramic foam, and they chose to study the local heat transfer between the air flow and the solid of porous ceramic numerically (Wu et al., 2011; Wang and Pan, 2008). There are also some researchers look into the design of the ceramic foam air receiver, the optimum configuration have been found by

doi:10.18086/swc.2015.04.01 Available at http://proceedings.ises.org

comparing the thermal efficiencies and flow instabilities of volumetric absorbers with different configurations (Roldan et al., 2014).

Most researchers among them study the performances of the ceramic foam air receiver using the approaches of CFD simulation and experimental testing. Both of the two methods are time-consuming and not convenience to obtain the performance of the air receiver at all operating conditions. On the one hand, CFD simulation is commonly applied to evaluating the complex internal heat and mass transfer process, the geometry and meshing of the model should be pre-determined, which will bring the difficulty to change the parameters. On the other hand, the experimental testing is very costly to study the performance of the receiver with different designs. Therefore, dynamic modeling stands out to evaluate the sensitivity and do the optimization of the air receiver because of its convenience of changing every parameter. Up to now, some dynamic models were made to simulate the performance of the receiver in molten salt (Ferriere A, 1989) or water/steam (Xu et al., 2011; Yao et al., 2009; Yu et al., 2012) STPT. However, very few studies (Alvarez et al., 2009; Kribus et al., 2001) have focused on the dynamic simulations of the air receiver, which are indispensable for the sensitivity study and optimization on the STPT using air as HTF.

In this study, one-dimensional dynamic simulations are carried out for the ceramic foam air receiver by spatial discretization method. This modeling is based on the Modelica modeling language under Dymola software. Modelica is an object-oriented modeling language, which is freely available and has obtained high attention in recent years (Modelica Association, 2012). The ThermoSypro Library of EDF (developed by EDF and released under open source license) was used in the modeling, and the basic elements model of thermal Engineering are embodied in the ThermoSypro Library.

In order to validate the dynamic model of the air receiver, an experimental platform was set up. The receiver outlet air temperature from the experimental measurements and simulation results are compared, which shows good agreement between them.

Based on this validated air receiver model, the sensitivity studies have been done to explore the effects of the absorber geometric properties (thickness, mean cell size and porosity) on the volumetric air receiver performances. The temperature distributions for the absorber with different geometric properties are analyzed in this article. Moreover, built on the foundation of the optimization function in Dymola software, the optimal solution of geometric properties has been found with the thermal efficiency as the objective function.

Nomenclature

A	absorber surface area(m^2)	Re	Reynolds number
Cp	heat capacity (J kg^{-1} K^{-1})	T	temperatures (K)
d	mean cell diameter of the ceramic foam (m)	t	time (s)
DNI	direct normal irradiance (W m^{-2})	U	internal energy per unit volume (J m^{-3})
h	specific enthalpy(J kg^{-1})	u	superficial velocity (m s^{-1})
h_v	mean volumetric heat transfer coefficient (W m^{-3} K^{-1})	x	x-directional coordinate (m)
K_1	permeability coefficient (m^2)	y	y-directional coordinate (m)
K_2	inertial coefficient (m^{-1})	Greek symbols	
k	thermal conductivity (W m^{-1} K^{-1})	ε	porosity
L	thickness (m)	δ	Stephan Boltzmann constant (W m^{-2} K^{-4})
Nu_v	Nusselt number based on h_v	β	Rosseland mean extinction coefficient (m^{-}

			^{1})
P	pressure (Pa)	μ	dynamic viscosity (kg m^{-1} s^{-1})
q_{in}	radiation energy at inlet (W m^{-2})	ρ	density (kg m^{-3})
q_f	fluid mass flow per unit area (kg s^{-1} m^{-2})	Subscripts	
		f	fluid
q_{rad}	solid radiation force (W m^{-2})	s	solid
Q	inlet air superficial velocity (Nm^3/h)	in	inlet
$S(y)$	radiation source (W m^{-2})	out	outlet

The schematic of air receiver physical model is shown in Fig.1, where (a) is the configuration of the receiver including the insulation and ceramic foam absorber while (b) is the size and coordinate.

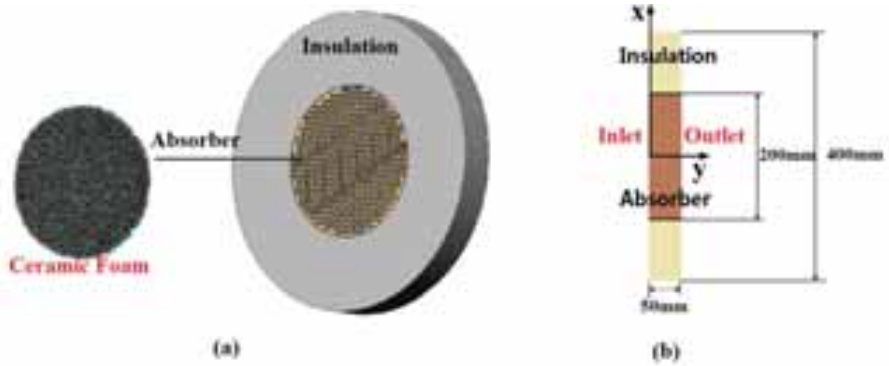

Fig. 1: Schematic of air receiver physical model: (a) configuration and (b) size and coordinates

Due to the difficulty of multidimensional simulation based on Modelica /Dymola, one dimension model was established by spatial discretization along the air flow direction (y-axis direction). The insulation was ignored in this model.

Air properties were defined as temperature dependent in this model, including the heat capacity, the density, the viscosity and the thermal conductivity because of the high working temperature of the receiver.

2.2. Numerical model

The following assumptions are made in order to simplify the problem. (1) The ceramic foam absorber is isotropic. (2) The air mass flow and the solar incident radiation flux are uniform on the surface of the absorber. (3) The heat insulation of the receiver is very well and the heat loss from the cylindrical out surface is ignored.

For spatial discretization, a number of sections are divided along the fluid flow direction. The energy conservation of section i is represented in Fig.2, including the conductive heat transfer inside air, the radiative and conductive heat transfer of the internal solid, the convective heat transfer between air and solid, and the penetrating solar energy source. Moreover, the convective and radiative heat losses at the air entrance surface are also embodied in the first section.

The energy conservation equations of solid and fluid are presented in eq. 1 and eq. 2, respectively.

For solid:

$$\frac{\partial\left[(1-\varepsilon)\cdot k_s\cdot\frac{\partial T_S}{\partial y}\right]}{\partial y}-\frac{\partial q_{rad}}{\partial y}-h_v\cdot(T_s-T_f)+\frac{\partial S(y)}{\partial y}=\rho_s\cdot(1-\varepsilon)\cdot Cp_s\cdot\frac{\partial T_S}{\partial t} \quad \text{(eq. 1)}$$

For fluid:

$$\frac{\partial\left(\varepsilon\cdot k_f\cdot\frac{\partial T_f}{\partial y}\right)}{\partial y}+h_v\cdot(T_s-T_f)-\frac{\partial(q_f\cdot h_f)}{\partial y}=\frac{\partial U_f}{\partial t}\cdot\varepsilon \quad \text{(eq. 2)}$$

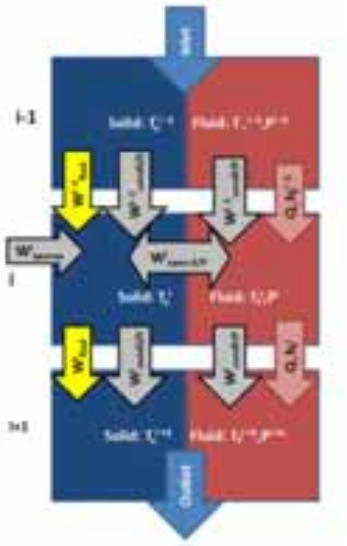

Fig. 2: Energy balance in absorber

In the equations, *S(y)* stands for the distribution of concentrated radiation flux inside the ceramic foam absorber as an exponential decay displayed in eq. 3 (Coquard et al., 2009). U_f represents the air internal energy expressed by eq. 4. q_{rad} means the radiation heat transfer in solid which plays a significant role as the absorber working at high temperature. According to the Rosseland radiation model, q_{rad} is determined using Eq. (5) (Cherif and Sifaoui, 2005; Zhao et al., 2004). β is the extinction coefficient of the ceramic foam, which can obtained by eq. 6 (Petrasch et al., 2007).

$$S(y) = q_{in} \cdot e^{-(\beta \cdot y)} \quad \text{(eq. 3)}$$

$$\frac{\partial U_f}{\partial t} = \left(\rho_f + h_f \cdot \frac{\partial \rho_f}{\partial h_f}\Big|_p\right) \cdot \frac{\partial h_f}{\partial t} + \left(h_f \cdot \frac{\partial \rho_f}{\partial P}\Big|_{h_f} - 1\right) \cdot \frac{\partial P}{\partial t} \quad \text{(eq. 4)}$$

$$q_{rad} = -\frac{16\delta \cdot T_s^3}{3\beta} \cdot \frac{\partial T_s}{\partial y} \quad \text{(eq. 5)}$$

$$\beta = \frac{0.56}{d} \quad \text{(eq. 6)}$$

The volumetric convective heat transfer coefficient between the air and the solid (h_v) is defined as a variation with the Nusselt number as eq. 7， which can be derived from eq. 8 and eq. 9 (Fu et al., 1998).

$$h_v = Nu_v \cdot \frac{k_f}{d^2} \quad \text{(eq. 7)}$$

$$Nu_v = \left(0.0426 + 1.236\frac{d}{L}\right) \cdot Re \quad \text{(eq. 8)}$$

($2 < Re < 836$)

$$Re = \frac{d \cdot u_f \cdot \rho_f}{\mu_f} \quad \text{(eq. 9)}$$

The expression of the pressure loss in the absorber is shown in eq. 10 – eq. 12 according to the classic Darcye-Forchheimer law (Moreira et al., 2004).

$$-\frac{\Delta P}{y} = \frac{\mu_f}{K_1} \cdot u_1 + 0.5K_2 \cdot \rho_f \cdot u_f^2 \quad \text{(eq. 10)}$$

$$K_1 = \frac{d^2}{150} \cdot \frac{\varepsilon^3}{(1-\varepsilon)^2} \quad \text{(eq. 11)}$$

$$K_2 = \frac{3.5}{d} \cdot \frac{1-\varepsilon}{\varepsilon^3} \quad \text{(eq. 12)}$$

Besides, the functions in ThermoSypro Library are used to obtain the variations of air's physical parameters, such as the heat capacity, the density, the viscosity and the thermal conductivity with corresponding air

temperatures and pressures.

3. Experimental validation

The experimental platform was set up in Badaling solar thermal power experimental base of China for validating the receiver model. The schematic diagram and one photograph of the experimental system are depicted in Fig. 3, and the system is compose of the solar furnace, air receiver, cooling device, draught fan and measuring devices. Air receiver of 200mm length is the key component of the system, which consists of the 50mm absorber, the 150mm cavity for air flow mixing, the insulation layer and the supporting component. The cooling device was used to cool the hot air to protect the draught fan and other devices, which was made up of a tank of honeycomb ceramic bulks.

Two thermocouples were installed on the central axis of the receiver 160 mm and 180 mm behind the front surface of the absorber to measure the receiver outlet air temperature. Since the input solar flux was not uniform, the air temperature distribution inside the absorber was not uniform in the radial direction. However, the air leaving the absorber was assumed to be thoroughly mixed 150 mm behind the front surface of the absorber which can be proved by that the temperatures of the two thermocouples differed by less than 5 K. Thus, the average temperature of these two thermocouples was used as the experimental receiver outlet air temperature.

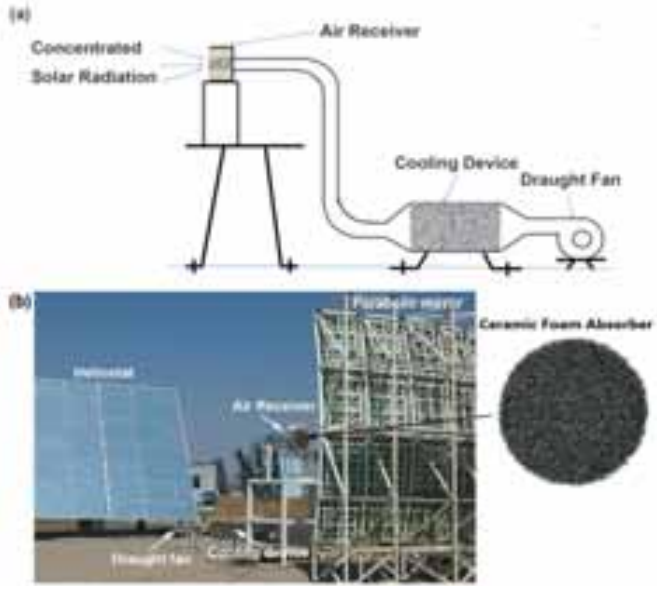

Fig. 3: Experiment system of air receiver: (a) schematic diagram and (b) system photograph

The solar radiation flux at the air receiver inlet surface is determined by the data tested through the "charge coupled device (CCD) camera + moving bar" indirect measurement, which is used as the inlet boundary condition in the dynamic simulation. The porosity, mean cell size, and thickness of the ceramic foam absorber are 0.65, 2.5 mm and 50mm, respectively. The air mass flow during the experiment was adjusted at 60Nm^3/h (the inlet air superficial velocity is 0.53m/s). The parameters of the absorber and the inlet air superficial velocity used in the dynamic simulation were set identical to the values in the experiment. The comparison between experimental measurements and simulation results of the air temperature at receiver outlet is shown in Fig. 4. The upper curve presents the DNI (direct normal irradiance) during the experiment time. DNI, solar radiation flux and air mass flow are the three inputs of the simulation model, which are achieved from the experiments. The receiver outlet air temperatures over time, obtained from experiment and simulation result, are depicted in the below diagram. We can see that the simulated outlet air temperature is in appreciable agreement with the experimental data, both of which show gentler variations than DNI. It can be concluded that the error between the two curves is less than 10%, mainly due to the limitations of the 1-D approach for the 3-D process, the discretization and round-off errors in the calculations, the uncertainties in the heat transfer coefficient model and radiation transfer functions and the measurement errors in the vortex

flow meter and the thermocouples. The vortex flow meter, model LUGBZ-40, had an accuracy of ±1.5% FS according to the manufacturer and the K type thermocouples used in the experiment had accuracies of ±2.5 K within the measurement range of 300-1000 K. Compared to experiments, using dynamic modeling approach can be more applicable for the investigation and optimization of the air receiver since it is more convenient to change the date of the receiver parameters such as the thickness, the mean cell size and the porosity.

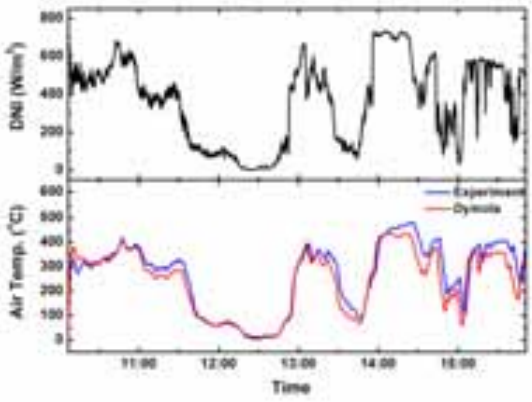

Fig. 4: Comparison between experimental measurements and simulation results of the outlet air temperature in air receiver system

4. Sensitivity studies

In order to research the influence of the structure of the absorber, we conducted a series of sensitivity study of the thickness, the mean cell size and the porosity of the ceramic foam absorber. The validated air receiver model described in this paper is the fundamental of these sensitivity studies. The inlet air superficial velocity is set as a constant value of 0.53m/s, and the inlet air temperature is 20°C. Also, we fix the concentrated solar radiation flux as 500 kW/m^2 in all the cases of this section. Under the same inlet air superficial velocity, inlet air temperature and incident energy flux, the thermal efficiencies for different cases can be reflected by the corresponding outlet air temperatures.

4.1. Effects of thickness

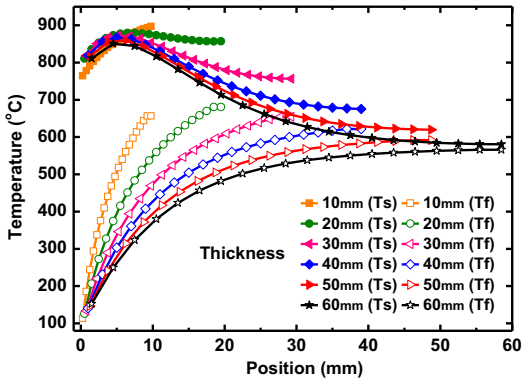

Fig. 5: The temperature distributions for different thicknesses

Fig. 5 shows the steady-state temperature distributions of the solid and fluid phase with different thickness but same porosity and mean cell size of the absorber (d = 3mm, ε = 0.5). As described in this figure, when the thickness is greater than 20mm, the fluid temperature decreases with the increasing of the thickness. Since the input power is fixed, the increase of the thickness will bring the decrease of the average volumetric heat power, which will reduce the fluid temperature. Another reason is that the volumetric convective heat transfer coefficient between the air and the solid will decrease with the increasing of the thickness, due to eq.

8, and it will decrease the heat exchange ability between air and solid. From the figure, we also can see the solid temperature at the outlet decreases with the increasing of the thickness. The reason is that the solid thermal resistance increases with the increasing of the thickness, which causes the large temperature drop of the solid. In addition, the temperature difference between the solid and air at the outlet decreases with the increasing of the thickness, that because the thicker the absorber is , the longer the heat exchange time and distance between fluid and solid are.

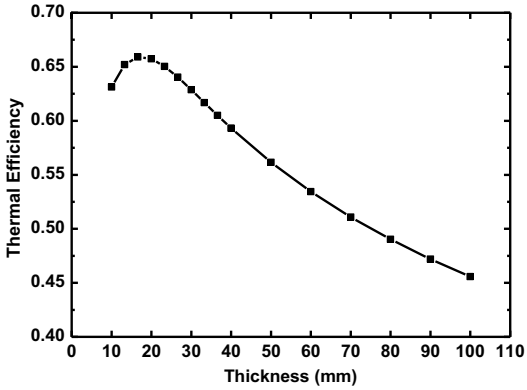

Fig. 6: The thermal efficiencies for different thicknesses on steady state

Fig. 6 is the thermal efficiencies at steady state with different absorber thicknesses but same porosity and mean cell size of the absorber (d = 3mm, ε= 0.5). It is can be seen in this figure, the thermal efficiency increases firstly and then decreases with the increasing of thickness, which comes highest when the thickness is 18mm. As mentioned before, the thermal efficiencies can be reflected by the outlet air temperatures under the same inlet air superficial velocity, inlet air temperature and incident energy flux, as eq.13. When the absorber thickness is rather small, the time of the air flow through the absorber will be very short, which caused the insufficiency of the heating and the reduction of the air outlet temperature. And also if the thickness is small enough, the solar radiation energy will penetrate out of the absorber, which will bring more heat loss. When the thickness is greater than 18mm, the fluid temperature will decrease with the increasing of the thickness. One reason is that the increasing of the thickness brings the reduction of the volumetric convective heat transfer coefficient between the air and the solid, as eq. 8, and the heat exchange ability between air and solid will drop. Another reason is that the solid temperature at the outlet decreases with the increasing of the thickness.

$$\eta = \frac{Q\cdot\left[\left(h_{f\,out}-\frac{P_{out}}{\rho_{f\,out}}\right)-\left(h_{f\,in}-\frac{P_{in}}{\rho_{f\,in}}\right)\right]}{q_{in}\cdot A} \qquad \text{(eq. 13)}$$

4.2. Effects of mean cell size

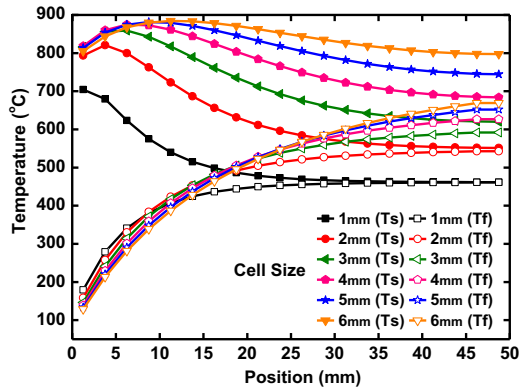

Fig. 7: The temperature distributions for different mean cell sizes

Fig. 7 shows the temperature distributions of the solid and fluid phase with same thickness and porosity of the absorber (L = 50mm, ε = 0.5) but different thickness at steady state. It can be seen in this figure that both the solid and fluid temperatures increase with the increasing of the mean cell size. According to eq. 6, the extinction coefficient of the absorber is inversely proportional to the mean cell size, means the bigger the mean cell size is, the small the extinction coefficient is, the more solar energy will penetrate into the absorber, which makes the increasing of the solid and fluid temperatures. From Fig. 7, we also can see the temperature difference between the solid and air at the outlet increases with the increasing of the mean cell size. The reason is that the volumetric convective heat transfer coefficient between the air and the solid decreases with the increasing of the mean cell size, as eq. 7.

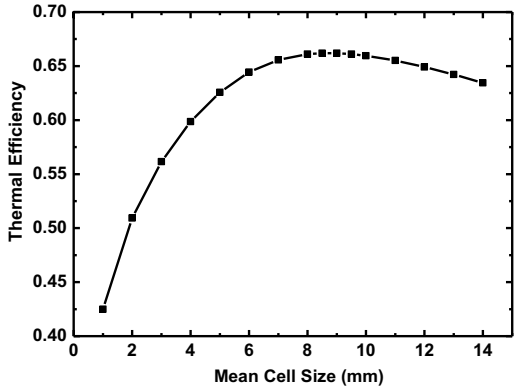

Fig. 8: The thermal efficiencies for different mean cell sizes on steady state

Fig. 8 is the thermal efficiencies at steady state with different mean cell sizes but same thickness and porosity of the absorber (L = 50mm, ε = 0.5). It is can be seen in this figure, the thermal efficiency increases first and then decreases with the increasing of mean cell size, which comes highest when the mean cell size is 8mm with the fixed inlet air superficial velocity, inlet air temperature, incident energy flux, absorber porosity, and absorber thickness. The reason is that when the mean cell size of the absorber is too big, the volumetric convective heat transfer coefficient between the air and the solid will be very small, and the heat exchanging capacity between air and solid will become weak, which will cause the decreasing of the air outlet temperature.

4.3. Effects of porosity

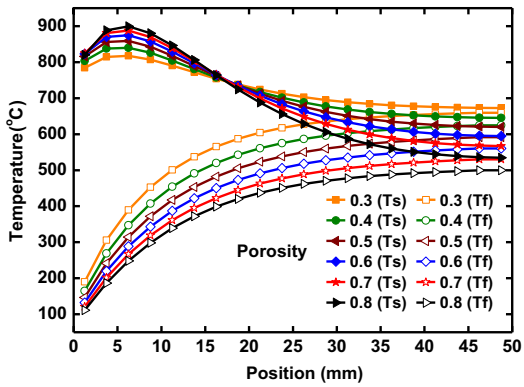

Fig. 9: The temperature distributions for different porosities

Fig. 9 shows the steady-state temperature distributions of the solid and fluid phase with different porosities but same thickness and mean cell size of the absorber (L = 50mm, d= 3mm). As we can see, the front solid temperatures of the absorbers with large porosities are higher than the temperatures of the absorbers with small porosities while the rear solid temperatures of the absorbers with large porosities are lower at the same position. The reason is that the solid of the absorber with large porosity is lighter, thus, the temperature of the

front solid is higher for absorbing the same incident energy. On the other side, the higher front temperature brings more heat loss on the surface of the receiver. It results in the reduction of the total energy penetrate into the receiver system, which makes the temperatures of the rear solid and the fluid relatively lower. The figure also shows that the solid temperature gradient of the absorber with large porosity is greater, which is owing to the larger solid thermal resistance. The larger the porosity is, the smaller the solid cross-sectional area is, and the larger the solid thermal resistance is. Furthermore, what we also can obtain from Fig. 9 is that the temperature difference between the solid and air at the outlet increases with the increasing of the porosity. The reason is that the lower air temperature makes the Reynolds number and the thermal conductivity decrease. According to eq. 7-eq. 9, the volumetric convective heat transfer coefficient between the air and the solid decreases with the lower air temperature, this makes the temperature difference between the solid and air at the outlet increases with the increase.

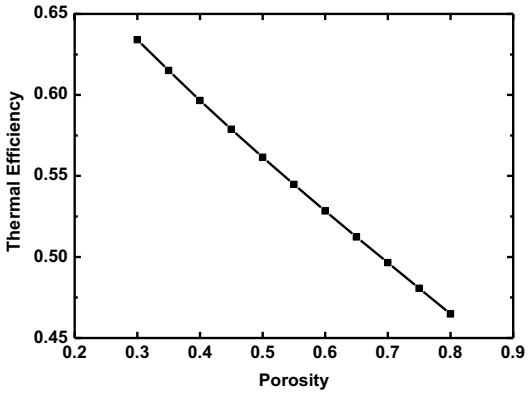

Fig. 10: The thermal efficiencies for different porosities on steady state

Fig. 10 is the thermal efficiencies at steady state with different porosities but same thickness and mean mean cell size of the absorber (L= 50mm, d= 3mm). It is can be seen in this figure, the thermal efficiency decreases with the increasing of the porosity. As explained before, larger porosity brings smaller solid cross-sectional area and larger thermal resistance in solid. And the larger thermal resistance causes greater temperature gradient in the solid, which results in the lower outlet solid and air temperatures. According to eq.13, the thermal efficiency also decreases with the increasing of the porosity as the outlet air temperature under the same inlet air superficial velocity, inlet air temperature and incident energy flux. Despite the smaller porosity can bring the greater the thermal efficiency, but considering the pressure drop and manufacture feasibility issues, the porosity should be kept in an appropriate range.

For the purpose of studying the influential factors of the heat transfer in the ceramic foam, the return air system is not considered in the model, which plays an important role in integrity and performance of open volumetric air receiver. Thus, the above-mentioned observations will be extended into the open volumetric air receiver integrated with the air return loop, based on the updated model in the future.

5. Optimization

The outlet air temperature and thermal efficiency at steady state are the most important indicators of air receiver performance, both of which are decided by the following five parameters: the solar radiation flux, the inlet air superficial velocity, the absorber thickness, the absorber mean cell size and the absorber porosity. In this section, we conduct the optimization of the air receiver system (without air return system) based on the air receiver model established in this article, and with the help of the optimization tool in Dymola software. Limited by the function of the Dymola software, we can only do the optimization on three parameters at most. Therefore, firstly we choose several different cases depend on the different solar radiation fluxes and inlet air superficial velocities. For each case, the optimal absorber geometric parameters (thickness, mean cell size and porosity) to achieve the maximum thermal efficiency are found, respectively. Table 1 shows the setting of the optimized parameters. Taking into account the feasibility of the manufacture, we define the ranges of these three parameters.

Tab. 1: Parameter setting of the optimization

Parameter	Minimum	Maximum	Unit
Thickness	10	100	mm
Mean cell size	1	6	mm
Porosity	0.3	0.8	1

Table 2 shows the optimization results under the same inlet air superficial velocity, as 0.53m/s, but with different solar radiation fluxes. As we can see, for various solar radiation fluxes, the optimized values of the absorber geometric parameters are the same. The highest outlet air temperature of the receiver increases with the increasing of the solar radiation flux, while the maximum thermal efficiency decreases with the increasing of the solar radiation flux.

Tab. 2: Optimization result with different solar radiation fluxes and fixed inlet air superficial velocity

Inlet air superficial velocity: 0.53m/s					
Solar radiation flux (kW/m^2)	400	450	500	550	600
Thickness (mm)	24.86	24.86	24.86	24.86	24.86
Mean cell size (mm)	4.09	4.09	4.09	4.09	4.09
Porosity	0.3	0.3	0.3	0.3	0.3
Pressure drop (Pa)	3753.70	3995.29	4222.97	4437.31	4639.05
Highest outlet air temperature (^{o}C)	618	674	727	775	821
Maximum thermal efficiency	0.737	0.722	0.707	0.692	0.677

Table 3 shows the optimization results under different inlet air superficial velocities, but with same solar radiation flux (500 kW/m^2). It can be seen from the table, for various inlet air superficial velocities, the optimized values of the absorber geometric parameters are almost the same. The highest outlet air temperature of the receiver decreases with the increasing of the inlet air superficial velocity, while the maximum thermal efficiency decreases with the increasing of the inlet air superficial velocity.

Tab. 3: Optimization result with different inlet air superficial velocities and fixed solar radiation flux

Solar radiation flux: 500 kW/m^2					
Inlet air superficial velocity (m/s)	0.35	0.44	0.53	0.62	0.71
Thickness (mm)	26.04	24.49	24.86	24.49	25.45
Mean cell size (mm)	4.06	4.11	4.09	4.11	4.07
Porosity	0.3	0.3	0.3	0.3	0.3
Pressure drop (Pa)	2514.22	3188.98	4222.97	5133.03	6558.83
Highest outlet air temperature (^{o}C)	870	772	727	628	564
Maximum thermal efficiency	0.608	0.681	0.707	0.751	0.771

Since the optimal geometric parameters for various solar radiation fluxes and inlet air superficial velocities are almost the same, we fixed the thickness, the mean cell size and porosity of the ceramic foam absorber as 25mm, 4.09 mm and 0.3, respectively; and we do the optimization of the solar radiation flux and inlet air superficial velocity to find the optimum condition to obtain the maximum thermal efficiency on the premise of the outlet air temperature is 800 ^{o}C. In consideration of the concentration ratio and the pressure loss, the ranges of the solar radiation flux and inlet air superficial velocity are limited as 0-2 m/s and 0-2000 kW/m^2. The result in Table 4 represents that when the solar radiation flux is 1825 kW/m^2 the inlet air superficial velocity is 1.75m/s, the maximum thermal efficiency of 0.769 can be achieved.

Tab. 4: Optimization result with fixed absorber geometric parameters and outlet air temperature

Thickness: 25mm, mean cell size:4.09mm, porosity:0.3, outlet air temperature: 800 ^{o}C			
Solar radiation flux (0-2000 kW/m2)	Inlet air superficial velocity (0-2 m/s)	Maximum thermal efficiency	Pressure drop (Pa)
1825 kW/m^2	1.75m/s	0.769	67885

The corresponding pressure drops are also depicted in the optimization result tables, which agree with the results in (Bai, 2010). The pressure drop in the ceramic foam is not the research emphasis of this paper.

6. Conclusions

In this article, the dynamic simulation model of ceramic foam open-loop air receiver, which is the most principal components in STPT using air as the HTF, was established using the object-oriented language Modelica based on Dymola simulation environment. The experiments of the air receiver had been carried out for the model validation, and the simulation results agree well with the experiment data. The sensitivity studies show that the absorber geometric properties (thickness, mean cell size and porosity) have distinct influences on the solid and fluid temperature distributions and the thermal efficiencies of the ceramic foam air receiver. The combination values of the absorber mean cell size, porosity, thickness, solar radiation flux and inlet air superficial velocity in certain ranges to achieve the highest thermal efficiency on the premise of the outlet air temperature is 800 ^{o}C were found by the optimization method using the receiver model.

In conclusion, this experiment validated model is reliable to predict the dynamic performance of the ceramic foam air receiver and can be used for receiver optimization in different STPT systems using this type of air receiver.

Abstract

Zirconium carbide-nitride absorber (ZrC-ZrN) and zirconium reflector tandem structures were prepared on glass and aluminum substrate, in conjunction with zirconium oxide (ZrO_x) anti-reflection coatings, using DC/RF magnetron sputtering system. The solar absorption properties of zirconium carbide-nitride absorber layers were optimized by controlling nitrogen flow during synthesis process for optimal solar thermal response. X-ray diffraction (XRD), scanning electron microscopy (SEM) and atomic force microscopy (AFM) measurements were carried out on fabricated absorber-reflector tandem structures to understand the structure-property correlation. We absorbed strong dependence of zirconium nitride fraction on solar thermal performance. We observed enhanced solar absorptance $\alpha \sim 0.86$ and thermal emittance $\varepsilon \sim 0.05$ at room temperature for structures fabricated with optimized synthesis parameters. The optimized structures are stable up to 150 °C in the air without any significant degradation in their solar performance.

1. Introduction

Solar thermal energy is getting attention due to its potential as compared to the other renewable energy resources. This can be used in various forms such as low temperature applications, e.g. solar water heating applications, intermediate and high temperature applications e.g. process heating (Mekhilef et al., 2011), power applications (Selvakumar and Barshilia, 2012). Such systems usually consist of several sub-systems such as collection/concentration of light, absorption/conversion of light into thermal energy and utilization to convert into electrical energy or for other application. The light to thermal energy conversion subsystem consists of special collection tubes, called as solar collectors (Kalogirou, 2004; Selvakumar and Barshilia, 2012). These collectors are coated with spectrally selective coatings, having a high absorptance in the wavelength range of 0.3- 2.5 μm and low emittance in wavelength range 2.5 to 25 μm in the mid to higher operating temperature ranges (Seraphin, 1997). The development of thermally stable solar selective coating is important for the maintenance free continuous operation of solar thermal systems/subsystems. There are continuous efforts to develop such material systems, which can withstand temperature, environmental conditions, and large thermal cycling for efficient photothermal conversion. Numerous solar selective coatings are developed using physical vapor deposition for mid-temperature (100 °C < T < 400 °C) applications. Some of them are commercialized successfully. For example, Zhang et al. developed SS-Al coatings using DC magnetron sputtering, with absorptance in the range of 0.93 - 0.96 and emittance of ~ 0.03 - 0.04 at room temperature. These are thermally stable upto 1h at 500 °C in vacuum (Zhang et al., 1998a, 1998b) and are used on evacuated glass tubes for solar hot water and steam applications. Lazarov's group

doi:10.18086/swc.2015.04.02 Available at http://proceedings.ises.org

developed TiN_xO_y oxynitride coatings with SiO_2 antireflection coatings on Cu and Al substrates with α=0.94 and ε=0.04 at 100 °C (Lazarov, 1993). S-Solar, Sweden, developed Ni-NiO metal-dielectric composite based absorber coating on Al substrates, with absorptance in the range 0.94-0.96 and thermal emittance of 0.13-0.15 at 100 °C for low temperature applications (Wackelgard and Hultmark, 1998). Electrodeposited black Chrome ($Cr-Cr_2O_3$) cermet coatings on Ni, Fe, Cu, stainless-steel substrate are developed and commercialized by by MTI in the United State and several other research and development groups (Bogaerts and Lampert, 1983; McDonald, 1975; Driver, 1981; Ignatiev et al., 1979; Smith et al., 1984; Sweet et al., 1984; Lampert, 1980; Holloway et al., 1980). H.C. Barshilia et al. developed $Cr_xO_y/Cr/Cr_2O_3$ transition metal oxide based multilayer absorber on Cu substrates for mid-temperature applications, exhibiting high absorptance (0.89-0.91) and low emittance at 82 °C (0.05-0.06) (Barshilia et al., 2008). N. Selvakumar et al and Vannoni et al have developed CrMoN/CrON tandem absorber on SS substrate with high absorptance (0.90 - 0.92) and low thermal emittance (0.13 - 0.15) for mid-temperature applications (Selvakumar et al., 2013, Vannoni et al., 2008). Yet such systems exhibit poor performance at elevated temperatures, especially thermal emittance at elevated temperatures, causing thermal loss in solar thermal systems. The oxidation of the metal content is the main reason for degradation of optical and thermal response in these cermet structures (Barshilia et al., 2008; Sebastian et al., 1997). Alike such oxide cermet structures, refractory metal carbo-nitride absorber systems may show significant improvement in their thermal stability in conjunction with their solar thermal performance. Considering the same, we investigated the solar thermal performance of zirconium carbide-nitride absorber- zirconium reflector tandem structures with zirconium oxide antireflection coating layer on glass and aluminum substrates.

2. Experimental details

The zirconium carbo-nitride absorber- zirconium reflector tandem structures were deposited on glass and aluminum substrate using DC/RF reactive magnetron sputtering. High purity (99.8%) zirconium (Zr) metal and (99.9%) ZrC targets were integrated with 4'' magnetron sputter gun for depositing Zr metal reflector, zirconium carbo-nitride absorber and zirconium oxide antireflecting coatings on glass and aluminum (Al) substrates. The glass substrates (25 x 76 x1 mm^3) were ultrasonically cleaned for 5 min in acetone and ethanol baths, respectively, without any mechanical polishing. Aluminum substrates were first mechanically polished with 2000 grade SiC abrasive paper to remove oxide layer and to reduce surface roughness, followed by ultrasonic cleaning in isopropyl alcohol and acetone for 10 minutes respectively. These cleaned substrates were used for fabricating the solar selective coating structures. The base pressure of deposition chamber was brought down ~ 6.0 x 10^{-6} mbar and sputtering processes were carried out at a constant working pressure ~ 2.0 x 10^{-2} mbar. The targets were pre-sputtered for ~15min before deposition of respective layers to clean any surface impurities such as oxide layers and process impurities. The detailed experimental process for deposition of individual layers is explained elsewhere (Usmani et al., 2015). Crystal phases and structure, microstructure and surface properties and elemental composition of the synthesized zirconium carbo-nitride absorber- zirconium reflector tandem structures in conjunction with zirconium oxide antireflection films were measured using X-ray diffraction (XRD), scanning electron microscope (SEM), atomic force microscope and X-ray energy dispersive system measurements. The reflectance spectra were measured in wavelength range (0.3 to 2.5 μm) by using Carry 5000 UV-Vis-NIR spectrophotometer in conjunction with standard Spectralon reference. The absorptance α was calculated using these measured reflectance spectra with respect to AM 1.5 solar spectrum. FTIR reflectance measurements were carried out in wavelength range (2.5 to 25 μm) and used to calculate the room temperature thermal emittance, ε. The thermal stability of these structures was studies by heating samples at ~ 150 °C for 2 hours at a constant heating rate ~ 5 °C/min, followed by free cooling to the room temperature. Thermal impact was investigated characterizing the structural/microstructural changes to understand the structure-property correlation on solar thermal performance on these zirconium carbo-nitride absorber-reflector structures.

3. Results and discussions

3.1 X-ray diffraction analysis

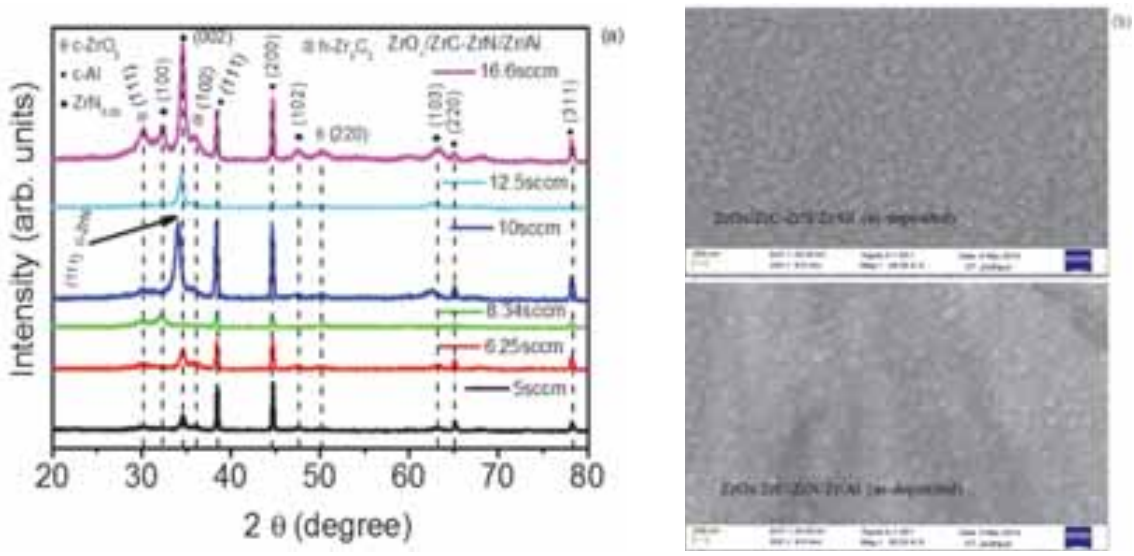

Fig. 1: (a) XRD spectra of ZrO_x/ZrC-ZrN/Zr absorber-reflector tandem selective coatings on aluminum substrate for different N_2 flow rates used for ZrC-ZrN absorber layer. **(b)** SEM images of ZrO_x/ZrC-ZrN/Zr absorber-reflector tandem structure deposited on aluminum and glass substrates.

The XRD pattern of ZrO_x/ZrC-ZrN/Zr absorber-reflector tandem selective coatings coated on Al substrate are shown in Fig. 1(a), with varying nitrogen flow rates used for synthesizing these structures. The diffraction peaks at 2θ = 38.42°, 44.74°, 65.07° and 78.22° correspond to (111), (200), (220) and (311) reflection plane from the aluminum substrate in all these XRD graphs. A strong peak at 2θ = 34.57° and weak peaks at 2θ = 32.39°, 47.57° and 63.18° correspond (002) and (100), (102), (103) diffraction planes for hexagonal zirconium nitride (h-$ZrN_{0.28}$) phase, respectively. Whereas, weak diffraction peak at 2θ = 36.09° correspond to (102) hexagonal zirconium carbide (h-Zr_3C_2) phase. The measured volume fraction of zirconium nitride is much larger than that of zirconium carbide suggesting a carbide system in nitride matrix. XRD results, for absorber-reflector tandem structure on glass substrates, are similar to that on aluminum substrates except Al substrate XRD pattern. XRD results on glass substrates, also substantiate larger zirconium nitride volume fraction in fabricated structures. Anti-reflecting ZrO_x layer exhibit mixed phase with dominating tetragonal zirconium oxide phase, as indexed in Fig. 1(a) (top panel). ZrO_x top layer scanning electron micrographs are shown in Fig. 1(b) for as deposited absorber-reflector tandem structures on glass and aluminum substrates. As deposited surfaces are smooth for both aluminum and glass substrates with micro granular structures ~ 100 nm, as shown in Fig. 1(b). In contrast to glass substrates, the surface structure of absorber-reflector tandem structures on Al substrates consists of substrate imprints and average surface roughness is ~ 10 ± 2 nm for both substrates.

3.2 Optical properties

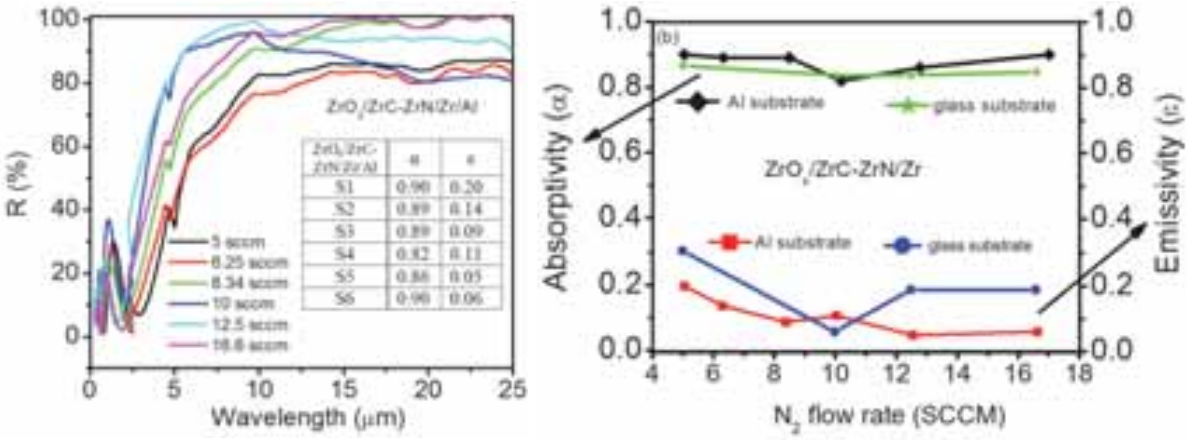

Fig. 2: (a) Reflectance spectra of absorber-reflector tandem selective coating deposited on aluminum substrate with varying nitrogen flow rate. **(b)** Calculated absorptance (α) and emittance (ε) values of absorber-reflector tandem structure selective coatings deposited on almunium and glass substrate.

The measured reflectance, as a function of wavelength, is plotted in Fig. 2(a) for ZrO_x/ZrC-ZrN/Zr absorber-reflector tandem structures on aluminum substrates in 0.2 – 25 μm range for different N_2 flow rates, used during synthesis. These reflectance measurments are used to calculate the absorptivity 'α' in ~ 0.3 – 2.5 μm range, and emissivity 'ε' in ~ 2.5 – 25 μm range, using Eq. (1) and (2);

$$\alpha = \frac{\int_{0.3}^{2.5} (1 - R(\lambda)) I_{sun}(\lambda) d\lambda}{\int_{0.3}^{2.5} I_{sun}(\lambda) d\lambda} \quad (1)$$

$$\varepsilon = \frac{\int_{2.5}^{25} (1 - R(\lambda)) E_b(\lambda) d\lambda}{\int_{2.5}^{25} E_b(\lambda) d\lambda} \quad (2)$$

Where $I_{sun}(\lambda)$ is ASTM G173-03 solar reference spectrum, AM1.5 and $E_b(\lambda)$ is the spectral radiance of a black body at temperature, T, and is given by Plank's law Eq. 3 (Duffie and Beckman, 1991) and R is the measured reflectance as a function wavelength. Here, Eq. 2 describes the emissivity against the total black-body radiation at given temperature T, which is defined as

$$E_b = \frac{C_1}{\lambda^5 [e^{C_2/\lambda T} - 1]} \quad (3)$$

Where $C_1 = 3.743 \times 10^{-16}$ W m^2 and $C_2 = 1.4387 \times 10^{-2}$ mK.

The measured values of α and ε are plotted in Fig. 2(b) as a function of different N_2 flow rates for both aluminum and glass substrates. The values of α and ε range from 0.86 – 0.90 and 0.05 – 0.14, respectively. The volumetric fraction of zirconium nitride strongly depends on the N_2 flow rates, and intermediate N_2 flow

rates produced optimal ZrN in ZrC-ZrN matrix structures. The absorber structure with maximum ZrN fraction showed optimal performance with absorptance ~ 0.86 and emittance ~ 0.05 for both substrates.

3.3 Thermal stability in air

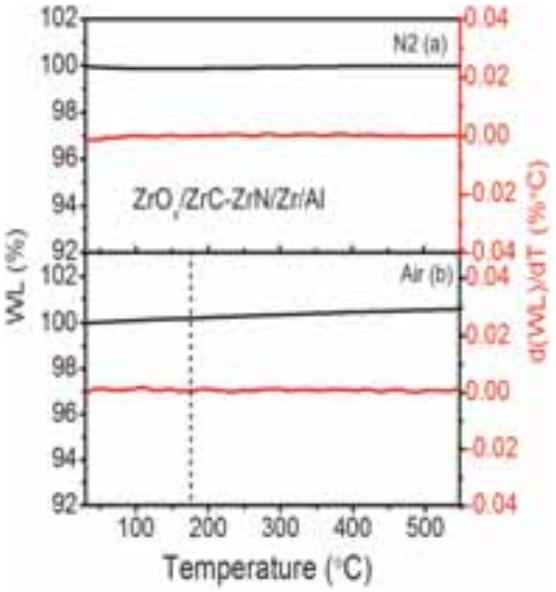

Fig. 3: Weight change percentage (WC %) versus temperature (°C) and differential of the weight change with temperature of ZrO_x/ZrC-ZrN/Zr absorber-reflector tandem selective structure deposited on aluminum substrate in (a) N_2 (b) air environment.

The ZrO_x/ZrC-ZrN/Zr absorber-reflector tandem selective structures were subjected to simultaneous thermal analysis (STA) measurements. The samples were heated upto 550 °C at a heating rate of 5 °C/min in nitrogen and air ambience. The measured weight change (WC) and differential weight change (d(WC)/dT) versus temperature are plotted in Fig. 3 for the best ZrO_x/ZrC-ZrN/Zr/Al sample with $\alpha \sim 0.86$ and $\varepsilon \sim 0.05$. These measurements did not exhibit any weight change under nitrogen ambience, whereas in air, weight gain started ~ 200 °C, as marked by dotted line in Fig. 3 (b). This weight gain was mainly due to oxidation of fabricated structures in air ambience, which was not observed in case of nitrogen ambience. These ZrO_x/ZrC-ZrN/Zr structures should be stable even at much higher temperatures, as Zr is the refractory material and ZrO_x top layer should avoid direct oxidation of underneath ZrC-ZrN absorber layer. Thus, another possibility for the observed weight change may be due to the oxidation of Al substrate itself. Such measurements were also carried out for ZrO_x/ZrC-ZrN/Zr structures on glass substrate and noticeable weight changes were not present at much higher temperatures, say 400 °C. Considering such degradation limit, ZrO_x/ZrC-ZrN/Zr structures with optimal solar performance $\alpha \sim 0.86$ and $\varepsilon \sim 0.05$ were subjected to the thermal cycling to 150 °C at 5 °C/min heating rate for 2 hours in air ambience to understand the thermal impact on solar performance. The X-ray diffraction patterns were recorded on these thermally treated samples and XRD graphs are plotted in Fig. 4 (a). The observed diffraction planes are in agreement with pristine samples with hexagonal zirconium nitride and zirconium carbide phases in conjunction with zirconium oxide mixed phases. These results suggest the robustness of ZrO_x/ZrC-ZrN/Zr absorber – reflector tandem structures against thermal impact. Surface microstructural degradations were investigated, for these ZrO_x/ZrC-ZrN/Zr heat treated structures, using SEM and AFM measurements and results are summarized in Fig. 4 (b) and (c). SEM micrographs, Fig. 4 (b), did not show any noticeable changes in surface morphology and are consistent with pristine samples, as shown in Fig. 2 (b). AFM measurements also substantiate the SEM results and the observed surface roughnesses are ~ 11.72 nm and ~ 17.85 nm for heat treated ZrO_x/ZrC-ZrN/Zr structures on aluminum and glass substrates. These roughness values are of the same order ~ 10.79 nm and ~ 17.20 nm for pristine ZrO_x/ZrC-ZrN/Zr structures on glass and aluminum substrates, respectively. These observations

suggest that ZrO_x/ZrC-ZrN/Zr structures are highly stable in the investigated temperature range and should have least impact on solar thermal properties.

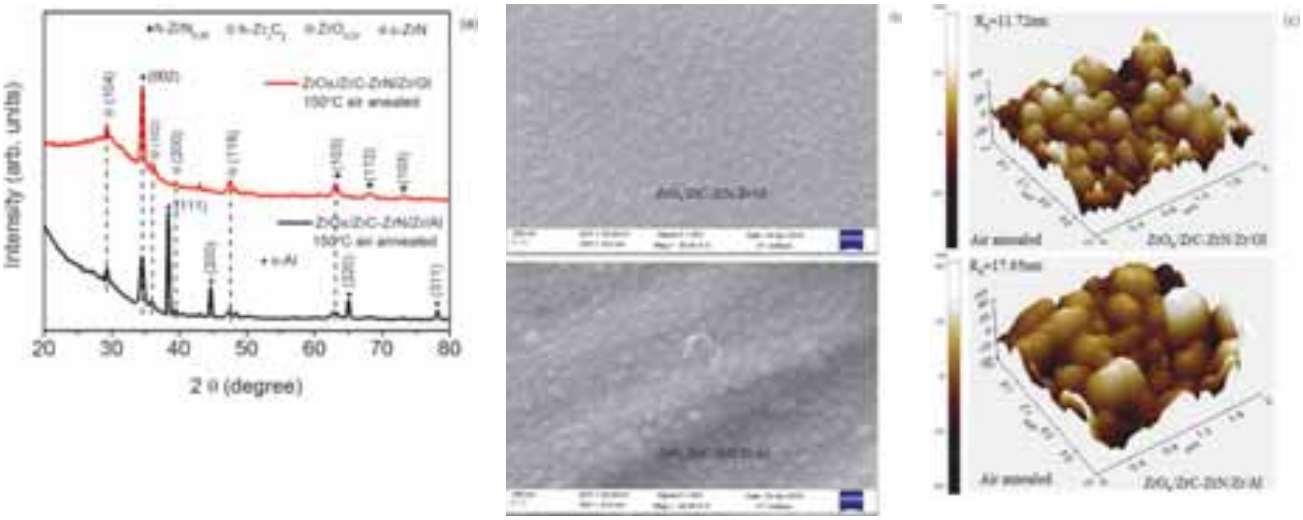

Fig. 4: (a) XRD graphs of air annealed ZrO_x/ZrC-ZrN/Zr absorber-reflector tandem selective structure deposited on glass and aluminum for 2h. **(b) & (c)** SEM and AFM images of air annealed ZrO_x/ZrC-ZrN/Zr absorber-reflector tandem selective structure deposited on glass and aluminum substrates for 2h.

The reflectance measurements were carried out for these ZrO_x/ZrC-ZrN/Zr heat treated samples in the entire 0.2 μm – 25 μm wavelength range and results are summarized in Fig. 5. The measured α and ε values are 0.82 and 0.09 as compared to 0.86 and 0.05 for pristine samples respectively. A small deviation in optical properties of these ZrO_x/ZrC-ZrN/Zr structures may be due to minor surface degradation, not noticeable in the present studies, suggesting insensitivity in the range of investigated temperature. This is in consistent with structural and microstructural measurements, where relatively no substantial changes were observed. These findings suggest that ZrO_x/ZrC-ZrN/Zr may be a good candidate for enhanced solar thermal performance and may exhibit long stability for low and medium temperature applications on glass and aluminum substrates.

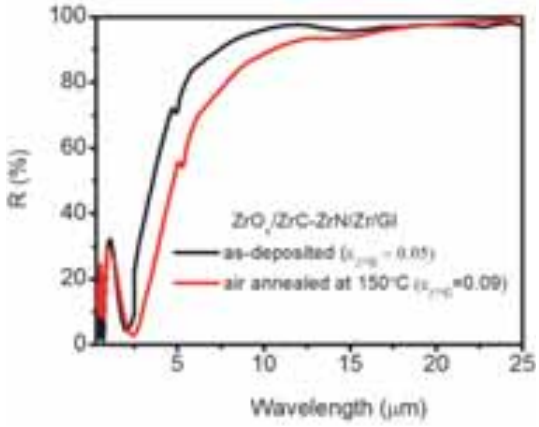

Fig. 5: Reflectance spectra of as-deposited and air annealed ZrO_x/ZrC-ZrN/Zr absorber-reflector tandem selective structure deposited on glass for 2h.

4. Conclusion

ZrO_x/ZrC-ZrN/Zr absorber-reflector tandem structures are optimized for both aluminum and glass substrates for optimal solar thermal performance by tailoring the zirconium nitride content in ZrC-ZrN absorbing layer. The intermediate nitrogen flow rate ~ 10 – 15 sccm has shown the best $\alpha \sim 0.86$ and $\varepsilon \sim 0.05$. The ZrO_x/ZrC-ZrN/Zr structures are stable in air upto ~ 150 °C without any noticeable degradation in their solar thermal performance as compared to pristine samples for both Al and glass substrates.

Abstract

This paper deals with heat transfer analysis in sub-systems for a concept of solar convective furnace system. This system makes use of open volumetric air receiver for heat transfer to air, which is employed as working fluid. In this paper, experimental and numerical evaluation of transient heat transfer (a) in porous absorber and (b) in an insulated pipe is presented. This shows temperature development in absorber and the heating up of an insulated pipe with transport of hot air. Mathematical models to analyze one-dimensional heat transfer in porous absorber and insulated pipe are developed and solved using numerical techniques. The tool, thus developed, is validated using the corresponding experiments. Comparative analysis shows that the predicted and experimentally obtained transient temperature profiles are comparable for both these components. Variations of about 5-15% are observed between numerically and experimentally obtained values.

Keywords: *Absorber, insulated pipe, transient heat transfer, 1-D numerical analysis, experiment*

1. Introduction

In the concept of solar convective furnace the reflected radiation from a heliostat field is concentrated onto porous absorbers of an open volumetric air receiver (OVAR); see e.g. Hoffschmidt et al., 2003. The sucked atmospheric air through the pores of absorber extracts the generated heat from concentrated solar irradiance. The detailed design basis and evaluation of cylindrical absorber based OVAR is presented by Sharma et al, 2015a, 2015b. The obtained thermally mixed hot air at the OVAR outlet can be stored in thermal energy storage for various applications, like metal processing, see e.g. Patidar et al., 2015a, 2015b. The schematic of designed and installed solar air tower simulator (SATS) facility for evaluation of such a system is presented in Sharma et al. 2015a, 2015b. It is realized that the transfer of hot air through the piping system will result in its heating up-to the desired steady state. In other words, the piping system will attain thermal equilibrium with convected hot air for solar convective furnace system. Achieving this equilibrium state may take several hours, which is quite considerable. Besides, heat loss through insulation due to temperature difference between hot air and ambient starts with the operation of furnace system, Patidar et al., 2015a. This depends on pipe material and its thermal properties. Also, the increase in insulation temperature with time will enhance natural convective heat loss to ambient. It is to be emphasized that steady inlet temperature is desired process heat applications, like material processing. To reduce the required time for achieving steady-state, pre heating of sub-systems/components are required, see e.g., Vasiliev et al., 1987. In view of these observations following are presented in the paper:

a. Numerical and experimental evaluation of transient heat transfer in a porous absorber
b. Numerical and experimental evaluation of transient heat transfer from hot air to ambient in an insulated pipe.

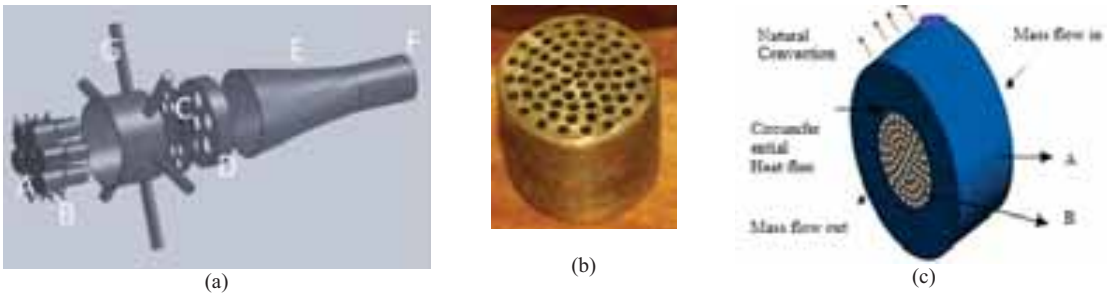
ex	external convection	p	Pores in absorber
f	fluid domain	s	solid domain
fd	fully developed length		

2. Transient heat transfer in porous absorber

As described, the developed concept of solar convective furnace concept is based on open volumetric air receiver (OVAR) (Fig. 1a), usually made of a ceramic or metal. The designed OVAR consists of cylindrical absorbers with circular porous and is made of brass (Fig. 1b). The thermal conductivity of brass is comparable to that of Silicon-carbide (SiC) in the considered temperature range. For more details refer to Sharma et al., 2015a, 2015b. Ambient air is heated to a high temperature as it flows through the circular pores. This unsteady process, eventually, leads to the desired steady state for given boundary conditions. Thus, to operate any process heat system based on such a receiver it is necessary to model the involved unsteady heat transfer process. For this purpose, both numerical and experimental evaluation of the designed circular pore based cylindrical absorber is presented in this section. The objective is to (a) develop an analysis tool and (b) understanding of the transient heat transfer process.

2.1 Mathematical model and numerical approach

For numerical analysis of a circular pore cylindrical absorber, the heat transfer process in porous absorber is mathematically modeled. The absorber is made of brass having thermal conductivity K_s~138W/mK. The involved modes are shown in Fig. 1c, which considers one-dimensional axial heat transfer in the pores with radial heat loss to ambient via insulation. During this process, air heats up to a higher temperature. This hot-air is utilized in a furnace and cooled to a temperature T_{ra}, which is higher than T_a. This relatively warm air is returned to OVAR through six injection ports that are marked G in Fig. 1a. The returned air gains heat from the absorber via external forced convection. A part of this air mixes with ambient and sucked through the pores of absorber. Thus, a fraction of the transferred heat to return air is reused. The return air system is not modeled in the presented analysis. This is obvious from the provided insulation around porous absorber as depicted in Fig. 1c. Further, the developed mathematical model assumes (a) uniform heat flux on the absorber surface exposed to electrical heating (b) volumetric heating owing to high thermal conductivity of brass (c) air as an ideal gas. Thus, the model simplifies the system into a one-dimensional heat transfer in solid, fluid and insulation domains. It should be emphasized that such a comprehensive tool will allow the first level analysis of new absorber designs.



(a) (b) (c)

Fig. 1(a): Components of OVAR with A: Absorbers, B: Foot-piece, C: Anchor plate, D: mixer or perforated plate, E: Convergent nozzle, F: Outlet, G: Recirculating air injection ports, (b)Porous absorber of OVAR, (c) Porous absorber system model for numerical analysis with A:Insulation domain, B: Absorber(solid domain)

The model includes one-dimension conservation of energy equations in fluid, solid and insulation domains as in Eqn. 1-3. First-order explicit finite difference scheme is used for simultaneous l solution of the system of equations. Figure 2a and b depicts the control volume for fluid and solid domains. In the performed experiment Joule heating is applied to solid circumference of absorber that results in the desired volumetric heating. A small fraction of the input power conducted to the insulation and is finally lost to the ambient via natural convection (Fig 2d, e). The balance is transferred to ambient air via internal forced convection as shown Fig. 2b and c. The experimental parameters are presented in Table 1. The selected parameters are based on Sharma et al., 2015a and 2015b. The CFL condition (Anderson, 1995; Patankar, 1980) allows maximum time step of 0.13 ms for the considered final grid, which is obtained based on a grid dependence study. However, a smaller time step of 0.1 ms is selected for numerical heat transfer analysis. The length of absorber pore is 25.4 mm. The flow inside each pore is Laminar with Re ~ 102 and the corresponding Nusselt number for fully developed flow is 4.36 (Cengel, 2011; Incropera & DeWitt, 1996; White, 1998). However, the length of the absorber is of the order of its entry length, therefore, the Nusselt number for fully developed flow is modified using Eqn. 4, Subbarao, 2015.

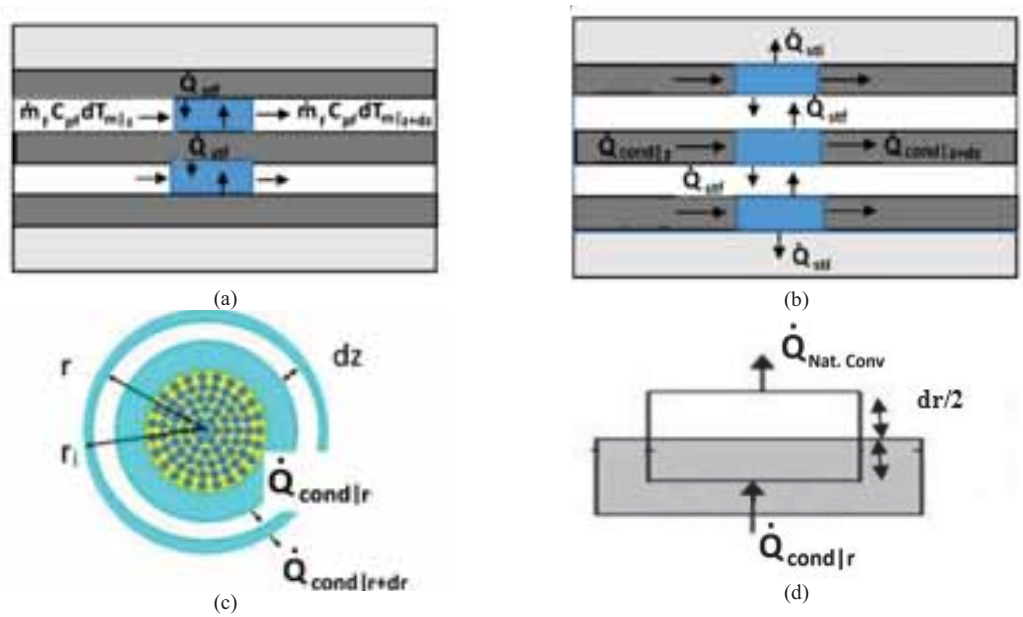


Figure 2: (a ,b)Control Volume for fluid and solid domain and (c, d) Control volume for insulation domain and its outer boundary condition

Solid:

$$\frac{\partial^2 T_s}{\partial z^2} - \frac{2h_f n_p r_p (T_s - T_m)}{K_s r_a^2 (1-\emptyset)} + \frac{2q''}{K_s r_a (1-\emptyset)} - \frac{2K_{ins}}{K_s r_a (1-\emptyset)} \frac{\partial T_{ins}}{\partial r}_{(r=r_a)} = \frac{1}{\alpha_s} \frac{\partial T_s}{\partial t} \quad \text{(eq. 1)}$$

Fluid:

$$\dot{m}_f \frac{\partial c_{pf} T_m}{\partial z} = 2\pi r_p n_p h_f (T_s - T_m) \quad \text{(eq. 2)}$$

Insulation:

$$\frac{\partial^2 T_{ins}}{\partial r^2} + \frac{1}{r} \frac{\partial T_{ins}}{\partial r} = \frac{1}{\alpha_{ins}} \frac{\partial T_{ins}}{\partial t} \quad \text{(eq. 3)}$$

The required heat transfer coefficient is estimated as follows:

$$Nu_f = 4.36 + \frac{0.086 (Re\ \mathrm{Pr} \frac{D}{L})^{133}}{1 + 0.1 Pr (Re \frac{D}{L})^{0.83}} \qquad 0.7 < \mathrm{Pr} < 7,\ \mathrm{Re} < 2300 \quad \text{(eq. 4)}$$

$$h_f = \frac{Nu_f k_f}{2r_p} \quad \text{(eq. 5)}$$

The initial and boundary conditions are as follows:

a. Initial condition: $T_{m.\ s.\ ins}(z = 0, t = 0) = 302.5K$
b. Inlet: $T_m(z = 0, t) = 305.7\mathrm{K}$, $\dot{m} = 0.00003\ kg/s$;
c. Insulated axial solid boundaries: $\frac{\partial T_s}{\partial z}\Big\}_{z=0.\ L\ and \forall t} = 0$
d. Solid-insulation interface: $T_s = T_{ins|r=r_s}$
e. External insulation surface: Natural convective heat loss is depicted as:

$$\frac{1}{r_{ins}} \frac{\partial T_{ins}}{\partial r}_{(r=r_{ins})} + \frac{h_{ex} (T_{ins(r=r_i)} - T_a)}{K_{ins} r_{ins}} = \frac{1}{2\alpha_{ins}} \frac{\partial T_{ins}}{\partial t}_{(r=r_{ins})} \quad \text{(eq. 6)}$$

Where h_{ex} is calculated using the following correlation for natural convection:

$$Nu_{ex} = \left[0.6 + \frac{0.387 Ra^{1/6}}{\left[1 + (0.559/Pr)^{4/9}\right]^{8/27}} \right]^2 \quad \text{(eq. 7)}$$

$$h_{ex} = \frac{Nu_{ex} K_f}{2r_{ins}} \quad \text{(eq. 8)}$$

2.2 Experimental set-up

Experiment is performed for validation of the developed transient tool for heat transfer in porous absorber. The schematic of experimental set-up is shown in Fig. 3a. Air is blown into a steel pipe with outer diameter (D) of 25.4 mm and length (L) of 24D. At the outlet of pipe an absorber is fitted, which is electrically heated by externally wrapped Nichrome wire, see Fig. 2a & b. The experimental absorber is made of brass with porosity ~52 percent (83 pores of diameter (D_p)=2mm), length (L_a) and diameter (D_a) of 25.4 mm. Pipe and absorber are insulated using ceramic wool for reducing heat loss to ambient as shown in Fig. 3a and 3b. The input power is controlled by varying voltage using an auto-transformer and mass-flow-rate of air is maintained using a flow control valve. Temperature is measured using the calibrated K-type thermocouples with uncertainty of about 1-2%. Data from thermocouples is recorded and stored in real-time using NI-WSN gateway data acquisition (DAQ) device. The temperatures were measured at various azimuthal and radial positions as depicted in Fig. 3c at the inlet and outlet of the absorber.

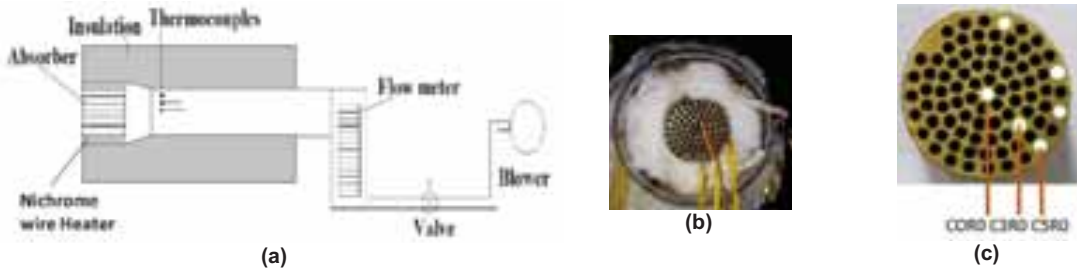

Figure 3: (a) Schematic of experiment set-up, (b): Front view of absorber with insulated , (c): Position of thermocouples on absorber

Table 1 shows the experimental parameters for the absorber. A part of the applied power to absorber is transferred to the connecting pipe via conduction. This heats up the air inside the pipe leading to an increase in temperature at the absorber inlet from 302.5 - 312K in 500 seconds. Thus, for validation of the developed numerical tool a time averaged inlet temperature of 305.7 K is used at the inlet. The net power input after subtracting the transfer to pipe as in Eqn. 9, is applied to absorber for this purpose. Thermocouples at various axial positions on the surface of insulation are mounted to estimate the rate of heat loss to ambient according to the second term on RHS of Eqn. 9. Also, thermocouples located on various radial positions at the pipe inlet and outlet are used to estimate mean air temperature at these positions, required for estimating the first term on RHS of Eqn. 9. An overall uncertainty of up-to 10% is attributed to (a) input power variation (b) temperature and mass flow rate measurements (c) manual operation and variable ambient conditions. Further, the numerical tool is designed to solve the equations with constant as well as variable fluid properties. For variable property the best fit curves are considered (Ekanayke, 2015; Boutelop, 2015). The properties of insulation and absorber materials are considered as constants. These are defined as average values in temperature range of 300-600K to cover the expected experimental conditions.

Tab. 1: Experimental and computational parameters for absorber

Parameter	Value	Parameter	Value
Mass Flow Rate	0.0003 *kg/s*	Power transfer to pipe ($\dot{P}$)	1.25 W
Reynolds Number	102	Net power input ($\dot{E}$- $\dot{P}$)	19.65 W
Current	1.95 ±0.05A	T_{inlet}	302.5 – 312 K
Resistance	5.5 ±0.1 Ω	$T_{inlet,\ time\ averaged}$	305.7 K
Electrical Power Input ($\dot{E}$)	20.9 W	Equivalent Radiative Heat Flux	20 kW/m2
Effective POA/MFR	65.5 kW/kg/s	Equivalent concentration (suns)	80 Suns
$K_{s,avg.}$	138.7W/mK	$Cp_{s,\ avg}$	0.413 kJ/kgK
$\alpha_{f,\ avg}$	19.9 m^2/s	$Cp_{f,\ avg}$	1.009 kJ/kgK

$$\dot{Q}_{atp} = \dot{m}_f c_{pf,}\left(T_{m,pipe\ outlet} - T_{m,pipe\ inlet}\right) + \Sigma h_{ex} 2\pi r_{ins} \Delta l (T_{ins} - T_a) \quad \text{(eq. 9)}$$

2.3 Results

Figure 4a shows the transient variation of temperature in pores located at different radial positions as shown in Fig. 3c. It is observed that the temperature development is practically comparable at all these three locations with a variation of about ±1˚C. This confirms the assumption that heat is uniformly distributed throughout the solid and that the bulk fluid temperature is, practically, comparable. This situation will be different including air return system in which radial variation of fluid temperature is expected as shown in Sharma et al., 2015a, 2015b. Thus the code will be extended in the near future including this effect as well. A

comparison between the numerically analyzed bulk-mean and measured air temperature with respect to time is shown in Fig. 4b. The maximum difference of ~ 10% is observed between these values. For simulation both constant and temperature dependent air properties are used. Thus, it can be safely stated that such a tool will be extremely useful for predicting unsteady heat transfer process in absorber for process heat application.

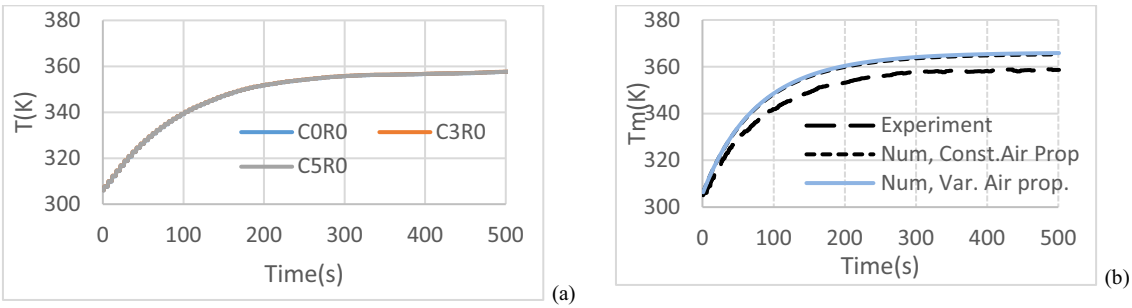

Figure 4 : (a)Variation in temperature between different absorber pores as observed in the experiment (b): Comparison between 1-D and measured bulk-mean air temperature with time

3. Heat transfer in an insulated pipe

As described, hot air is transported in an insulated pipe to thermal energy storage for its use in, for example, solar convective furnace to achieve steady state. Attaining the desired steady state will be influenced by (a) heating up of the piping network and (b) heat loss to ambient via insulation from hot air. Thus, understanding and development of a transient analysis tool will support the operation of such a system. For this purpose, a one-dimensional heat transfer model is developed and validated with the performed experiment under the same conditions.

3.1 Numerical approach

For the development of one-dimensional tool, the insulated piping system with air-flow is represented using three domains, namely, fluid (air), solid (pipe) and insulation. The control volumes for each domain are shown in Fig. 5a, b and d. The derived energy equations in each domain are solved, simultaneously, using a numerical scheme. The hot fluid entering the pipe loses heat to the solid (pipe material) and finally to ambient via insulation with external natural convection. Further, the solid domain loses heat to the ambient via natural convection at its axial boundary ($z=0,\ L$), the control volume of which is shown in Fig. 5c. For fluid domain, instantaneous mass-weighted average temperature equation is derived ignoring storage as heat is convected. For the solid domain, the conduction in the radial direction is neglected considering small pipe thickness in comparison to the pipe length. For insulation domain, heat transfer in radial direction is considered on account of a lower thermal resistance at its radial boundary in comparison to axial boundary as a result of higher surface area for convective losses.

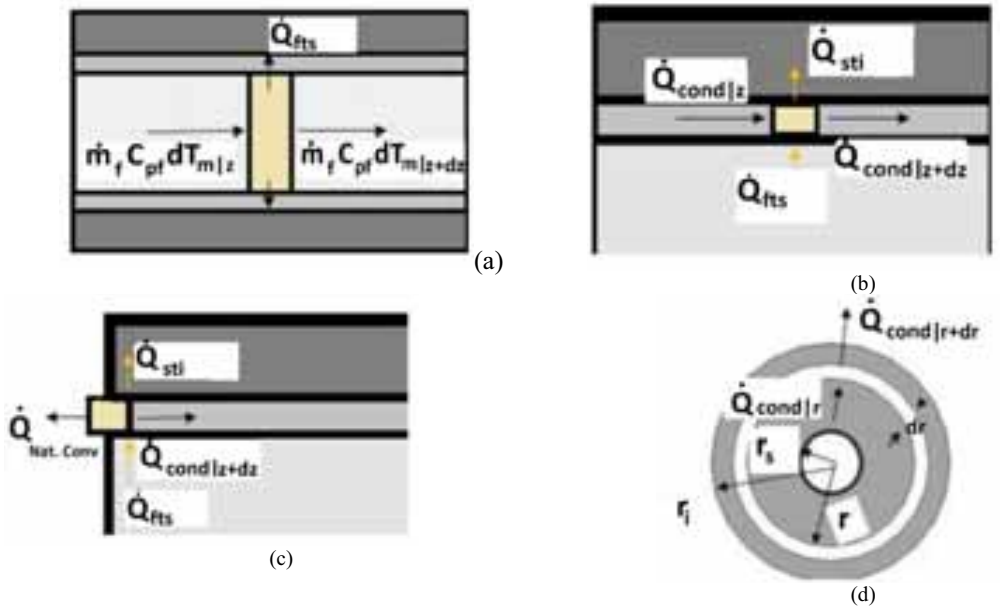

Figure 5 (a, b, d): Control volume of fluid, solid and insulation domain, (c): Control Volume for boundary conditions(z=0,L) for solid domain

Energy equations in solid (pipe), fluid and insulation domains are given by Eqn. 10, 11 and 12, respectively. The partial differential equations are solved with first-order accuracy. Explicit forward-difference-scheme with uniformly spaced grid points in fluid and solid pipe domain is employed for discretization. Corresponding CFL conditions (Patankar, 1980; Anderson, 1995) are satisfied in each domain for the considered mesh sizes and time steps. Average values of material properties, like thermal conductivity, density, viscosity, etc. in the temperature range was considered and assumed to be constant. This is acceptable for the performed experiment with limited temperature range. However, the tool will be generalized with variable fluid properties at the next step, once validated.

Solid (Pipe) Domain:

$$\frac{\partial^2 T_s}{\partial z^2} + \frac{h_f(T_m - T_s)}{K_s \delta} + \frac{K_{ins}}{K_s \delta} \frac{\partial T_{ins}}{\partial r}_{(r=r_s+\delta)} = \frac{1}{\alpha_s} \frac{\partial T_s}{\partial t} \quad \text{(eq. 10)}$$

Fluid Domain (instantaneous):

$$\frac{\partial T_m}{\partial z} = -\left(\frac{2\pi r_s h_f}{\dot{m}_f c_{pf}}\right)(T_m - T_s) \quad \text{(eq. 11)}$$

Insulation:

$$\frac{\partial^2 T_{ins}}{\partial r^2} + \frac{1}{r}\frac{\partial T_{ins}}{\partial r} = \frac{1}{\alpha_{ins}} \frac{\partial T_{ins}}{\partial t} \quad \text{(eq. 12)}$$

The boundary and initial conditions are as follows:

a. The inlet temp of fluid : $T_m(z = 0, t) = 400\text{K}$
b. Initially the solid pipe and insulation domain are at ambient temperature:
   $\therefore T_s(z, t = 0) = T_{amb} = T_{ins}(r, z, t = 0)$
c. Natural convection boundary condition at axial boundaries for solid domain i.e. z=0 and z=l represented by equation 10.

$$\frac{\partial}{dz}\left|(-1)^n (K_s 2\pi r\delta)\frac{\partial T_s}{dz}\right|_{z=0,L} + h_f 2\pi r(T_m - T_s) + K_{ins} 2\pi r \frac{\partial T_{ins}}{dr}_{(r=r_s+\delta)} + h_{ex} 2\pi r\delta(T_s - T_a) = 2\pi r(\delta)\rho_s C_{ps}\frac{\partial T_s}{dt} \quad \text{(eq. 13)}$$

Here, n= 1 if z=0 & n= 2 if z= L and h_{ex} is estimated using the following Nu correlation

d. Natural convection boundary condition at radial boundary of the insulation domain while axial boundaries are assumed to be insulated similar to absorber as shown in Eqn. 6

Dittus-Boelter correlation (Cengel, 2011) for internal air-flow is used for estimation of heat transfer coefficient in fully developed region as in Eqn. 14. This is modified in the entry length region using Eqn. 15. Natural convection based heat loss coefficient to ambient from the exposed solid and insulation surfaces is estimated through Rayleigh number using Eqn. 17. Equations 16 and 18 represent the heat transfer coefficient relationship with corresponding Nusselt no and characteristic length for internal and external flow respectively.

$$Nu_{f,fd} = 0.027 * Re^{0.8} Pr^{\frac{1}{3}} \quad \text{(eq. 14)}$$

$$\frac{Nu_f}{Nu_{f,fd}} = \left(\frac{x}{2r_s}\right)^{-0.0054} \quad \text{(eq. 15)}$$

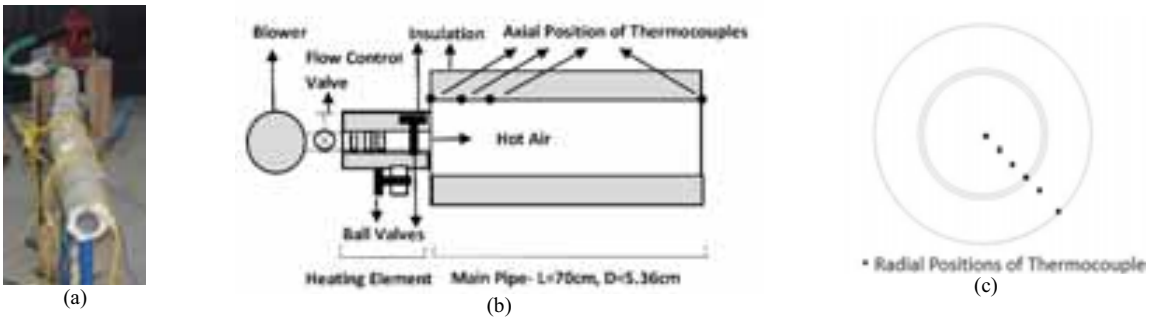
$$h_f = \frac{Nu_f k_f}{2r_s} \quad \text{(eq. 16)}$$

$$Nu_{ex} = \left[0.6 + \frac{0.387 Ra^{1/6}}{\left[1 + \left(^{0.559}/_{Pr}\right)^{4/9}\right]^{8/27}}\right]^2 \quad \text{(eq. 17)}$$

$$h_{ex} = \frac{Nu_{ex} k_f}{2\delta} \quad \text{(eq. 18)}$$

3.2 Experimental set-up

The designed and installed experimental set-up and its schematic are shown in Fig. 6a & 6b. In this experiment, to achieve a constant high temperature at the pipe inlet (*z=0)*, a heating element is designed. Heating element is a separate steel-pipe of 25.4 mm diameter in which three porous bodies (absorbers) are fitted at different axial locations. Their purpose is to allow effective heat transfer to air as well as thermal mixing. A Nichrome wire of 0.25 mm diameter is wrapped on external pipe surface for additional Joule heating. Needless to say, the porous bodies will introduce extra pressure drop, which is not of primary concern for the present purpose. Thus, in experiments, at the outlet of heating element air stream at uniform temperature is obtained. It requires sometime to achieve the steady value in the heating element. Therefore, it is bypassed through a valve into atmosphere. Once the steady air temperature is reached the inlet valve of main pipe is opened and atmospheric bypass valve is closed. In this way at the main pipe inlet of 53.6 mm diameter a constant temperature boundary condition is maintained throughout the experiment. Calibrated thermocouples are mounted inside and on the surface of 0.7 m long insulated main pipe at several axial and radial positions, see Fig. 6c. Temperature of pipe and insulation is also recorded using NI DAQ device. Table 2 presents the input parameters for the experiment conducted for code validation. For a fixed mass flow rate inlet, hot wire anemometer was used to measure the velocity at a reference temperature of 30 ˚C. Radius of Insulation greater than the critical radius of insulation (~53.6 mm) was chosen for validation (Incropera, 1996; White, 1998; Holman, 1997). An uncertainty of ~5-10% is attributed to fluctuations in ambient temperature, power and error in measuring the temperature via thermocouples.



(a) (b) (c)

Figure 6: (a, b) Experimental set-up and its schematic; (c) Position of Thermocouples

Tab. 2: Experiment Input Parameters for pipe

Parameter	Value
Avg. Mass Flow Rate	0.005 kg/s
Velocity	2.2 ±0.1m/s at 304K
Current for electrically heating the absorbers	3.15 ±0.05A
Resistance	62.5 ±0.1 ohm
Reynolds Number	4707
$T_{m \text{ at } z=0}$	400± 2 K
$T_{s \text{ at } z=0=t}$	314± 1 K

3.3 Results

Constant air temperature boundary condition at the main-pipe inlet ($T_{m \text{ at } z=0}$ = 400 K) with mass flow rate of ~0.005 kg/s is imposed on in both experiment and numerical analysis. A comparison between unsteady heat transfer experiment and 1-D numerical analyzed data for hot-air flow in the insulated pipe is shown in Fig. 7a, b and c. These are for bulk or mean temperature of air, solid (pipe) at the outlet and for insulation at the inlet and outlet over time. Generally, higher air temperatures are estimated numerically in comparison to experiment. The temperature differences of solid at the pipe inlet and outlet in Fig. 7b indicate a better correlation for heat loss is required within the thermal entry length. However, the general trend of temperature development is captured adequately. Figure 7c depicts that the code under-predicts the losses to the ambient as a result of under-prediction of insulation temperature. This is consistent with the over-predicted temperatures of solid and fluid at the outlet. The maximum differences between numerically and experimentally obtained values are ~5-15%. Therefore, it is expected that this tool will be helpful in analyzing and predicting unsteady heat transfer in a piping network for furnace system. (Patidar et al, 201b).

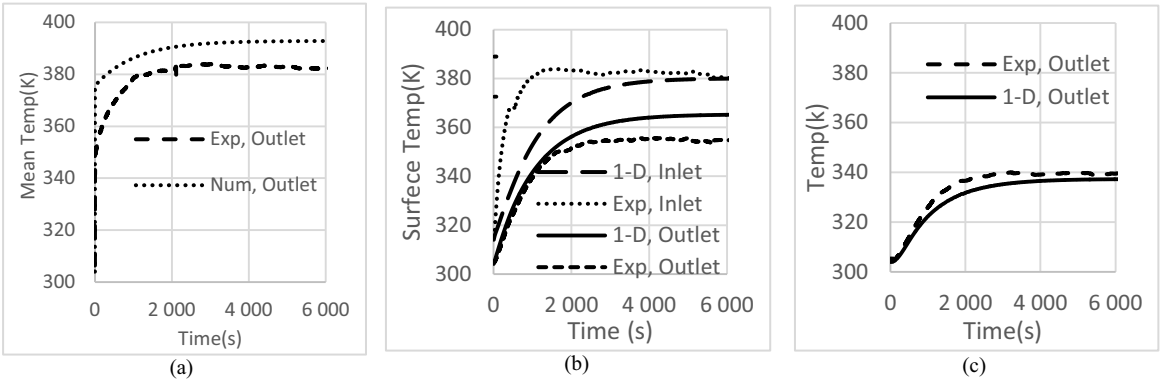


Fig7: Comparison between 1-D analysis and experiment for fluid (a), solid pipe (b) and insulation (c) domains.

4. Conclusion

The paper deals with the development of validated mathematical models for unsteady heat transfer analysis in a porous absorber and of an insulated pipe. These are sub-systems for a solar convective furnace. The developed tool has its application in designing receiver and piping network of a solar convective furnace system. For developing this system level tool one-dimensional modeling approach of the considered sub-systems/components, like, porous absorber and insulated pipe is considered. For solving these equations a first-order accurate explicit numerical scheme is utilized. Experiments are performed for validation of the adopted model and numerical method. The comparison between experiment and numerically analyzed data, namely, air, solid and insulation temperatures reveal a variation of about 5-15%. This is expected as the modeling is limited to one-dimension and utilizes simplified experimental correlations. However, even with these known limitations, it can be safely stated that such a tool will be extremely valuable in predicting performance of the desired solar convective furnace system.

Abstract

In this paper, design and evaluation of an experimental setup for analyzing air-flow and to understand dust deposition on heliostats in a field-layout is presented. For this purpose, a heliostat field is designed and air-flow is investigated for the selected staggered arrangement of heliostats. The evaluation clearly revealed the presence of flow separation and wake behind an inclined heliostat models. Such complex flow field will affect dust deposition on heliostat and may even induce vibration. Hence, experimentation would be necessary to investigate the flow field in these regions. The developed experimental set-up based on detailed flow analysis will be useful for understanding the dust deposition and wake induced vibration of heliostats in field layout.

1. Introduction

Depleting conventional sources of non-renewable energy has been one of the key reasons for research into alternate sources of energy like solar energy. There are different methods to harness solar energy. One of them is concentrated solar thermal power (CSP) which uses reflectors to focus solar radiation onto a receiver that transfers the received heat to a heat transfer fluid. One of the CSP technologies is heliostat based central power tower. The heliostats collectively focus incident sunlight onto a central receiver. On account of high concentration, temperature of the order of 1000 °C is achievable. This heat can be employed for process heat and power generation. Desert regions, like, Rajasthan receive high solar irradiation (~ 6-7 kW.hr/m^2/day) and are well suited for such a technology. However, dust poses a serious challenge in operating such a system (Gupta, 1986). High wind speed in such regions initiates saltation process (Singh et al., 2015). The lifted dust particles are carried by wind. When this wind blows over a field of heliostats, the particles get deposited on heliostats. The dust deposition reduces the reflectivity of heliostats (Niknia et al., 2012). This reduction lowers the overall heat recovery and, therefore, efficiency of the CSP plant. Therefore, if a parameter describing such a loss could be considered while designing the field itself, it would enable operating a plant under the desired condition.

With the importance of this aspect in mind, Yadav et al. (2014) investigated dust deposition on single and multiple aligned heliostat models in a wind tunnel at a Reynolds number of 60,000. The k-ε based Reynolds Averaged Navier-Stokes (RANS) approach was used for simulation. Further, flow measurement was performed around a heliostat using laser Doppler velocimetry technique. It was observed that the calculated time-averaged flow features are captured upstream and not reproduced downstream of the heliostat model with flow separation for an inclination angle of 25° with respect to horizontal surface. It was also observed that the wake region further downstream is adequately captured. Further, this investigation revealed that non-uniform or even localized dust deposition on heliostat is possible under certain condition. Localized deposition can be mitigated by cleaning effect, if predicted appropriately with a numerical tool. This investigation indicated the need for an improved modelling for analyzing air-flow around heliostats in a field layout, especially, in the flow separation region. However, it was insufficient for evaluating dust deposition on heliostats in a staggered arrangement, which is commonly employed (Falcone, 1986; Lipps and Vant-Hull, 1978; Vittitoe and Biggs, 1981). Considering these limitations, the presented paper aims at designing an experimental setup to understand the air-flow around heliostats in a field-type layout. For this purpose a step-wise strategy is adopted. The first step is a field design to simulate flow pattern around 1:10 scale-down heliostat models placed in staggered manner. For this purpose, geometric similarity of heliostat and field arrangement is adopted. In second step, different numbers of model heliostats, like, 3, 5, and 7 are organized in staggered fashion for a particular height of tower

doi:10.18086/swc.2015.04.04 Available at http://proceedings.ises.org

and latitude of location, which is Jodhpur based on the maximum elevation angle. In next step, detailed flow analysis is carried out using RANS approach to design an experimental set-up, which is capable of simulating a free-flow condition. Finally, Large Eddy Simulation (LES) is performed to understand, especially, the near-wake region behind a heliostat, which is not captured appropriately with RANS model. These steps are presented in the subsequent sections.

2. Field Design

As the starting point, a heliostat field is designed for Jodhpur (altitude ~ 26°) with 1m x 1m reflecting plate and 10m central tower height using Matlab code based on the mirror density criterion by Siala and Elayeb (2001) (see Fig. 1). This field design is intended for an indigenously developed open volumetric air receiver based 100kWth equivalent solar convective furnace system (Singh et al., 2015). In the Fig.1, heliostats are represented by circles. The diameter of the circles is equal to the diagonal of the heliostat. The designed field is extended up-to 30m in radius and span of 90°. The field consists of heliostats arranged in essential and staggered rows based on a no-blocking condition referred to by Siala and Elayeb (2001). The rows of heliostats are distributed radially into groups as shown in Fig. 1. These differ in their azimuthal and radial spacing. Rows of one group have equal azimuthal angular spacing between adjacent heliostats. It is to be noted that air-flow pattern depends on the positions, angular orientation and elevation of heliostats. The elevation and azimuthal angles are calculated (Xiudong et al., 2007) that vary with time and day. This yielded a maximum value of 65° throughout the year for 22nd of December. The designed field with the maximum elevation angle of 65° is scaled down geometrically for 1:10th size of the considered heliostats. The distances between heliostats are provided in Table 2. For flow similarity, the Reynolds number is to be maintained between actual and scaled-down heliostat models. The Re of the flow on the actual heliostat on a typical day in Jodhpur with an average of 7 m/s is ~ 421,000. To maintain Re with model-heliostat, the free stream air velocity ~ 70 m/s is required. Therefore, in future, attempts will be made to perform experiments with water at reduced velocity. The presented experimental set-up is designed for a free-stream air velocity up-to 20 m/s, which corresponds to Re ~ 132,000.

20	Minimum - 17.3
	Maximum - 22.1

3. Computational Fluid Dynamics (CFD) analysis

Yadav et al. (2014) observed higher dust deposition on heliostats encountering the free stream air compared to those in the wake of preceding heliostats. The relative positioning of aligned heliostats also affected dust deposition on the aft heliostats. Following design considerations are made for experimental set-up:

a. Height and width should allow free-stream flow development from heliostat surfaces

b. The length is sufficient to allow far-wake development, indicated by a uniform velocity.

Computational Fluid Dynamics is employed to numerically solve equations of fluid flow around heliostats. The two CFD methodologies are used considering time-averaged and unsteady flow features:

3.1. Reynolds Averaged Navier-Stokes (RANS) approach

For RANS simulation, based on previous investigations, the standard two-equation k-ε model proposed by Launder and Spalding (1972) is used. This is a semi-empirical model in which turbulence kinetic energy k and

its dissipation rate ε are analyzed using their transport equations. These additional equations are solved simultaneously with governing equations of mean velocity and pressure (Kuzmin and Mierka, 2006; Furbo, 2010) for incompressible flow:

$$\nabla \bullet \overline{u} = 0 \tag{1}$$

$$\frac{\partial \overline{u}}{\partial t} + \overline{u} \bullet \nabla \overline{u} = -\nabla \overline{p} + \nabla \bullet \left(\left(\nu + \nu_T \right) \left[\nabla \overline{u} + \nabla \overline{u}^T \right] \right) \tag{2}$$

Where, ν and ν_T are molecular and turbulent eddy kinematic viscosity, respectively. The statistical eddy viscosity models the effect of unresolved velocity fluctuations in mixing. In the standard k-ε model, it is calculated by $\nu_T = C_\mu k^2 / \varepsilon$. The transport equations of k and ε in space are as follows:

$$\frac{\partial k}{\partial t} + \overline{u}_j \frac{\partial k}{\partial x_j} = \frac{\partial}{\partial x_j} \left[\left(\nu + \frac{\nu_T}{\sigma_k} \right) \frac{\partial k}{\partial x_j} \right] + \nu_T \left(\frac{\partial \overline{u}_i}{\partial x_j} + \frac{\partial \overline{u}_j}{\partial x_i} \right) \frac{\partial \overline{u}_i}{\partial x_j} - \varepsilon \tag{3}$$

$$\frac{\partial \varepsilon}{\partial t} + \overline{u}_j \frac{\partial \varepsilon}{\partial x_j} = \frac{\partial}{\partial x_j} \left(\frac{\nu_T}{\sigma_\varepsilon} \frac{\partial \varepsilon}{\partial x_j} \right) + C_{e1} \frac{\varepsilon}{k} \nu_T \left(\frac{\partial \overline{u}_i}{\partial x_j} + \frac{\partial \overline{u}_j}{\partial x_i} \right) \frac{\partial \overline{u}_i}{\partial x_j} - C_{e2} \frac{\varepsilon^2}{k} \tag{4}$$

Where, σ_k is the turbulent Prandtl number for kinetic energy. The turbulent length scale (L_0) could be obtained from k and ε as $\varepsilon = k^{3/2} / L_0$. The standard values of the model constants of the above equations are: $C_\mu = 0.09$, $C_{\varepsilon 1} = 0.09$, $C_{\varepsilon 2} = 0.09$, $\sigma_k = 1.0$, $\sigma_\varepsilon = 1.3$

3.1.1. Geometry

The employed 3-D models representing a part of the designed heliostat field using scale-down heliostat models are presented in Fig. 2a, b and c. The required minimum numbers of heliostat for staggered configuration is 3. Here, there is no heliostat with more than one adjacent heliostat in the same row (Fig. 2a). To investigate the interaction of wake from nearby heliostats, a representative field with 5 and 7 heliostats is considered (Fig. 2b, c). These layouts correspond to an elevation angle of 25°. In Fig. 2 distance between adjacent heliostats is 20 cm and the distance between two rows is 22.1 cm as in Table 2 (Yadav et al., 2014).

3.1.2. Mesh

The flow domain is discretized by dividing into smaller control volumes called mesh elements. Polyhedral mesh elements are considered. A mesh with smaller element size is said to be a finer mesh. Figure 3 shows the employed polyhedral mesh element at the middle plane of domain. CFD simulations are performed for an average mesh resolution of 1, 2, 3 & 4 mm (Table 3) on all the geometries.

3.1.3. CFD set-up and Mesh dependency

The standard k-Ɛ turbulence model, elaborated earlier, using the pressure-velocity coupled SIMPLE algorithm as available in ANSYS-FLUENT 13.0 was employed for CFD analysis. The validation of adopted set-up is presented by Yadav et al. (2014) and Singh et al. (2015). Thus, no separate validation is provided in this paper. In these simulations, the considered maximum uniform axial-inlet velocity is 20 m/s with 3% turbulence intensity. For the gradient calculations, least-square scheme is employed. The first-order upwind scheme is employed for calculating momentum, kinetic energy (k) and its dissipation ($\mathcal{E}$) equations with a convergence criterion of 10^{-5}. The generated meshes for grid dependence investigation are given in Table 4.

Tab. 4: Mesh resolution

3	7 heliostats	4 mm	5.8	3.93 million

3.2. Large Eddy Simulation (LES) approach

In large eddy simulations, the sub-grid scales are filtered out and larger scales are resolved by the adopted filter or grid resolution and analyzed. The dimensionless implicit grid-filtered Navier-Stokes equations for an incompressible fluid are given as follows:

$$\frac{\partial \overline{u}_i}{\partial x_i} = 0 \tag{5}$$

$$\frac{\partial \overline{u}_i}{\partial t} + \frac{\partial}{\partial x_j}\left(\overline{u}_i \overline{u}_j\right) = -\frac{\partial \overline{p}}{\partial x_i} - \frac{\partial \tau_{ij}}{\partial x_j} + \frac{1}{\mathrm{Re}}\frac{\partial^2 \overline{u}_i}{\partial x_j x_j} \tag{6}$$

Where, $\overline{u}_i$ is the velocity component of the resolved scales, p is the pressure and Re is the Reynolds number. The turbulence stresses, τ_{ij} represent the effects of small scales on resolved structures and proportional to the mean velocity gradients, the large-scale strain rate tensor S_{ij}:

$$\tau_{ij}^a = \tau_{ij} - \frac{\delta_{ij}}{3}\tau_{kk} = -2\mu_T \overline{S}_{ij} \tag{7}$$

Where, τ_{ij}^a is the anisotropic part of the sub-grid scale Reynolds stresses τ_{ij} and δ_{ij} is Kronecker delta. The trace of the stress tensor is usually added to the filtered pressure p. The expression for eddy viscosity μ_T determined by Smagorinsky model (Smagorinsky, 1963) is as follows:

$$\mu_T = \rho\left(C_S \Delta\right)^2 \left|\overline{S}\right| \tag{8}$$

Where, Δ is the filter width which is proportional to the grid size, ρ is the density, C_S is the Smagorinsky constant, $\left|\overline{S}\right| = \left(2\overline{S}_{ij}\overline{S}_{ij}\right)^{1/2}$ is the magnitude of large-scale strain rate tensor. Further, Germano et al. (1991) proposed a dynamics sub-grid stress model which calculates C_S as a function of space and time by using two filters, test and grid filters. In dynamics model, Lilly (1992) proposed a least squares method to calculate C_S.

3.2.1. Geometry

Due to the computationally expensive nature of LES, this simulation is conducted over a smaller geometry with only one heliostat model as shown in Fig. 4 with corresponding dimensions in Table 5. This setup is experimentally analyzed in Yadav et al. (2014). This is utilized in this paper for validation of LES approach.

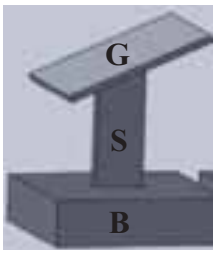

Fig. 4: Single heliostat

Tab. 5: Dimension of heliostat used in LES analysis

Component	Dimension (mm)
Glass Mirror (G)	60 x 60 x 3
Stand (S)	18 x 6 x 50
Base (B)	68 x 74 x 20

3.2.2. Mesh and CFD set-up

For the current study, sub-grid stress model is employed to simulate flow around a single heliostat with dimensions (see Table 5) as in Yadav et al. (2014). Uniform axial velocity as 16 m/s is applied at inlet with no perturbation as in the performed experiment. At walls, no slip boundary condition is used. SIMPLE algorithm is used with pressure-velocity coupling. Least-squares cell based scheme is used for gradient calculations. For continuity and momentum equations, bounded central differencing is used. The Y-plus at the heliostat plate ~ 2 (see Fig. 5b) as suggested by Davidson (2009). The total number of cells in the domain is around 1.0 Million. Fig. 5a shows the polyhedral mesh at the middle plane of the domain.

Fig. 5: (a) Polyhedral mesh at the middle plane of the domain; (b) Y-plus at the heliostat plate is ~ 2.

4. Results

4.1. RANS

Figure 6a shows various lines, namely, horizontal, longitudinal and vertical along which RANS analyzed axial-velocity is reported in Fig. 6b, c, and d. One of the representative heliostats is identified by symbol 'a'. Fig. 6b clearly depicts deceleration of axial velocity towards heliostat for the cases with 3, 5 and 7 heliostats. In these simulations the elevation angle is 25°. The arrow (→) indicates flow direction from left to right. It can be inferred that the axial-velocity, finally, develops to the maximum value, as expected, in far wake. This confirms that the considered length allows development of wake, as envisaged. The plotted time-averaged axial-velocity along the lines designated as "horizontal" and "vertical" enable tracking velocity changes. Figures 6c and 6d show that the calculated axial-velocity develops to free stream value of ~ 20 m/s near the wall along vertical and horizontal lines. Further, to evaluate whether the height of experimental set-up will allow using heliostat with the maximum elevation angle of 65°, additional calculations are performed. This is shown in Fig. 6d. This clearly indicates that the flow develops to free-stream condition over heliostat and eventually remains the same until viscous wall effect is encountered. Therefore, it can be safely stated that the considered length, breadth and height of 1700 mm x 1000 mm x 500 mm will be sufficient. However, a larger experimental domain of 2000 mm x 1200 mm x 600 mm is considered with ~ 20% safety margin. This is currently under fabrication and experimental results will be reported in near future.

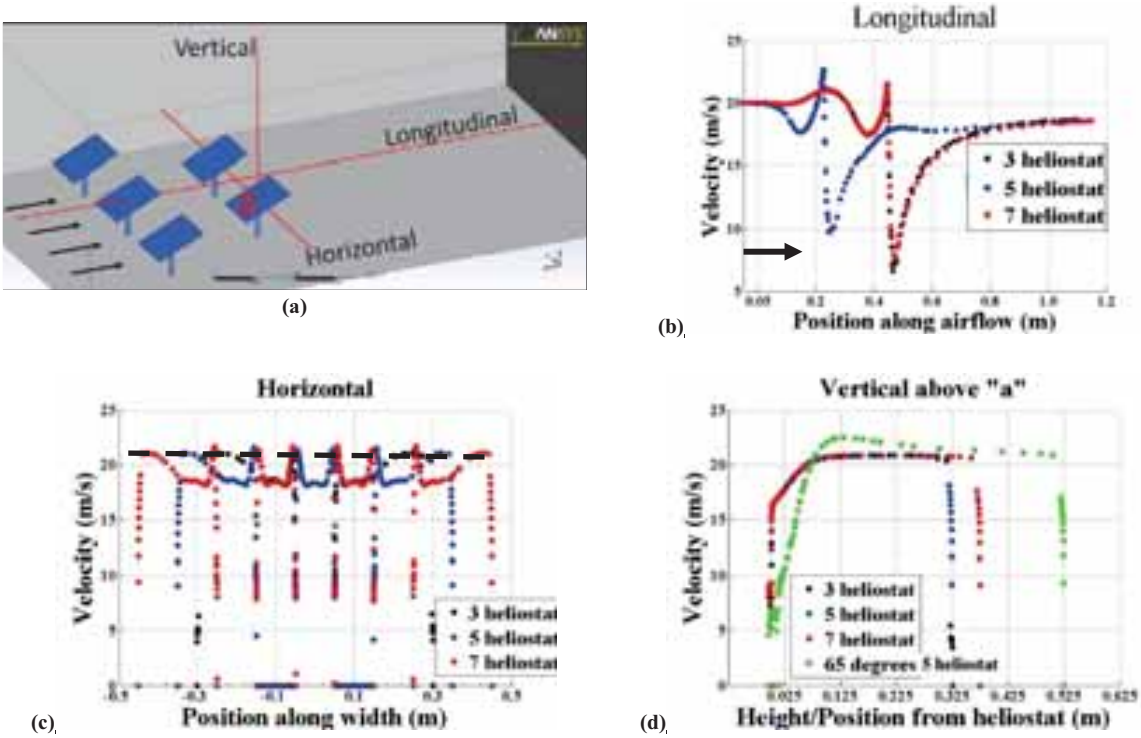

Fig. 6: (a) Geometry showing lines along which velocity is plotted. (b) Longitudinal line axial to the direction of flow, (c) Horizontal line through rear row of heliostats, (d) Vertical line above heliostat labeled "a" (including result for 65° elevation)

Velocity contours and streamlines are given in Fig. 7 for visual representation of the flow field. The velocity contour and streamlines in Fig. 7a and b clearly indicates the strongly affected region behind a heliostat. This results in formation of vortex, as expected, behind the heliostat. Figures 7c and d show the streamlines on a horizontal plane passing through the centers with 3 and 5 heliostats, respectively. Practically, no difference is observed as the wake develops eventually to free stream as depicted in Fig. 6b. However, the existence of heliostat in wake affected region may lead to its induced vibration resulting in a higher spillage loss or even distorted focus on receiver.

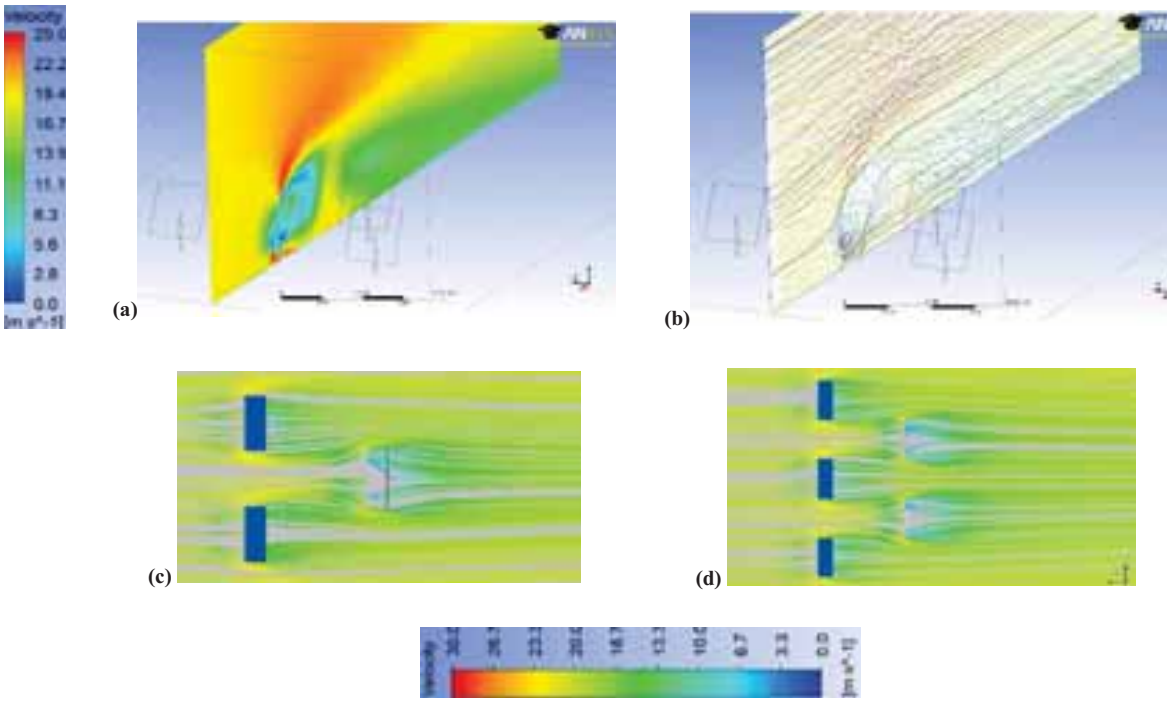

Fig. 7: (a) Velocity contour (b) Streamlines and vectors in vertical plane through a heliostat, (c) Streamlines at horizontal mid-plane through 3 heliostats and (d) through 5 heliostats

4.2. LES

It should be emphasized that RANS showed clear limitations in predicting near-wake region of heliostat. This region is characterized by high RMS values as observed in experiments. The previous studies (Breuer et al., 2003; Rodi, 1993) of flow past an inclined plate revealed that the separated flow shows complicated and highly unpredictable behavior. Obviously, the standard k-$\mathcal{E}$ model was not suitable. In order to capture the dynamic behavior of flow behind the heliostat model, LES analysis is performed using zero-equation sub-grid scale model as proposed by Germano et al. (1991). The LES analyzed instantaneous iso-surface of coherent structures for a given vorticity is shown in Fig. 8a behind the model heliostat. This is colored with velocity. These flow structures are expected to cause induced vibration and also affect the dust deposition on the subsequent heliostats. Thus, a parameter based on wake-based factor is required for field design. Fig. 8b shows the comparison between LES analyzed and measured axial-velocity using Laser Doppler Velocimetry (LDV). The velocities are plotted at seven locations, from 5 mm to 30 mm with 5 mm gap and at 200 mm from the trailing edge of the heliostat plate along the axial axis of plate, marked as 1 to 6 & 7 on horizontal axis respectively. Further, LES analyzed and experimentally estimated RMS values of axial-velocity are plotted at similar locations in Fig. 8c. It could be observed that the LES analyzed values are within ± 10% of the experimentally measured values. Thus, it can be safely stated that the performed LES provided useful details about mean and fluctuating flow quantities. However, further improvement using one-equation model is expected.

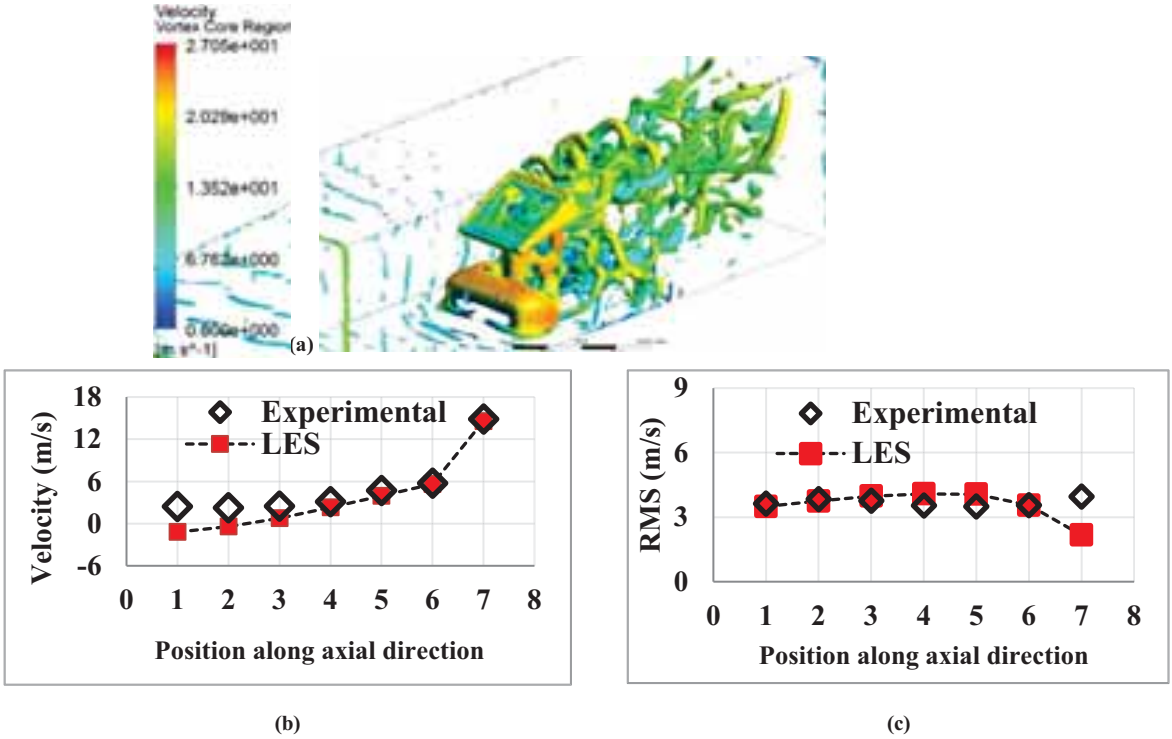

Fig. 8: (a) Coherent flow structures correspond to 620 Hz; (b) Time-averaged Mean Velocity and, (c) RMS velocity along an axial line behind the heliostat at 5, 10, 15, 20, 25, 30 & 200 mm from trailing edge represented by numbers 1 to 6 & 7, respectively.

5. Conclusion

This paper presents the design and evaluation of an experimental set-up for analysis of fluid flow and dust deposition on heliostats in a field layout. For this purpose, a basic field using scale-down heliostat models is designed using available literature. Afterwards, using the validated RANS CFD approach a detailed air-flow analysis around heliostats is performed. This reveals that even with an extreme inclination angle of 65°, an experimental domain of 2000 mm x 1200 mm x 600 mm will allow wake and flow development to free-stream values. Further, detailed LES analysis showed the presence of coherent structures behind a heliostat, which is expected to induce vibration if a heliostat is exposed. Therefore, it is concluded that correction parameters Considering the stability and safety of the operation based on wake-related and dust-deposition factors will be

required for a more realistic evaluation of field- design and performance. The designed experimental set-up is currently under fabrication and experimental results will be reported in future.

Comparison-based Study on A Novel Point and Line Coupling-focus Solar Tower System Employing Linear Fresnel Heliostats

Yanjun Dai, Xian Li

Institute of Refrigeration and Cryogenic Engineering, Shanghai (China)

Abstract

The design and analysis of a beam-down solar tower system represents an extremely complex problem due to its performance dependent on various interrelated factors. A novel heliostat with linear Fresnel reflecting technology is employed in the beam-down solar tower and investigated theoretically in this paper, being its superior wind-resistance performance compared with convectional heliostat. In order to investigate the concentrating principle of linear Fresnel heliostat, a comparison-based study of these parameters and efficiencies is implemented herein. The effects of the hyperboloid eccentricity on both the sun-shape and the geometry of the heliostat are analyzed. The effect of the aberration in optics for the linear Fresnel heliostat on the image at the focal plane has been investigated.

Keywords: *Point and line coupling-focus solar tower, beam-down, linear Fresnel heliostat, optical analysis*

1. Introduction

It is well known that the energy and environmental crisis has been promoting the development of solar thermal technologies, where concentrating solar tower technology has been proven to be a fairly efficient way of converting solar energy into thermal energy or electricity (Kalogirou, 2004). As for the traditional concentrating solar tower, solar energy from a large array of heliostats is focused onto a tower that captures the heat by a receiver, and then converts that heat to electricity using a steam generator and a steam turbine. However, it can be pretty expensive in terms of building a low heat-loss tower and pumping heat transfer fluid (HTF) such as molten salt up to the tower top which usually mounted at hundred meters high to the ground. In order to overcome these shortcomings, beam-down solar tower (BST) has been proposed and developed, where a second set of beam-down concentrator (BC) directs the solar radiation back down to a central receiver (CR) placed on the ground, instead of having the heat-capturing system up at a high tower. On account of aforementioned merits BST technology is considered as one of the promising ways to harvest solar energy and is worth continuing research.

A variety of studies on optical performance of various BST systems are in the literature. The concept of BST was proposed for the first time by Rabl (1976) and then developed at the Weizmann Institute in Israel (Segal and Epstein, 1997). Segal and Epstein (1999, 2000, 2003) described the optics of the BST system, where two types of secondary reflectors, hyperboloid and elliptical were investigated for a comparative study. However, a single solar ray per heliostat was considered, and shading and blocking effects have been neglected. Detailed optical analysis of BST systems with the hyperboloid concentrators and the compound parabolic concentrator (CPC) have been performed (Leonardi, 2012; Wei et al., 2013), but solar flux distribution on the absorber surface of the CR have not been involved.

In this paper, a BST system employing strong wind-resistance linear Fresnel concentrating technology which is named as point-line-coupling-focus (PLCF) system, is introduced and investigated theoretically. Based on the MCRT, the optical analysis model of PLCF system is developed considering the incident angle, solar position, optical errors, and sun-tracking angles. Comparison-based study on the optical performance between PLCF and convectional systems is implemented.

doi:10.18086/swc.2015.04.05 Available at http://proceedings.ises.org

2. PLCF system description

A schematic of concentrating concept of BST including a linear Fresnel heliostat and a beam-down concentrator (BC) is shown in Fig. 1. A hyperboloid reflector is used as the BC. The incident rays hit on the surfaces of Linear Fresnel heliostat facets. The heliostat tracks sun and reflects incident rays to the BC, and then these rays are concentrated downwards to the final focal point at the focal plane. The concentrating process of this BST is mainly composed of focusing effects of heliostat and BC. The detailed parameters of linear Fresnel heliostat has been introduced by Li et al. (2015). As shown in Fig. 1, l_m and H_h are the length and the height of the linear Fresnel heliostat, respectively. D is the distance between the heliostat and the cavity receiver. H and H_{max} are the height of point A and the maximum height of the hyperboloid reflector, respectively. F_1 and F_2 are the upper focus (target point) and lower focus (focal point), respectively. r_{max} is the maximum radius of the hyperboloid reflector.

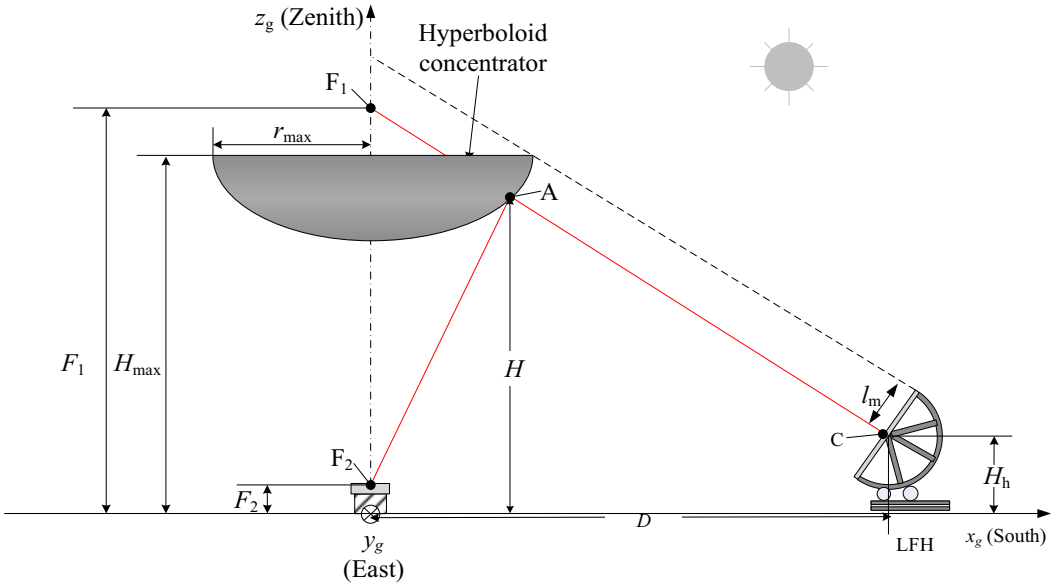

Fig. 1: Schematic diagram of geometric parameters of the PLCF system with the hyperboloid concentrator

3. Optical analysis models

3.1. Sunshape

Because sun rays are not strictly parallel, the sun rays hitting on the surface of the sub-mirror are modelled as a conic bundle where the rays of the bundle are weighted with a non-uniform energy distribution. Based on the concept of sun-shape profile, the intensity distribution I of solar disk proposed by Johnston (1998) can be calculated as

$$I = I_o \frac{1+\beta\sqrt{1-\frac{\vartheta}{\vartheta_s}}}{\pi\vartheta_s^2\left(1+\frac{2\beta}{3}\right)} \qquad \text{(eq. 1)}$$

where ϑ denotes the angle of a surface element on the solar sphere, I_o is the intensity in the center of the solar disk, β is the limb darkening parameter.

3.2. Normal vector of optical surface

The normal vector ($\mathbf{N_F}$) of the optical surface where rays currently hit is expressed by a unified differential formula (Cui et al., 2012) derived from surface equations f of the investigated geometric surface:

$$\mathbf{N_F} = \begin{bmatrix} f_x \\ f_y \\ f_z \end{bmatrix} = \begin{bmatrix} \dfrac{\partial f(x_g, y_g, z_g)}{\partial x_g} \\ \dfrac{\partial f(x_g, y_g, z_g)}{\partial y_g} \\ \dfrac{\partial f(x_g, y_g, z_g)}{\partial z_g} \end{bmatrix} \quad \text{(eq. 2)}$$

3.3. Optical surface errors

It is generally assumed that all surface errors follow a Gaussian distribution (Rabl, 1985) characterized by the standard deviation. The variances of each individual error distribution can be summed to one total equivalent variance, σerr, which describes the composite effect of all errors, namely the specularity error, the slope error, the shape error, the alignment error, and the tracking error. The simple Rayleigh method of surface error (Cooper and Steinfeld, 2011) for generating surface error is given as

$$\theta_{err} = \sigma_{err}\sqrt{-2\ln U} \quad \text{(eq. 3)}$$

$$\phi_{err} = 2\pi U \quad \text{(eq. 4)}$$

$$\mathbf{M}' = \cos\theta_{err}\mathbf{M} + \sin\theta_{err}\left(\sin\phi_{err}\mathbf{u}_x + \cos\phi_{err}\mathbf{u}_y\right) \quad \text{(eq. 5)}$$

where ζ_{err} and ϕ_{err} are defined as the azimuthal angular and circumferential components of the surface error, respectively. U is the random number with uniform distribution in the interval of 0 and 1. M′ is deviant reflected vector with surface error. $\mathbf{u_x}$ and $\mathbf{u_y}$ are unit vectors in the Cartesian x-component and y-component directions, respectively.

3.4. Concentration ratio

The concentration ratio is defined as

$$C = \frac{A_h}{A_{sp}} \quad \text{(eq. 6)}$$

where A_h and A_{sp} represent the total aperture area of heliostat field and the spot area at the lower focal plane.

3.5. Optical efficiency

Optical performance index Optical efficiency of the BCST system is related to significant factors involving cosine efficiency ε_{cos}, shading and blocking efficiency ε_{sb}, interception efficiency ε_{it}, and the atmospheric attenuation efficiency ε_{aa}. Instantaneous optical efficiency with respect to above efficiencies, proposed by Schmitz et al. (2006), is expressed as

$$\eta_o = \eta_{cos}\eta_{sb}\eta_{it}\eta_{aa}\rho_h\rho_{BC} \quad \text{(eq. 7)}$$

where ρ_h and ρ_{BC} indicate the reflectance of LHF and BC, respectively.

4. Results and discussion

4.1. The effect of the structure of hyperboloid reflector

As shown in Fig. 2, the optical surface of hyperboloid reflector is mainly affected by the eccentricity e and the upper and lower focuses. Considering F_1 = 75m and F_2 = 5m, the effect of e on the hyperboloid structure is analyzed. Fig. 2(a) shows the relationship between e and the maximum radius r_{max}. As shown in Fig. 2(a), the r_{max} increases with the increase of the eccentricity e which shows an increasing trend. When $e > 50$, the increase of r_{max} is limited and trends to be stable. In addition, the distance D increases with the increase of r_{max}. Fig. 2(b) reveals the effect of e on the hyperboloid surface. As can be seen, under the identical conditions, the size of the hyperboloid surface increases with the increasing e. When e trends to infinity, hyperbolic mirror transfers to be the plane mirror.

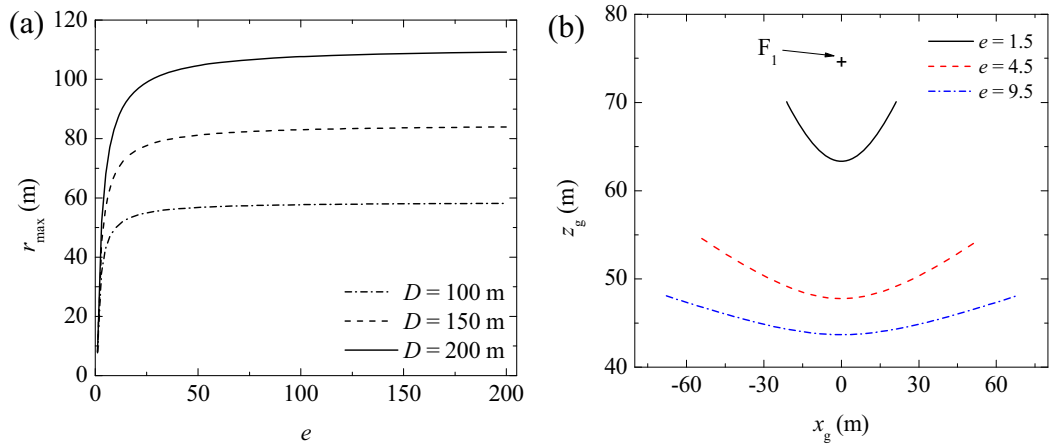

Fig. 2: The effects of D and e of geometric parameters on the shape of the hyperboloid reflector: (a) the maximum radiu r_{max} as a function of *e*; (b) the effect of parameter *e*

In this case, the magnification M is the ratio of the image size of the upper focal plane to the image size of lower focal plane. Based on the optical analysis of MCRT method, considering sun angle effects, the single ray reflected from point C is used to reveal characteristics of the spot on the lower focal plane. Fig. 3 shows the effects of D and e on the spot characteristics of a single ray reflected from the geometric center of heliostat. Fig. 3(a) shows the effect of the parameters of e and D on the spot sizes of the upper and lower focal planes. With the increase of e, the spot size of lower focal plane decreases. When e trends to infinity, the spot size of the focal plane trends to be the same. Fig. 3(b) is the relationship between e and M which increases sharply with the increase of e from 1 to 4.5, and the amplification factor decreases sharply. Therefore, the increase of D in a certain extent can weaken the negative effect caused by the magnification of the hyperboloid mirror, and can improve the concentration ratio. The comparison-based results show that the MCRT optical analysis model developed in this paper has the reasonable accuracy.

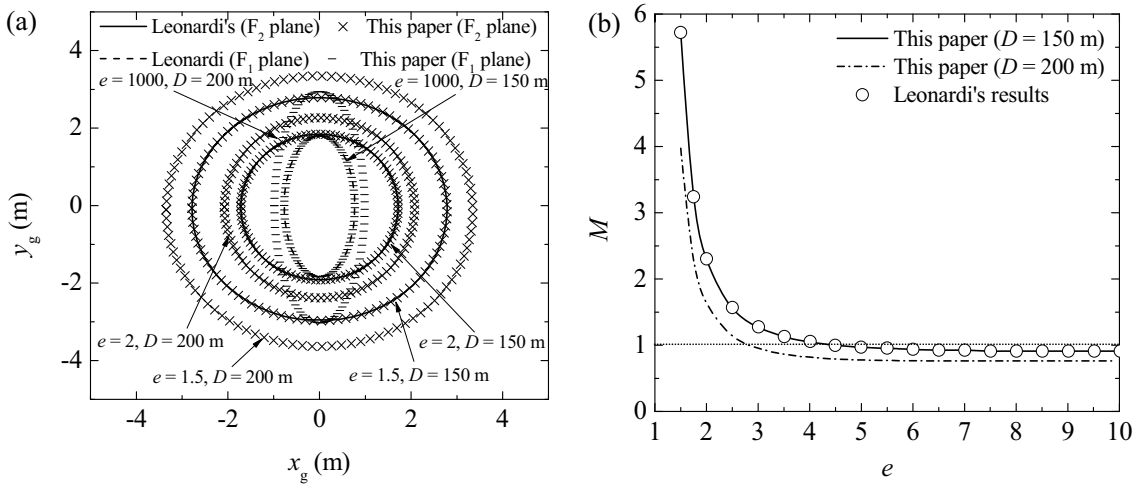

Fig. 3: The effects of *D* and *e* on the spot characteristics of a single ray reflected from the geometric center of heliostat: (a) the effect on the spot size; (b) the effect on the magnification *M*

4.2. The effect of structure parameters of linear Fresnel heliostat

The effect of heliostat structure parameters on optical properties is analyzed under the conditions of H_h=5m, F_1 = 75 m, F_2 = 5 m, r_{max} = 44.1 m, γ = 0°, α = 90°, D = 150 m, e = 3. With the diameter of 10 m of the circular heliostat (as shown in Fig. 4), the linear Fresnel heliostat is divided into five mirrors.

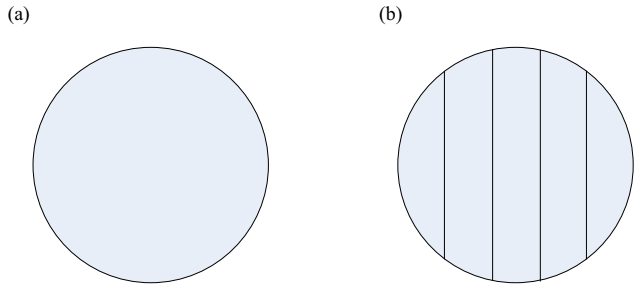

Fig. 4: Schematic diagram of heliostats: (a) convectional circle-plate heliostat (CH); (b) circle linear Fresnel heliostat (diameter of 10m)

Fig. 5 shows comparison results of the spot sizes of LFH and CH at the upper and lower focal planes. As shown in Fig. 5, the LFH has the smaller spot sizes compared to CH.

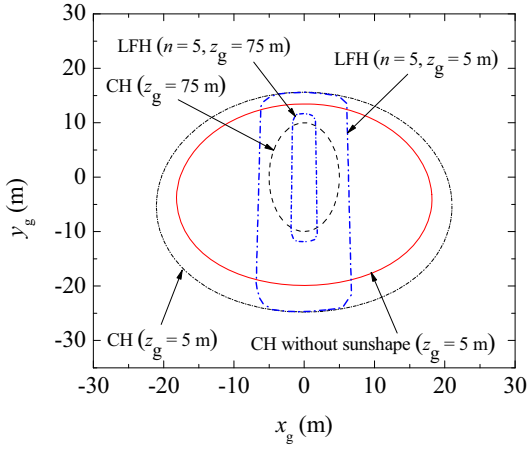

Fig. 5: Comparison results of the spot sizes of LFH and CH at the upper and lower focal planes

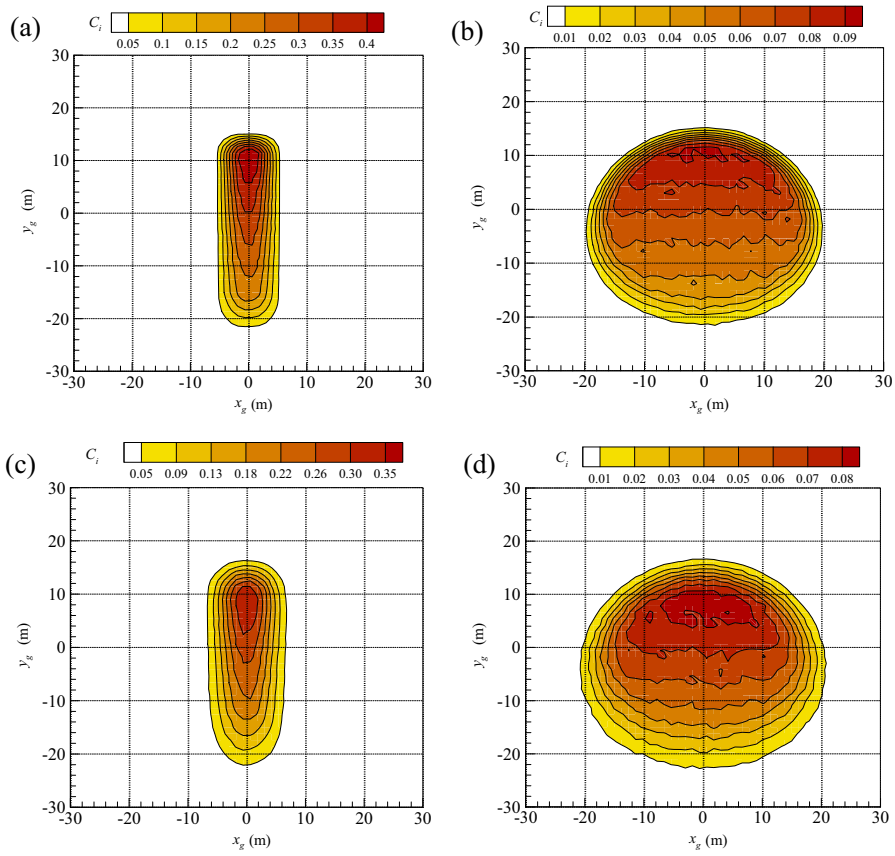

Fig. 6: Comparison results of the local concentration ratio of the spot for LFH and CH: (a) LFH without optical error; (b) CH without optical error; (c) LFH with optical error; (d) CH with optical error (σ_{err} = 3.5 mrad)

Concentrating ratio C is an important index to evaluate the solar concentrating characteristics. Fig. 6 shows comparison results of the local concentration ratio of the spot for LFH and CH. The effect of optical errors has been considered herein. Analysis shows that the linear Fresnel heliostat has obvious advantages in concentrating ratio. Comparative analysis of optical error of focal spot local concentration ratio can be found and certain extent increase of the focal spot size causes the decrease in concentrating ratio. However, the differences in local concentration ratio distribution between two heliostats are extremely limited.

4.3. The effect of structure parameters of heliostat mirror

The shape of the heliostat mirror has an important effect on the focusing performance. Here, the spot sizes of various length-width ratios are investigated with D = 150 m and e = 3. Fig. 7 reveals the effect of length-width ratio on the characteristic of the spot at the lower focal plane. The diameter of CPC is 20 m. Fig. 7(a), 7(b), and 7(c) represent the length-width ratios of 1:1, 5:1, and 2:1, respectively. As can be seen, when the length-width ratio is 1:1, the LFH has the highest optical efficiency of 73.1%.

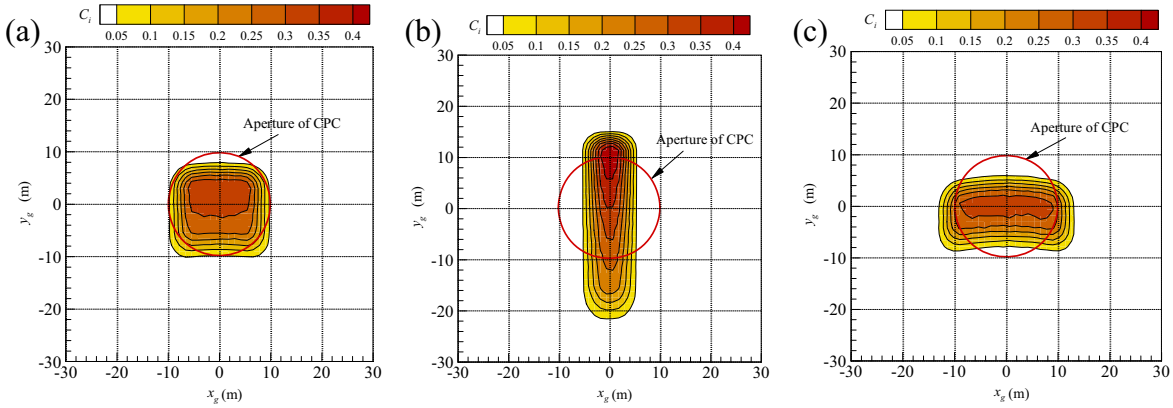

Fig. 7: The effect of length-width ratio on the characteristic of the spot at the lower focal plane: (a) length-width ratio of 1:1 with spillage loss of 26.9%; (b) length-width ratio of 5:1 with spillage loss of 41%; (c) length-width ratio of 2:1 with spillage loss of 31.2%

4.4. Comparison-based analysis of optical efficiency

The comparison-based analysis of optical efficiency is implemented considering the shape of heliostat shown in Fig. 8. Fig. 9 shows the effect of the solar position and design parameters on the cosine efficiency as well as the shading and blocking efficiency. The aperture area of heliostat is 100 m^2 facing south with the coordinates (-150, 0, 5). The parameters of hyperboloid reflector is e = 3, F_2 = 5 m. The aperture radius of CPC is 11 m.

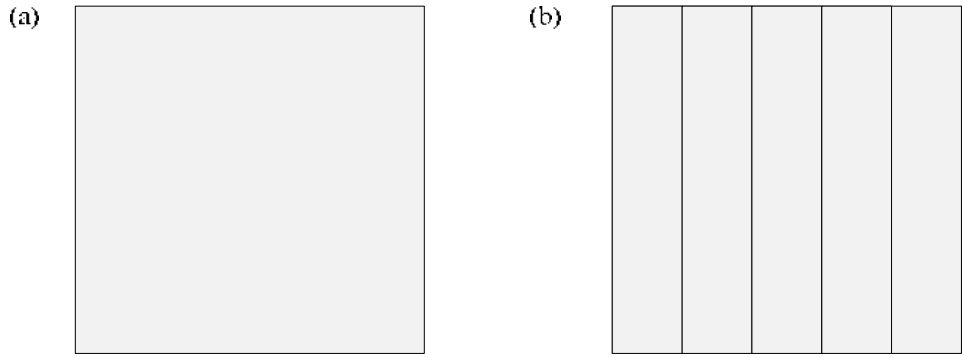

Fig. 8: Schematic diagram of heliostats: (a) convectional rectangle-plate heliostat; (b) rectangle linear Fresnel heliostat

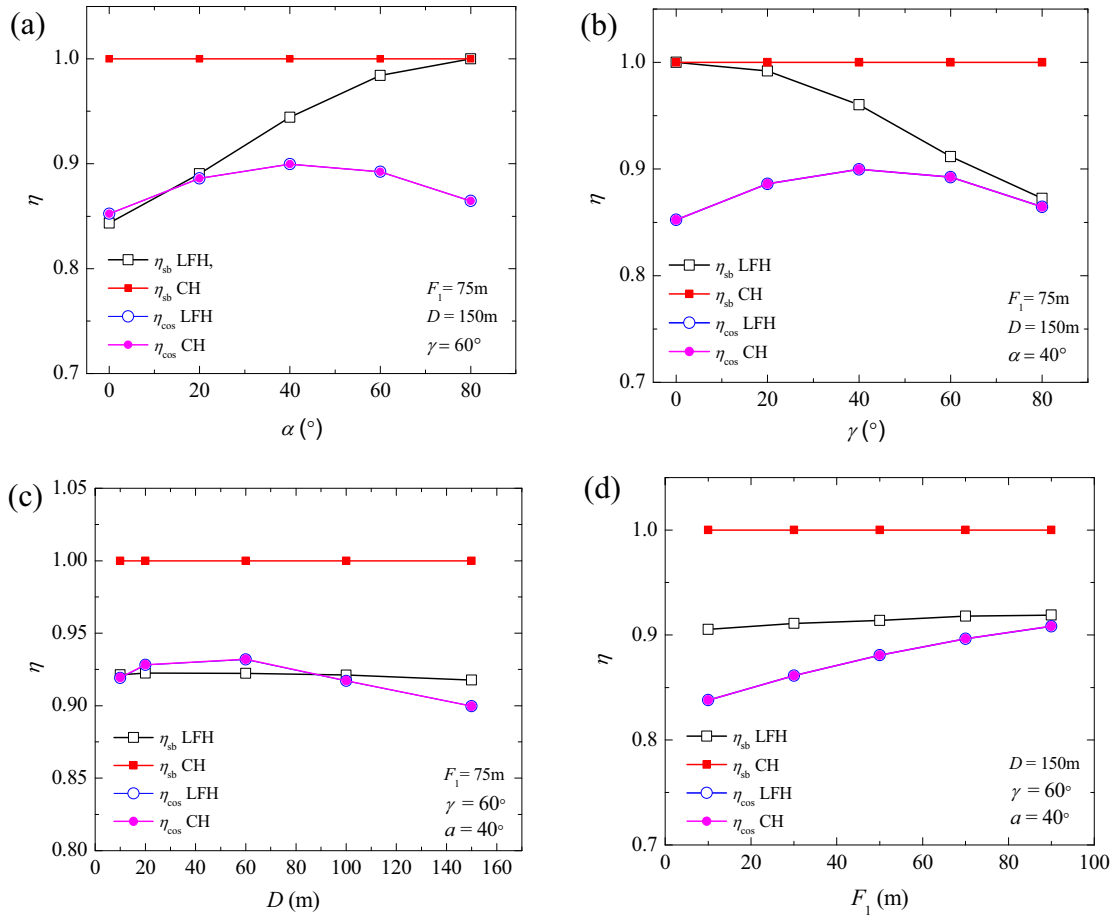

Fig. 9: The effect of the solar position and design parameters on the cosine efficiency as well as the shading and blocking efficiency: (a) the effect of solar altitude; (b) the effect of solar azumith; (c) the effect of the distance D; (d) the effect of the upper focus F1

As shown in Fig. 9, LFH and CH have the identical cosine efficiency which is not affected by the parameters of solar position and D. In addition, the LFH has a greater impact than CH with respect to the effects of solar position (solar angles) on shading and blocking efficiency. As shown in Fig. 9(c) and 9(d), the parameters of D and F_1 have limited impact on the shading and blocking efficiency. The effect of the shape of mirror (shown in Fig. 10) on the optical efficiency is studied herein.

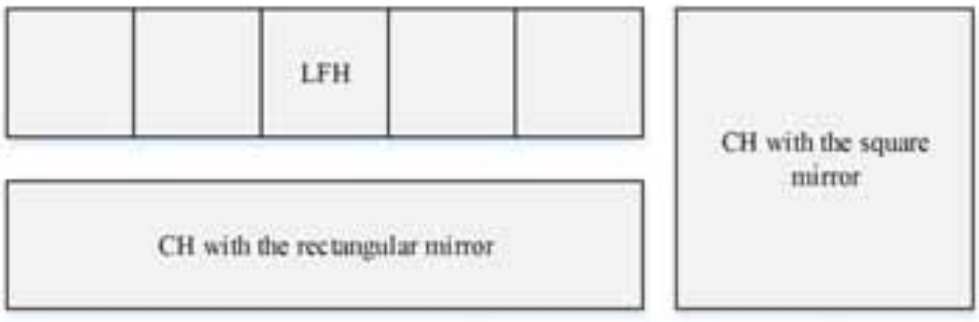

Fig. 10: The structures of LFH and CH with the identical area

Under the conditions of the aperture radius of 4.9 m, the solar altitude of 82°, the aperture area of the heliostat of 100 m^2 facing south, the coordinates (-150, 0, 5). The parameters of hyperboloid reflector (e = 3, F_1 = 75 m, F_2 = 5 m), the detailed comparison results are listed in Table 1. As can be seen, the shading and blocking efficiency of LFH is slightly lower than that of CH, however, the interception efficiency of LFH is obviously superior than that of CH. Thus, the optical efficiency of LFH is approximately 3.4 times the optical efficiency of a CH. In addition, the length-width ratio of 1:1 has the optimal optical efficiency.

Tab. 1: Comparison results of the optical efficiency of LFH and CH solar thermal system under various solar azimuth

5. Conclusions

A novel heliostat with linear Fresnel reflecting technology is employed in the beam-down solar tower and investigated theoretically in this paper, being its superior wind-resistance performance compared with convectional heliostat. The comparison-based study on the convectional heliostat and linear Fresnel heliostat is implemented. Following conclusions can be drawn:

(1) Analysis results shows that the linear Fresnel heliostat has obvious advantages in concentrating ratio and spot size.

(2) The shape of the heliostat mirror has an important effect on the focusing performance. The optimal length-width ratio is 1:1 in order to achieve the highest optical efficiency.

(3) Under the same conditions, the optical efficiency of LFH is approximately 3.4 times the optical efficiency of a CH.

3D Shape Measurement of Solar Concentrator Based on Orthogonal Fringe Reflection Method

Huibin Zhu[1], Zhifeng Wang[1], Jianhan Zhang[1] and Qiang Yu[1]

[1] Key Laboratory of Solar Thermal Energy and Photovoltaic System, Institute of Electrical Engineering, Chinese Academy of Sciences, Beijing 100190, China

Abstract

Fringe reflection technique is an effective tool to measure the solar concentrator surface slopes, and then reconstruct the surface shape from gradient. However, most of the fringe reflection systems are based on four-step phase shifting method, which need eight figures at least. In order to increase the measurement speed, a new orthogonal fringe reflection method is proposed to measure the shape of solar concentrator, which requires only two fringe images to complete the 3D shape measurement of solar concentrator. The performance of this 3D shape measurement system is demonstrated with experiments.

Keywords: *Shape measurement; Orthogonal fringe reflection; Solar concentrator*

1.Introduction

In a concentrating solar plant, the solar field consisting of a large number of collectors, which collects and concentrates the solar energy onto the receiver, is the major cost component of a plant. To obtain a homogeneous flux distribution on the receiver, the collectors shape must be highly precise to low the energy losses. The ideal shape and optical efficiency of the collector maximizes the energy input of the receiver and has a high impact on the plant performance. Therefore, it is very important to test and evaluate the quality of the surfaces for guaranteeing the optical performance. However, due to technical restraints in the manufacturing and installing process, deviations from the optimum collector shape leading to energy losses on the receiver cannot be completely avoided. On the other hand, it is necessary to measure and adjust the optical quality of the collectors in the manufacturing process. To test and qualify the collectors, a measurement tool for measuring the surface profile with adequate precision should be needed.

Many different techniques for shape measurement of solar collectors have been proposed by a variety of researchers in the past decades. In 1978, Sandia National Laboratories presented a measurement system based on a laser ray trace tester for solar parabolic trough collectors[1]. This system scanned the surface with a laser beam, detected the reflected beam on a target and obtains the normal of the collector surface. This system is sufficiently accurate, but the setup is time consuming and the implementation to large surfaces might be difficult. This limitation is overcame by photogrammetry which measure 3D shapes by calculating the coordinates of the collector surface based on a series of photographies of collector taken from different positions[2]. This method is also time consuming and not suitable for large surfaces since the measured surface has to be equipped with a large number of target points. Recently, Ulmer et al. developed a new

doi:10.18086/swc.2015.04.06 Available at http://proceedings.ises.org

method for measuring the slope error of heliostat based on deflectometry[3-6,22]. Later, we use the similar approach combined with temporal phase unwrapped technique and novel easy calibration method to measure the heliostat facet[7,21]. And there are some other methods to measure the shape of solar collector, which are shown in [8-16]. Most of the fringe reflection systems are based on four-step phase shifting method, which need eight figures at least. In order to increase the measurement speed, a new orthogonal fringe reflection method is proposed to measure the shape of solar concentrator, which requires only two fringe images to complete the 3D shape measurement of solar collector, and is very fast compared with the four-step phase shifting method.

On the other hand, one of the major challenges in fringe-reflection measurement is to realize the shape reconstruction efficiently. In several cases it is sufficient to know the local gradient; however, it is also important to obtain the height information of the solar collector as well. If the shape is known, it is easy to align the collector according to the measured shape results. To obtain the shape of the solar collector, a numerical shape reconstruction method is needed. Essentially there are two different approaches for integration: local and global integration techniques [17,18]. Local method: it integrates along predetermined paths. The advantage of this method is that it is simple and fast. However, the locality of calculation causes a high dependency from data accuracy, and the propagation of height increments along paths also means propagation of errors. Global method: it tries to minimize a designed cost function. The advantage of this method is that there is no propagation of error. But the implementation has certain difficulties and somehow is not easily convergent. So, the desired surface reconstruction method should have the properties of both local and global integration methods; it needs to preserve local details without propagating the error along a certain path. In order to handle this problem, we choose a generalized Hermite interpolation approach employing radial basis functions (RBFs) for the shape reconstruction from the gradient data. This method has the advantage that it can be applied to scattered data. It allows us to integrate data sets with holes, irregular sampling grids, or irregularly shaped boundaries [19]. Finally, the performance of this 3D shape measurement system is demonstrated with experiments.

2.Principle of fringe reflection method

The optical properties of solar collector such as reflectivity do not allow us to apply the direct structured light illumination principle, because the projected structured light is reflected along the mirror direction and no light reaches the CCD sensors. However, it is possible to capture the reflective structured light and obtain the surface information of solar collector based on the fringe reflection technique. The main idea of this reflection technique is that: a fringe pattern generated by the computer can be projected onto a target screen, and the distorted fringe pattern from the solar collector is captured by the CCD camera, which is reflected by the surface under test. The distortion of the fringe pattern depends on the local slope variations and the height of the surface. By establishing the mathematical models, which combine the phase difference between the corresponding point on the reference surface and the measured object, the surface height and slope, the shape of the measured solar collector surface can be determined based on approximation employing radial basis functions discussed below. The schematic diagram of this measurement principle is shown in Figure 1.

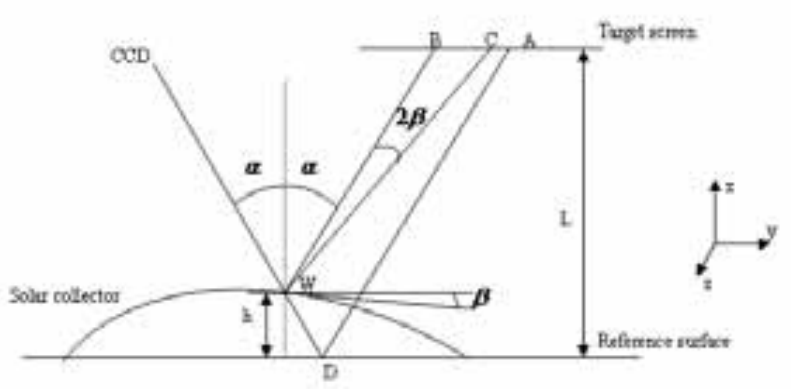

Figure 1: The schematic diagram of fringe reflection technique.

Figure 1 shows the optical configuration of the measured system. A fringe pattern generated by computer from a DLP projector is reflected off the solar collector and captured by CCD camera. The camera sees point A on the target screen with fringe pattern through the reference surface point D. Because of the solar collector surface with height value h and tilted at an angle β in the y direction, the collector surface point W reflects point C on the target screen. It is easy to obtain that the distance difference between the reflected point A and surface point C is related to the surface height and slope in both x and y direction. In this paper, the phase-shift profilmetry can be used to determine this difference. Based on the geometrical configurations in Figure 1, the relationship between the phase difference $\Delta\varphi(x,y)$, the slope $\tan\theta$ and the height h of the collector surface can be established as [24]:

$$\begin{aligned}\theta_x(x,y) &= \frac{\Delta\varphi_x(x,y)p_x}{2\pi(L-h)} \\ \theta_y(x,y) &= \frac{\Delta\varphi_y(x,y)p_y}{2\pi\sec(\alpha)^2(L-h)+\Delta\varphi_y(x,y)p_y\tan(\alpha)}\end{aligned} \tag{1}$$

where (x,y) is the pixel coordinate, $\theta_x(x,y)$ and $\theta_y(x,y)$ are the angles of the measured surface in the x and y directions, respectively, L is the height of the target screen to the reference surface, α is the angle of the camera, $\Delta\varphi_x(x,y)$ and $\Delta\varphi_y(x,y)$ are the phase difference, p_x and p_y are the period of the fringes projected onto the screen in the x and y directions, respectively, h is the height from surface point W to the reference surface. The pattern phase distribution of each observed point can be evaluated by the phase retrieved method.

3.Orthogonal fringe reflection method

Although the phase-shifting method which need eight figures at least is an effective tool to measure the solar concentrator surface slopes, reasonable faster way to obtain both horizontal and vertical phase maps from a single fringe image. In this section, a new orthogonal fringe reflection method is proposed to measure the shape of solar concentrator, which is designed as a two-directional fringe pattern shown in Fig. (2) and requires only two fringe images to complete the 3D shape measurement of solar concentrator. The orthogonal fringe pattern can be expressed as

$$I(x,y) = 255\left[0.5 + 0.25\cos\left(2\pi\frac{x}{p_x}\right) + 0.25\sin\left(2\pi\frac{y}{p_y}\right)\right] \tag{2}$$

where p_x and p_y are fringe periods in the horizontal and vertical directions. The fringe phase values in both x and y directions can be calculated by the two-dimensional windowed fourier ridges method.

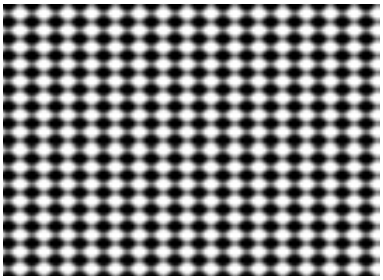

Figure 2: Orthogonal fringe

4.System calibration

The system calibration is very important in the shape measurement, because several different devices and objects are involved in the measurement system, such as CCD camera, projector, target screen, solar collector. Firstly, the CCD camera can be calibrated precisely by Tsai algorithm to provide the intrinsic and extrinsic parameters by using the checkerboard pattern. The system information about pixel size in both x and y directions, rotation angles and translational components for the transform between the measurement screen and the camera coordinate can be obtained. The next calibration algorithm is the reference plane calibration. This requires the measurement of the flat reference surface with respect to the camera position and involves the measurement of the phase distribution of the flat reflective surface across the measurement scene. This reference phase distribution is required in order to obtain the correct phase shift information from the measurement object. A novel virtual reference plane based on Zernike polynomials fitting method is presented. In the measurement system, the phase difference between the reference surface and collector surface should be determined. Because the solar collector is large, it is not easy to directly obtain the reference surface phase as size as the measured object. In order to solve this problem, the Zernike polynomials fitting method can be used to obtain the reference phase distribution: a small flat surface acts as reference plane, based on the phase distribution of the flat surface in both horizontal and vertical directions and Zernike polynomials fitting method, the phase distribution of virtual reference plane in the field of view during the whole measurement operation can be fitted. Once the calibration is finished, the system is ready for measurement.

5.Shape reconstruction

From Equation (1), it is easy to find out that not only the slopes but also the height of the collector surface has an influence on the position of the observed point on the screen. In order to obtain the height of object, we should reconstruct the collector shape from gradient data, which is very important to absolutely measure and evaluate the optical character of solar collector. To reconstruct the shape, one has to use the numerical integration method. But, most existing methods have different drawbacks: they either suffer from error propagation, or they introduce global errors due to unknown boundary conditions. The desired shape reconstruction method should have both local and global integration methods, which means that it should preserve the local details without propagating the error along a certain path. In this paper, the interpolation approach is used to reconstruct the shape from gradient data[19]. The gradient data is given as

pairs $(p_x(X_i), p_y(X_i))$, where $p_x(X_i)$ and $p_y(X_i)$ are the measured slopes of the collector at X_i in x and y directions, respectively ($1 \le i \le N$). Define the interpolate to be

$$z(X) = \sum_{i=1}^{N} \alpha_i \phi_x(X - X_i) + \sum_{i=1}^{N} \beta_i \phi_y(X - X_i) \tag{3}$$

where α_i and β_i are coefficients and ϕ is a radial basis function. ϕ_x and ϕ_y denote the analytic derivative of ϕ with respect to x and y , respectively. To obtain the coefficients in Equation (3), the analytic derivatives of the interpolate ϕ with the measured gradient data are matched as:

$$z_x(X_i) = p_x(X_i);\ z_y(X_i) = p_y(X_i); \tag{4}$$

The coefficients can be determined by solving the following linear equations:

$$\begin{pmatrix} \phi_{xx}(X_j - X_i) & \phi_{xy}(X_j - X_i) \\ \phi_{xy}(X_j - X_i) & \phi_{yy}(X_j - X_i) \end{pmatrix} \begin{pmatrix} \alpha_i \\ \beta_i \end{pmatrix} = \begin{pmatrix} p_x(X_i) \\ p_y(X_i) \end{pmatrix} \tag{5}$$

Based on the resulting coefficients α_i and β_i , the collector surface can be reconstructed by using the interpolate in Equation (3). The radial basis function ϕ can be chosen to be the Wendland's function[20] :

$$\phi(r) = \frac{1}{3}(1-r)_+^6(35r^2 + 18r + 3), r = \sqrt{x^2 + y^2} \tag{6}$$

This has two reasons for choosing the function. Firstly, Wendland's function allows one to choose their continuity according to the smoothness of the given data. This function is in $C^4(R_+)$ and leads to an interpolant, which is three times continuously differentiable and guarantees the integrability condition. Secondly, the compact support of the function allows one to adjust the support size in such a way that the solution of Eq. (5) is stable in the presence of noise [19]. To achieve this, one has to choose an appropriate scaling factor ρ . In [23], the authors showed that with an increasing support radius the interpolation error (i.e., the deviation from the measured slope data) increase, while the evaluation error (the deviation of the reconstructed shape) decreases. A larger support radius leads to more stable reconstruction in the presence of noise.

In the measurement, the amount of data is rather large. To solve such large data, the following method is presented: firstly, the data sets are split into a set of overlapping patches. On each patch, the data is interpolated and the calculated up to a constant of integration. Secondly, the least-squares fitting scheme is used to obtain the reconstructed surface on the entire field.

In Equation (1), both parameters L and α are unknown, an iterative strategy is applied to obtain the shape of measured collector surface:

1) Calculate the phase difference $\Delta\varphi_x$;
2) Let the height $z^0 = 0$, calculate the gradient $\tan\theta$ from Equation (1);
3) Reconstruct the height z^m of each patches from the gradient data, then obtain the entire field shape based on fitting scheme;
4) Calculate the difference between the adjacent iterative results $\Delta = z^m - z^{m-1}$;

5) If Δ is bigger than the iterative termination condition, calculate the gradient data from Equation (1) again. Then, return step 3); Otherwise, go to step 6);
6) Iterative terminate, recover the shape of collector.

In order to demonstrate the ability of proposed method, a simulation is conducted. The simulated function is defined by

$$z = 3(1-x)^2 \, \mathrm{e}^{(-x^2-(1+y)^2)} - 10\left(\frac{x}{5} - x^3 - y^5\right) \mathrm{e}^{(-x^2-y^2)} - \frac{1}{3}\mathrm{e}^{(-(1+x)^2-y^2)} \tag{7}$$

where the in-plane dimension x and y are both limited within a range from -3 to 3 mm with a sampling of 200×200 points. The true height is shown in Figure 3. The radial basis function integration method is used to integrate the shape within 13×13 subsets with a subset size of 20×20 and 25% overlap between neighboring subsets. Figure 4 (a) depicts the reconstructed shape on overlapping patches. Figure 4(b) and (c) show the reconstructed shape and the reconstructed height error. The deviation of height errors (RMS) is only less than 6×10^{-4} mm.

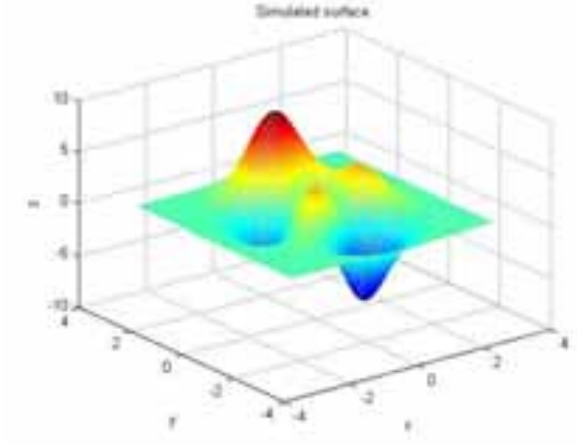

Figure 3: Simulated surface.

(c)

Figure 4: (a) Reconstructed shape on the overlapping patches; (b) Reconstructed shape of surface; (c) Reconstructed shape error.

6.Experiment

An experimental investigation of the feasibility of the proposed method is carried out as well. A RP3 inner mirror is measured with the fringe reflection technique. Figure 5(a) shows the two-dimensional pattern on the screen, which is projected on the target screen, the distorted patterns are captured by CCD camera (shown in Fig.5(b)). Figure 6 (a) - (d) show the slope distribution and slope error in both x and y directions, respectively, in which the local discontinuous areas are due to the phase unwrapped algorithm of the two-dimensional pattern. The slope errors (RMS, deviation from the ideal slope of shape) are: 2.6129mrad (x-direction), 0.1460mrad (y-direction). The proposed reconstructed method is then utilized to integrate the gradient data to reconstruct the shape of collector, which is shown in Figure 7 (a). In Fig. 7(b), it is the reconstruction error, (deviation from the ideal shape) which shows that this reconstruction method is efficient even in the presence of the phase-unwrapped errors of Fig 6(a)-(d).

7.Conclusion

In this paper, a solar collector surface measuring system based on orthogonal fringe reflection technique was built. The orthogonal fringe was projected onto a target screen and the deformed pattern modulated by the measured collector was captured by CCD camera. By establishing the mathematical relationship between phase difference and the gradient values of collector surface, the slope results were obtained. A shape reconstruction method based on approximation employing radial basis functions was proposed. Compared with the classical four-step phase shifting method, the proposed technique required only two fringe images to achieve 3D shape measurement of solar concentrator. The experiment measurement results demonstrated that not only were fine details preserved, but also the global shape was reconstructed as well, and even higher global accuracy. Furthermore, this measurement system made it possible to measure a large class of solar collectors.

Abstract

Recently, researchers of Niigata University and the Institute of Applied Energy (IAE) developed an air receiver-evaluation system equipped with 30kW_{th} point-concentration simulator to support solar-thermal usage in middle to high temperature. 147mm×147mm×100mm monolithic silicon carbide (SiC) honeycomb block used as volumetric receiver sample, and some experimental results were gathered from demonstration tests. Also, its three-dimensional simulation method was developed on FLUENT 14.5, in parallel. This simulation, based on dual-cell approach, considers that thermal non-equilibrium between solid and fluid domains in porous region defined as volumetric receiver material. And, its calculation regions include the upper and lower air domains in the porous region; therefore, this method is able to analyze the influence of inlet/outlet air flow. Under the same condition with tests, power on aperture (POA) and air-mass flow rate (AMF), some numerical results indicated similar results. This paper describes an example compared simulation and computational result. Also, a comparison between receiver outlet air temperature and solid/fluid max temperature caused by receiver material (SiC and Si_3N_4: silicon nitride) is presented.

1. Introduction

At present, solar thermal assessment have been carried out by many institutes and researchers, for renewable and clean solar thermal usage attract attention as an alternative energy to fossil fuels (Tsoutsos et al., 2003; Reif and Alhalabi, 2015). In Europe and United States, parabolic-trough solar plants are in operation to produce electricity to grid through the commercial operating. But its ability of electricity production is not enough for energy demand grown larger every year. On the other hands, tower type Concentrated Solar Power (CSP) plant is possible to achieve higher temperature than traditional solar plant because of its high concentrating ratio; therefore, there is a possibility of making a high efficiency generation (Ávila-Marín, 2011). A tower CSP plant combined with traditional Combined Cycle (CC), also called Solar-driven Combined Cycle (SCC), for practical solar-thermal utilization is expected to solve the energy problem people face today (Poživil et al., 2014). In order to realize the SCC technology, there are some studies of volumetric receiver using porosity material (mesh, foam, or honeycomb etc.) and its material (metal or ceramics etc.) (Fend et al., 2004; Ávila-Marín et al., 2014; Sallaberry et al., 2015). But, these research are still on fundamental stage and a lot of information (e. g. receiver geometry, material and thermal property etc.) are necessary to design high-temperature and -durability receiver.

In 2013, researchers of Niigata University and IAE developed an air receiver-evaluation system used a world-class 30kW_{th} beam-down point concentration sun simulator and its three-dimensional simulation method for

doi:10.18086/swc.2015.04.07 Available at http://proceedings.ises.org

research and development of solar-thermal receivers in middle to high temperature range (Nakakura et al., 2015). This evaluation system is possible to test by a beam-down point concentration, independent of unstable natural environment. Also, its simulation based on the dual-cell approach considers that thermal non-equilibrium between fluid and solid domain. Its numerical model includes upper/lower fluid domain on receiver; accordingly the influence of inlet-/outlet-air on receiver is able to analyze in detail. In this paper, the receivers of SiC and Si_3N_4 are simulated to reveal their suitability as volumetric receiver material.

2. Calculation model and boundary conditions

The computational model of the volumetric receiver flow and heat transfer was developed on ANSYS FLUENT 14.5. Figure 1 shows the mesh model of volumetric receiver and its calculation domain. Receiver material domain defines that porous medium have a solid domain within fluid one, and its size is similar to experimental sample 145mm×145mm×100mm. In this simulation, this porous domain is assumed to be a honeycomb geometry adapting the drag coefficient of rectangular to air flow direction. This three-dimensional simulation based on the dual-cell approach considers that the thermal non-equilibrium between the solid and fluid domain of the porous. Also heat flux distribution performed linear interpolation is adapted to the porous-surface as a boundary condition. This flux distribution was measured using Niigata University's $30kW_{th}$ sun simulator through the scanning of a gardon gage (Nakakura et al., 2015). The outlet plane is used to definite air-mass flow rate (AMF), and the boundary of each plane is insulated. This calculation domain include upper and lower domain of the porous as a feature, hence this method is able to analyze the influence of inlet-/outlet-air flow effected to the porous medium.

The continuity and momentum equations are expressed as:

$$\nabla \cdot (\gamma \rho \vec{v}) = 0 \; ; \qquad \text{(eq. 1)}$$

$$\nabla \cdot (\gamma \rho \vec{v} \vec{v}) = \; -\gamma \nabla \rho + \nabla \cdot \mu \gamma (\nabla \vec{v} + \nabla \vec{v}^T) + \gamma \vec{B}_f - \left(\frac{\gamma^2 \mu}{K} \vec{v} + \frac{\gamma^3 C_2}{2} \rho |\vec{v}| \vec{v} \right). \qquad \text{(eq. 2)}$$

This momentum equation is added by the pressure loss term arising from the viscosity and inertia in the porous domain. In this equation, γ represents porosity, B_f is body force, 1/K is viscous loss coefficient, and C_2 is inertial loss coefficient. This model assumes incompressible ideal gas, and considers the temperature dependency of density, viscosity and specific heat. Also SST k-ω model is used as turbulence equation; it follows,

$$\frac{\partial}{\partial x_i}(\rho k u_i) = \frac{\partial}{\partial x_j}\left(\Gamma_k \frac{\partial k}{\partial x_j} \right) + G_k - Y_k \; , \qquad \text{(eq. 3)}$$

$$\frac{\partial}{\partial x_i}(\rho \omega u_i) = \frac{\partial}{\partial x_j}\left(\Gamma_\omega \frac{\partial \omega}{\partial x_j} \right) + G_\omega - Y_\omega + D_\omega \; . \qquad \text{(eq. 4)}$$

In this instance, Γ is effective diffusivity, Y is dissipation due to turbulence, G is generation term, and D_ω is cross-diffusion term. The subscript k represents turbulence kinetic energy, and ω represents specific

Tab. 1: The calculation parameters.

Elements	Porosity γ	Material	Density ρ_s (kg m^{-3})	Thermal conductivity k_s ($Wm^{-1}K^{-1}$)	Specific heat C_{ps} ($J\ kg^{-1}\ K^{-1}$)	
179202	0.538	SiC	3200	90	1000	
		Si3N4	3300	27	650	
Specific surface A_{fs} (m^{-1})	Heat transfer coefficient at radiated surface h_{fs} ($W\ m^{-2}\ K^{-1}$)	Ambient air temperature T_{amb} (K)	Viscos loss coefficient 1/K[X, Y, Z]	Inertial loss coefficient C_2[X, Y, Z]	Apparent absorptivity α_{app}	Apparent emissivity ε_{app}
2105	114.2	300	0, 0, 0	100, 100, 0.432	0.70, 0.83	0.70, 0.83

dissipation rate. Energy equations based on the dual-cell approach can be written as:

$$\frac{\partial}{\partial t}\left(\gamma\rho_f E_f\right) + \nabla\cdot\left(\vec{v}\left(\rho_f E_f + p\right)\right) = \nabla\cdot\left(\gamma k_f \nabla T_f - \left(\sum_i h_i J_i\right) + \left(\bar{\bar{\tau}}\cdot\vec{v}\right)\right) + h_{fs}A_{fs}\left(T_s - T_f\right) \quad \text{(eq. 5)}$$

$$\frac{\partial}{\partial t}\left((1-\gamma)\rho_s E_s\right) = \nabla\cdot\left((1-\gamma)k_s\nabla T_s\right) + h_{fs}A_{fs}\left(T_f - T_s\right). \quad \text{(eq. 6)}$$

The dual-cell approach solves each energy equation for fluid/solid domains, under thermal non-equilibrium assumption; so it takes into consideration of the interaction of heat transfer, in porous domain. Each energy equation of solid/fluid domain is added non-equilibrium source. In these energy equations, E refers to total energy, k is thermal conductivity, and h_{fs} is heat transfer coefficient at radiated surface, A_{fs} is specific surface. The subscript f represents fluid domain, s represents solid domain. Also, surface-radiation is treated as a boundary condition without using radiation models, described as:

$$Q_{total} = \alpha_{app}Q_{solar} + Q_{rad} \quad \text{(eq. 7)}$$

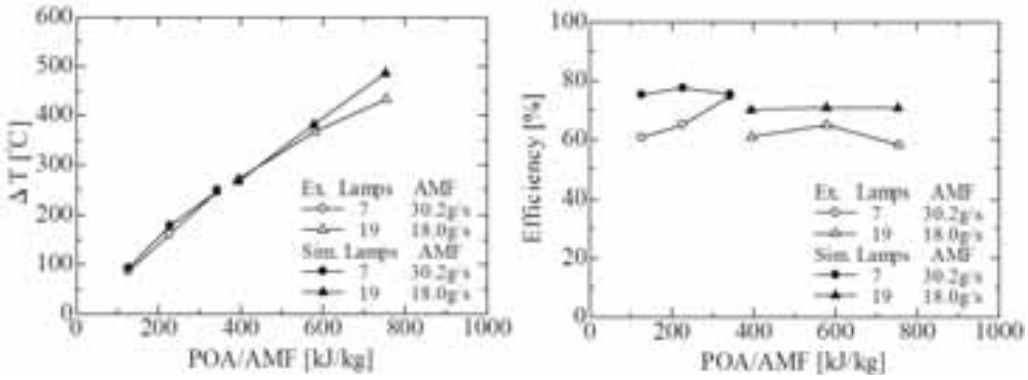
$$Q_{rad} = \sigma\varepsilon_{app}\left({T_{amb}}^4 - {T_{surf}}^4\right) \quad \text{(eq. 8)}$$

In this equation, Q_{solar} refers to heat flux distribution adapted to porous surface, α_{app} and ε_{app} are apparent absorptivity and emissivity due to receiver geometry, σ is Stefan-Boltzmann constant, T_{amb} is ambient air temperature, and T_{surf} is porous surface temperature. Table 1 summarizes numerical parameters used in this simulation.

3. Simulation results and analysis

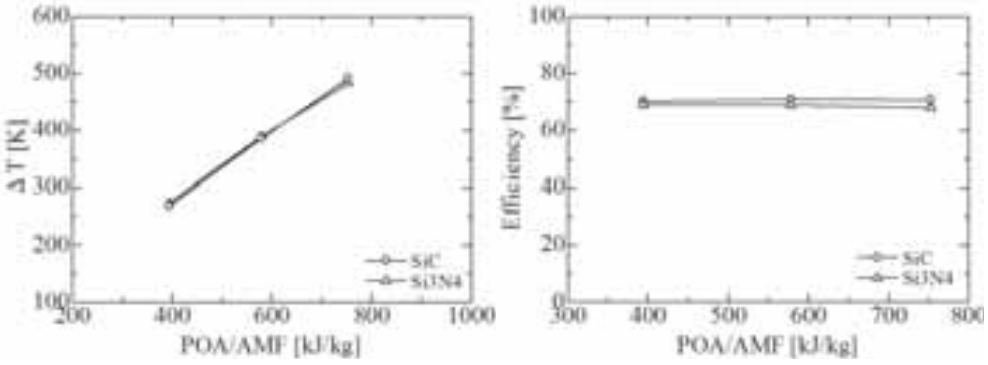
3.1. Results of three-dimensional simulation

Figure 2 indicates that a comparison between experimental results and simulation ones. The y-axis shows ΔT or efficiency, and the x-axis is POA/AMF. The ΔT is calculated from difference between the outlet air temperature and the ambient air temperature. Also, the efficiency represents the ratio of thermal absorption on an exhaust bulk air temperature to power-on-aperture (POA). Firstly, through some calculations under the same condition with the test, the numerical analysis is able to obtain the similar results with experimental ones in both of ΔT and efficiency. Hence, this simulation method indicates the accuracy of simulation as volumetric receiver evaluation. The difference of ΔT in the high-temperature range is estimated by temperature-independence on the porous media. Also, in the experimental tests, efficiency is calculated from heat-absorption of coolant water and exhaust air to POA; therefore, the value calculated from experimental results is lower than simulation results because there is a heat-conduction loss from air to water.



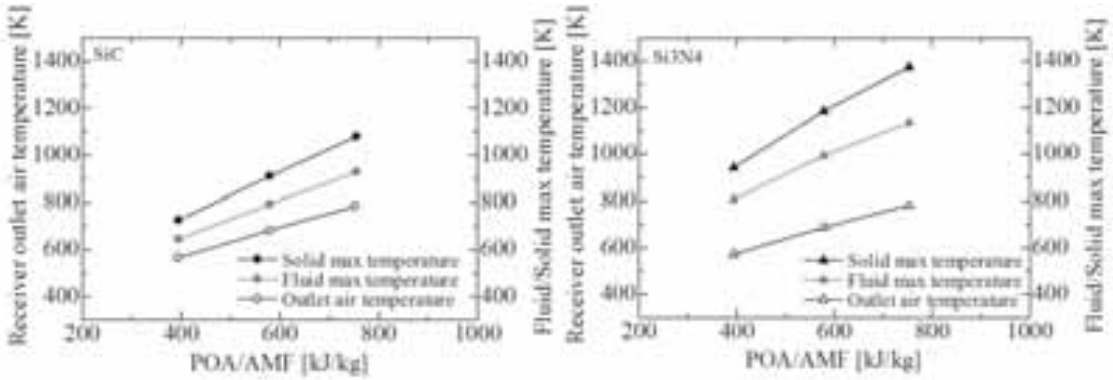
(a) Delta T (b) Efficiency

Fig. 2 Comparison between experimental results and simulation ones.



(a) Delta T (b) Efficiency

Fig. 3 Comparison between SiC and Si_3N_4.



(a) SiC (b) Si_3N_4

Fig. 4 Outlet air temperature and solid/fluid maximum temperature.

Figure 3 designates results of ΔT and efficiency from some calculation fed the physical property of SiC or Si_3N_4. There are no significant difference both of ΔT and efficiency on the values. Approximately, ΔT is 500K, and efficiency is 70% both of cases.

Figure 4 shows a comparison of the outlet air-temperature and the solid/fluid maximum temperature in SiC or Si_3N_4. The outlet air-temperature, as shown in Fig. 3, don't reveal a difference between SiC and Si_3N_4. However, there are large gap on the solid and fluid maximum temperature. In relation to the solid maximum temperature, Si_3N_4 derives 1375K, and SiC shows 1061K. The difference in temperature between the solid max- and outlet air-temperature is 592K and 270K, in each case. Also, on the fluid maximum temperature, Si_3N_4 is 1134K, and SiC is 932K. The difference in temperature between the fluid max- and outlet air-temperature shows 351K and 141K, in each case. This cause of the differences between Si_3N_4 and SiC will be

discussed in detail, below.

3.2. Analysis of contours

SiC and Si_3N_4 as a volumetric receiver material will be discussed from some counters of results acquired in subsection 3.1. All of the following figures are obtained from a state of POA/AMF=800kJ/kg.

Figure 5 indicates that fluid-temperature distribution on Z-X cross-section of the calculation model. The ambient air is heated on porous domain, and exhausted through the outlet pipe at approximately 800K. In the case of Si_3N_4, high temperature air reach down to more deep position than SiC. Also, the highest temperature appears into the slightly downward spot, not on the irradiated surface in both cases. These results are guessed from influence of inlet air-flow.

Similarly, figure 6 shows solid-temperature distribution on Z-X cross-section of the simulation model. There is the radial heat conductivity from irradiated centre in both cases. In the deep position of Si_3N_4, solid-temperature is higher than SiC, likewise the fluid-temperature. Also, slightly, solid-temperature at end of the porous media is lower; therefore large temperature distribution is able to be confirmed than SiC.

Figure 7 represents temperature distribution of porous surface. The thermal conductivity and specific heat of Si_3N_4 are lower than SiC. Hence, it is easy to increase temperature of irradiated point, but it is hard to expand the heat around the porous media.

Figure 8 shows a streamline of SiC. About a streamline, there was no noticeable difference between SiC and Si_3N_4. This simulation is possible to verify the behaviour of air-flow on the volumetric receiver from the upper and lower calculation domain. The ambient air is inhaled into the porous from extensive area, and accelerated at the outlet pipe.

By these counters, the solid maximum temperature of Si_3N_4 is approximately 300K higher, and, according to the low conductivity, temperature distribution is tend to be larger than SiC; therefore, only in the point of heat transfer performance, SiC is speculated the advantage as volumetric receiver material than Si_3N_4.

4. Conclusion

(1) Niigata University and the Institute of Applied Energy developed a volumetric receiver evaluation system using world-class 30kW_{th} point-concentration sun simulator and its three-dimensional simulation method.
(2) The accuracy as a simulation method was confirmed by the comparison between experimental- and numerical-results; therefore this method is able to be used in data acquisition related to the volumetric receiver or new design one.
(3) Under the same condition of POA and AMF, there was not much of a difference in the outlet air-temperature between SiC and Si_3N_4. Nevertheless, on the porous media, SiC possessed a small temperature distribution comparatively, hence the advantage of SiC as volumetric receiver was verified in the point of heat transfer ability.

Abstract

Three dimensional numerical modeling of parabolic trough receiver is performed to study the non uniform flux distribution on the outer surface of the receiver by coupling Monte Carlo Ray-Tracing Method (MCRT) with the Finite Volume Method (FVM) and calculated non uniform flux distribution is considered as a thermal boundary condition. The numerical model is solved by considering RNG k–ε turbulent model. In this paper, different Heat Transfer Fluids (HTF) with respect to the various operating parameters such as mass flow rate, Direct Normal Irradiation (DNI), inlet temperature and ambient conditions are considered. The temperature profile of both absorber and glass envelope follows the non-uniform solar heat flux distribution curve. Three dimensional temperature distribution of the absorber tube is calculated numerically for different inlet temperature and velocity of HTF. The maximum solar heat flux attained by the PTC receiver is 9753.3 W/m^2, 19506 W/m^2, 29260 W/m^2, and 39013 W/m^2 when the DNI are 200 W/m^2, 400 W/m^2, 600 W/m^2, and 800 W/m^2 respectively.

1. Introduction

Parabolic Trough Collector (PTC) system is having considerable attention among the other solar concentrators because it needs only single axis tracking and moderate receiver operating temperature. The receiver is the key element of the PTC system where solar radiation is absorbed and converted into thermal energy (Kalogirou, 2004). The receiver is placed on the focal line and it heats the Heat Transfer Fluid (HTF) which flows through it. The incident solar radiation which falls on the collector eventually gets concentrated on the receiver surface which gets converted into thermal energy. The heat transfer process of receiver can be summarized as: the incident solar radiation on the absorber, the convection heat transfer between the HTF and the absorber, the conduction and radiation heat transfer through the absorber wall and the glass tube, and the heat transfer from the glass tube to the ambient (Mahoney, 2002). Non uniform flux developed on the outer surface of receiver due to the concentration of solar energy results in thermal stress and circumferential temperature difference on the absorber wall are the prime reason for the failure of PTC receiver tube. The temperature increase depends on the geometrical concentration ratio and optical properties of the collector as well as fluid flow in the absorber tube. Accurate studies are needed to find three dimensional temperature distributions of the absorber tube and its thermal expansion and deformation for any safe and efficient operation. Deformation of the absorber tube takes place due to a non-uniform thermal expansion (Iverson et al., 2011). Due to this deformation of PTC receiver, it will go out of focal point and causes different problems such as decreasing the life time of collector, breakage of cover glass tube and also it drops optical efficiency of the collector. Edenburn et al., (1976) predicted the efficiency of a PTC by using an analytical heat transfer model for evacuated and non-evacuated cases. The results showed good agreement with

doi:10.18086/swc.2015.04.08 Available at http://proceedings.ises.org

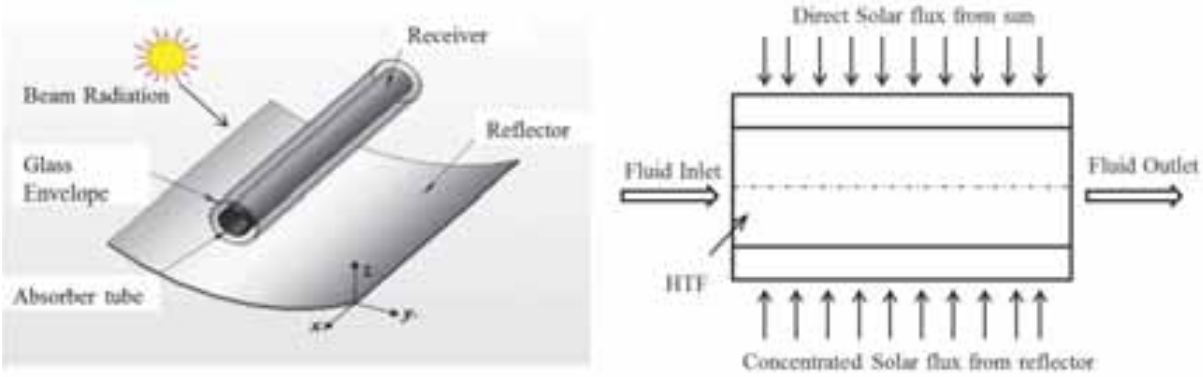
measured data obtained from SNL collector test facility (Pope et al., 1973). Ratzel et al., (1979) carried out both analytical and numerical study of the heat conduction and convective losses in an annular receiver for different geometries. Three techniques were proposed to reduce the conduction heat loss: evacuation, over sizing the annular receiver while keeping the Rayleigh number below 1000 over the range of operation and use of gases with low thermal conductivity. Clark (1982) analyzed the effects of design and manufacturing parameters that influenced the thermal and economical performance of parabolic trough receivers

Recently, Cheng et al., (2012) reported a three-dimensional simulation of a parabolic trough solar collector with non-uniform solar flux conditions by incorporating the FVM and the MCRT method, in which the effects of the properties of different HTFs to the whole temperature distributions in the receiver, the thermal loss and the collector efficiency were numerically studied Moreover, the effects of the DNI, Reynolds number and emissivity of the inner tube wall on the outlet temperature, average temperature of absorber outer wall, thermal radiation loss and efficiency, and the concentrating characteristics of the parabolic trough solar collectors PTC (He et al., 2011) were discussed. Because of the non-uniform distributions of the solar energy flux, there exist CTD of the absorber and the cover, which has a crucial influence on the circumferential stress and the deformation of the receiver tubes. Numerous studies have been carried out to investigate the temperature distributions and thermal stress fields of tubes and receivers with various material conditions. A numerical analysis had been conducted by Chen et al., (2004) to study the effect of using porous material for the receiver on temperature distributions. Experiments were conducted by Fend et al., (2004) to research the temperature distributions on the volumetric receivers used two novel porous materials. Numerical simulations are used to investigate the detailed temperature distribution, and its corresponding structural deformation of the stainless steel tube of PTR. The simulations are performed by combining a MCRT code and Finite Volume Method. The non-uniform concentrated solar heat flux on the steel pipe was obtained through the MCRT method (He et al., 2011). The fluid–solid coupled heat transfer was solved with the finite volume method. The concentrated solar heat flux was used as a boundary condition of the fluid–solid coupled heat transfer modeling. In the annular vacuum gap, the conduction was ignored, and the infrared radiation heat transfer was treated as a gray enclosure and modeled with S2S radiation model. In the CFD simulations, the studied PTR (Fig. 1) was assumed to be structurally rigid, and its surfaces have wavelength independent properties. The HTF (heat transfer fluid) had temperature dependent properties. Güven et al., (1986) established an optical model which used a ray-tracing technique to evaluate the optical performance and determined the optical errors by means of a statistical analysis. Valladares et al., (2009) proposed a numerical simulation of the optical, thermal and fluid dynamic behavior of a single-pass solar PTC and extended the study by replacing the absorber with counter-flow concentric circular heat exchangers (double-pass). Kumar et al., (2009) investigated heat transfer enhancement of solar receivers with porous insertions by numerical simulation and found that significant heat transfer improvement (64.3%) was obtained. Stuetzle et al., (2002) proposed a 2D unsteady state analysis of solar collector absorber to calculate the collector field outlet temperature: the model was solved by discretizing the partial differential equations obtained by the energy balance.

2. Description & Specification of PTC System

The parabolic solar collector tube consists of cylinder. The inner tube is a metallic tube and the outer tube is a glass tube. Fig. 1 shows the physical geometry and cross section of PTC, which is made by bending a sheet of reflective material into a parabolic shape surface. A receiver tube is placed along the focal line of the parabolic reflective collector. The receiver tube usually includes an inner absorber tube and a glass cover. The glass cover is used for reducing heat loss; as well as the annular space between the inner tube and the glass cover is vacuumed, which helps to decrease the convection heat loss. Fig.1, should include the following processes: convection heat transfer between the HTF and the absorber; solar irradiation absorption in the absorber; conduction heat transfer through the absorber wall; heat transfer from the absorber to the glass tube; solar irradiation absorption in the glass tube; conduction heat transfer through the glass tube; heat transfer from the glass tube to the atmosphere, etc. Particularly, both the convection and the radiation heat transfer occur between the outer absorber surface and the inner glass tube surface. The convection heat transfer mechanism depends on the annulus pressure (KJC Operating Company, 1993). It may either be

molecular conduction or free convection. The heat transfer from the glass tube to the atmosphere is also caused by convection and radiation, where the convection is either forced or natural, depending on whether there is wind around the glass tube.



(a) (b)

Fig. 1: Physical model (a) Schematic of PTC (b) Cross section view

The radiation heat transfer occurs due to the temperature difference between the outer absorber surface and the inner glass tube surface, so does the glass tube and sky.

3. Numerical modeling and analysis

The simulations consist of Monte-Carlo ray tracing, CFD modeling. Firstly, Monte-Carlo ray tracing was used to calculate the concentrated solar radiation heat flux distribution on the stainless steel tube (absorber tube) of PTR. This flux distribution is treated as a boundary condition of the CFD analysis. Secondly, CFD was used to model the flow and heat transfer (including convection, conduction and radiation heat transfer) in the PTC receiver.

3.1 Governing Equation

The geometrical model of PTC receiver is shown in Fig.1. The heat transfer process in PTC can be summarized as: the incident solar radiation on the absorber, convection heat transfer between HTF and absorber, conduction and radiation heat transfer through the absorber wall and the glass tube, and heat transfer from the glass tube to the ambient.

As the test conditions shown in Table 1, the fluid flow is in turbulent and in steady state conditions. So the governing equations is given by (Cheng et al., 2010)

$$\partial / \partial x_i(\rho u_i) = 0 \qquad \text{(eq. 1)}$$

$$\rho C_p u_i \frac{\partial T}{\partial x_i} = (k + k_i)\frac{\partial}{\partial x_i}\left(\frac{\partial T}{\partial x_i}\right) \qquad \text{(eq. 2)}$$

$$\frac{\partial T}{\partial x_j}\left(\rho u_i u_j\right) = -\frac{\partial P}{\partial x_i} + \frac{\partial}{\partial x_j}\left[(\mu + \mu_i)\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) - \frac{2}{3}(\mu + \mu_i)\frac{\partial u_i}{\partial x_i}\delta_{ij} - \frac{2}{3}\rho k\delta_{ij}\right] + F \qquad \text{(eq. 3)}$$

3.2 Boundary conditions

The boundary conditions used in this study are:

(1) For the fluid domain, the inlet boundary conditions are defined as the mass flow rate and inlet temperature of HTF. Similarly the outlet boundary condition is fully developed flow condition. Adiabatic boundary condition is applied at both the ends of the receiver walls (Thermal insulation at the absorber end).

Inlet: $m = m_{in}$, $T = T_{inlet}$ $kin = 0.005\rho u_x^2$, $\varepsilon_{in} = C\mu\, \rho_f\, k_{in}^2 / \mu_t$

Where $C\mu = 0.09$, $\mu_t = 100$

Outlet: Fully developed flow condition

(2) Periodic boundary conditions are used for the absorber tube's inlet and outlet. The inner absorber tube walls are considered no-slip and no-penetration .The outer wall of the absorber tube receives a non uniform heat flux. The lower half receives almost concentrated solar radiation while the upper half receives direct solar radiation

(3) The inner surface of absorber tube and the heat transfer fluid were defined as coupled fluid–solid interfaces in which the energy is conserved.

(4) The outer surface of absorber tube and inner surface of glass envelope are formulated by the surface-to-surface radiation

(5) The outer surface of the glass envelope was defined with a mixed boundary with convection and radiation.

(a) Convection boundary condition: (i) if the convection was assumed to be natural (no wind around the PTC receiver) the correlation to estimate heat transfer coefficient .

$$h = {Nu_{D,g}\lambda}\Big/{D_{g,o}} = {\left(\left(0.48\, Ra_{D,go}^{\,0.25}\right)\lambda\right)}\Big/{D_{g,o}} \qquad \text{(eq. 4)}$$

(ii) if the convection was assumed to be forced (presence of wind around the PTC receiver) the experimental correlation to calculate the heat transfer coefficient (Mullick and Nanda, 1989)

$$h = 4V_w^{\,0.58} D_{g,o}^{\,-0.42} \qquad \text{(eq. 5)}$$

(b) Radiative boundary condition**:** The Stefan– Boltzmann law is used to calculate the net radiation transfer by assuming that the glass cover is a small convex gray object in a large blackbody cavity (sky, approximated 8℃ below the ambient temperature). i.e. surface to ambient condition

(6) For the inlet and outlet of the receiver's annulus space, symmetry boundary condition is used such that the normal gradients of all flow variables are zero.

3.3 Computational domain and Properties of HTF:

The computational domain includes the absorber tube domain (solid), the liquid oil domain (fluid) . The material for the solid domain is stainless steel and the thermal conductivity is fixed at 54 W /m.K. Syltherm 800 liquid oil was used as the working fluid. And the properties of working fluid, such as: isobaric specific heat capacity (cp), thermal conductivity (l), density (r) and dynamic viscosity (m) should be selected to simulate the heat transfer process in absorber tube by FLUENT. The properties of HTF are considered to be temperature dependent (He et al., 2011).

3.4 Grid independent study

To guarantee that the computed results were accurate and reliable, a grid independence study was conducted. Simulations with three grids (50,000, 60,000, 70,000, 80,000 elements) were performed. Four different grids are chosen to calculate the temperature difference between the inlet and outlet of PTC receiver for the same boundary conditions. There are less than 2% differences temperature increment between grid 3

and grid 4. The authors concluded that 80,000 elements are enough for this study, and grid 4 with 80,000 elements was used all over this study. It is a traditional grid independence test method for the fluid and heat transfer problem. It should be noted that the minimum grid density is limited by the systematic error.

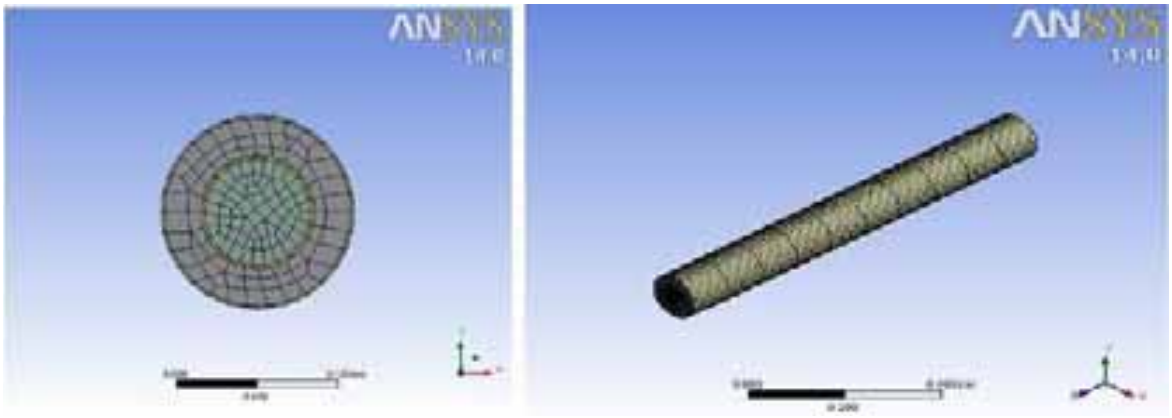


Fig. 2: Grid generated view of fluid region, absorber and glass envelope

4. Numerical modeling and Analysis

A three dimensional mesh was generated and used in this study, see Fig. 6. Dense grids were generated near the bellows where large temperature gradient exists. This three dimensional conjugate heat transfer problem was solved using the CFD software Ansys 14. The standard k–e model (high Reynolds number) was used along with conventional wall functions in this study. The SIMPLE algorithm was used to couple the pressure and the velocities with the second order upwind method used for the advection terms in the momentum equations and for the energy equation. User defined functions (UDF) were used to define the concentrated solar radiation flux on the selective coating and the circumferential distributed source term of the glass envelop. The used discretizations of all the solved equations were second order. The convergence criterion was set to 10^{-4} for continuity and momentum equations and 10^{-7} for energy equation. Radiative heat loss from the receiver pipe solely depends on the emissivity of the pipe, temperature of the pipe and the temperature of the surrounding objects. Hence the receiver pipe and the glass envelope were assumed to be gray and diffuse, and were simulated by surface-to-surface (S2S) radiation model. The glass envelope is assumed to be opaque to the radiation within the infrared energy spectrum.

.4.1 Monte Carlo Ray Tracing (MCRT) Method

The flowchart of the Monte Carlo Ray-Trace method for the photon energy concentrating and collecting process of the whole PTC system is shown. The reflection Ray vector Rs is expressed according to the Fresnel law. Once the photon packet is initialized, the photon is moved, traced in the PTC system, and judged if it hits a boundary (surface) of one of the subsystems or components (such as the glass tube, the reflector and the absorber) on the way of the photon propagated where it may be reflected, absorbed or transmitted. The photon is repeatedly moved until it either escapes from or is absorbed by the system. If the photon hits a boundary when propagating, the corresponding judgment of reflecting, absorbing or transmitting event is adopted by the Monte Carlo method. If the photon escapes from the system, the corresponding parameter of recording the escaped photons is updated. If the photon is absorbed, the position of the absorption and the absorbed energy weight are recorded. This process is repeated until the desired numbers of photons have been propagated. Then the code validations are made and the non-uniform solar energy flux distribution is calculated.

4.2 Combine MCRT Method with FVM

The solar energy flux distribution on the outer wall of the inner absorber tube calculated by in-house developed Monte Carlo Ray- Trace (MCRT) code, then this flux is treated as the heat flux boundary for the simulation model in the FLUENT software with a self developed subroutine program. The self-developed

subroutine program forms a data file of the solar energy flux distribution that can be read by the FLUENT software as a boundary condition, while treating the solar absorption as a surface phenomenon.

5. Validation of Proposed Numerical Model

To further validate the reliability of the presented model, numerical simulations are simulated at the same operating conditions as Sandia test (Dudley.et al., 1994). The calculated heat flux by coupled MCRT and FVM method is validated with the existing model .The present model shows the 15% deviation with the existing developed model. Similarly the simulated circumferential temperature distribution of absorber also validated with existing model.

5.1 Validation of MCRT Code:

To validate the MCRT code, the calculation is performed on the same conventional PTSC as described .(He et al., 2011).using the MCRT method. Figure 10 shows the comparison between the circumferential local concentration ratio (LCR) distribution calculated by the MCRT method in this paper and by the semi infinite integration formulation .From that can be obviously seen that the two LCR distributions have a good agreement, which proves the MCRT code applied in the present study is accurate and reliable. Fig.2 presents the heat flux on the parabolic trough receiver surface. Numerical results show that the predicted results agree well with Wu et al., (2014), which also proves that the MCRT method used in the present study are feasible and the numerical results are reliable.

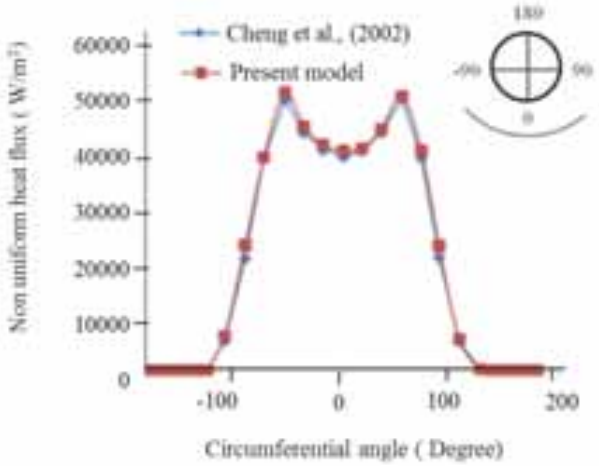

Fig. 4: Non uniform heat flux distribution around the receiver

5.2 Validation of Coupled FVM - MCRT Heat transfer Process:

To validate the simulation method for the coupled heat transfer process within the PTR, the simulation method is performed on the experimental model presented in Dudley et al (1994).

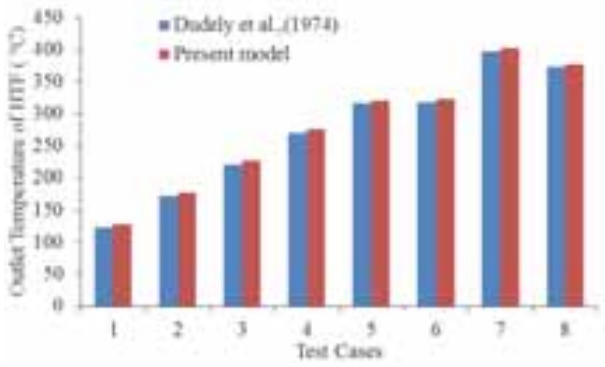

Fig. 5: Validation of receiver outlet temperature with Dudley et al., (1974)

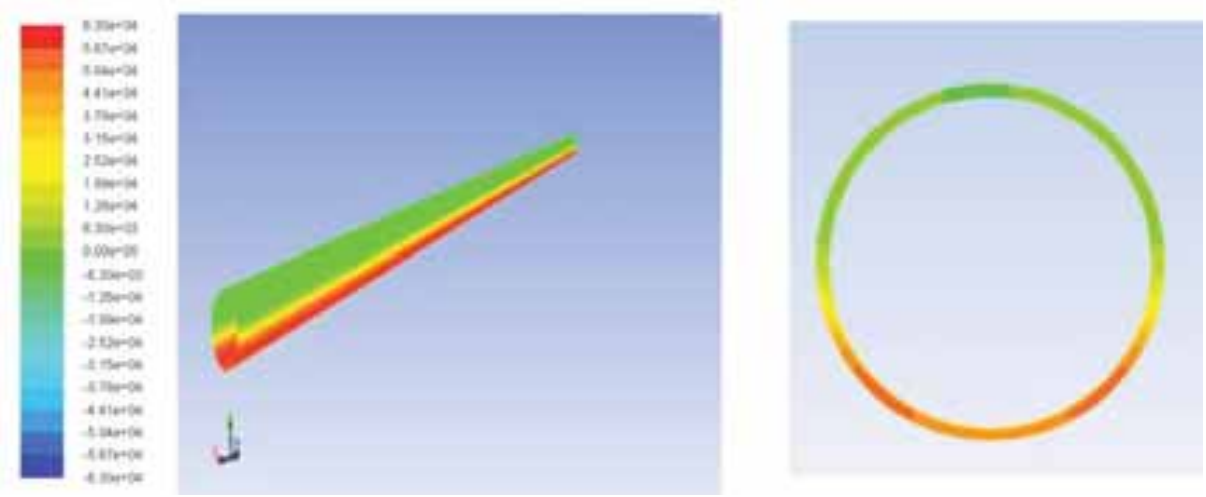
The simulation results and the experimental data under the same conditions. The model results are validated using the data provided by the Sandia National Laboratory .It is indicated that the simulation results agree well with the experiment data, validating the accuracy of the simulation method for the coupled heat transfer process. Tests were also performed with vacuum and with air at ambient pressure in the annulus, and without the glass envelope. The measured data considering the vacuum in the annulus is given in Table 2 and the corresponding validation results are demonstrated in Figure 5. Most of the experiments were done using Syltherm 800 as the HTF, and its thermal properties .The results obtained were overall close to the measured data, with a difference of 4 to 8 ºC.

6. Results and Discussion

The developed simulated model is used to simulate the Non uniform heat flux distribution of receiver. The temperature distribution of the receiver along the length of the absorber tube as well as around the circumferential direction of the PTC receiver. The outlet temperature of HTF is calculated for the given type and mass flow rate of HTF. The simulations are carried out with vacuum condition, around 10^{-4} Torr pressure in annulus region. Due to this the convective heat losses from the absorber to the envelope are negligible, and most of the solar energy absorbed by the coating surface is transferred to the HTF. The temperature distributions of the solar receiver are crucial for the collection of the heat, which will further affect the efficiency of the collector. It is found that the inlet velocity and temperature of the HTF and the DNI will bring an important impact on the temperature distribution of the receiver, which will be numerically investigated in this section. The density, specific heat capacity, viscosity and conductivity of the fluid and the physical properties on the tube material properties are dependent on the temperature distribution of the HTF and it is also estimated from the equations. In the calculation, the velocity in the receiver tube is a parabolic form in fully developed flows. However, it should be pointed out that in real cases the distribution of the inlet velocity of the HTF in tubes presents a parabolic form. In order to simulate a real environment, applying real inlet velocity distribution is important for the improvement of the simulation results, and this issue should be further investigated in the future.

6.1 Non uniform Solar Heat Flux distribution on the outer surface of absorber

An optical model is also developed to calculate the non uniform solar flux distribution around the receiver by using MCRT method. The solar flux density distributions on the outer surface of absorber tube are illustrated in Figures 6 (a) and (b), respectively. The concentrated solar energy is mainly distributed on the bottom surface of the absorber tube.



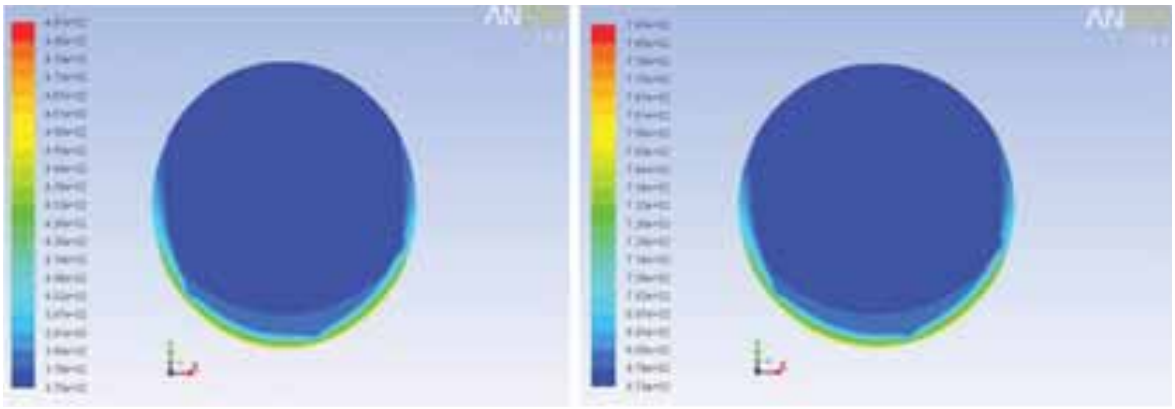
(a) (b)

Fig. 6: Non uniform flux distribution of the receiver for DNI =1000 W/m^2 (a) Axial length (b) Cross section view

The asymmetry in the two sides of the peak heat flux on the absorber is due to the presence of simulated tracking error. Because of this non uniform concentrated solar flux distribution, temperature distribution of PTC receiver in circumferential direction also non uniform. The heat flux distribution on the outer surface of absorber tube for the DNI of 800 W/m^2 and 1000 W/m^2 is shown in Figs. 6. The asymmetric distribution of heat flux in circle direction is obviously, but the heat flux distribution in axial direction (x) is uniform, as shown in Fig. 6. In order to further confirm the accuracy of the proposed MCRT code for calculating the solar energy flux distribution of the whole PTC system, numerical simulation is carried out at the same collector solar flux at about 48766 W/m^2 at the bottom portion of the absorber tube while the lowest solar flux is 1000 W/m^2 at the top portion of the absorber tube. The maximum solar heat flux attained by the PTC receiver is 9753.3 W/m^2, 19506 W/m^2, 29260 W/m^2, and 39013 W/m^2 when the DNI are 200 W/m^2, 400 W/m^2, 600 W/m^2, and 800 W/m^2 respectively.

6.2 Temperature Distribution of PTC Receiver:

Temperature distribution of PTC receiver plays the important role to determine the thermal efficiency and heat loss of PTC. The temperature contours at the absorber outlet with different inlet temperature of HTF for the DNI = 1000 W/m^2 and Inlet velocity = 1 m/s are shown in the Figure.7. The inlet temperature of HTF is high, the outlet temperature of absorber increased significantly.



(a) (b)

Fig.7 : Temperature contours at the absorber outlet for DNI = 1000 W/m^2, V = 1 m/s for different inlet temperature (a) 100°C (b) 400°C

The non uniform radiation distribution also causes a non uniform temperature distribution. The shape of that distribution. Figure .8 shows the circumferential temperature distribution for the outer absorber surface and

the outer glass surface as function of circumferential angle around the receiver when the inlet temperature of HTF is 100˚C & 400˚C and also the DNI is 1000 W/m^2. The temperature distributions are generally smoother than the incident radiation distributions. The difference between absorber tube and HTF temperatures is significant. This is primarily due to the low heat transfer coefficient which is caused by the lower mass flow rates of HTF.

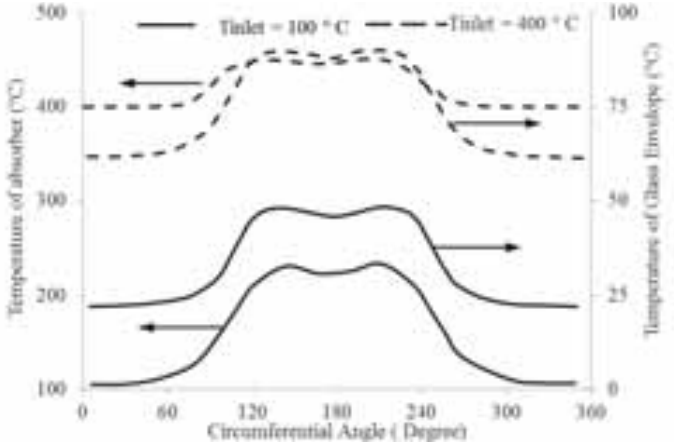


Fig. 8: Circumferential temperature distribution of absorber tube and glass envelope for Tinlet = 100˚C & Tinlet = 400˚C

For this reason, there is also a significant temperature difference between the bottom portion of the absorber surface exposed to the concentrated solar radiation and the top portion of the absorber surface which receives the direct normal irradiation from the sun. For the Tinlet = 100˚C & Tinlet = 400˚C , the difference between maximum and minimum absorber temperature is 131˚C and 55℃ respectively The convective heat transfer coefficient of HTF is increased by increasing the temperature of HTF, due to this temperature difference between the bottom and top of absorber surface and temperature difference between the HTF and absorber tube is also decreased. Similarly from the Figure , For the Tinlet = 100˚C & Tinlet = 400˚C , the difference between maximum and minimum glass envelope is 23˚C and 29 ˚C respectively. The temperature profile of both absorber and glass envelope follows the non-uniform solar heat flux distribution which indicates that the conduction in both tubes is relatively small. The temperature of the outer surface of the absorber is higher than that of the inner surface since the outer surface is the heating surface, and the maximum temperature difference is very small.

The temperature of the absorber is symmetric and increases by moving along the HCE far away from the inlet. The temperature distribution is estimated for the different inlet velocity of HTF .Fig. 9 shows the distribution of the temperature difference on the cross sectional planes of the absorber tube along the flow direction of HTF and length of the PTC receiver. The temperature difference was calculated through the difference between the maximum temperature and minimum temperature on the PTC receiver. At the entrance part of receiver, effect of temperature difference is maximum.

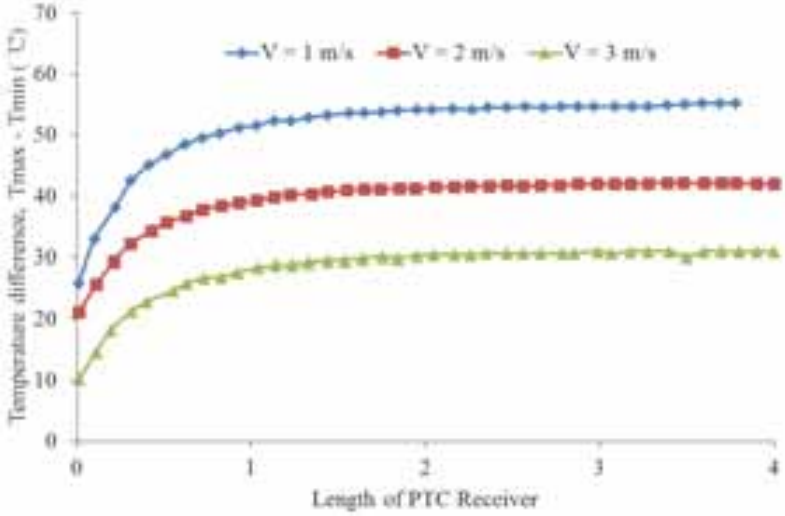

Fig. 9: Temperature distribution along the length of the PTC receiver for different inlet velocity

When the length of the receiver is within 1m, temperature difference of PTC receiver increases exponentially. Similarly when the length of receiver is greater than 1m (after the entrance region), the temperature difference almost approach constant path. This temperature difference is plotted for various HTF velocities from 1m/s to 3 m/s. However, the temperature difference decreases from 55.5˚C to 31˚C when the HTF velocity changes from 1 to 3 m/s. Therefore, the temperature differences are mainly dependent on the HTF velocity. The lower HTF velocity will cause higher temperature differences on sectional planes of the absorber tube, and this maximum temperature difference is the main cause of the breakage of PTC receiver

7. Conclusion

In this paper, three-dimensional numerical simulation of coupled heat transfer characteristics in the receiver tube is performed by combining the MCRT method and the FVM using Fluent software. Three typical testing conditions are chosen from the experiment to validate the physical model and simulation code. Numerical results show that the predicted results agree well with the experimental data, the average relative error is within 3%. The heat flux distribution on the outer surface of absorber tube was heterogeneous in circumferential direction but uniform in axial direction. Then, the coupled method was used to simulate the LS-2 Solar Collector for method verification. And the outlet temperatures of four cases were counted out and compared with Dudley et al.'s report data. The application of MC in combination with FV allowed for the incorporation of non-uniform temperature and heat transfer distributions and the identification of critical peak temperatures and heat fluxes. The temperature distributions of the absorber and the glass envelope surface are similar with the distributions of the solar energy flux. The HTF temperature difference of the cross-section decreases with the increase of the inlet velocity of the HTF, increases with the rising DNI, and almost remains the same with the increase of the inlet temperature of the HTF. Similarly when the length of receiver is greater than 1m (after the entrance region), the temperature difference almost approach constant path. This temperature difference is plotted for various HTF velocities from 1m/s to 3 m/s. However, the temperature difference decreases from 55.5˚C to 31˚C when the HTF velocity changes from 1 to 3 m/s. Therefore, the temperature differences are mainly dependent on the HTF velocity. The lower HTF velocity will cause higher temperature differences on sectional planes of the absorber tube, and this maximum temperature difference is the main cause of the breakage of PTC receiver.

Refractive based solar tracker with fixed concentration spot

Héctor Garcia[1], Carlos Ramirez[1] and Noel Leon[1]

[1] Tecnológico de Monterrey, Campus Monterrey, Monterrey (México)

Abstract

Solar energy has become one of the most promising renewable energies being the most widespread used nowadays. In order to achieve an optimum performance, both photovoltaic and solar thermal applications require the use of some kind of solar tracking technique. A solar tracking concentrator (STC) has to adapt to the changes in the sun's position throughout the day and even more so, throughout the year.

The present paper attempts to describe in detail the design of a state-of-the-art STC in which the concentration spot is fixed. The tracking system is based on refracting the sunlight onto a constant direction, contrary to existing solutions which reflects it. Having a constant direction of radiations makes possible to implement a stationary Fresnel lens to concentrate the solar power for any application desired. The system is designed and validated using mathematical models and simulation software to prove the feasibility of the concept.

Keywords: *Solar tracking system, solar concentration, solar energy, refraction*

1. Introduction

Most research efforts on solar energy have focused on photovoltaic (PV) cells development, however, commercial PV cells have only achieved an efficiency of 15% to 20% so far (Green et al. 2009), while high concentration photovoltaic (HCPV) have efficiency slightly above 40% (Pérez-Higueras et al. 2011).

Another research line explores the use of solar thermal energy (STE), in which case two main issues must be overcome. Firstly, solar radiation must be concentrated for high temperature applications; this is due the low density nature of such energy. Secondly, for most solar concentrators, solar rays must fall perpendicular to the concentrator at all times. Therefore, a solar tracking concentrator (STC) must be used. These requirements also apply for HCPV.

This work was carried on to explore the feasibility of a STC using a semi-passive solar tracking device consisting in two arrays of prisms and a Fresnel lens. A peculiarity of the system is the fixed position of the Fresnel lens therefore, if the prism array can indeed track effectively the sun's path there will be a constant position concentration spot that can be used either in HCPV or CSP applications.

Achieving this constant spot is non-trivial and could represent an important breakthrough since having a non-constant spot means that the receiver which captures the energy must move along with the tracker, elevating in many cases the cost of implementation.

2. Design of the STC

2.1 Concept Layout

The presented STC is an optic system that concentrates solar radiation with minimal movement. It has two layers of PMMA triangular prisms one placed above the other that redirect the received solar rays in a constant vertical direction toward a fixed Fresnel lens. Prism within a layer are identical one another. The first array of prisms rotate all of its components to the same angle, its rotation axis is parallel to the y-axis. In a similar manner, the second set of prisms rotate synchronously but having a rotation axis parallel to the x-axis. Both layers are located directly above a Fresnel lens as seen in Fig. 1.

doi:10.18086/swc.2015.04.09 Available at http://proceedings.ises.org

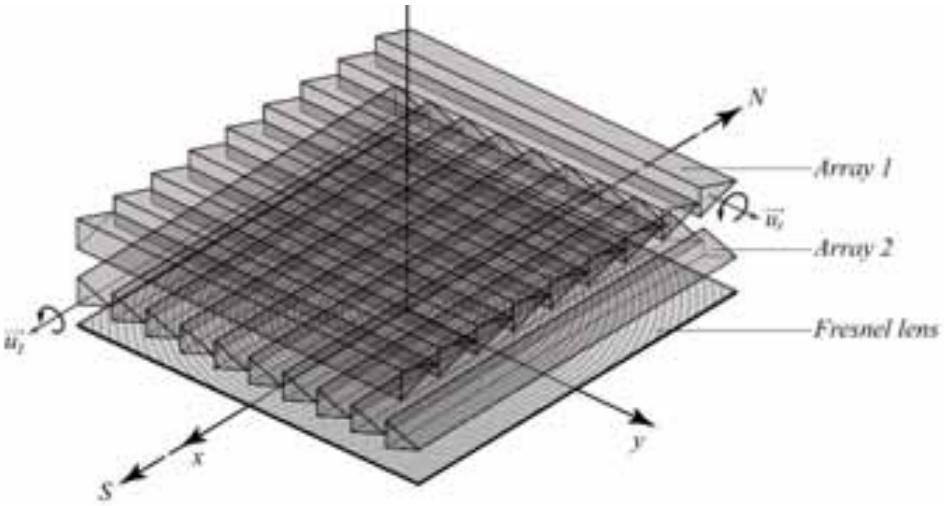

Fig. 1: STC system concept with fixed Fresnel lens

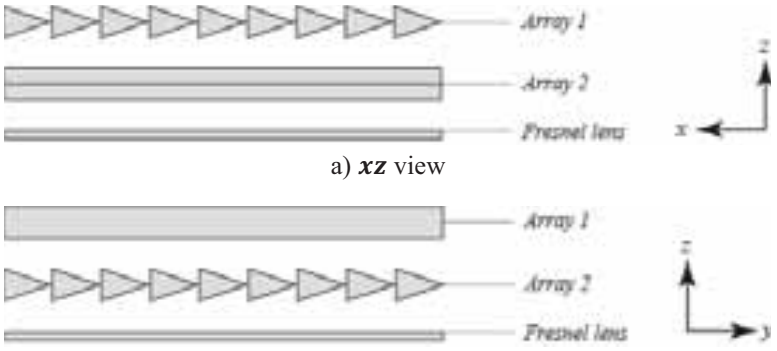
Figure 2 shows the lateral views of the proposed concept. This configuration allows to have the Fresnel lens in a fixed horizontal position; which significantly reduces the wind loads and more importantly it offers the virtue of having a stationary concentration spot, unlike many other STC which have a robust mechanical tracker that has to support all the moving components.



a) $\boldsymbol{xz}$ view

b) $\boldsymbol{yz}$ view

Fig. 2: STC system concept - XZ and YZ view

2.2 Prism

The initial concept employs triangular prisms, with the peculiarity that the polyhedron has an isosceles triangle as base, whose equal side's measure l and form an angle of ε. Prism's depth or height is h, as shown in Fig. 3. In any given prism the rotation axis goes through the body's center of mass, since prism are uniform longitudinally this coincides with the triangular gravicenter of the base. Consequently, the resultant torque due to gravity vanishes (Hibbeler, 2006).

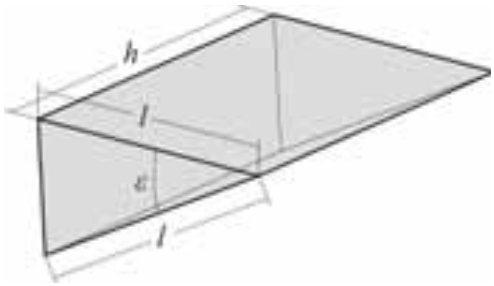


Fig. 3: Prism's dimensions

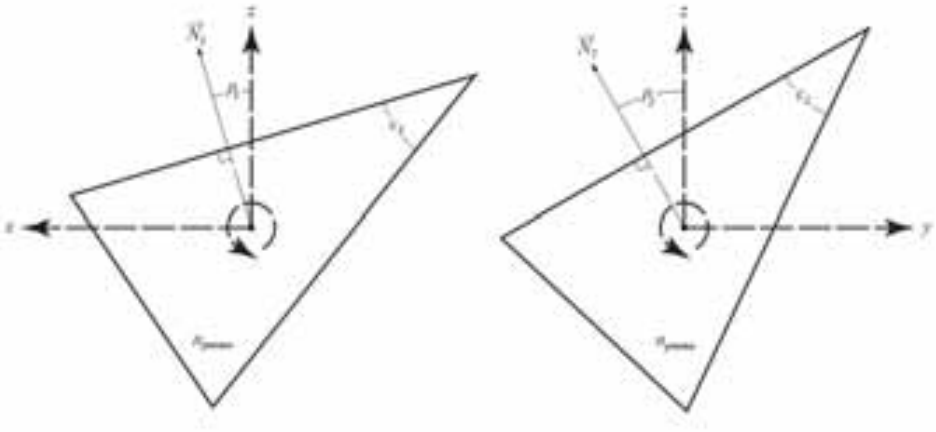
Since the rotation is the same within an array only one actuator for the mechanical movement is needed. The

mechanism can be idealize as a four-bar linkage similar to a window shutter but instead of blocking the sun's light, they redirect those solar rays by the refraction throughout the PMMA prisms.

There are two sets of prisms, upper and lower layer are identified by sub index 1 and 2 respectively. The prisms' inner angle are ε_1 and ε_2, as shown in Fig. 4. These values are not necessarily the same, although within each array all PMMA elements must be identical to one another.



a) Upper layer b) Lower layer

Fig. 4: Prism's parameters

The geometry and refractive index are the key parameters of the prism. The design assumes that all prisms within the array are identical in both key parameters, thus the angle of rotation is shared, allowing the array to be driven by a single actuator. Additionally, this concept contemplates both upper and lower arrays to be made of the same material, however such consideration is not necessary.

Figure 4a shows the upper layer geometry, rotation axis is parallel to system's y-axis and a rotation by an angle of ρ_1; likewise Fig. 4b illustrates lower layer prism geometry with rotation axis parallel to system's x-axis and prism rotation by an angle ρ_2. For both cases the default position and reference point for the measurement of the rotation angle is referenced to the z-axis and the normal vector to the face of the prism.

2.3 Light Trajectory

Figure 5a illustrates required trajectory of the solar rays to successfully reach the receiver. For illustrative purpose only one prism of each layer is shown. The circular mark indicates where the beam changes medium. Emphasizing that the rays B and D are within the respective prisms. The upper layer is the first part of the system responsible for starting the solar tracking. Prisms rotate an adequate angle ρ_1 as shown in Fig. 5b to obtain the following trajectory:

A. Solar rays from the sun: These beams change direction throughout the day, they reach the 1st array of prisms and refract according to Snell's law.

B. Solar rays within the prisms of the 1st array: Inside the prism rays travel until reaching the opposite prism's side, where they exit by refracting when they change mediums.

C. Solar rays exiting the 1st array, toward 2nd array: These beams have the peculiarity of lacking a x component; this is accomplished by selecting ρ_1 accordingly. The path is presented in a XZ view, however exiting solar ray C not necessarily has a downward vertical direction, and has a non-zero y component as seen in Fig. 5c.

The following layer is located immediately below and it constitutes the second stage of the solar tracking system. Similarly prisms rotate an adequate angle ρ_2 as shown in Fig. 5c to obtain the following trajectory:

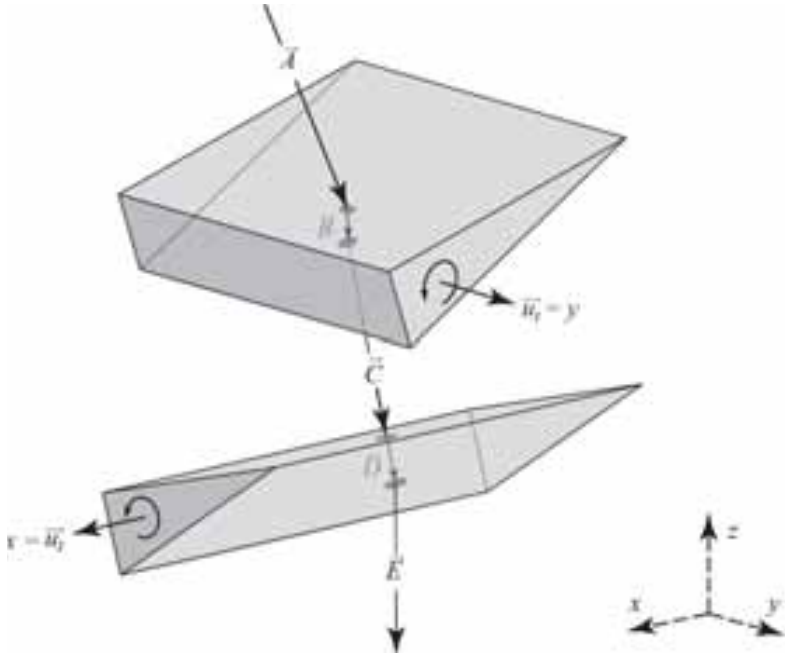
C. Solar rays from the 1st array: Coming from the upper layer, with the peculiarity of zero x component as described before. In other words ray is contained in plane YZ.

D. Solar rays within the prisms of the 2nd array: Inside the prism rays travel until reaching the opposite

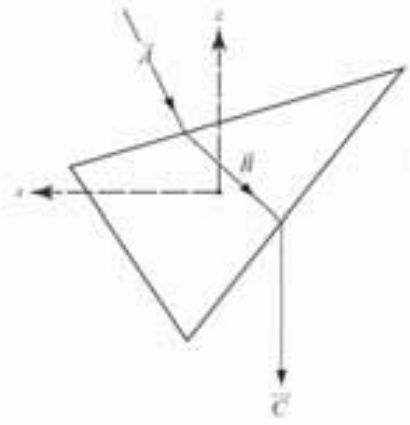
prism's side, where they exit by refracting when they change mediums. Rays are also contained in plane YZ.

E. Solar rays exiting the 2nd array, toward Fresnel lens: These beams have the peculiarity of lacking both a x and y components; this is accomplished by selecting ρ_2 accordingly. Contrary to rays exiting from the first array, these beams do have a downward vertical direction.

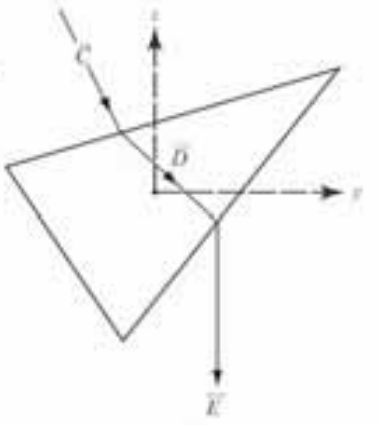
The joint work of both arrays complete the tracking system, afterwards the solar rays must be concentrated into a fixed spot, and this is achieved by the next part of the system.



a) Isometric view



b) Upper layer: XZ view



c) Lower layer: YZ view

Fig. 5: Ray's path through upper and lower layer.

2.4 Fresnel lens

The Fresnel lens is a type of compact lens that is able to concentrate solar energy in a reduced area; it is essentially a chain of prisms, in which each one represent the slope of a lens surface (Barone, 2005). The function of this optical device in the proposed system proposed is to receive the rays refracted by the two arrays of prisms and concentrate them in a fixed receiver. Since the solar rays reach the concentrator in a constant direction after going through both layers of prism, the lens can remain stationary.

3. Mathematical model

3.1 Dispersion by a prism

Many authors address the issue of the path of light through a prism, with one important consideration: it is assumed that the edge of the prism in which the two faces meet, with an angle ε, is perpendicular to the plane which contains the incident, transmitted, and emergent rays. (Born et al. 1999)

A ray entering a prism, as shown in Fig. 6, will emerge having been deflected from its original direction by an angle δ_{dev} known as the angular deviation. In terms of the SPSTC, this property is used to achieve the tracking as will be explain in detail later.

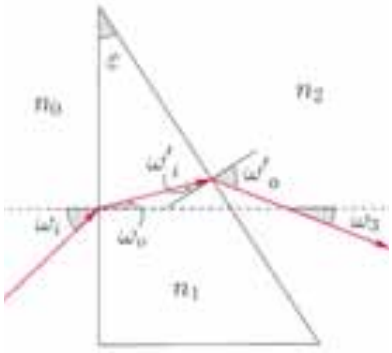


Fig. 6: Passage of a ray through a prism

Equations (1) and (2) are results of Snell's law, where n is the refractive index of the medium in question:

$$\omega_o = \sin^{-1}\left(\frac{n_0}{n_1}\sin\theta_0\right) \quad \text{(eq. 1)}$$

$$\omega'_o = \sin^{-1}\left(\frac{n_1}{n_2}\sin\omega'_i\right) \quad \text{(eq. 2)}$$

Additionally to Eqs. (3) and (4) are obtained by summation of angles, using the fact that the dashed line is perpendicular to the entrance face of the prism.

$$\omega'_i = \varepsilon - \omega_0 \quad \text{(eq. 3)}$$

$$\omega_3 = \omega'_0 - \varepsilon \quad \text{(eq. 4)}$$

For a prism in air as in the proposed concept, $n_0 = n_2 \simeq 1$. Defining $n_1 = n_{pmma}$, the deviation angle δ_{dev} is given by

$$\delta_{dev} = \omega_i + \omega_3 \quad \text{(eq. 5)}$$

Substituting Eqs. (1) to (4) into (5) yields:

$$\delta_{dev} = \omega_i + \sin^{-1}\left(n_{pmma}\sin\left[\varepsilon - \sin^{-1}\left(\frac{1}{n_{pmma}}\sin\omega_i\right)\right]\right) - \varepsilon \quad \text{(eq. 6)}$$

Abelman [2008] proposed a simplification of Eq. (6) if the incident angle ω_i and prism apex angle ε are both small, $\sin\theta \approx \theta$ and $\sin^{-1} x \approx x$, an important remark is that angles are expressed in radians. This allows the nonlinear equation in the deviation angle δ_{dev} to be approximated by:

$$\delta_{dev} \approx \omega_i + \left(n\left[\varepsilon - \left(\frac{1}{n}\omega_i\right)\right]\right) - \varepsilon \quad \text{(eq. 7)}$$

$$= \omega_i + n\,\varepsilon - \omega_i - \varepsilon \quad \text{(eq. 8)}$$

$$= (n - 1)\varepsilon \quad \text{(eq. 9)}$$

Furthermore the refractive index depends on wavelength λ, therefore for a thin prism the deviation angle varies with wavelength according to:

$$\delta_{dev}(\lambda) \approx [\,n(\lambda) - 1\,]\,\varepsilon \quad \text{(eq. 10)}$$

Considering to Eq. (6), it's evident that the deviation suffered by a monochromatic beam throughout a given prism is a function only of the incident angle at the first face, since apex angle ε and refractive index are fixed. Figure (7) shows a plot of the deviation angle for $n = 1.48$, for a variety of apex angles.

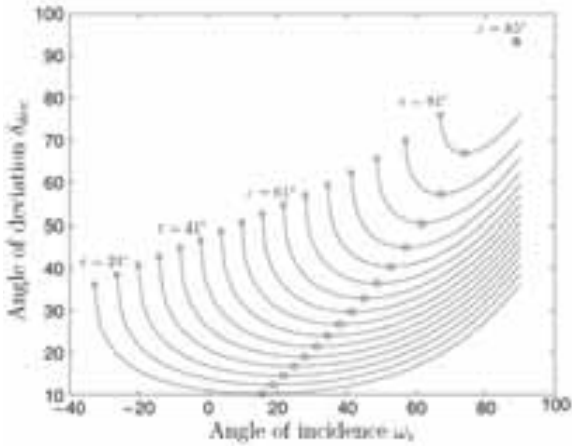

Fig. 7: Deviation δ_{dev} response to incident angle ω_i for several prism's apex angle ε (Abelman, 2008)

Figure 7 shows maximum and minimum deviation, for several values of ε, as squares and circles respectively. An important observation is how if the apex angle is increased the response plot tends to move up and to the right. Ultimately meaning a smaller range of admissible incident angles. For even larger apex angles, all rays that go inside the prism suffer a total internal reflection. On the contrary case if apex angle decreases too much, then Eq. (9) is a valid approximation and since refractive index is consider constant, then deviation depends solely on apex angle, which is also constant once implemented.

It should be notice that in the STC proposed the initial assumption described at the start of this section is not met for the first stage of the tracking system (upper layer). Since the plane which contains the incident, transmitted, and emergent rays is not always perpendicular to the prism edge; however, the repercussion apex angle has on deviation is a good starting point to understand how it affects the tracking system for redirecting sunlight. Furthermore another approach must be done to overcome the 3-dimensional ray.

3.2 Snell law in a 3-dimentional environment.

The physical phenomenon involved in this system, in both prisms arrays and Fresnel lens, is known as light refraction that obeys Snell's law. Nevertheless, the conventional form can only be applied when working in the same plane; however, the nature of solar rays' movement throughout the day and prism normal to the incident face produces non-constant working planes. Therefore, vector analysis must be performed to find an extrapolation of Snell's law for a 3-dimensional environment.

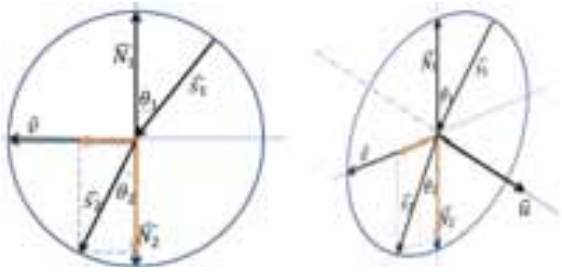

Fig.8: (a) Snell's law in a plane; (b) Snell's law in space

Equation (10) defines the output direction based on the orthogonal vectors that define the plane seen in Fig. 8a. An extrapolation of Snell's Law is shown in Eq. (11) in function of vectors $\hat{s}_1$ and $\widehat{N}_1$ only, which are the incident ray, and the normal vector to the surface, respectively. (Garcia et al, 2014)

$$\hat{s}_2 = (\sin\theta_2)\,\hat{v} + (\cos\theta_2)\widehat{N}_2 \qquad \text{(eq. 10)}$$

$$\hat{s}_2 = \frac{n_1}{n_2}\widehat{N} \times \left(-\widehat{N} \times \hat{s}_1\right) - \widehat{N}\sqrt{1 - \left(\frac{n_1}{n_2}\right)^2 \left(\widehat{N} \times \hat{s}_1\right) \cdot \left(\widehat{N} \times \hat{s}_1\right)} \qquad \text{(eq. 11)}$$

Equation (11) offers an analytical vectorial approach for light refraction; therefore, it is necessary to express incoming rays as unit vectors that represent the beam's direction, and the normal vector to the surface where rays incident.

3.3 Solar ray's directional vector

Figure 9 shows the direction of incoming solar rays. Setting the coordinate system as shown, where South and East coincide with x and y-axis respectively. Based Duffie and Beckman (1991) solar altitude α and azimuth γ may be obtained given a solar latitude, therefore the directional vector may be calculated.

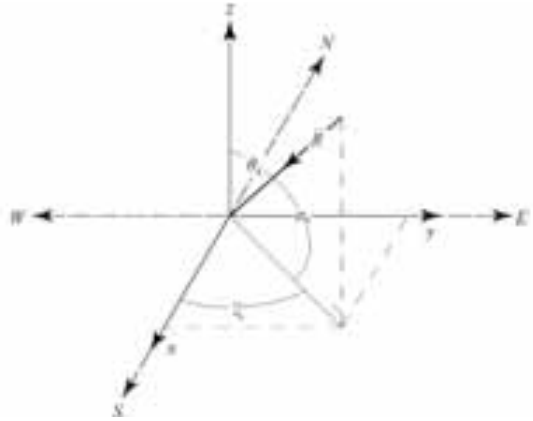

Fig. 9: solar ray in vector form

$$\vec{R}_{\gamma_s,\alpha_s} = -\cos(\alpha_s)\cos(\gamma_s)\,\hat{x} - \cos(\alpha_s)\sin(\gamma_s)\,\hat{y} - \sin(\alpha_s)\,\hat{z} \qquad \text{(eq. 12)}$$

Given any point of the year directional vector $\vec{R}_{\gamma_s,\alpha_s}$ is obtained. These beam will strike onto a prism, for which the normal vector to the plane must be calculated. This can be achieve rather easily doing a 2-dimensional analysis depending solely on the apex angle ε and the rotation ρ given to the prism

4. Solar Tracking

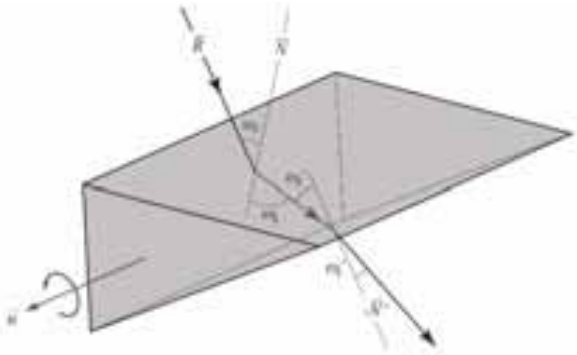

Fig. 10: Passage of a ray through a prism

Matlab implementation of mathematical model is based on Eqs. (11) and (12), functions are programed in order to know the path of light for any given parameters. One key element in the code is an analogy to the deviation formula, which for a given input ray's direction, incident normal vector is calculated and using Eq. (12) the direction inside the prism is obtained. Later internal normal vector in output face is computed to obtain the output direction of the path described by light beams as shown in Fig. 10

Tab. 1: Solar angles at given time at latitude $\varphi = 25°39'15''N$

Day of the year	120th
Solar time	10:30am
Solar azimuth angle (γ_s)	66.6257
Solar altitude angle (α_s)	66.2054

Tab. 2: Solar angles at given time at latitude $\varphi = 25°39'15''N$

Azimuth	Altitude	Incident solar ray		
γ_s	α_s	A_x	A_y	A_z
66.6257°	66.2054°	−0.160066	0.370348	−0.915

Given the solar angles, the directional components of solar rays are calculated, with the help of Matlab, the behavior of a ray through the prism for all possible rotations is obtained. The first stage of the STC is to control and eliminate if possible the component C_x, as stated earlier. It's important to realize that not all rotations generate an output ray, this happens when internally all light is reflected instead of being refracted, or if solar rays reach the prism at the non-active side of the triangle.

Figure 11a shows the behavior of x component for different apex angles ε_1 through all possible prism rotations ρ_1 (for a particular solar azimuth and altitude angles stated in Table 1).

It can be seen in Fig. 11 how if apex angle ε_1 increases the system will not be able to eliminate the desired component C_x; meanwhile when it does, there may be two rotations values: ρ_1 and ρ_1' that accomplish the desired output. Figure 11b shows a closer look to appreciate the points where response intersects horizontal line corresponding to $C_x = 0$.

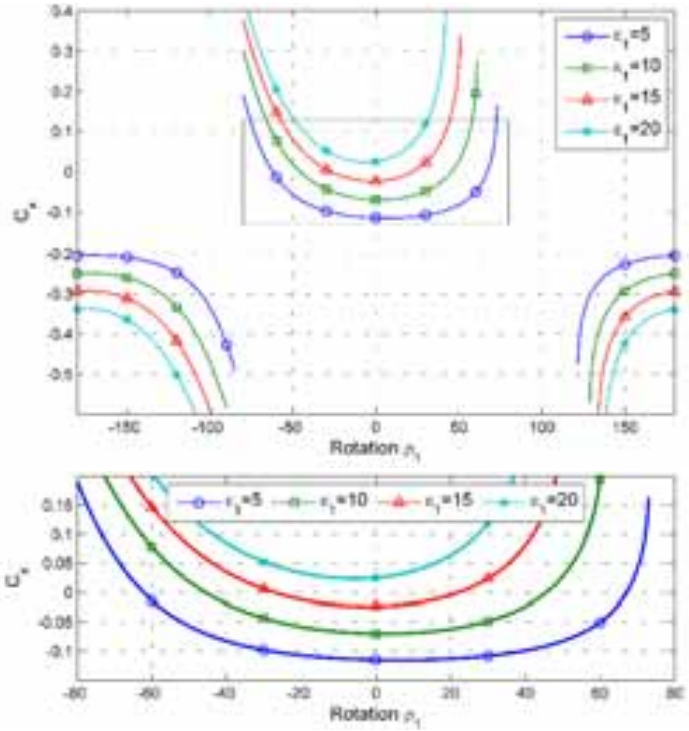

Fig. 11: a) Output response C_x for prism rotating ρ_1 for distinct values of ε_1, b) zoom view

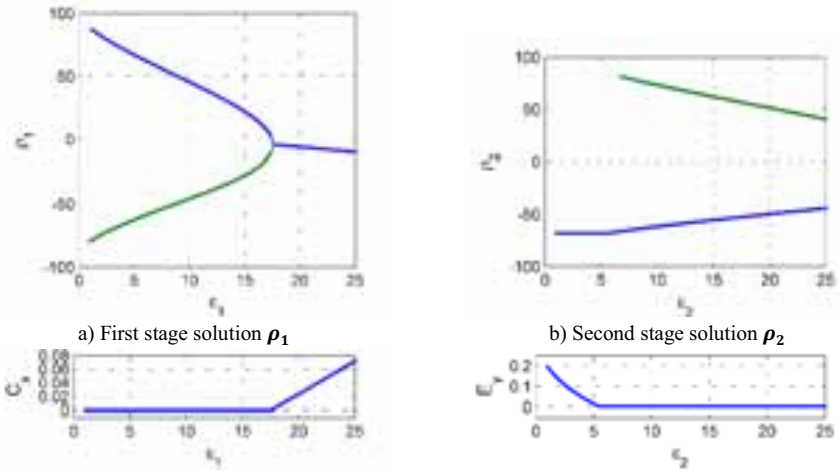
Figure 12a shows the best rotation available for a wide range of apex angles that accomplish the minimum component $|C_x|$, meanwhile Fig. 12c shows component C_x achieve, for instance, in this particular case how apex angles higher than 17° can't achieve the desire output.

It can be proved that when rotation ρ_1 exist such that $C_x = 0$ then Eqs (13) to (15) stand true, meaning the output ray's direction is constant despite being multiple values of rotation ρ and independent to the prism apex angle ε.

$$C_x = 0 \qquad \text{(eq. 13)}$$

$$C_y = A_y \qquad \text{(eq. 14)}$$

$$C_z = \sqrt{1 - C_y^2} \qquad \text{(eq. 15)}$$



a) First stage solution $\boldsymbol{\rho_1}$ b) Second stage solution $\boldsymbol{\rho_2}$

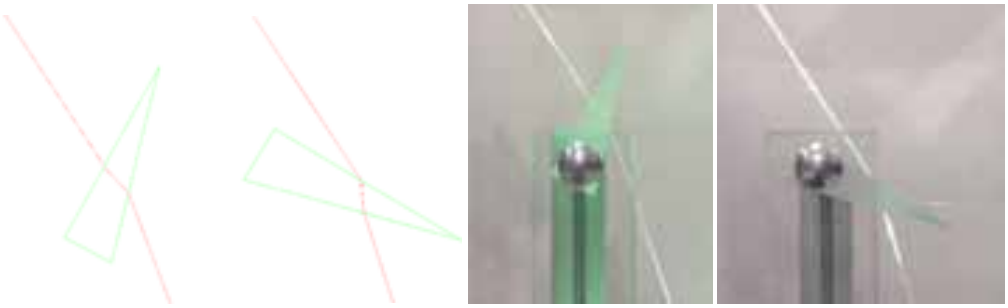
c) First stage $\boldsymbol{C_x}$ output d) Second stage $\boldsymbol{E_y}$ output

Fig. 12: Best solution found for distinct values of apex angle $\boldsymbol{\varepsilon}$

Therefore despite the system's parameters for the 1st stage the rays will reach the 2nd stage in a given direction $\vec{C}$, from where the same analysis is perform to obtaining the best rotation available and the permissible apex angle to achieve the desire task.

5. Proof of concept

Additionally to the mathematical model a computer simulation using ray trace software and an idealized scale model consisting of two individual prism was constructed to corroborate the behavior of rays through the prisms. For instance the fact that given an input direction there exist different rotations that provide the same output can be seen in Fig. 13.



a) TracePro simulation b) Experimental model

Fig. 13: Two different rotation angles $\boldsymbol{\rho}$ with same output

An important remark is the Fresnel lens beneath the tracking system is not included in the model. Since initial design contemplates a conventional Fresnel lens to deal with the concentration part, the only requirement is that rays reach the lens perpendicularly to the surface.

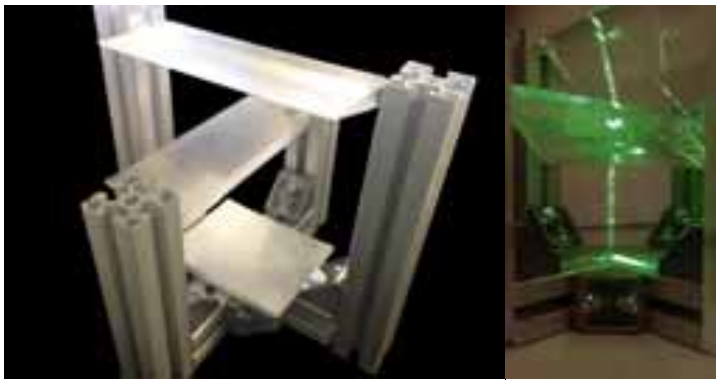


Fig. 14: Scale prototype as proof of concept

The present analysis was done for a particular time, however a deeper analysis is needed to see the system performance throughout the year, the fact that it works for an arbitrary moment does not assure the correct functionality for every day at all hours

6. System performance throughout the year

As stated before the behavior of solar angles throughout the year can be calculated as shown in Fig. 15, however we must acknowledge that the system may not be able to cover all possible solar values, therefore the system's target is set from 9 to 15hrs.

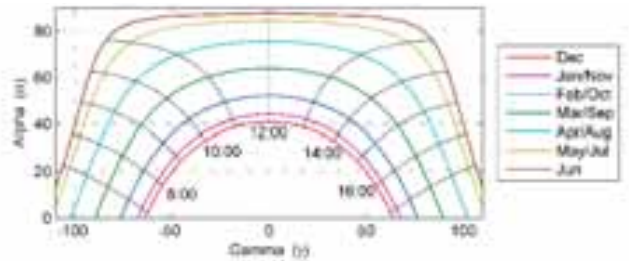

Fig. 15: Solar angles throughout the year, at latitude $\varphi = 25°39'15''N$

To view the tracker performance for a given pair of apex angles ε_1 and ε_2 the system is simulated via matlab to evaluate every possible pairwise values (γ, α) within the desired time window to apply the tracking algorithm and obtain the best output found. The primary interest is the angle θ formed between the theoretical direction $\vec{E}_s$ and the outcome ray $\vec{E}_r$ generated by the algorithm is closest to cero.

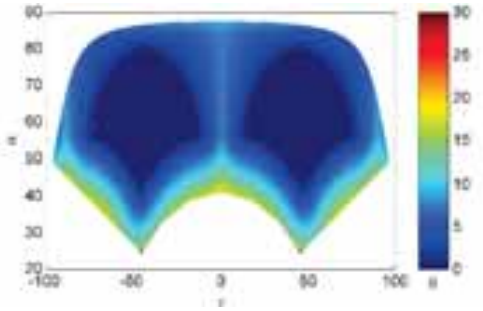

Fig. 16: Output ray variation θ from desire output with $\varepsilon_1 = 15.85$, $\varepsilon_2 = 15.28$

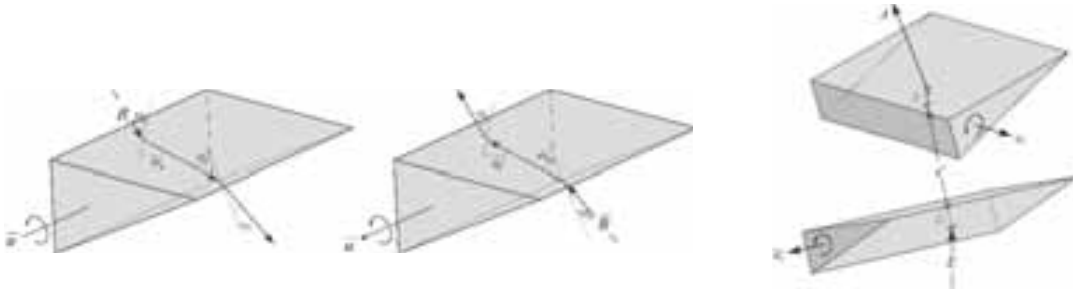
Notice there is a good tracking in two main areas shown in blue zones, however there is a gap at the center region $(\gamma = 0)$, additionally angles close to lower limit do not have a satisfactory response in the green zone.

6.1 Backtracking rays

Snell's refraction equation stands for both directions. Therefore one may think of refraction as a bijective function. Since the reversibility holds at each refracting surface, it holds also for even the most complicated light paths. In particular for the path define while going through an acrylic prism, as shown in Fig. 17a. Furthermore this same principle applies to the complete trajectory described by incoming solar rays and tracking system output rays as represented in Fig. 17b.



a) Throughout a single prism b) Through tracking system

Figure 17: Ray path in reverse direction

Therefore given a set of parameters ε_1 and ε_2 instead of doing the algorithm for every possible point (see fig. 15) a simpler approach arises which consists in calculating all possible reverse paths backtracking ray $\vec{E}$. This is simply obtained for every combination of rotation angles (ρ_1, ρ_2); graphing them to obtain a scatter plot that represents the system's admittance rays for which we can redirect accurately with $\theta = 0$, as shown in Fig 18.

Figure 18 shows just some simulations that were done, since plots are symmetrical only one side is computed. In the iterations the variations in ε shift the zone accordingly. Additionally the behavior of the system to ε also appears to have a direct correlation, as lower values tend to be close to upper limit and vice versa.

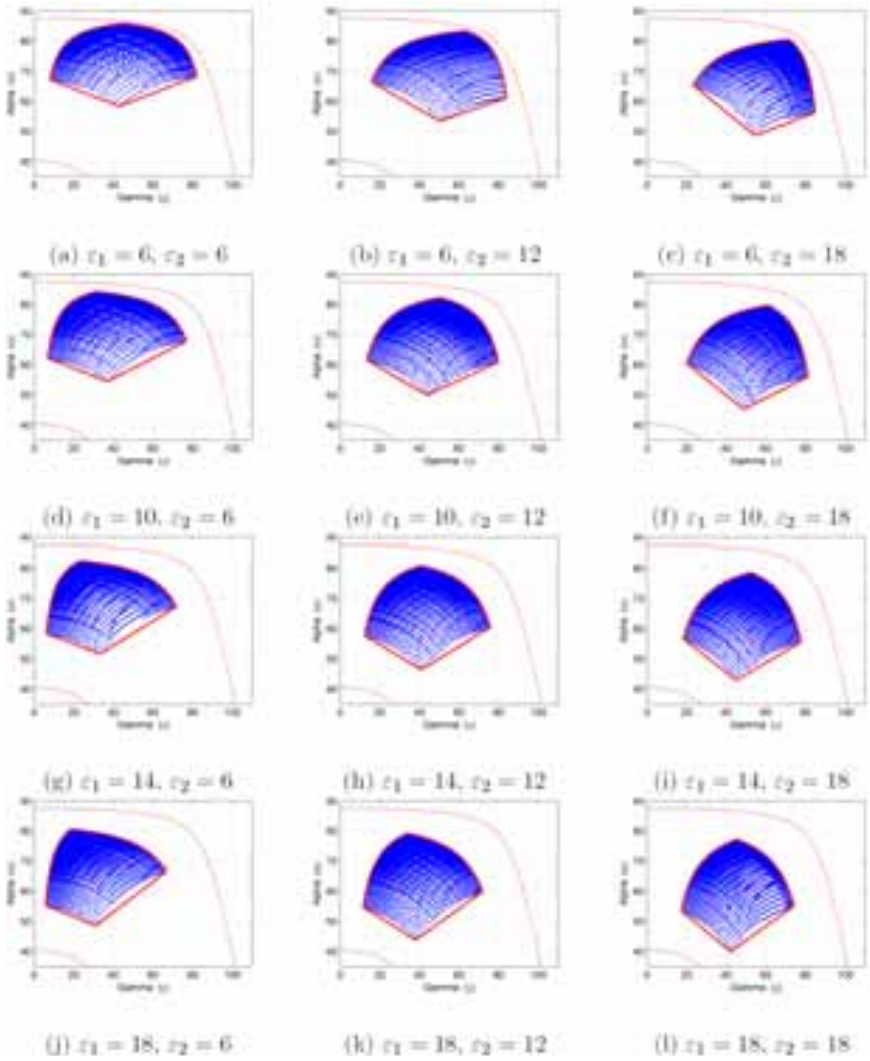


Fig. 19: Matlab simulation for different set of apex angles

7. Concluding remarks

A tracking algorithm was also implemented on Matlab to determine the required rotations values for a given time. The only design parameters for the present concept are the apex angles of the prisms in each layer, since the system relies on refraction of light there are physical constrains (Leutz and Susuki 2001): the critical angle plays an important role on the ability to correctly redirect light to the desire direction. For instance the second layer of prism al paths are in the same plane, since rays theoretically have $C_x = 0$, therefore analysis shown in Fig. 7 is valid, and deviation angle plays a direct role in the ability to redirect rays accordingly. Unfortunately this means that for times around noon ($\gamma = 0$) the gap previously mention in Fig. 16 will always be present, since at that time the prism needs to give a null deviation, but from Eq. (9) that may only be achieve having a low apex angle sin refractive index is constant. From Fig. 7 we know that a low value of ε restrain of ability

to redirect rays, since the maxium deviation is restricted therefore a small apex angle helps the center gap but impairs zones where γ is close to the limit.

A STC is feasible using solely PMMA prism that rotate accordantly to the suns position, but with range of operation limitants. The selected values must be such that the time of operation of the system is maximized.

A three-dimensional mathematical model was developed to describe the path of a collimated light beam through a translucid solid medium. This vectorial approach was successfully implemented in Matlab being able to characterize the ray's path along the system, additionally a real life scale prototype and the TracePro computer simulation were used to validate the model.

The tracking is achieved by separating the dual axis movement and implementing two independent rotational movements that work hand by hand to refract efficiently solar rays. Doing so offers a simpler approach in tracking the Sun which ultimately would result in cheaper but reliable solution for most of the possible Sun's positions.

The current implementation has a fixed Fresnel lens which reduces greatly the mechanical effort of the system, since the tracking is performed by the rotating prisms arrays, which have the virtue of being lightweight individual prisms instead of a robust big heliostat, with the already mentioned trade-off.

A tracking mathematical algorithm was program in Matlab to obtain the best rotations for a given set of parameters $(\varepsilon_1, \varepsilon_2)$ throughout the year, however a deeper analysis must be done to understand the efficiency of the system.

The article presents a functional design and model capable of tracking the sun fairly well; nonetheless, there is still a vast area of opportunity for the improvement and optimization of the proposed STC. Additionally the presented work focuses on the light path toward a fixed objective, however light attenuation effects caused by the prism material must be furthermore studied to understand the real amount of energy the system can harvest from the sun.

8. Acknowledgement

The authors would like to thank the Institute of Renewable Energy (IER-UNAM) and the Mexican Center for Innovation in Solar Energy (CeMIE-Sol) for funding the present project through the Strategic Project #05: "Development of solar thermal storage units"; otherwise its development would have not been possible.

Development of a Solarized Rotary Kiln for High-Temperature Chemical Processes

Lucia Arribas[1], Veselin Miroslavov[1], Selvan Bellan[1], Manuel Romero[1], Jose Gonzalez-Aguilar[1]

[1]Unit of High Temperature Processes, IMDEA Energy Institute, E-28935, Mostoles (Spain)

Abstract

This work presents the design, characterization and commissioning of a directly-irradiated solar rotary reactor, which can be used for multiple applications such as chemical reactions (solar chemistry), thermochemical process or studies about mechanical strength and attrition of different materials, focusing on thermochemical reactions of manganese oxide. The main features of the reactor and test bed are as follows: samples are directly irradiated by concentrated radiation provided by a 7kWe high-flux solar simulator (HFSS) and a rotating cavity that promotes good mass and heat transfer, as well as high surface area for the reactions. Optical simulations and CFD analysis show that 1 kW of incident power and 1700 K can be achieved at the reaction zone, which is located at the secondary focus of the high-flux solar simulator. Manganese oxide cylindrical pellets (85% Mn_3O_4, 15% Mn_2O_3, mean particle size 3.5 mm) are used to perform the thermochemical reactions. X-Ray Diffraction is used to analyze the pellets composition before and after the test. A full conversion of the initial 15% of Mn_2O_3 is achieved.

Keywords: *solar reactors, solar simulator, rotary kiln, manganese oxide*

1. Introduction

Enhance the renewable energy contribution to the global energy mix is necessary in order to reduce global warming. Generally, however, the main disadvantage of some renewable resources such as solar or wind is their lack of dispatchability, since their production depends on transient weather conditions. For the generated renewable energy to be used when it is needed, it should be either stored or transformed into another type of fuel.

Short-to-long term thermal storage can be achieved using concentrated solar energy with the addition of thermal storage, thermochemical storage or by producing solar fuels such as hydrogen; which makes possible to implement high-flexible dispatching strategies. Recent studies focus on thermochemical storage and solar fuels (Romero and Steinfeld, 2012). Both processes are based on the use of concentrated solar radiation, which requires adequate optical concentration systems and optimized solar reactors that are capable to withstand high temperatures, where thermal losses are minimized, and which favor mass and heat transfer (Alonso and Romero, 2015).

Solar reactors are classified into directly and indirectly heated reactors, depending on whether particles are directly irradiated or not. Particle reactors can be in turn classified into stacked, fluidized or suspended, and entrained bed configurations. This paper will focus on a rotary kiln that functions as a stacked bed and a brewed oven.

Advantages of a rotary kiln are that they produce relatively low radiation heat losses and uniformly high temperatures, and that the reactive material can be directly irradiated, which leads to intensive heat and mass transfer (Tescari et al., 2013). However, they present technical disadvantages associated with the presence of moving parts, such as the complexity of achieving a balanced rotation, sealing the structure and measuring temperatures inside the rotating tube.

A number of rotary solar reactors have been already employed in research. The Roca reactor (Haueter et al.,

doi:10.18086/swc.2015.04.10 Available at http://proceedings.ises.org

1999), commissioned at the Paul Scherrer Institute (PSI), is a solar rotary reactor of 10 kW designed to produce the thermal reduction of zinc oxide (ZnO) into zinc (Zn) and oxygen (O_2). The Zirrus reactor (Müller et al., 2006), also designed at the PSI to reduce zinc oxide, consisted of a rotating cavity where centripetal acceleration forced the reactant ZnO to cover the cavity wall. Unlike Roca, where the ZnO was both the reactant and the insulating material, these two functions were decoupled in the Zirrus. Thus, the Zirrus reactor was composed of an inner cavity wall impermeable to gas diffusion, but capable of functioning at the decomposition temperature of ZnO in a corrosive environment containing ZnO, gaseous Zn and O_2.

A rotary reactor that produced lime by calcination of calcite was tested in the solar furnace of PSI (Meier et al., 2004). This 10-kW reactor was basically a rotary kiln of 600 mm length and 350 mm diameter, operated horizontally and in a continuous mode. The raw material was stored in a hopper that is placed on top of the rear part of the reactor. The rotation speed was between 2-7 rpm.

A rotary reactor by the German Aerospace Center (DLR) for solar thermochemical energy storage (Neises et al., 2012) was used to perform the reduction of cobalt (II, III) oxide to cobalt (II) oxide and O_2. The total flow used was between 4-8 l/min and a maximum rotational speed of 6 rpm was achieved.

Recently, a rotary reactor for thermochemical energy storage with copper oxide was tested in the solar furnace HoSIER at UNAM, Mexico (Alonso et al., 2015). The reactor body, including the stainless steel housing and an insulation layer of porous alumina, was stationary. Only the reaction chamber rotated around a central axis, connected to an engine at the back of the reactor. The reaction chamber was a rotary cylinder made out of alumina, with an inner diameter of 57.5 mm, an outer diameter of 67 mm and a length of 74 mm. Typical operating conditions were a volumetric flow rate of 10 l/min and rotational speed of 4 rpm.

2. Reactor design and experimental setup

The objective of the reactor design is to get a versatile device that can be used in different processes without many changes. Examples of applications are chemical reactions (solar thermochemistry), thermochemical processes or studies about mechanical strength and/or attrition of different materials. Specifically, this work presents the reduction of manganese oxide (Mn_3O_4). The reactor is presented in Fig. 1 and is composed of the following elements:

A reacting cavity which consists of a fixed conical aperture with a large enough aperture for the incoming radiation (an upper diameter of 11 cm, a lower diameter of 38 mm and a height of 80 mm), and a rotary tube of alumina (with an outer diameter of 45 mm, an inner diameter of 35 mm, and a length of 500 mm). The axial rotation of the tube produces homogeneous temperature, and high mass and heat transfer in the reaction zone. To minimize heat losses, ceramics bricks are used as insulation.

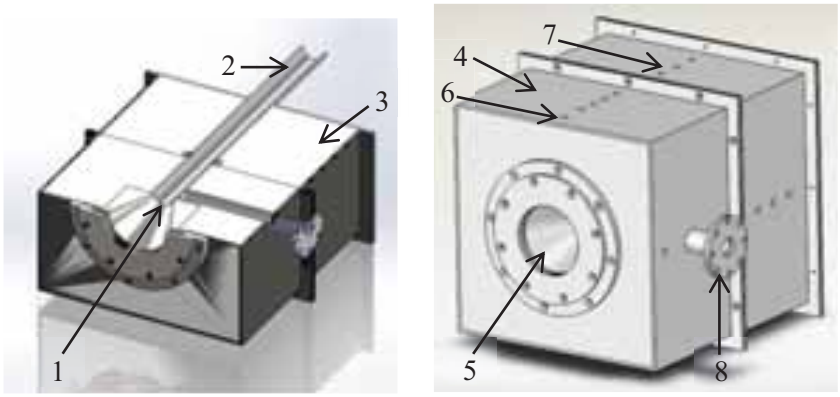

Fig. 1: Scheme of rotary kiln. (1) Cavity; (2) rotary tube of alumina; (3) ceramics bricks; (4) stainless steel housing; (5) quartz glass window; (6) gas inlet; (7) thermocouples places; (8) window for pyrometer

As working in a controlled atmosphere is desirable, air tightness is necessary. To achieve it, the reactor has an external housing of stainless steel, where measuring instrumentation is also located, and a quartz window of high transmittance that allows particles to be directly irradiated and seals the cavity. This window should be clean during experiments, thus the gas feeding is performed by four gas inlets located at the lateral wall of the reactor. The external dimensions of the reactor are 40x35x35 cm^3. 28 K-type thermocouples are installed at different axial and radial distances, and two inside the tube. A window has been included in one of the lateral walls of the facility in order to measure temperatures with a pyrometer. An electric motor rotating at 1390 rpm is employed to move the tube at approximately 92 rpm (9.63 rad/s) through a 1/15 reducer.

Two photographs of the rotary kiln are showed in Fig. 2, where it is possible see the final setup. The axis of rotation is fixed by two treads, one at back cover of the housing and another at gas outlet, behind the gear. Instruments devices installed are the following: a relative pressure transducer at gas inlet; a pressure drop transducer between inlet and outlet; a flowmeter; 30 K-type thermocouples; a pyrometer. All of them connected with data acquisitions cards in order to monitor the course of the experiments by a LabView software. Gas outlet is carried to the gas conditioner and later to the gas analyzer (Siemens Ultramat 23).

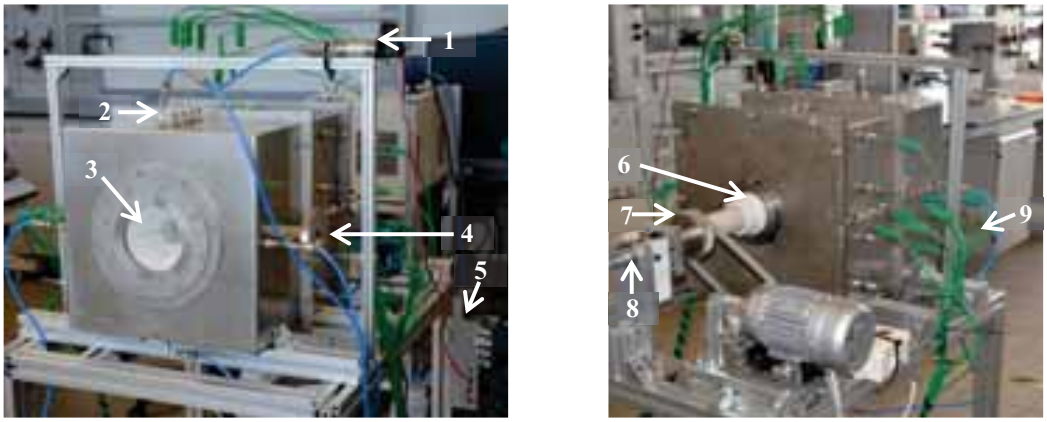

Fig. 2: Front view (left) and back view (right) of rotary kiln. (1) Pressure transducer; (2) gas inlet; (3) window; (4) window for pyrometer; (5) data acquisition card; (6) tread; (7) gear; (8) gas outlet; (9) thermocouples

To avoid particles reaching the conical part, the reactor is tilted 4º with respect to the horizontal and a ceramic ring is placed in the tube inlet. As particles can also move towards the outlet, another ceramic ring was placed at the end of the reaction zone (4 cm behind the inlet), but which did not restrict the gas flow. However, it was observed after the firsts commissioning experiments that some powder still reached the conical part, so the front ceramic ring was replaced by one with a smaller aperture (as shown in Fig. 3).

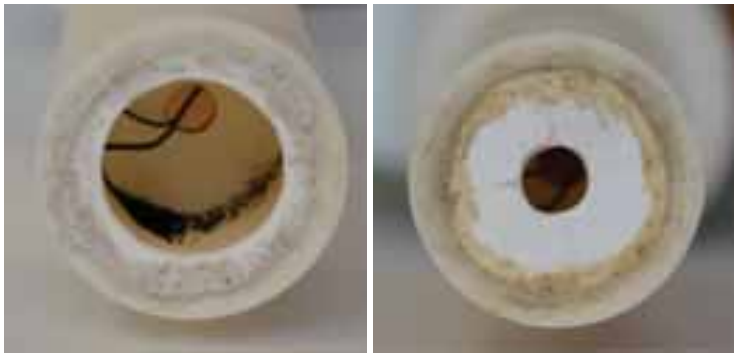

Fig. 3: Ceramics rings. Front ring was changed after first experiments in order to avoid sample losses

3. Numerical Analysis

In order to characterize the reactor, an optical analysis was conducted using the Monte Carlo Ray-tracing software TracePro 7.2, and the flow was numerically simulated by means of COMSOL Multiphysics 4.4.

The optical analysis aimed at determining the optimal position of the reactor with respect to the high flux solar simulator (HFSS) that maximizes sample temperatures and calculating the radiation distribution in the different parts of the reactor.

The optical system contains the main optical components of the high flux solar simulator, a 7kWe Xenon arc lamp and an ellipsoidal reflector. The lamp arc is located at the first focus of the reflector, and radiation is concentrated at the second focus. The optical model included a light source that accurately describes the arc shape and was obtained from CCD images of real arc discharge (showed in Fig. 4).

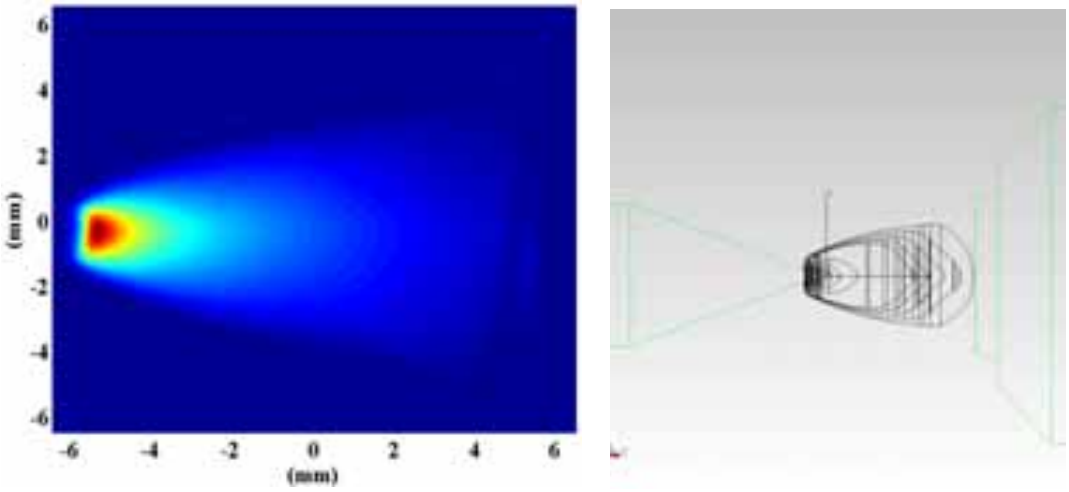

Fig. 4: Discharge arc, CCD image (left) and TracePro model (right)

The definition of the reflector scattering properties was based on the Bidirectional Scattering Distribution Function (BSDF), which consists of measuring the light scattering from a surface in difference directions. For this model, the Elliptical Gaussian BSDF was used.

The number of rays determines simulation times and the resolutions of maps. In order to obtain enough resolution in the simulated maps in reasonable time scales, 139,000 rays were fixed (1000 rays per surface). The total power of the light source was set to 1 kW and results were then scaled according to experimental measurements conducted at the focus.

A square surface (80 mm side length) was located at the focus and rays were traced. The total power in the surface is 443.21 W in the simulations, whereas 1397 W were measured experimentally (Fig. 5), therefore scale factor is 3.15.

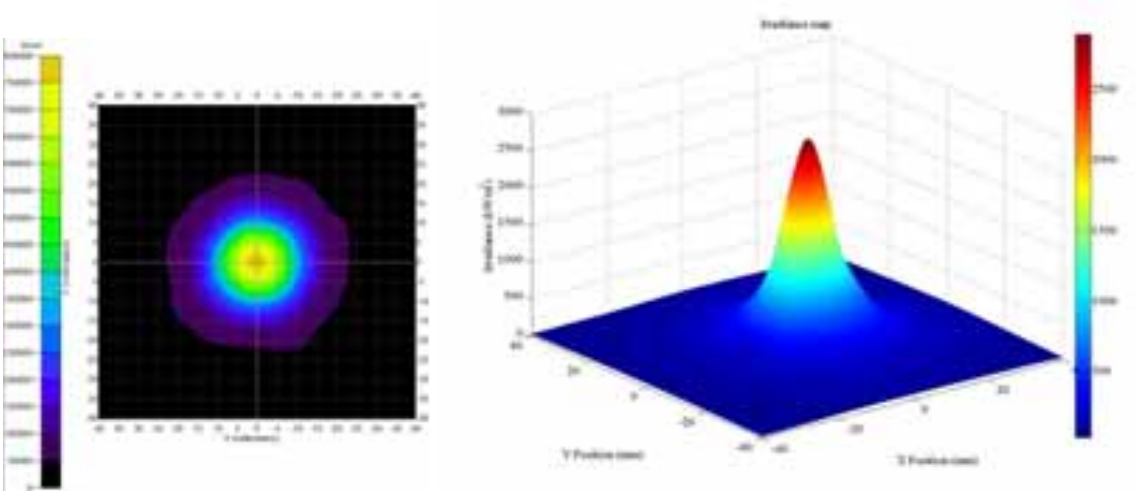

Fig. 5: Radiation measurement at the second focal point, ray tracing (left) and experimentally (right)

The cavity of the reactor (conical part and rotary tube) was implemented by means of gray-body Lambertian surfaces with a 30% absorptance. A schematic of geometry simulated can be seen in Fig. 6. The reactor is inclined 4 degrees with respect to the horizontal. The distance between the secondary focus (target plane) and the central point of the reactor cavity inlet is referred to as *d*. Four cases with different values of *d* were numerically simulated: 5 cm (outside tube), 0 cm (at the tube inlet), and 1 cm and 3 cm inside tube.

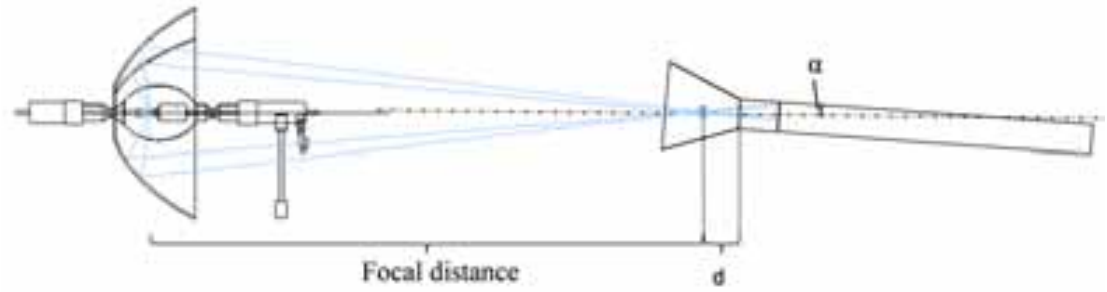

Fig. 6: Scheme of solar simulator and the cavity of the reactor

Results showed that the optimal positions of the reactor with respect to the solar simulator were either when *d* was equal to 0 cm or 1 cm, since the total power at reaction zone was higher than when *d* was equal to 5 cm outside tube and 3 cm inside tube. Table 1 shows the results from simulation with $d = 0$ cm. The total power is around 1 kW at the reaction zone (the first 4 centimeters of the tube), and the stagnation temperature, calculated from Stefan-Boltzmann law with emissivity equal to 1 (ideal radiator), is almost 1750 K.

Irradiance maps of the different parts of the reactor are shown in Figs. 7 and 8 (the latter covering the reaction zone). It can be seen that, from the reactor inlet to the ceramic ring, the maximum power is achieved just in front of the ceramic piece where the sample will be located. Case 2 refers to optical analysis results for ceramic ring with smaller aperture (Fig. 3) performed after experimental tests.

Tab. 1: Total Power at different parts of the reactor obtained by ray tracing, once weighed by real power of the source (2 kW)

Zone	Total Power (W)	Total Power (W) case 2
Cone	1243.59	1745.11
Ring	105.79	819.52
Reaction lower	525.34	101.26
Reaction upper	641.46	114.44
Reaction total	1166.81	215.70

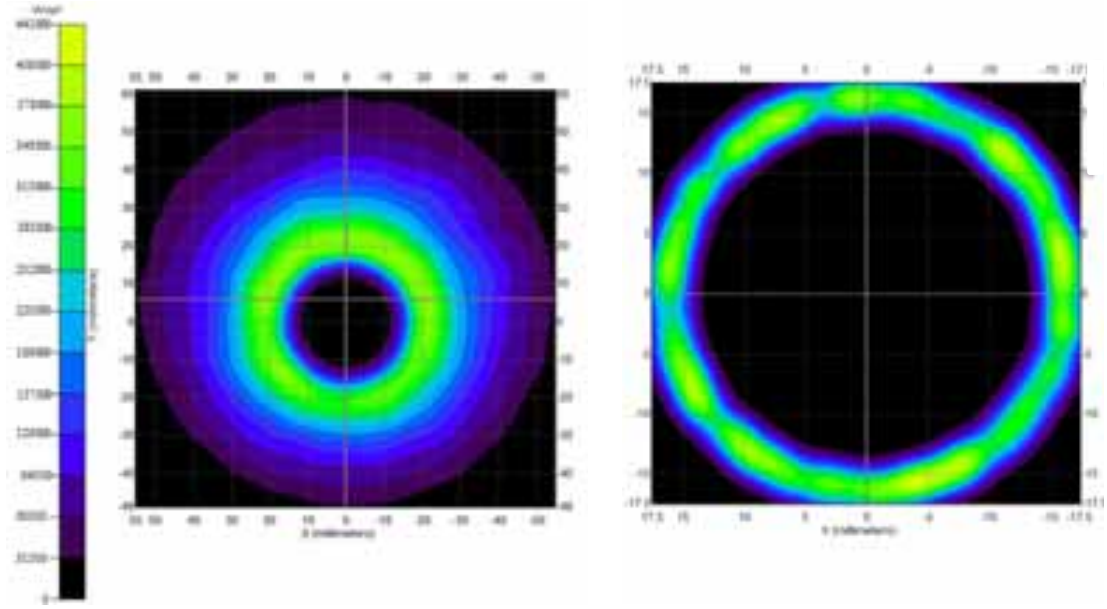

Fig. 7: Irradiance maps: cone (left) and front ring (right)

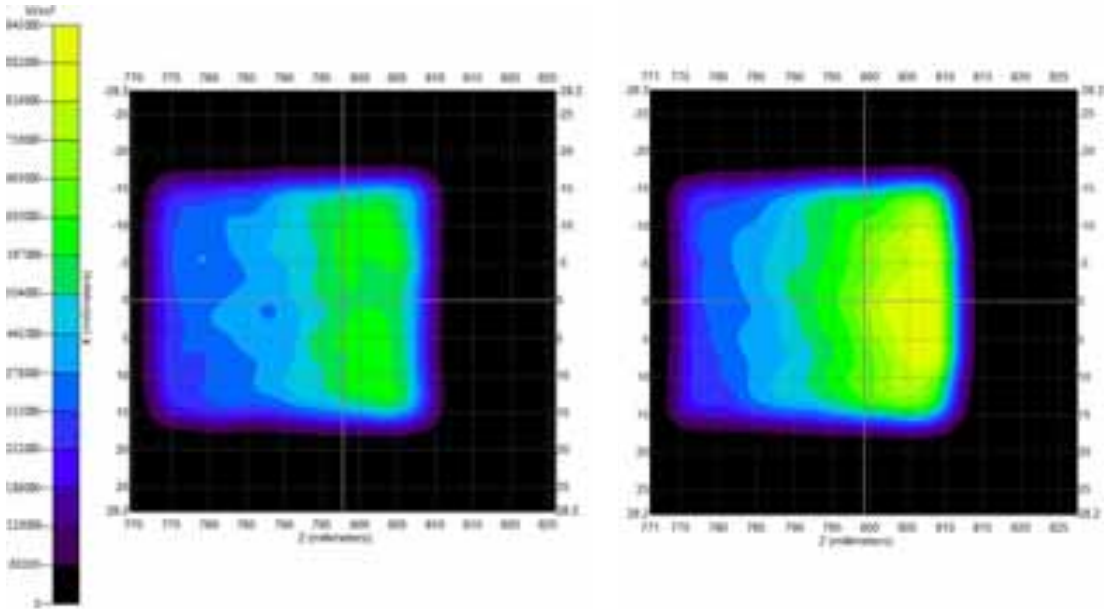

Fig. 8: Irradiance maps: lower half (left) and upper half (right)

The preliminary CFD analysis was conducted to study and assess the flow field and temperature distributions in the reactor. The reactor model was three-dimensional in order to take into account the four flow inlets, which are situated at fixed locations around the circumference. Simulations were thus conducted in one quarter of the geometry (including a flow inlet) in order to reduce the required computational times. Periodic boundary conditions were employed for the flow at the interfaces.

An unstructured mesh was built (with cell growth controlled by the flow physics), with around 65,000 elements. A conjugate heat transfer model was employed.

Boundary conditions of inlet velocity (varying between 1-20 m/s, in the parametric study), outlet pressure (atmospheric) and radiative flux were established. Irradiance variables in both the conical section and the reaction zone were fixed from the ray tracing results and taken as constant values in the simulation. Convective heat transfer between the reactor housing and ambient (at 300 K), and radiative heat transfer between the front window and ambient were simulated.

Figure 9 shows the velocity field in the cavity. As expected, maximum velocities are achieved in the center of the tube. Gas velocity increases along the conical section due to the reduction in the flow cross-sectional area. This enhances the mixing of the gas and avoid reactants deposits on the window.

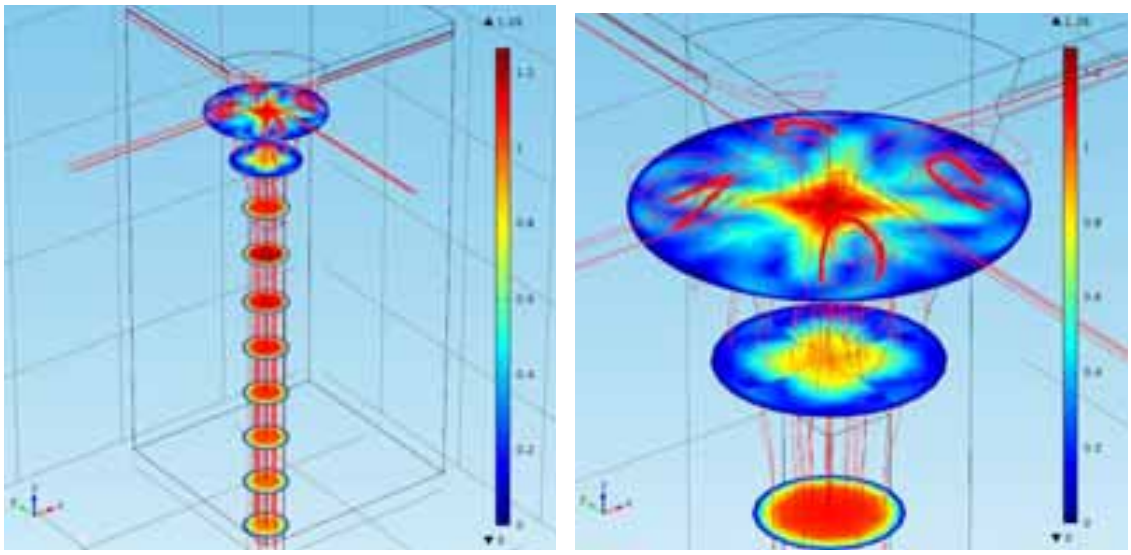

Fig. 9: Velocity field and streamlines at the cavity (left) and cone (right) for gas inlet velocity of 3 m/s (total flow 33 cl/s)

Temperature results are presented in Fig. 10. Maximum temperatures of around 1700 K are achieved in the reaction zone, in agreement with the optical calculations. The housing remains at 300 K, which demonstrates the correct sizing of the insulation. Simulations at higher velocities yield similar fields, with slightly lower temperatures (increasing velocity from 3 to 20 m/s gives a reduction in temperatures of around 50 K), since gas has room temperature at the inlets and cools the reactor more to higher flow (more gas, more convective heat transfer).

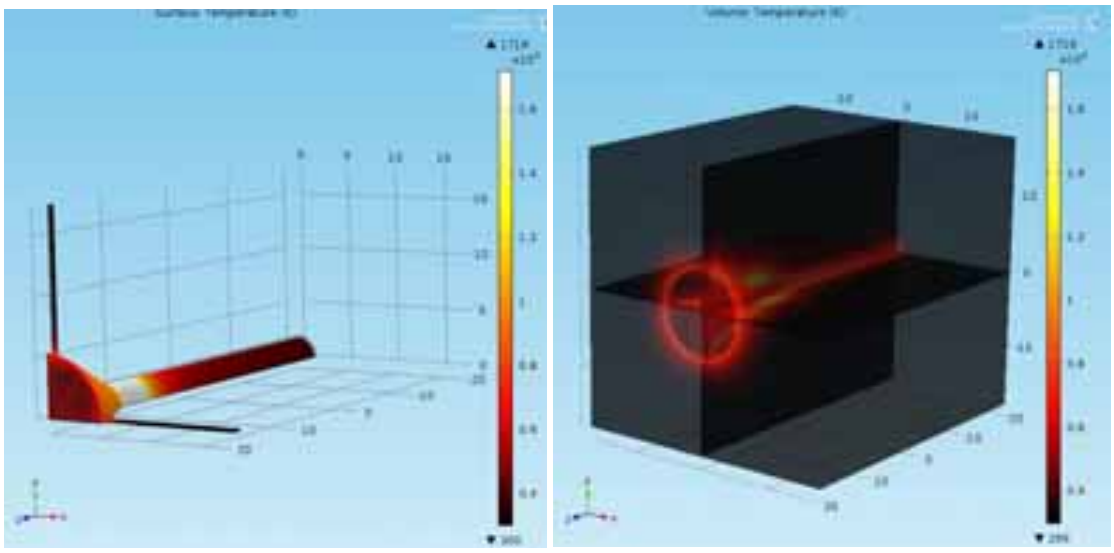

Fig. 10: Temperature distribution of the rotary kiln at a gas inlet velocity of 3 m/s (total flow 33 cl/s)

The evolution of temperature with time in different parts of the reactor is shown in Fig. 11. Temperature increases rapidly in the first minute (high slope), but the rate of change subsequently decreases. Temperatures are practically constant after 20 minutes, except at insulation, which has a much larger thermal inertia.

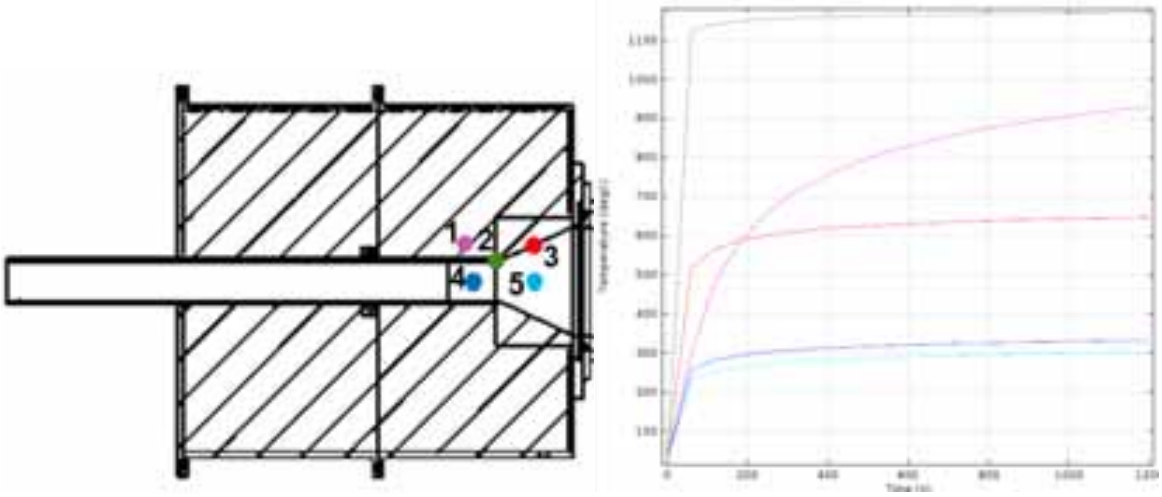

Fig. 11: Scheme of points studied (left) and temperature evolution versus time at those points of the reactor at initial velocities of gas of 3 m/s (total flow 33 cl/s) (right). Points: 1 (pink), 2 (green), 3 (red), 4 (blue), 5 (cyan)

Achieving homogenous temperatures rapidly means that is not necessary introduce rotation in the model with complete geometry of the reactor, since it is possible consider a constant radiation at surface of the tube. When a reactive material is located at the reaction zone, movement helps to get homogenous temperature at the sample and favoring heat and mass transfer with the gas.

Temperatures obtained from CFD results at the reaction zone are similar to the corresponding in experimentation. However, it is necessary improving CFD model in order to approximate it to reality at gas heating.

4. Experimental Results

The objective of the experimental part is the commissioning of the set up. Before the chemical reaction application, the reactor should be experimentally characterized. Firstly, response function of the reactor is determining monitoring evolution of the oxygen concentration at reactor outlet after fast changes in gas composition at reactor inlet. Secondly, an inert sample (silicon carbide) is used to perform thermal characterization in order to know the reactor behavior at high temperature with different irradiance, such as the changes in the reactor materials and maximum temperatures achieve at the different parts of the reactor. Finally, thermochemical reaction of manganese oxide is carried out.

In order to determine the response function, air is fed through the inlets until steady state conditions are established in the working section. It is considered that the steady state is reached when the oxygen concentration becomes stable (it does not change more than 2% in 3 minutes). At this point, the air feed is changed from air to nitrogen and the transient measurements of the oxygen concentration are analyzed (shown in Fig. 12). First, 66 seconds are necessary for the first nitrogen atoms to reach the location where gas is analyzed. Afterwards, the decrease in oxygen concentration approximately follows a negative exponential function, $\exp(-t/t_m)$, with a time constant of $t_m = 51$ seconds (the time constant has been taken as the time at which 63.21% of the total decrease has occurred).

Thermal characterization was conducted with the HFSS. An alumina screen was placed in front of the reactor as thermal shield to protect the external housing from the intense radiation (as shown in Fig. 13).

An inert silicon carbide sample was used in the first series of experiments to conduct the thermal characterization of the reactor. Different levels of radiation attenuation were employed in the facility, implemented by means of partially transparent radiation screens with various open area fractions.

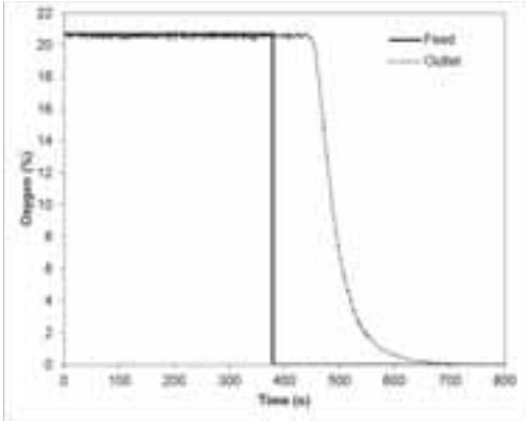

Fig. 12: Oxygen evolution when air is changed to nitrogen

Two tests are performed. A test with attenuation levels of 59%, 50% and 32%, and another test with attenuation levels of 32% and 0%. HFSS is turned off to change the screen attenuation and then it is turned on. Figure 14 shows the temporal evolution of temperatures in cavity, measured in both tests. Temperatures plotted in the figure include those measured at the conical section, the gas reaction zone (measured with two thermocouples), and outer tube wall temperature at the reaction zone. A list of the maximum operating temperatures achieved in the facility is given in Table 2. One of the thermocouples in the reaction zone was damaged during the test with lowest attenuation and data is not shown for it after that time (the maximum operating temperatures of K-type thermocouples is typically 1200 ºC).

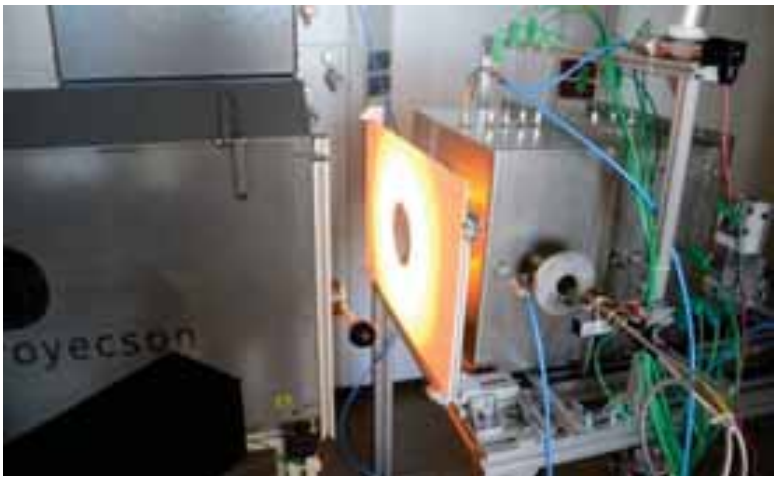

Fig. 13: Setup rotary kiln in front of high flux solar simulator

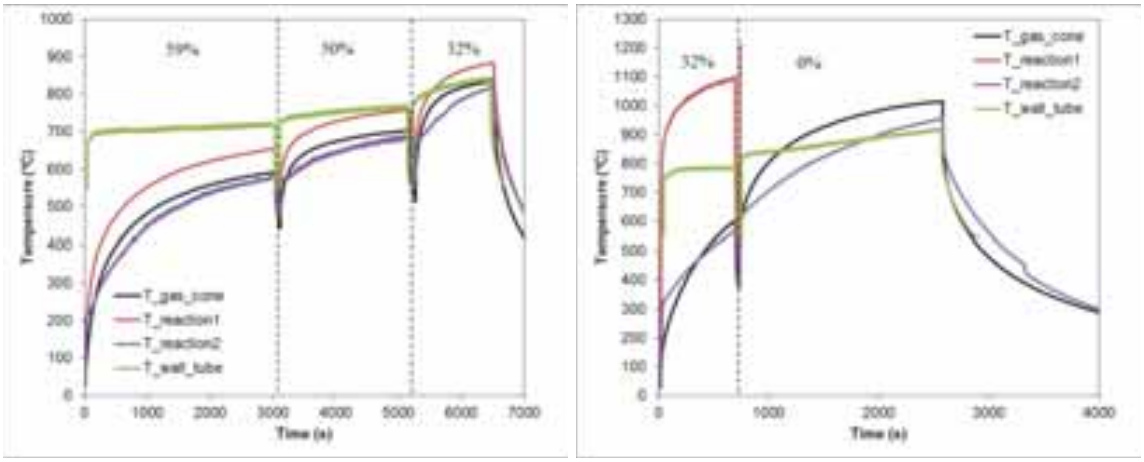

Fig. 14: Temperatures traces: attenuation levels of 59%, 50% and 32% (left); attenuation levels of 32% and 0% (right)

Tab. 2: Maximum temperature achieved in operation for different attenuations (the thermocouple was damaged during te test at 0% attenuation)

Attenuation	T max (ºC)
59%	655
50%	760
32%	1085
0%	>1200

Once the thermal characterization is done, experiments with thermochemical reactions were conducted. Manganese oxide cylindrical pellets (a mixture composed of 85% Mn_3O_4 and 15% Mn_2O_3, mean particle size 3.5 mm) were introduced in the reaction zone of the cavity. Redox reactions are the following:

Oxidation: $4\ Mn_3O_4 + O_2 \rightarrow 6\ Mn_2O_3$ (around 700 ºC)

Reduction: $6\ Mn_2O_3 \rightarrow 4\ Mn_3O_4 + O_2$ (around 950 ºC)

Air was fed while heating the working section in order to produce the complete oxidation of Mn_3O_4. The air supply was changed to nitrogen when temperatures of the reaction zone are higher than 700 ºC (temperature of the oxidation) in order to produce the reduction of Mn_2O_3. Results are showed in Fig. 15, where the full test is represented and reduction area is amplified. When oxygen concentration reaches steady state conditions at temperatures above 700 ºC, the air is changed to pure nitrogen. In this part of the experiment, an increase in the oxygen concentration is observed because of the reduction reaction. In order to study the variation in oxygen concentrations, this is compared to the variation that occurs at ambient temperatures (i.e., without reaction) when air is changed to pure nitrogen. The difference between both curves is due to the oxygen that is released during the reduction reaction.

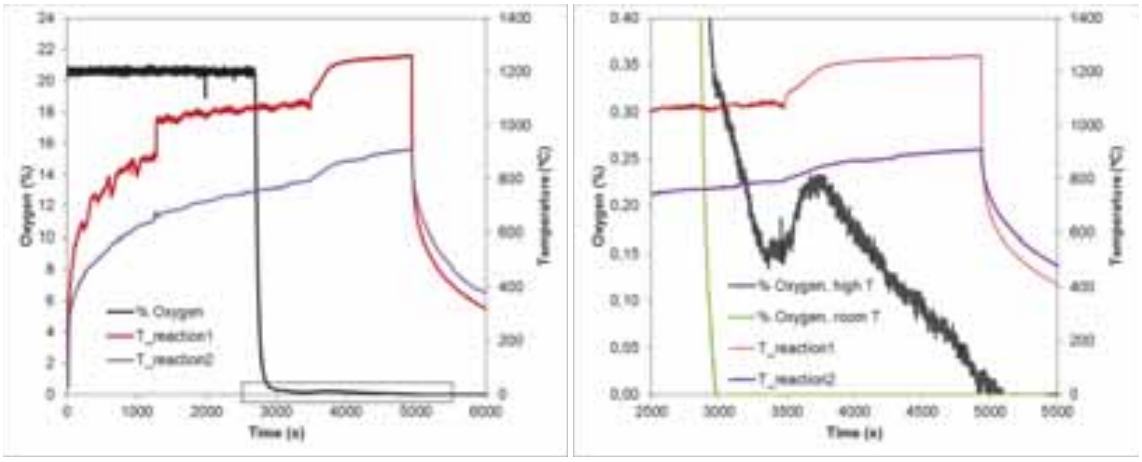

Fig. 15: Temperatures and oxygen concentration evolution, attenuation level of 32%. Full test (left), zoom on reduction reaction (right)

After the experiment, particles were removed from the reactor and analyzed (photographs of them before and after the experiment are shown in Fig. 16). It can be seen that after the tests, particles are brown in color (as opposed to black, initially) and partially worn down at the edges. Figure 17 presents histograms of particle sizes fed and discharged. It is clearly observable that sizes decrease during the test, between 0.2 and 0.4 mm, approximately. X-Ray Diffraction (Fig. 18) confirms that these particles are 100% Mn_3O_4; hence, a full conversion of the initial 15% of Mn_2O_3 is achieved.

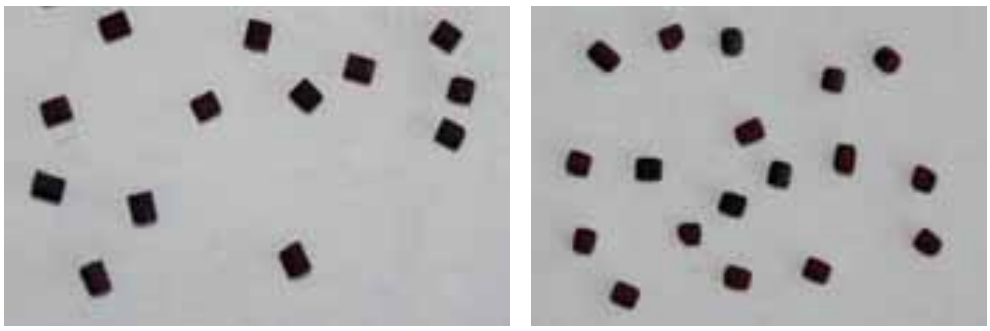

Fig. 16: Particles fed (left), particles discharged (right)

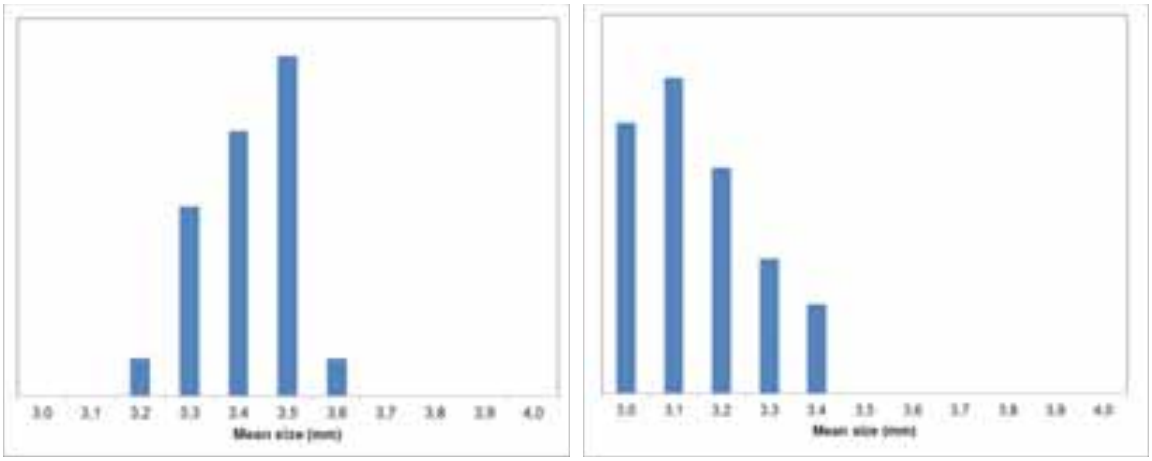

Fig. 17: Mean particle size distributions of particles fed (left) and particles discharged (right)

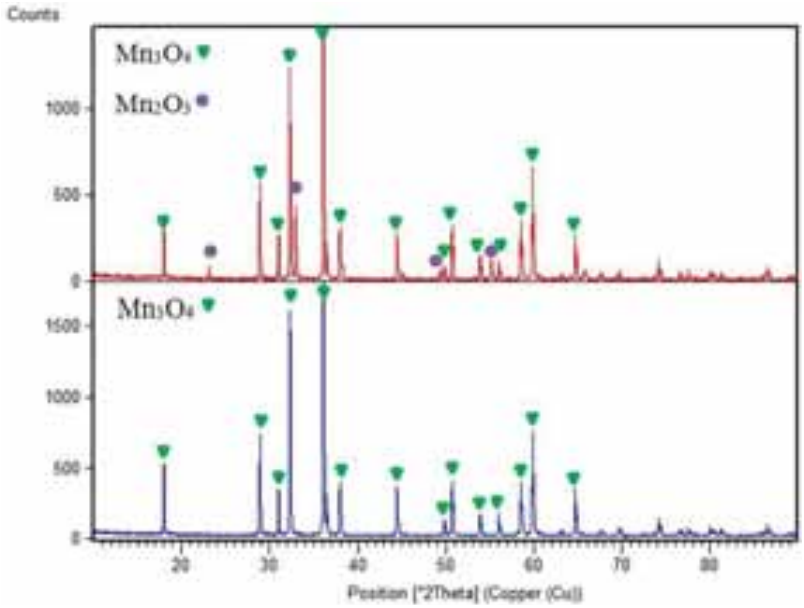

Fig. 18: X-Ray Diffraction results: particles fed (top), particles discharged (bottom)

5. Conclusions

A rotary kiln for experiments in a HFSS have been design, built, simulated and commissioned. The design allows reacting particles to be directly irradiated at high flux and high temperature conditions.

Optical analysis by Monte Carlo ray tracing was conducted to select the optimal position of the reactor relative to the HFSS in order to achieve a total power at the reaction zone of around 1 kW.

A preliminary CFD model was developed for the empty reactor and without rotation. Results indicated that

the maximum temperature was achieved at the reaction zone (1700 K).

Commissioning experiments in the 7kW$_e$ HFSS demonstrated that is possible to reach high temperatures at the reaction zone (1500 K). Thermochemical reaction experiments with manganese oxides (85% Mn_3O_4 y 15% Mn_2O_3) were performed, with air being fed during the heating of the kiln, and nitrogen when temperatures reached 700 ºC. The production of oxygen was measured at high temperatures from the reduction chemical reaction. Discharged material was 100% reduced (Mn_3O_4).

Abstract

A new Cr-Fe-Ni oxides/ZrO_2-SiO_2 composite oxide based tandem absorber is designed and developed for high performance ORC based solar thermal applications. The Cr-Fe-Ni composite oxide based absorber layer is designed to have nanoporous structure and covered with an antireflective protective layer. The tandem absorber layer was developed by a combination of chemical and sol-gel methods. By varying process parameters like duration, temperature and withdrawal speed, different combinations of Cr-Fe-Ni oxides/ ZrO_2-SiO_2 composite absorber layers with varying refractive indices were developed on a suitable SS substrate. The optimized thickness of absorber layer along with the antireflective layer exhibited high absorptance (α= > 0.94) and low thermal emittance (ε = 0.11– 0.14 at 300 °C). More specifically, this novel tandem coating has excellent optical properties along with high corrosion resistance (withstands > 400 h in salt spray test). It has good thermal stability in an open air atmosphere and is well suited for low and medium temperature solar thermal applications.

Keywords: *Tandem absorber layer, Cr-Fe-Ni composite oxide, ZrO_2-SiO_2, antireflective layer*

Introduction

Solar collectors play an important role in areas such as hot water heating systems of buildings and steam generation for various industrial applications and power production. They convert sunlight to thermal energy which is then converted to electrical energy (Agnihotri and Gupta, 1981; Duffie and Beckman, 1991; Gordon, 2001; Kennedy, 2002; Kalogirou, 2004). Conventionally, most of the selective absorber coatings preferred for concentrated solar collector application are developed by the expensive PVD route particularly magnetron sputtering (Adsten et al.,(2000); Barshilia et al., (2008); Graf et al., (1997); Juang et al., (2010); Koželj et al., (2009); Nunes et al., (2003); Selvakumar and Barshilia, 2012; Teixeira et al., (2001, 2002); Wäckelgård et al., (2001); Yin et al., (2009); Zhang, 1998). Currently the entire concentrated solar thermal power (CSP) program is working to reduce the cost of solar thermal power technology. One of the approaches is to operate the CSP system using cost effective solar collectors in open air atmosphere conditions instead of using expensive evacuated solar collectors. To accomplish this, efficient selective collectors are needed that have high optical properties and high stability to corrosion, in addition to enhanced thermal properties. For efficient photo thermal conversion, solar collectors must have high solar absorptance (α) in an active solar region (300-2500 nm) and a low thermal emittance (ε) in the IR radiation wavelength range (3-25 μm) at an optimal operational temperature. However, most of the current coatings do not have stability against corrosion and air and this is the main problem faced while operating the collectors in an open atmosphere (Barshilia et al., (2008); Koželj et al., (2009); Selvakumar and Barshilia, 2012; Tulchinsky et al., (2014)). Moreover, the coatings need to be stable in air in case the vacuum is breached.

doi:10.18086/swc.2015.04.11 Available at http://proceedings.ises.org

Solar selective coatings can have high optical properties, stability against air at operational temperature, long environmental stability, high scratch and abrasion resistance, and high mechanical integrity. Coatings prepared by an economic process (e.g. electrochemical deposition technique (Lee, 2007; Moise et al., (2001); Newby, 1999; Zeng et al., (2009)), thermal oxidation (Aries, 1986, 1987, 1991; Boydag, 1986; Douglass and Pettit, 1981), chemical oxidation (Sharma et al., (1988); Uma et al., (1987)), sol-gel process (Bostrom et al., (2008); Kozelj et al., (2009); Katumba et al., (2008)) etc on easily available substrates (e.g. stainless steel) with a combination of above mentioned properties would be a great choice for power generation by a concentrated solar power (CSP) system. Nowadays, solar absorptance of most common high-quality commercial absorbers is about 95 % and the thermal emittance is < 10 %. The techniques that have been attempted so far for the cost efficient solar absorber coatings such as electrochemical deposition, thermal oxidation, chemical and sol-gel process have faced many challenges to produce coatings with high optical efficiency, high environmental and thermal stability.

Very few studies have reported high optical efficiency with temperature and corrosion stabilities for solar absorber coatings made by sol-gel process. For example, such a coating was prepared from polysiloxane as a binder and Co_3O_4 as a spinel pigment on 304 stainless steel by spin-coating (Andrea Ambrosini et al., (2010)). Spectrally selective absorber coatings were prepared by spin- coating of nickel nanoparticles embedded in alumina and coated with an antireflective layer made of silica, alumina, or silica–titania mixture (Bostrom et al., (2005)); Orelet al., (2003)) reported doping of $CuCoMnO_x$ by Ti in a polysiloxane resin. The films were used in order to increase the weather resistance and showed absorptance of 0.86 – 0.91 and emittance below 0.036. Tulchinsky et al., (2014) reported the thermal chemical reaction between a titania sol–gel precursor with the copper manganese spinel to form a new material, $Cu_{0.44}$ $Ti_{0.44}$ $Mn_{0.84}Fe_{0.28}O_3$, having a bixbyite structure. Although solar absorptance of the films was reported around 97.4 %, no data was provided for the emittance of the film. Chao-Ching Chang reported poly(urethane)-based solar absorber coatings containing copper chloride and nanogold composite synthesised by solution-chemical technique. The solar absorptance and thermal emittance of this coating were shown to be only around 0.846 and 0.09, respectively (Chao-Ching Chang et al., (2013)). Copper–cobalt oxide thin films deposited on aluminium substrates via a facile sol–gel dip-coating method showed solar absorptance of 3.4 %. (Amun Amri et al., (2013)). A higher value of solar absorptance and better stability is needed for the films to be suitable for concentrated solar thermal power application.

Martin Joly et al., (2013) produced multilayered chrome-free black selective surfaces for solar thermal energy conversion by a low-cost sol–gel dip-coating method. The optical properties of solar absorptance and thermal emissivity at 100 °C of the Cu–Co–Mn–Si–O based nano crystalline thin films were shown around 0.95 and 0.12. The coatings were stable up to a maximum of 360 °C in air which surpasses that of the conventional robust black chrome coatings existing in the market. But there was no report on the weather stability of the novel multilayer absorber coating.

For concentrated solar thermal power plant (CSP) application, coatings are required in a large area and development of solar receiver tubes with all the properties like high solar absorptance, low thermal emissivity, high weather and thermal stabilities by an economic way is the main objective in order to reduce the cost of solar electricity production. In view of the above, herein, we report a novel Cr-Fe-Ni oxides/ ZrO_2-SiO_2 nanocomposite oxide based tandem absorber system developed by a combination of chemical oxidation and sol-gel process for high performance ORC based solar thermal applications having excellent optical properties along with high corrosion resistance and good thermal stability in an open air atmosphere and their optical and structural characterisations.

2. Experimental

2.1. Sample preparation

The thin nanoporous structure composite oxides of absorbing layers were developed on smooth highly specular reflecting mirror of stainless steel substrates. The base absorber films were developed by controlled chemical oxidation process on a special variety of stainless steel tube (SS-316) having the composition of C: 0.08, Mn: 2, P: 0.045, S: 0.030, Si: 0.75, Cr: 16-18 and Ni: 10-14**;** and Fe: 69-73 wt % respectively, using a precise temperature controllable chemical bath reactor and an optimum parameters like molar ratio of acid mixture, temperature, and duration. 1M sodium dichromate salt dispersed in a mixture of sulphuric acid and water (3:5) was used for the development of nanoporous base absorber layer. The detailed preparation procedure of the absorber layer has been described elsewhere (Sakthivel et al., (2013)). In a preliminary step of the process, the SS tube sample is cleaned with a mild detergent solution and rinsed with tap water followed by deionised water and finally wiped with a soft cotton cloth using an organic solvent, preferably

isopropyl alcohol (IPA), to make it free of any external impurities adhering to the surface. The cleaned substrate is then dried either by an air drier or by keeping it at 100 ^{0}C for 5-10 min in an air–oven. The dimensions of SS tube used for this study were 500 mm x 500 mm x 1.25 mm (L x W x Thickness).

2.2. Development of nanoporous composite absorber layer on SS 316 tubes

The cleaned substrates are immersed into an acid bath for chemical oxidation in a temperature range of 80-90 °C for 20-30 min. During the chemical oxidation process, the metal atoms on the surface of substrates are partially oxidized by the acid mixture to obtain a type of nanoporous composite oxide layer. After chemical oxidation, the SS tubes turned to grey in colour with a glassy appearance. The absorber layer developed SS tube was then washed thoroughly with tap and distilled water and finally wiped with a soft cotton cloth using with an organic solvent, preferably isopropyl alcohol (IPA). The cleaned absorber layer developed substrate was then dried by an air drier for 2-5 min.

2.3. Development of optical enhancing layer on absorber layer coated SS 316 tubes

After drying, the optical enhancing protective layer comprising ZrO_2–SiO_2 composite, was deposited by dip coating process using a composite sol obtained by mixing zirconium propoxide and 3-glycidoxy propyltrimethoxysilane (GPTS) compound in a mixture of isopropyl alcohol (IPA, Alfa Aesar) and Isopropoxyethanol (IPE, Alfa Aesar) to obtain a stable suspension. The composition of the coating suspension for this layer was in the ratio of Zr (n-Pro): IPA: IPE: GPTS = 6.94:78.52:12.94:1.60 (wt %). ZrO_2-SiO_2 composite coating sol was coated on the absorber coated steel substrates using dip-coating technique. No binder/additive was used for the coating. Increase in withdrawal speed resulted in increase of coating thickness and in turn the packing density. To obtain highly optical enhancing thin films, the coating speed and curing temperature were altered from 2 mm sec^{-1} to 5 mm $^{-1}$sec and 100-300 °C respectively. It was noted that the film showed a high optical enhancing (antireflection) property (> 8 % solar absorptance from 300-2500 nm) even at low possible curing temperature, 100 °C. Hence it is suitable for making cost effective tandem absorber layer for solar thermal application.

2.4. Characterization methods

Optical and structural properties of the absorber layers were measured after the coating layer development. The diffuse reflection spectral measurements in the UV/ Vis /near-IR region were carried out by a Cary 5000 spectrophotometer equipped with a standard integrating sphere (110 mm dia) at room temperature in the spectral interval of 0.3 – 2.5 μm with a scanning speed of 1200 nm min^{-1}. Normal emittance measurements in the infrared wavelength region were carried out by a Bruker vertex 70 FTIR (Fourier Transform Infrared) spectrophotometer equipped with a standard integrating sphere using an evaporated gold mirror as a reference plate. All the measurements were done in the spectral interval of 2.5 – 25 μm with a scanning velocity of 2.5 KHz.

The normal absorptance (α) and emittance (ε) values were calculated using standard equations as described in literature (Bostrom et al., (2003)). The solar absorptance, α_{sol} of the sample was calculated as a weighted fraction between absorbed radiation and incoming solar radiation using an AM 1.5 spectrum. The direct normal solar irradiance, I, is defined according to the ISO standard 9845-1 (1992) where an air mass of 1.5 is used (Bostrom et al., (2003)).

The thermal emissivity (thermal loss) of coatings corresponding to a particular temperature (ε_t) was calculated as described in literature (Sakthivel and Srinivasa rao, 2015). However, values of thermal emittance of black body at each temperature were used instead of using a theoretical black body distribution as is generally used in literature (Bostrom et al., (2003); Lundh et al., (2010)). FTIR spectrometer equipped with the standard accessories of black body furnace and a high pressure cell (sample compartment) supplied by Bruker optic GmbH was used for the measurement of thermal radiation emittance. For thermal emissivity calculation, initially the thermal radiation emittance spectra (2.5-25 μm) of both black body and selective absorber layer coated sample were measured one after another by heating black body furnace and coated sample in the sample compartment at temperature range starting from 100 to 300 °C. Finally, the thermal emissivity was calculated by using this formula, ε_t= sample emittance radiation /Black body emittance radiation generated at the same temperature from 2.5-25 μm.

X-ray diffraction pattern was recorded by using Bruker AX D8 XRD equipment having CuK_α X-ray source. The scan was taken in the range 0-100° with an increase of 0.01°at duration of 2s step^{-1}. Surface morphology of absorber layers was studied by field emission scanning electron microscopy, FESEM (Hitachi model S4300SE/N) operated at 20 kV. Energy dispersive spectroscopy (EDS) was carried out for all the films during SEM study.

Coating thickness and refractive index of the composite layers were measured using a spectroscopic ellipsometer (Model: M-2000V, J. A. Woollam Co. Inc.) in the wavelength range of 350–1000 nm. Water contact angle was measured by a drop shape analyser DSA 100 (Kruss GmbH, Germany) to verify the surface roughness (hydrophobicity/hydrophilicity) of the absorber layer. The chemical composition and oxidation state of the composite layers were analysed by X-ray photoelectron spectrometer (Omicron-ESCA+) equipped with Al Kα anode and Raman spectrophotometer (Model: HR 800, Horiba Jobin-Yvon, France).

3. Results and discussion

3. 1. Design of Cr-Fe-Ni nanocomposite oxide / ZrO_2-SiO_2 tandem absorber

The schematic diagram of Cr-Fe-Ni nanocomposite oxide / ZrO_2-SiO_2 tandem absorber is shown in Fig. 1. An absorber–reflector tandem absorber concept was used to develop the absorber on SS substrates, where in the Cr-Fe-Ni nanocomposite oxide layer and smooth SS surface (surface roughness around <1 micron) act as absorber layer and infrared reflector, respectively. It is well known that the optical properties of transition metal based coatings can be tailored by controlling the stoichiometry, which affects the density of free electrons in the d band (Seraphin, 1979). Based on this concept, the first absorber layer Cr-Fe-Ni composite oxide was designed to have higher amount of Cr oxide content (called as HfMoN(H)) than the Fe and Ni oxides in order to achieve high selective property with suitable refractive index which matches with second layer (optical enhancing layer (antireflective layer)) for further optical enhancement.

The tandem design used for the fabrication of highly environmentally stable absorber system is illustrated in Fig. 1. Cr-Fe-Ni nanocomposite oxide layer with nanoporous structure (11-14 nm pore size) was prepared by controlled chemical oxidation process using optimum process parameters like a process temperature, 80-90 ^{0}C, process duration, 20-30 min and an optimum concentration of acid mixture, 1M sodium dichromate salt dispersed in a mixture of sulphuric acid and water (3:5), respectively. Followed by the deposition of absorber layer by the above described controlled chemical oxidation, the optical enhancing layer (antireflective layer) with weather resistant property is deposited by the dip coating process using a composite sol of ZrO_2-SiO_2 prepared by a sol-gel method.

Figure 1. Schematic diagram of the Cr-Fe-Ni oxides / ZrO_2-SiO_2 composite oxide layer deposited on stainless steel tube

3.2 .FE-SEM

The FE-SEM representative images of Cr-Fe-Ni nanocomposite oxide absorber layer developed on SS-316 mirror (smooth surface) are shown in Fig. 2. It can be observed in this figure that the surface morphology of Cr-Fe-Ni composite oxide absorber layer on SS-316 polished surface (Fig. 2a) comprises a nanoporous morphological structure of 13–17 nm in diameter, because of the controlled chemical oxidation of metal atoms on the surface of SS plate. Particularly, Cr, Fe and Ni were the predominant metal atoms involved in the oxidation process. The surface morphology of ZrO_2-SiO_2 (Fig. 2b) deposited on the absorber layer in the tandem system uniformly covered all the nanopores. Furthermore, the layer deposited on the absorber layer for the optical enhancement and protection from weather and corrosion was very uniform and without cracks and pinholes.

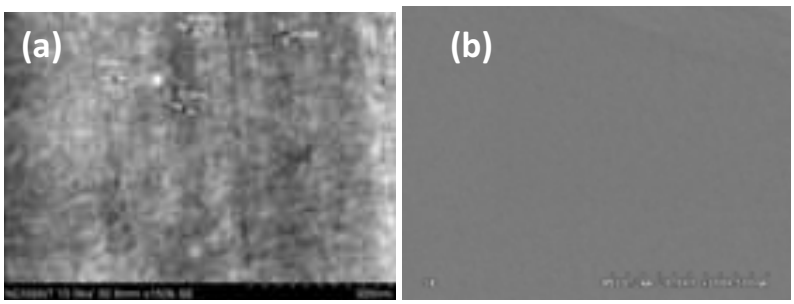

Figure 2. FE-SEM surface morphology of (a) Cr-Mn-Fe composite absorber layer with nanoporous structure (Pore size around 13-17nm); (b) Tandem absorber layer of Cr-Fe-Ni oxides / ZrO_2-SiO_2 composite oxide layer generated on SS tube

3.3. X-Ray Diffraction (XRD) results

The results of the incident angle XRD studies for the absorber layer comprised of Cr-Fe-Ni composite oxide layer developed using optimized conditions are shown in Fig. 2 and are compared with the diffraction peaks of bare SS-316 sample. The peaks observed in the bare substrate indicate an austenitic type of steel (Fig. 3 FCC peaks labelled "a"). It is surprisingly noted that the XRD patterns of chemically oxidized samples are quiet similar to the bare substrate. The reason could be that a high content of iron (69-73 %) in the substrate which dominated during analysis as compared to other components like chromium, manganese, nickel which are presented in lower concentration. Moreover, the atomic number of chromium, nickel, and copper are very close to metallic iron. From XRD analysis it is quite difficult to distinguish if the element is in low concentration or the layer thickness in nano range.

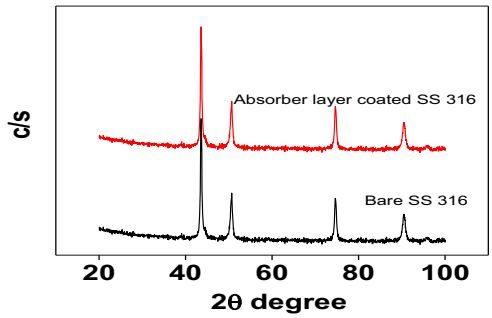

Figure 3. XRD patterns of both bare and absorber layer developed on SS-316 polished plate

3.4. X-Ray photoelectron spectroscopy (XPS) results

The coating compositions of the base absorber layer and the oxidation states of each element were clearly confirmed by XPS. Fig. 4 (a-d) shows the high resolution core level X-ray photoelectron spectra (XPS) for an absorber layer developed on SS 316 polished surface. The Cr 2p spectrum (Fig. 3(a)) consists of 2 peaks centered at 576.73 and586.35, which originate from Cr $2p^{3/2}$ and Cr $2p^{1/2}$ electrons in Cr_2O_3 (Hsin-Yen Cheng et al., (2013); Teixeira et al., (2002); Wu et al., (2013)). The Fe 2p spectrum (Fig. 3(b)) exhibited four peaks centered at 707.14, 709.29eV, 726.40 and 730.03 which correspond to Fe $2p^{3/2}$ and Fe $2p^{1/2}$ of FeO and Fe_2O_3 (Srinivasa Rao and S.Sakthivel, (2015); Tulchinsky et al., (2014)). The Ni 2p spectrum (Fig. 3(b)) exhibited 2 peaks centered at 853.05 and 870.39 eV, which correspond to Ni $2p^{2/3}$ and Ni $2p^{1/2}$ of NiO (Ewa Wackelgard et al., (1998)). The 1s spectrum of oxygen (Fig. 3(d)) of the absorber coating (Cr-Fe-Ni oxide layer) revealed the presence of two peaks centered at 530.42 and 531.25 eV, which correspond to oxides Fe, Ni and Cr. From this result, it is clear that the nature of composite absorber layers formed by the controlled chemical oxidation method may depend upon the process conditions. According to XPS analysis, the surface composition of the absorber layers in atomic percentage was in the ratio of 17.97: 6.28: 2.22: 73.53 (Cr: Fe: Ni: O).

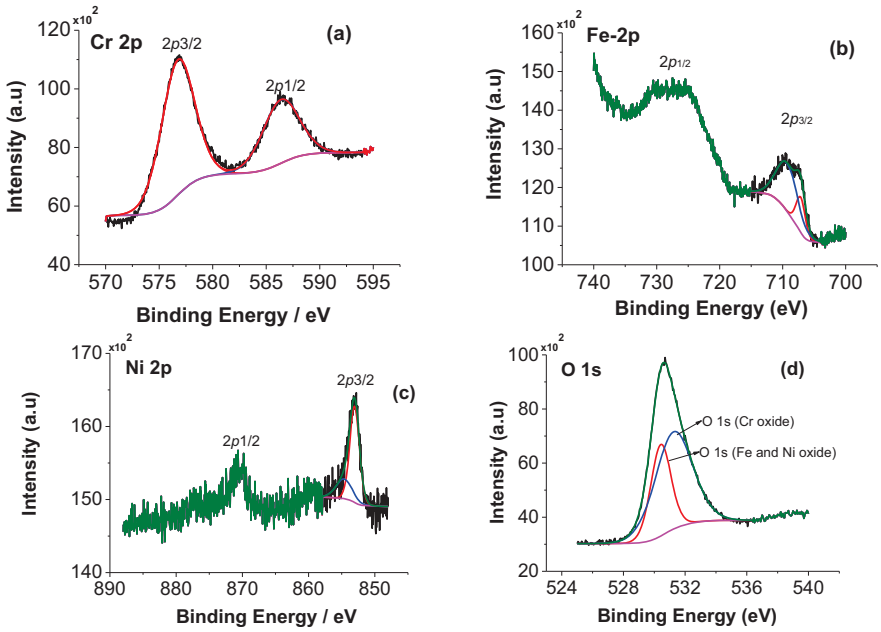

Figure 4. X-ray photon electron spectra of absorber layer developed on SS 316 polished surface

3.5. Solar absorptance of single and tandem absorber systems:

Fig. 5 and Table. 1 summarize the reflectance spectra measurement at room temperature for the absorptance characteristics of the corresponding nanocomposite selective absorber layer with nanoporous morphological structure prepared with the optimum conditions of process temperature, duration, and using with an optimum concentration of acid mixture: 85 °C, 20 min and 1M sodium dichromate salt dispersed in a mixture of sulphuric acid and water (3:5), respectively. The reflectance spectrum of Cr-Fe-Ni nanocomposite oxide layer with nanoporous morphological structure shows a little higher reflectance in the solar range corresponding to a low solar absorptance of 86.1 %. However, the absorber layer further coated with the optical enhancing layer (antireflective layer) using a composite sol of ZrO_2-SiO_2 by sol-gel dip coating process. The optical enhancing layer deposited with an optical withdrawal speed of 3 mm sec^{-1} followed by curing at 300 °C for 2 h exhibits high solar absorptance, 94.3 %.

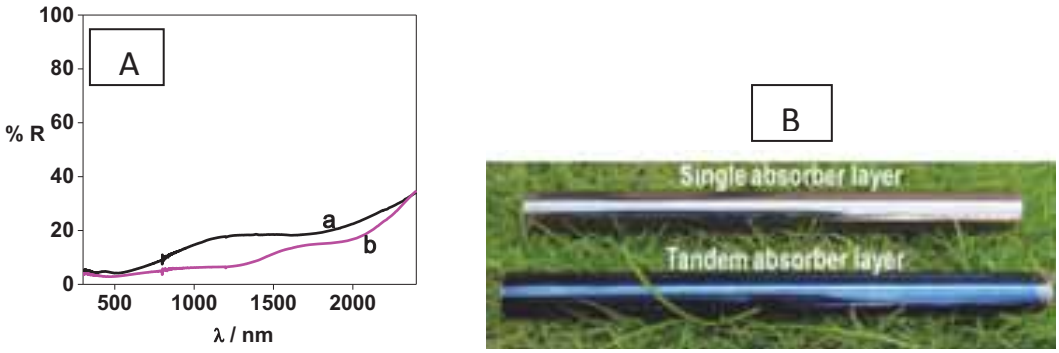

Figure 5A. Comparison of reflectance spectra of Cr-Fe-Ni nanocomposite oxide (a) and Cr-Fe-Ni oxides /ZrO_2-SiO_2 Tandem absorber layers (b), 5B. Image of 0.5 m long single and Tandem absorber layers coated SS 316 tubes.

3.6. Thermal emissivity characterization:

Thermal emissivity characterisation of the both single absorber layer (Cr-Fe-Ni nanocomposite oxide layer) and two layer tandem absorber layer (Cr-Fe-Ni nanocomposite oxide layer/ ZrO_2-SiO_2 sol-gel layer) exhibits high solar absorptance developed on the polished surface of SS 316 and was carried out by FT-IR spectrophotometer using special accessories like a black body furnace and high temperature sample cell unit. The thermal emittance of both black body furnace and samples were measured at different temperatures starting from 100 °C to 300 °C with an interval of 50 °C. Finally, the thermal emissivity of the coatings was

calculated from the measured thermal emittance data of sample and black body furnace using the standard equation as described in the literatures (Carlsson et al. (2000), Öhl et al. (2004), Price et al. (2004)).

Typical thermal emissivity spectra were derived for single and tandem absorber layers from their emittance and black body emittance spectra were recorded at different temperatures from 100-300 °C and represented in Fig. 6 and Table. 2. The thermal emissivity of heat radiations from both types of layers on SS substrates are increased with increasing of temperature. Compared to the single absorber layer coated sample, a little lower value of emissivity is noted for the tandem absorber sample due to covering of nanopores in the absorber layer by the AR layer. Further, it is clearly noted that the tandem absorber layer shows low thermal emissivity value of 0.067-0.144 at 300 °C. However, the single nanocomposite absorber layer having nanoporous morphological structure shows a high thermal emissivity range of 0.106-0.172 measured from 100 °C to 300 °C. The reason for observing a high thermal emissivity could be the presence of pores in the absorber layer.

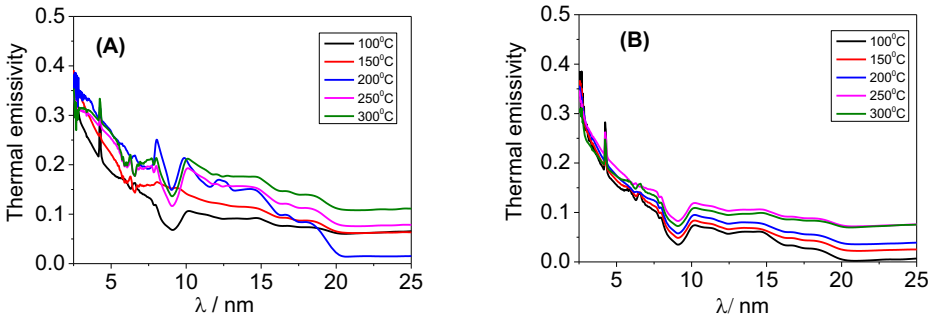

Figure 6. (A) Thermal emissivity spectra of single absorber layer (Cr-Fe-Ni nanocomposite oxide layer) and (B) Two layer tandem absorber layer (Cr-Fe-Ni nanocomposite oxide layer/ ZrO_2-SiO_2 sol-gel layer) developed on SS-316 polished surface measured at different temperatures.

Table 1. Thermal emissivity data of single absorber layer (Cr-Fe-Ni nanocomposite oxide layer) and two layer tandem absorber layer (Cr-Fe-Ni nanocomposite oxide layer/ ZrO_2-SiO_2 sol-gel layer) measured at different temperatures.

Temperature (^{0}C)	ε (2.5-25μm)	
	Single	Tandem
100	0.106	0.067
150	0.127	0.079
200	0.138	0.090
250	0.150	0.116
300	0.172	0.144

3.7. Optical thickness and refractive index results of nanocomposite oxide absorber and optical enhancing layers

The thickness and refractive index of Cr-Fe-Ni nanocomposite absorber and ZrO_2-SiO_2 based optical enhancing layer (antireflective along with corrosion protection) developed by the optimum conditions were estimated by ellipsometer are represented in Table. 2. The experimental data has been fitted with theoretically simulated spectra using a suitable mathematical model for optical constants of the materials. From the fitting, the thicknesses of the layers and the optical constants of the materials have been determined similar as our earlier work (Sakthivel and Srinivasa rao, 2015). The deposited absorber layer (Cr-Fe-Ni nanocomposite oxides) and optical enhancing layer (ZrO_2-SiO_2) layers were modelled using the Cauchy dispersion model for generating the refractive indices and extinction coefficients spectra. The thickness and refractive index values of the absorber layer are around 140 ± 5nm and 1.88 ± 0.01and optical enhancing layer 70 ± 5nm and 1.70 ± 0.01, respectively. High optical properties of high solar absorptance, >94 ±0.1% and low emittance,

<0.15±0.01 were observed only for the optimum thickness of the absorber and optical enhancing layer. The absorber layers generated at the thickness of < or > 140 ± 5 nm with optical enhancing layer (ZrO_2-SiO_2) at the thickness of 70 ± 5 nm the optical properties of either absorptance or emittance were not observed in a satisfactory level. Moreover, the thickness of the absorber layer was found to increase from 140 ± 5nm to 300 nm with increase in the net deposited oxide content on the substrate due to increase of process duration from 20 to 30 min. The refractive index value was also found to increase from 1.88 to 2.41 due to increase of oxide content.

Table 2. Summarises the optical property, thickness and refractive index data of composite oxide and Tandem absorber layers

Sample	α	$\varepsilon_{300\,^0C}$	Thickness (nm)	Refractive index
Cr-Fe-Mn composite absorber layer	86.28	0.172	140	1.88
Cr-Fe-Mn /ZrO_2 -SiO_2 Tandem absorber layer	94.30	0.144	140/70	1.88/1.7

3.8. Corrosion stability of nanocomposite oxide absorber layer and Tandem absorber system

To understand the corrosion and thermal resistance behaviour of both single and tandem absorber system, the coatings were subjected to a salt pray test for proving the corrosion and weather stability in a salt pray chamber following the *ASTM method (ASTM 13117)* using 5 % NaCl solution and generating vapours at a temperature of 35 °C /min. After every cycle test (24 hours) the coating was inspected for the change in properties of solar absorptance and thermal emissivity at a maximum temperature, 300 °C by UV-Vis-NIR and FT-IR spectrophotometer with thermal emissivity accessories of high pressure cell and black body furnace. According to the salt spray experiments, the tandem absorber layer was found to have no changes in its absorptance and emittance properties even after 20 days salt spray test. However, the sample deposited with the nanocomposite layer only could withstand the salt spray test for a maximum of 10 days.

Table. 3: Changes of solar absorptance and thermal emittance measured at 300^{0}C of single and Tandem absorber system developed on SS-316 polished surface.

Duration (day)	Abs (α)		$\varepsilon_{300\,^0C}$	
	Single	Tandem	Single	Tandem
	86.21	94.41	0.172	0.146
1	86.13	94.29	0.173	0.143
2	86.91	94.37	0.172	0.146
5	86.03	94.22	0.175	0.141
10	86.13	94.30	0.176	0.144
15	84.16	94.35	0.220	0.143
20	81.57	94.19	0.231	0.145

3.9. Thermal stability

An important requirement for absorber coatings is long-term thermal stability, ideally in air. Thermal stability is sometimes based on thermal properties of the individual materials or the processing temperature parameters. Since thermal instabilities and degradation of the solar absorber layers are major parameters of interest for long-term stability of the selective solar absorbers, the stability of the single and tandem absorber layer developed on the polished surface (SS 316) was tested under a thermal cycle test (maximum up to 300 °C) suitable for medium ORC based solar collectors usually operating at the temperature range from 200 °C-250 °C. To determine the durability and thermal stability of the coatings a precise temperature controllable furnace (Nabertherm model L 5/12/P330**)** in an open air environment and was utilized for this

study. It has digital PID-temperature control and temperature programme with 40 segments to allow the operator to run the furnace with a specific heating rate, soaking and cooling hours. To evaluate the thermal stability, the samples were annealed in air at 300 °C and for a maximum of 100 cycles. Each cycle comprised of 2h heating to attain 300 °C, 2h soaking duration, and 5-6h cooling to reach the ambient temperature. The dependence of optical properties of the coatings on the thermal treatment was investigated. The solar absorptance and thermal emittance at 300 ^{0}C were measured using a UV–Vis–IR and FT-IR-Spectrophotometer and the detailed measurement procedures have been reported elsewhere [Sakthivel et al]. According to the experiments, both the single and tandem absorber layer was found to have no remarkable changes in their absorptance and emittance properties even after 100 cycles. However, after 350 °C the coatings started to degrade, >10 % of absorptance changes were observed even after 10 cycles and no changes in thermal emissivity property.

Table 4. The effect of annealing at 300 ^{0}C in air, on the solar absorptance and thermal emittance measured at 300 ^{0}C single and Tandem absorber system developed on SS-316 polished surface.

Cycle	α_{sol}		$\varepsilon_{300^\circ C}$	
	Single	Tandem	Single	Tandem
0	86.29	94.32	0.170	0.143
10	86.32	94.56	0.172	0.144
20	86.41	94.18	0.171	0.145
30	86.24	94.53	0.169	0.141
40	86.46	94.48	0.172	0.144
50	86.42	94.41	0.173	0.145

4. Conclusion

A novel tandem layer design of Cr-Fe-Ni oxides/ZrO_2-SiO_2 composite oxide selective absorber layer developed on an austenitic stainless steel (SS-321) substrate has proved to show have excellent optical properties (α_{sol}:94.3 %; $\varepsilon_{300\,^\circ C}$; 0.144) along with high corrosion resistance (>400 h withstand in salt spray test) and good thermal stability in an open air atmosphere. This novel design will thus allow an increase in the operating temperature in the solar field up to 300 ^{o}C, leading to improved performance and reduced cost of ORC based solar thermal power generation.

Abstract

For Brazil, it is important to realize a high national production share because of high import fees and to obtain cost reduction related to implementation of the CSP technology. The rim drive concept offers an alternative for expensive heliostat drive solutions with slew and linear drives from abroad. Sandwich facets (which are usually foreseen for rim drive heliostats) are not available from Brazilian manufacturers and are replaced by a steel frame work structure with mounted 4 mm glass mirrors. The mirrors were bent along one axis. A two-axis curvature, while being optically more precise, would result in excessive stress of the mirrors when short focal lengths (present case: 30 m) have to be attained. For an 8 m² heliostat, the mirror panel was divided into six stripes. The stripes have to be canted to reach a sufficiently small focal spot. A prototype heliostat was designed and built. High stiffness and sufficient durability of the mirror facets against wind loads was reached. For the considered heliostat area of 8 m², the proposed framework design could be further simplified, but for 16m² heliostats (or bigger) it seems to be adequate. A heliostat with high local production share can be accomplished using the rim drive concept. High stiffness can be reached also without sandwich facet mirrors by using a framework mirror support structure with one rim as part of it. Short focal lengths can be achieved by dividing the mirror into several stripes bent in one single axis. The components described increases the feasibility of be manufactured in Brazil and makes possible to avoid increments in CSP plant costs related to import fees.

1. Introduction

Due to the great demand for renewable energy sources for electricity and heat generation, different technologies have been made available with increasingly affordable and competitive market costs. Concentrated Solar Power (CSP) technology uses direct solar radiation concentrated to generate heat onto a small area for producing electricity. The main concentrator types of CSP plants are the cylindrical-parabolic troughs concentrators, linear Fresnel concentrators, parabolic dish concentrators (also known as dish/engine systems) and heliostat fields, redirecting sunlight to a stationary receiver (power tower). The first type uses mirrors in the form of parabolic troughs. The absorber positioned at the focal line of the collector is usually a metal tube coated with a layer of selective paint and encased by a second glass tube which should be evacuated to avoid losses by convection. The second type, based on Fresnel technology, uses rotatable linear reflectors to concentrate the radiation on a fixed linear tube absorber. The third type consists of parabolic dishes which are reflectors of paraboloid shape usually with a Stirling engine and a generator located at each focal point. Finally, in the fourth type of technology, up to thousands of mirrors are used to concentrate sunlight on a fixed central receiver (Corgozinho et al., 2014). CSP technologies represent a good alternative to conventional sources for heat and electricity production in Brazil (EPE, 2012). Brazil is a country with high solar resource in significant areas of

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2015.04.12 Available at http://proceedings.ises.org

the country. On the other hand, with the presence of a strong industrial and agro-industrial sector entails a high demand of electricity, which is predominantly generated by hydroelectric plants. Increasingly often, due to lack of water, these plants cannot cover the demand during the dry season. The overall goal of the CEISA (Heliothermic Energy Studies (CSP): Educational Consortium for the Integration and Sustainability in the Agro-industry) project was to foster the international cooperation in the area of CSP generation. The project serves as a foundation for the research in the field of sustainable energy generation using the CSP technology and its applications within the agricultural sector in Brazil, where a process heat with a temperature of over 300 °C is needed. Within this project, a heliostat for Brazilian applications was developed with specifications according to the SMILE (Solar-hybrid Microturbine Systems for Cogeneration in Agroindustrial Electricity and Heat Production) project. SMILE is a national R&D project that aim to build two 100 kWel solar/biofuel hybrid thermal power tower plants in Brazil for generate electricity and co-generation of heat by integration with two agro-industrial applications (a dairy factory and a slaughterhouse in Caiçara do Rio do Vento, RN, and in Pirassununga, SP, respectively). The project is being financed by BNDES and industrial partners, coordinated by GREEN/USP (Research Group on Recycling, Energy Efficiency and Numerical Simulation/University of São Paulo), and implemented in partnership with DLR (German Aerospace Center) and Solar Institute Jülich – FH Aachen University of Applied Sciences. Due to the astigmatism effect and the relatively small power range smaller heliostats are expected to result in a better overall efficiency of the system. A small panel size of 8 m² (3.21 m x 2.5 m) was determined as optimal size, from both technical and transportation point of view. The HFLCAL software was used to determine the optimum number and positioning of the heliostats for the two plants. Based on these results, an optimum focal length of 30 m was calculated. Because of very high import tax rates, the use of domestic components and materials presents significant economic advantages. An already existing Brazilian heliostat design (Fig. 1) was considered too expensive, due to its reliance on imported drives, as well as the insufficient stiffness of its mechanical components. The aim of the present work is to find a design which allows for a high local production content and which has a sufficiently rigid structure.

Fig. 1: Drives of a first heliostat design with comparably expensive drives from abroad and too flexible mirror support structure (mirror not complete).

2. Approaches for high local content

2.1 Rim drives

From a broad variety of heliostat concepts (Coventry and Pye, 2014) (Pfahl, 2014) the rim drive concept (Pfahl et al., 2013) was individuated because of its avoidance of excessively expensive high precision drives, which would require to be imported. An illustration of a heliostat with horizontal primary axis and rim drives is given by Fig. 2. The 1st (red) rim can be supported by a guidance bar with rolls to increase stiffness. The 2nd rim (blue)

is fixed to the mirror panel. The drive for the primary axis is mounted at the pylon, the drive for the secondary axis on the first rim. The gears may be realized by chains with bevel wheels (which have low backlash when pre-tensioned) or by winch wheels (which eliminate backlash). Both rims are locked during stow to relieve the drives and cables or chains under storm conditions.

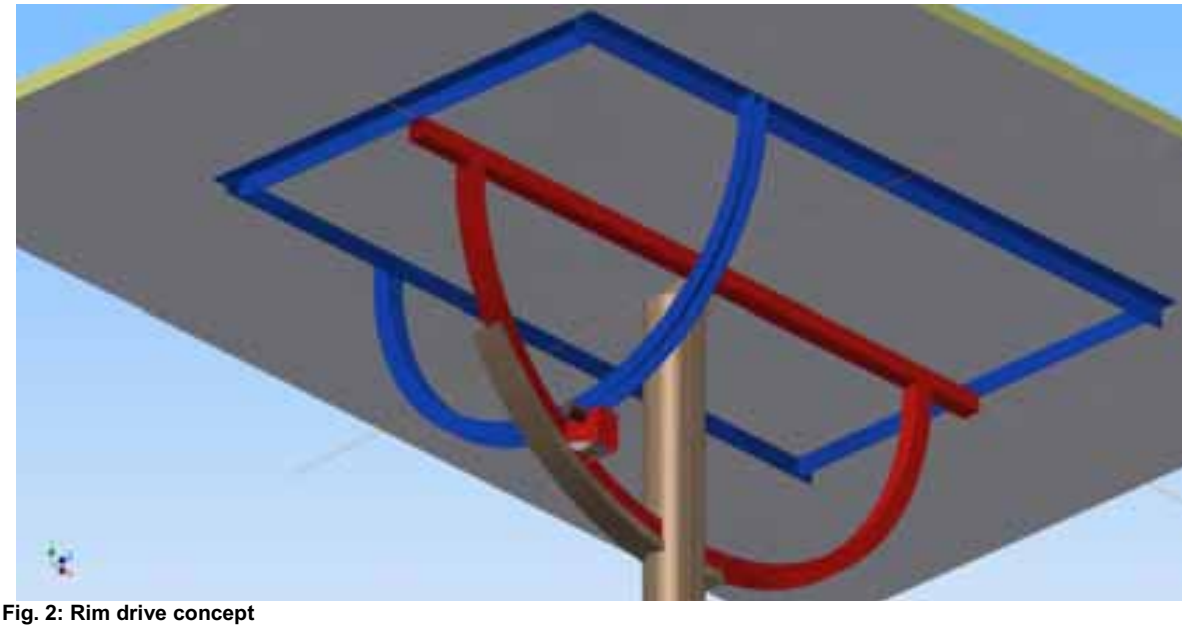

Fig. 2: Rim drive concept

The main advantages of the rim drive concept are: 1) small loads on the drives, 2) the backlash of the drives can be relatively high because of the long lever arm (distance between drives and centre of rotation) realized by the rims, which enables the usage of low cost drives (Fig. 3), 3) reduced loads on bearings, mirror panel, upper part of pylon and stow-position-locking devices during stow. On the other hand additional parts (rims, guidance bar for first rim, and stow-position-locking devices) are required. However, local manufacture of those is possible.

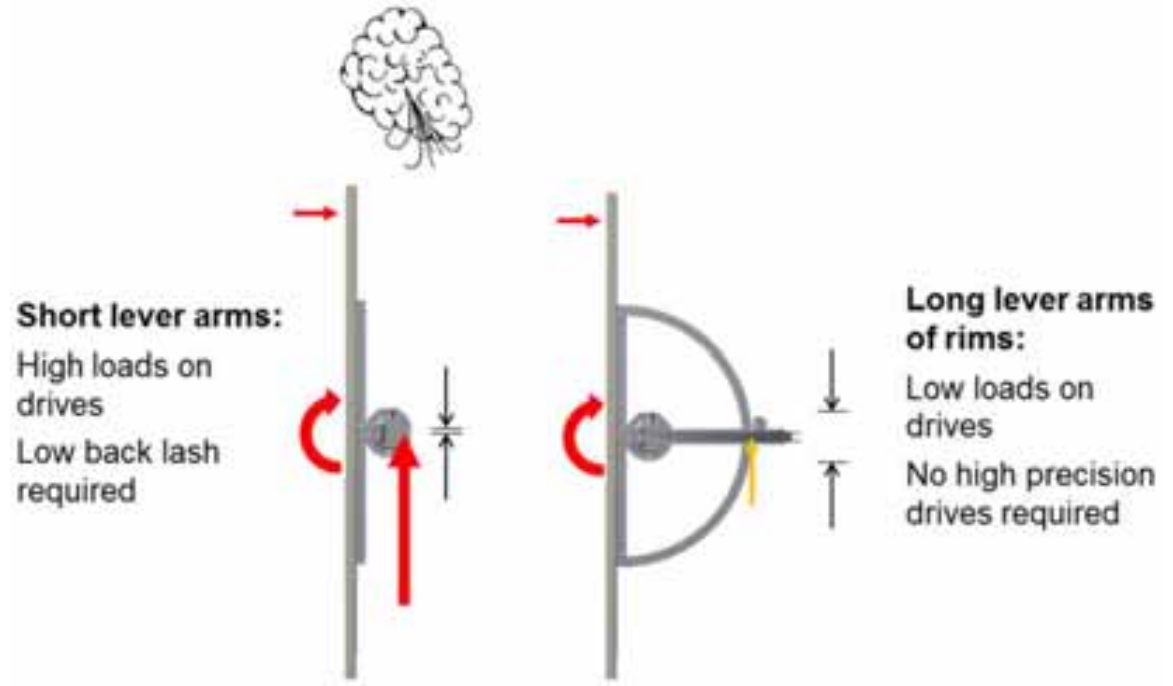

Fig. 3: Reduced requirements on drives due to longer lever arms realized by rims.

2.2 Framework mirror support structure

The first rim drive heliostat was built with sandwich panel (Fig. 4) (Pfahl et al., 2015). However, sandwich panels are not available in Brazil yet and thus their use would result in high transport cost and import taxes.

Fig. 4: First rim drive heliostat with sandwich mirror panel

Therefore, a framework mirror-support-structure with 4mm mirrors was chosen as an alternative for the sandwich facets. At this design the 2nd rim is integrated in the frame work (Fig. 5).

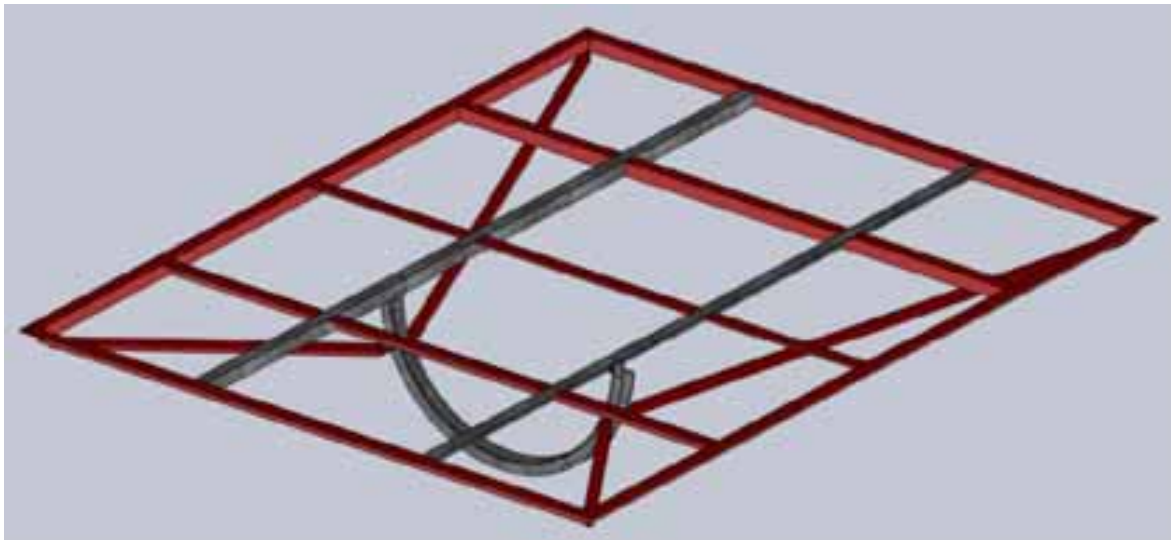

Fig. 5: Framework design of mirror support structure

2.3 One-dimensionally bent mirror stripes

For the solar power plants of the SMILE project, a relatively short focal length of only 30 m is required, resulting in a comparably small curvature radius of 60 m for the mirrors. To avoid excessive mechanical stress, the mirrors are bent only in one dimension. To achieve the required small focal spot of the reflected rays on the receiver the mirror is divided into six stripes of 2.5 m x 0.54 m x 4 mm. These mirror facets are canted to each other to achieve a step-wise approximation of a parabolic shape.

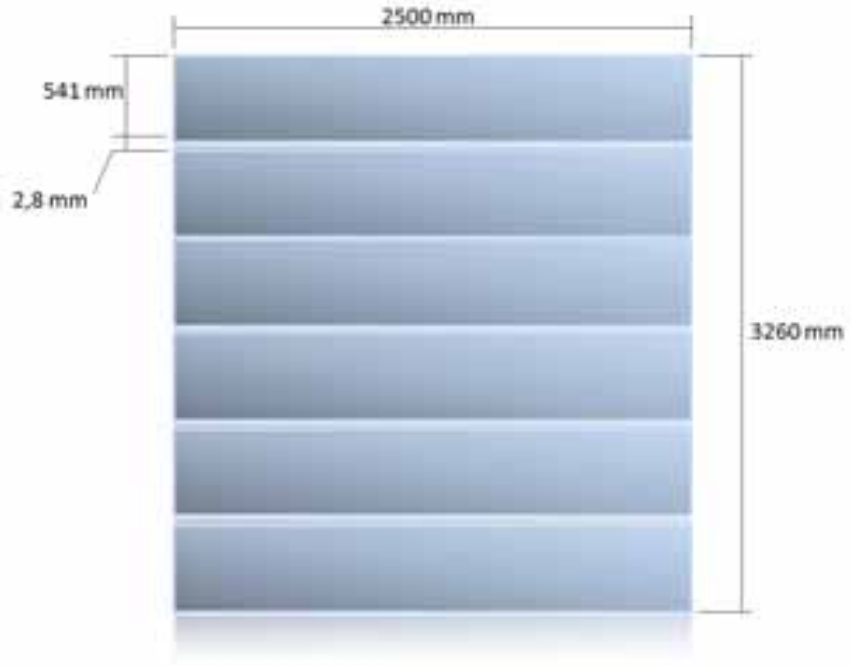

Fig. 6: Dividing of mirror surface into six stripes of only one dimensional bending.

Because of the small width of only 0.54 m thermal expansion is not critical in that direction. Hence, thermal expansion has to be accounted for only in the direction of the facet's length. This simplifies the connections of the mirrors with the steel frame which are realized by simple metal sheets bent to form "L" profiles. The metal sheet is flexible and allows for the compensation of thermal expansion differences between the steel frame and the mirror facets (Fig. 7). The "L"-shaped metal sheet can be adapted to the mirror curvature by choosing the angle α and by rotating it around the axis of the upper mounting screw. The defined geometry requires low amount of steel and simple handling during installation and further, it is an alternative with the ability to move even after installed on frame. The mirror stripes were switched on the metal sheet by double-faced scotch tape manufactured by 3M company, resistant to wind force and weather.

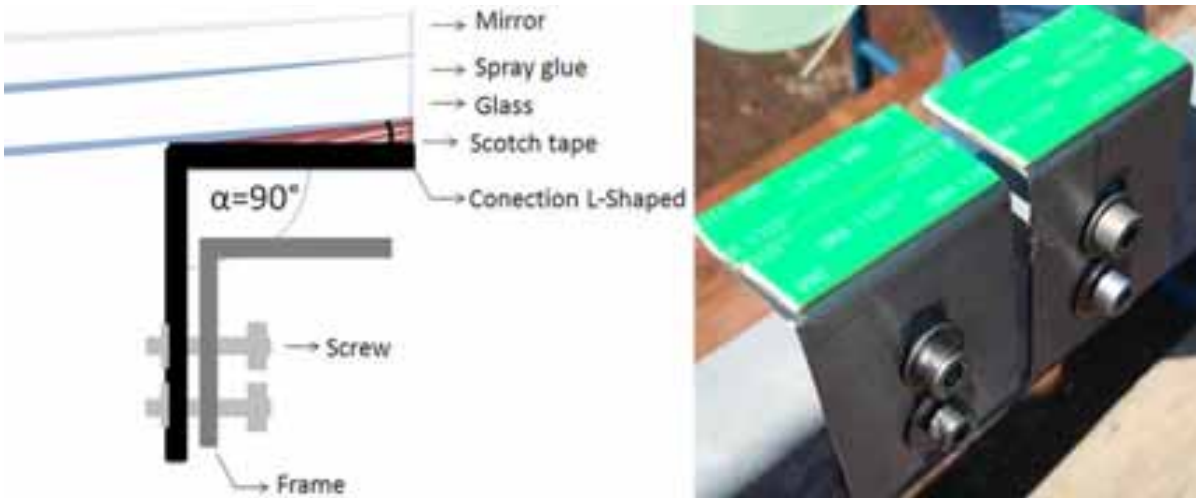

Fig. 7: "L"-shaped metal sheets as flexible connection between steel frame and mirror stripes.

3. Dimensioning

By FEM-analyses (Finite Elements Method), stress and deformation of the metal structure was computed. Maximum wind loads were determined according to (Pfahl et al., 2011b). The shape of the pressure distribution was known from full scale measurements (Pfahl et al., 2014). The maximum stress of 60 MPa is far below the acceptable value of structural steel (Fig. 8).

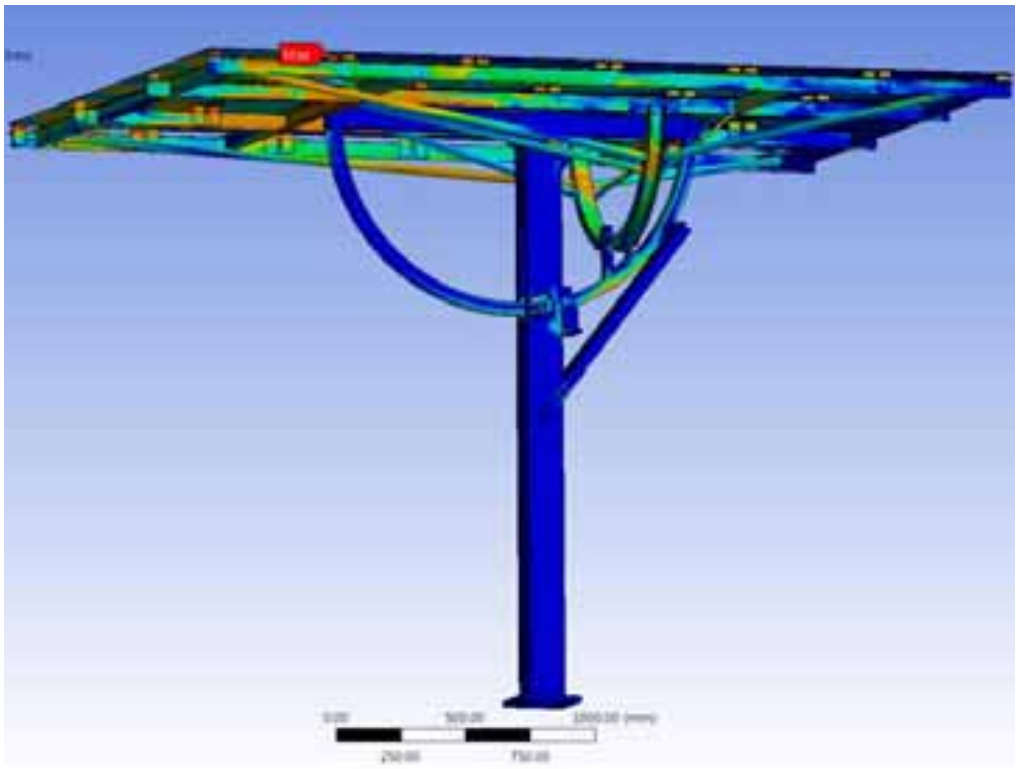

Fig. 8: FEM simulation of stress of the heliostat structure at storm conditions.

The stress of the mirror facets was calculated separately. It was concluded that four connecting points would lead to excessive stress (Fig. 9) (Von Reeken et al., 2011). Therefore, the amount of connecting elements per facet was increased to twelve.

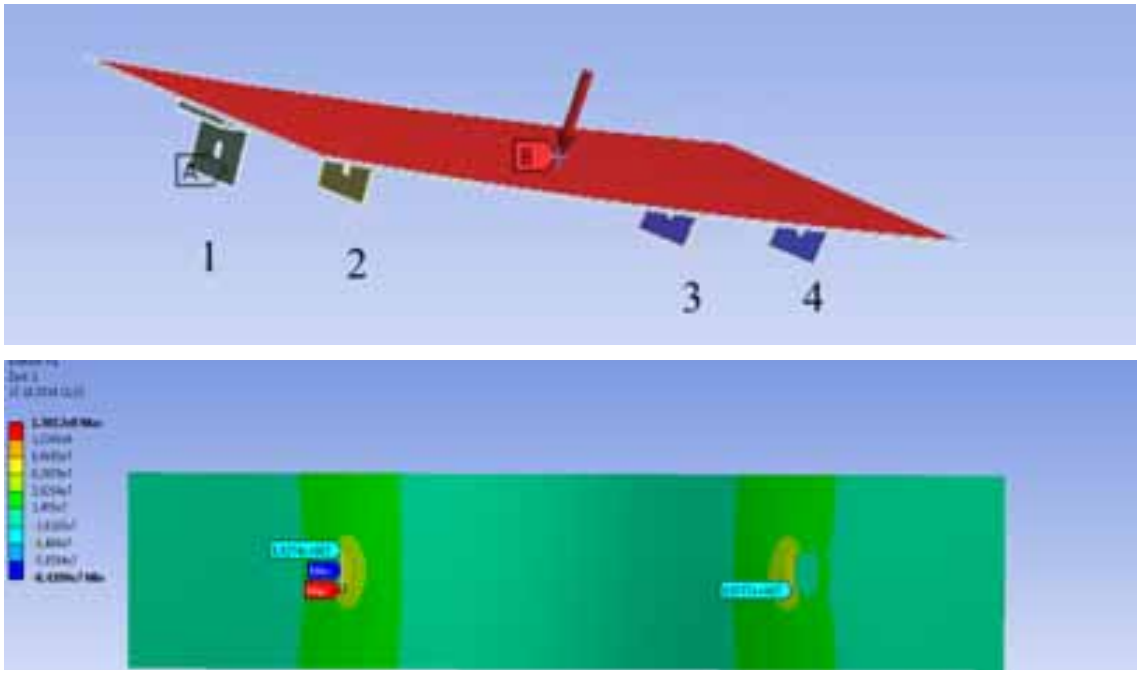

Fig. 9: FEM calculations of stress of mirror panel.

4. Improvements of prototype

4.1 Stiffness

A rim drive heliostat prototype with frame work mirror support structure of 8 m² was realized (Fig. 10). The mirror support structure was observed to be excessively flexible regarding bending about its diagonals, leading to deformation of the 2nd rim.

Fig. 10: First frame work mirror support structure with too high flexibility regarding bending about its diagonals.

Therefore, additional bars were included to avoid this deformation. Additionally, diagonal bars across the whole panel were added (Fig. 11). By these measures a sufficient stiffness was reached.

Fig. 11: Frame work mirror support structure with diagonal bars across the panel and bars for fixing of the 2nd rim for high stiffness.

Furthermore, for upright panel positioning, excessive flexibility of the vertical axis, entailing deformations of the 1st rim were observed. Therefore, the "U"-profile of the 1st rim was closed (Fig. 12) to mitigate this issue and improving the overall stiffness of the system.

Fig. 12: "U"-profile of 1st rim (left); closed profile of 1st rim (right) for increased stiffness.

4.2 Mirror support

The results of the FEM calculation of the mirror facets were validated by mechanical tests. The mirrors are connected to four bars of the steel frame. It was investigated whether only one connection per bar (and four connections per facet) would lead to excessive stress, as predicted by the FEM computations. For this, a glass stripe of 2.5m x 0.54m x 4mm was connected to the steel frame by twelve "L"-shaped metal sheets. The maximum hinge moment in stow position was determined according to Pfahl et al., (2011a). For the stow position, the peak hinge moment results from instantaneously increased pressure on the wind facing edge of the mirror panel. The pressure increase is caused by eddies hitting the mirror panel at the edge (Pfahl et al., 2011b). This was simulated by loading the glass stripe mounted at the edge of the panel by sand. The weight which would lead to the peak hinge moment was calculated. Indeed, the glass broke before the calculated required maximum weight was reached (Fig. 13). Hence, only four central mirror mounting devices would not be sufficient to withstand the expected storm wind loads.

Fig. 13: Breakage of 4mm glass stripe before reaching of maximum expected load.

In a successive step, the amount of mirror connections was doubled. Each glass stripe was connected to the four bars with two "L"-shaped metal sheets for each bar located at the edges of the glass stripe. With the eight mirror connections the glass stripe could be loaded with the full amount of sand simulating the maximum wind load (Fig. 14).

Fig. 14: Glass stripe of 4mm thickness loaded with sand simulating the maximum expected wind loads.

The established methodology for assembling the mirror facets was the best sequence found from the viewpoint of practicality reduced risk of damage. First, the "L"-shaped metal sheets were positioned coplanar to the metal frame (Fig. 15). The stripe composed by glass and mirrors showed sufficient stiffness to withstand the tension on the external connectors, while being flexible enough to provide the height of curvature.

Fig. 15: Assembling of the stripes using L-shaped metal sheet.

5. Conclusions

A heliostat with high local production share can be accomplished using the rim drive concept. High stiffness can be achieved also without sandwich facet mirrors by using a framework mirror support structure with one rim as part of it. Short focal lengths can be reached by dividing the mirror into several stripes bent in one single axis. For 8 m² heliostats the framework structure appears to be extensive. For bigger heliostats (16m² or 32m²) an accordant framework structure could be used and seems to be adequate. For 8 m² heliostats the framework structure should be simplified by using closed profiles for the basic frame which would allow to reduce the amount of bars of the framework. The components described increases the feasibility of be manufactured in Brazil and makes possible to avoid increments in CSP plant costs related to import fees.

Abstract

To achieve the 20-20-20 targets in 2020 and the European objectives in the longer term, it is imperative to drastically reduce greenhouse gas emissions from the residential building sector. In this context, the development of Positive Energy Buildings (PEB) is promising. This work compares the annual performance of two competing systems. First, a conventional solution, consisting of a passive house coupled with a water to water heat pump and photovoltaic panels (HP/PV). On the other hand, a passive house with a solar thermal roof combined with a reversible heat pump unit / organic Rankine cycle (HP/ORC). Both systems are designed for a maximum net electrical output of 5.29 kW. Dynamic simulations are performed using the Dymola software. The net annual electrical production (considering electricity consumed to fulfil the thermal load of the building) is 667 kWh for the reversible HP/ORC system and 3835 kWh for the HP/PV system in the basic Danish study case. Following that, a study of influence with different climates is performed and some guidelines are deduced to select optimum study cases where the HP/ORC system could become more competitive than the HP/PV classical solution.

Keywords: *Reversible heat pump/organic Rankine cycle unit, Photovoltaics panels, Positive Energy Building, annual simulation, economic analysis.*

1. Introduction

Positive Energy Buildings have been increasingly investigated recently. Moreover, from 2019, all new buildings will have to produce from renewable energy has much as they consume on an annual basis (European parliament, 2010). The objective of this paper is to assess an innovative technology to obtain a positive energy building and compare it with a conventional HP/PV solution. The innovative technology solution consists in coupling a reversible heat pump/organic Rankine cycle unit (HP/ORC) with a passive building, a solar roof and a horizontal ground heat exchanger (Quoilin et al, 2015). This system is flexible because of the reversibility of the heat pump (HP) which can also run in organic Rankine cycle mode (ORC) to generate electricity (Fig. 2). There are, in fact, three possible modes of operation. First, the heat pump mode can cover the thermal demand of the house (includes domestic hot water - DHW - and floor heating - FH) when weather conditions are unfavourable, for example in winter. But, when the sunlight is sufficient, the heat produced by the solar roof is directly used to charge the storage to supply DHW and FH (direct heating mode - DH). Finally, when the storage is fully charged, the excess heat produced by the solar roof generates electricity through the ORC cycle. The HP/ORC reversible system has been studied for the first time in 2011 (Schimpf et al, 2011). This study showed the economic benefits in the particular case of a house with geothermal borehole and a solar collector of modest size (12 m^2). Thereafter, the passive house concept coupled with a solar roof large (138.8 m^2) and coupled with a horizontal ground heat exchanger (300 m long) was patented by the company Innogie (Innogie, 2013). Following this, an optimal design (Quoilin et al, 2015), followed by an experimental campaign (Dumont et al, 2015) have demonstrated the feasibility of the system. The nominal power generation ORC mode is equal to 5.29 kW with an efficiency of 7%, while the HP mode presents a thermal power condenser of 13 kW with a nominal coefficient of performance (COP) of 4.2.

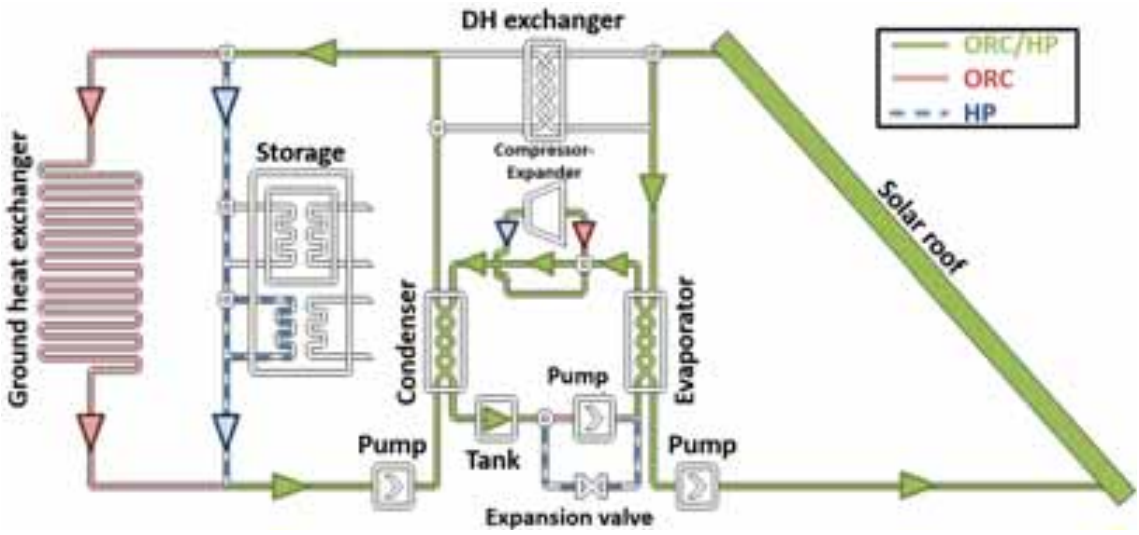

Fig. 1: Scheme of the global system showing the three operating modes (organic Rankine Cycle (ORC), heat pump (HP) and direct heating (DH))

2. Description of the model

The model is simulated with Dymola/modelica software coupled with Thermocycle (Quoilin et al, 2014) libraries and CoolProp (CoolProp, 2015). The global model with the passive house, the reversible HP/ORC unit, the solar roof, the horizontal ground heat exchanger and the thermal heat storage has been extensively described in a former paper (Dumont et al, 2014). This section briefly summarizes each sub-model.

2.1 Sub-models

- The reversible HP/ORC unit is modelled trough validated semi-empirical models based on experimentation (Dumont et al, 2015).
- The storage model (Heat Storage Water Heater) comes from the Thermocycle library (Quoilin et al, 2014).
- The solar roof is modelled with Klein's equation (Klein, 1975).
- The house model consider 5 zones based on the real Danish house. Solar gains, air infiltration, occupancy behaviour in terms of internal gain and domestic hot water consumption are taken into account.

More details are provided for each sub-model of the reversible HP/ORC system coupled with the passive house in (Dumont et al, 2014).

The performance of this system is compared with a mature system to get a Positive Energy Building (PEB), a water to water heat pump coupled with PV panels (HP/PV). The PV panels are modelled based on a detailed model (De Soto et al, 2006). The area of the PV panels is determined in a way to get the same peak electrical production in summer nominal conditions (5290 W for 44 m^2). The heat pump, the building model, the occupant behaviour are all fixed in the same way as for the reversible HP/ORC unit.

2.2 Global model

The inputs of the global model are the meteorological data (in terms of outdoor temperature and direct normal radiation) and occupant behaviour in terms of electrical consumption, internal gains and domestic hot water consumption. The control strategy to select the operating mode is based on the following idea: Insuring the thermal comfort inside the building while maximizing the net electrical production.

3. Results

Results from typical days of the year with mode changes are detailed in a former paper (Dumont et al, 2014). This section aims at evaluating the annual performance of the system.

3.1. *Performance criterions*

- Gross electrical production [kWh]: annual electrical production of the ORC (or of the PV panels in the case of the HP/PV).
- Net electrical production [kWh]: annual electrical production of the ORC (or of the PV panels in the case of the HP/PV) minus the heat pump consumption and the non-HVAC consumption.
- Running benefits [€], evaluated following Danish electricity market (Eq. 1). C_r is the retail price of electricity on the grid [€/kWh], $C_{r,HP}$ is the retail price for heat pump systems [€/kWh] and C_{bb} is the buy-back tarif of electricity to the grid [€/kWh]. C_x is equal to C_{bb} if electrical production is higher than the electrical consumption (non-HVAC) and equal to C_r in the opposite case. kW_{ORC} is the ORC electrical power [kW], $kW_{cons,l-a}$ is the electrical consumption (non-HVAC) et kW_{HP} is the heat pump power consumption. Tariffs are provided from real data (Energinet, 2015).

$$B = \int_0^t \left(C_x\,(kW_{ORC} - kW_{cons,l-a}) - C_{r,HP}.kW_{HP}\right).dt \qquad \text{(eq. 1)}$$

- Self-production rate (γ_S), which is the fraction of the gross production consumed directly in the building (eq. 2).

$$\gamma_S = \frac{\sum \min\,(W_{cons.},W_{prod})}{\sum W_{prod}} \qquad \text{(eq. 2)}$$

- Self-consumption rate (γ_d), which is the fraction of building electrical consumption produced by the gross electrical production (eq. 3).

$$\gamma_D = \frac{\sum \min\,(W_{cons.},W_{prod})}{\sum W_{cons.}} \qquad \text{(eq. 3)}$$

3.2. Basic case

The annual performance comparison is performed between the HP/ORC system and the HP/PV system in the case of the real house located in Denmark (500 litres storage and 1491 kWh of lightning and appliances electrical consumption) in Tab. 1. First, the heat pump electrical consumption is 45% higher in the case of the HP/PV because this system does not benefit from the thermal heat furnished by the direct heating mode (1394 kWh). Also, the gross electrical production is lower in the case of the HP/ORC system. This is explained by the rather constant efficiency of the PV panels while the ORC efficiency (and solar roof efficiency) are very largely affected by part load conditions (low solar irradiation, low outdoor temperature).

Tab. 1: Comparison of the annual performance between the reversible heat pump/organic Rankine cycle unit (HP/ORC) and the PV panels coupled with the heat pump (PV/HP)

System	HP/ORC	HP/PV
Non HVAC electrical consumption [kWh]	1491	
Heat pump consumption [kWh]	812	1185
Gross electrical production [kWh]	2970	6511
Net electrical production [kWh]	667	3835
Thermal load (domestic hot water & floor heating) [kWh]	4403	
Thermal energy provided by direct heating [kWh]	1394	0
Running benefits [€]	-78	494
Self-production rate [-]	8.9	9.1
Self-consumption rate [-]	9.2	39

Following this, it is logical that the net electrical production and the running benefits are higher in the case of the HP/PV system. Furthermore, the self-consumption and self-production rates are significantly lower in the case of the HP/ORC system. Fig. 2 allows to understand this. The peak electricity demand between 6 p.m. and 7 p.m. is covered by the PV panels while the ORC stop working a little bit before 6 p.m.

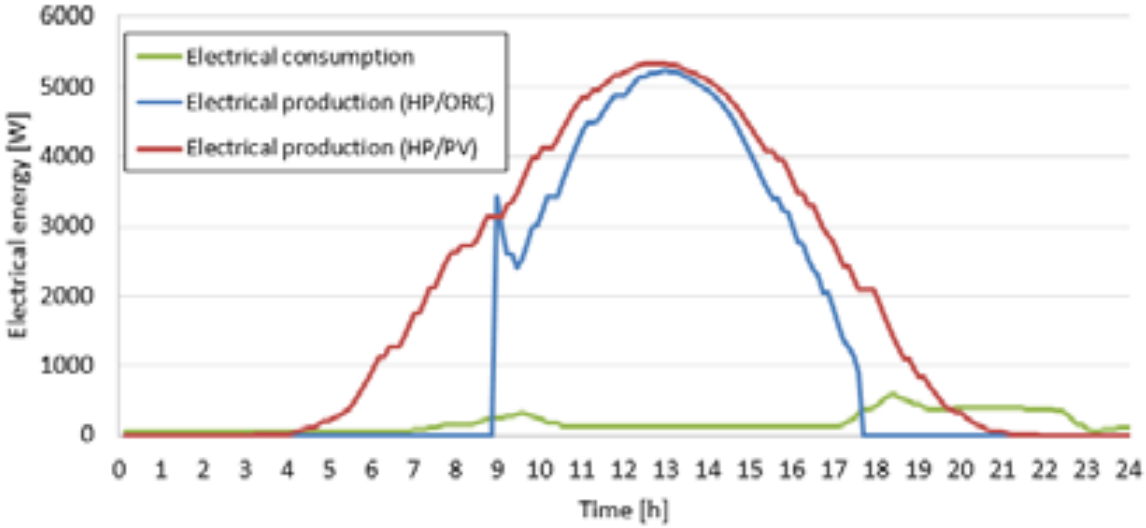

Fig. 2: Hourly electrical production and consumption for a typical summer day

3.3 Influence of the climate

The basic case has shown higher performances for the HP/PV system. It is also interesting to study the influence of the climate regarding the evolution of the performance of both systems. Fig. 3 presents the gross electrical production and the heat pump electrical consumption for 5 typical climate in Europe (from north to south). First, the same conclusion as stated in section 3.2 can be deduced: the heat pump consumption is significantly lower with the HP/ORC system thanks to the direct heating mode. In southernmost locations, the heat pump is not even necessary anymore to fulfil the heat requirements of the buildings for this system. This means that in location close to Roma and Palermo, the use of a reversible heat pump/organic Rankine cycle does not make any sense. Also, the ORC gross production increase more than the PV panels production because the ORC system works more and more often closer to nominal conditions in southernmost locations. The direct heating heat (not shown in Fig. 3) presents a maximum in Torino. This is explained by the fact that if the weather is too cold, the roof is not warm enough to heat the storage but if the weather is too warm, the thermal load is lower.

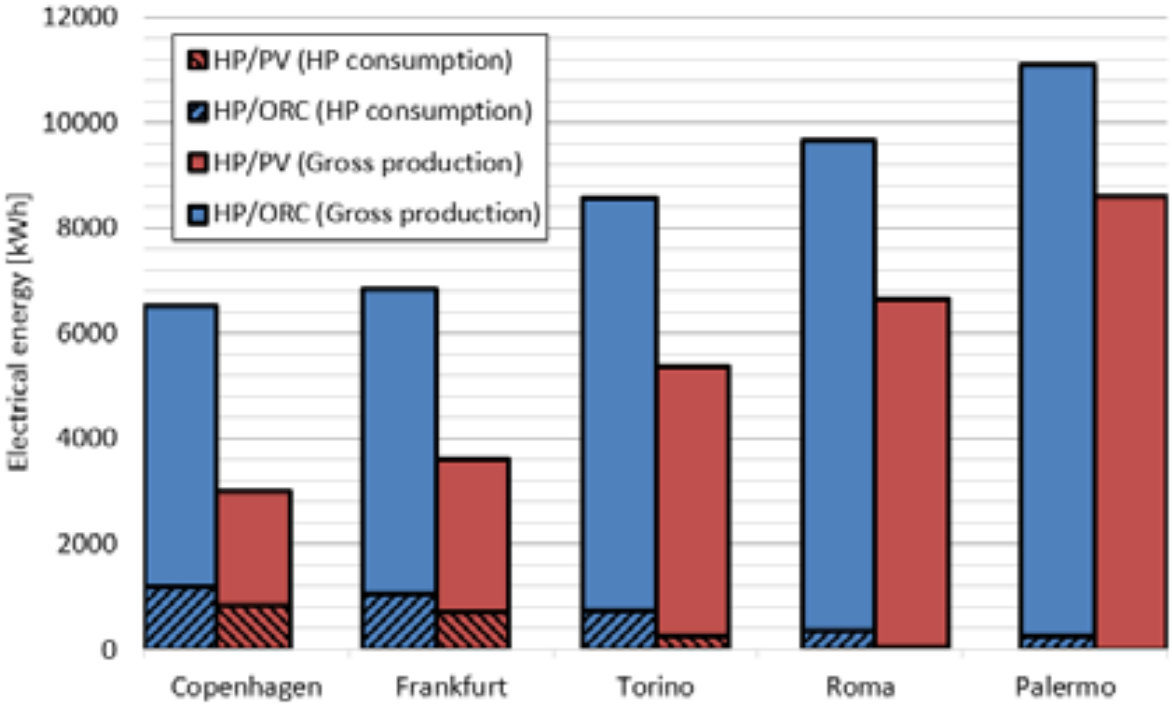

Fig. 3: Comparison of the gross electrical production and the heat pump electrical consumption for both systems (HP/ORC and HP/PV) for 5 typical climates in Europe.

3.3 Analysis of results

Results in the basic case and with five different location have shown that the HP/PV system present better overall performance in terms of net electrical production, running benefits and matching of electricity demand and consumption.

The HP/ORC system presents two advantages. On the one hand, the investment costs are rather low since the cost are very close to a classical heat pump (addition of a pump and a four way valve for the reversibility in ORC mode). On the other hand, the electrical consumption is lower for the HP/ORC system thanks to the heat provided by the roof (Direct Heating). This is a non-negligible advantage of the system since it can reduce electricity consumption during peak of electricity.

This study shows that the HP/ORC system is more efficient in location close to Torino thanks to the direct heating mode. The direct heating mode does not reduce ORC running hour because it works at much lower roof temperatures. Therefore, cases where thermal load are higher could be very interesting and make the HP/ORC system more competitive than the HP/PV system. Some examples with high thermal load could be large buildings, buildings with poor insulation, building with high domestic hot water needs (sports hall, swimming pool…

4. Conclusion

This paper compares two systems that allow getting a Positive Energy Building: a reversible HP/ORC unit and a HP/PV system. A dynamic model is developed and exploited to analyse annual performance. It has been shown that in the basic study case (Denmark), the HP/PV system is more profitable. Following this, a study of influence with five different typical European climates has shown that mid-Europe is an optimal location for the HP/ORC system. But, still, the HP/PV system performs better.

This lead to study more influence parameters. Since the direct heating mode is a significant advantage of the HP/ORC system, this could be exploited in cases where thermal load of the building is higher. This will be studied in future works.

5. Nomenclature

B	Running benefits [€]
DH	Direct Heating
DHW	Domestic hot water
γs	Self-production rate [-]
γd	Self-consumption rate [-]
FH	Floor-heating
HP	Heat Pump
ORC	Organic Rankine Cycle
PV	Photovoltaics panels
HP/ORC	Reversible HP/ORC system
HP/PV	PV panels coupled with a HP

Abstract

A concentrated solar power (CSP) biomass combined heat and power (CHP) system based on organic Rankine cycle (ORC) technology developed in the framework of the EU founded BRICKER project is presented. The CHP system coupled with heat recovery ventilation technology and novel insulation material has the aim of reducing the energy consumption of existing building by up to 50%. A simplified approach to implement a dynamic model of the CHP system is proposed. The model is firstly used to investigate the performances of the CHP system control logic under extreme working condition. Secondly, the effectiveness in ensuring safe working conditions and in maximizing the sun power usage of two different solar field control approaches is investigated simulating the developed model over a reference day.

Keywords: *Hybrid CSP, organic Rankine cycle system, Dynamic modeling*

1. Introduction

Over the past 30 years the electric industry has been characterized by a transition from a vertical production structure towards a horizontal one based on the deployment of intermittent renewable resources (Hinkley et al., 2011). Among renewable energy technologies, concentrated solar power (CSP) systems have been increasingly considered worldwide as a key technology for meeting the renewable energy demand (Resnick Institute, 2012) (Mediavilla et al., 2013). Due to the high capital cost, the total CSP installed capacity is still low, with only 3.6 GW_{el} installed at the end of 2013 (IEA, 2014) . Research activities, with a focus on cost reduction, have been commissioned by leading research institute in Europe and in the US (Pitz-Paal et al., 2007) (Hinkley et al., 2011), and significant reductions are expected especially for the thermal storage (TES) and the heat transfer fluid (HTF) components by the end of this decade. Another approach to achieve competitiveness in the current market consists in hybridization with fossil fuels (Peterseim et al., 2013). Hybridizing these plants has not only the benefit of reducing the cost but it also enables the CSP unit to be dispatchable when the solar source is low. Several plants worldwide have demonstrated the advantages of this solution (Agency, 2014). In recent years, the hybridization of CSP technology with biomass has gained attention and its potential has been investigated by several authors (Peterseim et al., 2014a) (Soria et al., 2015). The concept has been successfully demonstrated since the end of 2012 by the 22 MW_{el} Termosolar Borges plant in Catalonia, Spain (NREL, 2013). This solution allows to move CSP technology towards agricultural area, rich in biomass and waste material, enabling locations with lower levels of direct normal irradiance (DNI) compared to DNI required by CSP standalone systems (Peterseim et al., 2014b). A technical economic assessment of a combined heat and power (CHP) system, using organic Rankine cycle (ORC) technology integrated with a hybrid CSP-biomass heat source, has been recently investigated (Sterrer et al., 2014). The study compares, by means of a transient analysis, the economic profitability of a hybrid CSP system for three different locations in central Europe, concluding that the retrofit of biomass plants with

doi:10.18086/swc.2015.04.14 Available at http://proceedings.ises.org

CSP technology is a promising approach, to improve the economic performances. In this context the EU founded BRICKER project aims to develop a scalable, replicable, high energy efficient, zero emissions and cost effective CSP-Biomass trigeneration system, based on ORC technology, to refurbish existing public-owned non-residential buildings. The CHP unit together with lightweight facades, and phase change material insulation technology, is expected to reduce the building energy consumption by at least 50%. Three systems are being developed in Spain, Belgium and Turkey to demonstrate the concept feasibility. In this contribution, a dynamic model of the CSP-biomass CHP system under development in Cáceres, Spain is presented. The transient model, developed in the Modelica language (Mattson et al., 1997), is simulated under extreme conditions to investigate the capability of the control logic in ensuring safe working operation. During the last years dynamic modeling has been increasingly recognized as a powerful tool to analyze the performance of CSP power system under transient conditions. Casati et al. (2012) developed a dynamic model of a novel ORC power block for a CSP system with a direct thermal storage, in order to investigate the controllability aspect under extreme critical conditions. The performance of a micro CSP-ORC system, over four reference days, has been analyzed by means of a detailed dynamic model by (Ireland et al., 2014). More recently Dickes et al. (2015) investigated model reduction methods for dynamic modeling of the solar field and the thermal storage of a micro CSP power unit, in order to increase the computational effectiveness of the models. In the presented work, a simplified modeling approach of the CSP-Biomass-ORC system is proposed. The proposed modeling approach allows for a robust and efficient model still capable of predicting the main time constants characterizing the overall system. The simulation results are analyzed and discussed and guidelines for the future work are drawn.

2. System description

The EU founded BRICKER project aims at demonstrating that retrofitting existing buildings with passive and active cutting edge technologies can lead to enormous energy savings. The project comprises the installation of a novel CHP unit based on renewable energy sources to meet the thermal and electrical building demand, coupled with heat recovery ventilation system, lightweight facades and innovative insulation material to decrease the building energy consumption. In this work the control logic of the CHP system is presented and its effectiveness is investigated by means of dynamic modeling. The complete layout of the CHP system under development in Cáceres, Spain is reported in Figure 1. The system is composed by two main loops. In the first loop the thermal energy collected by the parabolic trough collectors (SF) and produced by biomass combustion in the boiler (BMB) is transferred by a heat transfer fluid (HTF) to the ORC power block for electricity production and to the second loop via a heat exchanger (HXI). The synthetic thermal oil, TherminolSP, is selected as heat transfer fluid as it is widely used for CSP applications thanks to its low operating pressure, high thermal stability (up to 335°C) and good heat transfer characteristics (Alberti et al., 2012). Starting from the bottom left of Figure 1 it is possible to recognize the solar field, where the HTF is pre-heated from (a) to (b) before entering the biomass system (d), reaching the maximum temperature at the outlet of the boiler (e). The fluid is then pumped through HXI from (f) to (g) and through the ORC power block which are connected in parallel. At the outlet of the ORC unit, the fluid mixes with the stream coming from HXI (h).

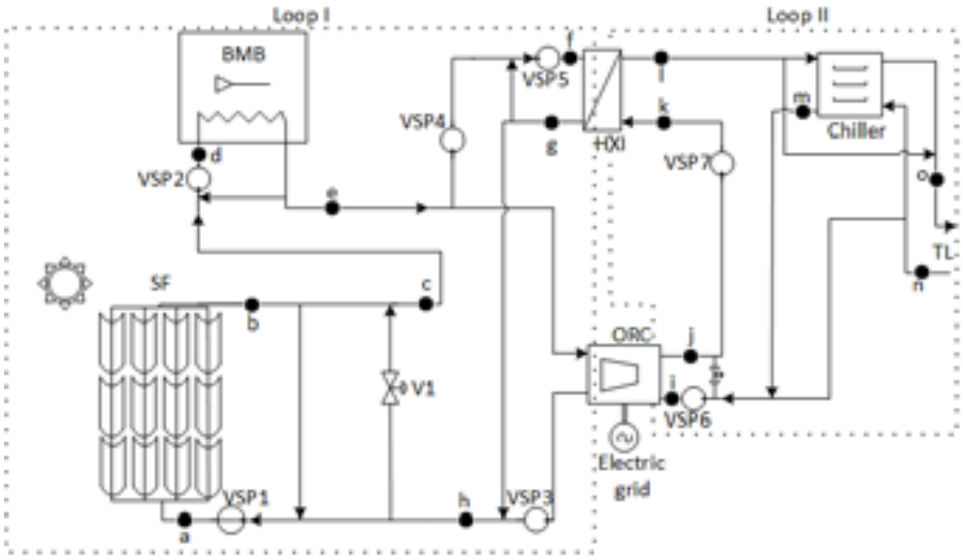

Fig. 1 Schematic flow diagram of the bricker CHP system.

Loop II comprises the adsorption chiller, the ORC condenser cooling side, the secondary side of HXI and the connection to the thermal load of the building. Looking at the right part of Figure 1 the heat transfer fluid is first pre-heated in the ORC condenser from (i) to (j), and then it is pumped through HXI from (k) to (l) where it reaches the maximum temperature of loop II. The fluid is then directed to the Chiller or to the building depending on the thermal demand. A description of the different components is reported in the list below.

- Parabolic trough collectors with evacuated tubular absorber are selected being the most reliable and proven technology in the CSP field (Cabello et al., 2011). In particular the selected collectors are characterized by a maximum temperature of 250°C that perfectly fits the nominal working temperature of the system. A total of 12 collectors are connected in 4 parallel loop of 3 collector each. The solar field dimension results from a compromise between the available area on the demo building roof and on the seasonal thermal demand. The solar field works as a pre-heater for the biomass boiler, reducing the amount of biomass burnt during the day. Each solar collector is characterized by a net collecting surface of 54 m^2.

- The biomass boiler covers a fundamental role in the system as it provides together with the solar field the thermal power required by the ORC unit and by HX1. If there is a sudden demand of extra power, a larger amount of biomass is burnt to keep the outlet temperature close to the set point value.

- The thermal energy from the biomass and the solar field is converted into electrical energy by the ORC power block. The ORC unit converts thermal energy into electrical energy based on the same principle of the steam Rankine cycle. The major difference with a traditional Rankine cycle is related to the employed working fluid which is an organic compound. The thermodynamic characteristics of the working fluid make the ORC technology a viable and interesting solution for low temperature power generation compared to a steam Rankine cycle. ORC systems have been proven to be a reliable mature and efficient technology over the years (Angelino et al., 1984) and their application to renewable energy sources for small scale power generation (5-200 kW_{el}) is gaining popularity at a commercial level (Quoilin et al., 2013). The unit installed in the system can be operated in generation or cogeneration mode with an electrical power ranging between 100 and 70 kW_{el} respectively. The electrical power can be sent to the building or the national grid. In cogeneration mode the thermal energy dissipated at the condenser is used by the cooling water for meeting the building thermal demand.

- A heat exchanger is used for thermal energy transfer between loop I and loop II. The brazed plate type is selected as it offers very good heat transfer performance in single phase with an extreme

compact design (Palm and Claesson, 2006). In order to satisfy the cooling demand during the summer season an adsorption chiller machine is included in Loop II. The selected chiller is of the silica gel-water type. This machine can be fed with a thermal input ranging between 60 – 90°C (Wang and Vineyard, 2011).

3. Control Strategy

3.1 Technical boundaries and operational logic

In this section a description of the control logic implemented on the presented system is described and discussed. The technical boundaries of the different components are listed hereunder:

- Solar field: a minimum mass flow rate must be guaranteed in the parabolic through collectors to avoid high film temperature that could deteriorate the thermal oil. An autonomous warning control is provided by the manufacturer. When the outlet temperature of the solar field reaches a certain value, electrical motors are activated defocusing the collectors in order to decrease the temperature. A partial or total defocusing can be selected by the user.
- Biomass boiler: the boiler works in a range between 150 and 500 kW_{el} with the former value representing the shutdown condition. The temperature gradient comprises between 5 K and 30 K. The system operates at a constant mass flow of 9.5 kg/s and is equipped with a recirculation circuit and an internal control which regulates the amount of biomass burnt to keep the temperature at the outlet at a user-defined set point. Power modulation is characterized by time constant between 30 seconds up to 2 minutes. This is mainly related to the kinetics limit of the combustion chemical process and to the air inflow adjustment. A limit of 1 daily start/stop is recommended by the manufacturer but it is preferably to maintain the biomass boiler at a minimum range in order to keep high efficiency, low pollutions and reduced maintenance. The boiler start-up is a slow process that can take up to 50 minute.
- ORC unit: it requires at the evaporator a constant thermal oil mass flow rate of 2.5 kg/s and it is capable of handling heat source temperature deviation in the order of 20 K from the nominal value of 245°C.
- Adsorption chiller: it can handle temperature inlet variation in the order of plus minus 5 K from its nominal value. Proper control of HXI are required in order to respect these boundary limits.

Given the above mentioned technical boundaries, a correct operation of the system depends on finding the right balance between the solar field and the biomass boiler working condition. In particular, high controllability of the solar field is required in order to guarantee safe biomass boiler operation avoiding biomass shut-down. In order to achieve this goal the solar field is equipped with a recirculation and a by-pass stream as shown in Figure 1. A constant mass flow rate equal to the nominal value required by the ORC evaporator of 2.5 kg/s is ensured to the solar field by running pump VSP1 at a fixed speed, avoiding high film temperature issues. A highly responsive control logic is developed by installing a PI controller (PI1) on the by-pass valve V1 to regulate the biomass inlet temperature T_d and by exploiting the solar field internal defocusing mechanism. In nominal condition the mass flow at the outlet of the ORC unit is pre-heated in the solar field and the by-pass valve V1 is closed. If the DNI overcome its nominal value the solar field outlet temperature T_b increases and so does the biomass boiler inlet temperature T_d. The by-pass valve is opened by the PI controller to mitigate the temperature increase at biomass inlet T_d. As VSP1 runs at constant speed, mass flow rate equal to the one flowing through V1 is recirculated from SF outlet to the inlet, further increasing the solar field outlet temperature T_b. A chain mechanism is activated pushing T_b towards the defocusing set-point value. When T_b overpasses the set-point, automatic defocusing occurs, reducing the thermal power delivered by the collector fields and avoiding biomass shut down. On the other hand, sudden decrease of sun power are handled by the biomass internal control (PI2) which increases the biomass fed to the combustion chamber maintaining T_e at its nominal value. In case the heat rejected from the ORC's condenser is not sufficient to satisfy the thermal demand of the building, extra power has to be delivered to the water loop of the system via HXI. The heat exchange rate of HXI is controlled by a recirculation system

with pump VSP4 and VSP5. The latter is kept constant at a fixed speed. As the adsorption chiller works at a constant inlet temperature, $T_{l,}$ to guarantee high COP values, an increase in thermal demand corresponds to an increase in mass flow through HXI. A PI (PI3) controlling the rotational speed of VSP4 is implemented to maintain the temperature, T_l, close to its set-point. In table 1 the controlled and control variables of the three PI characterizing the plant logic are summarized.

Tab 1. : Table summarazing the controlled and control variables of the three PI contrellers of the implemented control logic.

Controller	Controlled variables	Control variables
PI1	Valve V1 aperture	T_d
PI2	Amount of biomass burnt	T_e
PI3	Pump VSP4 rotational speed	T_l

4. Dynamic Modeling

The proposed control strategy presented in section 3 is investigated under transient conditions by means of a dynamic model of the plant. The model is developed using the Modelica object-oriented modeling language (Elmqvist and Mattsson, 1997), and are based on the ThermoCycle library (Quoilin et al., 2014). The thermal oil flowing through loop I of the plant is always in liquid state and it is assumed to behave as an incompressible fluid. It is modeled following the table based approach proposed by the Modelica standard library. Temperature, T, is selected as the fluid model state variable. Density, ρ, and specific heat capacity, c_p, are computed fitting constant n-order polynomials on user-defined table data. Specific enthalpy, h, specific entropy, s, and the other thermodynamic properties are calculated from the integrals and derivatives of the derived polynomials, $\rho(T)$ – $c_p(T)$. As the presented dynamic models can be used for both compressible and incompressible fluids, pressure, p, and specific enthalpy, h, are selected as state variables. The Modelica table based media model uses an internal solver to retrieve the temperature value in order to compute the other thermodynamic properties. In Figure 2 the developed dynamic model of the oil loop (loop I) of the system is shown. This work focuses on investigating the effectiveness of the control logic in the oil loop which is considered the most critical aspect of the system. Perfect ideal control is assumed in the water loop (loop II). The building thermal demand (TL) is modeled by means of a source of mass flow fed to the HXI secondary side. In the following sub-sections, the dynamic models of the system components are briefly described.

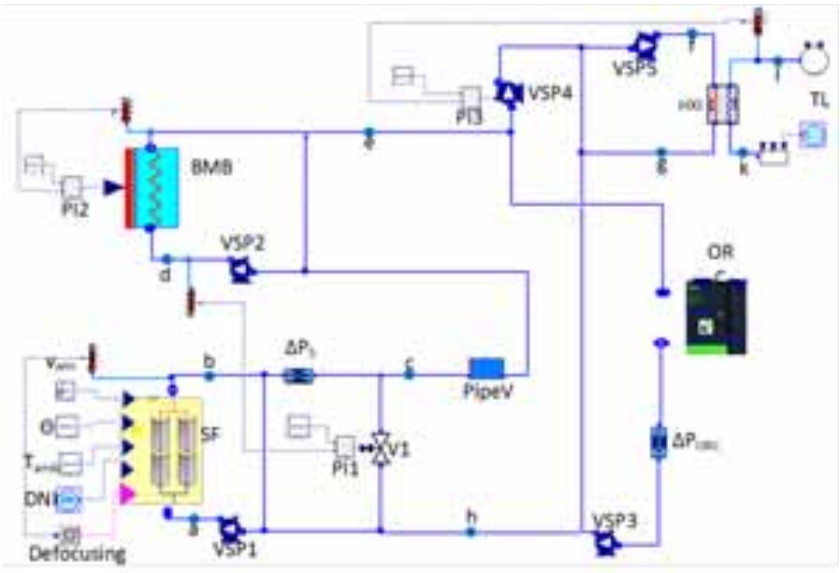

Fig. 2 Modelica model of the system from the Modelica/Dymola graphical user interface (GUI).

4.1 Solar field

Assuming homogeneous pressure drop and equal ambient input data, the solar field can be modeled as a single row of 3 collectors in series with a forth (1/4) of the total mass flow flowing through it. The parabolic through collector model of the *ThermoCycle* library is used. Given the large ratio between the diameter and the length of the parabolic through unit, the modeling approach is based on a finite volume one-dimensional discretization along the collector axial axis. The model is composed by two subcomponents. The *Flow1Dim* component models the fluid flow through the heat collector element (HCE) accounting for energy and mass accumulation. The thermal inertia in the HCE is accounted by a the *MetalWall* model. The radial energy balance between the HCE and the ambient is modeled with a semi-empirical correlation derived from typical values of solar collectors of comparable size. This approach allows reducing the number of equations increasing the computational time, while still modeling the main time constant characterizing the solar field dynamics.

4.2 Biomass boiler

No information where provided by the manufacturer on the biomass burning process. As a consequence a simplified approach is adopted to simulate the boiler. The biomass burning process is modeled as a zero-dimensional model where the power from the biomass combustion is imposed by the user, defining a value between 0, shut-down, and 1, maximum power. A first order model allows to account for the combustion dynamic with a fixed time constant. The oil side and the tube metal walls are modeled with a discretized one-dimensional approach. The oil flow through the boiler is modeled with a *Flow1Dim* component, accounting for energy accumulation, while the thermal energy capacity of the metal walls is modeled using the *MetalWall* component. The thermal inertia of the boiler is tuned in order to reproduce typical values that are found on boiler of the same size (500 kW_{el}). The dynamic is check by simulating the warm up of the boiler, and verifying that the period of time required to reach the desired set point in temperature is close to realistic values (1 to 2 hours).

4.3 Oil-Water heat exchanger

The oil-water heat exchanger is modeled using the *Hx1DInc* model of the ThermoCycle library. It models a counter-current plate heat exchanger based on the connection of three discretized one-dimensional subcomponents. Two *Flow1Dim* components accounting for mass and energy accumulation of the fluids flowing on the two sides of the exchanger, and one *MetalWall* component accounting for energy accumulation in the metal plates. The model are discretized based on the finite volume approach with an upwind scheme. No pressure losses are considered in the two *Flow1Dim* models. Equation 1 is used to model the convective fluid-wall heat transfer coefficient to account for mass flow variation:

$$U = U_{nom} \left(\frac{\dot{m}}{\dot{m}_{nom}}\right)^{n} \qquad \text{(eq. 1)}$$

where the exponent n varies depending on the flow regime between 0.65 and 0.8.

4.4 ORC power unit

In a small capacity ORC unit, the dynamic is mainly defined by energy and mass transfer phenomena characterizing the heat exchanger components, as the expansion and compression processes are characterized by very small time constants. A semi-empirical curve is derived based on experimental data to predict the electrical output power as a function of the heat source temperature at the evaporator inlet and the heat sink temperature at condenser inlet. In order to account for the dynamics characterizing the evaporation process a model equivalent to the one used for the oil-water heat exchanger is selected.

4.5 Piping

In order to account for the volume of the piping system between the solar field and the biomass boiler, the *PipeV* component is used. The model is a lumped one dimensional model accounting for mass accumulation in liquid phase in a defined constant volume. A constant pressure is imposed by the model, allowing for a robust resolution of the system of equation of the overall plant model.

4.6 Pump, pressure drop, bypass valve and PID

The *Pump* model from the ThermoCycle library is used to simulate the pump units installed on the system. It is a lumped fictitious model simulating the compression of a fluid in a turbo or volumetric machine, where given the flow fraction or the pump frequency, a constant volumetric and isentropic efficiency, the mass flow and the consumed power are computed. No dynamics are considered as the time constant characterizing the compression processes are very small compared to the ones regulating heat transfer phenomena. Pressure drop through the solar field and the ORC evaporator heat exchanger are modeled with the lumped ΔP model of the *ThermoCycle* library. The model computes a punctual pressure drop assuming fluid incompressibility and no thermal energy losses to the ambient. A linear and quadratic pressure drop terms are used to compute the total pressure drop. The homotopy function (Casella et al., 2011) is used during initialization to set the pressure drop to zero, facilitating the convergence of the solver. Finally the expansion of the fluid through the by-pass valve of the solar field system is modeled with the *Valve* model from the *ThermoCycle* library. The model is a lamped model where no dynamic and thermal energy losses to the ambient are considered. Finally the PID described in section 3 are implemented in Modelica using the *PID* model of the *ThermoCycle* library.

5. Results and discussion

The dynamic model of the complete system described in section 4 and controlled according to the control logic described in section 3 is simulated under transient conditions. The main goal of this study is to investigate if the whole system can be safely and efficiently operated with the proposed automated control logic. From the safety point of view, the main concern is related to the biomass boiler, the ORC system and the adsorption chiller, which need to be operated respecting the technical boundaries described in section 3. From the efficiency point of view, maximum exploitation of the solar resources should be ensured in order to minimize the biomass combustion rate. At the same time keeping the oil temperature at the ORC evaporator inlet (T_e) and the water temperature to the adsorption machine (T_l) close to their nominal values, allows for on-design working conditions maximizing the overall system efficiency. The dynamic model of the whole plant is simulated under a transient condition representative of an extreme reference situation characterized by a periodically sharp drop of the solar input due to the passage of a series of clouds (Casati et al., 2012). The thermal load at the oil-water heat exchanger is assumed constant over the simulation time imposing a constant mass flow rate on the secondary side of the HXI component. The results are shown in Figure 3.

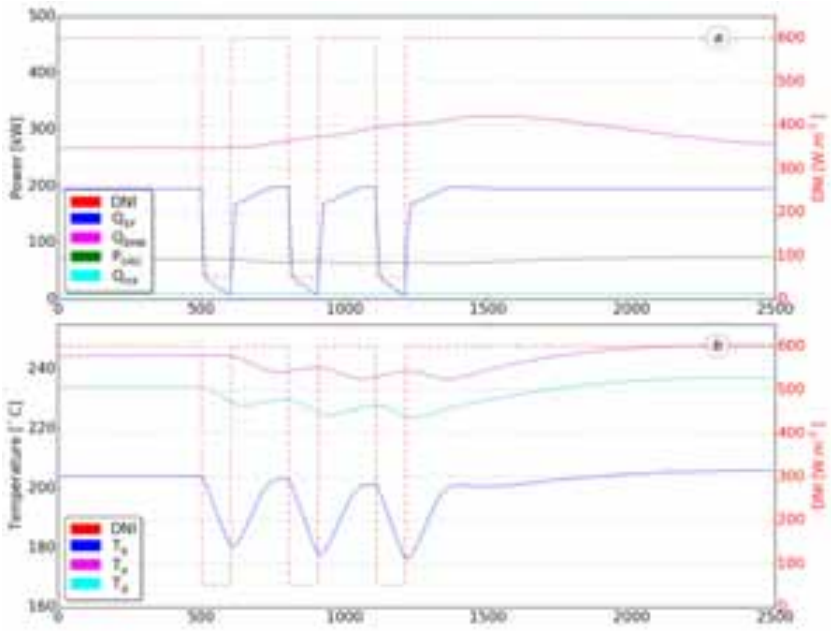

Fig. 3: Dynamic simulation results of the whole plant model as shown in Figure 2. The red dotted represents the DNI: it drops by 100% of its nominal value in 2 s, remain constant for 200 s then returns to its nominal value in 2 s. the interval between two subsequent drop is 200 s. (a) Thermal power delivered by the solar field, the biomass, the ORC evaporator and the HX oil/water evaporator (b) Temperature values in key points of the system.

The solar input drop is modeled by applying a signal with three subsequent ramps to the DNI input of the solar field model. The DNI drops by 90% of its nominal value, perturbing the initial steady state condition. From the results, it appears that the time constants characterizing the biomass system are large enough to cause an overlapping effect of the disturbances. The variation of the controlled biomass thermal power, Q_{BMB}, is shown in Figure 3a. Despite the sharp drop of the power absorbed in the solar field, Q_{SF}, the ORC electrical power, P_{orc}, is maintained close to its nominal value with a maximum deviation of 10%. The temperatures variation are reported in Figure 3b. The significant oscillations of the temperature at solar field outlet, T_b, are dumped by the biomass boiler recirculation system and the temperature at the boiler inlet, T_d, results characterized by much lower variations maintaining the biomass boiler temperature gradient between 9 and 15 K. The results show that through a mild regulation of the biomass boiler the system is able to run the ORC unit close to its nominal working condition despite the sharp drop of sun power. The effectiveness of the biomass system in decoupling the solar field from the ORC unit is assessed. In order to investigate and compare the performance of partial and total defocusing control logic implemented on the solar field, the dynamic model is simulated during a reference summer day in Caceres, Spain. The high value of the DNI is expected to trigger the defocusing mechanism. Two different simulations are run, one considering a constant negligible building thermal demand and one considering a variable thermal load based on available empirical data. In Figure 4 the simulation results for a partial (PD) and a total (TD) solar field defocusing are compared when a constant low building thermal demand is assumed. The simulation starts at 5:00 am and last for 17 hours. During the night the DNI is zero and the biomass is running close to its maximum power to provide the thermal energy required by the ORC power block. When the sun rises, at around 6:00 am, the thermal power provided by the solar field, Q_{SF}, starts increasing and the biomass power, Q_{BMB}, is consequently decreased by the control as the thermal power demand stays constant as shown in Figure 4a. Looking at Figure 4b, the increase of T_b causes the temperature at biomass inlet, T_d, to rise. As a consequence PI1 starts opening V1 to bypass the solar field and keep T_d close to its nominal point. The mass flow through the solar field by-pass valve and the solar field recirculation circuit increases proportionally as shown in Figure 4c. This mechanism boosts T_b towards its upper limit value, pushing the solar field into the defocusing mode and avoiding the shut-down of the biomass boiler. As the defocusing mode is activated, the system behavior changes significantly depending on the adopted defocusing approach. In the PD case, solid lines, one forth of the solar field is defocused. The partial decrease in the solar collector effective surface allows for a smooth decrease of the solar field outlet temperature, T_b, bringing the system in a second steady working condition. In the TD case, dashed lines, the total defocusing of the solar collector causes a sharp decrease of the evaporator outlet temperature down to its minimum value which consequently triggers the solar field to exit the defocusing mode. As the DNI is roughly constant during the simulated reference day, the focusing-defocusing control runs continuously. A continuous control of the biomass system to overcome the sharp changes of the solar field thermal power is deemed necessary. As a consequence the overall system is characterized by an oscillatory trend. When the sun starts to set between 17:00 and 18:00, T_b reaches its lowest value that triggers the solar field to exit the defocusing mode. The drop of solar energy at the end of the day is compensated by the biomass power which is increased to meet the required thermal power demand.

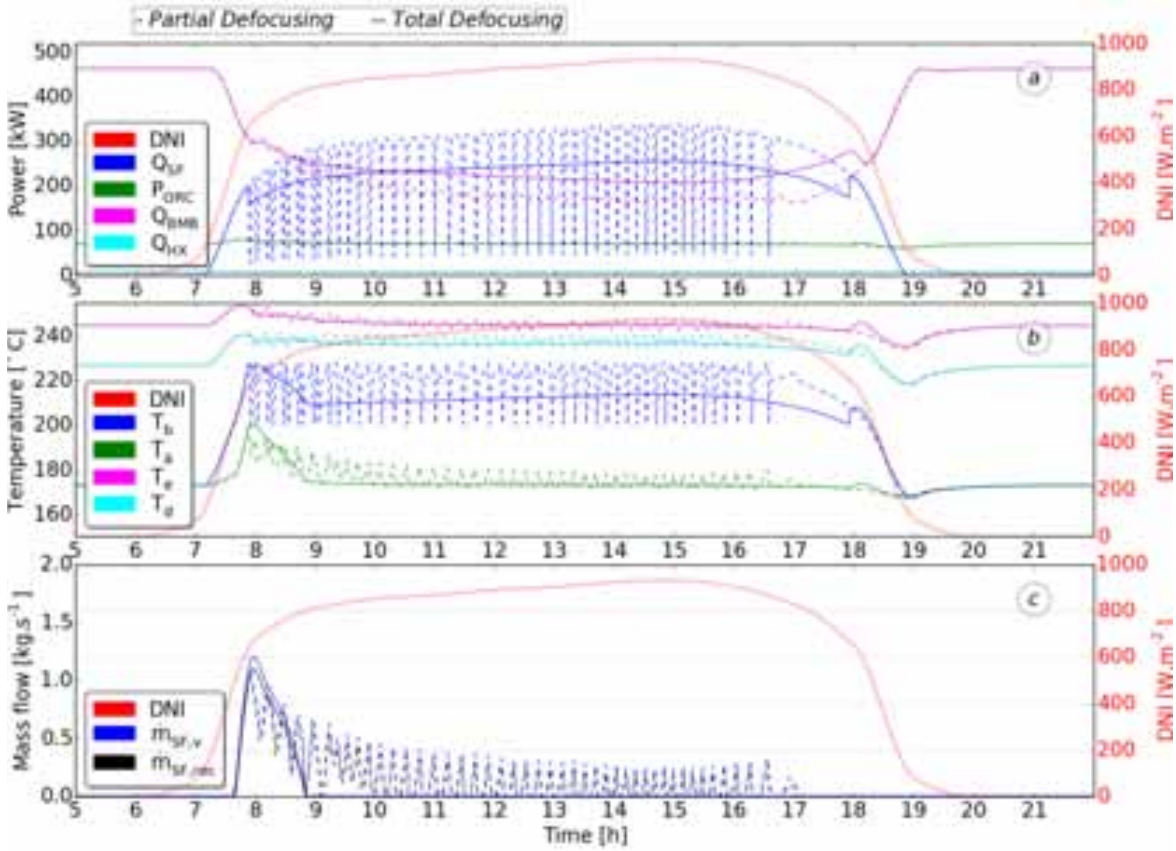

Fig. 4 Dynamic simulation results of the whole plant model during a reference summer day in Cáceres, Spain. The dashed line represents the results for a solar field control strategy based on a total defocusing, the solid line for a partial defocusing. (a) Thermal power delivered by the solar field, the biomass, the ORC evaporator and the HX oil/water evaporator (b) Temperature values in key points of the system (c) Mass flows of the solar field bypass and recirculation system.

Overall both defocusing methods are able to maintain the system in safe working conditions during the simulated reference day. The temperature gradient at the biomass boiler is kept between 18 and 8 K. The ORC power block is run continuously with a maximum power deviation of 12.6% and 14% in the PD and the TD case respectively. At the cost of a continuous regulation of the solar field inclination, the TD approach allows a reduction of the total thermal energy delivered by the biomass boiler of 8% with respect to the PD mode consuming a smaller amount of biomass. Defining the solar fraction, $E_{SF,r}$ as:

$$E_{SF,r} = \frac{E_{SF}}{E_{BM}} = \frac{\int \dot{Q}_{SF} dt}{\int \dot{Q}_{BM} dt} \qquad \text{(eq. 2)}$$

where E_{SF} is the total energy delivered by the solar field and E_{BM} is the total energy delivered by the biomass over a period of 17h from 5:00 to 22:00. The TD approach results in a solar fraction of 59% while the PD in a solar fraction of 47%. The simulation results for the same reference day considering a variable thermal load demand are reported in Figure 5. As in the previous simulation, the DNI increase triggers the defocusing mechanism around 8:00 am. The PD approach brings the system to a steady condition while the TD approach causes an oscillatory behavior in the system. As shown in Figure 5a, around 9:00 am the building thermal demand start increasing and more power is required by HX1, Q_{HX}. As more thermal energy is required, the solar field inlet temperature T_a decreases and so does T_b reaching its lowest value which causes the solar field to exit its defocusing mode around 9:30 am. From this time on the TD and PD approaches lead to the same results. As the thermal demand keeps increasing during the day, the biomass boiler power is regulated to meet the thermal needs. From a safety point of view the control logic is able to maintain the biomass boiler temperature gradient between the required limit with a minimum of 9 K and a maximum of 20 K. The ORC power block inlet temperature experience the biggest drop around 19:00 and 21:00 when the sun goes

down and the biomass is brought close to its maximum value to provide the requested thermal power. The ORC evaporator inlet temperature smoothly decrease reaching a minimum value of 233°C which corresponds to an electrical power drop of 17% with respect to the nominal power. Overall the TD case allows a reduction of the biomass boiler of only 0.5% with respect to the PD case as the two approaches leads to the same plant trend for most of the time. As a consequence a solar fraction of 53% and 54% is found for the PD and the TD case respectively.

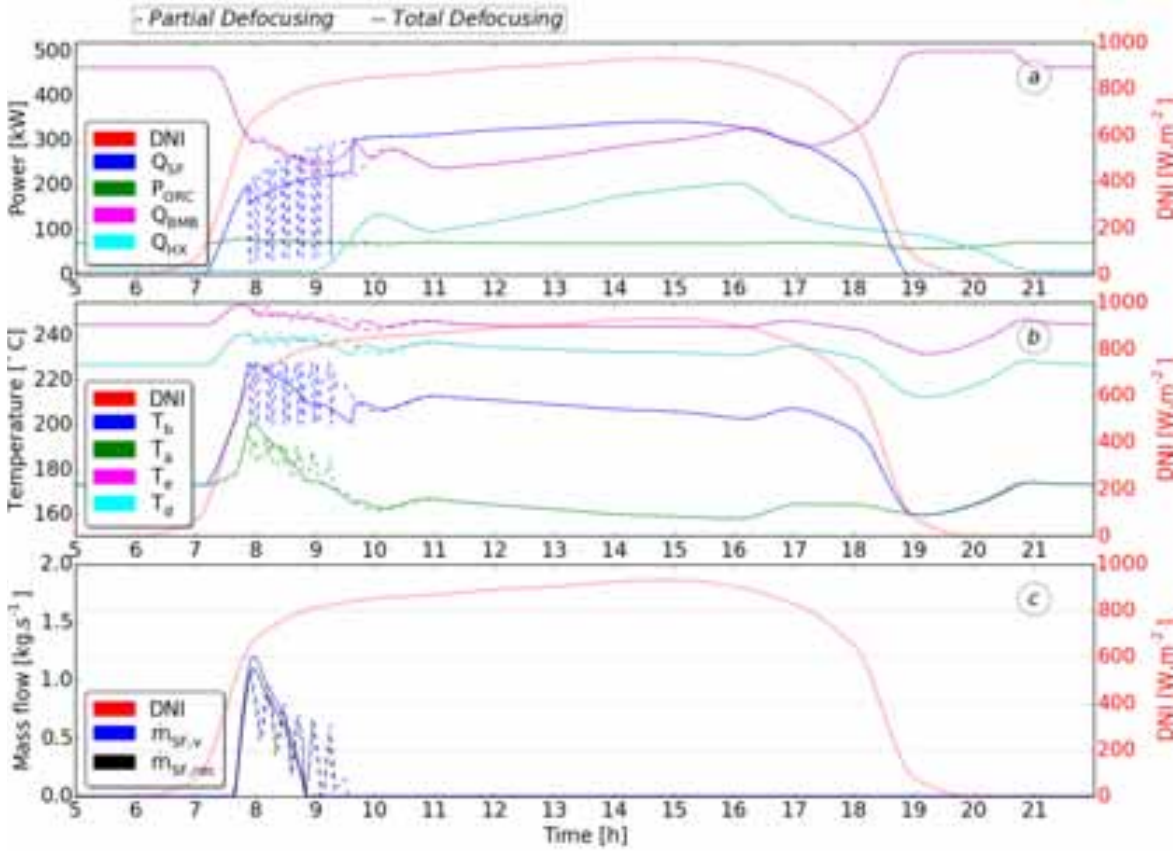

Fig. 5 Dynamic simulation results of the whole plant model during a reference summer day in Cáceres, Spain with variable thermal power load. The dashed line represents thre results for a solar field control strategy based on a total defocusing (TD) , the solid line for a partial defocusing (PD). (a) Thermal power delivered by the solar field, the biomass, the ORC evaporator and the HX oil/water evaporator (b) Temperature values in key points of the system (c) Mass flows of the solar field bypass and recirculation system.

6. Conclusions and future work

In this work the CSP-biomass CHP system based on ORC technology developed in the framework of the EU founded BRICKER project is presented. The system has the goal of meeting the building energy demand with the employment of only renewable energy sources. A detailed description of the different system component is reported. Given the technical boundaries of the different component, a control logic is developed to maintain safe operating condition during different working conditions. In order to test the implemented control logic a dynamic model of the whole system is developed. The dynamic model is based on the Modelica programming language and the components models are developed based on the *ThermoCycle* library adopting a simple modeling approach. The reaction to the passage of sub- sequent clouds, causing the solar input to drop to 90% of its nominal value, is simulated to test the control capability to ensure safe condition. The effectiveness of the biomass boiler to decouple the solar field to the HXI and ORC units is assessed. The system is able to withstand fast variation of the sun power as demonstrated by the results of the first simulation reported in Figure 3. Variation in solar field outlet temperature of 30 K results in variation at the evaporator ORC inlet temperature of 8 K causing a decrease in electrical power of 8% with respect to its nominal power. Furthermore, two solar field defocusing approach are investigated in two

different conditions, one with constant thermal power and one with variable thermal power. In both situations the two approaches allows to operate the system within the safety limits imposed by the ORC unit and the biomass boiler. The effectiveness of the two approaches in exploiting the sun power is assessed in terms of the solar fraction. The TD approach allows to increase the solar fraction of up to 12 percentage point compared to the PD case at the cost of continuously running the electric motor of the solar field. In the next phase of the project, the developed dynamic model will be integrated with the model of the adsorption chiller and of the reference building to investigate in detail the control strategy that allows to maximize the solar fraction while maintaining safe working conditions.

Abstract

Because of the intermittent nature of solar irradiances, micro-scale solar thermal power systems almost never operate in nominal operating conditions. They are characterized by strong transients and require robust, fast and accurate dynamic simulation tools to permit a proper evaluation of their performance. Model reduction, i.e. the simplification of detailed models, is an attractive method to improve the computational efficiency while simulating such systems. In this context, a μCSP plant featuring a solar field of parabolic troughs, a thermocline storage and a 5kWe power unit is investigated. Both the solar field and the thermocline storage are modeled with complex and simplified methods. The whole power plant is simulated under identical operating condition and deviations between the simulation results are analyzed. Benefits and limitations of the current modeling approach are assessed. Improvements for the modeling of the thermocline storage are identified, implemented and validated. The Modelica language is used as simulation tool and the models developed in this work are integrated in the open-source ThermoCycle library.

Keywords: *thermocline storage, concentrated solar power, model reduction, dynamic modeling*

1. Introduction

Energy security issues and global warming due to the extensive use of fossil fuels are nowadays almost universally recognized (IEA, 2015). Together with other growing technologies, concentrated solar power (CSP) is increasingly developed to help extend the share of renewable energy in the world's power generation (IEA, 2014). A major advantage of CSP over other technologies is the ability to couple the solar thermal power plant with a simple and cost-effective thermal energy storage (TES). Surplus of thermal power collected by the solar field during sunny periods can be easily stored to be latter used in low radiation conditions, hence improving the plant's capacity factor, its flexibility and reducing the cost of electricity. Besides well-known large-scale applications (Lovegrove and Stein, 2012), concentrated solar power can also be used in micro-systems (μCSP) for supplying useful heat and electricity to a local demand, e.g. in remote off-grid areas (Orosz, 2012). Given the intermittent nature of solar irradiances and the local energy demand, μCSP systems often work far from their nominal design conditions and are submitted to strong transients. Powerful dynamic modeling tools are therefore required to simulate the effective performance of μCSP systems in real operating conditions and to optimize the control strategy. However, high computational speed, robustness and accuracy must be achieved by the dynamic models to permit a direct application of these tools in optimization problems. An interesting method to reach such goals is to use simplified models for simulating each component of the power plant. This method is referred to as *model reduction* and is the subject of this contribution.

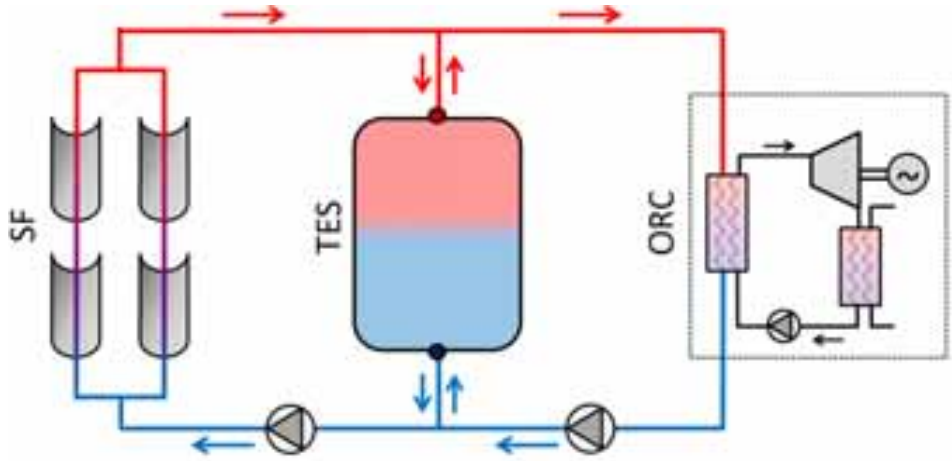

Fig. 1: Schematic layout of the µCSP plant considered in this work (red lines: hot HTF – blue line: cold HTF).

The CSP system considered here is depicted in Figure 1. The power plant features a solar field (SF) of parabolic trough collectors (130 m²), a 5kWe non-recuperative organic Rankine cycle (ORC) and a thermocline storage (15m³). Therminol 66 is used as heat transfer fluid (HTF) and two circulating pumps control its flow rate through the solar field, the TES and the ORC. For the sack of conciseness, neither the control strategy nor technical data of the power plant are described in this manuscript. Detailed information regarding these aspects is available in a previous article also dedicated to this research project (Dickes et al., 2014).

In a previous work (Dickes et al., 2015a), the authors proposed two innovative approaches for modeling both the solar field and the thermocline storage. These methods aimed to simplify the simulation of these components by making the models less complex. In order to assess the loss of accuracy caused by the simplified approaches, results of simulation in identical operating conditions were compared with predictions given by deterministic (i.e. detailed) models. However, this comparison was only performed for each component individually. In this contribution, it is proposed to further evaluate the validity of model reduction by simulating the whole µCSP plant with both detailed and simplified methods. Only the solar collectors and the thermal energy storage are studied in details. Model reduction of the organic Rankine cycle is beyond the scope of this report. Results of simulation under identical operating conditions are compared and analyzed to assess the limits and benefits of the current approach. Improvements required for the modeling of the thermal storage are identified, developed and validated.

The Modelica language (Elmqvist and Mattsson, 1997) is used as simulation platform and thermo-physical properties of the fluids are computed with the free-access CoolProp library (Bell et al., 2014). Furthermore, all the models developed in the frame of this project are included in the open-source ThermoCycle library (Quoilin et al., 2013) dedicated to the modeling of thermal systems and under development at the University of Liège. Results presented in this paper are mostly derived from a MSc thesis performed by Noé Weber at the University of Liège. Additional information unpublished in this paper can be found in the original manuscript (Weber, 2015).

2. Model reduction and global simulation

In this section, a short description of the models already developed for the thermal storage and the solar field is first given. Additional information about the models development and the results of the individual comparison can be found in the authors' preceding publication (Dickes et al., 2015a). The whole power plant is then simulated by coupling together the solar field and the thermocline storage. Results from detailed and simplified models in identical weather conditions are then discussed and analyzed. For the sake of clarity, the different models developed in the following sections, with their main characteristics, are summarized in the Appendix (see Table 2).

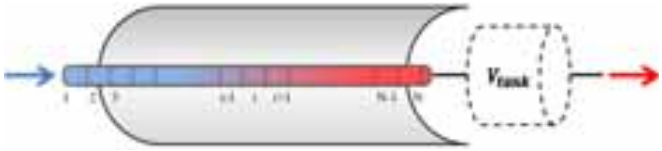

Fig. 2: one-dimensional discretization of a PTC (with a fictive tank connected to the outlet for the simplified model)

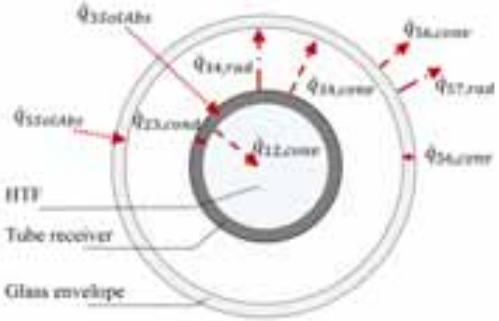

Fig. 3: Radial heat balance taking place in a parabolic trough collector

2.1. Solar thermal collectors – description of the simplified and the detailed models

Parabolic trough collectors (PTCs) are linear concentrating systems made of long, parabolic-shaped mirrors and an absorber tube placed along the focal axis of the parabola. In order to evaluate the temperature profile of the heat transfer fluid circulating along the receiver tube, a common approach is to discretize the tube along its axial axis in a number of cells of constant volume in which the energy balance is evaluated (see Figure 2). In order to determine the net heat power absorbed by the fluid in each cell, two options are proposed as described here below.

- Detailed method (referred to as *model PTC$_A$*): as depicted in Figure 3, the net heat power absorbed by the HTF can be evaluated by solving the radial heat balance between the surrounding environment, the glass envelop, the absorber tube and the fluid (Forristall, 2003). To account for the dynamic behavior of the collectors in transient operating conditions, thermal capacitances of the different components are considered. The number of cells used for the discretization is a key parameters that must be selected correctly. It must be high enough to limit the effects of numerical diffusion (Peterson, 1992) while ensuring low computational times.
- Simplified method (referred to as *model PTC$_B$*): an alternative approach to calculate the net heat power absorbed by the HTF is to use a calibrated correlation computing the effective heat losses of the PTC in function of the operating conditions (Dickes et al., 2015b). By using such correlation, the steady-state temperature profile along the collectors can be easily derived. The dynamic response of the parabolic troughs is accounted by connecting a fictitious fluid reservoir in series with the solar field outlet, as shown in Figure 2. The reservoir acts as a dynamic damper and smooth out the temperature changes simulated by steady-state model at the solar field outlet.

Results from the individual comparison demonstrate good agreements between the two modeling methods in most working conditions. Significant deviations are observed for fast transient conditions (i.e. with time constants lower than the residence time of the fluid within the collectors). Indeed, the single reservoir used as thermal inertia does not properly simulate the progression of the temperature gradients within the collector tubes. However, these fast effects are localized and remain negligible in long-term simulations.

2.2. Thermocline storage – description of the simplified and detailed models

The storage system used in the μCSP plant is a single-tank stratified storage, also called *thermocline* storage. It is entirely filled with heat transfer fluid and, by taking advantage of the vertical stratification due to the density gradient, both cold and hot zones are stored in a single reservoir. Like for the solar collectors, two modeling methods are used to characterize the thermocline storage.

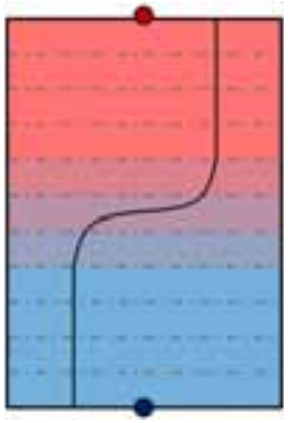

Fig. 4: one-dimensional finite-volume method for modeling a thermocline storage

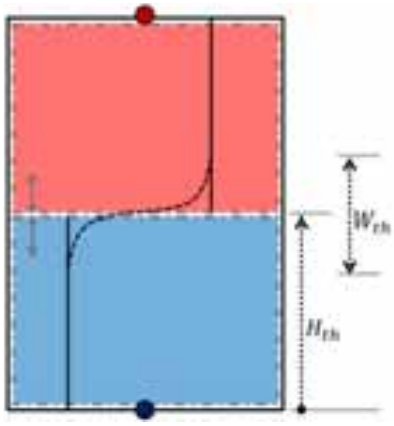

Fig. 5: two-zone moving-boundary method for modeling a thermocline storage

- Detailed method (referred to as *model TES_A*): in a physically-based approach, a thermocline system can be modeled with a one-dimensional finite-volume method. The reservoir is assumed cylindrical and discretized along its vertical axis in a finite number of isothermal cells of constant volume (as illustrated in Figure 4). In each cell, both mass and energy balances are evaluated while accounting for heat losses to the environment, mass exchange and conductive heat transfer between adjacent cells. Because of the low velocity of the fluid within the tank, a high discretization must be performed to limit the effect of numerical diffusion, resulting in long computational time. In this paper, a 200-cell discretization is chosen for the detailed model TES_A.
- Simplified method (referred to as *model TES_B*): a simpler approach to simulate a thermocline storage is to consider a two-zone moving-boundary model. The tank is divided into two isothermal zones, a hot and a cold one, of variable volume. Mass and energy balance only need to be calculated twice, once for each zone, which drastically increases simulation speed. If the tank is fully charged (resp. discharged), then only the hotter zone (resp. the colder zone) subsists in the tank. The temperature transition profile between the two zones is modelled as half a period of a cosine symmetrically centered on the boundary between the two zones, as depicted in Figure 5. In a first time, the thickness of the thermocline region (W_{th} in Figure 5) is assumed constant, whatever the operating conditions.

Results from the individual comparison demonstrate good agreements between the two modeling methods if a proper calibration of the thermocline thickness is performed. Furthermore, the simplified method demonstrate a drastic decrease in the simulation time (up to 99%) when compared to the deterministic model.

2.3 Power plant simulation

In order to further evaluate the validity of the simplified models, the whole power plant is simulated during two complete days by connecting together the model PTC_A (resp. PTC_B) to the model TES_A (resp. TES_B). The same control strategy is applied for the circulating pumps and identical weather conditions are used as inputs. The first day has a quasi-perfect solar irradiance shape and it is used as reference to calibrate the thermocline thickness W_{th} of the simplified model TES_B. As depicted in Figures 6 and 7, really good agreements are found between the simplified and the detailed simulations. Regarding to the solar field, both the outlet temperature and the mass flow rate are reproduced with high precision during shinny periods. It can also be seen that deviations in the outlet temperature prediction arise only in strong off-design conditions. However, these periods correspond to zero-flow conditions in the solar field which do not influence the rest of the power plant. The thermal storage is also well represented with the simplified model TES_B. As depicted in Figure 7, both the thermocline position (H_{th} in Figure 5) and the discharge temperature at the top port of the storage are correctly simulated along the day. Although promising, these results are biased since the thermocline thickness W_{th} of the model TES_B has been calibrated a posteriori to fit properly the predictions of the complex model.

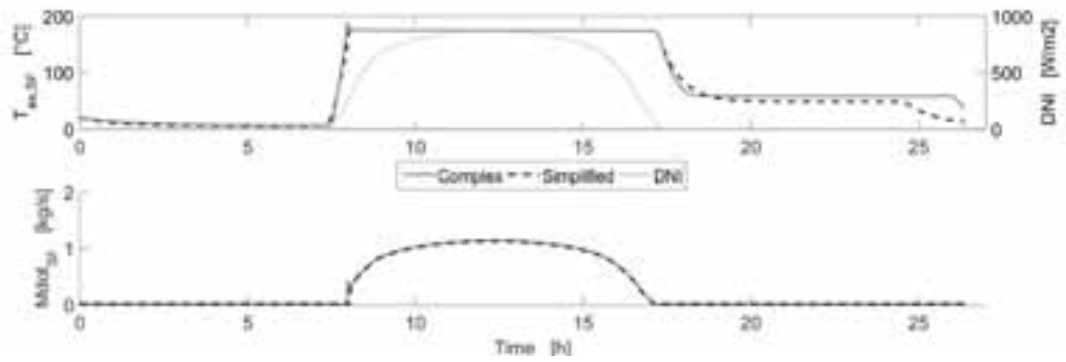

Fig. 6: Day 1 – Outlet temperature (top fig.) and mass flow rate (bottom fig.) modeled in the solar field

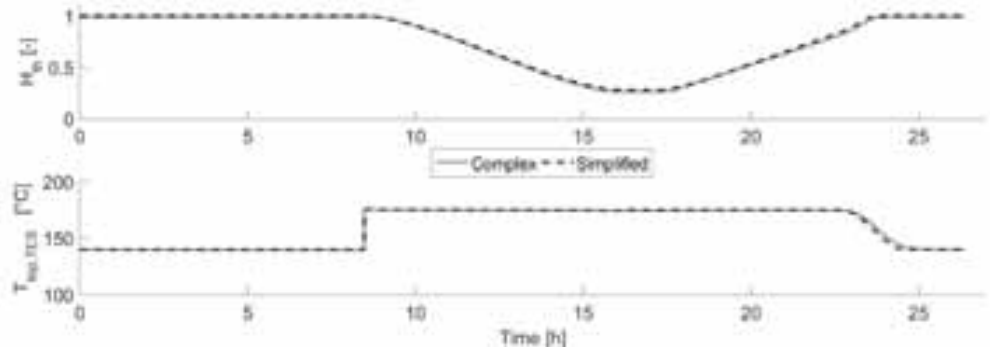

Fig. 7: Day 1 – Thermocline position in the tank (top fig.) and discharge temperature at the top port of the TES (bottom fig.)

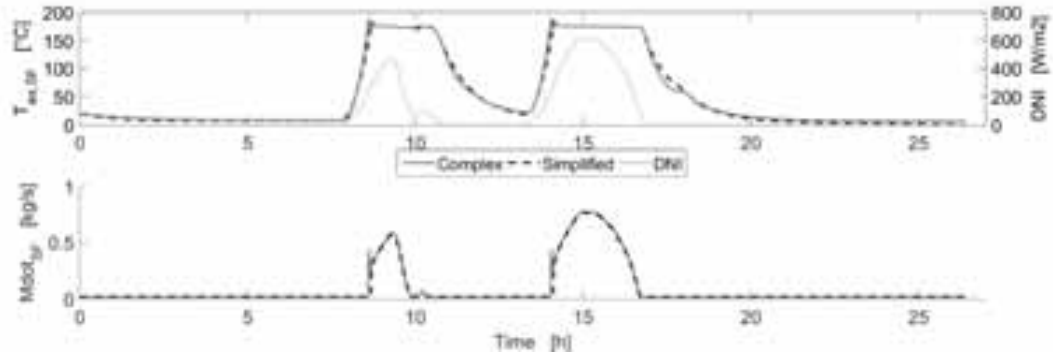

Fig. 8: Day 2 – Outlet temperature (top fig.) and mass flow rate (bottom fig.) modeled in the solar field

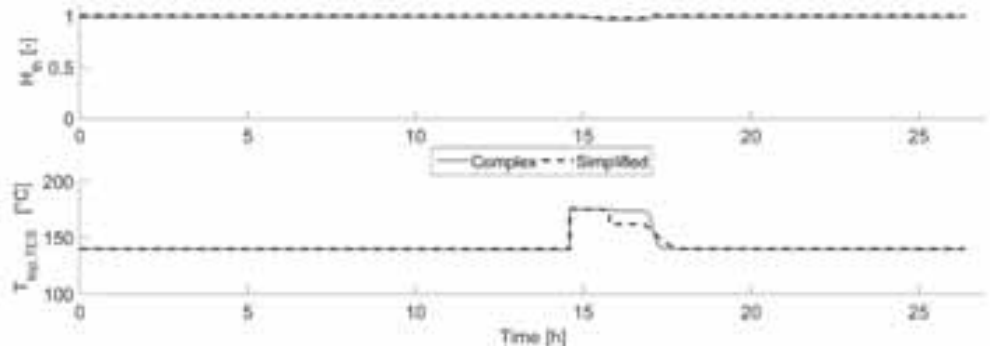

Fig. 9: Day 2 – Thermocline position in the tank (top fig.) and discharge temperature at the top port of the TES (bottom fig.)

The power plant is simulated during a second day characterized by poorer solar conditions and the thermocline thickness is kept unchanged. As shown in Figure 8, parabolic troughs are once again simulated correctly and good agreements are observed for both the mass flow and the outlet temperature of the solar field. Concerning the thermal energy storage, results are less enthusiastic. The assumption of a constant thermocline thickness leads to significant mispredictions of the discharge temperature at the top port of the tank, as illustrated in Figure 9. Indeed, the simplified model considers the thermocline as a fixed transition profile moving together with two sub-volumes. If a flow reversal happens before the storage is charged enough to have the "hypothetical" thermocline zone entirely comprised inside the tank, a nonphysical discontinuity of the temperature is simulated at the top port of the storage. Same errors also occur in the case of partial discharge of the TES. For more information about this numerical problem, a detailed description of the phenomena is provided in Weber's thesis (Weber, 2015). This observation poses the problem that, with the present simplified method, the thermocline thickness must be fitted a posteriori, when the results of the complex model are already available. A convenient method to thwart the issue is to determine the dynamic evolution of the thermocline thickness in the storage throughout the day, as a function of real-time parameters, so that the model could be used with no need of retrofitting. The next section is devoted to the development of such model.

3. Model improvements of the thermocline storage and global simulation

It this section, the methodology used to develop an improved model of the thermal energy storage is presented. This new model is then validated by simulating the complete power plant over the same two days as in section 2.3.

3.1 Thermocline storage – modelling improvement

As explained previously, the thermocline thickness within a stratified tank does not remain constant and making such an assumption leads to significant mispredicitons. In order to derive a law that represents the dynamic evolution of the thermocline thickness, the dynamics taking place inside the tank are simulated with the detailed model TES_A in various conditions. Evolutions of the thermocline thickness with different mass flow rates in both charging and discharging modes, but also in standby conditions, are calculated and analyzed. Results demonstrate that the evolution of the thermocline thickness is mainly function of the time and the fluid mass flow rate. As depicted in Figure 10 (in the case of charging processes), the thermocline thickness W_{th} can be interpolated by an equation of the form

$$W_{th} = K_{th} \,.\sqrt{t} \qquad \text{(eq. 1)}$$

where t is the time since the beginning of the charge and K_{th} is a parameter depending of the mass flow rate $\dot{m}$, i.e.

$$K_{th} = a \,.\sqrt{\dot{m}} + b \qquad \text{(eq. 2)}$$

as illustrated in Figure 11. Coefficients a and b in equation 2 are calibrated for both charging and discharging processes and their values are provided in the Appendix. Regarding standby periods, it is found that the thermocline thickness increases linearly with respect to the time i.e.

$$W_{th} = c_{sb} \,.\, t \qquad \text{(eq. 3)}$$

where c_{sb} is another constant parameter given in the Appendix. By implementing these correlations in the two-zone moving-boundary model, an improved approach for simulating the thermocline storage (referred to as *model* TES_C) is finally obtained.

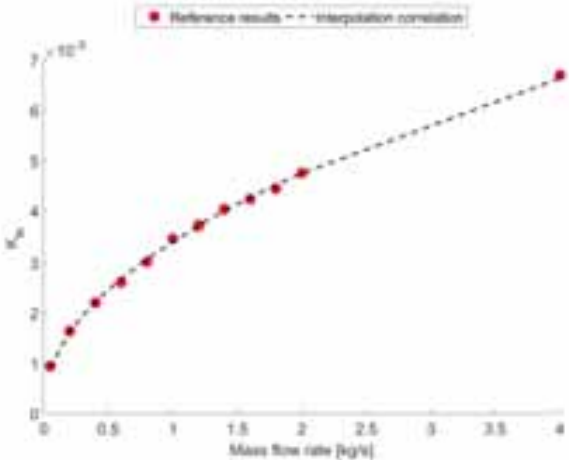

Fig. 11: Evolution of the parameter K_{th} as a function of the mass flow rate

3.2 Power plant simulation

In order to validate the new model TES_C presented here above, the whole power plant is simulated during the same two days as in section 2.3, and results obtained by the combination of models PTC_B-TES_C are compared to the reference/detailed model PTC_A-TES_A. Since the simplified method for modeling of solar field has demonstrated to be reliable, only results relative to the thermal storage are depicted in Figure 12 and 13; these figures corresponding to the first and the second day respectively. It can be seen that, for both days, the two-zone moving-boundary approach permits once again to predict correctly the position of the thermocline inside the tank (i.e. H_{th} in Figure 5). Furthermore, the correlations used to compute dynamically the thermocline thickness permit to replicate much better the behavior of the storage. Without any pre-calibration, the evaluation of the thickness W_{th} is properly predicted for both days and mispredictions of the discharge temperature are drastically decreased compared to results of the initial model TES_B. Simulations performed for two other days can be found in Weber's thesis (Weber, 2015) and identical observations are drawn. In conclusion, the new model TES_C of the thermocline coupled to the simplified model PTC_B of the solar collectors permit to replicate correctly predictions of the complex models.

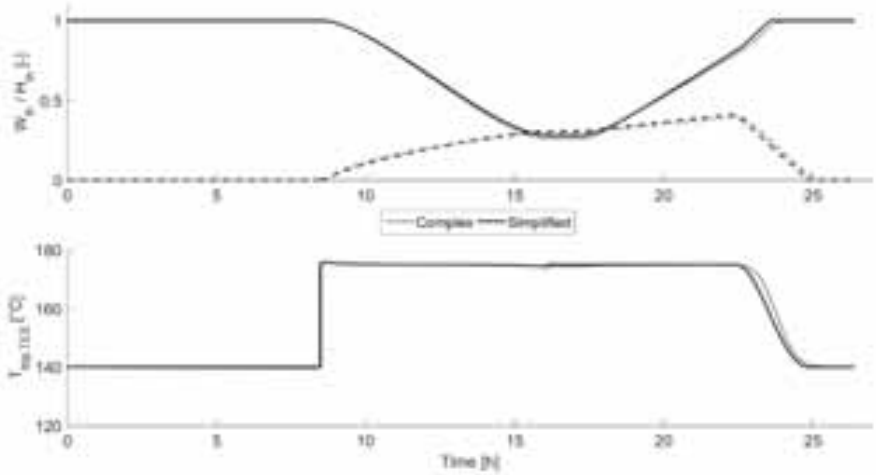

Fig. 12: Day 1 –Position H_{th} and thickness W_{th} of the thermocline inside the tank (top) and discharge temperature at the top port of the TES (bottom)

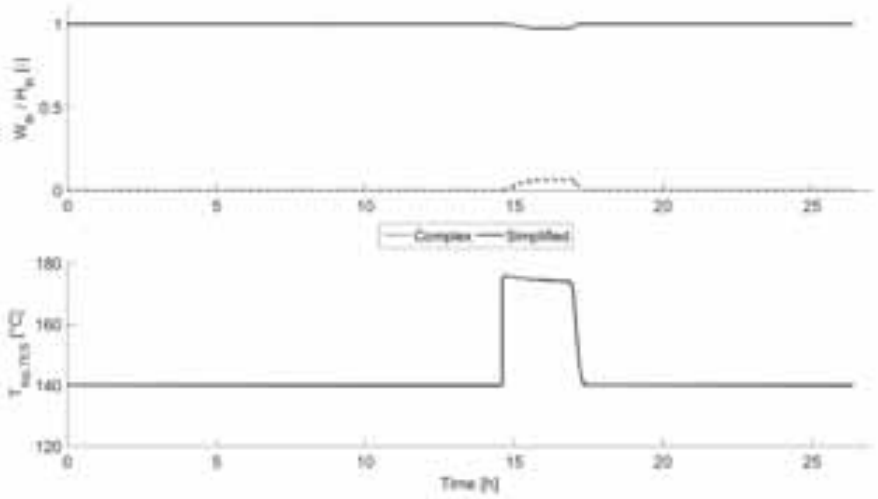

Fig. 13: Day 2 –Position H_{th} and thickness W_{th} of the thermocline inside the tank (top) and discharge temperature at the top port of the TES (bottom)

4. Simulation speed, number of variables and accuracy

In the previous sections, it is shown that simplified modeling methods can be used instead of complex ones to simulate a small-scale solar thermal power plant. The main motivation of this approach is to improve numerically the simulations by increasing the computational speed. In order to highlight such an improvement, both the number of variables and the simulation times required by the three models investigated in this paper are summarized in Table 1. All the simulations were run on Dymola© 2015 with an Acer Aspire V5, CPU Intel Core i5 2.7 Ghz, 8GB RAM.
